In general, gastric variceal bleeding is often more severe than esophageal variceal bleeding, requiring more blood transfusion. Similarly, the overall mortality from bleeding gastric varices is also higher, reaching close to 50% in some series with significantly higher risks when fundal varices bleed [39]. Because there are no controlled studies for primary prophylaxis of gastric or ectopic varices, it is difficult to recommend any special strategy. However, based on the data from esophageal varices, it is recommended that all patients with large gastric or ectopic varices are treated with nonselective β-blockers.

Primary prophylaxis: summary of recommendations

Nonselective β-blockers should be used for primary prophylaxis in cirrhotic patients with large varices and those with risk factors (red signs, HVWPG ≥ 12 mmHg) for bleeding. A summary of clinical trials is shown in Tables 124.5 and 124.6 (see also Table 124.4). Nitrovasodilators are possibly beneficial in combination with β-blockers in those who cannot tolerate maximal β-blocker therapy. Endoscopic sclerotherapy has no role for primary prophylaxis. Endoscopic banding may be an option for those with high risk of bleeding who do not tolerate, or are noncompliant or show poor response to β-blockers. An algorithm for primary prophylaxis is shown in Fig. 124.12.

Acute variceal bleeding

Patients with acute variceal bleeding should be managed in an optimal fashion to reduce early mortality. The past decade has seen significant progress in the management of acute variceal bleeding. A large number of randomized controlled studies have been published on this topic comparing various treatment options. Although these studies have uniformly lacked the sample size to show an improvement in survival, metaanalyses of these studies have been able to circumvent this problem to some extent. However, inclusion of heterogeneous studies has been a major weakness of such analyses. Despite these limitations, careful observations based on individual studies as well as metaanalyses have made it possible for clinicians to devise a more successful strategy to manage patients who present with acute variceal bleeding. A broad outline of the management is shown in Fig. 124.13.

Resuscitation and immediate management

Management of acute variceal bleeding includes general resuscitative measures and specific treatment aimed at arresting the variceal bleeding and prevention of early rebleeding. Airways must be protected in an encephalopathic patient, particularly during endoscopic procedures and balloon tamponade, because aspiration pneumonia is a major cause of morbidity and mortality in these patients. Measurement of central venous pressure is a useful guide to the blood volume status but caution should be exercised in the presence of tense ascites because diaphragmatic compression of the right atrium by the ascites may lead to an overestimation of the readings. Pulmonary capillary wedge pressure is an accurate guide to control blood volume and may be invaluable in the presence of major ongoing bleeding. Replacement of blood volume should be prompt and as accurate as possible to protect vital organs, particularly renal function. Although the ideal replacement fluid is blood, colloids (preferably) or crystalloids may be used for immediate infusion until blood becomes available. Isovolemic replacement should be the

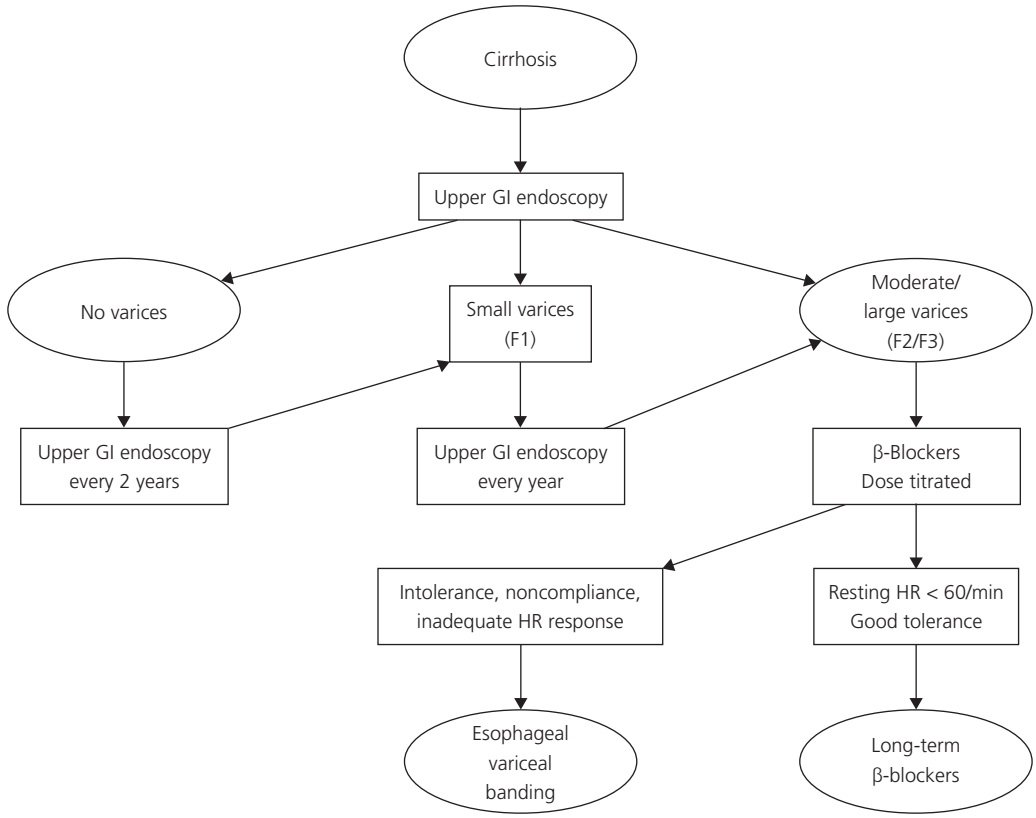

Figure 124.12 Algorithm for primary prophylaxis. HR, heartrate.

aim, with care taken to avoid major overexpansion of the circulation that may precipitate further bleeding due to the associated increase in portal pressure. Correction of clotting abnormalities may also be helpful in major bleeding.

There is convincing evidence to support routine prophylactic antibiotics, especially in those with ascites and in those with active bleeding at the time of endoscopy. Bacterial infection has been associated with higher rates of failure to control variceal bleeding [84]. Patients should be carefully observed for the development of aspiration pneumonia, spontaneous bacterial peritonitis, and other opportunistic (e.g., fungal infection) infections. These infections should be treated at the earliest opportunity with appropriate antibacterial or antifungal agents, with extreme care taken to avoid nephrotoxic drugs because these patients are susceptible to renal toxicity and failure. If variceal bleeding is suspected in patients who present with acute upper gastrointestinal bleeding, pharmacological treatment should be initiated while the patient is resuscitated, and this may improve the endoscopic diagnosis, efficacy of treatment, and survival. Because bleeding from a nonvariceal source is common in chronic liver disease, endoscopy should be performed as soon as the patient is stabilized.

Pharmacological therapy

The major benefit of pharmacological therapy is that it can be given without any specialized training to most patients. The safety margin and efficacy of some of the vasoconstrictor drugs used for this purpose have been less than desirable in the past, but improvements in these areas have been made.

Vasopressin and terlipressin

Vasopressin, a peptide hormone, causes splanchnic arterial vasoconstriction, thereby reducing portal blood flow and portal pressure. The main side effects of vasopressin are secondary to nonselective arterial vasoconstriction. These include ischemia of the myocardium, abdominal viscera, and lower limbs; left heart failure; hypertension; and arrhythmia. In randomized controlled studies, between 30% and 60% experienced one or more complications and about 25% of patients were withdrawn because of a major complication [85–87]. Selective infusion of vasopressin into the superior mesenteric artery has not been shown to overcome these adverse effects or improve efficacy. In a number of studies, a combination of vasopressin and nitroglycerine has been shown to reduce the hemodynamic side effects of vasopressin without attenuating the effect on portal inflow [88,89]. The transdermal route may be preferred because of ease of administration [88]. The addition of nitroglycerine to vasopressin is of proven benefit in reducing the side effects and improving hemostasis [88,89]. The reported efficacy of vasopressin is around 50%–60%, compared with 40% with placebo [46,85–89]. Because of the poor safety profile and

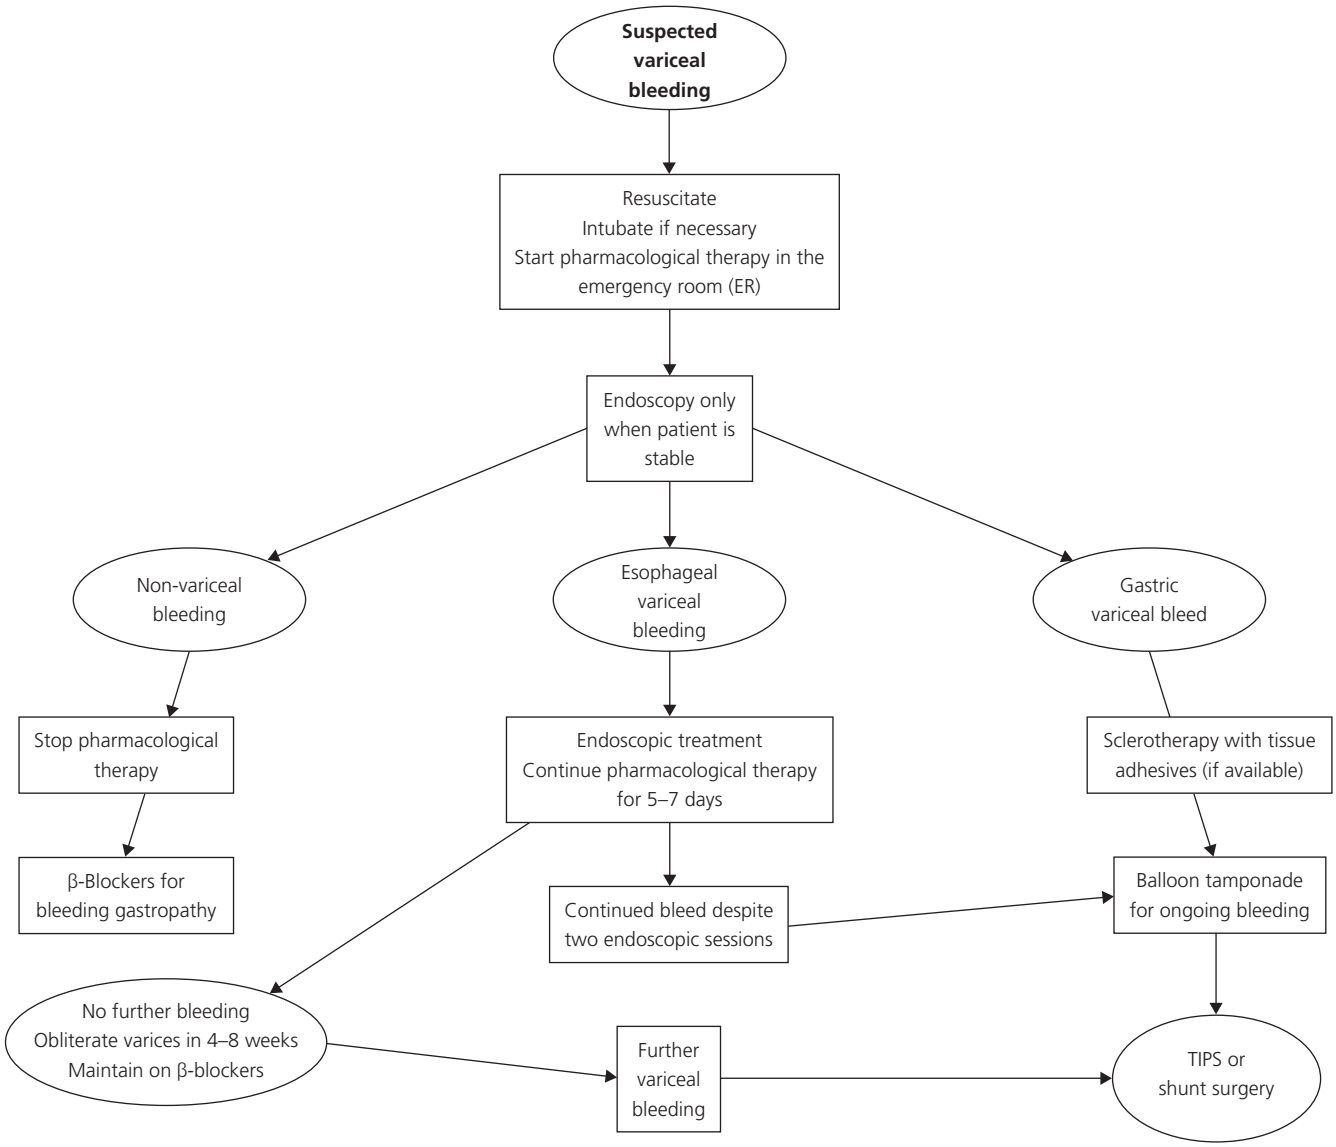

Figure 124.13 Broad outline of the management of acute variceal bleeding.

the availability of safer alternatives, vasopressin is not recommended for the management of acute variceal bleeding. However, if used because of its cost advantages, it should be used in combination with nitroglycerin.

Terlipressin (or Glypressin) (triglycyl lysine vasopressin) is a prodrug that is converted to lysine vasopressin in vivo; it is not approved for use in the United States. Terlipressin has properties similar to those of vasopressin, but unlike vasopressin, terlipressin can be given as bolus doses through a peripheral line. For unexplained reasons, terlipressin does appear to offer enhanced control of bleeding (efficacy around 80%) with fewer side effects compared with vasopressin or vasopressin used with nitroglycerin [90–94]. Repeated administration of terlipressin over a period of 6 days is as effective as sclerotherapy to control acute bleeding and to prevent early rebleeding [95].

Somatostatin and octreotide

Somatostatin and octreotide, a cyclic octapeptide analogue of somatostatin, cause splanchnic vasoconstriction by a direct effect on vascular smooth muscle and possibly by inhibiting the release of vasodilatory peptides such as glucagon [96]. Both drugs reduce portosystemic collateral blood flow as measured by azygos blood flow, but in cirrhotic patients the effect on portal pressure has been variable. Continuous infusion of somatostatin has been shown to produce a sustained decrease in HVWPG and blunt the rise in HVWPG in response to a test meal or blood transfusions [97]. However, to obtain optimal results, these drugs may need to be given as repeated bolus doses in addition to a continuous infusion. Although the standard dose of somatostatin is 250 μg bolus followed by 250 μg/h, a higher dose (500 μg/h) may benefit those who demonstrate active bleeding during emergency endoscopy

[98]. The addition of ISMN to somatostatin has not been shown to have any advantage over somatostatin alone [99].

A number of studies have compared somatostatin and octreotide with placebo, endoscopic treatment, or tamponade. These studies have clearly shown that both drugs are free of any major side effects, even when they were used as continuous infusion over 5–7 days. These studies also have shown a significant trend favoring somatostatin and octreotide (~ 85% efficacy) compared with either placebo or vasopressin [93,100–104]. Infusion of somatostatin or octreotide has also been shown to be comparable with balloon tamponade or endoscopic treatment [105–108]. A metaanalysis has shown that the control of bleeding was 40% better with octreotide (RR 0.6, CI 0.4–0.8) compared with vasopressin/terlipressin (bundled together), and comparable with sclerotherapy [109]. More importantly, the side-effect profile with octreotide was similar to placebo and significantly better than vasopressin/terlipressin (RR 0.3, CI 0.11–0.87).

Because of their excellent safety margin, these drugs can be used in the emergency department while the patient is resuscitated, and their use continued over the first few days after the bleeding to prevent early rebleeding. In a randomized controlled trial, the active bleeding rate was lower when vapreotide, another analogue of somatostatin, was administered prior to endoscopy, reinforcing the utility of early pharmacological therapy [110]. A combination of continuous infusion of these drugs for 5–7 days along with either sclerotherapy or band ligation has been shown to be superior to either sclerotherapy or band ligation alone in reducing early rebleeding and mortality [110–114]. In addition, the blood transfusion requirement is lower when these drugs are administered for 5–7 days after the bleeding. The combination treatment appears to benefit particularly those patients with shock and ongoing bleeding [114,115]. Another advantage of continuous pharmacological therapy is its efficacy in reducing bleeding from sclerotherapy- or banding-induced esophageal ulceration [115]. In fact, a Cochrane metaanalysis of randomized controlled trials suggested that there is no real advantage of endoscopic treatment as first-line therapy in patients with acute variceal bleeding [116]. The accumulating evidence favors the use of a combination of endoscopic treatment with either octreotide (or other analogues) or somatostatin. These drugs should be started prior to endoscopy and continued for 5–7 days after the bleeding episode.

Endoscopic therapy

The control of bleeding with either endoscopic sclerotherapy or band ligation is around 75%–90% [117,118]. The control of bleeding with endoscopic banding is comparable with sclerotherapy in patients with active variceal bleeding [119]. However, no specific benefits have been shown for band ligation over injection sclerotherapy during active bleeding [119,120]. Band ligation has also been found to be effective and probably safer than sclerotherapy in children with acute variceal bleeding [121]. Although endoscopic treatment was found to be marginally better than somatostatin/octreotide in some metaanalytical studies [120], many carefully performed studies and a metaanalysis have shown efficacy comparable with either form of treatment when used alone [116]. However, sclerotherapy was associated with more adverse events than somatostatin/octreotide [116,117]. About 15%–20% of patients treated with endoscopic sclerotherapy develop complications such as bleeding postsclerotherapy ulcers, esophageal stenosis, or perforation of esophagus. The complication rates are lower with band ligation.

Tissue adhesives, such as *n*-butyl-2-cyanoacrylate, have also been used by intravariceal injection to obliterate varices [122]. Tissue adhesives are not approved for intravariceal injection in the United States, but studies from elsewhere have claimed control of bleeding in approximately 90% of cases. The specific role for this treatment may be to obliterate fundal or ectopic varices that respond unreliably to intravariceal injection of sclerosant or band ligation [26,122]. There is no convincing evidence to recommend the use of tissue adhesives for esophageal variceal obliteration.

The optimum timing of endoscopic treatment with respect to the bleeding episode remains unknown. Formerly, it was generally believed that immediate endoscopic treatment is the optimum strategy for active variceal bleeding. The success rate of endoscopic treatment is operator dependent, and expertise varies widely among different centers [117]. The options are immediate treatment with associated technical difficulties and less than optimal expertise, or delayed treatment after temporary hemostasis is achieved using vasoconstrictive drugs. Because the efficacy of somatostatin, octreotide, or terlipressin is comparable with endoscopic treatment, it is reasonable to postpone endoscopy, for treatment as well as to confirm the diagnosis, until the patient is stabilized with pharmacological intervention [104–110,123,124]. Immediate endoscopic treatment could be reserved for nonresponders to pharmacological intervention. To reduce early rebleeding, it is advisable to continue vasoconstrictors such as somatostatin or octreotide (or terlipressin) for the first 5–7 days after the bleeding episode [110–114,123,124] (Table 124.5).

Predictors of failure to control acute variceal bleeding

A reliable model that can predict the failure of hemostasis after an acute variceal bleeding episode would be useful for risk stratification, management, and research. Many studies have been done, but small sample sizes, the retrospective nature of the studies, heterogeneity of offered therapies, and different patient characteristics make it difficult to draw any definite conclusions. However, active bleeding at the time of endoscopy has been shown independently to predict failure to control bleeding and early (30-day) mortality in many studies [125]. Other factors include higher HVWPG, encephalopathy, low platelet counts, alcoholic liver disease, shorter

interval between bleeding and hospitalization, and bacterial infections [97,125,126]. Mortality is clearly a reflection of the severity of liver disease and, therefore, particular attention should be given to providing "optimal" treatment to patients with more advanced liver disease. If bleeding continues despite a combination of pharmacological therapy and endoscopic treatment, or if endoscopic treatment is not feasible because of massive bleeding, the patient should be stabilized with balloon tamponade and considered for either transjugular intrahepatic portosystemic shunting (TIPS) or surgery.

Balloon tamponade

Balloon tamponade is a highly effective method of controlling active variceal bleeding. In experienced hands, it is equivalent to endoscopic treatment for the immediate control of bleeding. However, it is effective only when applied; when the balloon is deflated the rebleeding rate is extremely high. Moreover, in inexperienced hands (usually the case in most situations), the morbidity and mortality may be unacceptably high. Therefore, balloon tamponade is best reserved for the management of life-threatening bleeding when a risk of exsanguinations exists and endoscopic intervention is unlikely to be feasible. Balloon tamponade should not be applied for more than 24 h consecutively because of the risk of ischemic mucosal ulceration, and should be followed immediately by more definitive treatment. Depending on the situation, the definitive treatment may include endoscopic ligation or sclerotherapy (only in those who had no effective endoscopic treatment prior to balloon tamponade), surgery, or TIPS.

Role of surgery or transjugular intrahepatic portosystemic shunting (TIPS)

Although endoscopic therapy at the time of diagnostic endoscopy probably is the optimum approach to an episode of variceal bleeding, TIPS or surgical intervention (shunt or non-shunt procedure) has an important role, particularly in patients who continue to bleed despite early injection sclerotherapy or band ligation and pharmacological therapy (Fig. 124.14). It is reasonable to repeat endoscopic therapy on a second occasion before considering it to have failed, but the decision to progress to TIPS or surgery should not be further delayed, thereby preventing the inevitable escalation of complications or risks associated with TIPS or surgery in a deteriorating patient. Patients with ongoing variceal bleeding should be stabilized with balloon tamponade prior to TIPS or surgery. The choice between TIPS and surgery depends on local expertise, patient choice, patency of the portal vein, and the severity of the liver disease as determined by Child–Pugh score or Model for End-stage Liver Disease (MELD) score. Surgery should be reserved for patients with a Child A or low MELD score, or those with portal vein thrombosis.

Although the role of TIPS in the management of acute variceal bleeding is not well defined by controlled trials, it has evolved as the major "rescue" procedure for the management of acute variceal bleeding in most centers. It is being increasingly used in the United States as a rescue procedure because of the relative inexperience with emergency shunt surgery in many centers. The morbidity and mortality with

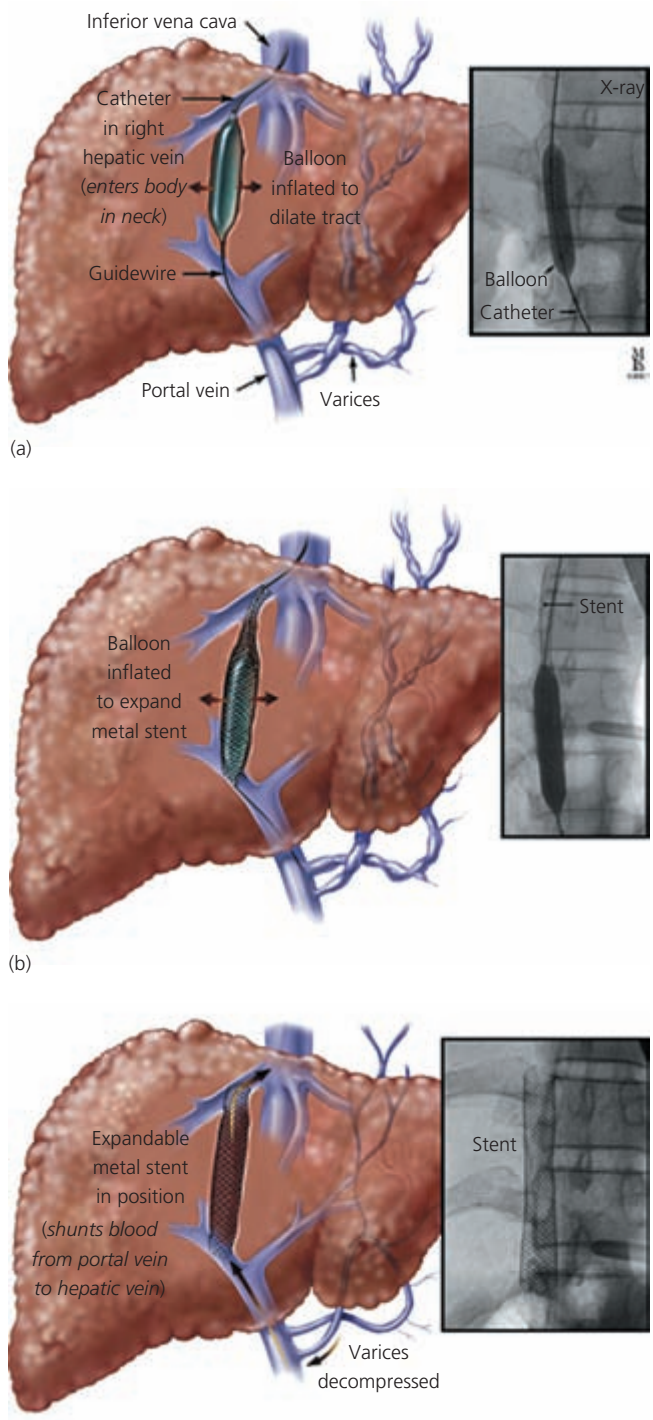

Figure 124.14 A cartoon showing the technique of transjugular intrahepatic portosystemic shunt (TIPS).

TIPS in patients with advanced cirrhosis and ongoing bleeding are similar to those of surgical procedures. In patients with ongoing bleeding and advanced liver disease (Child–Pugh C), the mortality with TIPS may be close to 30%–50%, which is more of a reflection of the severity of liver disease.

If surgical shunt was the choice of "rescue" procedure, the type of surgery chosen is dependent on the local expertise. Selective distal splenorenal shunt requires more operating time compared with either mesocaval or portacaval shunt, which makes it generally unsuitable as an emergency procedure (Fig. 124.15). Shunt surgery does not preclude subsequent transplantation, but could be associated with hepatic encephalopathy (~ 30%) in a significant number of patients. The most commonly used nonshunting surgery is esophageal transection with varying degrees of devascularization, but it is rarely done in Western countries because of better options [24]. In trials comparing sclerotherapy with esophageal transection or portacaval shunting, the survival rates were not different between the groups [1]. These studies have confirmed the utility of esophageal transection and shunt surgery as "rescue" procedures for patients who fail combined endoscopic and pharmacological therapy. The evidence suggests that TIPS may be the best option in patients who fail combined treatment and have ongoing bleeding. The shunt surgery may be reserved for secondary prophylaxis in Child A patients who bleed despite β-blockers and endoscopic treatment (Fig. 124.16) [127].

Bleeding from gastric varices

Although the management of gastric varices is similar to that of esophageal varices, endoscopic sclerotherapy using sclerosant should be reserved only for lesser curve varices or varices within a hiatus hernia [128]. Tissue adhesives (*n*-butyl-2-cyanoacrylate) may be used to inject fundal varices during active bleeding or preferably after the initial bleeding has stopped [25,129]. These adhesives polymerize rapidly in contact with blood, and plug the injection site as well as the bleeding site. However, it is technically difficult to inject fundal varices when there is active bleeding.

In one randomized controlled trial, 32 (GOV1 stage, 21; GOV2 stage, 7; IGV1 stage, 4) patients were randomized to butyl cyanoacrylate injection, and 29 (GOV1 stage, 20; GOV2 stage, 8; IGV1 stage, 1) to variceal banding; 15 and 11 patients had active bleeding at the time of randomization. When compared with band ligation, hemostasis (13/15, 87% vs 5/11, 45%; $P = 0.03$), and rebleeding rates (31% vs 54%, $P < 0.001$) were better with cyanoacrylate [25]. Complications (19% vs 38%, $P = 0.05$) and mortality (29% vs 48%, $P = 0.05$)

were higher in the banding group. Bleeding from ulcer was the most common complication (6% vs 28%, $P = 0.03$). One patient developed a cerebrovascular event 12 h after cyanoacrylate injection – this is one of the dreaded complications of cyanoacrylate injection. This study included predominantly GOV1 varices and may not be applicable to fundal varices. Of the four patients with isolated fundal varices treated with cyanoacrylate, two patients rebled after 2–3 sessions, one died, and the fourth one had to be rescued by TIPS. To my knowledge, there are no other controlled studies that have compared cyanoacrylate with variceal banding.

The FDA has not approved the use of *n*-butyl-2-cyanoacrylate for variceal treatment, although it is available for other purposes. If a decision was made not to treat gastric varices with "glue," the next best option for bleeding fundal varices is balloon tamponade for temporary hemostasis followed by more definitive therapy such as TIPS or shunt surgery. If balloon tamponade is unsuccessful in patients with bleeding fundal varices, the surgeon should proceed immediately to transjugular intrahepatic portosystemic shunting (TIPS) or shunt surgery [130–132]. In one case series, bovine thrombin was used effectively for bleeding gastric varices [133]. However, in the absence of controlled trials, this form of treatment is not recommended.

Barange et al. reported their experience with TIPS in 32 (GOV1 stage, 22; GOV2 stage, 10) consecutive patients who did not respond to pharmacological therapy ($n = 26$) or sclerotherapy ($n = 18$) [131]. Active bleeding was controlled by TIPS in 18 of 20 patients. Rebleeding rates for the entire cohort after TIPS were 14%, 26%, and 31% respectively at 1 month, 6 months, and 1 year. Other studies have also reported that TIPS is effective for gastric variceal bleeding [132]. Other options for bleeding gastric varices may include transhepatic embolization. However, rebleeding rates are high after this procedure. When isolated fundal varices are seen in association with splenic vein thrombosis, the treatment is splenectomy. Injection of tissue adhesive is another option in these patients if they are not candidates for splenectomy.

Bleeding from other ectopic varices

Management of the bleeding depends on the site of bleeding, the severity of liver disease, and the local expertise. Because there are no controlled studies, it is difficult to recommend any special strategy. Shunt surgery may be the best line of management for bleeding varices in the duodenum, jejunum, ileum, and enterostomy. If the portal vein is patent and the expertise for TIPS is readily available, TIPS should be considered as the first line of management before other forms of shunt surgery. Anecdotal reports suggest that duodenal varices and ileostomy varices can be managed successfully by sclerotherapy or feeding vessel embolization, but serious consideration must be given to the postsclerotherapy complications like duodenal perforation and stoma dysfunction, and the high recurrence rate after embolization. Colonic varices are usually localized and can be managed by local resection. When colonic varices are seen in association with esophageal varices, TIPS may be a safer alternative. Anorectal varices can be safely treated with sclerotherapy or by underrunning with an absorbable suture.

Acute variceal bleeding: summary of management recommendations

Optimal resuscitation in a timely fashion is crucial for a better outcome in patients with acute variceal bleeding. Pharmacological intervention while the patient is resuscitated is safe and beneficial, and pharmacological treatment should be continued for 5–7 days to prevent early rebleeding. Endoscopic diagnosis and therapy should be performed when the patient is adequately resuscitated and stabilized (Table 124.7). Shunt surgery or TIPS should be reserved for nonresponders to a combination of pharmacological and endoscopic therapy, and should not be delayed when endoscopic therapy fails on two separate occasions. Bleeding from fundal varices is managed by either early surgery or TIPS. If tissue adhesives are available, endoscopic treatment with these agents may be an alternate option for bleeding fundal varices before considering surgery or TIPS.

Secondary prophylaxis

Rebleeding is common after the first bleed; 50%–80% of those who survive the first bleed may rebleed within 2 years, and most rebleed within 6 weeks after the first bleed. A number of options are available to prevent recurrent esophageal variceal bleeding, including endoscopic sclerotherapy or banding, nonselective β-blockers, shunt or nonshunt surgery, TIPS, and liver transplantation [134–145].

Secondary prevention studies comparing propranolol with placebo have shown that propranolol reduces both the bleeding rate and the mortality rate by about 40% [1,145]. It has been shown that a 20% reduction in HVWPG can reduce the rebleeding rate significantly, and reduction to below 12 mmHg may completely abolish recurrent bleeding [3,136,145]. Trials comparing propranolol or nadolol with sclerotherapy have confirmed that both forms of treatment are similar in efficacy [1,137].

The recurrence of bleeding after the initial obliteration of varices is related to the development of new esophageal variceal columns; other sources include portal hypertensive gastropathy and gastric varices. Although it may appear logical to perform long-term follow-up endoscopic treatment, there is no convincing evidence to suggest that long-term follow-up treatment is superior to short-term treatment aimed at obliteration of varices, especially if patients are maintained on β-blockers. Based on the limited data, it appears that addition of β-blockers to short-term endoscopic therapy may reduce the bleeding rate compared with either treatment alone. This was to be expected because a significant number of patients on β-blockers do not attain the desired reduction in HVWPG. Combination treatment may be useful especially in patients who are less likely to comply with medical treatment or in those who cannot tolerate maximal medical treatment.

Shunt surgery (preferably mesocaval shunt or distal splenorenal shunt) is reserved for patients with good synthetic function (Child A) and recurrent variceal bleeding who fail endoscopic and pharmacological treatment [127] (Fig. 124.16). Although TIPS is effective in preventing recurrent rebleeding (50% reduction compared with endoscopic treatment), it is associated with high rates of shunt stenosis and occlusion [138–144] (Table 124.6). Periodic monitoring and revision of shunts is therefore necessary to obtain optimal results, and this may turn out to be expensive in the long run. In addition, TIPS is associated with high rates of hepatic encephalopathy (29%–55%). It has not been shown that TIPS reduces overall mortality compared with endoscopic treatment. The

indication for TIPS is as a bridge to transplantation in patients with advanced cirrhosis (Child B or C) who present with recurrent rebleeding despite endoscopic and pharmacological treatment. The mortality after variceal bleeding and the long-term survival following the index bleed are directly related to the severity of liver disease. It is difficult to imagine that the various treatment options discussed here are likely to improve liver function and hence survival. Liver transplantation, with a 5-year survival rate reaching 85%–90% percent, is the treatment of choice for patients with advanced liver disease.

The in-hospital mortality has remained high, even in tertiary care hospitals, despite advances in the management of acute variceal bleeding [2]. Moreover, there is a wide variation in mortality among various hospitals. One of the main reasons for this high mortality may be lack of a "critical pathway" for the management of acute variceal bleeding in most hospitals, leading to nonuniform and often suboptimal treatment regimens for these patients depending on the physician in charge. This could be improved with well-defined protocol-based management in the emergency room, in the intensive care unit, and in the wards, followed by a discharge summary with clear instructions for outpatient management to both the patient and the family physician.

Recommendations

A combination of β-blockers and endoscopic treatment (preferably banding) may be a logical approach for secondary prophylaxis. The objective of endoscopic therapy is to obliterate the varices over a period of 6–8 weeks after the index bleed. There is no evidence to suggest that long-term endoscopic surveillance is beneficial. Shunt surgery or TIPS should be reserved for patients who rebleed despite a combination of endoscopic and pharmacological therapy (Table 124.8; Fig. 124.16). Liver transplantation is the treatment of choice for patients with advanced liver disease and recurrent variceal bleeding.

Portal hypertensive gastropathy

Portal hypertensive gastropathy (PHG) is the term used to describe the endoscopic appearance of gastric mucosa seen in patients with cirrhotic or noncirrhotic portal hypertension, characterized by a mosaic-like pattern with or without red spots (Fig. 124.17) [146]. The "mosaic" pattern appears as a white reticular network separating areas of raised red or pink mucosa resembling the skin of a snake (also often described as snake-skin appearance). Portal hypertensive gastropathy is seen mainly in the body and the fundus of the stomach, but also is seen rarely in the gastric antrum. These changes are not unique to the gastric mucosa; similar changes are also rarely seen in the small intestine and colon (Fig. 124.18), especially in the presence of extrahepatic portal hypertension. When PHG is severe, it can include discrete cherry-red spots, fine pink speckling, or scarlatina-type rash, collectively called red marks [147]. The characteristic histological finding of PHG is dilated capillaries and venules in the mucosa and submucosa without erosion, inflammation, or fibrinous thrombi [148].

Classification

There is no general consensus on the endoscopic classification of PHG [146–151]. The most widely used classification is the one recommended by McCormack et al. [148], who classified PHG into mild and severe. Its popularity relates in part to its simplicity and also its ability to predict the risk of bleeding, with an increased risk of gastric hemorrhage in severe (38%–62%) compared with mild cases (3.5%–31%) [146]. However, often the observed endoscopic findings are of an intermediate severity and are not well represented as

(a) (b) (c)

Figure 124.17 Grading of portal hypertensive gastropathy.

Figure 124.18 Portal hypertensive colopathy (cecum).

being either mild or severe. Tanoue et al. and New Italian Endoscopy Club (NIEC) have subsequently described a more detailed scoring system [152]. Tanoue et al. classified PHG into four grades:

- Grade 0: none
- Grade 1: mild
- Grade 2: moderate
- Grade 3: severe.

Grading PHG as mild, moderate, and severe permits more informative description of the observed endoscopic findings. However, Yoo et al. found substantial limitations with regard to both specificity and reproducibility with both classification systems [149]. A simpler classification system as recommended by McCormack et al. had a relatively better intra- and inter-observer agreement and reproducibility as determined by kappa values [148,149].

Prevalence

The reported prevalence of severe PHG ranges from 9% to 46%, and that of mild PHG from 29% to 57%. Estimates of the overall prevalence of PHG vary from 51% to 98% (Table 124.7). The wide variation in the reported prevalence is perhaps related to patient selection, absence of uniform criteria and classification, and, more importantly, inter- and intra-observer variation [146,153,154].

The development of PHG correlates with the duration and severity of liver disease, presence and size of gastroesophageal varices, and previous variceal eradication by endoscopic variceal sclerotherapy or banding [152–156]. Although PHG is usually seen in association with either esophageal or gastric varices, there is no direct linear correlation between portal pressure and the presence or severity of PHG. The cause of portal hypertension is unlikely to be a significant factor. Sarin et al. reported a low prevalence of PHG (2.6%–37.1%) in studies from India, where many patients had noncirrhotic portal hypertension [155–157]. However, another large series from India reported a prevalence of 62% suggesting that the cause of portal hypertension may not play an important role in the development of PHG [157]. The prevalence of PHG does not appear to have a linear relationship with the severity of liver disease, as evidenced by a study that showed the lowest prevalence of severe PHG in Child C patients [151]. This may suggest that other hitherto unidentified factors may play a role in the pathogenesis of PHG. However, there is general agreement, based on longitudinal studies, that the prevalence of PHG does increase with variceal obliteration.

Pathogenesis

Portal hypertension, and not liver disease, seems to be the key factor for the development of PHG, because PHG is equally common in portal hypertensive patients with or without liver disease [158,159]. Moreover, the improvement or disappearance of PHG in many patients after TIPS and shunt surgery suggests that there is a significant association between PHG and portal hypertension. However, the severity and the presence of PHG do not have a linear correlation with the

severity of portal hypertension [154]. Chronic elevation in portal pressure and increased splenic circulation may increase gastric mucosal blood flow, and this may be one explanation for the development of PHG, although actual measurement of gastric blood flow using Doppler ultrasound has shown variable results, suggesting that there may be other explanations for the pathogenesis of PHG [159–164]. The severity of PHG may increase with more advanced liver disease, as shown in some studies, but the results are not consistent [151,153,154]. There have been many other explanations for the pathogenesis of PHG. In experimental models, noxious agents such as aspirin, bile acids, or alcohol have been shown to produce gastric mucosal damage in animals with portal hypertension compared with controls [165]. Circumstantial evidence in humans has shown similar results [166]. There is experimental evidence to suggest that gastric mucosal defense mechanisms are impaired in the presence of portal hypertension [165–173]. In addition, activation of cytokines and growth factors in the gastric mucosa may induce nitric oxide and endothelin-1, which in turn may further contribute to hyperdynamic circulation. In addition, endothelin-1 and peroxynitrite overproduction may also increase susceptibility of gastric mucosa to damage [174]. Kawanaka et al. [175] have shown that oxidative stress-induced ERK2 – a mitogen-activated protein (MAP) kinase – is defective in PHG, and this is mediated by over-expression of MAP kinase phosphatase 1 (MKP-1). Interestingly, in this study, MKP-1 over-expression was normalized after supplementation with vitamin E, and this may have therapeutic implications for the management of PHG.

Gastric antral vascular ectasia (GAVE)

An area that has not been resolved completely is the association of gastric antral vascular ectasia (GAVE) and PHG [146,166,176]. "Watermelon stomach," or GAVE, is a term used for the typical endoscopic findings of red stripes separated by normal mucosa, most commonly seen in the gastric antrum or proximal stomach [177] (Fig. 124.19). Watermelon stomach, or GAVE, has been reported in a variety of autoimmune diseases and connective tissue diseases including atrophic gastritis, scleroderma, sclerodactyly, hypothyroidism, pernicious anemia, and primary biliary cirrhosis [178]. Something similar to watermelon stomach is also seen in recipients of bone marrow transplants [179,180]. The typical histological appearance of GAVE includes marked dilation of capillaries and collecting venules in the gastric mucosa and submucosa with areas of intimal thickening characterized by fibromuscular hyperplasia, fibrohyalinosis, and thrombi [166,177,181,182]. The pathogenesis of GAVE is poorly understood and there is no single unifying hypothesis. Possible mechanisms include humoral factors (such as gastrin, prostaglandin, serotonin, or vasoactive intestinal peptide [VIP]), cellular growth factors (especially in bone marrow transplant recipients), and mechanical causes [166,181,183,184].

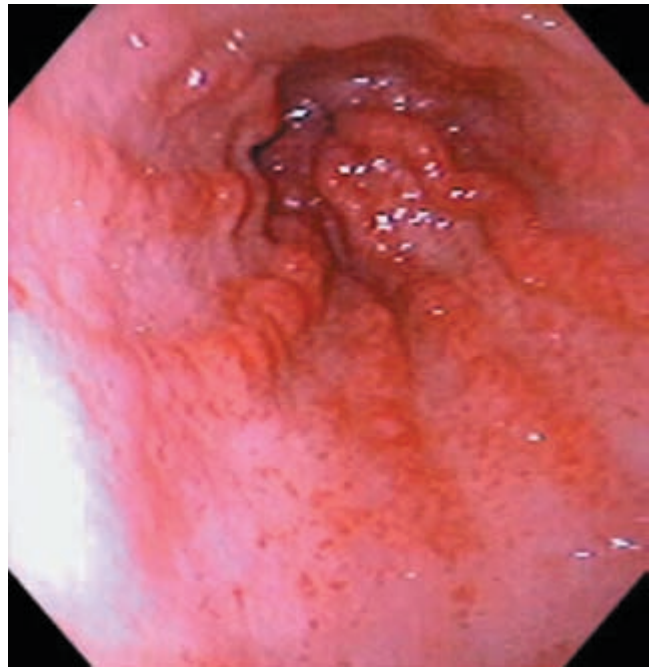

Figure 124.19 Gastric antral vascular ectasia (GAVE).

Proponents of the "mechanical" theory have suggested that chronic intermittent venous obstruction associated with powerful muscular contractions of the antrum and pylorus, or repeated trauma associated with a loosely attached antral mucosa and prolapse of the antral mucosa through the pylorus, may cause GAVE [177,182,185]. It is reasonable to suggest that despite the absence of a unifying hypothesis, GAVE is a distinct entity and the presence of GAVE is associated with intermittent bleeding in a significant number of subjects.

When the red marks seen in severe PHG become confluent, they may have a striped appearance producing a close resemblance to GAVE (Fig. 124.20). A "GAVE-like" appearance is not uncommon in patients with portal hypertension; indeed, in my experience, a "GAVE-like" appearance is more common in patients with portal hypertension than in those without. The dilemma is whether this appearance is called GAVE or severe PHG. The histological appearance of GAVE is different from PHG, but mucosal biopsies are rarely deep enough to make a firm diagnosis. Moreover, it may not be completely safe to do repeated biopsies in patients with portal hypertension and severe PHG. Bleeding from GAVE, unlike PHG, is not known to respond to nonselective β-blockers [166,186]. However, such a therapeutic challenge is not clinically useful to differentiate these two entities because the response to β-blockers is variable in patients with PHG. Kamath et al. showed that patients with GAVE, in the absence of a background mosaic appearance, did not respond to TIPS compared with those with PHG [187]. On the basis of their study, the authors suggested that the GAVE-like appearance seen in patients with portal hypertension is distinct from severe

(a)  (b)

Figure 124.20 GAVE-like appearance in portal hypertensive gastropathy. Note the typical background portal hypertensive gastropathy.

PHG. Although their observation merits further consideration, in their study TIPS was done for the prevention of recurrent gastric variceal bleeding and not for prevention of bleeding from PHG. The response of PHG bleeding to TIPS has been variable in anecdotal reports and this may suggest that a lack of response after TIPS is not evidence for a different pathogenesis.

There is circumstantial evidence to suggest a possible association between PHG and GAVE. Although GAVE is seen in patients without portal hypertension [178], it is seen more commonly in patients with cirrhosis and portal hypertension [181,182,187]. It has been suggested that the same gastric vascular alteration related to portal hypertension may appear different, grossly and histologically, depending on the anatomical location in the stomach [188]. The hemodynamics of venous drainage of the antrum are different from the body or fundus of the stomach. It can be argued that the "typical" histological changes, fibrosis and thrombosis, seen in GAVE may also be seen with more chronic and severe PHG. The variable response to β-blockers and TIPS may be a reflection of the advanced histological changes [166]. I believe that the term GAVE should be reserved for the presence of typical, linear red lesions in the gastric antrum without the "mosaic"-like appearance of mucosal background in the rest of the stomach. When there is evidence of a mosaic-like pattern or evidence of more severe PHG in the body and fundus, I favor classifying it as a spectrum of PHG (Fig. 124.17).

Natural history and complications of PHG

The overall incidence of acute bleeding from PHG is low, and bleeding is seen mostly in those with more severe PHG. Bleeding is often mild, and transfusion requirement is usually limited to one or two units of blood. The prevalence of chronic bleeding cannot be reliably estimated because of the uncertainty of making a firm diagnosis. D'Amico et al., in a long-term follow-up of 137 patients, reported PHG in 33 patients (mild 28, severe 5) on their initial endoscopy, and, during a mean follow-up of 46 months, 35 additional patients developed PHG (mild 33, severe 2) [189]. The frequency of bleeding was higher in those with severe PHG (38%–62%) compared with those with mild PHG (3.5%–31%) [156,189]. The wide variation in the reported incidence of acute bleeding from PHG is mainly related to the difficulty in making a firm diagnosis and the inaccuracy of classification of the severity of PHG. Unless an obvious bleeding point is identified, it is difficult to confirm that the source of bleeding is PHG in most patients. Moreover, if a drop in hematocrit is used to diagnose chronic bleeding, it is likely grossly to overestimate bleeding from PHG. The mortality associated with bleeding from PHG is low because most bleeds are minor compared with variceal bleeding. Death resulting from PHG is unusual and bleeding from PHG is not an independent risk factor for survival.

The presence and severity of PHG appear to change with time. In one study, during a follow-up of 2 years, the severity of PHG fluctuated with time in 25%, improved in 23%, remained stable in 29%, and deteriorated in 23% [151]. In the same study, 46% (65 mild PHG and 7 severe PHG) of patients with cirrhosis developed PHG during a 5-year follow-up. Endoscopic sclerotherapy appears to worsen the severity of PHG and increases the risk of bleeding [148,152,155,190]. In

one study, 44% of patients developed PHG following variceal eradication by sclerotherapy compared with only 9% before sclerotherapy [156]. Major determinants of bleeding from PHG are duration of the PHG, and the extent and severity of lesions. Aggravation of PHG after sclerotherapy might be caused by alterations in local hemodynamics following obliteration of the esophageal varices [155]. Increase in pressure and flow, and the differential hemodynamics within gastric veins are potential causes for the development of PHG after variceal obliteration [191–193]. Hepatofugal flow velocity is increased in the left gastric vein in direct relationship to the enlargement of esophageal varices. Gastric mucosal blood flow is higher in cirrhotic patients whose extrahepatic collaterals are predominantly through esophageal varices. Therefore, obliteration of the esophageal collateral venous network may cause higher flow velocity in the gastric vascular bed. It has been speculated that the extravasation of sclerosant into the mediastinum during sclerotherapy may result in chemical vagotomy, and this may cause esophageal dysmotility and delayed gastric emptying. Delayed gastric emptying, from the chemical vagotomy, has been proposed as a possible mechanism for the development of PHG [194]. However, there is no direct evidence to suggest that delayed gastric emptying causes PHG.

Management

Clinically significant bleeding is seen only when PHG is severe. Nonselective β-blockers such as propranolol and nadolol have been shown to reduce portal pressure and gastric mucosal blood flow. In small studies, propranolol has been shown to reduce bleeding related to PHG [195,196]. These observations were confirmed in a randomized controlled trial of 56 patients with PHG [183]. In this study, the bleeding was significantly lower in the treated group compared with the placebo group at 12 months (35% vs 62%) and 30 months (48% vs 93%). Multivariate analysis showed that absence of propranolol treatment was the only predictive variable for rebleeding. Other medications such as prednisone, estrogen, and progesterone are ineffective for bleeding related to PHG [197].

Somatostatin has been shown to reduce gastric mucosal blood flow by decreasing splanchnic blood flow [198]. Similar effects are also seen with vasopressin and Glypressin. In patients with acute bleeding, an uncontrolled study has shown therapeutic efficacy with both somatostatin and octreotide [199]. However, it has been shown that the decrease in portal pressure is only transient, therefore use of somatostatin or octreotide is unlikely to benefit patients with chronic PHG bleeding [200]. The use of these agents should be limited to patients with acute bleeding.

Endoscopic treatment does not have a significant role in the management of PHG bleeding because the bleeding is often mild and diffuse. If an active bleeding site is identified, it can be managed by injection of sclerosant, or by cauterization using the heater or bipolar probe. However, there are no controlled studies to suggest that these forms of treatment are either efficacious or safe. Although laser therapy has been shown to be safe and effective in reducing GAVE-associated bleeding, it is not known whether laser therapy is effective or safe in patients with severe PHG when the predominant lesion is in the gastric antrum [201]. A study reported success with argon plasma coagulation in eight patients with GAVE and cirrhosis [202]. The safety and efficacy of this treatment needs to be confirmed in large studies before it can be recommended for patients with portal hypertension. Both TIPS and shunt surgery have been shown to be effective for PHG bleeding in anecdotal reports [203]. In a small study, TIPS improved severe PHG in six of eight patients, and in mild PHG 23 of 27 patients showed improvement [186]. Despite these encouraging anecdotal reports, I believe that TIPS or shunt surgery should be used only as the last resort in these patients because the risks outweigh the benefits. The only treatment that can be recommended for prophylaxis of PHG bleeding is administration of nonselective β-blockers such as propranolol or nadalol.

Portal hypertensive gastropathy: summary

Portal hypertensive gastropathy has characteristic endoscopic features of a mosaic pattern with or without red spots, and is found most frequently in the fundus and body of the stomach. The classification systems have many limitations, but a simple grading system may assist inter- and intraobserver agreement. The pathogenesis of PHG is not clearly defined, but there is a close relationship between portal hypertension and development of PHG. Gastric antral vascular ectasia (GAVE) is a separate entity from PHG, but patients with severe PHG may have a GAVE-like appearance in the gastric antrum. If a "mosaic-like" pattern is seen in the rest of the gastric mucosa, I believe that a GAVE-like appearance should be considered as a spectrum of PHG. Acute bleeding from PHG is usually mild and seen in the presence of severe PHG. The only treatment that can be recommended for prophylaxis of bleeding from PHG is nonselective β-blockers.

Repeat endoscopic therapy, 3027
Prevention of rebleeding, 3027
Summary, 3028

Upper gastrointestinal (UGI) bleeding is a common clinical disorder. It is responsible for over 250 000–300 000 hospital admissions and $2.5 billion in costs in the USA each year [1–3]. The most common cause of nonvariceal UGI bleeding is peptic ulcer disease, but other disorders may have an identical presentation [4]. Gastrointestinal endoscopy remains the diagnostic and therapeutic procedure of choice for UGI bleeding. Despite progressive advances in the diagnosis, the mortality from acute UGI bleeding remains 10%–15% [3].

Initial evaluation and preparation for endoscopy: treat shock

The initial evaluation of patients with acute GI bleeding should focus on the hemodynamic status. Blood hemoglobin concentration and hematocrit are unreliable markers of acute blood loss. Intravenous access and vigorous volume replacement improves patient outcomes and should be immediately initiated in all patients with hemodynamically significant GI bleeding [5]. This requires large-bore vascular access in at least two locations and immediate infusion of isotonic electrolyte solutions until vital signs become stable. The use of blood products should be determined by the patient's clinical condition and the rapidity of blood loss [6]. Other diagnostic and treatment decisions should not take precedence over volume resuscitation.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Assessing the level of bleeding

Endoscopy is the optimal method for establishing the level of bleeding. A history of hematemesis with frank blood or coffee grounds-like material is sufficient to confirm the level of bleeding to be above the ligament of Treitz. A prior history of bleeding ulcers, nonsteroidal antiinflammatory drug (NSAID) use, or variceal bleeding is suggestive, but not sufficient, to establish the presence of a UGI bleeding source. A history of melena is also suggestive of UGI bleeding, but dark, melena-like, stool can occur with slow bleeding from the small bowel or proximal colon. Hematochezia is more suggestive of a bleeding site in the lower GI tract, but may also result from vigorous UGI bleeding in 10% of cases.

Nasogastric aspiration is 80% sensitive for an actively bleeding UGI source when it produces fresh or altered blood. False-negative aspirates occur when the tube is improperly positioned, or the reflux of blood from a duodenal source is prevented by pylorospasm or obstruction [7]. Continuous nasogastric suction can identify continued or recurrent bleeding prior to changes in vital signs or laboratory values. When vigorous bleeding is identified, gastric lavage using a large-bore orogastric tube can clear the stomach of blood and clots and improve visualization for endoscopic evaluation and treatment [8]. Intravenous erythromycin has also been demonstrated to promote passage of blood and clots from the stomach, improving visualization [9].

Role of endoscopy in diagnosis

After the patient has become hemodynamically stable, endoscopy is the diagnostic procedure of choice in the setting of

Table 125.1 Contraindications for upper gastrointestinal endoscopy

Absolute contraindications
Refusal of informed consent
When the risks of the procedure outweigh the potential benefits
Endoscopic information or therapy will not alter the outcome or care
Relative contraindications
Suspected gastroduodenal perforation
Hemodynamic instability
Combative, uncooperative patient
Severe coagulopathy
Unprotected airway

UGI bleeding. The contraindications to endoscopy are listed in Table 125.1. Absolute contraindications include refusal of the procedure by the patient, a situation where the risks of the procedure outweigh the potential benefits of the procedure (such as shock), and where the procedure will not alter the outcome or care of the patient [10]. The relative contraindications can often be overcome by appropriate patient preparation. For example, airway protection may be achieved by endotracheal intubation prior to endoscopy and coagulation disorders may be mitigated by the infusion of blood products.

Endoscopy has a sensitivity of 92% when the entire stomach and proximal duodenum can be carefully visualized and has a specificity that approaches 100% [11]. By comparison barium radiography has a sensitivity of only 54%. Residual blood can be removed from the stomach by nasogastric lavage. Intravenous erythromycin has been demonstrated to stimulate gastric emptying of clots prior to endoscopy [9]. Visualization of the bleeding lesion can be aided by local application of 3% hydrogen peroxide through the endoscope [12,13]. The ability to perform biopsies to diagnose malignancy and the presence of *Helicobacter pylori* infection is not available with barium studies. Most importantly, prior barium radiography prevents potential endoscopic therapy that can improve morbidity and mortality. As a result, barium radiography should be avoided in the setting of acute UGI bleeding.

Not only will a careful endoscopic examination identify the source of UGI bleeding, it can also provide predictive information about the prognosis (probability of rebleeding, morbidity and mortality). Clinical prognostic factors, including age, shock, volume of bleeding, need for transfusion, onset of bleeding in the hospital, and comorbid conditions, have been identified [14,15]. Since the advent of endoscopy, however, it has been demonstrated that the endoscopic appearance of bleeding ulcers more accurately predicts the risk of rebleeding morbidity and mortality. Shortly after the availability of endoscopy, Forrest recognized specific endoscopic findings that were associated with an increased risk of rebleeding [16]. The original classification by Forrest (in order of risk of rebleeding and increased mortality) includes the following features: ulcers with a clean base, the presence of flat pigmented spots in the base, an adherent clot resistant to vigorous flushing, a nonbleeding visible vessel, and active bleed (either oozing or vigorous bleeding) (Fig. 125.1a–e). This classification has been repeatedly shown to accurately predict the rate of rebleeding, morbidity, and mortality in multiple studies [1,17]. A review of the data from various studies by Laine and Peterson [1] is presented in Table 125.2, demonstrating that patients with high-risk stigmata for hemorrhage (active bleeding or a nonbleeding visible vessel) have a high rebleeding rate that is associated with a correspondingly high morbidity and mortality. Patients without high-risk stigmata (those with a clean ulcer base or flat pigmented spots) have an extremely low rate of rebleeding and a negligible mortality [1]. In a large study in the UK, Rockall and colleagues combined the above noted clinical predictors with the endoscopic appearance of lesions into a scoring system to predict the outcome of acute UGI bleeding (Table 125.3) [18]. This validated scoring system demonstrates the utility of endoscopy in predicting the outcome of acute UGI bleeding. Patients with a score of 2 or less have a risk of rebleeding of less than 5% and virtually no mortality [18]. The addition of endoscopic findings to the other clinical criteria dramatically increased the accuracy of prognosis prediction based on clinical factors alone. In another study Jaramillo and colleagues evaluated 1567 consecutive patients with acute UGI bleeding using multivariate analysis. None of the patients had endoscopic therapy. The rebleeding rate was 20%. The presence of endoscopic high-risk stigmata was the most powerful predictor for rebleeding (odds ratio [OR] 3.1, $P < 0.001$) [19].

Other endoscopic findings have been suggested to increase the risk of recurrent bleeding. These include the size and location of the ulcer [20]. Both of these findings relate to the proximity of the base of the ulcer to a major artery or arteriole. Doppler ultrasound probes have been used in an attempt to identify large vessels in or near ulcers to predict the risk of rebleeding. These attempts have met with moderate success in targeting endoscopic therapy, but have limited sensitivity and specificity [21,22]. The technology has not been widely accepted.

Diagnostic role of urgent endoscopy (endoscopic triage)

While it may seem intuitively obvious that endoscopy would improve patient outcomes, randomized trials have indicated that diagnostic endoscopy alone does not improve mortality, rebleeding rates, need for surgery, or hospital stay [23–25]. The overwhelming majority (75%–80%) of patients with bleeding ulcers stop bleeding spontaneously, limiting the impact of early endoscopy for diagnosis [17,19,25]. Based on these data, patients are often initially admitted to hospital for volume resuscitation and observation, then undergo diagnostic

(d) (e)

Figure 125.1 Endoscopic photos of stigmata of recent hemorrhage. **(a)** Clean base. Duodenal ulcer with a clean base. No evidence of protruding or pigmented areas is present. The rebleeding rate in this lesion is near zero. **(b)** Flat spot. Pyloric channel ulcer with a flat black spot in the center. The risk for rebleeding in this lesion is less than 10%. **(c)** Adherent clot. Duodenal ulcer with a large adherent clot in the base that could not be removed with vigorous irrigation. The nature of the lesion beneath the clot is unknown. The risk for rebleeding in this lesion is intermediate (up to 25%). **(d)** Nonbleeding visible vessel. A prominent protruding visible vessel with a bipolar probe in the foreground. This lesion has a high risk for recurrent bleeding (40%–50%) without endoscopic therapy. **(e)** Active bleeding. A duodenal ulcer with blood vigorously flowing. This is the lesion with the highest risk for continued or recurrent bleeding (approaching 60%). Endoscopic hemostasis can control active bleeding in most patients and can reduce the risk for rebleeding.

Table 125.2 Rate of rebleeding and mortality in multiple studies

Endoscopic finding	Risk of rebleeding (%)	Mortality (%)
Active bleeding	55	11
Visible vessel	43	11
Adherent clot	22	7
Flat spot	10	3
Clean base	5	2

endoscopy electively. Because urgent endoscopy improves morbidity and mortality only in the subset of patients with persistent or recurrent bleeding, both the National Institutes of Health and the American Society for Gastrointestinal Endoscopy have recommended that endoscopy be urgently performed in the subset of patients for whom endoscopic therapy is ancitipated [26,27].

Other data have raised the possibility of endoscopically identifying patients with acute UGI bleeding who have a low risk of rebleeding and require limited medical care. Laine and colleagues demonstrated that patients with clean ulcer bases or Mallory–Weiss esophageal tears had only a 2% risk of rebleeding and could be safely fed and immediately discharged from hospital [28]. Rockall and colleagues applied the previously mentioned scoring system to 2531 consecutive patients with acute UGI bleeding in the UK [29]. They identified 29.4% of the patients who had a score of 2 or less and a negligible risk of rebleeding or morbidity. Based on these data the authors suggested that a large number of patients without clinical risks or endoscopic stigmata for rebleeding could be safely managed without hospital admission, stating that "hospital admission has usually been regarded as obligatory until the risk of further hemorrhage has receded. This policy means that some patients at low risk stay in hospital for longer than is necessary especially when diagnostic endoscopy is delayed" [18]. Kodali and colleagues demonstrated that 21% of patients with bleeding from peptic ulcer disease had a clean ulcer base at endoscopy. These patients had a 3% risk of rebleeding [30]. The authors concluded that this group of patients could be safely managed as outpatients.

Table 125.3 Rockall classification of risk in acute upper gastrointestinal (UGI) bleeding

Variable	Score 0	Score 1	Score 2	Score 3	Points for this variable
Age (years)	< 60	≥ 60 and ≤ 79	≥ 80		Maximum 2
Shock	HR < 100 Systolic BP ≥ 100	HR ≥ 100 Systolic BP ≥ 100	Systolic BP < 100		Maximum 2
Comorbidity	None		Cardiac failure Cardiac ischemia Malignancy (undisseminated) Other comorbidity	Renal failure Liver disease Disseminated malignancy	Maximum 3
Diagnosis	Mallory–Weiss tear, no lesion	All other diagnoses	Malignancy of UGI tract		Maximum 2
Endoscopic stigmata	Clean base or flat spot		Active bleeding, adherent clot or nonbleeding visible vessel		Maximum 2
Total score					Maximum 11

BP, blood pressure (mmHg); HR, heart rate.

Two trials have retrospectively reviewed hospitalizations for UGI bleeding, and then developed criteria for same-day discharge (endoscopic triage) that were prospectively applied with success [31,32]. In a single-center study, Lee and colleagues demonstrated a decrease in costs of care associated with decreased resource utilization in patients undergoing endoscopic triage for nonvariceal UGI bleeding, with no increase in morbidity [33]. However, another similar-sized prospective multicenter study demonstrated no difference in the length of stay or clinical outcomes of patients undergoing urgent (preadmission) endoscopy or elective endoscopy after admission [34]. The major difference between these studies was the number of patients discharged from the emergency department. In the first study, 46% of the patients randomized to receive urgent endoscopy were discharged from the emergency room by the endoscopist, while in the second study the decision regarding admission was left to the attending physician (not the endoscopist) and only 4 of 47 eligible patients avoided hospitalization. These studies demonstrate the difference between efficacy and clinical effectiveness. In a situation where the endoscopic findings drive subsequent clinical care, endoscopic triage can significantly decrease hospitalization and costs of care for patients with a low risk of rebleeding. If the endoscopic findings do not affect subsequent care, then the information will not affect resource utilization.

Additional support for the effectiveness of endoscopic triage is provided by two studies by Hay and colleagues [35,36]. In the first study they developed a treatment guideline for UGI bleeding retrospectively, demonstrating the potential for substantial cost savings using endoscopy and three other factors as predictors for low risk and possible discharge [35]. In the second study they used an alternating time approach to evaluate implementation of the guideline [36]. During the intervention periods they aggressively modified physician behavior in the emergency department, promoting the previously developed clinical guideline that included preadmission endoscopy and discharge of patients with a low risk of rebleeding. During the control periods they allowed physicians to make the admission decisions. Compliance with the guideline was 70% during the period of aggressive promotion, but only 30% during the other periods. Aggressive implementation of the guideline resulted in substantially decreased hospitalization and costs without compromising patient care or satisfaction. The cost savings were lost during the control periods.

It appears that urgent endoscopy can substantially reduce the costs of care for UGI bleeding by identifying a group of patients that can be safely treated as outpatients only if the endoscopic findings, in conjunction with other clinical information, can alter the subsequent care of the patient.

A nonendoscopic scoring system based on data available at the time of presentation can distinguish between patients at high or low risk of needing further treatment for bleeding [37]. A retrospective study comparing this scoring system to that of Rockall with and without endoscopy showed that early endoscopy identifies more low-risk patients who may be treated as outpatients (30% compared with 8% using the Blatchford score) [38].

Endoscopic therapy for bleeding peptic ulcers

As previously noted, approximately 20% of patients with nonvariceal UGI bleeding have persistent or recurrent bleeding.

There is compelling evidence that endoscopic therapy reduces both the morbidity and mortality in these patients [26,27,39]. All available endoscopic techniques appear to have similar results, but vary in the approach to sealing the bleeding vessel and maintaining hemostasis. The methods may be divided into two major groups: thermal coagulation and mechanical tamponade.

Thermal coagulation

Thermal therapy of bleeding peptic ulcer disease is based on the understanding that the ulcer erodes into a submucosal vessel. Therapeutic interventions using heat have the goal of coagulating or sealing this vessel to stop active bleeding and prevent rebleeding [8].

Tissue has a characteristic response to thermal energy. When heated to 50–60°C, intracellular proteins become denatured, destroying the tissue and forming a white coagulum. This also produces a surrounding area with a zone of sublethal damage manifest by erythema and edema [40]. When heated to 100°C the water in cells is vaporized, resulting in cavitations and tissue ablation. The goal of endoscopic therapy is to coagulate the bleeding lesion and create a ring of edema that reduces blood flow and promotes hemostasis without causing tissue vaporization or cavitation that may exacerbate the bleeding. There are multiple methods of delivering different types of energy capable of raising tissue temperature, including light energy (lasers), electrical energy (monopolar or multipolar cautery), and direct application of a heated surface.

Laser therapy

Laser therapy was extensively used in the past for endoscopic hemostasis. While different lasers produce wavelengths of light with specific effects on tissue, the most commonly used laser was the neodymium:yttrium–aluminum–garnet (Nd:YAG) laser. The light from this laser (1060 nm wavelength) can be delivered through a flexible quartz fiber that is introduced through the working channel of a standard endoscope (Fig. 125.2). As the light strikes the tissue it is converted to thermal energy, creating the heat necessary for coagulation. Tissue contact is avoided while coagulating a ring of tissue surrounding the bleeding site. Other lasers (argon, KTP) commonly used in endoscopic therapy produce light of a shorter wavelength with more limited tissue penetration. As a result most work in acute UGI bleeding has been done with the Nd:YAG laser. This laser has been shown to stop bleeding lesions in the stomach and duodenum in over 90% of cases and reduce rebleeding to less than 20% [41].

Disadvantages of laser therapy include variable control of the depth and type of tissue injury, with the potential for overheating, vaporization, and charring of tissue that exacerbates bleeding. There is a small risk of perforation (< 2%) when used in the stomach. When coaxial gas is used around the quartz fiber, abdominal distention can result. The equipment necessary for laser therapy is expensive and requires special expertise for its use and maintenance. Most lasers are not portable, and require special safety precautions and training. Because of these logistical issues, and the availability of equally effective alternatives, lasers are now rarely used in the setting of acute UGI bleeding.

Electrocautery

Electrocautery uses an electrical current passed through tissue to generate thermal energy to coagulate the target tissue. The earliest use of electricity was with electrified endoscopic biopsy forceps touched to the tissue. In this case the electrical current flowed from the tip of the forceps through the patient to an electrical pad placed on the hip or thigh. In this method the degree of tissue injury depends on electrical current density at the site of contact with the forceps and local tissue factors that are poorly controlled. The result is an unpredictable depth of injury. For this reason, monopolar electrocautery is usually avoided in the treatment of acute UGI bleeding [26].

To avoid the problems associated with monopolar electrical current, endoscopic probes have been developed that have both the positive and negative electrical poles included in a circular design at the end of a catheter (Fig. 125.3). The result is limited delivery of electrical current within the diameter of the probe, using the electrical resistance of the tissue to heat only that area where the probe is placed. The depth and degree of tissue injury are well controlled. The probe also allows direct pressure to be applied to the bleeding lesion to seal the vessel (coaptive coagulation) [42].

This method was evaluated in a randomized prospective trial of patients with acute UGI bleeding by Laine [43]. Hemostasis was achieved in 90% of the patients treated with the multipolar probe, compared with 13% treated with

Figure 125.2 A quartz laser fiber with covering plastic sheath. Fibers may also have a sheath that provides coaxial gas flow. The quartz fiber conducts the laser light but is flexible enough to be passed through an endoscope channel. Similar fibers are used for argon, Nd:YAG, and KTP lasers.

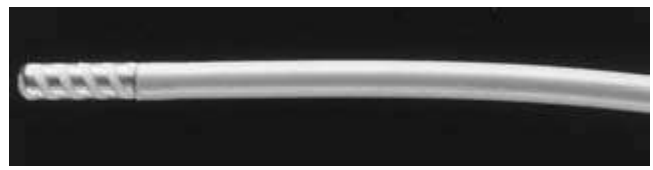

Figure 125.3 Bipolar electrocoagulation catheter. Electrodes circle the end of the catheter, and a central channel provides vigorous water irrigation. Some electrodes have a retractable central injection needle to allow combined electrocoagulation and injection therapy.

Figure 125.4 Heater probe. A flexible catheter tipped with a heating element that is placed directly on the tissue for coagulation. No electrical current passes through the patient. Vigorous water irrigation is possible through the central channel of the catheter.

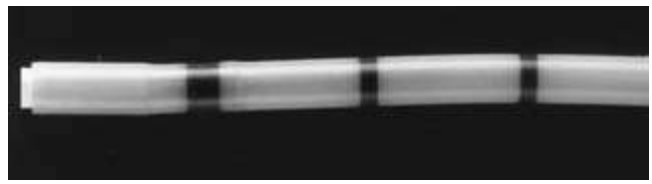

Figure 125.5 Argon plasma coagulation catheter. This hollow catheter produces a flow of electrically charged argon gas when activated. The catheter should not come in contact with the tissue. It allows rapid electrocoagulation of larger areas of tissue, or areas that are difficult to reach with a contact probe.

medical therapy [43]. There was also a significant reduction in transfusion requirement, hospital stay, morbidity, and costs for the patients receiving endoscopic therapy. In a similar trial limited to patients with nonbleeding visible vessels, the rebleeding rate was reduced by over 50% in the treatment group (18% vs 41%) [44]. There was a similar improvement in transfusion requirements, hospital stay, need for surgery, and cost in the treatment group. Many other trials have demonstrated similar results when using multipolar electrocautery [45,46].

Heater probe

Direct application of thermal energy can be applied to bleeding lesions using a heater probe. This device uses a catheter with a heating element at the tip that can be passed through the endoscope channel (Fig. 125.4). The heating element delivers a prespecified amount of energy by adjusting the time of the energy burst. The tissue effect is limited to the area in contact with the probe. As with the multipolar electrode, pressure can be applied directly to the bleeding site allowing coaptive coagulation of bleeding vessels.

The efficacy of this method is very similar to that of the multipolar probe. Initial randomized trials demonstrated that hemostasis could be achieved in actively bleeding lesions in 78% of patients, compared with none in a sham treatment group [47]. In a study limited to patients with nonbleeding visible vessels there was, again, a greater than 50% reduction in the rebleeding rate (10% vs 26%) in the treatment group [48]. As with multipolar electrocautery, many other studies have confirmed the ability of heater probe therapy to control active bleeding and reduce the risk of rebleeding from high-risk lesions [8].

Argon plasma coagulation

Another method of endoscopic hemostasis is the argon plasma coagulation (APC) device. This uses a flow of ionized argon gas to conduct electricity from the power generator to the tissue (Fig. 125.5). It is a type of monopolar electrocautery and should not be confused with the argon laser. Few controlled studies have evaluated the efficacy of this method of hemostasis. The distribution of tissue injury depends on the flow of gas and density of the electrical current at the tissue surface. One small study of 41 patients suggested no difference in results when comparing APC to heater probe therapy in acute UGI bleeding [49]. However, this methodology has not undergone the rigorous evaluation of other thermal hemostasis methods [50,51].

Technique of thermal therapy

The technical approach to thermal treatment of bleeding lesions is different in contact methods (multipolar electrocautery, heater probe) and noncontact methods (laser, APC). Sapphire tips can also be attached to laser fibers, creating a light-heated tip for contact therapy. Bleeding in peptic ulcer disease occurs when the ulcer erodes into a vessel. Either the vessel wall or the clot in the vessel can be identified endoscopically as a *visible vessel* (Fig. 125.6). In the noncontact method the vessel feeding the bleeding site is cauterized below the surface by treating circumferentially around the clot or point of bleeding (Fig. 125.7). This has the advantage of not disrupting any clot that may have formed in the lesion, but does not seal the vessel with coaptive coagulation. Contact probes, on the other hand, are used to apply direct pressure to the bleeding site, using the water jet capability of the

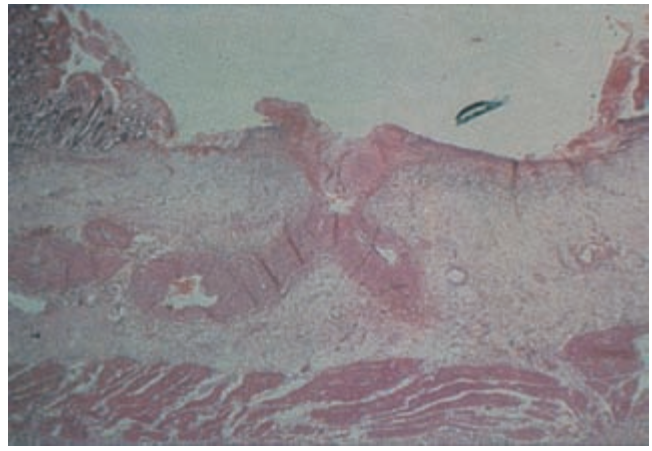

Figure 125.6 Visible vessel. This classic image demonstrates the histology of a bleeding vessel in the base of an ulcer. The submucosal vessel is seen extending to the ulcer surface, with a thrombus present in the "hole" in the arterial wall. Courtesy of C. Paul Swain MD.

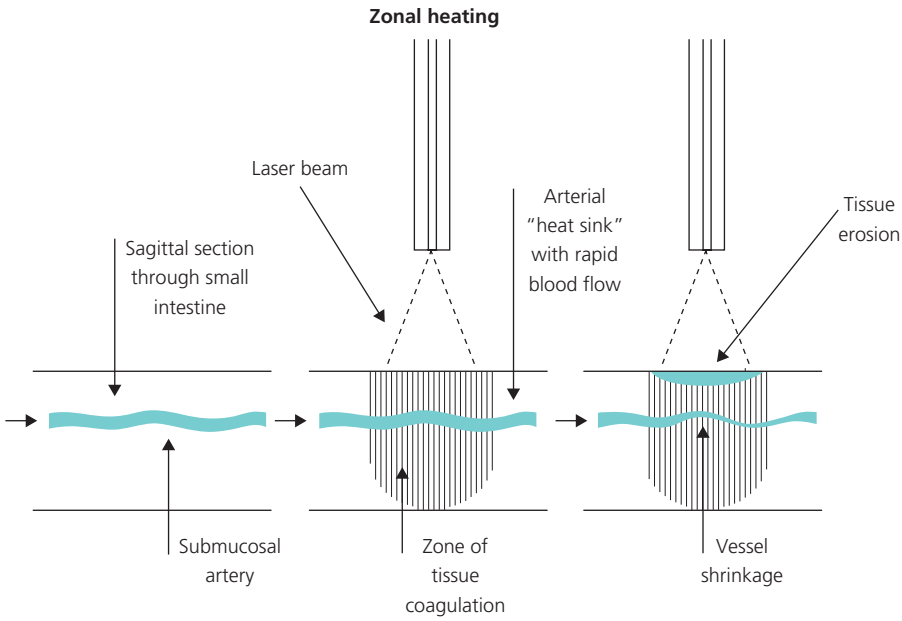

Figure 125.7 Noncontact therapy diagram. Coagulation of tissue with noncontact methods, such as laser therapy or argon plasma coagulation. The area surrounding the bleeding site is treated with the aim of coagulating the submucosal vessel. Even when the vessel is not coagulated, the resulting circumferential edema results in enough tamponade to control bleeding.

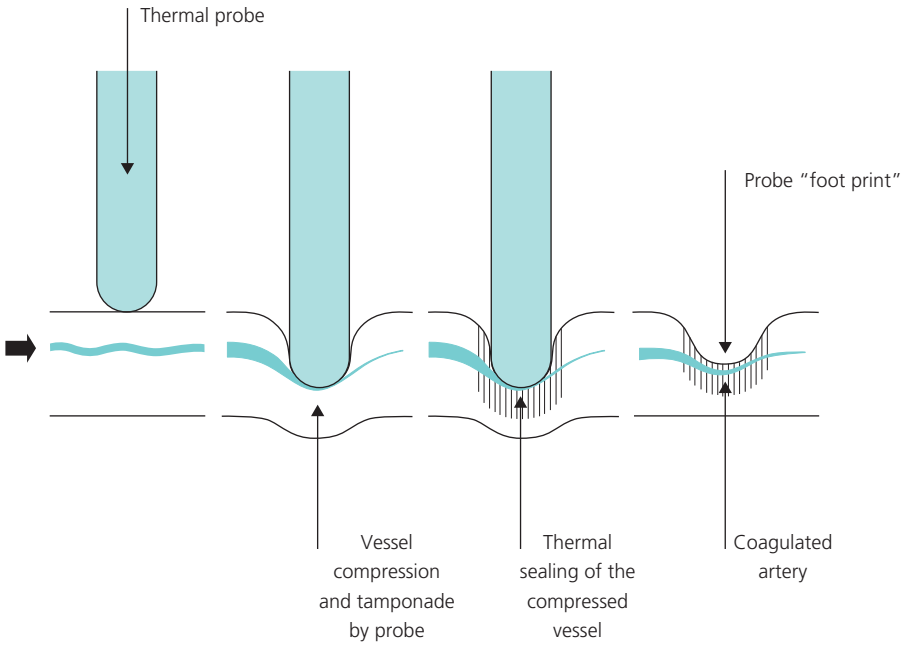

Figure 125.8 Contact therapy diagram. Treatment with contact probes focuses on coaptive coagulation of the bleeding site. Considerable pressure is applied with the probe to tamponade the bleeding vessel. Multiple bursts of energy are then delivered to coagulate the lesion and seal the bleeding vessel. Care must be taken to avoid dislodging coagulated tissue, which can adhere to the catheter tip. From Johnston JH, Jensen DM, Auth D. Experimental comparison of endoscopic yttrium–aluminum–garnet laser, electrosurgery, and heater probe for canine gut arterial coagulation. Importance of compression and avoidance of erosion. From Gastroenterology 1987;92:1101, with permission from Elsevier.

probes to clear away surrounding blood and debris. Multiple bursts of energy are applied to the lesion until hemostasis or adequate coagulation has been achieved (Fig. 125.8). Larger probes are more effective, as are longer pulses of lower energy [52]. The design of contact probes also allows tangential treatment of lesions in difficult locations. The disadvantage of contact probes is tissue adherence to the probe. When the probe is moved, the clot and coagulated tissue are dislodged, leading to more vigorous bleeding. This occurred in 18% of patients treated with contact probe therapy in one randomized trial [45].

The approach to patients with adherent clots in the base of ulcers remains controversial. Adherent clots are those which cannot be dislodged by prolonged application of a vigorous water jet. Unless the clot is removed the nature of the underlying lesion cannot be determined. A metaanalysis that compared six studies of endoscopic and medical therapy for adherent clots suggested that endoscopic therapy reduced rebleeding (pooled OR 0.35) but did not affect mortality or hospital stay [53]. In another study not included in the above metaanalysis, Laine and colleagues evaluated 46 patients with adherent clots [54]. They vigorously tried to remove

the clot with a water jet for 5 min. If the clot was dislodged, they treated the underlying lesion. In those where the clot remained no endoscopic therapy was applied. Only one of the patients rebled.

When clot removal is contemplated it should be done only if the endoscopist is prepared to deal with any underlying lesion, including vigorous bleeding. Freeman has advocated injection therapy of the base of the clot prior to attempted mechanical removal to reduce the risk of vigorous bleeding [17].

It appears that the clinical outcome of patients with adherent clots found at endoscopy depends on the lesion under the clot and the stability of the hemostatic plug formed by the clot. The removal of such clots should be determined by the patient's condition and the availability of appropriate therapy should clot removal precipitate vigorous bleeding.

Injection therapy

The most convenient and least expensive method of endoscopic therapy for UGI bleeding is the use of a simple needle catheter to inject the bleeding site with a compound selected to achieve and maintain hemostasis. There are different classes of materials used for injection therapy, including hemostatic agents, sclerosants and thrombogenic agents.

The most commonly used solution is diluted epinephrine (adrenaline), usually in the readily available 1 in 10 000 dilution. This is injected submucosally around the bleeding site in aliquots of 1–2 mL to a total volume of 5–10 mL (Fig. 125.9). Hemostasis is postulated to occur due to a combined effect of vasoconstriction by the epinephrine and tamponade of the bleeding vessel by the volume effect of the injection [55,56]. The efficacy of this method was demonstrated by Chung and colleagues in a study where 68 patients with actively bleeding ulcers were randomized to receive either injection therapy with 1 in 10 000 epinephrine or medical therapy [57]. Initial hemostasis was achieved in all patients in the injection therapy group. There were fewer patients who required surgery (5 vs 14), fewer blood transfusions, and a shorter hospital stay in the epinephrine-treated group. These findings were validated in a larger prospective trial of 555 patients with acute UGI bleeding. In this study, 98 patients were randomized to receive either 1 in 10 000 epinephrine injected in 1–2 mL aliquots around the lesion and 1–2 mL of ethanolamine into the bleeding site, or medical therapy alone. The rebleeding rate was 17% in the injected group and 47% in the control group ($P = 0.011$). There was also a reduced mortality, need for surgery, transfusion requirement, and length of hospital stay in the endoscopic treatment group [58].

Figure 125.9 Dilute epinephrine injection of an oozing ulcer using a metal-tipped injection catheter. Large volumes of dilute epinephrine or saline can be injected circumferentially around the ulcer to cause tamponade of the vessel and slow the bleeding. Definitive thermal or clip therapy should then be applied, as injection therapy alone is not sufficient to provide definitive hemostasis.

Other agents have also been used for subcutaneous injection to tamponade bleeding UGI lesions. These include normal saline, 3% saline, distilled water and 50% glucose in water. All these solutions have an effect similar to that of 1 in 10 000 epinephrine [59,60].

Sclerosing agents include absolute ethanol, polidocanol, ethanolamine, and sodium tetradecyl sulfate. An important difference between these compounds and those that act by local tamponade is that sclerosants cause tissue desiccation or destruction. As a result, much smaller volumes must be used (0.1–0.2 mL/injection, total volume < 2 mL) [55]. Even with these volumes there is a risk of extending tissue destruction and complications [61,62]. Initial trials demonstrated that ethanol injection could control active UGI bleeding [63], reduce the rate of rebleeding, and improve clinical outcomes [64] to a degree similar to that seen with epinephrine injection. Other sclerosants have mainly been used in conjunction with epinephrine injection. There are no convincing data to suggest that the combination of a sclerosant with epinephrine has a better outcome than epinephrine alone [65–67].

Two thrombogenic compounds, fibrinogen and thrombin, can be combined to form a glue-like substance that has been compared with polidocanol in a large European trial [68]. There was a significant improvement in the treatment group, but this required repeated endoscopy with multiple injections and is of limited utility in practice. Thrombin alone has also been investigated, but has not been widely adopted.

As the practice of endoscopic therapy progresses it has become clear that the combination of injection therapy and thermal therapy can be very useful. In the setting of an actively bleeding lesion initial therapy with injected 1 in 10 000 epinephrine, or other agent, around the bleeding site to tamponade the lesion helps slow the rate of bleeding and clears the field, facilitating subsequent thermal coagulation [55]. It has also been suggested that this injection pretreatment also creates a cushion of fluid that reduces the complication of a transmural thermal injury. Trials have demonstrated

that combination injection and thermal therapy is superior to injection therapy alone for the prevention of rebleeding in patients with high-risk endoscopic stigmata [69].

In summary, injection therapy using large volumes (10–20 mL) of nonsclerosing solutions is similar in efficacy to thermal therapy in patients with acute UGI bleeding from ulcer disease. There appears to be a significant advantage of combined injection/thermal therapy in the setting of active bleeding.

Hemostatic clips

The use of hemostatic clips was first reported in 1975 by Hayashi and colleagues [70]. The technique was based on the use of clips to halt blood flow in a specific vessel in both surgery and radiology. As the logistics of clip placement were improved, the use of clips was shown to be effective in the treatment of active bleeding in uncontrolled studies (Fig. 125.10) [71,72]. Binmoeller and colleagues treated 88 patients with either active bleeding ($n = 78$) or nonbleeding visible vessel ($n = 10$) with endoscopic clips [72]. Initial hemostasis was achieved in all patients with an average of three clips. With a mean follow-up of over 1 year, only five patients had rebled, all of whom were successfully retreated with clips. In randomized studies comparing the use of clips to injection therapy, thermal therapy, and injection therapy plus clips there was no difference in the outcomes between the three approaches [73,74]. One study compared the use of endoscopic clips to heater probe in ulcers with major stigmata of hemorrhage. The rebleeding rate was significantly lower in the patients treated with clips (1.8% vs 21%) [75]. However, this study has been criticized because the rebleeding rate in the heater probe group is at the high end of that reported in other studies, and the rebleeding rate in the clip-treated group is remarkably low [76]. Nonetheless, the study noted that logistical issues prevent adequate treatment of lesions that are in specific locations (lesser curve of the stomach, posterior gastric wall) where it is difficult to achieve an en face endoscopic approach for clip placement. A more recent study comparing epinephrine injection alone with injection plus clip placement in high-risk bleeding ulcer showed a reduction in rebleeding with combined therapy (3.8% vs 21%) [77]. Rare complications have been reported with clip placement [78].

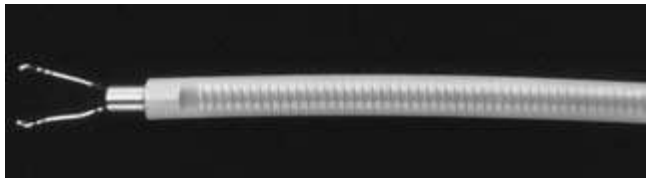

Figure 125.10 A hemostatic clip with its delivery catheter. The clip can be rotated to achieve optimal position, then closed and released from the delivery device. Multiple clips are often required to achieve the appropriate hemostatic effect.

Summary of the efficacy of endoscopic therapy

It is clear that endoscopic therapy for bleeding peptic ulcers can control active bleeding and reduce the risk of recurrent bleeding. Two large metaanalyses combining studies of endoscopic hemostasis in acute UGI bleeding demonstrate the efficacy of thermal therapies and injection techniques [39,46]. Very similar outcomes are achieved regardless of the treatment method used (laser, multipolar, heater probe or injection) [39]. In one analysis thermal endoscopic therapy reduced the rate of rebleeding (OR 0.38), surgery (OR 0.36), and mortality (OR 0.55). The overall complication rate, requiring surgery or causing perforation, was less than 1% for each method. Subgroup analysis showed no significant differences in the outcomes between the various thermal methods of therapy. However, the benefit of therapy was limited to patients with endoscopic stigmata, suggesting a high risk for rebleeding (visible vessels, active bleeding), but not in patients with low-risk stigmata (clean ulcer base, flat pigmented spots, adherent clots). This confirms the importance of endoscopic criteria in the selection of patients for therapy. As mentioned previously, rebleeding occurs in only 20%–25% of patients. Those with a low risk for rebleeding do not require endoscopic therapy. In the subset of patients with a high risk of rebleeding, however, endoscopic therapy improves clinical outcomes.

Nonulcer upper gastrointestinal bleeding

Upper gastrointestinal bleeding may also occur from sources other than peptic ulcers. The most common of these is a tear at the gastroesophageal junction, called a Mallory–Weiss tear (Fig. 125.11), which accounts for 5%–14% of UGI bleeding

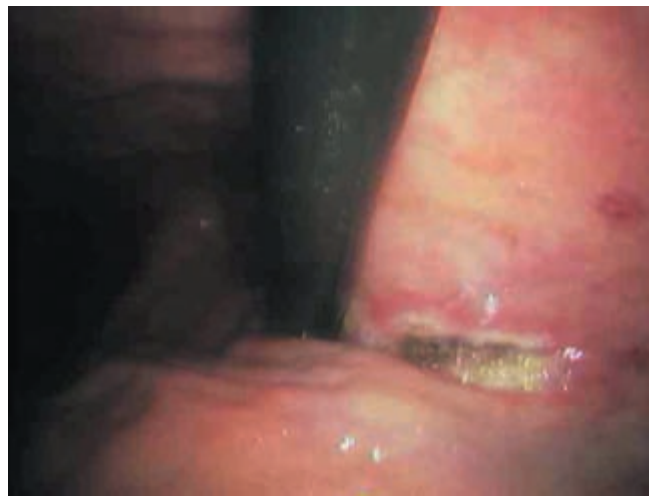

Figure 125.11 A deep Mallory–Weiss tear is adjacent to the shaft of the endoscope at the gastroesophageal junction. Bleeding from these lesions is often self-limited, but hemostasis can be achieved using the same methods applied to ulcers (injection, thermal therapy, clips).

[79,80]. This lesion should be treated in a similar manner as bleeding from peptic ulcers. Similar endoscopic stigmata also predict the risk for rebleeding in this lesion. Arterial bleeding in these patients is unlikely to stop spontaneously. On the other hand, patients who have self-limited bleeding have a good prognosis [28,81]. Active bleeding responds to the same methods outlined for peptic ulcers, including thermal therapy, injection therapy, and endoscopic clips [82,83]. Another method of hemostasis reported for therapy of a bleeding Mallory–Weiss tear is band ligation [84]. This method is commonly used for treatment of esophageal varices; a rubber band is placed around the bleeding lesion with excellent efficacy and safety [85].

Dieulafoy lesion is an aberrant submucosal artery that erodes into the lumen of the stomach and often presents as intermittent massive UGI bleeding [86]. While more common in the cardia, these lesions can occur anywhere in the stomach. The overall prevalence of Dieulafoy lesion in UGI bleeding is probably less than 5% [80]. Because these lesions are not accompanied by ulceration, they are often difficult to identify unless seen while actively bleeding. The infrequent nature of Dieulafoy lesion has prevented randomized trials on different types of endoscopic therapy. Combining uncontrolled experience, it appears that endoscopic therapy is effective for initial hemostasis in 96% of patients and achieves permanent hemostasis in 85%–90% [86,87]. As with Mallory–Weiss tears, ligation of the lesion, with either a rubber band [88] or endoscopically placed loop [89], has been reported to be successful.

Malignant and benign tumors are rare (< 1%) causes of acute UGI bleeding [89]. They more commonly present with other symptoms and chronic low-grade blood loss. When the cause of acute bleeding, the bleeding lesion usually responds to endoscopic therapy as outlined for peptic ulcer disease [8,89].

Another rare cause of acute UGI bleeding is a vascular ectasia. These lesions may occur as part of the hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu) syndrome or sporadically [90]. The sporadic lesions are a common cause of lower GI bleeding, but rarely present with hematemesis. These lesions also respond to standard thermal or injection therapy [90,91]. An uncommon cause of acute UGI bleeding is a diffuse antral form of vascular ectasia, often called a "watermelon stomach" or gastric antral vascular ectasia [92]. As with other vascular ectasias, chronic blood loss is a more common presentation of this lesion. Endoscopic laser therapy has been demonstrated to control acute bleeding and decrease transfusion requirements [93]. Other thermal methods have been demonstrated to also be effective, but may require more time than noncontact methods [94–96].

Diffuse bleeding from diffuse gastric erosions, as seen in critically ill patients, does not respond to endoscopic therapy and should be avoided by primary medical prevention [97–99].

Repeat endoscopic therapy

The issue of routine second-look endoscopy with repeated treatment remains controversial [100]. One randomized study of 40 patients with bleeding peptic ulcers showed that those who underwent a second session of endoscopic therapy with a heater probe 24 h after the initial therapy had a reduced transfusion requirement and rebleeding rate (0% vs 24%) [101]. Preliminary results of other studies have produced conflicting data on the value of routine retreatment of bleeding lesions [102,103]. When retreatment is provided only to those patients with persistent stigmata for rebleeding, the rates of permanent hemostasis can be improved [103].

It is clear that not all initial attempts at endoscopic therapy are equal. Patient condition, the presence of blood or clots in the stomach or duodenum, and other logistic factors can impact the efficacy of the treatment. The endoscopist often has a perception for how adequate the initial therapy was. In cases where the therapy was felt to be suboptimal, a second procedure timed to provide optimal therapy may be appropriate. However, routine second-look endoscopy for all patients requires further evaluation before the benefits can be demonstrated to outweigh the costs and risks to the patient.

On the other hand, it is clear that repeated endoscopic therapy is indicated in the setting of rebleeding. Lau and colleagues randomized 92 patients who had recurrent bleeding after endoscopic thermal therapy to either endoscopic retreatment or surgery [104]. The second endoscopic therapy session produced sustained hemostasis in 35 of 48 patients randomized to endoscopy; 13 patients went to surgery, 11 of whom had failure of the second endoscopic therapy and two because of a perforation resulting from the repeat endoscopy. The 30-day mortality rates were similar in the two groups, but complications were less in the endoscopy group, where seven patients (six of whom ultimately went to surgery) had complications compared with 16 of 44 patients in the surgery group. The authors concluded that a second attempt at endoscopic therapy can avoid surgery, with its associated complications, in many patients and does not increase mortality.

In most cases of rebleeding after endoscopic therapy a second attempt at endoscopic therapy is indicated before resorting to surgical therapy [105]. Thermal therapy in this situation may be associated with a higher rate of perforation.

Prevention of rebleeding

The prevention of recurrent bleeding after endoscopic therapy has been the source of considerable controversy. It is clear that the ulcerogenic conditions that led to peptic ulcer bleeding should be ameliorated. In most cases this means the discontinuation of NSAIDs or treating *Helicobacter pylori* infection [106]. However, there are no data to show that this

improves the short-term (72 h) outcome of the acute bleeding episode.

Normal hemostatic mechanisms are inhibited in the low pH of the stomach. Increasing the pH can improve coagulation and platelet aggregation [107]. In an attempt to increase gastric pH, intravenous histamine H_2-receptor antagonists have been routinely used in the setting of acute UGI bleeding. Unfortunately, they have been demonstrated to be no better than placebo in reducing the rate of recurrent bleeding [108]. This is probably because these agents have a decreased effect on acid reduction over time [109].

Despite the failure of H_2-receptor antagonists, it is clear that profound acid suppression can reduce the rebleeding rate of peptic ulcers with high-risk stigmata. Khuroo and colleagues randomized 220 patients to receive either oral omeprazole (40 mg b.i.d. for 5 days) or placebo [110]. No endoscopic therapy was provided. The rebleeding rates were 12 of 110 in the omeprazole group and 40 of 110 in the placebo group ($P < 0.001$). Subgroup analysis showed the benefit of omeprazole to be limited to those patients with nonbleeding visible vessels. In a prospective study of patients with either active bleeding or nonbleeding visible vessels (high-risk stigmata), Lau and colleagues randomized patients to either intravenous omeprazole (8 mg/h for 72 h) or placebo [111]. All patients received endoscopic therapy prior to randomization. Rebleeding occurred within 72 h in five of the patients receiving omeprazole and 24 of the patients receiving placebo ($P < 0.001$). This difference persisted through the 30-day follow-up.

Metaanalysis of randomized controlled trials comparing high-dose proton pump inhibitor (PPI) therapy with placebo or H_2-receptor antagonist therapy has demonstrated a reduction in rebleeding with PPI therapy [112,113]. The results vary somewhat with the route (intravenous or oral) and dose of the PPI. A post hoc analysis of one study demonstrated a more profound effect in studies performed in Asia compared with those performed in North America or Western Europe [114]. Mortality was only decreased in the Asian studies. The reason for this differential effect is not clear, but may be due to genetic differences in PPI metabolism.

The combination of endoscopic therapy with high-dose PPI administration is superior to PPI use alone. Sung and colleagues randomized 156 patients with nonbleeding visible vessels or adherent clots to receive intravenous PPI therapy and either endoscopic therapy or sham endoscopy [115]; 9% of the patients treated with the PPI alone rebled compared with none in the endoscopic therapy group. Based on these data it is clear that profound acid suppression using a PPI is an appropriate adjunct to endoscopic therapy of acute UGI bleeding. Intravenous therapy appears to have a greater effect, but oral administration also decreases rebleeding.

Somatostatin, or its analog octreotide, are standard therapy for bleeding esophageal varices. It has been suggested that the reduction in splanchnic blood flow caused by these agents could also treat acute UGI bleeding from other causes. In a metaanalysis Imperiale and Birgisson demonstrated a modest advantage of somatostatin/octreotide compared with H_2-receptor antagonists in the prevention of recurrent bleeding from peptic ulcer disease [116]. The authors suggest a possible role for these agents in patients awaiting endoscopy or when endoscopy is not available.

Summary

Acute UGI bleeding is a major medical problem, both in terms of the burden of disease and mortality of an individual episode. Endoscopy is the gold standard for diagnosis of the cause of bleeding and provides important prognostic information for the risk of continued bleeding or recurrent bleeding. Early endoscopy may also identify a group of patients with a very low risk of rebleeding who can be treated safely as outpatients. Endoscopic therapy using thermal, injection or mechanical methods is effective in controlling active bleeding, reducing the risk for recurrent bleeding, and decreasing morbidity and mortality from bleeding peptic ulcers. It has a similar efficacy in bleeding from most nonulcer lesions in the UGI tract. Endoscopic diagnosis and therapy is the standard of care for acute UGI bleeding.

Endoscopic resection of gastrointestinal polyps and tumors has become an important addition to traditional surgical therapy. At the same time endoscopic lesion removal has multiple advantages over open and laparoscopic surgery.

- Endoscopic lesion resection preserves the affected organ and is less traumatic and less risky than surgery.
- Endoscopic resection is usually done as outpatient procedure under sedation, obviating the need for general anesthesia and hospital admission with significant cost saving.
- Endoscopic procedures provide faster patient recovery and early return to work and normal physical activity compared with traditional open and laparoscopic surgery.

This chapter reviews currently available methods and tools for endoscopic therapy of polyps and tumors, the selection of candidates for endoscopic treatment, complications of endoscopic therapy, and endoscopic treatment of specific lesions in the esophagus, stomach, duodenum, and colon. Endoscopic therapy for tumors in the pancreas and biliary tree is covered in Chapter 121.

Methods of endoscopic therapy

Polypectomy

Polypectomy is the most commonly used method of endoscopic removal of lesions that are confined to the mucosal layer of the gastrointestinal tract and which have a stalk or are attached to the organ's wall with a relatively narrow base (7 mm or less). Other endoscopic techniques (endoscopic mucosal resection, endoscopic submucosal dissection) should be used for removal of lesions with a broad base or those originating from or expanding into the submucosal layer. Tumors extending into the muscularis propria or originating from it are usually not amenable to curative endoscopic resection [1].

Polypectomy can be done without use of electrical current ("cold" snare/forceps) or with electrical current ("hot" forceps/diathermic snare).

Cold snare/forceps polypectomy

Small (< 4 mm) polyps can be removed endoscopically without electrocautery using cold biopsy forceps [1,2]. Minor immediate bleeding is common, but it usually does not require any treatment and stops spontaneously within 1–2 min of observation. Delayed bleeding is uncommon in patients who are not anticoagulated and who do not have a bleeding tendency. Despite the apparently complete polypectomy, residual polypoid tissue was still detected on subsequent endoscopy in 29% of patients treated with cold biopsy [2].

Cold snare polypectomy (without electrocautery) is usually used for polyps 5 mm or less in size [3]. The polypectomy snare is placed around the base of a polyp which is then guillotined by mechanical closure of the snare [1]. Minor immediate bleeding is typical and usually stops spontaneously without any therapy within 1–2 min of observation. The major advantage of both cold forceps and cold snare polypectomy is a reduction in the risk of delayed bleeding when electrocautery is not used (delayed hemorrhage is usually caused by sloughing off of coagulated tissue or extension of coagulation-induced necrosis into larger diameter submucosal vessels) [2,3]. Cold snare polypectomy is not recommended for polyps larger than 7 mm in size [1].

Hot forceps polypectomy

Hot biopsy forceps are also used to remove polyps 1–3 mm in size [4]. Proper use of the hot biopsy forceps involves grasping the top of the polyp with the forceps and stretching or *tenting* the polyp to produce a stalk and then applying electrocautery (Fig. 126.1) [1,5]. Application of electrical current causes endoscopically visible whitening (coagulation) of the polypoid tissue

(a) (b) (c)

Figure 126.1 Use of hot biopsy forceps for removal of a diminutive polyp. **(a)** Diminutive polyp. **(b)** Correct use of hot biopsy forceps: the polyp is grasped with the forceps and pulled away from the bowel wall while cautery is applied. Notice how proper positioning of the forceps prevents coagulation injury to the colonic wall. **(c)** Wrong use of hot biopsy forceps: grasping too much tissue (i.e., too close to the colonic wall) or failure to "tent" the polyp by pulling it away from the wall may allow coagulation damage to the normal colonic wall.

starting at the tip of the forceps. After destruction of the polyp the forceps are withdrawn and the part of the polyp preserved in the forceps is sent for histological assessment [1]. Unfortunately, the extent of tissue coagulation by hot forceps is difficult to control and it may cause deep ulcers with subsequent delayed bleeding and even perforation [6–8].

Weston and Campbell summarized the results of removal of 1963 diminutive polyps and demonstrated that the risk of complications after hot forceps polypectomy was five times greater with right than left colon polyps [9]. Bipolar forceps limit the spread of electrical current and can potentially decrease the risk of a deep burn, although greater safety remains unproven and many gastroenterologists no longer use hot biopsy forceps [10,11]. Use of mini-snares is advocated instead of hot forceps for diminutive (< 6 mm) colorectal polyps, especially in the right colon [11,12].

Polypectomy with diathermic snare

Diathermic snares are usually used for polyps larger than 7 mm in size [4]. A variety of sizes (jumbo, standard, mini) and shapes (oval, crescent) of diathermic monopolar snares are used for endoscopic polypectomy. A snare is a wire loop contained inside an electrically isolating catheter. The diathermic snare is placed around the base or stalk of a polyp with subsequent application of electrocautery followed by mechanical transection of the polypoid tissue. Electrocautery heats the tissues to 45–100°C, which results in tissue coagulation and endoscopically visible coagulation necrosis (tissue whitening), reflecting denaturation of proteins and cell death [1]. Heat generated by the snare also causes desiccation and shrinkage of coagulated tissues with blood vessel constriction and thrombosis and thus prevents postpolypectomy hemorrhage and facilitates subsequent mechanical tissue transection.

Three modes of electrosurgical current are available: pure cut, pure coagulation, and a mixture (blend) [8]. In pure-cut mode, the electrical current waveform continuously oscillates between peak positive and negative voltage producing a local heating effect [8]. In pure-coagulation mode, the current wave is turned on in powerful bursts for short intervals of time [8]. For the blend mode, the periods of time when the duty cycle is off are attenuated compared with the cutting mode [8]. At the same power setting the peak power in a coagulation mode is five times higher than in blend mode and 10 times higher than in pure-cut mode, causing a wide coagulation zone [8].

Monopolar electrocautery should be used with caution in patients with implanted electrical devices (pacemakers, defibrillators) due to the risk of inactivation or electrical damage to these devices by the electrical current traveling from the monopolar snare to a grounding pad placed on the patient's skin. Bipolar snares decrease the energy required for polypectomy, limit the depth of coagulation and reduce damage to the underlying bowel wall, and potentially provide an added safety margin during polypectomy [10,13]. However, clinical studies have not shown significant advantages of bipolar snares over monopolar snares [14,15].

Special diathermic snares with barbs (Olympus Optical Ltd, Tokyo, Japan), spikes or needle at the tip of the snare (Wilson-Cook Medical Inc., Winston-Salem, NC) are designed to prevent snare slippage during polypectomy and are particularly useful for removal of large flat lesions [16].

When a pedunculated polyp is removed with a diathermic snare, most endoscopists recommend leaving a short portion (approximately half or one-third) of the stalk not involved with polypoid tissue. This remnant of the stalk, in case of postprocedure bleeding, can be injected, cauterized, or used for mechanical hemostasis with application of clips or detachable loops.

Endoscopic mucosal resection

Endoscopic mucosal resection (EMR) refers to removal of sessile or flat neoplasms confined to the mucosa or penetrating but not expanding beyond the submucosa [17]. There are multiple techniques of EMR: injection-assisted EMR, suction-assisted EMR, ligation-assisted EMR, and traction-assisted EMR.

Injection-assisted EMR

Injection-assisted EMR (also sometimes called saline-assisted polypectomy) was introduced by Rosenberg in 1955 for rigid sigmoidoscopy [18] and by Deyhle and colleagues in 1973 for flexible colonoscopy [19]. This procedure starts with injection of a solution into the submucosal space under the lesion to create a cushion. This cushion lifts the lesion, facilitating its removal and preventing damage to the deep layers of the gastrointestinal tract wall during EMR. Nonlifting of the tumor after submucosal injection is the best predictor of deep invasion and in this case endoscopic resection of the mass should not be attempted [20].

Various endoscopic needles are used for injection, for example 25G Carr-Locke injection needle (US Endoscopy), 23G Interject needle (Boston Scientific, Natick, MA), and VIN-23 (Wilson-Cook Medical Inc., Winston-Salem, NC). Various solutions can be used for injection including normal saline, hypertonic solution of sodium chloride, glycerol, dextrose, albumin at various concentrations, hydroxypropylmethylcellulose, fibrinogen mixture, and hyaluronic acid [21–23].

The ideal agent for submucosal cushion creation should be cheap, readily available, easy to inject, and should provide a long-lasting submucosal cushion without damaging the tissues at the site of injection [24]. A cushion created with normal saline, even with addition of epinephrine (adrenaline), lasts only a short time and is not suitable for removal of large lesions. Several studies have shown that hyaluronic acid, hydroxypropylmethylcellulose and glycerol provide a long-lasting submucosal cushion [25,26]. Unfortunately, these agents are expensive, not readily available in most endoscopy units, and difficult to store and inject [21,27,28]. Other studies have demonstrated tissue damage and local inflammatory reactions at the site of injections of hydroxypropylmethylcellulose and hypertonic solutions of sodium chloride (3.75%) and dextrose (≥ 20%) [27,29].

Autologous blood taken from the patient before the injection appears to be a new promising solution for submucosal injection [24,29]. The cushion created with autologous blood lasted seven times longer than the cushion created with normal saline [24]. Autologous blood did not impair visualization during EMR and facilitated subsequent endoscopic resection by separating the muscularis layer from the submucosal layer and promoting local hemostasis [24,29].

The volume of injected fluid depends on the size of the lesion. Usually between 5 and 50 mL of injected solution is required to create an adequate submucosal mound. After creation of the submucosal cushion, two different techniques can be used.

- Inject-and-cut technique (Fig. 126.2) is used with a single-channel endoscope: the endoscopic diathermic snare is placed around the lesion and electrical current is used to cut it off.
- Inject-lift-and-cut technique (Fig. 126.3) requires a double-channel endoscope: the resected lesion is grasped and lifted with endoscopic forceps through one channel of the endoscope [30]. Then through the second channel a diathermic snare is placed around the lesion to cut it off with electrical current.

Suction-assisted EMR

Suction-assisted EMR was originally performed using suction through an overtube [31,32]. This technique is now rarely performed and instead most physicians use specially designed caps (oval or round shape) that are frontloaded onto the tip of the endoscope (Fig. 126.4) [33]. This procedure requires several steps.

1 A specially designed crescent-shaped snare is placed around the margin of the cap. The lesion and surrounding normal mucosa are suctioned into the cap.
2 The snare is tightened around the lesion.
3 The suction is stopped to release the lesion from the cap (but still captured by the snare).
4 The snare is pulled up several times to ensure that only the lesion, not the entire wall, is moving; this prevents full-thickness resection of the gastrointestinal wall.
5 The EMR is completed with the snare using electrical current.
6 The resected lesion can then be aspirated into the cap to facilitate its removal for pathological examination.

Ligation-assisted EMR

A variceal ligation band can be placed around the mucosal lesion using commercially available variceal band ligators (Fig. 126.5) [34,35]. The lesion is then removed with electrical current using a diathermic snare above or below the band. The Duette Multi-Band Mucosectomy device (Wilson-Cook Medical Inc., Winston Salem, NC) is a combination of a specially designed six-band ligator with a large channel. This device allows banding and passage of a diathermic snare for subsequent resection of the banded lesion without the need to remove the banding device from the endoscope.

Traction-assisted EMR

Traction-assisted EMR uses countertraction of the lesion with grasping forceps placed via percutaneous endoscopic gastrostomy or anterior abdominal wall and gastric wall puncture [36]. This technique was successfully performed in eight patients with large gastric lesions (mean size 50 mm), facilitating endoscopic resection and shortening the procedure time [36].

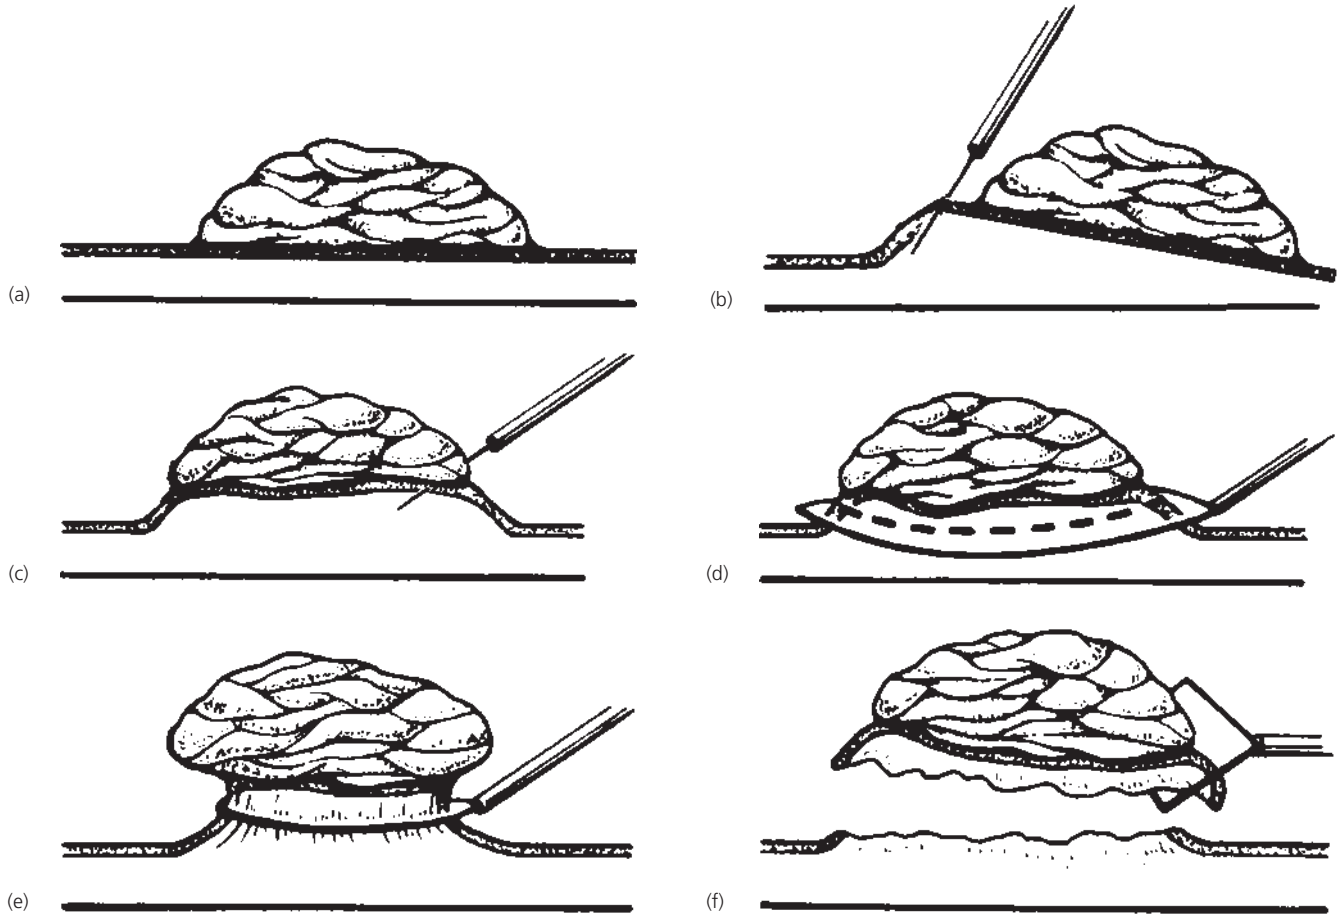

Figure 126.2 Endoscopic mucosal resection: inject-and-cut technique. **(a)** Sessile lesion limited to the mucosa. **(b)** Initial submucosal injection of fluid is recommended under the proximal edge of the lesion. **(c)** Subsequent submucosal injection of fluid is performed under the distal edge of the lesion to complete creation of a submucosal cushion. **(d, e)** The lesion is grasped and resected using a diathermic snare. **(f)** The entire specimen is retrieved for pathological examination.

Endoscopic submucosal dissection

Endoscopic submucosal dissection (ESD) has been developed for removal of large, flat, benign, and malignant gastrointestinal tract lesions [37–40]. The procedure is usually performed in several steps.

1 The margins of the lesion are marked by electrocautery (to facilitate its visualization when the submucosal injection changes the local anatomy).

2 The submucosal injection is made to lift the lesion.

3 A circumferential incision is made around the lesion to divide it from surrounding normal tissues.

4 The lesion is separated from underlying deep layers of the gastrointestinal tract wall, removed en bloc, and sent for pathological examination.

EMR and ESD have dramatically expanded the spectrum of endoscopically removable lesions. Large sessile, very flat, and even depressed lesions can now be removed endoscopically. EMR and ESD should not be attempted for lesions that do not "rise" during submucosal injection [41,42]. Failure to raise (the nonlifting sign) indicates fixation of the deep layers of the gastrointestinal wall (deep submucosal and muscularis) by the tumor [20,42]. Patients with such lesions should be referred for laparoscopic or open surgical resection.

Submucosal endoscopy

Submucosal endoscopy is a new promising approach for removal of gastrointestinal tumors. This procedure has only been tested in a live porcine model [43–45]. The first step of this procedure is creation of submucosal tunnel. Then the endoscope is advanced into the submucosal space under the lesion and the lesion is resected en bloc from submucosal space toward the lumen of the organ. Further human studies are necessary to validate and improve this promising technique, which may expand future indications for endoscopic removal of gastrointestinal tract lesions.

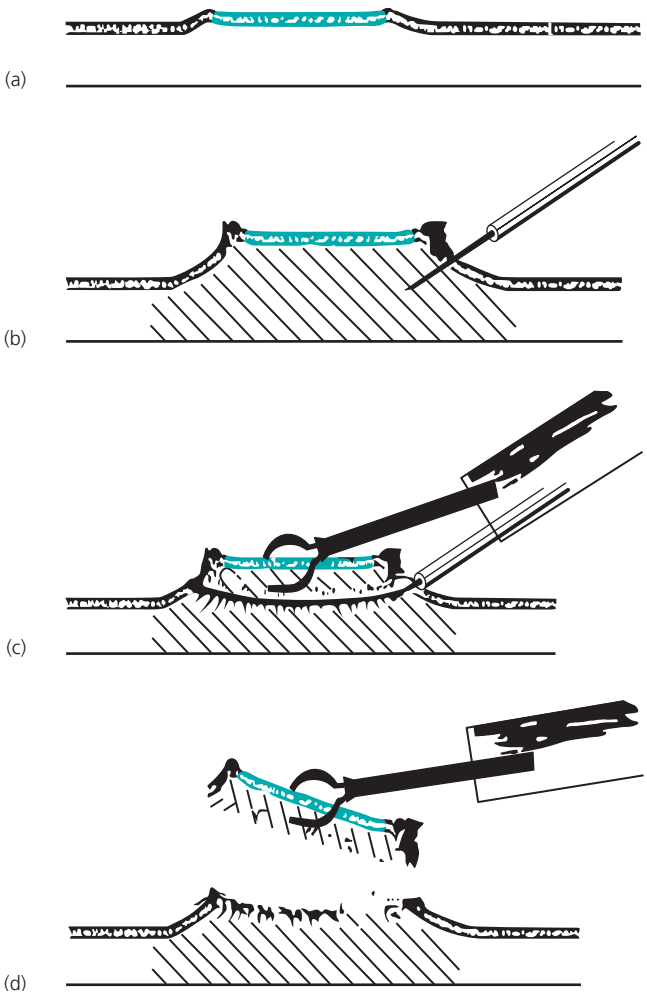

Figure 126.3 Endoscopic mucosal resection: inject-lift-and-cut technique. **(a)** Flat mucosal lesion (indicated by blue color). **(b)** Submucosal injection of fluid has lifted the mucosal lesion, separating it from the deep muscularis layer. **(c)** The lesion is grasped and lifted with a biopsy forceps, and a snare is advanced through the second channel of a dual-channel endoscope and placed around the lesion. **(d)** The lesion is resected and retrieved for pathological examination.

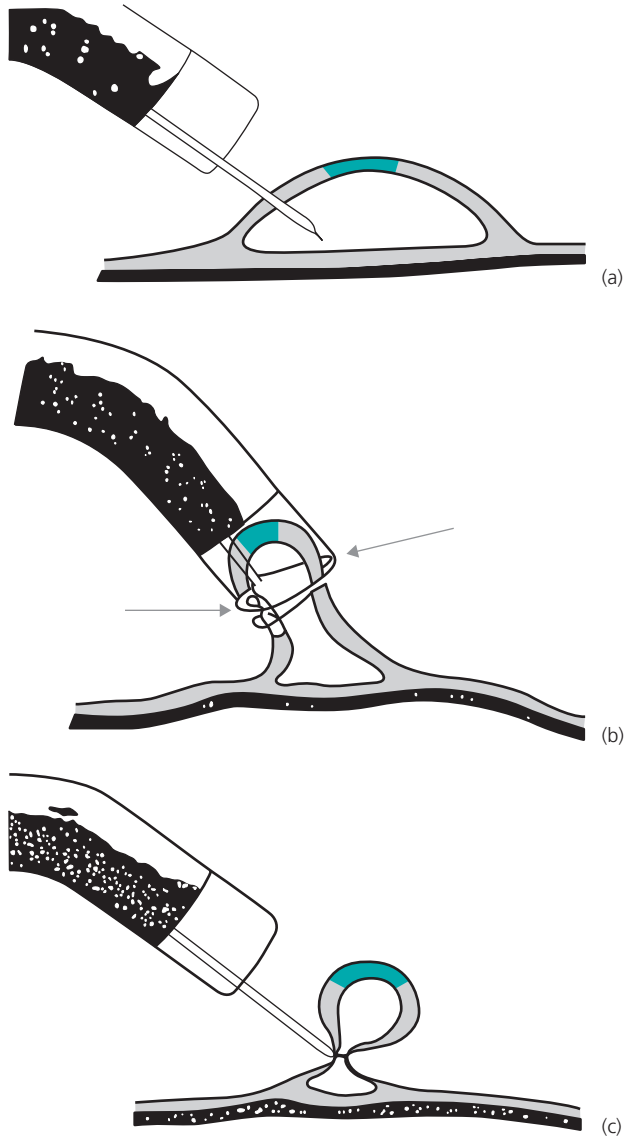

Figure 126.4 Suction-assisted endoscopic mucosal resection. **(a)** Submucosal injection of fluid to create a cushion under the mucosal lesion (indicated by blue color). **(b)** The mucosal lesion is aspirated into a cap mounted on the tip of the endoscope and grasped with a snare (arrows). **(c)** Suction is stopped so that the lesion is released from the cap. The lesion will be removed by application of electrical current and further tightening of the snare.

Additional tools for endoscopic lesion removal

Endoscopic clips

Endoscopic clips were developed to facilitate hemostasis and tissue approximation after endoscopic removal of gastrointestinal tract lesions [46–50]. The first commercially available endoscopic clips were introduced by Olympus Optical Ltd (Tokyo, Japan) and required preassembly with a reusable clip applicator before use [51,52]. Various sizes and shapes of clips were available, but because of the need to clean and reassemble the applicator prior to each use, this device has never become popular among endoscopists and gastroenterology nurses.

The first preassembled and ready-to-use endoscopic clip (HX-200L/U-135 or QuickClip) was also developed by Olympus Optical Ltd. Shortly afterwards other single-use endoscopic clips were introduced to the market by Wilson-Cook Medical Inc. (TriClip; Winston Salem, NC) and Boston Scientific Microvasive (Resolution; Natick, MA). The QuickClip and TriClip can only be closed once and cannot be repositioned after closure. The Resolution clip is gaining popularity among gastroenterologists because it can be opened and closed multiple times before its final application, which

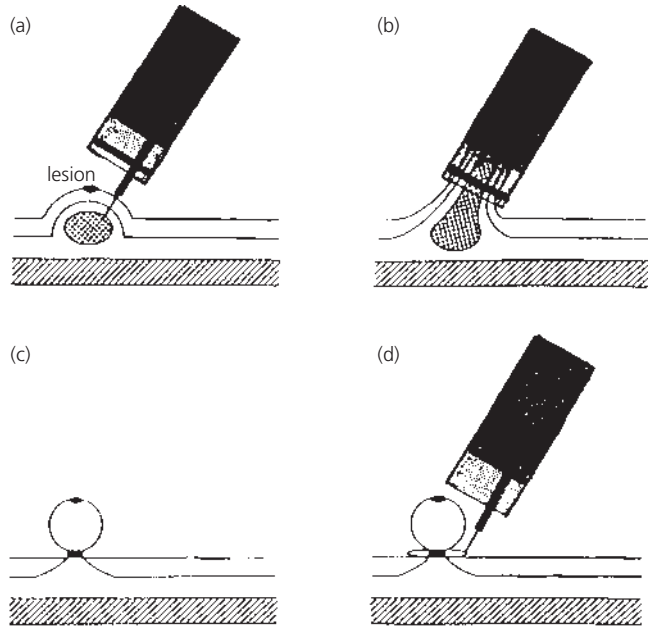

Figure 126.5 Ligation-assisted endoscopic mucosal resection. **(a)** Submucosal injection of fluid to create a cushion under the mucosal lesion. **(b)** The lesion is suctioned into the banding device mounted on the tip of the endoscope. **(c)** The rubber band is applied, ligating the mucosa below the lesion. **(d)** The ligated lesion will now be cut off using diathermic snare above or below the rubber band.

facilitates precision. A multiple clip applicator (MultiClip Applier) is under development by InScope (Cincinnati, OH) and will allow sequential application of up to four endoscopic clips without the need to reload the instrument [53].

In patients with endoscopically resected polyps and lesions of the gastrointestinal tract, endoscopic clips have been highly successful for prevention and control of complications [54]. Cipoletta and colleagues reported clipping of the large polyp stalk, preventing bleeding after polypectomy [55]. Other authors have reported successful use of endoscopic clips for control of bleeding and closure of perforations after endoscopic resection in a porcine model and in humans [56–58].

Detachable loops

Endoscopic detachable loops are also very useful during endoscopic removal of polyps and lesions of the gastrointestinal tract. As with clips, endoscopic detachable loops (Olympus Optical Ltd) first required a multiple use applicator and assembly prior to use. This model was quickly replaced by a preassembled single-use device. The loop can be applied to the base of the lesion or stalk of a polyp to prevent bleeding (Fig. 126.6) [59,60]. In a large randomized controlled trial of 488 consecutive patients with pedunculated colorectal polyps, application of a detachable loop prior to polypectomy helped to decrease the risk of bleeding by four times (from 7.9% to 1.8%) [61].

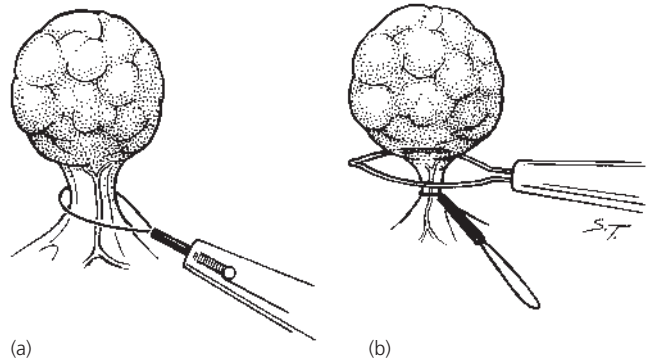

Figure 126.6 Use of a detachable loop for endoscopic resection of a pedunculated polyp. **(a)** A detachable loop is placed around the stalk of the polyp, tightened, and then released from its delivery device. **(b)** A cautery snare is placed above the loop (closer to the head of the polyp) to transect the stalk of the polyp.

Ablative (destructive) therapies

Ablative techniques result in destruction of tissue and are usually used for palliation of malignant tumors that cannot be resected surgically or endoscopically. The most common indications for endoscopic tumor ablation are restoration of lumenal patency and control of bleeding. Various endoscopic modalities are available for ablative therapy.

Bipolar electrocoagulation

Bipolar electrocoagulation uses a specially designed bipolar cautery probe with two active electrodes located at the tip of the device. Electrical current travels between these electrodes without the need for a grounding plate [62]. Compared with monopolar devices, the path of electric current in bipolar electrocautery is restricted to the distance between the electrodes, limiting the depth of tissue injury [63].

Bipolar probes are mostly used for eradication of very small polyps or ablation of residual flat neoplastic tissue that cannot be resected with a snare. These probes are rarely used for ablation of large benign or malignant tumors because of inadequate depth of injury and the need for repeated treatments and prolonged procedures with frequent cleaning of coagulated tissue from the working electrode [64–67].

Heater probe

The heater probe contains a thermal element and causes tissue coagulation at the point of contact with the heated tip. The heat is transferred to tissues regardless of the degree of coagulation, and the depth of injury tends to be deeper with the heater probe compared with bipolar electrocoagulation probes [1]. Because the depth of heat injury is difficult to control, the primary role of the heater probe has been limited to hemostasis rather than ablation of neoplastic lesions [68].

Laser

Energy generated by a laser (*l*ight *a*mplification by *s*timulated *e*mission of *r*adiation) can be delivered to tissues via specially designed light-transmitting fibers advanced through the biopsy channel of an endoscope. Laser energy is an effective modality for palliation of malignant obstruction, control of hemorrhage from tumor, and curative ablation of benign growths [69]. The use of endoscopically delivered laser energy has declined for the treatment of benign and malignant gastrointestinal tumors, mostly because of the high cost of equipment, prolonged duration of endoscopic procedures, difficulties in controlling depth of tissue penetration, and the need for repeated treatment [70,71].

Argon plasma coagulation

Argon plasma coagulation (APC) is another method for noncontact thermal tissue coagulation. APC is based on the conduction of high-frequency electric current to the treated tissue through the argon gas emitted from the tip of the APC probe. The depth of injury is determined by power settings and the duration of application. Inadvertent transmural injury with application of APC has been reported [72].

To decrease the risk of transmural injury in the cecum and right colon, power settings of 40–45 W and short bursts are usually used [1]. In the rectum and stomach, settings of 60–75 W and more prolonged applications are appropriate for benign tumor ablation [72]. For palliation of cancers, power settings of 90–100 W and repeated applications are usually necessary [1].

APC is widely used to treat actively bleeding diffuse mucosal lesions (arteriovenous malformations, radiation proctitis), eradicate gastrointestinal tumors and Barrett esophagus, restore stent patency in cases of tumor ingrowth or overgrowth, and treat residual flat neoplasia after snare resection of the main lesion [73–77].

Injection of chemicals

Small published series have reported palliation of malignant obstruction and control of bleeding through endoscopic injection of agents causing chemical necrosis [70,78]. Relief of obstruction occurs via tissue sloughing, and hemorrhage is controlled via thrombosis, edema, and vasoconstriction [1]. These techniques are usually inexpensive, easily performed, and the necessary equipment and agents are widely available [70]. Despite the obvious advantages of injection therapy, this endoscopic modality has not become popular, probably because of the absence of an immediate tissue destructive effect and difficulties in controlling and predicting the final extent of tissue destruction. Effective agents previously reported for injection therapy include sclerosants (ethanol, sodium morrhuate) and chemotherapeutic drugs (cisplatin) [70,71,78–81].

Other therapeutic modalities

Additional palliative modalities (photodynamic therapy, dilation and stent placement) are covered in other chapters of this book.

Endoscopic tissue tattooing

Tattooing refers to the local labeling of a lesion or site where a lesion was endoscopically resected by intramural injection of a pigment for future identification during subsequent surgery or repeat endoscopy. India ink and suspension of pure carbon particles (Spot, GI Supply, Camp Mill, PA) are the most commonly used solutions, producing a blue-black submucosal stain visible from serosal and lumenal surfaces [82–84]. A 1 in 10 or 1 in 100 dilution of ink saline can be autoclaved or filtered. Commercial preparations of both India ink and Spot for endoscopic injection are also available [84–86].

The tattoo mark is made by direct injection of 1–2 mL of India ink or Spot into each site through a sclerotherapy needle inserted tangentially to make a submucosal bleb. Injections into three or four quadrants are usually sufficient and ensure subsequent intraoperative or endoscopic identification of the lesion. Many endoscopists prefer Spot over India ink for marking of colonic polyps because transmural (intraperitoneal) injection of India ink can cause significant patient discomfort or even pain and can result in colonic abscess and focal peritonitis [84,87,88].

Several techniques have been developed to prevent transmural (intraperitoneal) injection of tattooing agents and to improve marking of the lesion. In the two-step method, a submucosal bleb is formed under the tumor with subsequent injection of the tattooing agent into this bleb through a separate needle [89]. A second method is called the sequential injection technique and starts with the creation of a submucosal bleb with injection of normal saline followed by injection of a tattooing agent (through the same needle without its withdrawal from the bleb) into this submucosal bleb [90,91]. Both methods ensure injection of the tattooing agent into the correct layer of the gastrointestinal wall, decrease the amount of agent needed, and prevent transmural puncture with subsequent injection of the tattooing agent into the peritoneal cavity.

Patient selection for endoscopic treatment

The ability to remove gastrointestinal tract lesions endoscopically depends on multiple factors: nature of the lesion, experience of the endoscopist, presence of all necessary equipment, local situation, and patient's condition.

Malignant lesions confined to the mucosal layer of the gastrointestinal tract can usually be removed endoscopically. If

the malignant lesion invades the submucosal layer, endoscopic removal is usually contraindicated. Inability to raise the lesion with submucosal injection (nonlifting sign) is generally a very reliable indication of possible invasion into the submucosal layer [20].

Endoscopic experience is very important for successful and safe completion of lesion removal. Most practicing endoscopists are experienced in polypectomy, especially removal of pedunculated polyps. EMR and ESD are more difficult than polypectomy and usually performed in specialized centers equipped with the necessary instruments. If an important piece of equipment is missing or malfunctioning, then endoscopic removal should not be attempted.

Local situation (shape, size, location of the lesion) can make endoscopic removal of the tumor impossible, especially if the lesion is located behind a fold or in an anatomically inaccessible portion of the gastrointestinal tract (e.g., in the duodenal bulb immediately after the pylorus or just proximal to the hepatic flexure). Similarly, very flat and broad-based lesions can be difficult to grasp with the diathermic snare and should not be removed endoscopically.

Endoscopic lesion removal should not be attempted if the patient is not adequately sedated or is agitated or uncooperative. If the physician who discovered the endoscopic lesion is not comfortable with its removal, the best course of action is to biopsy the lesion, mark it with a tattoo, and refer the patient to a more experienced colleague or for a surgical consultation.

Complications of endoscopic therapy

The most serious immediate complications of endoscopic lesion removal are perforation and bleeding. Perforations occur in 0.3% of patients after polypectomy [92]. Small perforations can be closed with application of endoscopic clips and treated conservatively, but larger perforations require immediate surgery [93,94].

The reported frequency of postpolypectomy bleeding ranges from 0.2% to 1.0% [95–100]. In a recently published large prospective study of 5152 patients with 9336 polyps immediately after polypectomy, bleeding was documented after removal of 262 polyps (2.8%) in 215 patients [101]. This study revealed nine factors associated with immediate postpolypectomy bleeding: age older than 65 years, comorbid cardiovascular or chronic renal disease, anticoagulant use, polyp size greater than 1 cm, gross morphology of polyps such as pedunculated polyp or laterally spreading tumor, poorer bowel preparation, cutting mode of electrosurgical current, and inadvertent cutting of a polyp before current application [101]. Most cases of active bleeding during endoscopic procedures can be successfully controlled by injection, local application of coagulation (bipolar, thermal or APC), or mechanical hemostasis (band ligation, endoscopic clips and detachable loops).

The most common delayed complications of endoscopic therapy for gastrointestinal tumors are formation of strictures, delayed bleeding, and postpolypectomy syndrome [102,103]. In general, the risk of stricture formation is higher when the lesion occupies more than half of the lumenal circumference [93,104,105].

Aspirin and other nonsteroidal antiinflammatory drugs in standard doses do not increase the risk of significant immediate or delayed bleeding after colonoscopy with biopsy and polypectomy [106,107]. However, the risk of bleeding is definitely higher in patients who have bleeding disorders, low platelet count, or who are therapeutically anticoagulated [107,108]. Friedland and Soetikno have demonstrated that in therapeutically anticoagulated patients with polyps less than 10 mm in diameter, prophylactic application of endoscopic clips after removal of the polyp can prevent postpolypectomy bleeding [109].

Electrocoagulation injury to the bowel wall during polypectomy can cause a transmural burn in approximately 0.51%–3.7% of patients, which may result in the postpolypectomy (postcoagulation) syndrome [97,103,110]. Patients with this syndrome usually present 1–5 days after colonoscopy with symptoms of localized abdominal pain, fever, peritoneal signs, and leukocytosis [111]. Abdominal radiography and computed tomography are not suggestive of perforation (no free air or extravasation of contrast into a free peritoneal cavity) and conservative therapy (bowel rest, antibiotics) is usually sufficient for resolution of the symptoms [111].

Esophageal lesions

EMR is indicated for early (M1 [intraepithelial] and M2 [cancer limited to lamina propria]), moderately differentiated, and well-differentiated squamous cell esophageal cancer without venous or lymphatic invasion [93]. EMR will not be curative for cancers involving the muscularis mucosa and submucosal layer [93]. These patients will have a high rate of metastases and endoscopic resection should be offered only to those who are not surgical candidates or who have declined surgery [112]. Inoue and colleagues have reported excellent results of endoscopic therapy for esophageal cancer with low complication rates and 5-year survival of 95% [112,113]. In another study, Ciocirlan and colleagues confirmed a disease-specific 5-year survival rate of 95% after EMR in patients with esophageal superficial squamous neoplasms [114].

Endoscopic therapy of Barrett esophagus and early esophageal adenocarcinoma is less established than treatment of esophageal squamous cell cancer [93]. Esophageal adenocarcinoma patients who are not surgical candidates can be

treated endoscopically (EMR, photodynamic therapy, balloon-based radio-ablation device) with attempt of cure (T1 disease) or palliation (dilation, photodynamic therapy, laser therapy, bipolar thermocoagulation, APC, stent placement) to restore esophageal patency and to improve swallowing [115,116].

Several authors have reported high rates of success with few complications after EMR of high-grade dysplasia and superficial esophageal adenocarcinoma. Using EMR, Conio and colleagues successfully treated 36 of 39 consecutive patients with high-grade dysplasia or intramucosal cancer arising from Barrett esophagus [117]. Bleeding complicated the procedures in 10.3% of patients and was controlled endoscopically in all cases. After a median follow-up of 34.9 months all patients were still in remission.

In another study, EMR was used to treat 41 patients with high-grade dysplasia and cancer (23) arising from Barrett esophagus [118]. The neoplastic lesions were removed on initial procedure and residual Barrett epithelium was resected 1 month later. After a mean follow-up period of 31.6 months, Barrett epithelium was completely replaced in 76.6% and recurred in 24.4% of cases. Recurrent or metachronous early cancer was diagnosed in five patients (12.2%) and again was treated endoscopically in four of the five patients. Postprocedure complications (bleeding and perforation) occurred in 14.3% of patients. Despite the circumferential removal of Barrett areas, only one patient developed esophageal stricture.

Overholt and colleagues randomized 485 patients with high-grade dysplasia originating from Barrett esophagus to photodynamic therapy versus omeprazole [119]. There was a statistically significant difference in complete ablation of high-grade dysplasia in patients treated with photodynamic therapy (77% vs 39%). Encouraging results of balloon-based endoscopic radio-ablation of Barrett esophagus in 100 patients have also been published [116]. A complete response to therapy (all biopsies negative for Barrett esophagus at 12 months follow-up) was achieved in 70% of patients. There were no strictures and no buried glandular mucosa was found during the entire period of follow-up. Conversely, a high recurrence rate of Barrett epithelium was found during long-term follow-up after APC ablation [120]. Twenty five patients were followed prospectively for 51 months and continuously treated with high-dose proton pump inhibitor. Barrett epithelium recurred in 66% of patients.

Gastric lesions

The most common gastric lesions found during endoscopy are gastric polyps (fundic gland, hyperplastic, and adenomatous), malignant neoplasms, and submucosal tumors (gastrointestinal stromal cell tumor, lipomas).

Fundic gland polyps are usually small, multiple, have negligible malignant potential, and do not need endoscopic removal [121,122]. Hyperplastic gastric polyps are typically located in the antrum, can be solitary or multiple, and are more common in elderly patients. If a hyperplastic polyp reaches significant size, it may cause gastrointestinal blood loss and iron deficiency anemia and can occasionally undergo malignant transformation [123–125]. Gastric adenomatous polyps are considered premalignant lesions, with an incidence of malignancy of 24% in polyps larger than 2 cm but only 4% in polyps smaller than 2 cm [125,126].

No clinical or endoscopic finding can reliably distinguish the variants of gastric polyps before histological examination [121]. At the same time, the histological examination of specimens obtained by forceps biopsy sampling of gastric polyps is of limited accuracy, and their management on this basis is controversial [127]. Therefore gastric polyps should be fully resected by EMR for a final diagnosis and (depending on lesion size and type) possible definitive treatment [127,128]. If the resected specimen reveals carcinoma with deep invasion into the submucosal layer or lymphatic vessels, surgical resection should be recommended [129,130]. A large study of 1177 patients with gastric polyps followed over a period of 7 years demonstrated recurrence of benign gastric polyps in 6.1% of patients (most within 1 year after polypectomy) and development of gastric carcinoma in 1.7% of patients [131]. Based on these results, the authors recommended yearly follow-up endoscopy after removal of benign gastric polyps [131].

The techniques of gastric and colonic polypectomy, EMR and ESD are similar (see above). However, the risk of perforation during endoscopic lesion removal is lower in the stomach, while the risk of bleeding is lower in the colon [127,132,133]. Special caution should be exercised during retrieval of the specimen from the stomach to protect the patient's airway [1]. After endoscopic resection of esophageal and gastric lesions many physicians recommend a liquid diet for 12–24 h followed by a mechanically soft diet for an additional 24 h and then regular diet. Proton pump inhibitors and liquid carafate are often prescribed for several weeks to promote local healing of ulcers caused by lesion removal.

The largest experience in endoscopic resection of early gastric cancer has been accumulated in Japan, where screening for early gastric cancer has been active since 1957 [93]. Approximately 50% of gastric cancers (10 000 cases yearly) in Japan are now discovered at an early stage [36,134–137]. EMR and ESD are now accepted as minimally invasive treatment of early gastric cancer in Japan. Kojima and colleagues summarized the outcomes of endoscopic therapy for early gastric cancer published in the Japanese literature by 1998: 1832 patients had EMR and ESD for early gastric cancer [138]. Endoscopic resection was complete in 73.9% and incomplete in 26.1% with a combined complication rate of 1.9% (1.4% bleeding, 0.5% perforation).

Duodenal lesions

Duodenal adenomas can be sporadic or part of a genetic syndrome (familial adenomatous polyposis, Peutz–Jeghers syndrome) [139]. Duodenal adenomas have potential for malignant transformation and should be removed surgically or endoscopically. The choice of an endoscope for removal of duodenal adenomas is largely determined by location of the lesion: polyps originating from the duodenal bulb are usually better visualized with a forward-viewing endoscope, whereas tumors located in the second and third portion of the duodenum are best evaluated with a side-viewing endoscope.

Various polypectomy and EMR techniques can be used to remove duodenal polyps. Periampullary lesions are usually removed with standard polypectomy technique without submucosal injection. There is no consensus in the literature regarding what type of electrical current should be used during ampullary polyp removal [139]. Some authors advocate pure cutting current (to prevent coagulation damage to the pancreatic duct), whereas others recommend blended current to avoid bleeding [140,141]. Endoscopic papillectomy is associated with an increased risk of postprocedure pancreatitis and several studies have demonstrated reduction in the incidence of pancreatitis after prophylactic stenting of the pancreatic duct after papillectomy [142,143]. APC is frequently used after papillectomy to destroy residual adenomatous tissue and to control postprocedure bleeding [144,145]. Large, firm, ulcerated, and nonlifting ampullary lesions are suspicious of malignancy [139]. Endoscopic removal of malignant ampullary tumors is usually inadequate and these patients should be referred for surgical evaluation [144,146,147].

Duodenal adenomas located outside the major duodenal papilla are usually flat and should be treated similarly to flat colonic polyps. These lesions are most commonly removed with inject-and-cut or suction-assisted EMR. Polyps that cannot be raised with submucosal injection should be referred for open surgery or laparoscopic removal.

Colorectal polyps and tumors

Most polyps are diagnosed in asymptomatic patients during routing screening colonoscopy. Larger polyps are found in patients evaluated for anemia, heme-positive stool, or overt lower gastrointestinal bleeding. Colorectal polyps should be removed to halt adenoma–carcinoma progression [148,149]. Several studies have demonstrated the effectiveness of colonoscopy with polypectomy in reducing the incidence of colorectal cancer [150–155].

Diminutive polyps

Diminutive polyps are lesions less than 6 mm in diameter [156–158]. In the right colon and transverse colon diminutive polyps are more likely to be adenomatous, but in the left colon most of the small polyps are hyperplastic [9]. Use of chromoendoscopy with magnification helps to differentiate adenomatous from hyperplastic polyps [159]. In a study of 240 small colonic polyps, the diagnostic accuracy of regular colonoscopy was only 76.3% compared with an accuracy of 95.4% achieved when chromoendoscopy with magnification was used [160]. This may be especially important when large numbers of diminutive polyps are present in the colon and endoscopic removal of all of them for histological examination is not feasible. A large study of 6722 polyps, of which 4281 (76%) were smaller than 6 mm, demonstrated unfavorable histology in 4.4% of diminutive polyps, emphasizing the clinical significance of small colorectal polyps [161].

Several endoscopic techniques can be used for removal of diminutive colonic polyps. Hot forceps polypectomy has a high rate of bleeding complications especially in the right colon and is rarely used [9,11]. Although cold forceps polypectomy appears safer than hot forceps polypectomy, residual polypoid tissue was detected on subsequent endoscopy in 29% of patients treated with cold biopsy [2]. Many experts advocate use of tiny snares instead of cold or hot forceps for eradication of diminutive colorectal polyps [11,12].

Pedunculated polyps

Pedunculated polyps are attached to the colonic wall by stalks of various sizes. Histologically, the head of a pedunculated polyp usually represents colonic adenoma, sometimes with dysplasia or cancer. Adenomatous changes rarely involve the stalk of pedunculated polyps. Large polyps may be fed with significant caliber blood vessels. Pedunculated polyps can be found in different areas of the colon, but most commonly in the left colon.

Most pedunculated polyps are removed with diathermic snare. It is advisable to leave a short portion (approximately half or one-third) of stalk not involved with polypoid tissue. This prevents extension of coagulation necrosis to the colonic wall and the remnant of the stalk in cases of postpolypectomy bleeding can be injected, cauterized, or grasped with endoscopic snares, clips or detachable loops for mechanical hemostasis. If malignant transformation of the polyp is suspected, the snare should be positioned as far from the polyp head as possible to avoid residual polypoid tissue within the resection margins [1].

Endoscopic polypectomy of large pedunculated polyps, especially those in the tortuous sigmoid colon, can be technically difficult [162–164]. Large polyps may partially occlude the colonic lumen, preventing the manipulation of colonoscope and endoscopic snare [55,163]. Polyps on a long stalk can possess additional difficulties due to their excessive mobility [162].

Several maneuvers can be used when placement of a snare over the polyp cannot be easily performed [165]. If the optimal position for snare application cannot be achieved by

manipulation of the endoscope, changing the patient's position is recommended to move the polyp to a better view. Sometimes even retroflexion of the endoscope may be needed to gain the best conditions for polypectomy [166]. Changing the colonoscope to a double-channel endoscope or attachment of an additional improvised channel to a regular colonoscope and use of a second grasping instrument can significantly facilitate polypectomy [162,163,165]. Piecemeal reduction of the polyp can be performed if the head of the polyp is too large and will not fit even into the largest polypectomy snare or into a detachable loop [167]. Finally, clip application to the stalk with subsequent needle-knife transection of the stalk can be performed if placement of a diathermic snare around the stalk is impossible [55].

To prevent electrical damage to the colonic wall during polypectomy when monopolar snares are used, special attention should be paid to avoid touching the intact colonic wall with any part of the snare or polyp (Fig. 126.7). Most endoscopists recommend lifting the polyp into the colonic lumen with the snare and gently shaking the polyp while the electrosurgical unit is activated to dissipate the electrical current at sites of inadvertent contact with the colonic wall and to decrease the possibility of prolonged unwanted electrical contact. Electrical current during polypectomy should be applied continuously, as intermittent application allows cooling of the snare and may seal it to the tissue ("stuck snare") [1].

Even large pedunculated polyps can be removed endoscopically with a low rate of complications [110,168]. The risk of perforation during removal of pedunculated polyps is lower compared with removal of sessile lesions. Cold snare polypectomy is not recommended in polyps with a sizable stalk: application of electrical energy should precede complete closure of the snare to allow adequate coagulation of blood vessels inside the stalk [169]. Many authors recommend saline and epinephrine injection into the stalk or application of detachable loops to prevent postpolypectomy bleeding from polyps with a large stalk [59,170].

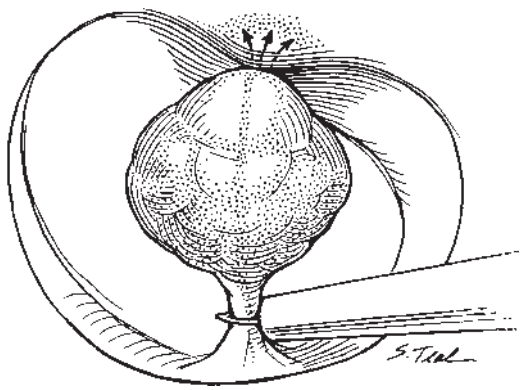

Figure 126.7 Current dissipation through the contralateral colonic wall during polypectomy. The electrosurgical snare is tightened around the stalk of a pedunculated polyp. The polyp head is touching the contralateral wall of the colon. Electrical current can spread through this unwanted contact and may cause thermal injury to the contralateral wall (arrows). This injury to the colonic wall can be easily avoided by moving the polyp head away from the opposite colonic wall during application of electrocautery.

Ideally all resected polyps should be sent for pathological examination [11,171]. In reality, some of the resected polyps are lost, but more than 95% of polyps can be retrieved using suction and special retrieval instruments [172,173]. J.D. Waye, a world-renowned polypectomy expert, has a very practical recommendation: "Remove small polyps in any position on the way in, remove medium size polyps (up to 1 cm) if they are in good position during intubation, and do not remove large polyps during instrument insertion, because most of the time they are readily seen upon withdrawal" [11]. Suction through the working channel of the endoscope allows transfer of small polyps and pieces of large polyp to a trap connected to the colonoscope [173]. Various constructions of trap devices are currently available [174]. Traps should be prepared in advance. Larger polyps can be regrasped for removal by endoscopic snare, graspers with multiple prongs, or specially designed retrieval nets and instruments combining a snare and a removal basket [175,176].

Sessile polyps

Sessile polyps with a base larger than 5 mm in diameter are usually removed with hot snare polypectomy or EMR. Polyps larger than 20 mm in diameter can present a significant challenge for endoscopic therapy, especially those located in the right colon [110]. Endoscopic resection of large polyps can be done en bloc or piecemeal according to the size and location of the lesion [110]. The piecemeal technique is used most frequently, but is associated with a higher risk of recurrence [177].

The inject-and-cut EMR technique is most commonly used for piecemeal removal of sessile colonic lesions. After the submucosal injection, the snare is placed around the polyp and gently pressed against the mucosa. Excess air is aspirated to decrease colonic distention and facilitate grasping of the polyp [110]. If the polyp is very flat and regular and the snare cannot grasp it, use of barbed snares or snares with spikes or a needle on the tip can prevent slippage [1,16]. A circumferential mucosal cut around the polyp with the tip of the polypectomy snare or a needle-knife can create a groove that allows the snare to grasp the polyp [178]. After the polyp is resected the colon should be redistended with air to visualize any residual polypoid tissue, which is then removed in similar fashion until all polypoid tissue is resected and the muscularis propria is visualized [179]. If EMR is technically difficult due to the unfavorable position of the polyp (behind a fold or colonic turn), colonoscopic polypectomy in retroflexion can facilitate the procedure [166,180].

A high adenoma recurrence rate (up to 46%) has been documented after piecemeal removal of large colonic polyps

even without any visible adenoma remnants after EMR [181]. When endoscopically visible remnants of adenoma remain after EMR, APC has been used to reduce the frequency of residual adenoma by 50% [177]. Brooker and colleagues randomly assigned patients with large sessile colonic polyps to either EMR or EMR followed by application of APC to the rim and any residual mucosal or submucosal tissue in the base of the polypectomy site [177]. They observed statistically significant reduction of adenoma recurrence (1 of 10) in patients treated with both EMR and APC compared with those who had only EMR (recurrence in 7 of 11 patients; $P = 0.02$).

All resected tissue should be collected and sent for pathological examination. If malignancy with submucosal infiltration is detected in the resection specimens, surgery should be recommended [110]. It is estimated that about 10% of submucosally invasive cancers have metastasized to lymph nodes and endoscopic resection alone is not adequate for tumors invading the deep submucosal layers of the colon [182].

Endoscopic treatment of colorectal cancers

Flat adenomas, rectal carcinoids, adenomas with high-grade dysplasia, and early-stage colon cancers can be successfully removed by EMR [183–186]. Invasive carcinoma is found in 2%–4% of colonic polyps removed endoscopically [186]. The growth pattern of colorectal tumors can be divided into three main types: protruding (exophytically) growing, depressed (endophytically) growing, and laterally spreading lesions [185,187]. Laterally spreading tumors are further subdivided into a granular (homogeneous) type, a nodular (mixed) type, and a nongranular type [187]. Laterally spreading and depressed lesions are more difficult to recognize endoscopically and these tumors have malignant potential up to 10 times greater than polypoid adenomas [188–191].

Several techniques have been introduced into clinical practice to improve visualization of the flat colonic lesions. Magnification endoscopy, topical spraying of the lesion with 0.4% indigo carmine or 0.05% crystal violet, and use of high-frequency endoscopic ultrasound probes (20–30 MHz) allow adequate identification of lateral margins of the tumor and depth of invasion into the colonic wall [187,192–194]. Accurate determination of invasion depth is crucial when making a decision about possible endoscopic removal of the lesion. Lesions with deeper submucosal invasion should not be treated with EMR due to a higher risk of lymph node metastases [20,195]. After analysis of 511 colorectal laterally spreading tumors, Uraoka and colleagues recommended endoscopic piecemeal resection (with the large nodule resected first) for the granular type of laterally spreading tumors and en bloc resection of the nongranular type of laterally spreading tumors [195].

Polypectomy or EMR with curative intent is feasible in carefully selected patients with only superficially invasive colon cancers. The rate of lymph node metastases is directly proportional to the depth of tumor invasion into the submucosa. Colorectal tumors invading the upper third, middle third, and lower third of the submucosa have 2%, 9%, and 35% rates of lymph node metastases, respectively [196]. Several factors are associated with a high rate of lymph node metastasis and local cancer recurrence after endoscopic resection of malignant polyps confined to the submucosa: poorly differentiated histology, vascular or lymphatic invasion, and incomplete resection with positive resection margins [186,196–198].

There is a consensus in the literature that, after endoscopic removal of large premalignant and early malignant colorectal tumors, patients should have endoscopic surveillance but the recommendations about the optimal follow-up differ from publication to publication. Some authors recommend follow-up endoscopic evaluation at 3 months post endoscopic removal with subsequent endoscopies at 1, 3, and 5 or more years if no residual or recurrent polyps are detected [187]. Other experts advocate follow-up colonoscopy at 3, 6, and 12 months and then yearly [110]. This schedule was able to detect early local recurrence of a polyp in 21.9% of resected polyps (which were then easily treated with APC) [110].

In patients with large sessile tumors, especially if piecemeal removal was performed or if the endoscopist is unsure about the completeness of resection, repeat colonoscopy should be performed within 3–6 months to rule out residual neoplastic tissue at the polypectomy site [186]. If residual tissue is again found and removed during repeat colonoscopy, then a follow-up examination should be performed again within another 3–6 months to verify complete resection of the lesion [186]. If the polyps cannot be removed completely within one to three examinations, surgery should be recommended [199,200].

If curative endoscopic or surgical resection is not possible, tumor palliation with ablative techniques (laser, APC, photodynamic therapy) or restoration of lumenal patency with endoscopic stents can be recommended [201–209].

A ENDOSCOPIC

127 Laparoscopy and laparotomy

Wenliang Chen, David W. Rattner

Laparoscopy, 3049 Laparotomy, 3056

Laparoscopy and laparotomy are surgical techniques that provide direct access to the abdominopelvic cavity for diagnosis and therapy. The word "laparoscopy" was compounded from two Greek roots, *lapara* (meaning the soft parts of the body between ribcage and hips) and *skopein* (*scope* in English, meaning to see or examine). Similarly, laparotomy was compounded from the Greek roots *lapara* and *tome* (meaning to cut). Since most gastrointestinal (GI) organs reside in the abdominopelvic cavity, laparotomy has traditionally been the gold standard in diagnosing and treating GI conditions. However, the dominance of laparotomy has been challenged by laparoscopy. Nowadays, laparoscopy has replaced laparotomy as the standard approach for gallbladder surgery, antireflux surgery, and weight-loss surgery. In colon surgery and hernia surgery, laparoscopic approaches are rapidly gaining popularity. In this chapter, we trace the history of laparoscopy and laparotomy. We also describe the techniques of laparoscopy and laparotomy as they are applied in modern GI surgical practice. We end by projecting future developments of laparoscopy and laparotomy.

Laparoscopy

History

The history of endo-laparoscopy dates back to the Greco-Roman period, when Hippocrates used an anoscope to diagnose anorectal diseases. Over the next 2000 years, however, very little progress was made in this technique because of inability to provide adequate illumination. The invention of incandescent light bulbs and the three-lens optical system facilitated development of rigid endoscopes in the late 19th century. These were first introduced through natural orifices to examine the bladder, esophagus, and rectum and subsequently the peritoneal cavity. In the abdominopelvic cavity, controlled carbon dioxide insufflation was subsequently added to create a pneumoperitoneum, which improved visualization and working space. Laparoscopic surgery first became popular in gynecological surgery. In 1990s, the development of videoendoscopes allowed images to be projected on video screens in real time. For the first time, a laparoscopic surgeon and his assistant could see the same image and work as a team with both hands free to manipulate surgical instruments. In 1987, Mouret in France reported the first laparoscopic cholecystectomy. Since then, the number of GI operations performed laparoscopically has increased exponentially.

Techniques

Equipment

The practice of modern laparoscopic surgery requires special equipment. A rod-like laparoscope combined with a charge-coupled device (CCD) video camera acquires images that are displayed on one or more video monitors. High-intensity light is transmitted through the laparoscope to illuminate the peritoneal cavity. Carbon dioxide is used to insufflate the abdomen and an insufflator maintains a pneumoperitoneum at a set pressure (usually 10–15 mmHg). Trocars (or ports) are hollow plastic tubes that allow instruments to be repeatedly inserted into and withdrawn from the abdominal cavity without releasing the pneumoperitoneum. A side port on the trocars also allows carbon dioxide to be pumped continuously into the abdomen. Laparoscopic instruments are thin and long to allow for access into the abdomen through the trocars. Laparoscopic stapling devices have been developed for intracorporeal tissue division and approximation. Electrocautery, ultrasonic shears, and the bipolar cautery are energy sources used for tissue dissection and hemostasis. Other instruments specially made for laparoscopy include intracorporeal suturing devices, preformed knots, tacking devices, specimen removal bags, and laparoscopic ultrasound probes. While some of these devices have been adapted from their open surgical counterparts, others have been engineered to overcome the limitations of working through small ports. Their development has been a key factor in the widespread adoption of laparoscopic surgery.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Access to the peritoneum

The Veress needle is the most commonly used device for initially accessing the peritoneal cavity. The Veress needle is a large-bore hollow needle with a retractable, spring-loaded inner stylet. When pushed against the abdominal wall, the blunt-tipped stylet retracts, allowing the sharp needle to engage the layers of anterior abdominal wall. Once inside the abdominal cavity, the stylet springs out to protect viscera from the sharp needle sheath. After a saline drop test to confirm the needle tip is in a free space, carbon dioxide is infused into the peritoneal cavity through the Veress needle. Once a pneumoperitoneum is established, a trocar can then be placed without risk of injuring internal organs. Although it is theoretically safe, the Veress needle is a "blind" technique: the surgeon has no knowledge of the precise location of the tip and inserts the needle unsighted. Reports of visceral and vascular injuries resulting from Veress needle placement led to the development of an alternative technique. The so-called open technique is in fact a mini-laparotomy during which the surgeon incises the skin, fascia, and peritoneum under direct vision. A blunt trocar is then inserted and secured to the fascial edge and pneumoperitoneum is established through the trocar. A metaanalysis concluded that the Veress needle technique results in a higher incidence of vascular injuries (1 in 1333) than the open technique, while both techniques result in similar incidences of visceral injuries [1]. The choice of access technique is therefore left up to the surgeon, who must exercise utmost vigilance in entering the abdomen to avoid troublesome, and at times devastating, complications. Newer "optical" trocars with transparent tips have become available. By inserting the laparoscope into the trocar, the surgeon can watch as the trocar traverses the anterior abdominal wall layer by layer. The widespread use of these newer devices may help further reduce the incidence of access-related injuries in laparoscopy.

Exploration

After gaining initial access to the abdomen and establishing pneumoperitoneum, additional trocars are placed under laparoscopic vision. The positioning of these additional trocars is critical to the ease or even success of the subsequent operation. It is ideal to place the working trocars in front, and to either side, of the camera port, much like the diamond design of the baseball field with the camera port at home base and the target organ at second base (Fig. 127.1). There should be a minimal distance of 8–10 cm between trocars to avoid collisions between instruments. It is advisable to avoid placing trocars low in the abdomen since the bony pelvis and thighs may limit the movement of instruments. The use of an angled laparoscope such as a 30° laparoscope aids in visualization of the entire abdomen. Gravity is used to help with exposure, especially when retraction is limited. When viewing the upper abdomen, the operating table should be placed in reverse Trendelenburg (head-up) position so that omentum, small bowel, and transverse colon will fall caudally, exposing the stomach, liver and spleen. Conversely, the operating table needs to be in Trendelenburg (head-down) position when viewing the pelvis. The operating table can also roll sideways to expose structures in the flank better (e.g., right and left colon). Because of the frequent position changes, patients need to be well secured to the operating table with multiple straps, wide tapes, and a footboard.

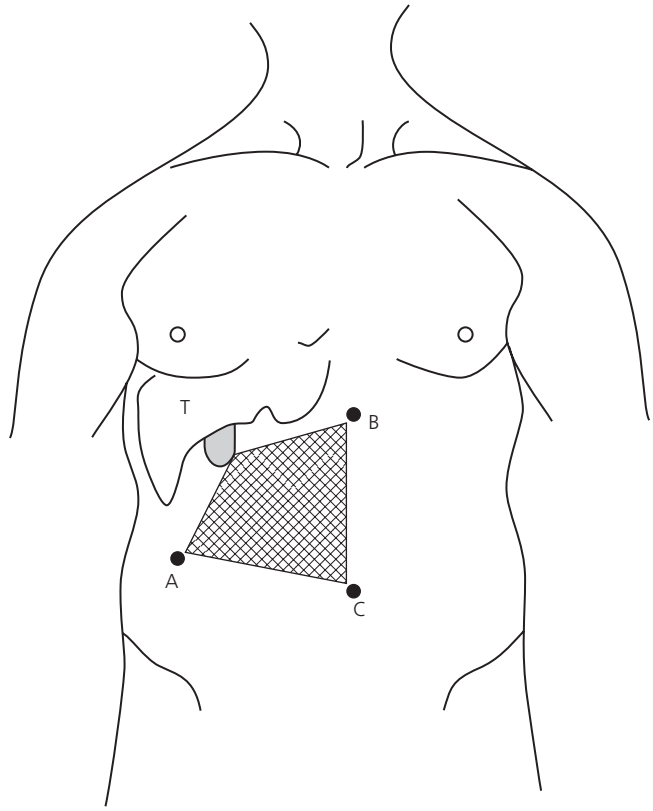

Figure 127.1 Optimal trocar placement in laparoscopic surgery: T, target organ, in this case the gallbladder; C, camera port; A and B, ports for laparoscopic instruments.

Specimen extraction

Small specimens such as the gallbladder or appendix may be extracted directly through large trocar sites. Alternatively, they may be placed in a plastic bag before extraction to prevent contamination of the wound. Larger specimens such as the spleen require morcellation in order to remove them through a small incision. Morcellation can be accomplished either manually with a pair of long clamps or mechanically with a specially designed morcellator. In bowel surgery, after mobilizing a segment of small bowel or colon intracorporeally and dividing the mesentery, most surgeons exteriorize the bowel by enlarging one of the trocar incisions. An impermeable wound protector should be used in all cancer cases to prevent tumor implantation. Specimen extraction and

anastomosis are then carried out before the bowel is returned to the abdomen.

Closure

At the completion of a laparoscopic procedure, the surgeon must ensure that all foreign materials (including tapes, drains, vessel loops, and gauze) have been removed from the abdominal cavity. The trocars are then slowly withdrawn under laparoscopic vision. Bleeding may be encountered on withdrawal of the trocars, particularly when they are placed in the vicinity of epigastric vessels. If bleeding is detected, electrocautery may be used to stop it, or a transfascial figure-of-eight suture may be placed to ligate the bleeding vessel. Routine closure of all trocar sites larger than 5 mm should be performed to prevent trocar site hernias. It is important to ensure that the pneumoperitoneum is completely released before closing the trocar sites since retained carbon dioxide may cause postoperative diaphragmatic irritation. It is also important to avoid trapping the omentum or small bowel as the trocar closure sutures are tied. The skin and fascia at the trocar sites should be injected with long-acting local anesthetics to reduce postoperative pain.

Therapeutic laparoscopy

Laparoscopic cholecystectomy and common bile duct exploration

Since the initial introduction of laparoscopic cholecystectomy to the surgical community in 1991 [2], it has rapidly emerged as the procedure of choice in treating gallbladder diseases [3]. Nowadays, in the USA over 95% of cholecystectomies are performed laparoscopically. The indications have expanded from symptomatic cholelithiasis and chronic cholecystitis to include gallstone pancreatitis and acute cholecystitis.

The American technique of laparoscopic cholecystectomy uses four trocars, one at the umbilicus, one in the epigastrium, and two in the right upper quadrant. After incising any adhesions or omental attachments to the gallbladder, the gallbladder fundus is grasped and retracted cephalad, thereby elevating the right lobe of the liver and exposing the porta hepatis. The dissection begins in the triangle of Calot. With lateral retraction of the infundibulum of the gallbladder, the cystic duct is put on stretch at a right angle to the common bile duct (CBD) and dissected circumferentially at the cystic duct–infundibulum junction. The cystic duct can be partially transected at this point for the insertion of a cholangiogram catheter or it can be divided between clips. The cystic artery is divided between clips. The gallbladder is then detached from its liver bed in a retrograde direction and extracted in a plastic bag.

Postoperatively, patients are discharged on the day of surgery or the next morning. Major complications include bleeding, bile leak, biliary obstruction, and pancreatitis. Bile leaks result from cystic stump leak, unrecognized injury to major bile duct, or injury to a subcholecystic duct. Biliary obstruction may be caused by either retained CBD stones or iatrogenic clipping of the CBD.

Patients with postoperative severe right upper quadrant pain, fever, or hyperbilirubinemia should be suspected of having a bile duct injury. They should be promptly evaluated radiographically. Computed tomography (CT) may demonstrate intraabdominal fluid collections (bile leak) and biliary dilatation (biliary obstruction). Percutaneous drainage should be pursued to treat symptomatic biloma, followed by endoscopic retrograde cholangiopancreatography (ERCP) to delineate the anatomy of the biliary tree and identify the site of leak. A sphincterotomy with or without stent placement usually decreases the volume of the leak if injury is to the cystic duct stump or distal bile duct. Most small leaks will seal with this approach and can be managed without a reoperation. Patients who develop postoperative biliary obstruction should be suspected of having CBD injury. In patients with dilated bile ducts, percutaneous transhepatic cholangiograms should be performed urgently to assess the bile duct anatomy and the level of injury. If an injury is identified, the cholangiogram catheter should be externalized to provide temporary drainage. Patients diagnosed of such injury should be promptly referred to specialized tertiary centers for biliary reconstruction. Results for biliary reconstruction following injury are superior at high-volume centers compared with community practices [4].

When the technique of laparoscopic cholecystectomy was first introduced, CBD injuries occurred at a much higher rate than seen previously with open cholecystectomies. Since then, the incidence of CBD injury has decreased and now occurs in approximately 4 in 1000 cases. Nevertheless, such an injury is devastating to both the patient and the surgeon involved. Way and colleagues analyzed 252 cases of such complications and concluded that 97% were caused by a visual perceptual illusion; technical error accounted for only 3% of the cases [5]. Therefore, it is crucial to obtain what surgeons call the *critical view* prior to dividing the cystic duct. The key to achieving the critical view is proper cephalad–lateral retraction of the gallbladder to open up the angle between cystic duct and CBD. It is especially important in cases where the gallbladder is acutely inflamed and the cystic duct appears foreshortened. Some surgeons routinely perform intraoperative cholangiogram (IOC) during laparoscopic cholecystectomy, arguing that it prevents bile duct injury, while others perform IOC on a selective basis. The clinical indications for IOC include gallstone pancreatitis, elevated liver enzymes, or the presence of CBD stones on imaging studies. A metaanalysis by Metcalfe and colleagues did not support the routine nonselective use of IOC. They noted that a policy of routine use of cholangiogram did not significantly decrease the incidence of bile duct transection. It did increase the detection rate of CBD stones, but only 15% of those CBD stones detected would go on to cause symptoms [6]. A positive IOC should be

followed up with either operative exploration of the CBD (see below) or a postoperative ERCP to interrogate and clear the duct.

The most straightforward, least invasive method of bile duct exploration for a patient already in the operating room is laparoscopic transcystic CBD exploration. Under laparoscopic vision, the cholangiogram cannula is exchanged for a guidewire. A balloon over the wire is then used to dilate the cystic duct to a size sufficient to accommodate a choledochoscope. A choledochoscope is then advanced over the guidewire transcystically into the CBD. Once a CBD stone is visualized, a wire basket is deployed via the working channel of the choledochoscope and the stone is engaged. The stone is then extracted under direct vision along with the choledochoscope. The process is repeated until all the CBD stones have been removed and the duodenum is reached. Usually a completion cholangiogram is obtained to document clearance of the CBD. If a CBD stone is too large to be extracted through the cystic duct, the CBD can also be dissected out laparoscopically and accessed through a longitudinal choledochotomy. The stones can then be retrieved as described above, with the choledochotomy closed over a T tube at the end.

Compared with postoperative ERCP, laparoscopic cholecystectomy with loparoscopic common duct exploration spares patients a second procedure. Operative clearance of the CBD is also associated with a lower incidence of pancreatitis than ERCP. Some clinicians are concerned that long-term duodenobiliary reflux and bacteriobilia can eventually lead to biliary neoplasia [7,8]. Therefore, a good case can be made to preserve the biliary sphincter especially in young patients with gallstone disease. Laparoscopic CBD clearance negates the need for a sphincterotomy.

Laparoscopic Nissen fundoplication

Gastroesophageal reflux disease (GERD) is the most common chronic condition of the GI tract. While most patients respond well to acid suppressive therapy, some are either intolerant of medications or do not desire to stay on lifelong medication. In these patients surgical antireflux procedures provide excellent symptom control. The current surgical antireflux procedure of choice is laparoscopic Nissen fundoplication (LNF). The efficacy of Nissen fundoplication was first validated against standard medical therapy in 1992 [9]. Most recently in a randomized trial against proton-pump inhibitors (PPIs), LNF led to significantly less acid exposure of the lower esophagus at 3 months and significantly greater improvement in quality of life as measured by both condition-specific and general well-being instruments after 12 months [10].

Patient selection is paramount to the success of LNF. Esophagogastroduodenoscopy is essential to assess the presence of erosive esophagitis and Barrett esophagus, and to rule out a stricture or malignancy. Before recommending surgery, there must be proof that the patient's symptoms are caused by acid reflux. Patients who respond to PPIs and have endoscopic evidence of esophagitis are good candidates for LNF. However, in patients with nonerosive disease or atypical symptoms, a 24-hour pH study is the gold standard for confirming the diagnosis of GERD and should be routinely performed. Esophageal manometry should be routinely utilized to exclude primary esophageal motility disorders such as achalasia and diffuse esophageal spasm. Many surgeons find an upper GI series to be useful as it locates the gastroesophageal junction and alerts the surgeon to the presence of a paraesophageal hernia or short esophagus. In patients with chronic GERD, an esophagus shortened by chronic inflammation may require a concomitant lengthening procedure such as a Collis gastroplasty.

LNF uses five trocars with one placed supraumbilically for the camera, and the other four placed in a semicircle just beneath the costal arch. The left lobe of the liver is elevated to expose the gastroesophageal junction. The right and left crus are completely dissected away from the esophagus and both vagi are identified and preserved. The esophageal hiatus is reinforced from posterior to anterior with either permanent sutures or a prosthetic mesh to restore it to a normal diameter. This crural closure step prevents the fundoplication from herniating into the mediastinum. It also causes cephalad transposition of the esophageal hiatus, which lengthens the intraabdominal segment of the esophagus. The short gastric vessels are divided to allow the gastric fundus to be passed posterior to the esophagus toward the lesser curvature. A short plication of 2 cm is then constructed over a 56Fr Maloney bougie passed down the esophagus orally to construct a loose wrap.

Postoperatively, patients are observed overnight and discharged home the following day if they can tolerate liquids. They are maintained on a liquid diet for 1 week to allow edema at the gastroesophageal junction to subside before they are advanced to an unrestricted diet. Intraoperative complications include bleeding (which may necessitate conversion to open surgery if visualization is impaired), esophageal injury, vagal nerve injury, and pneumothorax. Postoperative complications include dysphagia due to perioperative hematoma or edema or an improperly constructed tight wrap. Fundoplication failure is associated with obesity, Barrett esophagus, and surgeon inexperience. The most common anatomical cause of failure is wrap herniation through the crural closure. A slipped Nissen is an intussusception of the body of the stomach through the wrap that leads to a two-compartment stomach. A slipped Nissen can present with symptoms of both dysphagia and heartburn. Failed LNF can be redone laparoscopically, but should be attempted by experienced laparoscopists since repeat operations are quite challenging and the risk of vagal nerve injury and esophageal injury is substantial.

The results of LNF are excellent as reported in several large series [11–14]. Early clinical studies document successful

relief of reflux symptoms in nearly 90% of patients [15]. At 5 years after the operation, 12% of patients experienced recurrence of reflux-type symptoms, but only 3% of patients required repeat surgery [16]. A recent study from England showed that LNF becomes cost saving after 8 years compared with maintenance PPI therapy for the treatment of GERD [17].

With long-standing GERD, about 10% of patients will develop Barrett esophagus or intestinal metaplasia of the distal esophagus. Without reduction in acid exposure, Barrett esophagus may progress to dysplasia and eventually adenocarcinoma of the esophagus. Therefore, the presence of Barrett esophagus, especially the presence of low-grade dysplasia, mandates effective antacid reflux treatment [18]. For patients already on maximum medical therapy but who still demonstrate pathological acid reflux, LNF should be performed. Many believe that bile or nonacid reflux is an essential element in the development and progression of Barrett esophagus, but thus far there is no convincing proof that antireflux surgery is more effective than adequate medical therapy in preventing the development of esophageal carcinoma.

Other commonly performed laparoscopic foregut procedures include laparoscopic Heller myotomy for achalasia and laparoscopic repair of paraesophageal hernias. These techniques are similar to LNF with almost identical trocar placements and dissection at the esophageal hiatus. Laparoscopic foregut surgery affords patients less operative trauma and faster, easier postoperative recovery compared with either a thoracotomy or a large upper midline laparotomy incision.

Laparoscopic colorectal surgery

Laparoscopic colon resections are performed for both benign and malignant conditions. The most common benign conditions are diverticular disease, ulcerative colitis, and large colonoscopically unresectable adenomatous polyps. Several large randomized controlled trials have demonstrated the safety and efficacy of laparoscopic colorectal surgery (LCRS) for cancer. One of them, the Clinical Outcomes of Surgical Therapy Study Group (COST) trial, showed that LCRS is both surgically and oncologically sound, as measured against the benchmark of traditional open surgery [19]. This report galvanized a new wave of interest in LCRS for the treatment of benign and malignant colorectal diseases alike.

The technique of laparoscopic right colectomy uses three or four trocars. It begins with mobilization of the cecum and right colon from its lateral attachments. The hepatic flexure is then mobilized. The ileocolic vascular pedicle is then identified and divided intracorporeally with a vascular stapler. The right colon is externalized through a small incision made by enlarging one of the trocar sites. Bowel resection and ileotransverse colon anastomosis is carried out extracorporeally before the bowel is returned to the abdomen.

Laparoscopic left colectomy is usually performed through three or four trocars placed in the midline and right lower quadrant of the abdomen. It also begins with mobilization of the left colon at the white line of Toldt (lateral peritoneal attachment). The splenic flexure is then taken down with the spleen carefully preserved. Pelvic dissection then begins with identification and preservation of the left ureter. The presacral plane is entered by incising the peritoneum from both sides. For cancer operations, the presacral plane is followed down toward the pelvic floor and levator muscles so the mesorectum can be resected en bloc. Once a distal margin is selected, the rectal wall is cleared circumferentially and transected with a stapler. The colon is then exteriorized through a small incision where resection is carried out. The anvil of an EEA (circular) stapler is secured to the proximal colon before it is returned to the abdomen. The EEA stapler is then advanced transanally and coupled with the anvil intraperitoneally. An end-to-end colorectal anastomosis is then created by firing the EEA stapler.

Over the years multiple studies have compared LCRS with open surgery. Intraoperatively, laparoscopy takes longer but loses less blood; postoperatively, LCRS patients require less narcotics, have faster return of bowel function, and shorter length of stay [20]. Studies have also shown that LCRS causes less of a systemic inflammatory response than open surgery [21]. Over long-term follow-up, LCRS reduces the incidence of incisional hernias and adhesive small bowel obstruction compared with open surgery [22].

LCRS has also been evaluated in special patient groups. It has been found to be safe and effective for elderly patients over 65 years old, resulting in shorter hospitalization and less complication [23]. Obese patients with body mass index (BMI) over 30 may also undergo LCRS, with shorter postoperative recovery than open surgery [24]. Nevertheless, LCRS is a difficult procedure that requires specialized training to perform. Tekkis and colleagues demonstrated a fairly lengthy learning curve for the procedure [25]. They found that surgeons reduced their operative time, conversion rate, and complication rate significantly only after 55 cases of laparoscopic right colectomies and 62 cases of laparoscopic left colectomies. Based on this and other studies with similar findings it is recommended that novice surgeons first successfully complete 20–30 cases of LCRS for benign indications such as diverticular disease before performing LCRS for colorectal cancer.

In experienced hands, LCRS for colon cancer is oncologically sound. The best evidence comes from the COST trial in which 872 patients from 48 institutions with colon cancer participated. At 3 years, the primary outcome (rate of recurrence) was similar in the laparoscopic and open groups. Recurrence rate in surgical wounds and trocar sites was similar, less than 1% in both groups, alleviating the concern for so-called port-site metastasis. Overall survival, intraoperative complication rate, 30-day surgical mortality, postoperative complication rate, readmission rate, and reoperation rate were also not significantly different between the two groups [19]. Another randomized controlled trial conducted in

Barcelona actually found better cancer-related mortality in the laparoscopic group compared with the open group [26]. This difference was due to improvement in survival of patients with stage III tumors. The long-term results of another large-scale European trial, the COLOR trial (Hazelbrook EJ, Color Study Group. COLOR: a randomized clinical brial comparing laparoscopic and open resection for colon cancer. Surg Endosc 2002;16:949).

Laparoscopic weight loss (bariatric) surgery

About two-thirds of Americans are overweight, and of these almost half are obese (BMI > 30). Obesity can both cause and exacerbate preexisting conditions such as diabetes, high blood pressure, hyperlipidemia, heart disease, obstructive sleep apnea, arthritis, and acid reflux disease. These comorbidities are responsible for over 2.5 million deaths per year worldwide. It does not come as a surprise that a morbidly obese person has a life expectancy 12 years shorter than a normal weight individual [27]. Unfortunately, dietary and medical treatments for moderate to morbid obesity do not have long-lasting effect. In 1991, the National Institutes of Health (NIH) acknowledged surgery as an accepted treatment modality for morbid obesity. The guidelines stated that patients with a BMI over 40 (or BMI of 35 with comorbidities) should be considered for weight loss (bariatric) surgery [28]. As a consequence, the volume of bariatric surgery has increased steadily since 1991. Nowadays, two types of weight-loss operations are performed regularly in the USA. The Roux-en-Y gastric bypass, which has a long track record, has remained the gold standard of bariatric surgery. However, the original technique has been modified and adapted into a laparoscopic version with great success. The laparoscopic adjustable gastric banding procedure, popular in Europe for many years, has now been introduced into the USA. Compared with gastric bypass, it is much easier to perform but the rate of weight loss is slower.

The laparoscopic Roux-en-Y gastric bypass is a technically demanding procedure and has quite a steep learning curve for the surgeon. The first step is to create a 30-mL gastric pouch by dividing the stomach between the lesser curvature and the angle of His. Following that, the small bowel is divided 60–100 cm distal to the ligament of Treitz. An enteroenterostomy is created 100–150 cm further distally, hence reestablishing bowel continuity. The Roux limb is then brought to the upper abdomen. A gastrojejunostomy is then constructed between the small gastric pouch and the Roux limb by hand sewing, linear stapling, or EEA stapling techniques. The gastrojejunostomy is then tested for leaks by upper endoscopy, and all the mesenteric defects are closed to prevent future internal hernia and intestinal obstruction. By creating a long Roux limb, this procedure allows for weight loss through both restrictive (i.e., small gastric pouch) and malabsorptive means (Fig. 127.2).

Postoperatively, patients typically stay in the hospital for 2–3 days. They are allowed scheduled advances of diet after a Gastrografin swallow study on the first postoperative day confirms the integrity of the gastrojejunostomy. The morbidly obese patient has extremely limited cardiopulmonary reserve and usually decompensates rather quickly. Major complications, such as leaks from suture lines, intestinal obstruction, gastric remnant distention and postoperative bleeding, are not well tolerated. Therefore, exceptional vigilance during the initial postoperative course is warranted. Every sign or symptom of possible complication such as tachycardia, tachypnea, fever, or excess pain should be thoroughly investigated with imaging studies (Gastrografin swallow, CT, chest X-ray). Reexploration via laparoscopy or laparotomy may ultimately be required for diagnostic and

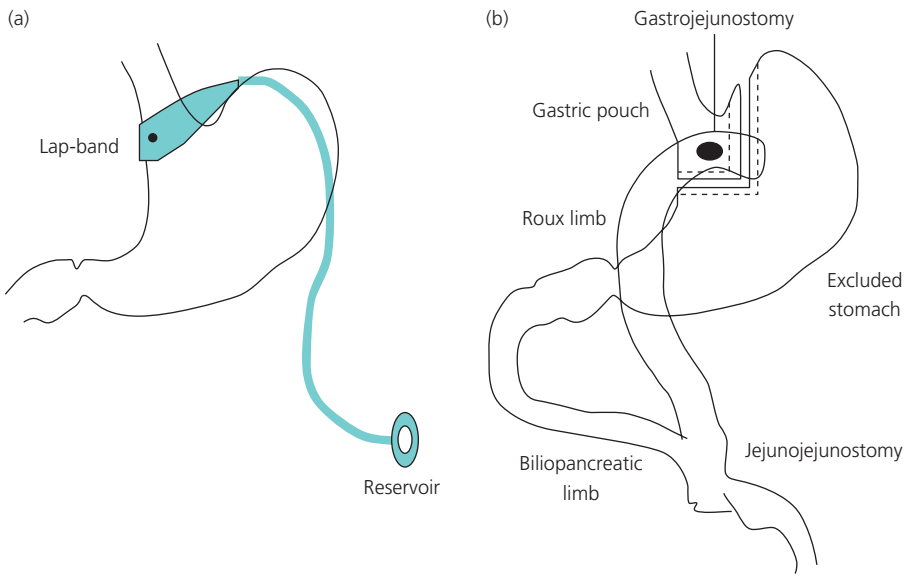

Figure 127.2 Weight loss surgery: **(a)** laparoscopic adjustable gastric band; **(b)** Roux-en-Y gastric bypass.

therapeutic purposes when there are persistent clinical signs and symptoms despite negative radiographic studies.

The 30-day mortality rate for gastric bypass surgery is quite low (0.5%–1.0%). Overall complication rates are similar between laparoscopic and open methods. In general, laparoscopic gastric bypass has a slightly higher leak rate at the gastrojejunostomy. Open gastric bypass has a much higher abdominal hernia rate (15% vs 1%), while laparoscopic gastric bypass has a higher internal hernia or bowel obstruction rate (5% vs 1%). Wound infection rate is also higher in open gastric bypass. The length of stay is shorter for laparoscopic gastric bypass by 1–2 days [29].

In 2004, Buchwald and colleagues performed a systematic review and metaanalysis of bariatric surgery that included a total of 22 094 patients [30]. The average excess weight loss was 61.2% for all patients, 47.5% for gastric banding patients, and 61.6% for gastric bypass patients. The 30-day mortality was 0.1% for gastric banding procedure and 0.5% for gastric bypass. Diabetes completely resolved in 76.8% of patients and improved in 10% of patients. Interestingly, the changes in insulin resistance seen after gastric bypass, which are responsible for the resolution or improvement of diabetes, occur within 6 days of surgery, before any appreciable weight loss has occurred [31]. Hyperlipidemia improved in 70% of patients. Hypertension resolved in 62% of patients and improved in another 17% of patients. Obstructive sleep apnea resolved in 86% of patients. In addition, patients surviving at least 1 year following the procedure had a 33% reduction in actuarial death rate [32]. The results speak for the safety and efficacy of bariatric surgery.

A Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) position paper advocated laparoscopic gastric bypass based on its improved short-term recovery [33]. Nevertheless, the learning curve is formidable so only surgeons skilled in advanced laparoscopy and bariatric surgery should be performing it. As an example, Shikora and colleagues reported that the morbidity and mortality of their patients were reduced by 50% after the first 100 cases of laparoscopic gastric bypass. Specifically, mortality rate fell from 1% to 0.3%, leak rate from 3% to 1.1%, small bowel obstruction from 5% to 1.1%, overall complication rate from 26% to 13%, and operative time from 212 min to 132 min [34].

As surgeons gain more experience with this procedure, laparoscopic gastric bypass can be offered to super-obese patients with BMI over 50 and 60 with good results [35]. This procedure is also offered to increasingly older patients (> 60 years) and to those with major comorbidities (diabetes, renal failure, post transplant).

Laparoscopy in the management of common surgical emergencies

Appendectomy

Appendectomy is one of the most commonly performed emergency surgical procedures. The standard technique of laparoscopic appendectomy (LA) uses three trocars, one at the umbilicus, one suprapubically, and another in either the left lower quadrant or right upper quadrant. Once the appendix is identified laparoscopically, it is retracted anteriorly revealing the cecal base. A window between the base of the appendix and the mesoappendix is created bluntly. The appendix and its mesentery are transected with separate firing of the staplers or divided between clips/endo-loops. The appendix is retrieved through the trocar if uninflamed or in a plastic bag if engorged.

A recent metaanalysis of 45 studies showed that LA carried a lower rate of wound infection (odds ratio 0.47) but a higher intraabdominal abscess rate (odds ratio 2.77) than traditional open appendectomy. Based on these data, the authors cautioned against using laparoscopy to treat complicated (i.e., gangrenous or perforated) appendicitis. The other differences between the two techniques are much more subtle. The operative time of LA is longer, but only by 14 min. Hospital stay after LA is shorter, but only by 0.7 days. Patients also have less pain after LA and return to normal activity, work and exercise earlier by 6, 3, and 7 days, respectively [36].

Another advantage of LA is that any intraabdominal organ can be inspected at the time of surgery. This feature is particularly helpful in young female patients in whom gynecological conditions such as ruptured ovarian cyst, tuboovarian abscess or pelvic inflammatory disease could be misdiagnosed as appendicitis.

Peptic ulcer disease

With the advent of effective acid suppressive medication and antibiotic eradication of *Helicobacter pylori*, peptic ulcer disease rarely requires surgical intervention. An expedient laparotomy with either Graham patching of a perforation or oversewing of a bleeding vessel is still a life-saving operation for a critically ill, unstable patient. For patients who present with signs and symptoms of perforated gastric or duodenal ulcer, and who are hemodynamically stable, laparoscopic exploration and closure can be performed.

As in the open operation, the site of perforation is identified first, usually on the anterior wall of the duodenum. A healthy, soft, well-vascularized omental pedicle is mobilized to cover the defect and secured with sutures. The abdomen is then thoroughly irrigated laparoscopically and the patient treated with PPIs as well as an antibiotic cocktail for *H. pylori*. Patients with perforated gastric ulcers should have the ulcer excised and a wedge excision of the surrounding stomach performed to rule out cancer.

Laparoscopic treatment of peptic ulcer disease has been more commonly performed in Europe and Asia than the USA. Series from Hong Kong, India, Russia, and France report success rates ranging from 79% to 86%. The reported complication rate ranges from 6% to 16%, with less than 2% of patients requiring reexploration. Both operative time and postoperative recovery compare favorably with control open series [37–40].

Obstructive disease of the small bowel

Although obstructive disease of the small bowel is a relatively common occurrence in most surgical wards, laparoscopic treatment is quite difficult. Franklin and colleagues reported a series of 167 patients who were treated for intestinal obstruction with laparoscopy. All patients had the site of obstruction diagnosed laparoscopically, most of whom (92%) were also treated laparoscopically without conversion to open surgery [41]. In another series, laparoscopy was successful in treating only 48% of the patients. Laparoscopic lysis of adhesion was also associated with higher incidence of intraoperative complications including bowel perforation [42]. The dilation of the small bowel that occurs with obstruction makes the safe procurement of a reasonable working space for the insertion of laparoscopic instruments very difficult. The dilated and sometimes friable bowel wall is difficult to handle safely with the available laparoscopic instruments. Therefore, the current use of laparoscopy in patients with intestinal obstruction is quite limited.

Future of laparoscopy

Laparoscopic surgery can be used for more complex procedures such as pancreatectomy and hepatectomy. While feasibility is established, their safety and efficacy compared with standard open techniques is not yet clear.

The future of laparoscopy rests in further refinement of special equipment. Most of the current laparoscopic instruments are crude prong-like adaptations of their open counterparts. They lack the degree of freedom and fluidity of movement afforded by human hands and fingers. They fail to provide the tactile feedback that is taken for granted in open surgery. Minute tasks such tying knots or placing sutures take a long time to complete, especially for the novice. The future generation of laparoscopic instruments will need to be flexible and allow for added levels of articulation. Surgical robotics provides a glimpse of what is on the horizon for laparoscopy in the future. However, much work is still needed to make the technology affordable and easily adaptable to the everyday surgical practice.

Laparotomy

History

For centuries, laparotomies were only performed in trauma or emergency situations. The outcome of these heroic efforts was predictably poor, although a few miraculous success stories were recorded. In 1474, for example, a French prisoner was operated on for an abdominal "colic." The operation was permitted because he had been condemned to death for robbery and was awaiting execution. The exploratory laparotomy was a success and the patient made a good recovery, after which his punishment was commuted [43]. It was the discovery of the three As, namely anesthesia (Morton, 1844), antisepsis (Lister, 1867), and antibiotics (Fleming, 1929) that made elective abdominal surgery or laparotomy possible.

Techniques

Incisions

Laparotomy incisions vary by surgical indication and surgeon preference. The most versatile incision is a midline incision. In a midline incision, the linea alba is opened longitudinally before the peritoneum is entered (Fig. 127.3). It is at the midline that the aponeuroses of the external oblique, internal oblique, and transversus abdominis muscles all fuse into one layer, which makes entry and closure of the abdomen fast and secure. The length and location of the incision vary with the type of surgery performed. Because only the terminal branches of blood vessels and nerves reach the linea alba, vascular and nerve damage caused by a midline incision is limited. Therefore a midline incision is also well suited for anticoagulated patients. In situations where a diagnosis is uncertain, a midline incision allows for maximal versatility and stoma placement if needed.

The abdominal cavity can also be accessed through a paramedian incision (Fig. 127.3). This vertical incision is made on the side of anticipated pathology but, compared with a

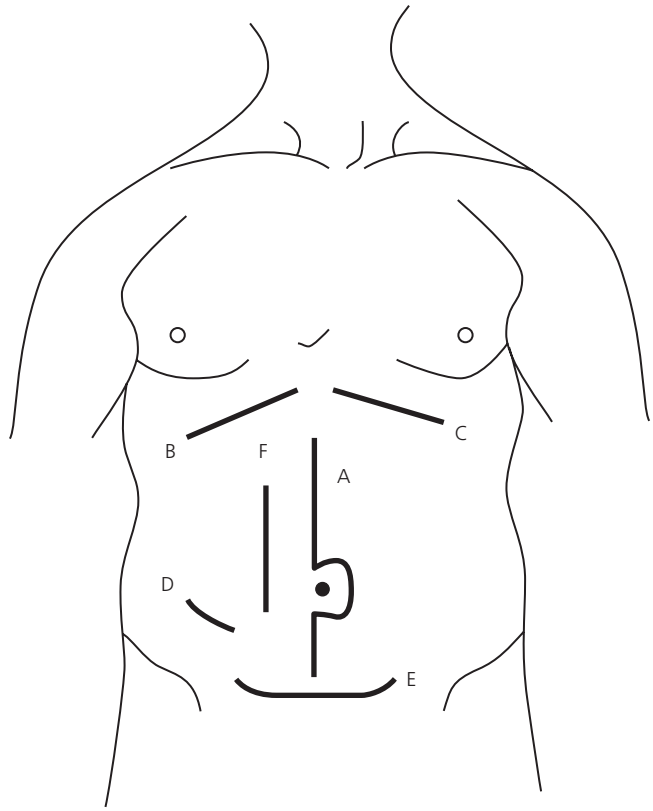

Figure 127.3 Laparotomy incisions: A, midline; B, right subcostal; C, left subcostal; D, McBurney; E, Pfannenstiel; F, right paramedian.

midline incision, takes longer to perform, poses a greater risk of injury to the epigastric vessels, and provides less versatility if unexpected findings are encountered.

Transverse incisions provide excellent cosmesis because they can be placed parallel to Langer lines and natural skin folds. The most popular transverse incision is the Pfannenstiel incision. This transverse incision is made 2–5 cm above the pubic symphysis and is commonly used for gynecological procedures (Fig. 127.3). In females, this skin incision is just above or at the pubic hairline and can be easily hidden under clothing. While the Pfannenstiel incision provides nice exposure of the pelvic organs, the fascial incision cannot be extended above the umbilicus so is not suited for surgery involving the middle and upper abdomen. Another popular transverse incision is one that traverses the rectus sheath in the midabdomen. Such an incision on the right side is frequently used for colectomies or creating stomas.

Surgery in the upper abdomen can also be performed through subcostal incisions (Fig. 127.3). These provide excellent exposure for hepatic and biliary procedures. In addition the presence of two strong fascial layers (i.e., both anterior and posterior rectus sheath) provides for a very secure closure with low rates of incisional hernia formation.

The McBurney incision (and its variant the Rockey–Davis incision) is an oblique muscle-splitting incision in the right lower quadrant used primarily for appendectomy (Fig. 127.3). These incisions can be placed directly over the target organ, so can be made quite small. Closure and healing are facilitated by muscle contraction and return to full activity is faster than with a midline or transverse incision since there is little fascial disruption.

Exploration

Once the abdominopelvic cavity is entered via one of the incisions detailed above, a thorough exploration is usually first carried out. One advantage of laparotomy compared with laparoscopy is the ability to carry out a very thorough abdominal examination and this should be a standard opening maneuver in all laparotomies. Any free fluid (e.g., ascites, succus, or feculent material) is noted, cultured, and sent for cytology if malignancy is suspected. The liver is inspected and palpated for cirrhosis, mass, or abscess. The gallbladder is examined for inflammation or gallstones. The stomach and duodenum are examined for perforation, mass, or ulcer. The nasogastric tube position is confirmed. The spleen is visualized and palpated with the aid of retraction. The omentum is then lifted from the pelvis and delivered into the upper abdomen. Any omental "caking" or evidence of tumor metastasis is noted. The ligament of Treitz is located and the small bowel is examined in its entirety to the ileocecal valve. Any perforation, mass, stricture, or change in caliber (transition point in small bowel obstruction) is noted and marked with a suture for later identification. Attention is usually also paid to the small bowel mesentery for lymphadenopathy or mass. Certain mass lesions such as carcinoid or desmoid tumors tend to grow in the root of the small bowel mesentery. The total length of small bowel should be estimated in patients whom have undergone prior surgery, especially in patients with Crohn's disease. The appendix is examined for inflammation or perforation. The colon and rectum are then examined for perforation, mass, diverticula, or stricture. In females, the uterus, ovaries, and fallopian tubes are also carefully inspected and palpated for mass or cyst. Retroperitoneal organs such as the pancreas, portions of the duodenum, and kidneys are palpated to rule out mass lesion. Visual inspection of the retroperitoneum is also required to discover any hematomas that would suggest aortoiliac artery or inferior vena caval injury.

Closure

At the completion of the procedure, the laparotomy incision must be reapproximated in a secure fashion. A considerable amount of research has been done to find the optimal method of closing the incision [44,45]. These studies show that most abdominal incisions are best closed with a continuous mass closure of slowly absorbable monofilament sutures placed 1 cm from the fascial edge and 1 cm apart. The peritoneum layer does not need to be closed separately. The suture to wound length ratio should be at or above 4 : 1 to prevent hernias. Most surgeons have incorporated these principles of abdominal wound closure into their daily practice with minor modifications based on individual preference and patient characteristics. During the first postoperative week, the abdominal wound has less than 5% of normal tissue strength and is therefore almost entirely held together by sutures. Abdominal wounds achieve 80% tensile strength by the sixth postoperative week and 90% tensile strength at 6 months. Therefore most patients are instructed to avoid vigorous physical activity for 6 weeks following a laparotomy, although activities of daily living such as driving are permitted as soon as patients no longer require pain medication.

Complications

Wound complications

Wound-related complications after laparotomy include seroma, hematoma, and infection. Small seromas and hematomas are generally managed expectantly. Larger fluid collections in the wound need to be drained to relieve symptoms and prevent superinfection. The occurrence of wound infection is affected by a multitude of patient and surgery-related factors. Obesity, poor preoperative nutritional status, diabetes, tobacco abuse, and immunocompromise all increase the risk of wound infection. It has been shown that administration of one dose of appropriate antibiotics prior to skin incision decreases the incidence of wound infection. This has become a universal practice by all surgeons. All wound infections need to be promptly opened, drained, and

cultured for offending organisms. Initially, debridement-type dressings (e.g., normal saline wet-to-dry) should be applied and changed frequently to remove pus and necrotic tissues. After the wound base is clean, moisture barrier-type dressings (e.g., calcium alginate, hydrogel) can then be placed to promote granulation. In large open wounds, a negative-pressure wound vacuum dressing (VAC dressing) can also be applied to speed up wound contraction. During operations where there is gross contamination of the wound, the surgeon may elect to leave the subcutaneous tissue and skin open for either delayed primary closure or healing by secondary intention. This is done to prevent the development of necrotizing fasciitis, a rare but lethal complication. If necrotizing fasciitis develops, the wound (including the underlying fascia) needs to be widely debrided in the operating room. Broad-spectrum antibiotics should be instituted based on microbiological data. The abdomen should also be reexplored at the time of debridement to rule out any intraabdominal source of sepsis (leak, fluid collection).

Fascial dehiscence and hernia

Fascial dehiscence and hernia are early and late manifestations of wound disruption at the fascial level. The etiologies include underlying conditions (advanced age, obesity, comorbidities, poor nutrition, radiation, wound infection) and surgeon factors (length and orientation of incision, suture material and length, wound closure technique). Most dehiscences occur within the first 2 weeks of the operation. Drainage of large amounts of serous fluid through the incision usually heralds a wound dehiscence. If left unattended, evisceration may follow with severe consequences. Dehiscence or evisceration are surgical emergencies and mandate immediate return to the operating room. Limited exploration should be undertaken to rule out an intraabdominal source of sepsis. Mass closure of the abdominal wall should be done with interrupted permanent sutures. Retention sutures may also be placed if the patient's underlying conditions are judged prone to recurrence of fascial disruption. The skin can be either closed loose or left open to heal by secondary intention.

Incisional hernias develop in as many as 11% of surgical patients. Postoperative wound infection doubles the risk of developing an incisional hernia [46]. Some patients with incisional hernias need to undergo emergency surgery for bowel incarceration or strangulation [47]. Others are forced to make lifestyle modifications because of their hernias [48]. The traditional open repair of incisional hernias that did not employ mesh carried recurrence rates as high as 30%–50%. Repeat repairs led to pain, suffering, dense adhesion formation, and eventually significant loss of domain at the anterior abdominal wall. Most surgeons have now adopted the Rives–Stoppa technique that uses large sheets of mesh placed deep to the rectus sheath. This repair has had a success rate in excess of 90% [49].

Nerve injuries

The risk of nerve injury in a midline incision or a short transverse incision is low because only terminal nerve fibers are transected as a result of the incision. Longer incisions, especially at the level of the anterior superior iliac spine, may risk injuring the ilioinguinal or iliohypogastric nerves. Similarly, long subcostal incisions invariably transect branches of the intercostal nerves and create areas of diminished sensation inferior to the incision. Neuromas, although rare, may develop. Rarely, the femoral nerve can be compressed by retractor blades in pelvic surgery. Up to 10% of patients who undergo pelvic surgery develop symptoms due to femoral nerve compression [50]. Fortunately, the resultant neurapraxia is generally mild and transient.

Adhesive small bowel obstruction

Another unintended consequence of laparotomies is intraabdominal adhesion formation and resulting small bowel obstruction. In a large series, 12.4%–17% of patients developed symptoms consistent with small bowel obstruction 2 years after laparotomy and 2.6%–3.1% of patients required adhesiolysis operatively [51]. This translates into 300 000 admissions, 800 000 days of inpatient care, and $1.3 billion of expenditure per annum in the USA [52]. For patients who are admitted for adhesive small bowel obstruction, the risk of recurrence is 34% by 4 years and 42% by 10 years [53]. It is estimated that three-quarters of small bowel obstructions are caused by postoperative adhesions. Adhesion barriers have been developed and used in laparotomies to prevent the formation of dense adhesions (e.g., Interceed, Seprafilm). When properly used, they have been shown to decrease postoperative adhesion formation [54]. Unfortunately, there are no data to show that this reduces the rate of small bowel obstruction since these adhesive barriers only prevent adhesions to the abdominal wall and pelvic side wall. Because of cost and lack of reduction of the important consequences of adhesion formation, they are not commonly used. In comparison, however, laparoscopy induces much less adhesion formation than laparotomy. With the gradual replacement of laparotomy by laparoscopic procedures, it is anticipated that the incidence of postoperative adhesive small bowel obstruction will decline.

Future of laparotomy

Increasingly sophisticated imaging modalities and the advent of modern laparoscopic surgery have limited the role of laparotomy to complex procedures. Nowadays, it is rare to perform a laparotomy without an a priori radiographic diagnosis. The majority of those diagnoses are confirmed at the time of laparotomy. Staging laparotomies and exploratory laparotomies are rarely performed nowadays. Despite this trend, laparotomy is still the gold standard in many situations. A laparotomy is fast. A well-trained surgeon can gain entry to the abdominopelvic cavity in minutes without injur-

ing any internal organ. For this reason, laparotomies are still performed routinely for trauma patients in whom rapid control of bleeding vessels and perforated viscus is paramount. A laparotomy is inexpensive. Most, if not all, instruments used to perform laparotomies are reusable. For this reason, laparotomies will have advantages in countries where health-care dollars are limited or expertise in advanced laparoscopy is lacking. Laparotomy is versatile. A large midline incision affords surgeons direct, hands-on access to all intraabdominal and pelvic organs. This versatility makes laparotomy the safe fallback procedure if other less invasive procedures fail. Laparotomy will always be performed when a laparoscopic procedure is unable to be completed or a percutaneous intervention is unsuccessful. Laparotomy and traditional open surgery are still taught at every surgical training program, and for a good reason. Patients undergoing complex operations such as liver transplantation and Whipple procedures are unlikely to be treated with laparoscopic approaches. Hence it is unlikely that laparoscopy will replace laparotomy as the workhorse of complex abdominal surgery.

Abdominal radiographs, 3061 Contrast studies, 3065

Abdominal radiographs

Abdominal radiographs often play an important role in the evaluation of patients with abdominal pain or distention or clinical signs of an acute abdomen [1]. The purpose of this section is to review radiographic findings such as bowel dilation, pneumoperitoneum, and pneumatosis, and to discuss their significance. However, computed tomography (CT) is increasingly recognized as a more sensitive technique than abdominal radiography for diagnosing a host of conditions in patients with acute abdominal symptoms.

Technique

In patients with acute abdominal findings, both supine and upright radiographs of the abdomen should be obtained. The upright radiographs should be centered to include the diaphragms. This permits assessment of not only free intraperitoneal air beneath the diaphragms but also air–fluid levels within the bowel that can be detected only on horizontal-beam views. If patients are too sick or debilitated to stand, left lateral decubitus views should be obtained instead to detect free air between the liver and the right lateral abdominal wall.

Abnormalities

Bowel dilation

Bowel dilation is usually caused by obstruction or ileus. The small bowel is a more common site of obstruction than the colon. Other patients may develop an adynamic ileus without evidence of mechanical obstruction. These conditions are considered separately in the following sections.

Small bowel obstruction

Because of the great increase in abdominal surgery in recent decades, most small bowel obstructions are caused by postoperative intraperitoneal adhesions [1]. Other less common causes include incarcerated hernias, metastases, radiation, Crohn's disease, intussusception, and gallstone ileus.

In a mechanical small bowel obstruction, supine abdominal radiographs usually reveal multiple loops of dilated small bowel and a paucity of colonic gas (Fig. 128.1a); multiple air–fluid levels are almost always seen on upright or decubitus views (Fig. 128.1b). Dilated small bowel can usually be differentiated from dilated colon by its more central location in the abdomen as well as the presence of tightly spaced folds or valvulae conniventes that completely traverse the diameter of the bowel.

While advanced small bowel obstructions are easily recognized on abdominal radiographs, the diagnosis can be more difficult in patients who do not swallow a large amount of gas. In such cases, gaseous distention of bowel can be minimal or absent. Nevertheless, accumulation of fluid still occurs, and horizontal-beam views may still demonstrate numerous air–fluid levels in nondilated bowel. Occasionally, a row of tiny gas bubbles or "string of pearls" may be seen on upright or decubitus radiographs due to small amounts of gas trapped along the superior margin of small bowel loops almost completely filled with fluid [2]. In patients who swallow virtually no air whatsoever, abdominal radiographs may reveal a gasless abdomen with multiple fluid-filled loops of bowel appearing as tubular or sausage-shaped densities in the bowel that may be indistinguishable from true abdominal masses [2].

A simple mechanical obstruction does not usually cause bowel ischemia. However, a closed-loop obstruction due to an incarcerated hernia, volvulus, or other cause may occasionally produce a strangulating obstruction with ischemia or necrosis of the involved segment of bowel. Recently, CT has been recognized as a sensitive technique for detecting strangulation of bowel in patients with closed-loop obstruction [3].

It is important to recognize that advanced cecal carcinomas may obstruct the ileocecal valve, mimicking the radiographic appearance of a distal small bowel obstruction [1]. More distal colonic obstructions may also be masked by an incompetent ileocecal valve that allows gas to reflux from the obstructed

colon into the small bowel. A barium enema may be performed on patients with radiographic evidence of a distal small bowel obstruction to rule out an unsuspected colonic carcinoma, particularly when there is no history of prior abdominal surgery.

Colonic obstruction

In colonic obstruction, supine abdominal plain radiographs usually reveal disproportionate colonic distention proximal to the obstructing lesion, with air–fluid levels in the dilated bowel on upright radiographs. The transition from dilated to nondilated bowel can often be recognized and most commonly occurs in the sigmoid colon because of an obstructing carcinoma. Primary colonic carcinoma accounts for 80%–90% of all colonic obstructions, but diverticulitis, metastases, and volvulus are other less common causes [1].

The most devastating complication of colonic obstruction is cecal perforation. Because of the high mortality associated with cecal perforation, colonic obstruction should be considered a surgical emergency. In general, a cecal diameter greater than 10–12 cm on abdominal radiographs is thought to be an indication for urgent colonic decompression because of the high risk of perforation [4].

Colonic volvulus should be distinguished from a simple colonic obstruction because it results from twisting of the colon around a fixed point on its mesentery, producing a closed-loop obstruction. The vast majority of cases involve the sigmoid colon or cecum [5]. Sigmoid volvulus is an acquired condition that often occurs in elderly patients who have chronic constipation or a high-residue diet [6]. In contrast, cecal volvulus tends to occur in younger patients due to congenital failure of retroperitoneal fixation of the cecum and ascending colon [6]. As a result, the right side of the colon has a persistent mesentery on which a volvulus can take place.

In sigmoid volvulus, abdominal radiographs usually reveal a massively dilated sigmoid colon that extends out of the pelvis into the upper abdomen with some degree of proximal colonic distention (Fig. 128.2) [1,7]. In contrast, cecal volvulus usually produces a massively dilated cecum that flips into the left upper quadrant with a single air–fluid level on upright or decubitus horizontal-beam views [1,7]. Because colonic volvulus is a closed-loop obstruction, twisting of the

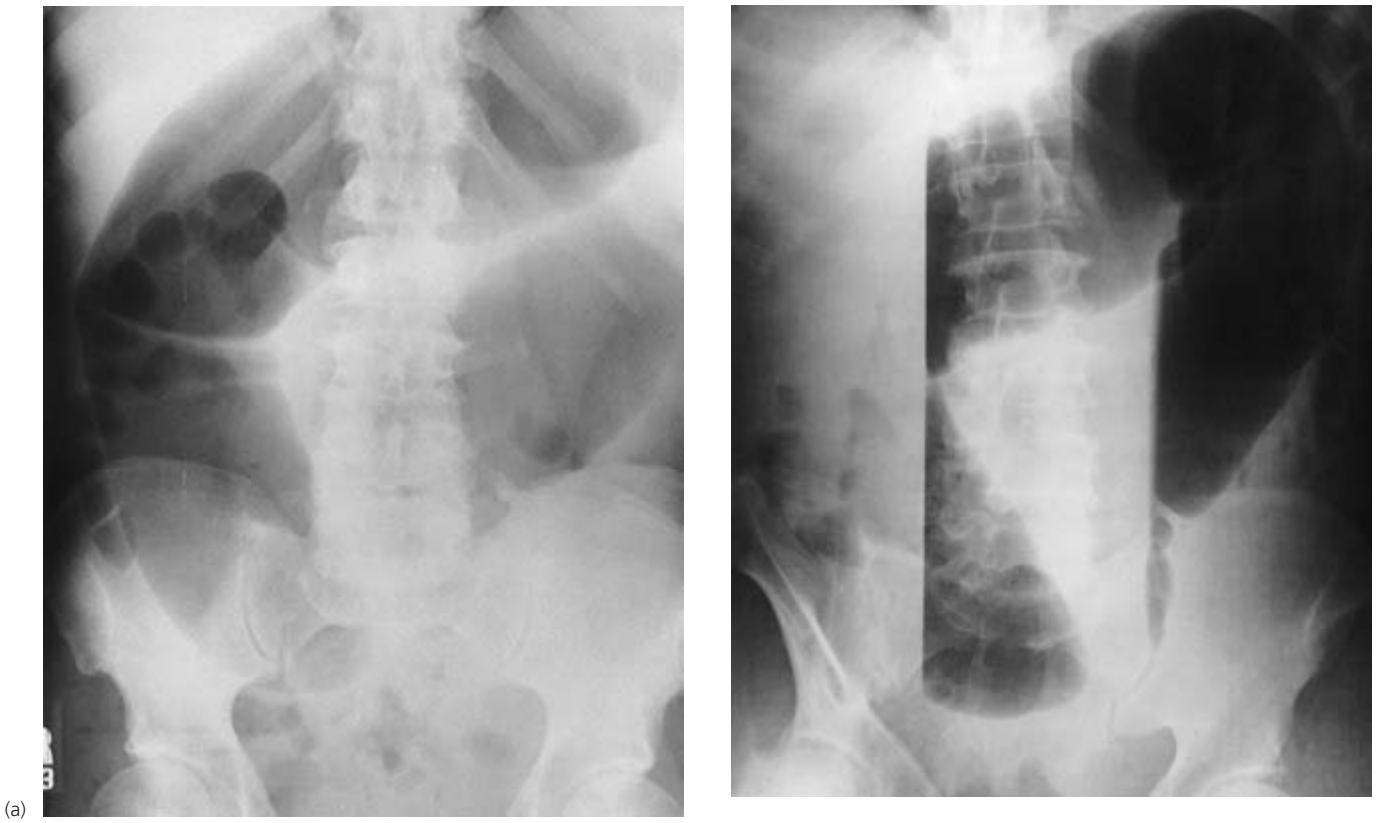

Figure 128.2 Sigmoid volvulus. **(a)** Supine abdominal radiograph shows a massively dilated sigmoid colon rising out of the pelvis into the abdomen. **(b)** Right lateral decubitus radiograph shows long air–fluid levels in both limbs of this dilated sigmoid loop. From Levine [1], with permission from Elsevier.

mesentery may compromise the vascular supply of the bowel, leading to strangulation, infarction, and perforation of the involved loop. Early diagnosis is therefore essential so that colonic volvulus can be treated before strangulation occurs.

Because of the risk of cecal perforation in patients with colonic obstruction, a barium enema may be required as an emergency procedure to determine whether an obstruction is present and to delineate the nature and site of the obstructing lesion. Carcinoma of the colon typically manifests as an annular lesion with shelf-like overhanging borders, whereas diverticulitis produces a tapered area of narrowing with intact but distorted mucosal folds. In colonic volvulus, the barium enema reveals a typical "bird-beak" deformity at the site of the volvulus.

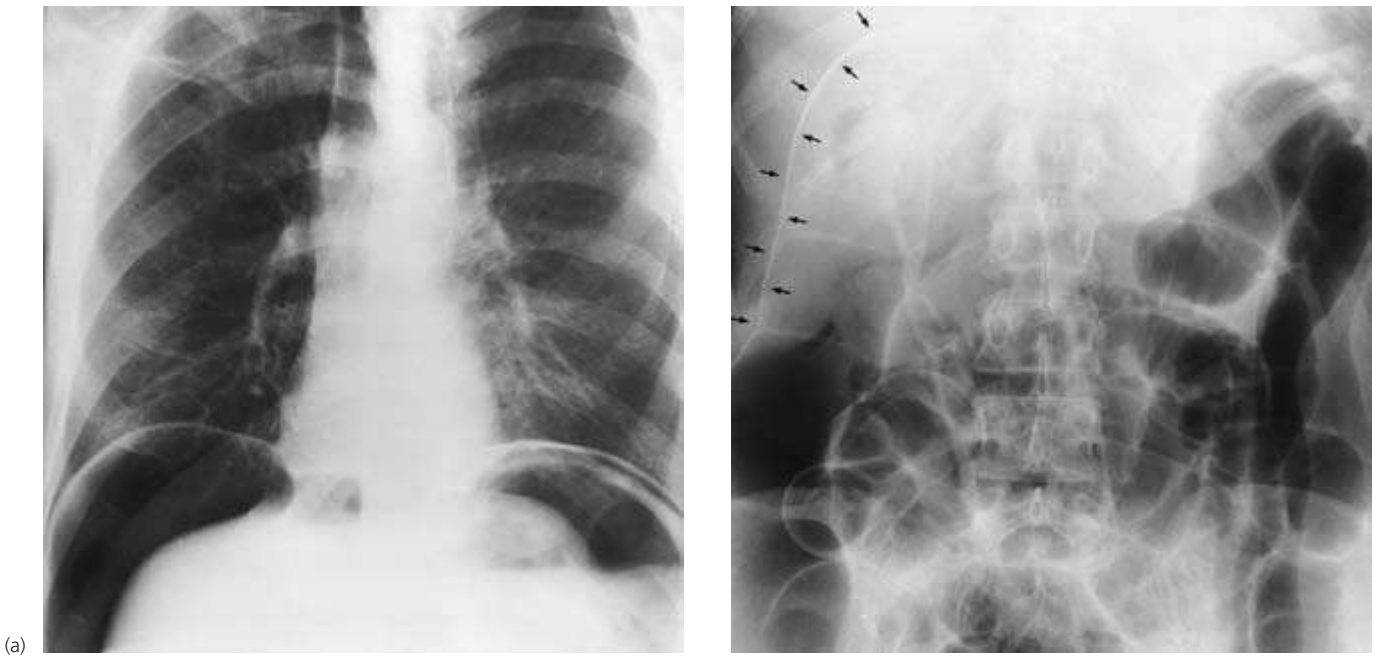
Adynamic ileus

In patients with an adynamic or paralytic ileus, there is interference with intestinal transport without an actual mechanical obstruction. As a result, supine abdominal radiographs classically show diffusely dilated small and large bowel. Although the degree of distention depends on the degree of air swallowing, horizontal-beam views usually demonstrate air–fluid levels throughout the bowel [8]. For reasons that are unclear, however, abdominal radiographs sometimes reveal an isolated small bowel or colonic ileus. In such cases, the findings may be indistinguishable radiographically from a mechanical small bowel or colonic obstruction [1,8]. When the colon appears dilated, the presence of a significant amount of rectal gas on left lateral views of the rectum should favor an ileus [9]. If it is unclear whether the patient has a distal colonic obstruction or an ileus, a single-contrast barium enema may be performed to differentiate these conditions.

Pneumoperitoneum

Upright chest and abdominal radiographs and left lateral decubitus radiographs of the abdomen are extremely sensitive for detecting free intraperitoneal air (i.e., pneumoperitoneum) and may demonstrate collections of intraperitoneal air as small as 1 mL [10]. In patients with an acute abdomen, the presence of free air almost always indicates a perforated viscus with subsequent peritonitis. The most common cause is a perforated duodenal ulcer [1]. Colonic perforation due to ischemic bowel disease, toxic megacolon, and diverticulitis is much less common but should be suspected in any patient with pneumoperitoneum and colonic distention on abdominal radiographs [11].

Pneumoperitoneum can readily be documented on upright chest radiographs or upright or left lateral decubitus



(a) (b)

Figure 128.3 Pneumoperitoneum. **(a)** Upright chest radiograph shows large amounts of free intraperitoneal air beneath the diaphragm in this patient with a perforated duodenal ulcer. **(b)** Supine abdominal radiograph in a different patient shows an indirect sign of pneumoperitoneum with air on both sides of the bowel wall (Rigler sign) (arrows) following inadvertent perforation at colonoscopy. From Levine [1], with permission from Elsevier.

radiographs of the abdomen by the presence of free intraperitoneal air directly beneath the diaphragms (Fig. 128.3a) or between the liver and the right lateral abdominal wall. Unfortunately, some patients are too ill or debilitated to stand or lie on their side; supine abdominal radiographs may be the only images obtained in these patients. However, pneumoperitoneum can be recognized on supine radiographs by the presence of air on both sides of the bowel wall (i.e., Rigler sign) (Fig. 128.3b), by linear or triangular collections of gas in the subhepatic space, or by air outlining the falciform ligament as a linear density in the right upper quadrant [1,2]. In one study, one or more signs of free intraperitoneal air were present on supine abdominal radiographs in 59% of patients with pneumoperitoneum [12].

Pneumatosis

In patients with intestinal ischemia or necrosis, gas may dissect into the wall of the affected bowel, producing intramural bowel gas or pneumatosis. This finding is recognized on abdominal radiographs by mottled or linear gas shadows that have a characteristic radiographic appearance (Fig. 128.4) [1,13]. CT has been recognized as a more sensitive technique than abdominal radiography for detecting pneumatosis [14]. It has classically been taught that the presence of pneumatosis indicates bowel infarction in the clinical setting of intestinal ischemia. However, studies have shown that pneumatosis can be detected on CT in patients with ischemic bowel disease who have viable bowel with partial mural

Figure 128.4 Pneumatosis due to an infarcted descending colon following abdominal surgery. Close-up view from supine abdominal radiograph shows tiny, mottled, and linear collections of gas in the wall of the descending colon.

ischemia rather than transmural infarction, so these individuals may recover without need for surgery [15,16].

In patients with intestinal necrosis, tiny, linear, peripherally branching gas shadows may occasionally be identified over the liver due to gas within the portal venous system [13]. This finding usually indicates severe disease with an extremely ominous prognosis. However, portal venous gas should be distinguished radiographically from biliary gas (i.e., pneumobilia), which tends to collect centrally in the common bile duct due to the opposite direction of bile flow. Pneumobilia can result from a variety of causes, including gallstone ileus, emphysematous cholecystitis, and a surgical or spontaneous biliary–enteric fistula [1].

Pneumatosis can also occur as a benign condition in which multiple gas-filled cysts or blebs are present in the wall of the bowel [1,13]. These patients are rarely ill, and the condition is usually discovered accidentally on abdominal radiographs obtained for other reasons. Radiographically, these gas-filled blebs are typically recognized as cystic or grape-like collections of gas that appear quite different from the linear gas shadows associated with intestinal necrosis.

Contrast studies

Contrast studies of the gastrointestinal tract can be performed using single- or double-contrast techniques. Single-contrast studies entail filling the lumen with a relatively low-density barium suspension and evaluating for contour abnormalities or filling defects in the barium pool. In contrast, double-contrast studies utilize a smaller amount of high-density barium and gas to evaluate the en face appearance of the mucosal surface. As a result, double-contrast techniques have dramatically improved the radiologist's ability to diagnose a variety of inflammatory and neoplastic diseases throughout the gastrointestinal tract. A major advantage of these techniques is their ability to demonstrate superficial mucosal abnormalities that cannot easily be recognized on conventional single-contrast examinations. In other cases, double-contrast studies may detect lesions that are missed or misinterpreted at endoscopy. Double-contrast radiography is also less expensive and less invasive than endoscopy. Thus, it is a valuable technique for evaluating patients with suspected gastrointestinal disease. All radiologists should strive for excellent double-contrast studies to maximize the information available from the procedure.

Pharynx

Indications

With increased survival of the elderly, pharyngeal disorders have become an increasingly frequent problem in modern medical practice. Approximately 35% of nursing home patients have some form of swallowing dysfunction [17]. Aspiration pneumonia and choking are particularly common causes of morbidity and mortality. Radiographic examination of the pharynx is now recognized as a valuable tool in the diagnostic workup of this large group of patients with pharyngeal disorders.

Contrast studies of the pharynx are most frequently performed on patients who have difficulty swallowing. However, disorders of the pharynx may also be manifested by respiratory and speech problems. Laryngeal penetration or overflow aspiration may lead to recurrent pneumonia, asthma, chronic bronchitis, coughing, or choking. In other patients, soft-palate insufficiency may result in nasal regurgitation or may give the voice a nasal quality. A pharyngoesophagram may be helpful in patients who have a wide spectrum of respiratory, speech, and swallowing difficulties. Barium studies are also useful in assessing pharyngeal function and morphology in patients with a history of neuromuscular disease, stroke, pharyngeal tumor, or prior head and neck surgery or radiation.

Normal anatomy

The pharynx is a complex muscular tube suspended superiorly from the skull base and styloid process, posteriorly from the cervical spine, and anteriorly from the mandible and hyoid bone. At least 26 muscles and six cranial nerves participate in pharyngeal function [18,19].

The pharynx can be arbitrarily divided into three portions: the nasopharynx, oropharynx, and hypopharynx. The soft palate separates the nasopharynx from the oropharynx, and the pharyngoepiglottic fold separates the oropharynx from the hypopharynx. The tongue forms the anterior wall of the oropharynx. The larynx, with its associated epiglottic, thyroid, cricoid, and arytenoid cartilages, forms the anterior wall of the hypopharynx. This laryngeal complex often protrudes into the lower hypopharynx as an apparent mass.

The mucosal surface of the pharynx is thrown into a series of folds by underlying lymphoid and muscular tissue. The vertical surface of the base of the tongue often has a nodular appearance due to the circumvallate papillae and lingual tonsil. Nodular lymphoid tissue or linear webs may also interrupt the normally smooth surface of the valleculae. Although the anterior border of the hypopharynx usually has a smooth contour, close apposition of the longitudinal muscles of the pharynx to the overlying squamous mucosa results in longitudinal striations of the lateral and posterior walls of the hypopharynx [16]. Horizontal mucosal striations are seen in the redundant mucosa overlying the arytenoid processes and cricoid cartilages [19].

Technique

A complete radiographic examination of the pharynx includes a cine or video pharyngoesophagram to evaluate motility and a series of spot images to evaluate morphology [20–22]. In patients with suspected foreign body, fistula, or abscess, frontal and lateral radiographs of the neck should also be obtained.

The barium study is initially performed with a high-density barium suspension for optimal visualization of the pharynx. The patient is asked to swallow barium in frontal, lateral, and oblique projections. A video recording of each swallow permits a frame-by-frame or slow-motion analysis of the various parameters of deglutition. Movement of the tongue, soft palate, and epiglottis as well as laryngeal closure and cricopharyngeal opening are best evaluated in the lateral projection. However, symmetry of tongue motion, pharyngeal peristalsis, and epiglottic tilt are best evaluated in the frontal projection.

After individual swallows of barium, double-contrast spot images of the pharynx are obtained in frontal and lateral projections. The spot images are obtained during suspended respiration and during a modified Valsalva maneuver or phonation to optimally distend the pharynx [23]. The frontal view is best for demonstrating the contours of the valleculae and piriform sinuses, the lateral walls of the tonsillar fossae and hypopharynx, and the superior border of the base of the tongue. The lateral view is best for demonstrating the inferior border of the base of the tongue, the soft palate, the posterior pharyngeal wall, the anterior hypopharyngeal wall, the epiglottis, and the cricopharyngeus.

After the pharyngeal examination has been completed, upright double-contrast and prone single-contrast views of the esophagus are obtained to rule out associated esophageal disease.

Abnormalities

Laryngeal penetration and aspiration

Laryngeal penetration occurs when barium enters the laryngeal vestibule during swallowing. Penetration may be limited to the region of the subepiglottic space or may extend as far as the true vocal cords or trachea. Laryngeal penetration occurs because of poor timing of oral and pharyngeal events associated with swallowing or pharyngeal dysmotility due to neuromuscular disorders such as amyotrophic lateral sclerosis, multiple sclerosis, or cerebrovascular accidents. Inflammatory or neoplastic diseases that restrict pharyngeal motility may also cause penetration. One study found that patients with epiglottic carcinoma may present with signs and symptoms of aspiration because of decreased epiglottic excursion when this structure is involved by tumor [24].

Aspiration occurs when barium enters the laryngeal vestibule during normal breathing. Aspiration results from stasis and retention of pharyngeal contents because of tumor, diverticula, or neuromuscular disease in the pharynx. Aspiration may also be caused by gastroesophageal reflux or reflux of esophageal contents above an obstructing esophageal lesion such as a stricture or carcinoma. Penetration is primarily associated with dysmotility, whereas aspiration is associated with stasis. Some patients can have "silent" tracheobronchial aspiration that fails to elicit a cough reflex. It has been shown that the risk of developing aspiration pneumonia correlates directly with the degree of pharyngeal dysfunction on barium studies [25].

Cricopharyngeal prominence

The pharyngoesophageal segment, the radiographic equivalent of the manometrically defined upper esophageal sphincter (UES), is formed by the inferior portion of the cricopharyngeus and the proximal cervical esophagus [26,27]. Although the UES is tonically contracted at rest, initiation of swallowing causes the sphincter to relax ahead of the oncoming bolus. The UES also acts as part of the pharyngeal peristaltic wave, functioning in sequence with the constrictor musculature. The pharyngoesophageal segment is best evaluated on a dynamic recording of the pharynx in a lateral projection.

During swallowing, a prominent cricopharyngeus appears as a smooth, 1-cm high, bar-like protrusion of the posterior pharyngeal wall into the barium column on lateral projections (Fig. 128.5). The cricopharyngeus may show delayed opening, incomplete opening, or early closure. A prominent cricopharyngeus is detected on barium studies in about 5% of asymptomatic individuals [28,29]. However, some patients

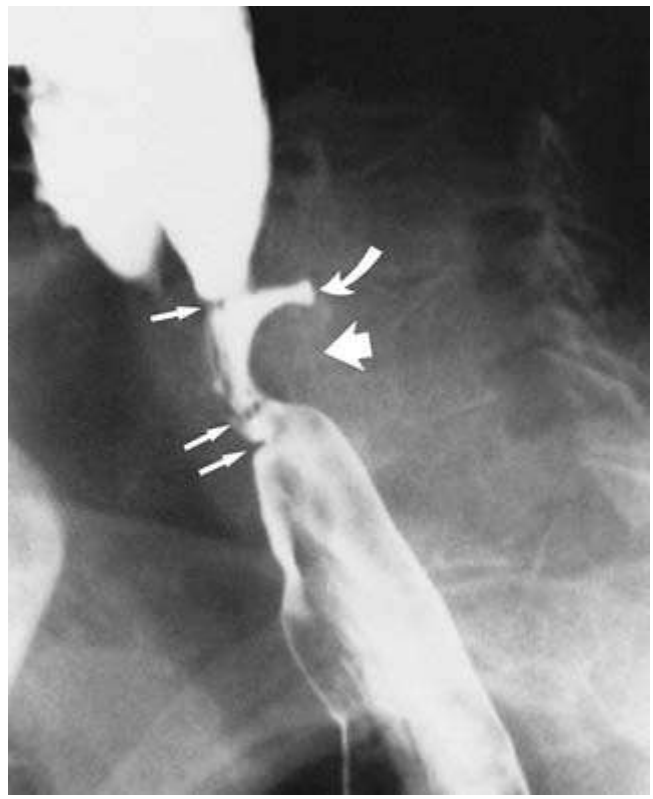


Figure 128.5 Incomplete opening of cricopharyngeus, manifested by a posterior indentation on the pharyngoesophageal segment (large arrow). Notice the associated webs anteriorly (small arrows) and pseudo-Zenker diverticulum posteriorly (curved arrow) that is seen as a result of trapping of barium above a prominent cricopharyngeus. Cricopharyngeal dysmotility is often related to underlying gastroesophageal reflux or pharyngeal paresis.

with this finding complain of dysphagia. In symptomatic patients, a prominent cricopharyngeus is often associated with pharyngeal paresis or occurs as a compensatory response to gastroesophageal reflux or esophageal obstruction.

Lateral pharyngeal pouches and diverticula

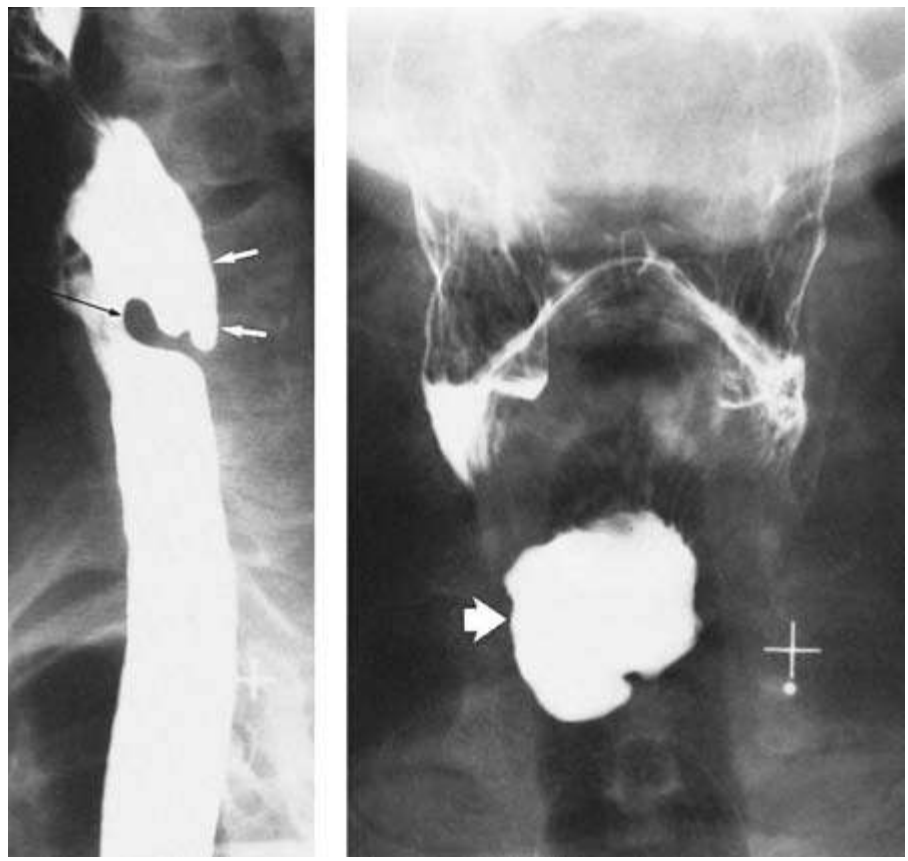
Lateral pharyngeal pouches are transient protrusions of the lateral pharyngeal wall at sites of anatomical weakness, such as the posterior thyrohyoid membrane and tonsillar fossae after a tonsillectomy [30]. These pouches are common findings, usually occurring as normal variants in asymptomatic patients. In contrast, lateral pharyngeal diverticula are persistent protrusions from the tonsillar fossae or region of the thyrohyoid membrane. These diverticula are much less common than pharyngeal pouches, occurring primarily in individuals who have markedly elevated pharyngeal pressure, such as glassblowers and tuba players. If stasis occurs in pharyngeal pouches or diverticula, subsequent spillage of pouch contents into the hypopharynx may result in aspiration into the larynx or tracheobronchial tree. Stasis with delayed spill into the hypopharynx may also cause mild neck discomfort or dysphagia after swallowing. Diverticula may also be manifested by neck masses and may occasionally be sites of ulceration or neoplasia.

Lateral pharyngeal pouches appear on frontal views as transient hemispheric protrusions of mucosa in the upper hypopharynx above the calcified edge of the thyroid cartilage. These pouches can be recognized on lateral views as ovoid barium collections or rings anteriorly in the upper hypopharynx just below the hyoid bone. In contrast, lateral pharyngeal diverticula appear as persistent protrusions in these areas.

Zenker diverticulum

Zenker diverticulum or posterior hypopharyngeal diverticulum is an acquired mucosal herniation through an area of anatomical weakness in the region of the cricopharyngeus (i.e., dehiscence of Killian). This area of anatomical weakness is located between the thyropharyngeus and cricopharyngeus or between the oblique and horizontal fibers of the cricopharyngeus [26,27]. Most patients with Zenker diverticulum have an associated hiatal hernia or gastroesophageal reflux. Rarely, these diverticula are complicated by ulceration or malignancy.

During swallowing, a Zenker diverticulum appears radiographically as a posterior bulging of the distal pharyngeal lumen above an anteriorly protruding cricopharyngeal bar (Fig. 128.6a). At rest, the barium-filled diverticular sac often



(a) (b)

Figure 128.6 **(a)** Zenker diverticulum seen as a posterior outpouching of the hypopharyngeal wall (white arrows) above a prominent cricopharyngeus (black arrow) during swallowing. **(b)** A frontal view shows retention of barium in the diverticulum (arrow) at completion of the swallow.

extends below the level of the cricopharyngeus posterior to the proximal cervical esophagus (Fig. 128.6b).

Inflammatory conditions

Barium studies are of limited value in patients with viral, bacterial, or fungal infection of the pharynx [31]. Such patients usually have normal pharyngograms or nonspecific lymphoid hyperplasia of the palatine tonsil or base of the tongue. Occasionally, however, *Candida* or herpes pharyngitis may be manifested on double-contrast radiographs by plaques or ulcers in the pharynx, particularly in patients with acquired immunodeficiency syndrome (AIDS). Barium studies may also be helpful in a patient who has a chronic sore throat in order to determine whether there is underlying gastroesophageal reflux or reflux esophagitis.

Tumors

Double-contrast pharyngography has an important role in the initial detection and subsequent workup of pharyngeal tumors [32,33]. Double-contrast radiographs of the pharynx can accurately define the size, level, and extent of the lesion. Radiological examination is particularly helpful in demonstrating regions of the pharynx (e.g., valleculae, lower hypopharynx, cricopharyngeus) that are difficult to visualize at endoscopy. It also enables detection of submucosal masses that are easily missed at endoscopy. Although its accuracy is limited in the region of the palatine tonsil, the double-contrast examination is capable of detecting more than 95% of all mucosal neoplasms in the pharynx below the level of the pharyngoepiglottic fold [32].

Squamous cell carcinoma is by far the most common malignant tumor of the pharynx. With an overall 5-year survival rate of approximately 20%, this tumor has a somewhat better prognosis than esophageal carcinoma. These lesions may be manifested on double-contrast radiographs by an intralumenal mass, mucosal irregularity, or loss of distensibility [34]. An intralumenal mass may cause asymmetry or obliteration of the normal pharyngeal contour, barium-coated lines in unusual locations, or a superimposed radiodensity. Mucosal irregularity may be manifested by an irregular, lobulated, nodular, or granular surface pattern. Loss of distensibility may be associated with fixation of pharyngeal structures by infiltrating tumor. When malignant lesions are detected in the pharynx, the esophagus should be carefully evaluated radiographically because of the increased incidence of synchronous esophageal cancers in these patients [35].

Upper gastrointestinal tract

The development of routine double-contrast techniques for examining the upper gastrointestinal tract has dramatically improved our ability to diagnose a variety of inflammatory and neoplastic diseases in the esophagus, stomach, and duodenum. Despite increasing acceptance of this technique, some investigators advocate endoscopy as the initial screening study in patients with dyspepsia or other upper gastrointestinal symptoms. Although endoscopy has been recognized as a highly accurate technique for examining the upper gastrointestinal tract, it is also an invasive technique with a small but measurable risk of gastric perforation or other complications. Furthermore, it is an expensive technique, costing three to four times more in the USA than double-contrast upper gastrointestinal examinations. Because barium studies are safer and less expensive than endoscopy, radiological evaluation of the upper gastrointestinal tract remains a viable alternative as long as its accuracy approaches that of endoscopy for clinically significant disease. We believe that a carefully performed double-contrast examination provides the best opportunity for radiology to be competitive with endoscopy as a diagnostic modality.

Technique

The routine double-contrast upper gastrointestinal examination should be performed as a biphasic study in which double-contrast and single-contrast views of the esophagus, stomach, and duodenum are obtained [36]. In the double-contrast portion of the study, a series of maneuvers is required to achieve adequate gaseous distention of the lumen while a thin layer of high-density barium is spread on the mucosa. The double-contrast examination is facilitated by the use of pharmacological agents (e.g., glucagon 0.1 mg i.v.) to induce gastric hypotonia. After the double-contrast portion of the study has been completed, prone or upright single-contrast views of the esophagus, stomach, and duodenum are obtained with a low-density barium suspension and various degrees of compression to supplement the double-contrast study. Because of its greater diagnostic yield, this biphasic study has been advocated as the best radiological technique for examining the upper gastrointestinal tract.

Indications

Esophagus

In patients with reflux symptoms, barium studies have traditionally been advocated to document the presence of a sliding hiatal hernia or gastroesophageal reflux, to detect complications such as strictures, and to exclude other abnormalities in the esophagus that can mimic reflux esophagitis. However, by permitting a more detailed assessment of the esophageal mucosa, double-contrast radiographic techniques have made it possible to detect superficial ulceration and other changes of esophagitis before the development of deep ulcers and strictures.

Because modern medical care is prolonging the survival of patients who are immunosuppressed, infectious esophagitis has become an increasingly frequent problem. When infectious esophagitis is suspected on clinical grounds, double-contrast esophagography may be performed to confirm the diagnosis and differentiate the various underlying organisms. The radiologist's ability to differentiate fungal and viral

esophagitis is particularly important for patients with AIDS, because some gastroenterologists are reluctant to perform endoscopy on these individuals because of fear of contaminating their endoscopic instruments or exposing themselves to human immunodeficiency virus (HIV). However, endoscopy should be performed if the radiographic findings are equivocal.

Dysphagia is another important indication for performing barium studies. If the sensation of dysphagia is localized to the pharynx, a careful pharyngeal examination should be obtained. However, some lesions involving the distal esophagus or cardia may cause dysphagia referred to the upper esophagus or pharynx. Thus, the gastric cardia and esophagus should be carefully evaluated radiographically in all patients with unexplained pharyngeal dysphagia to rule out a distal lesion masquerading as a pharyngeal disorder.

Stomach and duodenum

The most common indications for performing a double-contrast examination of the stomach and duodenum include epigastric pain or discomfort, bloating, belching, early satiety, and signs or symptoms of upper gastrointestinal bleeding such as hematemesis, melena, and guaiac-positive stool. If gastritis, duodenitis, duodenal ulcers, or unequivocally benign-appearing gastric ulcers are diagnosed radiographically, the patient can be treated medically without need for endoscopic intervention. However, if the double-contrast examination demonstrates a gastric ulcer or other lesion that is equivocal or suspicious for malignancy, endoscopy and biopsy should be performed for a more definitive diagnosis. If the double-contrast examination is normal, the decision for endoscopy should be based on the severity of symptoms, age, and overall health of the patient.

Contraindications and risks

Because oral barium sulfate is contraindicated in patients with suspected esophageal or gastric perforation, water-soluble contrast media should be used if there are any clinical or radiographic signs of mediastinitis or peritonitis. Otherwise, the risks of the barium study are negligible. Nevertheless, a double-contrast examination may be difficult to perform on elderly or debilitated patients who cannot undergo the turning maneuvers required for this examination. These patients may be evaluated by conventional single-contrast barium studies.

Abnormalities

Gastroesophageal reflux disease

In patients with suspected gastroesophageal reflux disease, barium studies may be performed not only to detect gastroesophageal reflux but also to look for the morphological sequelae of reflux, including reflux esophagitis, peptic strictures, and Barrett esophagus. Conventional single-contrast esophagography has been considered an unreliable technique for diagnosing reflux esophagitis, with an overall sensitivity of only 50%–75% reported in the literature. However, the use of double-contrast esophagography has increased the radiographic sensitivity to almost 90% [37]. The single most common sign of mild reflux esophagitis on double-contrast studies is the presence of a nodular or granular mucosa due to mucosal edema and inflammation [37,38]. Other patients may have shallow ulcers and erosions appearing as one or more tiny collections of barium in the distal esophagus near the gastroesophageal junction (Fig. 128.7). In more severe disease, the esophagus may have a grossly irregular contour, with serrated margins and decreased distensibility due to extensive ulceration, edema, and spasm.

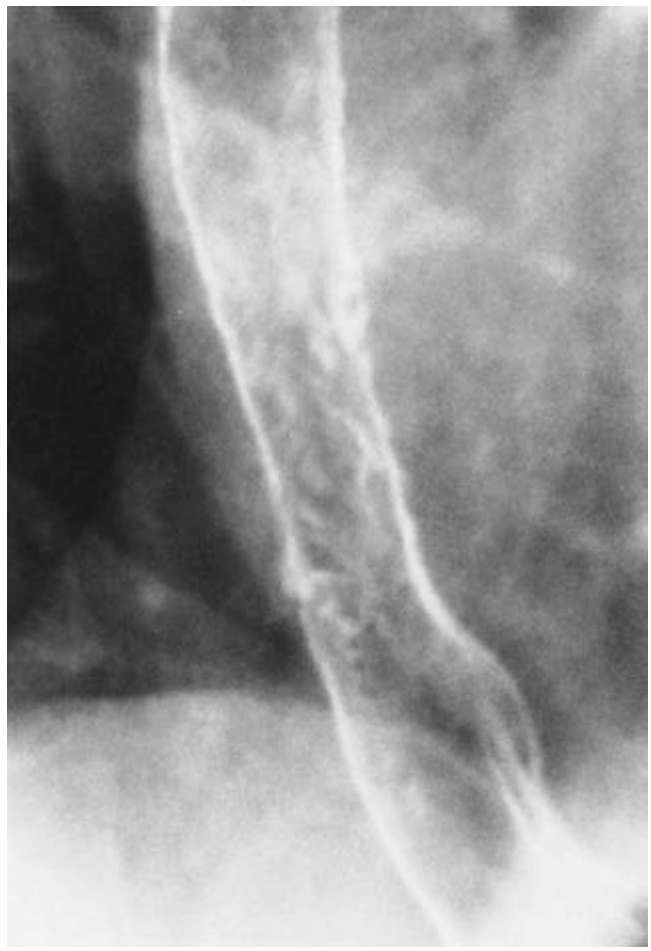


Figure 128.7 Reflux esophagitis with multiple areas of shallow ulceration seen en face and in profile in the distal esophagus. From Levine et al. [36], with permission from the Radiological Society of North America.

Scarring from reflux esophagitis may lead to the development of reflux-induced or peptic strictures, most commonly seen as tapered areas of concentric narrowing in the distal esophagus above a hiatal hernia. Less frequently, peptic strictures may appear as ring-like areas of narrowing that can be difficult to differentiate from Schatzki rings [39].

Barrett esophagus is a well-recognized complication of reflux esophagitis that is associated with a significantly increased risk

of developing esophageal adenocarcinoma. Unfortunately, the classic radiological features of Barrett esophagus (i.e., a high esophageal stricture or ulcer or a reticular mucosal pattern) occur in only a minority of patients [40]. However, data suggest that patients without reflux esophagitis or peptic strictures on double-contrast examinations rarely have Barrett esophagus at endoscopy [41]. Thus, double-contrast esophagography may be a useful screening study for Barrett esophagus to determine the relative need for endoscopy and biopsy in patients with reflux symptoms.

Infectious esophagitis

Esophagography has traditionally been considered an unreliable technique for diagnosing *Candida* esophagitis, with an overall sensitivity of less than 50% [42]. With double-contrast techniques, however, esophagography has a sensitivity as high as 90% in diagnosing *Candida* esophagitis [43]. The major advantage of this technique is its ability to demonstrate mucosal plaques that cannot easily be recognized on conventional single-contrast studies. These discrete plaque-like lesions tend to be longitudinally oriented, appearing on double-contrast radiographs as linear or irregular filling defects with normal intervening mucosa (Fig. 128.8a).

The AIDS epidemic has led to the development of a more fulminant form of *Candida* esophagitis, manifested by a "shaggy" esophagus with a grossly irregular contour due to multiple plaques, pseudomembranes, and ulcers (Fig. 128.8b) [44]. Because this degree of esophagitis rarely occurs in other immunocompromised patients, the possibility of AIDS should be suspected when a shaggy esophagus is detected on barium studies, particularly in young homosexual men.

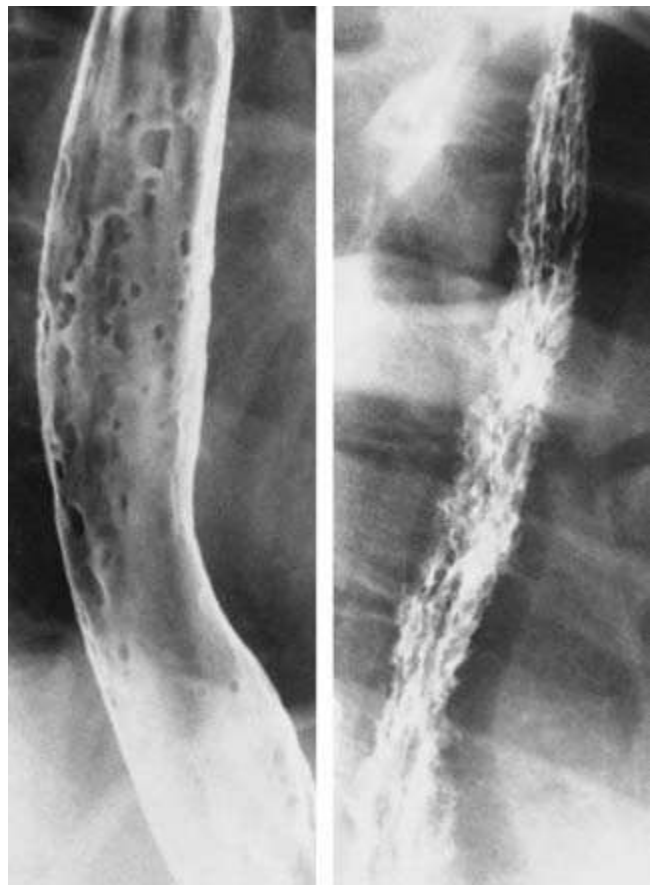
Herpes and, less frequently, cytomegalovirus (CMV) esophagitis also occur in immunosuppressed patients with odynophagia; these conditions should be suspected in the same clinical setting as *Candida* esophagitis. More than 50% of patients with herpes esophagitis have discrete superficial ulcers on the esophageal mucosa that are readily detected on double-contrast radiographs (Fig. 128.9) [45]. In contrast, CMV esophagitis, which occurs primarily in patients with AIDS, is often manifested by the development of one or more large, relatively flat ulcers in the esophagus [44].

HIV itself has also been associated with the development of giant esophageal ulcers in HIV-positive patients with odynophagia. The lesions typically appear radiographically as giant flat ulcers indistinguishable from those caused by CMV [46]. Because HIV-related ulcers may respond dramatically to treatment with oral steroids, endoscopy is required to differentiate HIV from CMV infection in the esophagus before initiating treatment.

Esophageal carcinoma

Esophageal carcinoma is a deadly disease with an overall 5-year survival rate of only 5%–10%. This dismal prognosis is primarily related to the advanced stage of the disease at the time of clinical presentation. Occasionally, however, esophageal cancer may be discovered at an early stage. Unlike advanced esophageal carcinoma, early esophageal cancer is a readily curable lesion with reported 5-year survival rates approaching 90%. In Western countries, detection of these lesions is best accomplished by some form of radiological or endoscopic surveillance of patients known to be at increased risk for developing esophageal cancer.

Early esophageal cancers classically appear on double-contrast esophagrams as protruded lesions less than 3.5 cm in diameter [47]. They may be plaque-like lesions or small sessile polyps with smooth or slightly lobulated contours. Other superficial spreading carcinomas may be manifested radiographically by tiny coalescent nodules or plaques, causing localized nodularity or granularity of the mucosa [47]. In contrast, advanced esophageal carcinomas appear as poly-



(a) (b)

Figure 128.8 *Candida* esophagitis. **(a)** Double-contrast esophagram shows discrete plaque-like defects with normal intervening mucosa. This appearance is characteristic of candidiasis. From Levine et al. [43], with permission from the Radiological Society of North America. **(b)** Severe *Candida* esophagitis in AIDS patient. Notice the shaggy contour of the esophagus, caused by multiple plaques, pseudomembranes, and ulcers.

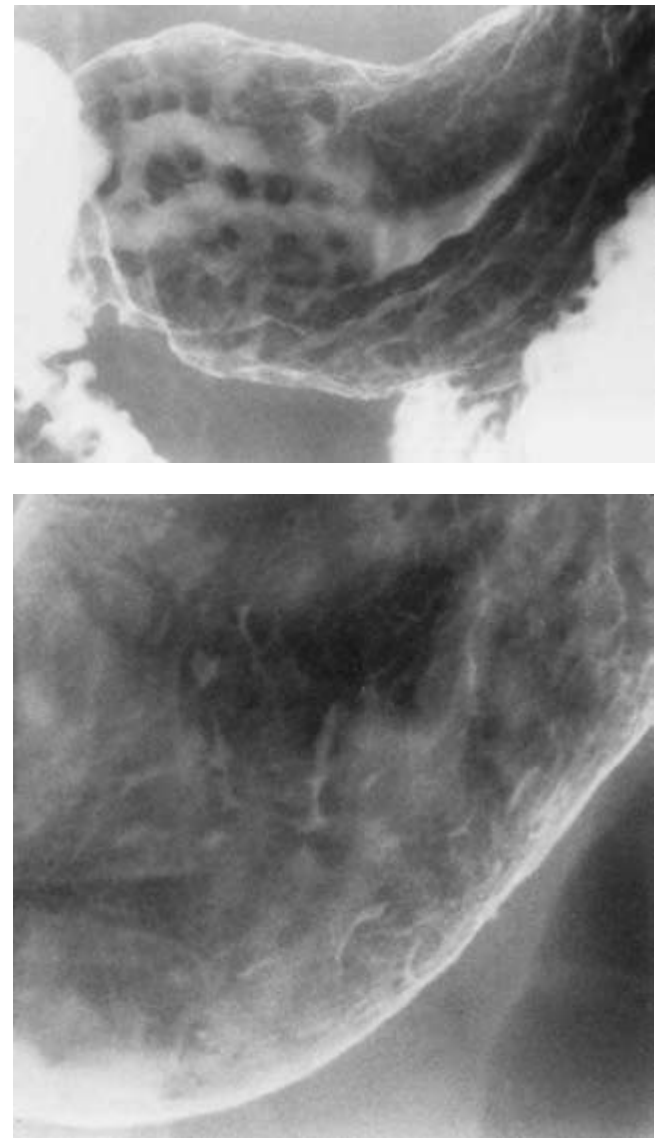
poid, ulcerated, or infiltrating lesions with mass effect, ulceration, or irregular narrowing of the lumen.

Some authors believe that endoscopy is warranted for all patients with dysphagia who have negative esophagrams because of the risk of missing esophageal cancer on barium studies. In one study, however, carcinoma of the esophagus or esophagogastric junction was diagnosed or suspected on double-contrast esophagography in 96% of patients with proven cancers [48]. In the same study, endoscopy was recommended to rule out malignant tumors of the esophagus or esophagogastric junction in only about 1% of all patients who had barium examinations. Thus, a high sensitivity can be achieved in the radiographic diagnosis of these tumors without exposing an inordinate number of patients to unnecessary endoscopy.

Erosive gastritis

Gastric erosions may be classified radiographically as complete or incomplete erosions. Most patients have complete or varioliform erosions in which a punctate or slit-like collection of barium is surrounded by a radiolucent halo of edematous mucosa (Fig. 128.10a) [49]. Varioliform erosions are most commonly found in the gastric antrum and are often aligned on the crests of the rugal folds. In the majority of patients, this finding is caused by ingestion of aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) [50]. In contrast, incomplete or "flat" erosions appear as dots or streaks of barium without an edematous halo. Because the surrounding mucosa is normal, incomplete erosions have been extremely difficult to detect radiographically, accounting for less than 5% of all erosions seen on double-contrast studies.



(a)

(b)

Figure 128.10 Erosive gastritis. **(a)** Typical varioliform erosions in the gastric antrum. The erosions are aligned on the rugal folds. **(b)** Linear and serpiginous erosions in the body of the stomach near the greater curvature are the result of recent ingestion of indomethacin.

Although erosions caused by aspirin or other NSAIDs are usually located in the gastric antrum, they sometimes occur in the gastric body, appearing as distinctive linear or serpiginous erosions that tend to be clustered together on or near the greater curvature (Fig. 128.10b) [51]. In such cases, it has been postulated that these erosions result from localized mucosal injury as the dissolving tablets collect by gravity in the most dependent portion of the stomach.

Helicobacter pylori gastritis

Helicobacter pylori gastritis can be diagnosed on barium studies by the presence of thickened folds or thickened polypoid folds in the antrum, body or, less commonly, fundus of the stomach [50,52]. It is important to recognize that fold thickening is a nonspecific radiographic finding. Nevertheless, *H. pylori* gastritis should be a leading consideration in the differential diagnosis of thickened gastric folds (particularly in the gastric antrum) in patients with dyspepsia, epigastric pain, or other upper gastrointestinal symptoms [50].

Patients suspected of having peptic ulcer disease could be evaluated by a noninvasive *H. pylori* test combined with a double-contrast upper gastrointestinal examination. If the barium study reveals a gastric or duodenal ulcer, a noninvasive *H. pylori* test could be performed to determine whether antibiotic therapy should be initiated as well as conventional antiulcer therapy. Such an approach might avoid the need for endoscopy in many symptomatic patients.

Gastric ulcers

In the past, some researchers have advocated endoscopy and biopsy of all radiographically diagnosed gastric ulcers to rule out cancer in these patients. However, several studies have found that virtually all gastric ulcers with an unequivocally benign appearance on double-contrast upper gastrointestinal examinations are benign lesions [53,54]. In these studies, about two-thirds of all benign ulcers had a benign radiographic appearance. As a result, unnecessary endoscopy could be avoided in the initial evaluation of most gastric ulcers diagnosed on double-contrast examinations. Instead, typically benign gastric ulcers could be followed radiographically to complete healing without need for endoscopic intervention. Because endoscopy is a considerably more expensive procedure than double-contrast radiography, the potential financial savings are enormous.

Benign gastric ulcers classically appear en face as round or ovoid collections of barium, often surrounded by a smooth mound of edema or thin straight folds that radiate directly to the edge of the ulcer crater [54]. When viewed in profile, benign ulcers project beyond the contour of the adjacent gastric wall and are often associated with an ulcer mound or collar. In contrast, malignant gastric ulcers classically appear en face as irregular ulcer craters within a discrete tumor mass, sometimes associated with nodularity or clubbing of adjacent folds due to infiltration of the folds by tumor. When viewed in profile, malignant ulcers project inside the gastric lumen within a tumor mass that forms acute angles with the adjacent gastric wall rather than the obtuse, gently sloping angles expected for a benign mound of edema.

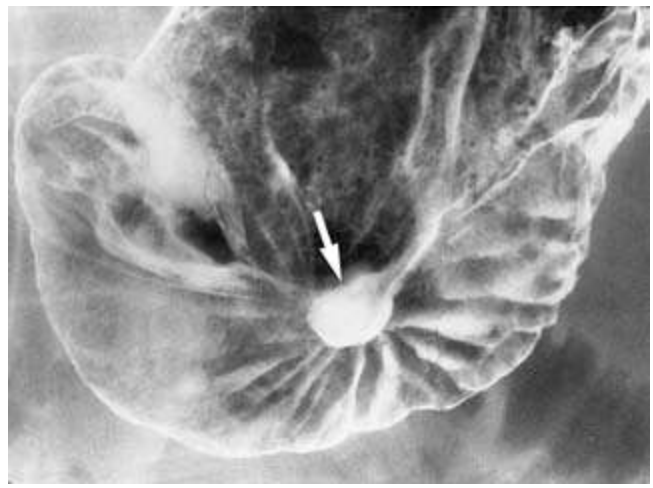


Figure 128.11 Benign gastric ulcer. Round symmetric ulcer (arrow) is seen on the posterior gastric wall, with smooth folds radiating to the edge of the crater. This ulcer has the typical radiological features of a benign gastric ulcer.

Most gastric ulcers detected on double-contrast studies are less than 1 cm in diameter [54]. Although some benign ulcers are round and symmetric, others have a rod-shaped or linear appearance. Almost all benign ulcers occur in the antrum or body of the stomach, and most are located on the lesser curvature or posterior wall (Fig. 128.11) [54]. Occasionally, benign gastric ulcers may be found on the greater curvature of the distal stomach. The latter ulcers are almost always caused by ingestion of aspirin [54]. As these aspirin-induced greater curvature ulcers enlarge, they have a tendency to penetrate inferiorly into the gastrocolic ligament, occasionally leading to the development of gastrocolic fistulae [55].

Ulcer healing may be manifested radiographically by a decrease in the size of the ulcer and by a change in its shape. In most cases, ulcer healing produces a radiographically visible scar with a central pit or depression, radiating folds, or retraction of the adjacent gastric wall [54].

Gastric carcinoma

Gastric carcinoma has a relatively bleak prognosis, with 5-year survival rates of only 10%–30%. Advanced tumors may appear radiographically as polypoid or infiltrating lesions or, less frequently, as scirrhous lesions with diffuse narrowing of the stomach, producing a linitis plastica appearance [56]. In contrast, early gastric cancer is a curable disease, with reported 5-year survival rates as high as 95%. The Japanese have developed an elaborate system for classifying these tumors based on whether they are predominantly elevated, flat, or depressed lesions. Unfortunately, most patients in the USA with gastric carcinoma already have advanced lesions

at the time of clinical presentation. As a result, early gastric cancer is unlikely to be detected on double-contrast studies or endoscopy as long as these examinations are performed predominantly on symptomatic patients [57].

The average sensitivity of single-contrast barium studies for the diagnosis of gastric carcinoma has only been about 75% [58]. Concern about missing gastric cancers on barium studies has therefore been used as a rationale for performing endoscopy as the initial diagnostic test in patients with upper gastrointestinal signs or symptoms. In one study, however, gastric carcinomas were diagnosed or suspected on double-contrast examinations in 96% of patients with proven lesions [58]. In a separate part of the study, only 3.5% of all patients who had double-contrast examinations during this period underwent endoscopy because of findings that were equivocal or suspicious for gastric carcinoma. Thus, a high sensitivity can be achieved in the radiographic diagnosis of gastric cancer while referring only a small percentage of symptomatic patients for endoscopy.

Gastric lymphoma

It is well recognized that chronic *H. pylori* gastritis leads to the development of mucosa-associated lymphoid tissue (MALT) in the stomach. This lymphoid tissue is thought to be the precursor of low-grade B-cell gastric MALT lymphomas which, if untreated, may undergo transformation to more high-grade lymphomas [59]. Gastric MALT lymphomas can sometimes be recognized on double-contrast upper gastrointestinal examinations by variably sized, rounded, often confluent nodules in the stomach (Fig. 128.12) [60]. However, focal gastritis due to *H. pylori* or other causes may produce similar findings, so that endoscopic biopsy specimens are required for a definitive diagnosis. In contrast, advanced gastric lymphoma may be manifested on barium studies by thickened folds, multiple submucosal masses, centrally ulcerated bull's-eye lesions, or giant cavitated lesions [61].

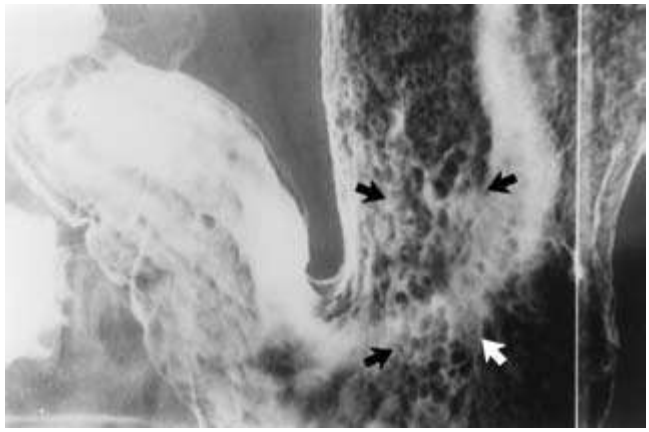

Figure 128.12 Low-grade gastric MALT lymphoma. Multiple confluent nodules of varying sizes (arrows) are seen in the gastric body. From Yoo et al. [60], with permission from the Radiological Society of North America.

Other gastric tumors

Leiomyomas are the most common benign submucosal tumors found in the stomach. These tumors usually appear on barium studies as smooth submucosal masses (with or without central ulceration) that form right angles or slightly obtuse angles with the adjacent gastric wall. Most leiomyomas are less than 3 cm in diameter. In contrast, malignant gastrointestinal stromal tumors usually appear as larger, more lobulated submucosal masses, often containing one or more ulcers or giant areas of cavitation [61]. Ectopic pancreatic rests are usually located on the greater curvature of the distal antrum, appearing as small submucosal masses, sometimes with central umbilication or ulceration. Rarely, barium may reflux into rudimentary ductal structures. Gastric carcinoids may also be manifested on barium studies by one or more small submucosal masses, occasionally containing central ulcers.

Duodenitis

Duodenitis may be manifested radiographically by thickened folds, mucosal nodules, erosions, or deformity of the bulb [62]. Duodenal erosions are detected less frequently than gastric erosions on double-contrast studies because of the difficulty in differentiating these lesions from normal mucosal pits. However, erosive duodenitis can be diagnosed when double-contrast radiographs reveal central barium collections surrounded by radiolucent halos of edematous mucosa.

Duodenal ulcers

Unlike gastric ulcers, which occur primarily on the lesser curvature or posterior wall of the stomach, as many as 50% of duodenal ulcers are located in the anterior wall [36]. Because most double-contrast radiographs are obtained with the patient in a supine or supine oblique position, the anterior wall of the duodenum is not optimally coated with barium, and anterior wall ulcers can be missed on the double-contrast portion of the study. For this reason, double-contrast views of the duodenum should be supplemented with prone compression views obtained with a low-density barium suspension to demonstrate ulcers on the anterior wall. Thus, the biphasic technique is particularly important for evaluating the duodenum.

Small bowel

The conventional small bowel follow-through examination usually consists of a series of overhead abdominal radiographs obtained at regular intervals after ingestion of barium. With this technique, the small bowel is evaluated fluoroscopically only if the overhead radiographs appear abnormal. Because this technique is extremely unreliable in detecting pathology in the small bowel, this form of examination should have no place in modern radiological practice. Instead, adequate evaluation of the small bowel requires more detailed methods of examination, such as the small bowel meal and

enteroclysis. However, these techniques require time, effort, and interest by the radiologist. Barium studies of the small bowel should be requested only if there are legitimate clinical indications of small bowel disease.

Techniques

Small-bowel meal

The dedicated or fluoroscopic small-bowel meal (SBM) includes overhead radiographs but uses fluoroscopy as the primary means of examining the small bowel. Unless contraindicated, metoclopramide (20 mg) is often administered orally 20 min before the examination to accelerate transit of barium through the stomach and small bowel. The patient then ingests 500–600 mL of an appropriate 35%–40% (weight/volume) suspension of barium sulfate. After a brief examination of the upper gastrointestinal tract, intermittent fluoroscopy is performed until all small bowel loops have been demonstrated. Periodic spot images are obtained to document the fluoroscopic findings.

Enteroclysis (small-bowel enema)

A more detailed study of the entire small bowel may be performed by enteroclysis [63]. If not contraindicated, the patient swallows 20 mg of metoclopramide to accelerate small-bowel transit. Surface anesthesia to the throat precedes intubation of the distal duodenum or proximal jejunum. Between 200 and 250 mL of a 75%–80% suspension of barium is then injected, followed by infusion of 1–2 L of a 0.5% solution of methylcellulose in water. These biphasic examinations first demonstrate the small bowel in single contrast (Fig. 128.13a) and then in lumen-distended double contrast (Fig. 128.13b). The radiologist must be present throughout the study to assess individual bowel loops by graded compression and to document the fluoroscopic findings with spot images. An overhead radiograph of the entire small bowel completes the examination.

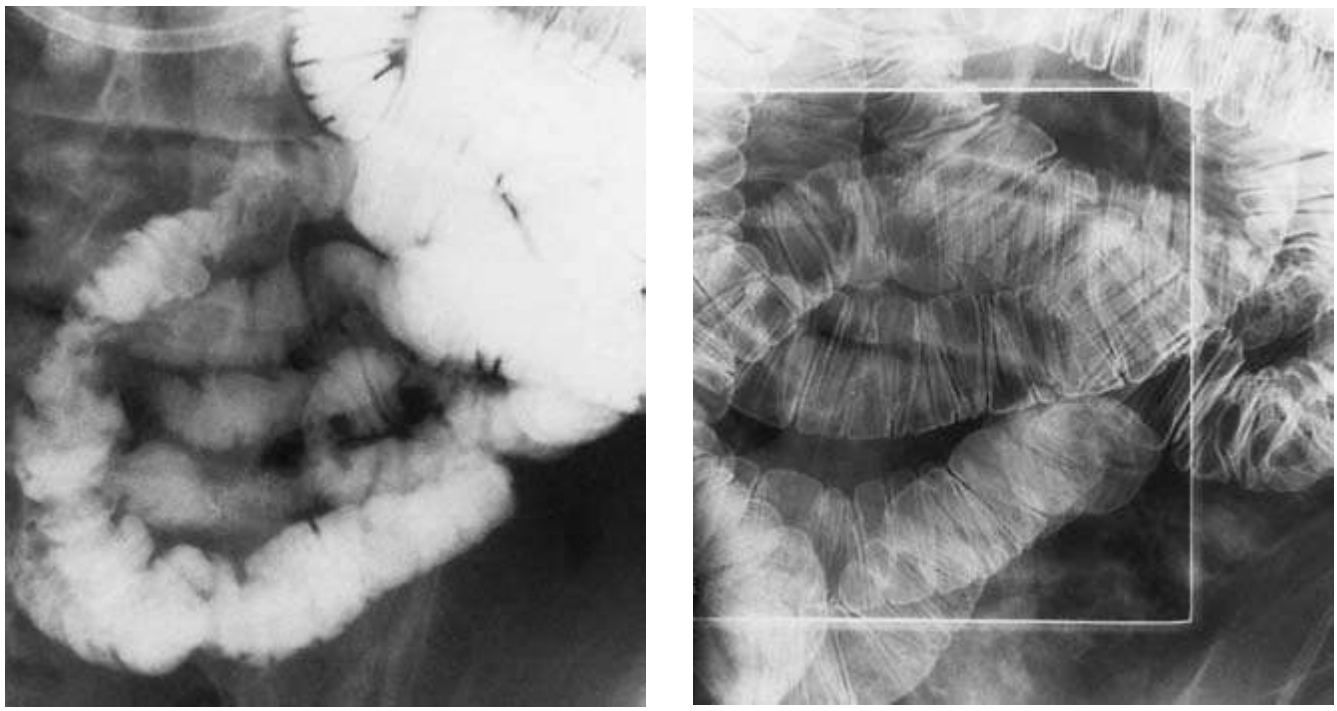
Application of techniques

Small-bowel meal

The major advantage of an SBM is that it does not require intubation. Transit acceleration by oral metoclopramide is an important component of the examination because it decreases flocculation of barium and the time needed to perform the study. However, distention of the bowel lumen cannot be achieved by this technique. The SBM is an appropriate examination for evaluating established diseases of the small bowel, such as Crohn's disease. It is also adequate for investigating pathological conditions not associated with lumenal distention such as radiation enteritis, ischemia, and hematomas. This technique can be used to demonstrate the level and degree of small-bowel obstruction, although it is less successful in determining the cause.

Enteroclysis

The major advantage of enteroclysis is that it combines transit acceleration with lumenal distention. Enteroclysis virtually



(a) (b)

Figure 128.13 Normal small-bowel enema. **(a)** Distal jejunum seen on a preliminary single-contrast examination. **(b)** Same jejunal loops on double-contrast examination.

prevents flocculation of barium. As a result, the double-contrast images permit assessment of mucosal surface detail, even through overlapping small bowel loops. The straightening of mucosal folds that occurs with lumenal distention permits detection of small, relatively subtle lesions. Normality becomes measurable in terms of wall thickness; fold thickness, shape, and height; and distance between folds.

The major indications for enteroclysis include the following:

- Small-bowel obstruction, particularly intermittent obstruction: enteroclysis often permits differentiation of the various causes of obstruction [64].
- Malabsorption states: enteroclysis can identify features of celiac disease, lymphangiectasia, Whipple disease, morphological changes associated with bacterial overgrowth, and other conditions associated with malabsorption.
- Crohn's disease: enteroclysis can delineate the full extent of disease, including skip lesions and fistulae and can be used to distinguish fibrous strictures from stenotic disease.
- Small-bowel tumors, particularly carcinoids, other primary and secondary malignancies, and lymphoma.
- Meckel diverticulum: increased lumenal distention greatly improves the detection rate [65].
- Normality: enteroclysis is the most reliable radiological examination for establishing morphological normality of the small bowel.

Abnormalities

Small-bowel obstruction

Concern has been expressed regarding the possible inspissation of barium within obstructed small bowel. Although animal studies and clinical experience have shown that such inspissation does not occur [66], it is often recommended that barium-based techniques be replaced by CT or by CT enteroclysis in patients who have high-grade or complete small-bowel obstructions [63]. With lower grades of obstruction, barium enteroclysis remains a useful test for delineating the site and cause of obstruction, particularly in patients with intermittent obstruction. If a decompression tube has already been positioned beyond the duodenum, it can be used to perform the enteroclysis examination.

Adhesions

Adhesions account for almost 75% of small-bowel obstructions. Enteroclysis can identify features that favor obstruction by a single band, multiple bands, or extensive adhesions. Single bands are more likely to produce high-grade obstruction. A closed-loop obstruction may be caused by prolapse of a bowel loop beneath an adhesive band. This type of obstruction is associated with twisting of bowel, with a high risk of ischemia and necrosis. Although barium studies may be helpful in the early stages of a closed-loop obstruction, CT is essential for establishing the degree of vascular compromise in these patients.

Hernias

Barium studies are not required for small-bowel obstructions caused by clinically evident external hernias. However, enteroclysis is useful in detecting small-bowel obstructions caused by hernias of developmental or postsurgical origin, including incisional, peristomal, Spigelian, or Richter hernias.

Malignancy

In patients who have undergone laparotomy for abdominal malignancy, small-bowel obstruction may be caused by adhesions, metastases, radiation, or residual tumor. These conditions can be differentiated by enteroclysis in more than 80% of patients [63]. This information can facilitate surgical management by providing a preoperative choice between resection of tumor, bypass of radiation-damaged bowel, or lysis of adhesions.

Malabsorption states

Malabsorption is usually diagnosed by clinical and laboratory criteria. The purpose of barium studies is to determine the most likely cause of a clinically diagnosed malabsorption state or to document complications. In many conditions associated with malabsorption, abnormal accumulation of intralumenal fluid causes flocculation of barium on SBM. Because flocculated barium prevents accurate depiction of mucosal surface detail, enteroclysis is the preferred radiological examination in these patients.

Celiac disease

The diagnosis of celiac disease must be firmly established to justify placing the patient on lifelong dietary restrictions. A confident diagnosis can be made in patients who have characteristic mucosal changes on duodenal biopsy and have shown a satisfactory response to gluten withdrawal. However, more than 50% of patients have atypical clinical presentations. As a result, the diagnosis may first be suggested by enteroclysis, which can demonstrate a measurably increased separation of folds in the distended proximal jejunum (Fig. 128.14). In one study, zero to three folds per 2.5 cm of jejunum were found by enteroclysis in 73% of celiac patients but in only 2% of controls [67]. Conversely, patients with five or more folds per 2.5 cm of jejunum rarely had celiac disease.

Enteroclysis is especially important in celiac patients who relapse after an initial dietary response; this technique can aid in the diagnosis of ulcerative jejunoileitis, T-cell lymphoma, and intestinal carcinoma as complications of long-standing celiac disease.

Bacterial overgrowth syndrome

Barium studies can accurately depict many structural abnormalities in the small bowel that cause stasis or contamination and lead to bacterial overgrowth. These abnormalities include strictures, blind pouch and blind loop syndromes, jejunoileal diverticulosis, and coloenteric fistulae. Other patients with

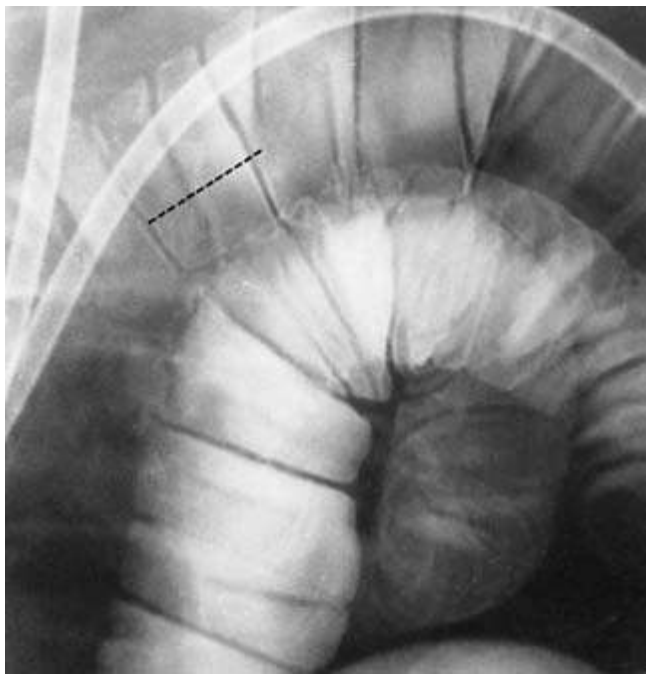


Figure 128.14 Diagnosis of celiac disease on a small-bowel enema. The distended proximal jejunum shows an increased separation of folds, with only three folds per 2.5 cm (dotted line).

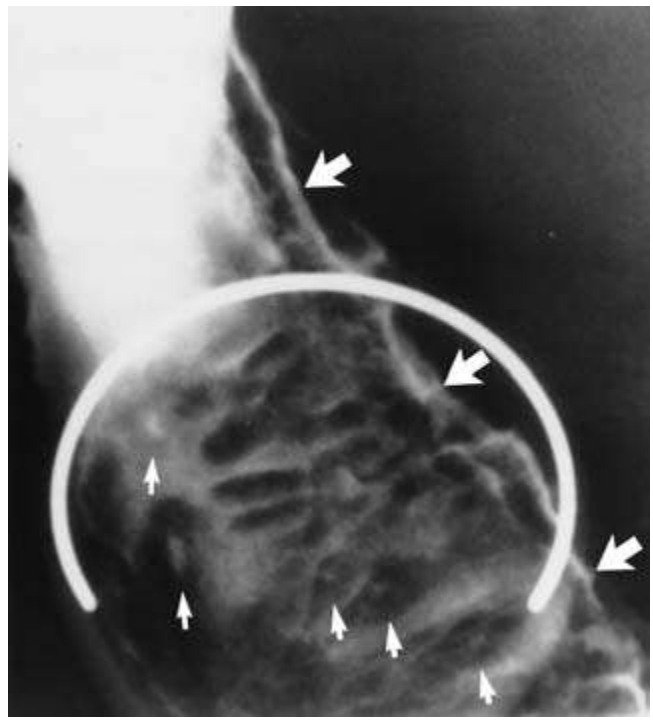

Figure 128.15 Small-bowel Crohn's disease. Spot image from enteroclysis examination shows a long linear ulcer (large arrows) on the mesenteric border of the bowel with multiple aphthous ulcers (small arrows) and thickened, interrupted folds. The linear mesenteric border ulcer is characteristic of Crohn's disease.

bacterial overgrowth syndrome may have chronic intestinal pseudoobstruction due to scleroderma or other causes. Small-bowel involvement by scleroderma may lead to intestinal dilatation with crowded folds, producing the "hide-bound" sign that is virtually pathognomonic of this condition [68].

Intestinal lymphangiectasia

The primary and secondary forms of intestinal lymphangiectasia are manifested by nonspecific changes of fold thickening and fluid increase on conventional barium studies. With enteroclysis, it is possible to demonstrate 1–2 mm micronodules representing villi distended by dilated lacteals. Whipple disease involving the small bowel may also be manifested by tiny nodules due to villous distention by the enlarged lamina propria laden with foamy macrophages, bacilli, and periodic acid–Schiff (PAS)-positive material. A similar nodular pattern may be demonstrated in patients with *Mycobacterium avium* complex enteritis, macroglobulinemia, IgA deficiency, and other unusual conditions.

Crohn's disease

Early radiological findings of Crohn's disease in the small bowel include a coarse villous pattern of the mucosa, thickened folds, and aphthous ulcers. The presence of linear ulcers along the mesenteric border of the bowel with pleating or sacculation of the uninvolved antimesenteric border is virtually diagnostic of Crohn's disease (Fig. 128.15). With progression of disease, transaxial extension of linear ulcers and fissures produces a cobblestone appearance with narrowing of the lumen. Further progression of Crohn's disease leads to complications such as fibrous strictures, fistulae, inflammatory masses, and abscesses.

Many features of Crohn's disease can be demonstrated as effectively by SBM as by enteroclysis. Disease of the terminal ileum is particularly well shown by combining SBM with a peroral pneumocolon (i.e., introducing barium by mouth and air via the rectum) [69]. However, enteroclysis is the optimal radiological examination for detecting early lesions, particularly the more proximal skip lesions. It is also a better examination for distinguishing Crohn's disease from other pathological conditions such as lymphoma, tuberculosis, ischemia, and metastatic disease.

Malignant tumors

Adenocarcinoma

Most primary adenocarcinomas of the small bowel are advanced tumors with regional lymph node involvement at the time of clinical presentation. In the absence of obstruction, these tumors can be missed on conventional small bowel follow-through examinations. Enteroclysis is the best radiological technique for demonstrating these lesions (Fig. 128.16).

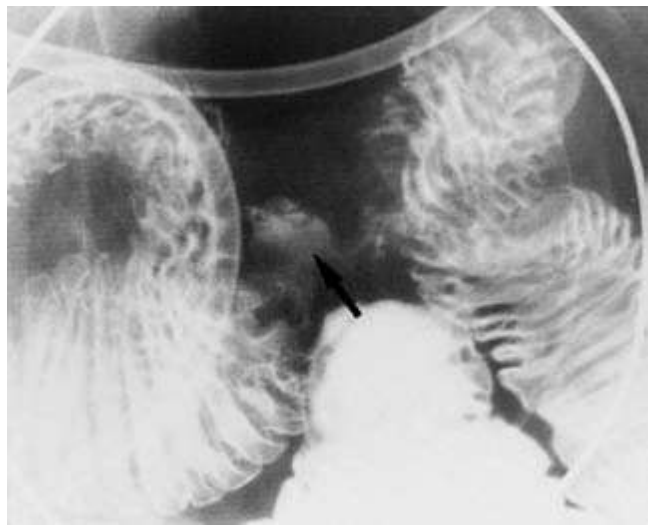

Figure 128.16 Annular adenocarcinoma of the proximal jejunum with a central ulceration (arrow).

Non-Hodgkin lymphoma

Primary small-bowel lymphomas typically appear as cavitary lesions extending into the mesentery or as segmental infiltrating lesions. In other patients with disseminated lymphoma, barium studies may demonstrate submucosal nodules of various sizes. An enlarging mass of mesenteric nodal lymphoma also can secondarily infiltrate a loop of small bowel [63]. CT can be used to better delineate the extent of mesenteric and lymph node involvement.

Other malignancies

Small-bowel carcinoids can be diagnosed by enteroclysis at the stage of incipient transmural extension of the primary tumor or tumors (Fig. 128.17). More advanced carcinoids are typically associated with distorted folds. Enlarging mesenteric metastases produce mass effect and secondary fibrotic alterations in adjacent bowel loops. Early carcinoids may appear as small polypoid nodules, more often in the terminal ileum.

Both hematogenous and intraperitoneal-seeded metastases to the small bowel tend to occur as multiple lesions, often associated with signs of obstruction. Gastrointestinal stromal tumors may appear as excavated exoenteric masses.

Meckel diverticulum

Enteroclysis is the best radiological technique for diagnosing Meckel diverticulum, with an overall detection rate comparable to that found at autopsy [65]. The diverticulum arises from the antimesenteric border of the distal ileum, forming a blind sac, with a characteristic mucosal fold pattern at its site of origin. Occasionally, it is possible to identify a defect in the diverticulum due to ectopic gastric mucosa. It is also possible to identify an inverted Meckel diverticulum acting as the lead point for a small-bowel intussusception [70].

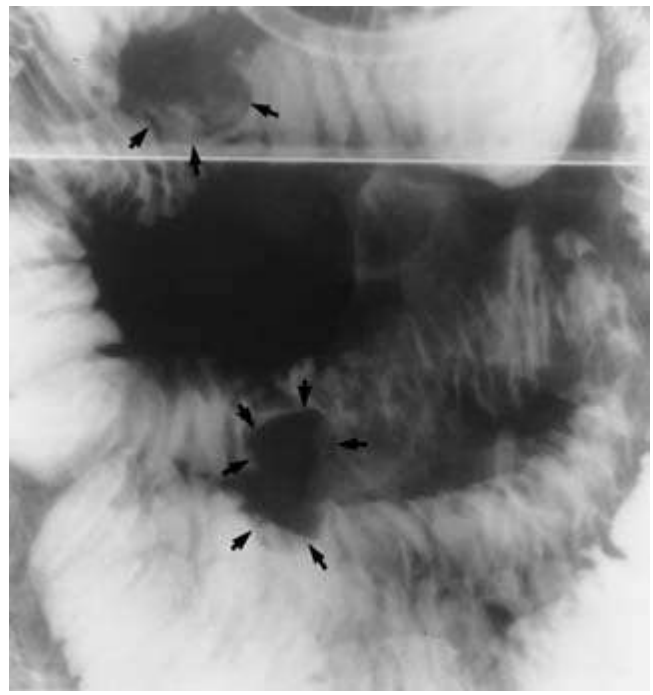

Figure 128.17 Small-bowel carcinoids. Discrete submucosal masses (arrows) are seen in the mid small bowel. Also note separation of small bowel loops caused by spread of tumor into the mesentery.

Obscure blood loss

In patients with unexplained gastrointestinal blood loss, enteroclysis is indicated when radiological and endoscopic examinations of the upper gastrointestinal tract and colon fail to demonstrate a source of bleeding. Enteroclysis has a diagnostic yield of 21% in identifying the presumptive source of obscure gastrointestinal bleeding [71]. The majority of these patients are found to have tumors involving the small bowel; other causes include ischemia, arteriovenous malformations, Meckel diverticulum, and celiac disease.

Colon

Since the 1920s, the barium enema has been used as the primary nonsurgical method for investigating the colon. Since the 1970s, colonoscopy has become an important diagnostic modality for evaluating the colonic mucosa and for removing polyps. Cross-sectional imaging techniques, particularly CT, have also become important for evaluating the extramucosal extent of disease. CT and ultrasound may also be used to assess bowel wall thickness. However, because of its simplicity, low cost, safety, and accuracy, the barium enema remains a useful diagnostic technique for investigating the colon.

Single versus double contrast

Radiological examination of the colon can be performed by single- or double-contrast technique. In single-contrast studies, the entire colon is filled with a low-density barium suspension. The examination is performed under fluoroscopic

control, with extensive palpation and compression of the colon as it fills. A postevacuation radiograph is usually obtained to demonstrate additional mucosal detail. In double-contrast studies, a smaller volume of high-density barium is introduced into the colon, followed by insufflation of air. With this technique, the mucosal surface is coated by a thin layer of high-density barium, and the lumen is distended with air.

The double-contrast examination is considered to be an extremely useful radiological technique for showing fine mucosal lesions such as small polyps and the early changes of inflammatory bowel disease (IBD) [72,73]. It can also better demonstrate segments of the large bowel that are inaccessible to palpation, such as the rectum and the hepatic and splenic flexures. The single-contrast barium enema is the preferred technique when careful control of the flow of barium is required in patients with suspected obstruction, acute diverticulitis, fistulae, or Hirschsprung disease. This technique is also frequently used in patients who are too old or debilitated to tolerate a double-contrast study.

Radiology versus colonoscopy

There is ongoing controversy about the relative roles of radiology and endoscopy in investigating colonic disease. In general, the choice of technique depends on the clinical setting and the relative skill and experience of the examiner. Nevertheless, it should be recognized that colonoscopy is primarily of value for detecting mucosal lesions. It should not be used as the primary diagnostic modality when the patient's symptoms suggest an intramural or extrinsic lesion involving the bowel.

Colonoscopy is probably more accurate than radiology in demonstrating subtle mucosal abnormalities in the colon. When compared with high-quality double-contrast barium enemas, this benefit applies primarily to the detection of polypoid lesions less than 1 cm in diameter and the early preulcerative changes of IBD. However, this benefit must be balanced against the higher cost and complication rate of colonoscopy. The colonoscopist is unsuccessful in advancing the endoscope to the cecum in about 10% of patients [74], but the cecum is almost always visualized on barium enema studies.

We recommend contrast examination of the colon for patients with symptoms that could be caused by diseases of the colon (e.g., abdominal pain, constipation, change in bowel habit, anemia). Colonoscopy is generally the examination of choice for the evaluation of uncertain radiological findings, for removal or biopsy of lesions found at barium enema, and for the evaluation of patients at high risk for developing colorectal cancer or who have occult blood in the stool.

Indications

Although radiological examination of the colon may be performed for a wide variety of indications, the most common include detection of colorectal polyps and cancer; diagnosis of IBD and assessment of the type, extent, and severity of disease; diagnosis of diverticular disease and its complications; evaluation of extrinsic mass lesions involving the colon; and evaluation of the rectum.

Colorectal polyps and cancer

The barium enema is a valuable diagnostic test for symptomatic patients with colorectal cancer. It is useful not only for diagnosing the primary lesion but also for detecting synchronous cancers elsewhere in the colon. The double-contrast barium enema has an overall accuracy of about 95% in detecting colorectal cancer. However, there appears to be an irreducible minimum error rate of approximately 5%, primarily the result of perceptive error [75].

The double-contrast barium enema is also used to evaluate patients who have overt rectal bleeding or occult blood in the stool on routine screening tests for colorectal cancer. In such cases, the goal is to detect invasive carcinomas as well as small adenomas that are precursors of colonic carcinoma (Fig. 128.18). These adenomatous polyps should be removed endoscopically to prevent the subsequent development of cancer.

Contrast examination of the colon may also have a role in the routine screening of average-risk patients for colorectal cancer. Eddy and colleagues suggested that annual fecal occult

Figure 128.18 Example of a coexisting colonic carcinoma and benign adenoma in the same patient. Note the polypoid carcinoma (black arrows) in the transverse colon and small tubulovillous adenoma (white arrow) in the distal sigmoid colon.

blood testing and barium enema every 5 years may be the most cost-effective way of reducing mortality from colorectal cancer [76]. Recently, CT colonography (virtual colonoscopy) has also been widely advocated as a noninvasive radiological test for colorectal cancer screening [77], although the ultimate value of this technique remains uncertain.

Inflammatory bowel disease

Radiological examination of the colon serves a variety of purposes in patients with known or suspected IBD. It can establish the presence of disease in patients who have not had prior sigmoidoscopy or in those with negative sigmoidoscopy because the disease did not involve the rectosigmoid colon. It can also define the extent of disease in the colon. This information is particularly important in patients with ulcerative colitis, because the risk of developing carcinoma is related to the extent of colonic involvement.

Radiological examination of the colon can differentiate ulcerative from granulomatous colitis. In typical cases, ulcerative colitis is characterized on double-contrast radiographs by a granular mucosa involving the rectum and extending proximally to a variable degree (Fig. 128.19a). In contrast, granulomatous colitis is characterized by progression from discrete aphthous ulcers (Fig. 128.19b) to transmural disease with deep ulcers, fissures, fistulae, and abscesses. The rectum is often spared, and colonic involvement tends to be discontinuous and patchy.

Radiological examination can also detect complications of chronic ulcerative or granulomatous colitis, including strictures, abscesses, fistulae, and inflammatory or post-inflammatory polyps. In patients who develop carcinoma as a complication of chronic ulcerative colitis, the tumor can be diagnosed and in some cases the development of macroscopic dysplasia can also be recognized on double-contrast studies [78].

Diverticular disease

Diverticular disease is one of the most common afflictions of Western society. The presence of massive diverticulosis poses a particular dilemma in interpreting double-contrast studies, because the multiplicity of ring shadows makes it difficult to differentiate diverticula from polyps. As a result, single-contrast studies may be easier to interpret than double-contrast studies in patients with severe diverticulosis.

Diverticulitis is a complication of diverticulosis in which a diverticular perforation leads to the formation of a pericolic abscess. Because barium may extravasate into the abscess, it is important to control the flow of barium into the colon in these patients. We therefore prefer a single-contrast technique when a barium enema is performed for suspected diverticulitis (Fig. 128.20). In recent years, however, CT has increasingly been used as the primary radiological modality in patients with suspected diverticulitis because of its relatively high sensitivity and specificity for diagnosing this condition [79].

(b)

Figure 128.19 Early findings of inflammatory bowel disease on double-contrast barium enemas. **(a)** Ulcerative colitis with typical granular mucosa in the sigmoid colon. **(b)** Granulomatous colitis with discrete aphthous ulcers in the transverse colon.

Extrinsic mass lesions

In patients with abdominal or pelvic masses, the barium enema is a useful technique for determining whether the colon is displaced, compressed, or actually invaded by these lesions. The barium enema can also detect intraperitoneal seeding of the colon by metastatic tumor, inflammatory lesions, or endometriosis. In many cases, the barium study must be correlated with CT or other cross-sectional imaging

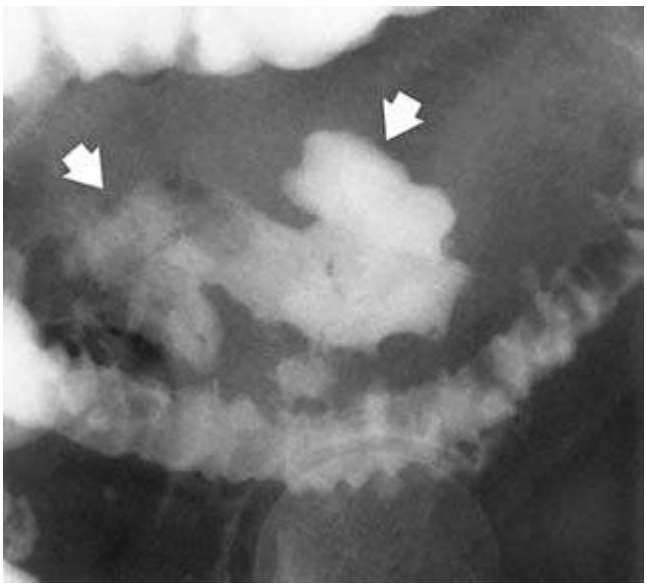

Figure 128.20 Diverticulitis with pericolic abscess. Barium has extravasated from a perforated diverticulum into an abscess (arrows). Notice the diverticula in the sigmoid colon.

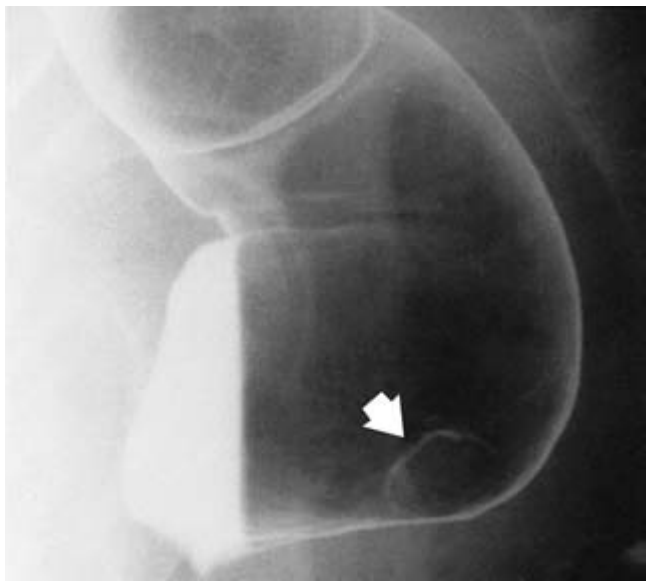

Figure 128.21 Villous carcinoma (arrow) of the posterior wall of the rectum that had been missed on prior digital and proctoscopic examinations.

modalities to determine the true extent of disease in the abdomen.

Rectum

When barium enemas were performed primarily by single-contrast technique, the rectum was not considered to be the province of radiology. With the use of double-contrast technique, however, the rectum has become one of the simplest portions of the large bowel to evaluate on barium studies.

The anatomy of the rectum, including the columns of Morgagni and the valves of Houston, can be demonstrated in exquisite detail [80]. Radiological evaluation of the rectum is particularly important for the diagnosis of rectal tumors, IBD, and other unusual conditions such as the solitary rectal ulcer syndrome [81]. The double-contrast examination can also detect rectal carcinomas that are missed by digital rectal examination and proctoscopy (Fig. 128.21) [82]. The routine double-contrast barium enema should therefore include a careful examination of the rectum.

Contraindications

The barium enema examination is generally a safe procedure, but there are several conditions where the study is contraindicated or should be performed with extreme caution. These conditions include toxic megacolon, ischemic colitis, pseudomembranous colitis, or other diseases in which the bowel wall is friable and more likely to perforate during the procedure. When a colonic perforation is suspected, the radiological examination should be performed with water-soluble iodinated contrast material that can be reabsorbed from the peritoneal cavity if extravasation occurs.

Complications

The most feared complication of the barium enema is colonic perforation [83]. When this occurs, the perforation usually involves the intraperitoneal portion of the colon. Extravasated barium in the peritoneal cavity may be seen outlining loops of bowel. Surgical treatment is usually required. On some double-contrast barium enemas, a colonic perforation may be manifested only by a pneumoperitoneum without extravasation of barium into the peritoneal cavity. If these patients are aggressively treated with intravenous fluids and antibiotics, surgery may be avoided in some cases.

Retroperitoneal perforations usually result from laceration of the rectum by an inflated retention balloon on the enema tip in patients with diffuse rectal disease such as ulcerative or radiation proctitis. In such cases, barium may be observed in the rectal wall or in the perirectal soft tissues. Because of the risk of rectal laceration, it is our practice not to routinely inflate the retention balloon. When the balloon is required in patients who have poor anal sphincter tone, it should be inflated under careful fluoroscopic control after barium has been instilled into the rectum.

Despite occasional complications, the barium enema examination is a safe, simple, and relatively inexpensive procedure. It provides reliable information about the nature and extent of mucosal disease and about disease within and outside the bowel wall. Most patients undergo barium enemas to rule out colonic neoplasm or IBD, and a double-contrast study is the best radiological technique for evaluating these individuals. In other patients with suspected diverticulitis or colonic obstruction, a single-contrast barium enema may be performed. Whether a single- or double-contrast technique

is used, the barium enema examination has few contraindications, and the complications can be minimized by careful attention to the clinical history and examination technique. In complicated or difficult cases, correlation of the radiological and endoscopic findings may be necessary to clarify the nature and extent of colonic disease.

Basic principles of diagnostic ultrasound

Sonography is complex and technically challenging. It requires knowledge of physics, instrumentation, ultrasound anatomy, pathology, and, most important, scanning technique. Small handheld scanners make the concept of sonography as an extension of the physical examination a real possibility. But those wishing to use sonography must learn the technique adequately, otherwise erroneous and misleading results are inevitable. At least 4 months of full-time intensive training is needed for those wishing to perform even the simplest sonographic evaluation.

Ultrasound refers to the frequencies of sound above the audible range – more than 20 000 cycles per second (i.e., > 20 000 hertz [Hz]). Diagnostic sonography uses sound frequencies far higher than this, in the 1–20 million Hz range (i.e., 1–20 megahertz [MHz]). Diagnostic ultrasound systems transmit sound pulses into the body. The echoes reflected from tissue are then processed to produce ultrasound images. The heart of a modern transducer is a complex array of specially manufactured piezoelectric elements that convert electrical energy into sound waves when transmitting and then convert the faint returning sound into electrical signals that can be processed into images.

In sonograms, the depth of any tissue is determined by timing how long it takes an echo to return, then calculating depth (distance from the transducer) based on an assumed average velocity of sound in human tissue. This is the pulse–echo principle. The earliest returning echoes arise from tissue reflectors closer to the transducer; later echoes come from progressively deeper reflectors. The exact anatomical location of each reflector may be calculated from the known direction of the sound beam in the body and the measured time of arrival of its echo. Repeated pulses are used to generate a two-dimensional image of the region interrogated.

Acoustic interfaces reflect sound and generate the echoes that make up the returning ultrasound information. Acoustic interfaces occur where two tissues of different acoustic impedance are in contact. Acoustic impedance is related to tissue density and the speed of sound in the tissues. The greater the acoustic impedance difference between the two tissues at an interface, the greater the percentage of incident sound reflected and the stronger the returning echo. This explains why ultrasound cannot "see through" gas or bone. The soft tissue–bone and soft tissue–gas interfaces have huge acoustic impedance differences, causing nearly all sound to be reflected. Clearly, if nearly all the sound beam is reflected, tissues deep to the bone or gas will not be imaged.

The amplitude (loudness) of echoes reflected from any given tissue is represented by different shades of gray. Most ultrasound images use a black background display. With this display convention, whiter shades of gray represent higher amplitude echoes. Descriptively, echo-free structures are said to be anechoic. Isoechoic means identical in echogenicity to another tissue. Hypoechoic means lower in echogenicity than another tissue, whereas hyperechoic (or echogenic) means higher in echogenicity than another tissue.

The ultrasound beam is progressively attenuated (weakened) as it travels deeper into the body. Soft tissues are more attenuative than fluid-filled structures. Cystic structures cause little attenuation of sound so tissues deep to the gallbladder or liver cysts appear more echogenic (brighter echoes) than do neighboring areas at a similar depth. This is called *distal acoustic enhancement* or *through transmission* of sound.

There is a tradeoff between the use of high-frequency and low-frequency transducers in ultrasound imaging. Low-frequency sound penetrates tissue effectively, facilitating good images of deep tissues (e.g., large livers). Higher-frequency transducers produce higher-resolution images, but cannot penetrate sufficiently well to produce images deeper than relatively superficial structures. As a practical matter, abdominal

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

organ sonography is done with lower-frequency transducers (3–7 MHz). When the bowel itself (e.g., appendiceal ultrasound) is evaluated, higher-frequency transducers (5–10 MHz) are generally used. It is generally best to choose the highest-frequency transducer that allows adequate penetration.

Artifacts are a significant problem in ultrasound imaging. They may be related to equipment problems, but unavoidable artifacts caused by the interaction of sound and tissues are the most troublesome. Speckle is the result of interference patterns caused by the sound beams sent into tissue. Reverberation of sound between tissue and the face of the transducer can obscure detail, most notably in the near field. Blockage of sound results in acoustic shadowing – a "void" in the image deep to the structure or tissue that causes the shadowing. Acoustic shadowing may be complete or partial. Reflection, refraction, or absorption of the sound beam may cause acoustic shadowing. Shadowing occurs deep to obstructing objects (such as gallstones, bone, or gas), or deep to curved interfaces at the margin of cysts. Shadowing is one of the diagnostic criteria for gallstones; it can be useful in distinguishing gas or calcification from other echogenic reflectors. The mirror image and multipath reflection artifacts can cause tissue to appear at an incorrect depth or location, simulating, for example, liver tissue above the diaphragm, or an apparent double inferior vena cava (IVC). Side lobe and partial thickness artifacts may lead to spurious hazy echoes that are most evident when superimposed on echo-free structures (e.g., the gallbladder). Comet-tail artifacts appear as highly echogenic "tails" deep to small intense reflectors such as small air bubbles, surgical clips, and small cholesterol crystals.

Tissue harmonic imaging is a technique that results in less image artifact. It uses the nonlinear sound produced by the ultrasound beam passing through tissue to produce images. This is distinct from conventional ultrasound, which produces images from echoes (reflected sound). Because of the decrease in artifact, tissue harmonics are becoming more popular as a way to obtain grayscale images.

Doppler sonography

Doppler sonography is a routine component of most modern sonographic examinations. It adds dynamic real-time flow information to the morphological information provided by grayscale imaging. Flowing blood is detected by its Doppler frequency shift. Stationary soft tissue lacks a Doppler frequency shift; echoes without a Doppler shift are ignored in the production of flow images.

Color Doppler sonography passively and automatically displays color-coded flow information superimposed on all or a selected portion of the grayscale image, all in real time. It detects flow, and displays both flow direction and frequency shift (a rough estimate of flow velocity). Flow direction is usually displayed as red or blue; velocity estimates are depicted as different hues or a change in color saturation. Color Doppler sonography is invaluable when flow detection or global anatomical information about blood flow is needed. The ability of color Doppler sonography passively to display flow in real time minimizes the chance of missing flow in an unexpected area, and facilitates comparisons of flow in different anatomical locations. Color Doppler sonography has the advantage of displaying both flow and anatomical information in a real-time image, which is much easier to understand than a combined grayscale/spectral "duplex Doppler" display.

Spectral Doppler acquires detailed flow information from a small area (the sample volume or range gate). Spectral Doppler is often erroneously called *duplex Doppler*. In fact, both color and spectral Doppler are "duplex" – both display flow and morphological information simultaneously. Spectral Doppler is useful when detailed quantitative information about flow velocity or pulsatility is important (e.g., liver transplants). The information is displayed graphically as a "time–velocity waveform," scrolled out across the screen. Spectral Doppler information can also be processed into an audible signal that is useful to experienced examiners. For example, arteries can be distinguished from veins audibly, and the higher pitched sound of stenosis can be useful in detecting arterial narrowing. In many situations, color Doppler sonography is first used to survey a vessel to facilitate fast and accurate spectral Doppler sample volume placement.

Ultrasound contrast agents

No ultrasound contrast agent (USCA) has so far received the approval of the US Food and Drug Administration (FDA) for radiological imaging. Limited approval has been granted for cardiac sonography. However, significant contrast research, as well as daily clinical use, is occurring worldwide. Use of these agents improves the diagnostic power of ultrasound imaging and may expand ultrasound's role into diagnosis of conditions where computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine are dominant. Most USCAs are intravenously injected microbubbles smaller than a red blood cell and thus capable of passing through capillary beds.

Microbubble ultrasound contrast agents enhance the useful ultrasound signal detected by the ultrasound transducer. The increased signal is depicted as an increase in echogenicity [1] or increase in signal strength. Ultrasound contrast agents thus affect grayscale imaging as well as color or spectral Doppler imaging.

Vascular enhancement with USCAs may improve examination quality by improving flow visualization and analysis. Stenosis and thrombus determinations are made with more confidence [2]. Smaller, deeper vessels and greater lengths of vessels may be visible, and the Doppler signal from vessels is increased.

Although some USCAs do not enter the tissues, all traverse both large vessels and small capillaries. Thus, on grayscale imaging, they can appear to enhance an entire organ rather

than merely its large arteries and veins. Grayscale enhancement is a new method of ultrasound imaging, which may dramatically change sonographic tumor evaluation and diagnosis [3]. Grayscale enhancement with harmonic imaging dramatically increases the conspicuity of the ultrasound signal from microbubbles. Harmonic imaging takes advantage of the microbubbles' property of resonance during insonation [4]. Benefits of harmonic imaging and other techniques include a significantly increased signal-to-noise ratio of the image [4].

Strengths and weaknesses compared with other modalities

When sonography can image the area of clinical interest, it is a near ideal modality. The ability of diagnostic sonography to display flow and soft tissue in real time is unique among imaging techniques. Its spatial resolution is superior to CT and MRI. It is safe and tolerated well by patients. When needed, ultrasound can be performed quickly and at the bedside. Unfortunately, there are circumstances in which optimal, or even adequate images cannot be obtained. The single most important problem is sonography's inability to see beyond gas–soft tissue or bone–soft tissue interfaces. This makes comprehensive survey scanning essentially impossible. Computed tomography especially, and MRI are better survey modalities. Thus, some abnormalities displayed automatically on whole-body CT or MRI are either impossible or difficult to see sonographically. Lastly, sonography is technically challenging – scanning to obtain optimal images is more of an art than a science. Producing acceptable diagnostic images sonographically is usually harder than obtaining acceptable CT or MRI images. Sonography, however, is often superior to CT and MRI in patients who are uncooperative, unable to hold their breath, or unable to remain relatively still during examination. Sonography is often superior in patients with little body fat. This makes sonography useful in pediatric imaging, for example. Patient factors that impede optimal sonography include extreme obesity and limited cutaneous access, such as burns, incisions, dressings that cannot be removed, and cutaneous gastrointestinal (GI) enterostomies.

Liver

Indications for sonography

Primary indications include suspected or known cirrhosis, suspected liver abscess, suspected liver tumor, suspected fatty liver, suspected vascular abnormalities, trauma, and transplantation. Sonography can also be used to characterize abnormalities found on other imaging examinations. Its safety and relatively modest cost make it an ideal means to assess the therapeutic response of known lesions, or sequentially to follow liver lesions of unknown significance. Sonography is often a simple and effective way to guide percutaneous aspiration, drainage, biopsy, or tumor ablation.

Patient preparation and technique

Hepatic sonography can be performed without special preparation. As the other upper abdominal organs are often evaluated with the liver, an overnight fast or 8–12 h of a clear liquid diet is recommended to decrease bowel gas and distend the gallbladder. In some patients, it may be difficult to image the entire liver. Potentially difficult areas include the superficial liver above the costal margin, the left tip of the lateral segment of the left lobe, and the ventral subdiaphragmatic regions [5].

The liver is best imaged with the patient in the supine and left lateral decubitus positions, starting with 3–8-MHz curved linear array transducers. A subcostal acoustic window should be used first, supplemented with intercostal scans. Small sector transducers should be used to image areas inaccessible with the larger curved linear transducers. The liver surface (usually the ventral left lobe in the subxyphoid region) should be evaluated for nodularity with a near field-optimized 7–15-MHz linear array transducer. It is easier to appreciate nodularity during real-time examination than on hard copy images. Routine color Doppler imaging is useful in patients with suspected liver pathology. Optimal color Doppler and spectral Doppler sonography of the liver generally require relatively low frequency (2–3-MHz) scanning and good acoustic access.

Normal anatomy

The liver parenchyma is of uniform medium echogenicity, interspersed with vessels and fissures. The liver parenchyma is slightly less echogenic than the spleen, equal to or slightly more echogenic than the renal cortex, and isoechoic or somewhat less echogenic than the pancreas.

The liver has three lobes – the large right lobe, the left lobe, and the small caudate lobe. Sonographic landmarks can be used to segregate the liver into lobes and segments (Figs 129.1 and 129.2). Fissures and ligaments can be identified because they are echogenic, fat-containing structures. Portal veins, with their accompanying bile ducts and hepatic arteries, make up the portal triad. These triads are encased in echogenic fibrofatty tissue. This associated echogenic tissue is, as a practical matter, the feature that allows differentiation from hepatic veins (HVs). Portal veins, HVs, hepatic arteries, and bile ducts can also be identified with Doppler imaging. Within the porta hepatis, the left and right bile ducts lie anterior to the portal veins. More peripherally this relationship is not constant. A transverse oblique sonogram through the porta hepatis is one of the simplest methods for determining the presence of intrahepatic biliary dilation and obstruction.

Diffuse disease

Diffuse liver disease does not always cause distortion of liver anatomy or architecture. This can make sonographic detection difficult. Liver surface nodularity or atrophy of the right lobe, when present, can be useful signs of cirrhosis.

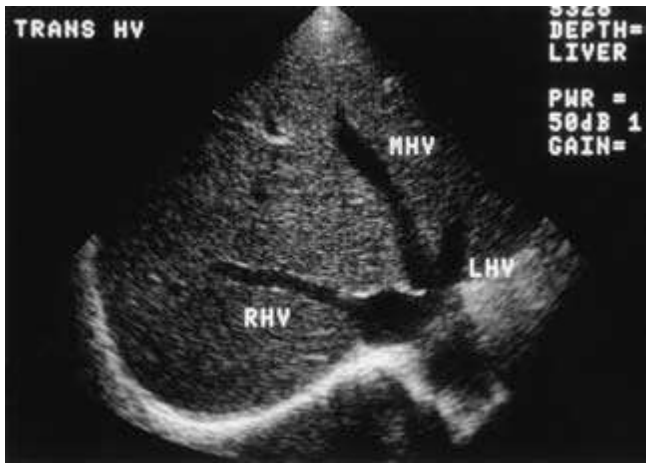

Figure 129.1 Normal hepatic veins. Transverse ultrasound of the upper portion of the liver shows the right hepatic vein (RHV), middle hepatic vein (MHV), and left hepatic vein (LHV) entering the inferior vena cava. Note the relative paucity of echogenic material around the hepatic veins, a characteristic that distinguishes them from portal veins, which have peripheral echogenic fibrofatty tissue. The middle hepatic vein separates the right and left lobes. The right hepatic vein and left hepatic vein separate the segments of the left and right lobes.

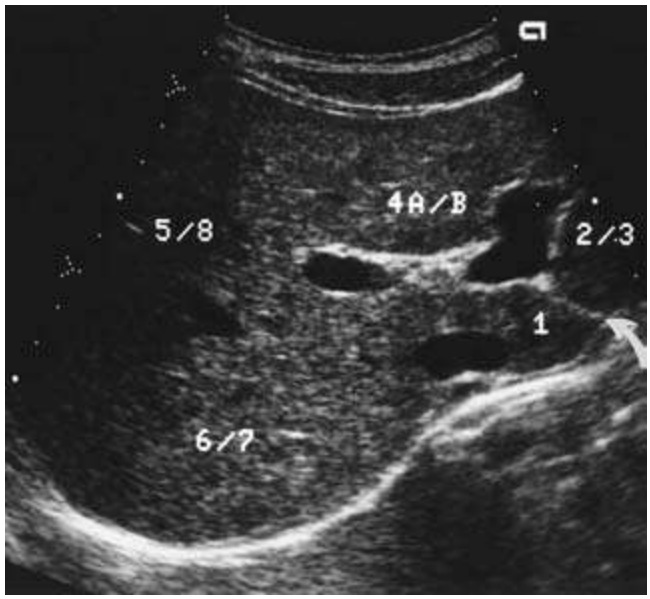

Figure 129.2 Couinaud segments. Transverse sonogram through the left and right portal veins, the axis through which the liver is divided into Couinaud segments. Segment 1 is the caudate lobe, bordered ventrally by the fissure for the ligament of venosum (curved arrow) interposed between the caudate lobe and the lateral segment of the left lobe (Couinaud segments 2 and 3). The medial segment of the left lobe is composed of Couinaud segments 4A (cephalically) and 4B (caudally). The anterior segment of the right lobe is composed of segments 5 and 8, and the posterior segment of the right lobe of segments 6 and 7. Couinaud segmental anatomy is important in planning hepatic surgery.

Parenchymal echogenicity may be increased in diffuse disease but is difficult to evaluate, as no absolute echo amplitude standard exists (analogous to CT attenuation numbers). Liver echogenicity is judged by comparison with adjacent organs, usually the kidney.

Hepatomegaly

Hepatomegaly can be difficult to diagnose objectively with sonography. The normal span of the adult liver is 15–17 cm. Single measurements are imperfect, but the sagittal dimension from the dome to the tip of the right lobe, measured at the midclavicular line, is the most frequently used. If this exceeds 15.5 cm, the liver is usually enlarged [6]. Hepatomegaly can be diagnosed qualitatively when the liver extends caudal to the right kidney and the left lobe is of normal size or larger. Better, volumetric measurements using 3D techniques may be feasible in the future.

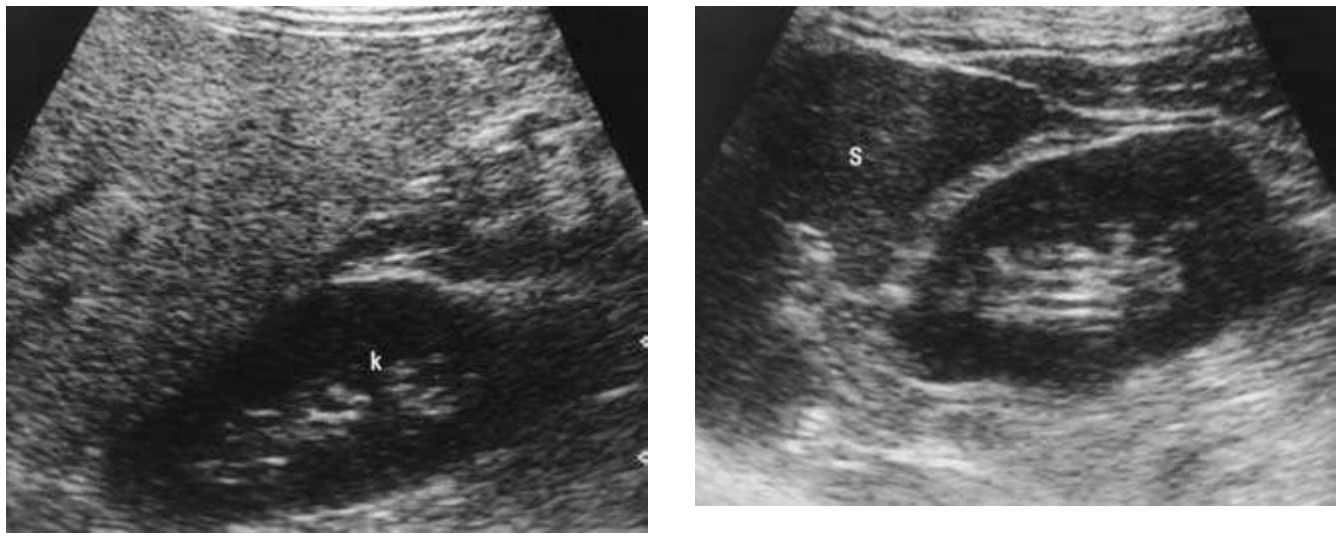
Hepatitis

Because many different diseases cause hepatic inflammation, sonographic findings are variable. The liver is generally normal in acute viral hepatitis. Although the "starry sky" pattern (increased periportal echoes with decreased parenchymal echogenicity) has been described in older studies [7,8], only 19 of 791 patients in a large series had this pattern [9]. In the same study, there was no difference in ultrasound findings between a normal control group and patients with acute viral hepatitis. Striking irregular gallbladder wall thickening is sometimes present in patients with acute hepatitis, especially hepatitis A [10]. Direct inflammation and edema cause wall thickening, sometimes reaching 20 mm (normal < 3 mm).

Hepatomegaly and inhomogeneous patchy or diffuse increased echogenicity are common in chronic hepatitis and are related to the amount of fatty infiltration and fibrosis present. The liver surface is smooth, unless cirrhosis is present. Enlarged arteries are noted on color Doppler sonography when there is increased arterial flow. This may cause a "double channel" sign on grayscale images that can potentially be confused with biliary dilation. Enlarged lymph nodes may be seen in the hepatoduodenal ligament [11]. Ultrasound findings in alcoholic hepatitis depend on the amount of fibrosis or fat present. Patchy, irregular increased parenchymal echogenicity is often present. The liver is often enlarged but the surface is usually smooth, in contrast to the nodularity sometimes detected in cirrhosis. Similar to chronic hepatitis, the arteries may be enlarged.

Fatty liver disease

The hallmark of fatty infiltration of the liver is increased echogenicity, usually diffuse. Severe fatty infiltration often results in an enlarged, echogenic liver (Fig. 129.3) with decreased acoustic penetration that may result in indistinct vessels or diaphragm. The liver surface is smooth. Fatty infiltration is often patchy and sometimes focal. Focal fat appears



(a) (b)

Figure 129.3 Fatty infiltration of the liver. Longitudinal sonogram **(a)** of the liver shows that the liver is much more echogenic than the right kidney (k). The echogenicity of the splenic parenchyma (S) and left renal cortex sonogram **(b)** are nearly equivalent. This internal comparison of the liver and spleen with adjacent kidneys allows a more reliable determination of the increased liver echogenicity associated with fatty infiltration.

as an area of increased echogenicity. A less affected region ("spared" area) may appear as a conspicuous hypoechoic area. Both focal fat and spared areas have a tendency to be pyramidal, with flame-shaped tapered margins. Frequent locations include the region of the porta hepatis, near the falciform ligament, the dorsal left lobe, and the caudate lobe. Although both focal fatty infiltration and focal sparing can simulate neoplasm [12–14], an appreciation of the usual appearance and location generally suffices to avoid confusion. Rarely, noncontrast CT scanning, MRI, or even biopsy may be required to clarify the diagnosis. Geographic fatty infiltration typically has well-defined margins between areas of greater and lesser involvement. No image features are known that can distinguish nonalcoholic steatohepatitis from other conditions in which there is fatty infiltration of the liver.

Cirrhosis

Sonographic findings of cirrhosis include changes in the shape of the liver, parenchymal inhomogeneity, and nodularity of the liver, notably at the surface. Intrahepatic vessels may be indistinct. Unfortunately, these signs are both insensitive and insufficiently specific to diagnose cirrhosis reliably. The caudate and left lobes tend to be relatively less affected by cirrhotic scarring than the right lobe. This sometimes results in a small right lobe with left and caudate lobe hypertrophy, especially in hepatitis B. Ratios comparing the size or volume of the caudate to the shrunken right lobe have been used to diagnose cirrhosis [15,16]. These ratios are not always useful; a large series revealed a sensitivity of 43% and an accuracy of 79% for the caudate-to-right lobe ratio [17].

Evaluation of the smoothness or nodularity of the liver surface using a high-resolution linear array transducer is useful [18–20]. Surface nodularity may be the only sonographic sign of cirrhosis. Some studies have not confirmed the usefulness of evaluating surface nodularity [20]. We believe that the specificity for macronodular cirrhosis is good, although micronodular cirrhosis is often missed. The only other common cause of surface nodularity is multiple subcapsular tumor nodules, usually from metastasis. Occasional causes are carcinomatosis with liver surface implants and acute massive liver necrosis.

Color Doppler sonography may detect portal vein flow reversal or portal collaterals, prompting the diagnosis of portal hypertension. These may be the only findings indicating severe liver disease in an otherwise normal study. Enlarged tortuous arteries are sometimes imaged by color Doppler sonography in cirrhotic livers. This finding, similar to "corkscrew" arteries seen angiographically, occurs because of increased arterial flow that occurs when portal venous flow decreases [21] and tortuosity of arteries from liver atrophy related to cirrhosis. Focal fatty infiltration, hepatocellular carcinoma (HCC), regenerating nodules (adenomatous hyperplastic nodule), or other focal lesions may occur in a cirrhotic liver. A liver mass in a cirrhotic patient strongly suggests the possibility of HCC.

Hepatic vascular disease

Portal hypertension

Sonographic evaluation of portal hypertension includes evaluation of the portal venous system and a search for portosystemic collaterals. The normal main portal vein measures slightly more than 1 cm in diameter. Although absolute portal vein size is not useful, lack of respiratory variation in size can be helpful in diagnosing portal hypertension [22].

Normally, blood flows toward the liver (hepatopetal) in portal veins. Reversed (hepatofugal) flow, although often associated with collaterals [21], may be the sole indication of portal hypertension. Other portal flow abnormalities include bidirectional flow and, rarely, nearly static blood flow. Ultrasound contrast agents can be useful in aiding the detection of flow in the main portal vein and other hepatic vessels. Detection of portal collaterals may prompt diagnosis of unsuspected portal hypertension, or reinforce it when suspected. Portal collaterals should be sought with color Doppler sonography, as they are often invisible on grayscale images.

The most common collaterals are left gastric (coronary) and paraumbilical veins. Left gastric collaterals, although the most common, are often difficult to image because of their deep location. Paraumbilical veins are easier to image, as they are superficial. They arise from the ventral tip of the left portal vein and flow caudally through the ligamentum teres, where they communicate with superficial peritoneal collaterals. Other types of portal collaterals occur, including retroperitoneal, splenorenal, splenoretroperitoneal, short gastric, and omental.

Therapeutic portosystemic shunts

Therapeutic surgical shunts may be seen with color Doppler, even when not apparent on grayscale images [23]. Shunt thrombosis can be reliably diagnosed only when no color flow is seen in the shunt. Secondary signs of shunt thrombosis, such as hepatopetal intrahepatic portal flow, may be misleading [24].

Candidates for transjugular intrahepatic portosystemic shunt (TIPS) stents can be evaluated by spectral and color Doppler before, after, and sometimes during the procedure. Doppler is imperfectly accurate in diagnosing shunt dysfunction, but is a useful screening tool to select patients for repeat venography and potential maintenance. We feel that the most useful of the many parameters [25,26] employed to evaluate stent function are intrastent velocity, flow direction in the native portal veins, and overall clinical judgment of the radiologist performing the study. Mid and distal stent velocity should be between 90 and 200 cm/s, and blood flow in the native portal veins should be toward the stent.

Venous thrombosis

Sonographically, intralumenal echoes are suggestive of clot, but not diagnostic. When hypoechoic or anechoic, clot may be virtually invisible without color Doppler. Anechoic thrombus is rare in neoplastic invasion but is fairly common with bland clot. Color Doppler sonography highlights clot by displaying flow around the clot and in adjacent patent vessels [21]. Common causes of portal venous thrombosis include neoplastic invasion, septic portal thrombosis (pylephlebitis), and pancreatitis. We concur with other investigators [21,27,28] that thrombosis in portal hypertensive patients is considerably more common than the 1% previously reported [29]. Color Doppler sonography is unrivaled in diagnosing partially occluded vessels. Small residual flow channels are automatically displayed in color. Clot resolution or progression can be documented on serial examinations. Contrast agents may be useful in difficult cases.

Cavernous transformation of the portal vein, resulting from main portal vein clot, consists of prominent hepatopetal portal collaterals. In acute portal vein thrombosis, color Doppler sonography may reveal small, acute hepatopetal portal collaterals, invisible on grayscale sonography. This may be a precursor to cavernous transformation of the portal vein.

Budd–Chiari syndrome

Sonography, especially with color Doppler imaging, is the preferred screening technique for evaluating patients with suspected Budd–Chiari syndrome [30]. Grayscale findings include HV abnormalities: absence, stenosis, dilation, irregularity, and abnormal or absent junction with the IVC. The IVC may be narrowed or occluded. Less specific changes include caudate hypertrophy and atrophy/enlargement of the other lobes and segments, and parenchymal inhomogeneity. Absent or reversed hepatic venous flow and intrahepatic HV to HV "spider-web" collaterals are diagnostic of Budd–Chiari syndrome. A flat HV waveform, lacking the normal cardiac-related phasic fluctuation, indicates HV compression – a finding that, although nonspecific, supports the diagnosis of Budd–Chiari syndrome. Other collaterals seen in Budd–Chiari syndrome include HV to portal vein collaterals with portosystemic shunting (e.g., through enlarged paraumbilical veins, esophageal varices) and HV to systemic veins.

Other vascular diseases

Sonographic findings in hepatic venoocclusive disease are nonspecific changes related to fibrous obliteration of microscopic central hepatic lobular veins. These findings, not universally present, include thickened gallbladder wall, abnormal or reversed portal venous flow [31], and increased hepatic artery peripheral resistance [32]. Hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu), characterized by telangiectases, arteriovenous (AV) fistulae, and aneurysms, involves the liver in about one-third of patients. Grayscale findings include enlarged hepatic arteries, and increased echogenicity from fatty infiltration or cirrhosis [33,34]. Color Doppler sonography reveals enlarged, tortuous, arteries with high-velocity flow, and also clarifies the potentially confusing grayscale appearance that may mimic biliary dilation. Visualization of hepatic AV fistulae is variable, and probably depends on their size.

Color Doppler sonography can be used to diagnose and follow hepatic pseudoaneurysms and AV fistulae, to assess the results and adequacy of vascular interventional procedures without recourse to angiography, and to demonstrate portal and HV malformations. Thrombosis or occlusion of the hepatic artery is the most common cause of hepatic

infarction [35]. Sonographically, infarcts are usually peripherally located hypoechoic wedge-shaped lesions. Others are round and centrally located. In the acute phase, the infarcts are ill-defined hypoechoic lesions that evolve into more anechoic or cystic areas [36]. After hepatic infarction, cystic collections of bile (bile lakes) may develop.

Focal liver disease

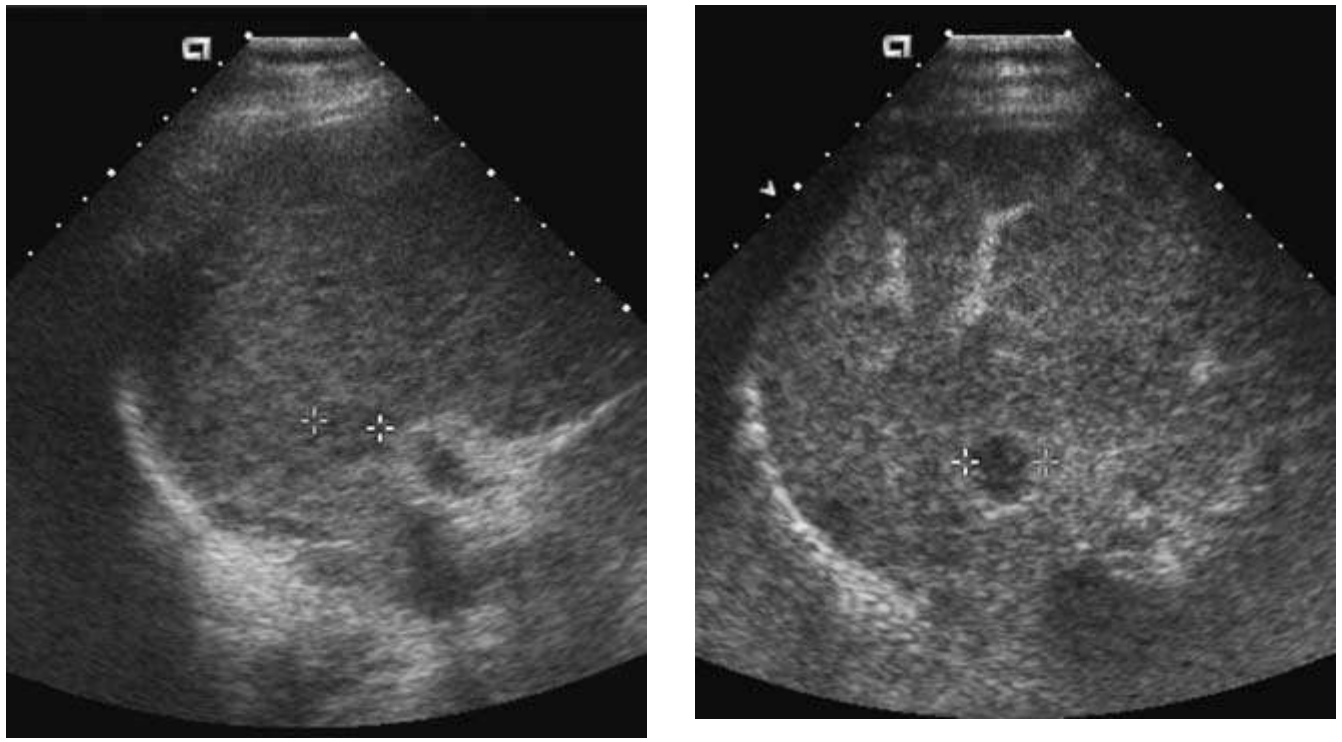
All standard noninvasive imaging modalities are imperfect detectors of focal hepatic disease, despite the improvement in detection rates achieved with multidetector CT, fast-scan contrast-enhanced MRI, and PET imaging [37–39]. Focal hepatic lesions are still missed with one modality, and then detected with another. Although sonography is less sensitive in detecting metastatic lesions than CT and MRI [40–43], modern sonography can perform well in detecting focal liver disease, outperforming CT, MRI, and PET in HCC detection in liver transplant candidates [43]. Arterial and portal venous phase imaging with ultrasound contrast agents can increase both the detection and characterization of lesions in patients with cirrhosis or liver metastasis [2]. Ultrasound contrast enhancement may prove useful in differentiating benign from malignant tumors [3,44] (Fig. 129.4).

Sonography's main strengths are its abilities to guide biopsy and characterize common benign lesions (cysts, hemangiomas), its safety, and its low cost. Its weaknesses include its inability to image the entire liver in some patients and its inferiority to CT in detecting extrahepatic disease. Ultrasound-guided biopsy is efficient and cost-effective, even when lesions are initially detected with some other modality. Sonography may be used to evaluate resectability of primary or metastatic liver tumors. Color Doppler sonography improves detection of focal lesions, especially anechoic or hypoechoic lesions. Some tumors are more conspicuous because of increased flow compared to normal liver: these include focal nodular hyperplasia (FNH), most HCCs, some metastases, and occasionally other masses [45–47]. Color and spectral Doppler can be used to help discriminate between benign and various types of malignant liver tumors [46,48–51].

Simple cysts

The prevalence of simple cysts increases with age [52]. When a cyst is found in a young patient, other diseases should be considered, including: autosomal dominant polycystic disease, von Hippel–Lindau disease, and conditions simulating simple cysts (e.g., echinococcal disease, residua from trauma or infection, and cystic neoplasia). Sonography is usually superior to CT or MRI for evaluating cysts.

Simple cysts are usually well-defined, echo-free round or oval lesions with imperceptible walls and good



(a) (b)

Figure 129.4 Transverse ultrasound images through the medial segment of the left lobe in a patient with prior right hepatectomy for metastatic disease from adenocarcinoma of unknown primary tumor. **(a)** Precontrast grayscale image shows a mass that is difficult to see (cursors). **(b)** Postcontrast grayscale image shows a small hypoechoic metastasis (cursors). Note that the surrounding liver is hyperechoic, consistent with increased vascularity with respect to the metastasis.

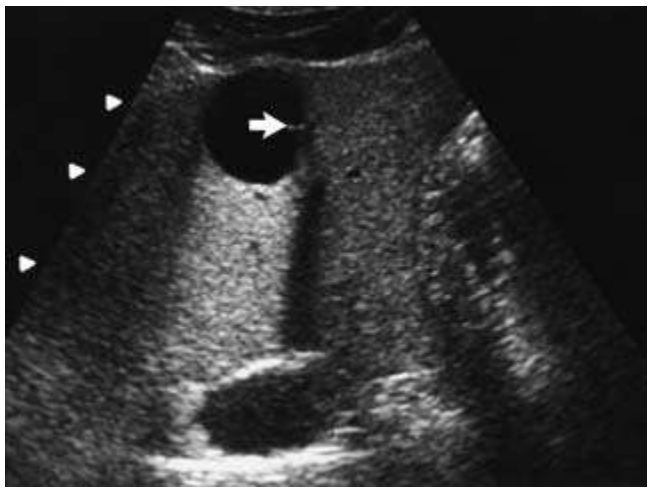


Figure 129.5 Simple liver cyst. This 2.5-cm cyst is anechoic, has imperceptible walls, and has prominent through-transmission (whiter area, deep to the cyst). There is a thin septation within the cyst (arrow). Thin (but not thick) septations are perfectly compatible with diagnosis of a classic simple cyst.

through-transmission (Fig. 129.5). Thin septations are frequent, and should not suggest a different diagnosis. Thicker septations are generally a sign of a complicated cyst or of a cystic neoplasm.

Hepatic polycystic disease

Sonographic findings include multiple, often contiguous simple cysts. Irregular shape and septae are common. Hemorrhage or infection may cause debris-like echoes within one or more cysts [53]. About one-half of patients have renal cysts. von Meyenburg complex [54] is a rare disorder characterized by multiple small cystic hamartomas of the bile ducts, which may be detected with CT, MRI, or sonography.

Other cystic lesions

Acquired cysts may occur as a result of trauma or infection [55–57]. Neoplasms that simulate simple cysts are unusual; metastases from squamous cell carcinoma, GI stromal tumors, and cystic adenocarcinomas occasionally do this. Hepatobiliary cystadenoma is a rare neoplasm probably arising from bile duct epithelium. These lesions are predominantly multicystic with varying amounts of solid tissue [58–60].

The liver is the most frequently involved organ in hydatid (echinococcal) disease. A spectrum of sonographic findings from purely cystic to solid-appearing pseudotumors occurs. Internally, wavy bands of delaminated endocyst (the "water lily" sign) may be noted [61]. Daughter cysts, sometimes surrounded by echogenic debris ("matrix"), are frequent. Calcifications, varying from tiny to massive, are often present. A densely calcified cyst usually indicates a dead, inactive lesion. Previously considered contraindicated, percutaneous drainage and treatment are gaining wider acceptance [62].

Figure 129.6 Pyogenic liver abscess. This transverse sonogram of the right lobe of the liver shows a mixed-echogenicity, predominantly hypoechoic liver abscess at the hepatic dome. The lesion is not well defined medially, a feature of pyogenic liver abscess on ultrasonography.

Pyogenic liver abscess

When liver abscess is suspected clinically, sonography is the preferred screening modality. Sonographically, pyogenic liver abscesses are variable in appearance (Fig. 129.6). Typically, features include a mixed echogenicity, primarily hypoechoic mass with irregular margins. Irregular areas of increased echogenicity are frequent. On occasion, a diffusely hyperechoic appearance may be noted, owing to microbubbles from gas-forming organisms. Diffuse microabscesses, often associated with biliary obstruction, may cause a confusing sonographic pattern of increased irregular hepatic echogenicity. Clusters of small low-echogenicity lesions may also be noted [63]. Septic portal venous thrombosis (pylephlebitis), which may be imaged sonographically, may lead to liver abscess [64].

Amebic liver abscess

Amebic liver abscesses tend to have a round or oval shape and hypoechoic appearance with fine, homogeneous, low-level echoes throughout. Image findings alone, however, are insufficient to distinguish amebic from pyogenic liver abscesses [65]. Amebic liver abscess can have sonographic patterns that are bizarre, including diffuse increased echogenicity, debris levels, and prominent heterogeneity. When it is unclear clinically if an abscess is amebic or pyogenic, percutaneous aspiration should be performed (necessary in 15% of patients in our institution). In contrast to pyogenic liver abscesses, percutaneous drainage of amebic liver abscess is rarely indicated [66]. Therapeutic aspiration provides no

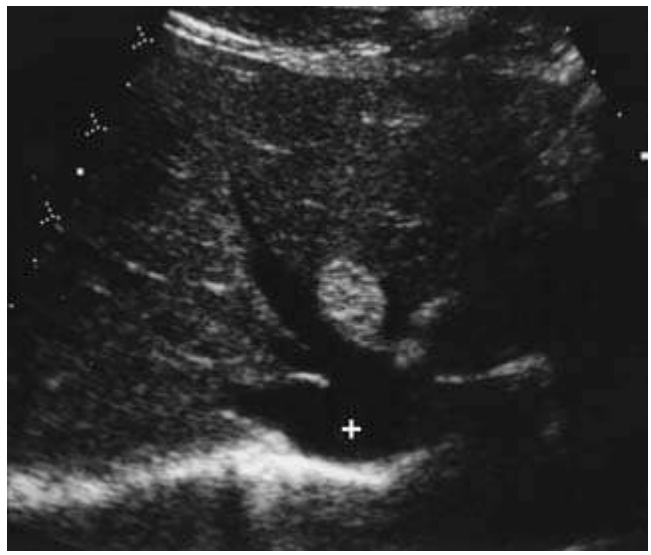

Figure 129.7 Small hepatic hemangioma. This transverse sonogram at the level where the hepatic veins enter the inferior vena cava (+) reveals a well-defined, white, echogenic focus that is virtually diagnostic for hepatic hemangioma.

objective benefit when compared with the use of oral amebicidals alone [67].

Candidiasis

Candidiasis, occurring in leukemic and other immunocompromised patients, causes multifocal hypoechoic lesions typically smaller than 2 cm. Four distinct sonographic patterns of hepatic microabscesses from candidiasis have been described by Pastakia and colleagues [68]. These include discrete hypoechoic nodule, a "bull's eye" configuration, a discrete echogenic focus with variable degrees of acoustic enhancement, and a "wheel within a wheel" appearance. Internal echogenic foci produce the target or "wheel within a wheel" appearance [69,70]; echogenic lesions and lesions larger than 2 cm are much less common.

Benign neoplasms

Cavernous hemangioma

Cavernous hemangioma, the commonest benign hepatic neoplasm (prevalence 1%–4%), rarely causes clinical symptoms. Classic hemangiomas are well-defined, echogenic lesions sometimes exhibiting enhanced through-transmission (Fig. 129.7) [71]. Another typical appearance is of variable internal echogenicity surrounded by a complete echogenic margin [72] (Fig. 129.8). Larger hemangiomas frequently diverge from these classic patterns. Mixed-echogenicity lesions and even hypoechoic hemangiomas may occur. Hemangiomas rarely change on serial exams [73].

Classic hemangiomas in low-risk patients (patients without malignancy or chronic liver disease) do not need further evaluation with imaging [74]. In patients with malignancy or cirrhosis, hemangiomas must often be evaluated further to exclude more significant lesions. Preliminary results suggest that addition of ultrasound contrast agents may be sufficient confidently to diagnose incidentally detected hemangiomas at US (Fig. 129.9). Computed tomography and MRI may fail to identify small (< 1 cm) hemangiomas detected with ultrasound. If needed, thin-needle biopsy is a reasonable and safe way to evaluate hemangiomas [75,76], provided skilled cytological consultation is available.

Focal nodular hyperplasia/liver cell adenoma

Focal nodular hyperplasia (FNH) is a clinically insignificant lesion, whereas liver cell adenoma (LCA) can cause morbidity and mortality because of hemorrhage and, occasionally

(a) (b) (c)

Figure 129.8 Atypical hemangioma (stable for 11 years): transverse grayscale ultrasound image through the right lobe. **(a)** Precontrast shows large ill-defined heterogeneous mass (cursors). **(b)** Postcontrast, normal liver (black arrow) and the medial wall of the hemangioma (white arrow) enhanced. **(c)** At 90 s postcontrast administration, a larger volume of tissue with delayed enhancement is seen (arrows).

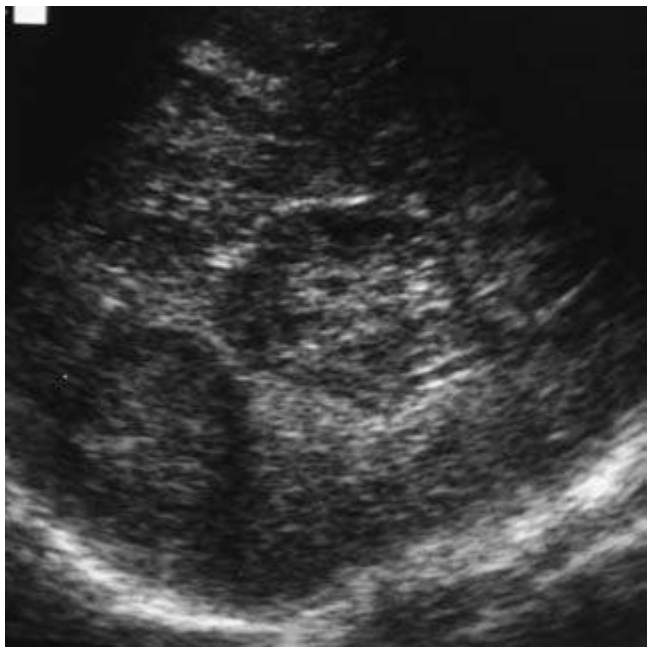

Figure 129.9 Multifocular hepatocellular cancer. A transverse sonogram shows multiple tumor nodules in the right lobe of the liver. Some of these are hypoechoic whereas others have echogenic centers with hypoechoic rims.

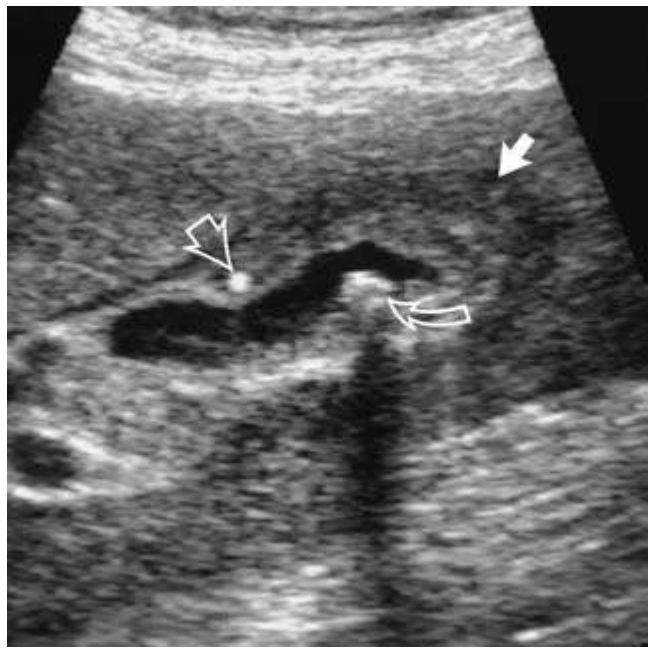

Figure 129.10 Gallstones in a patient with adenomyomatosis. Note the intralumenal gallstone (curved open arrow). There is an intramural gallstone (straight open arrow) within a diffusely thickened gallbladder wall (arrows) as a result of adenomyomatosis.

malignant degeneration. The sonographic features of FNH and LCA are variable. There is a tendency for FNH to be more homogeneous than LCA. Focal nodular hyperplasia often has mildly increased echogenicity compared with normal parenchyma, whereas LCAs are usually hypoechoic and more inhomogeneous [77–81]. On color Doppler imaging, FNH usually has markedly increased flow, sometimes with vessels radiating peripherally from a central feeding artery.

Malignant neoplasms

Hepatocellular carcinoma

Advanced HCC is almost always multifocal, making it difficult to distinguish from metastatic disease (Fig. 129.10). Small HCCs (< 5 cm) are often (75%) hypoechoic [82]. As HCCs grow, they tend to develop hypoechoic peripheral rims [83]. With further progression, lesions become more numerous and heterogeneous. Fatty tissue within the lesion may cause increased echogenicity and confusion with hemangioma [84]. Portal vein or hepatic vein invasion should suggest the diagnosis of HCC, although other liver tumors also invade veins [85]. Rarely, HCC invades the bile duct. About three-fourths of HCCs have identifiable internal color flow compared with only one-third of metastases. With ultrasound contrast agents, most HCCs reveal abnormal tortuous tumor vessels on the periphery, a pattern distinct from benign tumors. Fibrolamellar HCC, which accounts for 2% of HCCs, but 25%–50% of HCCs in young adults, is typically a single well-circumscribed lesion in an otherwise normal liver. Other features include a "central scar" and calcification, both of which also occur in other subtypes of HCC and lesions of other histology [81].

Hepatic metastasis

Metastatic disease, the most common liver malignancy in North America, is multifocal in 90% of patients. Virtually any sonographic appearance may occur. Metastatic lesions, whether diffuse or focal, are usually heterogeneous. Hypoechoic halos, target, or bull's-eye patterns, with rings of varying echogenicity, are common. Ill-defined infiltration with focal nodularity is another frequent pattern. Metastases that simulate simple cysts or "classic" hemangiomas are rare. Predominantly fluid-filled, presumably necrotic metastases occur most frequently with squamous cell carcinoma, sarcomas, and ovarian and testicular carcinoma. Calcified lesions, especially mucinous adenocarcinoma, may occur. Although sonographic appearance is a poor predictor of the primary tumor, certain patterns are suggestive. Large to moderate-sized hyperechoic metastases should suggest the possibility of a colonic primary. Lesions with fluid-fluid levels (representing intralesional necrosis and hemorrhage) are often found with metastatic GI stromal tumor.

Distinguishing between metastasis and HCC occasionally requires biopsy. Invasion of the portal or HVs suggests HCC rather than metastasis. Although portal venous invasion in metastatic disease has been reported in as many as 8% of patients [86], our experience suggests a lower frequency.

Human immunodeficiency virus infection

In patients with human immunodeficiency virus (HIV) infection the liver is often involved by neoplasm – non-Hodgkin lymphoma, Kaposi sarcoma (KS) – or by opportunistic infection. Sonographic findings of uncertain cause, such as decreased periportal echogenicity or focal hyperechoic areas, are frequent.

High- and intermediate-grade HIV-related B-cell lymphomas cause focal liver lesions more frequently than other lymphomas. These are usually hypoechoic masses that may exhibit increased peripheral color flow. Kaposi sarcoma usually infiltrates the liver, causing little or no sonographic abnormality; it may cause focal masses and increased periportal echogenicity [87].

Multiple echogenic foci, often imaged more clearly sonographically than with CT, may give a "starry sky" pattern with disseminated *Pneumocystis carinii* infection [88]. This pattern also occurs with mycobacterial or cytomegalovirus infection [89]. On occasion, disseminated *Pneumocystis* infection results in larger calcifications or large hypoechoic lesions.

Other focal lesions

Hepatic lymphoma and leukemia are usually microscopic. Only about 5% cause sonographically detectable focal liver lesions [90]. The lesions are usually anechoic or hypoechoic, although other patterns occur [91]. Chloroma of the liver, associated with myelogenous leukemia, can be hypoechoic or echogenic. Lymphomas related to HIV cause more frequent and conspicuous focal lesions than other lymphomas.

Hepatic sarcomas are rare. Angiosarcomas and undifferentiated embryonal sarcomas are usually large, internally inhomogeneous masses [92]. Hepatic epithelioid hemangioendothelioma (EHE), a rare vascular sarcoma [93], starts as a multinodular tumor, coalescing as it grows. It is usually hypoechoic compared with normal liver. Hypertrophy of the uninvolved normal liver may occur.

Adenomatous hyperplastic nodules in cirrhotic livers (regenerating nodules) are premalignant lesions that, when visualized, are usually hypoechoic and may have a thin echogenic rim [94]. Intrahepatic extramedullary hematopoiesis may cause inhomogeneous, mainly hypoechoic masses [95]. Mesenchymal hamartoma of the liver is usually a large, mainly cystic mass with septae of variable thickness and solid internal tissue [96]. Intrahepatic hematomas may cause sonographically visible masses.

Trauma

Computed tomography is the mainstay for evaluating hemodynamically stable patients with suspected blunt hepatic trauma. Sonography can be used effectively to detect hemoperitoneum, but it has a rather limited role in the initial diagnostic evaluation of hepatic trauma. A high percentage of liver and other parenchymal injuries are missed sonographically [97]. Ultrasound contrast may improve the usefulness of ultrasound in trauma [98]. Sonography may be valuable in the follow-up of nonoperated patients [99] and in diagnosing posttraumatic complications including biloma, vascular pseudoaneurysms and arteriovenous (AV) fistulae, and abscesses.

Liver transplantation

Sonography, especially Doppler imaging, is important in evaluating liver transplant candidates and potential donors [100]. Sonography can be useful in defining portal hypertension-related collaterals, detecting portal vein clot, delineating spontaneous or surgical portosystemic shunts, and detecting HCC in the native liver.

After transplantation, sonography can screen for hepatic arterial occlusion [101]. Absent flow on color Doppler or decreased peripheral resistance, measured by resistive index (RI) [102], are signs of arterial compromise. The use of ultrasound contrast agents may improve the accuracy and speed of examination in transplant patients [103]. When abnormalities are noted, arteriographic evaluation and intervention are often indicated [104]. Hypoechoic infarcts or intrahepatic fluid collections may result when arterial occlusion occurs. Cholangiography is generally needed to detect bile duct injuries reliably, as sonography may miss 50% of bile duct complications [105]. Posttransplant fluid collections include abscess, biloma, seroma, lymphocele, and hematoma [106].

Overview of hepatic imaging

Hepatic sonography's main strengths are its ability to characterize common benign lesions (cysts, hemangiomas) and guide percutaneous procedures, plus its safety, excellent patient tolerance, and low cost. In the near future, the application of ultrasound contrast agents to the liver may extend ultrasound's utility from a screening examination into a lesion detection and diagnosis modality. Its weaknesses include an inability to image the entire liver in some patients and inferiority to CT in detecting extrahepatic disease. When liver abscess is suspected clinically, sonography is the preferred screening modality [41]. Sonography's ability to image in any oblique plane often makes it superior to CT and MRI in localizing lesions to an anatomical hepatic segment when evaluating resectability of a liver tumor.

In experienced hands, sonographically guided liver biopsy is often quicker and easier than CT guidance. Sonography can directly visualize the needle tip as it is placed in the lesion, facilitating biopsy of small lesions and lesions in uncooperative patients. Ultrasound-guided biopsy is more efficient and cost-effective, even when lesions are initially detected with some other modality. Despite sonography's advantages, CT-guided biopsy is often more popular with radiologists because it almost always shows needle location. Sonographic needle visualization may be difficult or impossible when the liver is echogenic or when acoustic access is imperfect. Newer sonographic techniques that enhance needle-tip visualization

and improved biopsy guides promise to make sonographically guided biopsies easier.

Ultrasound contrast enhancement also may be useful in delineating residual tumor after ablation. Viable tumor can be identified and targeted for retreatment with ultrasound contrast during or after ethanol [107] or radio-frequency ablation. Interestingly, US failed to demonstrate flow in residual tumor prior to contrast enhancement, an indication of the potential usefulness of ultrasound contrast agents in these patients.

Gallbladder

Indications for sonography

Sonography is the imaging method of choice for the initial evaluation of all suspected diseases of the gallbladder. It is particularly valuable in patients with acute right upper quadrant pain and possible acute cholecystitis [108,109]. Sonography is highly reliably in detecting tiny gallstones and is useful for evaluating focal or diffuse abnormalities of the gallbladder wall [110]. Biliary sonography has several distinct advantages compared with scintigraphy and CT. Sonography is less expensive and can be performed rapidly without patient preparation or contrast agents. Unlike biliary scintigraphy, sonography is not "organ specific" and may provide important diagnostic information regarding the liver, pancreas, and peritoneal cavity. Sonography can readily be performed in patients with abnormal liver function that may preclude scintigraphy. Finally, sonography may be used at the bedside to guide percutaneous cholecystostomy for critically ill patients.

Patient preparation and technique

In patients undergoing sonography for acute right upper quadrant pain and possible acute cholecystitis, no prior preparation is necessary and patients can be imaged directly from the emergency room. Patients undergoing elective sonography to evaluate the gallbladder should be fasted for a minimum of 6 h. This will ensure adequate distention of the gallbladder to visualize small stones and facilitate imaging of the gallbladder wall.

Normal anatomy

Except in the rare instance of agenesis, the normal gallbladder can be seen in virtually all fasting patients [111,112] as a pear-shaped, fluid-filled structure along the inferomedial aspect of the right lobe of the liver. The gallbladder is typically less than 12 cm in length and is up to 3 cm in anteroposterior diameter. The normal gallbladder wall measures less than 3 mm. In addition to agenesis, other rare anomalies of the gallbladder that may be diagnosed with sonography include duplication and septations between the fundus and body (phrygian cap) [113].

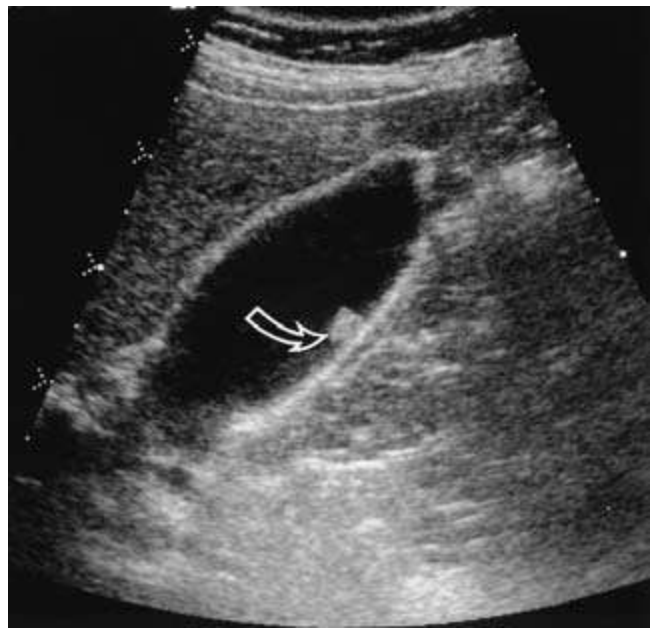

Figure 129.11 Gallbladder polyp. Note the echogenic mucosal mass without an acoustic shadow (arrow).

Gallstone disease

Stones as small as 3–5 mm can be easily seen sonographically. The characteristic sonographic appearance is an intralumenal echogenic focus casting a distal acoustic shadow (Fig. 129.11). It may be difficult to document acoustic shadowing in all patients with small gallstones. By varying the patient's position, mobility of the gallstones may be demonstrated in a high percentage of patients. Demonstrating mobility helps to differentiate small stones from polyps arising from the gallbladder wall that do change in position.

Although sonography is accurate for detecting stones within the gallbladder, once stones migrate into the cystic duct they are often difficult to see [114]. It is important to perform parasagittal images of the neck, gallbladder, and cystic duct region in patients with right upper quadrant pain. The identification of impacted cystic duct stones strongly suggests cystic duct obstruction.

Sometimes, echogenic abnormalities within or adjacent to the gallbladder may sonographically mimic gallstones. Such abnormalities include polyps, tumefactive sludge, surgical clips, and air bubbles. Gallbladder polyps are echogenic mucosal lesions that do not shadow. Sludge within the gallbladder is never a normal finding. It generally indicates lack of gallbladder emptying with precipitation of cholesterol or calcium bilirubinate crystals. At times sludge crystals may adhere together as "tumefactive" sludge and mimic a gallstone or mucosal mass. Gas within the gallbladder may be due to surgically created biliary–enteric anastomoses, endoscopic biliary procedures, or gas-forming infection from emphysematous cholecystitis.

Acute cholecystitis

The most important sonographic findings to confirm the diagnosis of acute cholecystitis are gallstones, gallbladder wall thickening, and a positive sonographic Murphy sign [108,109]. The sonographic Murphy sign differs significantly from the clinical sign. It refers to focal, unequivocal tenderness directly over the visualized gallbladder when the transducer applies pressure. In a prospective study of 497 patients with acute right upper quadrant pain, the combination of gallstones and a positive Murphy sign had a 92% positive predictive value for acute cholecystitis [108]. Gallbladder wall thickening (> 3 mm) and pericholecystic fluid in the appropriate clinical setting are secondary findings of acute cholecystitis, but both nonspecific findings may be due to a variety of other disorders. Biliary scintigraphy should be performed whenever the sonographic findings are equivocal.

In a small percentage of patients (5%–10%), acute cholecystitis develops in the absence of gallstones or cystic duct obstruction [115]. Conditions implicated in acalculous cholecystitis include trauma, major surgical procedures, hyperalimentation, burns, sepsis, and other severe intercurrent illnesses. The sonographic findings in early acalculous cholecystitis are often subtle and nonspecific. In a small percentage of patients, the gallbladder may be normal early in the clinical course [116]. Generalized symmetric thickening of the gallbladder wall is frequently not due to cholecystitis and must be interpreted with caution. It may be caused by such diverse conditions as hepatitis, fluid overload, portal hypertension, or hypoalbuminemia. In the appropriate clinical setting, gallbladder wall thickening with a positive sonographic Murphy sign is suggestive of acute acalculous cholecystitis. The sensitivity of sonography for the diagnosis of acalculous cholecystitis, however, is substantially less than with calculous cholecystitis, in the range of 63%–67% [117]. Interval follow-up studies performed at 24–48 h may be valuable in demonstrating progressive gallbladder wall edema or the development of fluid.

In patients without acute right upper quadrant pain, stones within a contracted gallbladder often indicate chronic cholecystitis. Shrinking of the gallbladder wall is a common associated finding. Marked contraction of the gallbladder around a large stone resultsin the wall-echo shadow sign and there is prominent acoustic shadowing from the gallbladder fossa.

There are several sonographic features that, in the appropriate clinical setting, may suggest gangrenous cholecystitis. These include pericholecystic fluid, intralumenal membranes (due to sloughed mucosa or fibrinous debris), and asymmetric thickening of the gallbladder wall [117] due to intramural microabscesses or hemorrhage. A high percentage of patients with gangrenous cholecystitis do not have a positive sonographic Murphy sign [118]. In critically ill patients with suspected gangrenous cholecystitis, sonography may be useful to guide percutaneous cholecystostomy even at the bedside.

Perforation of the gallbladder with pericholecystic abscess is a major cause of sepsis and morbidity from acute cholecystitis [119]. Pericholecystic abscesses appear sonographically as complex fluid collections in direct contiguity with the gallbladder. Mural necrosis may be identified sonographically as a focal loss of the normal reflectivity of the gallbladder wall. Inflamed omental and pericholecystic fat has been noted adjacent to pericholecystic abscesses. These fatty structures "wall off" the abscesses from the greater peritoneal cavity.

Hyperemia of the inflamed omental fat may be demonstrated with color Doppler imaging [120].

Gallbladder tumors

The vast majority of benign neoplasms of the gallbladder originate from the mucosal surface of the gallbladder and are either adenomatous or cholesterol polyps (Fig. 129.12) [121,122]. Small polyps are often incidental findings that, when less than 5 mm in diameter, are of no cause for clinical concern. Enlarging gallbladder polyps on serial sonograms or polyps greater than 1 cm in diameter are usually an indication for cholecystectomy due to the slight increased risk for carcinoma.

The sonographic findings of gallbladder carcinoma are variable and include a polypoid mucosal lesion or focal or irregular thickening of the gallbladder wall, sometimes associated with an extramural mass [123]. In advanced cases of gallbladder carcinoma patients may present with a large mass arising from the gallbladder fossa [123]. Direct hepatic invasion and nodal metastases may also be demonstrated sonographically. However, in many instances CT is required to delineate more precisely the extent of tumor and to detect distant spread of the disease.

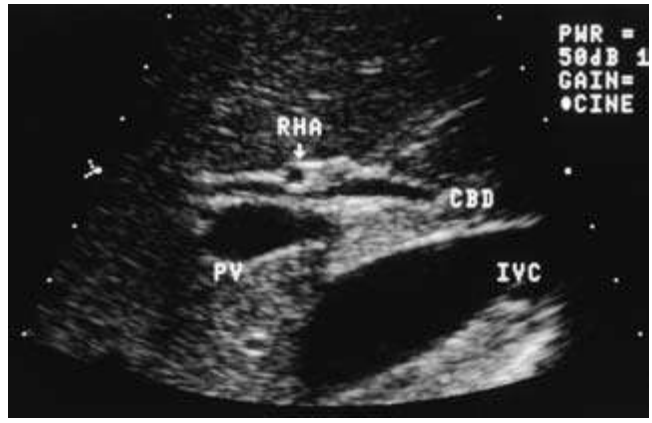

Figure 129.12 Normal common bile duct. This long-axis view of the normal common bile duct (CBD) shows the relationship of the bile duct to the portal vein (PV). Note that the right hepatic artery (RHA) passes ventrally to (above) the bile duct. This occurs in 10% of patients. In 90% of patients, the right hepatic artery passes between the portal vein and the bile duct. The common bile duct enters the pancreatic parenchyma. IVC, inferior vena cava.

Other conditions

Adenomyomatosis and cholesterolosis are benign disorders of the gallbladder that are classified as hyperplastic cholecystoses [121,122]. Cholesterolosis typically results in either single or multiple small mucosal polyps. It is due to the subepithelial accumulation of cholesterol-laden histiocytes that ultimately extends to the mucosal surface. Adenomyomatosis causes either focal or diffuse hypertrophy of the normal Rokitansky–Aschoff sinuses and smooth muscle within the gallbladder wall. Crystals and debris may be trapped within the sinuses of the hypertrophied wall and produce echogenic foci with echogenic "comet-tail" artifacts.

Bile ducts

Indications for sonography

Sonography's ability to detect dilated bile ducts and the level of biliary obstruction makes it the technique of choice for evaluating jaundiced patients. Sonography can also detect the cause of obstruction, albeit with less accuracy. Infectious cholangitis and conditions such as HIV cholangiopathy are indications for sonography. Sonography can detect and assess, with the help of color Doppler, resectability of cholangiocarcinoma and other tumors affecting the bile ducts.

Patient preparation and technique

Biliary sonography is best performed after an overnight fast or 8–12 h of a clear liquid diet. Because distention of the gallbladder is desirable, fatty foods should be avoided. The biliary tree is best imaged with the patient in the supine and right anterior oblique positions, starting with 3- to 7-MHz curved linear array transducers. A subcostal acoustic window should be used first, supplemented with intercostal scans. Sector or other small-footprint transducers are often useful to image the extrahepatic bile duct and the cystic duct of the gallbladder. Transverse compression views of the pancreatic head region with large-footprint curved linear transducers are useful to visualize the intrapancreatic bile duct, where about 90% of symptomatic common duct stones are located [124]. Color Doppler imaging is useful to differentiate the bile ducts from vessels and in detecting hyperemia in and near the gallbladder.

Normal anatomy

Sonography routinely displays the normal intra- and extrahepatic ducts. The normal extrahepatic bile duct ("common duct") runs ventral to the main portal vein (Fig. 129.13) and to the left of the proper hepatic artery. The internal diameter of the normal extrahepatic bile duct is 5 mm or less, although elderly patients and patients with cholelithiasis may have ducts of internal diameter 6–9 mm. The distal common duct is usually seen within the pancreatic head, and has a somewhat smaller caliber. The intrahepatic bile ducts may be seen ventral to the left and right portal veins. The normal internal diameter of the main left and right intrahepatic bile ducts is about 1 mm.

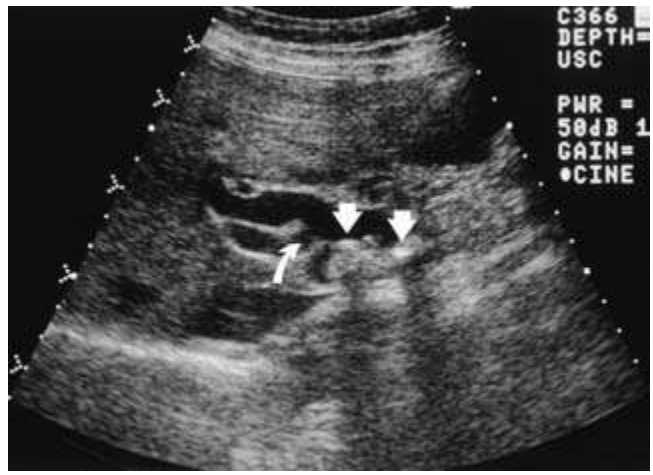

Figure 129.13 Common duct stone. This long-axis view of the intrahepatic and extrahepatic bile ducts reveals two echogenic common duct stones (arrows). Note the cystic duct (curved arrow) entering the common duct dorsally.

Bile duct obstruction

Stones are the most common cause of distal bile duct obstruction. Tumors are a more frequent cause of proximal bile duct obstruction. Sonographically, dilated intrahepatic bile ducts are tubular anechoic structures that demonstrate posterior acoustic enhancement. Centrally, in the porta hepatis, dilated ducts are usually ventral to the portal veins. Peripheral ducts have a variable relationship to the portal veins. The "too many tubes" sign is the classic pattern indicative of intrahepatic biliary dilation. Color Doppler is useful to distinguish veins and enlarged arteries from dilated bile ducts, simplifying detection of abnormal ducts and preventing misidentification of vessels as bile ducts.

Surprisingly, "normal" bile duct size is controversial. Obstruction is rarely present when the extrahepatic bile duct is 5 mm or less in maximal internal diameter. Nondilated obstruction may be seen in cholangiocarcinoma or sclerosing cholangitis. Bile ducts with maximal internal diameters of 10 mm or more are almost always obstructed. In most patients, 6–9-mm ducts ("gray zone" size ducts) are enlarged not because of obstruction but because of breakdown of the elastic fibers within the duct wall. Patients over 50 years old are "allowed" 1 mm per decade in duct diameter. For example, a 7-mm duct should be considered normal in a 70-year-old. Patients with cholelithiasis often have 6- to 9-mm-diameter ducts. We postulate that this is caused by degeneration of elastic tissue within the duct wall from transient obstruction caused by recurrent passage of stones. This is analogous to the increased residual diameter of a deflated balloon that has

been repeatedly blown up and deflated. Rarely, an unobstructed duct measuring 10 mm or larger may be found. Administration of a fatty meal may aid in evaluating "gray zone"-sized ducts. A decrease of 2 mm in duct size after a fatty meal indicates normal bile dynamics and excludes obstruction. If the extrahepatic duct enlarges after the fatty meal, obstruction is likely.

Distal bile duct obstruction causes extrahepatic bile duct dilation and often intrahepatic bile duct dilation. Intrahepatic duct dilation is almost always a sign of obstruction, although rare exceptions are seen. Thus, intrahepatic dilation is specific for obstruction, but it is less sensitive than extrahepatic bile duct dilation. Obstruction at sites other than the distal duct results in proximal dilation, with a normal-caliber distal duct.

Choledocholithiasis

Choledocholithiasis occurs in at least 15% of patients with cholelithiasis. Conversely, 95% of patients with common duct stones also have gallstones [125]. The prevalence of choledocholithiasis in patients with gallstones increases with age [126]. A shadowing echogenic focus in the bile duct is virtually diagnostic of cholelithiasis (Fig. 129.14). Shadowing may be difficult to demonstrate in some impacted stones. Potential pitfalls include the Mirizzi syndrome, air in the bile duct, extrabiliary calcifications, or surgical clips. On occasion, a completely stone-filled duct may be confused with a gas-containing segment of bowel. Extrahepatic biliary dilation is present in 70%–94% of patients with choledocholithiasis [127,128]. Although stones in normal-sized ducts can be identified, these are probably harder to detect than stones in dilated ducts.

Figure 129.14 Cholangiocarcinoma. Transverse sonogram in the region of the porta hepatis shows biliary dilation and a hypoechoic mass (M).

Bile duct stones are harder to detect than gallstones, with optimal reported sensitivity of 75%–80% [129]. The difficulty relates to gas sometimes obscuring the distal duct and the lack of echo-free bile around impacted stones. About 90% of proximal, suprapancreatic bile duct stones (approximately 10% of cases) are detected [130]. Meticulous technique is necessary to achieve optimal sensitivity. A prospective Finnish trial reported detection rates of only 22% for sonography and 25% for CT in patients with choledocholithiasis [130].

Infectious cholangitis

Contrast CT is probably the best screening examination in patients with severe cholangitis [131]. Sonography is the study of choice in patients with clinically less severe cholangitis. Diffuse bile duct wall thickening is often present [132]. Debris in the bile duct suggests the presence of pus and, hence, infectious cholangitis. Liver abscesses can be identified.

Recurrent pyogenic cholangitis

Recurrent pyogenic cholangitis (also known as Oriental cholangiohepatitis) is characterized by recurrent bacterial cholangitis promoted by strictures and primary bile duct stones that may occur in any part of the biliary tree. Gallstones and liver abscesses are frequent [133]. Sonography is the preferred initial imaging [134,135]. Most patients have huge stones with dramatic shadowing that can obscure the biliary tree. The soft, mud-like stones are often of medium echogenicity, however, and may lack acoustic shadowing. This appearance can mimic sludge, pus, blood, or even neoplasm within the biliary tree. Markedly dilated intra- and extrahepatic ducts are the rule. It is not unusual for duct size to exceed 2 cm [136]. Sonography is limited in patients with prior biliary enteric anastomosis, as intraductal gas obscures both the ducts and intrahepatic calculi. Gas may also make detection of liver abscesses difficult.

HIV-related cholangiopathy

HIV-related cholangiopathy is a diffuse biliary tract disease, affecting the gallbladder and the bile ducts. More than 80% of patients have alkaline phosphatase greater than twice normal, but bilirubin is usually normal or minimally elevated [136–138]. Sonography, although less sensitive than endoscopic retrograde cholangiopancreatography (ERCP), is useful in evaluating patients suspected of having HIV-related cholangiopathy [138]. Smooth or irregular thickening of the bile duct wall (45%) and biliary dilation (about 70%) are frequent abnormalities [139]. Biliary dilation often occurs in association with ampullary stenosis. An echogenic nodule at the end of the common duct, thought to represent an edematous ampulla of Vater, has been described. Striking thickening of the gallbladder wall with prominent wall striations suggestive of acute acalculous cholecystitis, may occur [136,138,140].

Tumors

Cholangiocarcinoma

Primary bile duct tumor, or cholangiocarcinoma, has two forms, peripheral cholangiocarcinoma and hilar cholangiocarcinoma (Klatskin tumor) [141,142]. In the United States, peripheral cholangiocarcinoma is three times more common than hilar cholangiocarcinoma, whereas in Japan hilar and peripheral cholangiocarcinomas occur with equal frequency [143]. Peripheral cholangiocarcinoma is usually a large tumor. Hilar cholangiocarcinomas present earlier with ductal obstruction and jaundice and are more difficult to image, as the tumors are smaller. Cholangiocarcinoma is usually hypoechoic (Fig. 129.15), but isoechoic and hyperechoic tumors may occur [144].

Both color and spectral Doppler sonography are useful in determining if cholangiocarcinoma is resectable [145,146]. Cholangiocarcinoma is unresectable when one of the following is present in both the left and the right lobes: lobar atrophy, vascular invasion, or obstruction of two or more sectorial (segmental) ducts. Vascular invasion, narrowing, and tumor contiguity are readily demonstrated with color Doppler sonography. Duct involvement can be diagnosed when a duct is obstructed by a mass, or when wall thickening or an intraductal mass is identified. When two or more ducts peripheral to the left or right hepatic duct are involved by the mass, sectorial (segmental) duct involvement is present. Sectorial ducts are those that arise from different liver segments and join to form the main left and right hepatic ducts.

The sonographic evaluation of the bile ducts should be performed before stenting, if at all possible. Stenting may cause mural and periductal hemorrhage or edema that can obscure or simulate tumor. It may also interfere with identification of dilated sectorial ducts by decompressing them.

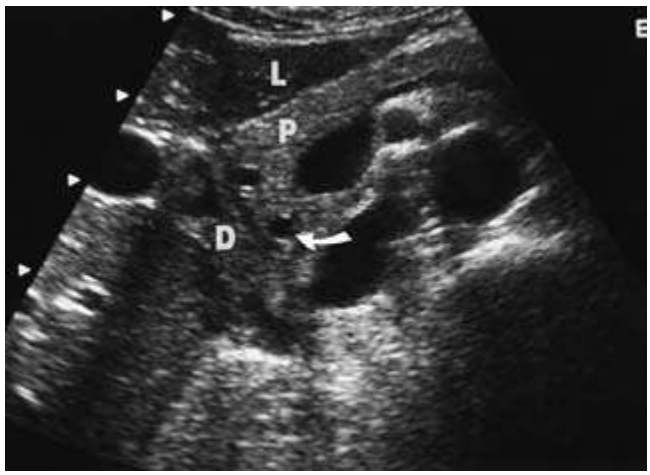

Figure 129.15 Normal pancreatic head. The pancreas (P) is more echogenic than the hepatic parenchyma (L). Note the anatomical relationship of the duodenum (D) to the pancreatic head. The rounded anechoic areas within the pancreatic head are the gastroduodenal artery (anteriorly) and the common bile duct (curved arrow).

Biliary cystic neoplasms

Biliary cystic neoplasms (formerly called biliary cystadenoma and cystadenocarcinoma) are rare. Lesion morphology ranges from completely cystic with a few thin septations to cystic with thick septations and large amounts of internal soft tissue. Thick, sometimes papillary septations and larger amounts of internal soft tissue characterize the mesenchymal variant, which has a greater potential for malignant behavior.

Other conditions

Biliary parasites

Biliary parasites such as *Ascaris* species or *Clonorchis sinensis* may infest the biliary tree and cause secondary biliary tract obstruction [147]. Sonographically, the adult *Ascaris* worm may be seen as a tubular structure within the bile ducts or gallbladder. The flukes of *Clonorchis sinensis* are small and not generally visible with sonography. However, aggregates or clumps of parasites may be identified within the extrahepatic bile duct or within the gallbladder.

Mirizzi syndrome

Mirizzi syndrome is biliary obstruction caused by a gallstone impacted in the cystic duct or gallbladder neck. Extrinsic compression and inflammation obstruct the extrahepatic bile duct. Sonography may suggest the diagnosis when a stone is impacted in the neck of the gallbladder, proximal bile duct dilation is present, and the distal common bile duct is normal.

Choledochal cysts

Of the four main types of choledochal cysts, about 90% of cases involve dilation of the extrahepatic bile duct (type I). Sonographically, there is obvious dilation of the extrahepatic duct, often associated with varying degrees of intrahepatic dilation. Dilation may be cystic (IA), focal (IB), or fusiform (IC). Other types include choledochal diverticula (type II), choledochocele (type III), and multiple intra- or extrahepatic cysts (type IV) [148].

Caroli disease

Caroli disease is cystic dilation of the intrahepatic bile ducts. Some cases are associated with a choledochal cyst (Todani type 4A). Sonographically, multiple small cystic areas that may or may not appear to communicate with the unaffected bile ducts characterize Caroli disease. A central vessel identified with Doppler sonography supports the diagnosis. Other findings include renal cysts, cirrhosis, or liver abscess.

Bilomas

Bilomas are encapsulated bile collections caused by rupture, usually traumatic; of the biliary tree [149]. Large asymptomatic bilomas are not rare. Sonographically, bilomas are usually well-defined anechoic collections with striking through transmission of sound. Detection of a lesion with this appearance 2–6 weeks after liver trauma strongly suggests the diag-

nosis [150]. Occasionally, bilomas are more complex, with internal debris and septations, and less pronounced through transmission, which are features that may also occur with abscesses. In these cases, needle aspiration can exclude infection and confirm the presence of bile by laboratory analysis for bilirubin.

Bilomas discovered incidentally in asymptomatic patients generally do not require treatment; they resolve spontaneously within a few weeks. Imaging studies alone cannot always distinguish bilomas from abscesses, chronic hematomas, or hepatic cysts. Percutaneous drainage, when required, is often an effective alternative to surgery [149,151].

Pancreas

Indications for sonography

Although CT remains the most sensitive means of evaluating pancreatic disease, modern ultrasound technology and new scanning techniques (oral contrast, compression scanning) are reestablishing sonography as a useful and clinically relevant pancreatic imaging technique. Sonography is indicated in all patients with acute pancreatitis, not to evaluate the pancreas itself but rather to detect gallstones and biliary dilation. Computed tomography is superior to sonography in evaluating potential complications of pancreatitis, but sonography may be used to follow pancreatitis-associated fluid collections and can guide biopsy, drainage, or aspiration of selected pancreatic lesions. Sonography is the primary imaging method to screen patients with jaundice or abdominal pain. Thus, sonography may detect acute or chronic pancreatitis or reveal pancreatic masses. Sonography may be more effective than CT in determining whether a lesion is pancreatic or contiguous to the pancreas. Sonography is occasionally useful to characterize abnormalities noted on CT, determining, for example, whether a lesion is cystic or solid.

Patient preparation and technique

Pancreatic sonography is easier after the patient has fasted overnight or for at least 6 h. This improves visualization of the gallbladder, and minimizes GI gas. Sonography's spatial resolution is better than CT and MRI when conventional scanning parameters are used. In some patients, however, CT is needed to visualize the pancreas adequately. With sonography, optimal pancreatic visualization requires that intervening GI content (gas and fluid) be displaced by compression or by filling the gut with water or GI contrast material. For the head and body, we prefer compression, using 3- to 7-MHz curved array transducers. Compression results in better resolution – the transducer is closer to the pancreas. The left lateral decubitus position may be useful, with visualization of the pancreatic head through the gallbladder or liver. Oral administration of water may be helpful if compression is unsuccessful.

The tail of the pancreas is more difficult to image. Routine pancreatic scanning should include coronal and axial views through the spleen and left kidney. The normal tail is usually not seen, but lesions invisible on other views, especially pseudocysts, are occasionally delineated. Water or contrast in the stomach is useful for imaging the tail. Right anterior oblique positioning is useful to view the tail through the water-containing stomach. Color Doppler imaging can assess vascular complications of pancreatitis and delineate vascular relationships to pancreatic neoplasms.

Normal anatomy

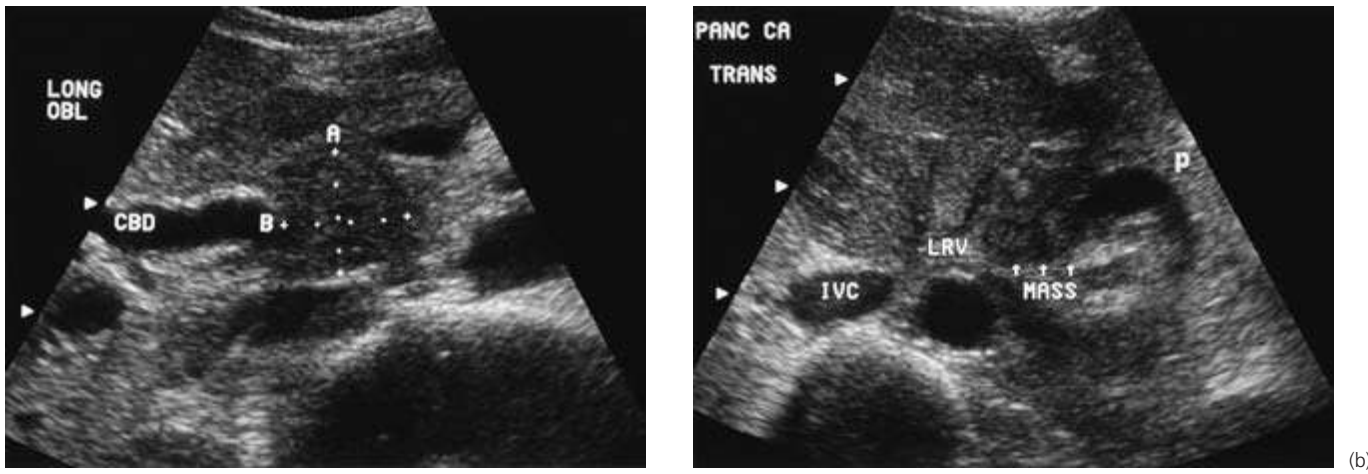
The normal pancreatic parenchyma is finely homogeneous and isoechoic to hyperechoic compared with liver parenchyma. The pancreas is a retroperitoneal organ that lies draped over the spine, aorta, and IVC. The pancreatic head is medial to and intimately related to the sweep of the second and third portions of the duodenum. The head is ventral to the IVC and medial to the superior mesenteric artery and vein (Fig. 129.16). In cross-section, the round and sonolucent common bile duct is seen in the posterior head, sweeping caudally and to the right as it passes into the duodenum. The body lies ventral to the aorta, splenic vein, and superior mesenteric artery, behind the stomach (with the collapsed potential space of the lesser peritoneal sac between). The pancreatic tail nestles into the splenic hilus and is closely related to the upper pole of the left kidney.

Acute pancreatitis

Evaluation with sonography is mandatory for all patients, even alcoholics, during their first attack of acute pancreatitis. Sonography in patients with acute pancreatitis focuses on the gallbladder and bile ducts – the gallbladder for stones (as a cause of pancreatitis) and the bile duct for choledocholithiasis and obstruction.

The reported prevalence of acute pancreatitis-associated abnormalities varies widely, from 33% to 90% of patients. Pancreatic echogenicity typically decreases in acute pancreatitis because of interstitial edema, but can be considered abnormally hypoechoic only when echogenicity is less than liver parenchyma. As the normal pancreas may be more echogenic than the liver, echogenicity is normal in many patients with acute pancreatitis. In patients with echogenic livers from fatty infiltration, the normal pancreas may be relatively hypoechoic, simulating the findings of pancreatitis. This is called pseudopancreatitis. Rarely, echogenicity may actually increase with acute pancreatitis, owing to hemorrhage, necrosis, or fat saponification. With newer sonographic systems, inhomogeneity of the parenchyma is often evident in acute pancreatitis.

Enlargement of the pancreas in acute pancreatitis is probably almost universal. Unfortunately, enlargement may be difficult to judge, as pancreatic size before the onset of pancreatitis is unknown and varies widely from individual to



(a) (b)

Figure 129.16 Pancreatic carcinoma with obstruction of the bile duct. **(a)** The long-axis view of the common bile duct shows a 3.5-cm mass (highlighted by calipers A and B) that obstructs the common bile duct (CBD). **(b)** A transverse sonogram obtained with the patient in the right anterior oblique position shows the mass (arrows). The mass is hypoechoic, compared with the normal pancreatic parenchyma (p). IVC, inferior vena cava; LRV, left renal vein.

individual. It is not unusual to detect extrapancreatic inflammatory changes even when the pancreas appears normal. Thus, extrapancreatic abnormalities may be the only sonographic findings that suggest the diagnosis of acute pancreatitis. Hypoechoic inflammation is often seen around the pancreas, in the anterior retroperitoneal spaces bilaterally, in the transverse mesocolon, around splanchnic vessels, and elsewhere [152]. Acute fluid collections, pseudocysts, and abscesses may be imaged. Color and spectral Doppler sonography may be useful in detecting pancreatitis-associated vascular complications, such as pseudoaneurysms and portal thrombosis.

Acute pancreatic fluid collections and pseudocysts

Acute pancreatic fluid collections and pseudocysts are the most common complications of pancreatitis. Pancreatic fluid collections consist of a combination of pancreatic juice, edema fluid, hemorrhage, and necrotic tissue resulting from acute pancreatic inflammation, enzymatic autolysis, and pancreatic ductal disruption. Two features distinguish a pancreatic pseudocyst from an acute fluid collection: persistence past 4–6 weeks and a well-defined wall (fibrous pseudocapsule) [153]. Acute fluid collections occur in approximately 30%–50% of patients with severe pancreatitis, but more than half of these regress spontaneously.

Computed tomography is more sensitive than sonography in diagnosing acute pancreatic fluid collections and pseudocysts [152]. When an acute pancreatic fluid collection is identified with CT or sonography, serial studies should be performed to document either resolution or persistence as a pseudocyst. If sonography shows the pancreatic fluid collection well, it is the most cost-effective method for serial evaluation. But CT should be performed immediately before any surgical drainage of a pseudocyst, to identify any lesions not detected by sonography.

Acute fluid collections and pseudocysts have a variable sonographic appearance depending on the associated internal hemorrhage and debris. Acute fluid collections may be anechoic to hyperechoic, but are generally hypoechoic with internal debris. Enhanced through transmission of sound is almost always present, but is variable in degree. Color Doppler sonography should be used to ensure that all discrete "cystic" areas are not pseudoaneurysms.

Pancreatic abscess and infected pancreatic necrosis

The two major infectious complications of acute pancreatitis are infected pancreatic necrosis and pancreatic abscess. Pancreatic abscess is a circumscribed collection of pus that contains little or no necrosis. Infected pancreatic necrosis is a region of infected nonviable pancreatic parenchyma. Pancreatic abscess is associated with a lower mortality (7%–33%) than infected pancreatic necrosis (~ 40%) [154]. Necrosis is diagnosed by contrast CT – no enhancement of the pancreatic parenchyma corresponds to necrosis. Ultrasound cannot diagnose pancreatic necrosis. Contrast CT, because of its superiority to sonography as a survey modality, is preferred when infectious complications are sought. Unfortunately, image findings alone cannot distinguish infected from uninfected collections [155], so aggressive use of CT- or US-guided needle aspiration is mandatory to diagnose infection.

The treatment of infectious complications of pancreatitis is controversial. Localized pancreatic abscess responds well, albeit imperfectly, to percutaneous drainage. vanSonnenberg et al. [156] reported successful cure of 69% of patients with pancreatic abscess by percutaneous drainage alone.

Hemorrhage and vascular complications

Erosion of small vessels is the most frequent cause of pancreatitis-associated hemorrhage. It may result in bleeding

into the pancreatic bed, the pancreatic duct, or a pseudocyst. Peripancreatic pseudoaneurysm [157] is rare, but potentially catastrophic. Pseudoaneurysms occur most often in the splenic artery (42%), the gastroduodenal artery (22%), and small peripancreatic arteries (25%). Contrast CT and Doppler sonography can identify pseudoaneurysms, but smaller pseudoaneurysms (i.e., < 1 cm) are more reliably diagnosed angiographically.

Inflammation from acute pancreatitis may cause venous occlusion. The splenic vein is most commonly affected and may result in gastric varices. The superior mesenteric or portal veins are also occasionally involved. Color Doppler sonography and contrast CT may be useful to diagnose pancreatitis-related thrombosis in the portal venous system.

Chronic pancreatitis

Image findings are poor predictors of the clinical severity of chronic pancreatitis [158], although patients with severe exocrine insufficiency are more likely to have abnormal pancreatic size and contour irregularity [159]. Multiple calcified stones located within the main or branch pancreatic ducts are the hallmark of chronic pancreatitis, usually alcohol related. Sonography is less sensitive than CT in detecting pancreatic calcifications. On occasion, the pancreas is diffusely hyperechoic. This may be difficult to judge sonographically, as the pancreas is normally more echogenic than adjacent parenchymal organs like the liver. Bolondi et al. believe that dilation of the main pancreatic duct is the most reliable sign of chronic pancreatitis [160]. The "double-duct sign" (dilation of pancreatic and bile ducts) may occur not only in pancreatic carcinoma but also in chronic pancreatitis [161]. Glandular atrophy or fatty infiltration may occur, making evaluation of the pancreas difficult sonographically. Chronic asymptomatic pseudocysts may be found in patients with chronic pancreatitis.

Focal masses that can simulate neoplasm occur in about one-third of patients with chronic pancreatitis. Calcification within the mass is strongly suggestive, but not definitive, for chronic pancreatitis. Uncalcified isoechoic or hypoechoic masses may require ERCP or biopsy to exclude malignancy [158].

Neoplasms

Sonography is the primary imaging method to screen patients with jaundice or abdominal pain. Thus, sonography often detects pancreatic masses. Sonography may be useful to characterize the internal architecture of masses, information that can be useful in classifying neoplasms. Sonography may detect a carcinoma as an area of decreased echogenicity within the gland when no morphological or attenuation abnormality is noted on CT [162].

Ductal adenocarcinoma

Sonographically, pancreatic carcinoma is typically a hypoechoic mass that deforms the gland's morphology (Fig. 129.17).

Figure 129.17 Acute appendicitis. Note distended appendix (A) with dilated tip (cursors).

Occasionally, pancreatic carcinoma is echogenic. A few scattered calcifications or cystic areas may occur occasionally (about 5% each) [163]. Secondary findings of carcinoma include ductal dilation (Fig. 129.17) (biliary and pancreatic), vascular and extraglandular invasion, and metastatic disease. Pseudocysts, related to obstruction of a pancreatic duct, have been reported in up to 11% of patients [164], although in our experience carcinoma-related pseudocysts are less frequent.

Most discussions of imaging in pancreatic and periampullary neoplasms have virtually ignored sonography [165,166], despite a 1988 study showing that grayscale sonography was useful in assessing resectability [167]. We and others have shown that color Doppler sonography can effectively assess resectability, specifically vascular involvement by tumor, with accuracy comparable with that of CT [168–171].

Ductal adenocarcinoma variants

Many histological variants of pancreatic ductal adenocarcinoma are indistinguishable on imaging from tumors with the usual histological features. Acinar center cell carcinoma and pleomorphic giant cell carcinoma can be larger and exhibit central necrosis [172]. Mucinous ductectatic carcinoma and mucin-hypersecreting carcinoma are variants of ductal adenocarcinoma [172,173]. These lesions have markedly dilated, mucin-filled, pancreatic branch ducts, usually in the pancreatic head. Sonographically, mucinous ductectatic carcinomas show multiple sonolucent, dilated ducts. A discrete mass may not be evident. Mucin-hypersecreting carcinoma usually has more extensive ductal dilation.

Cystic pancreatic lesions

The most common cystic pancreatic neoplasms are serous cystic neoplasm (microcystic adenoma), and mucinous cystic

neoplasms [174]. Morphologically, microcystic adenomas comprise many tiny cysts, most smaller than 2 mm. The most distinctive feature, present in about one-half of tumors, is a central radial fibrotic scar that frequently calcifies. Sonographically, microcystic adenomas are echogenic in regions where there are many tiny cysts. Through transmission is frequent. Larger cysts (2–3 cm) may be seen at the periphery of the lesion. Calcifications are imaged more often with CT than sonography. Microcystic adenomas are almost universally benign [175].

Mucinous cystic neoplasms consist of large cysts, usually easily imaged with CT or sonography. Most are located in the tail or body of the pancreas and are much more common in females. Calcifications occur in approximately 20% of these neoplasms (compared with about one-half of serous/microcystic neoplasms). Sonography usually reveals a mass with internal cysts of variable size. Unilocular lesions may occur. The septations may be few or many, thin or thick and polypoid. The internal architecture is often shown to better advantage by sonography than CT. Mucinous cystic neoplasms may be confused with rarer cystic neoplasms such as papillary cystic tumor, cystic islet cell tumor, lymphangioma, cystic metastases, or nonneoplastic lesions such as pseudocyst, abscess, and echinococcal disease [176].

Solid and papillary epithelial neoplasm, a low-grade malignancy found most frequently in young females, tends to be large and well encapsulated. Tumors can be mostly solid, mixed cystic and solid, or almost entirely cystic. Less common cystic neoplastic tumors include papillary cystic tumor, cystic islet cell tumors, and acinar cell cystadenocarcinoma. Simple cysts of the pancreas are uncommon. They occur sporadically or in association with von Hippel–Lindau syndrome and, rarely, in renal polycystic disease.

Endocrine tumors

It is difficult to image functional islet cell tumors; they are usually small when the patient presents with hormonal abnormalities. Insulinomas and gastrinomas are frequently less than 2 cm in diameter. In contrast, "nonfunctional" islet cell tumors can be large at the time of presentation. Sonographic detection rates are 25%–60% for insulinomas [177] and approximately 20% for gastrinomas [178]. Sonographically, islet cell tumors are usually hypoechoic, well defined, and round or oval in shape. Intraoperative sonography is useful in localizing occult neoplasms.

Gastrointestinal tract

Indications for sonography

The most common indication for GI tract sonography is evaluation of the patient with right lower quadrant pain and possible appendicitis. Sonography may also be useful in the diagnosis of diverticulitis, small bowel obstruction, and bulky mesenteric or GI neoplasms. One of the more useful applications of sonography of the GI tract is endolumenal ultrasound to stage the depth of GI tract neoplasms. This is discussed in Chapter 154.

Patient preparation and technique

Patients undergoing sonographic evaluation for possible GI tract abnormalities typically require no special preparation. Patients with right lower quadrant pain and possible appendicitis can be imaged immediately after initial assessment in the emergency room. Having the patient drink sufficient water to distend the upper GI tract may facilitate evaluation of the stomach and duodenum. A water enema may be useful in selected patients to evaluate pelvic masses.

Graded compression sonography is the most important technique for evaluation of possible appendicitis and other focal GI tract abnormalities [179]. This technique takes advantage of the fact that lesions infiltrating the bowel wall alter its compressibility. The normal GI tract can be readily compressed by the sonologist when moderate pressure is applied with the transducer. However, inflammatory or neoplastic disorders of the bowel alter its compressibility and render it relatively noncompressible [180,181].

Sonography has a number of important advantages compared with CT in evaluating the GI tract. Real-time observation of bowel peristalsis is possible with sonography. Delineation of layers of the bowel wall (most importantly, the echogenic submucosal layer) is also readily apparent with sonography. Rapid multiplanar imaging can be performed and vascular flow can be assessed without contrast agents with the use of color and power (the most sensitive form of color Doppler sonography) Doppler [182,183]. Finally, sonography is an interactive technique and the patient can be scanned at the site of maximal pain and tenderness to correlate symptoms with anatomical abnormalities. It should be noted, however, that sonography is often unable to image all the lumenal GI tract mesentery and subperitoneal space reliably because of bowel gas.

Graded compression is generally performed with a high-resolution linear array transducer (5–10-MHz) depending on the depth of the structures to be imaged. For most other GI studies, a 5-MHz curved array transducer yields the best results.

Normal anatomy

Standard abdominal transducers do not delineate all five layers of the bowel wall. The echogenic submucosal layer, however, is clearly visible and serves as a constant anatomical feature that is an extremely useful landmark in identifying an intraabdominal structure as a bowel loop. Pathological processes that cause ulceration and necrosis of the bowel lead to either focal or global loss of visualization of the echogenic submucosa [184]. Primary neoplasms involving the bowel wall may result in focal bowel wall thickening referred to as the target sign or "pseudokidney" sign [185]. Tumor infiltrat-

ing the bowel wall appears as a hypoechoic mass (mimicking the cortex of the kidney). The echogenic mucosal surface lumen is preserved mimicking the fat-containing hilum of the kidney. Gas trapped within ulcerating lesions involving bowel wall may result in high-amplitude echoes with acoustic reverberation artifacts within the submucosal layers of the bowel wall.

Color Doppler sonography may be a useful adjunct to grayscale imaging in evaluation of patients with focal bowel wall thickening [182,183]. Increased arterial flow within the involved segment suggests either inflammation or infection; diminished or absent flow suggests intramural hemorrhage, ischemia, or infarction. The vascularity of GI tract tumors is variable but, in general, adenocarcinomas are hypovascular.

Acute appendicitis

In patients with an uncertain clinical diagnosis of appendicitis, sonography is preferred to CT in women of childbearing age, in pediatric patients, and in thin adult male patients. Computed tomography is preferred in patients who are obese or if appendiceal perforation is suspected [186]. The sonographic criteria for diagnosing acute appendicitis include a noncompressible appendix measuring 7 mm or more in greatest anteroposterior diameter (Fig. 129.18) [187]. An appendix measuring 5 mm or less is virtually always normal. Appendices measuring 5–6 mm are equivocal for appendicitis, and clinical observation or repeated sonography should be considered [187]. In a patient with right lower quadrant pain, the presence of an appendicolith within a noncompressible appendix generally indicates acute appendicitis regardless of the size of the appendix. In some patients, early acute appendicitis is confined to the distal tip of the appendix [188]. It is therefore important always to visualize the entire length of the appendix to evaluate for distal appendicitis.

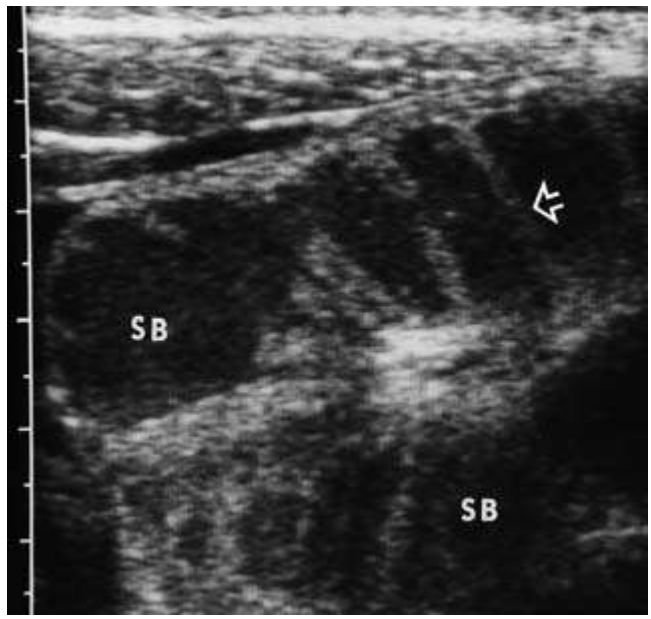


Figure 129.18 Closed-loop small bowel obstruction. Dilated U-shaped loop of small bowel (SB) represents closed-loop obstruction (arrow). Small bowel can be distinguished from other gastrointestinal viscera by identification of the valvulae conniventes (open arrow).

Diverticulitis

In most patients, CT is the imaging method of choice to evaluate patients who present with left lower quadrant pain and possible sigmoid diverticulitis [189]. This is particularly true in septic patients with possible paracolonic abscesses that may require percutaneous or surgical drainage [190]. Nevertheless, sonography may play a useful role as a screening examination in patients with pelvic pain and unclear signs and symptoms of diverticulitis. The sonographic findings in acute diverticulitis include focal mural thickening of the bowel and increased echogenicity of the mesenteric fat with hyperemia on color Doppler imaging [191]. In some patients, the infected colonic diverticulum may be identified as an echogenic intramural focus due to either gas or echogenic pus within the diverticulum [191]. On occasion, ectopic gas bubbles may be identified in the sigmoid mesentery due to their characteristic high-amplitude linear echoes and distal reverberation artifacts.

Enteritis and colitis

The sonographic findings of enteritis or colitis are often nonspecific [192]. Typical findings include focal areas of mural thickening of the bowel, often with associated adjacent adenopathy. There is lack of compressibility of the involved segment with graded compression. Increased flow on color Doppler may be demonstrated with high-frequency probes. Fibrofatty mesenteric masses may be identified as focal echogenic areas in Crohn's disease. In general, CT is superior to sonography in identifying mesenteric abscesses, colovesicular fistulae, and retroperitoneal abnormalities that accompany Crohn's disease [192].

Mesenteric adenitis

In the presence of a normal appendix or sonography, the identification of enlarged mesenteric lymph nodes is highly suggestive of mesenteric adenitis. There may also be associated thickening of the terminal ileum [193]. Once this diagnosis is suggested, patients should be observed clinically without surgical intervention. Symptoms of mesenteric adenitis typically resolve spontaneously without specific therapy. Color Doppler may be useful to highlight the hypoechoic lymph nodes adjacent to the flow in mesenteric vessels.

Intestinal obstruction

Sonography and CT may play an important role in the patient with possible small bowel obstruction [194]. The characteristic sonographic features are dilated fluid-filled loops with increased peristalsis on real-time examination. Fluid-filled levels and echogenic intralumenal debris may also be seen

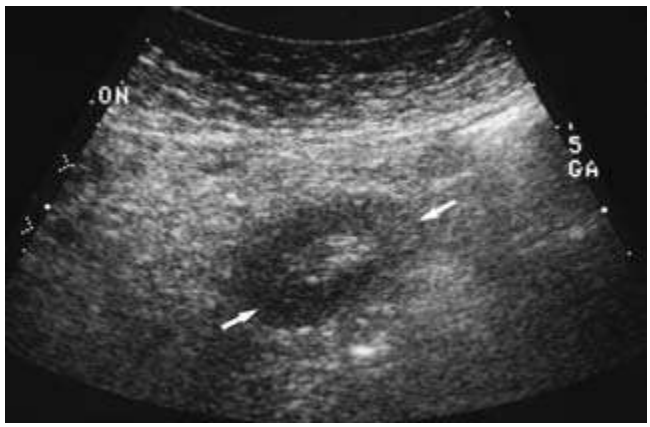

Figure 129.19 Pseudokidney sign of gastrointestinal tumor. Sagittal sonogram of midabdomen demonstrating a mass (arrows) that resembles a kidney.

within the dilated, obstructed bowel. In any patient with possible obstruction, a specific attempt should be made to identify a transition zone between dilated and nondilated bowel. This is often the most specific finding to confirm the diagnosis of obstruction. On occasion, sonography may identify GI tract tumors, mesenteric masses, abscesses, and other intra-abdominal pathology that caused the obstruction. The appearance of intussusception is characteristic on sonography as there is a target appearance of the invaginated intussusceptum. A crescent-shaped intralumenal area of echogenic fat representing invaginated mesentery is identified at the level of the lead point.

Gastric outlet obstruction may be diagnosed whenever marked dilation of the stomach is noted with a collapsed duodenum. In selected patients, however, gastroparesis may have a similar appearance. Closed-loop obstruction characteristically results in a single U-shaped aperistaltic loop of dilated bowel (Fig. 129.19). Hyperperistaltic bowel is noted proximal to this loop.

Small bowel infarction

In most patients with suspected mesenteric ischemia and small bowel infarction, CT or mesenteric angiography are performed emergently. However, in selected patients, sonography may be performed because of confusing signs and symptoms on clinical presentation. Mural thickening of the small bowel wall resulting from either intramural hemorrhage or edema may be visualized as a noncompressible area of mural thickening [182,183]. In the appropriate clinical setting, absence of vascular flow on color and more specifically with power Doppler suggests the diagnosis of ischemia.

Gastrointestinal tract tumors

In patients with palpable abdominal masses, sonography is often valuable in identifying the organ of origin of the lesion. As previously noted, the pseudokidney sign may be due to tumors infiltrating through muscular elements of the bowel wall (Fig. 129.20). Caution must be observed, however, in that focal inflammatory or ischemic processes may mimic neoplasms on sonography. Endoscopy, barium studies, or CT are often required to establish a more precise diagnosis. Both lymphoma and GI stromal tumors result in bulky, exophytic masses that are typically hypoechoic on sonography. Areas of liquefied hemorrhage or necroses are more typical of GI stromal tumor.

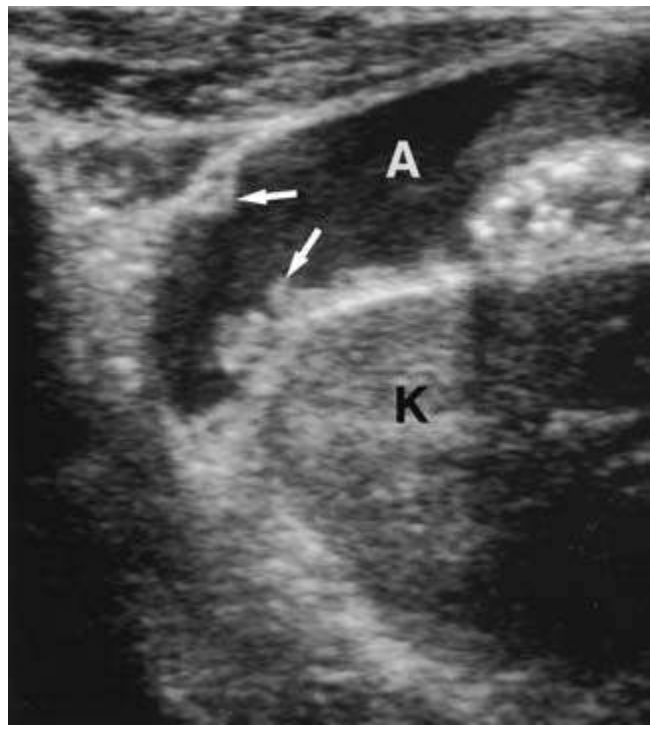

Figure 129.20 Peritoneal implants from mesothelioma. Transverse scan of right lower quadrant demonstrates ascites (A) and plaque-like peritoneal implants (arrows). K, right kidney.

Peritoneal cavity

Indications for sonography

The most common indication for evaluating the peritoneal cavity with sonography is to search for intraperitoneal fluid collections such as ascites, abscesses, or hemorrhage. Sonography is useful not only to identify intraperitoneal fluid collections but also to guide percutaneous needle aspiration for definitive diagnosis. Solid peritoneal masses representing either primary or metastatic tumors may also be detected on occasion with sonography. However, CT is the preferred imaging modality in patients with a clinical suspicion for peritoneal metastases.

Patient preparation and technique

Scanning of the pelvic peritoneal spaces is easier when the bladder is full. The distended bladder provides an excellent

acoustic window to evaluate the cul-de-sac or retrovesical recess. However, the remainder of the peritoneal cavity can readily be imaged with little or no patient preparation. In general, a curved 3.5- or 5-MHz transducer provides adequate penetration for a general abdominal survey to detect intraperitoneal fluid in the upper peritoneal compartments. Where access is difficult, sector transducers may be useful. High-resolution linear arrays (5–7.5 MHz) are best for evaluation of superficial peritoneal implants or omental abnormalities.

Intraperitoneal fluid collections

Sonography excels in demonstrating even minute quantities of intraperitoneal fluid (Fig. 129.21). With endovaginal scanning, small amounts of intraperitoneal fluid may routinely be demonstrated in the cul-de-sac as a normal finding in ovulating women. In the upper abdomen, free intraperitoneal fluid first collects in the hepatorenal fossa, which is the most dependent portion of the supramesocolic peritoneal cavity [195]. As fluid increases within the peritoneal cavity, it involves the subphrenic, subhepatic, and intraloop compartments [196]. Massive ascites typically displaces bowel loops centrally unless tethered by adhesions [197].

Uncomplicated serous fluid collections are typically anechoic. On sonography, complex fluid characteristically demonstrates internal debris, septations, and low-level echoes. The differential diagnosis of complex intraperitoneal fluid includes hemorrhage, infection, or carcinomatosis. On occasion, longstanding bland ascites may contain internal septations and be loculated. However, ascites that is not infected generally has no mass effect and passively conforms to its intraperitoneal components. Intraperitoneal abscesses, by contrast, typically exhibit mass effect and may displace adjacent bowel and or adjacent solid organs. It is not always possible to differentiate loculated bland ascites from an abscess by sonographic criteria alone. Therefore, diagnostic needle aspiration is often required.

Intraperitoneal abscesses

Computed tomography and sonography have greatly facilitated the diagnosis of intraabdominal abscesses [198–201]. With both modalities the predominant finding is a localized fluid collection with mass effect. Gas bubbles or an air–fluid level may be present in some patients, but are not identified in the majority of intraabdominal abscesses. Sonography is the imaging method of choice for hepatic, pericholecystic, and pelvic abscesses, whereas CT is superior to sonography in patients with pancreatic, retroperitoneal, paraspinous, intraloop, or gas-forming abscess [199]. In the postoperative setting, CT is often preferred to sonography because of frequent problems with access as a consequence of open wounds and surgical drains.

The sonographic appearance of intraabdominal abscesses is variable and depends on the presence or absence of septations or solid debris [201]. Also, there is considerable overlap with the sonographic appearance of other complex intraperitoneal fluid collections such as lymphoceles, bilomas, pancreatic pseudocysts, postoperative seromas, and hematomas. Because of the attenuation of sound by proteinaceous debris, many intraabdominal abscesses demonstrate little if any enhanced through transmission of sound. Thus, an intraabdominal abscess may sonographically mimic a solid hypoechoic mass [201]. This pitfall should always be kept in mind in a febrile patient. Color Doppler may be of value in resolving this dilemma as liquefied abscesses lack internal vascularity. Intraabdominal enteric abscesses are often "walled-off" by adjacent mesenteric or omental fat. In some patients, it may be possible, with sonography, to identify adjacent abnormal bowel to identify the cause of the abscess (i.e., appendicitis or diverticulitis). Both CT and sonography may be valuable for guidance of percutaneous needle aspiration for confirmation of an abscess and subsequent catheter insertion for definitive therapy [198].

Tumors of the peritoneum, mesentery, and omentum

The most common intraperitoneal neoplasms are metastatic carcinomas. The majority of these lesions are tiny plaque-like implants on the surface of the bowel or mesentery that cannot be imaged with any diagnostic techniques. In the presence of ascites, peritoneal implants may be detected by sonography as solid masses arising from the peritoneum or mesentery surrounded by peritoneal fluid (Fig. 129.21). Thickened septations may also be demonstrated sonographically. Diffuse infiltration of the omentum is a characteristic finding in patients with ovarian metastases, carcinomatosis from GI tract malignances, and primary omental tumors. Primary neoplasms involving the omentum, such as mesothelioma, can be imaged with graded compression sonography using high-frequency linear array transducers [202]. Diffuse omental infiltration ("omental caking") typically results in a broad band-like mass anterior to the transverse colon. Because of their superficial location, these abnormalities are often best imaged with high-resolution linear array transducers.

Pseudomyxoma peritonei, an unusual form of peritoneal carcinomatosis caused by mucinous adenocarcinomas of the appendix, ovary, or colon [203], results in gelatinous intraperitoneal masses that cause subtle scalloping of solid viscera such as the liver and spleen. Echogenic intraperitoneal masses containing debris may be detected sonographically.

Mesenteric masses may often be best imaged with sonography using a graded compression technique and color Doppler imaging. Adenopathy with the dorsal and ventral leaves of the mesentery may be noted to encase the mesenteric vessels highlighted by color Doppler. Primary mesenteric and peritoneal tumors such as mesothelioma cannot be distinguished from the more common metastatic peritoneal tumors.

Intraoperative ultrasonography

The information obtained by intraoperative ultrasonography (IOUS) and laparoscopic ultrasonography (LUS) often has a direct impact on clinical management and choice of surgical procedures at the time of surgery [204]. The demand for IOUS has grown steadily, and the proliferation of minimally invasive surgical techniques has led to increased utilization of LUS. The latter can provide both diagnostic information as well as guidance for interventional procedures, such as biopsy, aspiration, and tumor ablation [205].

Indications

In gastroenterology, IOUS is most often used in evaluating patients who are candidates for surgical resection of primary or metastatic hepatic malignancies [206]. Formerly, IOUS was far superior to conventional preoperative imaging, including CT and MRI, routinely detecting 25%–30% more lesions than on preoperative studies [207]. However, with the development of faster MRI, and multidetector CT and PET scanning, the percentage of additional lesions picked up by IOUS has diminished to approximately 10% [37–39]. Intraoperative ultrasound of the liver is important in defining the precise anatomical location of tumors to help decide the extent of resection. It is used in adult living related liver transplantation to define the avascular plane of resection when harvesting the donor right lobe.

Laparoscopic ultrasound is often used to assess pancreatic neoplasms, chiefly to look for signs of unresectability (e.g., vascular invasion, liver metastases) prior to commitment to open laparotomy. Intraoperative ultrasound may be helpful in localizing nonpalpable islet cell tumors, evaluating cystic pancreatic malignancies, and helping with surgical drainage procedures in chronic pancreatitis. Moreover, LUS is useful in evaluating choledocholithiasis, inflammatory and neoplastic biliary tract diseases. Both IOUS and LUS can provide accurate guidance for interventional procedures, including biopsies, aspiration of cysts, drainage of pseudocysts or abscesses, and guidance for a variety of tumor ablation techniques.

Patient preparation and technique

No patient preparation is needed for IOUS beyond that required for surgery itself. For the liver and intrahepatic bile ducts, a 5-MHz T-shaped side-fire probe is best because it can penetrate the entire liver, often 12–15 cm in depth. The liver is usually imaged from the anterior surface because it is accessible and provides a smooth scanning surface. The pancreas and extrahepatic biliary tract are better imaged with end-fire probes with frequencies up to 7.5 MHz, because the depth is much less than with the liver. Laparoscopic ultrasound probes can be either linear or curvilinear arrays, and must be small enough to fit through a standard 10–11-mm laparoscopic port; they range from 5 to 7.5 MHz, depending on the target organ being scanned.

All intraoperative transducers must either be sterilized or covered with sterile sheaths, which must cover the entire electrical cord [208]. Direct sterilization (if allowed by the manufacturer) is preferable to the use of sheaths, which take time to apply and may tear during the procedure. Sterile gel or sterile saline must be applied inside the sheath for acoustic coupling with the transducer. Natural moisture on the intraabdominal organs is usually sufficient for acoustic coupling, but warmed sterile saline can be also used.

Liver

The principal uses of liver IOUS include:

- detection of occult primary or metastatic tumors
- demonstration of lobar and segmental anatomy, vascular supply, and any anomalous or accessory vasculature
- determination of resectability and guidance for planning appropriate lobar, segmental, or nonsegmental wedge resections
- guidance for biopsy, aspiration, or therapeutic ablation.

The superb spatial resolution of IOUS and LUS allows for consistent imaging of cysts as small as 1–3 mm and solid nodules as small as 3–5 mm. This spatial resolution is slightly better than the usual lower limit of 5–10 mm for detection of solid lesions by preoperative imaging techniques. Most of the additional IOUS-detected lesions will be extremely small, subcentimeter nodules that frequently cannot be visualized or palpated by the surgeon.

Many lesions that IOUS detects are unrelated to the patient's primary or metastatic neoplasm. These include hemangiomas, cysts, bile duct hamartomas, focal nodular hyperplasia, and focal areas of sparing in fatty livers. Usually, these lesions are distinguishable from malignancy, but if questions persist, IOUS-guided biopsy can be readily obtained.

Demonstration of the relationship of tumors to the hepatic vasculature by IOUS may be important in determining tumor resectability. Hepatocellular carcinoma frequently invades the portal or hepatic veins. This can be demonstrated by IOUS and confirmed by IOUS-guided biopsy. Surgeons strive for a 1-cm tumor-free resection margin, and the demonstration by IOUS of the tumor boundaries may influence the extent of resection. Demonstration of standard or anomalous hepatic vasculature may be of critical importance during donor hepatectomy for adult living related transplantation procedures.

Guided biopsies and aspirations are usually performed freehand using the IOUS images to define the accurate placement of the tip of the biopsy or aspiration devices. Guidance by IOUS or LUS is indispensable for successful intraoperative tumor ablation techniques [209]. For cryosurgery, guidance is important both for placement of the cryoprobes as well as real-time monitoring of the expanding cryolesion to ensure that the cryoablation margin extends beyond the tumor into

the surrounding liver. For ethanol ablation and hyperthermic ablation techniques, IOUS guidance is critical for accurate placement of the needles and probes [210], although the microbubbles generated during the actual ablation make it more difficult accurately to assess the ablation margins because of scatter of the ultrasound waves.

Pancreas

As with liver imaging, improvements in CT, MR, and radionuclide imaging have changed the role of pancreatic IOUS. Whereas formerly, IOUS was by far the most accurate technique for localizing islet cell tumors [211], the vast majority of these tumors are nowadays accurately identified and localized with preoperative imaging. Most islet cell tumors are homogeneous and hypoechoic when compared with the more highly echogenic background of the pancreas [212]. These lesions are usually hypervascular, and color Doppler imaging may be helpful in lesion detection. Insulinomas are usually solitary, benign, and hypoechoic [213], but when performing IOUS for evaluation of islet cell tumors, a complete study should also involve imaging of the liver and the periportal and peripancreatic beds for evidence of metastatic disease. Metastases are more frequently found in other forms of islet cell tumors, such as gastrinomas, glucagonomas, and VIPomas. Gastrinomas may frequently be found in extrapancreatic locations, in the so-called "gastrinoma triangle" between the head of the pancreas, duodenal sweep, and root of the mesentery, including locations within peripancreatic lymph nodes and even within the wall of the adjacent duodenum [214]. The role of IOUS is primarily to identify those nonpalpable small islet cell tumors for the surgeon to facilitate an appropriate and complete tumor resection.

For pancreatic ductal adenocarcinoma, preoperative imaging techniques are fairly accurate in defining unresectability as a consequence of invasion of critical vascular structures. Laparoscopy is often performed to search for small peritoneal or surface liver metastases to avoid unnecessary open surgical procedures for those with incurable pancreatic carcinoma. Laparoscopic ultrasound can evaluate the liver for occult metastases beneath the surface, and search for signs of unresectability due to vascular invasion [214,215].

Intraoperative ultrasound is also useful for assessing cystic neoplasms of the pancreas and intraductal papillary mucinous neoplasms (IPMN). Imaging findings may be helpful in distinguishing serous microcystic cystadenomas from the more likely malignant mucinous cystadenomas and cystadenocarcinomas [216]. The mucinous lesions are more likely to have thick septations, mural nodules, or other solid components. In IPMN, intraductal papillary masses can be demonstrated, as well as small side branch cysts, which may help to define the total extent of the neoplasm and help select the best resection plane [217]. For more benign-appearing cystic neoplasms, IOUS may demonstrate the relationship of the tumor to the common bile duct or pancreatic duct and may allow for conservative wedge resections if the lesion is sufficiently distant from these structures.

In patients undergoing surgical drainage procedures for pancreatitis, IOUS may be helpful to guide pseudocyst drainage [218]. The size, extent, internal contents, and site of origin of pseudocysts and other peripancreatic fluid collections can easily be demonstrated, and real-time guidance may facilitate drainage of these collections. The pancreatic duct can be well visualized by IOUS. Color Doppler imaging may also be important in evaluating fluid collections for the presence of pancreatitis-associated pseudoaneurysms.

In patients with chronic pancreatitis and focal masses, IOUS may allow for definition of "a mass within the mass," which would be suggestive of concurrent pancreatic carcinoma. These masses may be difficult to palpate because of surrounding fibrosis, and IOUS-guided biopsy can be important. Patients with chronic pancreatitis refractory to medical treatment may undergo a Puestow (pancreaticojejunostomy) drainage procedure. Identification of the dilated pancreatic duct and selection of the appropriate site for pancreatotomy can be difficult because of fibrosis and calculi. Intraoperative ultrasound can facilitate placement of a needle, guide wire, or surgical instrument into the pancreatic duct [219], which can then be used as a visual guide to assist in the surgical drainage procedure.

Biliary tract

In patients undergoing resection for gallbladder carcinoma, IOUS is useful to evaluate the depth of invasion of tumor into the contiguous liver, thereby helping to decide the extent of hepatectomy. Careful scanning of the liver and contiguous lymph node bed is important to identify metastatic disease, which would obviate curative surgery [220].

Intraoperative ultrasound of the bile ducts is at least as good as standard intraoperative cholangiography [221], and LUS may be preferable to laparoscopic cholangiography, in both its ease of performance and accuracy [222]. In most instances choledocholithiasis is diagnosed with preoperative imaging and frequently treated with endoscopic sphincterotomy and stone retrieval. As a result, the routine use of IOUS or LUS for common duct stones is not favored because of the low yield of positive studies [223].

In patients with the Klatskin-type cholangiocarcinoma, IOUS can provide indispensable information regarding tumor resectability. With IOUS defining the full extent of tumor, appropriate decisions can be made regarding radical hepatic resections, in contrast with conservative biliary drainage procedures in patients with bilobar disease [224]. When bilobar tumor prevents surgical resection and hepaticojejunostomy, IOUS can be used to identify the largest dilated peripheral bile ducts, which may be suitable for internal drainage. Similar information can be obtained by laparoscopic ultrasonography,

thereby avoiding unnecessary laparotomies in patients who are unresectable because of the extent of disease [225]. These patients can then be better palliated by percutaneous catheter biliary drainage. We have also found IOUS useful in the surgical approach to patients with segmental Caroli disease and recurrent pyogenic cholangitis, by accurately defining the extent of disease and affected ducts and segments, including visualization of tiny intraductal stones, which may be missed with preoperative imaging studies.

Miscellaneous

Some authors have advocated laparoscopic ultrasound for staging tumors of the esophagogastric junction and stomach. Laparoscopy is useful in these patients to visualize peritoneal metastases or small surface liver metastases [226], and a small percentage of this group had subsurface liver metastases that could only be discovered by LUS [227]. However, the discovery of deep liver lesions on LUS requires biopsy confirmation to diagnose metastatic disease, because incidental benign liver nodules are frequently encountered. Laparoscopic ultrasound-guided liver biopsies are technically feasible but difficult and not always successful. An analysis of the contributions of LUS for staging gastrointestinal malignancies concluded that the additional value of LUS to laparoscopy was small [228].

B IMAGING

130 Endoscopic ultrasonography

Sanjay B. Jagannath, Marcia I. Canto

Technical considerations, 3113
Equipment, 3115
EUS imaging: general considerations, 3116
EUS in common clinical scenarios, 3118

Endoscopic ultrasonography (EUS) is an established diagnostic and therapeutic modality in gastroenterology with increasing widespread use. Although most gastroenterologists are not trained in the practice of EUS, it is important that they all understand the principles of the technique and the indications (diagnostic and therapeutic) for EUS to offer optimal patient care.

This chapter outlines the principles of EUS, provides a brief overview of the equipment, and details the indications for EUS in commonly encountered clinical scenarios. Particular attention is paid to the role of EUS and EUS-guided tissue sampling in relation to other imaging modalities. This is not a comprehensive chapter on the practice of endosonography and the authors recommend that anyone interested in learning EUS should review textbooks dedicated to the practice of EUS and to seek out an established EUS training program.

Technical considerations

Basic properties of sound waves

EUS is the addition of an ultrasound transducer to the tip of an endoscope, which allows ultrasound-generated imaging of the gastrointestinal tract and adjacent anatomical structures. The ability to image in real time from inside the gastrointestinal tract has led to diagnostic and therapeutic indications. A basic knowledge of the principles of ultrasonography is required to understand EUS. Chapter 129 is a detailed review of sonography, and this section reviews those ultrasound principles related to EUS generation and interpretation.

Sound is mechanical energy generated in the form of vibrations as they propagate through a medium such as air, water, or tissue [1]. The frequency of a sound wave is measured in Hertz (1 Hz = 1 cycle/s) and the ultrasound frequency used in medical technology is in the range 1–30 MHz (1 MHz = 1 000 000 cycles/s). The velocity of an ultrasound wave is a product of the frequency and wavelength, and the velocity in a specific tissue depends on the acoustic impedance of that particular tissue. Hence, each tissue, based on its density and elastic properties, propagates sound waves at a particular velocity. Tissues with similar acoustic impedance will propagate similar amounts of sound waves, whereas tissues with different acoustic impedance will reflect the majority of sound waves. Air, bone, and fat have different acoustic impedances compared with soft tissue [2].

Ultrasound waves interact with tissue in four ways: reflection, refraction, scattering, and absorption.

- Reflection is when the sound wave strikes a surface at a nonperpendicular angle and is thus reflected at an angle equal to the angle of incidence. If a sound wave encounters a medium interface with different acoustic impedance, a proportion of the ultrasound waves will be reflected back to the transducer while the remainder of the waves will be transmitted to the second medium.
- Refraction is the amount of bending the transmitted wave experiences. This occurs when there is a difference in the acoustic velocities of the incident and transmitted mediums, and is analogous to light traveling though a prism.
- Scattering occurs when a propagating ultrasound wave interacts with different components in a tissue that are smaller than the wavelength and with different acoustic impedance than the propagating medium. When scattering occurs, only a small portion of the scattered wave is reflected back to the transducer. Examples of scatterers include collagen, fat goblets, and individual cells [1].
- Absorption is when tissue assimilates the ultrasound wave and generates heat. Higher frequencies cause more tissue vibration resulting in greater absorption of the ultrasound energy and more heat generation.

Components of an echoendoscope

The main components of an EUS system include the transducer, processor, and display monitor. A transducer is a device

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

that generates the ultrasound pulse by converting electrical energy into mechanical energy. The piezoceramic element is the component responsible for the conversion of energy. The piezoelectric crystals vibrate when an electrical impulse is applied to them, generating an ultrasound wave that is propagated toward the surrounding tissue. A proportion of the ultrasound waves are reflected back to the transducer and subsequently converted back into an electrical impulse that is processed and displayed as an image on the monitor. The intensity of the returning echoes determines the brightness of the pixels on the screen, thus generating shades of black and white [2].

There are two types of the transducers, single element and phased array. Single-element transducers are mechanically rotated 270°–360° on an axis that is perpendicular to the axis of the endoscope; these are referred to as mechanical echoendoscopes. This is in contrast to phased-array transducers, where the piezoceramic crystals are stimulated by electric pulses sweeping along the long axis of the endoscope; these are referred to as electronic echoendoscopes [2].

The processor controls the transducer and amplifies the returning signal. When a transducer is perpendicular to the reflected waves, the greatest quantity of echoes are garnered by the transducer and the resulting image is optimized. As a result of scattering and absorption (see previous section for details), echoes that are returning to the transducer from greater distances are attenuated. These weak signals may require amplification, i.e., time gain compensation (TGC). TGC allows the EUS operator to adjust the amplification (gain) of the signal at varying distances from the transducer. Increasing the gain will increase detection of weak echoes while sacrificing resolution [2]. The operator can also increase the frequency of the ultrasound, which improves the resolution of the image. However, higher frequencies result in greater ultrasound wave absorption and decreased penetration, which leads to a reduced range of imaging.

Principles of imaging

It is important that the endosonographer has a basic understanding of the characteristics involved in determining image quality and the various modes available for imaging. These characteristics include resolution and artifacts of imaging, and modes such as A-mode and B-mode scanning, and Doppler.

Spatial resolution (the ability to discriminate two points as separate) is vital for quality imaging. Axial resolution is the ability to discriminate between two points along the beam path and is dependent on the frequency of the ultrasound wave. Axial resolution is the most important property in imaging the layers of the gastrointestinal tract. Lateral resolution is the ability to discriminate between two points in the same plane perpendicular to the transmitted ultrasound wave [1]. To achieve optimal lateral resolution, the ultrasound beam from the object of interest must lie in the narrowest portion, termed the focal zone. Radial echoendoscopes have a fixed focal zone (1.5–3.5 cm), which requires that the operator manipulate the EUS endoscope such that the target being imaged is located within the focal zone. Electronic array echoendoscopes have a variable fixed focal zone that is adjusted using the processor [2].

Since EUS imaging and interpretation are performed in real time, the endosonographer must be able to recognize image artifacts. Ultrasound waves can interact with adjacent tissue and fluid to create artifacts of imaging. An artifact is any phenomenon that does not accurately represent the target being imaged. The most common image artifacts are listed in Table 130.1, and several of these are reviewed below. A trained endosonographer must accurately identify and interpret such artifacts, so as to provide an accurate assessment of the ultrasound image and procedure.

Reverberation can occur when a single ultrasound beam is bounced back and forth between the transducer and a highly reflective surface until the signal is attenuated beyond detection of the processor. This can result in a false image deep to the true image; this artifact can be mitigated using TGC [1,2]. Acoustic shadowing occurs when a large impedance mismatch is encountered by the ultrasound wave, and there is intense hyperechoic reflection at the surface associated with an anechoic signal beyond the interface. Acoustic shadowing is a phenomenon often seen when imaging calcified lesions, such as in chronic pancreatitis or gallstones. Acoustic enhancement is the relative increase in ultrasound transmission in structures beyond a fluid-filled structure, and is due to less attenuation of the ultrasound wave as it travels through a fluid-filled structure in comparison to the surrounding tissues. This is commonly seen in the gallbladder, urinary bladder, vascular structures, and cysts [2]. The mirror image

Table 130.1 Artifacts of ultrasound imaging

Reverberation: multiple reflections between transducer and a strongly reflective surface
Reflection (mirror image): an air–water interface acts as a mirror, placing image at deeper depth than in reality
Refraction: difference in the acoustic velocities of the incident and transmitted mediums, resulting in objects placed erroneously at locations different from their true location
Acoustic shadowing: large impedance mismatch results in hyperechoic signal at interface and anechoic signal beyond interface
Acoustic enhancement: enhancement of structure beyond a fluid-filled structure
Side-lobe artifacts: a hyperechoic signal within an anechoic structure that disappears with scope repositioning

artifact occurs in the setting of a highly reflective surface behaving as a mirror. The EUS machine places the image at a deeper depth than in reality, and is commonly seen when visualizing the rectum or intralumenal gas in the rectum.

Scanning is the processing of the received signal, which can be visualized in several imaging modes. The received signal is amplified (A-mode, or amplitude mode) by the processor to yield an A-mode signal. Most clinicians do not image using A-mode but it forms the basis of the most common type of imaging, B-mode. B-mode (brightness mode) scanning is created by processing a series of A-mode signals, the amplitude of the signal being reflected by the brightness of the dot on the display monitor. EUS systems generate images from a compound B-mode scan [1].

Doppler is a feature available on all EUS processors and takes advantage of the Doppler shift phenomenon. This states that an object in motion relative to the transducer will reflect an ultrasound wave at a different frequency relative to the frequency transmitted by the transducer. Hence, the returning wave reflected from an object moving toward the transducer will contain a higher frequency, and vice versa. The most common application of Doppler is imaging of blood flow, and assisting in the identification of blood vessels. Continuous-wave Doppler is the simplest configuration of Doppler ultrasound, consisting of a receiving and transmitting transducer. However, continuous-wave Doppler does not provide information about the depth at which the movement is occurring. Pulsed-wave Doppler consists of a single transmitting and receiving transducer that emits and receives a lengthy pulse wave and uses electronic gating to calculate depth information. Using pulse-wave Doppler with B-mode imaging is called duplex scanning. Color Doppler combines the principles of pulse-wave Doppler and shades of red or blue to reflect the relative velocities of blood flow. Immobile objects are represented on gray-scale B-mode imaging, and on this background, information regarding direction and relative velocity of blood flow are obtained. Power Doppler is the most sensitive Doppler for detecting blood flow, providing information on the presence of blood flow but no information on the relative velocity or direction of blood flow [1].

Equipment

Echoendoscopes can be broadly classified into two types, radial (or sector) and linear (convex array); each type is available with either a mechanical or electronic transducer. A variety of EUS catheter probes are available for imaging of small submucosal lesions and from within the biliary and pancreatic ducts. Along with the echoendoscope, the standard equipment must include an EUS processor, balloons, and needles for tissue sampling if fine-needle aspiration (FNA) is planned. This section focuses on the main types of echoendoscope and their uses. It does not focus on the specific competing products available for purchase in the market.

Radial echoendoscopes

Radial echoendoscopes provide circumferential views at right angles to the echoendoscope. The mechanical radial echoendoscope has been the workhorse of EUS by providing cross-sectional anatomical images with a 270°–360° field of imaging coupled with an oblique-viewing endoscope. Newer generations of radial echoendoscope include electronic array with forward-viewing endoscopic optics. The electronic technique allows for the addition of Doppler to the radial echoendoscope. A balloon is situated over the transducer tip to allow for water-filled acoustic coupling to the wall of the gastrointestinal tract, and imaging can be performed at a variety of frequencies from 5 to 20 MHz with a range of up to 12 cm (Fig. 130.1a).

Linear echoendoscopes

The linear echoendoscope provides an imaging view analogous to transabdominal ultrasonography. The ultrasound waves are transmitted in the same axis as the long shaft of the transducer, which allows for real-time therapeutic intervention, most commonly FNA. By advancing the FNA needle in the plane of the ultrasound wave, the endosonographer can visualize the needle in real time as it is inserted into the lesion for cellular acquisition. The linear echoendoscope has a 120°–180° field of imaging, and biopsy channel diameters range from 2.0 to 3.8 mm (therapeutic) (Fig. 130.1b).

Catheter probes

Ultrasound probes vary in their design and capabilities. They consist of a flexible shaft with a central wire that drives the rotation of the mechanical transducer at the tip. The transducer is surrounded by oil, which provides the acoustic interface with tissue, providing a 360° view. Techniques to improve probe-based imaging include close apposition of the probe to tissue with air aspiration, instillation of liquid into the gut lumen, use of a condom over the tip of the endoscope, and use of a balloon sheath over the probe. Catheter probes are available in various diameters (2–2.9 mm) and frequencies (12–30 MHz) [3–5]. A 2.9-mm guidewire-based EUS probe is available with imaging at 20 MHz that can be advanced via a side-viewing duodenoscope into either the biliary or pancreatic duct for intraductal imaging. The most common applications for catheter-based probes include assessment of small superficial lesions of the gastrointestinal tract, evaluation of submucosal nodules, and examination of pancreaticobiliary ductal pathology including choledocholithiasis and ductal strictures.

FNA needle

Various needles are available for use, ranging from 19G to 25G. The 22G needle is most often employed for FNA sampling

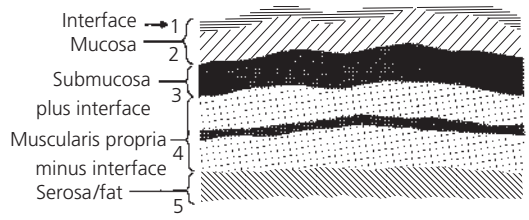
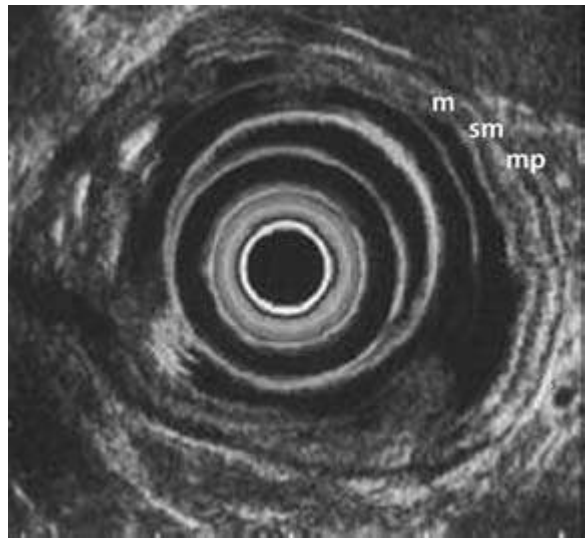
and the 19G needle is most often employed for therapeutic interventions, such as celiac plexus neurolysis and pancreatic pseudocyst drainage. There is no single needle diameter or technique that is proven to result in higher cytological yield [6]. The EUS Tru-Cut biopsy needle (Quickcore, Wilson-Cook, Winston-Salem, NC) is designed to provide core tissue sampling through a linear echoendoscope. Overall, studies demonstrate an equivalent diagnostic accuracy between the Tru-Cut needle and the traditional FNA needles; however, widespread experience with the Tru-Cut needle is lacking [7–11].

EUS imaging: general considerations

The ultrasound image of the normal gastrointestinal tract is dependent on the ultrasound frequencies used. Frequencies of 5–12 MHz produce five layers, while frequencies of 20–30 MHz depict seven to nine layers (Fig. 130.2) [12]. Most commonly, there are three echogenic layers separated by two echo-poor layers. The first echogenic layer, beginning at the mucosal surface, is thin and is produced by the interface between lumenal fluid or the balloon and the mucosa. The second layer is echo-poor and represents the remainder of the mucosa. This layer was formerly attributed to the muscularis mucosae; however, the normal muscularis mucosae is



(a)



(b)

Figure 130.2 The five layers of the stomach wall. **(a)** Normal five-layer endoscopic ultrasonography image of the stomach wall: m, mucosa; sm, submucosa; mp, muscularis propria. **(b)** The layers of the normal gastrointestinal wall as seen on ultrasound images. The ultrasound image comprises echoes arising from the anatomical layers and from the acoustic interfaces between tissue layers.

too thin to account for entire second layer [12]. The muscularis mucosae is usually obscured by an echo occurring at its interface with the lamina propria so that the location of the muscularis mucosae corresponds to the most superficial part of the third (submucosal) layer. If the muscularis mucosae is thicker than the interface echo, a separate thin hypoechoic layer is seen between this interface echo and the underlying submucosal layer [13]. The third ultrasound layer is easily recognizable because it is the most echogenic. This layer corresponds to the submucosa but is thicker because it also includes the interface between the submucosa and muscularis propria [12]. The fourth layer is echo-poor and corresponds to the muscularis propria. In areas with a well-developed inner circular and outer longitudinal muscle component, a small amount of connective tissue between the muscle layers may produce a line of echoes within the muscularis propria [12,13]. The fifth layer is echogenic but of variable thickness. If no subserosal fat or inflammation is present, this echogenic layer corresponds to the serosa and the interface between the serosa and the surrounding tissue. The layer can be thick in the rectum, where there is often abundant echogenic perirectal fat.

The appearance of organs in the mediastinum and abdomen is roughly similar to that seen by transcorporeal ultrasound, but often in greater detail. The posterior mediastinum, the aortopulmonary and subcarinal regions, portions of the heart, and the great vessels can be visualized with the transducer in the esophagus. The liver and spleen are homogeneous and of intermediate echogenicity; the liver can usually be differentiated from the spleen by the bright echoes adjacent to the intrahepatic portal venous branches.

The normal pancreas has a characteristic "salt and pepper" appearance (Fig. 130.3). The kidneys are easily recognized by the characteristic appearance of the urinary collecting system. In most patients, the left adrenal gland can be seen cephalad to the upper pole of the kidney as a seagull-shaped echo-poor structure. Large arteries and veins in the upper abdomen are key landmarks for orienting EUS images and include the aorta, celiac and superior mesenteric arteries, and the inferior vena cava and portal, splenic, and superior mesenteric veins.

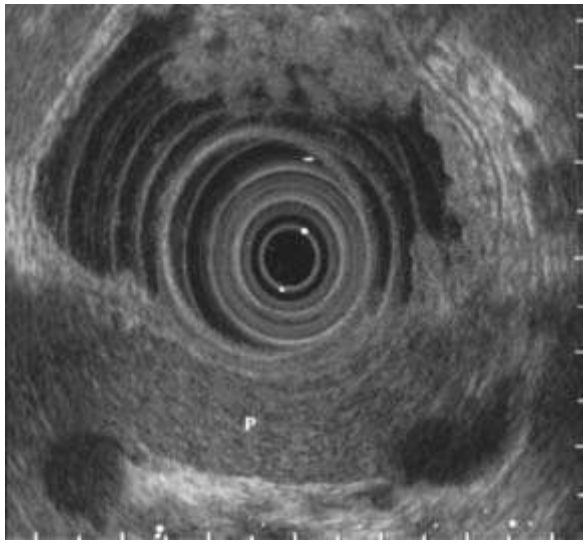


Figure 130.3 Normal pancreas. Radial endoscopic ultrasonography image showing characteristic "salt and pepper" pattern of the pancreas (P).

Efforts to differentiate malignant from benign lymph nodes by analysis of ultrasound features such as size, shape, echogenicity, internal echo pattern, and the character of their outer margin have been reported [14–16]. Malignant lymph nodes are usually echo-poor with sharply defined borders. The internal echoes from the nodes can be homogeneous or inhomogeneous. Benign nodes tend to have poorly defined boundaries and may be hyperechoic (Fig. 130.4). When nodes are over 1 cm in diameter, hypoechoic, and have a rounded distinct border, there is an 80%–100% probability of malignant involvement [17,18]. However, it is increasingly clear that the diagnosis of a malignant lymph node by

EUS appearance alone has limitations, which has led to the increased use of EUS-guided needle aspiration for pathological confirmation of suspicious nodes [6,19].

EUS in common clinical scenarios

Lung cancer

The annual incidence and mortality of lung cancer worldwide is estimated to be 1.35 million and 1.18 million respectively [20]. The prognosis and treatment depends on histology (small cell vs nonsmall cell), accurate assessment of mediastinal lymph node spread, and the presence or absence of T4 disease (tumor invasion into adjacent organs, central vessels, or vertebrae). Nearly half of patients diagnosed with nonsmall cell lung cancer (NSCLC) present with advanced disease. It is clinically relevant to differentiate malignant spread to the ipsilateral lymph nodes or subcarinal lymph nodes (N2, stage IIIA) from spread to the contralateral lymph nodes (N3) or T4 disease (stage IIIB). Although 5-year survival in stage III NSCLC is dismal, neoadjuvant chemoradiation for stage IIIA improves median survival [21–23].

In patients with suspected lung cancer, EUS can visualize the following lymph node stations: station 4L (left paratracheal), station 5 (aortopulmonary window), station 7 (subcarinal), station 8 (lower paraesophageal), and station 9 (pulmonary ligamentum). Since ultrasound cannot penetrate the air-filled trachea, EUS cannot reliably assess anterior mediastinal lymph nodes at levels 2R (upper paratracheal), 4R (lower paratracheal), 3 (prevascular, retrotracheal), and 6 (paraaortic) [24,25].

Posterior mediastinal assessment

The most common clinical indication for EUS in NSCLC is for mediastinal staging. Prior to the advent of EUS-FNA, patients underwent various procedures including bronchoscopy with transbronchial FNA, computed tomography (CT), positron emission tomography (PET), video-assisted thoracoscopy, and mediastinoscopy to accurately assess metastatic disease. EUS-FNA (as opposed to EUS alone) [18,26–28] provides accurate evaluation of the posterior mediastinum, and is complementary to those imaging modalities that assess the anterior mediastinum.

The performance characteristics of EUS-FNA have been reported in numerous studies [28–44] and a metaanalysis of over 1200 patients [25]. EUS-FNA for mediastinal staging or in suspected mediastinal malignancy has a pooled sensitivity of 83%, specificity of 97%, negative predictive value (NPV) of 78%, and positive predictive value (PPV) of 98%. EUS-FNA is more sensitive (88% vs 57%) and specific (91% vs 82%) than CT for the detection of suspected malignant lymph nodes [26,27], and detects malignant lymphadenopathy in 35% of patients without lymphadenopathy on prior CT. This reduces the number of patients requiring mediastinoscopy and exploratory thoracotomy [25,33,35,39,43] (Fig. 130.5).

Figure 130.5 Lung cancer. Endoscopic ultrasonography fine-needle aspiration of a lung mass.

Fluorodeoxyglucose (FDG)-PET and CT are comparably sensitive for the detection of enlarged mediastinal lymph nodes; however, in cases where lymph nodes are not enlarged on CT, FDG-PET had a higher sensitivity than both CT and EUS-FNA (82% vs 58%). Due to the false-positive rate of benign granulomatous disease on PET, a positive PET should be confirmed with tissue diagnosis. When available, EUS-FNA is a more accurate and a preferential alternative to "blind" transbronchial FNA [26,28,35,42,45].

EUS-FNA can assess intrapulmonary lesions in the posterior mediastinum. The accuracy of EUS-FNA for such lesions is 97%–100% [9,46], and EUS is more accurate than CT or PET for assessing T4 disease (sensitivity 88%, specificity 98%, PPV 70%, NPV 99%) [47]. CT and PET have limited sensitivity and specificity for T4 detection [48,49].

Impact on clinical care

The clinical impact of EUS-FNA in patients with NSCLC is its ability to accurately stage the posterior mediastinum, subsequently reducing the number of invasive mediastinoscopies and thoracotomies. EUS-FNA prevents further invasive staging procedures in up to 70% of cases [34,38,40,41,50,51]. The role for EUS-FNA in the clinical algorithm for NSCLC patients continues to evolve, but the general consensus is that it should be utilized early in the clinical staging algorithm since EUS, by itself, can demonstrate T4 disease or mediastinal metastases in 25% of patients regardless of CT findings [39,43]. PET, if available, should be performed before EUS-FNA.

The future staging of NSCLC is likely to involve endobronchial ultrasound (EBUS). Compared with CT and PET, EBUS with transbronchial needle aspiration has high sensitivity and specificity for mediastinal and hilar lymph node evaluation [52,53]. The challenge will be for bronchoscopists and endoscopists to integrate the two techniques efficiently and to work together to achieve complete mediastinal staging.

EUS-FNA plays a vital role in the management of patients with suspected NSCLC. Given that it is minimally invasive,

safe, more accurate than CT and transbronchial FNA, and more specific than FDG-PET, EUS-FNA impacts patient care by reducing the number of invasive diagnostic surgical procedures. Indications for EUS-FNA in the diagnosis and staging of NSCLC include the evaluation of mediastinal lymphadenopathy, identification of adjacent intrapulmonary lesions and diagnosis of T4 disease, and mediastinal FNA of PET-positive lesions, and should be the first invasive procedure performed after CT [54]. Since EUS cannot visualize the anterior mediastinal structures, it is most appropriate to proceed to mediastinoscopy if EUS-FNA is nondiagnostic. Mediastinoscopy provides evaluation of the upper and lower paratracheal regions (stations 2 and 4). In a comparison of EUS-FNA and mediastinoscopy, both procedures demonstrated a comparable accuracy rate of 90%, and the combination detected significantly more patients with lymph node metastases than either technique alone [40]. The role of EBUS remains to be clearly defined.

Esophageal cancer

It is estimated that in 2007, esophageal cancer will affect over 14 000 individuals in the USA and result in over 13 000 deaths [55]. The 5-year survival from esophageal cancer is 10%–15% [56]. Most patients present with locally advanced disease because there are few early signs or symptoms of the tumor, because the esophagus lacks a serosa, and because there is early spread to the lymph nodes since the esophageal submucosa has a rich plexus of lymphatic vessels.

The International Union Against Cancer and American Joint Committee on Cancer updated the guidelines in 2002 for staging esophageal cancer. The involvement of cervical or celiac axis lymph nodes is classified as metastatic disease (M1a or M1b, depending on tumor location). Tumor of the lower esophagus with celiac axis lymph node spread is classified as M1a disease, as is tumor of the upper esophagus with cervical lymph node involvement. Tumor of the mid esophagus with either cervical or celiac axis lymph node spread is classified as M1b disease, and also stage IV disease [57]. In general, early lesions (T1N0, T2N0) undergo surgery while presence of any lymph nodes usually mandates neoadjuvant therapy. Esophageal cancer patients who undergo EUS are associated with improved survival, probably due to accurate staging resulting in the use of stage-appropriate adjuvant therapy and surgical resection. [58].

Early esophageal cancer

Early esophageal cancer (carcinoma-in-situ or T1N0Mx) is most commonly detected in patients undergoing aggressive surveillance. When such lesions are identified, high-frequency EUS demonstrates excellent cross-sectional gastrointestinal tract images to assess T and N stage. In patients with Barrett esophagus with high-grade dysplasia or intramucosal carcinoma, EUS is more sensitive than CT for T and N stage. It can detect previously unknown submucosal involvement (sensitivity 100%, specificity 94%) and lymph node metastasis (sensitivity 100%, specificity 81%), and the absence of these findings on EUS is reassuring to physicians that the patient has early esophageal cancer or carcinoma-in-situ (NPV 100%) [59,60]. EUS confirmation of early malignant lesions allows nonoperative curative endoscopic ablative techniques, if desired.

Advanced esophageal cancer

Patients with locally advanced esophageal cancer should initially be evaluated with CT (and FDG-PET if available), searching for distant metastatic disease. The accuracy of CT ranges from 63% to 90% [61,62], and is not as sensitive in detecting small hepatic lesions or peritoneal metastases compared with diagnostic laparoscopy [63,64]. EUS can complement CT by improving the accuracy for M-staging by detecting cervical or celiac axis lymphadenopathy (M1a or M1b disease) [61], adrenal gland or liver metastases, or malignant ascites. FDG-PET is superior for detecting distant metastasis and nonregional lymph nodes compared with CT plus EUS (82% vs 64%), and may up-stage patients to stage IV [65–67] (Fig. 130.6).

The locoregional staging of a malignant esophageal stricture is a common indication for EUS. The overall accuracy of EUS for T-stage is 80%–85%, with highest accuracy in staging T3 and T4 disease [61,68–76]. EUS is superior to CT and PET for assessing T-stage of esophageal malignancy, and should be the test of choice.

Although less than 5% of T1m tumors are associated with nodal spread, 60% of T2 and more than 80% of T3/T4 lesions are associated with malignant nodal spread [77–79]. The presence and number of malignant lymph nodes portends poor prognosis and often shifts the treatment paradigm toward neoadjuvant therapy [80,81]. CT and FDG-PET are inferior to EUS in the evaluation of locoregional lymphadenopathy. The accuracy of CT is estimated to be only 51%–70% [61,82], and FDG-PET lacks the spatial resolution to differentiate local nodal involvement from adjacent primary tumor, and reactive inflammatory lymph nodes can lead to false-positive results. The sensitivity of PET for detection of N1 disease is approximately 33% [65].

EUS assessment of lymphadenopathy is accomplished by visualization and FNA. The accuracy of EUS in classifying a lymph node as malignant based on appearance is approximately 80% [17,18,57] and the overall sensitivity of EUS in detecting malignant lymphadenopathy ranges from 50% to 75% with an accuracy of 65% [17,18,61,75]. The accuracy is increased to 85%–93% with the addition of FNA [31,83]. It should be noted that when performing FNA of a lymph node, a false-positive sample can be obtained if the needle tract penetrates through primary tumor, thus contaminating the FNA sample. Hence, FNA of peritumoral lymph nodes may not be always feasible. Common hiding places for metastases from esophageal malignancies are the region above the aortic

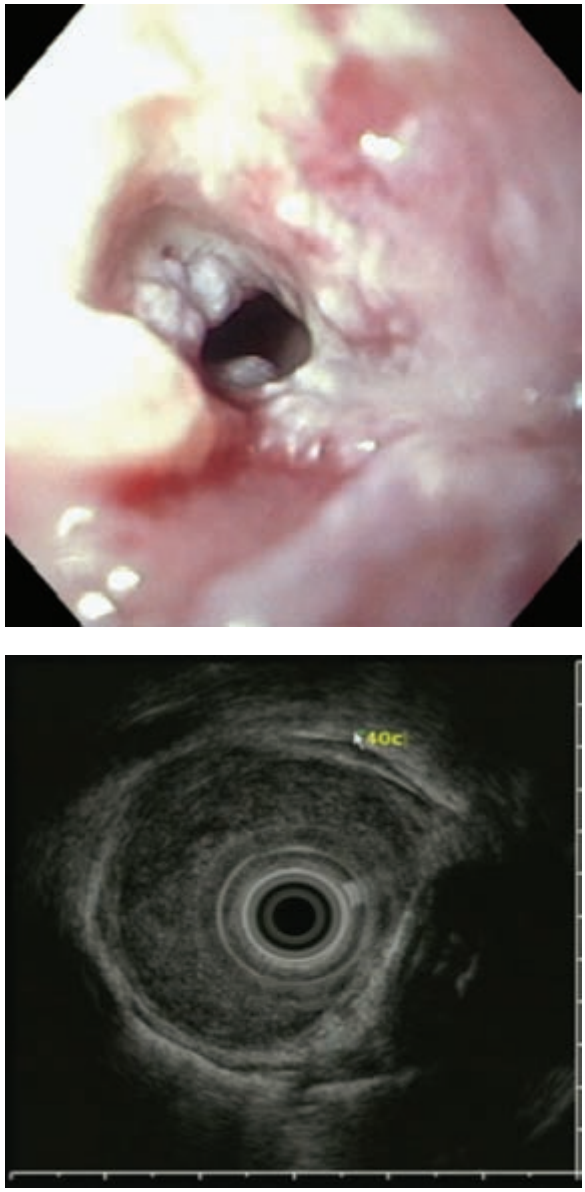

Figure 130.6 Esophageal cancer. **(a)** Carcinoma of the esophagus causing a malignant stricture. **(b)** Endoscopic ultrasonography image of esophageal carcinoma (T4) with pleural invasion.

arch (outside the cervical esophagus), the gastrohepatic ligament, and the celiac axis region.

A common clinical scenario is the nontraversable malignant esophageal stricture, where the standard echoendoscope is unable to pass beyond the stricture without prior dilatation to 14–16 mm. Although perforation is a risk, dilation can be performed safely, and is indicated. Wallace and colleagues reported that 32% of their 132 patients required dilation for adequate staging, and only one patient suffered a perforation. In addition, 19% of patients would have been under-staged if dilation had not been performed [84]. In cases when the stricture is so tight that dilation and passage of the standard echoendoscope is not feasible, a catheter ultrasound probe or an over-the-wire esophagoprobe (Olympus MH-908, Tokyo, Japan) can be used [57]. Unfortunately, if celiac lymphadenopathy is detected, FNA cannot be performed.

Submucosal lesions

A submucosal lesion is an endoscopically visible, often incidental finding (i.e., a "bump") with normal overlying mucosa. The estimated prevalence of gastrointestinal submucosal findings is less than 1%, and is most commonly found in the stomach [85,86]. EUS is well suited for evaluating submucosal lesions because of its ability to visualize gut wall layers and abdominal structures and to safely perform FNA. Table 130.2 lists the common etiologies of submucosal gastrointestinal lesions and their descriptive EUS features.

Causes of extrinsic compression include adjacent organs, bowel, blood vessels, retroperitoneum, omentum, and lymph nodes [85,87–95]. The frequency is approximately 30%. The accuracy of CT and transabdominal ultrasonography for differentiating between extrinsic compression and a true submucosal lesion is 22% and 28% respectively compared with an EUS accuracy of 100% [93].

After excluding extrinsic compression, the approximate frequency of gastrointestinal submucosal lesions is as follows: smooth muscle neoplasm (53%), aberrant pancreas (8%), carcinoid (6%), cystic lesion (7%), granular cell tumor (4%), lymphangioma or hemangioma (4%), Brunner gland hyperplasia (1%), malignant lymphoma (1%), and other (8%) [85]. Most smooth muscle neoplasms are gastrointestinal stromal cell tumors (GISTs), but older studies do not differentiate GISTs from other mesenchymal tumors.

When evaluating a submucosal lesion by EUS, a variety of clinical issues need to be addressed. In many cases, the endosonographic appearance and characterization of which gut layer(s) the lesion originates from will narrow the differential. However, issues regarding differentiation between benign and malignant lesions, role of FNA and surveillance of lesions need further clarification. Several of the submucosal lesions are discussed in further detail.

Gastrointestinal stromal cell tumor

Gastrointestinal stromal tumors, the most common mesenchymal tumors, arise from the interstitial cells of Cajal and often express a protooncogene called c-*kit*, which confers a gain-of-function mutation to such lesions. Immunohistochemical staining can differentiate GISTs from other related lesions [96]. Approximately 80% of gastrointestinal mesenchymal tumors are GISTs, and 10%–30% of GISTs are malignant [96,97]. All GISTs are considered to be potentially cancerous, and are stratified into low-, medium-, or high-risk category depending on tumor size and mitotic count. However, GISTs can be unpredictable, and low-risk lesions have been reported to metastasize [85,98].

Table 130.2 Etiology of submucosal lesions

Etiology	EUS layer	EUS appearance
Extrinsic compression	None	Normal gastrointestinal tract
Stromal cell tumor	Third/fourth	Hypoechoic, well circumscribed
Lipoma	Third	Hyperechoic
Carcinoid	Second/third	Homogeneous, hypoechoic
Granular cell tumor	Second/third	Homogeneous
Varices	Third	Anechoic, tubular
Cysts	Third	Anechoic, duplication of wall layers
Inflammatory polyp	Second/third	Hypoechoic, indistinct margin
Glomus tumor	Third/fourth	Hypoechoic, smooth margin
Metastatic deposits	Second/third/fourth	Hypoechoic
Lymphoma	Second/third/fourth	Distortion of wall layers
Heterotopic pancreas	Second/third/fourth	Hypoechoic, anechoic ductal structure

EUS, endoscopic ultrasonography.

Most GISTs are located in the stomach or duodenum [99] and under EUS appear as a homogeneous, hypoechoic, well-circumscribed lesion that originates from either the muscularis mucosae or muscularis propria (Fig. 130.7). EUS features suggestive of malignancy include tumor size more than 4 cm, an irregular extralumenal border, echogenic foci, and cystic anechoic spaces (suggestive of necrosis). If two of the four features are present, the sensitivity ranges from 80% to 100% for detecting a malignant GIST [100]. Additional notable features suggestive of malignancy include malignant-appearing lymph nodes, ulcerated mucosa, and nonoval shape [87,100–103]. The lack of these features does not rule out malignancy. FNA of suspected GISTs should be performed, when possible, and immunohistochemical staining is the only reliable method for diagnosing GIST. Approximately 90% of GISTs express CD117 (c-*kit*) and its presence confirms the diagnosis but does not assess malignant potential [104].

The question remains of how to manage an asymptomatic mesenchymal lesion, particularly if it is less than 1 cm in size, where the risk of malignancy is believed to be low. It may be useful to perform FNA on a small suspected GIST for immunohistochemical confirmation. Medications that target CD117-positive GISTs are available. There is no proven EUS-based strategy for optimal surveillance of suspected GISTs; however, a reasonable strategy may be annual EUS surveillance for small asymptomatic lesions without any features of malignant transformation.

Lipoma

Lipoma, a benign tumor composed of mature lipocytes, is most often asymptomatic. It appears as a well-circumscribed, homogeneous, hyperechoic lesion arising from the submucosa (third layer). FNA is not required to confirm the diagnosis as its appearance is pathognomonic [105,106].

Carcinoid

Carcinoids are slow-growing, premalignant, neuroendocrine tumors primarily found in the lung and gastrointestinal tract. Approximately 17% of carcinoids are found in the rectum and 3% are located in the stomach, both sites amenable to EUS evaluation. Sporadic gastric carcinoids tend to behave more aggressively than the multifocal gastric carcinoids seen in hypergastrinemic states.

The EUS appearance is a well-circumscribed, mildly hypoechoic or isoechoic mass arising from either the mucosa (second layer) or submucosa (third layer). EUS identifies carcinoid lesions amenable to endoscopic versus surgical resection [107–109].

Granular cell tumor

Granular cell tumors are uncommon lesions of neural derivation that appear endoscopically as yellowish mucosal or submucosal nodules. The majority of these lesions are less than 2 cm in size [110] and typically considered to be benign, although approximately 2%–3% of lesions are malignant [111]. Under EUS, these tumors appear as homogeneous, hypoechoic, well-circumscribed lesions originating from the mucosa (second layer) or submucosa (third layer) [112,113].

Stomach

Gastric cancer

Worldwide, gastric cancer accounts for approximately 10% of all malignancies, and in 2006 over 21 000 patients were diagnosed with gastric cancer in the USA [55]. Despite a reduction in mortality during the 1980s and 1990s, gastric cancer remains the second leading cause of cancer-related mortality worldwide [114]. A major clinical challenge is to diagnose gastric cancer in its early curable stages, a feat unfortunately rarely accomplished in the absence of a screening program. The Japanese have the most experience with early gastric cancer.

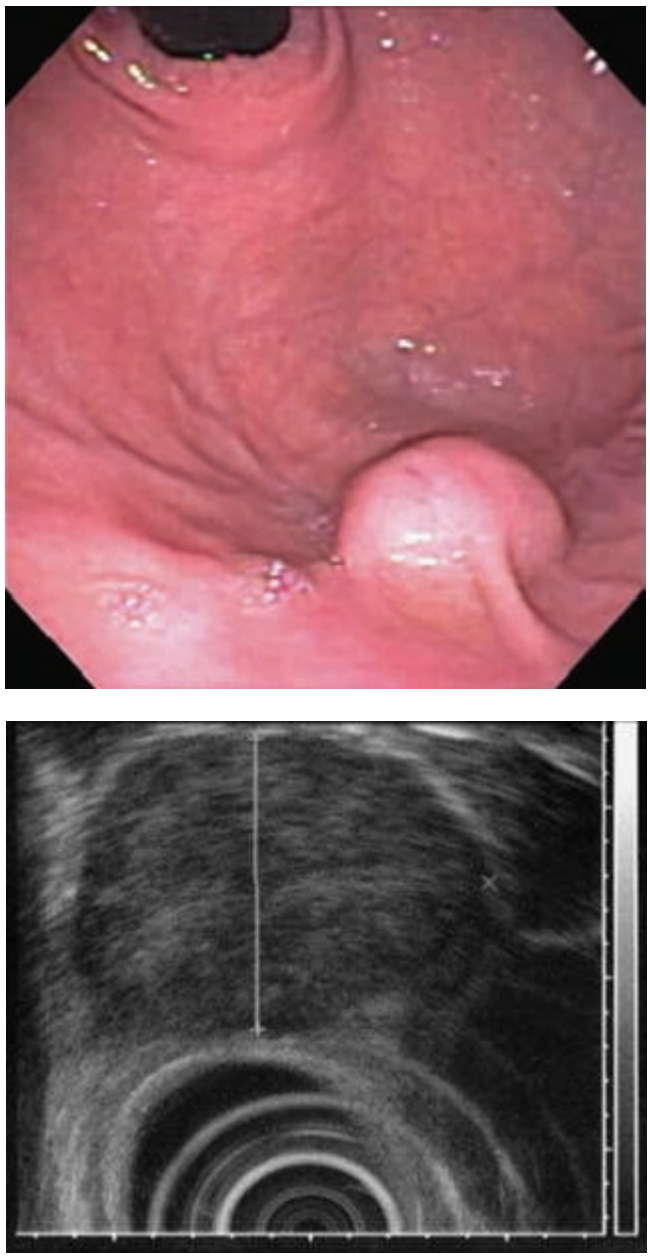

Figure 130.7 Gastrointestinal stromal cell tumor (GIST). **(a)** A submucosal lesion visualized on upper endoscopy. **(b)** Typical endoscopic ultrasonography appearance of a GIST.

They use the Japanese classification for management while worldwide the TNM system is most commonly used.

Because gastric cancer confined to the mucosa and submucosa can be treated with surgical resection, endoscopic mucosal resection (EMR), or endoscopic submucosal dissection (ESD), EUS plays a role in local staging. Cancers with involvement of only the mucosa (m) and submucosal invasion less than 500 μm (sm1) have negligible risk of metastasis and are ideal for EMR. Some conservative authorities advocate EMR and ESD only for lesions with mucosal involvement and less than 2 cm in diameter [115]. Stage T2 or T3 tumor is treated with surgical resection and T4 lesions are managed with neoadjuvant chemotherapy and radiation.

EUS is an accurate method for local staging of gastric cancer: it can visualize infiltrating scirrhous malignancies, which appear as diffuse thickening of the normal layers of the gastric wall, or assess tumor invasion based on disruption of wall layers [116–126] (Fig. 130.8). The accuracy of dynamic CT and magnetic resonance imaging (MRI) for T-staging is 50%–70% [127–131], whereas the overall accuracy of EUS for T-stage ranges from 70% to 93% [61,117,125,132–138]. In particular, the accuracy for detecting submucosal invasion has been reported to be as high as 90% with a highfrequency catheter probe [133,139]. EUS T-staging is lowest for T2 lesions (accuracy 60%–70%), and the difficulty is in differentiating between subserosal (T2) from serosal (T3) involvement, particularly since the entire stomach is not covered by a serosa.

EUS has long been the test of choice for assessing T-stage in gastric cancer; however, with the advent of multidetector CT and the advanced imaging techniques of MRI, the accuracy of T-staging among the different modalities has been reevaluated. Table 130.3 shows the performance characteristics of EUS, multidetector CT, and MRI in assessing tumor stage in gastric cancer. These imaging modalities appear to be equivalent, although the greatest expertise remains with EUS and further experience needs to be gained with multidetector CT and MRI [73,125,126,132,135,137,138,140–54]. A limitation of EUS is that depth of invasion may be overestimated if there is an ulcer scar or inflammatory reaction below the cancer (peritumorous inflammation) or a protruding lesion, and underestimated if there is microinvasion [123].

The overall accuracy of EUS nodal staging in gastric cancer ranges from 50% to 87% [73,124,125,132,136,137,140–143,145,151,155,156], and is highest for T3 and T4 lesions, for lymph nodes located within 3 cm of the tumor, and along the lesser curvature. Only 15% of T1 lesions are associated with malignant lymph nodes, but detection of these lymph nodes is critical, particularly if EMR or ESD is contemplated. The overall accuracy of EUS for detection of lymph nodes is approximately 69%, and FNA should be employed, if needed. Nodal staging with CT and MRI is not clearly superior to EUS [131,138,157,158].

Gastric wall layer abnormalities

EUS is indicated in the presence of thickened gastric folds. By definition, the gastric folds are considered thickened if they fail to flatten with endoscopic insufflation or if an upper gastrointestinal series or CT suggests a thickness greater than 1.5 cm [159]. The normal thickness of the gastric wall ranges from 0.8 to 3.6 mm [12] and is considered to be thickened when the diameter of the five-layer EUS image of the gastric wall is greater than 4 mm [160,161]. The differential diagnosis (Table 130.4) includes benign and malignant conditions. A clear diagnosis may not always be possible; however, based on the EUS origin of the lesion, the differential can be narrowed.

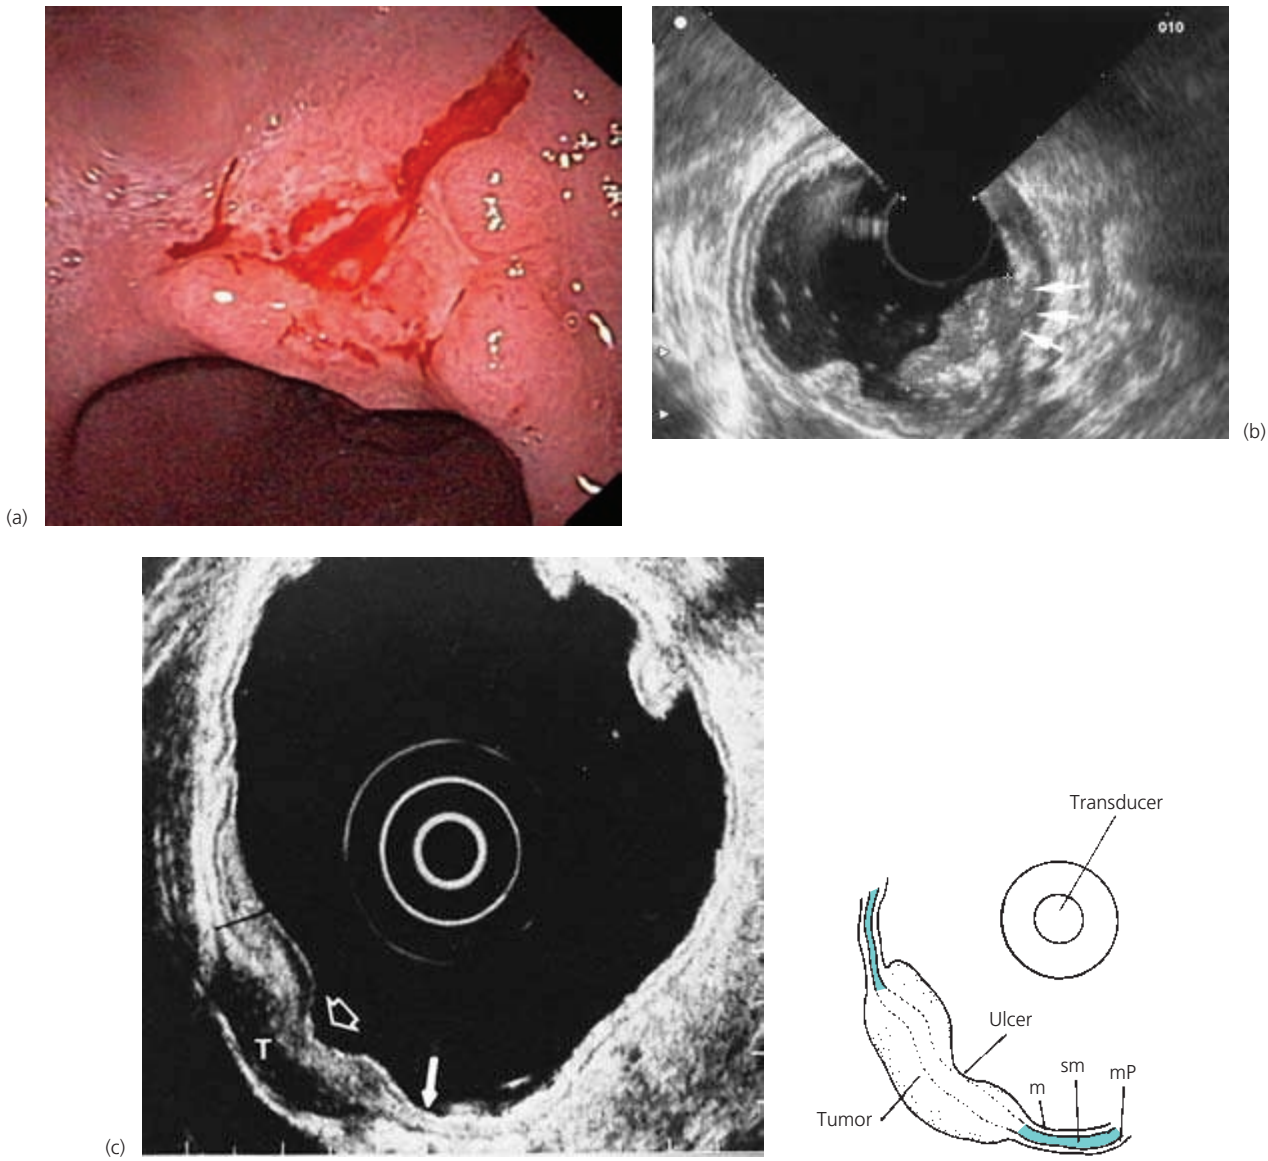

Figure 130.8 Cancer of the stomach. **(a)** Shallow gastric ulcer on upper endoscopy. **(b)** Endoscopic ultrasonography (EUS) of early gastric cancer. **(c)** EUS of advanced gastric cancer, showing raised borders with central ulceration (open arrow). The tumor mass (T) arises from the normal wall (arrow), where layers corresponding to the mucosa (m), submucosa (sm), and muscularis propria (mP) can be seen. The cancer invades the fat and other tissue around the gastric wall.

Table 130.3 Performance characteristics of various imaging modalities to assess T-stage in gastric cancer

Imaging test	Sensitivity (%)	Specificity (%)	Accuracy (%)
EUS	77.8–100	67.9–100	65–92.1
MDCT	82.8–100	80–96.8	77.1–88.9
MRI	89.5–93.1	94.1–100	71.4–82.6

EUS, endoscopic ultrasound; MDCT, multidetector computed tomography; MRI, magnetic resonance imaging.

Multiple studies have reported EUS findings in patients with large gastric folds [162–165]. The presence of gastric varices is diagnostic and biopsy specimens can be avoided. If EUS demonstrates abnormalities in layers 3 or 4, malignancy needs to be strongly considered, even if biopsies are negative [162,163]. Most cases with a scirrhous carcinoma have a thickened third and fourth layer [163], and the second and third layers can be thickened in benign or malignant conditions [163]. Endoscopic biopsy of an abnormality in layer 2 should be diagnostic and if biopsies are negative for cancer, follow-up studies report that malignancy will often not develop [162] (Fig. 130.9).

Metastatic disease

EUS can diagnose early infiltrative gastric lymphoma, which is typically a non-Hodgkin lymphoma. An early-stage lymphoma can be subtle in its endoscopic and endosonographic appearance, revealing only a thickened second layer with preservation of the gastric layers and endoscopically normal-appearing mucosa [166,167]. More advanced stages show a diffuse hypoechoic thickening with distortion of the gastric layers. The accuracy of EUS for staging gastric lymphoma is approximately 95% [141,168], and EUS can also be used to evaluate tumor response to chemoradiation [169–172].

Ampullary and pancreatic neoplasms

The role of EUS in the management of suspected ampullary or pancreatic neoplasms is to identify the lesion, assess for surgical resectability, and acquire cytological confirmation if needed.

Ampullary neoplasm

Ampullary adenomas, the most common tumors of the ampulla of Vater, can be sporadic or part of a genetic polyposis syndrome. They follow the adenoma–carcinoma sequence for neoplastic progression, [173] and identification of an asymptomatic precancerous lesion mandates further endoscopic intervention. The two major roles of EUS in this clinical scenario are to confirm the diagnosis of an ampullary tumor and to stage the adenocarcinoma.

Endoscopically, ampullary neoplasms appear polypoid or ulcerated, and can be associated with choledocholithiasis and marked inflammation [174–176]. The latter may result in false-negative biopsies or, in cases where the tumor is intramural, the inability to accurately diagnose the malignancy [175,176]. In as many as 19%–30% of cases, biopsies may not reveal the presence of adenocarcinoma [175–178] (Fig. 130.10).

EUS is more sensitive than CT or transabdominal ultrasonography for diagnosing ampullary neoplasm and more accurate than CT and MRI for staging early ampullary lesions [179–183]. Endosonographic features specific for malignancy include presence of tumor invasion (at least infiltration of the duodenal muscularis propria) or growth into the biliary or pancreatic ductal system. In the absence of clear invasive features, EUS cannot differentiate between malignant and nonmalignant conditions (e.g., odditis, inflammation, normal ampulla) [184]. EUS sensitivity is higher in symptomatic patients and patients at risk for adenomas.

Accurate staging is critical in the management of ampullary neoplasms, since endoscopic options are feasible in selected cases. According to the TNM classification used to stage ampullary neoplasms, T1 corresponds to tumors not extending beyond the sphincter of Oddi, T2 to tumors invading the muscularis propria of the duodenal wall, T3 to tumors with less than 2 cm of invasion into the adjacent pancreas, and T4 tumors deeply invade the pancreas or adjacent vasculature [185].

EUS is the most reliable modality for local preoperative staging of ampullary neoplasms, including assessing for portal venous involvement. It is superior to MRI, CT, transabdominal ultrasound, and angiography, regardless of whether the radial or linear echoendoscope is used [182,184,186–188]. Peritumoral pancreatitis due to the desmoplastic reaction of malignant cells can lead to under-staging of true T3 lesions or over-staging of true T2 lesions, but typically the surgical treatment for both lesions is identical [181]. The accuracy of EUS in determining whether endoscopic resection for a T1 lesion can be performed with curative intent ranges between 87% and 94% [180,181,186,189,190]. The Japanese staging system subdivides T1 lesions into do (tumors limited to the sphincter of Oddi) and d1 lesions (tumors extending into the submucosa). The prevalence of malignant lymph nodes varies from 0 to 30% in T1 tumors, with the highest risk associated with tumors that invade the submucosa [180,181,187,191].

Intraductal ultrasonography (IDUS) complements radial or linear EUS. Imaging at 20 MHz demonstrates the muscle

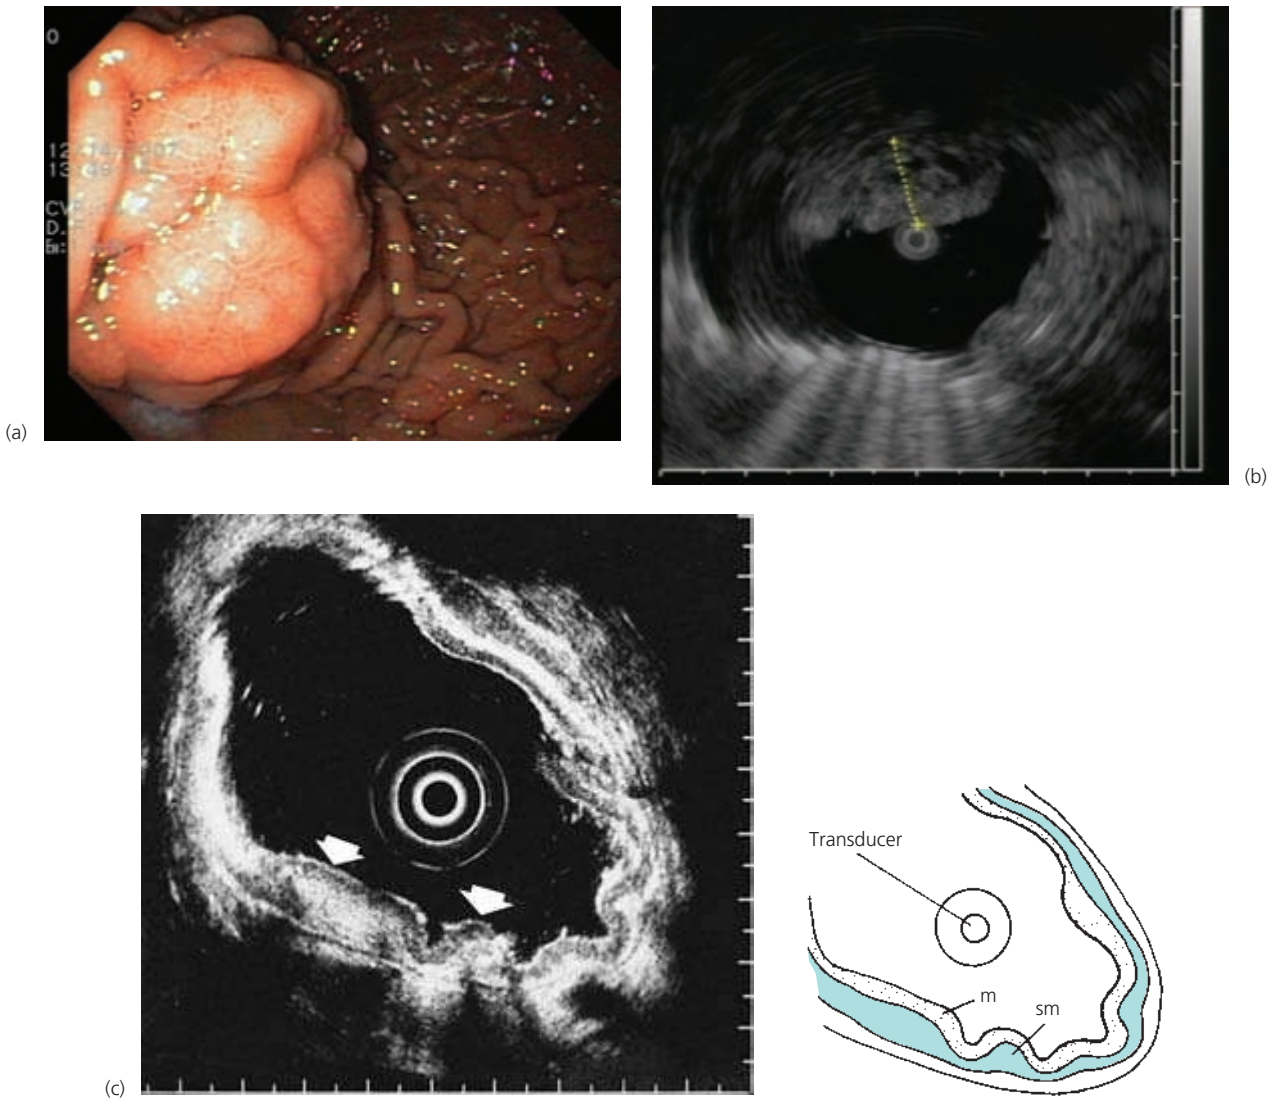

Figure 130.9 Gastric lymphoma. **(a)** A "mass-like" thickening of gastric folds is noted on upper endoscopy. **(b)** Catheter-based endoscopic ultrasonography demonstrates heterogeneous infiltrative lesion of the gastric mucosa and submucosa. Pathology confirms lymphoma. **(c)** EUS image showing thickening of ultrasound layers corresponding to mucosa (m) and submucosa (sm) in the region under arrows, caused by gastric lymphoma.

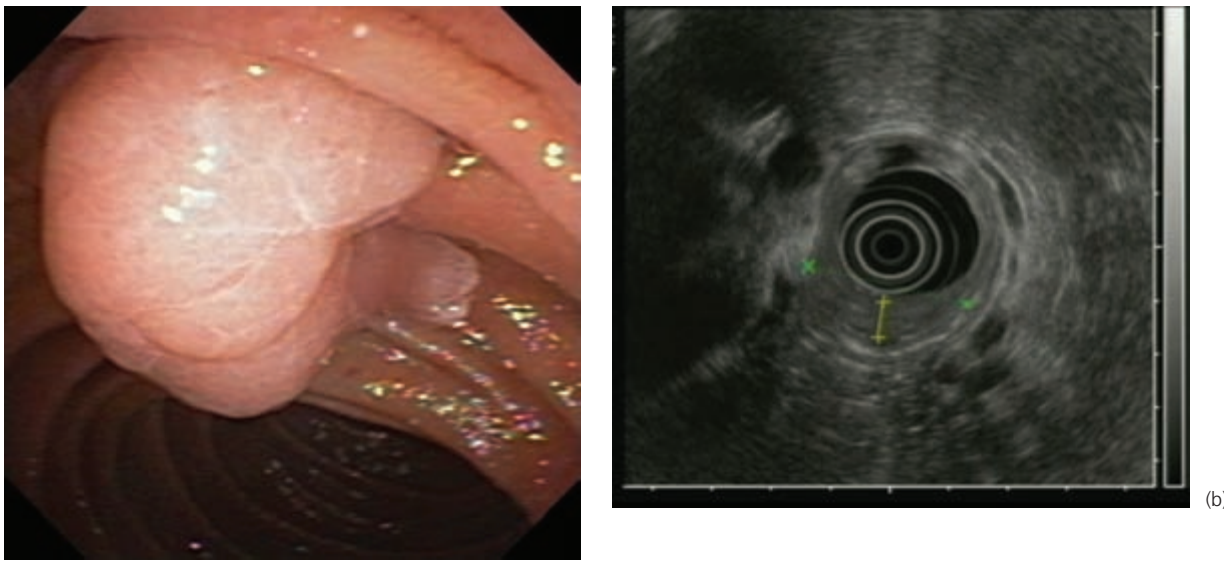
layer of the sphincter of Oddi as a distinct hypoechoic layer, which allows greater tissue layer resolution and the ability to discern d0 lesions from d1 lesions with an approximate accuracy of 89% [190]. IDUS is nearly 100% accurate in visualizing tumor invasion into the pancreaticobiliary ductal system [190]. The combination of EUS and IDUS is believed to provide the most accurate staging information, and reliably select candidates eligible for curative endoscopic ampullectomy versus surgical treatment.

Pancreatic neoplasms

One of the first targets for EUS imaging was pancreatic cancer. The early detection of this usually lethal neoplasm has eluded other diagnostic abdominal modalities such as transabdominal ultrasound. The increased spatial resolution of EUS allows detection of smaller resectable neoplasms in patients with vague symptoms [192] and is the most sensitive imaging modality for the detection of a pancreatic mass. Numerous studies have documented the high sensitivity (98%–100%) of EUS for detection of pancreatic tumors [193–204]. EUS may play a role in the screening of asymptomatic high-risk populations for early cancer detection [205–208].

As an imaging modality, EUS is not as widely available as transabdominal ultrasound, CT, and PET. Transabdominal ultrasound is inferior to EUS for detection of pancreatic masses, particularly those located in the pancreatic head or uncinate [184]. Despite the advent of multidetector CT [209,210], studies suggest that EUS remains a superior imaging modality, particularly for small lesions. Compared with multidetector CT, EUS is more sensitive (98% vs 86%) [201] and more



(a) (b)

Figure 130.10 Ampullary mass. **(a)** Endoscopic appearance of ampullary mass. **(b)** Endoscopic ultrasonography of ampullary mass limited to mucosa. Lesion treated with endoscopic ampullectomy.

accurate (94% vs 74%) [203]. In patients with indeterminate findings on CT, EUS has an accuracy of 92% for detection of a pancreatic tumor and an NPV of nearly 100% for excluding a focal pancreatic mass [211,212]. A normal EUS of the pancreas in the setting of subtle radiological findings, nonspecific symptoms, or laboratory values effectively rules out a pancreatic neoplasm.

MRI and PET may detect small pancreatic tumors; however, inflammatory conditions such as chronic pancreatitis can result in glucose uptake and false-positive PET [213,214]. The anatomical resolution from PET is inferior to CT and MRI for determining locoregional tumor spread; however, PET can identify distant metastases that can alter clinical treatment in up to 40% of patients with pancreatic cancer [215–217].

For locoregional staging of pancreatic cancer, multidetector CT and MRI provide excellent assessment of tumor staging, vascular involvement, and nodal staging [188,218,219]. Both modalities are superior to EUS for detection of metastatic disease, but EUS can provide information suggesting metastatic disease by detecting previously unknown hepatic metastases [220–224], small pockets of ascites [225], and malignant mediastinal lymphadenopathy [226]. These findings preclude surgical resection.

Vascular invasion generally precludes surgical intervention, with the possible exception of portal vein and superior mesenteric vein involvement [218]. The accuracy of EUS in assessing for vascular invasion ranges from 62% to 100% [182,202,218,219,227,228]. EUS is most accurate (> 80%) when assessing for invasion of the portal vein or portal vein/superior mesenteric vein confluence [188,192,229–231], and least accurate when assessing invasion of the superior mesenteric artery or vein and celiac axis [184,187,227]. On a practical level, optimal assessment of tumor invasion is accomplished with multidetector CT or MRI, and EUS if needed for clarification of the portal vein or superior mesenteric vein [232].

A common indication for endosonography is to obtain tissue diagnosis of an unresectable pancreatic mass (Fig. 130.11). If available, EUS-guided FNA of a pancreatic mass should be the preferred method for tissue acquisition. It has an approximate sensitivity of 85%, specificity of 98%, and accuracy of 88%. However, the NPV of EUS-guided FNA is 55%–80% [30,31,83,203,233–247]. Hence, a negative or nondiagnostic aspirate does not rule out the possibility of malignancy. This is of particular concern in patients who have underlying chronic pancreatitis, where the sensitivity of EUS for diagnosis of malignancy drops to approximately 55% [239]. In comparison with CT- or transabdominal ultrasound-guided FNA, EUS-FNA is equivalent in sensitivity but perceived advantages of the EUS approach include reduced risk of needle-track seeding [248–251] and improved patient comfort.

An on-site cytopathologist or technician should be present for FNA, which can improve diagnostic accuracy and reduce the number of unsatisfactory samples and repeat procedures [252]. If a cytopathologist is unavailable, the EUS physician should obtain five to seven specimens for cytological interpretation to maximize diagnostic yield [253,254]. The overall risk of complications from an EUS-FNA of a pancreatic mass is 0.5%–2% [30,83,245,255–257], with a higher complication rate for cystic lesions (14%) compared with solid tumors (0.5%) [83]. Complications of EUS-FNA include pancreatitis, perforation, bleeding, and infection.

Islet cell neoplasm

The anatomical localization of hormone-producing pancreatic tumors is important for guiding their surgical resection. Most of these neoplasms arise from islet cells within the pancreas, and conventional transcorporeal imaging with ultrasound and CT detects less than one-third of tumors. In particular, insulinomas are less likely to be detected by CT. MRI and selective arteriography may also fail to localize the neoplasm.

Careful examination of the pancreas with EUS detects about 77%–94% of islet cell neoplasms within the pancreas not found on CT or MRI [258–268]. Islet cell neoplasms are usually round, well-circumscribed, homogeneous, and hypoechoic compared with the surrounding parenchyma, and lesions as small as 5 mm in diameter have been imaged by EUS [258,268,269]. All patients diagnosed with a resectable pancreatic neuroendocrine tumor should undergo preoperative EUS and octreotide scanning to localize the neoplasm and facilitate surgical planning [270,271]. EUS-FNA is not required in the setting of a well-defined clinical syndrome and documented excessive hormone secretion.

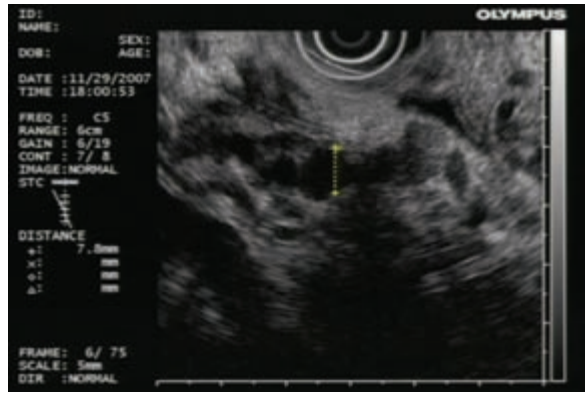

Figure 130.12 Chronic pancreatitis. Endoscopic ultrasonography image showing features of chronic pancreatitis and dilated main pancreatic duct.

Chronic pancreatitis

Chronic pancreatitis is an ongoing inflammatory process that results in irreversible destruction of pancreatic tissue leading to exocrine and endocrine insufficiency. It can be a diagnostic challenge, particularly in nonsevere cases when radiological imaging tests and functional diagnostic tests are equivocal or negative. There is no perfect test (imaging or functional) that accurately diagnoses early chronic pancreatitis, but EUS offers several advantages because of its minimal risk of causing pancreatitis and its ability to characterize both pancreatic parenchymal and ductal abnormalities (Fig. 130.12).

The endosonographic criteria and the histological correlates for chronic pancreatitis are listed in Table 130.5 [272–274]. Additional proposed criteria include gland contour (lobular vs smooth), echogenic foci with and without shadowing, and accentuation of the gland's lobular pattern [273,275]. Despite the specific terminology of these EUS

Table 130.5 Histological correlates for endoscopic ultrasonography (EUS) findings as related to chronic pancreatitis

EUS finding	Histological correlate
Parenchymal features	
Hyperechoic foci	Focal areas of fibrosis
Hyperechoic strands	Linear areas of fibrosis
Pseudolobule	Linear fibrosis containing focal edema
Cysts	Cysts or cyst side branches
Ductal features	
Main pancreatic duct dilation	Dilated duct
Side-branch dilation	Dilated side branches
Irregular duct contour	Periductal fibrosis
Hyperechoic duct wall	Periductal fibrosis
Stones	Calcified stones

features, the interobserver agreement for these features and the collective assessment of an EUS examination is only moderate [274] and clinical bias exists in the interpretation of the examination as it applies to each patient [276].

When evaluating the performance characteristics of EUS for the diagnosis of chronic pancreatitis, the best reference standard is pathological confirmation of the presence of inflammation, atrophy, or fibrosis, but only a few studies have tried to correlate EUS features of chronic pancreatitis with microscopic findings. Most studies have compared EUS with morphological tests such as CT, MRI/magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) and with the functional secretin test [276–280].

EUS has an approximate sensitivity and specificity of 85% and 75% respectively when ERCP is used as the gold standard to diagnose chronic pancreatitis [272,273,275,276,281]. Wiersema and colleagues enrolled 69 patients with suspected pancreatic pain and noted that the sensitivity and specificity of EUS was 80% and 86% respectively when three or more criteria were used [275]. Sahai and colleagues [272] performed EUS in a prospective blinded study of patients with unexplained pain who were referred for ERCP. They noted that patients with five or more EUS features correlated with at least moderate chronic pancreatitis on ERCP. Fewer than three features essentially ruled out moderate or severe chronic pancreatitis (NPV > 85%), and three to four EUS features was equivocal. However, three to four EUS features in patients with history of alcohol intake or pancreatic pain symptoms may be significant [272,282]. When compared with secretin testing, the overall sensitivity and specificity of EUS is 80% and 70% respectively [273,275,276]. Catalano and colleagues [273] compared EUS with ERCP and secretin testing in patients with recurrent pancreatitis. There was 100% agreement between EUS findings for normal pancreas (no EUS features of chronic pancreatitis were seen) and severe chronic pancreatitis (more than five EUS features) when compared with ERCP and secretin testing. For moderate chronic pancreatitis (three to five EUS features), there was 92% agreement with ERCP and 52% agreement with secretin testing [273].

It is unclear if focal chronic pancreatitis is a normal variant, a sign of focal fibrosis, or early malignancy. When the clinical suspicion and EUS features of moderate chronic pancreatitis are present throughout the gland, performing FNA does not improve the accuracy of the examination [283]. However, EUS-FNA should be considered in patients with focal chronic pancreatitis, despite the relatively low sensitivity of EUS-FNA in chronic pancreatitis (54%) [284]. A nondiagnostic FNA may eliminate an underlying malignancy, and careful follow-up is mandated in 1–3 months.

The EUS diagnosis of chronic pancreatitis depends on the threshold set for the number of positive criteria required to establish a definitive diagnosis. Changing the threshold affects the performance characteristics of EUS. In general, if less than two criteria are present, chronic pancreatitis is highly improbable. If three or four criteria are present, the test outcome is equivocal. If more than five criteria are present, the probability of chronic pancreatitis is high.

Pancreatic cysts and intraductal papillary mucinous neoplasms

Asymptomatic pancreatic cysts are increasingly recognized due to widespread imaging of the abdomen. While the majority of cysts are benign, approximately 10% represent cystic neoplasms [285,286]. Accurate characterization of the malignant potential of a pancreatic cyst remains challenging. EUS-FNA is often used in the management of such lesions. This section reviews the diagnostic accuracy of the various imaging modalities and recommends a current clinical algorithm.

The potential advantages of EUS and FNA include the ability to evaluate lesions for high-risk stigmata (e.g., thick septae and mural nodules) and to obtain specimens for cytological analysis and fluid for cyst fluid analysis. The EUS examination should note the following cyst characteristics: size; location (including relationship to adjacent vasculature); wall thickness; presence of focal wall irregularity, papillary projections, associated mass, or septae, echogenic debris or mucus; and dilation of the main pancreatic duct. Some of these findings are considered high-risk EUS features suggestive of malignant transformation; however, they do not reliably differentiate between benign and malignant cysts [287–291]. In addition, the absence of these features does not exclude the presence of malignancy.

When performing FNA, the recommendation is to undertake a single puncture, aspirate the cyst dry, describe the appearance of the aspirated cyst fluid, and analyze the cyst fluid for specific proteins, tumor markers, or genetic changes. All patients should receive antibiotic prophylaxis prior to FNA followed by 1–3 days of oral antibiotic treatment to theoretically reduce the risk of infection.

A multicenter trial [292] of 341 patients showed the accuracy of EUS morphology to be 51%, with the addition of FNA increasing the accuracy to 59%. A smaller trial of 67 patients found the overall EUS accuracy to be 73% (range 43%–88%). Cytology improved the sensitivity for mucinous lesions (94%), malignant mucinous lesions (100%), serous lesions (100%), and pseudocysts (100%), with a specificity of 98%–100% [293]. Additional findings were that a low carcinoembryonic antigen (CEA) level (< 5 ng/mL) was predictive of a serous cystadenoma, and high amylase or lipase concentration was associated with pseudocysts. Studies have reported a wide accuracy of EUS with or without FNA, ranging from 40% to 96% [287–289,291–296]. Studies have evaluated a variety of cyst fluid tumor markers or cyst fluid properties (CEA, CA19-9, CA72-4, CA125, amylase, lipase, viscosity, mucin stain). CEA is found in high levels in mucin-

ous tumors, whereas levels are low in pseudocysts (unless infected) and serous cystadenomas [294,297,298]. A large, prospective, multicenter trial reported that a CEA level of 192 ng/mL or more was 79% accurate for differentiating mucinous neoplasms from other types of cysts. In this study, no combination of morphological features, cytology results, and cyst fluid analysis improved the accuracy rate over that obtained with CEA alone [292]. Other studies have reported variable accuracies with CEA [293,299,300]. It has also been reported that an elevated CEA (≥ 480 ng/mL) and viscosity (> 1.6) accurately predicted mucinous cystic neoplasm from serous cystadenoma and pseudocysts. Mucinous cystadenocarcinoma lesions had a CEA level greater than 6000 ng/mL in one study [301].

CA19-9 (> 50 000 units/mL) has been associated with sensitivity of 86% and specificity of 85% in distinguishing cystadenocarcinoma from other lesions. However, CA19-9 is often elevated in inflammatory conditions and biliary obstruction, which limits its usefulness [294,297]. Amylase has been found in high concentrations in pseudocysts and intraductal papillary mucinous neoplasms (IPMNs), and amylase levels greater than 5000 U/L are associated with varying sensitivity (61%–94%) and specificity (58%–74%) in differentiating pseudocysts from other cystic lesions [293,298,302].

The ideal diagnostic approach to patients with pancreatic cysts is unclear and not validated, and is variable among medical institutions. Management often depends on local expertise. An international consensus guideline for management of IPMNs and mucinous cystic neoplasms has been published [303], and this algorithm should serve as a general framework in the management of patients with pancreatic cysts.

Biliary tract indications and cholangiocarcinoma

The common bile duct and gallbladder are in close proximity to the antrum and duodenum, allowing EUS to image these organs. EUS is a safe and accurate alternative imaging modality to ERCP, the traditional method most often used to evaluate the biliary tract. In many cases, EUS-guided therapy can be performed and can nearly eliminate the need for diagnostic ERCP.

A common indication for endoscopic biliary intervention is for suspected choledocholithiasis. An ERCP is often performed in such cases, but the risk of complications is significant [304–307] and it should be performed only in cases requiring therapeutic intervention.

Choledocholithiasis

EUS is superior to other imaging modalities for evaluation of the extrahepatic biliary tree for suspected choledocholithiasis. Transabdominal ultrasound detects approximately 30% of common bile duct stones [308,309] and helical CT has a reported diagnostic accuracy of 86%–94% [310,311] but with reduced accuracy for small bile duct stones. EUS and MRCP are both accurate imaging modalities for detection of common bile duct stones, with EUS slightly more accurate (approximately 96% vs 90%) [312–320]. EUS has greater resolution than MRCP, and hence EUS can detect stones as small as 1–2 mm without the loss of accuracy seen with MRCP [313,321]. EUS is the most accurate imaging test available for detection of microlithiasis [318,321].

Although long considered the gold standard for detection of choledocholithiasis, ERCP is less accurate and more invasive and has a higher failure rate compared with EUS. The NPV (the ability to rule out a common bile duct stone) of EUS is nearly 100%, with up to 32 months of patient follow-up [322–326].

When managing patients with suspected choledocholithiasis, adopt a treatment algorithm of performing EUS on patients with low or intermediate risk for choledocholithiasis, and proceed directly to ERCP in patients with a high clinical suspicion for choledocholithiasis. The EUS-based approach reduces the number of unnecessary ERCP procedures and is cost-effective [313,322,327].

Indeterminate biliary strictures

The critical question in the characterization of an indeterminate bile duct stricture is whether the stricture is malignant. Brushings or forceps biopsy obtained at ERCP has an accuracy that ranges from 30% to 70%, primarily due to the desmoplastic reaction associated with such tumors [328–333]. EUS (radial, linear, and IDUS) can visualize the extrahepatic biliary tree and extrinsic masses [334,335]. A prospective study of 40 patients with an indeterminate biliary stricture who underwent various imaging and endoscopic techniques found that the combination of MRCP and EUS had the highest specificity for diagnosis of an indeterminate biliary duct stricture [336].

For bile duct lesions, radial or linear EUS provides excellent visualization and ability to obtain tissue [337,338]. For lesions located in the porta hepatis region, the 20-MHz IDUS miniprobe provides accurate images of the bile duct wall and surrounding structures. The IDUS miniprobe is advanced to the stricture without a prior papillotomy. The first hyperechoic layer corresponds to the mucosa in addition to a border echo, the second hypoechoic layer is smooth muscle fibers with fibroelastic tissue, and the third hyperechoic layer is the thin and loose connective tissue with a border echo [339]. IDUS findings concerning for malignancy include disruption of the bile duct wall, sessile lesions, and tumor size greater than 10 mm. The accuracy of IDUS in differentiating between benign and malignant strictures ranges from 76% to 92% [340–344]. The presence of two of these three features is considered specific for the diagnosis of malignancy, and the absence of all these features carries a very high NPV for ruling out malignancy [343]. However, IDUS is not accurate when evaluating for metastatic lymphadenopathy [342]. The linear EUS echoendoscope is still required for FNA. Studies have shown that EUS-FNA may aid in the diagnosis of a hilar

cholangiocarcinoma when other standard methods of tissue acquisition have failed [345].

Cholangiocarcinoma

When cholangiocarcinoma is diagnosed, EUS can assist in staging and assessment of surgical resectability. Bile duct cancer T-staging is as follows: T1, limited to the wall of the common bile duct; T2, invasion beyond the wall of the common bile duct; and T3, invasion to adjacent structures. The accuracy of IDUS is higher than EUS for assessing T-staging (77.7% vs 54.1%) [346], particularly for hilar or common hepatic duct strictures.

When assessing for surgical resectability, the key question is longitudinal extent of tumor spread and involvement of adjacent structures, particularly the portal vein and right hepatic artery. The accuracy of IDUS for assessment of longitudinal tumor spread ranges from 72% to 86%, when using notching of the outer margins and asymmetric wall thickening as visualized endosonographic features. However, thickening due to inflammation can reduce the accuracy [347]. IDUS is highly accurate at visualizing portal vein and right hepatic artery involvement, and is more accurate than angiography [348,349].

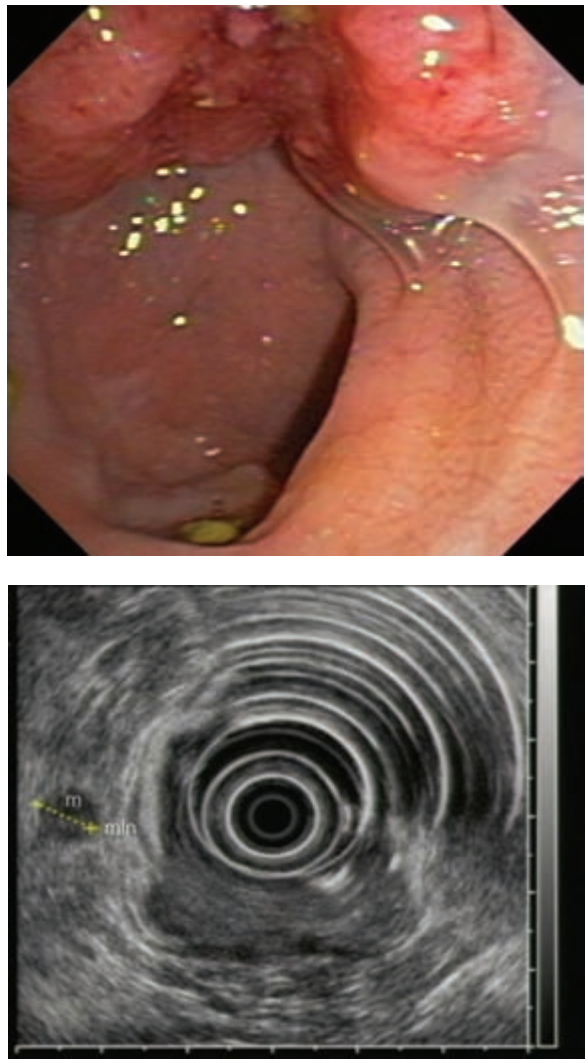
Anorectal EUS

Common indications for rectal EUS include evaluation of suspicious polyps and locoregional staging of rectal cancer, assessment of submucosal lesions, and evaluation of incontinence (for possible anal sphincter defects). Most patients can be adequately prepared for this unsedated procedure with enemas.

Malignancy often appears as an irregular hypoechoic lesion with disruption of the rectal wall layers (Fig. 130.13). Since neoadjuvant therapy in locally advanced rectal cancer is associated with an improvement in recurrent-free survival, the accurate preoperative staging of such lesions is critical [350–357]. EUS is indicated in the locoregional staging of patients with rectal cancer and in the evaluation of patients with recurrent malignancy [358,359].

When M0 rectal cancer has been established, EUS is the next step in staging because it has superior performance characteristics to CT and MRI [360]. The accuracy of EUS for T-staging ranges between 80% and 95%, with a mean sensitivity of 87.5% and specificity of 83.5%; this compares with an accuracy of 65%–75% for CT and 75%–85% for MRI [359,361–366]. The accuracy of EUS for determining nodal metastases is approximately 70%–75%, whereas that for CT is 55%–65% and MRI 60%–70% [359,362,364]. The presence of perirectal lymph nodes often warrants FNA, which can be performed safely with low risk of infection [367,368]. EUS has been shown to alter the treatment plan in nearly one-third of rectal cancer cases [369].

A common submucosal rectal lesion may be rectal carcinoid, often an incidental finding [370,371]. Poor prognosis is associated with larger tumor size, deep invasion of tumor, and lymphovascular invasion [371]. EUS can assess lesions to determine eligibility for local excision versus surgical resection [372].



(a)

(b)

Figure 130.13 Rectal carcinoma. **(a)** Endoscopic image of ulcerated rectal mass. **(b)** Endoscopic ultrasonography image demonstrates T3N1 stage: m, mass; mln, malignant lymph node.

Anorectal EUS also plays a role in detecting sphincter defects in patients with fecal incontinence, and helping to assess whether the defect is amenable to surgical correction [373]. EUS findings have been correlated accurately with operative findings [374]. EUS may also be useful in assessing perianal inflammatory conditions [375].

Since its introduction in the late 1970s computed tomography (CT) has made unparalleled technical advancements in both scanner hardware and software. Today's multidetector CT (MDCT) scanners allow submillimeter collimation (0.6 mm) and fast scanning speeds (0.33 s per rotation) [1]. The resultant temporal and spatial resolution have greatly improved our ability to image the body. For example, 64-slice MDCT scanners can image the entire abdomen and pelvis in less than 10 s using submillimeter slices. This narrow temporal window has directly impacted protocol design, enabling data acquisition during the phase of maximum lesion conspicuity. Consequently, specific acquisition phases have been delineated for pancreatic tumor and hepatocellular carcinoma detection using multislice technology [2,3]. Following data acquisition, easy-to-use three-dimensional postprocessing software is now widely available, which enables the radiologist to view the scan data in any imaging plane. Beyond improved image quality and diagnostic efficacy for existing applications, these advancements have facilitated the development of new CT applications such as virtual colonoscopy and coronary CT angiography.

In this chapter, we review the current state of CT imaging of the gastrointestinal tract, including the hollow viscera and the hepatobiliary tree and pancreas. New CT innovations such as three-dimensional rendering and virtual imaging are also discussed.

Hollow viscera of the gastrointestinal tract

Techniques

Oral contrast

Identifying abnormalities of the lumenal gastrointestinal tract, whether it be neoplastic or inflammatory, relies on the ability to adequately visualize the bowel wall [4,5]. Optimal distention of the bowel is necessary for evaluation of the wall. There are a variety of CT contrast agents that can be administered orally or rectally. These are categorized as positive agents, neutral agents, or negative agents [6–8].

Positive agents appear "white" on CT and usually consist of diluted (1.5%–2%) iodinated water-soluble contrast or diluted (2%) barium suspensions. These are the agents traditionally used for routine CT scans of the abdomen.

Neutral contrast agents appear "gray" on CT and usually have a density similar to water. Currently used neutral agents include water, methylcellulose compounds, and commercially available products such as Volumen (EZ-Em; Lake Success, NY), which has a density slightly greater than that of water [8]. Megibow and colleagues have compared the neutral oral contrast agents Volumen and methylcellulose in 60 patients undergoing CT of the pancreas [8]. Half of the patients consumed 1200 mL of Volumen over 30 min and the other half consumed a 3 : 1 mixture of water and methylcellulose. Volumen, which has an attenuation of 20–40 Hounsfield units (HU), resulted in superior distention of the bowel and better demonstration of mural features.

More studies are needed to determine which oral agent is best for specific CT applications [8]. Neutral agents may be beneficial for detailed imaging of the stomach and small bowel because they allow excellent visualization of the enhancing wall that may otherwise be obscured by positive agents [8,9–11]. In addition, if three-dimensional imaging is performed, it is beneficial to use either neutral or negative contrast agents because they still allow three-dimensional visualization of the vasculature without extensive postprocessing to segment the bowel loops from the volume [12,13]. When positive oral agents are used, these "white" loops need to be removed, as they obscure the adjacent contrast-enhanced vessels, particularly with maximum intensity projection.

Negative agents appear "black" on CT and usually consist of either gas granules administered orally to distend the stomach or insufflation of the colon with air or carbon dioxide for

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

virtual colonoscopy. Other negative agents such as oil-based products (peanut oil) are not used routinely [14]. In clinical practice, the choice of oral contrast depends on the clinical indication and is reviewed in the appropriate subsections of this chapter.

Intravenous contrast

Intravenous contrast-enhanced images expand the diagnostic range of CT and have become essential for most clinical indications. Intravenous contrast enhancement improves conspicuity of pathological processes in evaluation of the alimentary canal by increasing the level of confidence in diagnosing a thickened bowel loop as being truly diseased, as well as allowing assessment of bowel wall enhancement and detection of small-bowel masses. This refines the differential diagnosis by highlighting attenuation differences within the thickened loop, or by accentuating the "vascularity" of a bowel-related mass, thereby facilitating the determination of histological type and neoplastic potential [15]. Variations in blood supply of pathological processes demand a tailored approach to intravenous contrast administration for evaluation of the alimentary tract.

Nonionic iodinated contrast agents are typically utilized for CT. The protocol for administration will vary depending on the clinical indication. For example, in patients with suspected mesenteric ischemia, it is important to acquire images in both the arterial and venous phases to ensure adequate visualization of both the mesenteric arteries and veins in addition to assessment of bowel wall enhancement [16]. The radiologist will tailor the intravenous contrast injection rate and scan delay based on the clinical question. Therefore, it is essential that appropriate clinical information be provided by the ordering physician in order for scans to be performed correctly.

Scanning protocol

In general, CT imaging of the abdomen, and the alimentary tract in particular, requires high-resolution volumetric datasets. Data acquisition parameters are dictated by the clinical question. For example, if three-dimensional imaging is performed, it is helpful that the CT scan be performed using the thinnest possible detectors. State-of-the-art 64-slice scanners have detectors as narrow as 0.6 mm, which can be used to create 0.75-mm overlapping sections reconstructed every 0.5 mm to produce a volume dataset that is ideal for three-dimensional imaging. The data may also be reconstructed with 3–5-mm sections for axial review of the abdomen and pelvis. With respect to voltage and tube current, 120 kV and 270 mAs (effective) are usually adequate for three-dimensional studies. For studies not requiring three-dimensional imaging, thicker collimator settings can be used (e.g., 1.2 mm) and the tube current can be reduced appropriately.

Three-dimensional imaging

A comprehensive CT examination in patients with suspected gastrointestinal tract pathology may be aided by review of the dataset with three-dimensional software. The interpretation is tailored to fit the specific clinical question, and different rendering algorithms may be needed to optimally display specific findings. Current three-dimensional imaging software varies by vendor, but typically includes a combination of multiplanar reconstruction (MPR), volume rendering and maximum intensity projection (MIP) [17–19]. MPR is the simplest to use and allows scrolling through the dataset in any plane. However, for full analysis of gastrointestinal tract and abdominal vasculature, volume rendering is the most robust three-dimensional imaging tool. Volume rendering allows the brightness, opacity, window width, and window level to be adjusted in real time in order to accentuate certain tissue types or selective viewing of the vasculature [19]. Manipulating trapezoidal transfer functions interactively modifies the image contrast and the related pixel attenuations in the final image. This function allows color and opacity assignments to each voxel and can be adjusted to alter the display. Although initial volume rendering software was somewhat labor intensive, software packages are now easy to use and can be adjusted in real time. Also, the process can be simplified by creating pre-sets, which can be applied quickly and then only minor adjustments are needed. MIP is a projection technique in which the brightest voxel is displayed along a ray [19]. This can be valuable using thin slabs of data to accentuate small vessels. The radiologist often utilizes a combination of these three-dimensional tools to optimally display the relevant anatomy and pathology. Specialized three-dimensional software has been developed for specific CT applications, including virtual colonoscopy.

Esophagus

Neoplasms

For evaluation of suspected or known esophageal masses, CT aids in identification of the mass, assessment of local extension, detection of local and regional lymphadenopathy, and identification of sites of metastases. Esophageal neoplasms usually appear on CT as focal, asymmetric, soft tissue masses arising from the wall or as concentric areas of wall thickening. However, these findings are nonspecific and can be seen in benign and malignant tumors as well as in inflammatory conditions [20].

Carcinoma of the esophagus typically appears on CT as a focal eccentric mass or as concentric thickening of the esophageal wall, neither of which is a specific finding [21] (Fig. 131.1). CT provides no histological specificity; squamous cell carcinoma, adenocarcinoma, lymphoma, and metastatic disease to the esophagus all have similar CT appearances. However, esophageal stromal tumor should be considered when there is a prominent exophytic component to the mass [22].

It is important to note that early superficial esophageal lesions may not be visible on CT, and therefore CT is typically not used to screen for esophageal cancer [23]. Also, despite technical advances in CT scanners and three-dimensional

Figure 131.1 **(a)** Axial intravenous contrast-enhanced multidetector computed tomography (MDCT) image reveals a large circumferential esophageal mass (arrows). The mass splays the carina. An esophageal stent is in place (arrowhead). **(b)** Axial intravenous contrast-enhanced MDCT image demonstrates bulky mediastinal adenopathy (arrows). The esophageal stent is again noted (arrowhead).

imaging software, CT cannot visualize individual layers of the esophageal wall and therefore endoscopy with endoscopic ultrasound (EUS) is definitely more valuable for T-staging [23]. EUS may also be more valuable than CT for identifying locoregional nodes [23]. However, EUS alone is not sufficient to stage patients with esophageal cancer. It should be combined with CT and possibly positron emission tomography (PET) for comprehensive staging [23].

The real value of CT in patients with esophageal carcinoma includes staging the extent of disease (highest use in detecting extraesophageal disease), evaluating patients after therapy, and evaluating the complications of surgical therapies. Therapy success or failure can be based on documentation of the development of enlarged mediastinal or upper abdominal lymphadenopathy, lung nodules, or liver or adrenal metastases. Recent studies suggest that PET may also be useful in detecting metastatic disease, and in a study by Pfau and colleagues PET identified more patients with metastatic disease than did CT [23].

CT criteria for extensive esophageal cancer include demonstration of local invasion (aorta, diaphragm, tracheobronchial tree), distant lymphadenopathy, and distant metastases. Local extension is the most difficult parameter to accurately diagnose. Contact angles of more than 45° have been suggested to accurately predict aortic invasion, although several studies have shown this finding to result in frequent over-staging [24]. In an interesting study by Wayman and colleagues, the authors performed supine and prone CT imaging in 39 patients with esophageal carcinoma. Results revealed that the combination of supine and prone imaging improved accuracy for determining the presence of aortic invasion compared with the supine images alone [25]. Tumor invasion of the pericardium is suspected if the normal surrounding fat plane is obliterated. The addition of MPR, three-dimensional imaging, or CT esophagography may help improved accuracy [26,27].

Pathological lymphadenopathy can be more reliably determined when regional adenopathy of more than 5 mm in the short axis is used as a criterion [28]. However, it should be noted that even nodes smaller than 5 mm can harbor malignancy. Therefore, PET or EUS may play a role here [23].

CT has been shown to be a helpful addition to fiberoptic bronchoscopy to identify tracheobronchial invasion [29]. For this indication three-dimensional imaging is especially helpful for demonstrating the relationship of the esophageal mass to the airway, as well as for identifying tumor extension. The addition of virtual bronchoscopy viewing of the airway may also be beneficial for this indication [29].

Postsurgical complications after esophagectomy are not uncommon, and can occur in up to 50% of patients [30]. The most frequently noted complication on CT is an anastomotic leak, which may not be detected by standard contrast esophagography [30]. In some cases it may be beneficial to perform CT immediately after contrast esophagography to increase sensitivity in detecting small leaks that may be subtle at fluoroscopy. In patients who have undergone esophageal stent placement, CT is also valuable for documenting patency and detecting complications [31].

Varices

Esophagogastric varices are easily detected with contrast-enhanced CT and diagnosis is improved using three-dimensional CT techniques [32]. CT is particularly useful in demonstrating extraserosal varices, which may be underestimated by EUS [32]. Thickening of the esophageal wall, a scalloped contour, and enhancing intralumenal protrusions after a bolus intravenous contrast injection are seen [33]. Low attenuation in the esophageal wall in patients with other stigmata of portal hypertension should suggest a history of sclerotherapy.

Esophagitis

Esophagitis may produce thickening of the distal esophageal wall. CT is neither sensitive nor specific for this finding. CT

does not aid in the differentiation of distal esophageal abnormalities and cannot distinguish carcinoma from severe esophagitis. CT may be useful in recognizing distal esophageal changes in immunocompromised patients, prompting endoscopic evaluation to determine the specific etiology.

Achalasia

CT is not the imaging modality of choice in patients with suspected achalasia. However, CT is sometimes the first modality to suggest the diagnosis in patients with nonspecific symptoms. The CT appearance of achalasia can be dramatic, showing a markedly distended esophagus with retained fluid and food [34].

Stomach

CT can evaluate the position of the stomach, the lumenal contour, the gastric wall, surrounding lymph nodes, peritoneal ligaments, and surrounding viscera. When the stomach is distended adequately, the gastric wall should measure less than 5 mm. However, at the esophagogastric junction, the wall may be up to 1 cm thick and still be normal. This is related to the scanning plane and the orientation of the lower esophageal sphincter. Similarly, because of muscle orientation in the antrum as well as antral contraction, it has been shown that in this region the wall commonly exceeds 5 mm in thickness and can measure up to 13 mm and still be normal [35]. Using absolute gastric wall measurements is not always valuable for distinguishing malignant from benign disease. In a study by Insko and colleagues, the authors noted that a gastric wall thickness of 1 cm had a sensitivity of 100% for detecting malignant or potentially malignant lesions, but had a specificity of only 50% [36]. The authors also noted that focal eccentric enhancing wall thickening was always malignant but was only present in a small percentage of cases [36].

Changes in positioning may be necessary to maximally distend regions of the stomach where the wall is questionably thickened. Several studies have confirmed the value of three-dimensional imaging to improve evaluation of the stomach and its perigastric relationships [37].

The gastric wall displays uniform enhancement following intravenous contrast administration. The use of dual-phase imaging may be helpful for evaluating differences in enhancement in a variety of gastric pathologies [38]. Administration of neutral or negative oral contrast allows assessment of the distribution of the rugal fold pattern in the proximal stomach as well as optimal visualization of mural enhancement [6,39–41].

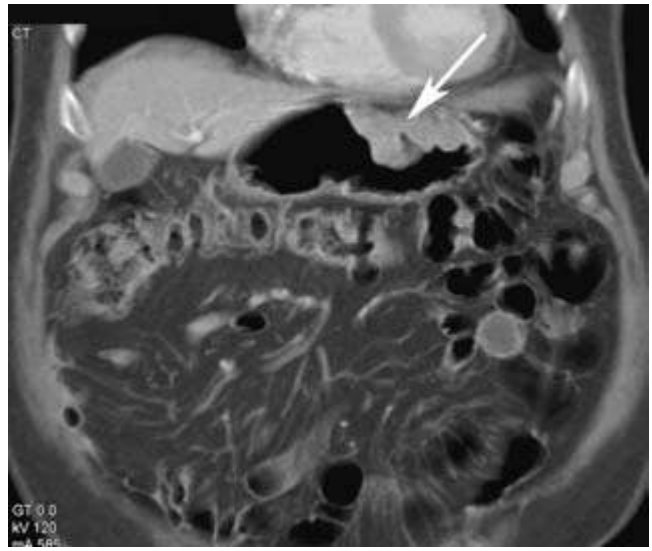
Neoplasms

Gastric adenocarcinoma

Gastric carcinoma appears as a region of focal gastric wall thickening or mass (Fig. 131.2). Polypoid and scirrhous forms (with or without ulceration) are encountered. Scirrhous tumors (linitis plastica) can be difficult to diagnose as the degree of wall thickening is less than in polypoid tumors [42].

CT is typically used for staging once the diagnosis has been made by endoscopy. Overall staging accuracy has been reported to be as high as 94%, with better results for advanced tumors than early gastric cancers [43]. Studies have shown that EUS is more accurate than CT for determining depth of mural invasion and for local lymph node staging [43]. Because CT cannot resolve the individual gastric wall layers, superficial early gastric cancers may not be detected [43].

(a)



(b)

Figure 131.2 (a) Axial intravenous contrast-enhanced multidetector computed tomography image in a patient with gastric adenocarcinoma shows an infiltrating mass in the gastric body (arrows). There is extension into the gastrohepatic ligament (arrowhead). **(b)** Coronal volume-rendered image nicely demonstrates the bulky gastric mass (arrow).

However, the CT detection rates and T-staging of gastric cancer have improved with the incorporation of MDCT three-dimensional imaging [44].

There has also been some interest in the use of CT virtual gastroscopy for improving gastric cancer detection and perhaps even for screening high-risk patients [43,45,46]. To perform virtual gastroscopy, the stomach is distended with air. Thin collimation CT is then performed and virtual software is used to image the stomach. The computer can travel through the gastric lumen to provide images similar to those seen during conventional endoscopy. The exact role for virtual gastroscopy in gastric cancer detection is not yet known.

As with esophageal tumors, CT is not consistently accurate in T-staging (especially T1 vs T2 lesions) due to its inability to resolve the bowel wall layers. However, three-dimensional imaging has been shown to improve T-staging compared with axial images alone [43,44]. With single-slice helical CT, using thin sections and intravenous contrast, resultant density discrimination improves staging accuracy over conventional CT. In a Japanese study, overall T-staging was correct in 66% (27 of 41), despite a large number of "early" carcinomas that might bias the sample against CT accuracy [47], implying that results should be improved in populations where patients present with more advanced disease. Dedicated imaging protocols have yielded detection of lesions in greater than 95% of patients and accurate detection of lymph node disease in approximately 71% [38].

Gastric cancer spreads along the perigastric peritoneal reflections through intramural lymphatics, by peritoneal seeding, and hematogenously. Lymphatic submucosal spread into the esophagus occurs in approximately 30% of patients with tumors in the gastric fundus. Extension into the serosa allows tumor access to the supporting mesenteries of the stomach, providing pathways into omentum, kidney, liver, pancreas, transverse colon, and spleen. Proximal lesions can extend into the diaphragm and the aorta. Again, these complex pathways of tumor spread are best appreciated with the ability to visualize the CT data in three dimensions.

Lymphoma

Gastric lymphomas produce significantly greater wall thickness than carcinoma, although this finding is of limited value for differential diagnosis in individual cases [48,49]. Following intravenous contrast enhancement, lymphoma masses minimally enhance and remain homogeneous, as opposed to the heterogeneous appearance typical for adenocarcinoma. In cases presenting with fold hypertrophy, there may be demonstrable clefts between the thickened folds extending through the wall into the extraserosal tumor [50].

Gastrointestinal stromal tumors

Gastrointestinal stromal tumors (GISTs) are mesenchymal tumors that arise within the muscularis propria of the gastrointestinal tract wall. Approximately 60% of GISTs occur in the stomach, although they only represent 1–3% of all gastric malignancies [51]. CT plays an important role in the detection and staging of these tumors, as CT can detect the tumor and assess for local spread and distant metastases [11]. When small, GISTs are confined to the gastric wall, and they usually appear as rounded intramural masses (Fig. 131.3). Lesions as small as 1 cm have been detected on MDCT [52]. In a series of patients described by Nishida and colleagues, all GISTs over 2 cm were visible on four-slice CT [52]. As all tumors 2 cm or greater in size were detected with MDCT, these findings suggest that MDCT can be useful in screening symptomatic patients suspected of having GIST.

Large tumors can either protrude into the gastric lumen or be exophytic [11], often demonstrating central necrosis or ulceration. Three-dimensional imaging is particularly helpful for demonstrating the relationship of the mass to the stomach. When very large and exophytic, a gastric GIST may be misdiagnosed as a mass from the adrenal, pancreas or colon using only axial sections for interpretation [11].

Inflammatory diseases

CT has no primary indication for the evaluation of patients with suspected gastric inflammatory diseases. However, because CT is so frequently ordered in patients with abdominal pain, it may be the first modality to suggest the presence of gastritis or peptic ulcer disease [53]. In patients with gastritis, CT may show focal or diffuse wall thickening. The thickened wall will display some degree of low attenuation, reflecting intramural edema [54]. This would be an uncommon finding in a patient with a gastric neoplasm. Although CT is not sensitive for the detection of ulcers, they can occasionally be seen, especially when large [53]. However, the

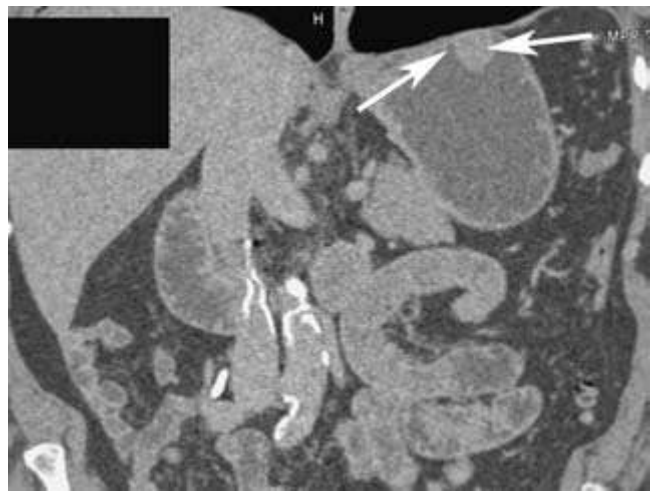


Figure 131.3 Intravenous contrast-enhanced coronal multiplanar reconstruction using water as oral contrast demonstrates a 1.3-cm intramural gastric mass (arrows) compatible with a gastrointestinal stromal tumor. This was an incidental finding.

CT appearances of inflammatory and malignant conditions overlap.

Small intestine

The key to evaluation of the small intestine lies in adequate opacification with orally administered contrast material [7]. Typically, 750 mL of oral contrast material should be administered approximately 1 h before examining the abdomen to opacificy the small bowel. An additional 250 mL is administered just prior to the scan to ensure adequate distention of the stomach and duodenum. The choice of neutral or positive agent will depend on the clinical indications. Some investigators advocate the use of oral metoclopramide to aid in gastric emptying and filling of the terminal ileum, while others utilize glucagon to help improve small bowel distention by decreasing peristalsis.

Neoplasms

Early diagnosis of small-bowel tumors continues to pose a significant challenge for both clinicians and radiologists. This is because small-bowel neoplasms are relatively uncommon, representing less than 25% of all gastrointestinal neoplasms and less than 2% of all malignant tumors [55]. Also, small-bowel tumors tend to be small initially and may be difficult to diagnose by conventional radiological studies [56]. In addition to contrast fluoroscopy studies, CT is now recognized as an important tool for evaluation of these patients. CT has the advantage of visualizing both the entire gastrointestinal tract and extralumenal structures such as lymph nodes [10].

Adenocarcinoma

Adenocarcinoma of the small intestine produces soft tissue attenuation, wall thickening and irregular narrowing of the lumen, which can lead to obstruction [10]. These lesions most frequently arise in the periampullary duodenum, but may occur anywhere along the mesenteric small bowel (Fig. 131.4). Malignant lesions appear as exophytic or intramural masses with central necrosis and ulceration [57]. However, ulceration is not always well demonstrated on CT [58].

Lymphoma

Four major patterns of small-bowel lymphoma have been identified on radiographic studies [59].

- Lymphoma can appear as multiple nodules within the small bowel. Involvement of multiple sites along the small intestine aids in differentiation of lymphoma from adenocarcinoma and carcinoid tumor.
- Lymphoma can appear as a single mass lesion, which varies in size. These isolated lesions can cause small-bowel intussusception.
- Lymphoma can be infiltrating and appear as wall thickening with destruction of the normal small-bowel folds. Unlike adenocarcinoma, these tumors are typically soft and are unlikely to result in obstruction. In addition, as the tumor infiltrates the musculature of the wall, it can inhibit peristalsis and result in aneurysmal dilatation of the involved loop, as opposed to obstruction [59].
- Lymphoma can appear as an exophytic mass, which can ulcerate.

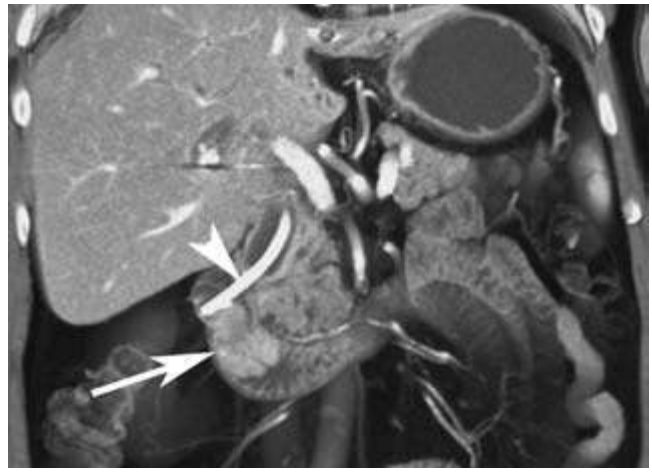

Figure 131.4 Intravenous contrast-enhanced coronal volume-rendered image using water as oral contrast demonstrates a 2-cm lobulated mass (arrow) in the second portion of the duodenum. A common bile duct stent is in place (arrowhead). The patient underwent Whipple surgery and pathology revealed adenocarcinoma arising in a tubular adenoma.

The morphological patterns of nodular, ulcerative, and aneurysmal disease due to lymphoma are best visualized with CT [48]. Acquired immunodeficiency syndrome (AIDS)-related lymphomas display two main patterns on CT: single or multiple segments with homogeneous circumferential wall thickening, or single or multiple cavitary lesions. The gross morphological features, distribution pattern, degree of wall thickening, and length of involvement are similar in AIDS-related and non-AIDS-related lymphomas [60].

Carcinoid tumors

Small-bowel carcinoid tumors are neuroendocrine neoplasms. In early stages, the tumor is small, confined to the bowel wall, and appears as an enhancing intramural lesion [61]. At this time small-bowel series and enteroclysis may be more sensitive for detection than CT or magnetic resonance imaging (MRI). As the tumor grows, it can extend beyond the involved bowel loop causing infiltration of the mesentery and desmoplastic reaction (Fig. 131.5). This results in a characteristic appearance on small-bowel contrast examinations and cross-sectional imaging studies. The CT appearance is characterized by radially oriented linear densities in the perienteric fat. A lymph node mass (frequently calcified) is present centrally [62]. Bowel loops are drawn toward the center. The mesenteric desmoplasia may produce ischemic thickening of the involved loops. In addition to contrast studies and CT, nuclear medicine techniques utilizing indium 111- (or iodine 123)-labeled octreotide or iodine 131-labeled

Figure 131.5 (a) Axial intravenous contrast-enhanced multidetector computed tomography image shows a 1.5-cm infiltrating mass (arrow) in the root of the mesentery, compatible with carcinoid. **(b)** Coronal maximum intensity projection nicely demonstrates encasement of the superior mesenteric artery branches (arrowhead) by the infiltrating tumor (arrows).

metaiodobenzylguanidine (MIBG) are useful tools to diagnose and localize carcinoid tumors and to identify their metastases.

Gastrointestinal stromal cell tumor

The fourth most common small-bowel malignancy is GIST, which arises from smooth muscle cells within the wall of the gastrointestinal tract and most commonly involves the stomach. Small-bowel GISTs more likely arise in the jejunum or ileum, as compared to the duodenum. It is usually not possible to distinguish benign from malignant GISTs radiographically unless obvious metastases are present. As with gastric GISTs, small-bowel lesions, when small, may go undetected on CT. However, as they enlarge, they typically become exophytic and often ulcerate, producing a characteristic appearance on CT [11]. These tumors can be bulky. Central necrosis or ulceration is also common. These tumors may be so large that it may be difficult to appreciate the site of origin. The communication of the tumor with the intestinal lumen may sometimes be difficult to appreciate. However, three-dimensional imaging can be helpful to make this determination. Tumor spread is usually through direct extension into adjacent organs or hematogenously to the liver. Liver metastasis can appear low-density or cystic [11].

Metastatic disease

Metastatic disease to the small bowel results from hematogenous spread, peritoneal seeding, or direct extension of a contiguous lesion. Each has a recognizable CT appearance. Hematogenous metastases are commonly seen from melanoma, Kaposi sarcoma, and breast carcinoma. Discrete masses eccentrically localized along the bowel circumference are present. Tethering of the mesenteric border of individual bowel loops in the presence of peritoneal carcinomatosis is indicative of seeded metastases. Variable degrees of partial bowel obstruction are common. Nodular thickening of the mesenteric reflections is observed. These findings are seen in metastatic ovarian, colonic, breast, and lung carcinoma.

Nonneoplastic diseases

Crohn's disease

One of the earliest applications of CT in the alimentary tract was the evaluation of Crohn's disease [63]. Markedly expanded contrast resolution compared with plain film and barium radiography make CT ideal in displaying the transmural inflammation, effects in local fat, and global assessment of disease [64]. The affected bowel wall displays variable degrees of mural thickening. When intravenous contrast is administered, submucosal hypoattenuation, reflecting submucosal edema, may be seen. This "target sign," although nonspecific for Crohn's disease, was first described with this entity [65]. This appearance may be mimicked in long-standing disease from deposition of submucosal fat. The bowel may become isolated in a "sea" of hypertrophied fat. CT definitively establishes this fatty proliferation as a cause of separation of bowel loops. The fatty proliferation is accompanied by hypervascularity in the local mesentery [66].

Linear nonvascular densities are correlated with the presence of sinus tracts or fistulae. When these are identified on CT, barium studies are sometimes necessary to precisely map their relationships, although, 3D imaging can also be helpful. Local lymphadenopathy (generally not greater than 15 mm) is associated with these findings. Increased density in the fat reflects inflammatory exudate and, when contained, frank abscess. Intraabdominal abscess is not uncommon, with severe steroid-refractory relapses of Crohn's disease being present in about one-third of patients. CT is superior to ^{111}In-labeled leukocyte scintigraphy, which is sensitive for detecting inflammation but poor at documenting extent. Nonetheless, ^{111}In-labeled leukocyte scintigraphy is the most specific method for imaging active inflammation.

Figure 131.6 Coronal volume-rendered image from an intravenous and oral contrast-enhanced computed tomograph in a patient with Crohn's disease demonstrates small bowel wall thickening, mucosal hyperemia, and engorgement of the vasa recta. This is an example of the comb sign, indicating active disease.

With advancements in CT technology resulting in improved resolution and speed, investigators are starting to assess if CT can provide more useful information regarding disease activity in Crohn's patients. In a recent study by Bodily and colleagues, the authors retrospectively obtained quantitative information from CT scans of 96 patients with Crohn's disease, including measurements of small-bowel mural attenuation and thickness [67]. Mural attenuation correlated significantly with active Crohn's disease, although small-bowel wall thickness by itself was not a significant factor [67]. In a study of 143 patients with CT studies, Colombel and colleagues found that endoscopic score correlated significantly with CT bowel enhancement, comb sign (vascular enlargement of the vasa recta), and increased density in the fat [68] (Fig. 131.6). C-reactive protein correlated with increased fat density, but not when the inflammation was limited to the bowel wall [68]. This is currently a topic of active research.

Vascular diseases

Isotropic volumes from submillimeter MDCT scanners facilitate routine use of CT angiography, and dedicated CT of the mesenteric vessels is now possible [9,69]. Detailed imaging of the mesenteric vessels requires rapid intravenous contrast administration combined with appropriately timed dual-phase scanning to ensure adequate visualization of both the mesenteric arteries and veins. Also, if evaluation of mesenteric vessels is requested, low-density oral contrast is administered in order to allow evaluation of bowel enhancement as well as to facilitate three-dimensional imaging of the vasculature without the need to edit high-density oral contrast-filled bowel.

In many cases, CT angiography can replace initial diagnostic angiography. CT angiography can be used to evaluate a variety of vascular pathology including splanchnic artery aneurysms, median arcuate ligament syndrome, and superior mesenteric artery syndrome [9,70,71]. A common clinical indication requiring detailed CT imaging of the mesenteric vessels and bowel is the evaluation of suspected mesenteric ischemia (Fig. 131.7). Dual-phase three-dimensional CT can evaluate the mesenteric arteries and veins and identify potential causes of ischemia such as superior mesenteric artery or vein thrombus or tumors such as small-bowel carcinoid or pancreatic cancer, both of which can result in small-bowel ischemia [16,69,72]. Even in the absence of obvious pathology of the mesenteric vessels, CT can suggest the presence of mesenteric ischemia based on the appearance of the small bowel. Delayed or absent enhancement can indicate underlying ischemia. Pneumatosis may reflect infarcted bowel, but can also occur in benign conditions and should therefore be correlated with clinical findings.

Small bowel obstruction

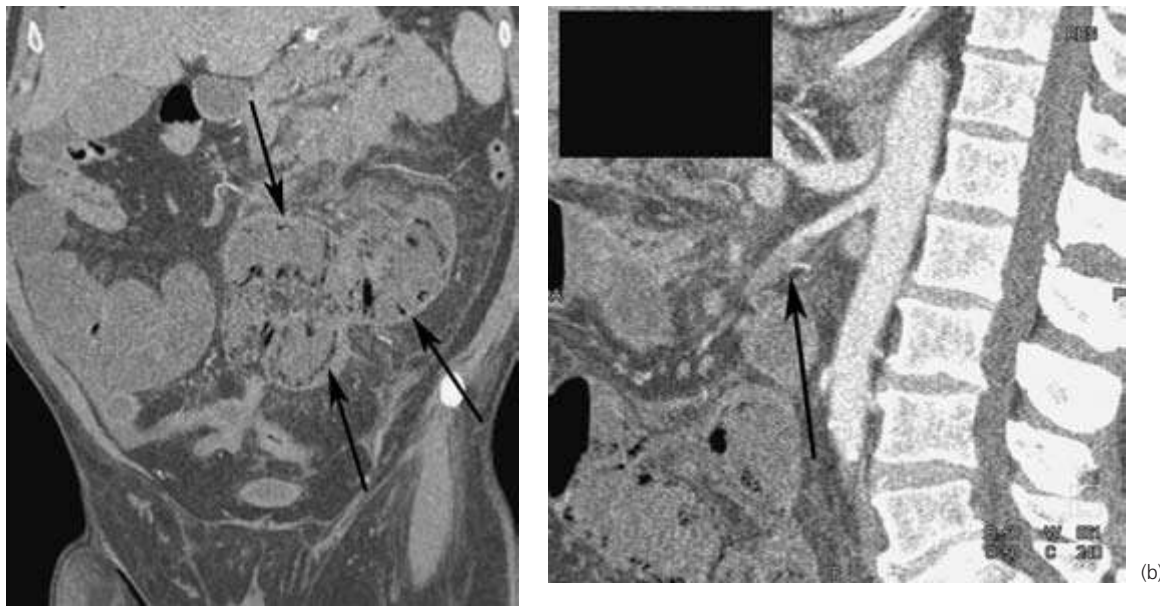
CT findings of obstruction are similar to traditional radiographic findings: disparate dilation of proximal bowel loops compared with more distal bowel (Fig. 131.8). Comparative studies have shown that CT is superior to plain film radiography in detecting intestinal obstruction and in determining the cause of obstruction [73]. Studies have shown that CT sensitivities reportedly range from 90% to 95% in detecting obstruction. CT establishes the etiology in a majority of cases [74]. The major contribution of CT in these patients is the ability to detect signs of strangulation. These signs include thickening and edema in affected loops (ischemic signs) and mesenteric clouding, ascites, or infiltration (mesenteric signs) [75]. The combination of multiple findings has improved reliability in predicting obstruction as compared to any single sign in isolation [76].

CT can change management by accelerating surgical treatment in obstructed patients, resulting in verifiable improvements in outcome [77,78]. CT efficacy decreases in patients with chronic obstructive symptoms and low-grade obstruction. For these patients, barium radiography, especially enteroclysis, is the method of choice [79].

The ability to view the CT data in more than one plane can be useful in the evaluation of patients with small bowel obstruction, as the exact site of transition may be difficult to detect on axial images. The use of MPR for this clinical indication has been shown to increase reader confidence [80].

Colon

CT is useful in the evaluation of many colonic disorders. Because CT shows both the colonic wall (generally < 3 mm) and surrounding pericolic fat, it can identify extension of pathological processes into the surrounding tissues. This results in improved staging of tumors and preoperative assessment



(a) (b)

Figure 131.7 (a) Coronal multiplanar reconstruction (MPR) from intravenous contrast-enhanced computed tomography demonstrates dilated small bowel with pneumatosis (arrows). **(b)** Sagittal MPR demonstrates thrombosis in the superior mesenteric artery (arrow).

This was the source of the small bowel obstruction in this patient with Crohn's disease.

of complex inflammatory reactions with a single examination, thereby facilitating both diagnosis and treatment decisions.

Neoplasms

Malignant neoplasms

A thorough preoperative evaluation is essential in selecting appropriate operative therapy and for sequencing surgery with available adjuvant treatments [81]. These decisions are based on the anatomical location of the primary tumor(s) and the presence or absence of metastatic disease. An additional element in rectal cancer patients is assessment of transmural penetration and the distance from the anal verge. Although EUS excels in local staging of accessible lesions, CT provides the most efficient methodology by which all these components can be comprehensively evaluated. Results from a multiinstitutional study reported 74% accuracy for CT assessment of wall invasion; the sensitivity in evaluating lymph node metastases was only 48%. CT demonstrated 85% accuracy and 97% specificity in detection of liver metastases [82].

The detection of colorectal carcinoma with CT depends on the degree of colonic distention and adequacy of the preparation [83]. In the unprepared bowel, all but the largest lesions will be overlooked. Adenocarcinoma appears as a soft tissue attenuation focal mass, which focally or circumferentially thickens the bowel wall (Fig. 131.9). Using air insufflation and a colon preparation, detection rate was increased from 68% to 95% [83].

Transmural invasion is suggested when streaky, spike-like, soft tissue attenuation changes are seen in the peritumoral fat. The main limitation of CT staging is under-staging the extent of local disease, with few over-staging problems. CT is useful in identifying complications of colorectal cancer such as perforation, obstruction, as well as synchronous lesions. These may be clinically silent but their presence impacts long-term survival. The negative predictive value of CT has been estimated at 90% [84]. Although most surgeons have come to rely on preoperative CT to survey the abdomen and pelvis, there is no routine agreement regarding widespread use [85].

Figure 131.9 Axial intravenous and oral contrast-enhanced multidetector computed tomography image demonstrates a subtle mass (arrows) in the right colon. Colonoscopy and biopsy revealed adenocarcinoma.

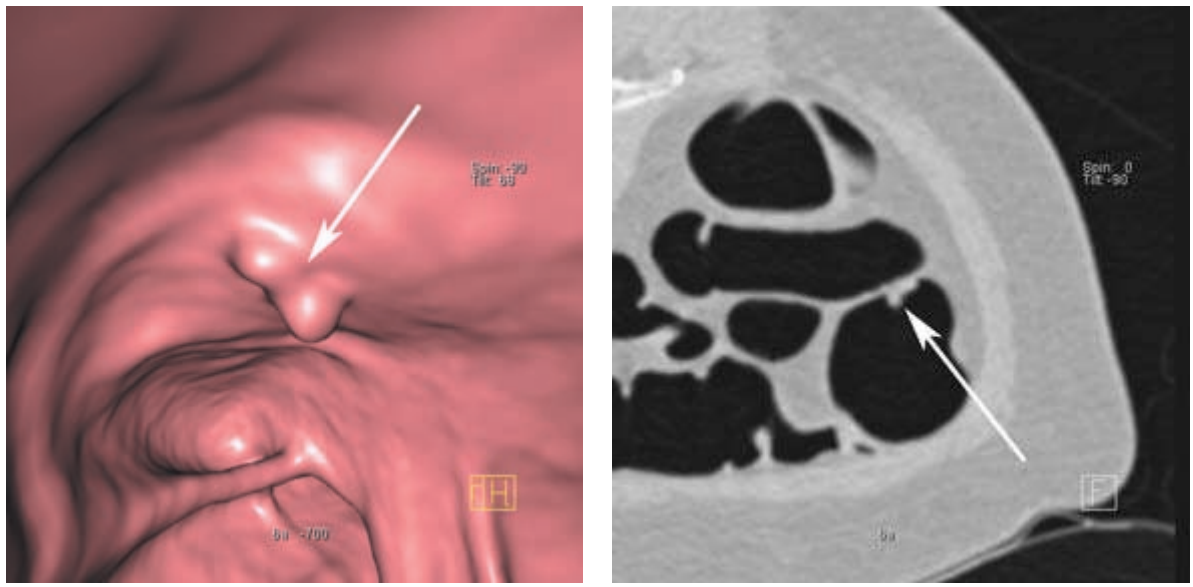
CT plays an adjunctive role in evaluating recurrent disease after abdominoperineal resection or colonic resection. CT is capable of demonstrating locally recurrent pelvic masses, lymphadenopathy, and liver metastases. Locally recurrent rectal cancer appears as spiculated densities or a fibrous soft tissue layer around the rectum; when the abnormal tissue is attached to the perirectal fascia or extends beyond it, positive predictive value is high [86]. CT or ultrasound imaging combined with colonoscopy have been shown to detect recurrent colon cancer at a lower total cost per patient than routine use of carcinoembryonic antigen, physical examination, and chest X-ray [87].

CT colonography (virtual colonoscopy)

The ability of helical CT to acquire a continuous volumetric dataset allows application of rendering techniques that result in display of the lumenal (mucosal) surface of the colon, a process known as CT colonography or virtual colonoscopy [88] (Fig. 131.10). The method was first introduced in the mid 1990s but was initially limited by slow scanner speeds, relatively thick 3–5-mm slice collimation, and the lack of easy-to-use software. The introduction of thin-slice MDCT now allows submillimeter collimation, which is crucial to high-quality virtual colonoscopy. Scanner speeds have also improved.

The study requires adequate bowel cleansing, which can be achieved with any of the traditional conventional colonoscopy agents such as polyethylene glycol, sodium phospate or magnesium citrate. For CT colonography, the patient also drinks special tagging agents such as dilute barium suspensions and iodinated solutions. The tagging agents mix with the residual solid and liquid stool, which will then appear "white," easily distinguishing stool from soft tissue polyps. Sophisticated software is now available from a variety of manufacturers and allows time-efficient review of the datasets using a combination of MPR and endolumenal fly-through views that simulate conventional colonoscopy. Most expert readers can review a study in 15 min.

The largest study of virtual colonoscopy in a screening population was published by Perry Pickhardt and colleagues in 2003 [89]. This study included 1233 symptomatic adults who underwent both CT colonography and conventional colonoscopy in the same day. For adenomas more than 10 mm in size, the sensitivity for virtual colonoscopy was 94% compared with 88% for conventional colonography. Per-patient sensitivity for virtual colonoscopy was 96% [89]. These results were very encouraging, especially when one considers that the study included only four- and eight-detector row CT



(a) (b)

Figure 131.10 (a) Endolumenal fly-through view from virtual colonoscopy shows 8-mm polyp (arrow). **(b)** Axial prone image from virtual colonoscopy demonstrates an 8-mm polyp (arrow) in the right colon.

scanners. A smaller screening virtual colonoscopy study of 615 patients was subsequently published with disappointing results [90]. This study showed less than ideal results for virtual colonoscopy, but included relatively inexperienced radiologists as readers [90]. It is clear that virtual colonoscopy requires training, and the American College of Radiology (ACR) has recommended training of at least 50 cases for radiologists.

Results of the multicenter ACRIN National CT Colonography trial, which was completed in late 2006, are pending. This trial included over 2600 patients from 15 institutions. Inexperienced readers (less than 500 cases in practice) were required to undergo training and pass a competency test before joining the study. All scans were performed on either 16- or 64-slice scanners such that data analysis will reveal the utility of currently implemented CT technology.

Nonneoplastic diseases

Diverticulitis

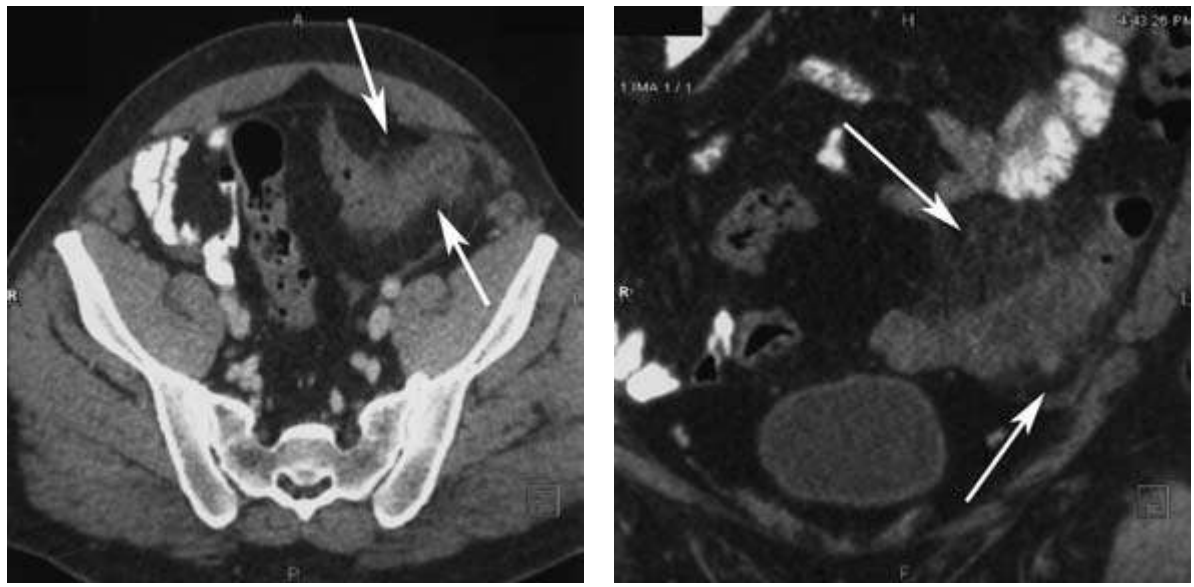
In those patients in whom the clinician requires imaging clarification or confirmation of a diagnosis of diverticulitis, CT is the primary and, in most instances, the only necessary test [91,92] (Fig. 131.11). Although CT and contrast enemas have equal accuracy in establishing the diagnosis, CT is clearly superior in determining whether abscess is present and in documenting the extent of the inflammatory mass [93]. When abscess is present, resection of the perforated segment with anastomosis is desirable; however, if the field is contaminated by pus, temporary colostomy may be necessary. Percutaneous abscess drainage reduces surgical morbidity and allows a primary anastomosis [94].

CT is excellent in diagnosing diverticulitis as a cause of fistulae arising from the colon, particularly those to the urinary bladder or the vagina [95]. The major limitation of CT is the inability to assess the integrity of the colonic mucosa, and perforated neoplasm may be overlooked. This is estimated to be a problem in approximately 10% of cases [96]. In these individuals, lumenal evaluation with either endoscopic or contrast radiography is indicated [97]. Of note, underlying colon cancers may also result in an increased number of pericolonic nodes as compared with diverticulitis, and this has been reported as a potentially useful finding to suggest the possibility of an underlying neoplasm [98,99].

Appendicitis

CT has emerged as the primary imaging modality in patients suspected of acute appendicitis [100]. Outcome-based studies have documented an impact on negative appendectomy rates in patients who have undergone CT [101,102]. CT has similar accuracy to ultrasound, although the negative predictive value of CT is significantly higher [103]. Local expertise and body habitus (thinner patients for ultrasound and larger patients for CT) should dictate the use of ultrasound or CT.

The diagnosis is dependent on visualizing an abnormal appendix (Fig. 131.12). The collapsed normal appendix usually measures 6 mm or less in cross-section; when distended, the appendix can measure up to 10 mm in diameter in normal patients [104]. A dilated appendix, as an isolated finding, can be suspicious but is not necessarily diagnostic of acute appendicitis. Defining criteria include a dilated thick-walled tubular structure that enhances following intravenous contrast [105]. If present, periappendiceal inflammation, phlegmon,



(a) (b)

Figure 131.11 (a) Axial oral and intravenous contrast-enhanced multidetector computed tomography image reveals thickening of the sigmoid colon with pericolonic stranding (arrows) compatible with diverticulitis. **(b)** Coronal multiplanar reconstruction shows extensive inflammation and minimal fluid in the pericolonic fat (arrows) typical of diverticulitis.

Figure 131.12 Axial intravenous contrast-enhanced multidetector computed tomography in a patient with right lower quadrant pain demonstrates an enlarged fluid-filled appendix (arrow) with moderate periappendiceal inflammation, compatible with acute appendicitis.

or abscess may also be identified. However, periappendiceal inflammatory changes are not always present in the setting of appendicitis [106], or may be minimal, even when the appendix is found to be gangrenous at surgery. Although it is possible to recognize findings of acute appendicitis on unenhanced studies [107], we strongly believe that intravenous contrast and oral contrast and acquisition using thin sections [108] are essential in patients referred for evaluation of right lower quadrant pain. In urgent cases, rectal contrast can be substituted for oral contrast.

Colitis

CT is useful in patients with nonspecific abdominal symptoms, directing the workup to an unsuspected colitis [109]. In an attempt to suggest a specific diagnosis, one evaluates mural thickness and enhancement pattern, distribution of bowel involvement, and associated mesenteric and small-bowel disease.

The mean colon wall thickness in Crohn's colitis, for example, is significantly greater than in ulcerative colitis [110]. Exclusive involvement of the right colon and small bowel is more frequent with Crohn's and infectious colitis rather than ulcerative colitis. Abscess is associated almost exclusively with Crohn's colitis rather than ulcerative colitis. In Crohn's colitis, CT has additional use in that pericolic disease is frequent. CT can also evaluate for perianal complications [111].

CT is not always needed in the workup of patients with ulcerative colitis, but may be obtained in symptomatic patients. On CT, the disease is recognized by a continuously thickened segment of colonic wall, displaying a target-like appearance. Fat hypertrophy in the presacral region is seen. In patients with long-standing colitis, fat deposition within the wall may occur [110].

An accordion-like appearance of the colon can be seen in a variety of acute colitides but was first described in pseudomembranous colitis (*Clostridium difficile*) [112]. In the hospital setting, CT may be the first test to suggest the possibility of pseudomembranous colitis in debilitated patients with suspected infection. The condition can involve the entire colon or may be segmental (Fig. 131.13). CT findings in

Figure 131.13 Axial intravenous and oral contrast-enhanced multidetector computed tomography demonstrates marked diffuse colonic thickening compatible with pseudomembranous colitis.

pseudomembranous colitis include dramatic wall thickening. CT can be used to help guide patient management, as some patients will ultimately require colectomy [113].

Solid organs of the gastrointestinal tract

Liver

Techniques

The CT technique used to examine the liver is based on whether the study is to be performed to exclude the presence of hepatic disease, determine the precise disease burden for preoperative planning, or characterize masses previously identified on other imaging studies. Separating these imaging tasks allows the radiologist to optimize contrast administration, acquisition speed, and timing.

Hepatic parenchymal enhancement following a rapid bolus infusion of intravenous contrast is characterized by three distinct phases: a hepatic artery phase, a portal phase, and an equilibrium phase. The hepatic artery phase, useful in detection of hypervascular lesions including hepatocellular carcinoma (HCC), lasts between 30 and 50 s following the initiation of injection. All primary hepatic lesions are supplied by the hepatic artery, and it is during this time that hypervascular lesions are brightly enhanced, because background parenchyma has not reached peak enhancement. Rapid scanning with MDCT enables subdivision of the arterial phase and the ability to acquire data during the early portion or the late portion of the arterial phase. The early arterial phase is used for arterial vascular imaging, and can be timed with a test-bolus technique or bolus tracking to correspond to peak aortic enhancement. The late arterial phase has been shown be superior to the early arterial phase for identification of hypervascular HCCs [3,114–116]. At approximately 70–90 s, peak hepatic enhancement is achieved (portal phase; also called the hepatic venous phase [3]). Peak enhancement is maintained for approximately 30 s and then slowly decays. For many liver tumors, including hypovascular metastases, scanning is performed during this portal phase because this is the time when there are maximal differences in attenuation between normal liver parenchyma and the tumor. Delayed scanning during the equilibrium phase usually results in decreased lesion conspicuity and is therefore avoided when imaging for hypovascular metastases. However, a delayed phase acquisition (180s) is used by some in conjunction with other acquisitions for HCC imaging, as a comparative investigation revealed that a small percentage of HCCs, which are hypovascular, increase in conspicuity during the delayed phase in cirrhotic patients [117].

Unenhanced scans may be useful in patients with suspected hypervascular lesions, including metastases from renal, thyroid, breast, islet-cell, and carcinoid tumors and HCC [118]. The clinician should communicate a specific clinical history or suspicion of these diagnoses to the radiologist for proper examination [119].

With MDCT, images of the entire liver can be acquired in a single breath-hold. Using 16- or 64-slice CT, the liver can be scanned in under 15 s or less than 5 s, respectively. This allows the arterial acquisition timing to be tailored to the clinical question. Early arterial acquisitions are used to perform three-dimensional CT angiography for tumor mapping and preoperative determination of arterial anatomy, while late arterial acquisitions are optimal for HCC detection. Following hepatic arterial acquisition, the liver can be immediately rescanned to capture peak parenchymal enhancement during the portal vein phase [120]. Imaging for hypovascular metastases typically requires only the portal venous phase. Combination of arterial and portal phases, referred to as dual-phase helical CT [121], is used for hypervascular lesion detection, or an early arterial phase can be combined with portal phase if CT angiography is indicated. A three-phase study can include unenhanced scans [118,122]. In order to achieve a diagnostic arterial-phase image, contrast must be power injected at a rate exceeding 4 mL/s. High infusion rates have been shown to increase both visualization of small hepatic arterial branches and conspicuity of HCC [116,123,124].

Intravenous, portal-phase, contrast-enhanced, single-detector helical CT was shown to be sensitive (91%) for detecting malignant hepatic tumors measuring larger than 1 cm, but relatively insensitive (56%) for tumors smaller than 1 cm [125]. Technological advances have not succeeded in dramatically improving sensitivity for small metastases. A mean sensitivity of 31% has been reported for lesions smaller than 1 cm in an investigation using four-slice or eight-slice MDCT [126], increasing to 41% with 16-slice technology

[127]. The availability of multislice CT does facilitate simultaneous lesion characterization and detection, because both phases of hepatic enhancement are accessible from the same dose of intravenous contrast [128]. Additionally, the high-quality three-dimensional display resulting from isotropic datasets improves localization.

If documenting the exact number and location of liver metastases is imperative, such as before contemplating resection of apparently isolated metastases, angiographic-assisted CT improves sensitivity. CT portography (CTAP) has the highest reported sensitivity for detecting focal liver masses, approaching that of intraoperative ultrasound, but is considerably more invasive [129]. The improved sensitivity may lead to better patient selection for resection of metastases [130]. The volumetric dataset from helical and particularly multislice acquisitions allows angiographic and three-dimensional volume-rendered data displays; these aid in lesion localization and surgical planning [131]. Improvements in contrast sensitivity afforded by MRI, with similar sensitivity for identifying colorectal metastases compared with CTAP [132], have significantly reduced the use of CTAP in most clinical practices compared with the late 1990s. For detection of HCC larger than 1.0 cm in cirrhotic patients, combined approaches using MDCT and MRI resulted in similar detection rates to those of CTAP with CTHA (CT during hepatic arterigraphy) in one investigation [127]. In our practice, which includes a large number of transplant patients in whom hepatic surgery is dependent on accurate demonstration of entire tumor burden, CTAP is almost never performed.

Diffuse diseases

Fatty infiltration

Fatty infiltration of the liver may occur in a diffuse or focal distribution. This intracellular fat lowers the CT attenuation of the liver, reversing the relation to splenic density as judged on unenhanced scans [133]. Fatty infiltration of the liver is best appreciated on noncontrast scans and may be difficult to detect accurately once intravenous contrast has been administered. Measurement of the liver attenuation only on unenhanced CT has been shown to be best for prediction of pathological fat content [134].

Focal fatty deposition can be confused with hepatic space-occupying lesions. Lack of displacement of adjacent vessels, location, and rapid change with time can be helpful in differentiation of focal fat from a true mass lesion [135]. When problematic, the presence of focal fat can be established by biopsy or "chemical shift" MRI [136].

Cirrhosis

Characteristic CT features can be seen in patients with advanced cirrhosis. The right lobe and medial segment of the left lobe are often decreased in size, but the lateral segment of the left lobe and caudate lobe are enlarged [137] (Fig. 131.14). Additionally, cirrhotic livers demonstrate irregular nodular liver margins, with apparent widening of the intrahepatic fissures and the porta hepatis as the liver retracts and shrinks. Associated changes of portal hypertension, including varices and venous collaterals, commonly occur. Enhancement of the cirrhotic liver is similar to normal liver during the arterial phase, but may be slightly less dense during the portal phase [138]. A normal CT does not exclude the diagnosis of cirrhosis as fibrosis may still be severe on liver biopsy.

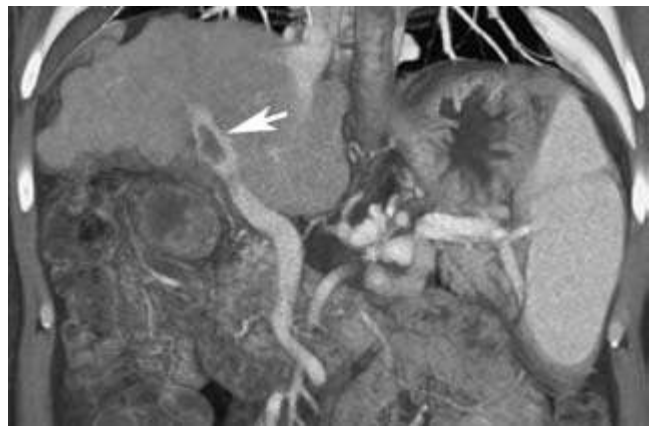


Figure 131.14 Coronal volume-rendered image from intravenous contrast-enhanced computed tomography demonstrates a small shrunken nodular liver compatible with cirrhosis. Splenomegaly reflects portal hypertension. Thrombus is present in the intrahepatic portal vein (arrow).

The distorted liver appearance caused by cirrhosis obscures many small tumors on CT. Considering the worldwide frequency of hepatitis C, the number of cases is expected to increase. Using conventional CT imaging, Miller and colleagues [139] reported detection of HCC in only 68% of cirrhotic patients with tumor. Incorporating arterial-phase helical CT scanning improves detection of HCC tumor nodules over portal venous-phase imaging alone [140]. Correlation with subsequent transplant specimens has shown that arterial-phase imaging for detecting HCC in cirrhotic patients is a significant improvement over conventional or portal venous contrast imaging. However, using multiphasic MDCT, sensitivity for small lesions remains low (47%–57% for those ≤ 1 cm) [141]. The addition of a delayed phase (after portal venous) to a biphasic acquisition protocol has been shown to improve diagnostic performance for identifying lesions 2 cm or less in size in cirrhotic patients [142]. Nonetheless, despite the combination of arterial, portal, and delayed acquisitions, the prospective and retrospective sensitivity of MDCT for detection of HCC lesions in cirrhotics has been reported to be 64% and 73%, respectively, and false positives resulted in disease overestimation [141].

Comparison of MDCT with MRI has produced variable results, with individual studies reporting superior sensitivity of MDCT [143] or MRI [144] for lesions 1 cm or less in size. However, the accuracy of the two technologies was comparable in both studies [143,144]. While the significance of dysplastic

nodules remains a controversial issue, it is known that CT is poor at detecting dysplastic nodules in cirrhotic livers [145].

Other diffuse diseases

Iron deposition and hemochromatosis, whether primary or secondary, increase the attenuation of the liver and spleen on CT [146]. CT is valuable in evaluating long-term iron deposition in the reticuloendothelial system from chronic transfusion therapy. The hepatic density may also be increased in patients receiving amiodarone therapy, those with glycogen storage disease, and following gold therapy for rheumatoid arthritis. Despite high serum copper levels, CT of the liver does not show significant elevations over normal attenuation measurements in patients with Wilson disease.

Masses

Cysts

Cysts appear as homogeneous, low-attenuation (0–10 HU) masses having smooth sharp margins without a perceptible wall. Cysts less than 1 cm in size may cause concern, particularly in patients with cancer, because of artifactually higher attenuation measurements from volume averaging. Comparison with prior studies is necessary [147], and MRI can be more specific for confirming that a small lesion is a cyst as opposed to a solid mass [148].

Benign neoplasms

Hepatic hemangioma is the most common tumor of the liver. Taking advantage of the improved contrast and temporal sensitivity of helical CT, hemangioma may be accurately and definitively diagnosed in over 90% of cases by CT alone [149]. On noncontrast studies, hemangiomas are usually hypoattenuating relative to normal liver. Their density is similar to that of the unenhanced blood vessels. After intravenous contrast administration, the lesions demonstrate peripheral globular enhancement and a centripetal fill-in pattern (Fig. 131.15). The enhancing areas have attenuation values identical to that of the aorta. Globular enhancement, isodense with the aorta, is 67% sensitive and 100% specific in differentiating cavernous hemangiomas and hepatic metastases. When demonstrated, no further workup is needed. However, hemangiomas can have atypical CT appearances [150]. For example, small hemangiomas can be hypoattenuating, especially on early-phase scans and may demonstrate no identifiable enhancement. Alternatively, due to arterioportal shunting, hemangiomas can show rapid enhancement [150]. Atypical hemangiomas can therefore mimic metastases in cancer patients.

Hepatic adenomas and focal nodular hyperplasia (FNH) are vascular lesions that can present with a variety of CT appearances that are often indistinguishable, unless there is hemorrhage (indicating adenoma). Both lesions usually demonstrate homogeneous increased attenuation during the hepatic arterial phase of enhancement, rapidly becoming isodense or slightly hypodense as peak portal enhancement is achieved. The identification of a central, stellate, low-density area is helpful in the diagnosis of FNH, but is seen only in a minority of patients [151] (Fig. 131.16). The introduction of MDCT has resulted in better visualization of the angioarchitecture of these lesions, useful for diagnosis [152]. CT angiography evaluation of FNH can reveal the presence of large feeding arteries and draining veins and helps to better visualize the pseudocapsule and central scar [152]. These features can be used to help distinguish FNH from hepatic adenomas on CT.

Figure 131.15 Intravenous contrast-enhanced axial multidetector computed tomography demonstrates a 2.5-cm mass (arrows) in the right lobe of the liver with peripheral nodular enhancement characteristic of a hemangioma.

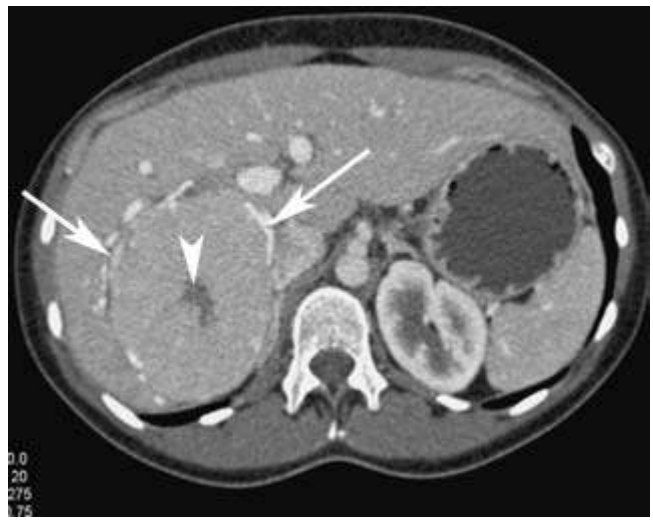

Figure 131.16 Axial intravenous contrast-enhanced multidetector computed tomography during portal venous phase of enhancement demonstrates a large mass in the right lobe of the liver (arrows), with a central scar (arrowhead). This is a typical CT appearance of focal nodular hyperplasia.

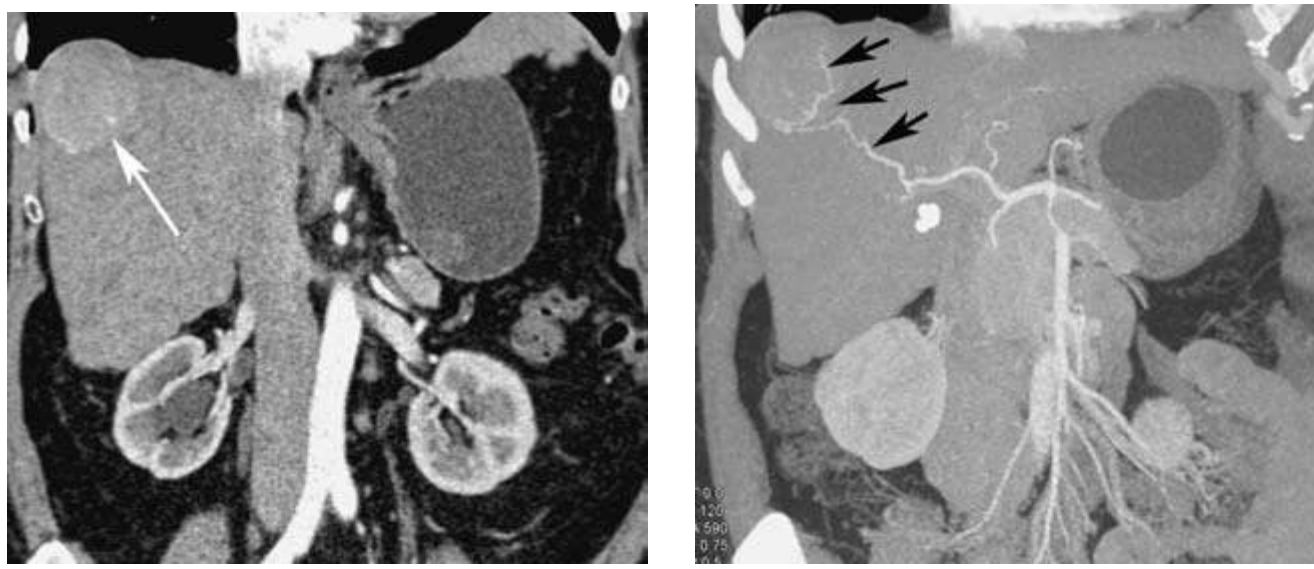

Figure 131.17 (a) Coronal intravenous contrast-enhanced multiplanar reconstruction from an arterial phase acquistion demonstrates a 4-cm enhancing hepatoma (arrow) in the dome of the liver. The liver is shrunken, compatible with cirrhosis. **(b)** Coronal maximum intensity projection demonstrates the arterial vessel (arrows) feeding the hepatoma.

Malignant neoplasms

HCC can appear on CT as a focal solitary mass, a multifocal process, or a diffuse infiltrating process. These lesions appear hypodense or isodense to normal liver on noncontrast-enhanced images. Following contrast administration, smaller masses are typically hypervascular on arterial phase acquisitions [142,153] (Fig. 131.17). Hypovascular HCC, which accounts for a small percentage of these tumors, becomes increasingly conspicuous as lowdensity lesions on portal or delayed-phase acquisitions [142,153]. However, the imaging appearance varies according to histology, with most (93%) moderately or poorly differentiated lesions demonstrating hypervascularity during the arterial phase, as opposed to 44% of well-differentiated HCCs [142]. During the portal phase, regardless of histology, smaller lesions are often hypodense, or may be isodense (and are rarely hyperdense) [142,154]. However, if a lesion is hyperattenuating on arterial phase and isodense on the portal phase, possible etiologies are broad. Differential diagnosis for lesions that are apparent exclusively during the arterial phase includes HCC, dysplastic nodule, hemangioma, FNH, arterioportal shunt, and aberrant venous drainage, among others [153].

Characteristic appearances of HCC include fibrous capsules, fibrous septa, and mosaic appearances. The fibrous capsules of HCCs are readily detected by CT and MRI [155]. The mosaic pattern is a result of variable tissue composition of HCC. In most patients, enhancing nodules indicate viable tumor cells, and low-attenuation areas represent necrosis, fibrosis, or hemorrhage [156]. With the increase in prevalence and incidence of hepatitis B and C viruses worldwide, interest in imaging surveillance of these high-risk populations is gaining momentum. Sonography is not adequately sensitive in this role [157], whereas CT and MRI are the imaging modalities of choice.

There is considerable interest in regional therapy for HCC, including chemoembolization and radiofrequency ablation. CT imaging aids in localization of foci of tumor for which angiographic administered chemoembolization can be applied [158]. Smaller lesions are amenable to percutaneous alcohol ablation [159].

Liver metastases demonstrate a variety of CT appearances. The majority typically appear hypodense compared with adjacent enhanced liver parenchyma on portal renous phase images, although vascular lesions can appear hypodense, isodense, or hyperdense, depending on the timing of contrast administration and scanning. Hypervascular metastatic lesions, as found in renal cell carcinoma, islet-cell tumors, leiomyosarcoma, and thyroid carcinoma, may be demonstrated on noncontrast-enhanced CT [118]. Metastatic lesions do not have a pathognomonic appearance and can be simulated by HCC, hemangiomas, abscesses, complicated cysts, or hematomas.

Abscesses

The diagnosis of liver abscess depends heavily on radiological imaging, particularly ultrasound and CT [160]. CT has become the screening procedure of choice for detecting pyogenic liver abscesses, with detection rates as high as 97%. The typical CT features of a pyogenic abscess include a mass hypodense to normal liver parenchyma, often with a contrast-enhanced rim. Gas collections are seen in approximately 20% of cases; internal septations may be present. The mass is usually of higher density than a simple cyst, but overlap in these densities can make it difficult to differentiate a simple cyst from an abscess [161]. Some malignant lesions

can simulate liver abscess. Clinical correlation and percutaneous aspiration are necessary to differentiate the entities.

Fungal abscesses usually present on CT as multiple, small, low-density, nonenhancing lesions spread throughout the liver and spleen. Although CT is sensitive for detecting these lesions, active disease can evade CT visualization [162]. Almost always caused by *Candida albicans*, biopsy is the only way to establish the specific etiological diagnosis.

An amebic abscess appears similar to a pyogenic lesion, as a low-density mass, usually solitary, but with 20% of patients demonstrating multiple lesions [163]. Echinococcal infection (i.e., hydatid cysts) also appears as low-density cysts, often with internal septations and daughter or inclusion cysts, creating the appearance of a cyst within a cyst. Calcification may be seen in the cyst wall or septations.

Vascular diseases

Increasing awareness of imaging findings secondary to altered hepatic perfusion is the direct result of growing use of helical CT and improvements in technology that have facilitated the synchronization of contrast infusion with data acquisition. Hepatic perfusion disorders are related to obstruction of arterial or venous flow, focal liver lesions, inflammatory disease, or portosystemic shunts. MDCT, especially with three-dimensional imaging, allows comprehensive evaluation of the hepatic vasculature.

Portal vein

Portal vein thrombosis can be detected on CT by visualizing clot within the portal vein, accompanied by peripheral enhancement from opacification and thickening of the vasovasorum (see Fig. 131.14). Chronic extensive collateral formation involving the porta hepatis is called cavernous transformation and is readily visible on MDCT. Intrahepatic portal vein thrombi produce slow flow peripherally in the liver, resulting in paradoxical hyperattenuation in the periphery related to increased hepatic arterial supply. The changes appear similar whether caused by a primary vascular abnormality with intrinsic thrombosis or secondary tumoral obstruction of the portal venous system, such as HCC.

Zonal perfusion abnormalities may be seen in radiation hepatitis. The radiated liver demonstrates decreased perfusion in the portal venous phase. In fatty livers, the radiated portions appear to have normal attenuation because the damaged hepatocytes cannot undergo fatty metamorphosis [164]. Similar changes may be seen in hepatic parenchyma surrounding masses that alter the regional portal vein flow.

Hepatic veins

CT reveals a variety of findings in hepatic venoocclusive disease (Budd–Chiari syndrome). Because of their noninvasive nature and optimal demonstration of vessel morphology and flow without the use of intravenous contrast, MRI and Doppler ultrasound are preferred for screening examinations of suspected patients. Noncontrast-enhanced CT findings include hepatomegaly with a hypodense parenchyma that spares the caudate lobe and perihilar regions of the left lobe. After intravenous contrast administration, the liver parenchyma demonstrates a mottled enhancement pattern. Initially, the greatest contrast enhancement is seen in the caudate lobe and the periportal regions of the left lobe, but a reversal of this pattern is seen on later images. Delayed images generally show a homogeneous enhancement pattern of the liver. Although direct visualization of thrombus within the hepatic vein or inferior vena cava can be demonstrated, in most cases the hepatic veins are not well seen and their nonvisualization may be the clue to the diagnosis. A similar mottled enhancement pattern is present in patients with chronic passive congestion, regardless of etiology, although, in this instance, the hepatic veins are patent [165].

Hepatic arteries

MDCT and CT angiography is playing an increasing role in evaluation of the hepatic vasculature. Contrast-enhanced CT with three-dimensional imaging can visualize both the intrahepatic and the common hepatic arteries and is useful for a variety of indications. For example, CT is helpful for identifying vascular anatomy and anatomical variants in both liver donors and recipients. CT is also useful for detecting vascular complications after liver transplant, which may include infarcts, stenosis, occlusion, or pseudoaneurysm of the hepatic artery [166].

Pancreas

Pancreatic CT requires thin collimation (preferably submillimeter), overlapped reconstruction, bolus injection of iodinated contrast material (best performed with a power injector), and rapid scanning to improve tumor detection, visualize relationships of peripancreatic vessels, and display findings three-dimensionally for optimized surgical and therapeutic planning. Properly timed contrast-enhanced studies will image the pancreas when its parenchyma is maximally enhanced and the peripancreatic vessels optimally opacified [167]. Accuracy in depicting variations in peripancreatic arterial anatomy, as well as clear depiction of vessel encasement, has resulted in the elimination of invasive angiography [168,169]. MDCT facilitates the use of multiphase imaging. For pancreatic CT, arterial, pancreatic or portal phases can be acquired [2,170]. The early arterial phase is used for CT angiography, because the arteries are optimally enhanced. However, maximum parenchymal and venous enhancement during the pancreatic and portal phases facilitates lesion detection and also aids in the determination of resectability [2].

Anatomical variants

Pancreas divisum is the most common congenital anomaly of the pancreas. Although this often goes unrecognized on CT, the pancreatic head can appear enlarged and simulate a mass lesion. Occasionally, the dorsal duct can be visualized

Figure 131.18 Oral and intravenous contrast-enhanced axial computed homography demonstrates pancreatic tissue (arrows) surrounding the second portion of the duodenum (arrowhead), compatible with annular pancreas.

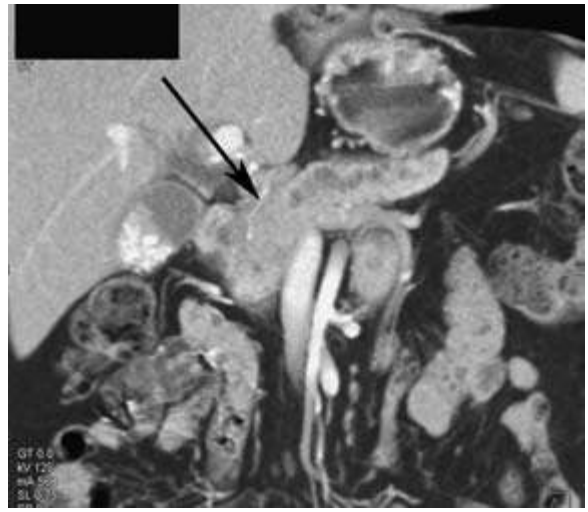

Figure 131.19 Intravenous contrast-enhanced coronal volume-rendered image demonstrates 1.5-cm pancreatic mass (arrow) with distal pancreatic ductal obstruction. At surgery this was an adenocarcinoma.

emptying into the accessory duct, confirming the diagnosis. In a study of 77 patients using four-detector MDCT with 3.2-mm slice thickness and endoscopic retrograde cholangiopancreatography (ERCP), pancreatic ductal anatomy was visualized adequately in 95% of patients [170]. ERCP detected pancreatic divisum in 10 patients, nine of whom were also identified on MDCT. For the radiologists, there were a total of three false-positive diagnoses [170]. Submillimeter MDCT, which is now possible with current 64-slice MDCT and three-dimensional imaging with minimum intensity projection, may allow more reliable visualization of aberrant pancreatic duct anatomy. However, magnetic resonance cholangiopancreatography (MRCP) may still be a more sensitive noninvasive method for diagnosis [171].

Agenesis of the dorsal pancreatic duct is identified with CT by visualizing only the head of the pancreas without a body or tail portion, and the condition may be confused with a mass in the head of the pancreas with distal pancreatic atrophy [172].

Annular pancreas is an anomaly formed during embryogenesis by the ventral anlage of the pancreas as the duodenum rotates, mainly due to hypertrophy of the left ventral bud. According to the fusion pattern of the ventral and dorsal pancreatic ducts, annular pancreas can be divided into three types: type I, divisional annular pancreas; type II, branch annular pancreas; and type III, main duct annular pancreas. Final diagnosis is based on the evidence of ERCP combined with CT. The CT diagnosis is suggested by visualizing a collar of pancreatic tissue surrounding the descending duodenum [173] (Fig. 131.18).

Neoplasms

Adenocarcinoma

The most common CT finding in adenocarcinoma is a focal mass isodense with the pancreas on noncontrast images and hypodense to the pancreas after intravenous contrast administration [174] (Fig. 131.19). This is more obvious using dual-phase helical CT protocols, which are now considered to be standard of care [175]. With improvements in CT resolution, faster contrast administration, and widespread availability of three-dimensional imaging, it is now possible to detect even smaller tumors using current technology. Studies using MDCT and three-dimensional imaging have an accuracy for detection of pancreatic cancer in the 95% range [2,176]. However small tumors less than 2 cm in size may nonetheless be difficult to detect. In a study by Bronstein and colleagues, the sensitivity of triple-phase helical MDCT for the detection of pancreatic masses less than 2 cm in size was only 77% with a specificity of 100% [177].

Even if the mass itself is not well visualized on CT, the presence of secondary findings can be used to infer the presence of an underlying tumor. For example, segmental pancreatic duct obstruction is a crucial finding and may be the only indicator of an obstructing mass. The pancreas distal to the tumor also usually appears atrophic. Lesions located in the pancreatic head will result in obstruction of the common duct as well as the pancreatic duct.

In addition to detecting the primary pancreatic mass, the major role of imaging is the determination of potential surgical resectability. CT is the modality of choice for preoperative staging and for identifying patients for a possible curative resection. Nonresectability is defined as the presence of either major arterial or venous encasement, hepatic (or other distant) metastases, or distant lymph node metastases [178] (Fig. 131.20). Realistically, at the time of initial diagnosis, 50% of patients have distant metastases to the liver or peritoneal surface, and more than 80% of the remaining patients have locally advanced tumors. However, it is the role of CT to

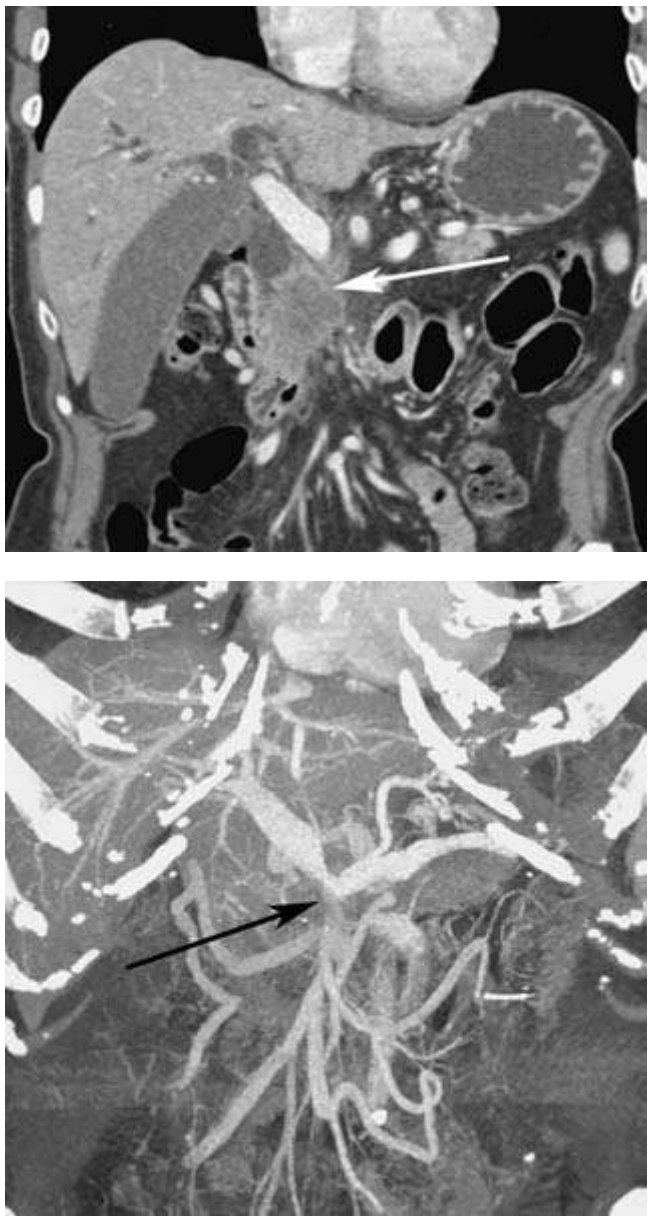

Figure 131.20 **(a)** Intravenous contrast-enhanced coronal MPR image demonstrates a 4-cm mass (arrow) in the head of the pancreas causing common bile duct obstruction. The gallbladder is also distended. Biopsy revealed pancreatic adenocarcinoma. **(b)** Coronal maximum intensity projection demonstrates encasement of the superior mesenteric vein (arrow) with resulting collaterals. The patient was deemed unresectable.

identify that small percentage of patients who might benefit from attempt at curative resection.

CT has been shown to have a high predictive value for unresectability (90%–100%) with a slightly lower predictive value of resectability (76%–90%) [176,179,180]. This is usually due to its inability to detect tiny liver metastases or minimal peritoneal spread [181]. These values are a marked improvement from conventional CT, which yielded accuracy in the range of 44%–73% [182,183]. The key to evaluation of the peripancreatic vasculature is high-resolution thin-collimation scans performed during the arterial and venous phases [184,185]. The ability to visualize the celiac axis, superior mesenteric artery, superior mesenteric vein, and portal vein in three dimensions with a combination of MPR, MIP and volume rendering is essential for detecting vascular encasement. CT angiography has replaced the need for preoperative conventional angiography for this indication.

In addition to assessing potential vascular encasement in patients with pancreatic cancer, CT can also identify adenopathy. Radiologists usually rely on nodal measurements to identify potentially malignant nodes. However, this is not always accurate, as even tiny nodes can harbor malignancy and large nodes can simply be reactive. In a study by Roche and colleagues, 62 patients with pancreatic cancer underwent detailed nodal analysis [186]. Applying a threshold of greater than 10 mm to identify malignant nodes, this study showed a sensitivity of only 14% with specificity of 85% [186]. This resulted in a positive predictive value of 17% and a negative predictive value of 82% [186]. Therefore, when determining resectability of ductal adenocarcinoma, CT is not necessarily helpful in the prediction of nodal involvement. Hence, in a patient thought otherwise to be resectable, the presence of peripancreatic lymph nodes should not prevent attempted surgical resection.

CT is the modality of choice for detecting distant metastasis, most commonly to the liver. These typically appear low density on the portal venous phase of the study. There is a size limitation for CT detection of metastasis in the liver. Even normal patients commonly have a few small-density lesions in the liver, thought to represent tiny cysts, hemangiomas, or bile duct hamartomas. Therefore, the presence of a few tiny lesions in the liver would not necessarily indicate metastases. Larger lesions in the liver can be confidently diagnosed as metastasis. However, small liver and peritoneal implants below the resolution of current CT scanners can be seen at surgery [181].

Islet cell tumors

Pancreatic islet cell tumors are neuroendocrine neoplasms that produce and secrete hormones to a variable degree. Depending on the clinical presentation, they can be classified as syndromic or nonsyndromic.

Syndromic islet cell neoplasms have clinical evidence of hormone production and produce a recognizable endocrinopathy. These include insulinoma and gastrinoma, glucagonoma, vipoma, and somatostatinoma. Such neoplasms usually present at a relatively smaller size compared with nonsyndromic neoplasms, because of the symptoms produced by the associated hormone production. Nonsyndromic islet cell tumors typically represent half of all islet cell tumors and present at a larger size than functioning tumors. Nonsyndromic islet cell tumors show no clinical evidence of hormone production, although the tumors are still hormonally active.

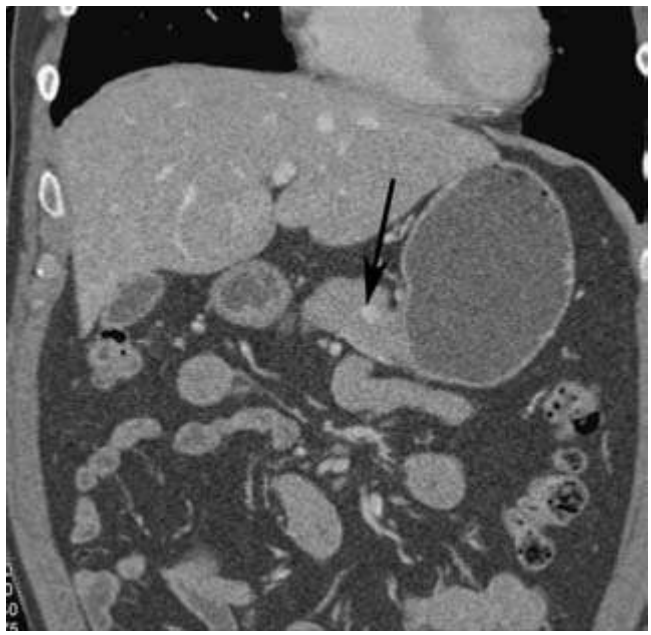

Figure 131.21 Coronal intravenous contrast-enhanced multiplanar reconstruction demonstrates a 5-mm enhancing lesion (arrow) in the body of the pancreas. This was an insulinoma.

MDCT plays an important role in the diagnosis and staging of both syndromic and nonsyndromic islet cell neoplasms [187]. In general, syndromic islet cell tumors are less than 3 cm in size (Fig. 131.21). Typically they are hyperenhancing and usually can best be seen on the arterial phase, although some are better visualized during the portal venous phase [188]. Nonsyndromic islet cell neoplasms tend to be larger at presentation than syndromic islet call neoplasms and are more likely to be cystic or necrotic [189]. Unlike pancreatic adenocarcinoma, these neuroendocrine tumors usually do not obstruct the pancreatic duct.

Multiple radiological techniques can be used for tumor localization, including preoperative and intraoperative ultrasound, EUS, CT, MRI, radionuclide scanning, angiography, and venous sampling [190]. There are conflicting claims as to the relative accuracies of angiography and venous sampling, and many of these investigations are difficult to justify because of their high cost, degree of invasiveness, or lack of precise anatomical information obtained [191]. If surgical resection of a neuroendocrine tumor is planned, intraoperative ultrasound is the best method for detecting nonpalpable masses and discerning the relationship of the tumor to vital adjacent pancreatic ductal anatomy.

The choice of preoperative imaging is more controversial, and depends on the clinical problem, local expertise, and availability of imaging techniques. Ultrasound and contrast-enhanced helical CT using two-phase helical CT in both the arterial and the parenchymal phase are the most commonly used preoperative imaging methods [192] because of their relatively low cost and widespread availability. Radionuclide scanning with ^{111}In-labeled DTPA-D-octreotide may be valuable in patients with equivocal CT scans or those with symptoms of tumor recurrence.

Cystic neoplasms

Cystic lesions of the pancreas are being identified with increasing frequency, due partly to the dramatic improvements in CT resolution. Most of these lesions are discovered incidentally [193]. While many will prove benign, some represent the precursors of pancreatic malignancy. A considerable amount of research has focused on whether imaging modalities (CT, MRI, EUS) can distinguish benign from premalignant or malignant cystic lesions, and the proper management for lesions that are too small to characterize [194,195].

Three cystic masses with distinguishing CT features arise in the pancreas: microcystic or serous cystic neoplasms; macrocystic or mucinous cystic neoplasms; and intraductal pancreatic mucinous neoplasms. The earliest pathological differentiation of microcystic and macrocystic lesions remains a useful framework, but considerable variation and overlap is becoming more obvious [196–198]. Currently, lesion characterization can be performed with MRI, CT, or EUS [194,198,199]. The ability of CT and MRI to accurately differentiate between the different classes of cystic neoplasms is limited, even in the setting of high diagnostic confidence [198,200,201]. Advances in technology have not resulted in a definitive means of pathological characterization through imaging.

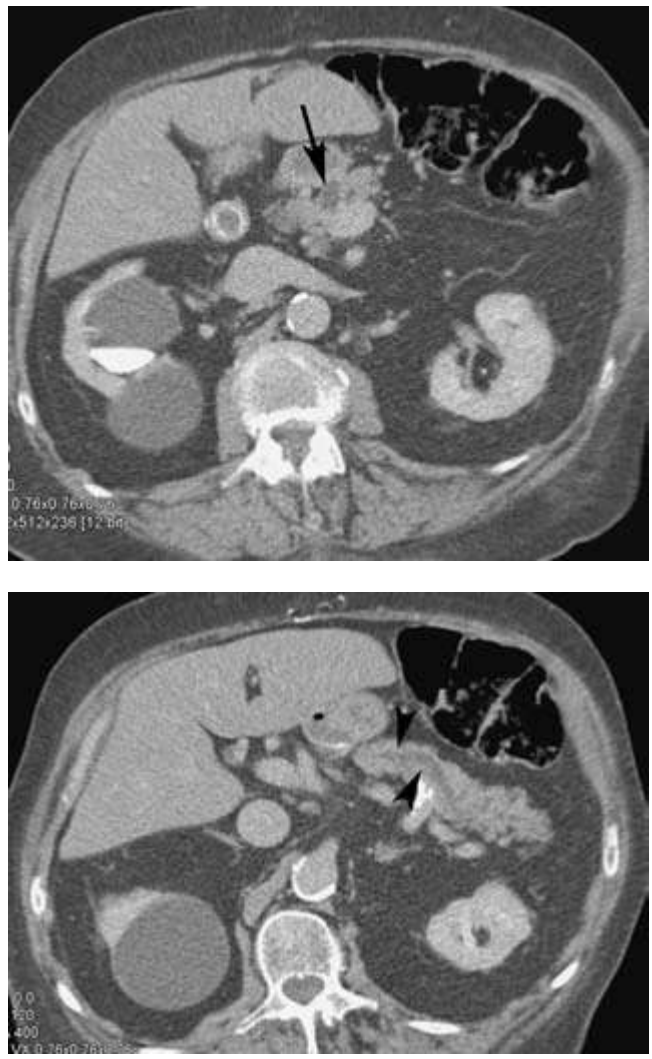
Most older published series intimated that while distinctions can be suggested on CT, surgical management was considered the standard of care [202,203]. However, new algorithms are evolving, and management decisions take into consideration patient characteristics (age, surgical risk, aspiration risk, symptoms), imaging findings, and analysis of endoscopically guided fine-needle aspiration [194,195,198]. Small lesion size (< 4 cm) does not ensure benignity [201], and neither imaging findings nor aspiration can prove that a lesion is benign or malignant in all cases [195,198]. Nonetheless, surgery remains indicated in the appropriate patient for lesions that appear malignant on imaging, for those which are symptomatic, or for those with tumor markers, mucin or malignant cells identified in aspirated fluid [194]. For patients who do not undergo surgery, follow-up is performed with serial imaging.

Cyst size is accurately determined by imaging and aids in distinguishing microcystic from macrocystic lesions [204,205]. Microcystic (≤ 1 cm) lesions are almost always serous. The classic appearance is a focal mass with innumerable cysts interspersed within a dense fibrous honeycomb. However, up to 25% of serous cystadenomas appear as a single cyst [198]. Central calcification occurs in approximately 30% of the lesions [206]. Serous microcystic cystadenoma is considered benign; there are scattered reports of metachronous

adenocarcinoma arising at a distant site in the pancreas of the same patient [207].

Mucinous lesions present as macrocystic (≥ 2 cm) unilocular cysts or as intraductal neoplasms. Peripheral soft tissue nodules, peripheral calcification (in < 5% of lesions), and minimal septation aid in radiological differentiation from microcystic adenoma. Reports of serous macrocystic adenomas reflect the lack of precision of absolute diagnosis from imaging alone [208]. Using thin collimation, mural nodules can often be resolved in malignant lesions. However, it is impossible to definitively distinguish benign from malignant mucinous lesions using imaging criteria. Most authorities recommend needle aspiration of the cyst fluid for preoperative diagnosis [209].

Intraductal pancreatic mucinous neoplasms are becoming increasingly recognized [210] (Fig. 131.22). These lesions have a wide range of clinical presentation, from small foci of duct ectasia with hyperplastic epithelium to frank carcinoma. The most frequent feature of intraductal papillary mucinous tumors is a lobulated multilocular cystic mass located in the uncinate process in contiguity with the dilated main pancreatic duct [211]. Demonstration of a connection with the duct aids in making this diagnosis [199]. In some patients, a bulging papilla and papillary projections in the ducts, which are specific findings, can be visualized on CT. When these lesions are branch type, under 2.5 cm in size, and have no solid components, clinical behavior appears nonaggressive [212]. Main duct-type lesions are often malignant. The possibility of a sequential change from nonpapillary and papillary hyperplasia, via adenoma, to carcinoma in intraductal papillary mucinous neoplasms associated with mucinous ductal ectasia has been speculated [213]. Investigations have delineated MDCT findings that reflect invasion or malignancy, including larger tumors, greater degrees of pancreatic and biliary ductal dilatation, and the presence of a solid lesion in the adjacent pancreatic parenchyma [214,215].



(a)

(b)

Figure 131.22 (a) Axial intravenous contrast-enhanced multidetector computed tomography demonstrates a 1-cm cystic lesion (arrow) in the pancreatic neck. **(b)** Axial image also demonstrates pancreatic ductal dilatation (arrowheads). These findings are very suspicious for intraductal pancreatic mucinous neoplasm.

Pancreatitis

Acute pancreatitis presents clinically and on imaging with a variety of forms. Interstitial edematous pancreatitis and necrotizing pancreatitis are the most frequent clinical manifestations; pancreatic pseudocyst and pancreatic abscess are late complications after necrotizing pancreatitis, developing after 3–5 weeks [216]. CT has become integrated into the evaluation of virtually all patients suspected of acute pancreatitis, and is considered mandatory in patients suspected of pancreatic necrosis [217,218]. CT offers excellent anatomical and morphological representation of the pancreas and peripancreatic tissue [219,220].

The value of CT is based on its ability to show the presence and distribution of pancreas-related fluid collections and the presence or absence of pancreatic necrosis. These two prognostic factors are evaluated in the Balthazar severity index. The presence of acute pancreatitis is graded as normal (grade A), gland enlargement (grade B), enlarged gland with peripancreatic edema (grade C), or single (grade D) or multiple (grade E) fluid collections [221]. Pancreatic necrosis on CT is recognized by regional nonenhancement on contrast-enhanced CT [222,223]. The degree of necrosis, combined with CT grading of the appearance of the gland and fluid collections, has greater prognostic implication than either manifestation alone [224].

The detection of necrosis is one of the primary goals of the imaging study. Intravenous contrast is required to make this assessment. Studies in laboratory rats have shown that intravenous iodinated contrast may increase cellular damage and potentially increase the severity of acute pancreatitis by promoting further necrosis and higher mortality [225]. These

findings are not reproducible in other animal models [226]. Most clinicians believe that the importance of establishing the presence of necrosis justifies the preferred use of intravenous contrast. In addition, pseudoaneurysm formation occurs in 2%–5% of cases. Intravenous contrast and rapid MDCT scanning are required for detection, which is improved with helical CT supplemented by angiographic renderings [70]. Treatment is aimed at drainage of periarterial fluid collections and possibly embolization of the affected vessel.

CT in patients with documented chronic pancreatitis reveals findings in over 90% of cases. These findings, in decreasing order of frequency, include dilation of the main pancreatic duct, parenchymal atrophy, pancreatic calcifications, fluid collections, focal pancreatic enlargement, biliary ductal dilation, and alterations in peripancreatic fat or fascia [227]. Focal mass-like chronic pancreatitis can result in pancreaticoduodenectomy for presumed neoplasm. In a Mayo Clinic series [228], 22 of 603 pancreaticoduodenectomies performed between 1956 and 1990 ultimately proved to be for chronic pancreatitis. When a patient with a pancreatic mass has a history of alcoholism and pancreatitis, and normal serum levels of CA19-9, mass-forming pancreatitis should be kept in mind in the differential diagnosis of a tumor suspicious for pancreatic carcinoma [229].

Pseudocyst formation is a well-recognized sequela of chronic pancreatitis. Percutaneous catheter drainage of both infected and noninfected pancreatic fluid has a reported average success rate of 80% and a complication rate of about 15% [230]. Cyst "maturity" is difficult to diagnose by imaging. A visible wall and lack of change over several weeks indicate the patient is most likely a candidate for successful cystogastrostomy.

Biliary tract

CT is good at documenting the presence and extent of biliary tract malignant disease and, because of its use as a general survey tool in the abdomen, varying forms of bile duct disease are frequently encountered on abdominal CT examinations. Ultrasound and MRI are superior in the evaluation of calculous disease.

Using current CT technology and intravenous contrast enhancement, normal intrahepatic bile ducts may be visualized in over 40% of normal patients; these should not be confused with ductal dilation [231]. The extrahepatic bile ducts are identified in 80% of normal patients and usually have diameters of 4–10 mm [232]. The extrahepatic biliary tree may be up to 10 mm in diameter in patients who have undergone cholecystectomy.

Studies have shown that CT is comparable to ultrasound in its ability to detect biliary obstruction and generally exceeds ultrasound in the ability to predict the level and cause of biliary obstruction, although some controversy still exists [233–235]. If there is a high degree of suspicion for obstruction and if malignancy is strongly suspected, CT is the examination of choice because it allows the staging of disease extent in a standard reproducible fashion with excellent depiction of all regions surrounding the duct and distant sites as well.

Three-dimensional helical CT cholangiography following intravenous infusion of a biliary contrast agent has been reported and rivals direct cholangiography for displaying biliary tract anatomy and pathology [236,237]. This technique, which uses postprocessing reconstructions (maximum intensity and shaded surface display projections), has not achieved widespread use due to the invasive nature of intravenous biliary contrast agents and the availability of noninvasive MRCP. However, advances in postprocessing have led to new display methods for the biliary system (in coronal and sagittal orientations) without cholangiographic contrast. These include two-dimensional MPRs, and specialized three-dimensional rendering using minimum intensity projection and volume rendering [17]. The minimum intensity projection algorithm selects the lowest attenuation voxels along rays projected through the dataset, to display bile-filled ducts in any plane [237]. With volume rendering, the settings can be adjusted to depict the biliary tree as a high-attenuation structure in a three-dimensional display from any viewing orientation [238,239].

Congenital anomalies

Congenital anomalies of the biliary tract are diagnosed definitively with direct cholangiography, but CT and ultrasound can suggest their presence. Congenital anomalies of the gallbladder are rare, consisting mostly of positional variants. The gallbladder can be seen in the left abdomen or in suprahepatic, intrahepatic, and other rare locations. CT can identify these anomalies if the gallbladder is not seen in its usual location at ultrasound.

Congenital cystic diseases of the biliary tree, including choledochal cysts, choledochoceles [240], and Caroli disease, can often be diagnosed by demonstrating the dilated biliary tree with appropriate patterns of dilation. Choledochal cysts appear as focal dilations of the extrahepatic bile ducts that may be mild and simulate a dilated duct or may be as large as 15 cm in diameter [241].

Gallbladder disease

Ultrasound is the modality of choice for evaluating the gallbladder. However, CT may demonstrate gallbladder wall abnormalities. Thickening of the gallbladder wall, although nonspecific, can be a clue to underlying pathology. Unusual right upper quadrant abdominal calcifications can be clarified with CT. CT can document the location of these as stones within the gallbladder calcification, within the gallbladder wall (e.g., porcelain gallbladder), or calcifications extrinsic to the gallbladder. CT is able to demonstrate gallstones in 74%–79% of patients with cholelithiasis; the remainder are isoattenuating with bile and cannot be delineated [242,243]. This lower sensitivity limits the usefulness of CT in screening for gallbladder stone disease.

Neoplasms

Gallbladder carcinoma is usually far advanced when patients are first seen by a physician, and CT findings will reflect these changes. Early gallbladder cancer has been classified on the basis of its CT appearance [244]. In the more commonly seen advanced disease, total replacement of the gallbladder lumen by a soft-tissue-density mass usually invading adjacent hepatic parenchyma characterizes this lesion. Less common appearances include focal gallbladder wall thickening or polypoid intralumenal masses, similar to those seen with ultrasound [245]. The extent of tumor can be depicted on CT in the common regions of spread, including liver, lymph nodes, peritoneal metastases and invasion of adjacent organs such as liver and duodenum.

The gallbladder can be secondarily involved by tumor from other organs. Direct invasion from adjacent organs is usually by means of porta hepatis metastases, most often from gastric or pancreatic carcinoma. Blood-borne metastases to the gallbladder are uncommon but can be seen in patients with melanoma.

Cholecystitis

The most common CT findings in cholecystitis are gallbladder wall thickening (> 3 mm) and cholelithiasis [246]. These findings are neither specific nor sensitive indicators and are also found with gallbladder carcinoma and hyperplastic cholecystosis. Other CT findings suggestive of the diagnosis include increased attenuation of the bile (> 20 HU) and loss of clear definition of the gallbladder wall. Increased attenuation in the adjacent hepatic parenchyma is a useful indicator of acute inflammation [247]. With more advanced cases, streaky inflammatory changes infiltrating adjacent pericholecystic fat can be seen. Air within the gallbladder wall or lumen in the absence of a history of prior enteric anastomosis or sphincterotomy is virtually pathognomonic of complicated emhysematous cholecystitis [248]. A low-attenuation halo around the gallbladder may indicate edema or minimal fluid collections and is a useful clue in differentiating complicated cholecystitis from carcinoma on CT [249].

Bile duct diseases

Neoplasms

Primary bile duct cancers take three forms: mass-forming, periductal infiltrating, and intraductal [250]. Hilar cholangiocarcinoma usually presents centrally near the porta hepatis, producing obstruction of the main hepatic ducts and intrahepatic branches. Peripheral intrahepatic cholangiocarcinoma will present as a hypodense hepatic lesion with peripheral enhancement, biliary dilation, capsular retraction, and contrast enhancement on delayed images [251]. In cirrhotic patients, small peripheral cholangiocarcinomas may be indistinguishable from HCC [252]. Hilar cholangiocarcinomas are generally seen on well-timed arterial phase images, and most will be seen during portal venous phase imaging. Using 16-slice MDCT with a multiphasic protocol, the diagnostic accuracy for hilar cholangiocarcinoma detection (64%) was similar to that of MRI (71%) [253]. A characteristic CT feature of cholangiocarcinoma is the delayed retention of iodine diffusely throughout the tumor during equilibrium phase imaging at 8–20 min following contrast initiation [254]. This retention is seen in tumors with a marked fibrous stroma and can be helpful in delineating the extent of hilar cholangiocarcinoma and in differentiating it from HCC [255]. CT is useful in the preoperative assessment of extent of disease and resectability of cholangiocarcinoma; CT sensitivity for resectability was approximately 60% with single-detector helical CT [256]. In an investigation that used 16-slice MDCT with 0.75-mm detector thickness, Park and colleagues evaluated accuracy for TNM staging of extrahepatic bile duct cholangiocarcinoma. Using axial sections and MPRs, accuracy was 77% for T-staging, 63% for N-staging, and 97% for M-staging [257].

Inflammatory diseases

Acute cholangitis is usually found in patients with underlying biliary tract obstruction. Most patients demonstrate dilated intrahepatic and extrahepatic bile ducts. Suppurative material within the bile ducts may be seen on CT images as high-attenuation debris within the duct lumen. Bile duct wall thickening may be present and appears diffuse and concentric, often demonstrating marked contrast enhancement [232]. Gas can be seen within the biliary tree in cases of infection with gas-forming organisms. Acute suppurative cholangitis can progress to frank liver abscesses, demonstrated on CT as low-attenuation areas in the liver in contiguity with the biliary tree.

The characteristic findings seen by means of cholangiography in primary and secondary sclerosing cholangitis can also be demonstrated on CT images [258]. Intrahepatic duct stenoses, dilated peripheral ducts with no apparent connection to the central ducts, and irregular intrahepatic duct dilation with a beaded appearance are characteristic CT findings of sclerosing cholangitis. CT findings in the extrahepatic ducts in this condition include duct wall thickening and irregularity, as well as duct wall enhancement after intravenous contrast.

Primary sclerosing cholangitis should be considered as premalignant, with more than 15% of patients at risk [259]. Careful search for masses, delayed contrast enhancement, progressive biliary dilation, and thickening of the bile duct wall is required to recognize complicating cancer [260].

Other less common causes of infection can produce characteristic CT images. Recurrent pyogenic cholangitis (also known as oriental cholangiohepatitis) is found in patients of lower socioeconomic status from Asia. The CT findings include marked intrahepatic and extrahepatic bile duct dilation, sharp tapering of peripheral extrahepatic bile ducts with loss of arborization, giant ductal calculi, and intraductal debris.

Organisms such as cytomegalovirus and *Cryptosporidium* can cause inflammation of the biliary tract in patients with

AIDS, resulting in changes on CT, ultrasound, and cholangiography similar to those of sclerosing cholangitis, with bile duct wall thickening, multiple strictures, and duct wall contrast enhancement [261].

Choledocholithiasis

The noninvasive diagnosis of common bile duct stone disease has been simplified with the development of MRCP, which has a sensitivity and specificity similar to ERCP [262]. Most patients with obstructive jaundice will undergo ultrasound, with CT used as a problem-solving modality [263]. Reported CT sensitivity for common duct stone detection varies from 45% to 97% [264–266]. The higher figures (up to 90%) reflect series with selected patient populations, often patients with known dilated ducts in whom it is easier to visualize stones, the highest sensitivity (97%) being reported using submillimeter MDCT [264]. The ability to use thin collimation and overlapping image reconstruction available with volume data acquisition of helical CT scanners improves stone detection rates [267]. However, even with submillimeter MDCT (0.75 and 0.625 mm), small stones are missed [264,268]. Postprocessing with multiplanar display is critical [264,268] (Fig. 131.23). Using MPRs and multiphasic acquisitions with 40 × 0.625 mm detector configuration, Kim and colleagues reported 97% sensitivity and 96% specificity for choledocholithiaisis in 34 patients with stones confirmed by ERCP or percutaneous transhepatic cholangiography [264].

CT is often performed without contrast, as it may improve the recognition of choledocholithiasis to more than 90% [269]. However, a 16-slice MDCT study has shown that combining intravenous contrast-enhanced axial sections with MPRs resulted in diagnostic accuracy comparable to the use of combined pre- and post-contrast CT (both techniques 89% sensitive) [268]. These results suggest that a single intravenous contrast-enhanced acquisition with two-dimensional postprocessing should be considered to obviate the need for multiple acquisitions and the additional radiation exposure to the patient [268].

The CT appearance of common duct stones parallels that of gallstones and depends on the chemical composition of each stone. Densely calcified stones can be seen as high-attenuation structures within the duct lumen, but most duct stones are isoattenuating with soft tissue or bile on CT [266].

Several processes can simulate duct stones on CT, and care must be taken to avoid misdiagnosis. Critically placed pancreatic calculi, oral contrast in an adjacent duodenal diverticulum, residual contrast material from a prior cholangiogram, and papillary ductal neoplasms can simulate choledocholithiasis.

Figure 131.23 **(a)** Axial intravenous contrast-enhanced multidetector computed tomography in a patient with obstructive jaundice shows a subtle filling defect in the common duct (arrow). **(b)** Coronal multiplanar reconstruction better demonstrates the stone (arrow) in the distal common bile duct.

Peritoneum

Many gastrointestinal diseases can have associated peritoneal findings. Many of these are subtle; recognition of abnormalities requires a systematic evaluation of the peritoneal structures based on understanding the spread of disease processes within the abdominal cavity. The majority of ligaments and mesenteries in the abdomen are formed from remnants of the ventral and dorsal mesenteries, which suspend the primitive gut. The pelvic ligaments are mainly formed by reflections of peritoneum over the pelvic organs or structures. The mesenteries and ligaments form the boundaries of the peritoneal spaces. Accurate localization of fluid collections and detection of neoplasms is facilitated when the

pathway of spread through adjacent ligaments and mesenteries is understood [270]. For purposes of radiological diagnosis, the peritoneal cavity can be thought of as an "end organ," in that the response to a pathological process is similar regardless of etiology.

Neoplasms

The radiological appearances of the more common peritoneal abnormalities may be thought of in three basic patterns: solid but relatively well-defined masses; cystic-appearing masses; and ill-defined or infiltrative processes. The most common solid masses to affect these anatomical regions are secondary neoplasms. The various cystic-appearing masses (including duplication cyst, cystic lymphangioma, cystic mesothelioma, teratoma, and loculated ascites) and infiltrating masses (e.g., peritoneal mesothelioma, retractile mesenteritis, desmoid, and carcinoid) must be differentiated on the basis of clinical findings and additional imaging findings (e.g., CT depiction of fat and calcium in teratomas and the radiating appearance of carcinoid) [271]. However, there is overlap in the CT appearance of inflammatory and neoplastic disease, which may necessitate biopsy for definitive diagnosis. Examples include retractile mesenteritic fibrosis (a form of sclerosing mesenteritis) and carcinoid tumor, which can be indistinguishable on CT [272]. Similarly, tuberculous peritonitis can be difficult to distinguish from peritoneal carcinomatosis.

Peritoneal carcinomatosis is a form of metastatic disease most frequently associated with primary lesions in the ovary, large bowel (including appendix), and stomach; however, any primary malignancy may disseminate through the peritoneal cavity. Peritoneal lymphoma (not unique to AIDS patients) [273], peritoneal leiomyosarcoma [274], and melanoma have also been reported. Loculated ascites is the most common finding. Bowel wall thickening and irregularity with or without obstruction may occur, the most common site of involvement being at the rectosigmoid junction. Additional findings include parietal peritoneal thickening and enhancement [275].

Tumor involvement of the omentum is visible as soft-tissue-attenuation nodular or reticular densities within the peritoneal fat. This can coalesce into an omental cake [275]. Implants may be present without ascites [276] and careful inspection of the omentum and sites of peritoneal ligamentous attachments is necessary to detect these subcentimeter nodules [277]. An MDCT investigation showed that use of MPR increases lesion detection rates in patients with ovarian cancer metastatic to the peritoneum, including lesions involving the infracolic omentum [278]. However, in patients with single-site disease and no ascites, small isolated metastatic lesions were still missed [278].

Pseudomyxoma peritonei has a unique appearance of large low-attenuation masses distributed within the peritoneal cavity (Fig. 131.24). Calcifications may occur along the periphery. When pseudomyxoma peritonei is suspected, careful attention should be given to the appendix or ovaries as the potential source.

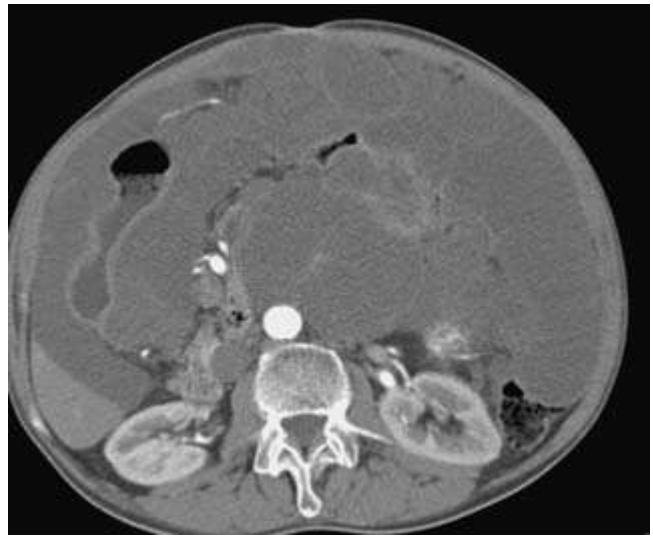


Figure 131.24 Intravenous contrast-enhanced axial computed tomography in a patient with pseudomyxoma peritonei demonstrates extensive low-density implants filling the peritoneal cavity.

Primary peritoneal tumors include a variety of benign mesenteric cysts, stromal neoplasms, lymphoid neoplasms (such as Castleman disease), mesothelioma, and desmoid tumors.

Nonneoplastic peritoneal diseases

Enteric inflammatory processes will cause local increased attenuation within the adjacent mesenteric and intraperitoneal fat [279]; however, one should not diagnose acute generalized peritonitis unless there is evidence of free fluid. A variety of intraabdominal pathologies can give rise to secondary peritonitis, including appendicitis and bowel perforation. In chronic peritonitis, such as in *Mycobacterium tuberculosis* peritonitis, one may see retraction of the parietal peritoneum from the abdominal wall and apparent enhancement of the peritoneal surfaces [280]. In all other ways, the findings may be identical to those of peritoneal carcinomatosis.

For patients with an acute abdomen, CT is useful for diagnosing a range of possible etiologies. In the setting of bowel perforation, CT has a higher sensitivity for the detection of pneumoperitoneum than plain radiography, including upright chest films [281]. When subhepatic free air tracks into the porta hepatis intrahepatic reflections of the peritoneal cavity, it may resemble biliary air [282]. The prevalence of pneumoperitoneum in the postoperative period based on CT findings is greater than that previously reported. Half of patients may demonstrate free intraperitoneal air 6 days after surgery [283].

In the setting of blunt abdominal trauma, pneumoperitoneum does not necessarily indicate hollow viscus injury. It may be secondary to other etiologies, especially dissection of interstitial air from the chest [284]. When free air is due to

bowel perforation (traumatic and nontraumatic), the precise location of bowel rupture may be difficult to delineate on CT. The site of nontraumatic bowel perforation was "directly visualized" in 12%–41% of patients in a study by Ghekiere and colleagues [285]. Findings that indicated the region of bowel disruption in a separate MDCT investigation included the location of clustered extralumenal air bubbles, thickening of the bowel wall, or a focal bowel wall defect, enabling identification of the point of disruption in 86% of subjects [286].

Hemoperitoneum is seen most frequently in trauma [287], acute gynecological disease, or hemorrhage from neoplasm [288]. Unclotted intraperitoneal hemorrhage typically measures 30–45 HU, higher than water and bile [289]. The CT attenuation of hemoperitoneum may be falsely low in the upper abdomen, because the blood products have settled to the dependent portion of the peritoneum (hematocrit effect). When blood is clotted, the density is in the range 45–70 HU. Detection of a site of high-density hemorrhage, the sentinel clot, can lead to identification of the injured organ [289,290]. In patients with blunt abdominal trauma, scanning through the lower pelvis, regardless of the site of injury, can detect hemoperitoneum in the cul-de-sac, even without signs of hemorrhage in the upper abdomen.

Hernias

The diagnosis of abdominal wall hernia is aided by CT [291]. Although most hernias are diagnosed clinically, they may be occult, particularly in obese patients, and they can be a source of abdominal pain. A wide variety of abdominal wall hernias have been described, including lumbar, spigelian, obturator, and perineal. When a hernia is suspected as the cause of bowel obstruction, it is important to be able to identify a transition zone within the hernia; if both afferent and efferent limbs are dilated, then a downstream etiology should be sought. Complications of hernias include incarceration and strangulation (Fig. 131.25). The CT findings are similar to those seen in strangulated small bowel obstruction [292].

The CT appearance of internal hernias, when bowel protrudes through an opening or defect in the mesentery or peritoneum, has been described [293]. Predisposing factors that can cause such a defect include surgery, trauma and inflammatory disease, or the opening may be congenital [294]. Of the six types described, paraduodenal hernias are most common, followed by pericecal, transmesenteric, foramen of Winslow, intersigmoid and, least commonly, paravesical hernias [293]. CT findings of right paraduodenal hernia are encapsulation of small bowel loops in the right midabdomen with looping of arterial and venous jejunal branches behind the superior mesenteric artery. The findings of left paraduodenal hernia, which is more common than right paraduodenal hernia [293], are less specific, but include clustering of small bowel loops or encapsulation of bowel

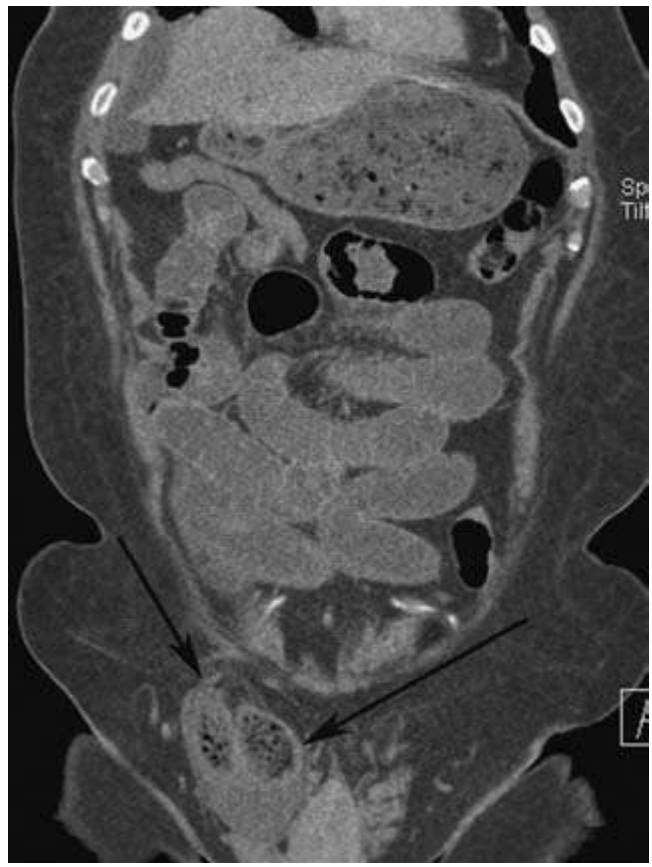

Figure 131.25 Coronal multiplanar reconstruction shows moderate dilatation of small bowel loops due to an obstructing right inguinal hernia (arrows).

loops at or above the level of the ligament of Treitz with intermittent dilation, depression of the duodenal–jejunal junction, and compression of the posterior gastric wall [295,296].

Traumatic diaphragmatic hernia may cause diagnostic difficulty. Left-sided diaphragmatic hernia is easier to diagnose than right [297]. CT can supplant barium studies and nuclear scans. However, in a helical CT study, the diagnosis was missed using subjective prospective interpretation in up to 50% of cases. Identification of numerous predefined criteria increased sensitivity for detecting blunt diaphragmatic rupture to 100% [298]. Continuity of the diaphragm should be assessed to aid in differentiation of ectopic organ position due to hernia or diaphragmatic paralysis. Multiplanar or reconstructions or volume tendering are especially helpful. A careful history of trauma should be sought.

Magnetic resonance imaging (MRI) is a powerful imaging tool for the evaluation of disease processes of the abdomen. It has an established role as a primary diagnostic technique in abdominal imaging, with evidence showing MRI to have advantages over computed tomography (CT) with regard to diagnostic sensitivity and specificity for many pathological processes of solid organs, bile and pancreatic ducts, bowel, peritoneum, and retroperitoneum.

Since the development of MRI, applications for its use in the gastrointestinal tract have expanded rapidly. The evaluation of the abdomen by MRI was initially hampered somewhat because of artifacts associated with respiratory and bowel motion. However, the development of newer fast imaging techniques has overcome these motion effects, enabling examination of structures and organs that were previously not reliably imaged. These new techniques have improved the results of MRI of the abdomen, particularly when compared with CT.

MRI has certain advantages over CT. CT relies on the single variable of X-ray attenuation for tissue contrast. All image contrast with CT relies on attenuation, and vascularity of structures can be inferred by the changes in attenuation imparted by intravenous contrast agents. Basic differences that can be distinguished include air, calcification, bone, soft tissue, fat, and changes in soft-tissue attenuation imparted by intravenous contrast agents. However, MRI incorporates several parameters that can distinguish pathological tissues. These include T1, T2 (see following section), lipid content, the magnetic susceptibility imparted by metal ions such as iron in the liver, and specific characteristics of flowing blood. In addition, various types of contrast agents, some of them targeted receptor agents, have been developed for imaging the abdomen. Finally, newer techniques such as diffusion and perfusion imaging, are being developed for imaging the abdomen. Compared with CT, MRI has a range of tissue characteristics with which to build the image, and therefore has a greater potential for tissue characterization.

The risks of CT derive from the dose of radiation and from the risk of nephrotoxicity with intravenous contrast agents. The risks of radiation dose may be significant, particularly in younger patients. The probability of a radiation-induced cancer in a young adult undergoing CT of the abdomen and pelvis is about 1 in 2000 or greater. The cost of this one-time radiation dose has been estimated at $30/mSv, or $300 per abdominal CT. These considerations have led one author to suggest that MRI in younger patients may be cost-effective compared with CT based on considerations of radiation risk alone. Costs associated with irradiation of unsuspected pregnancies have not been assessed.

Risk of nephrogenic systemic fibrosis (NSF) has been reported following intravenous gadolinium contrast agent in patients with severe renal failure (stage 4 or 5; glomerular filtration rate <30 mL/min/1.73 m^2) [1]. Nephrogenic systemic fibrosis (NSF) is a rare and serious syndrome that involves fibrosis of skin, joints, eyes, and internal organs. Its cause is not fully understood, but it is associated with exposure to gadolinium in patients with severe kidney failure. If, after review of clinical indications, gadolinium enhancement is judged to be important for diagnosis in patients with severe renal failure, the lowest effective dose of contrast agent should be used. Current reports on NSF suggest that MRI using 20 mL or less of gadolinium contrast agents poses negligible risk of NSF. Most NSF has occurred using more than 30 mL of gadolinium contrast agent, and most have been following gadodiamide [2]. For patients treated with hemodialysis, a hemodialysis session within a few hours following gadolinium contrast injection is likely to further reduce risk of NSF.

CT of the abdomen routinely employs iodinated contrast agents for delineation of vascular anatomy, and to increase

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

the tissue contrast between tumors and normal organs. Iodinated contrast agents pose three dangers to patients: anaphylactic reaction, renal nephrotoxicity, and osmotic load. Certain patients, such as those with diabetic nephropathy or renal insufficiency from any cause, are at increased risk from renal nephrotoxicity from iodinated contrast agents. It is safer and cost-effective for these patients to be imaged with MRI. MRI poses significant risk only to patients with certain types of implanted devices such as cochlear implants, cerebral aneurysm clips, or cardiac pacemakers. The risk of anaphylactic reaction associated with currently available gadolinium agents is very low. These agents have no known cross-reactivity with the iodinated contrast agents used for CT, so these patients may be safely imaged with MRI.

In this chapter, we explain some of the tissue characteristics and basic principles of imaging and discuss specific applications and techniques in MRI.

Basic principles (Table 132.1)

Differences in tissue contrast with CT are measured by Hounsfield units, which are a measure of X-ray attenuation. In MRI, the difference in tissue contrast (white, gray, black) depicted on the image is termed its signal intensity. High signal intensity refers to structures which are white on the image and low signal intensity to structures which are dark on the image. Unlike Hounsfield units in CT, signal intensity units are arbitrary and have no real meaning as absolute numbers.

The terms T1 and T2 refer to specific tissue properties that describe the way protons (mostly in water and lipids) behave after being excited by a radiofrequency pulse in a strong magnetic field. Each type of tissue will show a typical T1 and T2. When the image tissue contrast is based mostly on the differences in T1 between the tissues, the image is termed a T1-weighted image. T1 is termed the longitudinal relaxation rate and T2 the transverse relaxation rate or spin-relaxation rate. Structures or fluids that are bright on T1-weighted images have a short (lower) T1 because of greater longitudinal magnetization, and images which are dark have a long T1. Structures containing no water or fat, such as bone or air, also will appear black on a T1-weighted image.

The specific parameters chosen to acquire the image determine whether an image is T1-weighted or T2-weighted or some other type of image. TE and TR refer to the echo time and repetition time, respectively, and are the parameters chosen by the operator to acquire a T1-weighted or T2-weighted image. The specific parameters chosen by the technician determine exactly what kind of image is obtained and are termed the pulse sequence. This sequence therefore describes a set of images covering a specific anatomical area, with identical imaging parameters such as TE, TR, and resolution. T1-weighted images have a short TE and a relatively short TR.

Images designed to show contrast based mostly on the T2 values of the tissues are called T2-weighted. Such images generally have a long TE and a long TR. Structures which are high signal intensity (white) on the T2-weighted image are generally fluid-containing structures such as cysts, intestinal contents, or gallbladder bile. Most tissues in the abdomen, such as liver, pancreas and intestinal wall, have low signal intensity (dark) on T2-weighted images. Structures which have a high fluid content or contain more fluid than normal tissues are brighter on the T2-weighted image. Examples are cysts and hemangiomas of the liver. Structures such as malignant tumors contain higher water content than normal tissues, and therefore show higher signal intensity than normal tissues. Because of their long repetition time (2–3 s), T2-weighted images usually take longer to acquire than T1-weighted images, and therefore are somewhat more susceptible to motion artifact.

Within a strong magnetic field, protons (hydrogen atoms in water or lipid) have a physical property termed spin (angular momentum). These spins can be perturbed by a radiofrequency pulse at a specific frequency, the resonant frequency of the spin. After this excitation pulse or tip, the spins will emit a radiofrequency wave that can be registered by a receiver called the receiver coil. A radiofrequency pulse of sufficient magnitude to tip the spins 90° away from the main magnetic field is referred to as a 90° pulse. Similarly, a radiofrequency pulse that tips the spin 180° is called a 180° pulse or an inversion pulse. After tipping the spin 90°, the spins emit a signal termed the free-induction decay (FID). This radiowave signal is the basis of the magnetic resonance signal.

Because it occurs soon after the initial radiofrequency pulse, the FID is not received normally. The FID rapidly decays in signal amplitude because of dephasing of the spins. This means the spins precess out of phase relative to each other because of small differences in the magnetic field strength in the tissues and therefore have no net signal. This effect of signal amplitude decay, because of dephasing, can be overcome by the application of the 180° pulse after the 90° pulse, in order to refocus the spins and bring the spins back into phase with a corresponding rapid increase in signal amplitude. This process is termed the spin echo and is used in spin echo sequences, which are the most frequently used sequences in MRI. Spin echo sequences can be T1-weighted, T2-weighted, or intermediate-weighted. Intermediate-weighted images use a short TE and a long TR, and are sometimes called proton density-weighted images. They generally have limited usefulness for abdominal imaging.

The signal from the spin echo is localized in space within the body by applying magnetic field gradients. These gradients change the resonant frequency and phase of the spins linearly across the body so that the source of the radio signal can be localized. These gradients are termed the frequency-encoding and phase-encoding gradients. A map of the location of the signal and the strength of the signal strength linearly

Table 132.1 Terms used in magnetic resonance imaging

Term	Synonym	Definition
Longitudinal magnetization		Amplitude of magnetization (and potential signal intensity) that is oriented along the main magnetic field
Transverse magnetization		Amplitude of magnetization (and actual signal intensity) that is oriented perpendicular to the main magnetic field in the plane of the receiving coil
Tissue characteristics		
T1	Longitudinal relaxation time or spin-lattice relaxation time	Measurement of the rate at which the longitudinal relaxation returns to the direction of the main magnetic field after perturbation by a radiofrequency pulse
T2	Transverse relaxation time or spin-spin relaxation time	Measurement of the rate at which spins dephase relative to each other in the transverse plane which cannot be refocused by a 180° refocusing pulse
Magnetic susceptibility		Local distortion of the magnetic field induced by paramagnetic compounds, metal, air–tissue interfaces, etc., which decrease the signal intensity
Chemical shift		Reference to the different resonant frequencies of certain compounds such as fat or silicone relative to water, which allows their selective saturation
User-controlled parameters		
TE	Time to echo or echo time	Time interval between the alpha pulse (a 90° pulse in a spin echo pulse sequence) and the center of the received signal
TR	Repetition time	Time interval between the phase-encoding steps
TI	Inversion time	Time interval between an inversion pulse in an inversion recovery sequence. The time interval between the inversion pulse and the TE
Pulse sequence	Sequence	Complex set of commands that control the magnetic resonance system, gradients and radiofrequency generator in a specific manner, to generate the received signal
In-phase image		Image in which fat and water in the image are in-phase with one another and therefore their signal intensity is additive in the image
Opposed-phase image		Image in which the fat and water signals are out of phase with one another and therefore subtractive or cancel in the image
Acquisition matrix	Matrix	Number of frequency-encoded steps and phase-encoded steps, which determines the resolution of the image
Magnetic resonance angiography	MRA	Set of images, usually gradient echo images, which are designed to emphasize flow within blood vessels. These are displayed in a format via computer reconstructions to resemble conventional angiograms
Magnetic resonance cholangiopancreatography	MRCP	Set of images that are heavily T2-weighted and designed to demonstrate fluid within the biliary tree and pancreatic duct
Contrast agent		Chemical compound injected or ingested to change the tissue contrast on the magnetic resonance image
Paramagnetic (e.g., gadopentetate dimeglumine)		Chemical compound that alters the relaxation properties of water, generally shortening T1 (producing brighter signal intensity on T1-weighted images) more than T2
Superparamagnetic (e.g., iron oxides)	SPIO	Chemical compound that alters the relaxation properties of water, generally shortening T2 (producing low signal on T2-weighted sequences) more than T1

across the body is the image. The complex radio signal received by the receiver coil from the body is decoded into the spatial location of the signals and the strength of the signals by a mathematic algorithm called the Fourier transform.

Another way of refocusing the signal after the 90° pulse is by the application of bipolar gradients, which are gradients that are switched on in one direction and then switched on rapidly in the opposite direction. This will cause refocusing of

the FID signal in a manner that is appropriate for spatial localization of the signal. These sequences are termed gradient refocused echoes or gradient echo (GRE) sequences. The advantage of GRE sequences is that they are acquired very rapidly, allowing acquisition within a breath-hold period. GRE images designed specifically to image blood flow are termed magnetic resonance angiography sequences, because flowing blood appears bright on these sequences.

The resonant frequencies of water differ from the protons in lipid molecules, such as adipose tissue or fat. Because of this difference in resonant frequencies, these two populations of protons in the body can be imaged separately, sometimes termed chemical shift imaging. The most frequently used method is the application of a radiofrequency pulse which saturates the signal selectively from fat or water. If this is performed at the resonant frequency of fat, it is called a fat saturation sequence or fat saturation image.

On GRE images, fat and water may be out of phase with one another and thus cancel their signal. Whether the fat and water spins are out of phase with one another depends on the TE. If fat and water are out of phase relative to each other, small volumes of tissue containing both fat and water (such as fatty infiltrated liver) will cancel their signal and appear dark on the image. This type of image is called an opposed-phase image. In contrast, an in-phase image shows the lipid and water protons in the image as bright. In-phase and opposed-phase images are very sensitive to the presence of small amount of lipid in tissues. These sequences are used to detect fatty liver and the lipid that commonly occurs in adrenal adenomas.

Magnetic resonance angiography (MRA) refers to a family of pulse sequences that image flow within blood vessels. These pulse sequences take advantage of the fact that flowing blood is bright (high signal intensity) on certain GRE sequences. Blood flowing into a slice being imaged is fully unsaturated (i.e., has greater longitudinal magnetization) because it has not experienced prior excitation pulses. This effect renders the blood flowing into the slice as very high signal intensity on the image. Blood flowing through the slice shows less signal intensity because it experiences the excitation pulses used to acquire the data for the image. If thin slices are obtained continuously, preferably with the blood vessel of interest in cross-section, the resulting data can be reconstructed into a dataset representing the entire volume of tissue and then projected into images which resemble conventional angiograms. The principle described here is called *time-of-flight MRA*.

There are other forms of MRA that rely on different physical principles, such as phase contrast angiography, bolus tracking, black blood techniques, and three-dimensional gadolinium-enhanced MRA. Description of these techniques is beyond the scope of this chapter. However, these techniques have in common the principle of imaging flowing blood, while not necessarily imaging the vascular structures themselves. They are all susceptible to certain artifacts that give the impression of occluded or stenotic vessels, such as slowly flowing blood and turbulent flow, and artifacts from adjacent structures such as metallic surgical clips. The basic goal of these sequences is to increase the contrast between the vessel and surrounding structures dramatically. Thus, the vessels are selectively displayed with markedly higher signal intensity than surrounding stationary tissue.

A magnetic resonance technique that simulates MRA but which differs in principle is *magnetic resonance cholangiopancreatography* (MRCP). The goal of MRCP is to selectively image fluid within the biliary tree and pancreatic duct. Very heavily T2-weighted images are used to achieve this effect. With the very long TEs used for these heavily T2-weighted images, virtually all solid tissue has low signal (dark on the image). By virtue of its long T2, fluid within the biliary tree, gallbladder, and pancreatic duct retain signal intensity and therefore appears bright on the image. Like MRA, multiple projections in a manner similar to conventional cholangiography or endoscopic retrograde cholangiopancreatography (ERCP) can be obtained.

Current pulse sequences for imaging the liver are designed for very fast acquisition of images so that motion artifacts are limited or absent. These very fast images generally require improved (high performance) gradient systems. For T1-weighted images, fast GRE sequences are used. T1-weighted images that acquire the whole liver as a volume (three-dimensional imaging) can be used for dynamic perfusion studies, or MRA studies, or both. For T2-weighted images, subsecond pulse sequences have been developed so that motion-free images are obtained, whether or not the patient is holding their breath. These sequences are called HASTE (half-Fourier acquisition single-shot turbo spin echo), EXPRESS, or single-shot fast spin echo (FSE) sequences, depending on the manufacturer of the system. Echo planar imaging is not a new development but has been adapted to average clinical scanners with improved gradient systems and can also acquire subsecond images.

Injected contrast agents identify vascular structures and areas of abnormality within organs by differences in their vascularity. Contrast agents for use during MRI are available and have similar functions to the iodinated contrast agents used in CT. The most frequently used agent in MRI is gadopentetate dimeglumine. This fills the arteries and capillary beds and rapidly diffuses into the interstitium and the sinusoids in the liver. Because of this sequence of events, it is important to rapidly image abdominal organs to capture this temporal progression. In the liver, for example, it is advantageous to image an arterial phase, followed by a portal phase, followed by a delayed phase. This imaging of the arterial and venous phases is important in the differential diagnosis of liver tumors. Specifically, hypervascular tumors such as hepatocellular carcinoma will be seen better on an arterial phase and may be invisible on delayed phases. Similarly, other liver tumors such as hemangiomas can be characterized accurately based on their temporal sequence of enhancement with the

contrast agent. Gadolinium chelate-enhanced images are important for detecting and characterizing vascular abnormalities.

Agents that are accumulated selectively by hepatocytes and which undergo some biliary excretion have been developed. These show prolonged liver enhancement on T1-weighted images and increase the signal intensity difference between metastases and liver.

Superparamagnetic iron oxide agents have been approved for imaging the liver by the Food and Drug Administration. These agents are taken up by normal Kupffer cells in the liver and spleen. Most tumors, such as metastases, contain no Kupffer cells and therefore do not accumulate the agent. Thus, the signal intensity difference between liver and tumors is increased, making tumors more conspicuous on T2-weighted images. Greater sensitivity to metastases using these agents has been reported. Hepatocellular tumors such as focal nodular hyperplasia and hepatic adenoma take up these agents, providing a valuable diagnostic tool for evaluating liver tumors.

Liver (Table 132.2)

Various comparisons of contrast-enhanced CT and MRI have shown that MRI has significantly better capacity to characterize liver lesions [3–5]. MRI consistently characterizes over 95% of detected hepatic lesions and compares favorably with percutaneous biopsy, which typically has a diagnostic yield of only 61%–67% for liver masses, regardless of the imaging modality used for percutaneous needle guidance [3,4]. Given that about one-fourth of liver lesions detected in patients with a history of malignancy are subsequently determined to be malignant, it may be cost-effective to image those patients requiring tumor staging directly using MRI. In patients with malignancy, the ability to characterize a benign liver lesion can be as important as identifying metastases. For example, small liver cysts are common in adult patients and are frequently too small for accurate density measurement on CT, but can be resolved and characterized down to 1 mm on MRI because of the very high signal produced on T2-weighted images [6]. Generally, the advantages of MRI over CT arise from the greater contrast resolution, and the variety of different soft tissue contrast achieved through implementation of multiple sequences.

Benign lesions

Cysts

Benign lesions of the liver are common in the adult, and cysts represent the most common benign lesion. Pathology typically shows a wall comprising a single layer of epithelial cells. Etiologies are mostly idiopathic, but cysts may be seen in association with developmental disorders such as polycystic kidney disease or von Hippel–Lindau disease, infections including *Echinococcus*, or hemorrhage. Cysts appear uniform and high in signal intensity on T2-weighted images and low in signal intensity on T1-weighted images, with well-defined margins (Fig. 132.1) and no evidence of enhancement on gadolinium-enhanced spoiled gradient echo (SGE) images [6,7]. Benign cysts may appear slightly complicated with lobulation of borders and septations, and may have elevated signal on SGE T1-weighted images, typically in association with protein or related to prior hemorrhage. As complexity becomes more prominent, other possibilities should include biliary cystadenoma (Fig. 132.2), biliary cystadenocarcinoma, and mucinous cystadenocarcinoma of ovarian or other origin, usually bowel or pancreas. These tumors typically show perilesional gadolinium enhancement. These lesions may also have internal septations and enhancing mural nodules. These lesions will also increase in size on follow-up imaging.

Table 132.2 Classical MRI features of common liver lesions

Hepatic lesion	T1	T2	Opposed-phase GRE	Arterial enhancement	Portal venous enhancement	Delayed enhancement
Benign cyst	Low	High	NA	None	None	None
Hemangioma	Low	High	NA	+/– peripheral nodular	+/– peripheral nodular	Yes
Hepatic adenoma	Intermediate/high	Isointense	+/– reduced signal	Yes	Isointense	Isointense
Focal nodular hyperplasia	Isointense	Isointense/slightly increased	NA	Yes	Isointense	Isointense with delayed enhancement of central scar
Hepatocellular carcinoma	Low	Increased	+/– drop	Yes	Isointense/reduced	Reduced/washout
Cholangiocarcinoma	Low	Slightly increased	NA	Isointense	Isointense/increased	Delayed ill-defined

GRE, gradient echo; MRI, magnetic resonance imaging; NA, not applicable.

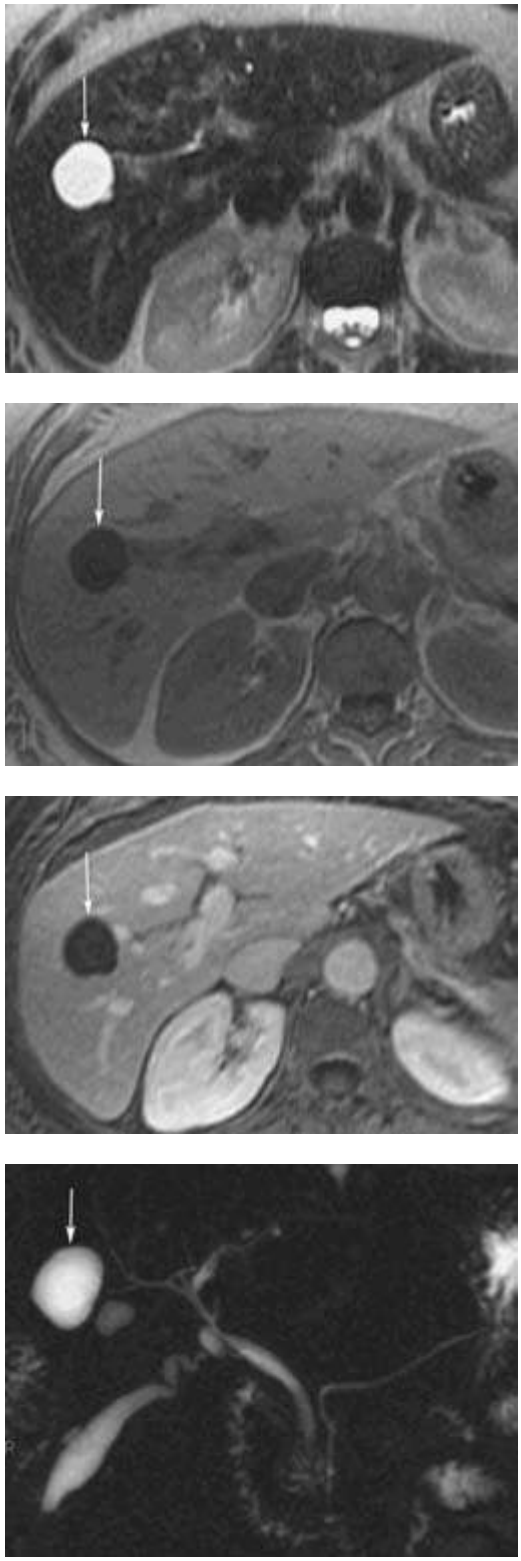

Figure 132.1 Simple hepatic cyst. **(a)** Axial T2 image, **(b)** axial T1 image, **(c)** postcontrast three-dimensional gradient echo image, and **(d)** magnetic resonance cholangiopancreatography demonstrate high T2 signal lesion (arrow on **a** and **d**) and low T1 signal nonenhancing lesion (arrow on **b** and **c**) consistent with simple hepatic cyst.

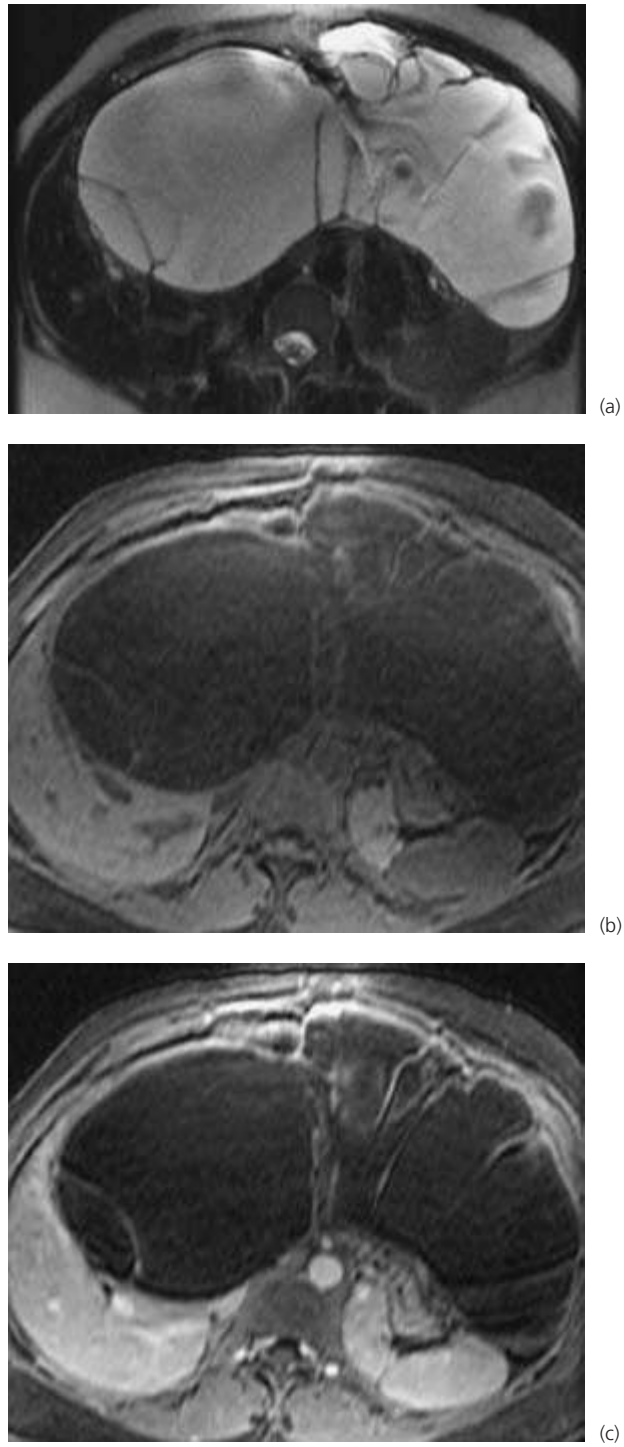

Figure 132.2 Biliary cystadenoma. Axial T2 image **(a)** and corresponding axial three-dimensional gradient echo images of the liver **(b)** before and **(c)** after contrast demonstrate large cystic lesion in the left and right lobes of the liver with internal enhancing septations that was surgically proven to be biliary cystadenoma.

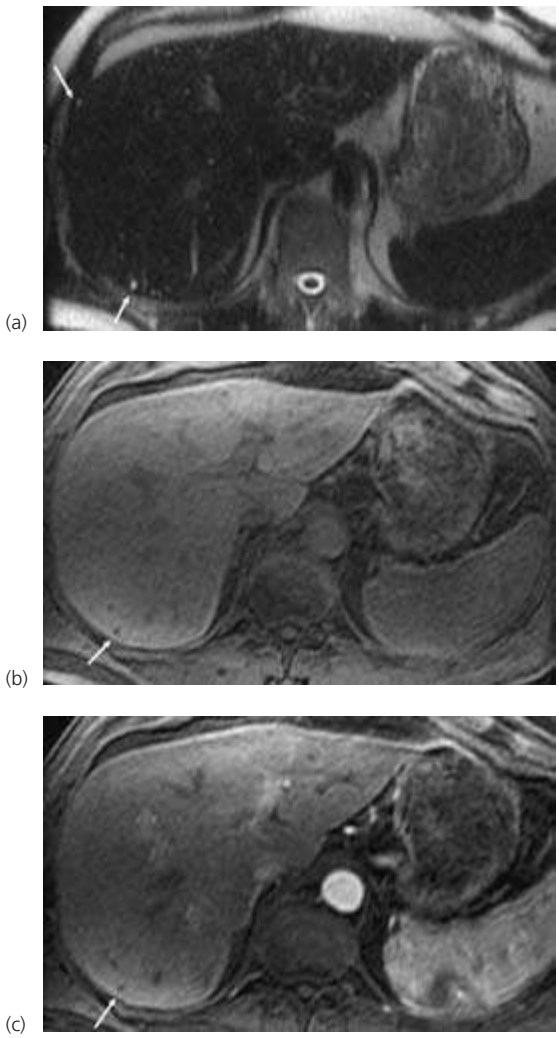

Figure 132.3 Bile duct hamartomas. Axial T2 image **(a)** and corresponding axial three-dimensional gradient echo images of the liver **(b)** before and **(c)** after contrast demonstrate scattered, less than 1-cm cysts (arrows) in the liver with thin peripheral rim of enhancement consistent with biliary hamartomas.

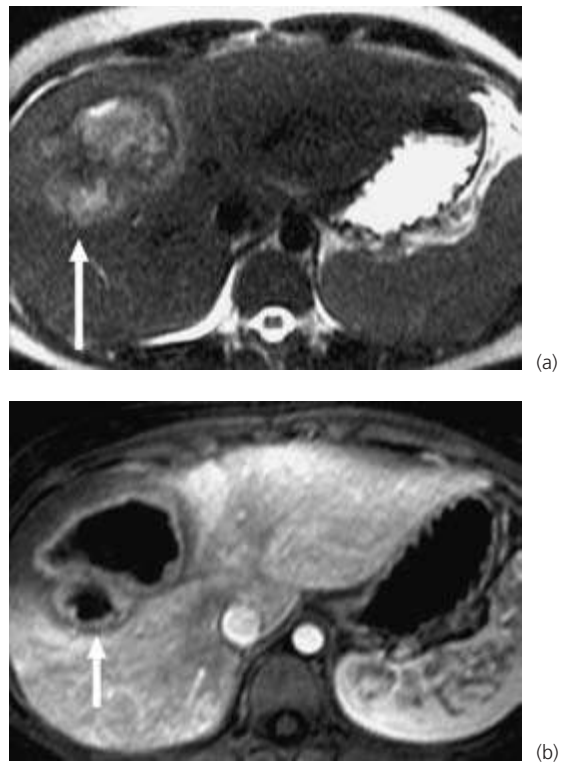

Figure 132.4 Hepatic abscess. **(a)** Axial T2 image and **(b)** postcontrast three-dimensional gradient echo image of the liver demonstrate large, peripheral, enhancing, thick-walled abscess (arrow).

Bile duct hamartomas

These lesions are relatively common, occurring in 3% of the population, and comprise irregular branching bile-dilated bile ducts. Bile duct hamartomas are frequently peripheral, multiple, and less than 1 cm in size. These lesions have features identical to cysts on T2- and unenhanced T1-weighted images, with the exception of demonstrating a peripheral thin and uniform rim of gadolinium enhancement (Fig. 132.3). Metastases show perilesional enhancement, and hypervascular tumors show central enhancement on arterial phase [7,8].

Abscess

Pyogenic abscesses are associated with sepsis, recent bowel surgery, diverticulitis, Crohn's disease, and appendicitis. Fungal microabscesses are more common in immunocompromised patients. Typically, abscess (Fig. 132.4) has high central increased signal and intermediate peripheral rim on T2-weighted images. The central portion is low on T1-weighted images and does not enhance on postcontrast images [9]. The peripheral rim shows persistent late enhancement without centripetal progression of enhancement [10]. There is indistinct perilesional enhancement on the early phase because of hyperemia [11].

Hemangiomas

Hemangiomas are the most common benign liver neoplasm, are multiple in up to 70% of cases, and are found with highest incidence in young adult women. Histology shows a series of vascular lakes and channels, with larger lesions developing areas of thrombosis and fibrosis. Imaging shows moderately elevated signal on single-shot T2-weighted images, typically less intense than demonstrated by simple cysts, and low signal on T1-weighted images [6,12]. Enhanced images show peripheral interrupted nodules on arterial phase (Fig. 132.5), and this finding is pathognomonic for this pathology. Venous and delayed phases may show progressive enlargement and coalescence of the peripheral nodules with variable degrees of central filling [6,13]. Smaller lesions generally fill more quickly, and larger lesions are progressively more likely to show slower central filling. Giant hemangiomas, usually larger than 5–10 cm, typically develop central areas that fail

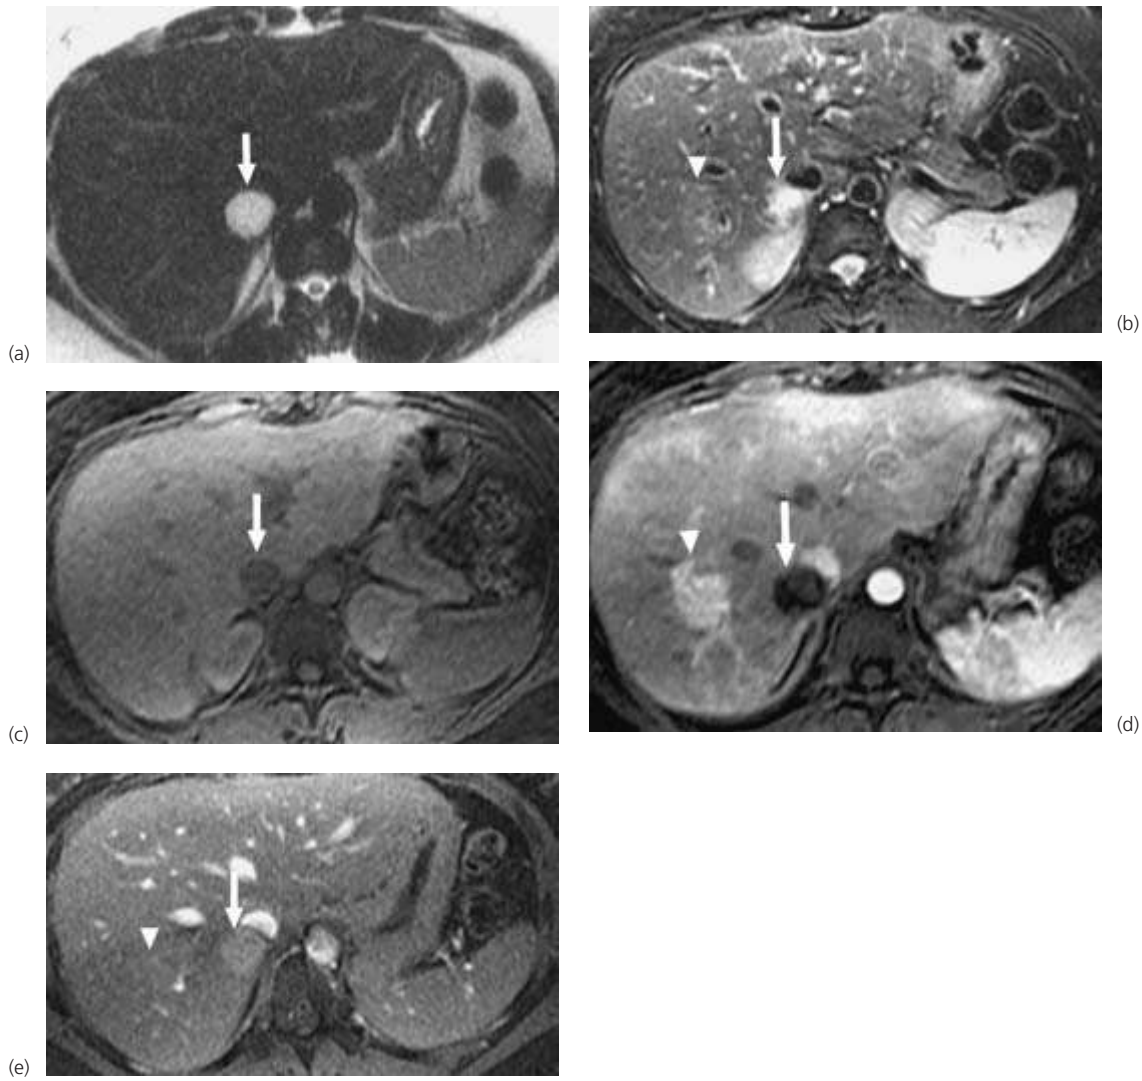

Figure 132.5 Hepatic hemangioma (arrow) and focal nodular hyperplasia (arrowhead). **(a)** Long TE (180 ms) and **(b)** fat-suppressed intermediate TE (80 ms) axial T2-weighted images of the liver demonstrate a high T2 signal lesion (arrow) adjacent to the inferior vena cava. Of note, a second lesion (arrowhead) is also seen on **(b)** but not on **(a)**. Three-dimensional gradient echo images **(c)** before contrast, **(d)** during arterial phase, and **(e)** delayed post contrast demonstrate peripheral enhancement of the paracaval lesion (arrow) with progressive delayed enhancement consistent with a hemangioma. The second lesion (arrowhead) enhances avidly in the arterial phase and becomes isointense to hepatic parenchyma on delayed imaging, consistent with focal nodular hyperplasia.

to fill in on delayed enhanced images, and may show central cystic areas that are as bright as simple fluid, such as cerebrospinal fluid, with well-defined margins and no enhancement. Small (< 1 cm) lesions may fill quickly and be difficult to delineate from other arterial-phase enhancing neoplasms, such as a small hepatocellular carcinoma (HCC) or hypervascular metastases [14]. In such cases, the distinguishing features can be found on venous and delayed images, where the other hypervascular neoplasms may typically show washout whereas hemangiomas may demonstrate persistent enhancement with signal above that of the adjacent liver parenchyma. Metastases have been described as enhancing progressively from outside-in; however, the pattern of enhancement does not show peripheral interrupted nodules with coalescence, as is typical of hemangiomas [15,16]. An optimally timed arterial-phase enhanced image typically provides the most critical diagnostic information [16].

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is most commonly seen in young adult women and seems to represent a hamartomatous lesion with a disorganized growth pattern of hepatocytes and ducts that can form an unencapsulated mass with abnormally structured vessels and bile ducts. These lesions may appear isointense to mildly hyperintense on T2-weighted images, and isointense to mildly hypointense on T1-weighted

images (Fig. 132.5). An important, and unique, characteristic of FNH is the presence of a central fibrovascular core, which may produce a high signal on T2-weighted images [6,7,12,16]. On gadolinium-enhanced imaging the fibrovascular core may demonstrate slowly progressive enhancement, with no perceived enhancement on arterial phase, and becoming maximally conspicuous on delayed-phase images [16,17]. This is in contrast to the bulk of the mass surrounding the core that typically enhances uniformly and intensely in the arterial phase, and which becomes isointense or slightly hyperintense to surrounding liver on venous and delayed phases. Small lesions (less than 1–2 cm) may appear more uniform in enhancement and a fibrovascular core may not be perceived. Other distinguishing features on gadolinium-enhanced imaging from other arterial-phase enhancing tumors include the lack of capsule enhancement, as is observed with adenomas and HCC [16–19]. Fibrolamellar HCCs are typically large, greater than 10 cm at presentation, but may share features of FNH with the exception that the central scar of fibrolamellar tumors is typically lower than surrounding tumor on T2-weighted images and shows radiating enhancing bands on postgadolinium images [16,20]. Alternative contrast agents may be helpful in a small fraction of cases that remain ambiguous. Gadolinium-EOB-DTPA may demonstrate early arterial-phase tumor enhancement and late hepatocellular uptake caused by uptake by hepatocytes within the mass and excretion into poorly draining malformed bile ducts. Manganese or superparamagnetic iron oxide particles (SPIO) may be taken up by hepatocytes within FNH and darken the lesion similar to surrounding normal liver [15,16].

Adenomas

Adenomas are benign neoplasms of epithelial origin, with predominant incidence in young women. They are associated with oral contraceptives, and rarely with exogenous anabolic steroids, galactosemia, and glycogen storage disease type Ia. Spontaneous hemorrhage may be related to larger masses, typically greater than 4–5 cm in diameter, and can result in presentation with abdominal pain, with a risk of extrahepatic extension and intraperitoneal bleeding. Hepatic adenomas comprise sheets of hepatocytes and form a pseudocapsule related to compression of adjacent hepatic parenchyma; however, in contrast to FNH, they do not form bile ducts. T2-weighted images show isointense to slightly hyperintense signal and T1-weighted images show mildly hypointense to mildly hyperintense signal (Fig. 132.6) [5]. Opposed-phase SGE T1-weighted images may demonstrate signal drop related to lipid accumulation in approximately half of adenomas [21]. Blood products may result in irregular foci of mixed high or low signal on T1- and T2-weighted images. Gadolinium enhancement is maximal during arterial phase and seen as an arterial-phase blush with rapid fading in the venous and delayed phases to hypointensity or isointensity to adjacent liver, with development of a persistent

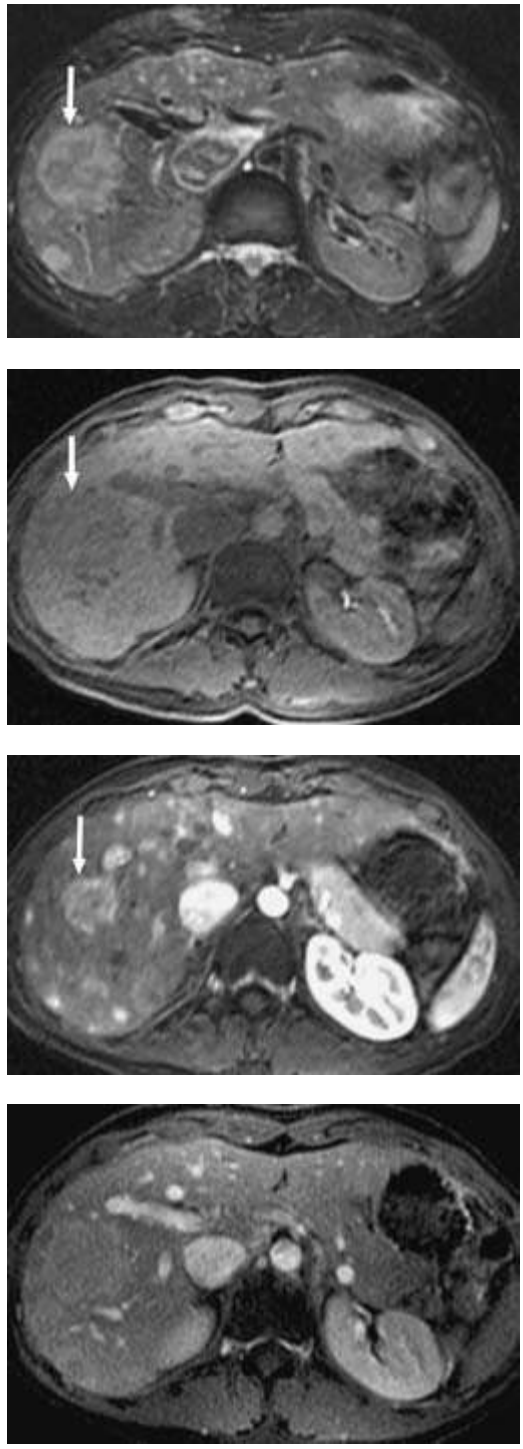

Figure 132.6 Hepatic adenoma. **(a)** Axial, fat-suppressed, intermediate TE, T2-weighted image shows scattered mildly increased T2 signal lesions (largest indicated by arrow). Three-dimensional gradient echo images **(b)** before contrast and **(c)** during arterial phase demonstrate arterial enhancing hepatic adenomas (largest indicated by arrow) that become near isointense on delayed postcontrast image **(d)**.

enhancing rim related to the pseudocapsule [5,19]. An enhancing scar may be observed in a small subset, but such a scar does not produce high signal on T2-weighted images as seen in FNH. Although most features of adenoma mimic HCC, HCC is usually associated with a background of chronic liver disease with evidence of cirrhosis [5,19]. However, in patients with HCC risk factors where the liver is normal and tumor markers are negative, differentiation may be difficult. The presence of portal venous involvement helps differentiate HCC, and the presence of blood products helps differentiate adenoma. Hepatic adenomatosis is a rare and separate entity that involves numerous adenomas scattered throughout the liver, which have malignant potential [22].

Malignant lesions

Primary HCC is the most common primary liver malignancy and usually occurs in the setting of cirrhosis [23]. These tumors are thought to arise from premalignant dysplastic nodules, and dysplastic nodules are thought to progressively dedifferentiate from low- to high-grade histology [24]. HCC occurs as a solitary lesion in 50% of cases, is multifocal in 40%, and diffuse in 10%, and is typically greater than 2 cm in diameter, in contrast to dysplastic nodules, which are typically less than 2 cm [25]. Imaging features are variable, but the pattern of elevated signal on T2-weighted images and diminished signal on T1-weighted images increases the likelihood of HCC as compared with dysplastic nodules (Fig. 132.7) [5]. In the setting of cirrhosis, however, highly specific imaging features for HCC are reliably found on gadolinium-enhanced SGE images, which show irregular marked arterial-phase enhancement with rapidly diminished enhancement on venous and delayed-phase images, and development of a peripheral enhancing rim resulting from a pseudocapsule [26]. High-grade dysplastic nodules may show enhancement, but do not develop a pseudocapsule [27]. Diffuse HCC shows irregular T2 and T1 signal, with heterogenous enhancement. Regions within the tumor may washout on delayed images while enhancement in other areas persist. Associated portal venous tumor thrombosis typically enhances in the arterial phase [27].

Hypovascular metastases

Most common malignant hepatic tumors can be further classified as hypovascular or hypervascular based on imaging features. Hypovascular metastases are the most common and usually arise from colon adenocarcinoma. These tumors tend to have mixed arterial and portal venous supply, and usually develop central necrosis presumably because of poor vascular perfusion to the center of enlarging tumors [28]. Hypovascular

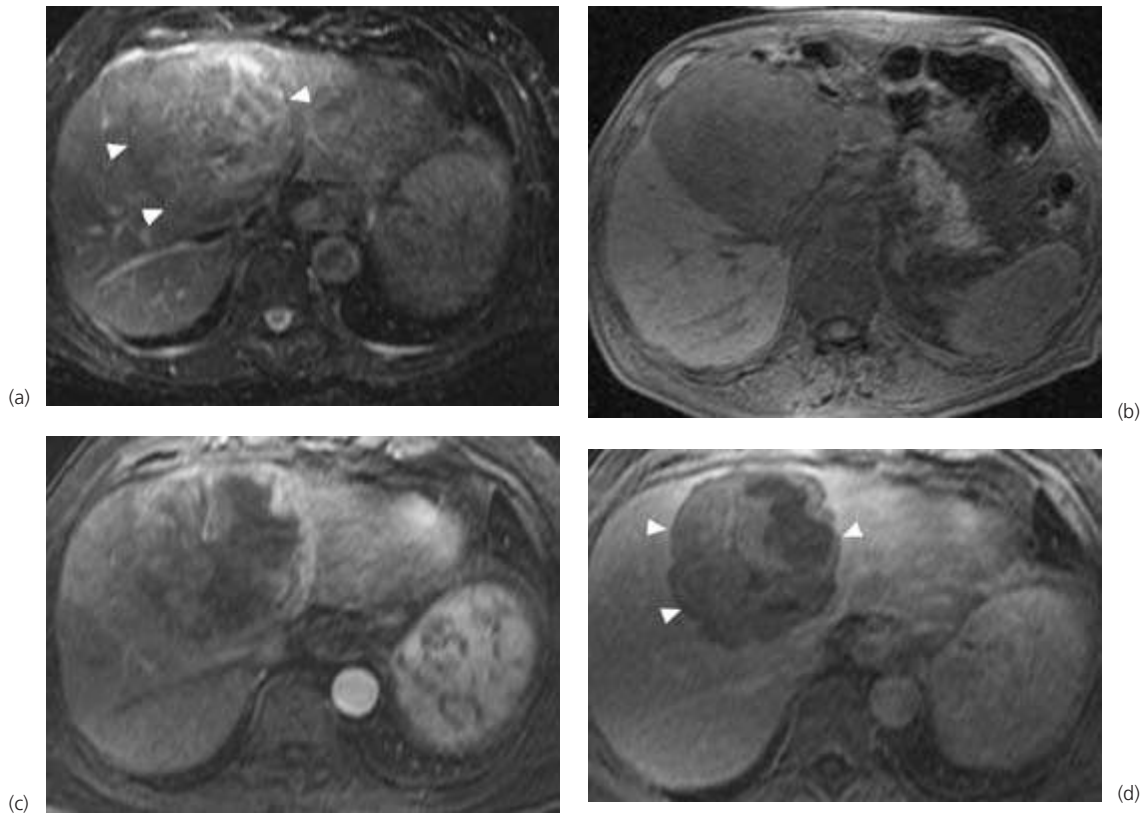

Figure 132.7 Hepatocellular carcinoma. Axial, fat-suppressed, intermediate TE, T2-weighted image **(a)** and three-dimensional gradient echo images **(b)** before contrast, **(c)** during arterial phase, and **(d)** delayed post contrast demonstrate increased T2 signal lesion with preferential arterial enhancement and washout on delayed images following contrast. Note low T2 signal and hypoenhancing peripheral pseudocapsule (arrowheads) of this lesion.

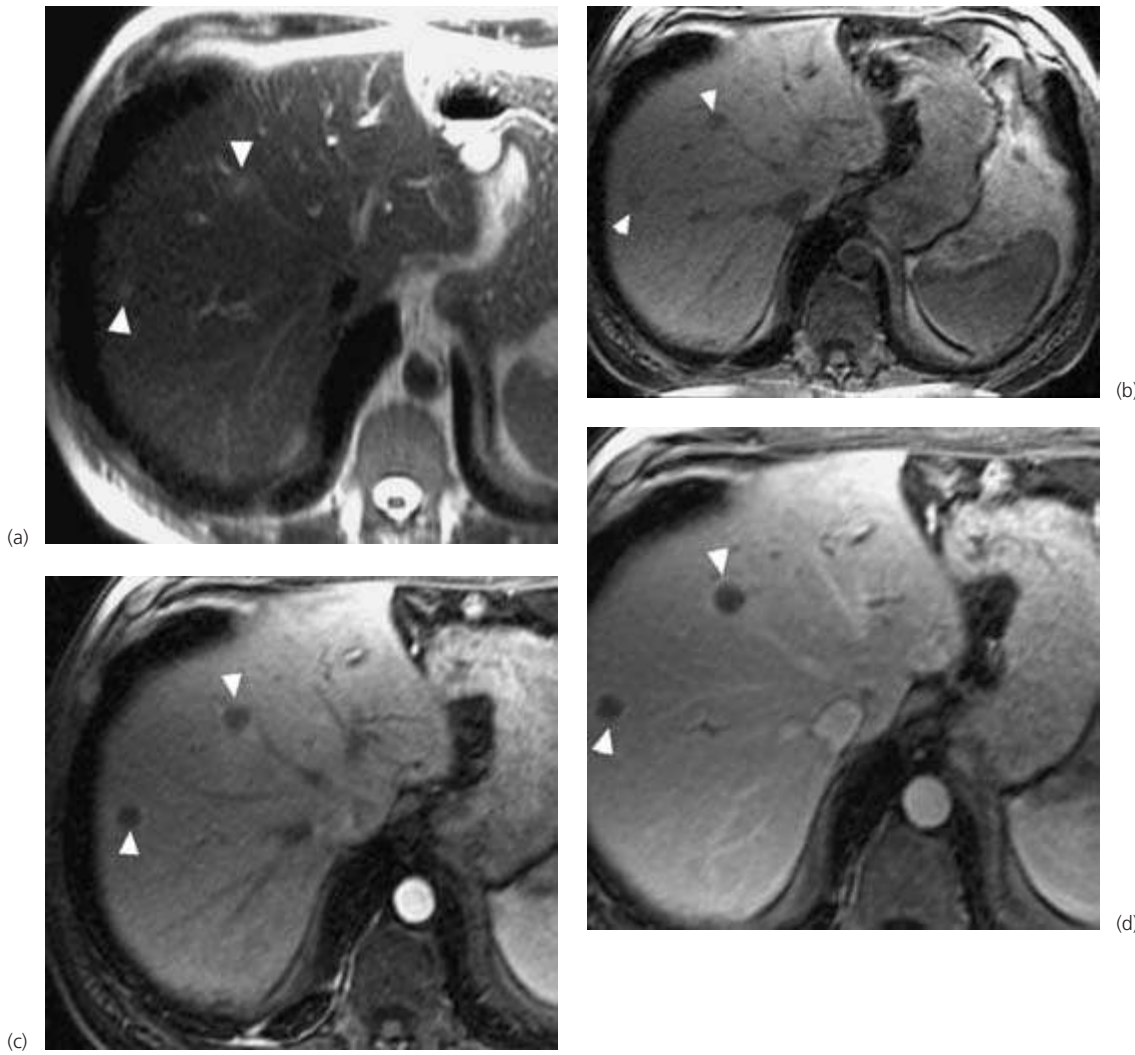

Figure 132.8 Hypovascular hepatic metastases. Axial T2 image **(a)** and three-dimensional gradient echo images **(b)** before contrast, **(c)** during arterial phase, and **(d)** after contrast demonstrate hypoenhancing metastatic lesions (arrowheads) with rim enhancement in a patient with metastatic pancreatic carcinoma.

metastases may have variable appearance on T2-weighted images and are usually most conspicuous on pregadolinium- and postgadolinium-enhanced SGE T1-weighted images, showing slowly progressive irregular enhancement from outside-in (Fig. 132.8) [29]. Unlike hemangioma, the enhancement on arterial phase is less and does not show peripheral interrupted nodular enhancement. Arterial-phase perilesional enhancement may be observed, and is typically seen with colon, pancreatic, or stomach adenocarcinoma metastases [30].

Hypervascular metastases

Hypervascular metastases are frequently neuroendocrine, renal, melanoma or breast in origin. T2-weighted images show variable signal, usually moderately elevated, and low signal on T1-weighted images [30]. Melanoma is an exception, where melanin accumulation, having T1 shortening properties, may result in elevated signal on T1-weighted images (Fig. 132.9). Characteristic gadolinium enhancement shows that the lesions demonstrate maximal conspicuity on arterial-phase images [16,29].

Posttherapeutic imaging

Cross-sectional imaging has largely relied on anatomical depiction of disease, including tumors. There is a large subset of patients with malignancy being treated by nonsurgical approaches, including chemotherapy and radiation, where the ability to follow tumor response is valuable [31]. Current methods have mostly relied on anatomical depiction of tumor and measurement of tumor size to evaluate tumor response [32]. This is believed to require a relatively long follow-up period in most applications, and other measures of tumor response sensitive to cellular and vascular reactions may be more useful [33]. A multitude of approaches are being evaluated using MRI [34]. One simple test that may be helpful is the evaluation of perfusion by gadolinium enhancement pattern within a treated malignant mass [34]. Demonstration of decreased

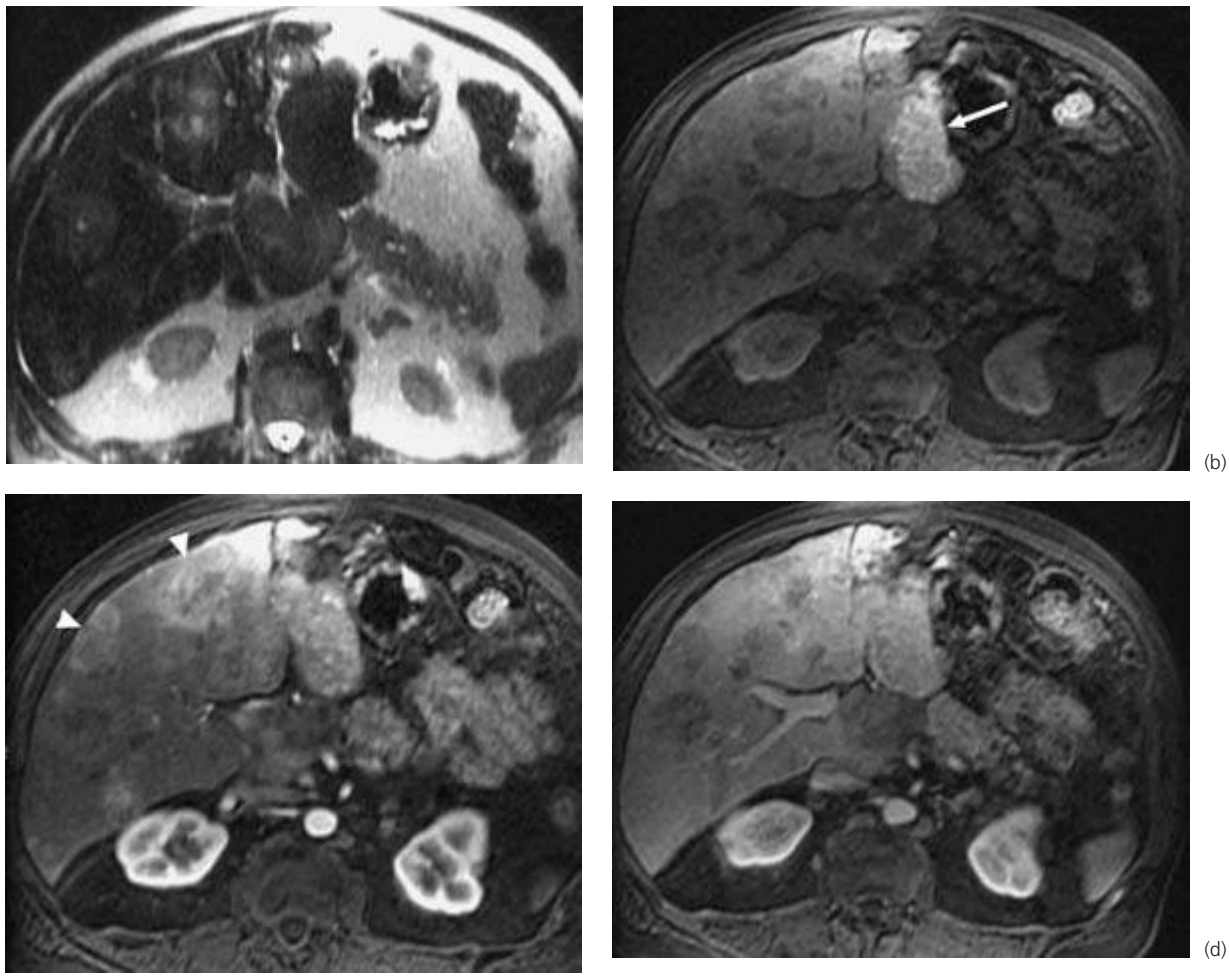

Figure 132.9 Hypervascular hepatic metastases. Axial T2 image **(a)** and three-dimensional gradient echo images **(b)** before contrast, **(c)** during arterial phase, and **(d)** during portal venous phase demonstrate multiple arterial enhancing lesions (arrowheads) in this patient with melanoma metastases. Note increased signal on precontrast T1-weighted images in lesion in the lateral segment of the left lobe of liver (arrow) secondary to melanin or hemorrhage.

vascularity after therapy, reflected by reduced enhancement, reduced intermediate T2 signal, and necrosis, has been associated with tumor response (Fig. 132.10) [35,36].

Diffuse liver diseases

MRI of the liver may also be used for the evaluation of diffuse liver diseases, including abnormal lipid metabolism, iron deposition disease, and perfusion abnormalities related to inflammation, fibrosis, vascular occlusion, or infarction and hemorrhage [37].

Fatty liver

Lipid accumulation in hepatocytes can occur as a result of impaired liver function secondary to a variety of etiologies. In the USA, fatty liver can be detected in over 20% of the population, and the most common association with fatty liver is obesity [38,39]. There has been further association of fatty liver with development of hepatitis, resulting from nonalcoholic acute steatohepatitis, and potential progression to cirrhosis [40]. In the setting of liver transplantation, a living related donor liver assessment must include evaluation for the presence of fatty infiltration, which is considered a contraindication to transplantation when severe and can lead to failure of the transplant. Abnormal lipid accumulation in liver can be detected on MRI, and can be evaluated by comparing liver signal on SGE images acquired in-phase and out-of-phase [40,41]. Protons in a voxel containing 100% fat precess 220–230 Hz slower than a voxel comprising 100% water at 1.5 T. That means every 4.4 ms the fat protons migrate 360° and regain in-phase orientation relative to water protons, whereas at 2.2 ms, or at half this time, the fat and water protons are 180° out-of-phase [38]. Current generation MRI systems have incorporated dual echo breath-hold SGE sequences that can acquire two sets of k-space filled to obtain two sets of images, one set in-phase, the other out-of-phase, with spatially matched slices. Liver containing lipid results in image voxels with a physical mixture of water and lipid, which when imaged out-of-phase results in phase

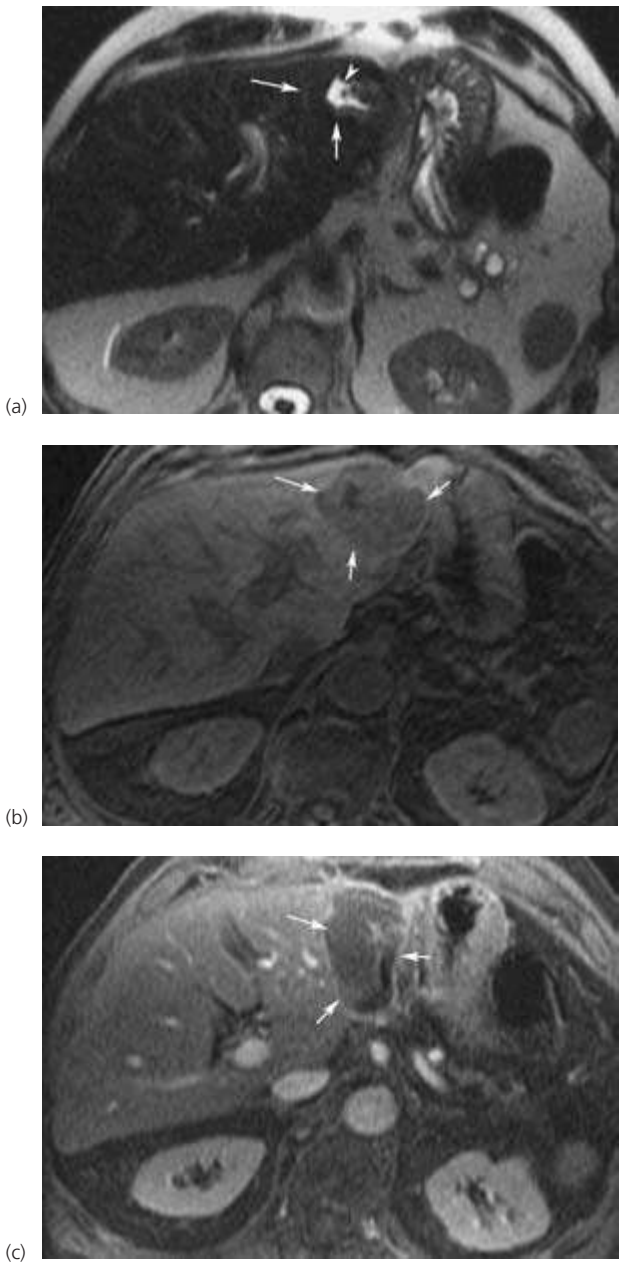

Figure 132.10 Radiofrequency-ablated lesion. **(a)** Axial T2 image demonstrates fluid signal consistent with cavitation (arrowhead) of lesion (borders of lesion indicated by arrows) treated with radiofrequency ablation. Three-dimensional gradient echo images **(b)** before and **(c)** after contrast demonstrate minimal peripheral enhancement of lesion consistent with granulation tissue. There is some residual central enhancement suspicious for persistent viable tumor and will warrant continued surveillance.

cancellation and diminished signal (Fig. 132.11) [37,38]. Spleen is an organ that does not accumulate fat, and can be used as a control against which liver signal can be assessed as a ratio to test for relative diminishment in liver signal on out-of-phase images. Spleen signal can change as a result of iron deposition, and use of kidney or skeletal muscle within the image may be more reliable for assessment of relative liver

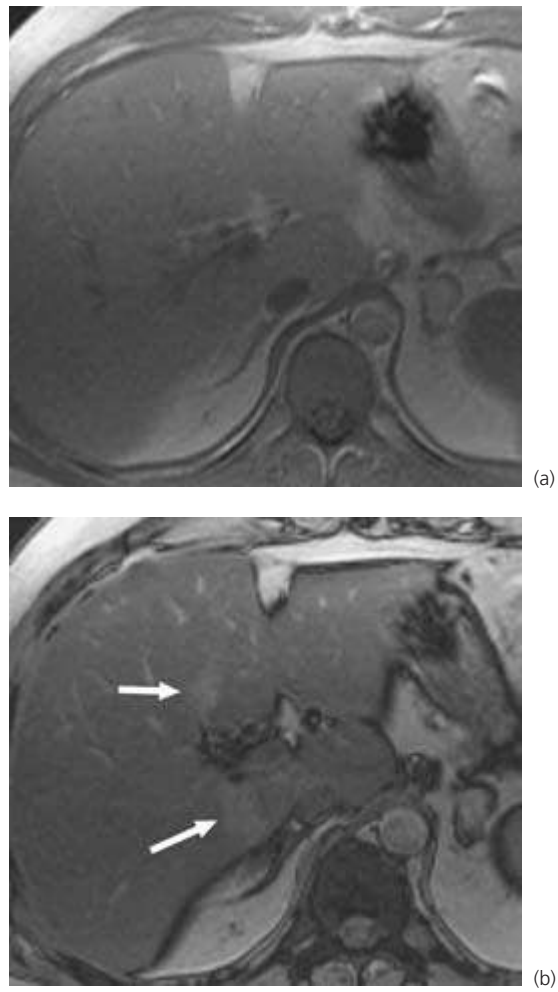

Figure 132.11 Hepatic steatosis. **(a)** Axial in-phase gradient echo (GRE) image (TE 4.6 ms) and **(b)** opposed-phase GRE image (TE 2.2 ms) of the liver demonstrates drop in signal of the liver parenchyma on opposed-phase images consistent with hepatic steatosis. There is relative lack of drop in signal near the gallbladder fossa (arrows) consistent with focal fatty sparing.

signal changes between in-phase and out-of-phase images. Fat accumulation in liver can be diffuse, diffuse with focal sparing, or focal. Typical regions affected by focal fatty accumulation occur around the falciform ligament, gallbladder fossa, and inferior vena cava [39]. One possible explanation is that these are areas of liver prone to irritation or stimulation, resulting in local changes in carbohydrate–lipid metabolism. Contrast-enhanced CT and standard ultrasound are relatively nonspecific and less sensitive for assessment of fatty liver, and can confuse irregularly accumulated lipid with a mass [39]. Fatty liver can lead to reduced CT density, and diminish contrast between a low-density mass and adjacent liver, making the mass less conspicuous.

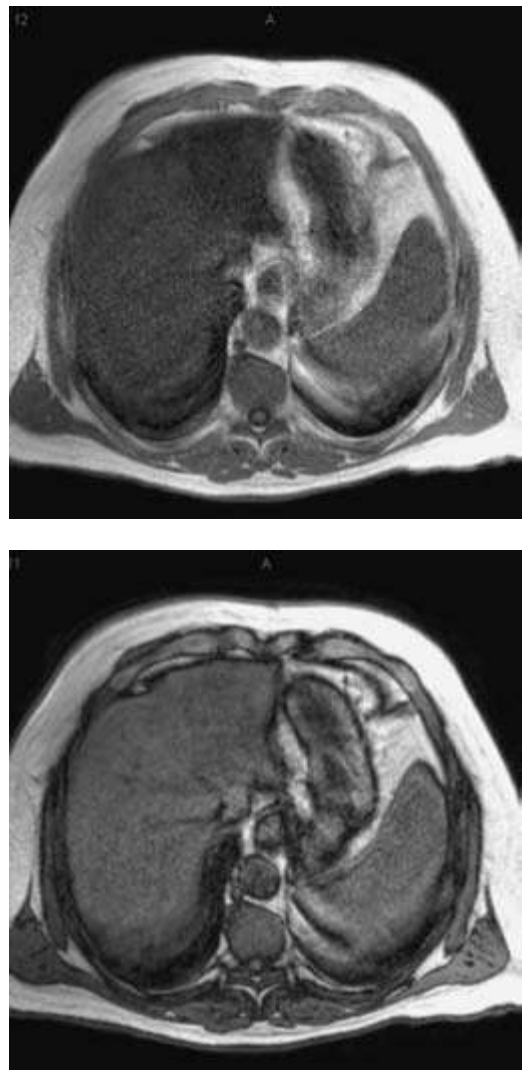
Iron deposition disease

Iron can accumulate within the liver by two basic mechanisms: accumulation within hepatocytes through normal

metabolic chelation mechanisms; or uptake within the phagocytic Kupffer cells, representing part of the reticuloendothelial system. Serum iron and transferrin saturation are poorly correlated with the degree of iron overload. Hepatocytes chelate the iron that accumulates within the cytosol. Pancreas also has chelation mechanisms within acinar cells, and can accumulate excess intracellular iron. To some degree, however, iron accumulation can occur in most tissues, typically as a late feature occurring after hepatic stores have reached high levels. Important examples include the pituitary and heart, where this can result in impaired pituitary function and fatal cardiac arrhythmias and congestive heart failure. Patients presenting with a first-time diagnosis of primary hemochromatosis with the combined findings of elevated liver and cardiac iron deposition, and congestive heart failure, have a poor prognosis with a 6-month life expectancy. There is now a clinically available genetic test that can be used for screening purposes and which is relatively inexpensive.

In secondary hemochromatosis, iron overload occurs secondary to excess red cell turnover from exogenously derived red cells as a result of blood transfusion therapy, as seen in patients with underlying red cell or bone marrow abnormalities such as thalassemia, mastocytosis, or myelofibrosis. Alternatively, endogenously derived excess iron from red cell turnover can result from polycythemia rubra vera or from myoglobin in rhabdomyolysis, or from siderosis related to alcoholic liver disease. In secondary hemochromatosis, the mechanism of iron accumulation is different from that in primary hemochromatosis: increased uptake of iron derived from hemoglobin from dying or abnormal red cells taken up by the reticuloendothelial system leads to iron accumulation in Kupffer cells within liver sinusoids and in splenic tissue. In contrast to primary hemochromatosis, the pancreas does not typically accumulate iron. The clinical significance of primary hemochromatosis includes the observation that many patients develop cirrhosis and approximately 25% of patients develop HCC.

The presence of iron deposition within the liver may be detected by MRI of the liver [42]. Liver biopsy has been used for biochemical determination of iron overload and has been used as the basis for therapy management in patients treated by periodic phlebotomy and iron chelation therapy; however, this method has bleeding risks associated with the invasive procedure, and is susceptible to sampling error in patients with heterogeneous iron deposition in the liver. The sensitivity of CT is insufficient, with a minimum threshold for liver iron more than five times above the normal liver iron load, particularly in cases with fatty liver. MRI is sensitive to iron concentration in the liver because of the paramagnetic properties of iron, resulting in T2 or T2* effects that diminish the signal intensity on both single-shot breath-hold T2 images and breath-hold T1-weighted multiecho SGE images (Fig. 132.12) [42]. Quantitative assessment of liver iron concentration based on MRI has been demonstrated using both SGE and spin echo sequences, relying on measurements of T2* and T2 decay. Coronal breath-hold T2-weighted single-shot FSE images, which should be obtained as part of a routine abdominal MRI examination, are very useful for rapid visual evaluation, providing slices that include liver, psoas muscle, and spleen within the same image [43]. Normally, liver signal intensity is near the midpoint between the lower signal intensity of muscle and the higher signal intensity of spleen. In iron overload disease, the liver signal intensity becomes as low as or lower than skeletal muscle. In secondary iron overload, spleen similarly becomes dark. In cases where there is bone marrow abnormality, such as in myelofibrosis, normal high-signal marrow fat becomes replaced with low-signal cellular marrow hypertrophy and



(a)

(b)

Figure 132.12 Secondary hepatic hemosiderosis. **(a)** Axial in-phase gradient echo (GRE) image (TE 4.6 ms) and **(b)** opposed-phase GRE image (TE 2.2 ms) demonstrate relatively decreased signal on the in-phase images of the hepatic and splenic parenchyma consistent with secondary hemosiderosis.

sclerosis [43]. Chronic iron overload can lead to cirrhosis and increased risk for HCC, complications that can be assessed on MRI. For more sensitive and potentially quantitative noninvasive measurement of liver iron, T2* and T2 decay rate measurements can be performed. T2* decay is a measure of how quickly protons lose phase coherence without use of refocusing pulses, and T2 decay is a measure of proton-dephasing rates after application of refocusing pulses, measuring only dephasing effects that are not correctable [44]. Generally, the T2* decay rate is more sensitive to lower levels of intracellular iron accumulation [42]. Intracellular iron accumulation can cause localized magnetic field distortion that leads to susceptibility effects, which result in more rapid loss of phase-dependent signal [42].

One method used to detect this effect is based on multiecho GRE imaging to measure T2* decay, whereas a spin echo single-shot or echo-planar technique with increasing echo times may be used for T2 decay measurements [42]. When performing imaging dedicated to iron measurement, a series of GRE images are acquired with increasing increments of TE [45]. As TE lengthens, the proton dephasing leads to progressively increased loss of signal intensity, and this process has been shown to be proportionately increased in relation to intracellular liver iron concentration. When performing a dedicated T2* analysis of liver iron, TEs may be selected to correspond to in-phase echoes to avoid potential out-of-phase effects from fat, a potentially spurious effect in the setting of fatty liver infiltration [42]. At minimum, however, routine imaging of the abdomen and liver should include a dual-echo SGE acquisition that can be used in conjunction with the coronal single-shot T2. The longer second echo image (TE 4.4 ms) should show darkening of the liver compared with the shorter echo image (TE 2.2 ms) in the setting of elevated liver iron concentration (Figs 132.12 and 132.13) [42]. The sensitivity to liver iron may be increased on SGE imaging by increasing the echo time to include, for example, echoes at 8.8 and 13.2 ms. If only routine shortest possible dual-echo out-of-phase (TE 2.2 ms) and in-phase (TE 4.4 ms) imaging is used, then the relative sensitivity of the single-shot spin echo technique is more sensitive. With this approach, demonstration of low liver signal on single-shot spin echo alone indicates a relatively lower liver iron concentration, and demonstration of low liver signal on both single-shot spin echo and on the longer dual-echo SGE indicates relatively higher liver iron burden. Others have shown that liver iron concentration may be calculated and that noninvasive measurement of tissue iron concentration may be feasible. This represents the only noninvasive technique available for liver iron quantitation, and could be used for example for following hemochromatosis patients on therapy, minimizing the need for liver biopsy. Although it is tempting to suggest the use of MRI for genetic hemochromatosis screening, it has been noted that a genetic marker test is accurate and relatively inexpensive [45]. Regardless, the

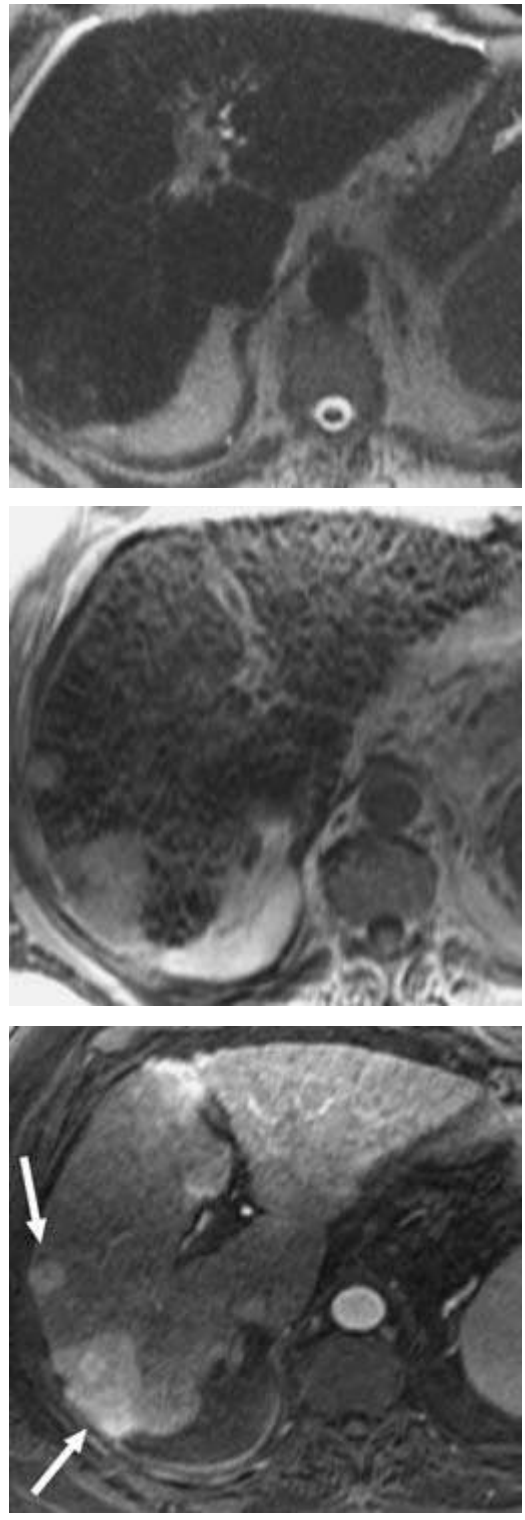


Figure 132.13 Primary hemochromatosis with hepatocellular carcinoma. **(a)** Axial T2 image and **(b)** axial T1 gradient echo (GRE) image demonstrate low signal in the hepatic parenchyma consistent with iron deposition. **(c)** Axial three-dimensionalGRE image during arterial phase after contrast administration demonstrates arterial enhancing lesions (arrows) in the right lobe of liver consistent with multifocal hepatocellular carcinoma in patient with hemochromatosis.

ability to determine tissue iron concentration quantitatively by MRI is a clinically valuable test and there are attempts to develop useful methodology for routine clinical imaging [46].

Acute hepatitis

Inflammatory liver disease can result from a large number of etiologies, including idiopathic, drug induced, viral, alcoholic, and gallstone bile duct obstruction. It has been noted that MRI may be sensitive to acute hepatitis [47]. On MRI, the most sensitive images are the postgadolinium breath-hold SGE images acquired during arterial phase. It has been reported that this abnormal enhancement becomes more marked and can persist into the venous and delayed phases as the severity of disease increases, and can resolve in cases when hepatitis resolves. Furthermore, the arterial-phase timing critically determines sensitivity to mild acute hepatitis. By performing SGE imaging every 5 s after administration of gadolinium in a patient with mild acute hepatitis, irregular liver enhancement is detectable only during the time when the portal veins are filling with contrast, and the hepatic veins are still unenhanced. In mild hepatitis, images acquired before portal venous filling are too early, and liver images acquired when the hepatic veins are filled are too late. For most patients, optimal timing falls between 18 and 22 s after initiation of the gadolinium injection into an antecubital vein, administered at 2 mL/s, followed by a 20-mL saline wash-in bolus. No other imaging technique has been shown to be sensitive for detection of acute hepatitis. MRI could be used as a diagnostic aid in patients with equivocal liver enzyme elevation and nonspecific symptoms, and in patients presenting with fatty infiltration. The reasons for heterogeneous liver enhancement in acute hepatitis have not been fully determined. Hypothetically, it may be that the areas of relative arterial-phase hyperenhancement represent regions of abnormality [48]. In this case, periportal inflammation may differentially compress the lower pressure portal vein intrahepatic branches, leading to preferential segmental hepatic arterial perfusion. Alternatively, the inflammation may lead to altered vascular regulatory effects, with vasodilation and increased hepatic arterial flow to the involved regions. Pathological correlation is challenging given that histopathological correlation lacks the ability to determine pathophysiological in-vivo processes involved in hemodynamics, an advantage inherent to contrast-enhanced imaging.

Findings suggestive of acute hepatitis (seen as irregular arterial-phase gadolinium enhancement) in the setting of fatty liver (seen as signal drop on opposed-phase GRE images) are consistent with steatohepatitis and raise the possible diagnosis of nonalcoholic steatohepatitis or nonalcoholic acute steatohepatitis. Nonalcoholic acute steatohepatitis is a recognized disease entity thought to represent a hepatitis that is directly related to excess intracellular fat accumulation within hepatocytes [48,49]. This disease has a strong association with obesity and has a risk of progression to chronic hepatitis and cirrhosis. Given that obesity is an epidemic in the USA, the health concerns regarding nonalcoholic acute steatohepatitis is significant. MRI has greater sensitivity and specificity for detection of fatty liver, and is the only imaging test sensitive for milder cases of hepatitis as compared with CT or ultrasound. Multiple causes of transient hepatic perfusion abnormalities have been described; however, in cases presenting clinically with right upper quadrant pain and abnormal liver arterial-phase perfusion, as described in this study, acute hepatitis should be the major diagnostic consideration [48]. It may be argued that patients with right upper quadrant abdominal symptoms should be preferentially examined by MRI rather than CT. MRI has potential relative strengths with regard to contrast sensitivity, and can provide excellent temporal resolution because of the small contrast volume used, in combination with the acquisition of contrast data for the entire liver over approximately 4–5 s, usually in the center of a two-dimensional T1-weighted GRE sequence using interleaved phase acquisition. The safety profile of gadolinium agents and nonionizing radiation imaging for a multiphase examination are also attractive characteristics of MRI.

Chronic hepatitis and cirrhosis

A major complication of chronic hepatitis is cirrhosis. In Western nations, alcohol-induced hepatitis used to be the most common etiology, but viral hepatitis is now the most common cause. Globally, viral hepatitis is the most common association with chronic hepatitis, cirrhosis, and HCC. The feature of fibrosis associated with cirrhosis is progressive enhancement on delayed MRI, resulting from leakage of gadolinium contrast agent from the intravascular into the interstitial space within the fibrotic regions [50]. The typical patterns of cirrhosis include fine reticular and coarse linear bands, with these fibrotic bands outlining foci of regenerative nodules. If active hepatitis is present, the fibrotic tissue bands may have edema, and appear high in signal on T2-weighted images, and the liver tissue may develop irregular patchy areas of enhancement seen mostly on arterial-phase images [50]. Regenerative nodules occur in the setting of cirrhosis, and represent relatively more normal hepatic parenchyma that derives the major blood supply from the portal venous system [51]. These nodules maximally enhance during portal venous-phase postgadolinium SGE images, and are usually less than 1 cm in diameter. These nodules can accumulate iron, and appear low in signal on both SGE T1- and single-shot FSE T2-weighted images, with little enhancement appreciated on postgadolinium SGE images (Fig. 132.14) [49].

Dysplastic nodules are premalignant and are believed to have the potential to transform into progressively higher grades of dysplasia, and finally into HCC [51]. Dysplastic nodules are typically larger than regenerative nodules, and can be seen to grow over a period of weeks or months [50,51]. These lesions can show overlap with HCC, and may show mildly elevated T1-weighted signal and low T2-weighted

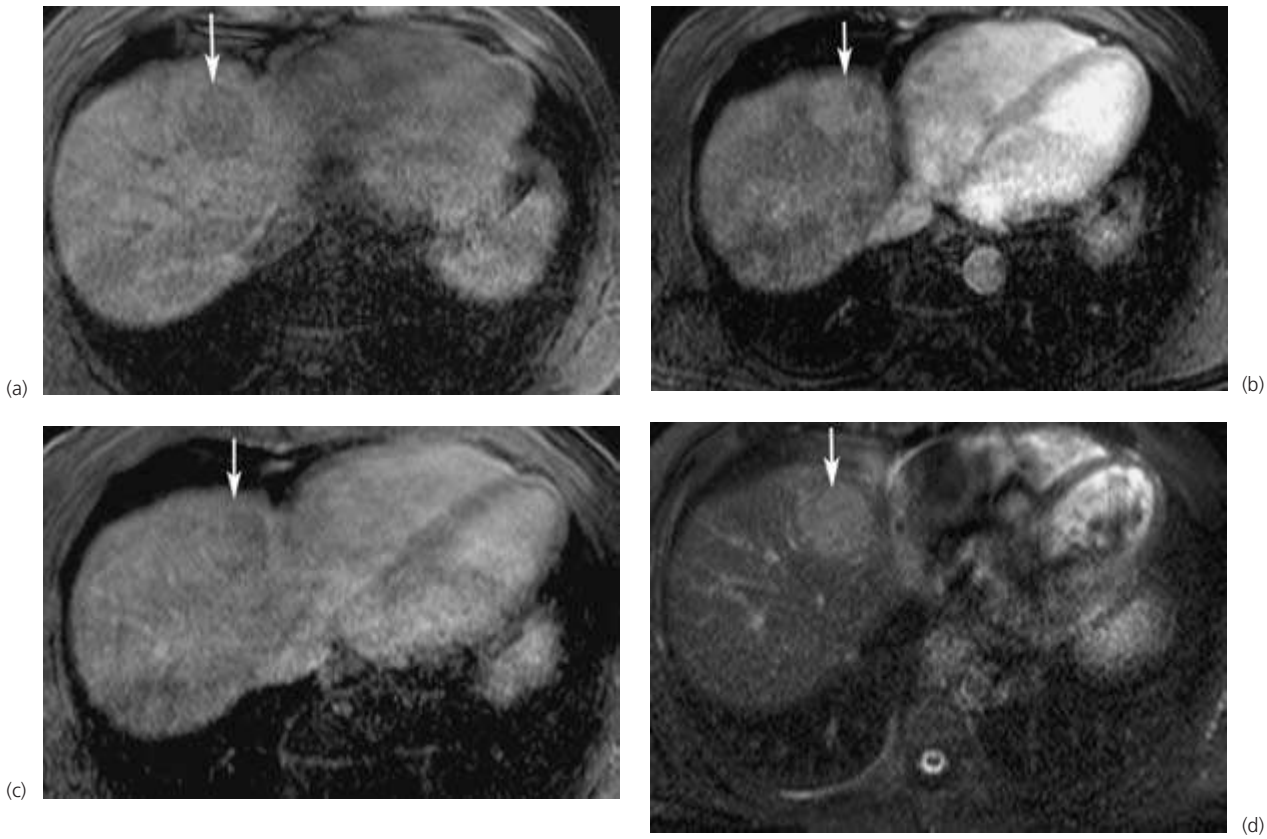

Figure 132.14 Hepatic cirrhosis with hepatocellular carcinoma. **(a)** Axial, fat-suppressed, intermediate T2-weighted image demonstrates cirrhotic liver with nodular contour. Lesion (arrow) in the hepatic dome shows increased signal on the intermediate T2-weighted image **(a)**, is isointense to liver on precontrast, fat-suppressed, three-dimensional gradient echo (GRE) image **(b)**, and enhances avidly during arterial phase on postcontrast, fat-suppressed, three-dimensional GRE image **(c)**. It "washes out", becoming isointense relative to adjacent liver parenchyma on delayed fat-suppressed, three-dimensional GRE image.

signal. Features that help distinguish HCC include increased T2-weighted signal, transient marked arterial-phase post-gadolinium enhancement, capsular peripheral rim enhancement on venous- and equilibrium-phase images, relative washout on delayed images, and size greater than 2–3 cm. It may be that higher-grade dysplastic nodules overlap more with the HCC features; however, this distinction may be of small clinical significance because higher-grade dysplasia has the potential to transform to HCC rapidly (Fig. 132.14). HCC frequently invades vessels and a small subset may contain fat.

Portal hypertension may result from obstruction at presinusoidal, sinusoidal, postsinusoidal, or a combination of these sites, corresponding to abnormalities of portal venous, hepatic fibrosis, hepatic venous, or mixed disease. Images optimal for visualizing changes related to portal hypertension are obtained on equilibrium-phase SGE images with fat suppression. In early or mild portal hypertension images show dilation of the portal vein, and possibly splenic vein. In more severe and chronic cases, the portal vein can occlude and become thin or not visualized, with development of multiple smaller-caliber collaterals seen within the porta hepatis, so-called cavernous transformation. Furthermore, portosystemic collaterals can form and be seen as increased number and size of retroperitoneal vessels in the region of the splenic hilum, gastrohepatic ligament, paraesophageal region, and with demonstration of splenorenal venous connections. A patent periumbilical vein can be seen as a vessel, sometimes massive, extending from the left portal vein anteriorly along the falciform ligament toward the anterior abdominal wall umbilical region. Ascites is commonly seen in combination with more advanced portal hypertension as simple uniform high-signal T2-weighted fluid in the free intraperitoneal space.

Biliary tree

MRI has evolved to become a valuable imaging tool for the pancreas and biliary tree. Applications in this area have been aided greatly by developments in MRA and MRCP, which allow selective visualization of the vascular structures and biliary and pancreatic ducts. MRCP is useful for the detection of biliary obstruction, calculi, and normal variants of biliary

anatomy that have surgical importance [52]. The bile ducts appear as high signal intensity with this technique. Calculi appear as low signal intensity filling defects. Unlike CT, where the attenuation of calculi is variable and may approximate that of surrounding soft tissue, calculi identified by MRI are almost universally low signal intensity on T2-weighted images. MRCP has been shown to be accurate for the detection of calculi in the common bile duct [52].

Cholangiocarcinoma

Because of its ability to image bile ducts, vascular structures, and soft tissue of the hepatic parenchyma in one examination, MRI is useful for the detection of cholangiocarcinoma [53]. Cholangiocarcinoma shows a characteristic pattern of enhancement on dynamic-enhanced images. Classically it shows little uptake of contrast on the arterial and portal phases and increased enhancement on delayed images (see section Magnetic resonance cholangiopancreatography) [53,54]. With hilar cholangiocarcinomas (Klatskin tumors), MRCP can show the multiple obstructed ductal segments. Unlike percutaneous transhepatic cholangiography, which requires separate injection of the different ductal segments if they are completely obstructed, MRCP visualizes all the obstructive ductal segments simultaneously [32]. Therefore, MRCP can assist in treatment planning for these tumors [32].

Pancreas

Developments in faster imaging systems with improved contrast resolution continue to enhance the role of MRI in imaging pancreatic abnormalities with equivocal features on CT. In addition, MRCP is accepted as a noninvasive and accurate method of imaging the pancreatic duct and is now considered an important imaging technique for the diagnosis of chronic pancreatitis. Endoscopic ultrasound (EUS) and positron emission tomography (PET) have emerged as important complementary imaging modalities for imaging of pancreatic abnormalities.

MRI of the pancreas is optimally performed with a high-performance gradient system (1.5 T) using phased-array torso coil to improve the signal-to-noise ratio with a smaller field of view and thin-slice profile [55]. Breath-hold GRE or FSE sequences are most commonly used. Moderately T2-weighted FSE and single-shot FSE (HASTE) sequences, followed by T1-weighted in-phase GRE and T1-weighted opposed-phase GRE images are included in the MRI protocol. To evaluate cystic lesions of the pancreas or pancreatic ducts in patients with chronic pancreatitis, coronal and axial MRCP with single-shot FSE or HASTE are obtained. For gadolinium-DTPA-enhanced MRI (0.1 mmol/kg body weight), triple-phase, breath-hold, fat-suppressed, three-dimensional, fast SGE sequences are acquired. Fat-suppressed, high-resolution, T1-weighted images acquired 10 min after administration of mangafodipir trisodium (5 mol/kg, in a slow bolus over 1–2 min) are useful for lesion detection in equivocal cases. The basis for utilization of mangafodipir is that normal pancreatic parenchyma enhances following mangafodipir administration and becomes hyperintense on T1-weighted images, whereas tumors do not enhance. Mangafodipir is usually reserved for equivocal cases for tumor detection and differentiation from benign inflammatory masses of the pancreas.

MRCP with single breath-hold, thick (2–5 cm) section can provide excellent selective display of the whole extrahepatic biliary tract and pancreatic duct with no respiratory artifacts and few susceptibility artifacts. Some authors have stressed the value of secretin administration in improving pancreatic ductal details in MRCP. The basis of secretin-enhanced MRCP is that exogenous administration of secretin stimulates secretion of pancreatic juice, notably fluid and bicarbonate, which consequently increases the volume of stationary fluid in the pancreatic ducts. Secretin (1 mL per 10 kg body weight) administration 10–15 min prior to MRCP improves pancreatic duct and side-branch delineation and permits evaluation of pancreatic flow dynamics and assessment of pancreatic exocrine function.

Normal anatomy and variants

On MRI, the normal pancreas has signal intensity similar to that of the liver. It has relatively high signal intensity compared with the liver on in-phase T1-weighted images. In opposed-phase T1 images, a hypointense rim surrounding the pancreas is observed due to etching artifact. On fat-suppressed images, the relative signal intensity of pancreas increases, thus facilitating detection of pathological conditions with decreased signal intensity. Being a very vascular organ, the pancreas shows intense contrast enhancement in the arterial phase followed by rapid washout of contrast agent (Fig. 132.15). This makes optimum arterial-phase imaging crucial for accurate detection of most focal pancreatic lesions, which usually enhance less than the normal parenchyma and hence are rendered more conspicuous.

The head and neck regions of pancreas reveal lateral contour anomalies in up to 35% of individuals, the most common of which is discrete lobulation of pancreatic tissue lateral to the gastroduodenal or anterior superior pancreaticoduodenal artery. Pancreas divisum results from failure of fusion of ventral and dorsal pancreatic buds [56]. In this anomaly, the dorsal pancreatic duct drains the neck, body, and tail regions through the minor papilla of duodenum, whereas the ventral pancreatic duct drains the head and uncinate process through the major papilla (Fig. 132.16) [52]. The dorsal duct is prone to obstruction, with associated increased incidence of pancreatitis. Bret and colleagues have reported an accuracy of 100% for MRCP in the diagnosis of pancreas divisum. In patients with recurrent episodes of acute pancreatitis, MRI and MRCP are extremely useful for detecting anatomical variants such as pancreas divisum [56].

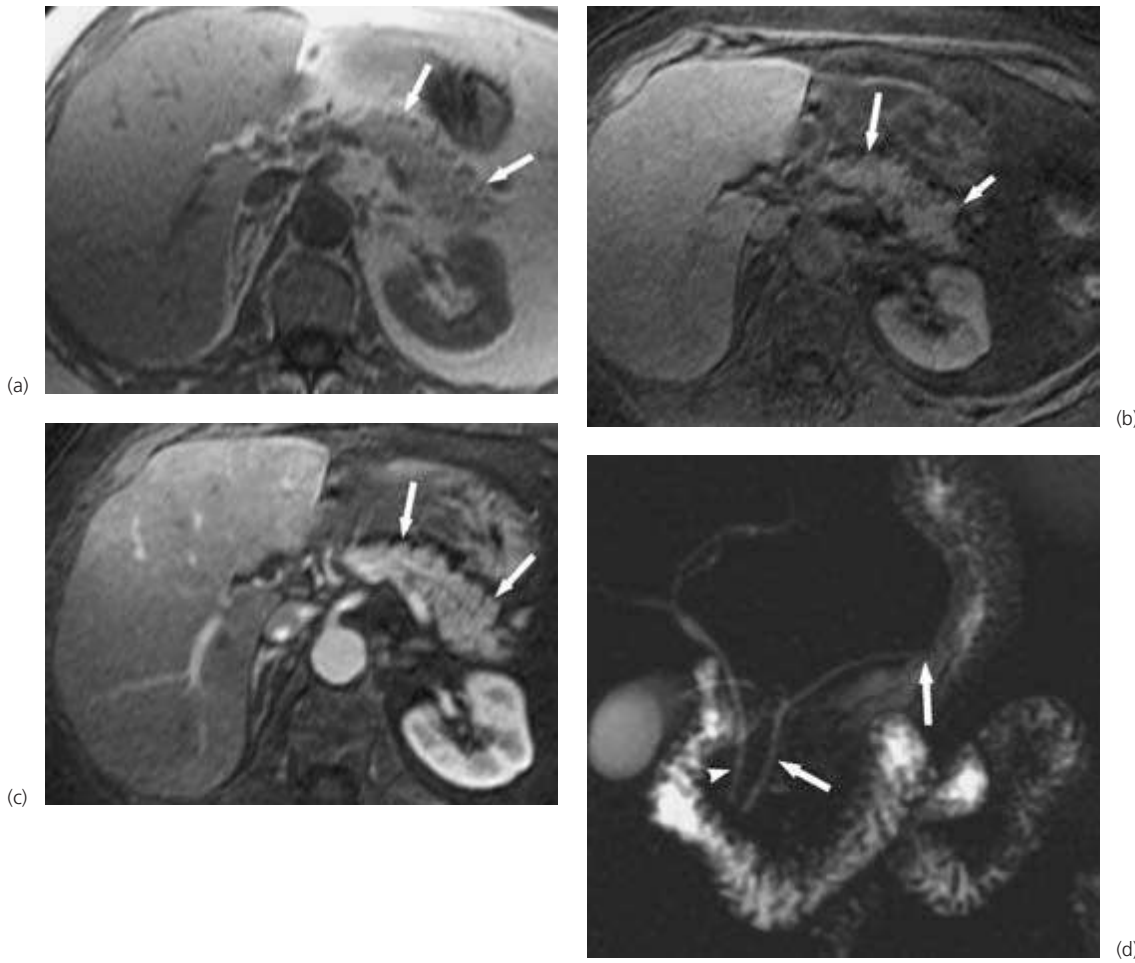

Figure 132.15 Normal pancreas. **(a)** Axial, two-dimensional, T1-weighted and **(b)** precontrast, three-dimensional, fat-suppressed, T1-weighted gradient echo (GRE) images demonstrate normal nonenhanced T1 signal of the pancreatic parenchyma of the body and tail of pancreas that is isointense or higher in signal than liver parenchyma. **(c)** Axial, three-dimensional, postcontrast GRE image demonstrates normal peak enhancement of the pancreatic parenchyma during the arterial phase. **(d)** Magnetic resonance cholangiopancreatography demonstrates normal relative anatomy of the common bile duct (arrowhead) and the pancreatic duct (arrows).

Annular pancreas is an anomaly characterized by pancreatic tissue partially or completely encircling the duodenum. In annular pancreas, MRI shows apparent thickening of the posterior, anterior, and lateral walls of the descending duodenum caused by tissue having signal intensity and enhancement pattern similar to that of pancreatic parenchyma. In addition, MRCP demonstrates the aberrant pancreatic duct encircling and extending lateral to the duodenum. Anomalous union of the pancreatic and bile ducts has been postulated to allow reflux of pancreatic enzymes into the bile duct, thus weakening the bile duct wall. This mechanism has also been postulated as a predisposing factor for the development of a choledochal cyst [56].

Acute pancreatitis

Acute pancreatitis is an acute inflammatory process of the pancreas that may include suppuration, necrosis, and hemorrhage of pancreatic tissue with variable involvement of other regional and remote tissues. The diagnosis can often be made with serum amylase and lipase levels, and cross-sectional imaging techniques are immensely useful for staging, detecting complications such as infection, necrosis and pseudocyst formation, and guiding percutaneous and surgical interventions. At the International Symposium on Acute Pancreatitis held in Atlanta, Georgia in 1992, an acceptable series of clinical definitions for classifying the disease and its complications was described [57]. In patients with mild acute pancreatitis, interstitial and peripancreatic edema predominates.

The severe form of acute pancreatitis is characterized by extensive pancreatic necrosis and inflammation of the peripancreatic fat tissues that may lead to variable degrees of tissue necrosis, pancreatic and peripancreatic abscess, and parenchymal hemorrhage. Pancreatic gland necrosis has been defined as focal or diffuse areas of nonviable parenchyma typically associated with peripancreatic fat necrosis. Acute fluid collections occur in about 50% of patients in the early

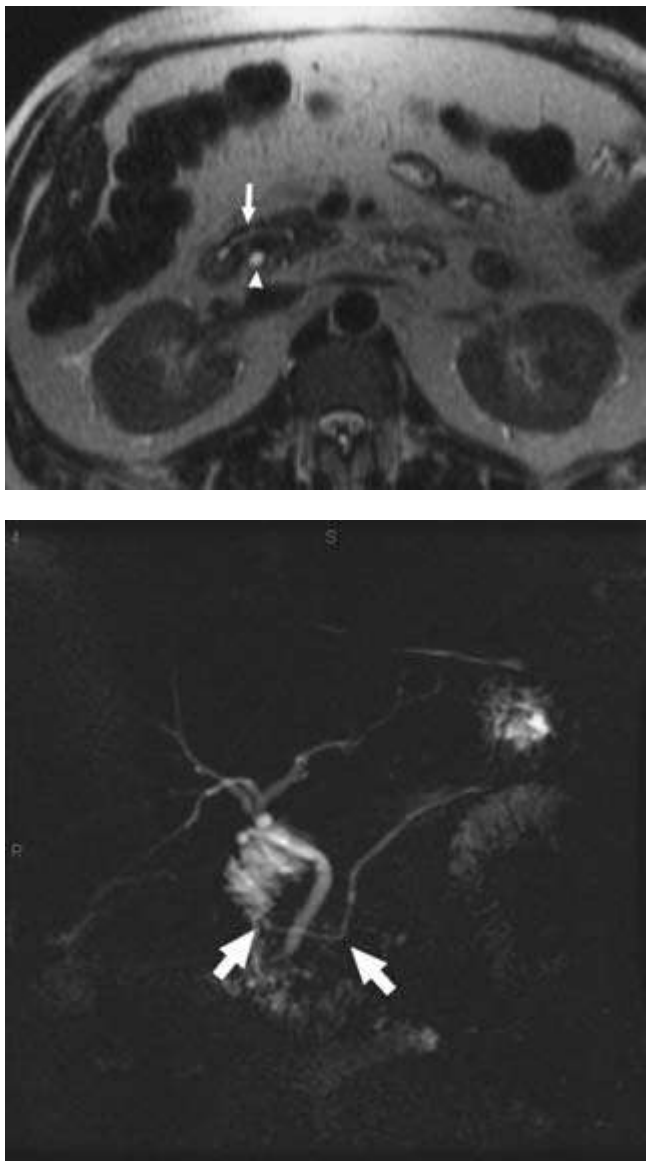

Figure 132.16 Pancreas divisum. **(a)** Axial T2-weighted image and **(b)** magnetic resonance cholangiopancreatography demonstrate pancreas divisum with primary draining pancreatic duct of Santorini (arrow) crossing the common bile duct (arrowhead) to empty via the minor ampulla.

course of the disease and contain enzyme-rich pancreatic juice. Encapsulated collections of pancreatic fluid called pseudocysts evolve from the persistent peripancreatic fluid collections. Peripancreatic abscesses represent circumscribed pus collections that occur in areas of limited necrosis with secondary infections. The frequency of development of sepsis increases with time after onset of symptoms of pancreatitis. Infected necrosis is associated with high mortality and represents infected pancreatic or peripancreatic necrotic tissue.

CT is the imaging modality of choice for diagnosis and staging of suspected acute pancreatitis, follow-up evaluations, and guidance for percutaneous and surgical intervention. Some reports have raised concerns about possible aggravation of pancreatic injury with the use of iodinated contrast agents in experimental and human studies. In these circumstances and in patients who have other contraindications to iodinated contrast, such as renal dysfunction, MRI with gadolinium offers a safer alternative and excludes the radiation burden associated with CT [57]. MRCP using T2-weighted and gadolinium-enhanced, fat-suppressed, T1-weighted sequences also helps therapeutic planning and demonstrates the size, location, and possible communication of a pseudocyst with the pancreatic duct, possible choledocholithiasis, presence of ductal distention, or disruption of the pancreatic duct. Normal pancreatic parenchyma shows high signal intensity on T1-weighted fat-suppressed images and possesses a uniform capillary blush in mild pancreatitis. More severe cases of pancreatitis are associated with variable diminution of signal intensity on T1-weighted fat-suppressed images and immediate postgadolinium GRE images (Fig. 132.17) [58]. Nonenhancing pancreatic parenchyma suggests the possibility of necrosis or suppuration. MRI is at least as sensitive as CT in depiction of necrosis and peripancreatic fluid collections and is superior to CT in demonstration of the internal consistency and drainability of these collections. Some authors have recommended that predrainage MRI should be performed in patients with pancreatic collections to differentiate pancreatic abscess from pancreatic necrosis, which is not usually amenable to percutaneous management, to avoid infectious complications [57].

Chronic pancreatitis

Chronic pancreatitis is an irreversible inflammatory disease of the pancreas characterized by replacement of glandular acini, ducts, and blood vessels by fibrous tissue that causes ductal strictures, obstruction, and dilatation leading to parenchymal atrophy and stone formation. Early changes of chronic pancreatitis are difficult to recognize with CT. MRI and MRCP have been widely accepted as the primary imaging modalities for the diagnosis of chronic pancreatitis [59]. Findings with MRI and MRCP include atrophy of the gland, changes in signal intensity of pancreatic parenchyma with reduced signal on T1-weighted images, irregular dilatation of the pancreatic duct, pancreatic calcification, and chronic pseudocysts [60]. Pancreatic parenchyma shows decreased signal intensity on T1-weighted fat-suppressed images attributed to fibrosis and reduced concentration of soluble proteins. On T2-weighted images, the signal intensity of the pancreas may be normal because of the presence of fibrosis with variable degrees of inflammation and residual pancreatic tissue (Fig. 132.18) [60]. Differentiation between pseudotumorous lesions in cases of chronic pancreatitis and pancreatic carcinoma may be difficult due to similar mild contrast enhancement of focal lesions. However, MRI with mangafodipir may improve the detection rate and characterization of focal pancreatic lesions because of better delineation of the abnor-

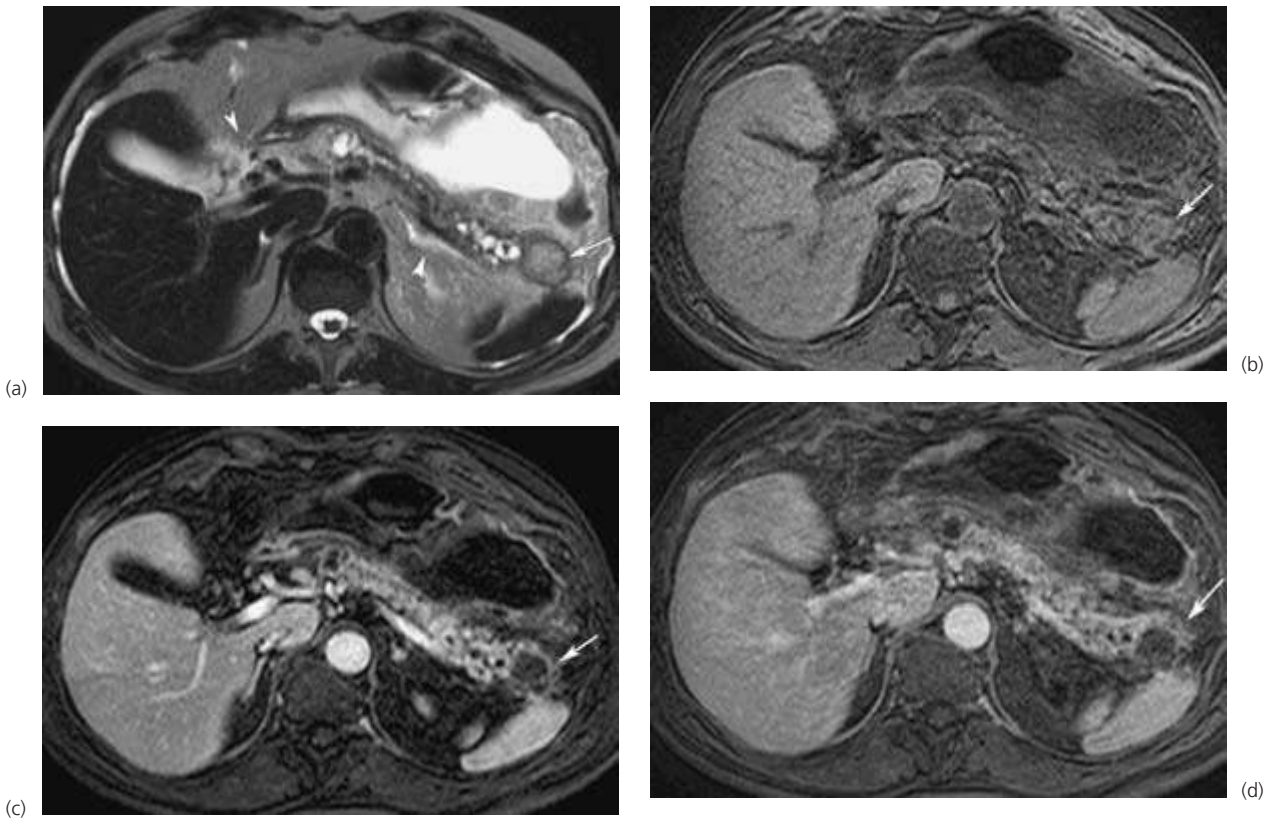

Figure 132.17 Acute on chronic gradient echo pancreatitis. Axial T2 image **(a)** and three-dimensional precontrast images **(b)** before contrast, **(c)** during arterial phase, and **(d)** delayed post contrast demonstrate peripancreatic edema and fluid (arrowheads), relatively low T1 signal in the pancreatic parenchyma, with focal area of necrosis and evolving pseudocyst formation at the tail of the pancreas (arrow) secondary to pancreatic necrosis. There is mild diffuse pancreatic ductal dilation likely reflecting change of prior pancreatitis.

mal area. MRCP demonstrates pseudocysts in or near the pancreas and ductal abnormalities, including segmental dilatation, narrowing, ductal filling defects representing calculi, or mucinous casts in pancreatic ducts [61]. In some instances, the ductal communication of pseudocyst can be demonstrated with MRCP, which can frequently be difficult with ERCP. Prior studies have reported significant increase in pancreatic duct visibility after secretin injection ($P < 0.05$) [62]. These authors have also reported significantly higher fluid filling of the duodenum in healthy persons and in those with pancreas divisum compared with those with chronic pancreatitis or pancreatic tumors [62]. Focal pancreatitis has been reported to occur in 20% of cases and typically involves the pancreatic head. It often simulates pancreatic malignancy, and differentiation, though critical, is often difficult. Although signal intensity of chronic pancreatitis is decreased compared with the normal pancreas on T1-weighted images, there is considerable overlap of signal characteristics and contrast enhancement patterns with pancreatic malignancies. MRCP following secretin may help in demonstrating an associated stricture of the pancreatic duct and the altered filling dynamics of pancreatic fluid that is generally absent in pancreatic malignancy [62]. A positive duct-penetrating sign, seen on MRCP as a smoothly stenotic or normal main pancreatic duct penetrating through the apparent tumor, may be useful in the distinction from pancreatic malignancies. Autoimmune pancreatitis is defined as a special form of chronic pancreatitis caused by an autoimmune mechanism or associated with autoimmune and related diseases such as primary sclerosing cholangitis and ulcerative colitis. Typical MRI characteristics include focal or diffuse pancreatic enlargement, absence of parenchymal atrophy, and significant pancreatic duct dilatation proximal to the site of stenosis. In patients with cystic fibrosis, the pancreatic glandular tissue is significantly reduced in size and is replaced with fat. In older cystic fibrosis patients, complete or incomplete lipomatosis of the pancreas is the most frequent pattern and correlates with pancreatic exocrine dysfunction. In addition, pancreatic calcification and cystic and macrocystic pancreas may be seen on MRI.

Trauma

CT plays an important role in the detection and management of pancreatic trauma. In some instances, MRCP may show the duct disruption and associated fluid collections. MRCP offers a useful alternative to invasive ERCP in assessing delayed complications secondary to pancreatic duct injury [63].

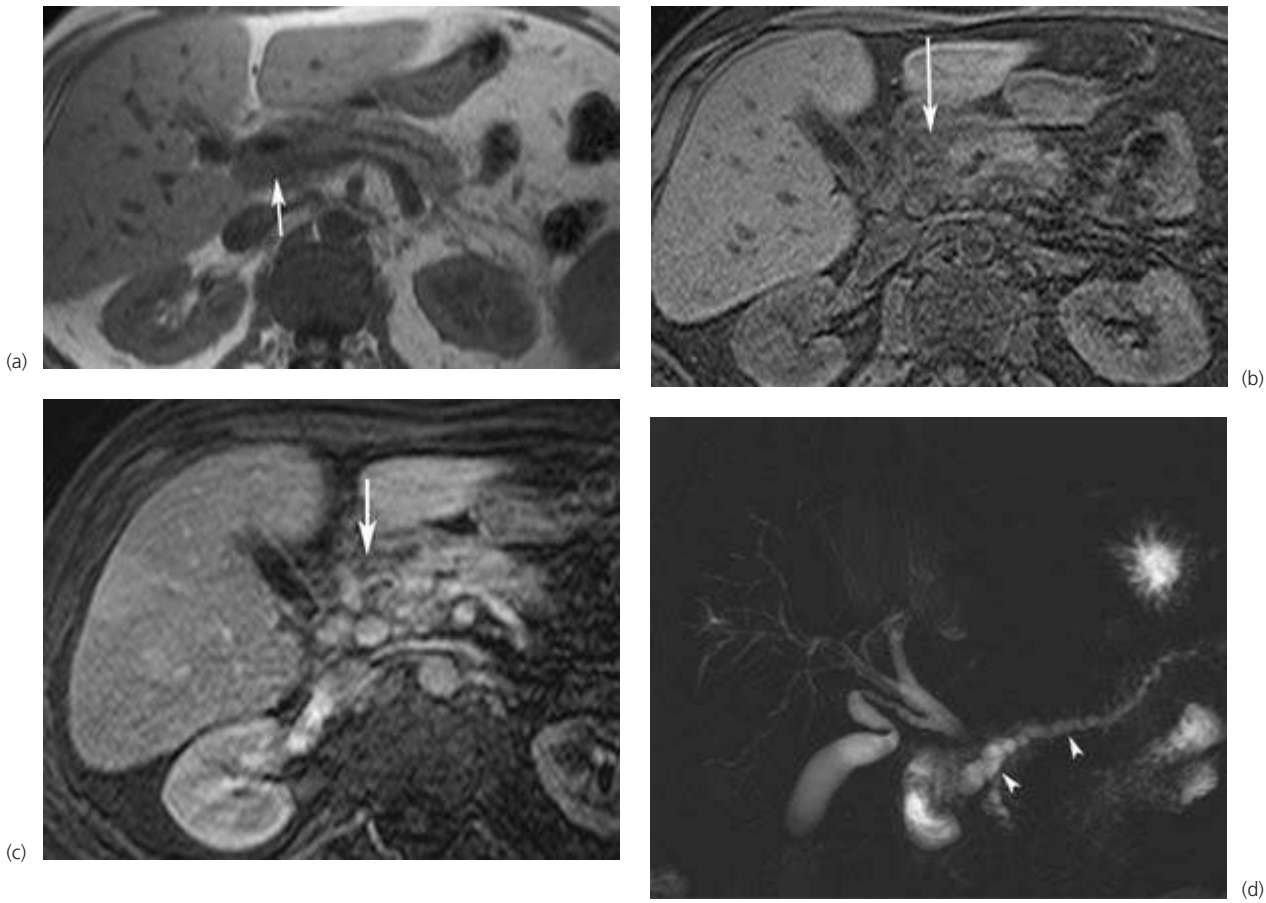

Figure 132.18 Chronic pancreatitis. **(a)** Axial T1 image and **(b)** precontrast three-dimensional gradient echo image demonstrate relatively low signal (arrow) in the region of the head of the pancreas with relative hypoenhancement following contrast **(c)**. **(d)** Magnetic resonance cholangiopancreatography demonstrates associated diffuse dilation of the pancreatic duct (arrowheads).

Neoplasms

Adenocarcinoma

Pancreatic adenocarcinoma is the fourth most common tumor in the USA. About 90% of pancreatic tumors are ductal adenocarcinomas. Neuroendocrine tumors and acinar cell carcinomas constitute about 2%–5% of all pancreatic tumors. The major aims of imaging pancreatic malignancies are detection and staging, which determine the appropriate management options and ultimate prognosis of the disease. Most commonly, adenocarcinoma appears as a mass distorting the contour of the gland with associated findings such as dilated pancreatic duct and common bile duct, atrophy of the gland, vascular invasion, and metastases to regional nodes, liver, and peritoneal cavity. On MRI, T1-weighted spin-echo images with and without fat suppression and immediate post-gadolinium SGE images have been found to be superior to spiral CT for detecting small lesions. Because of their scirrhous character from dense fibrotic tissue, pancreatic adenocarcinomas are generally slightly hypointense relative to the pancreas on T2-weighted images but are difficult to visualize unless there is substantial necrosis [64]. Being relatively hypovascular, ductal adenocarcinomas enhance to a lesser extent than normal pancreatic tissue on early postcontrast images. Hence, they appear distinctly hypointense to the maximally enhanced pancreas during the arterial phase of dynamic contrast enhancement (Fig. 132.19) [65]. However, a thin rim of greater enhancing pancreatic tissue is commonly observed in patients with pancreatic cancers and may help to establish the focal nature of the disease process. Normal pancreatic tissue becomes hyperintense on T1-weighted images after intravenous administration of the tissue-specific contrast agent mangafodipir trisodium [66–69]. Because pancreatic adenocarcinomas do not take up manganese, they are well delineated in the background of enhanced normal pancreatic parenchyma on T1-weighted fat-suppressed images. T1-weighted spin-echo imaging has been reported to be superior to dynamic contrast-enhanced CT for the determination of vascular encasement. Gadolinium-enhanced T1-weighted SGE is extremely useful for evaluating arterial and venous patency. Three-dimensional, contrast-enhanced,

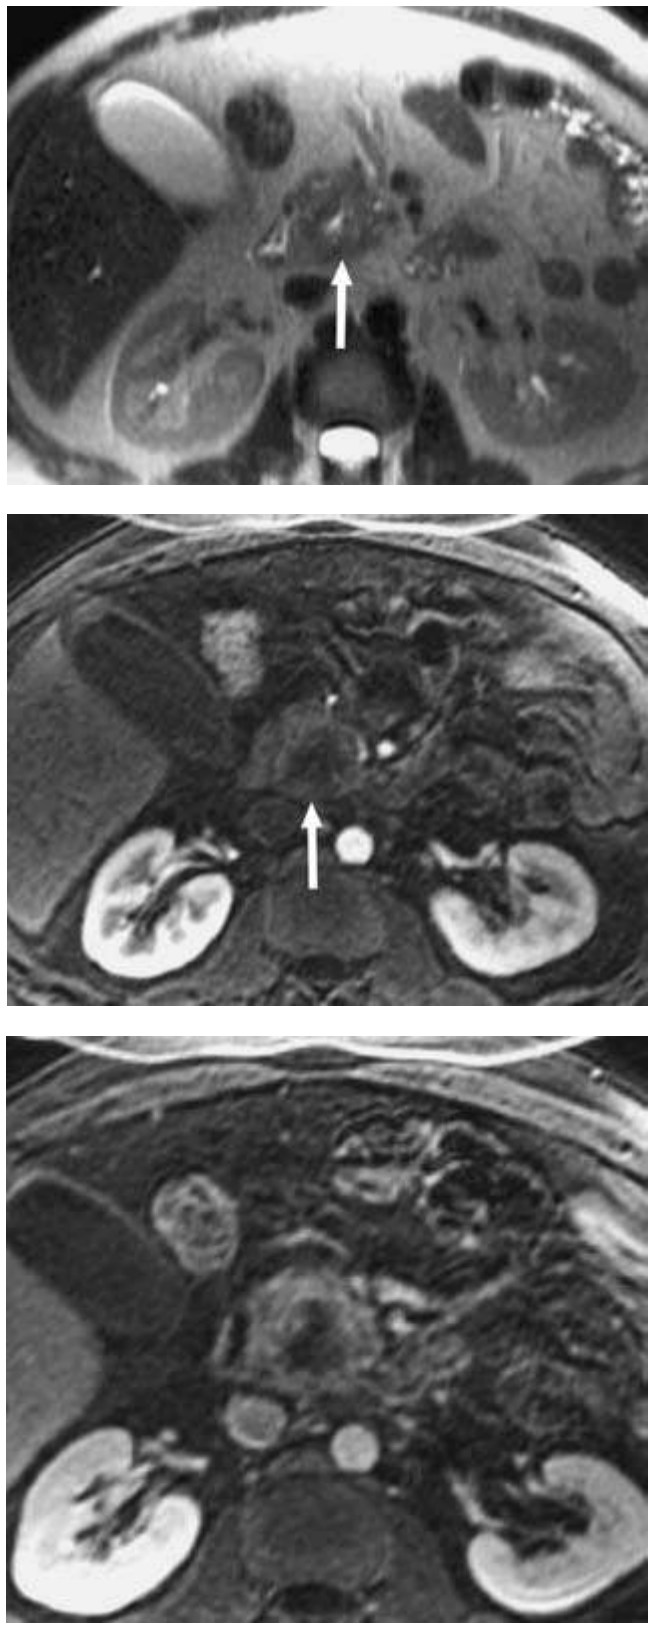

Figure 132.19 Pancreatic carcinoma. **(a)** Axial T2 image demonstrates mass in the head of the pancreas (arrow) with some central necrosis that hypoenhances relative to the remainder of the pancreas during arterial phase **(b)** and portal venous phase **(c)** on postcontrast three-dimensional gradient echo images.

dynamic MRA with fat suppression exquisitely delineates vascular encasement or occlusion for the determination of nonresectability and regional vascular anatomy. MRCP features of pancreatic head adenocarcinoma include encasement and obstruction of the pancreatic duct or bile duct. Dilatation of biliary and pancreatic ducts (double-duct sign) occurs in 77% of cases of pancreatic head carcinoma, biliary duct dilatation occurs alone in 9%, and pancreatic duct dilatation in 12%. MRCP readily demonstrates this double-duct pattern of obstruction, strongly suggesting a pancreatic or ampullary carcinoma. When performed in conjunction with abdominal MRI, MRCP is useful in detecting pancreatic malignancies and in establishing resectability and preventing unnecessary preoperative ERCP. In addition, MRCP is helpful in planning percutaneous biliary drainage and radiation therapy. Metastases to peripancreatic and paraaortic lymph nodes and the lymph nodes in mesenteric and celiac chains can be well depicted on T2-weighted, fat suppressed, spin-echo images and gadolinium-enhanced, T1-weighted, fat-suppressed images. However, detection of small peripancreatic lymph nodes can be difficult on MRI. Gadolinium-enhanced MRI has greater accuracy for detection and characterization of liver metastasis compared with helical CT. MRI is more sensitive than helical CT in the detection of subcentimeter-sized liver metastases and visualization of peritoneal implants [66]. In patients with a focal pancreatic lesion, Diehl and colleagues have documented a significant increase in contrast-to-noise ratio with mangafodipir-enhanced MRI without (106%) and with (82%) fat saturation [67]. In their study, qualitative image analysis also demonstrated a significant improvement of mangafodipir-enhanced fat-suppressed MRI in delineating pancreatic parenchyma ($P < 0.01$) and pancreatic tumors ($P < 0.01$). Romijn and colleagues have reported that MRI following mangafodipir trisodium administration provides better delineation of pancreatic tumors but does not significantly improve the detection rate and staging accuracy of focal pancreatic lesions over MRI without this contrast medium [68].

Neuroendocrine tumors

Pancreatic neuroendocrine tumors or islet cell tumors are believed to originate from the neuroendocrine cells of the pancreas [70,71]. They are uncommon, slow-growing pancreatic or peripancreatic masses that either result in symptomatic hormonal overproduction (functional) or show no clinical findings of hormone secretion (nonfunctional). On MRI islet tumors are well depicted, being hypointense relative to normal high-signal pancreatic parenchyma on precontrast T1-weighted images and typically hypervascular following contrast enhancement (Fig. 132.20) [70,71]. On fat-suppressed T2-weighted images, tumors may be high signal compared with adjacent pancreatic parenchyma. Lesions with increased fibrous component may be T2 hypointense or isointense to pancreas [70,71].

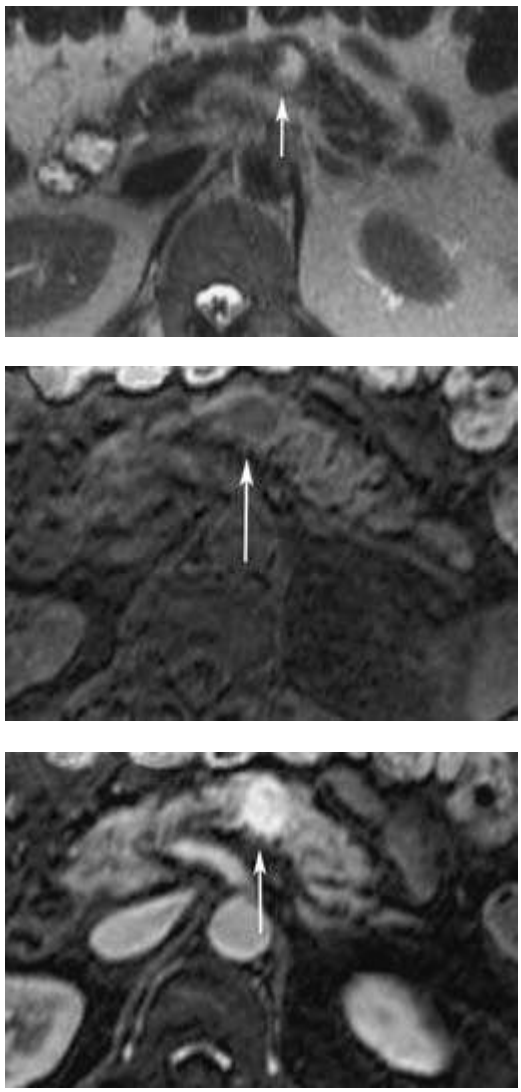

Figure 132.20 Pancreatic islet cell tumor. **(a)** Axial T2 image demonstrates high-T2 signal lesion in the body (arrow). Three-dimensional gradient echo images **(b)** before contrast and **(c)** during arterial phase show prominent enhancement in the arterial phase characteristic of an islet cell tumor (arrow).

Cystic tumors

The differential diagnosis of cystic pancreatic lesions includes both congenital true cysts and acquired cysts.

- Congenital cysts: simple cysts, cysts associated with polycystic disease of pancreas or other disorders.
- Acquired cysts: pseudocysts, hydatid cysts, retention cysts, angiomatous cysts, and cystic neoplasms, i.e., serous cystadenoma, mucinous cystadenoma, mucinous cystadenocarcinoma, papillary cystic neoplasm, intraductal papillary mucinous neoplasm [IPMN], ductal adenocarcinoma with cystic necrosis, teratomatous cysts, cystic choriocarcinoma, and neuroendocrine cystic tumors of pancreas [72].

The most common types of cystic neoplasms of the pancreas are serous and mucinous tumors and IPMN [73]. Serous tumors are benign and typically contain more than six cysts that are smaller than 20 mm and which have a central stellate scar. These tumors typically occur between the ages of 34 and 88 years and have a strong female predilection. Accurate radiological diagnosis and differentiation from mucinous cystic tumors are crucial to avoid aggressive surgical intervention in the case of an asymptomatic serous cystadenoma, which has low malignant potential [73]. On MRI, serous cystadenoma appears as a well-defined lesion that does not show invasion of fat or adjacent organs. On T2-weighted images, the small cysts and intervening septations may look like a cluster of small grape-like hyperintense cysts, best depicted on breathing-independent, single-shot, echo-train, spin-echo sequences. Cyst components are typically smaller than 1.5 cm. Tumor septa usually enhance minimally on early and late postgadolinium images. Delayed enhancement of the central scar may occasionally be observed. Mucinous cystic neoplasms are most often located in the body or tail of the pancreas and have a strong female predilection [74]. These lesions are unilocular or have larger internal (> 1.5 cm) cystic components. These tumors are more sinister neoplasms with malignant potential. They display cysts that are less numerous and larger in size than typically seen with serous cystadenoma. The higher inherent soft-tissue contrast of MRI allows better differentiation between serous and mucinous cystic neoplasms than CT. Mucin produced by mucinous cystic tumors may result in high signal intensity on T1- and T2-weighted images of the primary tumor [75]. If present, liver metastases frequently follow the appearance of the primary pancreatic lesion on T1- and T2-weighted and contrast-enhanced images. Thick irregular septa and solid portions or papillary excrescences may be seen on gadolinium-enhanced, T1-weighted, fat-suppressed images (Fig. 132.21) [76]. Mucinous cystadenoma and cystadenocarcinoma do not reveal a central scar.

IPMN is recognized by dilatation of the main pancreatic duct or branch ducts associated with mucin overproduction. IPMN originates from the main pancreatic duct and its collateral branches and may be differentiated from other mucinous cystic tumors that typically originate from peripheral ducts. IPMN is divided into main duct type (Fig. 132.22), branch duct type, or a combination, depending on the major site of involvement. Cross-sectional imaging of main-duct IPMN shows either diffuse or segmental dilatation of the main pancreatic duct, associated with parenchymal atrophy, especially in more advanced cases [77,78]. Intraductal fungating lesions or mucin deposits may cause small intraductal areas with solid signal intensity seen on MRI. MRCP can demonstrate the dilated ducts as hyperintense collections that are not frequently conspicuous on ERCP [77,78]. Branch-duct IPMN is characterized by cystic ectasia of the branch ducts, forming a mass with lobulated contours that usually

involves the uncinate process (Fig. 132.23). MRCP demonstrates a grape-like appearance of the lesion and its wide communication with the main pancreatic duct. Rarely, ectasia of a single duct communicating with the main pancreatic duct through a long pedicle may be seen [77,78].

Solid pseudopapillary tumor

Solid pseudopapillary tumor of pancreas is a rare low-grade malignant neoplasm typically occurring in young women, particularly of African American or Asian descent. The mean age of presentation is 25 years. The tumor is usually large (mean 9 cm) and well circumscribed with internal solid and cystic components. MRI shows a complex mass that may have hemorrhagic necrosis with high signal on T1-weighted images and heterogeneous variable signal on T2-weighted images. The differential diagnosis is nonfunctioning cystic islet cell tumor.

Lymphoma

Pancreatic lymphoma is almost invariably of the non-Hodgkin B-cell type and may be associated with concomitant infection with a retrovirus or Epstein–Barr virus (Burkitt lymphoma). It is usually associated with peripancreatic and retroperitoneal lymphadenopathy or splenic, hepatic, renal, and epidural space lesions. Presence of intact fat planes between the nodes and the pancreas, and anterior displacement of the pancreas help to distinguish peripancreatic lymphadenopathy from a primary neoplasm [79]. Diffuse pancreatic enlargement often noted in pancreatic lymphoma may be due to diffuse pancreatic tumor, tumor-induced pancreatitis, or pancreatitis associated with tumor lysis from chemotherapy. MRI demonstrates diffuse or focal pancreatic enlargement that is isointense to normal pancreatic parenchyma on T1- and T2-weighted images. Contrary to the

enhancement of the normal pancreas after mangafodipir administration, these lesions do not show any uptake of mangafodipir [80].

Pancreatic metastases

The most common primary tumors that metastasize to the pancreas are from the lung, breast, kidney, and melanoma. There are three different patterns of pancreatic involvement, namely localized, multifocal, or diffuse enlargement. Pancreatic metastases should be suspected in the presence of multiple pancreatic masses in a patient with a known primary carcinoma. On MRI most pancreatic metastases appear hypointense on T1-weighted images and hyperintense on T2-weighted images [81]. The majority of metastases are hypointense to a background of high-signal pancreas on T1-weighted fat-suppressed images. Contrast-enhanced MRI may be useful in the evaluation of pancreatic metastases by showing features such as increased vascularity in the presence of a hypervascular primary malignancy [81].

Gallbladder

Magnetic resonance sequences used to evaluate the gallbladder are similar to other imaging protocols used in the abdomen, including axial T1-weighted breath-hold GRE chemical shift sequences, T2-weighted sequences, MRCP, and contrast-enhanced T1-weighted sequences. Both T2-weighted and MRCP sequences are essential in the evaluation of the gallbladder and surrounding structures. Gallstones are low signal intensity against the higher signal intensity of bile. Gallbladder wall edema and pericholecystic fluid are hyperintense on both sequences because of their fluid content.

Contrast-enhanced, breath-hold, fat-suppressed, T1-weighted sequences are used to evaluate the gallbladder and adjacent hepatic parenchyma. Dynamic gadolinium-enhanced MRI may also play a role in differentiating benign and malignant gallbladder masses based on early and delayed enhancement patterns [82].

Hepatocyte-specific T1-shortening agents such as mangafodopir trisodium have biliary excretion. These agents may provide temporal information on hepatobiliary excretion (Fig. 132.24). Lack of excretion into the gallbladder lumen implies cystic duct obstruction, which in conjunction with additional findings may be used to diagnose acute cholecystitis.

The normal gallbladder contents show high signal intensity on T2- and heavily T2-weighted images (MRCP) because of static fluid content of bile. The T1-weighted signal intensity of bile varies depending on patient's fasting status, bile viscosity, and bile salt concentration. In the fasting state, 90% of water is removed from the bile with a resultant increase in concentration of phospholipids, cholesterol and bile salts. Concentrated bile can therefore be hyperintense to liver and fat on T1-weighted images due to T1 shortening [82].

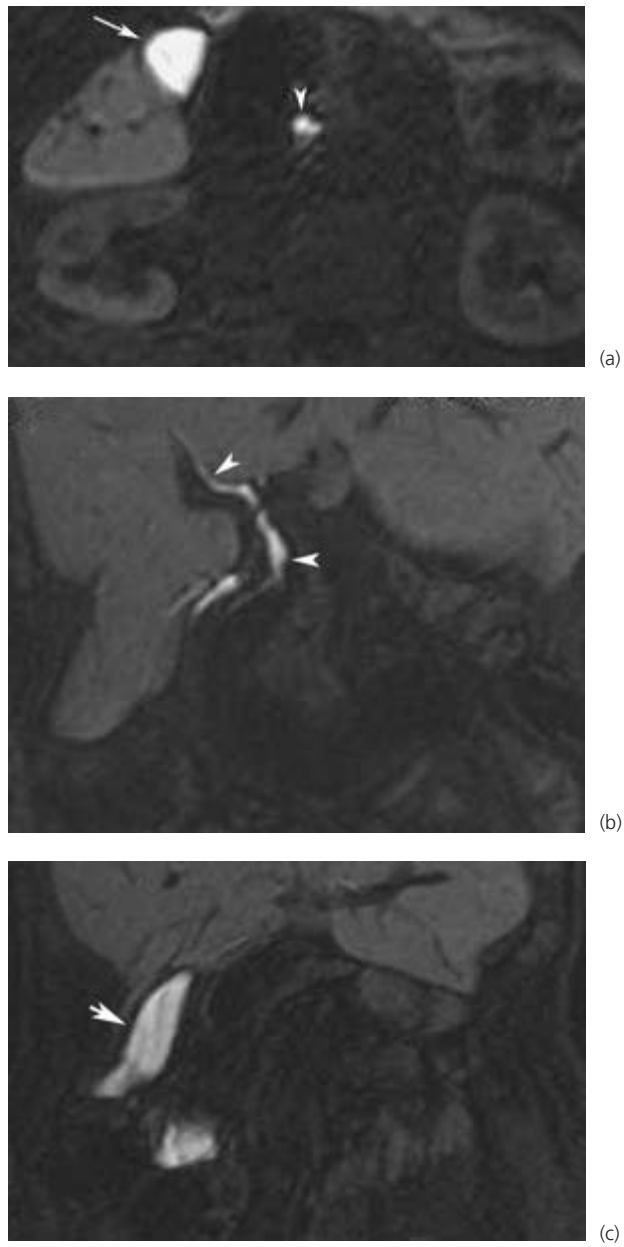

Figure 132.24 Functional magnetic resonance cholangiograms. Increased signal consistent with secreted mangafodopir trisodium in the normal common hepatic duct, common bile duct (arrowheads), and gallbladder (arrow) on axial **(a)** and coronal **(b, c)** images.

Although MRI is as sensitive as ultrasound for the detection of gallstones, it is not used as a primary modality for the diagnosis of cholelithiasis, since sonography is the imaging modality of choice [83]. Cholesterol is the main component in 80% of stones and makes up less than 25% of bilirubin pigment stones. Gallstones have low signal intensity on T1- and T2-weighted images compared with surrounding bile. High signal intensity stones on T1-weighted images have also been attributed to a high fatty acid content or concentrated bilirubin.

Acute cholecystitis occurs when the outflow of bile is prevented by occlusion of the cystic duct, often by a gallstone impacted in the gallbladder neck or cystic duct. Although not used as a screening test for acute cholecystitis, MRI may be used as a primary modality for diagnosis in certain patients with a confusing clinical presentation or equivocal sonographic or cholescintigraphic findings. The presence of cholelithiasis, pericholecystic fluid in the absence of ascites, gallbladder thickening (< 3 mm), and gallbladder edema on T2-weighted images suggest a diagnosis of acute cholecystitis. Gallbladder thickening and pericholecystic fluid in themselves are nonspecific findings and can also occur in the setting of hypoalbuminemia, hepatitis, chronic cholecystitis, cirrhosis, and renal disease. Contrast-enhanced MRI can help confirm a diagnosis of acute cholecystitis by showing hyperemia (> 80% enhancement) of the gallbladder wall and transient hyperenhancement of the adjacent hepatic parenchyma (Fig. 132.25) [84]. Pericholecystic enhancement is present in more than 70% of patients with acute cholecystitis and may extend into the medial segment of the left hepatic lobe. Pericholecystic enhancement is secondary to increased hepatic arterial flow in response to local inflammation of the gallbladder. The finding of segmental absence of mucosal enhancement on contrast-enhanced MRI can suggest a diagnosis of complicating gangrene in patients with suspected acute cholecystitis [84,85]. Chronic cholecystitis can present as a small and irregularly shaped gallbladder with a thickened gallbladder wall. Fibrosis in the gallbladder wall shows delayed enhancement. The degree of wall enhancement is significantly lower than that present in acute cholecystitis [84].

Gallbladder adenomyomatosis is characterized by overgrowth of mucosa, hypertrophy of the muscularis layer, and extension of mucosa into the thickened gallbladder wall, forming intramural diverticula known as Rokitansky–Aschoff sinuses. Adenomyomatosis is found incidentally in 20% of patients who have cholecystectomy. There are three subtypes: localized (usually in the gallbladder fundus), diffuse, and segmental (segmental stricture composed of a thickened wall that divides the gallbladder lumen into separate interconnecting compartments) [83]. The MRI diagnosis of adenomyomatosis is based on the demonstration of Rokitansky–Aschoff sinuses. The thickened gallbladder wall appears hypintense on T2-weighted images, while the intramural diverticula are revealed as discrete, linearly arranged, smoothly marginated, intramural cyst-like structures that are isointense to bile on T2-weighted images and MRCP. The appearance of the intramural cysts in a circumferential distribution has been described as the "pearl necklace" sign.

Gallbladder polyps are elevated lesions of the mucosal surface of the gallbladder wall and are often incidental findings on imaging evaluation of the abdomen. The majority of resected polyps are cholesterol polyps that have no malignant potential. Polyp size is a significant predictor of malignant potential, with a 40%–88% prevalence of malignancy in polyps larger than 10 mm. On MRI, polyps are discrete wall-based lesions that contrast against the high T2 signal of the adjacent bile. They enhance following contrast administration, best appreciated on fat-suppressed T1-weighted images. They are distinguished from stones because of their fixation to the gallbladder wall and their enhancement. Size greater than 10 mm, solitary polyp, age greater than 60 years, sessile morphology, coexistence of gallstones, and rapid growth increase the risk of polyps being malignant.

Gallbladder carcinoma is a rare but aggressive malignancy. It predominantly affects females (3 : 1 over males) and gallstones are present in 90% of patients with gallbladder cancer. Symptoms occur with advanced disease: anorexia, weight loss, jaundice, and abdominal pain. The most common mode of spread is direct invasion into the liver. Tumor can also directly invade the duodenum, colon, and pancreas. On MRI, the primary gallbladder cancer is hypointense to liver on T1-weighted images and slightly hyperintense to liver on T2-weighted images [86]. T2-weighted and MRCP images

(a)   (b)

Figure 132.25 Acute cholecystitis. **(a)** Coronal T2 and **(b)** axial postcontrast images demonstrate thickening of the gallbladder wall (arrowheads) and mild pericholecystic edema consistent with acute cholecystitis.

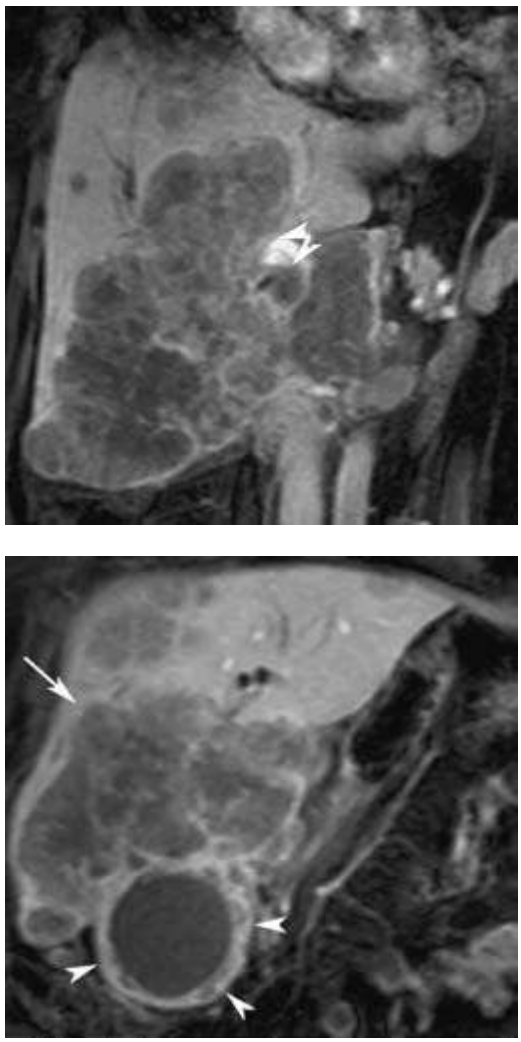

Figure 132.26 Gallbladder carcinoma. Coronal postcontrast images **(a, b)** demonstrate circumferential thickening of the gallbladder wall (arrowheads) inseparable from the liver with tumor extension into the right hepatic lobe (arrow). Note hypoenhancing metastatic lesions in the right heptic dome and left lobe.

typically depict gallstones surrounded by a tumor mass. Direct liver invasion, when present, is typically an ill-defined mass in the adjacent hepatic parenchyma contiguous with the gallbladder mass (Fig. 132.26). Dynamic contrast-enhanced MRI can demonstrate the margin of tumor extension, facilitating accurate staging. The identification of regional lymph nodes larger than 10 mm with ring-like or heterogeneous enhancement suggests lymphatic spread.

The gallbladder is very rarely the site of involvement by other malignancies. Metastatic breast or metastatic melanoma can occasionally involve the gallbladder, the latter being more frequent [87]. Primary non-Hodgkin lymphoma of the gallbladder is also very rare and has a very poor prognosis. This presents with diffuse thickening of the gallbladder wall with moderate enhancement.

Magnetic resonance cholangiopancreatography

In the initial evaluation of biliary and pancreatic disorders, MRCP has replaced the use of diagnostic ERCP at many institutions. This technique uses MRI to visualize stationary or slow-moving fluid, such as bile, displaying them as high signal intensity. Heavily T2-weighted sequences are generally used for MRCP with the single-shot, echo-train, spin-echo technique achieving the most widespread use. Because of the heavy T2 weighting of this sequence, signals from the fluid in the biliary system and pancreatic duct are hyperintense, whereas the signal of background tissue is rendered hypointense, enabling excellent depiction of the biliary system and pancreatic duct (see Fig. 132.15). Single-shot, echo-train, spin-echo sequence can be performed as single-slab acquisition or multiple thin-slice acquisitions. In the single-slab approach, a thick-collimation (30–70 mm) single section is acquired in an oblique coronal plane, obtained in 2–3 s. The single slab can be acquired in various rotations to view the biliary system and pancreatic duct from different angles. ERCP-like images can be acquired without maximum intensity projection (MIP) post processing. It is important also to acquire a multiple-slice thin-collimation sequence to examine the details of the intraductal structures. A slice thickness of 3–4 mm is needed to detect small intraductal stones. Three-dimensional reconstruction may be performed by MIP postprocessing from the thin-collimation source images. However, volume-averaging effects can obscure small stones and subtle mural irregularity, so source thin-section images must always be reviewed. With these images, however, it is not possible to evaluate periductal structures, such as tumors, which may cause narrowing or obstruction of the ducts. Also, fluids with relatively short TE, such as concentrated bile or mucinous fluid, may produce very little signal with long effective TE sequences and may obscure small bile ducts or mucinous lesions. To overcome those drawbacks of MRCP with long effective TE, an intermediate effective TE (80–100 ms) can be used. This produces images where not only all fluid including concentrated bile and mucinous fluid is bright, but also periductal structures are well depicted. This combination of MRCP with intermediate effective TE and ERCP-like images gives detailed evaluation of both intraductal and periductal structures.

Studies show that MRCP is comparable with or more useful than other techniques, such as ultrasound, CT, and ERCP, for studying choledocholithiasis, malignant obstruction of the biliary or pancreatic ducts, congenital anomalies, and chronic pancreatitis [88]. MRCP is noninvasive and safe because it does not require anesthesia or injection of intraductal or intravenous contrast agent. Using current MRI systems, high-quality images can be obtained consistently. MRCP is useful in patients after incomplete or unsuccessful

ERCP. In some patients, such as those who have undergone surgery with biliary enteric anastomosis or Billroth II, it may not be possible to perform ERCP, so MRCP is the modality of choice for evaluating these postsurgical patients. Unlike ERCP, MRCP produces images of the ducts in their natural state, because it does not involve distention of the ducts by injected contrast medium. ERCP cannot evaluate extraductal structures directly, whereas MRCP can be combined with conventional MRI for the evaluation of extraductal disease, such as tumors [62]. ERCP has advantages over MRCP, including the ability to perform direct therapeutic interventional procedures concurrently with diagnostic imaging. ERCP is generally a safe procedure, but is still associated with nonnegligible morbidity and mortality rates. Also, technical failures occur in up to 10% of cases because of unsuccessful cannulation of the common bile duct (CBD) or pancreatic duct. In some institutions MRCP is gradually replacing ERCP as a primary diagnostic imaging modality to evaluate the biliary system and pancreatic duct.

Benign cystic disease

MRCP can be effective and comparable with ERCP for the evaluation of congenital cystic lesions of the bile duct. Also, the combination of MRCP and gadolinium-enhanced T1-weighted images is useful for diagnosing associated findings, such as gallstone disease and cancer. MRCP has been demonstrated to be effective in evaluating choledochal cyst (Fig. 132.27), choledochocele, and Caroli disease.

Congenital variants of the biliary system

Anatomical variants of the cystic duct have received much attention because of the higher risk of complications during cholecystectomy. In a study evaluating anatomical variants of the biliary tree, MRCP could accurately demonstrate a range of variants, such as low cystic duct insertion, medial cystic duct insertion, parallel course of the cystic and hepatic ducts, and aberrant right hepatic duct [56].

Pancreas divisum

Pancreas divisum is the most common anatomical variant of the pancreas and results from failure of fusion of the duct of the embryonic dorsal pancreas and the duct of the ventral pancreas. As a result, the pancreas has two separate ductal systems (see Fig. 132.16). The incidence of this anomaly is reported to be 1.3%–6.7% of the general population. In patients with pancreas divisum, the minor papilla may cause impaired pancreatic drainage and result in chronic pancreatitis [56]. Another clinically relevant issue with pancreas divisum is that at ERCP only the ventral duct can be cannulated through the major papilla, and a small ventral duct may be misdiagnosed as an obstructed pancreatic duct. On MRCP images, pancreas divisum can be diagnosed by finding a dorsal dominant pancreatic duct running anteriorly to the CBD and draining into the minor papilla (see Fig. 132.16). A study that evaluated 108 patients who underwent both ERCP and MRCP demonstrated exact correlation between the two techniques for the depiction and exclusion of pancreas divisum [56].

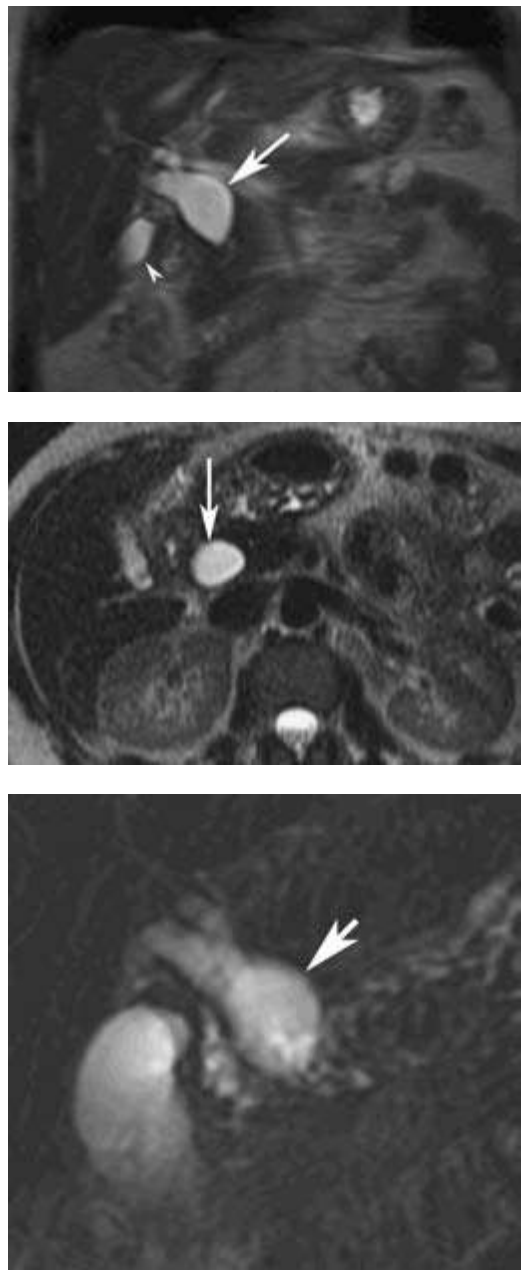

Figure 132.27 Choledochal cyst. **(a)** Coronal T2 image, **(b)** axial T2 image, and **(c)** magnetic resonance cholangiopancreatography demonstrate fusiform dilation of the common bile duct (arrow) consistent with choledochal cyst. Arrowhead indicates gallbladder.

Cholelithiasis

The primary imaging modality for cholelithiasis is sonography. However, MRCP is highly sensitive and accurate in diagnosing cholelithiasis and can outperform ultrasound and

CT. The most reliable approach for detecting gallstones is with the use of single-shot T2-weighted sequences, such as MRCP [89].

Choledocholithiasis

Accurate diagnosis of stones in the biliary ducts is crucial because their presence is a difficult challenge for cholecystectomy. Ultrasound and CT show relatively low sensitivity and accuracy for the diagnosis of bile duct stones. ERCP is considered the gold standard procedure for the evaluation of the biliary system and has a major advantage over other imaging modalities because it can be used to perform therapeutic interventions and diagnosis [89]. However, even in diagnostic ERCP alone, the rate of major complications or death is not negligible and the rate of failed ERCP is 5%–20%. MRCP has been shown to be an excellent method for detecting bile duct stones [90]. It is superior to CT or ultrasound and comparable or superior to ERCP in detecting bile duct stones. On thin-slice source images, stones appear as signal-void lesions, with stones as small as 2 mm being detected in dilated and nondilated ducts (Fig. 132.28). On thick-slab images, large or medium-sized stones in normal-caliber ducts are easily detectable, but small stones that are completely surrounded by fluid may be obscured and difficult to detect because of volume-averaging effects [91]. There are several pitfalls and mimickers of stones with MRCP. Intraductal air bubbles (pneumobilia) may mimic the appearance of stones (Fig. 132.29) [89,91]. An important differentiating feature from

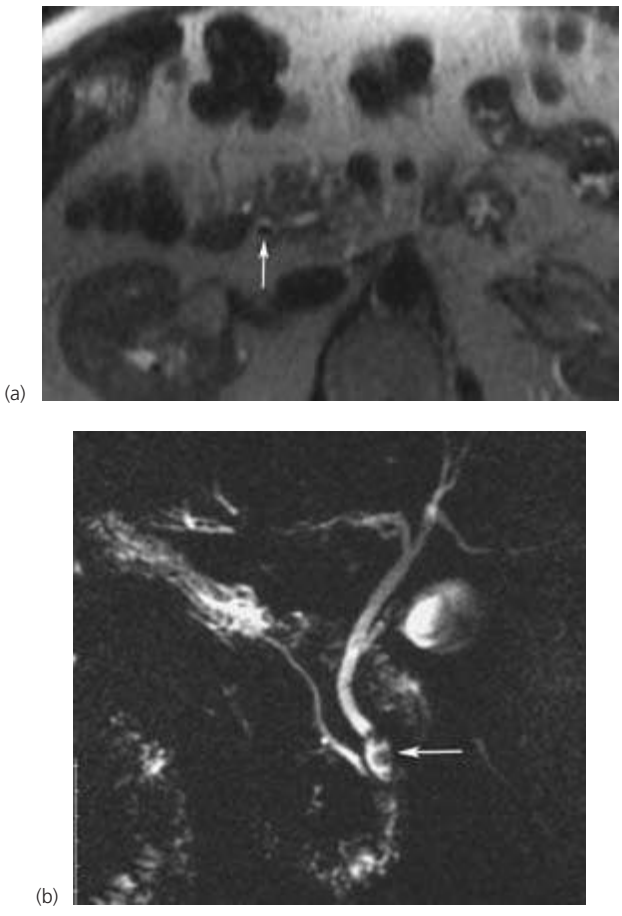

Figure 132.28 Choledocholithiasis. **(a)** Axial T2 image and **(b)** magnetic resonance cholangiopancreatography show low signal void (arrow) consistent with common bile duct calculi.

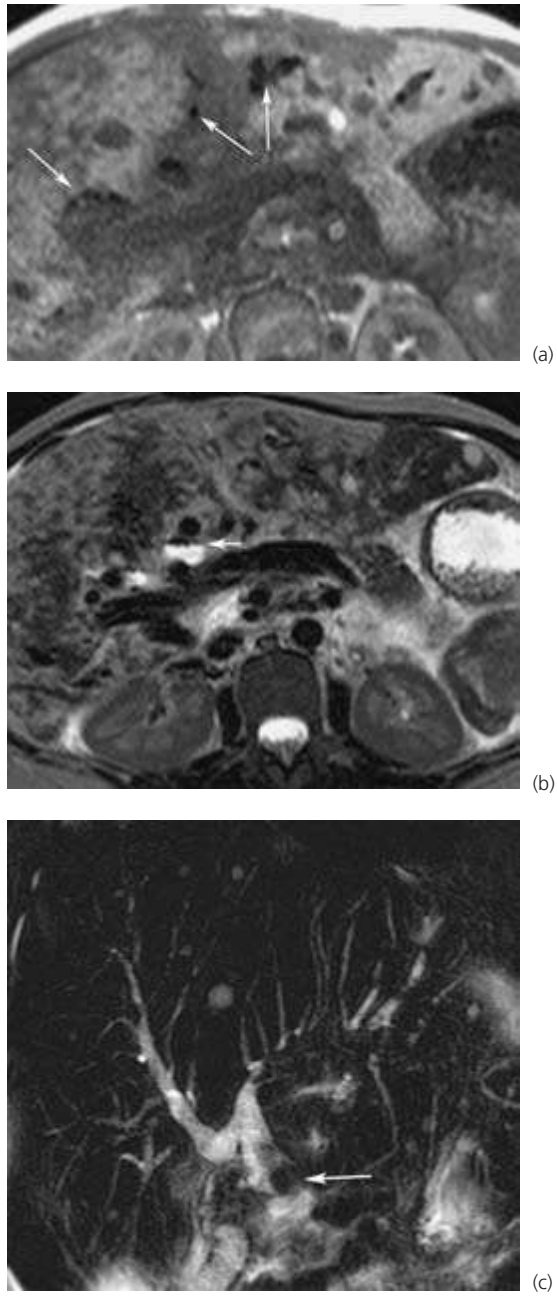

Figure 132.29 Pneumobilia. **(a)** Axial T1 image, **(b)** axial T2 FSE image, and **(c)** magnetic resonance cholangiopancreatography demonstrate low signal (arrows) in the intrahepatic and extrahepatic biliary ducts. This low signal is nondependent in the axial T2 image in the common bile duct consistent with pneumobilia.

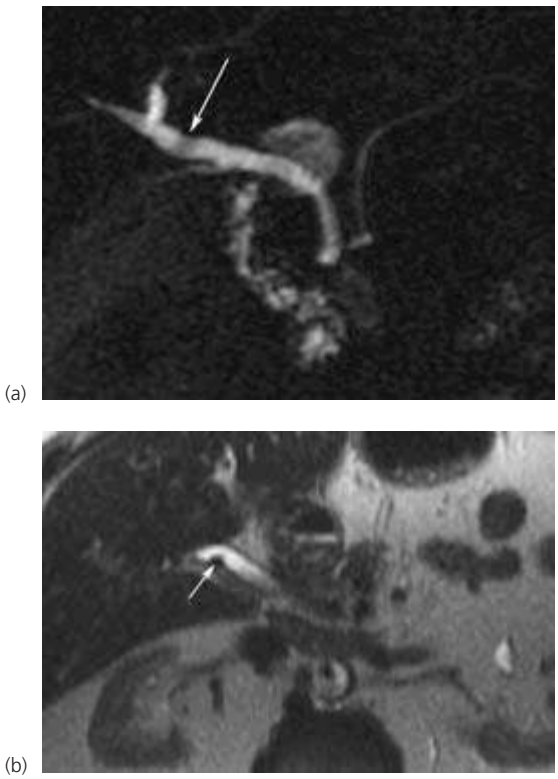

Figure 132.30 Pseudodefect of the common hepatic duct secondary to crossing vessel. Low signal void in the common hepatic duct on magnetic resonance cholangiopancreatography **(a)** secondary to adjacent crossing vessel (arrow) confirmed on axial T2 image **(b)**.

stones is that air bubble filling defects lie on the nondependent portion of the bile duct against the wall on axial images. Blood clots may appear indistinguishable from bile duct stones [92]. Other pitfalls that may mimic bile duct stones include:

- tortuosity of the bile duct running in and out of the imaging plane
- merging of the cystic duct into the CBD when observed en face on coronal images, which may result in a round hypointense focus
- metallic clips
- extraductal compression from the right hepatic or gastroduodenal artery, which may result in a signal-void focus (Fig. 132.30).

Correct diagnosis can usually be achieved by careful attention to the exact location of these foci and interpretation of thick-slab MRCP or MIP-reconstructed images in conjunction with the thin-slice source images [92].

Primary sclerosing cholangitis

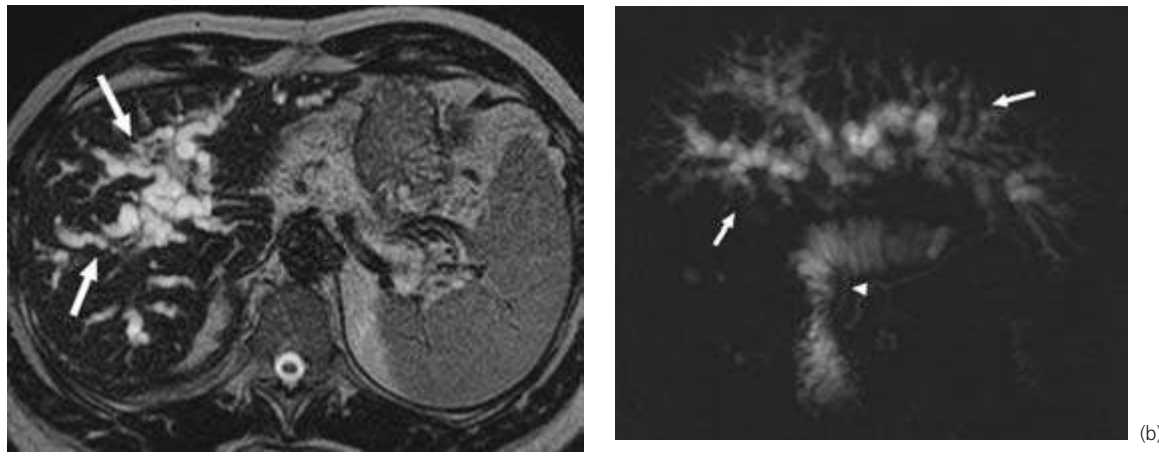
Primary sclerosing cholangitis is characterized by chronic fibrosing inflammation of the biliary system of unknown etiology. The diagnosis of primary sclerosing cholangitis is made by cholangiographic findings supported by histological results. The imaging appearance of primary sclerosing cholangitis is characterized by multiple irregular strictures and saccular dilatations of the intrahepatic and extrahepatic bile ducts, producing a beaded appearance. The conventional imaging modality for the diagnosis of primary sclerosing cholangitis is ERCP. However, complications from ERCP may result in progression of cholestasis in patients with primary sclerosing cholangitis. MRCP has been shown to be useful for the diagnosis and follow-up of primary sclerosing cholangitis [93]. A study evaluating MRCP in patients with primary sclerosing cholangitis demonstrated a sensitivity of 85%–88% and specificity of 92%–97% [93]. However, diagnostic challenges remain: subtle changes of mild primary sclerosing cholangitis may be difficult to detect by current MRI techniques, and cirrhosis may cause distortion of the intrahepatic bile ducts and mimic primary sclerosing cholangitis [94]. A major strength is that MRCP provides visualization of bile ducts proximal to even severe stenoses, which may not be evaluable by ERCP. The characteristic feature is of intrahepatic ductal dilation with areas of dilation and stenosis characterized as "beading" (Fig. 132.31).

Postsurgical biliary complications

The most common postsurgical biliary complication is benign biliary stricture. MRCP can visualize the biliary tree distal and proximal to a high-grade stricture or complete obstruction. However, the bile ducts distal to a stenosis may be collapsed and nonvisualized on MIP-reconstructed images, leading to overestimation of the stricture. Thin-section source images must be used to evaluate the extent of high-grade stenoses, because even small amounts of fluid in collapsed ducts can be depicted on these images. Other postsurgical biliary complications include retained bile duct stones, biliary leak, and biliary fistula. These conditions can be evaluated effectively by MRCP. In patients with biliary–enteric anastomoses, it may be difficult or impossible to perform ERCP. On the other hand, MRCP is very effective in evaluating the anatomy of the anastomosis, strictures of the anastomosis, strictures of the biliary ducts, and biliary stones proximal to the anastomosis in up to 100% of patients. Thin-section source images should be examined thoroughly because the biliary–enteric anastomosis and stones may be obscured on thick-slab and MIP-reconstructed images by the high signal intensity of surrounding bile and bowel fluid. Also, metallic surgical clips and pneumobilia can also produce artifacts that should not be mistaken as stones or strictures.

Chronic pancreatitis

On ERCP, typical findings of chronic pancreatitis include dilatation, narrowing or stricture, or irregularity of the pancreatic duct. Prominent dilatation of side branches is a feature of chronic pancreatitis that helps distinguish this entity from obstructed pancreatic duct caused by pancreatic cancer (see Fig. 132.18). A study evaluating 30 patients with chronic pancreatitis undergoing ERCP and MRCP demonstrated



(a) (b)

Figure 132.31 Primary sclerosing cholangitis. **(a)** Axial T2 image and **(b)** magnetic resonance cholangiopancreatography demonstrate marked intrahepatic duct dilation with "beaded" morphology (arrow) and normal bile duct (arrowhead).

sensitivity and specificity of 91% and 92%, respectively, and excellent correlation between ERCP and MRCP was reported.

Cholangiocarcinoma

Cholangiocarcinoma can be classified into three types according to anatomical location: peripheral type, originating from peripheral bile ducts in the liver; hilar type (Klatskin tumor), originating from the confluence of the right and left hepatic ducts; and extrahepatic type, originating from the main hepatic ducts, common hepatic duct, or CBD. Ductal obstruction is observed in all cases of Klatskin tumor and extrahepatic cholangiocarcinoma. Evaluation of the level of obstruction is important for treatment planning. In a study evaluating malignant perihilar biliary obstruction in 40 patients including 26 Klatskin tumors, it was reported that MRCP was as effective as ERCP at detecting the presence and the level of biliary obstruction (40 of 40 cases on MRCP and 38 of 38 cases on ERCP). On MRI, cholangiocarcinoma is poorly defined with low to intermediate signal on T2-weighted images and demonstrates delayed enhancement following contrast (Fig. 132.32). The disadvantage of ERCP is that it may result in sepsis caused by overdistention of an obstructed biliary duct with stagnant bile colonized by bacteria; additionally, ERCP may be unable to provide sufficient biliary opacification to adequately evaluate the region of narrowing. However, MRCP can demonstrate the bile duct proximal to the obstructing site safely and efficiently. T1-weighted fat-suppressed SGE acquired 2–5 min after gadolinium administration is the most consistent technique for demonstrating cholangiocarcinoma, which appears as moderately enhancing tissue (Fig. 132.32).

Pancreatic cancer

Typical pancreatographic features of pancreatic cancer include irregular narrowing or obstruction of the main pancreatic duct and dilatation proximal to the lesion. Pancreatic head tumors also result in obstruction of the CBD. MRCP is able to evaluate the pancreatic duct proximal to an obstructing site that ERCP may be unable to demonstrate. In a study evaluating 124 patients with suspicion of pancreatic cancer, MRCP was as effective as ERCP for the detection of the pancreatic cancer, with sensitivity and specificity of 84% and 97% respectively for MRCP, and 70% and 94% respectively for ERCP. As with other malignant tumors, when pancreatic ductal adenocarcinoma is suspected clinically routine MRI sequences are also performed. T1-weighted SGE acquired immediately after gadolinium administration is the most consistent technique for demonstrating pancreatic cancer (see Fig. 132.19).

Additional uses of MRCP

In a study evaluating 31 patients with chronic pancreatitis and 84 patients with suspicion of pancreatic disease, MRCP after secretin stimulation showed reduced duodenal filling in patients with severe chronic pancreatitis. Another advance in MRCP is the use of contrast agents that are hepatocyte-selective and eliminated, at least in part, by the biliary system. With these agents and faster acquisition with thin-section, three-dimensional, T1-weighted images of the biliary system, demonstration of smaller intrahepatic biliary branches is feasible. This approach may also facilitate detection of functional obstruction or bile duct leak or injury.

Intestine

MRI has had limited value in evaluating the bowel compared with CT and conventional barium studies. This is mostly because motion of the bowel, caused by either respiratory motion or peristalsis, degrades the magnetic resonance images. Newer techniques such as single-shot FSE have reduced these problems to some extent. Antiperistaltic agents are also

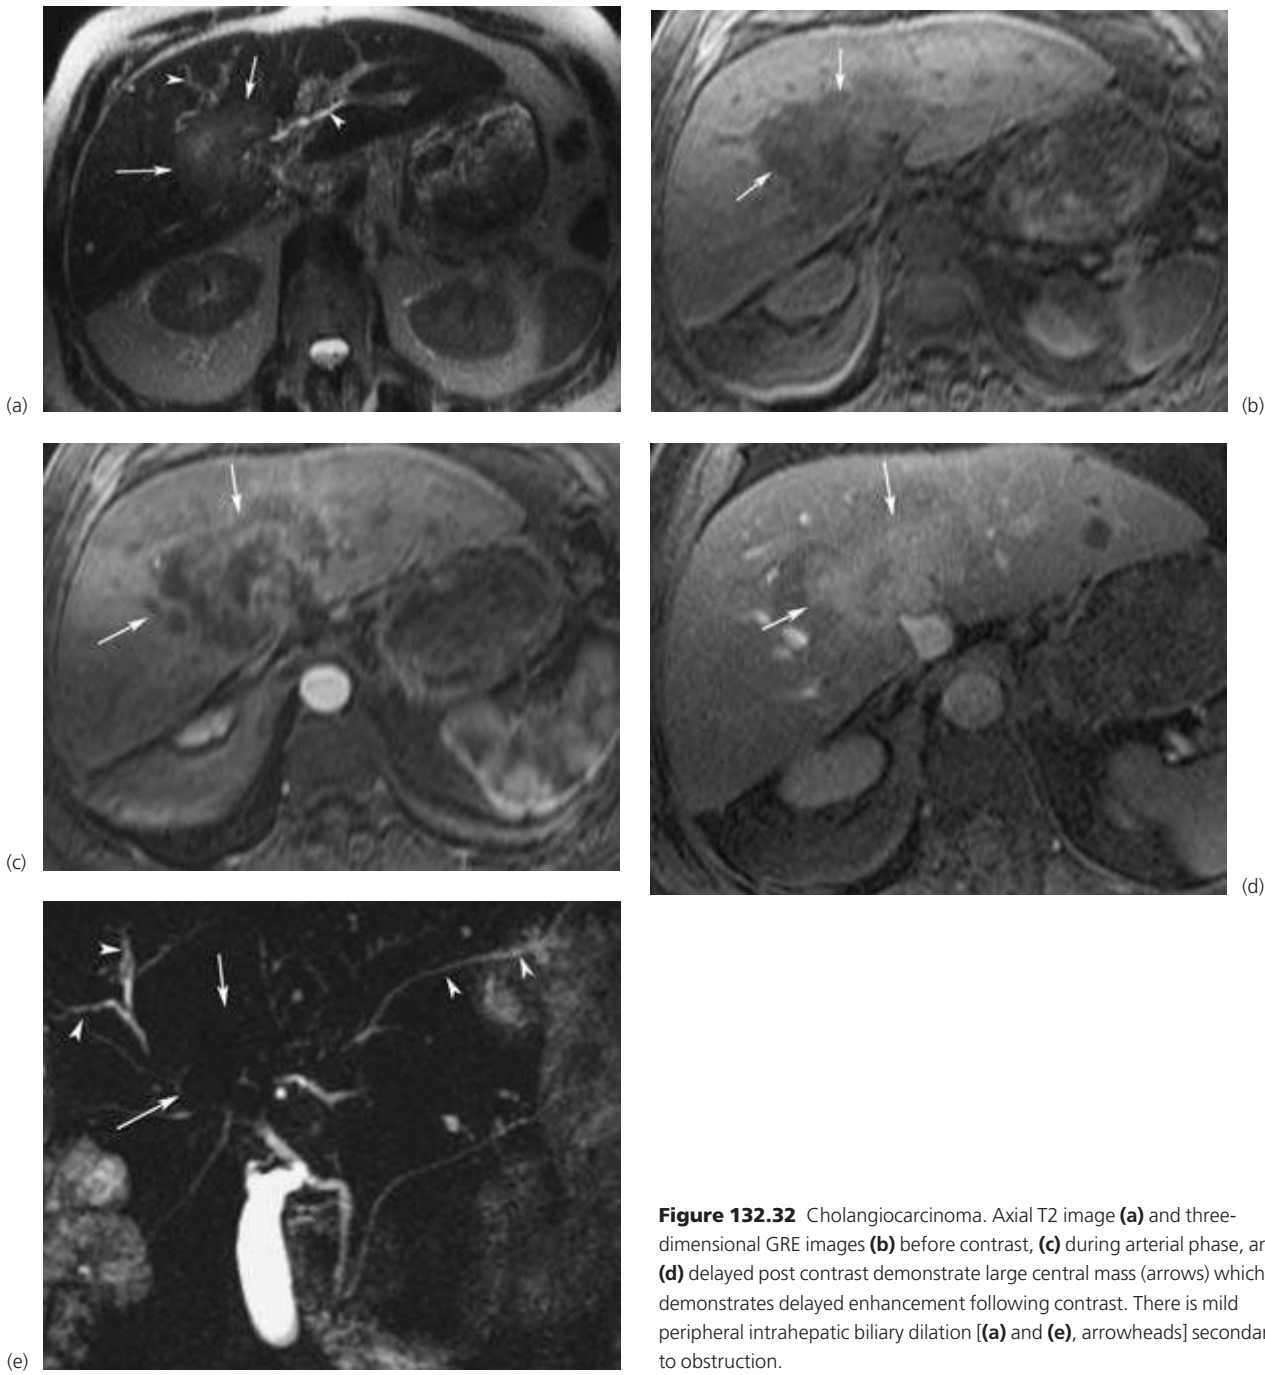


Figure 132.32 Cholangiocarcinoma. Axial T2 image **(a)** and three-dimensional GRE images **(b)** before contrast, **(c)** during arterial phase, and **(d)** delayed post contrast demonstrate large central mass (arrows) which demonstrates delayed enhancement following contrast. There is mild peripheral intrahepatic biliary dilation [**(a)** and **(e)**, arrowheads] secondary to obstruction.

helpful for reducing bowel-related motion artifacts. Now MRI has greater potential for evaluating the small bowel and colon, particularly for judging the extent of wall involvement with various pathological processes. MRI has been shown to be valuable in assessing the severity and extent of ulcerative colitis and Crohn's disease [95,96] (Fig. 132.33).

MRI is useful for showing the extent of pelvic fistulae from any cause. T2-weighted images display the muscularis propria of the bowel as low signal intensity. Breaks in the muscularis due to fistulae are seen as discontinuities in this layer. Fistulae can be seen without the administration of contrast material. The high signal intensity of granulation tissue is seen surrounded by low signal intensity fibrosis (Fig. 132.34). Because of the intrinsic soft-tissue contrast of T2-weighted images, MRI has shown promise for staging gastrointestinal tract tumors, particularly rectal carcinoma. With high

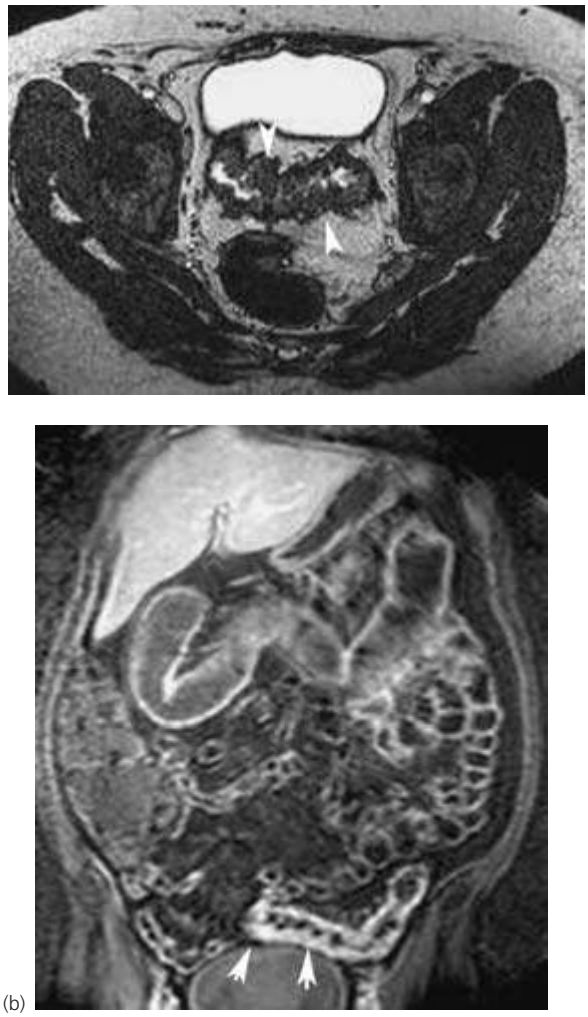

Figure 132.33 Crohn's colitis. **(a)** Axial fat-suppressed T2 image and **(b)** coronal postcontrast three-dimensional GRE image demonstrate circumferential wall thickening of the sigmoid colon (arrowheads) consistent with reactivation of colitis in this patient with history of Crohn's disease. Courtesy of Thomas Lauenstein MD, Atlanta, GA.

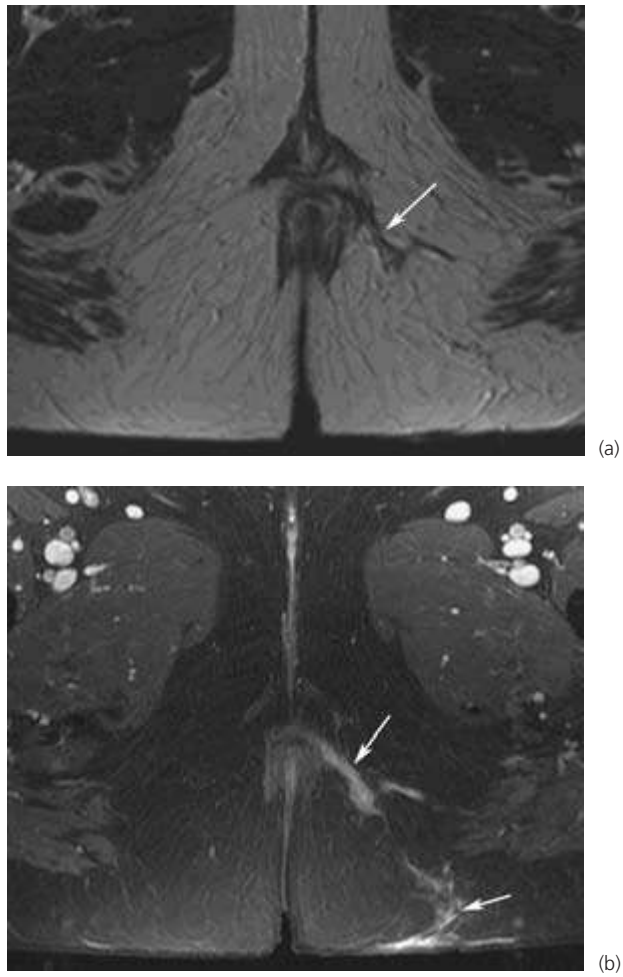

Figure 132.34 Perianal fistula. **(a)** Axial T2 image and **(b)** postcontrast three-dimensional GRE image demonstrate fluid-containing and rim-enhancing rectoanal fistulous tracts (arrows).

resolution, layers of the rectal wall can be visualized discretely. The muscularis propria appears as low signal intensity, whereas the submucosa appears as higher signal intensity. This has led to preliminary attempts to locally stage rectal carcinoma, with good results reported. MRI is an excellent method for evaluating the pelvis in general and to determine the local extent of tumors.

In addition, MRI can be used to evaluate for recurrent tumor after surgery or after radiation therapy. Radiation edema and radiation fibrosis are differentiated from tumor on T2-weighted images and dynamic gadolinium-enhanced images. Fibrosis appears as low signal intensity on T2-weighted images. Recurrent tumor shows nodules of higher-signal tissue. Recurrent tumor enhances rapidly during dynamic injection of gadolinium, whereas postradiation changes enhance more slowly.

Magnetic resonance enteroclysis

Because of its excellent soft-tissue contrast and multiplanar imaging capabilities, MRI may be used for evaluation of the small bowel. However, long acquisition times, peristalsis, and respiratory motion artifacts were severe limitations and MRI was rarely used for evaluation of small bowel diseases. With the development of ultrafast sequences, there is increasing interest in small bowel evaluation with MRI [97], although problems related to small bowel distention and to functional information remain limitations. Collapsed bowel loops may hide or simulate small bowel disease. Adequate distention of the entire small bowel is a key requirement of any small bowel imaging method. Different methods have been used to achieve adequate distention of the entire small bowel for MRI. Magnetic resonance enteroclysis was introduced to overcome the individual deficiencies of MRI and enteroclysis and to combine the advantages of both into one technique. Magnetic resonance enteroclysis consists of two parts: magnetic resonance fluoroscopy and cross-sectional imaging. Mag-

netic resonance fluoroscopy allows real-time control and monitoring of small bowel filling during the small bowel enema and provides functional information. Cross-sectional imaging sequences are used for morphological evaluation of the distended small bowel.

Magnetic resonance colonography

Magnetic resonance colonography was introduced after CT colonography. First reports described breath-hold, three-dimensional, GRE sequences that covered the entire enema-filled colon in the coronal plane. Air and carbon dioxide have been used as colonic distention agents, but most reports address liquid enema techniques.

Three different liquid enema techniques are used: bright lumen, black lumen, and fecal tagging. Both bright and black lumen methods are used after bowel cleansing. The bright lumen is based on a gadolinium–water enema with a gadolinium concentration of at least 10 mmol/L (i.e., 40 mL of 0.5 mol/L gadolinium in 2 L of water) (Fig. 132.35). Because of the lack of radiation, a magnetic resonance fluoroscopy sequence can be applied to monitor filling of the colon. After complete filling, a thin-section, three-dimensional, T1-weighted SGE sequence (3.7/1.1; flip angle 40°–50°) is performed. With this sequence, the lumen appears bright because of the presence of gadolinium, and polyps are visible as filling defects. A two-dimensional HASTE sequence can be used for delineation of the colonic wall. The black lumen technique is based on a water enema for luminal distention and an intravenous infusion of gadolinium for enhancement of the colonic wall (Fig. 132.35). After complete filling, a three-dimensional T1-weighted SGE sequence is performed before and after the intravenous administration of gadolinium. The lumen appears dark with this T1-weighted sequence, and enhancement of the colonic wall and possible inflammatory changes and polyps can be seen. A combination of three-dimensional T1-weighted SGE sequence and balanced GRE sequence makes bright and black lumen colonography possible with one protocol. The fecal tagging technique is based on a diet that contains barium to give stools the same signal intensity as water on T1-weighted GRE images. Patients are instructed to avoid fiber-rich foods and foods with a high concentration of manganese, such as fruit and chocolate. Magnetic resonance colonography starts with filling of the colon with water [96,98]. Intravenous gadolinium is administered, and a three-dimensional T1-weighted SGE sequence is performed. The lumen appears black, and enhancement of the colonic wall and possible polyps are seen.

In symptomatic patients, this new technique shows promising results for the detection of polyps equal to or larger than 1 cm in diameter. Its value in polyp detection still needs to be determined in large studies. Before this technique can be implemented in daily practice, it must show the same accuracy as colonoscopy and should be cost-effective in both high-risk and screening patients.

MRI of perianal fistula

MRI has been shown to accurately demonstrate the anatomy of the perianal region. On CT the attenuation values for the sphincters, levator ani, fibrotic fistulous tracks, and active fistula are so similar that it is difficult to characterize these structures accurately, unless the track contains gas or leaked contrast material. The MRI appearance of perianal fistula shows greater concordance with surgical findings than any other imaging evaluation. Many different MRI techniques

have been described. MRI in the coronal and axial planes demonstrates fistulous tracks in relation to the sphincter complex, ischiorectal fossa, and levator ani. Imaging in the sagittal and oblique planes is helpful in selected cases such as anovaginal and presacral disease [99]. MRI using pelvic surface coil requires no patient preparation and is well tolerated. Use of endoanal coils was initially hoped to further improve the MRI evaluation of perianal fistula. However, this technique is poorly tolerated in symptomatic patients, and although it provides excellent anatomical detail of the anal sphincters, it fails to provide the overview required for surgical management. The anatomy of the perianal region is well demonstrated on coronal and axial T1-weighted images. In normal subjects, the internal and external sphincters are not separately resolved on MRI obtained with a pelvic surface coil, but the sphincter complex, ischiorectal fossae and levator sling are clearly seen. Unenhanced T1-weighted images provide an excellent anatomical overview of the sphincter complex, levator plate, and ischiorectal fossae. However, fistulous tracks, inflammation, and abscesses appear as areas of low to intermediate signal intensity and may not be distinguished from normal structures such as sphincters and levator ani muscles. On T2-weighted and STIR (short tau inversion recovery) images, pathological processes including fistulae, secondary tracks, and fluid collections are clearly depicted. They appear as areas of high signal intensity in contrast with the lower signal intensity of the sphincters, muscles, and fat (especially on STIR images). The only comparative study of imaging sequences suggested for use in this condition showed that STIR imaging has certain limitations [99]. In some cases, STIR imaging failed to demonstrate secondary tracks, and in others it did not reveal small residual abscesses within edematous inflammatory change [99]. Furthermore, spurious incidences of high signal intensity in inactive tracks were also observed. Fat-suppression techniques used with T2-weighted imaging have also been proposed. We use GRE, T1-weighted, dynamic, intravenous contrast-enhanced MRI combined with T2-weighted imaging to assess perianal fistulae and their complications. With use of this technique, active fistulous tracks, secondary ramifications, and abscesses are clearly demonstrated (see Fig. 132.34). The walls of the tracks as well as the abscess cavities enhance. This breath-hold technique is rapid, noninvasive and well tolerated, a particular advantage in patients with acutely inflamed perianal regions.

Contrast agents

The primary goal of MRI contrast agents is to improve the detection of focal liver lesions. This is achieved by creating a larger difference in signal intensity between hepatic lesions and surrounding parenchyma. Although a variety of liver-targeted contrast agents have been developed for MRI, gadolinium chelate remains the most widely accepted. There are three types of contrast agents commonly used in clinical practice: hepatocyte-selective agents; reticuloendothelial system (RES)-specific agents; and agents combining perfusion and hepatocyte-selective properties, namely gadolinium ethoxybenzyl diethylenetriaminepentaacetic acid (Gd-EOB-DTPA) and gadolinium benzyloxypropionictetraacetate (Gd-BOPTA). Nonspecific extracellular gadolinium chelate is a paramagnetic substance causing increased signal intensity within targeted tissues on T1-weighted images. After intravenous injection, these agents are distributed in the intravascular compartment and subsequently diffuse throughout the extracellular space. The gain of information provided by this contrast agent is dependent on tumor perfusion and enables assessment of tumor vascularity. For instance, liver metastases may be characterized as hypovascular, hypervascular, or isovascular based on the degree and pattern of lesion enhancement after gadolinium administration. The MRI assessment of vascularization is critical in the management and follow-up of liver metastases. For instance, hypovascular metastases as characterized by MRI may reflect lesion response to systemic therapy. Although liver metastases demonstrate variable degree and pattern of enhancement, the presence of ring enhancement observed on immediate postcontrast images with peripheral washout on subsequent images is the most characteristic feature. The relatively low cost, safety, good patient tolerance, and ability to detect and characterize liver metastases justifies the use of gadolinium contrast enhanced MRI for the assessment of oncology patients.

Hepatocyte-selective contrast agents (e.g., mangafodipir trisodium) are specifically captured by hepatocytes and excreted by bile ducts. After intravenous injection of mangafodipir trisodium, the normal liver parenchyma shows an increase in signal intensity on T1-weighted images, which becomes brighter compared with the spleen or muscle. However, hepatic lesions that do not contain hepatocytes (e.g., metastases) will maintain identical signal intensity prior to and after contrast injection. Therefore, the difference in signal intensity between liver parenchyma and metastases are accentuated after contrast injection. Unlike metastases, HCC displays variable enhancement patterns after injection of mangafodipir trisodium due to variability in contrast uptake and excretion, with more pronounced uptake in well-differentiated tumors. RES-specific agents (e.g., SPIO) are selectively captured by organs containing RES, such as the liver (Kupffer cells), spleen, and bone marrow. The administration of RES-specific contrast agents results in signal loss (darkening) of liver, spleen, and bone marrow on T2-weighted sequences due to the presence of iron particles in the contrast composition. As liver metastases do not take up RES-specific agents and thus maintain identical signal intensity after contrast injection, the signal difference between liver metastases and background parenchyma is increased. This improves the detection of liver metastases after contrast injection. Like metastases, most HCCs do not take up

RES-specific agents. The required long injection time (approximately 30 min) represents a drawback for the use of RES-specific agents, because the acquisition of nonenhanced and enhanced sequences in the same study is not feasible.

Imaging recommendations

There is a wide range of MRI systems in the community which, both in terms of hardware and software capabilities, provide clinicians with a corresponding range of diagnostic capabilities. In addition, there is a greater range of technical expertise and experience among radiologists in the performance and interpretation of MRI studies compared with CT. For these reasons, specific recommendations about the appropriateness of MRI examinations are difficult to make. The types of examinations well suited to MRI and which most radiologists in the community can perform include the following.

- Characterization of a liver mass identified on ultrasound, CT, or other study. Most frequently this would involve distinguishing hemangiomas or cysts from solid liver masses, although MRI diagnosis of other liver masses, such as FNH or HCC, is possible.
- Evaluation of the complications of cirrhosis. Specific techniques can identify ascites, collaterals and varices, vascular occlusions, and HCC.
- Identification of diffuse liver disease such as steatosis or iron deposition. Transfusional iron overload can be distinguished from hemochromatosis.
- Identification of small pancreatic masses or exclusion of tumor in the large or bulbous pancreas.
- Identification and characterization of a pelvic fistula, specifically perianal fistula and the degree of levator muscle involvement.
- Identification of biliary calculi.
- Evaluation of any disorders of the liver, biliary tree, or pancreas when the patient is allergic to iodinated contrast medium or is at risk from the nephrotoxic effects of iodine (e.g., creatinine > 1.5 mg/dL, diabetic nephropathy).

Clinical situations in which CT may be more effective than routine MRI include:

- routine evaluation of the abdomen and pelvis in an oncologic patient to search for metastases of the liver, lymph nodes, etc.
- initial evaluation of obstructive jaundice
- evaluation of primarily peritoneal or bowel abnormalities
- abdominal trauma.

B IMAGING

133 Positron emission tomography

Uri Ladabaum, Satoshi Minoshima

Principles and technical considerations, 3212
Clinical applications of PET in gastroenterology, 3214
Applications of PET in gastroenterology research, 3220
Future directions, 3221

Positron emission tomography (PET) allows noninvasive imaging of physiological parameters within the body, such as metabolic activity and perfusion, using tracers labeled with positron-emitting radioisotopes. In contrast with imaging techniques that reflect primarily anatomical structure, such as computed tomography (CT) and magnetic resonance imaging (MRI), PET reflects biological functions in tissue. In PET, the spatial distribution and concentration of administered positron-emitting compounds are used to generate cross-sectional images through the body that reflect pathological states or elucidate physiological processes, leading to applications in clinical practice as well as in research. The principal clinical uses of PET in gastroenterology are in the area of oncology. Functional and anatomical imaging are increasingly being used together, as in combined PET/CT scanners. The potential uses of PET in research are greatly varied. Functional imaging of the central nervous system with PET as well as functional MRI (fMRI) has been applied in research on visceral pain and perception in health and in functional gastrointestinal disorders.

Principles and technical considerations

PET relies on detecting the radiation produced by a systemically administered radiotracer labeled with a positron emitter, and determining the distribution of the positron emitter within the subject under study [1,2]. A small number of proton-rich radioisotopes can decay by emitting a positron (sometimes referred to as a positive electron or antielectron), whose existence is fleeting. After emission, a positron travels a short path and ultimately combines with an ambient electron. This combination of a positron and electron undergoes a process referred to as annihilation, during which the masses of the positron and electron are converted into electromagnetic radiation in the form of two photons (γ-rays) of equal energy (approximately 511 keV) that travel in nearly opposite directions to each other (Fig. 133.1). PET scanners are designed to detect the photons produced by the annihilation of emitted positrons. Using a computer-assisted image reconstruction method similar to that used with CT, this information is ultimately used to construct transaxial images depicting the concentration of the positron emitter within the object of interest. Owing to the thinner slice thickness of current PET and PET/CT scanners, three-dimensional images of the target body area (transverse, coronal, and sagittal views) can be created from the reconstructed images.

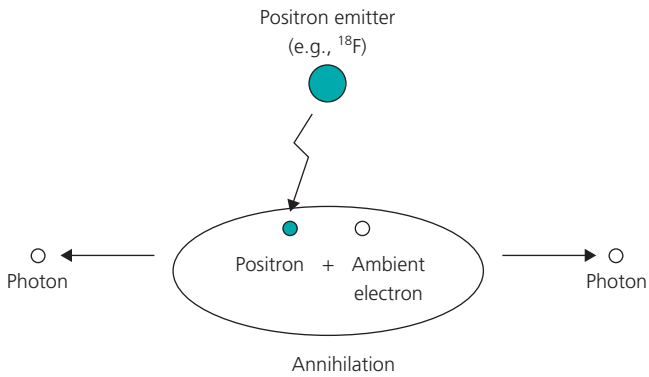

Figure 133.1 Positron emission and annihilation. Certain radioisotopes decay by emitting a positron, which travels a short path in tissue and ultimately combines with an ambient electron. This combination of particles undergoes annihilation, during which the masses of the positron and electron are converted into electromagnetic radiation in the form of two photons of equal energy that travel in nearly opposite directions to each other.

Radionuclide tracers

The first step in PET imaging consists of labeling a suitable molecule with a positron-emitting radionuclide. Positron-emitting isotopes exist for carbon, nitrogen and oxygen, three prominent atoms in biochemistry. The radionuclides

Table 133.1 Examples of radionuclides used in positron emission tomography.

Radionuclide	Half-life (min)	Positron decay (%)	Daughter atom after decay
^{11}C	20.4	99.8	^{11}B
^{13}N	9.96	100	^{13}C
^{15}O	2.07	99.9	^{15}N
^{18}F	109.7	96.9	^{18}O
^{68}Ga	68.1	90	^{68}Zn
^{75}Br	101	76	^{75}Se (radioactive)

Adapted from Wolf & Fowler [4].

carbon 11, nitrogen 13, and oxygen 15 are commonly used in PET imaging in what is sometimes called *isotopic labeling* [3]. ^{11}C-methionine, ^{13}N-ammonia, and ^{15}O-water are examples of PET tracers labeled with these isotopes. In contrast, hydrogen, another important constituent of biochemical molecules, has no positron-emitting isotope. However, positron-emitting isotopes of halogens, most commonly fluorine 18, can be substituted for a hydroxyl group in what is termed *analogical labeling* [3]. The PET tracer most commonly used in clinical applications is a glucose analogue, 2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}F-fluorodeoxyglucose or ^{18}F-FDG). Other positron-emitting isotopes have been used in clinical and research settings, such as rubidium 82 for clinical myocardial perfusion studies and iodine 124 for emerging research applications.

Examples of radionuclides used in PET and their properties are listed in Table 133.1 [4]. Due to the relatively short half-lives of these compounds, a small amount of tracer with high specific activity can be administered, translating into relatively low radiation exposure during the imaging session [3]. Because the quantity of tracer used is very small, there is no risk of pharmacological activity or chemical toxicity. Preparation of PET tracers requires the generation of a positron-emitting radionuclide followed by incorporation of the radionuclide into a molecule of choice. In theory, an unlimited variety of molecules could be labeled. Hundreds of tracers have been labeled with positron emitters, including simple molecules used to measure blood volume and blood flow, amino acids to study protein synthesis, fatty acids and sugars to study metabolic pathways, and specific receptor ligands including pharmaceuticals to map receptor distribution. Positron emitters are generated in accelerators, commonly small medical cyclotrons [4]. The positron-emitting atoms must be incorporated quickly into a tracer molecule as a purified, sterile, isotonic, pyrogen-free solution [3]. This underscores the importance of cooperation among experts in multiple disciplines including physics, chemistry, computer science, imaging, and medicine in the original development of PET and in the maintenance of an active PET program. The short half-life of many radiotracers mandates that they be produced on site, as with ^{15}O-water. However, the comparatively longer half-life of ^{18}F-FDG allows it to be produced at a regional facility, possibly in close proximity to several PET centers. Currently, ^{18}F-FDG is commercially available and distributed for PET imaging in the USA. There have been active discussions regarding commercial distribution of other ^{18}F-labeled compounds.

2-Deoxy-2-[^{18}F]fluoro-D-glucose

The utility of ^{18}F-FDG for PET applications in oncology rests on the high demand for glucose by many tumors [5] and the similarities in the initial cellular metabolism of glucose and ^{18}F-FDG [6,7]. A great deal of research has been conducted to characterize the cellular transport and utilization of glucose. Briefly, cells take up glucose and ^{18}F-FDG through specific transporters, and both undergo phosphorylation by hexokinase inside the cell. Whereas glucose-6-phosphate can be a substrate for subsequent reactions in the glycolytic pathway, deoxyglucose-6-phosphate and fluorodeoxyglucose-6-phosphate cannot be metabolized further and are trapped in the cell, where the activity of the reverse enzyme glucose 6-phosphatase is limited. The contrast in ^{18}F-FDG uptake between tumors and metastases compared with surrounding tissue is often detectable by PET imaging and serves as the basis for PET cancer detection and staging.

Data acquisition and processing

The second key step in PET imaging comprises detection of photons emitted by the annihilation of positrons, followed by processing of these data to form cross-sectional images. The fact that positron annihilation produces photons traveling in nearly opposite directions serves as a sort of natural collimation and forms the basis for PET detector design and arrangement.

The typical PET scanner design includes multiple pairs of photon detectors oriented opposite each other in a circular arrangement around a field of view where the subject is placed [7]. *Coincidence detection* refers to the method of accepting photons as indicative of a true positron annihilation only when a pair of photons is detected nearly simultaneously (current time windows are approximately 12 ns) by an

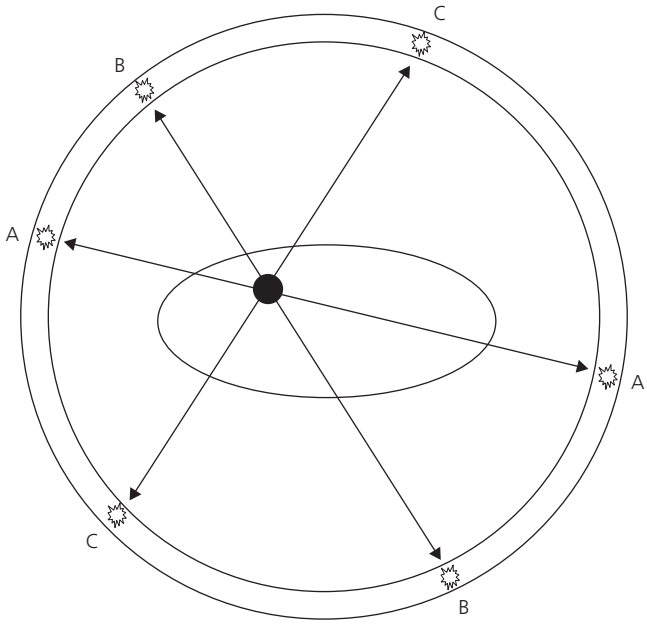

Figure 133.2 Coincidence detection is the basis for positron emission tomography (PET) detector design. Coincidence detection refers to the method of accepting photons as indicative of a true positron annihilation only when a pair of photons is detected nearly simultaneously by an oppositely aligned pair of detectors. In this schematic diagram, accumulation of a PET radiotracer within a lesion (black circle) in the PET subject (oval) produces three pairs of coincident detections (A, B, and C) in one ring of detectors surrounding the subject.

oppositely aligned pair of detectors (Fig. 133.2). Such coincident detection indicates that the photons originated somewhere near the imaginary line connecting the pair of detectors. Current PET scanners contain more than 40 adjacent rings and some 18 000 detector elements in the scanner. Each detector is connected in coincidence with an arc of detectors on the opposite side of the ring. In addition, rings can be connected in coincidence with each other. Standard two-dimensional image acquisition treats individually each pair of adjacent rings, or each "slice" through the subject. Three-dimensional acquisition has also been developed, in which all possible coincident detections across rings are used in generating image volume data. However, three-dimensional data acquisition increases the scatter fraction of noise, and it has been debated if three-dimensional imaging is well suited for abdominal PET imaging. The axial fields of view of current scanners are on the order of 15–20 cm, but whole-body scanning can be performed clinically with axial movement of the scanner table.

Corrections to coincident detection counts are often performed before image generation to account for a number of factors, including random coincidences at detector pairs and attenuation of photons inside the subject [7]. Attenuation refers to the scattering or absorption of emitted γ-rays within the subject's body. Attenuation correction is achieved by directly measuring tissue attenuation through the subject using an external radiation source equipped in the scanner. External rotating rods of germanium 68, which are shielded when not in use, are commonly used to perform a *transmission scan* before PET tracer administration. This transmission scan is equivalent to a CT scan that visualizes differences in tissue attenuation within the body for diagnostic purposes. In PET/CT scanners, CT data are used for attenuation correction as well as anatomical localization. Because of the speed of CT scanners combined with PET, PET/CT scanners can significantly reduce total imaging time.

Computerized mathematical algorithms can be applied for image reconstruction. These usually rely on filtered back-projection, the same technique used in X-ray CT. The image produced by this technique represents the solution to the question of what spatial and temporal distribution of positron emitter can account for the pattern of coincident detections recorded by the PET scanner. An iterative image reconstruction method based on statistical modeling and segmented transmission data has now become available for commercial scanners. This method generally produces better image quality, particularly when count rates are low and when large patients are scanned. However, it is important to recognize that noise distribution and potential artifacts introduced by iterative image reconstruction are quite distinct from those seen with conventional filtered back-projection reconstruction techniques. Due to a variety of factors, including the short path that positrons can travel before annihilation and the slight deviations in photon direction that can result from residual angular momentum in a positron or electron before annihilation, the intrinsic resolution of modern PET is on the order of 4–6 mm.

Clinical applications of PET in gastroenterology

In recent years, the recognized clinical uses of PET have expanded, particularly in the imaging of tumors. Regarding gastrointestinal cancers, the United States Health Care Financing Administration (HCFA), currently the Centers for Medicare and Medicaid Services (CMS), first announced Medicare coverage in 1999 for ^{18}F-FDG PET in the evaluation of patients with colorectal cancer and rising carcinoembryonic antigen (CEA) levels. In December 2000, HCFA issued a decision memorandum broadening the indications for ^{18}F-FDG PET covered by Medicare to include diagnosis, staging and restaging of nonsmall cell lung cancer, colorectal cancer, esophageal cancer, lymphoma, melanoma, and head and neck (excluding thyroid and brain) cancers; myocardial viability studies; and presurgical evaluation of refractory seizures [8]. A survey of 22 institutions found no adverse reactions in over 80 000 positron-emitting radiopharmaceutical administrations, highlighting the extraordinary safety record of PET [9]. As of 2006, head and neck cancers, eso-

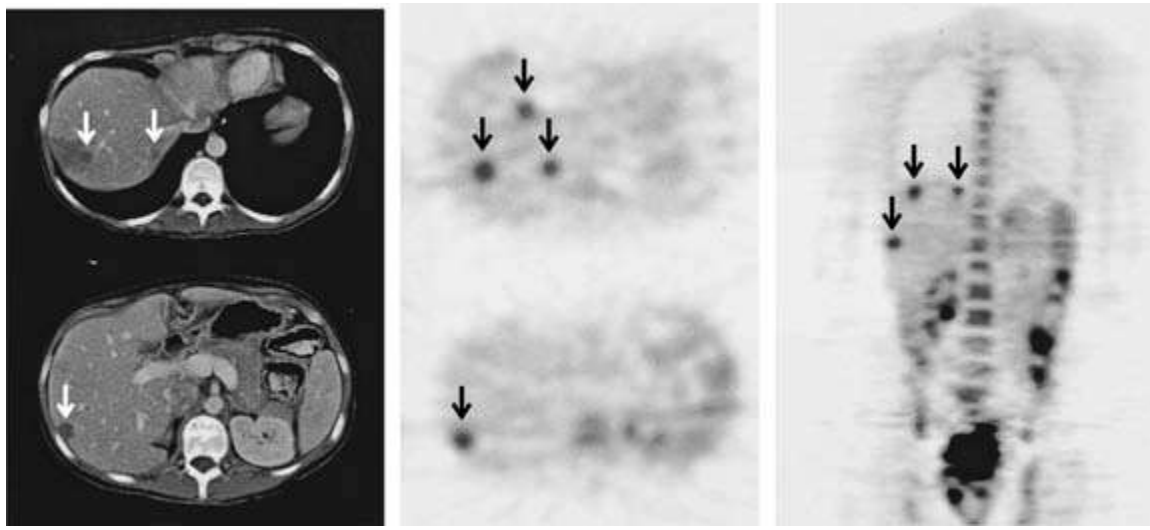
phageal cancer, colorectal cancer, nonsmall cell lung cancer, melanoma, breast cancer, lymphoma, cervical cancer, thyroid cancer, and solitary pulmonary nodule are covered by CMS reimbursement for one or more of the indications of diagnosis, staging, restaging, or monitoring. In response to the CMS proposal to expand further PET coverage for cancer workups, the National Oncologic PET Registry (NOPR) was developed for ^{18}F-FDG PET to include cancers and indications not presently eligible for CMS reimbursement.

Because anatomical information is often necessary in evaluating patients, including determining the potential resectability of the tumor, ^{18}F-FDG PET cannot be considered a substitute for anatomical imaging. However, it can provide important additional information in a variety of clinical situations. A major advance has been the development of combined PET/CT scanners, which can provide both functional and anatomical imaging [10,11], with performance that is superior to that of PET alone or that of software fusion of independently acquired PET and CT images [12]. Serious incorrect lesion localization with PET/CT is rare (2%) [13]. Evidence is accumulating that PET imaging alters medical decision making in a significant minority of cases with respect to surgical interventions and radiation therapy.

Colorectal cancer

Increased ^{18}F-FDG uptake in hepatic metastases from colorectal cancer was demonstrated at a very early stage in PET technology development [14]. Later studies suggested that ^{18}F-FDG PET could be useful in differentiating recurrent rectal cancer from surgical scar or a nonmalignant mass [15,16]. When anatomical imaging techniques could not reliably distinguish malignant from nonmalignant tissue, the enhanced glycolytic activity of malignant tissue could be detected by ^{18}F-FDG PET. Subsequently, ^{18}F-FDG PET has been investigated in the evaluation of patients with suspected colorectal cancer recurrence, as well as in preoperative staging of patients with known recurrence and in staging of primary disease. Recent studies have focused on the incremental value of PET/CT. Figure 133.3 shows an example of ^{18}F-FDG PET in a patient with rectal cancer metastatic to the liver.

In suspected metastatic or recurrent colorectal cancer, the reported sensitivity of whole-body or local/pelvic ^{18}F-FDG PET is 87%–100% and specificity 67%–100%, with sensitivity for hepatic disease of 89%–100% and specificity of 67%–100% [17–28]. In all studies that compared PET with CT with respect to hepatic metastases detection, PET performance was better (CT sensitivity 65%–89% and specificity 62%–89%). A metaanalysis of 11 studies yielded overall estimates (and 95% confidence intervals [CI]) for the sensitivity of whole-body ^{18}F-FDG PET in recurrent colorectal cancer of 97% (CI 95%–99%) and specificity of 76% [29]. For local/pelvic disease, the estimated sensitivity was 95% (CI 91%–98%) and specificity 98% (CI 96%–99.7%). For hepatic involvement, estimated sensitivity was 96% (CI 94%–99%) and specificity 99% (CI 98%–100%). Another metaanalysis reported per-patient sensitivities for nonhelical CT, helical CT, MRI, and ^{18}F-FDG PET of 60%, 65%, 76%, and 95%, respectively [30]. Another systematic review reported sensitivity of 88% and specificity of 96% for hepatic disease and 92% and 95% for extrahepatic disease using ^{18}F-FDG PET, compared with 83% and 84% for hepatic disease and 61% and 91% for extrahepatic disease using CT [31].



CT PET (slice) PET (whole body)

Figure 133.3 Imaging with contrast computed tomography (CT) and ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET) in a patient with rectal cancer metastatic to the liver. Contrast CT shows at least three hepatic hypovascular lesions (white arrows). Corresponding PET slice images show a total of four hepatic lesions (black arrows). Whole-body PET shows at least three of the hepatic lesions (black arrows). A large focus of uptake in the pelvis is excreted ^{18}F-FDG in the bladder. Uptake is also visible in the right kidney next to the lumbar spine and in the descending colon.

While in many investigations ^{18}F-FDG PET images were interpreted visually, some authors have reported higher signal intensity in malignant compared with benign lesions using semiquantitative methods, such as the standardized uptake value (SUV) or SUV corrected for lean body mass (SUL) [32], which normalizes signal intensity by radioactive dose injected and body weight, and the target-to-background ratio, which compares signal intensity within and outside a region of interest [18,21,25,28].

^{18}F-FDG PET/CT performed better than ^{18}F-FDG PET alone in detecting recurrent colorectal cancer, with sensitivity of 89%, specificity of 92%, and overall accuracy of 90%, compared with 80%, 69%, and 75%, respectively [33]. ^{18}F-FDG PET/CT has also been reported to be superior to ^{18}F-FDG PET alone in detecting recurrence of rectal cancer after abdominoperitoneal resection [34]. Dedicated interpretation of the CT portion of the ^{18}F-FDG PET/CT examination improves performance (sensitivity, specificity, and accuracy of 99%, 100% and 98% compared with 91%, 63% and 83% for the PET/CT report alone; $P < 0.05$) [35].

Patients may be suspected of having colorectal cancer recurrence on the basis of symptoms, physical findings, rising CEA levels, or anatomical imaging studies. In a study of 22 patients with previous colorectal cancer resection who had abnormal CEA but normal anatomical imaging studies, 15 patients were ultimately considered to have recurrent disease. ^{18}F-FDG PET detected abnormalities in 17 patients, including the 15 with proven recurrence, yielding a positive predictive value of 89% and a negative predictive value of 100% [24]. ^{18}F-FDG PET may predict which patients with abnormal CEA might benefit from laparotomy [36]. It may help triage patients with CEA elevations under 25 ng/mL into potentially resectable rather than unresectable subgroups, while in those with higher elevations it may primarily confirm advanced disease [37]. The additional value of ^{18}F-FDG PET was examined in 103 patients with suspected or proven colorectal cancer recurrence who also underwent conventional imaging including CT [26]. In 12 of 60 patients considered to have resectable disease on conventional imaging, ^{18}F-FDG PET detected additional disease in nine and excluded disease in three, yielding additional diagnostic value in 20%. In 13 patients with inconclusive conventional imaging or isolated elevated CEA, ^{18}F-FDG PET was of additional diagnostic value in 62%.

Accurate staging is of paramount importance in guiding potential surgical intervention, including resection of hepatic metastases. An important contribution of ^{18}F-FDG PET appears to be demonstration of hepatic and extrahepatic foci of disease not identified on conventional imaging [38,39]. However, a study directly comparing ^{18}F-FDG PET results with surgical resection specimens found that ^{18}F-FDG PET detected only 25% of hepatic lesions smaller than 1 cm, compared with 85% of lesions larger than 1 cm [40]. A prospective evaluation of 53 patients with potentially resectable hepatic metastases revealed comparable sensitivities (75% vs 76%) and accuracies (88% vs 86%) for ^{18}F-FDG PET and CT, with ^{18}F-FDG PET providing additional information in 10% of patients [41], comparable to the incremental information in 11% of patients reported in an earlier study [42].

One study has assessed ^{18}F-FDG PET in the staging of primary colorectal cancer [43]. The sensitivity and specificity of ^{18}F-FDG PET for the primary tumor were 100% and 43% respectively. For liver metastases, the sensitivity and specificity were 88% and 100%, compared with 38% and 97% for CT. For lymph node metastases, the sensitivity and specificity of ^{18}F-FDG PET were 29% and 96%, compared with 29% and 85% for CT. Thus, the utility of ^{18}F-FDG PET appears greater in detecting distant metastases than local nodal involvement. Another study found that ^{18}F-FDG PET was not superior to multidetector helical CT in the initial staging of colorectal cancer [44]. Whole-body ^{18}F-FDG PET/CT colonography has been proposed for initial staging of patients with colorectal cancer [45].

The ultimate value of a diagnostic test is manifest in its impact on patient outcomes. Several investigators have reported the impact of ^{18}F-FDG PET on medical decision making. In the metaanalysis by Huebner and colleagues, it was estimated that ^{18}F-FDG PET affected management in 29% (95% CI 25%–34%) of patients undergoing evaluation for recurrent colorectal cancer [29]. Subsequent studies have reported similar results, with ^{18}F-FDG PET affecting management in 23% of patients undergoing evaluation for possible resection of hepatic metastases [40], 20%–61% of patients suspected of having metastatic or recurrent colorectal cancer [28,46–49], and 17% of patients with primary rectal cancer [50]. In a study of 76 patients, ^{18}F-FDG PET/CT and contrast-enhanced CT provided similar information about hepatic metastases, whereas PET/CT was superior in detecting recurrent intrahepatic tumors after hepatectomy, extrahepatic metastases, and local recurrence, thus affecting management in 21% of cases [51]. ^{18}F-FDG PET was more accurate than conventional imaging tests in predicting the resectability of the recurrent disease (82% vs 68%; $P = 0.02$) [52]. Wiering and colleagues reported a change in management due to ^{18}F-FDG PET in 32% of patients in all studies in their systematic review, and a somewhat lower 25% in the highest quality studies [31]. ^{18}F-FDG PET/CT was reported to affect patient management in 7 of 23 patients with suspected hepatic metastases or recurrent disease [53]. More important than any impact on decision making is the observation that patients who underwent hepatic resection for metastases after staging with ^{18}F-FDG PET had a 5-year actuarial survival of 58% compared with a median of 30% in historic controls without preoperative PET examination [54].

The ability to monitor response to therapy or to assess a patient's candidacy for chemotherapy based on tumor characteristics are potentially of great clinical relevance. Decreases in ^{18}F-FDG uptake after chemotherapy have been shown to

correlate with response to chemotherapy [55,56]. In contrast, because inflammatory tissue may show similar glycolytic activity to that of tumor, ^{18}F-FDG PET may not be able to accurately assess the response to radiation therapy in the short term [57,58]. However, one pilot study has suggested that ^{18}F-FDG PET might be of incremental value in selecting patients with rectal cancer for sphincter-preserving surgery after preoperative radiation and chemotherapy [59]. ^{18}F-FDG PET may be useful in predicting the response of liver metastases to treatment with bevacizumab and irinotecan [60].

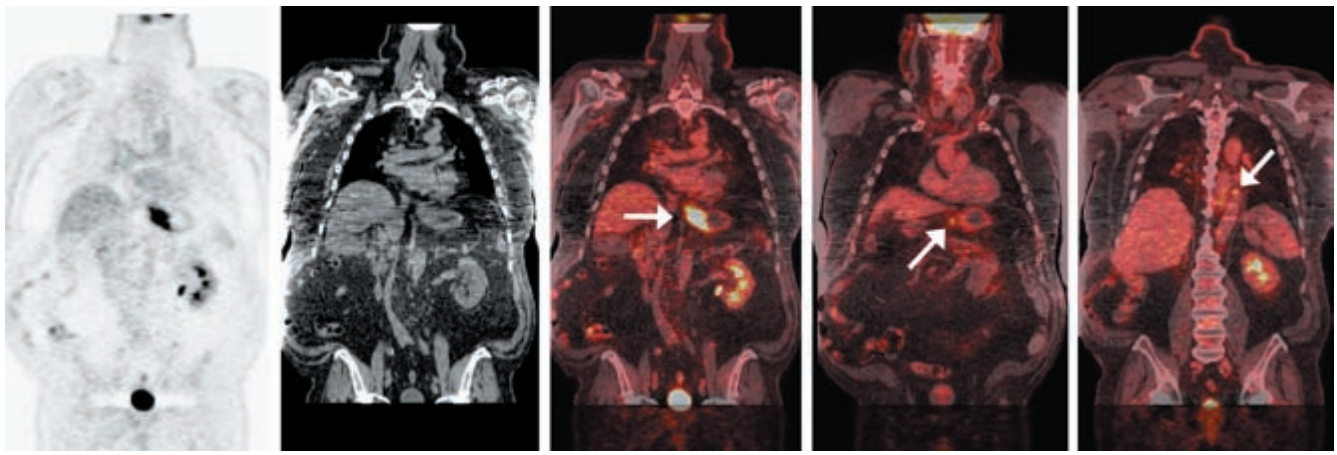
In patients with unresectable liver metastases, PET has been performed with ^{18}F-fluorouracil before 5-fluorouracil chemotherapy to determine its potential role in predicting prognosis [61]. Overall, patients with higher values for ^{18}F-fluorouracil uptake were more likely to achieve stabilization of disease with chemotherapy, but trapping of ^{18}F-fluorouracil varied among metastases even within the same patient. Quantitative modeling of ^{18}F-fluorouracil uptake has been investigated as a way to optimize treatment schedules for individual patients [62]. Specific kinetic parameters of ^{18}F-FDG PET may be useful in determining prognosis with 5-fluorouracil/folinic acid/oxaliplatin chemotherapy [63].

van Kouwen and colleagues reported increasing sensitivity of ^{18}F-FDG PET for colorectal adenomas as a function of size (e.g., 21% for 1–5 mm vs 72% for > 11 mm) and grade of dysplasia (e.g., 33% for low-grade vs 76% for high-grade dysplasia vs 89% for carcinoma) [64]. Others have reported limited sensitivity of ^{18}F-FDG PET for flat or less than 3 cm protruded premalignant lesions, and for cancers under 2 cm [65].

Esophageal cancer

Various studies have compared ^{18}F-FDG PET and CT for staging of esophageal cancer [66–70]. The specificity of the two tests appears to be comparable in the evaluation of nodal disease (PET 79%–94%, CT 73%–100%), while the sensitivity of ^{18}F-FDG PET appears to be superior (PET 69%–92%, CT 28%–46%). For both techniques, detecting local nodal involvement is problematic. In one study, the overall accuracy in determining resectability was 88% for ^{18}F-FDG PET and 65% for CT ($P = 0.04$), but neither modality could assess the extent of wall invasion [68]. Differences in accuracy of similar magnitude have been found in other studies [66,69,70]. As with colorectal cancer staging, an important contribution of ^{18}F-FDG PET appears to be its ability to detect distant metastases not visible on anatomical imaging, and thus alter management. One group has reported additional diagnostic value in 22% of patients, with up-staging in 15% and down-staging in 7% [71]. Another study reported a change in management based on ^{18}F-FDG PET results in 17% of patients [66]. PET/CT delineated tumor better than CT alone in another study, contributing to radiotherapy treatment planning [72]. Figure 133.4 shows an example of ^{18}F-FDG PET/CT staging of esophageal cancer.

^{18}F-FDG PET has been compared with the combination of CT and endoscopic ultrasound (EUS) in staging potentially operable esophageal cancers [71]. EUS demonstrated a higher sensitivity than ^{18}F-FDG PET for local nodal involvement (81% vs 33%; $P = 0.027$). In evaluating regional and distant nodal involvement, ^{18}F-FDG PET was more specific than CT and EUS combined (98% vs 90%; $P = 0.025$), with both testing strategies having similar sensitivity (43% vs 46%). PET/CT was more accurate than EUS with fine-needle aspiration (FNA) and CT in detecting nodal disease and response to neoadjuvant chemoradiotherapy [73]. The role of PET in staging adenocarcinoma of the esophagus or gastroesophageal junction may be primarily to detect organ metastases [74].



(a) (b) (c) (d) (e)

Figure 133.4 ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET)/computed tomography (CT) staging of esophageal cancer. Coronal ^{18}F-FDG PET scan **(a)**, corresponding CT scan **(b)**, and fused image **(c)** demonstrate primary cancer in the distal esophagus extending to the gastric fundus (arrow in **c**). ^{18}F-FDG PET/CT detected two small lymph node metastases: left gastric node (arrow in **d**) and paraesophageal node (arrow in **e**).

The combination of ^{18}F-FDG PET and ^{11}C-choline PET, which relies on uptake of choline by tumors for integration into phospholipids, has been reported to improve the accuracy of PET in staging esophageal cancer [75]. ^{11}C-choline PET had a sensitivity of 88% for mediastinal lymph nodes, compared with 34% for ^{18}F-FDG PET. However, ^{11}C-choline PET demonstrated 0% sensitivity in the upper abdomen due to high ^{11}C-choline uptake by the liver, compared with 79% for ^{18}F-FDG PET. The combination of both modalities detected 85% of all lymph node metastases.

Differences in survival have been reported based on stratification by initial ^{18}F-FDG PET result [69]. Survival at 30 months was 60% in patients with localized disease compared with 20% in patients with distant disease ($P = 0.01$), suggesting that ^{18}F-FDG PET results may be of prognostic significance. The number of PET abnormalities at baseline is an independent predictor of survival [76]. Serial ^{18}F-FDG PET appears to have a strong correlation with pathological response to neaoadjuvant chemoradiation therapy in locally advanced esophageal cancer, with PET major responders surviving a median of 16.3 months compared with 4 months for PET nonmajor responders [77]. The reported 3-year survival after surgery was 57% for patients with SUV maximum greater than 4.5, and 95% for those with SUV maximum 4.5 or less [78].

Pancreatic cancer

The initial HCFA decision memorandum of December 2000 did not include pancreatic imaging as an approved indication for ^{18}F-FDG PET under Medicare. However, pancreatic imaging is considered a recognized application of ^{18}F-FDG PET by some experts [38] and is now eligible for NOPR coverage as of 2006.

Various studies have evaluated ^{18}F-FDG PET in the diagnosis of pancreatic cancer and its differentiation from chronic pancreatitis [79–87]. The reported sensitivity of PET in this setting is 85%–96% with specificity of 78%–100%, compared with 65%–89% and 62%–89% for CT. ^{18}F-FDG PET may be useful in assessing pancreatic masses that are indeterminate for malignancy on conventional imaging, with sensitivity of 68%–96% and specificity of 78%–100% [88]. Beyond visual interpretation of images, semiquantitative analysis has demonstrated differences between signal intensity, such as SUV, in tumor and chronic pancreatitis [80,81,84,86,89]. In one study, ^{18}F-FDG PET suggested potential alterations in clinical management in 43% of patients [85].

Two important factors may affect the results of ^{18}F-FDG PET in pancreatic imaging. First, hyperglycemia can result in false-negative studies in pancreatic cancer [83,90]. The cancer itself may cause endocrine insufficiency, and hyperglycemia results in greater competition between glucose and ^{18}F-FDG for uptake into cells. In patients with normal serum glucose, for instance, the sensitivity and specificity of ^{18}F-FDG PET in diagnosing pancreatic cancer were reported as 98% and 84%, compared with 63% and 86% in hyperglycemic patients [83]. Second, inflammation can produce ^{18}F-FDG uptake as intense as that seen in tumor, either in the setting of pancreatic masses without clear evidence of acute pancreatitis, or during and after attacks of acute pancreatitis [91].

Multiple imaging modalities can be used in evaluating patients with suspected pancreatic malignancy. One study reported sensitivity and specificity for four different modalities in patients with suspected pancreatic cancer: 94% and 82% for ^{18}F-FDG PET, 89% and 73% for CT, 97% and 64% for EUS, and 89% and 45% for abdominal ultrasound [79]. Subsequent studies found sensitivity for detecting pancreatic cancer of 87% for ^{18}F-FDG PET, 53% for CT and 93% for EUS [92] and 87% for ^{18}F-FDG PET, 87% for MRI and 98% for EUS [93]. Overall accuracy values (defined as area under receiver operating characteristic curves, with 1 reflecting a perfect test) for differentiating malignant from benign pancreatic masses have been reported for various imaging strategies [90]. Overall accuracy was 0.86 for ^{18}F-FDG PET, 0.93 for endoscopic retrograde cholangiopancreatography (ERCP), 0.82 for CT, and 0.95 for the combination of ^{18}F-FDG PET and ERCP. In the subgroup of euglycemic patients with contradictory or indeterminate CT and ERCP results, ^{18}F-FDG PET was accurate in 84% of cases.

^{18}F-FDG PET has also been studied for staging of metastatic disease. One study of ^{18}F-FDG PET in pancreatic cancer found sensitivity and specificity of, respectively, 49% and 63% for lymph node staging and 70% and 95% for hepatic metastases [90]. As in colorectal cancer, ^{18}F-FDG PET may miss smaller metastases (< 1 cm). A study designed specifically to assess the detection of hepatic metastases of pancreatic cancer found sensitivity of 90% and specificity of 91% for ^{18}F-FDG PET, compared with 69% and 100% for CT, and 82% and 100% for abdominal ultrasound [94]. In another investigation, the sensitivity of ^{18}F-FDG PET for hepatic and extrahepatic disease was 78% compared with 33% for CT [92].

^{18}F-FDG PET has also been used to monitor patients after therapy [95,96]. Survival in patients without measurable pancreatic ^{18}F-FDG uptake 1 month after chemotherapy was improved compared with patients with residual ^{18}F-FDG uptake (319 vs 139 days; $P = 0.034$). When used for detecting malignancy in cystic tumors of the pancreas, ^{18}F-FDG PET had a sensitivity of 94% and specificity of 97% compared with 65% and 87% for CT [97].

Hepatic imaging

Liver and bile duct cancers are a part of the NOPR coverage as of 2006. ^{18}F-FDG PET has been evaluated in the setting of hepatocellular carcinoma as well as in metastatic disease to the liver. The sensitivity of ^{18}F-FDG PET for hepatoma is poor [98]. In one study, only 50% of sonographically detectable hepatomas demonstrated increased ^{18}F-FDG uptake, whereas 79% were detectable by CT [99]. None of the well-differenti-

ated tumors was visualized by ^{18}F-FDG PET compared with 88% of the moderately or poorly differentiated tumors. Similar results were reported in a second study, with ^{18}F-FDG PET showing a sensitivity of 55% in the diagnosis of hepatoma compared with 90% for CT [100]. In patients with rising α-fetoprotein levels after hepatoma treatment but normal conventional imaging, ^{18}F-FDG PET had 73% sensitivity and 100% specificity for detecting recurrent disease [101].

In contrast to poor results in the diagnosis of hepatoma, ^{18}F-FDG PET can be useful in evaluating metastatic disease to the liver [102], as discussed above for primary gastrointestinal tumors. One study of patients with various primary tumors and possible liver involvement found sensitivity of 97% and specificity of 88% for ^{18}F-FDG PET compared with 93% and 75% for CT (not statistically different) [103]. ^{18}F-FDG PET yielded new information for 23% of patients, including demonstrating liver metastases in 17% when other imaging was equivocal or negative. In patients undergoing CT-guided FNA of liver lesions, ^{18}F-FDG PET was positive for malignancy in 96% of cases in which malignancy was diagnosed by FNA, and was negative in 86% of cases where FNA was negative [104].

^{18}F-FDG PET has been examined in the setting of hepatic lesions requiring further characterization. In a series of 110 patients with hepatic lesions 1 cm or larger on CT, all liver metastases from adenocarcinomas and sarcomas and all cholangiocarcinomas showed increased ^{18}F-FDG uptake values, whereas only 70% of hepatomas showed increased uptake [105]. All benign lesions had poor uptake, and abscesses showed equivocal or increased uptake. A series of 78 patients with various liver tumors has confirmed that ^{18}F-FDG uptake tends to be lower in hepatocellular carcinoma compared with metastatic disease or cholangiocarcinoma [106]. Case reports have suggested that ^{18}F-FDG PET might be useful in detecting cholangiocarcinoma in patients with primary sclerosing cholangitis [107,108]. ^{18}F-FDG PET has also been used to monitor response to chemoembolization [109] and local ablative therapies [110]. ^{18}F-FDG PET/CT may have a role in monitoring response to radiofrequency ablation [111,112] or yttrium 90 glass microsphere treatment [113] of unresectable metastases.

Neuroendocrine tumors

Carcinoid tumors synthesize serotonin from 5-hydroxytryptophan (5-HTP). An early study with seven patients suggested that hepatic metatstases from carcinoid tumors could be imaged with ^{11}C-5-HTP PET [114]. In 22 patients with neuroendocrine tumors, ^{11}C-L-dihydroxyphenylalanine (^{11}C-L-DOPA) PET detected tumor in 50% [115]. In those imaged with both ^{11}C-L-DOPA and ^{11}C-5-HTP, results were similar. One study has reported similar overall results for ^{11}C-5-HTP PET and CT in 16 patients with gut carcinoids and two with endocrine pancreatic tumors [116]. Although ^{11}C-5-HTP detected more lesions than CT in 10 patients, it is not clear that this is of clinical significance. Carbidopa pretreatment improves tumor visualization [117]. ^{18}F-DOPA PET had 65% sensitivity for carcinoid tumors, and performed better than CT or MRI for primary lesion localization and lymph node staging [118]. In patients with carcinoid tumors, PET with a carbohydrated ^{18}F-labeled somatostatin receptor ligand revealed more lymph node or ossesous metastases than CT or MRI, but MRI revealed more hepatic metastases, making PET/MRI a promising approach [119].

Somatostatin receptor scintigraphy (SRS) is commonly used for imaging neuroendocrine tumors. In 15 patients with neuroendocrine tumors, SRS was found to be more useful overall than ^{18}F-FDG PET, although SRS was negative and ^{18}F-FDG PET positive in two patients with less differentiated tumors [120]. A second study with 16 patients found an overall sensitivity of 85% for SRS in neuroendocrine tumor imaging. ^{18}F-FDG PET did not seem to provide much additional value, even though it was able to image aggressive tumors [121]. Notably, in this study, CT scans were abnormal in all patients with abnormal ^{18}F-FDG PET and in all but one patient with abnormal SRS. However, a later study reported better performance for whole-body ^{11}C-5-HTP PET than for SRS or CT [122].

The difficulty in detecting pancreatic islet cell tumors is highlighted by a study in which the sensitivity of ^{18}F-FDG PET was 53%, compared with 53% for ultrasonography, 50% for CT, and 53% for MRI [123]. ^{18}F-FDG PET was negative or equivocal in all cases where the other modalities were negative.

Gastrointestinal stromal tumors

The degree of ^{18}F-FDG uptake may be useful in predicting the malignant potential of gastrointestinal stromal tumors [124]. In addition, ^{18}F-FDG PET can detect response to imatinib mesylate treatment in patients with malignant gastrointestinal stromal tumors [125–127] as early as 1 week after starting therapy [128]. PET/CT delineated lesions better than the combination of PET and contrast-enhanced helical CT [129,130].

Other diseases

^{18}F-FDG PET appears to have reasonable sensitivity and specificity for inflammation in Crohn's disease in adults [131] and in Crohn's disease and ulcerative colitis in children [132] but its clinical role is not yet established. It may be useful in selecting patients with familial adenomatous polyposis for further investigations to rule out malignancy [133]. ^{18}F-FDG PET may have a role in some cases of gastrointestinal lymphoma [134]. ^{18}F-FDG PET facilitated early detection of hereditary diffuse gastric cancer in an asymptomatic carrier of a germline E-cadherin mutation [135], but it is generally not a first-line test for staging gastric cancer [136,137]. ^{18}F-FDG PET results may predict response to preoperative chemotherapy in gastric cancer, and patients with a metabolic

response appear to have improved survival compared with metabolic nonresponders [138].

Incidental gastrointestinal uptake may be seen in approximately 3% of PET or PET/CT studies performed for pulmonary or other imaging, and often reflects clinically significant lesions, with pathology including unsuspected gastrointestinal malignancy [139–142].

Applications of PET in gastroenterology research

The ability of PET to use a theoretically unlimited variety of molecules radiolabeled with different positron emitters to image biological processes in vivo opens numerous possibilities for PET applications in research. The following studies illustrate the broad range of questions that has been addressed in PET research studies relevant to gastroenterology. An anticolorectal carcinoma monoclonal antibody labeled with copper 64 (radioimmuno-PET) has shown 71% sensitivity for imaging tumor foci [143]. ^{11}C-methionine uptake by the pancreas has been investigated by PET as a possible reflection of pancreatic exocrine function [144]. Biliary bicarbonate secretion in humans has been studied after intravenous injection of sodium ^{11}C-bicarbonate [145]. In cholestatic conditions, an impaired response to secretin was observed. Glucose utilization has been studied with ^{18}F-FDG PET in a patient with hepatoma and hypoglycemia [146]. The mechanism and kinetics of percutaneous ethanol injection of hepatomas has been studied with ^{11}C-ethanol [147].

Neurological abnormalities can accompany various forms of liver disease. ^{18}F-FDG PET of the brain in patients with Wilson disease has demonstrated decreases in regional cerebral glucose metabolism in the cerebellum, striatum, cortex, and thalamus compared with controls [148]. In this study, striatal metabolism was most affected in those patients who had received therapy for the shortest time. Altered cerebral blood flow and metabolism have been observed in patients with severe liver disease and low-grade encephalopathy [149]. Normalization of brain glucose metabolism has been observed following liver transplantation [150]. In patients with hepatic encephalopathy, central benzodiazepine receptor binding has been studied with ^{11}C-flumazenil, with significant increases shown in the thalamus, cerebellum and pons but not in the cortex or whole brain, when modeling corrected for altered hepatic metabolism [151]. In patients with cirrhosis, ^{13}N-ammonia and ^{15}O-water have been used to demonstrate regional differences in cerebral ammonia metabolism and blood flow that correlate with the distribution of histopathological changes and clinical features of hepatic encephalopathy [152].

In animal studies, liver regeneration has been assessed with ^{11}C-thymidine PET [153], the trafficking of radiolabeled tumor cells in vivo has been assessed with PET [154], ^{11}C-octanoate PET has been investigated for assessing liver function [155], and ^{11}C-labeled cholecystokinin receptor antagonists have been synthesized and evaluated [156].

Functional brain imaging and visceral sensation

One application that has received intense interest is functional imaging of the central nervous system as a tool for studying visceral sensation, particularly in the context of visceral hypersensitivity in functional gastrointestinal disorders [157]. In brain activation studies with PET, regional cerebral blood flow (assessed with ^{15}O-water) during a task of interest is compared with regional cerebral blood flow during baseline to identify cerebral regions with increased activation during the particular task. This widely used technique is based on the assumption that regional blood flow is coupled with regional neuronal activity under physiological conditions. In visceral sensation research, the stimulation task has consisted most often of visceral distention with a balloon.

In an early study, rectal distention in healthy volunteers led to activation in the precentral and postcentral gyrus and thalamus [158]. In one of the first studies of functional brain imaging in patients with functional gastrointestinal disease, rectal distention in controls but not patients with irritable bowel syndrome (IBS) produced activation of the anterior cingulate cortex, a region implicated in the affective response to pain [159]. A subsequent study with fMRI reported activation in the anterior cingulate cortex, prefrontal cortex, insular cortex, and thalamus in most IBS and control subjects, with increased anterior cingulate cortex activation in IBS subjects compared with controls [160]. Compared with female subjects with IBS, male subjects with IBS have demonstrated increased activation in the insula, considered a visceral sensory cortex [161]. In this study, insular activation was associated most strongly with distending pressure, whereas anterior cingulate activation was associated more with subjective discomfort. Activation patterns differ by gender during both actual and anticipated rectal distention [162]. Reduction in symptoms in patients with IBS treated with alosetron correlated with reductions in blood flow in regions believed to mediate emotion [163]. During alosetron treatment, male subjects showed greater levels of serotonin synthesis in several brain regions than did female subjects, as assessed by ^{11}C-methyl-L-tryptophan PET [164]. IBS patients have shown altered brain responses to anticipated as well as actual rectal distention [165]. Changes in activity of various cortical–limbic regions have been reported in patients with severe IBS after cognitive therapy [166].

The cerebral representation of esophageal distention has also been studied with ^{15}O-water PET [167]. During nonpainful stimulation, activation was seen bilaterally along the central sulcus, in the insula, and in the frontal/parietal operculum. Painful stimulation led to greater activation in the same regions, with additional activation of the right anterior insula and the anterior cingulate gyrus, leading the authors

to suggest that these latter structures are involved in esophageal pain processing. The activation pattern during volitional swallowing has been studied with ^{18}F-FDG PET [168].

Cerebral activation has been investigated with ^{15}O-water PET during gastric distention producing bloating, pain, and nausea [169]. Paralleling increases in distention stimulus and symptoms, progressive increases in activation were observed in the thalami, insulae, anterior cingulate cortex, caudate nuclei, brainstem periaqueductal gray matter, cerebellum, and occipital cortex. This activation pattern showed important similarities to activation patterns reported in studies of painful somatic stimulation. Proximal gastric distention has been reported to activate the postcentral gyri, left superior temporal gyrus, right inferior frontal and midanterior cingulate gyri and anterior insula, and left cerebellum, with increasing activation observed as a function of increased stimulus intensity [170].

Many functional brain imaging studies concerning visceral pain and intestinal sensation are now carried out by fMRI. The advantages of fMRI over PET include general accessibility, no involvement of radiation, repeatability, and time and spatial resolution.

Future directions

PET has been called the most sensitive and specific means of studying, through imaging, the molecular processes in humans in vivo [171]. The development of a micro-PET scanner for small animals, combined with rapidly growing experimental capabilities in molecular biology, presents the opportunity to carry out molecular imaging assays in vivo, including studies of gene expression [172].

In the clinical arena, the number of clinical PET facilities has grown over time, and PET is becoming an essential diagnostic tool for the management of certain patients with cancer. Given the ability to produce ^{18}F-FDG off-site and its commercial availability in the USA, not all clinical PET centers will require an on-site cyclotron. This may facilitate further the widespread use of PET. Newer tracers, including ^{18}F-labeled radiopharmaceuticals that can be prepared and delivered commercially owing to their relatively long half-life, may ultimately find clinical applications [173]. The availability of PET/CT scanners is likely to increase, providing both functional and anatomical information simultaneously with minimal incremental burden to patients.

134 Applications of radionuclide imaging in gastroenterology

Harvey A. Ziessman

Radiopharmaceuticals and radiation detection instrumentation, 3226

Clinical nuclear medicine studies, 3227

Radionuclide diagnostic methods have been used by gastroenterologists for decades. For example, the first publication on the use of radionuclides to quantify gastric emptying was reported in the *Lancet* in 1966 [1]. The advantage of methods employing nuclear medicine is that interpretation is made based on physiology and function, information that is often markedly different from that of anatomical imaging methods, such as ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI).

Radiopharmaceuticals and radiation detection instrumentation

Radionuclide methodology requires a radiopharmaceutical (radioactive chemical or drug), which is administered to the patient, and radiation detection or imaging instrumentation.

*Radionuclide*s are used as "radiotracers," that is, a radioactive label that allows for the detection, localization, and quantification of the chemical/drug to which it is bound. Radionuclides are unstable isotopes that emit radiation as they decay to a more stable isotope. Different radionuclides decay at different rates. For example, technetium 99m (^{99m}Tc) has a 6-h half-life. If 10 millicuries (mCi) (370 MBq) is administered to a patient, 5 mCi (185 MBq) will remain undecayed 6 h later. Thus, images are usually performed early after administration, before it decays away – for ^{99m}Tc, within 24 h.

When a radionuclide is chemically bound to a chemical, for example, ^{99m}Tc in sodium pertechnetate ([^{99m}Tc]pertechnetate) and iodine 123 in sodium iodide (sodium [^{123}I]iodide), or to a pharmaceutical, for example, fluorine 18 in fluorodeoxyglucose ([^{18}F]FDG) or indium 111 in octreotide ([^{111}In]octreotide), it is referred to as a radiopharmaceutical. The pharmaceutical or chemical determines its distribution in the body. Different routes of administration result in different distributions within the body. Technetium 99m sulfur colloid (^{99m}Tc-SC) administered intravenously will be extracted by the liver and spleen (liver–spleen scan), but when given orally is not absorbed and transits according to gastrointestinal motility (gastric emptying study). Diagnoses are made based on physiological deviations from the normal ranges in uptake, localization, distribution, and clearance. [^{18}F]Fluorodeoxyglucose, a glucose analogue, distributes throughout the body to all cells that metabolize glucose. Because malignant tumors have increased glucose metabolism compared with most nonmalignant tissues, cancers have increased uptake of [^{18}F]FDG.

Radiopharmaceuticals are administered in subpharmacological doses; that is, they have no pharmacological effect in humans. Thus, allergic reactions are rare. Radiation exposure to the patient from radiopharmaceuticals is generally low, often greater than a chest radiograph but usually less than a CT scan, depending on the radiopharmaceutical's distribution, total body clearance, and decay rate.

Three general types of instrumentation are used to detect radiotracers in the body. First, nonimaging radiation detectors, for example, specialized probes, are used for thyroid uptake measurements or intraoperative tumor localization. Second, well-counters are used to detect radiation in body tissues or fluids, for example red blood cell volume or Shilling tests. Third, imaging instrumentation includes gamma cameras and positron emission tomography (PET) cameras. Gamma cameras image radionuclides that give off one photon per atomic disintegration (single-photon radionuclides), e.g., ^{99m}Tc, ^{123}I, ^{111}In, and gallium 67 (^{67}Ga) [2]. Positron emission tomography cameras image radionuclides that give off two photons per disintegration (dual-photon radionuclides), e.g., ^{18}F, carbon 11 (^{11}C), oxygen 15 (^{15}O), or nitrogen 13 (^{13}N). Gamma cameras and PET cameras have radiation detectors that are positioned close to the patient's body. The radiation is detected by scintillation crystals within the detector head.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

When radionuclides interact with the crystals, light is emitted. The greater the radiation detected, the brighter the signal.

Traditional nuclear medicine images are two-dimensional, for example, the bone scan or a Meckel study. The camera is placed adjacent to the patient and an image is acquired in one or multiple views. Images can also be acquired in a movie mode to view movement, as in a gastric emptying study. However, technical developments have enabled three-dimensional images, similar to CT or MRI, to be commonly acquired and viewed for various indications. For the gamma camera, this is referred to as single photon *emission* computed tomography (SPECT). The radiation is emitted from an internal source of radiation. By comparison, conventional CT is *transmission* computed tomography, that is, the radiation comes from an external source that transits from one side of the body to the other, where it is detected. During SPECT there is acquisition of approximately 100 two-dimensional images at incremental angles around the patient. The multiple images are reconstructed by computer software into cross-sectional images (transverse, coronal, and sagittal views) by the same mathematical algorithms used for CT. In PET, many scintillation detectors encircle the patient.

The decay of PET radionuclides, for example, ^{18}F, ^{11}C, ^{15}O, and ^{13}N, is different than single-photon decay [2]. Positrons are antimatter, that is, positive electrons. With decay, positron particles are emitted, and they interact with negatively charged particles, namely electrons. Both particles are annihilated in the process, producing two gamma photons 180° apart. Hence, PET imaging is dual-photon emission tomography. The conversion of mass (positron/electrons) to energy (gamma photons) was predicted by Albert Einstein with his famous equation, $E = mc^2$. The potential of PET is unlimited if one appreciates that positron radionuclides include carbon, oxygen, nitrogen, and fluorine (fluorine can replace hydrogen), making possible tracing and imaging of any biological molecule.

The two PET photons are detected by scintillating crystal detectors that surround a region of the body. For a region larger than the brain or heart, the bed position can move in 30–43-cm (12–15-inch) sequential increments along the length of the body. Specialized electronics (coincidence circuitry) determines if the two photons detected are from the same decay event – that is, 180° apart and emitted simultaneously.

Images from PET are processed as cross-sectional images, which can be reformatted into rotating three-dimensional displays (MIPS, or maximal intensity projection images). and some SPECT cameras have CT scanners as part of the imaging system. The two cameras (the PET or SPECT camera, and the CT camera) are situated back to back. The studies are acquired sequentially with the patient in the same position the same table that moves from one instrument to the other. After acquisition, the images are registered and fused. The purpose is to combine the functional, physiological, and biochemical information from the PET or SPECT images with the superior anatomical localization of the CT scans.

Clinical nuclear medicine studies

This chapter will review radionuclide studies most pertinent to the modern practice of gastroenterology. There have been many advances since the previous edition of this textbook. Some of the diagnostic studies reviewed in the previous edition are uncommonly performed today and many studies that are in common use today are new to clinical practice since the previous edition.

Hepatobiliary imaging: cholescintigraphy

Iodine 123-labeled rose Bengal was the first radiopharmaceutical used for hepatobiliary imaging (cholescintigraphy). In 1976 the [^{99m}Tc]HIDA (hepatic iminodiacetic acid)-derived radiopharmaceuticals were introduced, and have subsequently entered routine use. Two HIDA radiopharmaceuticals are approved by the US Food and Drug Administration (FDA) for clinical use in the United States:

- [^{99m}Tc]disofenin (FDA name), DISIDA (diisopropyl-IDA), or Hepatolite (commercial name)
- [^{99m}Tc]mebrofenin, bromotrimethyl-IDA, or Choletec.

After intravenous injection, the radiopharmaceutical is extracted by hepatocytes and travels the same metabolic pathway as bilirubin, except it is not conjugated. [^{99m}Tc]mebrofenin has somewhat higher liver extraction (98% vs 89%) and more rapid hepatic clearance (17 vs 23 min half-time) than [^{99m}Tc]disofenin and is increasingly the agent of choice, particularly for patients with hepatic dysfunction, and in children. Less than 2% of [^{99m}Tc]mebrofenin is excreted in the urine in patients with normal serum bilirubin levels.

Technetium 99m IDA radiopharmaceuticals make possible physiological imaging of hepatic function and biliary flow. Because Tc-IDA travels the same pathway as bilirubin, it is subject to competitive inhibition by elevated levels of serum bilirubin. However, diagnostic studies can usually be obtained with serum bilirubin levels as high as 20–30 mg/dL. With severe hepatic dysfunction, normal pharmacokinetics is altered, with delayed uptake and clearance. In this situation there is increased percentage of the administered radiopharmaceutical cleared by the kidneys.

Preparation for cholescintigraphy requires that the patient has nothing by mouth for 3–4 h prior to starting the study. This allows time for the gallbladder to relax after contraction from endogenous cholecystokinin (CCK) stimulation produced by the recent ingested meal. A contracted gallbladder may not allow radiotracer to enter and could result in a false-positive study for acute cholecystitis (nonfilling of the gallbladder). However, if the patient has fasted for more than 24 h, CCK is often administered prior to the start of the study to empty the gallbladder of viscous bile, which can prevent

HIDA tracer entry. It is recommended that all opiate drugs be withheld for at least 6 h prior to the study because they produce a functional partial biliary obstruction by contracting the sphincter of Oddi, complicating interpretation of biliary duct obstruction.

The standard cholescintigraphic study lasts 1 h (1-min sequential frames) after radiopharmaceutical injection. By 60 min, the normal gallbladder fills and bile clears from biliary ducts into the intestinal tract. However, if the study is not normal at 60 min, modifications of the protocol require delayed imaging, or the administration of morphine or CCK. All of these ancillary procedures will be discussed.

Acute cholecystitis

The most common clinical indication for cholescintigraphy (nuclear medicine hepatobiliary imaging) is suspected acute cholecystitis. Cholescintigraphy reveals the specific underlying pathophysiology, namely, obstruction of the cystic duct, manifested on cholescintigraphy as nonfilling of the gallbladder [3]. Although ultrasonography is valuable in the workup of patients with suspected hepatobiliary disease, it is both insensitive and nonspecific for the diagnosis of acute cholecystitis. Gallstones are common, frequently asymptomatic, and may be unrelated to the patient's pain. Gallbladder wall thickening and pericholecystic fluid have numerous causes. And the sonographic Murphy sign is operator dependent and not always reliable. Cystic duct stones are rarely seen because of their small size. The more sonographic findings that present on ultrasonography, the greater the likelihood that the patient has acute cholecystitis; however, many patients with acute cholecystitis have only evidence of stones or other nonspecific findings. However, ultrasonography can detect other causes for pain, such as biliary dilation caused by biliary obstruction.

A stone obstructing the cystic duct is the usual initiating event of acute cholecystitis. This results in the gallbladder wall becoming edematous, followed by inflammatory cell infiltration, then hemorrhage and necrosis, and finally gangrene and perforation and other complications. Cholescintigraphy becomes positive for acute cholecystitis as soon as the cystic duct is obstructed.

Many published investigations have validated the accuracy of cholescintigraphy for making the diagnosis of acute cholecystitis. The sensitivity of the test is high, greater than 95%, and the specificity is 90% [4]. False-positive studies are uncommon, but can occur in sick hospitalized patients, those who have been fasting for a prolonged time or are receiving hyperalimentation, and some patients with chronic cholecystitis.

Nonvisualization of the gallbladder at 60 min is abnormal. However, delayed imaging is required to confirm the diagnosis of acute cholecystitis. Continued nonvisualization at 3–4 h after injection is diagnostic. Visualization of the gallbladder excludes the disease. The majority of patients with delayed gallbladder nonvisualization (between 1 and 4 h) have chronic cholecystitis. An alternative to delayed imaging is the use of morphine sulfate 0.04 mg/kg intravenously (Fig. 134.1). Morphine contracts the sphincter of Oddi, increases intrabiliary pressure, and produces preferential bile flow toward and through the cystic duct, if it is patent. The study can be completed and a diagnosis made in a total of 90 min, rather than the 3–4 h required with delayed imaging. The diagnostic accuracy is similar [5].

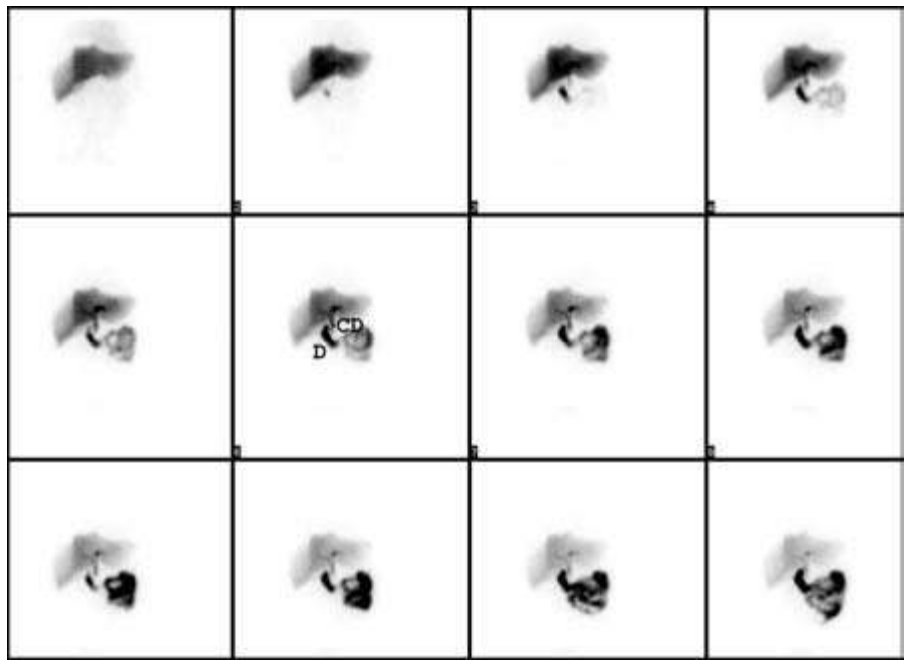
The scintigraphic "rim sign" is seen in 25%–35% of patients with acute cholecystitis. This cholescintigraphic sign is manifested as increased radiotracer uptake in the liver adjacent to the gallbladder fossa (Fig. 134.2). Although insensitive for the diagnosis of acute cholecystitis, it is highly specific. This finding has important clinical implications because patients who have this scintigraphic sign have an increased incidence of complications, such as, gangrene and perforation. The rim sign is the result of severe inflammation spreading from the gallbladder to the adjacent liver. Blood flow to this region is increased, resulting in higher than normal delivery and extraction of the HIDA tracer in the region of the inflamed liver.

Acute acalculous cholecystitis occurs in seriously ill hospitalized patients, for example, those with extensive burns, fractures, or postoperative complications. The disease has a high morbidity and mortality. As the name suggests, it is acute cholecystitis but without stones. The pathophysiology is poorly understood. Although the majority of patients have cystic duct obstruction due to inflammatory debris, inspissated bile, or local edema rather than cholelithiasis, a minority of patients do not have an obstructed duct but rather have direct inflammation of the gallbladder wall due to sepsis, ischemia, or toxemia. The lack of cystic duct obstruction makes the preoperative imaging diagnosis more difficult.

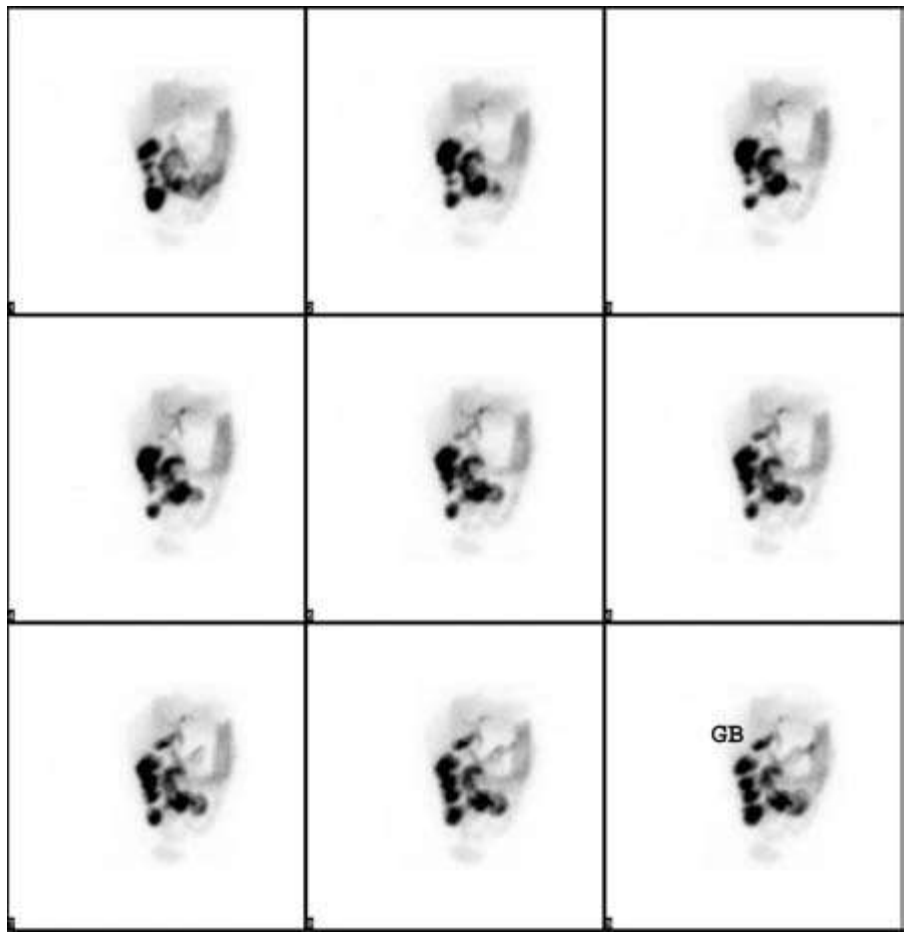
Because the majority of patients have obstruction of the cystic duct, cholescintigraphy is often diagnostic. However, the false-negative rate (gallbladder filling in patients with acute cholecystitis) is higher in acute acalculous disease than in acute calculous cholecystitis. Instead of over 95% sensitivity for the acute calculous disease, the sensitivity of HIDA imaging for acute acalculous cholecystitis is probably in the range of 75%–85%. If a patient is suspected of having a false-negative study, two approaches may be helpful. First, after the gallbladder has filled, CCK can be administered. A diseased gallbladder will not contract well. Good contraction rules out gallbladder disease; however, poor gallbladder contraction occurs with both acute and chronic disease. An ^{111}In-labeled leukocyte study can confirm acute inflammation of the gallbladder.

Chronic cholecystitis

Chronic calculous cholecystitis is commonly diagnosed in patients who have symptoms of recurrent biliary colic and imaging evidence of cholelithiasis, leading to cholecystectomy. Postoperative gallbladder histopathology shows evidence of



(a)



(b)

Figure 134.1 Delayed gallbladder visualization with intravenous morphine on a 45-year-old female referred for suspected acute cholecystitis. **(a)** Sequential images over 60 min. The right lobe has an abnormal appearance due to a loculated pleural effusion. There is normal hepatic uptake and biliary clearance of the radiotracer into the common duct (CD) and duodenum (D) and more distal small bowel. However, there is no filling of the gallbladder. **(b)** Thirty minutes of additional imaging after administration of morphine sulfate. The gallbladder (GB) progressively fills. This rules out acute cholecystitis. Transit of radiotracer can be seen in the ascending colon.

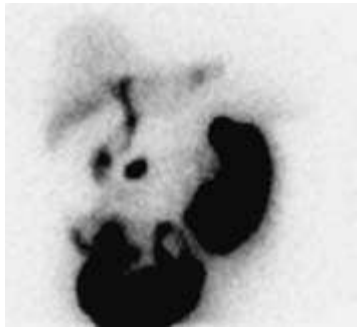


Figure 134.2 Rim sign in acute cholecystitis. This 40-year-old female was referred for suspected acute cholecystitis. The technetium 99m-labeled hepatic iminodiacetic acid ([^{99m}Tc]HIDA) study showed nonfilling of the gallbladder at 1 h (not shown). Further delayed images were obtained at 3 h. The image shows a "rim" sign with increased uptake in the liver adjacent to the gallbladder fossa along the inferior aspect of the right lobe. There is no gallbladder filling and normal transit to the small bowel. The rim sign is additional evidence that this is acute cholecystitis and suggests that there is severe inflammation and an increased likelihood of complications such as gangrene and perforation.

chronic inflammation and fibrosis. If these patients were studied preoperatively, they would be found to have poor gallbladder contraction. Patients with asymptomatic cholelithiasis have normal gallbladder contraction. Thus, in patients with atypical abdominal pain, a study of gallbladder contraction can sometimes be helpful. A poorly contracting gallbladder suggests that the pain and gallstones are related and the patient has symptomatic chronic cholecystitis. If gallbladder contraction is normal, the pain and stones are probably unrelated, and another cause for pain should be sought.

Chronic acalculous gallbladder disease is reported in approximately 5%–10% of patients who have had cholecystectomy for symptoms of chronic cholecystitis, and the laparoscopic literature suggests that the incidence may be higher [6]. Chronic acalculous gallbladder disease is clinically and histopathologically indistinguishable from chronic calculous cholecystitis, except for the absence of gallstones. Over 90% of patients with acalculous disease have evidence of chronic inflammatory changes in the gallbladder, similar to patients with chronic calculous cholecysitis. A small minority of patients do not have inflammatory changes. They also improve with cholecystectomy. The clinical problem is how to make the diagnosis noninvasively and preoperatively.

More than 20 published investigations have confirmed the value of CKK (sincalide) cholescintigraphy for the preoperative diagnosis of chronic acalculous gallbladder disease [7]. One particularly well-designed prospective investigation randomized patients referred for suspected disease who had a low gallbladder ejection fraction (GBEF), to either surgical or nonsurgical therapy [8]. Of those patients who had cholecystectomy, over 91% had resolution of their symptoms and histopathological evidence of chronic cholecystitis. Those patients with a low GBEF who did not have surgery continued to be symptomatic. Several demanded surgery and postoperatively had resolution of their symptoms. Although a few reports have not found the test useful, the overwhelming evidence is that CCK cholescintigraphy can predict which patients will benefit from cholecystectomy.

Unfortunately, the methodology for CCK cholescintigraphy is not standardized between imaging clinics and hospitals. The prospective randomized study described above used a 45-min infusion of sincalide with the GBEF calculated at 60 min. The authors established normal values in 40 normal controls. Abnormal was determined to be less than 40% (mean ± 3 SD). In another investigation of 23 normals, using a 60-min CCK infusion, normal gallbladder contraction was also found to be greater than 40% (Fig. 134.3) [9]. Other methods used include a 15- and 30-min infusion [10,11]. Normal values will vary somewhat depending on the methodology used, with a GBEF in the range of 30%–40%. Any method used should have published validated normal values.

A 1–3-min CCK infusion method is sometimes used on the strength of a retrospective report with good clinical outcome results. However, normal values have never been established with these shorter infusion methods because of the wide range in response in normals. Two published investigations have found that approximately one-third of normal subjects have poor gallbladder contraction when CCK is given as a 3-min infusion; however, they have normal gallbladder contraction when CCK is given as a 30-min or 60-min infusion [9,10]. It was noted in the early 1970s that when CCK is infused rapidly, it can cause spasm of the neck of the gallbladder and result in ineffective contraction. Infusions of 1–3 min have a similar effect in a subset of normals and patients. Thus, 30- to 60-min infusions are recommended.

A persistent misconception is that reproduction of the patient's pain during CCK infusion is a diagnostic sign of gallbladder disease. Although some older data from the 1970s suggested this, other data at that time did not support it, and subsequent investigations have not confirmed the diagnostic utility of this observation [12]. At that time CCK was administered as a bolus. Cholecystokinin has physiological effects other than gallbladder contraction and sphincter of Oddi relaxation, such as intestinal motility, which can cause intestinal abdominal cramping. Approximately one-half of normal subjects have abdominal cramping when given a 3-min or shorter CCK infusion [9,10]. When these same patients are given the dose as a slow infusion over 30 or 60 min, none has pain. Also, the symptoms of irritable bowel syndrome can be exacerbated by CCK [13]. Thus, abdominal cramping during CCK infusion is related to the method of infusion and not to the presence or absence of disease.

Cholecystokinin cholescintigraphy should be requested and interpreted in the proper clinical setting. Published studies confirming the utility of CCK cholescintigraphy to diagnose chronic acalculous gallbladder disease were performed in patients with recurrent biliary colic-type pain who had

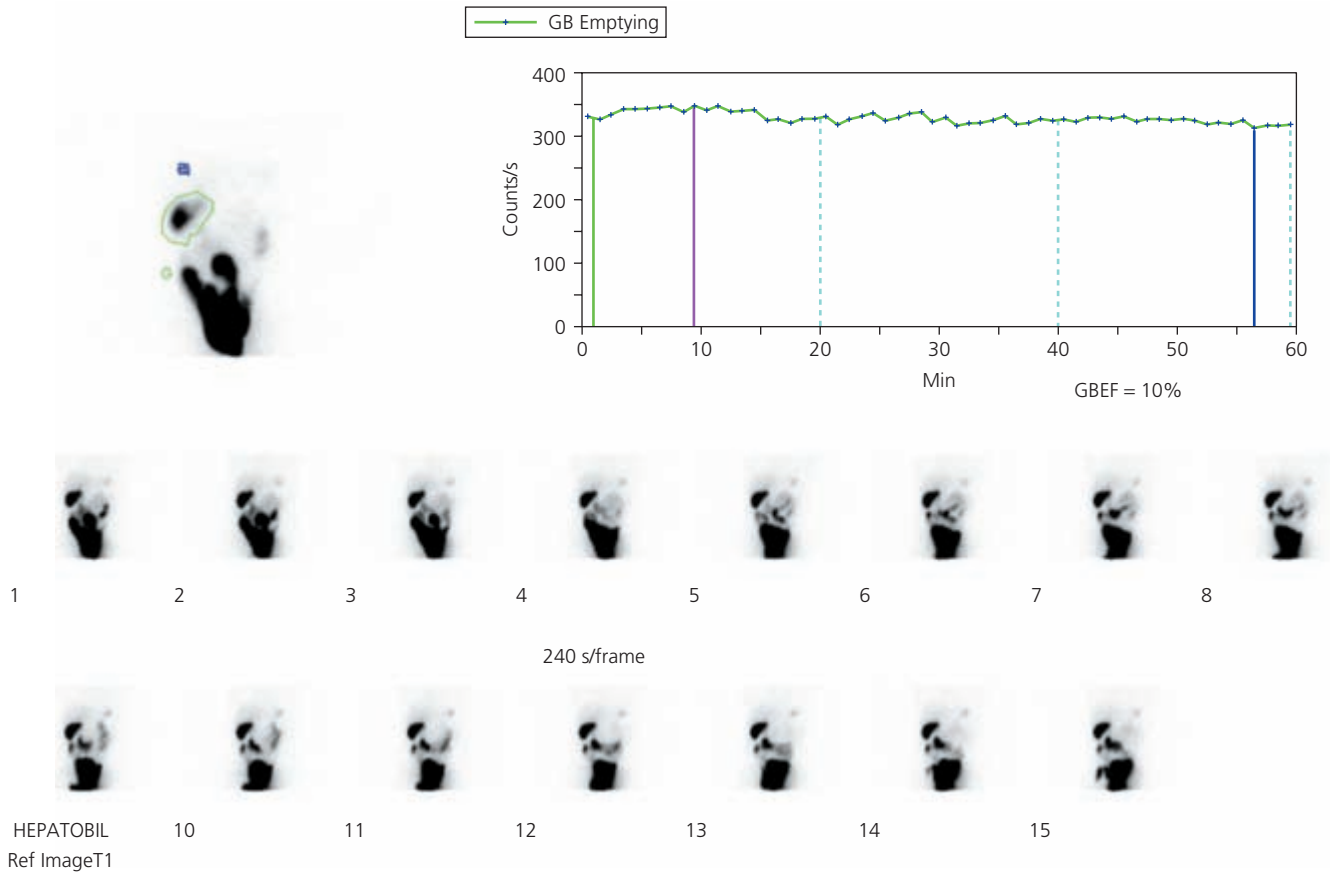

Figure 134.3 Chronic acalculous gallbladder disease in a 52-year-old patient with recurrent biliary-colic-like pain. Ultrasonography showed no stones. The gallbladder filled during the first 60 min of the study (not shown). Shown are sequential 2-min images made during the 60-min infusion of sincalide (cholecystokinin, CCK). Images show poor gallbladder (GB) contraction. A region of interest is drawn on the computer and a time–activity curve generated. The calculated gallbladder ejection fraction (GBEF) was 10% (normal ± 40%). The patient became asymptomatic postcholecystectomy and histopathology showed a chronically inflamed gallbladder.

had medical workup to exclude other diseases and were followed for months to years prior to CCK cholescintigraphy, allowing time for other diseases to manifest. Some clinicians, convinced of the utility of the test, are requesting the study after a first episode of pain and with minimal other medical evaluation [14]. The likelihood of disease in this new referable group is lower than in the published investigations, thus the accuracy of the test in this population is less certain. The posttest probability of a test is affected by the pretest likelihood of the disease (Bayes theorem). Thus, in a high-likelihood population, a positive test is likely to be a true positive, but, in a low-likelihood population, a positive test is likely to be a false positive. Cholecystokinin cholescintigraphy is a confirmatory test, not a screening test.

To confirm the diagnosis of chronic gallbladder disease, CCK cholescintigraphy should be done in an outpatient setting, not during an emergency room visit or while the patient is hospitalized. Acute illnesses and various drugs may affect gallbladder function. For example, calcium channel blockers, progesterone, octreotide, theophylline, and benzodiazepine can cause reduced gallbladder contraction.

Biliary obstruction

In patients who are clinically suspected of having biliary obstruction, anatomical imaging is often confirmatory, demonstrating dilated biliary ducts. However, early after the acute onset of obstruction caused by cholelithiasis, bile ducts may not be dilated. Dilation sometimes takes 24–72 h to become apparent. Cholescintigraphy can confirm the diagnosis early after onset because it demonstrates the pathophysiology of obstruction.

In high-grade biliary obstruction, cholescintigraphy demonstrates a severe reduction in bile flow. The diagnostic scintigraphic pattern of acute high-grade obstruction is that of good hepatic extraction but no biliary clearance, that is, a persistent hepatogram (Fig. 134.4). The accuracy of cholescintigraphy for the diagnosis of high-grade obstruction is greater than 97% [15,16]. Cholestatic jaundice, for example,

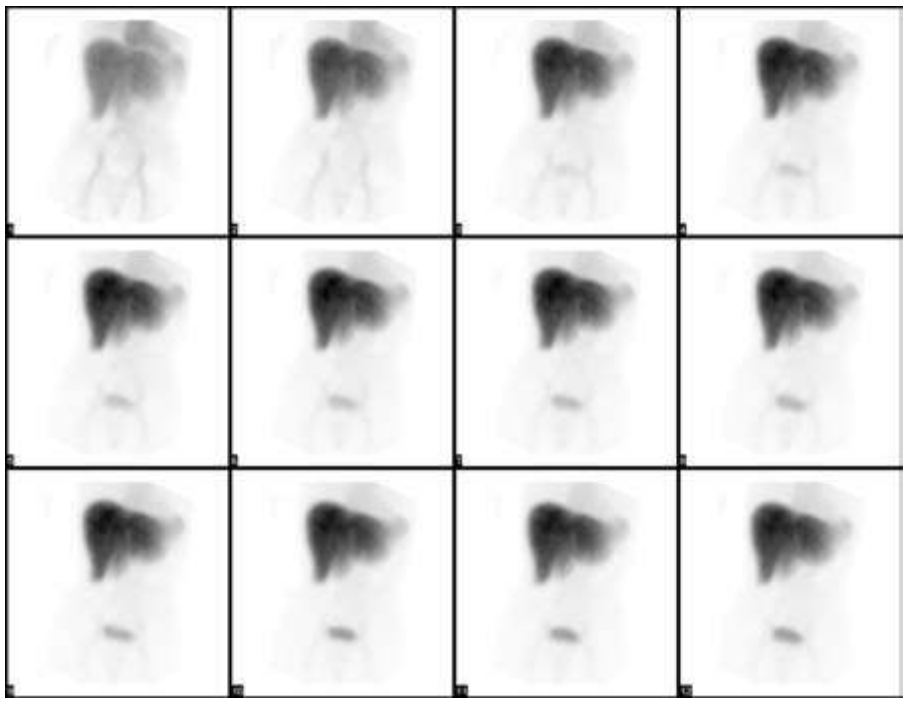

Figure 134.4 High-grade biliary obstruction. Technetium 99m-labeled hepatic iminodiacetic acid ([^{99m}Tc]HIDA) study for patient with recent onset of upper abdominal pain. Ultrasonography showed normal-sized biliary ducts. Sequential images over 1 h show prompt radiotracer extraction, but no biliary excretion into biliary ducts, consistent with high-grade biliary obstruction.

drug-induced or a resolving hepatitis, may rarely have a similar pattern, but the clinical presentation is usually different.

Partial biliary obstruction presents differently. With low-grade or intermittent obstruction, ducts are often not dilated because of the lower intraductal pressure and the intermittent nature of the process. The cholescintigraphic pattern shows good hepatic function, prompt secretion into biliary ducts, but retention of radiotracer in biliary ducts and delayed transit into the small intestines. Opiate drugs produce a functional partial biliary obstruction and should be withheld for 6 h prior to the study.

The accuracy of diagnosis for partial obstruction is also high [17]. In the largest published study, the sensitivity for cholescintigraphy was 97%, versus 78% for sonography. Specificity was similar (86%). Patients who have had prior obstruction may have persistent ductal dilation after successful therapy. Thus sonography would not be able to distinguish obstructed from nonobstructed ducts. Physiological imaging with cholescintigraphy is required to make the diagnosis. Of 125 patients thought to have early, partial, or intermittent biliary obstruction, sonography and scintigraphy disagreed in 23%. Scintigraphy diagnosed obstruction in 13 patients with no evidence of dilated ducts, whereas 7 patients with dilation from prior obstruction showed normal clearance [17].

The longer an obstruction goes untreated, the greater the likelihood of hepatic dysfunction developing. Poor hepatic function on cholescintigraphy is seen as delayed extraction and clearance from the liver. In late obstruction, the scintigraphic findings of hepatic dysfunction and obstruction can overlap, making interpretation more difficult. Good extraction and function is most consistent with obstruction, and poor hepatic uptake is more likely due to hepatic dysfunction. The two can usually be distinguished.

Postcholecystectomy syndrome

Cholescintigraphy can provide valuable diagnostic information in many patients with the postcholecystectomy syndrome. The most common biliary cause for recurrent pain after cholecystectomy is recurrent or residual biliary duct stones. Biliary stricture and sphincter of Oddi dysfunction are less common but important causes. All of these produce a scintigraphic picture of partial biliary obstruction.

Sphincter of Oddi dysfunction is a partial biliary obstruction at the level of the sphincter of Oddi. It is the cause of pain in up to 14% of patients with the postcholecystectomy pain syndrome. Clinically it presents as recurrent biliary colic-like pain and transient liver function abnormalities. In the past, endoscopic retrograde cholangiopancreatography (ERCP) was used to exclude stones, tumor, and biliary stricture as the cause. Magnetic resonance cholangiopancreatography (MRCP) has largely replaced ERCP for detection of dilation and tumor. Sphincter of Oddi manometry is considered the diagnostic gold standard of sphincter dysfunction. However, it is technically demanding, not widely available, and associated with a high incidence of adverse effects (e.g., pancreatitis).

A noninvasive screening test would be valuable to determine which patients require invasive workup. Cholescintigraphy permits physiological assessment of duct drainage, which correlates well with the washout of contrast material

from the biliary tract observed on ERCP. The scintigraphic findings are those of delayed biliary duct clearance and delayed biliary-to-bowel transit, the findings of partial biliary obstruction [18].

Quantitative cholescintigraphy has been used to improve the accuracy over image analysis alone. Various methods have been published [8,19,20]. Using a computer, regions of interest are drawn around biliary ducts or the hepatic hilum, time–activity curves are generated, and quantitative parameters of bile clearance are determined. Of the numerous methods reported, it is not certain which is most accurate. Some of the quantitative studies have relied on quantification without image analysis [7]. One investigation found a high level of accuracy by combining image analysis and quantitative analysis [20]. A unique aspect of this protocol is the infusion of sincalide prior to the study to increase bile flow and "stress" the biliary ducts, bringing out an otherwise more subtle obstruction. The authors of this study reported 100% accuracy in 23 patients, and this is the method that we use routinely (Fig. 134.5).

It is stated in the medical literature that a characteristic finding of sphincter of Oddi dysfunction is a paradoxical response of the sphincter to CCK, that is, contraction rather than relaxation, and that this finding can be used diagnostically and scintigraphically to confirm the disease. This paradoxical response was first reported using manometry, albeit in a minority of patients with sphincter dysfunction [21]. In those investigations, CCK was infused as a bolus. It has never been shown that a paradoxical response of the sphincter occurs when CCK is given at physiological doses. Unlike elevated sphincter pressure, a paradoxical response to CCK at manometry is not predictive of a good response to sphincterotomy. Scintigraphic investigations have not noted a paradoxical response when CCK was infused at physiological rate [22].

Biliary leak

Biliary leaks occur usually as a complication of cholecystectomy or biliary tract surgery. Although ultrasonography and CT can detect a fluid collection, its etiology and origin is often uncertain. Cholescintigraphy can determine whether the fluid collection is of biliary origin, rather than due to ascites or abscess, for example. Cholescintigraphy can also provide an estimate of the rate of leakage. Slow bile leaks often resolve spontaneously with conservative therapy, whereas more rapid leaks require intervention. Before percutaneous drainage of a biloma, cholescintigraphy can ensure that proximal biliary obstruction is not the underlying cause. With obstruction, bile leakage cannot be effectively treated by percutaneous drainage without addressing the underlying cause of obstruction. Follow-up cholescintigraphy can confirm resolution or persistence of the leak.

Bile leakage is seen on cholescintigraphy as progressively increasing radiotracer collection in the region of the gallbladder fossa or hepatic hilum. The radioactivity may move into the subdiaphragmatic space, over the dome of the liver, into the colonic gutters, or diffusely as free bile within the abdomen. Peritoneal tubing, drains, and collection bags may exhibit accumulation and may be the only evidence of leakage.

Other indications for cholescintigraphy

Biliary scintigraphy is useful for evaluating the patency of *surgical biliary diversion procedures*, particularly choledochojejunostomy. Scintigraphy can confirm bile leakage, determine functional patency of the anastomosis, and show evidence of recurrent obstruction. Cholescintigraphy is the only noninvasive method that can distinguish obstructed dilated ducts from those that are chronically dilated but not obstructed. In Billroth II anastomoses, afferent loop patency can be evaluated.

Cholescintigraphy can be an important diagnostic aid in evaluation of postoperative complications of liver transplatation, for example, in differentiating bile leaks and obstruction from rejection [23]. Scintigraphy has also been used to diagnose enterogastric bile reflux.

Cavernous hemangioma of the liver: ^{99m}Tc-labeled red blood cells

Technetium 99m-labeled red blood cell (RBC) scintigraphy has been used for decades to diagnose cavernous hemangiomas of the liver. However, MRI has become more commonly ordered for this purpose because of its superior anatomical resolution and high sensitivity for detecting small lesions and hemangiomas adjacent to vascular structures. However, its specificity is not as high as the ^{99m}Tc-labeled RBC method, because numerous benign and malignant lesions may have findings similar to hemangioma on MRI. Specificity of the ^{99m}Tc-RBC method is extremely high, with only a handful of false-positive studies reported in as many decades. With multiheaded SPECT, sensitivity approaches 100% for hemangiomas greater than 1.4 cm in size [24]. The sensitivity decreases for small hemangiomas, although ones measuring only 0.5 cm have been detected. The patient's own RBCs are radiolabeled using standard methodology similar to that for gastrointestinal bleeding studies and cardiac radionuclide rentriculograms or multi-gated acquisition (MUGA) studies.

Technetium 99m sulfur colloid liver–spleen scanning

Before the advent of CT, ^{99m}Tc-sulfur colloid (^{99m}Tc-SC) was routinely used for liver–spleen imaging. Although CT has replaced ^{99m}Tc-SC for routine liver–spleen scans for most indications because of its superior image resolution, the ^{99m}Tc-SC liver–spleen scan is still valuable for answering some specific clinical questions [2]. Technetium 99m-SC is extracted by the reticuloendothelial cells of the liver (Kupffer cells). Because most benign and malignant tumors do not have Kupffer cells, most liver masses have no uptake and are

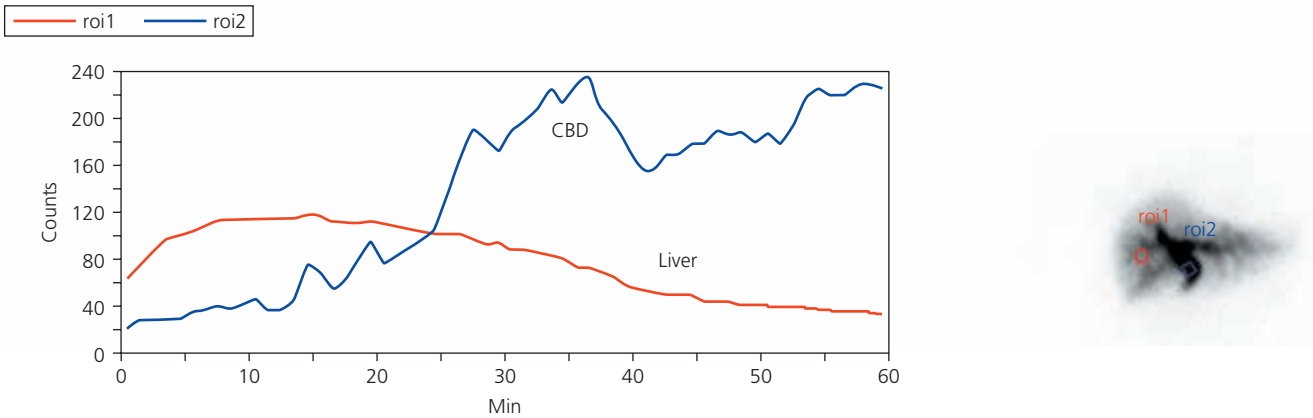

Figure 134.5 Sphincter of Oddi obstruction in a 38-year-old female with chronic recurrent biliary colic starting 5 months postcholecystectomy. Sequential technetium 99m-labeled hepatic iminodiacetic acid ([^{99m}Tc]HIDA) images over 1 h show persistent prominent activity in biliary ducts (best seen on image to right of time–activity curve) and little bile transit to the intestines (best seen on large image to right of sequential images). The common bile duct (CBD) time–activity curve shows a progressive rise. This is consistent with a partial biliary obstruction. No stones or biliary stricture were found on further evaluation and sphincterotomy was performed with subsequent symptom resolution.

cold on liver–spleen scans, with one exception, *focal nodular hyperplasia* (FNH).

Because FNH has all three liver cell types, that is, hepatocytes, biliary ducts, and Kupffer cells, the majority of these tumors show ^{99m}Tc-SC uptake. About two-thirds have normal or increased uptake and one-third have decreased uptake. Normal or increased uptake is consistent with FNH, and this differentiates FNH from other liver tumors, including hepatic adenoma, which almost always is cold. Hepatic adenoma and FNH have different prognoses and therapy.

Technetium 99m-IDA cholescintigraphy also reveals characteristics diagnostic of FNH, including increased blood flow, normal or increased uptake relative to adjacent liver, and delayed clearance of the tracer. This pattern has an accuracy matching or even exceeding that of ^{99m}Tc-SC. Other tumors with hepatocytes, for example, hepatic adenoma and hepatocellular carcinoma, have decreased uptake.

The *Budd–Chiari syndrome* (hepatic vein thrombosis) also has a characteristic pattern with ^{99m}Tc-SC, that is, reduced uptake in the liver, except for the caudate lobe. The impaired venous drainage of the liver results in poor hepatic function and radiotracer uptake. The caudate lobe retains good function because it has direct venous drainage into the inferior vena cava. Patients with *chronic hepatic dysfunction* often have a characteristic pattern based on the abnormal pathophysiology of portal hypertension, called "colloid shift," that is, decreased hepatic uptake due to poor function, and increased uptake in the spleen and bone marrow.

Technetium 99m-SC is useful in patients thought to have splenosis or splenic remnants. Because of its high target-to-background ratio, small foci of splenic tissue can be detected. Detectability is further increased by SPECT imaging. Splenic tissue next to the liver may be difficult to see because of the adjacent intense liver uptake. In that case, damaged RBCs (i.e., heat or chemically treated) will have specific splenic uptake without much liver uptake. Although perhaps superior, this latter technique is not routine because of its increased technical complexity. Most splenic tissue is detected by ^{99m}Tc-SC.

Gastrointestinal motility

The radionuclide gastric emptying study is generally considered the gold standard for measuring gastric motility and is a frequently requested clinical study. Esophageal radionuclide motility studies have been around for several decades; although in less demand because of alternative methods used, they still have a limited role. Small and large bowel transit studies are performed at a relatively small number of centers, but the methodology is underutilized and growth is expected.

Esophageal motility

In the evaluation of suspected esophageal motility disorders, a barium swallow or endoscopy is often performed initially to exclude an anatomical lesion. Esophageal manometry is commonly used to evaluate primary esophageal motor disorders. However, it has limitations. For example, in achalasia, quantification of the volume of retained food is not possible with manometry, limiting its ability to assess the effectiveness of therapy.

Esophageal transit scintigraphy is noninvasive, relatively simple to perform, and can provide clinically useful physiological information [25]. Dynamic rapid sequence swallowing scintigrams are acquired during a patient's swallow of a small volume of water mixed with 200 mCi ^{99m}Tc-SC or [^{99m}Tc]diethylenetriamine pentaacetic acid (DTPA). The computer acquisition rate must be rapid, for example, one second per frame. Qualitative analysis with cinematic display is often sufficient to diagnose abnormal esophageal motility; however, a strength of the radionuclide method is quantification. This is particularly valuable for evaluating the effectiveness of therapy. Different methods of quantification have been described [26]. An esophageal transit time or the residual esophageal activity is measured. Semisolid food swallows have been reported to be more sensitive for abnormal motility than clear liquid swallows, although less commonly used (Fig. 134.6).

The sensitivity for detection of abnormal esophageal transit is reported in the older literature to be 50%–75%. Subsequent studies have reported higher sensitivity and all reports have shown a high sensitivity for achalasia [27]. Esophageal scintigraphy, being noninvasive and quantitative, is felt to be underutilized by some; others feel it is not an ideal screening test. Most agree that its strength lies in evaluating response to therapy [28].

Gastric motility

The radionuclide gastric emptying study has been the gold standard for the evaluation of gastric motility for decades. The method is relatively straightforward, noninvasive, results in low radiation dose to the patient, and, importantly, is quantitative [29].

Although various radiolabeled meals have been used over the years, some form of egg meal, often a sandwich, is commonly used. Good binding of the radiopharmaceutical (^{99m}Tc-SC) to the meal is mandatory for accurate determination of solid or semisolid emptying. During cooking, ^{99m}Tc-SC binds tightly to the albumen in egg white. Simultaneous solid and liquid emptying studies are possible using two different radionuclides with different photopeak energies, for example ^{99m}Tc (140 keV) for the solid meal and [^{111}In]DTPA (175 and 225 keV) for the liquid meal. Solid emptying studies are reported to be more sensitive for detection of delayed emptying than liquid meals. Thus, the main indication for a clear liquid study has been for a patient who cannot tolerate solid food. Recent data suggest that liquid emptying can be abnormal when solid emptying is normal [30].

Solids empty differently than liquids. Tonic contraction of the fundus is responsible for liquid emptying. Clear liquids empty rapidly and exponentially with a half-time of less than 20 min (Fig. 134.7). When calories are added to a clear liquid meal, emptying slows. Phasic contraction of the antrum is responsible for solid emptying. With solid emptying, there is a delay before emptying begins. This *lag phase* is the time required for the antrum to grind up food into small enough particles so that they can pass through the pylorus. Emptying is generally linear after that, at least through 2 h (Fig. 134.8).

Normal values used must be based on the specific meal and methodology. Normal values must be established either in the clinic using the same methodology, or by following carefully a published protocol and using its normal values.

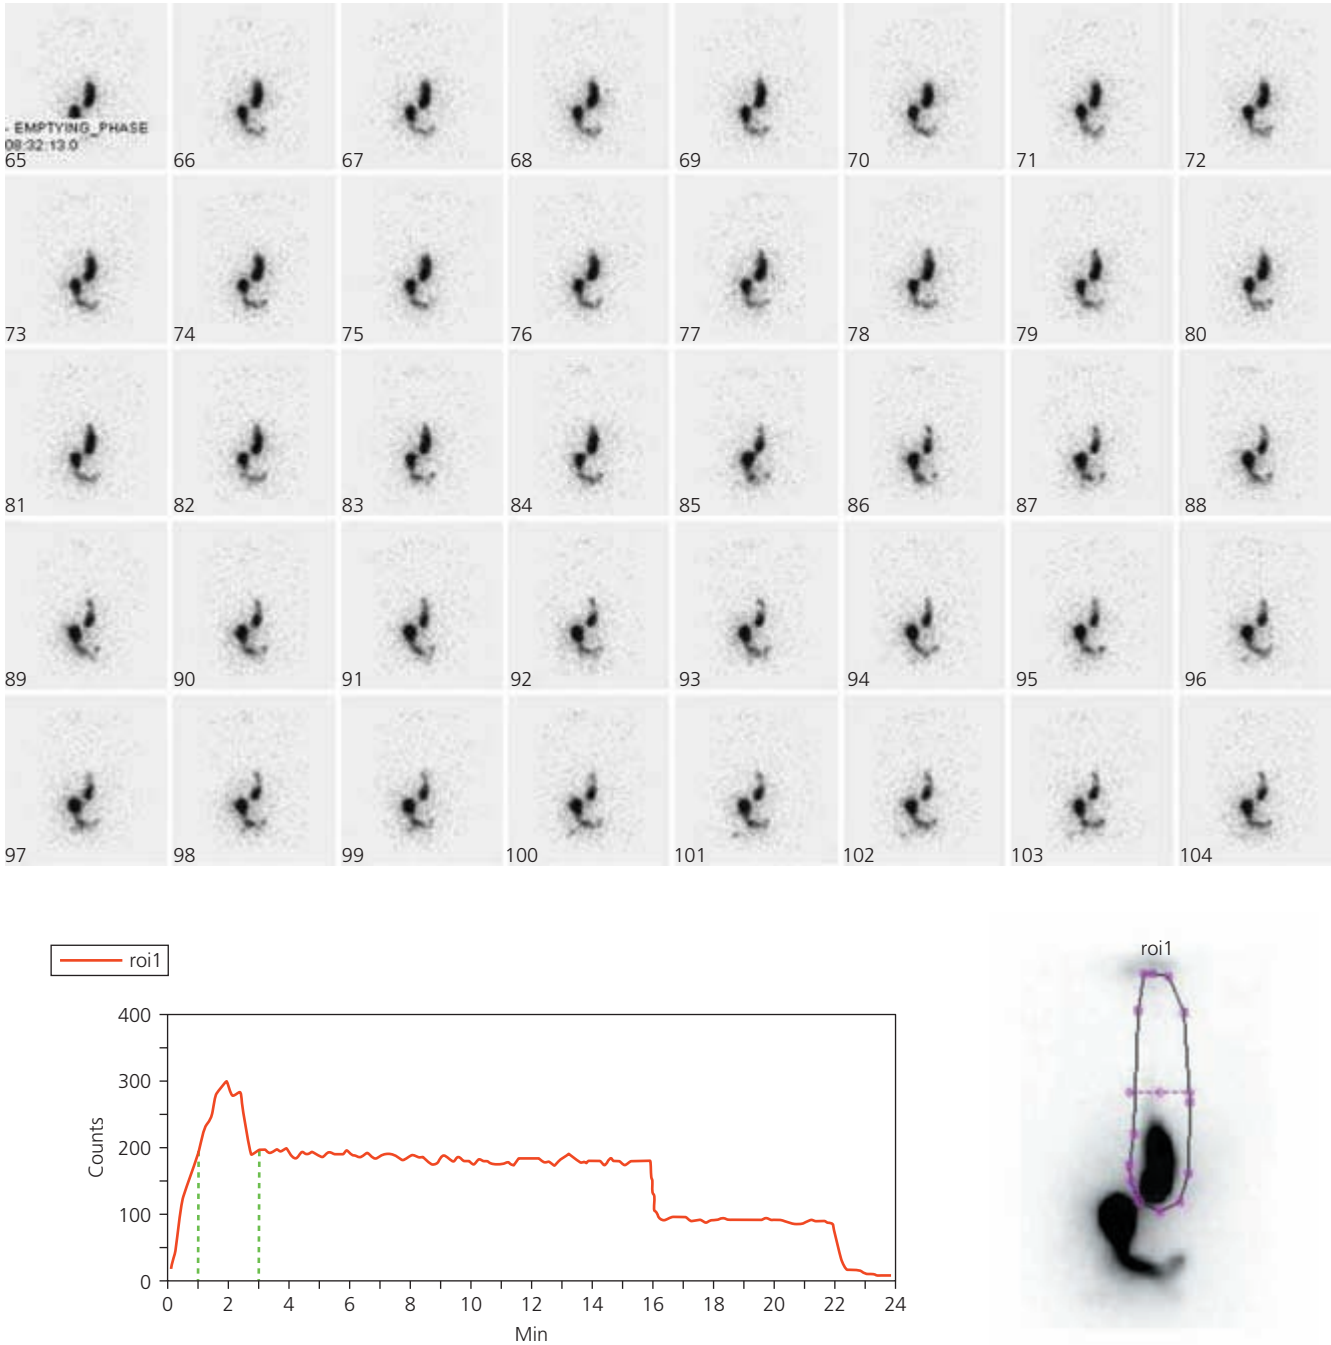

Figure 134.6 Achalasia. Esophageal swallow study of 24-min duration. Sequential 15-s images (posterior view) of ingestion of a cornflake and milk meal demonstrates delayed clearance from the esophagus. A region of interest (ROI) drawn around the esophagus generates a time–activity curve confirming the slow clearance and permits quantification. The drop in counts at 16 and 24 min is due to the ingestion of additional clear liquids.

Correction for radioactive decay and soft tissue attenuation is mandatory. Overlying soft tissue will decrease detectable counts in the stomach, and this attenuation effect varies as the stomach contents move through the stomach. The standard method for correcting for attenuation is mathematical, that is, calculation of the geometric mean (square root of the product of the anterior and posterior detector counts). If attenuation correction is not performed, gastric emptying will be underestimated. The left anterior oblique view is an acceptable alternative if only a single-headed camera is available. In this view the stomach contents move roughly parallel to the head of the camera, compensating for varying attenuation, and mathematical correction is not necessary.

In spite of its wide acceptance, the methodology used for

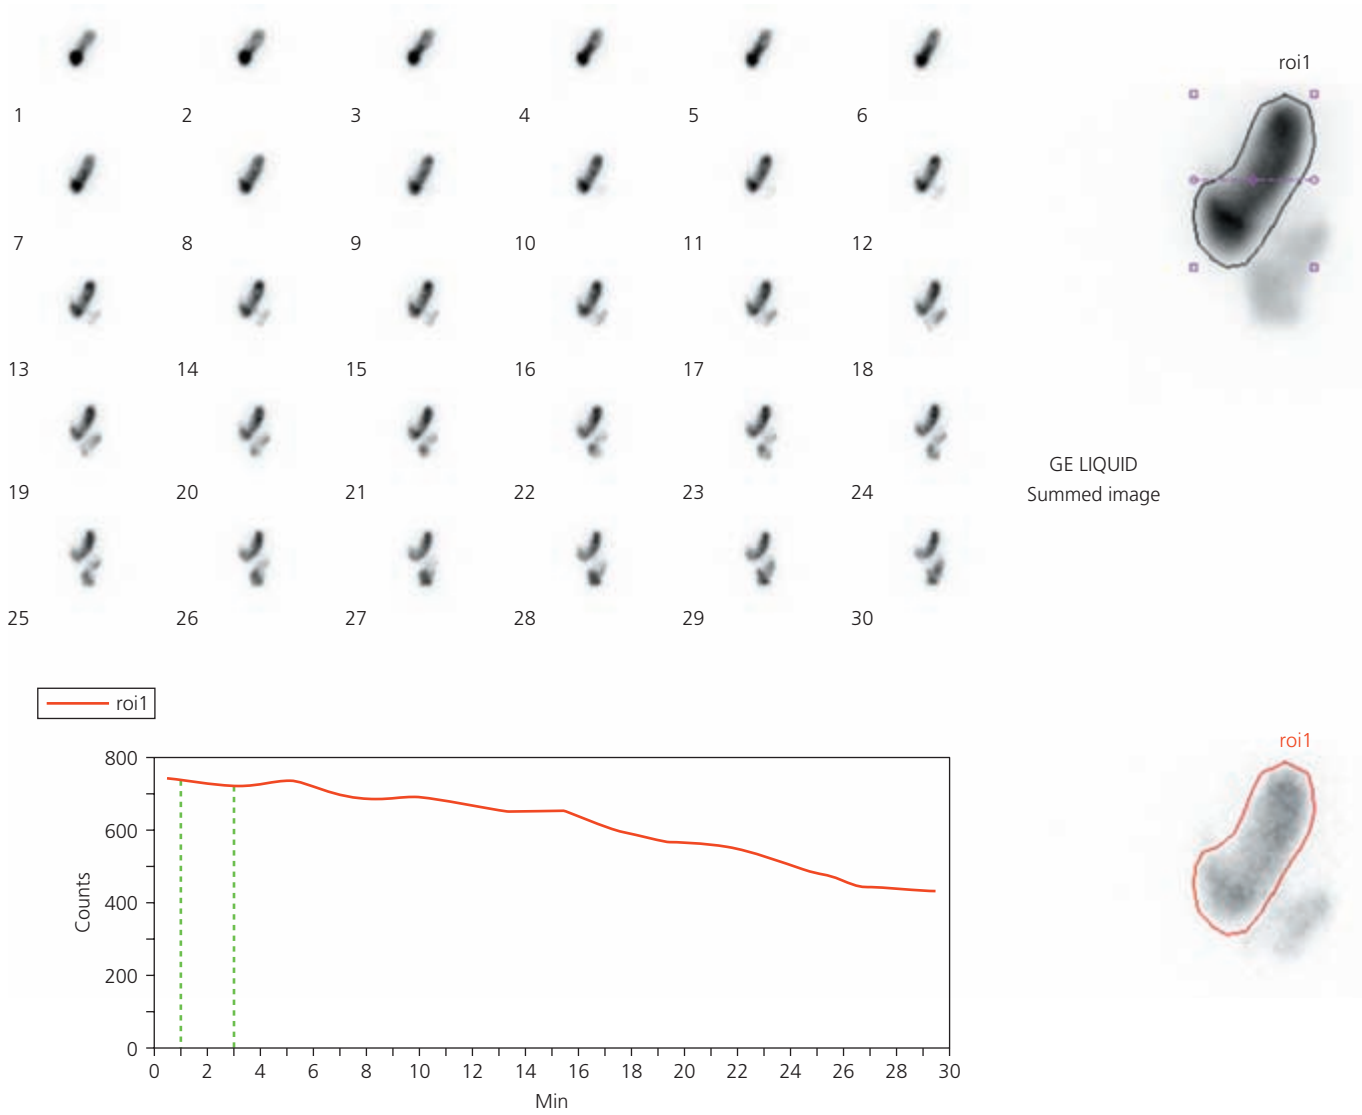

Figure 134.7 Delayed liquid gastric emptying. The patient could not tolerate solid food. Water (500 mL) mixed with technetium 99m-labeled sulfur colloid was ingested and images acquired every minute for 30 min. A region of interest (roi) was drawn around the stomach. A time–activity curve shows delayed emptying. The extrapolated emptying half-time is approximately 45 min (normal 6–18 min).

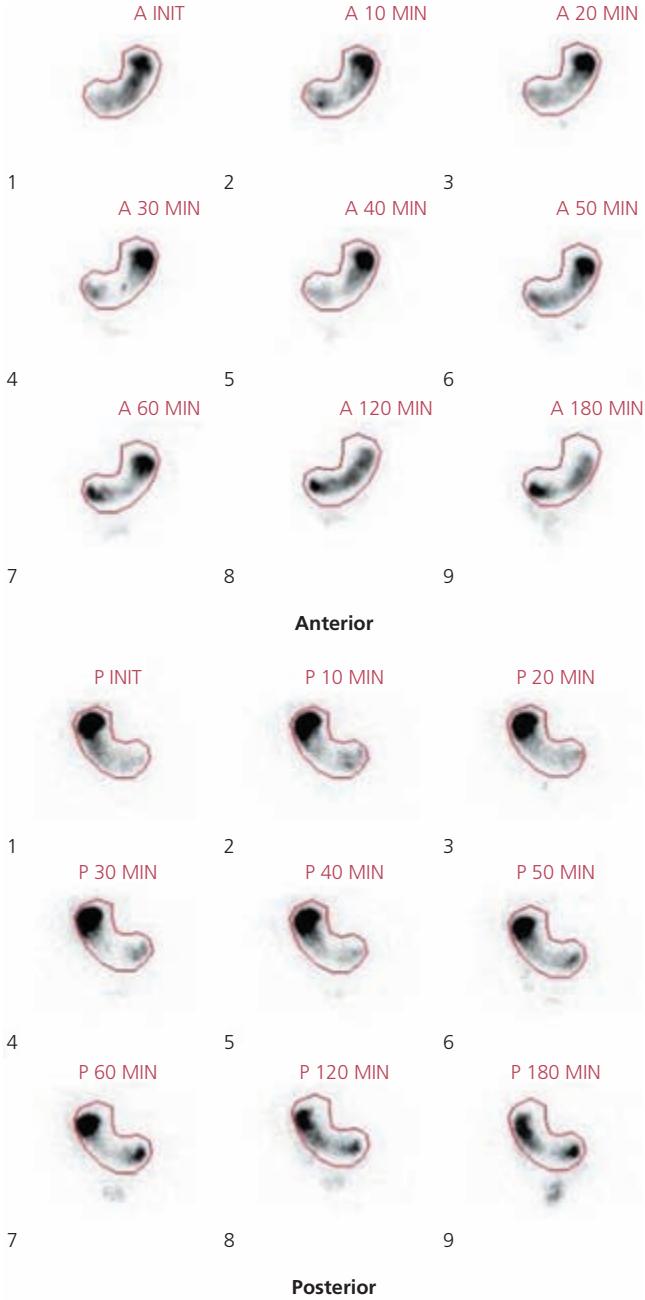
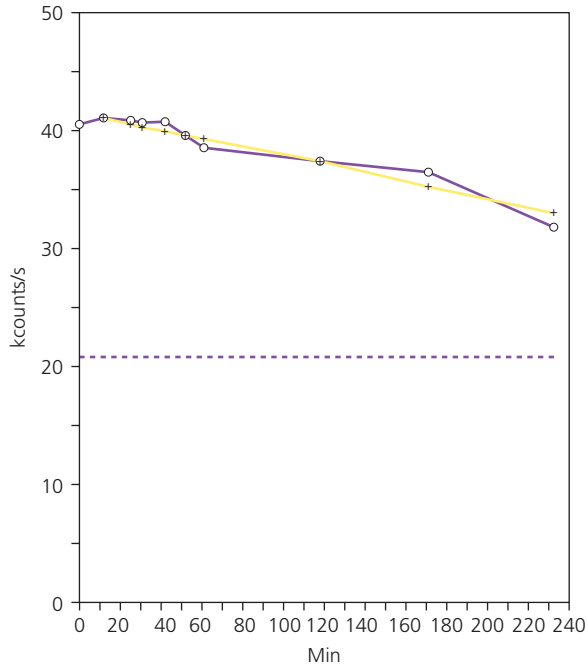
gastric emptying is not standardized between different hospitals and clinics. Various radiolabeled meals, acquisition, processing, and quantitative methods are used. Study length varies between 1 h and 4 h, although 90–120 min is most common. Normal values vary between institutions, which would be expected because normal values are affected by all the above methodological factors. Moreover, results are reported in different ways; for example, the percent emptying at the end of the study, or a half-time of emptying; also, sometimes, the length of the lag phase, and a rate of emptying. This can be confusing to referring physicians and makes it difficult to compare results between institutions.

There have been attempts to standardize gastric emptying methodology [31]. A collaboration between the American Motility Society and the Society of Nuclear Medicine is spearheading efforts to find a consensus for a generally accepted standardized protocol. One protocol of particular interest is that of Tougas et al., which was published as a multicenter, multinational normal database of 123 subjects [32]. This was designed as a simplified screening test with only four imaging times, at 0, 1, 2, and 4 h. The meal is a ^{99m}Tc-labeled egg substitute sandwich with jam and water. The study length is based on published evidence that a 4-h study detects more abnormal emptying than a 2-h study [33,34].

However, this simplified protocol does not allow analysis of the physiology of gastric emptying. With shorter length studies of 90–120 min, frequent image acquisition is standard. This allows for sophisticated qualitative and quantitative analysis. Images can be reviewed in cinematic mode. Movement of the radiolabeled meal from the fundus to the antrum





Frame/time		Fit/raw	% Empty	Kcounts**	Tc_99m ** Geometric mean Anterior	Posterior
1	0.0	0	0	40.55	55.74	29.50

Figure 134.8 Delayed solid gastric emptying. Anterior and posterior images were acquired every 10 min during the first hour, then once per hour for 4 h. The purpose of early frequent imaging was to get an estimate of the lag phase, which is delayed. The horizontal dashed line represents 50% emptying. Overall emptying in this patient is markedly delayed with only 21% emptying at 4 h (normal > 90%). Without the images at 10, 20, 30, 40, and 50 min and the 3-h image, this would be similar to the Tougas et al. protocol [32].

and through the pylorus into the intestines can be evaluated and a lag phase (time delay before emptying begins) and a rate of emptying (linear or exponential emptying rate), as well as other emptying parameters, can be determined. However, with the Tougas et al. protocol, only delayed emptying at 2 and 4 h is determined (Fig. 134.8). Furthermore, rapid emptying has not been defined. Further work is needed to devise a standardized protocol that will provide the clinical information needed and is flexible enough to accommodate modification for research purposes [35].

Intestinal motility

Small and large bowel radionuclide intestinal transit studies are not widely performed, although methods have been

described. The Mayo Clinic and Temple University groups have been the most active in this area. Some limitations of the methodology have hindered its more widespread use. The Mayo Clinic approach has used a radiopharmaceutical that does not break down until it reaches the small bowel [33]. This is physiologically appealing; however, the radiopharmaceutical is not approved for clinical use nor is likely to be in the foreseeable future. The Temple approach is to use two isotopes with different photopeaks that can be imaged simultaneously, that is, the ^{99m}Tc-SC egg meal for gastric emptying and [^{111}In]DTPA for intestinal transit [36]. However, the test requires 3 days of intermittent imaging, at 0, 1, 2, and 4 h for gastric emptying, at 6 h for small bowel transit determination, and at 24, 28, and 72 h for large bowel transit.

Quantification is not as straightforward for intestinal transit as it is for gastric emptying. With gastric emptying, the percent emptying is determined by the amount of radioactivity in the stomach at time zero immediately after ingesting the radiolabeled meal minus the activity at end of the study, divided by the amount at time zero. However, unlike the stomach, the small and large bowel do not have a time zero where all the activity is in one place, but rather the activity enters the small and large intestines over a period of time. This requires some form of semiquantification or index of transit. One method has defined an approach for calculating the geometric center of activity [36].

Gastroesophageal reflux

The radionuclide gastroesophageal reflux study is a sensitive, noninvasive, and relatively straightforward method for detecting reflux. In the past, the methodology used for adults mimicked the radiographic method, that is, a stepwise increase in abdominal pressure using an inflatable binder to produce detectable reflux events. However, this method is not physiological. A method developed and successfully used for pediatric patients is also applicable to adults. This method has proven to be sensitive for detecting gastroesophageal reflux events, due to the rapid framing rate used for acquisition (10-s frames for 1 h). Early reports of low sensitivity for detecting reflux events date back to days when framing rates of 30 s or longer were used, which resulted in poor temporal resolution and consequent inability to detect repetitive events (Fig. 134.9). The rapid acquisition method has superior sensitivity for detecting reflux [37].

For children, formula or milk mixed with ^{99m}Tc-SC is administered. For adults, orange juice is commonly used. Various

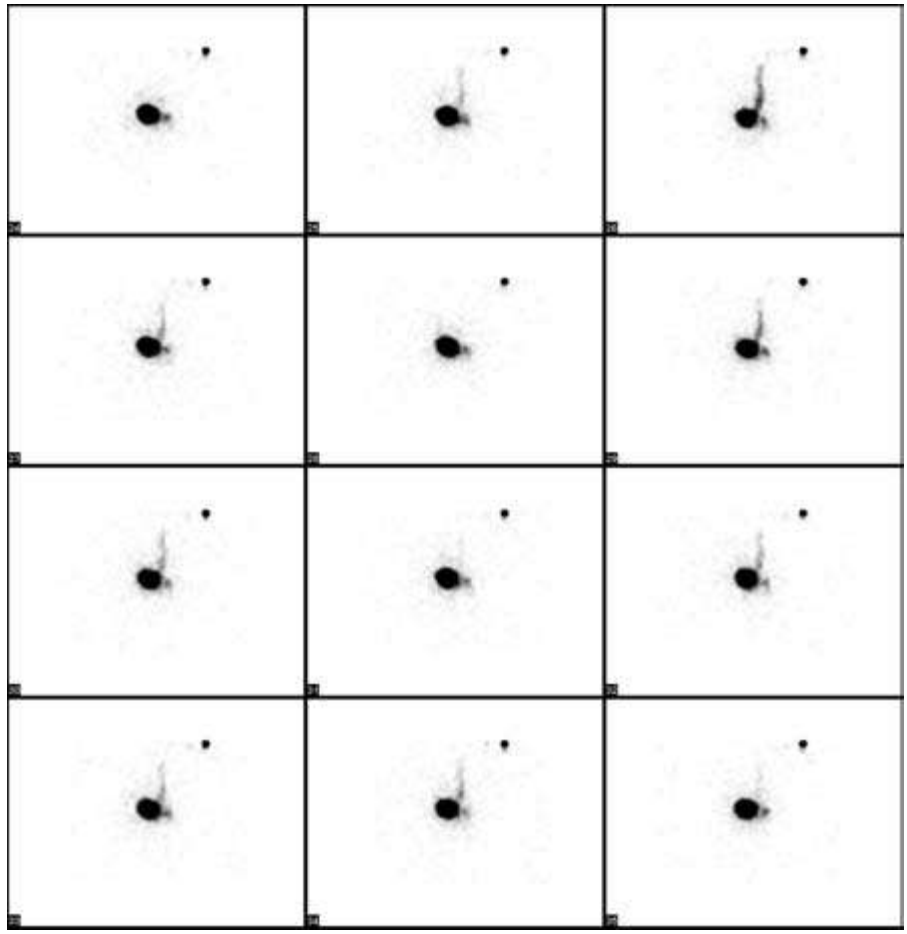

Figure 134.9 Gastroesophageal reflux. A neonate with failure to thrive ingested the usual formula meal with technetium 99m-labeled SC. Ten-second sequential frames show frequent episodes of reflux of varying duration, but mostly high level. The hot dot in the left upper corner is a radioactive marker to show the level of the mouth.

different methods have been described for quantification. A simple method is to count the reflux events and to note whether they are long events (> 10 s) or short, and high (greater than half the distance to the mouth) or low events, and to then sum the results. Evidence for aspiration is routinely sought on these studies.

Gastrointestinal bleeding

The radionuclide gastrointestinal bleeding study was described several decades ago and continues to be a commonly requested study [38]. The standard methodology is to radiolabel the patient's own RBCs with ^{99m}Tc. In order for ^{99m}Tc to bind to the β chain of the hemoglobin, it must be reduced with stannous ion (tin). High labeling efficiency is important because free (unlabeled) ^{99m}Tc is secreted by the salivary glands and stomach, then moves distally, and may be misinterpreted as bleeding. Several different radiolabeling methods have been used over the years. The in vitro commercial kit method is the preferred method because of its high labeling efficiency, greater than 97%. Because free unlabeled ^{99m}Tc is also taken up by the thyroid, routine imaging over the thyroid can confirm whether or not there is a significant amount that might confuse interpretation of the study.

The test is used primarily for lower gastrointestinal bleeding. Its sensitivity for detection of active bleeding is high. Bleeding rates as low as 0.1 mL/min can be detected. For comparison, contrast angiography can detect bleeding rates of 1.0 mL/min, a 10-fold difference. Scintigraphic images are routinely obtained at a framing rate of 1 min per frame for 60–90 min, and delayed imaging can be obtained as needed for up to 24 h [2]. Gastrointestinal bleeding is typically intermittent and the clinical signs and symptoms often are noted after an acute bleeding episode has resolved. The ^{99m}Tc-RBC bleeding study allows for continuous imaging, routinely for 60–90 min, as well as delayed imaging for up to 24 h without relabeling the patient's blood.

Angiographers often request the radionuclide study prior to performing a contrast media angiographic study, for two reasons. First, if the radionuclide study is negative, a contrast study is unlikely to detect bleeding. Second, if the radionuclide study is positive, it can guide the angiographer to the approximate bleeding site, thus saving time and contrast media.

There has been some controversy over the years regarding the accuracy of the radionuclide method, particularly its sensitivity and specificity for the detection of bleeding. Evidence can be found in the literature that its accuracy is good, mediocre, or poor, thus supporting any shade of prior bias in the reader. The discrepancies in the published literature can be explained and attributed to several factors. First, there is the problem of a gold standard used in investigations. Contrast angiography that localizes the site of active bleeding is best; however, only a small number of subjects in any reported series have this direct correlation. Surgery is also a good standard, but these correlations are usually limited to a minority of patients. Thus, contrast gastrointestinal radiography and colonoscopy become a common standard. However, colonoscopy, cannot easily be performed during active bleeding, and the finding of polyps, ulcers, arteriovenous malformations, or angiodysplasia, for instance, does not ensure that they were the source of bleeding unless active bleeding is seen at the time of the procedure. The length of time between the radionuclide study and the standard becomes a factor. Thus, a large number of patients are without confirmatory correlation for the radionuclide study. Good investigational studies are difficult to perform and evaluate.

A major cause of negative gastrointestinal bleeding studies is the clinical method of evaluation and workup of these patients. A not uncommon clinical approach is to admit patients to the hospital, put them to rest, stabilize them with fluids and transfusion, and cleanse the colon for colonoscopy the following day. The problem with this approach is that the radionuclide gastrointestinal bleeding study is most likely to be positive early after the onset of bleeding. What often happens at some centers is that if no site of bleeding is found at colonoscopy and other subsequent workup, then the scintigraphic study is considered and ordered. However, in many cases the bleeding has ceased, and the yield at this time point will be low. Using this approach, the bleeding study will have a low sensitivity. If the bleeding study is performed soon after the patient's arrival in the emergency room or admission, a positive bleeding study is much more likely and this can lead to successful angiography and appropriate therapy. This approach does not preclude stabilizing the patient and prepping them for colonoscopy the next day.

Concerns about a high incidence of false positives, although perhaps valid in the past, should no longer be problematic because of improved methodology and interpretative criteria. Regarding methodology, a 1-min continuous framing rate is standard. In the past intermittent static imaging was performed. Bleeding can move rapidly, anterograde or retrograde, and intermittent imaging can miss the site of origin.

The criteria used to diagnose active bleeding are as follows: new onset of radioactivity where there was none at first; increasing radionuclide activity with time; and movement of the activity in a pattern consistent with bowel anatomy. The images should be obtained for a duration sufficient that the pattern of movement can distinguish small from large intestine and localization is as certain as possible. The images should always be viewed on the computer in movie mode. Finally, if delayed images are performed, the acquisition method – for example, 1-min frames × 30 min – should be similar to the initial methodology and the diagnostic criteria the same. In the past the presence of blood on delayed imaging at a site was sometimes called positive, but it turned out to be false positive. Today, it is better appreciated that a single static image only reveals evidence of blood, which could have come from anywhere above or below that site. Finally,

radiolabeling is superior today than in the past, minimizing the problem of free [^{99m}Tc]pertechnetate.

Suspected upper gastrointestinal bleeding is not an indication for the radionuclide study. However, upper gastrointestinal bleeding may occasionally be diagnosed, although seemingly adequate workup had excluded it prior to the study.

Use of modern methodology and interpretative criteria and prompt performance of the test when the patient presents will ensure a reliable test for detecting active bleeding and localization of the site of bleeding.

Meckel diverticulum and ectopic gastric mucosa

Gastric mucosa takes up [^{99m}Tc]pertechnetate whether the mucosa is in the stomach or ectopic. For decades, the [^{99m}Tc]pertechnetate *Meckel scan* has been an accurate and accepted methodology to confirm the diagnosis preoperatively. The accuracy of the study is high, with a sensitivity of approximately 85% [39]. Cimetidine administered prior to the study can increase diagnostic yield. The drug inhibits release of ^{99m}Tc from the gastric mucosa, making detection more likely. Data are limited regarding its effectiveness, but 20 mg/kg orally in divided doses for 2 days prior to the study is usually without side effects. The diagnosis is made by detecting uptake, usually in the right lower quadrant. The uptake of the ectopic tissue occurs at a rate similar to stomach uptake. The most common cause for a false-positive study is urinary tract activity, a normal excretory route of the radiotracer, misinterpreted as ectopic mucosa. False positives are occasionally seen due to gastrointestinal duplications or local inflammatory hyperemia, increased permeability, or obstruction, for example, occurring with regional enteritis.

Shilling test

The Shilling test is a time-tested standard radionuclide technique for the diagnosis of vitamin B-12 malabsorption. The study is initially performed by using oral administration of cobalt 57-labeled B-12. Intramuscular B-12 is given prior to the study so that all binding sites are saturated, and thus all orally administered B-12 will clear through the kidney. Urine is collected for 48 h, and the percent excretion is calculated. If B-12 clearance is low, a second-stage study is performed with intrinsic factor and radiolabeled B-12. If the clearance improves substantially, pernicious anemia is diagnosed. If it does not improve, intestinal malabsorption is the cause. Alternative second stages can be done with pancreatic enzymes for suspected pancreatic insufficiency, or with antibiotics for suspected overgrowth syndromes.

Somatostatin receptor imaging

Somatostatin receptor imaging has an important role for imaging neuroendocrine tumors, for example, gastroenteropancreatic and carcinoid tumors. Somatostatin receptors are integral membrane glycoproteins located on normal cells of neuroendocrine origin, such as pancreatic islet cells. Five somatostatin receptor types have been described. The receptors are also found in neuroendocrine tumors derived from neural crest cells belonging to the amine precursor uptake and decarboxylation (APUD) system. [^{111}In]pentetreotide (octreotide) binds with high affinity to type 2 somatostatin receptors. Only gastroenteropancratic (gastrinomas, insulinomas) and carcinoid tumors will be discussed.

Gastroenteropancreatic tumors are highly differentiated, slow growing, and often small. Most have high concentrations of somatostatin receptors [40]. Symptoms are often secondary to the hormonal activity expressed, for example, hypoglycemia, gastric ulcers, severe diarrhea, and flushing. Frequently the tumors have metastasized by the time of diagnosis, to liver, lymph nodes, bone, lungs, and skin. *Gastrointestinal carcinoid tumors* are derived from the foregut, midgut, or hindgut. The midgut carcinoids with liver metastases cause the carcinoid syndrome, with symptoms and signs of flushing, diarrhea, wheezing, and valvular right-sided heart disease.

Although ^{99m}Tc-labeled somatostatin receptor imaging agents have been developed, ^{111}In is preferable because of its longer physical half-life (2.8 days vs 6 h), allowing time for background clearance and improved target-to-background ratio for optimal diagnostic images. Normal distribution after intravenous injection of [^{111}In]pentetreotide (OctreoScan) includes prominent uptake in the kidneys and spleen. The liver has less uptake and gallbladder clearance is variably seen. Whole body and SPECT imaging is performed 24 h after injection of the radiopharmaceutical.

Sensitivity for detection of carcinoid tumors and gastrinomas is high, at 80%–90%, but somewhat lower for VIPomas and glucagonomas (75%), and lowest for insulinomas (50%). Many of these tumors are small and difficult to detect with conventional imaging, for example, ultrasonography, MRI, and CT, which have considerably lower tumor detection rates. [^{111}In]OctreoScan is superior to [^{123}I]meta-iodobenzylguanidine (MIBG), although the latter is taken up by some tumors. Because the tumors are usually highly differentiated, FDG PET imaging, described in the next section, is often negative. Uptake of FDG PET is more likely with poorly differentiated tumors. New somatostatin receptor radiopharmaceuticals are being deeveloped for SPECT and PET.

Somatostatin receptor imaging is sometimes used to select patients likely to respond favorably to octreotide therapy. Scintigraphy is most useful for detection of metastases and can direct patients with inoperable tumors to other forms of therapy (Figs 134.10 and 134.11). [^{111}In]OctreoScan imaging positively impacts patient management in 25%–45% of patients [41].

[^{18}F]FDG PET imaging of gastrointestinal malignancy

The use of [^{18}F]fluorodeoxyglucose ([^{18}F]FDG) PET and PET-CT is growing rapidly, and these techniques play an important

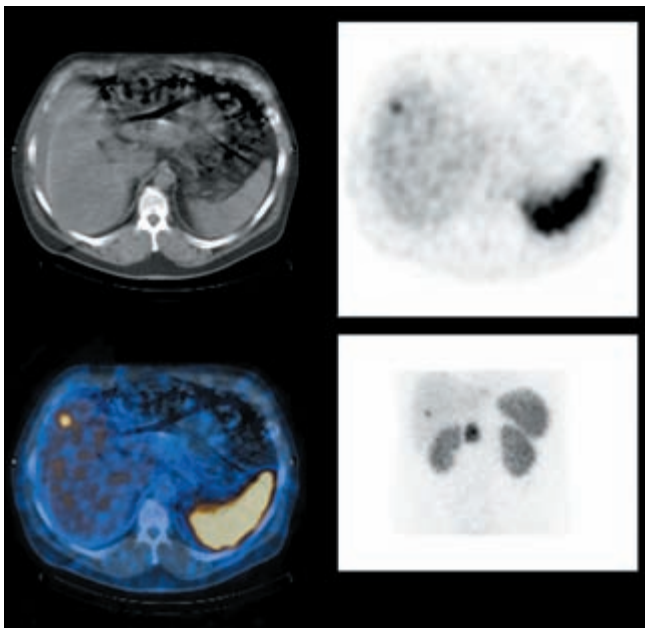

Figure 134.10 OctreoScan single photon emission computed tomography (SPECT) for a pancreatic islet cell tumor. This patient was imaged with indium 111-labeled OctreoScan on a SPECT–CT system, combining both imaging modalities. CT slice **(upper left)**, SPECT image **(upper right)**, fused SPECT–CT image **(lower left)**. The MIPS (maximal intensity projection images) image, a 3-D reconstructed abdominal image **(lower right)**, shows normal high uptake in spleen and kidneys and focal hot uptake in a midline mass, which is the patient's islet cell tumor. Also a small focus of uptake due to a metastasis is see in the anterior inferior portion of the liver on the MIPS view and the SPECT and fused images.

role in the diagnosis, staging, restaging, and monitoring of response to therapy of various gastrointestinal malignancies.

[^{18}F]fluorodeoxyglucose is a radiolabeled PET glucose analog. It is transported into the cell and phosphorylated by the same mechanism as glucose but cannot be metabolized further and is therefore trapped intracellularly. Most malignant tumor cells have increased glucose metabolism compared with normal tissue cells and thus have increased uptake of [^{18}F]FDG. Patients must have fasted for 6–8 h prior to injection, otherwise the radiopharmaceutical will distribute primarily to muscle and soft tissue and not to tumor. This is due to competition with serum glucose and the effect of insulin. This is a particular problem in diabetics. Insulin should not be injected within 2 h of the study. The 2-h half-life of ^{18}F requires imaging at 1 h after injection.

Whole-body cross-sectional imaging is performed. Most PET scanners are PET-CT cameras. The PET and CT images are obtained sequentially with the patient lying on a table that moves between the two adjacent scanners, and then the images are registered and fused (overlayed) for functional and anatomical correlation (Fig. 134.12).

Colorectal cancer

Cancer of the colon is the third leading cause of death after lung, breast, and prostate cancers. Although FDG PET has little role in initial tumor staging, it is routinely used for restaging, preoperative evaluation prior to hepatic tumor resection, and for evaluating response to therapy [42].

[^{18}F]fluorodeoxyglucose uptake is usually high in colorectal cancer, with a sensitivity for tumor detection greater than 95%. The one exception is mucinous adenocarcinoma, for which the sensitivity is considerably less, at approximately 60%. Because most patients with newly diagnosed colorectal cancer require surgery to prevent obstruction and the incidence of unsuspected distant metastases is not high, FDG PET is not routinely required preoperatively. Postoperatively, one-third of patients whose tumors are thought to be resectable with curative intent at the time of surgery, have recurrence within 2 years. Serial serum carcinoembryonic antigen (CEA) levels have sensitivity for recurrence of less than 60% and, importantly, provide no localizing information. A common clinical problem is the patient with a rising CEA level but negative findings on conventional imaging, including CT. The sensitivity of FDG PET for detecting recurrence is approximately 95%, compared with CT sensitivity of 70% [43].

Twenty percent of colorectal recurrences occur in the liver, where FDG PET has a high accuracy – 92%, compared with 78% for CT. Patients with a single liver metastasis are potentially curable. However, in the past, only 25% of patients were cured because of the presence of unknown extrahepatic metastases. Preoperative detection of distant metastases is poor by conventional methods, so FDG PET plays an important role in selecting patients for surgical resection.

Patient management is changed by FDG PET. It is reported to have a clinical impact in 30%–40% of patients, often obviating the need for unnecessary surgery. Also, FDG PET can determine the effectiveness of chemotherapy and radiation therapy. With successful therapy, FDG uptake markedly decreases. There is a growing body of data to suggest that response to chemotherapy can be predicted by FDG PET within 3 weeks after initiation of chemotherapy. Furthermore, FDG PET can differentiate postsurgical changes of necrosis and fibrosis from recurrent tumor with high accuracy, which is often not possible with CT or MRI.

Cancer of the esophagus

Early-stage esophageal cancer is potentially curable with surgery; however, up to 80% of patients have local metastases and 50% have distant metastases at initial diagnosis. Prognosis depends on the extent of the primary tumor (TNM classification). Regional metastases occur anywhere from the cervical chain to mediastinal, gastrohepatic, and celiac nodes. Neoadjuvant chemotherapy is increasingly used in patients thought to have resectable disease because it improves tumor control, prevents distant disease, and decreases tumor burden, allowing for more complete resection.

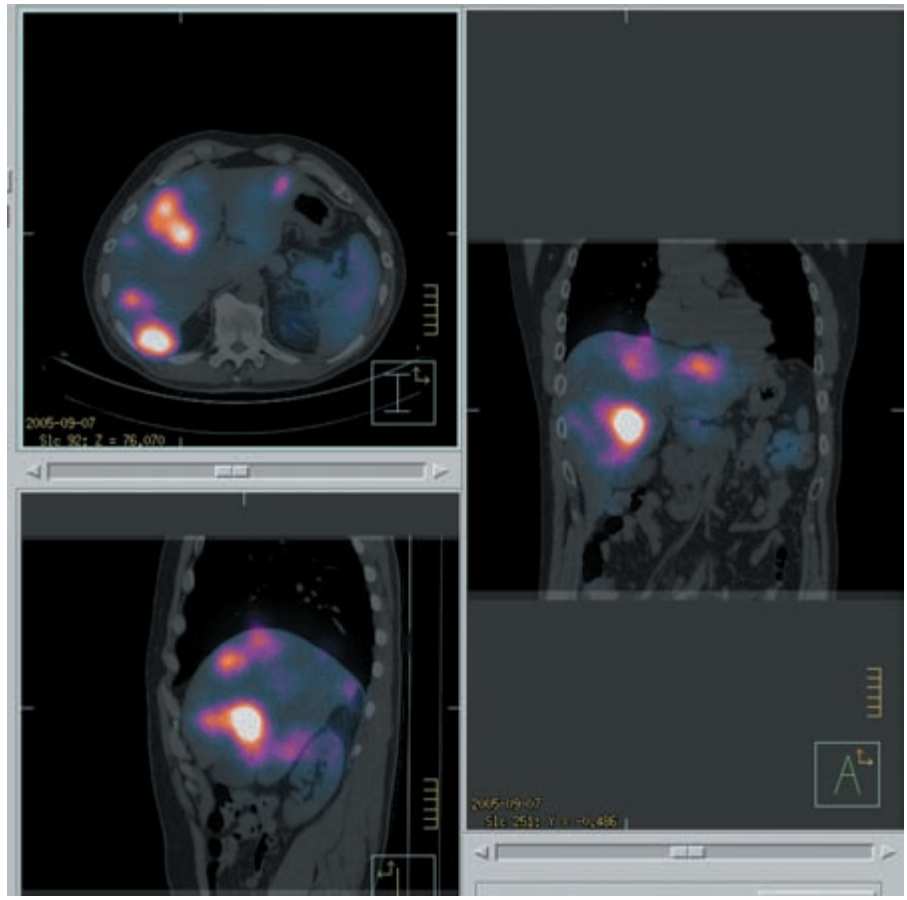

Figure 134.11 OctreoScan single photon emission computed tomography (SPECT)–computed tomography (CT) of carcinoid tumor. Fused SPECT and CT images with transverse **(left upper)**, sagittal **(left lower)**, and coronal **(right)** slices. Intense uptake is seen in multiple large carcinoid tumors metastatic to the liver.

Uptake of FDG is high in primary colorectal cancer, with detection sensitivity greater than 95%. However, FDG PET cannot provide staging information on the depth of invasion and periesophageal tissue invasion (T staging), and has relatively poor sensitivity (50%–75%) for determining nodal involvement (N stage). Five-year survival in patients without nodal involvement reaches 75%; survival is 10% for those with nodal disease.

An important role of FDG PET in primary staging is detection of distant metastases, commonly found in the liver and lung. Sensitivity for distant metastases is 80%–90%, compared with 50%–75% for CT. Imaging using FDG PET upstages as many as 15% of patients, and has a major impact by improving detection of occult stage IV disease. Exceptions to this high sensitivity are its poorer sensitivity for brain metastases compared with CT or MRI, and lower sensitivity than CT for lung metastases.

The effectiveness of therapy can be monintored using FDG PET [44]. Resolution of uptake is seen with a complete response, reduced uptake with a partial response, and persistent uptake with no response. The accuracy of FDG PET is high for detecting recurrence, and posttherapy changes can be differentiated from residual tumor. Chemotherapy responders can be differentiated from nonresponders within a few cycles of chemotherapy.

Pancreatic carcinoma

Although early diagnosis and resection can make pancreatic cancer potentially curative, it is unresectable in most patients at the time of diagnosis. The sensitivity of FDG PET for primary tumor detection is greater than 90% [45], and the technique is reported to have good accuracy for differentiating benign from malignant disease; however, pancreatitis can produce false-positive studies and hyperglycemia can result in false negatives [46].

Anatomical imaging is required for T and N staging. The main role of FDG PET is in the detection of liver and distant metastases (M staging). Overall accuracy is approximately 83% for PET and 63% for CT [47]. Management can be altered by FDG PET in 45% of patients.

For detecting recurrent disease, FDG PET is better than other imaging modalities and can differentiate postoperative changes from recurrence. Its major impact is in the identification of recurrent nodal or distant metastatic disease. Positron emission tomography can clarify uncertain regions seen on CT, detect new hepatic lesions, and evaluate patients

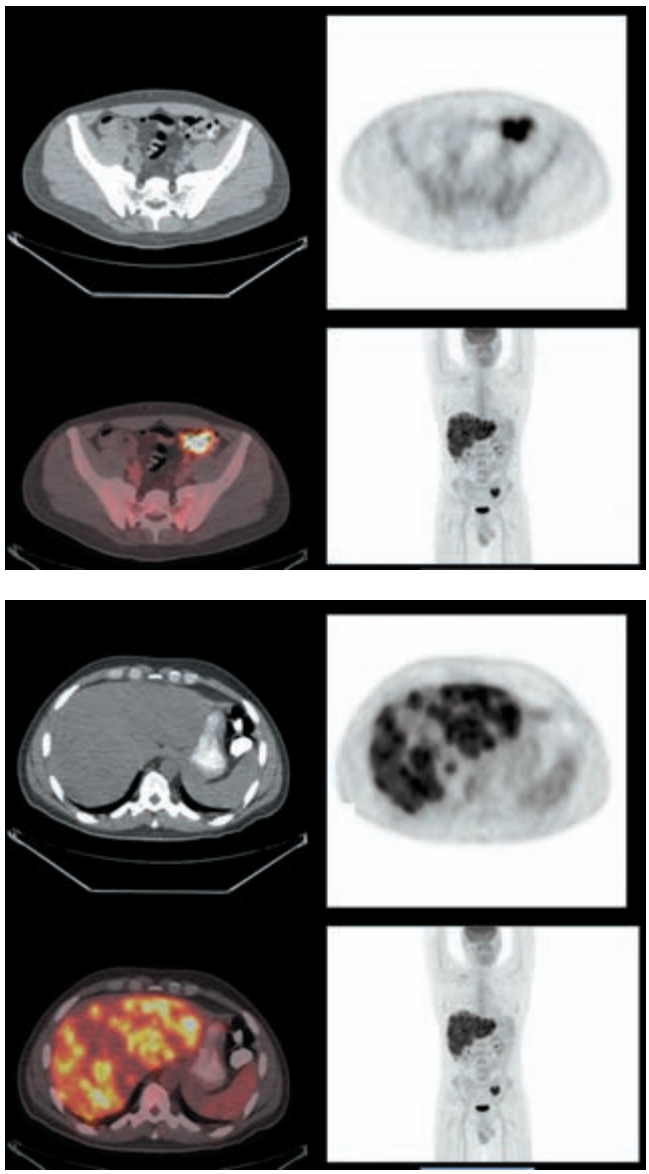

Figure 134.12 Fluorine 18-labeled fluorodeoxyglucose ([^{18}F]FDG) positron emission tomography (PET) of metastatic colon cancer: newly diagnosed adenocarcinoma of sigmoid colon. **(a)** Whole-body MIPS view **(lower right)** shows the primary cancer in the left lower quadrant and extensive metastases to the liver. There is normal bladder clearance. Transverse cross-sectional FDG PET slice **(upper right)** shows intense FDG uptake in the primary malignancy that corresponds to the CT lesion **(upper left)** and fused CT and FDG images **(lower left)**. **(b)** Multiple regions of uptake in the liver consistent with metastases.

with rising serum tumor markers but negative findings on conventional imaging. The absence of FDG uptake 1 month following chemotherapy is an indicator of improved survival.

Gastrointestinal stromal tumors

Thirty percent of these rare mesenchymal gastrointestinal tract tumors are malignant and 70% are benign. The malignant tumors tend to recur and metastasize to the liver and peritoneum, less commonly to the lungs, pleura, retroperitoneum, bone, and subcutaneous tissue. These tumors are generally resistant to chemotherapy and radiation therapy. However, many patients have a dramatic response to the tyrosine kinase inhibitor, imatinib mesylate (Gleevac, Novartis).

Both CT and FDG PET have high sensitivity and specificity for primary tumor detection, greater than 90%. In approximately 25% of patients, FDG PET can detect a good response to therapy earlier than CT [48]. In 5% of patients, CT detects the response first. Response to therapy is correctly characterized by FDG PET in 95% of patients at 1 month, and in 100% of patients at 3 and 6 months.

[^{14}C]urea breath test for *Helicobacter pylori* infection

Although the initial diagnosis of *Helicobacter pylori* infection is usually made by gastric biopsy, this approach is not practical for routinely evaluating response to antibiotic therapy. Also, serological markers fall too slowly to be diagnostically helpful in determining the effectiveness of therapy. The [^{14}C]urea breath test is accurate for this purpose. The test is noninvasive, inexpensive, relatively simple to perform, and generally available.

In the presence of the bacterial enzyme urease, orally administered urea is hydrolyzed to carbon dioxide and ammonia. The ^{14}C radioactive beta particle emitter is detected in the breath as labeled CO_2. The test has high accuracy. False-negative results may occur because of recent use of antibiotics or bismuth-containing medications. False-positive results occur in patients with achlorhydria, contamination with oral urease-containg bacteria, and colonization with another *Helicobacter* species.

Since the introduction of the newer imaging modalities, including ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI), diagnostic angiography has been used less frequently in the evaluation of gastrointestinal (GI) disease. Angiography is currently used to establish a specific diagnosis of mesenteric vascular disease, localize GI bleeding, evaluate portal hypertension, assess tumor extension, demonstrate traumatic arterial injury, and obtain the necessary vascular information before percutaneous or surgical intervention. This chapter reviews the vascular anatomy as well as the techniques and role of angiography in the diagnosis and treatment of GI disease.

Technical considerations

Intraarterial digital subtraction angiography (DSA) is used in GI angiography. DSA requires a smaller amount of dilute contrast medium, causes less discomfort to patients, and reduces the risks of renal toxicity and fluid overload. DSA images may be viewed on a video monitor during and after injection of iodinated contrast material.

Two types of iodinated contrast material have been used for angiography: the conventional high osmolar (ionic) contrast agent has been replaced by the low osmolar (nonionic) or isosmolar (iodixanol, Visipaque, GE Healthcare, Princeton, NJ, USA) contrast agent. The nonionic contrast agents are more expensive but cause less pain and burning sensation. Patients with a history of contrast media allergy and renal failure will benefit from the use of low osmolar contrast media [1–3].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Carbon dioxide (CO_2) gas is used as an alternative contrast agent in both the arterial and venous circulations. CO_2 is approximately 20 times more soluble than air, allowing intravascular injection of the gas without causing clinically significant gas embolism. CO_2 angiography is useful for patients with a history of contrast allergy or renal failure [4]. CO_2 can be used as a contrast agent for visualization of the abdominal aorta and renal, mesenteric, and peripheral arteries. CO_2 is used as a contrast agent for the diagnosis of GI bleeding, and traumatic hepatic and splenic bleeding. Because of the buoyancy of the gas, CO_2 is useful in visualizing the origins of the celiac and superior mesenteric arteries that arise from the ventral surface of the abdominal aorta. CO_2 is a safe contrast agent in the venous circulation. An injection of 30–50 mL of the gas into a peripheral or central vein causes no significant changes in vital signs. Because of its low viscosity, CO_2 is the preferred contrast agent for wedged hepatic venography to demonstrate the portal vein. CO_2 can also be used as a contrast agent for splenoportography [5,6]. CO_2 is also used as a contrast agent to guide a variety of vascular interventions.

Percutaneous catheterization

Gastrointestinal angiography is performed using the technique described by Seldinger in 1953 [7]. The arteries used for catheterization of the visceral arteries are the femoral, axillary, and brachial arteries. Of these, the femoral approach is preferable. When the needle is introduced into the artery, the guidewire is inserted through the needle into the abdominal aorta and a diagnostic catheter is introduced over the guidewire. The technique used for femoral vein catheterization is similar to that used for arterial introduction. The guidewire is inserted into the inferior vena cava (IVC) and the catheter is advanced over the guidewire. If thrombosis has occurred in the femoral veins or IVC, the catheter is introduced by way of an antecubital, brachial, or jugular vein.

General angiographic approach

Gastrointestinal angiography can be performed as an outpatient procedure. On the day of the procedure, the patient is allowed to take fluids by mouth. Patients usually receive conscious sedation with a narcotic analgesic (fentanyl) and a benzodiazepine central nervous system depressant (midazolam) immediately before and during the procedure. For the evaluation of mesenteric ischemia and median arcuate ligament compression, lateral aortography is performed in both full inspiration and expiration. Otherwise, visceral angiography begins with catheterization of the celiac and superior mesenteric arteries. Selective catheterization of the branches of the visceral arteries is performed as needed: splenic, dorsal pancreatic, and gastroduodenal arterial catheterization for evaluation of pancreatic disease, left gastric and gastroduodenal arterial catheterization for gastric and duodenal bleeding, superior mesenteric branch catheterization for small bowel and right-sided colonic bleeding, and inferior mesenteric artery catheterization for left-sided colonic and rectosigmoidal bleeding.

Visualization of the portal venous system is essential in angiographic study for evaluating intraabdominal masses, vascular diseases, and portal hypertension. The presence or absence of a venous abnormality plays an important role in determining whether the arterial abnormality is neoplastic or arteriosclerotic in nature. Arterial involvement by a neoplasm is usually associated with narrowing or occlusion of the adjacent vein. Visualization of the portal vein (indirect portography or arterial portography) requires the injection of a large volume of contrast medium into the superior mesenteric or splenic artery. Portal vein visualization can be enhanced by the intraarterial injection of a vasodilator (nitroglycerin 150 μg) before the injection of contrast medium.

Under normal conditions, puncture site hemostasis can be achieved with manual compression for 5–10 min following GI angiography. No pressure dressing is required. The patient may resume a normal diet after the procedure and ambulate after 4 h of bed rest.

Transhepatic portal vein catheterization

The indications for percutaneous transhepatic portal vein catheterization include evaluation of portal hemodynamics with manometry; venous sampling to localize islet cell tumor; coronary vein embolization for control of variceal bleeding; portal vein embolization prior to hepatic resection [8]; and recanalization of stenotic or occluded portal vein [9]. Ultrasound, CT, or magnetic resonance angiography (MRA) is used to verify portal vein patency prior to the procedure. The venous phase of a celiac or superior mesenteric angiogram is also useful in visualizing the portal vein. Wedged hepatic venography with CO_2 may be performed from the jugular or femoral vein to visualize the portal vein. CO_2 (20–30 mL) may be injected into the liver parenchyma using a 22G needle to fill the portal vein. After the procedure has been completed, the catheter track is sealed near the hepatic capsule with a gelatin sponge or coil to arrest bleeding from the puncture site.

Transjugular portal vein catheterization

The transjugular approach to the portal venous system is commonly used to create a transjugular intrahepatic portosystemic shunt (TIPS) [10,11]. The right or left internal jugular vein is punctured under US guidance. A 10Fr vascular sheath is advanced into the right atrium. A 16G Colapinto-type needle is used to puncture the right portal vein near the portal vein bifurcation under fluoroscopic control. When the portal vein is entered, a guidewire is introduced into the portal vein. Over the guidewire a 5Fr catheter is advanced into the portal vein and manometry is performed. A splenoportogram is performed to demonstrate portal vein anatomy and portosystemic collateral veins. For a TIPS procedure, the parenchymal tract is dilated with an 8-mm angioplasty balloon catheter and covered with 10-mm metallic stents such as Wallstent or covered stents such as VIATORR.

Balloon occlusion hepatic venography

The balloon occlusion method is useful in hepatic venography, facilitating measurement of the wedged hepatic venous pressure. Injection of contrast medium (4–5 mL/s for a total volume of 10–20 mL) or CO_2 (30–50 mL) into the hepatic vein distal to balloon occlusion results in visualization of the portal vein [12]. When the portal vein is not seen after either wedged hepatic or balloon occlusion venography, CO_2 (15–20 mL) is injected into the liver parenchyma using a 21G needle, and digital subtraction venography is performed to visualize the portal vein.

Splenoportography

Since the advent of the imaging modalities and the development of indirect portography (arterial portography), splenoportography is rarely performed. CO_2 is a useful contrast agent for splenoportography. Because of its low viscosity, the gas can be injected using a 22G or 25G needle. Because of the relative safety of the small needle and the lack of nephrotoxicity of CO_2, CO_2 splenoportography is useful in pediatric patients [5,13].

Risks and contraindications

The overall complication rates of transfemoral and transaxillary angiography are 1.73% and 3.29%, respectively [14]. The complications of transfemoral angiography include puncture-site complications, complications related to catheter manipulation, contrast material reactions, contrast material toxicity (renal failure), and systemic complications (cardiac and neurological). Brachial nerve injury is the most serious complication of transaxillary arterial catheterization. Nerve injury is

less likely to occur with a brachial artery puncture because the brachial plexus is not as close to the brachial artery as it is to the axillary artery. The use of intraarterial nitroglycerin and calcium-channel blocking drugs is helpful in preventing arterial spasm. Mortality related to angiographic procedures other than reactions to contrast agents is extremely rare.

The overall mortality associated with the intravenous use of ionic contrast agents is 1 in 40 000 [15]. The risk factors involved in the use of contrast material are renal failure, a history of previous reactions (major and minor), and allergic diathesis. Before the administration of contrast medium for angiography, risk factors for contrast nephropathy should be identified. These include preexisting renal insufficiency, diabetes mellitus, intravascular volume depletion, congestive heart failure, repeat contrast procedures, and multiple myeloma [16]. Recommendations for prevention of contrast nephropathy include use of alternative contrast such as CO_2, discontinuation of potential nephrotoxic agents 48–72 h before the procedure, adequate hydration before and after the procedure, use of low-osmolar or isosmolar contrast material, and use of minimal volume of contrast material. Pretreatment with prednisone 50 mg at 13, 7, and 1 h before contrast administration has been advocated to prevent reaction to contrast agents for patients with a history of hypersensitivity to iodinated contrast medium. Before the procedure, Benadryl 50 mg is administered. For emergency cases, hydrocortisone 100 mg is administered intravenously before the procedure.

There are no absolute contraindications to GI angiography. Relative contraindications include severe coagulopathy, recent myocardial infarction, congestive heart failure, renal failure, and pregnancy. Patients undergoing brachial or axillary artery puncture or a percutaneous transhepatic procedure are at increased risk for hemorrhagic complications in the presence of coagulopathy or hypertension. Depending on the urgency and nature of the procedure, coagulopathy should be reversed with appropriate treatment. Prothrombin time should be less than 18 s for femoral artery puncture and less than 13 s for brachial artery puncture. Platelets should be greater than 50 000/mL. In heparinized patients, heparin should be discontinued at least 2 h before the arterial puncture. In patients on warfarin, the warfarin should be stopped several days before any arterial puncture. If urgent GI angiography is needed, the patient should be treated with fresh-frozen plasma and vitamin K 25–50 mg i.m. Gastrointestinal angiography cannot be performed if the patient is unable to lie flat on the bed.

Vascular anatomy of the abdominal viscera

A thorough knowledge of vascular anatomy of the abdominal viscera is essential in performing and interpreting an angiogram and in planning therapeutic intervention for GI disease.

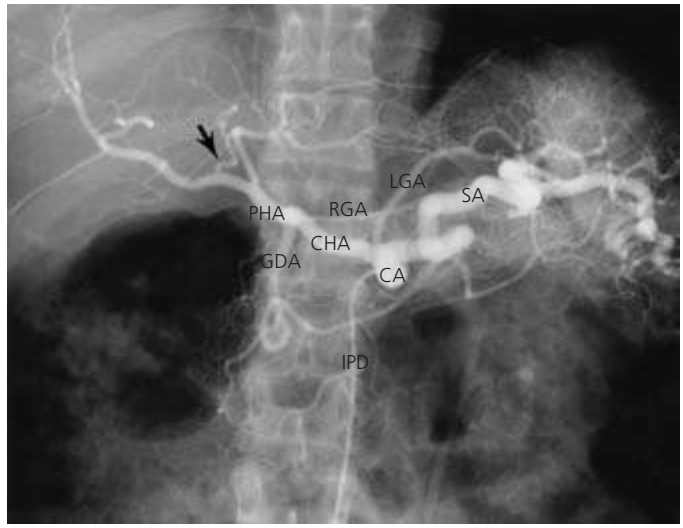
Arterial vasculature

The abdominal viscera receive their blood supply from the celiac, superior, and inferior mesenteric arteries. The superior mesenteric artery arises from the ventral aspect of the abdominal aorta 1–2 cm below the celiac artery and above the renal artery. It courses anterior to the third portion of the duodenum and the left renal vein into the mesentery. The celiac artery gives off the left gastric, splenic, and common hepatic arteries (Fig. 135.1). Occasionally, the inferior phrenic or dorsal pancreatic artery originates from the celiac axis. The inferior phrenic artery may arise from the left gastric artery or renal artery, or directly from the aorta. One or more branches of the celiac artery may originate from sources other than the celiac axis: the left gastric artery from the aorta, the splenic artery from the superior mesenteric artery, and the hepatic artery from the aorta, superior mesenteric artery, gastroduodenal artery, or left gastric artery.

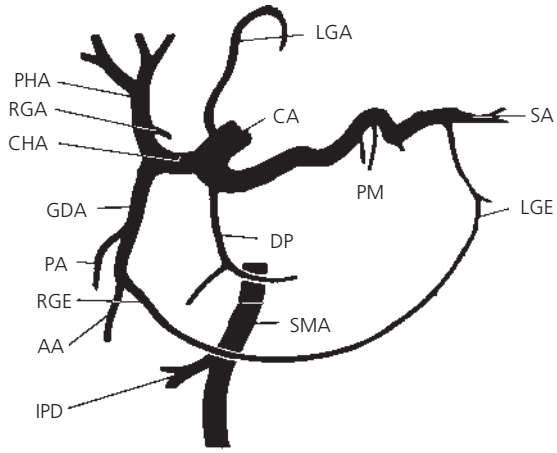
The common hepatic artery divides into the proper hepatic and gastroduodenal arteries. The proper hepatic artery ascends in the hepatoduodenal ligament for a variable distance and divides into a right and a left hepatic artery. The right hepatic artery usually courses behind the common hepatic duct and divides into an anterior and posterior segmental artery. Each of the segmental arteries gives off arterial branches to the superior and inferior subsegments of the liver. The left hepatic artery divides into a medial segmental (middle hepatic) and a lateral segmental artery. Each segmental artery gives rise to superior and inferior subsegmental branches. The middle hepatic artery may arise from a right hepatic, a left hepatic, or a proper hepatic artery. The proper hepatic artery also gives off arterial branches to the bile duct (peribiliary artery), the portal vein (vasa vasorum), and the subcapsular branches. These nonparenchymal branches may provide collateral circulation to the liver in hepatic arterial occlusion distal to the gastroduodenal artery.

In about half of cases, one or more branches of the hepatic artery arise from sources other than the celiac/hepatic artery. Two types of aberrant hepatic artery may occur: replaced (the origin of the artery is "replaced" and the aberrant artery serves as a substitute) or accessory (additive to the celiac/hepatic artery). According to Michels' dissection of 200 cadavers [17], aberrant right hepatic arteries occur in 26% of patients (18% replaced, 8% accessory), most frequently originating from the superior mesenteric artery (17%); aberrant left hepatic arteries occur in 27% of patients (15.5% replaced, 11.5% accessory), most frequently from the left gastric artery (13%).

The gastroduodenal artery usually originates from the common hepatic artery. In 25% of the population, it may have an aberrant origin. The three main branches originating from the gastroduodenal artery are the posterior superior pancreaticoduodenal (posterior arcade), anterior superior pancreaticoduodenal (anterior arcade), and right gastroepiploic arteries. The posterior and anterior arcade arteries join



(a)



(b)

Figure 135.1 Normal celiac trunk. **(a)** Celiac arteriogram showing standard arterial anatomy. The left gastric (LGA), splenic (SA), and common hepatic (CHA) arteries arise from the celiac trunk (CA). The proper hepatic artery (PHA) divides into the right and left hepatic arteries. The middle hepatic artery (arrow) arises from the right hepatic artery. The right gastric artery (RGA) arises from the PHA. **(b)** Line drawing of branches of the celiac trunk. DP, dorsal pancreatic artery; PM, pancreatica magna artery; LGE, left gastroepiploic; PA, posterior arcade; AA, anterior arcade; RGE, right gastroepiploic; IPD, inferior pancreaticoduodenal; SMA, superior mesenteric artery; GDA, gastroduodenal artery.

inferomedially and anastomose with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The gastroduodenal artery supplies arterial blood to the stomach, duodenum, pancreas, and bile duct. In the presence of a celiac artery occlusion, the pancreaticoduodenal arcade arteries function as the major collateral pathway to the liver from the superior mesenteric artery. Normally, the gastroduodenal blood flows away from the liver, but with stenosis or occlusion in the celiac or common hepatic artery the blood flow is reversed. Recognition of flow reversal in the gastroduodenal artery is important in planning resection of pancreatic head tumors, for placement of a hepatic artery infusion catheter for chemotherapy, and for intraarterial stimulation with calcium or secretin for the localization of insulinoma or gastrinoma respectively.

The superior mesenteric artery supplies the pancreas, duodenum, small intestine, cecum, ascending colon, and the proximal half of the transverse colon. The inferior pancreaticoduodenal and occasionally the dorsal pancreatic arteries originate from the proximal portion of the superior mesenteric artery. The other branches of the superior mesenteric artery are the middle colic, jejunal, ileal, right colic, and ileocolic arteries (Fig. 135.2). A true right colic artery is an inconstant branch (present in 13% of people), and the ascending colon often receives its blood supply from a paracolic arcade fed from the middle and ileocolic arteries [18]. However, Michels asserted that any branch proximal to the paracolic arcade that supplies the ascending colon is a right colic artery [19]. With this definition, the right colic artery arises from the superior mesenteric artery in 38%, from a common right colic/middle colic trunk in 52%, and from an ileocolic/right colic trunk in 8% of individuals. The right colic artery is absent in 2% and an accessory right colic artery is present in 8% of individuals.

The inferior mesenteric artery arises from the anterolateral aspect of the aorta near the level of the L3–4 interspace, and courses caudally and to the left for up to 5 cm before giving off the left colic artery (see Fig. 135.2). The ascending branch of the left colic artery supplies the descending colon and a variable amount of the splenic flexure. The inferior mesenteric artery gives off several additional branches to the descending and sigmoid colon before terminating in the superior hemorrhoidal artery. The inferior mesenteric artery communicates through the left colic/middle colic anastomosis to the superior mesenteric artery. It also communicates through the superior hemorrhoidal/middle and inferior hemorrhoidal arterial anastomoses to the internal iliac artery. They function as collaterals in mesenteric arterial or distal aortic occlusion.

Portal venous system

The portal vein is formed by the junction of the splenic and superior mesenteric veins behind the head of the pancreas (Fig. 135.3) and ascends toward the hepatic hilus in the hepatoduodenal ligament, dorsal and to the left of the bile duct, and to the right of the hepatic artery. The portal vein is joined by the left gastric, right gastric, posterior superior pancreaticoduodenal, and cystic veins. These tributaries provide the

The inferior mesenteric artery (IMA) gives off the left colic (LCA), sigmoidal (SA), and superior hemorrhoidal (SHA) arteries. The middle colic (MCA) branch of the superior mesenteric artery anastomoses with the left colic branch of the inferior mesenteric artery via the marginal artery of Drummond (arrowheads). Opacification of the middle colic artery is due to forceful injection of contrast medium into the inferior mesenteric artery. **(b)** Line drawing of the arterial supply to the colon. RCA, right colic artery; ICA, ileocolic artery; AOR, arc of Riolan; MCA, middle colic artery; SMA, superior mesenteric artery; LCA, left colic artery; IMA, inferior mesenteric artery; SHA, superior hemorrhoidal artery; SA, sigmoidal artery; AMC, accessory middle colic artery; MAR, marginal artery of Drummond.

portosystemic collaterals in patients with cirrhosis and portal hypertension. The right branch of the portal vein divides into the anterior and posterior segmental branches. The left portal branch divides into the superior and inferior subsegmental branches after giving off branches to the caudate and quadrate lobes. The umbilical vein joins the left portal vein at its bifurcation into the subsegmental branches. It is normally obliterated but may be recanalized in the presence of portal hypertension. The inferior mesenteric vein joins the splenic vein or, less frequently, the superior mesenteric vein. Portosystemic collaterals develop from the inferior mesenteric vein via the superior hemorrhoidal vein to the branches of the internal iliac vein and via the retroperitoneal vein to the IVC.

The portal venous system receives venous blood from the GI tract, the pancreas, the spleen, the gallbladder, and the omentum. Normally the portal vein blood flows toward the liver (hepatopetal). Reversal in flow (hepatofugal) in any tributaries of the portal venous system indicates the presence of portal hypertension; visualization of the coronary vein or inferior mesenteric vein in the portal venous phase of a superior mesenteric angiogram indicates reversal in flow of these veins functioning as portosystemic collaterals. Reversal of portal vein flow may be partial or complete. Partial reversal of portal flow may occur in the extrahepatic or intrahepatic branches of the portal venous system. Complete reversal of intrahepatic portal flow may occur in some patients with severe cirrhosis, hepatic vein obstruction, surgical portosystemic shunts, and TIPS. In such cases, the portal vein is the principal outflow conduit of the liver, and the hepatic artery blood leaves the liver through the portal vein. Blood flow direction in the intrahepatic and extrahepatic portal veins can be assessed by Doppler US, transhepatic portal vein catheterization, superior mesenteric and celiac angiography, and wedged hepatic venography. When the main portosystemic collateral develops from the umbilical vein, the extrahepatic portal blood flow can be hepatopetal in the presence of hepatofugal intrahepatic portal flow.

CT, US, and magnetic resonance venography (MRV) can be used to accurately visualize the portal venous system [20–22]. Portal and hepatic venous imaging can be obtained immediately following MRA with gadolinium enhancement for arterial examination (see Fig. 135.3). The method is useful when a TIPS procedure, liver transplantation, or resection of intraabdominal tumors is contemplated. CO_2 wedged hepatic venography is used to visualize the portal vein during TIPS or transjugular liver biopsy, or when hepatic vein outflow obstruction is suspected (Fig. 135.4).

Hepatic veins

The hepatic veins begin in the center of the hepatic lobules as intralobular veins. These veins join together to form sub-

Venous anastomoses are seen between the short gastric and left gastric veins, and between the left and right gastroepiploic veins.

lobular veins. The hepatic veins are intersegmental or interlobar in course: the right hepatic vein lies in the intersegmental fissure of the right hepatic lobe, dividing it into the anterior and posterior segments; the middle hepatic vein lies in the

Figure 135.4 CO_2 wedged hepatic venogram: 30 mL of CO_2 was injected into the 5Fr end-hole catheter wedged in a branch of the right hepatic vein (arrow). CO_2 filled the right hepatic vein (hv) and both intrahepatic and extrahepatic portal vein (pv).

interlobar fissure; and the left hepatic vein lies between the medial and lateral segments of the left hepatic lobe. The hepatic veins converge posteriorly and run near the hepatic capsule before emptying into the IVC (see Fig. 135.3).

The accessory hepatic veins, which originate from the right hepatic and caudate lobes, are small and empty into the IVC between the main hepatic and renal veins. They function as collaterals in hepatic vein occlusion and occlusion of the hepatic portion of the IVC. Diagnostic imaging of the hepatic veins may be obtained by spiral CT [23], US [24], or MRA [25].

Arterial disease

Arteriography remains the gold standard in the diagnosis of visceral arterial disease. It can provide a specific diagnosis, and the necessary information on the vascular anatomy and arterial hemodynamics before endovascular intervention or surgery.

Acute mesenteric ischemia

Early angiography in patients with suspected acute mesenteric ischemia permits early differentiation between occlusive (thrombotic or embolic) and nonocclusive types that allows appropriate treatment [26] (Fig. 135.5). In clinical practice, contrast-enhanced CT is frequently performed in patients with acute abdomen. It can demonstrate the signs of acute mesenteric ischemia, mesenteric arterial or venous thrombosis, intramural gas, portal vein gas, and focal lack of bowel-wall enhancement [27]. Angiography is superior to CT for identifying

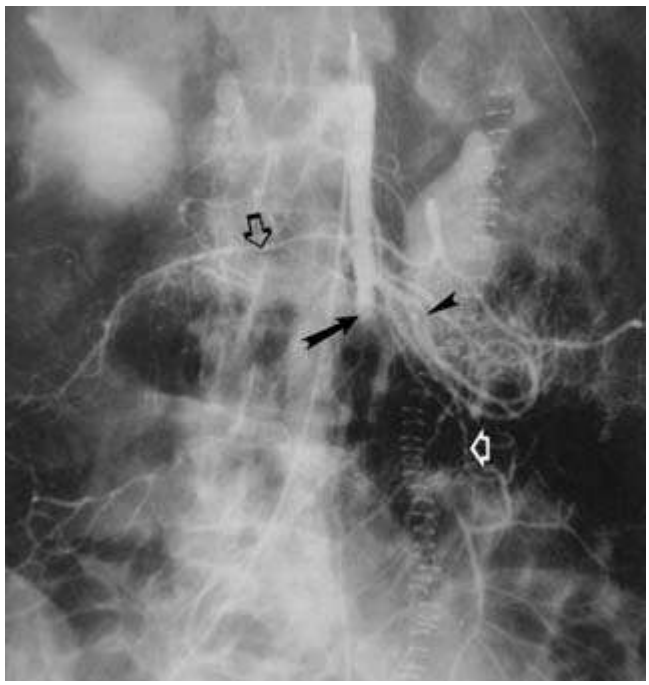

Figure 135.5 Superior mesenteric artery embolus. Superior mesenteric angiogram in an elderly woman with atrial fibrillation and abdominal pain. There is an embolus in the superior mesenteric artery (black arrow) distal to the second jejunal artery. A small embolus is seen in the jejunal artery (arrowhead). The distal mesenteric branches reconstitute through collaterals from the middle colic (open black arrow) and jejunal arteries (open white arrow).

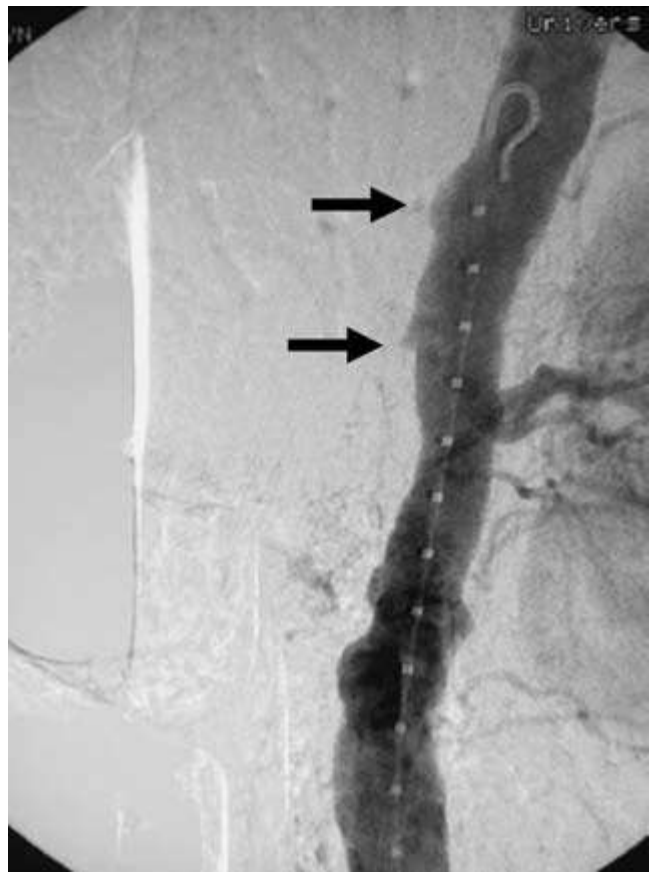

Figure 135.6 Celiac and superior mesenteric artery occlusion. Lateral aortogram in a 66-year-old woman with abdominal pain and 9-kg weight loss. Both the celiac and the superior mesenteric arteries are occluded at the origins (arrows). There is poor collateral circulation into the mesenteric arteries. The inferior mesenteric artery is also occluded. Computed tomography showed ileus, pneumatosis intestinalis, and gas in the portal. At surgery diffuse bowel infarction was found.

mesenteric artery branch occlusions or mesenteric artery spasm in patients with nonocclusive mesenteric ischemia.

After percutaneous catheterization of the femoral artery, a lateral aortogram is performed to demonstrate the origin of the celiac and superior mesenteric arteries. Occlusion of the celiac and superior mesenteric arteries with poor collateral circulation indicates acute occlusive mesenteric ischemia, and urgent surgery should be performed (Fig. 135.6). When colonic ischemia is suspected, an inferior mesenteric arteriogram is performed. When the celiac, superior and inferior mesenteric arteries are occluded, the collateral blood supply to these arteries comes primarily from the pelvic branches of the internal iliac arteries through the inferior and middle hemorrhoidal/superior hemorrhoidal arterial anastomoses. The collaterals to the superior hemorrhoidal artery and branches of the superior mesenteric artery can be demonstrated by injecting contrast medium into the distal abdominal aorta or internal iliac arteries.

Acute mesenteric ischemia may be occlusive or nonocclusive in type. Occlusive lesions include embolism, atherosclerotic plaques, aortic dissection, neoplasms, and vasculitis. Arteriography can accurately identify the level of occlusion and evaluate collateral circulation. In superior mesenteric artery embolism, the occlusion may be proximal or distal to the middle colic artery. Arteriosclerosis usually involves the origin of the superior mesenteric artery, allowing collateral development through the left colic and middle colic anastomosis, and through the posterior and anterior pancreaticoduodenal arcades and the gastroduodenal artery. Inferior mesenteric artery stenosis or occlusion causes collaterals to develop through the middle colic/left colic anastomosis. If both superior mesenteric and inferior mesenteric arteries are occluded, collaterals develop from the middle and inferior hemorrhoidal arteries of the internal iliac arteries.

Nonocclusive mesenteric ischemia is caused by severe and prolonged intestinal vasoconstriction from various causes, including systemic shock usually secondary to reduced cardiac output, cocaine ingestion, ergot poisoning, digoxin toxicity, and use of α-adrenergic agonists. The typical angiographic findings include diffuse mesenteric arterial constriction, slowing of mesenteric arterial flow, and decreased intestinal mucosal staining. When mesenteric vasospasm is identified, intraarterial infusion of papaverine is used to relieve mesenteric vasoconstriction. In patients with occlusive mesenteric ischemia and positive peritoneal signs, the infusion of papaver-

ine may be continued before, during and even after surgical intervention.

Colonic ischemia

Ischemic colitis is the most common form of mesenteric ischemia, frequently affecting the elderly. In most patients, colonic ischemia is transient and resolves without sequelae. Only some patients develop bowel necrosis or persistent ischemia that results in a stricture. The common causes of colonic ischemia are ligation of the inferior mesenteric artery during surgery [28] and low flow after cardiopulmonary bypass, myocardial ischemia, or sepsis. The other etiological factors include idiopathic, shock, colonic obstruction, digitalis, cocaine abuse, mesenteric artery thrombosis or embolism, vasculitis, radiation injury, and hematological disorders.

CT is a useful tool for the diagnosis of ischemic colitis. The CT findings for colonic ischemia include mural thickening, lumenal narrowing, polypoid defect, decreased mucosal perfusion, pneumatosis, and pneumoperitoneum. Colonoscopy is the most sensitive examination for colonic ischemia and can demonstrate the mucosal changes. Biopsies can be obtained if necessary. The angiographic findings may be nonspecific. In the early stage, the mesenteric arteries are constricted and blood flow is slowed with decreased parenchymal vascularity. In the late stage, the colon may appear hypervascular with prominent intramural arteries and increased accumulation of contrast material in the wall of the bowel. Treatment depends on the severity of colonic ischemia and includes medical therapy and surgical intervention.

Intestinal angina

Intestinal angina, also called chronic mesenteric ischemia, is characterized clinically by a combination of postprandial abdominal pain and weight loss. At least two of the three splanchnic arteries (celiac artery, superior and inferior mesenteric arteries) usually have significant occlusive disease before the syndrome of intestinal angina occurs [29]. Duplex US with spectral analysis is used for screening patients thought to have chronic mesenteric artery occlusive disease. Gadolinium-enhanced three-dimensional MRA is sensitive in assessing patency of the origins of the celiac and superior mesenteric arteries, but its resolution is inadequate for evaluation of mesenteric artery branch stenosis. Angiography provides information regarding the hemodynamic significance of mesenteric artery stenoses and the circulation distal to the stenosis necessary for endolumenal intervention (usually angioplasty and stent placement) [30] or surgical revascularization. Demonstration of collateral circulation distal to a superior mesenteric artery stenosis indicates that the stenosis is hemodynamically significant.

Celiac axis compression

Celiac axis compression syndrome (median arcuate compression syndrome) is controversial as a cause of abdominal pain. The celiac axis may be narrowed or, in severe cases, occluded by the median arcuate ligament of the diaphragm. Surgical correction of the lesion by decompression or reconstruction of the vessel usually ameliorates the pain. Because balloon dilation is not helpful in eliminating the compression, stent placement is required [31]. Celiac axis stenosis is frequently an incidental finding, with a reported prevalence of 12%–49% [32,33]. A lateral aortogram demonstrates a concave impression on the cranial aspect of the celiac axis. The compression is usually accentuated during deep expiration. A superior mesenteric angiogram will demonstrate collateral circulation to the hepatic and splenic arteries through the gastroduodenal and pancreatic arcade arteries from the superior mesenteric artery.

Superior mesenteric artery syndrome

The superior mesenteric artery can compress the third portion of the duodenum, causing duodenal obstruction. Such compression is most often found in patients with chronic immobilization with weight loss and a body cast [34,35]. The upper GI barium examination shows a characteristic oblique indentation toward the right lower quadrant on the third portion of the duodenum, corresponding to the course of the superior mesenteric artery. A narrow aortomesenteric angle corresponding to the site of obstruction is usually found on a lateral aortogram.

Vasculitis

The causes of mesenteric vasculitis include Wegener granulomatosis, systemic lupus, polyarteritis nodosa, Henoch–Schönlein purpura, Buerger disease, and giant cell arteritis. Mesenteric vasculitis may cause acute or chronic mesenteric ischemia. The angiographic findings vary with the type of vasculitis. In polyarteritis nodosa, celiac and superior mesenteric angiograms demonstrate occluded small- and medium-sized arteries and microaneurysms (Fig. 135.7). In ergot or digitalis toxicity, the mesenteric artery branches are narrowed or occluded with collaterals. In lupus mesenteric vasculitis, angiography demonstrates diffusely decreased small bowel vascularity. Angiography is the most sensitive method of visualizing microaneurysms. The angiographic examination should include the renal, celiac, and mesenteric arteries.

Splanchnic artery aneurysms

Splanchnic artery aneurysms and pseudoaneurysms are rare and often found incidentally during angiographic studies for other indications. Angiography is usually necessary to identify the exact site of the aneurysm and its relationship to adjacent vascular structures, as well as to plan surgical resection or embolization to prevent catastrophic hemorrhage [36]. Aneurysms occur in virtually all splanchnic arteries.

Splenic artery aneurysms account for 60% of all visceral artery aneurysms [37]. They occur four times more frequently in women than in men and are multiple in 20% of patients.

Figure 135.7 Multiple microaneurysms in polyarteritis nodosa. Arterial phase of a celiac angiogram shows numerous aneurysms involving the hepatic and pancreatic arteries.

Causes include atherosclerosis, medial fibrodysplasia, multiple pregnancies, pancreatitis, portal hypertension, polyarteritis nodosa, Ehlers–Danlos syndrome, and trauma. In portal hypertension, aneurysms tend to occur at the bifurcation of the intrasplenic branches of the splenic artery. Most atherosclerotic splenic artery aneurysms are asymptomatic, and calcified aneurysms less than 2 cm in diameter require no treatment. On the other hand, aneurysms occurring in pregnant women and those associated with pancreatitis require treatment because of their propensity to bleed. Splenic artery aneurysms can be treated with embolization by the transcatheter approach or percutaneous puncture with thrombin injection.

The hepatic artery is the second most common site for splanchnic aneurysms, accounting for 20% of all splanchnic aneurysms [37]. Most hepatic pseudoaneurysms are traumatic in origin and are secondary to blunt or penetrating abdominal trauma, liver biopsy, liver surgery, biliary stent placement, pancreatitis, or placement of a hepatic arterial infusion catheter. Most spontaneous aneurysms occur in the common hepatic or right hepatic artery. Clinical presentations include right upper quadrant pain, hemobilia, GI bleeding, or obstructive jaundice. Rarely hepatic artery aneurysms rupture into the peritoneal cavity, portal vein, or pancreatic pseudocyst. The diagnosis can be made by US, contrast-enhanced CT, MRA, or arteriography. Treatment includes embolization by transcatheter approach or percutaneous puncture with thrombin injection.

Mesenteric aneurysms are arteriosclerotic and may cause GI bleeding or mesenteric ischemia. Celiac axis aneurysms account for 4% of all visceral aneurysms and should be differentiated from pseudocysts when encountered during US or unenhanced CT scanning. A lateral aortogram is necessary to confirm the diagnosis of aneurysms arising from the origins of the celiac and superior mesenteric arteries.

Gastroduodenal and pancreatic arterial aneurysms are associated with pancreatitis and pseudocysts. They may cause GI and intraperitoneal hemorrhage. Aneurysms rarely rupture into the pancreatic duct or a pseudocyst. Contrast-enhanced CT usually differentiates pseudocysts and aneurysms. Angiography is required to delineate the vascular anatomy and the exact origin of the aneurysm before surgical treatment or transcatheter embolotherapy.

Abdominal trauma

Abdominal trauma can be due to penetrating or blunt injuries. The patient with signs of intraabdominal injuries should undergo exploratory laparotomy. Most traumatized patients require radiological studies to assess the extent of the injury. Contrast-enhanced CT should be the first imaging modality for the evaluation of abdominal trauma. Angiography is indicated when CT shows a high-grade injury of solid organs, contrast extravasation, pseudoaneurysm, or vascular injuries.

Venous disease

Occlusion of the portal, mesenteric, splenic, and hepatic veins may be asymptomatic or associated with ascites, hepatic failure, or GI hemorrhage. Contrast-enhanced CT and MRV can diagnose occlusion of the portal and splenic vein by demonstrating intraabdominal varices and aneurysms in the portal venous system [21]. Duplex scanning is useful in the assessment of patency and direction of blood flow of the portal vein and portosystemic shunts [38]. The portal venous phases of the celiac, superior mesenteric, and splenic angiograms are used to evaluate the patency of the splenic, mesenteric, and portal veins. An inferior vena cavogram and hepatic venogram are performed in patients with suspected Budd–Chiari syndrome.

Portal vein occlusion

The pattern of portal vein occlusion usually varies with its etiology [39]. Idiopathic intrahepatic portal vein occlusion (hepatoportal sclerosis) usually occurs in children. Occlusion of the main portal vein is the most common type and is probably of congenital etiology. Thrombosis of the main and superior mesenteric veins may be caused by intraabdominal sepsis. Extensive thrombosis of the portal venous system commonly occurs in patients with hypercoagulable states.

Angiographic findings include large collateral veins originating from the superior mesenteric vein, ascending in the hepatoduodenal ligament in the venous phase of the superior mesenteric angiogram (Fig. 135.8). The collateral vessels reconstitute the patent intrahepatic portal vein. If the intrahepatic portal venous branches are occluded, the collateral

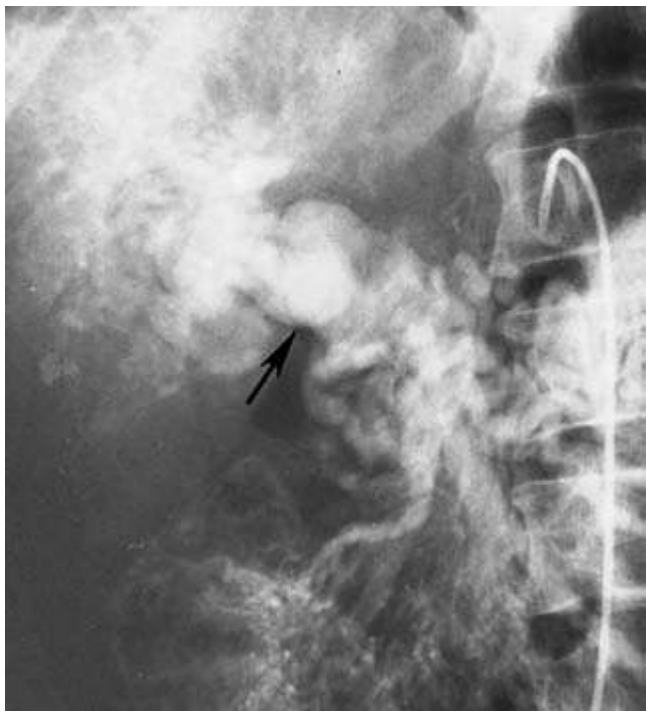

Figure 135.8 Portal vein occlusion. Portal venous phase of a superior mesenteric angiogram (oblique view) demonstrates tortuous venous collaterals (arrow) running along the hepatoduodenal ligament adjacent to the occluded portal vein. The collateral veins reconstitute intrahepatic portal venous branches. From Reuter SR, Redman HC, Cho KJ. Gastroenterology Angiography, 3rd edn. Philadelphia: WB Saunders, 1986:121.

vessels continue to run along the intrahepatic bile ducts, giving the appearance of railroad tracks [40]. In mesenteric vein thrombosis, numerous tiny collateral veins are demonstrated throughout the mesentery without visualization of the superior mesenteric vein in the venous phase of the superior mesenteric angiogram.

The angiographic abnormality of portal vein occlusion due to neoplasms varies with the type of neoplasm. Pancreatic and biliary cancers cause localized narrowing or occlusion of the portal vein without associated tumor vessels. In contrast, portal vein invasion by hepatocellular carcinoma has a characteristic appearance, with abnormal vascular channels coursing within the portal vein branches in the vicinity of the tumors. Arteriovenous shunting is often associated with portal vein invasion by tumors [41].

Splenic vein occlusion

Splenic vein occlusion is usually clinically silent but may cause hypersplenism or gastric variceal bleeding [42,43]. The diagnosis can be made by dynamic CT, duplex US, and three-dimensional contrast MRV. Angiography should be performed when noninvasive studies are inconclusive or when additional vascular information is needed. A celiac or splenic arteriogram is performed for the diagnosis; the angiographic findings include splenoportal collaterals through the short gastric/coronary and gastroepiploic veins, as well as non-opacification of the splenic vein during the venous phase. The treatment of choice for bleeding gastric varices associated with splenic vein occlusion is splenectomy. If surgical intervention is contraindicated, partial splenic artery embolization by transcatheter approach is an effective alternative treatment.

Budd–Chiari syndrome

In Budd–Chiari syndrome, a significant portion of the hepatic venous system is obstructed. CT is usually used as the initial test and may reveal nonuniform contrast enhancement of the liver parenchyma and enlarged caudate lobe. Increased central venous pressure from right heart failure may produce a contrast enhancement pattern similar to that of Budd–Chiari syndrome. MRI is useful in identifying the underlying lesions, such as hepatic and vena caval thrombi, and congenital membrane.

Angiography is the most important procedure for the diagnosis of Budd–Chiari syndrome. Superior mesenteric and celiac angiograms are obtained to vizualize the portal vein and exclude hepatic neoplasms. An inferior vena cavogram is obtained to exclude occlusion of, or membrane in, the hepatic portion of the IVC. Demonstration of hepatic vein patency excludes the diagnosis of Budd–Chiari syndrome. When the hepatic vein is occluded, the catheter is wedged into the occluded hepatic vein, and contrast medium is injected to visualize the collateral channels (Fig. 135.9). If the right hepatic vein cannot be entered, catheterization of the accessory hepatic vein should be performed. If any of the hepatic veins cannot be catheterized, a 22G needle is inserted into the liver parenchyma using the same technique used for percutaneous transhepatic portal vein catheterization. Injection of iodinated contrast medium or CO_2 usually demonstrates hepatic vein occlusion and collateral veins [44].

Percutaneous translumenal angioplasty and stent placement has been used to treat Budd–Chiari syndrome caused by obstruction of the hepatic vein and hepatic segment of the IVC [45,46]. Restenosis or reocclusion occurs frequently at the angioplasty site. Patency of the vein may be improved with use of metallic stents after unsuccessful angioplasty. The transjugular or transhepatic approach is used for angioplasty and stent placement for right hepatic vein occlusion causing Budd–Chiari syndrome [47,48]. The TIPS procedure is used to treat intractable ascites and bleeding varices from hepatic venous occlusive disease and as an effective bridge to transplantation for hepatic failure associated with Budd–Chiari syndrome [49].

Gastrointestinal disease

When evaluating GI disease, angiography is indicated for the diagnosis of vascular disease, visualization of vascular anatomy,

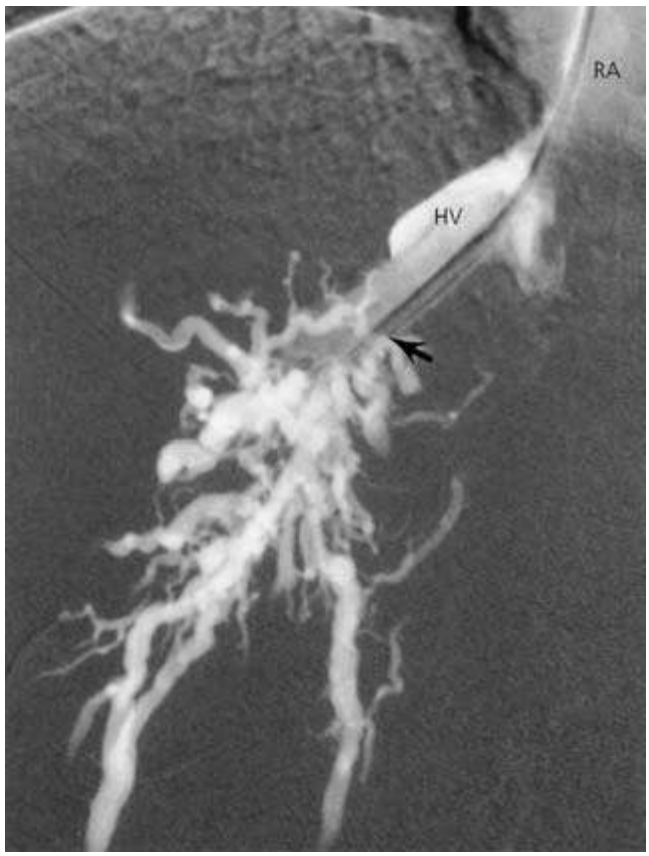

Figure 135.9 Budd–Chiari syndrome. Digital subtraction hepatic venogram was performed with contrast injection into the right hepatic vein (HV), demonstrating numerous collateral veins pathognomonic of hepatic vein occlusion. The arrow indicates the level of hepatic vein occlusion. RA, right atrium.

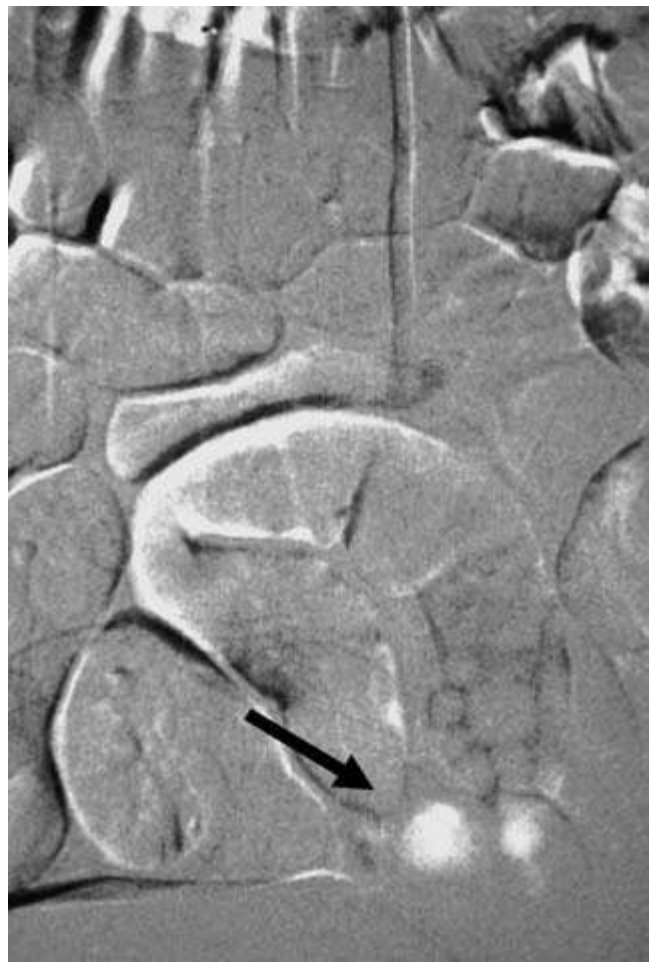

Figure 135.10 Active small bowel bleeding. A superior mesenteric angiogram with CO_2 demonstrates extravasation of the gas into the ileum (arrow). The bleeding was controlled with superselective embolization of the bleeding branch from the superior mesenteric artery.

and diagnosis and treatment of GI bleeding. If active GI bleeding is diagnosed, angiography should be urgently performed for localization of the bleeding site as well as control of the bleeding. The rate of bleeding should be at least 0.5 mL/min to be detected by angiography. Angiography is insensitive in detecting capillary or venous bleeding because of the dilution of the contrast material. Helical CT angiography with intraarterial or intravenous injection of contrast medium is useful in detecting active GI bleeding as well as GI bleeding of obscure origin, and facilitates angiographic localization of the bleeding [50,51]. CO_2 is a sensitive contrast agent in detecting active bleeding that may not be seen with contrast medium (Fig. 135.10). Once the bleeding site has been identified by CO_2, contrast medium is injected for a vascular "roadmap" before superselective catheterization of the bleeding artery for embolotherapy. Angiography is useful in identifying vascular malformations and vascular neoplasms. A catheter may be placed in the mesenteric branch supplying a vascular malformation preoperatively to facilitate intraoperative localization of the lesion.

Upper gastrointestinal bleeding

Endoscopy is the primary procedure for the diagnosis and treatment of upper GI bleeding. If endoscopy has failed to localize or control the bleeding, celiac and superior mesenteric angiograms are obtained with CO_2 and contrast medium. Because of its lower viscosity, CO_2 is a useful contrast agent in detecting GI bleeding (see Fig. 135.10). If a bleeding site is identified, the bleeding artery is selectively catheterized to control the bleeding by embolization [52]. If a bleeding site has not been demonstrated, left gastric and gastroduodenal arteriograms are obtained. If the source of bleeding has still not been identified and nasogastric aspiration reveals dark blood, a catheter may be placed in the left gastric artery for the next 6–12 h. The bleeding may be precipitated by intraarterial administration of heparin, vasodilators, or thrombolytic agents, allowing accurate localization of the bleeding site and prompt treatment [53,54]. Prophylactic embolization (left gastric artery embolization for gastric bleeding and

gastroduodenal artery embolization for duodenal bleeding) is an acceptable alternative when the massive bleeding has ceased at the time of angiography [55].

Angiography is usually not helpful in determining the cause of upper GI hemorrhage. Hemorrhagic gastritis is the most common cause of capillary bleeding and imaging may demonstrate a hypervascular stomach with dilated gastric arteries and increased parenchymal staining. Peptic ulceration is the most common cause of arterial bleeding and usually produces no angiographic abnormality. Gastric bleeding usually arises from the left gastric artery and occasionally from the short gastric, right gastric, or gastroepiploic artery. Duodenal bleeding may originate from the celiac or superior mesenteric artery or from both arteries. Angiographically the arterial bleeding appears as a localized accumulation of contrast material extravasation during the arterial phase of the angiogram. The escaped contrast material persists throughout the venous phase and may outline the mucosa. Selective arterial embolization is an effective means of controlling bleeding from peptic ulceration.

Upper GI endoscopy should be obtained in all patients suspected of bleeding from the biliary tract (hemobilia) and pancreatic duct (hemosuccus pancreaticus). Once bleeding from the ampulla of Vater is documented, angiography is performed to demonstrate the underlying lesion and rarely contrast extravasation into the bile duct. Hemobilia can be treated by embolizing the feeding artery. Bleeding into the pancreatic duct is amenable to selective arterial embolization of the associated arterial lesions. Aortoenteric fistulae rarely cause GI bleeding, and the duodenum is the most common site of fistulae. Biplane aortography may show a false aneurysm at the aortic anastomotic site.

Percutaneous transhepatic coronary vein embolization may be used to treat variceal bleeding when endoscopy is not available or fails to control the bleeding. Variceal embolization may be necessary if the varices continue to fill after creation of TIPS. TIPS is an effective method of controlling variceal bleeding and is currently indicated when the bleeding is unresponsive to endoscopic therapy [56,57]. A transfemoral retrograde approach may be used to obliterate gastric varices. The gastrorenal or splenorenal shunt is cannulated through the renal vein and then occluded with an occlusion balloon catheter before injecting sclerosing agents or glue into the gastric varices.

Lower gastrointestinal bleeding

Once lower GI bleeding is diagnosed, a superior mesenteric angiogram is performed to detect the bleeding from the small intestine and the right side of the colon. If no bleeding site is seen, a celiac arteriogram is obtained because massive gastroduodenal bleeding may present as lower GI bleeding. If a radionuclide scan has localized the bleeding to the left side of colon, inferior mesenteric arteriograms are obtained with coverage from the rectum to the splenic flexure of the colon. Active bleeding shows a localized accumulation of escaped contrast material during the arterial phase of the mesenteric angiogram, which usually persists through the venous phase (Fig. 135.11). CO_2 should be used as a contrast agent for the superior and inferior mesenteric angiograms if contrast angiograms have failed to demonstrate the bleeding site.

Figure 135.11 Superior mesenteric angiogram in an elderly man who developed massive colonic bleeding. Extravasation of contrast medium is seen from the hepatic flexure of the colon (arrow). The bleeding was controlled with embolization of the bleeding branch from the right colic artery (arrowheads).

Selective infusion of vasopressin is usually effective in controlling the bleeding in up to 80% of patients, but the recurrence rate is as high as 50% [58]. Patients with coronary artery disease should not be treated with vasopressin because of the risk for myocardial infarction. Selective embolization is an acceptable alternative when vasopressin is contraindicated. Superselective catheterization and embolization of the bleeding artery can be achieved with use of the 3Fr coaxial catheter system with minimal risk for intestinal necrosis [59–61].

Angiodysplasia

Angiodysplasia may occur in a variety of pathological types: vascular ectasia, arteriovenous malformations, and capillary telangiectasia [62]. Clinical presentation and angiography allow identification of each type of angiodysplasia.

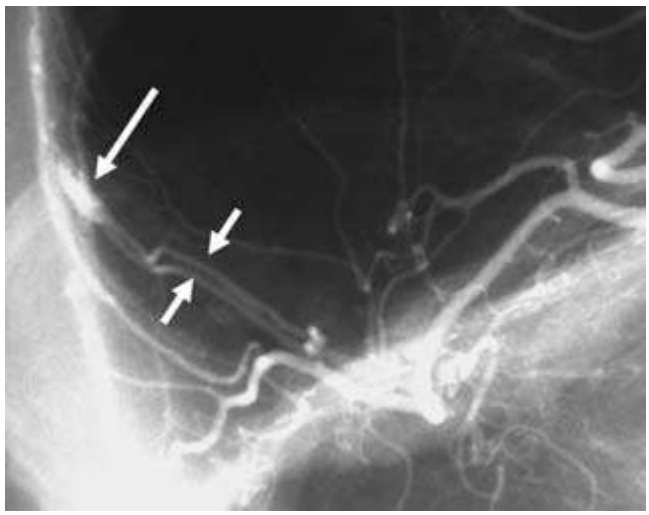

Figure 135.12 Vascular ectasia of the cecum. Superior mesenteric angiogram in a 60-year-old woman with recurrent lower gastrointestinal bleeding. A 1-cm mucosal vascular ectasia is seen on the antimesenteric surface of the cecum (longer arrow). The feeding artery and vein (shorter arrows) are opacified during the arterial phase.

Vascular ectasia usually occurs in the cecum and ascending colon. Most patients are older than 60 years of age. The angiographic findings include a small vascular cluster and blush in the wall of the colon and early dense opacification of the draining vein (Fig. 135.12) [63]. Normal mesenteric angiography is usually accepted for exclusion of vascular ectasia, although data supporting this assumption are not available. Two or more vascular ectasias are frequently present at microscopic examination of the injected specimen, although most patients demonstrate a single vascular lesion at angiography. Endoscopy is superior to angiography in identifying vascular ectasia. If active extravasation is demonstrated, selective arterial embolization is an effective treatment. Arteriovenous malformations are of developmental origin and usually affect people younger than 50 years of age. The angiographic findings include tortuous dilated arteries with early prominent veins. The lesions are frequently found in the small intestine and vary in size. Vascular malformations should be differentiated from vascular tumors, such as leiomyomas.

Capillary telangiectasia may occur in any part of the GI tract and may be associated with hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease). The angiographic findings usually include tiny areas of blush without arteriovenous shunting. Hepatic angiography may demonstrate dilated hepatic arteries and increased hepatic parenchymal staining [64,65].

Meckel diverticulum

Angiography is obtained only when active bleeding occurs. Angiographically, a Meckel diverticulum appears as a short segment of bowel with increased contrast accumulation supplied by an abnormal branch (a remnant of the omphalomesenteric artery) from the superior mesenteric artery [66]. Superselective catheterization of the distal ileal branches of the superior mesenteric artery may be necessary to identify the abnormal artery. Superselective arterial embolization may be performed to control life-threatening GI bleeding from a Meckel diverticulum before surgical resection [67].

Rectal trauma

Inferior mesenteric angiography is performed for localization and treatment of the bleeding from rectal trama. Infusion of vasopressin into the inferior mesenteric artery is effective in controlling the bleeding. If the patient has coronary artery disease or if vasopressin fails, selective embolization is performed with Gelfoam, Ivalon particles, or microcoils [68].

Intestinal varices

Intestinal varices represent varices at an unusual site in patients with cirrhosis and portal hypertension. Contrast-enhanced CT and MRV are used to diagnose intestinal varices. Angiography provides the necessary information about the location and extent of the varices, and the status of the portal venous system. The varices are demonstrated in the portal venous phase of a superior mesenteric angiogram. Percutaneous transhepatic or transjugular portal vein catheterization may be necessary for evaluation of portal hemodynamics and embolization. TIPS is effective in treating stomal or rectal varices unresponsive to conservative treatment [69].

Neoplasms of the small intestine

Leiomyomas

Leiomyomas (GI stromal tumor) is the most common tumor of small bowel. CT is the primary imaging modality for the detection of GI stromal tumors [70]. Angiography is useful in diagnosing small bowel leiomyomas. The tumors are usually hypervascular with abundant tumor vessels and dense blush (Fig. 135.13). The draining vein usually is densely opacified. Angiographic differentiation between benign and malignant tumors is not possible unless venous invasion or metastasis is demonstrated [71]. When active bleeding occurs from the tumor, a radionuclide bleeding scan is performed to localize the bleeding site. Angiography is then performed to localize and control the bleeding. Once the bleeding has been controlled by selective embolization, the tumor should be resected.

Carcinoid tumor

Carcinoid tumors arise from enterochromaffin cells that are present in the GI tract, lung, ovary, pancreas, and other organs. They produce various hormones, including serotonin, histamine, dopamine, and tachykinins. Angiography may be used for diagnosis and staging of carcinoid tumors. The angiographic findings include retraction, kinking, and occlusion

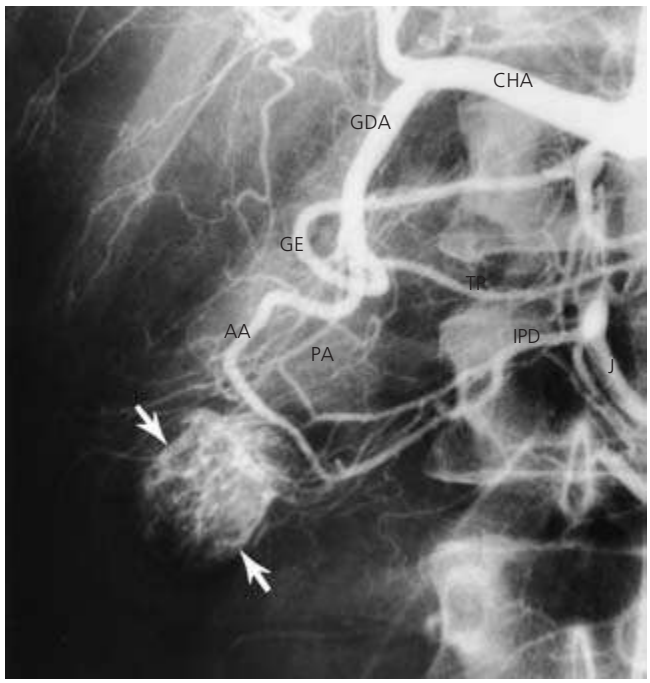

Figure 135.13 Duodenal leiomyoma. Late arterial phase of a gastroduodenal arteriogram in a young woman with upper gastrointestinal hemorrhage. A vascular mass (arrows) in the second portion of the duodenum receives blood supply from the dilated anterior arcade artery (AA). CHA, common hepatic artery; GDA, gastroduodenal artery; GE, gastroepiploic; IPD, inferior pancreaticoduodenal; J, jejunal; PA, posterior arcade artery; TP, transverse pancreatic. Surgical removal of the mass confirmed the diagnosis.

of the mesenteric arteries. Carcinoid tumors metastatic to the liver are usually hypervascular with abundant tumor vessels. Venous sampling with hormone assay may be necessary for localizing occult carcinoid tumors, especially those occurring in the ovary and lungs. When the patient with liver involvement has severe carcinoid syndrome, hepatic artery embolization is an acceptable palliative treatment [72,73]. Carcinoid crisis is a potentially life-threatening condition that can occur spontaneously or at the time of hepatic artery embolization. The clinical manifestations of carcinoid crisis vary depending on the hormones released from the tumors and include sudden flushing, sweating, hypotension, hypertension, and even cardiac arrest. Treatment should include intravenous administration of Sandostatin [72].

Other tumors

Hemangiomas of the small bowel are an uncommon cause of GI bleeding. Angiography may be used to identify small hemangiomas. The angiographic findings include small areas of abnormal vessels with contrast accumulation in the capillary phase, with or without early draining veins. Angiography is not useful in diagnosing adenomas, lipomas, carcinomas, or Kaposi sarcoma.

Pancreatic disease

Pancreatic tumors have been extensively studied by angiography, both to identify the actual tumor by its angiographic features and to assess the extent of the lesion before surgery. The newer imaging modalities are used to both diagnose and stage the lesion [74]. Angiography is performed to obtain a specific diagnosis, to determine the extent of the tumor, and to demonstrate vascular anatomy. In patients with pancreatitis, pseudocysts or vascular lesions, angiography is necessary when surgery or endovascular therapy is contemplated.

Adenocarcinoma

Current imaging techniques, including helical CT, multidetector CT, MRI, endoscopic ultrasound (EUS), and positron emission tomography are important in early diagnosis and staging of pancreatic cancer [75,76]. Angiography is performed to evaluate vascular anatomy and involvement of any major peripancreatic artery (splenic, hepatic, or superior mesenteric artery) or vein (superior mesenteric, splenic, or portal vein). When any major peripancreatic artery or vein is involved, the tumor may be unresectable (Fig. 135.14). Surgical resection offers the only potential cure if pancreatic cancer is confined within the pancreas.

Cystic tumors

Cystic lesions may be found on imaging studies of patients without symptoms. A wide variety of cystic lesions occurs in the pancreas including cystic neoplasms and pseudocysts. CT, US, and MRI should be used to diagnose cystic lesions of the pancreas [77,78].

Angiography is reserved for determining the extent of the tumor and vascular anatomy before surgical resection. Angiographically, microcystic adenomas are usually hypervascular with abundant tumor vessels and blush, whereas mucinous cystic tumors are hypovascular with sparse tumor vessels mimicking a pseudocyst.

Pancreatic endocrine tumors

CT, MRI, and EUS have all been used to demonstrate endocrine tumors of the pancreas with varying success. Angiography is infrequently used for localization of islet cell adenomas. Angiographic technique in the examination of the pancreas requires meticulous catheterization of the superior mesenteric artery and celiac artery, and its branches. Angiographically, islet cell tumors appear as a localized area of contrast material accumulation (tumor blush) with or without tumor vessels (Fig. 135.15). Malignant islet cell tumors may grow into the portal vein. Most hepatic metastases from islet cell carcinomas are hypervascular and are readily detected by hepatic angiography. Angiography is sensitive in localizing insulinomas (accuracy 60%–90%) but is less sensitive in detecting gastrin-producing tumors. Other endocrine

tumors, such as vasoactive intestinal peptideproducing tumors (VIPoma), glucagonoma, and somatostatinoma, are usually hypervascular with abundant tumor vessels.

Percutaneous transhepatic venous sampling with hormone assay is a useful method for localizing occult islet cell tumors. This method may be used to localize the source of abnormal hormone secretion to the head, body, and tail of the pancreas, as well as to the liver. This is helpful in avoiding blind resection of the pancreas [79]. Simultaneous arterial and venous sampling from the splenic, superior mesenteric, and portal veins can detect localized elevation of hormones near the tumor site; adenomas of the body and tail of the pancreas produce increased hormone concentrations in the splenic vein, and those of the pancreatic head produce increased hormone concentrations in the superior mesenteric and portal veins. Simultaneous blood sampling from the hepatic and portal veins helps to determine the presence of hepatic metastases from gastrinomas [80].

Selective intraarterial injection of secretin with assay of hepatic venous gastrin has been useful in localizing gastrinomas and hepatic metastases [81,82]. It involves injection of 30 units of secretin into the splenic, gastroduodenal, proper hepatic, and superior mesenteric arteries, as well as blood sampling from the hepatic vein to measure the changes in gastrin concentration. An increase (> 50%) in gastrin concentration in the hepatic vein after secretin injection localizes the tumor to the part of the pancreas supplied by the artery injected: the gastroduodenal and superior mesenteric arteries for the head of the pancreas and the splenic artery for the

body or tail. The selective arterial secretin injection test is more sensitive than transhepatic portal venous sampling for localizing occult gastrinomas [83]. An increase in hepatic venous gastrin concentration of at least 25% at 20 s or 50% at 30 s after hepatic arterial injection of secretin indicates the presence of hepatic metastases [84].

In patients with suspected insulinomas, calcium gluconate is injected intraarterially and the level of insulin is measured in the hepatic vein for localization of insulinomas [85]. The patient is admitted the night before the procedure to stabilize the glucose level with intravenous administration of 10% dextrose. Blood samples are obtained from the hepatic vein before and at 30, 60, 90, and 120 s after the injection of calcium gluconate (Ca^{2+} 0.015 mEq/kg body weight) into the superior mesenteric, gastroduodenal, splenic and hepatic arteries, respectively. Calcium injection should be separated by 20–30 min to allow the insulin level to return to baseline. A 1.5–2.0-fold rise in insulin level in the hepatic vein at 30 and 60 s after intraarterial injection of calcium localizes the source of insulin to the region of the pancreas supplied by the artery stimulated.

Pancreatic arteriovenous malformations

These rare vascular lesions may bleed directly into the intestine, the pancreatic duct, or the bile duct [86–88]. Portal hypertension and varices associated with the malformation may be the cause of the bleeding. Angiography is important in the preoperative diagnosis and localization of the lesion (Fig. 135.16). The lesion may mimic chronic pancreatitis or a vascular tumor.

Vascular lesions associated with pancreatitis

Angiography has little diagnostic use in patients with pancreatitis because the diagnosis is well established clinically. When vascular complications occur, angiography is necessary for the diagnosis of vascular involvement and treatment. In about half of cases of pseudocyst, peripancreatic venous narrowing or occlusion is found. Bleeding associated with pancreatitis may be venous or arterial in origin. Venous bleeding usually results from gastric varices associated with splenic or portal vein occlusion. Venous bleeding rarely results from duodenal varices caused by superior mesenteric or portal vein occlusion. Arterial hemorrhage is a rare but life-threatening complication of pancreatitis, usually secondary to rupture of intrapancreatic or peripancreatic aneurysms. Arteriography is indicated for the diagnosis of arterial bleeding and pseudoaneurysm, and selective embolization should be used as a definitive or preoperative temporizing procedure [89–91].

Hepatic disease

Radionuclide scintigraphy, US, CT, and MRI have all been used for demonstration of liver masses [92–95]. Angiography still is important in evaluating liver tumors for the specific diagnosis, resectability of the tumor, and before therapeutic hepatic artery embolization.

Knowledge of the hepatic circulation is important in the performance and interpretation of hepatic angiograms and in planning for hepatic arterial chemotherapy. The liver receives a dual blood supply: about 75% of the total hepatic blood flow comes from the portal vein, and the remaining 25% comes from the hepatic artery. The relationship between the portal vein and hepatic artery is reciprocal: a decrease in portal blood flow results in an immediate compensatory increase in hepatic arterial flow. When portal blood flow is diminished in cirrhosis or obstructive jaundice, hepatic arterial embolization for bleeding or tumors must be undertaken cautiously because the liver in these conditions depends primarily on arterial blood.

(a)  (b)

Figure 135.16 Pancreatic arteriovenous malformation (AVM). **(a)** Splenic angiogram, arterial phase, shows a tangle of vessels in the tail of the pancreas (longer arrow). Early draining splenic vein is beginning to opacify (shorter arrow). **(b)** Dense filling of the splenic and portal (arrow) veins indicates the presence of arteriovenous shunting through the AVM.

Cavernous hemangiomas

Cavernous hemangiomas, the most common benign hepatic tumors, are composed of large sinusoidal spaces with fibrosis and thrombosis. CT, MRI, and technetium-99m scintigraphy with the use of single photon emission computed tomography (SPECT) are useful for obtaining a specific diagnosis [96,97]. The lesions usually appear well defined and hypodense on unenhanced CT. When contrast medium is administered, the lesions initially show nodular peripheral enhancement, which becomes confluent gradually. On MRI, the lesions usually show bright signal intensity on T2-weighted images. The angiographic findings are characteristic, with normal feeding arteries and dense persistent pooling of contrast material through the venous phase of a hepatic angiogram.

Adenoma

Hepatic adenoma usually occurs in young women with a history of oral contraceptive use, and rarely in patients with glycogen storage disease [98,99]. Because of the risk of bleeding, hepatic adenoma must be resected. Hepatic adenomas are nonspecific at ultrasonography, and are usually evaluated by CT or MRI. Angiographically, hepatic adenomas are usually vascular, with abnormal vessels and tumor blush. The definitive diagnosis cannot be established on the basis of the angiographic abnormality. When an adenoma bleeds, angiography is necessary to evaluate the extent of bleeding and identify the tumor. If active contrast extravasation is identified, selective arterial embolization is an acceptable alternative treatment. When the patient becomes stable, resection should be performed. Adenomas associated with bleeding may become hypovascular or avascular, making their angiographic localization difficult.

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is a benign liver tumor, often found incidentally on imaging studies performed for other indications. Asymptomatic FNH rarely bleeds and therefore no treatment is necessary. CT and MRI have been used to differentiate FNH from other hepatic tumors [100]. Because of the difficulty in differentiating from hepatic adenoma and fibrolamellar hepatocellular carcinoma, FNH is often resected. Angiographically, FNH is usually hypervascular with abnormal vessels and granular blush. Multiple septa radiating from the central area of scar is usually demonstrated.

Biliary cystadenoma

Biliary cystadenomas are benign multiloculated cystic tumors arising from the intrahepatic or extrahepatic bile duct. US and CT can demonstrate the lesions [101]. Angiography is performed to define hepatic arterial anatomy and determine the extent of the tumor before surgery. The angiographic findings are usually nonspecific and may demonstrate subtle neovascularity and rim-like staining in the wall of the tumor, mimicking a hepatic abscess, echinococcal cyst, or congenital hepatic cyst.

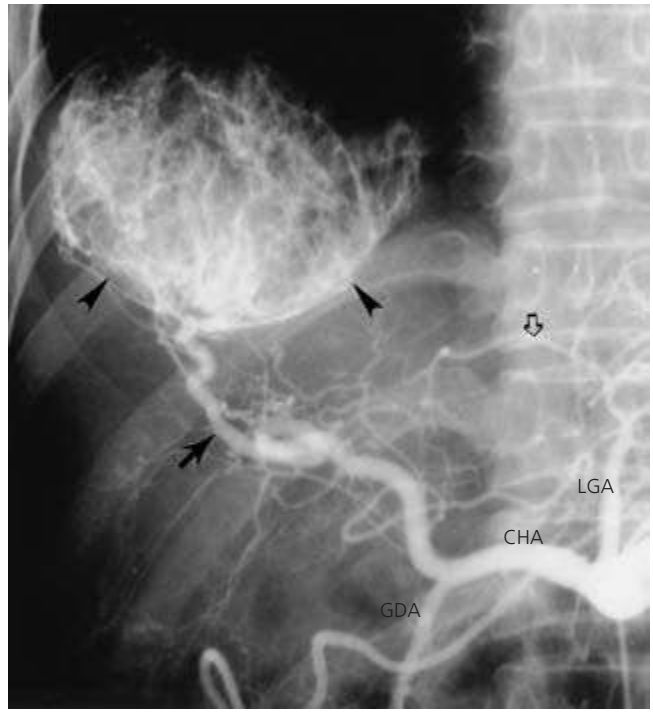

Figure 135.17 Hepatoma. Hepatic arteriogram shows a hypervascular mass (arrowheads) with tumor blush. Numerous tumor vessels supplied by a dilated right hepatic artery branch (arrow) are seen. The left hepatic artery (open arrow) arises from the left gastric artery (LGA). CHA, common hepatic artery; GDA, gastroduodenal artery.

Hepatocellular carcinoma

CT and MRI are the primary imaging methods used for the diagnosis of hepatocellular carcinoma (HCC) [102–104]. Angiography is necessary to define the extent of the tumor, blood supply, and portal venous anatomy. Most hepatomas are hypervascular angiographically, with coarse tumor vessels (Fig. 135.17). Involvement of the extrahepatic portal vein by HCC indicates that the tumor is unresectable. Angiography is also performed for a vascular "roadmap" before hepatic artery chemoembolization for HCC.

Cholangiocarcinoma

Angiography has a limited role in the diagnosis but may be performed to provide a vascular "roadmap" and evaluation of portal vein patency when surgical resection is contemplated. The angiographic findings include encasement of the hepatic arterial branches, which may be associated with encasement of the portal vein.

Figure 135.18 Hepatic carcinoid metastases. Celiac angiogram, lateral arterial and parenchymal phase, in a patient with carcinoid syndrome. Hypervascular metastases are present in the liver.

Metastatic hepatic neoplasms

Hepatic metastases from renal cell carcinomas, islet cell carcinomas, carcinoid tumors, and medullary thyroid carcinomas are hypervascular, and other metastases are less vascular. Angiography is sensitive in detecting hypervascular metastases (Fig. 135.18). Angiography is performed to determine resectability of hepatic metastases and the presence of aberrant hepatic arteries before the surgical placement of a hepatic arterial catheter for chemotherapy.

Panhepatic angiography

Increased resistance to the flow of portal vein blood is the principal cause of portal hypertension. The location of the blockage in portal blood flow may be intrahepatic or extrahepatic. Cirrhosis is the most common cause of intrahepatic sinusoidal block. Hepatic vein (postsinusoidal) and portal vein (presinusoidal) occlusion produce an extrahepatic block to portal vein flow. An increase in portal vein blood flow secondary to splenomegaly or arterioportal fistulae rarely causes portal hypertension (hyperkinetic) [105]. Transcatheter embolization may be used to occlude the arterioportal fistula and lower portal pressure.

The term *panhepatic angiography* is used for the angiographic study performed for the evaluation of portal hypertension. It includes celiac, superior mesenteric, hepatic, and splenic angiograms; wedged hepatic and left renal venograms; and manometry. Panhepatic angiography determines hepatic arterial variations, assesses portal hemodynamics, and excludes hepatoma. Visualization of aberrant hepatic arteries is important because accidental ligation of the hepatic artery in the presence of portal hypertension may result in hepatic necrosis. A right hepatic artery that originates from the superior mesenteric artery poses technical difficulty for portacaval shunt surgery.

A hepatic angiogram is necessary to exclude hepatomas and helps determine the hemodynamics of intrahepatic portal flow. In advanced cirrhosis with reversed portal flow, the portal vein may be visualized in the venous phase of the hepatic arteriogram. High-dose superior mesenteric and splenic angiograms are necessary to see the superior mesenteric, splenic, and portal veins, as well as the portosystemic collaterals. In alcoholic cirrhosis, a pressure measurement from the catheter wedged in the hepatic vein reflects portal vein pressure and is useful in determining whether the location of the obstruction is intrahepatic or extrahepatic. However, wedged hepatic vein pressure is not a useful determinant for selecting the type of shunt surgery. It is also a poor predictor of prognosis and survival after shunt surgery. The TIPS procedure has largely replaced surgical shunt in recent years. Wedged hepatic venography is the most accurate means of assessing the morphological features of the hepatic sinusoids and parenchyma. CO_2 is used as a contrast agent for most wedged hepatic venography to visualize the portal vein. Manometry of the right atrium, hepatic vein, and IVC helps determine the level of hepatic venous outflow obstruction.

Transcatheter therapy

Diagnostic angiography should be performed before any transcatheter intervention for GI disease. Interventional radiological procedures are reviewed in detail in Chapter 160.

Percutaneous translumenal angioplasty and stent placement

Surgical therapy (endarterectomy and bypass surgery) for superior mesenteric artery obstruction has significant mortality and recurrence rates. Percutaneous translumenal angioplasty (PTA) is a safe and effective alternative to surgery in treating intestinal angina resulting from arteriosclerotic occlusive disease of the visceral arteries. Stent placement is required for ostial stenosis or complete occlusion of the celiac and superior mesenteric artery, failed PTA because of elastic recoil, and mesenteric arterial compression by the false lumen of an aortic dissection [106–109]. Celiac axis stenosis caused by median arcuate ligament compression is not amenable to angioplasty and thus requires stent placement or surgery.

PTA is effective in treating Budd–Chiari syndrome caused by a membrane in the IVC and a stenosis of the hepatic vein [110,111]. The method may not be technically possible in patients with diffuse hepatic vein thrombosis and sclerosis. TIPS is used for the treatment of severe hepatic venoocclusive disease [112]. Percutaneous transhepatic angioplasty

and stent placement has been used to treat portal vein stenosis and postoperative stricture of the portal vein complicating liver transplantation [113–115].

PTA should be performed for hepatic artery stenosis in liver transplant recipients because of a significant risk of thrombosis of untreated stenosis [116].

Transcatheter embolotherapy

Transcatheter embolotherapy is an acceptable alternative to surgery in treating massive arterial GI bleeding, visceral aneurysms, hypersplenism, isolated gastric varices associated with splenic vein occlusion, and traumatic hepatic and splenic bleeding [117–122]. Occlusion of the hepatic artery by embolization for control of hepatic bleeding is usually tolerated because the hepatic sinusoidal perfusion can be maintained by collateral circulation and the portal venous blood. Hepatic arterial embolization is used for the treatment of traumatic hepatic bleeding, hemobilia, and symptomatic arterioportal fistula. However, hepatic artery embolization in patients with symptomatic hepatic arteriovenous malformations associated with hereditary hemorrhagic telangiectasia has a high risk for hepatic infarction and death [123]. The spleen receives adequate collateral blood flow through the pancreatic, left gastric/short gastric, inferior phrenic/short gastric, and gastroepiploic arteries after occlusion of the splenic artery. Superselective catheterization of the splenic artery is performed using the coaxial catheterization method using a 3Fr microcatheter. Microcoils are the most frequently used occluding agent and produces arterial occlusion equivalent to surgical ligation. Injection of thrombin into an aneurysm promotes clot formation. A 3Fr coaxial catheter system is extremely useful in catheterization and embolization of a mesenteric branch artery. If an aneurysm cannot be catheterized transarterially, a 22G needle is used for percutaneous puncture, and embolization of the lesion is accomplished with microcoils and thrombin.

Thrombolytic therapy

Thrombolytic therapy may be used for superior mesenteric artery embolism and portal vein thrombosis. A report of thrombolytic therapy for superior mesenteric artery embolism indicates that the method is safe and effective, with technical success in 90% and clinical success in 70% [124], but the treatment requires at least 6–8 h of infusion. A percutaneous transhepatic or transjugular approach is necessary for thrombolysis of mesenteric and portal vein thrombosis. The technique involves placement of a catheter into the embolus or thrombus, and infusion of a lytic agent. During thrombolysis, the patient should be monitored for bleeding and evidence of bowel infarction in the intensive care unit. The transcatheter use of a mechanical thrombectomy device, such as AngioJet (Possis Medical Inc., Minneapolis, MN) may be used for removal of thrombi from the mesenteric and portal vein thrombosis.

Hepatic arterial infusion chemotherapy

Regional delivery of antineoplastic agents through a selectively placed arterial catheter produces higher tumor response than systemic infusion [125,126]. The success of hepatic arterial chemotherapy depends on accurate evaluation of the hepatic arterial anatomy and hemodynamics, and correct catheter placement. To ensure total liver perfusion and drug delivery to the tumor site, the hepatic arterial anatomy is meticulously evaluated by celiac and superior mesenteric arteriograms. Multiple hepatic arteries can be converted to a single hepatic artery using the transcatheter embolization technique to facilitate catheter placement [127]. For example, if an aberrant left hepatic artery from the left gastric artery is embolized, the left hepatic lobe receives blood supply through intrahepatic collaterals from the right hepatic artery. If the infusion catheter cannot be placed in the proper hepatic artery, the gastroduodenal artery may be occluded by embolization to allow infusion of drugs with a catheter placed in the common hepatic artery [128]. Hepatic arterial catheters can be placed through a percutaneous approach from the femoral or brachial artery, or surgically. The introduction of the totally implantable pump has improved regional chemotherapy with surgical catheter placement [129]. Radionuclide flow study using ^{99m}Tc-labeled macroaggregated serum albumin is the most accurate means of assessing hepatic perfusion pattern after catheter placement. The complications of percutaneous catheter placement are brachial artery thrombosis, hepatic artery thrombosis, catheter displacement, and puncture-site bleeding. The complications of surgical catheter placement are hepatic artery thrombosis, incorrect catheter placement, catheter occlusion, and pump malfunction. Complications related to the toxicity of chemotherapeutic agents are chemical hepatitis, biliary sclerosis, chemical cholecystitis, and gastroduodenal inflammation and ulceration.

Hepatic tumor embolization

Transarterial chemoembolization (TACE) is used to palliate hepatic tumors including hepatoma, metastatic neuroendocrine tumors, and metastatic colon cancer if the tumors cannot be treated by the percutaneous ablation method (Fig. 135.19). Generally, TACE has been shown to be beneficial and improve survival [130–133]. TACE has also been used to prevent tumor progression or shrink the tumor while awaiting liver transplantation in order to improve clinical outcome [134–137].

CT or MRI of the liver must be reviewed for evaluation of location of tumor, extent of disease, and any associated findings (portal vein occlusion, biliary obstruction). Adequate portal venous flow should be available to maintain hepatic parenchymal vitality. If the intrahepatic portal flow is reversed (hepatofugal), embolization should not be performed or limited to the subsegment containing tumor.

Hepatic arterial embolization results in selective destruction of the tumors exclusively dependent on arterial supply

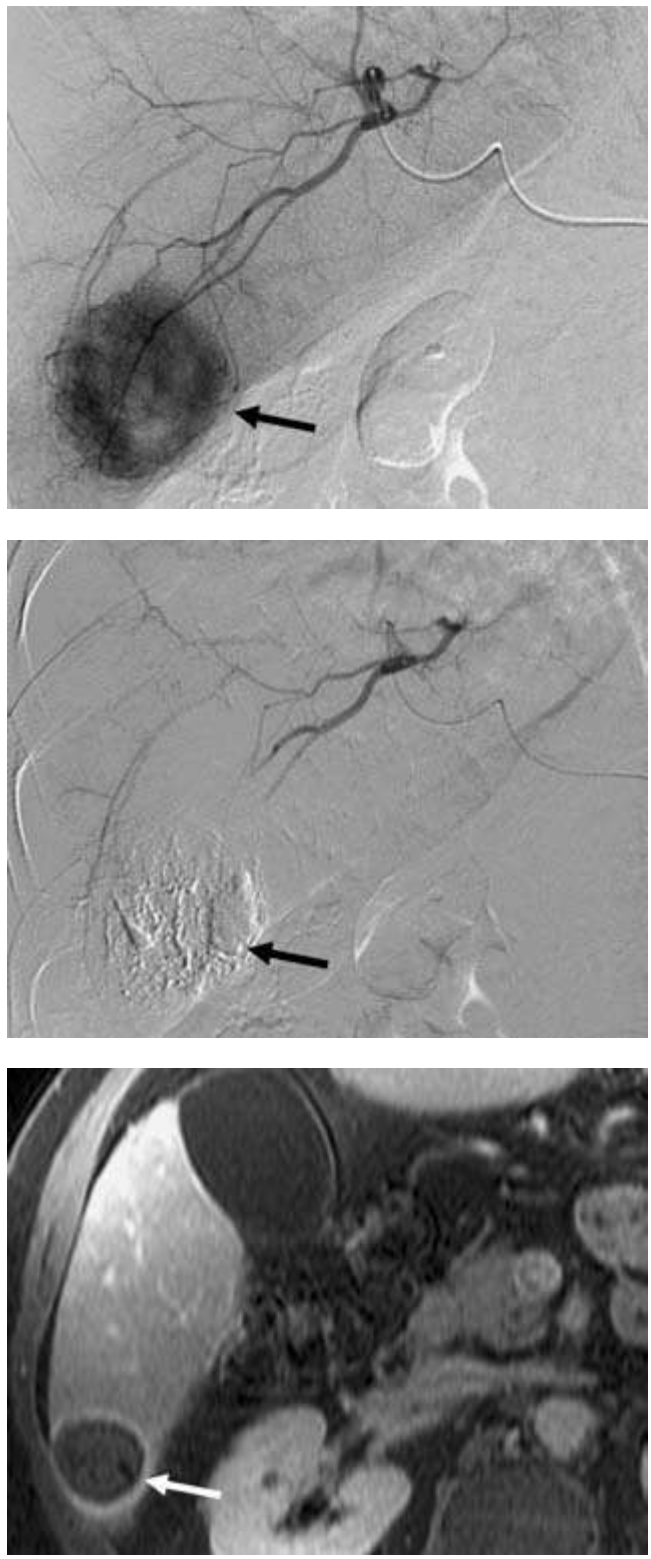

Figure 135.19 Hepatic artery chemoembolization in a 63-year-old patient with hepatitis C cirrhosis and hepatocellular carcinoma (HCC). **(a)** Right hepatic arteriogram. Branches of the right posterior segmental hepatic artery supply a hypervascular mass in the liver (arrow). **(b)** Hepatic arteriogram performed shortly after embolization showing complete devascularization of the HCC (arrow). **(c)** Contrast-enhanced magnetic resonance image obtained 6 weeks after chemoembolization confirmed complete necrosis of HCC (arrow).

while maintaining the vitality of the normal liver with portal vein blood. Small particles such as polyvinyl alcohol (Ivalon 150–250 μm) are used to occlude peripheral arteries to decrease the development of collateral blood flow. Concurrent embolization increases the effect of the drug by prolonging exposure of the tumor to the drug and producing tumor anoxia while minimizing systemic drug effects. Injection of iodized oil into the hepatic artery results in selective accumulation of the oil within most vascular hepatic tumors. This phenomenon has been exploited to selectively deliver antineoplastic agents and radioactive isotopes to hepatic cancers, with intraarterial injection of a mixture of iodized oil and antineoplastic agents or radioactive iodized oil solution. Yttrium-90 microspheres (TheraSphere) have been used for treatment of HCC and metastatic liver tumors [138–140]. TheraSphere is injected into the hepatic artery to deliver radiation directly to tumors with concurrent ischemia from microsphereres. Another new agent, DC Bead, has been used for hepatic artery chemoembolization. The DC Bead is an embolic agent loaded with chemotherapeutic agents [140,141]. When introduced into the tumors, it eludes drug over weeks.

Hepatic artery embolization may be associated with the postembolization syndrome: abdominal pain, nausea, vomiting, and fever lasting 2–7 days. Mildly abnormal liver tests are common. Other complications include hepatic necrosis, gallbladder infarction, and gastroduodenal ulcers. Follow-up CT or MRI is obtained at 3-month intervals and repeated embolizations are performed for recurrent tumors.

Forthcoming advances

Noninvasive imaging modalities (spiral CT, three-dimensional contrast MRA, color Doppler imaging, EUS and duplex US) will play an increasing role in the evaluation of suspected GI diseases. Angiography will be used less frequently but will continue to be used in the preoperative evaluation of vascular disease, portal hypertension, neoplasms of the pancreas and liver, and GI hemorrhage. Therapeutic applications of angiography will expand in the treatment of lower GI bleeding, vascular lesions, hepatic neoplasms, mesenteric vascular obstruction, variceal bleeding unresponsive to endoscopic therapy, intractable ascites, and Budd–Chiari syndrome.

The field of interventional radiology has evolved following the introduction of the percutaneous transarterial technique devised by Seldinger in 1953 [1]. Interventional radiologists perform a variety of diagnostic and interventional procedures of the circulatory system and nonvascular tracts under imaging guidance. The imaging guidance includes fluoroscopy, ultrasound (US), computed tomography (CT), magnetic resonance (MR) imaging, and digital subtraction angiography (DSA). The interventional radiological procedures can be divided into vascular and nonvascular procedures. The vascular procedures include infusion, embolization, angioplasty, stent placement, transjugular intrahepatic portosystemic shunt, and foreign body retrieval. The nonvascular procedures include biopsy, percutaneous drainage, dilation, and ostomy formation.

Vascular intervention

Control of arterial gastrointestinal bleeding

Angiographic management is indicated for endoscopic failures, especially in poor operative candidates and for inaccessible sites of bleeding, such as hemobilia and bleeding into the pancreatic duct, and bleeding associated with aneurysms or pseudoaneurysms. Angiographic therapy for massive gastrointestinal (GI) bleeding includes intraarterial infusion of vasopressin and selective arterial embolization. The success of angiographic treatment depends on accurate localization of the bleeding site and selective catheterization of the bleeding artery.

Vasopressin infusion

Vasopressin is effective for bleeding from Mallory–Weiss tears, hemorrhagic gastritis, and small bowel and colonic bleeding [2,3], but it is less effective for bleeding from a peptic ulcer because ulcers rupture larger arteries. Vasopressin infusion can control lower GI tract bleeding in 80%–90% of patients, but 40%–50% of these patients rebleed and eventually require surgery. Therefore, vasopressin infusion is infrequently used for control of lower GI bleeding.

When the bleeding site has been demonstrated, a catheter is selectively placed in the bleeding artery. Vasopressin is infused into the left gastric artery for gastric bleeding, into the superior mesenteric artery for small bowel and right colonic bleeding, and into the inferior mesenteric artery for left colonic and rectosigmoid bleeding. Vasopressin infusion may be initiated at the rate of 0.2 U/min. After 20 min of infusion, a repeat arteriogram is performed to assess treatment effectiveness. If no bleeding is demonstrated and vasoconstriction is moderate, the infusion is continued for the next 24 h at the same rate. When the bleeding has stopped, the rate should be reduced to 0.1 U/min and continued for an additional 6–12 h before termination of the infusion. If the bleeding is not controlled after vasopressin infusion of 0.4 U/min for 20 min, increasing the rate is not recommended; embolization or surgery should be considered.

Serious side effects from vasopressin infusion occur infrequently. Most side effects are dose dependent. They are coronary ischemia, arrhythmia, bradycardia, hypertension, bowel ischemia, peripheral vascular ischemia, and oliguria. In patients with a history of coronary artery disease, the infusion should be done with caution and concomitant administration of nitroglycerin.

Selective arterial embolization

Selective arterial embolization is an effective method of therapy for control of massive upper GI hemorrhage when endoscopic therapy has failed. Selective occlusion of the bleeding artery with embolic agents such as gelatin sponge, polyvinyl alcohol (Ivalon), microcoil, and *n*-butyl cyanoacrylate (*n*-BCA) results in prompt cessation of the bleeding, and it usually obviates the need for surgical intervention [4,5] (Fig. 136.1). It is important to localize the bleeding site before embolization (Fig. 136.2). Prophylactic embolization of the left gastric

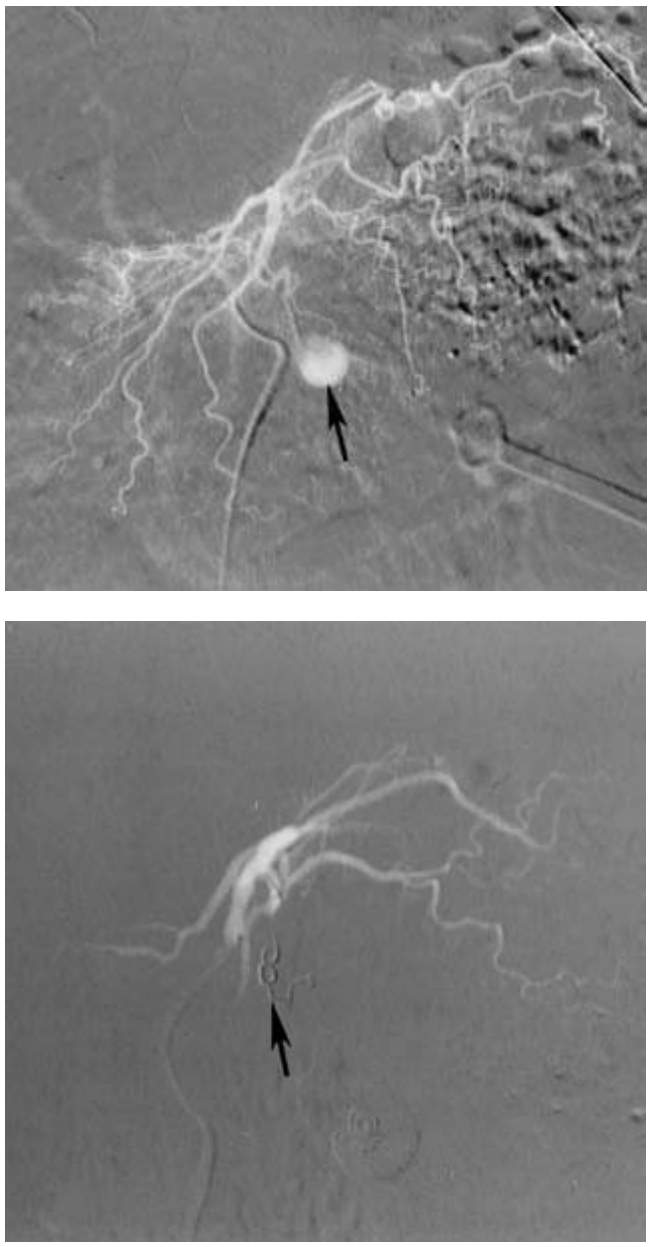

Figure 136.1 Massive arterial bleeding from a branch of the left gastric artery. **(a)** Superselective left gastric arteriogram (digital subtraction technique). Active bleeding is seen from a branch of the left gastric artery in the body of the stomach. The extravasated contrast medium has formed a pseudoaneurysm (arrow). **(b)** The bleeding has stopped following microcoil embolization (arrow).

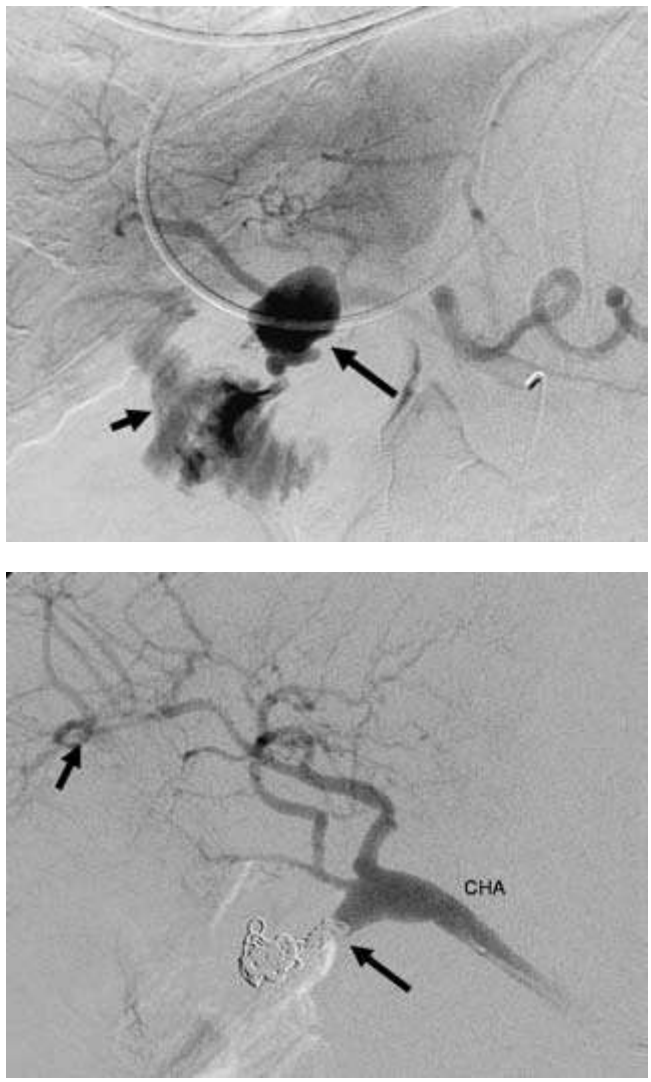

Figure 136.2 Control of duodenal hemorrhage by coil and thrombin embolization. Celiac angiogram in an 83-year-old man with a gastroduodenal artery pseudoaneurysm 1 month after a Whipple procedure for pancreatic cancer. No source of bleeding was seen at upper gastrointestinal endoscopy. **(a)** Celiac angiogram. Contrast medium (shorter arrow) extravasates from the large pseudoaneurysm (arrow) of the proximal gastroduodenal artery (GDA). The right hepatic artery arises from the GDA. **(b)** Common hepatic angiogram after embolization. The gastroduodenal artery and pseudoaneurysm are occluded. The right hepatic artery (arrow) reconstitutes distally through the hilar collateral from the middle and left hepatic arteries. CHA, common hepatic artery.

or gastroduodenal artery for upper GI bleeding can be performed, but endoscopic localization of the bleeding is necessary before embolization [6,7]. Correction of coagulopathy before and after the embolization reduces the risk for bleeding recurrence [8,9]. The use of coils as the sole embolic agent, and concurrent coagulopathy in patients with upper GI bleeding are associated with a high risk of early recurrent hemorrhage. The stomach and duodenum have sufficient collateral pathways; hence, infarction is unlikely to occur after embolization. On rare occasions, patients with previous surgery or those receiving vasopressin therapies after the embolization may develop infarction of the stomach. Duodenal ischemia, duodenal stenosis, and pancreatic necrosis are the potential complications of gastroduodenal artery embolization.

The localization procedures for lower GI bleeding before angiography include colonoscopy, technetium 99m (^{99m}Tc)-

labeled red blood cell scintigraphy, and helical CT [10]. Colonoscopy is usually performed when the bleeding has ceased. Selective arterial embolization is a safe and effective method of therapy for control of lower GI bleeding [11,12] (Fig. 136.3). Gelfoam pledgets and Ivalon particles are the commonly used embolization agents. The use of a 3-Fr coaxial catheter allows catheterization of the extravasating arterial branch for embolization with microcoil. Rectal hemorrhage is usually diagnosed and treated by interventional endoscopy. When the rectum is filled with fresh blood, endoscopic identification of the bleeding site may be difficult. Regardless of the underlying etiology, embolization can be effective in controlling superior hemorrhoidal arterial hemorrhage.

Lower GI bleeding is frequently intermittent and ceases spontaneously before and during an angiographic localization procedure. Surgical intervention without angiographic localization of the bleeding may be difficult on the basis of the results of scintigraphy. When the standard angiography has failed to demonstrate the bleeding site, provocative angiography may be used to induce bleeding; hence embolization or surgery can be performed. The agents used for the provocative angiography are heparin and intraarterial infusion of a vasodilator such as nitroglycerin and a thrombolytic agent (alteplase or reteplase) [13,14].

If superselective catheterization of the bleeding artery is not possible due to technical difficulty, vasopressin should be infused into the superior mesenteric artery proximal to the bleeding artery [15].

Variceal embolization

In 1974, Lunderquist and Yang [16] reported the technique of percutaneous transhepatic coronary vein embolization as a means of controlling gastroesophageal variceal bleeding. Portal vein catheterization can also be done using the transjugular, umbilical, and intestinal veins after minilaparotomy. In the presence of massive ascites, coagulopathy, or liver tumors, the transjugular approach is used. Coronary vein embolization can effectively control variceal hemorrhage in 80% of cases, but recurrent bleeding is common because of the development of new gastric and esophageal varices. Coronary vein embolization is infrequently performed because endoscopic therapy is more effective in preventing recurrent hemorrhage.

Balloon-occluded retrograde transvenous obliteration (BRTO) [17,18] is a safe and effective treatment of gastric varices. The technique involves the retrograde catheterization of the portosystemic collateral vein through the left renal and adrenal veins from the femoral vein (Fig. 136.4). An occlusion balloon is wedged in the collateral vein, and a sclerosing agent (i.e., 5% ethanolamine oleate mixed with contrast medium) is injected through the shunt into the gastric varices. After the injected sclerosing agent is allowed to sclerose the varices for 20–50 min, the residual sclerosing agent is aspirated through the catheter and the balloon is deflated. Alternatively *n*-butyl cyanoacrylate mixed with lipiodol can be injected through a 3-Fr microcatheter to achieve prompt occlusion of the varices. If complete obliteration of the varices is not possible with the retrograde approach, the varices can be embolized by the transhepatic approach or the transjugular intrahepatic portosystemic shunt (TIPS) if present.

Rarely, bleeding may occur from the portosystemic collaterals at unusual sites including the small bowel, colon, rectum, and enterostomy [19,20]. If the bleeding is unresponsive to conservative therapy, variceal embolization can be performed through the transhepatic or transjugular approaches [21,22]. The TIPS usually is preferable for the treatment of bleeding from varices at unusual sites owing to the risk of rebleeding with embolization alone [23–25] (Fig. 136.5).

Another reported unusual indication for variceal embolization is chronic recurrent hepatic encephalopathy [26,27]. Embolization of portosystemic shunts can decrease diversion of portal blood flow through the shunts, resulting in an increase in portal blood flow. Portosystemic shunts amenable to such embolic therapy are splenorenal shunts, gastrorenal shunts, hepatic portal vein–hepatic vein shunts, and ileal vein–gonadal vein communications. Embolization can be done through the transfemoral or transhepatic approaches, depending on the site of shunts.

Budd–Chiari syndrome

Patients with hepatic vein outflow obstruction (Budd–Chiari syndrome) usually present with abdominal pain, hepatomegaly, jaundice, and ascites. Treatment must be directed to relieve the hepatic outflow obstruction and to provide a bridge to liver transplantation in patients with acute hepatic failure. Depending on the extent, level, and nature of the hepatic venous outflow obstruction, various combinations of interventions are used, including catheter-directed thrombolysis, mechanical thrombectomy, recanalization, angioplasty, stent placement, and TIPS [28–31].

Percutaneous translumenal balloon angioplasty (PTA) is an effective therapy in patients with the Budd–Chiari syndrome secondary to obstruction of the inferior vena cava (IVC) or hepatic vein. However, recurrence is common, and therefore stent placement is usually performed. The transfemoral or transjugular approach usually is used for IVC and hepatic vein obstruction. A percutaneous transhepatic approach is used for the treatment of hepatic vein occlusion if a transjugular approach fails to cannulate the occluded hepatic vein (Fig. 136.6). When the hepatic venous outflow obstruction extends into the peripheral hepatic veins, requiring portal decompression, a TIPS procedure is a viable alternative to surgical shunting and provides a bridge to liver transplantation [32–34]. When portal, splenic, or mesenteric venous thrombosis is associated with Budd–Chiari syndrome, the thrombi can be dissolved by catheter-directed thrombolysis or removed by a mechanical thrombectomy device before placement of a TIPS. The TIPS stent may be

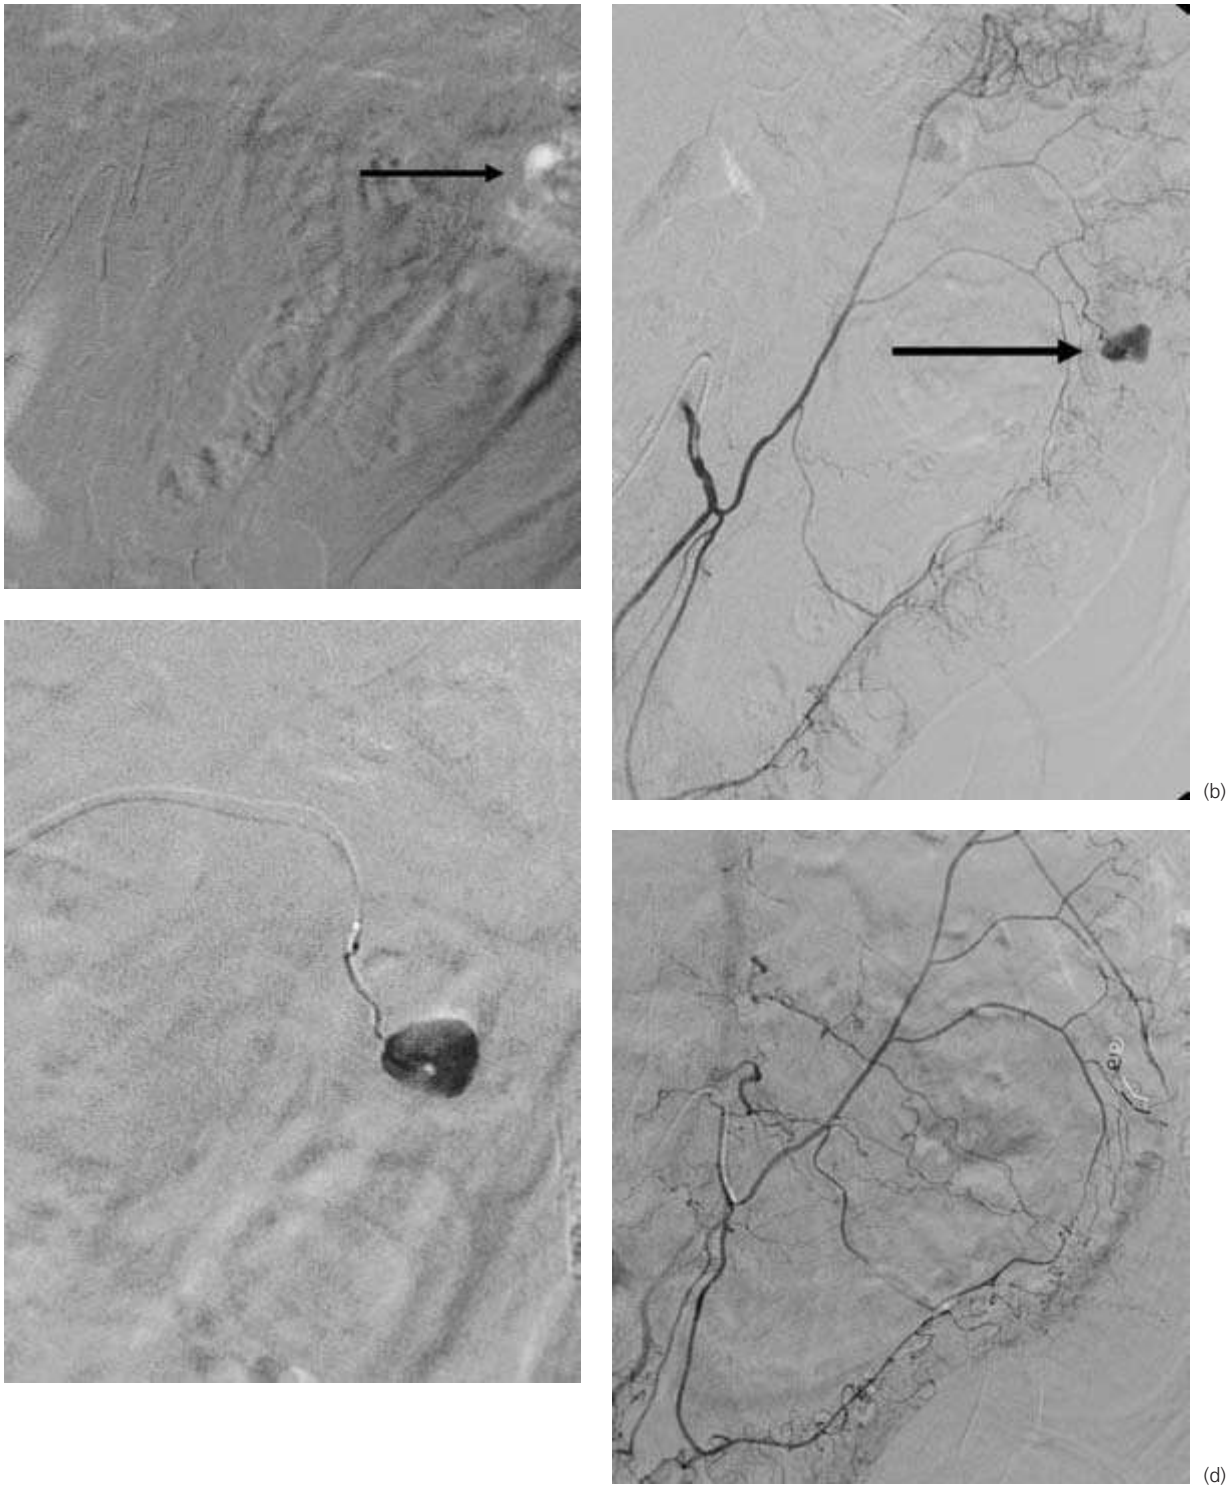

Figure 136.3 Control of left colonic hemorrhage by microcoil embolization. Inferior mesenteric arteriogram in an 82-year-old man with atrial fibrillation, diabetes mellitus, congestive heart failure, and massive lower gastrointestrial bleeding. The patient was on aspirin and Plavix. Despite transfusion of four units of packed red blood cells, his blood pressure was 90 mmHg. Neither colonoscopy nor radionuclide scintigraphy was performed. **(a)** Inferior mesenteric angiogram with CO_2. Carbon dioxide extravasates into the proximal descending colon (arrow). **(b)** Inferior mesenteric angiogram with contrast medium demonstrates extravasation (arrow) from a branch of the left colic artery. **(c)** Superselective angiogram with the injection of contrast medium into the bleeding arterial branch from the terminal arch. A dense accumulation of contrast medium is seen, likely representing a diverticulum. **(d)** Inferior mesenteric arteriogram following the embolization with microcoil. The bleeding artery is occluded and no bleeding is seen.

Figure 136.4 Balloon-occluded retrograde transvenous obliteration of gastric varices. Splenoportogram in a 52-year-old woman with alcoholic cirrhosis and hepatitis B who had undergone a transjugular intrahepatic portosystemic shunt (TIPS) procedure 14 months previously, and in whom esophagogastroduodenoscopy now revealed bleeding gastric varices. A TIPS stent stenosis was treated with balloon dilation. **(a)** Injection of the splenic vein that was catheterized through the TIPS stent demonstrates gastric varices. **(b)** Embolization of the left gastric varices with *n*-butyl cyanoacrylate through the balloon-occluded inferior phrenic vein (arrow) that was catheterized from the femoral vein.

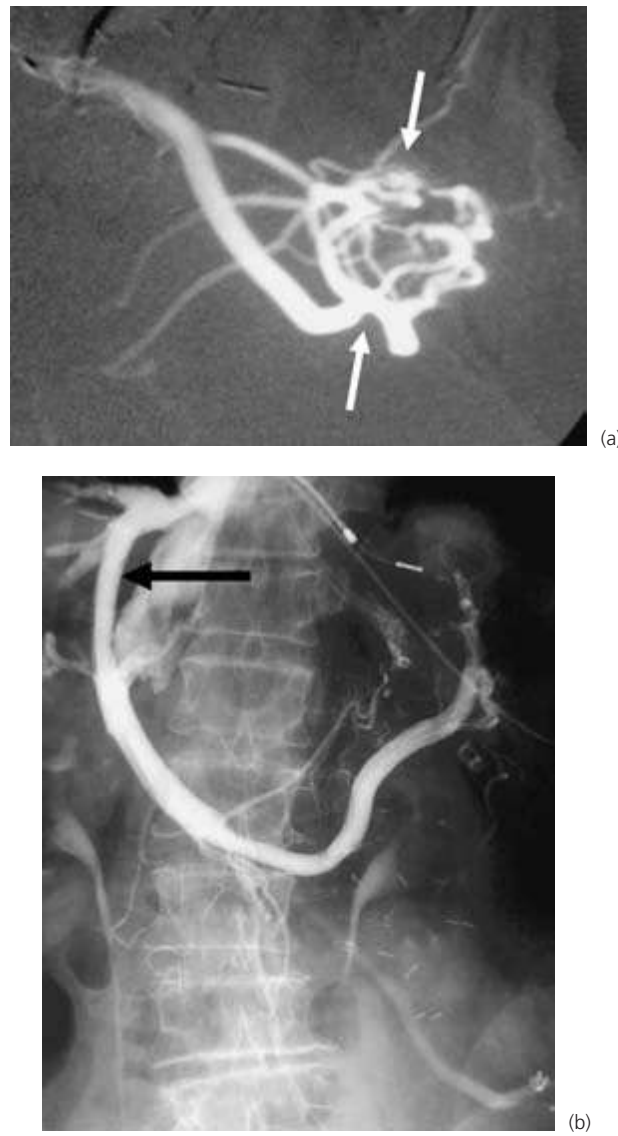

Figure 136.5 Transjugular embolization of stomal varices and placement of a transjugular intrahepatic portosystemic shunt (TIPS) in a 75-year-old woman with a 6-month history of recurrent bleeding from colostomy varices. The bleeding began 12 years after colostomy following resection of colorectal cancer. **(a)** Transjugular catheterization of the middle colic vein. Contrast medium fills the stomal varices (arrows). **(b)** A TIPS (arrow) was placed following coil embolization of the stomal varices. Stomal bleeding had not recurred 6 years after the embolization and placement of a TIPS.

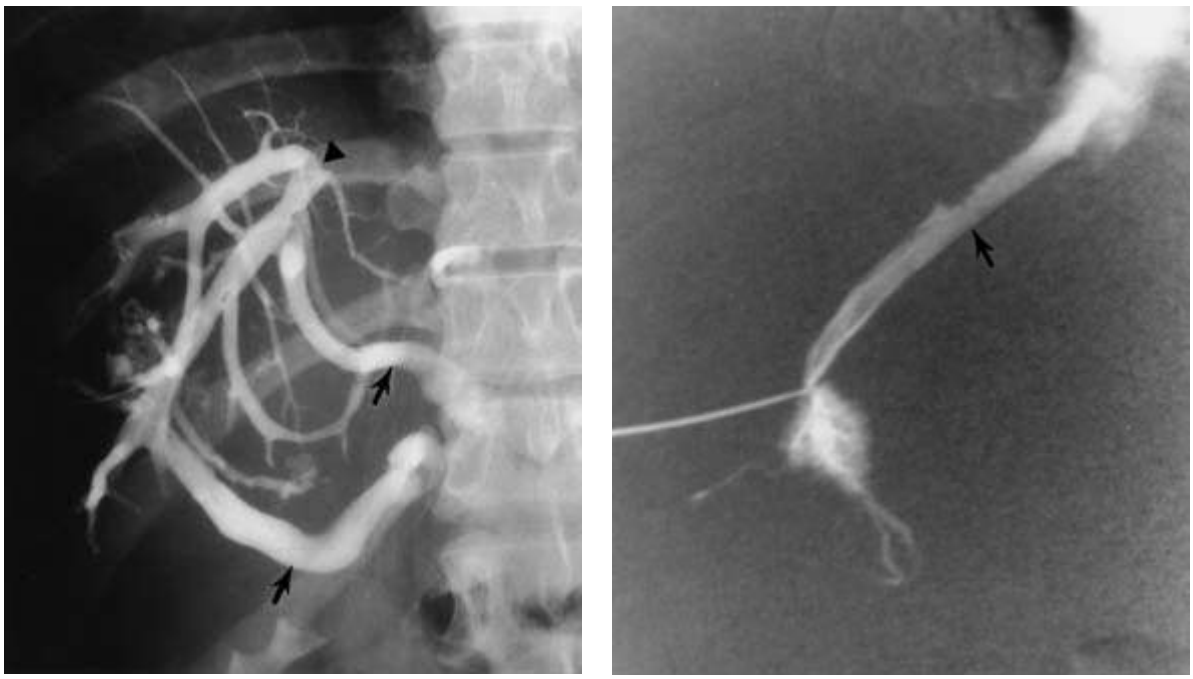
extended into the splenic or mesenteric vein to achieve adequate inflow.

Portal vein stenosis

Percutaneous translumenal balloon angioplasty and stent implantation using the percutaneous transhepatic and transjugular approaches are safe and effective in the therapy of portal vein stenosis, including cases complicating liver transplantation [35–38]. Although most cases of portal vein stenosis or occlusion are amenable to percutaneous techniques, the long-term efficacy of these techniques is not known; therefore, follow-up with imaging studies is needed to detect restenosis of the treated lesion.

Mesenteric vein thrombosis

Mesenteric vein thrombosis (MVT) may cause a severe mesenteric ischemia. It has been associated with portal hypertension, abdominal infection, inflammatory disease, trauma, surgery, and hypercoagulable states. It may occur following a TIPS placement. An endovascular technique plays an important role in managing symptomatic MVT. A thrombolytic agent is administered directly into the mesenteric vein



(a) (b)

Figure 136.6 Hepatic vein stent placement for Budd–Chiari syndrome. Transhepatic hepatic venogram in a 23-year-old woman with right upper quadrant pain and tenderness, ascites, and liver failure. **(a)** Transhepatic hepatic venogram. The hepatic vein is occluded (arrowhead). The contrast medium fills hepatic venous collaterals (arrows), draining toward the inferior vena cava. **(b)** Transhepatic hepatic venogram following recanalization of the hepatic vein and placement of a 10-mm-diameter WALLSTENT. The hepatic vein is patent with excellent blood flow (arrow). The venous collaterals are no longer filled. The hepatic vein pressure decreased from 29 mmHg to 7 mmHg after stent placement. One year later, the patient received an orthotopic liver transplant because of occlusion of the stent.

through the transjugular or transhepatic approach [39,40]. Mechanical thrombectomy using a thrombectomy device or a Fogarty catheter can be used for removal of acute thrombus. This technique can be used for recanalization of acute portal vein thrombosis complicating TIPS. Portal vein reconstruction with recanalization and stent placement may be performed in patients with symptomatic chronic splenic-mesenteric-portal venous thrombosis.

Visceral arterial stenosis

Atherosclerotic stenoses of the celiac and superior mesenteric arteries are a common cause of chronic mesenteric ischemia in elderly patients. Surgical revascularization is the standard treatment for clinically significant stenoses of the celiac and superior mesenteric arteries. Percutaneous translumenal balloon angioplasty and stenting is a safe and effective alternative to surgical treatment [41,42]. In a review of 83 reported patients who had PTA of visceral arteries, the initial technical success was 88%; the initial clinical success rate was 92%; the recurrence rate was 24%; the primary long-term clinical success rate was 76%; the rate of successful repeat PTA was 92%; secondary long-term clinical success was 92%; and major complications affected 6% [42]. Stent placement has been shown to be safe and clinically effective as an adjunctive treatment to PTA or as a primary therapy for patients with chronic mesenteric ischemia caused by calcified ostial stenoses, high-grade eccentric stenoses, chronic occlusions, and flow-limiting dissection of mesenteric arteries [43].

Percutaneous translumenal balloon angioplasty and stent placement are usually done through the femoral approach. If the femoral artery cannot be used, the left axillary approach is used. Before the procedure, lateral aortography and selective mesenteric arteriography are performed to evaluate the arterial lesions and visceral arterial circulation. The origin of the artery to be dilated is then catheterized and the stenosis is crossed using either a soft-tipped guidewire or a hydrophilic guidewire. The patient is given an intravenous bolus of 5000 units of heparin. Over a 0.035-inch (0.89-mm) heavy-duty guidewire, a PTA balloon catheter of appropriate balloon size is placed across the stenosis and dilated to pressures of 7–10 atm (102.9–147.0 psi; 1 psi = 6894.7 PA). If a gradient exceeds 10 mmHg after balloon dilation or if a hemodynamically significant dissection is seen, a metallic stent is placed. Stents may be used as the primary treatment for mesenteric artery stenosis (Fig. 136.7). A balloon-expandable stent is used for a focal proximal stenosis of the superior mesenteric or celiac stenosis. Nitinol self-expanding stents are used for longer lesions. Neither PTA nor stent placement is effective in treating celiac stenosis caused by median arcuate ligament compression. Systemic anticoagulation is not usually necessary after the procedure. Percutaneous translumenal balloon angioplasty should have a limited role in the patient with acute mesenteric ischemia.

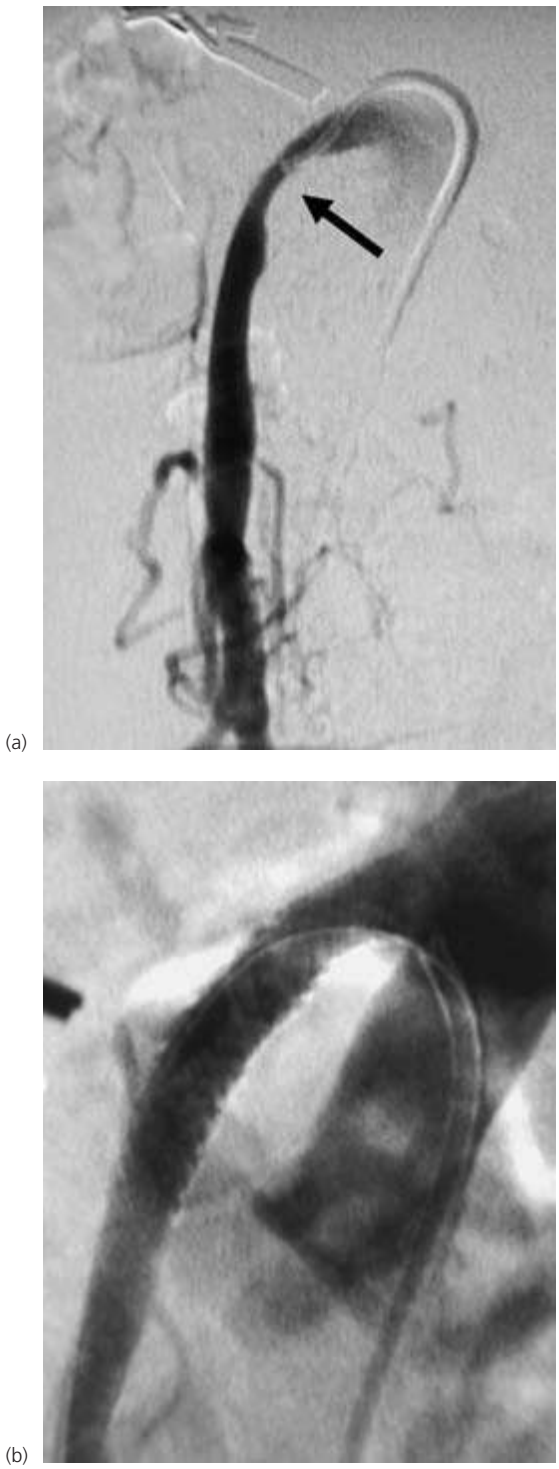


Figure 136.7 Angioplasty and stent placement for chronic mesenteric ischemia caused by superior mesenteric artery stenosis in a 65-year-old woman. **(a)** Superior mesenteric arteriogram in the lateral projection shows high-grade stenosis of the superior mesenteric artery (arrow). **(b)** Following angioplasty and stent placement the artery is widely open.

Superior mesenteric artery embolism

Embolism of the superior mesenteric artery is an important cause of acute intestinal ischemia, with high mortality rates [44]. Survival is often directly related to early diagnosis by emergency mesenteric arteriography. If an embolus is found in the proximal superior mesenteric artery, surgical treatment usually is indicated. In selected patients with an early diagnosis of peripheral embolism of the mesenteric arteries, intraarterial thrombolysis may be a therapeutic alternative [45].

Splanchnic artery aneurysm

Selective arterial embolization is safe and effective in treating visceral arterial aneurysms in poor surgical risk patients, particularly those with pancreatitis-associated aneurysms and pseudoaneurysms [46,47]. The embolization is usually done using the transfemoral approach. Celiac and superior mesenteric arteriograms are performed to evaluate the lesion and arterial anatomy. A 5-Fr catheter is advanced into the feeding artery as close to the lesion as possible. A 3-Fr coaxial catheter system is usually required to place the tip of the catheter close to or in the aneurysm. Coils are the most commonly used embolic agent. Thrombin may be added to the coils to promote clot formation.

If transarterial access to the aneurysm cannot be obtained owing to unfavorable arterial anatomy, the aneurysm is punctured percutaneously using a 22-gauge, skinny needle under ultrasonic or angiographic guidance. After confirmation of the position of the needle in the lesion, microcoils are deposited through the needle using a 0.018-inch (0.457-mm) guidewire, or thrombin is injected into the aneurysm [48,49].

Vascular lesions are uncommon complications of laparoscopic cholecystectomy. Most bleeding complications that occur intraoperatively are treated during the procedure. Any delayed vascular complications, such as hepatic artery pseudoaneurysm and arteriobiliary fistula, can be treated by selective embolization [50].

Transjugular intrahepatic portosystemic shunt

In patients with variceal bleeding who fail medical and endoscopic treatment, TIPS is invaluable and has largely replaced surgical shunts [51]. Transjugular intrahepatic portosystemic shunt is a nonsurgical method of achieving portal decompression in patients with portal hypertension and variceal hemorrhage. The indications for TIPS are variceal bleeding unresponsive to endoscopic therapy, recurrent variceal bleeding despite endoscopic therapy, portal hypertensive gastropathy, refractory ascites, hepatic hydrothorax, Budd–Chiari syndrome, stomal variceal hemorrhage, and portal venous thrombosis [52–58]. Transjugular intrahepatic portosystemic shunt may also be a treatment option for liver transplant

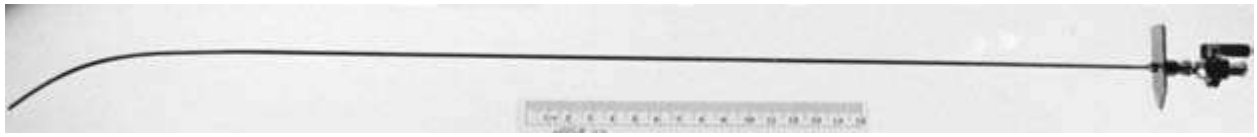

Figure 136.8 Colapinto needle used in transjugular intrahepatic portosystemic shunt procedure.

recipients with refractory variceal bleeding and intractable ascites [59]. There are no absolute contraindications for creating TIPS. The relative contraindications include elevated right heart pressure, heart failure, fulminant hepatic failure, severe hepatic encephalopathy, uncontrolled systemic infection or bacteremia, unrelieved biliary obstruction, multiple hepatic cysts, extensive primary or metastatic hepatic malignancy, and severe uncorrectable coagulopathy.

Technique

Before a TIPS procedure, patency of the portal vein should be demonstrated by imaging methods. Ultrasound is the most commonly used method for evaluation of portal vein patency. The other methods include CT arterial portography, MR venography, indirect portography (arterial portography), and carbon dioxide (CO_2) wedged hepatic venography.

Preprocedure, fresh-frozen plasma or a platelet transfusion is given if needed. The procedure can be performed under conscious sedation or a general anesthesia for uncooperative patients. The patient lies on his or her back and the neck is slightly extended backward and turned to the left for the right jugular approach or to the right for the left jugular approach. The right or left internal jugular vein is catheterized using a 21-gauge, single wall, puncture needle under US guidance. A 10-Fr vascular sheath is advanced into the right atrium. A 5-Fr catheter is then introduced coaxially and pressures are measured of the right atrium, IVC, and free and wedged hepatic veins. Carbon dioxide digital subtraction wedged hepatic venography is performed to see the portal vein.

A 16-gauge Colapinto needle (Fig. 136.8) is advanced over a 0.035-inch (0.89-mm) Amplatz, super stiff guidewire into the right or middle hepatic vein. The guidewire is removed and the needle is advanced with fluoroscopic guidance into the expected position of the right main portal vein 3 cm from the portal vein bifurcation (Fig. 136.9). The needle is withdrawn until blood can be aspirated, and contrast medium is injected to see the vascular structure entered. When the portal vein is entered, a guidewire is introduced into the superior mesenteric or splenic vein. The 9-Fr catheter is advanced over the Colapinto needle and guidewire into the portal vein. The needle is removed, and a 5-Fr catheter is advanced into the portal vein. Pressure in the portal vein is measured, and a portal venogram is performed (Fig. 136.9) to see the portal venous system and portosystemic collaterals. The parenchymal tract is injected with CO_2 and contrast medium to see whether the needle tract has passed through the bile duct or hepatic artery. The tract is then dilated with an 8-mm PTA balloon catheter, and a 10-mm diameter metallic stent is placed in the tract bridging the distance from the portal to the central hepatic vein (Fig. 136.9). Sometimes more than one stent must be used to cover the tract. The stents are then dilated with a 10-mm PTA balloon to ensure their maximal expansion. The use of covered stents, such as the GORE VIATORR TIPS (Tempe, AZ) Endoprosthesis, is preferable to bare stents, such as the WALLSTENT (Boston Scientific Corp., Natick, MA) Endoprosthesis, because the former with its expanded polytetrafluoroethylene (ePTFE) graft lining minimizes transmural permeation of bile and mucin, which are known to cause early stent occlusion, The covered stents are used in both de novo and revision TIPS procedures. Portal and systemic venous pressures are measured and another portal venogram is obtained (Fig. 136.9). If the gastroesophageal varices or gastrorenal or splenorenal shunts continue to fill despite a satisfactory portal–right atrial gradient, the collaterals are embolized with coils, alcohol, or *n*-butyl cyanoacrylate.

A portosystemic gradient of less than 12 mmHg after creation of a TIPS is deemed satisfactory. The hemodynamic alterations caused by TIPS are similar to those caused by H-mesocaval and side-to-side portacaval shunts, but there appears to be slightly better preservation of hepatic portal perfusion following the TIPS. The flow through the shunt can be controlled by modifying the size of the shunt. Intrahepatic portal vein blood flow is usually reversed after creation of TIPS, and when injected into the portal vein, contrast medium will flow directly toward the shunt into the IVC and right atrium. The intrahepatic portal venous branches will not fill. No benefit in terms of shunt patency and survival has been demonstrated by using a 12-mm stent [60].

The transfemoral approach is used in patients with severely stenotic, angulated, or thrombotic hepatic veins, which make the standard jugular approach impossible. The procedure involves the placement of loop snares in the right portal vein and hepatic segment of the IVC and puncture of the IVC from the portal vein side using a sheathed needle. A guidewire is then advanced into the IVC and is snared and withdrawn through the transjugular sheath. A sheathed, 16-gauge Colapinto needle is advanced over the guidewire into the right portal vein. The parenchymal tract is dilated, and a stent is deployed from the main portal vein into the IVC.

Surveillance

Doppler US is an effective noninvasive screening tool for assessing TIPS patency and detecting an increased portosys-

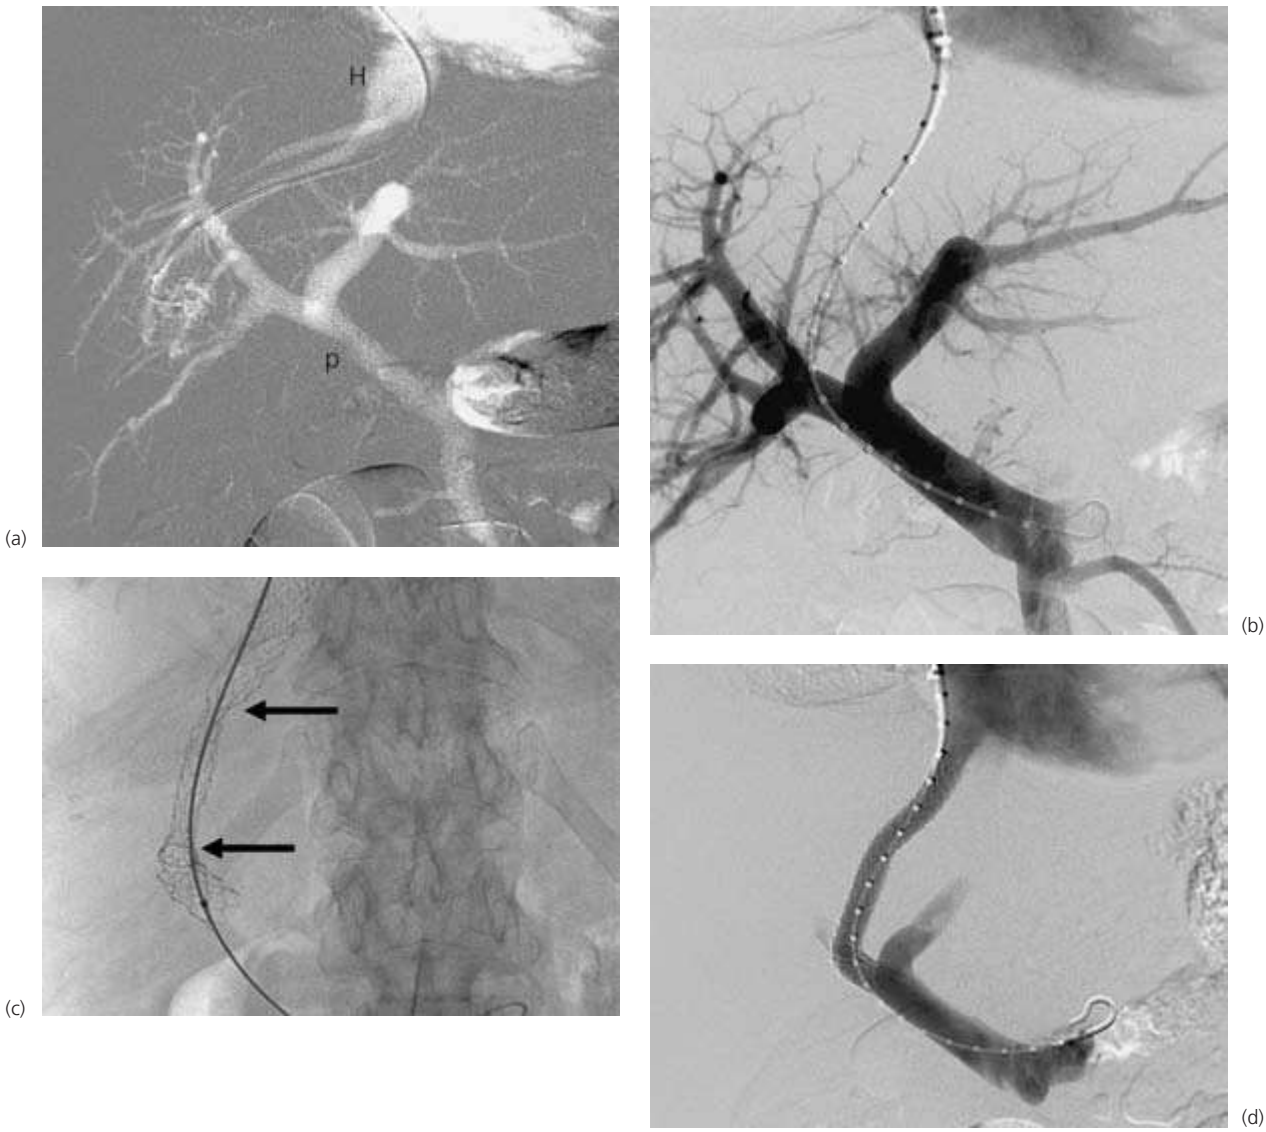

Figure 136.9 Transjugular intrahepatic portosystemic shunt (TIPS) in a patient with portal hypertension and variceal bleeding unresponsive to endoscopic therapy. **(a)** CO_2 wedged hepatic venogram shows hepatic (H) and portal (p) veins. **(b)** Transjugular catheterization of the portal vein. The transjugular portal vein catheter has been introduced into the portal vein from the right hepatic vein. Contrast medium fills the portal vein. The portal venous blood flows toward the liver (hepatopetal). **(c)** A covered stent (GORE VIATORR Endoprosthesis) is placed from the right portal vein to the right hepatic veins (arrows). **(d)** Following balloon dilation of the stent to a diameter of 10 mm, contrast injection fills the TIPS stent. The portal blood flows through the shunt directly into the right atrium. The intrahepatic portal veins are not seen due to reversal of portal blood flow. The variceal bleeding has stopped after TIPS.

temic gradient. Ultrasound examination after placement of TIPS is undertaken before discharge from the hospital and 3, 6, 9, and 12 months after the shunt. If US indicates shunt stenosis or occlusion, portal venography and pressure measurements are performed through the right internal jugular vein. Midshunt velocities of less than 60 cm/s, main portal vein velocities less than 40 cm/s, or interval change from hepatofugal to hepatopetal intrahepatic portal flow at US examination should suggest shunt stenosis [61,62]. Because US screening of TIPS is not 100% sensitive or specific, angiographic evaluation may be required if clinical suspicion for stenosis is high. Helical CT angiography has been used to identify both normal and abnormal TIPS and to image focal or diffuse stenoses of the stents and hepatic vein [63].

Therapeutic procedures can be performed easily on a failing TIPS in the outpatient setting. Patients whose shunts are occluded at US should undergo revision of their shunts. The shunt is catheterized from the jugular or femoral vein, and pressures are measured at the right atrium, IVC, hepatic vein, shunt, and portal vein. A portosystemic gradient of greater than 15 mmHg usually indicates a malfunctioning shunt, and a portal venogram will disclose a stenosis anywhere from

the portal vein to the hepatic vein. An angioplasty balloon catheter with the same size of the shunt can be used to dilate a narrowed shunt. If this is unsuccessful, a metallic stent or a covered stent is placed across the lesion.

Complications

The risks of TIPS vary greatly with the patient's bleeding status at the time of shunt creation. Data suggest that the 30-day survival of patients undergoing a TIPS procedure is approximately 95%. However, in patients who are actively bleeding and who undergo TIPS, a 55% mortality rate has been seen [64]. Major complications include hemoperitoneum, gallbladder puncture, stent malposition, hemobilia, hepatic infarction, renal failure requiring dialysis, hepatic artery injury, accelerated liver failure, severe encephalopathy, cardiac perforation, intraperitoneal hemorrhage, and death [65–68]. The reported incidence of new or worsened encephalopathy after TIPS is 20% [53,54]. In almost all cases, the encephalopathy occurring after TIPS creation can be controlled medically. A balloon catheter can be used to occlude the shunt temporarily in a patient who develops refractory hepatic encephalopathy. Balloon occlusion of the shunt for more than 12 h produces shunt thrombosis and improves encephalopathy [69] (Fig. 136.10). If the patient develops variceal bleeding after TIPS occlusion using an occlusion balloon catheter, shunt recanalization can be performed. The flow through the shunt can also be reduced by placing a WALLSTENT with constriction [70]. Minor complications include transient contrast-induced renal failure, encephalopathy controlled by medical therapy, transient pulmonary edema, and puncture site hematoma.

Outcome and prognosis

Patients with TIPS require intensive follow-up for at least 2 years after shunt placement, with shunt revision frequently being required. Primary shunt patency at 1 year after placement is only 25%–60% [52,71,72]; however, with careful monitoring and treatment of shunt stenoses with balloon dilation, additional stent placement, or both, a primary-assisted patency rate of 83%–96% can be achieved 1 year after placement. Some patients require more than one reintervention.

Acute and subacute TIPS thrombosis occurs in up to 10% of cases. Rarely, TIPS thrombosis may extend into the portal, splenic, and mesenteric veins. Percutaneous management in such cases includes thrombolysis, balloon embolectomy, suction embolectomy, and basket extraction of clot. Long-term results of each of the treatments are unknown, but a combination of methods may be required to restore mesenteric blood flow through the TIPS [73].

Inadvertent traversal of bile ducts during creation of the intrahepatic tract results in biliary-to-TIPS fistulae that result in intimal hyperplasia and eventual shunt occlusion. Testing the parenchymal tract with injections of contrast material is useful in detecting inadvertent traversal of the bile duct before stent placement. If stent occlusion is associated with biliary fistula, stent-grafts such as VIATORR can be used to isolate the shunt from the fistula, and to help prevent reocclusion [74,75].

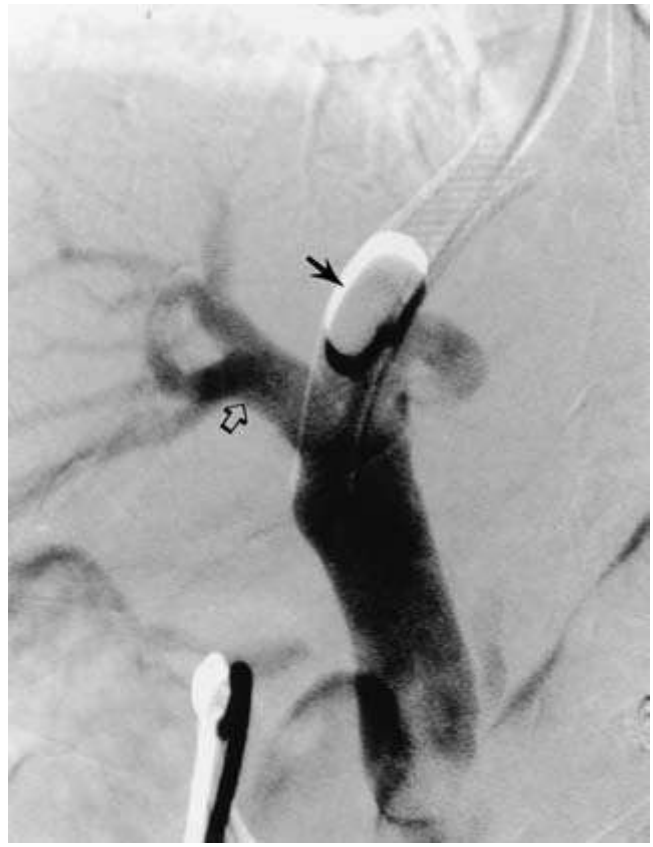

Figure 136.10 Temporary balloon occlusion of transjugular intrahepatic portosystemic shunt (TIPS) for refractory hepatic encephalopathy complicating TIPS placement. Balloon occlusion of the shunt (arrow) for 24 h improved hepatic portal perfusion and encephalopathy. The portal venogram shows hepatopetal blood flow in the right portal vein (open arrow). Subsequently, a smaller shunt (7-mm diameter) was placed. One month later, the patient underwent successful hepatic transplantation.

The long-term patency rate of TIPS remains to be determined. Unless the stenosis rate of TIPS can be reduced, either with covered stents or pharmacological therapy, TIPS will have to be thought of as a temporary treatment of portal hypertension. Even as a temporary treatment, TIPS can effectively control variceal bleeding and stabilize patients who will undergo liver transplantation. As a method to control bleeding in Child class C patients when other therapy has failed, TIPS is useful. In these patients, who have short life expectancies, a durable procedure is not required.

The role of endoscopic therapy and TIPS in elective treatment of variceal bleeding remains to be determined. Transjugular intrahepatic portosystemic shunt is more effective in preventing recurrent bleeding than endoscopic therapy but may result in encephalopathy. Both procedures require repetitive reintervention, and survival rates are similar.

Biliary intervention

Percutaneous transhepatic cholangiography

Diagnostic information about the biliary tree, bile leakage, or intraductal lesions should first be obtained by noninvasive tests – CT, US, MR imaging, biliary scintigraphy, or endoscopic US. When further diagnostic information or the opportunity for therapy is required, endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) are indicated. The choice between ERCP and PTC depends on local expertise, indication for the procedure, and the patient's anatomy.

The indications for PTC include:

- differentiation of obstructive from nonobstructive jaundice
- identification of the cause of ductal obstruction
- delineation of congenital anomalies
- determination of the site of biliary leakage
- documentation of communication of hepatic abscess with the biliary tree
- visualization of ductal anatomy before percutaneous transhepatic biliary drainage (PTBD).

Contraindications include:

- uncorrectable coagulopathy
- history of severe reaction to iodinated contrast medium
- uncooperative patient (may require general anesthesia)
- massive ascites
- the presence of a vascular tumor or arteriovenous malformations.

Risks include bleeding, sepsis, bile leakage, and death, with a 3% morbidity rate and a 0.1% mortality rate [76].

Technique

Coagulation tests are performed on all patients, and significant abnormalities are corrected by the administration of fresh-frozen plasma, platelets, or both. Because of the high incidence of bacterial colonization of the biliary tree in patients with biliary obstruction, broad-spectrum intravenous antibiotics, such as ceftriaxone, are administered before and for 48 h after the procedure [77].

The imaging studies should be reviewed for the presence of intrahepatic masses and the distribution of intrahepatic biliary dilation. The puncture site is chosen in the midaxillary line midway between the costophrenic angle and the lower margin of the liver. Selection of a puncture site caudal to the 10th rib usually helps avoid the pleural space. In certain situations, an anterior approach to the left hepatic duct is used. After the puncture site is selected, the area is washed with 10% povidone-iodine antiseptic and isolated with drapes. The skin and planned puncture tract is anesthetized with 2% lidocaine. The skin nick is made in the caudal portion of an intercostal space to avoid the intercostal vessels and nerves.

Under fluoroscopic control or US guidance, a 22-gauge, skinny needle is directed, in a plane parallel to the table top, to a position 3 cm cephalad to the hilum of the liver. The position of the hilum is estimated fluoroscopically by observing the position of the dome of the liver and the air in the first and second portions of the duodenum. The stylet is removed and the needle is connected through a connecting tube to a contrast-filled syringe. The needle is slowly withdrawn while small amounts of nonionic contrast medium are injected. Alternatively, contrast medium may be injected as the needle is slowly advanced through the parenchyma to avoid portal or hepatic vein branches and rarely hepatic artery [78].

When the needle tip is in the hepatic parenchyma, the contrast agent remains adjacent to the needle tip or opacifies the hepatic sinusoids. When the tip of the needle is in a hepatic artery or portal vein, the contrast agent washes out promptly to the liver periphery. When the tip of the needle is in a hepatic vein, the contrast agent washes out promptly toward the IVC. When the tip of the needle is in a biliary duct, the contrast material flows away slowly to reveal branching ducts as well as the central bile ducts. When the tip is in a lymphatic duct, the contrast material enhances small channels that run toward the liver hilum, often filling the lymph nodes and thoracic duct.

If no bile ducts have been encountered by the time the needle has been withdrawn to within 2–3 cm of the liver edge, the stylet is reinserted and the needle readvanced to a slightly different position. With dilated ducts, the biliary tree can be punctured almost always within several needle passes. When the intrahepatic ducts are not dilated, additional needle passes frequently are required.

For optimal visualization of the left hepatic ducts, or if a left-sided drainage is anticipated, a skin puncture site is chosen below the xiphoid process with the help of real-time US. A peripheral location in a duct of the lateral segment of the left lobe is chosen to be the puncture site so that if drainage is desired, the catheter will have a long segment with multiple side holes within the hepatic duct above the obstruction. The needle is angled parallel to the duct in the axial plane toward the hilum of the liver and at a 30°–50° angle to the table top. The needle is advanced under real-time US guidance and its position is confirmed with injection of contrast medium. If a left-sided drainage is needed after a right-sided drainage, air or CO_2 is injected into the right hepatic duct to fill the left hepatic duct for a target for a puncture.

If the site of obstruction has previously been determined by cross-sectional imaging and biliary drainage is to be performed, only a small amount of contrast agent is injected to assist guidewire placement. If a diagnostic study is to be performed, first an attempt is made to aspirate as much bile as possible, although typically, little or no bile can be aspirated through the fine needle because of its viscosity. Any bile obtained is sent for a Gram stain, and culture and sensitivity tests.

Iodinated contrast medium is slowly injected, and the contrast medium can be seen to flow into the most dependent ducts. Distention of the biliary tree is minimized to avoid

causing bacteremia. By tilting the table, the radiologist takes advantage of the higher specific gravity of contrast material, allowing it to flow to opacify ducts not seen with the patient in the supine position. Radiographs are obtained in multiple obliquities, and the needle is removed. The patient is placed on bed rest for 6 h, and vital signs are monitored.

Fine-needle PTC is successful in 98% of patients with dilated ducts and in 70% of patients with nondilated ducts [76]. Major complications of PTC are sepsis, cholangitis, bile leak, hemorrhage, or pneumothorax, occurring in 2% of cases [77].

Percutaneous transhepatic biliary drainage

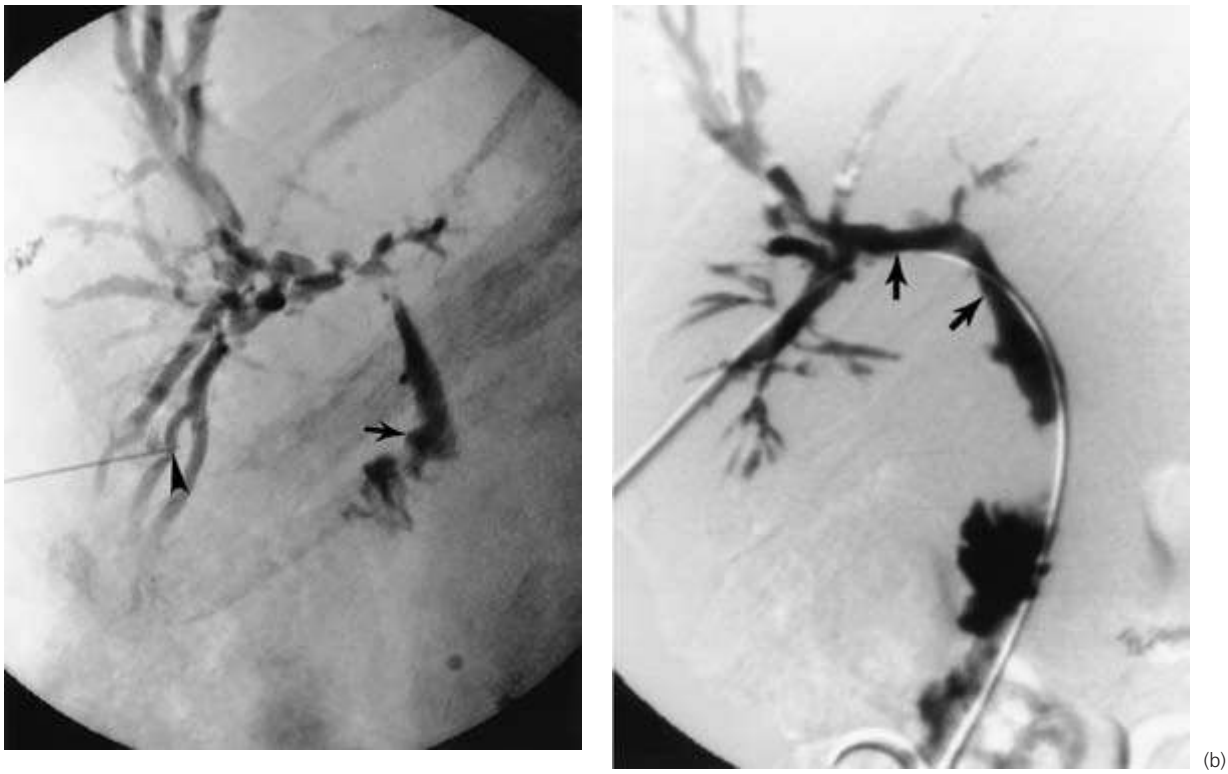
Nonoperative biliary drainage can be performed percutaneously or endoscopically in patients with biliary obstruction. Endoscopic techniques should be used when possible because the morbidity of an endoscopic approach is lower than that of PTBD. With biliary obstruction at or above the hilar level, ERCP has a higher failure rate, making PTBD frequently necessary in these patients (Fig. 136.11). In technically difficult situations in which endoscopic access has failed, a guidewire can be placed into the duodenum transhepatically to facilitate repeat ERCP and intervention. These "combined procedures" are associated with increased complications but have high success rates.

The indications for PTBD include:

- palliation of obstruction of the biliary tree by tumor
- treatment of cholangitis
- nonoperative removal of common bile duct or intrahepatic stones when ERCP is unsuccessful
- access for dilation of benign biliary strictures
- diversion of bile for treatment of biliary leaks or fistulae.

An uncorrectable coagulopathy is a contraindication to PTBD. Prominent ascites is a relative contraindication because the liver is displaced from the abdominal wall. This displacement can cause buckling of guidewires and catheters between the abdominal wall and liver, making the procedure difficult. Also, in patients with ascites, a risk exists of creating a peritoneal–cutaneous fistula with chronic leakage of ascitic fluid. Paracentesis can be performed before PTBD to minimize these problems.

The complications of PTBD include bleeding, sepsis, cholangitis, bile leakage, hemorrhage, pancreatitis, peritonitis, and death. Immediate significant complications are seen in 5%–10% of patients [79]. Patients who have chemotherapy-induced biliary sclerosis and obstructive jaundice have a higher incidence of bleeding complications with development of central pseudoaneurysm following PTBD [80]. After access to the bile duct has been made, the tract may be



(a) (b)

Figure 136.11 Percutaneous transhepatic cholangiography and cholangioplasty in a 46-year-old woman who 9 years earlier had undergone orthotopic liver transplantation for primary sclerosing cholangitis. **(a)** Contrast medium was injected into a peripheral branch of the right hepatic duct through a 22-gauge needle (arrowhead) showing multiple intrahepatic and hilar biliary strictures. Contrast medium flows through the choledochoenterostomy (arrow) into the bowel. **(b)** Cholangioplasty with a 6-mm-diameter balloon catheter improved biliary strictures (arrows). The left hepatic duct has been occluded.

injected with contrast medium to exclude communication with large vascular structures. If vascular communication is seen, the access should be abandoned and a new puncture of a peripheral bile duct is made. This technique reduces the incidence of hemobilia [81]. The overall mortality reported with PTBD is 1.7%.

Technique

The puncture of a bile duct for biliary drainage is the same as that for PTC. After a small injection of contrast medium confirms the needle position in a bile duct, a 0.018-inch (0.46-mm) wire is passed through the needle into the bile duct. Over the guidewire, a 6.3-Fr introducing catheter with a stiffening cannula is advanced into the common bile duct. The stiffening cannula and the wire are removed, and bile is aspirated. After the biliary tree has been decompressed, a cholangiogram is performed with injection of contrast medium in the bile duct near the obstruction. The introducer is then exchanged for a 50-cm catheter with an angle tip (Kumpe catheter, Cook Inc., Bloomington, IN). A 7-Fr sheath may be inserted into the right hepatic duct to prevent escape of bile into the circulation during catheter manipulation within the bile duct.

The catheter is then advanced to the point of obstruction, and a hydrophilic guidewire is manipulated through the obstruction into the duodenum. The catheter is advanced into the duodenum over the guidewire. The parenchymal tract is then dilated using sequential dilators over a 0.035-inch (0.89-mm), stiff guidewire, and an 8.5-Fr (outer diameter 2.8 mm) internal–external drainage catheter is advanced into the duodenum, its distal retention loop is formed, and the drawstring is locked at the catheter hub to prevent catheter displacement.

The drainage catheter is connected to a drainage bag to allow maximal drainage, which reduces the risk of sepsis. On the second day, the catheter is capped to allow internal drainage only. Once the internal drainage has been established, placement of a biliary endoprosthesis, if desired, is performed. If the guidewire does not traverse the occlusion, an external drainage catheter is placed above the obstruction, and the catheter is allowed to drain externally for 2–3 days. After a period of decompression, the obstruction usually can be crossed, and an internal–external drain can be placed. If the drainage is being performed for the treatment of biliary sepsis, no attempt is made to traverse the obstruction. Rather, an external drainage catheter is placed above the obstruction for drainage, and the obstruction should be crossed in several days after sepsis has resolved. Catheter and guidewire manipulation in purulent bile should be minimized because of the profound bacteremia that can ensue.

The success rate of PTBD is high, and most malignant biliary obstruction can be accessed. In patients with malignant biliary obstruction, bilirubin levels fall quickly (2 mg/day) after decompression and patients drained for sepsis improve within 24 h [82].

Percutaneous transhepatic cholangioplasty

An angioplasty balloon catheter can be used to dilate benign biliary strictures through endoscopy, a transhepatic access (Fig. 136.11), a mature T-tube tract, or a percutaneous transjejunal route [83]. Endoscopic dilation is generally preferred by the patient owing to the lack of an external appliance and has long-term success rates of 70%–85%, although it requires two to five ERCP sessions [84,85]. The usefulness of temporary stent placement after cholangioplasty, for both the endoscopic and percutaneous routes, is debated, and even among those who favor using stents the stent size and appropriate duration of placement is controversial. Long-term patency rates of percutaneous cholangioplasty are 67%–93% for anastomotic strictures [86–88], 76%–88% for iatrogenic strictures [86,87], and 42%–54% for strictures of primary sclerosing cholangitis [86,89]. Balloon dilation works well, is less expensive than placing stents, and will not interfere with a future operation, as might a metallic stent. Maccioni and colleagues [90] report a 69% 3-year patency rate in a series of patients composed of anastomotic stenoses and iatrogenic bile duct injuries.

Transhepatic balloon dilation is a safe and effective treatment for biliary stricture in liver transplant recipients [91]. The dilation procedure usually requires multiple sessions (one to six sessions; mean, three). Balloon sizes to be used depend on the estimated size of the duct and are usually 25%–30% larger than the duct. Balloon size is increased by 1–2 mm at each session and the balloon is inflated two to five times to a pressure of 10–12 atm (147–176 psi) for 10–20 min. After dilation, an 8.5–14-Fr drainage catheter is placed. The complications associated with cholangioplasty of biliary strictures include cholangitis, hematoma, bile leak, hemobilia, and pseudoaneurysm of the hepatic artery.

Percutaneous transhepatic biliary stent placement

Internal stents (endoprostheses) can be placed at ERCP or PTC to provide biliary drainage without an external catheter and thus improve quality of life. The problem with internal stents is limited patency, which ranges from 4 months to 1 year [92–96]. Endoscopically placed metallic biliary stents have longer patency than plastic stents owing to larger diameters but are not indicated in benign disease or in patients with operable tumors because they are permanent [95]. Endoscopic placement of internal stents is preferable to the percutaneous route because it can be achieved in a single session without the need for temporary percutaneous drainage. Percutaneous endoprosthesis placement is usually reserved for patients who have failed ERCP or who already have percutaneous access [97].

Hilar biliary stricture formation is a common complication of orthotopic liver transplantation, occurring in 10% of transplants [98]. Intrahepatic strictures unresponsive to balloon dilation have been treated with metallic stents with relatively poor long-term patency. Culp and colleagues [99]

reported on placement of 61 metallic stents in 36 liver transplant recipients with biliary stricture. Their primary patency was 44% at 3 years, with a secondary patency rate of 88%. Major stent-related complications occurred in 26% of their patients. Obstructed stents often require percutaneous drainage and additional stent placement to maintain patency [100]. Therefore, metallic stents play a limited role in the treatment of biliary stricture in the liver transplant patient. Metallic stents are not generally used for treatment of other benign biliary strictures [101]. In patients with malignant biliary strictures, a significant decrease in bilirubin level occurs in 83% following metallic stent implantation, and 30% of patients develop recurrent jaundice after an average of 97 days [102].

A variety of plastic and metal stents are in clinical use. Plastic stents require 12–14-Fr sheaths for placement, whereas metal stents can be placed through 7-Fr sheaths (Figs 136.12–136.14). Stent placement is usually done through the existing percutaneous transhepatic tract (Fig. 136.15) or endoscopically. The most common size of metallic stents is 10 mm diameter (4–8 cm in length), longer than the 10–14-Fr plastic stents. After the stent has been placed, an external drainage catheter is left above the stent for 48 h and with-

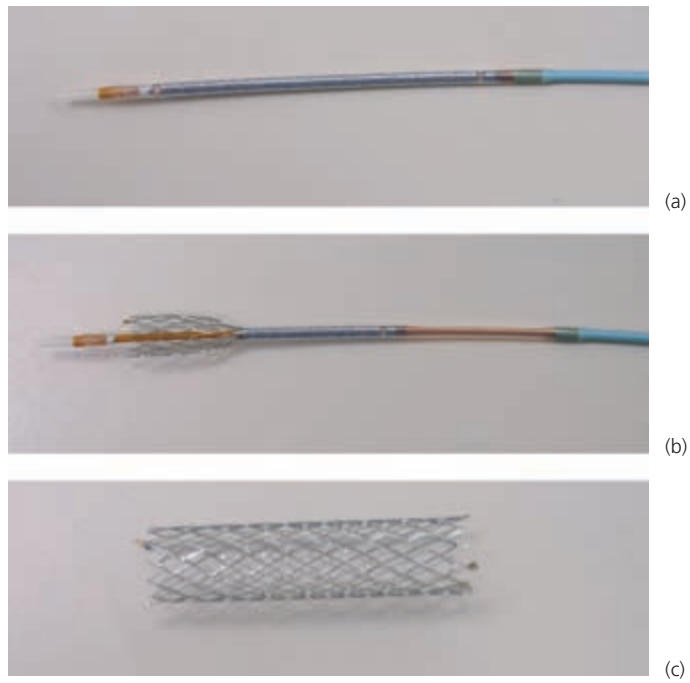

Figure 136.14 The Nitinol stent **(a)** in its constrained form and **(b)** partially deployed. **(c)** The fully deployed stent. Unlike the WALLSTENT, the nitinol stent has minimal shortening following deployment.

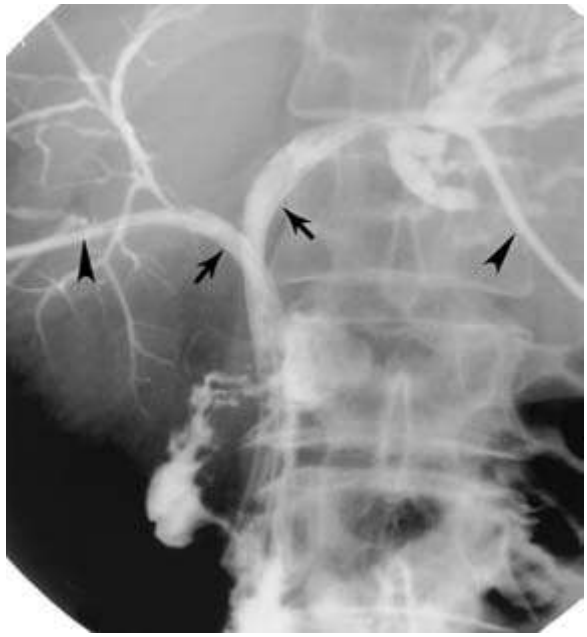

Figure 136.15 Transhepatic biliary stent placement in a 61-year-old man with Klatskin tumor. After bilateral percutaneous transhepatic drainage catheter placement for 6 months for hilar duct obstruction, 8-mm-diameter WALLSTENTS (arrows) were deployed simultaneously in both hilar ducts. The percutaneous catheters (arrowheads) were removed after demonstration of patency of the stents.

drawn following demonstration of stent patency. If there is no bleeding or other complications associated with stent placement, the external catheter is removed following stent placement.

The complications of endoprostheses are occlusion, migration, cholangitis, bowel obstruction, and perforation. The occlusion is usually caused by either tumor overgrowth or ingrowth or clogging of the stent by sludge or debris [103]. Covered stents may reduce the rate of tumor ingrowth in patients with malignant biliary obstruction, but their application should be limited to the common bile duct to avoid obstruction of the hepatic ducts [104].

Combined therapy with stent placement and brachytherapy with iridium 192 wire in patients with malignant biliary obstruction appears to extend stent patency to a mean of 19.5 months for cholangiocarcinoma and 4.8 months for metastatic disease [105,106]. The combination of arterial chemoembolization and brachytherapy following stent placement may result in additional palliation for biliary obstruction. Covered Gianturco stents have been used for malignant biliary obstruction, achieving longer patency rate without increased complication rates.

In patients with a Hutson loop (afferent limb of a Roux-en-Y choledochojejunostomy or hepaticojejunostomy sutured to the anterior abdominal wall), repeat access to the bile duct can be done for biliary drainage, cholangioplasty, or placement of biliary endoprostheses [107–109].

Percutaneous cholecystostomy

Percutaneous cholecystostomy (PC) has become an effective technique in the management of acute cholecystitis. The indications for PC include:

- suspected cholecystitis in severely ill patients unlikely to tolerate cholecystectomy [110]
- sepsis of unknown cause and a distended gallbladder in critically ill patients
- acalculous cholecystitis [111]
- obstructive jaundice because of distal common bile duct obstruction when PTBD and endoscopic drainage are unsuccessful [112]
- diagnostic cholecystocholangiography in patients without dilated intrahepatic ducts or in whom PTC and ERCP are unsuccessful
- gallstones requiring percutaneous removal or dissolution, in selected patients.

The relative contraindications for PC include the visualization of a necrotic or perforated gallbladder wall on US examination and an uncorrectable bleeding diathesis.

Once the PC tract is matured, percutaneous techniques – including contact dissolution using methyl-tert-butyl ether or monooctanoin, mechanical lithotripsy, electrohydraulic lithotripsy, and laser lithotripsy – can be used to remove gallstones. Aside from the cost and multiple sittings required for many of these procedures, the main failing is that the gallbladder remains in situ to reform stones in 20%–50% of patients [113], with an increased risk of gallbladder carcinoma [114]. The rapid evolution of laparoscopic cholecystectomy has supplanted these percutaneous techniques in most circumstances, because laparoscopic cholecystectomy does not leave the gallbladder in place. Percutaneous cholecystostomy should be performed in severely ill patients who may not tolerate laparoscopic cholecystectomy.

Technique

Intravenous antibiotics are given and coagulopathies are corrected before the procedure. Ideally, the procedure is performed in the angiography suite with a combination of US guidance for gallbladder puncture and fluoroscopy for guidewire and catheter placement. Extremely ill patients may be treated at their bedside with the entire procedure guided by US. The procedure is performed under local anesthesia.

Initially, PC was performed using a transhepatic approach in an attempt to puncture the gallbladder through the liver and avoid the possible complication of bile peritonitis [115]. Transhepatic transperitoneal punctures are common [116]. Subhepatic puncture has been shown to be safe and avoids the risk of bleeding from hepatic injury [117–119].

A variety of techniques are used for PC, including the standard Seldinger technique with needle puncture, guidewire placement, removal of the needle, tract dilation, and advancement of a drainage catheter over the guidewire into the gallbladder. Another technique more suitable for use at the

bedside involves the use of a trocar. A tapered catheter with an inner stiffener and a central mandril with a sharp point are advanced into the gallbladder under US guidance. Another technique appropriate for bedside use involves a long, 22-gauge needle with a 6-Fr Teflon catheter loaded on the back of the needle. The needle is placed into the gallbladder under US guidance and its mandril is removed. Injection of a small volume of saline and observation with US can be used to confirm the intralumenal position of the needle tip if the bile is too viscous to be aspirated through the long 22-gauge needle. A 0.046-cm guidewire is advanced through the needle and the needle tip is positioned in the center of the gallbladder. The catheter is advanced over the needle–wire unit into the gallbladder. The needle and guidewire are removed, and the monofilament suture present within the catheter is tightened to accordion the catheter into a Z-shaped self-retaining configuration.

Bile is obtained for aerobic and anaerobic bacterial cultures, and the catheter is secured to the skin. Although a small amount of contrast medium may be injected to confirm catheter position, if the PC is being performed for cholecystitis, a cholecystogram should not be performed at this time to reduce the risk for gallbladder distention and bacteremia. The catheter then is connected to gravity drainage. The use of a self-retaining catheter is essential to reduce the risk of catheter dislodgment and bile leakage.

A diagnostic cholecystocholangiogram can be performed to evaluate cystic duct patency and cholelithiasis after 48 h and after the patient's condition stabilizes (Fig. 136.16). Options for definitive therapy include surgical or laparoscopic cholecystectomy [119], percutaneous stone removal, or, if the patient had acalculous cholecystitis and cystic duct patency is confirmed, eventual removal of the catheter with no further treatment. The catheter cannot be removed until the tract is mature or bile leakage can occur. Patients with transhepatic PC catheters have mature tracts at 20 days. If a question exists about the maturity of the tract, it can be evaluated under fluoroscopy with injection of contrast medium. For patients with severe nonbiliary problems, the catheter frequently is left in place until other medical problems resolve.

Figure 136.16 Percutaneous cholecystostomy in a 52-year-old man with cardiomyopathy and acute cholecystitis. A hepatobiliary scan showed no filling of the gallbladder. Percutaneous ultrasound-guided cholecystogram shows partially filled gallbladder (arrow). The cystic duct did not fill.

Complications

The complication rate is 5%–8%; complications include bile leakage, vasovagal reaction, catheter dislodgment, hemorrhage, and a 0.5% procedure-related mortality rate [120]. In comparison, emergency surgical cholecystostomy has a mortality rate of 8% [121].

Results

Percutaneous cholecystostomy for presumed cholecystitis in critically ill patients is useful for diagnosis and treatment. Although initially it was thought that Gram stain and culture of aspirated gallbladder contents would be useful to diagnose cholecystitis, many of these patients are already on broad-spectrum antibiotics. The 48% sensitivity rate of Gram stain and 38% sensitivity rate of bile culture are sufficiently low to make gallbladder aspiration a procedure of limited value [120]. However, PC is useful as a clinical diagnostic test. Essentially all patients who have cholecystitis without a necrotic gallbladder wall will improve and normalize their leukocyte count after drainage [111,122].

Severely ill patients who have ultrasonographic evidence of a necrotic gallbladder wall are less likely to respond to PC and should undergo immediate operation or a trial of PC with operation to follow if no clinical improvement is seen in 24 h, depending on the patient's risk for surgery [123]. In patients without a necrotic gallbladder wall and no response to PC, cholecystitis is excluded, and the search for a non-gallbladder source of sepsis should continue.

Biliary duct biopsy

The most difficult diagnostic problem of bile duct lesions is differentiating between malignancy and inflammatory disease in the patient with biliary strictures. Bile aspiration yields only 35% positive cytology. Brush biopsy, clamshell forceps biopsy, and shave biopsy are somewhat more sensitive, with sensitivities of 44%–67% reported [124–126].

Endoscopically, a combination of tissue sampling techniques, such as direct forceps biopsy, brush cytology, or aspiration cytology has the highest yield [127]. An advantage of endoscopic over percutaneous tissue sampling is that all techniques can be performed during the initial procedure.

For the percutaneous route, in the absence of bacteremia or hemobilia following drainage, biopsy can be performed 1–2 days after the procedure [128]. Broad-spectrum antibiotics are administered before the procedure. The transhepatic drain-

age catheter is exchanged over a guidewire for an introducer, which is advanced distal to the stricture or to the duodenum, and a second safety guidewire is placed into the duodenum. A 3-mm bronchoscopy brush or a removable ureteral biopsy brush is advanced through the sheath or an introducing catheter beyond the lesion. After brushing of the lesion has been performed, the brush is pulled into the introducing catheter or the sheath before withdrawal. The brush is cut from the wire and submitted for cytological examination.

Another technique for biliary biopsy involves the use of forceps (Fig. 136.17). After placing a safety wire in the duodenum, a 7-Fr peel-away sheath is placed immediately proximal to the lesion, a 5.2-Fr or a 7-Fr flexible clamshell forceps is advanced to the lesion, and biopsy is performed. Clamshell forceps biopsies can also be performed through a choledochofiberscope.

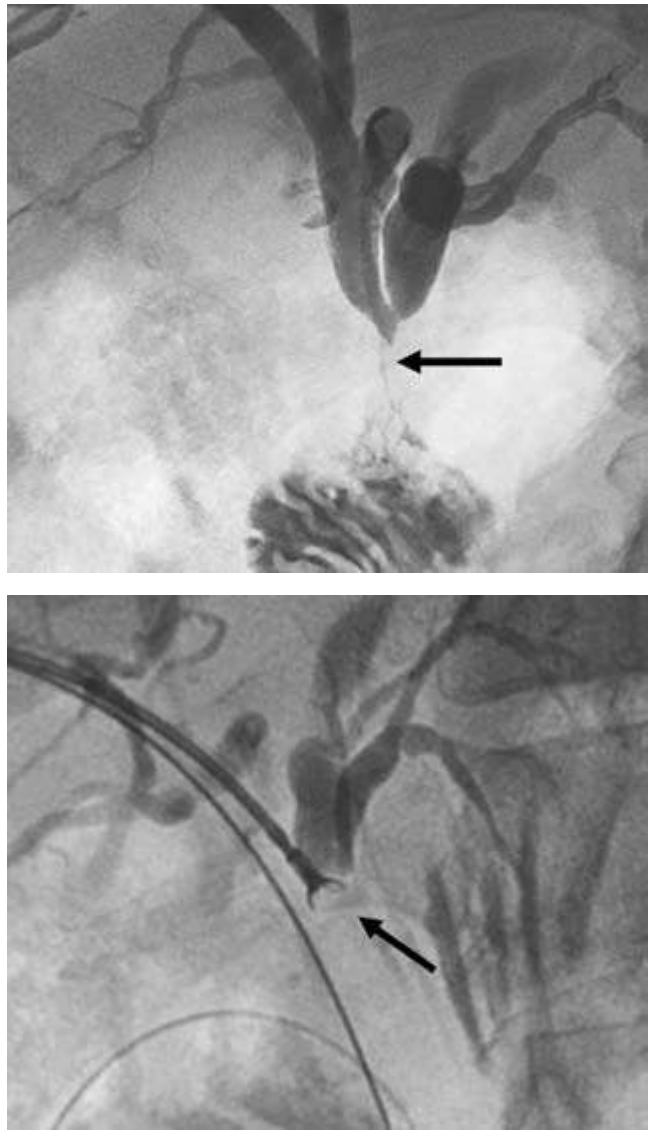

Figure 136.17 Forceps biopsy of the bile duct in a 43-year-old man with bile duct stricture after a Whipple procedure for pancreatic cancer. **(a)** Percutaneous cholangiogram shows stricture at the choledochal–enteric anastomosis (arrow). **(b)** Forceps biopsy (arrow) was performed through the transhepatic route. The result of the biopsy showed scar. A safety wire is seen crossing the stricture into the bowel.

Laparoscopic injuries to the biliary system

Both endoscopic and interventional radiological management plays an important role in the treatment of patients with bile duct injuries resulting from laparoscopic cholecystectomy. The injuries include biliary obstruction from bile duct transection or stricture, biliary leakage with formation of biloma, and retained stones. Ultrasound or CT is the initial imaging method used for the diagnosis of the biliary complications; ERCP is then performed to obtain the necessary anatomical information for therapy. If ERCP is unsuccessful or unable to cross the obstruction secondary to inadvertent ligation of the bile duct, a drainage catheter must be placed above the obstruction.

Biliary strictures that are not amenable to surgical intervention may be treated with percutaneous or endoscopic balloon dilation. Before the procedure, the patient is given broad-spectrum antibiotics. The procedure can be done on an outpatient basis with conscious sedation and local anesthetic. After placing a 0.035-inch (0.89-mm) guidewire across the stricture, a balloon catheter (usually 8–10 mm in diameter) is placed over the guidewire and inflated two to three times for 3–5 min. A drainage catheter, such as an 8.5-Fr Cope loop catheter, is left across the stricture for external drainage, and the treatment effectiveness is then assessed in 2 weeks. If a satisfactory response is demonstrated by a follow-up cholangiogram, a catheter is placed above the stricture and capped to allow internal drainage for 1–2 weeks before withdrawal of the catheter. Metallic stents should be reserved for patients with a recurrent biliary stricture following multiple balloon dilations and who are not candidates for surgery.

Bile leak is treated with temporary diversion of bile through endoscopic biliary intubation or transhepatic biliary drainage. After 3–4 weeks of bile diversion, the plastic stent is removed over a guidewire, and a cholangiogram is performed through a sheath to show healing of the leak. If no leak is demonstrated, a drainage catheter is placed above the area of leakage and capped for 1–2 weeks to reassess bile duct leak before removal of the catheter. If the leak is associated with significant bile collection, percutaneous drainage is performed under CT or US guidance.

Retained common bile duct stones may be found after laparoscopic cholecystectomy. Endoscopic extraction after sphincterotomy is the preferred method in such patients. If an endoscopic approach is unsuccessful, a percutaneous transhepatic approach may be used. Stone extraction should be deferred for 4–6 weeks to allow the tract to mature after placement of a transhepatic catheter. Alternatively, combined ERCP and PTC, with the PTC wire facilitating endoscopic access, may be used.

Biliary manometry

Biliary manometry is used to assess bile pressure and flow dynamics. This is different from the sphincter of Oddi manometry performed at ERCP, which measures sphincter muscle function. Measurement of bile pressure at PTC has been shown to be useful in predicting long-term success after treatment of biliary strictures with balloon cholangioplasty [129].

The patient is treated with prophylactic antibiotics before the examination. In patients with transhepatic biliary intubation, the indwelling tube is removed over a guidewire and an end-hole catheter is placed through a sheath above the treated stricture and connected to a manometer. Pressure is measured at the level of the midaxillary line. Continuous pressure measurements are obtained before and during perfusion of 30% contrast medium at the rate of 5 mL/min for 5 min, then 10 mL/min for a further 5 min. If the biliary pressure still remains less than 30 cmH_2O, the perfusion rate can be increased to 15 or 20 mL/min for 2 min. The perfusion should be discontinued if the patient experiences right upper abdominal pain or chills, or if the biliary pressure increases to more than 30 cmH_2O. In the absence of a significant stricture, the biliary pressure will remain below 20 cmH_2O during the perfusion.

Percutaneous biliary stone extraction

Endoscopic sphincterotomy or papillary balloon dilation with stone extraction is the primary mode of treatment for choledocholithiasis [130]. However, if a T-tube tract or transhepatic access is available, radiologically guided stone extraction may be performed. Intrahepatic stones occasionally are inaccessible at ERCP and require the percutaneous transhepatic route. Choledoscopy facilitates stone extraction [131]. Percutaneous stone extraction is a radiologically guided procedure for the treatment of biliary stones not amenable to surgical, endoscopic, or extracorporeal shock-wave therapy [132]. Stone removal can be done through the preexisting, mature transhepatic biliary drain tracts, T-tube tracts, cholecystostomy tube tracts, and hepaticocutaneous enterostomy.

Basket removal of retained stones through the T-tube tract is a safe and simple method of removing retained stones. With the advent of the steerable catheter system, stone extraction has become a technically easy procedure. The Dormia-type basket is most commonly used for stone extraction. The steps for stone extraction are:

1. removal of the T-tube over a guidewire
2. insertion of a steerable catheter through the T-tube tract
3. extraction of the stone using a wire basket.

After the stone has been extracted, a drainage catheter is placed in the common bile duct. When no residual stones are present, the catheter is capped for 1–2 weeks of "clinical trial" before withdrawal of the catheter. Large stones must be fragmented by using crushing baskets or an electrohydraulic lithotriptor before extraction [133]. Extracorporeal shock-wave lithotripsy is effective in fragmenting bile duct stones but often requires extraction of fragments [134,135]. Percutaneous techniques may be used for removal of gallstones in patients with high surgical or general anesthetic risk [136]. Because the percutaneous method is a gallbladder-sparing procedure, it carries the risk for recurrence of stone (40%) and symptoms (12%).

Percutaneous management of biliary fistula

Biliary fistulae that originate in the liver may result from trauma, surgery (cholecystectomy, resection of hepatic tumor, and liver transplantation), or local infection, such as hydatid disease. Small biliary fistulae may close spontaneously, and no specific treatment is required. When a biliary fistula is associated with distal biliary obstruction, however, biliary decompression is usually required by using endoscopic, percutaneous transhepatic, or transbronchial approaches [137–140].

The nonoperative methods for managing biliary fistulae include external biliary drainage, nasobiliary catheter drainage, bile duct stent placement, and sphincterotomy. Selective embolization through a percutaneous transhepatic or endoscopic approach may be used for the treatment of biliary fistulae unresponsive to biliary decompression [141].

Percutaneous biopsy

Percutaneous image-guided sampling of abdominal lesions is a safe and effective method of obtaining material for cytological or histological analysis and for microbiological and chemical analysis of fluid collections. Advances in CT and US have allowed accurate localization of smaller and more subtle lesions, and experience has demonstrated the safety of percutaneous biopsy through windows previously thought to be unsafe.

Technique

The optimal imaging modality for guiding a needle biopsy depends on the position and visualization of the lesion, the patient's body habitus, the ability to introduce radiopaque contrast medium adjacent to the lesion, and the experience of the radiologist. Patients undergoing biopsy have their prothrombin time, activated partial thromboplastin time, and platelet count checked and corrected if necessary. Patients who are to receive intravenous contrast medium are hydrated and have their blood urea nitrogen and creatinine levels checked. Most patients do not require a sedative, but those who are unusually anxious or find it painful to lie in the required position are given midazolam, fentanyl, or both.

Fluoroscopy in multiple planes, most frequently with a C-arm, provides easy and efficient guidance for biopsy of large, superficially located lesions. Fluoroscopic landmarks, such as distance from a particular bony structure or position adjacent to a radiopaque stent, can be used to position the needle. If an indwelling biliary catheter is present, contrast medium

can be introduced to allow fluoroscopically guided biopsy of biliary duct lesions. Fluoroscopy also is useful for biopsy of abnormal lymph nodes identified at lymphangiography that still contain lymphangiographic contrast medium.

Real-time US has many advantages for intraabdominal biopsy. Perhaps its greatest advantage is that, unlike CT, it allows continuous monitoring of the course of the needle while the needle is being advanced, allowing instant readjustment of the needle path as necessary. Ultrasound guidance may be applied when the lesion is ultrasonographically visible and the needle path avoids gas-filled bowel – the soft tissue–gas interfaces reflect most of the sound waves and preclude visualization of the needle tip and the lesion. Ultrasound is also advantageous when the ideal needle path is at a steep angle to the axial plane because such an angle makes CT guidance more difficult. However, US guidance is difficult in obese patients because fat degrades the US image.

Computed tomography is most frequently used to guide biopsies that cannot be performed reliably with fluoroscopy or US, and CT usually is the imaging modality of choice for small, deep-seated lesions. Oral, intravenous, and rectal contrast medium is administered as needed for lesion visualization. To perform CT-guided biopsies, a localizing radiopaque grid is placed on the skin covering the region of the skin entry site as estimated from prior scans, and a scan at the level of the lesion is repeated. A needle path is chosen, preferably in the axial plane, and the skin puncture site is marked on the skin. The depth of the lesion and the angle between the needle path and a vertical line through the lesion are measured.

The types of needles available for percutaneous biopsy are nearly as numerous as the types of diseases for which biopsy is performed. Needles can be classified into those that obtain material for cytological analysis and those that obtain tissue for histological analysis. Needles from 25-gauge to 14-gauge are used: the smaller sizes predominantly for aspiration cytological study and the larger ones for obtaining a core of tissue. Aspiration cytological study with a skinny needle (20–25 gauge) is the most frequently performed percutaneous biopsy. When a tissue core is desirable, the spring-loaded, mechanically triggered biopsy needles (guns) are used. These needles have a Tru-Cut-type design, and once in position, the inner or outer parts (depending on the manufacturer) of the needle are advanced rapidly forward by a preloaded spring mechanism. These guns offer the benefit of producing less pain than the Tru-Cut needle, and some 18-gauge guns produce a specimen as good as that obtained with a 14-gauge Tru-Cut needle [142].

A needle path is chosen that avoids lung, gallbladder, spleen, and, if possible, bowel and vascular structures. Passing 21-gauge needles through the stomach and small and large bowel is safe [143], and some institutions routinely place 18-gauge needles through bowel without complication. It appears judicious to avoid puncturing the bowel in immunocompromised patients and those with ascites.

Local anesthetic and a small skin nick precede needle placement. The needle may then be advanced directly into position. If a larger needle is being used, a skinny needle may be first positioned within the lesion, then the larger needle may be placed parallel to the smaller needle. This allows the needle repositioning that is common with CT guidance to take place with the smaller needle, and allows the larger needle to be properly positioned on the first pass. A coaxial needle technique also is useful for small or difficult lesions. The technique involves placement of a larger needle up to the lesion with the biopsy performed through a smaller inner needle. This allows simple, repetitive sampling by removing only the smaller inner needle, assessing its yield and, if necessary, replacing the inner needle and repeating the biopsy.

Indications

In most cases, an aspiration biopsy is adequate to make the diagnosis of malignancy, although specific tumor characterization may require a core of tissue. Aspiration biopsy is useful in diagnosing acute liver transplant rejection, but core biopsy is more useful in diagnosing chronic rejection [144]. Core soft tissue should be obtained routinely whenever the cellular architecture is important for microscopic diagnosis (e.g., diffuse liver disease, likely benign focal liver lesions, lymphoma).

Contraindications and risks

A patient who will not lie still is an absolute contraindication to image-guided needle biopsy. It is impossible to target a moving lesion, and there is the risk for visceral injury. For biopsy of abdominal lesions, patients must be capable of holding their breath for a minimum of 10 s so that respiratory excursion of the lesion is suspended during needle placement. A bleeding diathesis is a relative contraindication depending on the severity of the diathesis, the location of the lesion, lesion vascularity, and the size of the needle required. If a coagulopathy would otherwise contraindicate biopsy and the lesion is intrahepatic, transvenous biopsy or biopsy with embolization of the needle tract (plugged biopsy) can be performed. Ascites does not affect the major or minor complication rate of image-guided hepatic biopsy [145].

Suspected hemangiomas have been listed as a contraindication to needle biopsy; however, after unintended aspirations of such lesions were reported, several authors reported series of safe biopsies of these two entities [146,147]. With use of a 20-gauge cutting needle, a percutaneous hepatic biopsy can be safely performed for histological diagnosis of hemangioma [147]. A needle path traversing normal liver before reaching the lesion is recommended to reduce the possibility of hemorrhage.

Percutaneous needle biopsy is a relatively safe, invasive procedure with low morbidity and mortality. Severe pancreatitis can occur after pancreatic biopsy and the incidence of pancreatitis increases when biopsy is performed on a normal pancreas. Needle tract tumor seeding after intraabdominal

biopsy is a rare occurrence. Traversing normal parenchyma before entering a lesion may reduce the risk for seeding. Hemorrhage is the most common complication of liver biopsy. Hemorrhage may occur as intraabdominal bleeding or hemobilia after creation of an arteriobiliary fistula. Severe hemobilia after needle biopsy is best managed with selective embolization of the bleeding artery. Severe intraabdominal bleeding may be more common if the needle does not initially traverse normal parenchyma.

Results

Image-guided hepatic biopsy using skinny needles is accurate in the diagnosis of malignancy in more than 90% of patients [148]. Accurate diagnosis of hemangioma can be made 100% of the time using a 20-gauge coring needle [147]. Skinny needle biopsy of the pancreas has been reported to be accurate 60%–90% of the time. The coexistence of pancreatic carcinoma and pancreatitis may result in biopsy of the inflammatory area, which frequently cannot be distinguished by CT or US from the neoplastic area. The possibility of sampling error suggests that an initial negative result from percutaneous pancreatic biopsy should not be accepted, and either a repeat percutaneous biopsy or an operative biopsy should be performed as warranted by clinical circumstances.

Percutaneous image-guided aspiration biopsy of lymph nodes has been performed more often than large-core biopsy for evaluation of lymphadenopathy. Fine-needle aspiration of lymph nodes using cytological examination for detection of metastatic carcinoma is highly accurate [149], and the accuracy of detecting lymphoma is about 80% [149]. Accurate typing of lymphoma by fine-needle aspiration remains problematic, but advances in immunocytochemistry [150] and flow cytometry may prove helpful. The accuracy of percutaneous core biopsies for classifying lymphomas remains to be determined.

Alternative techniques to biopsy

A number of catheter-based techniques have evolved that are useful in specific situations when percutaneous needle biopsy is difficult or contraindicated.

Transjugular liver biopsy

If coagulopathy or marked ascites are present, transjugular liver biopsy provides an alternative to percutaneous biopsy because the needle does not traverse the liver capsule, thereby avoiding hemorrhage [151]. An 18-gauge, 60-cm-long automated biopsy device has been designed for obtaining liver histological samples through a jugular venous approach.

The technique is similar to that used for the TIPS procedure. The right or left internal jugular vein is punctured using a 21-gauge, single-wall access needle under US guidance, and a 9-Fr sheath is inserted. Through the sheath a 5-Fr catheter is advanced through the right atrium into the IVC. Pressures are measured in the right atrium, IVC, hepatic, and wedged hepatic veins. A CO_2 wedged hepatic venogram is obtained to demonstrate the portal vein and to identify the right or left hepatic vein. A 7-Fr, 49-cm-long curved catheter is then advanced into the right hepatic vein over an Amplatz super-stiff guide wire. Through this sheath, a 14-gauge stiffening cannula is advanced into the right hepatic vein and directed anteriorly against the wall of the vein. Liver biopsy is performed near the IVC (Fig. 136.18). Biopsy from a peripheral hepatic vein may result in perforation of the hepatic capsule and increases the possibility of bleeding. This technique is successful in more than 90% of patients [151,152]. Major complications occur in 2% of patients and include cardiac arrhythmias and intraperitoneal hemorrhage from inadvertent capsular puncture. Transjugular liver biopsy with hepatic venography and manometry can provide the anatomical, hemodynamic, and histological information on the liver and hepatoportal venous system.

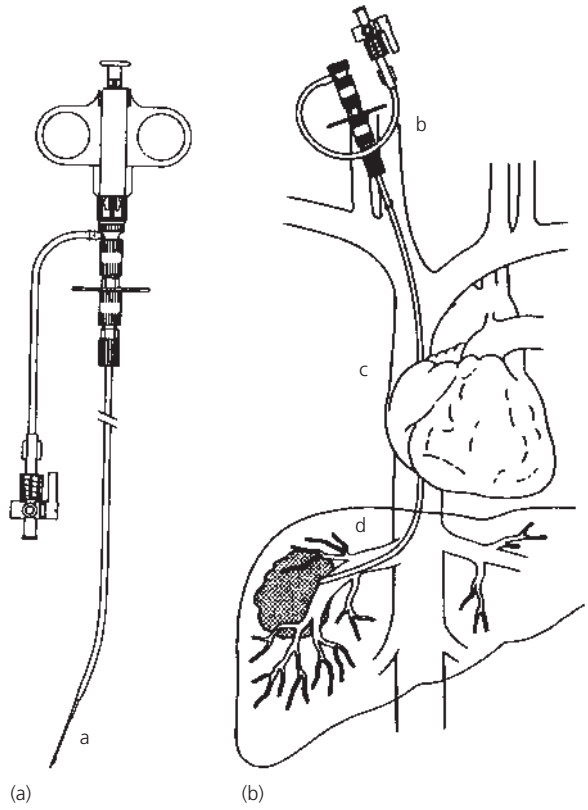

Figure 136.18 Transjugular liver biopsy. **(a)** Liver access set assembled with Quick-Core biopsy needle. **(b)** The preassembled liver access set has been introduced into the right hepatic vein over the guidewire from the internal jugular vein. The directional arrow on the hub of the stiffening cannula is used to direct the needle anteriorly and gentle pressure is applied to the wall of the central hepatic vein. The Quick-Core biopsy needle is advanced through the sheath into the liver tissue. The stylet is then advanced to expose the specimen notch (*a*), and the cutting cannula is fired to obtain tissue within the specimen notch. The biopsy needle is withdrawn and the tissue specimen is removed from the notch and placed in formalin. *b*, right internal jugular vein; *c*, superior vena cava; *d*, right hepatic vein.

Transhepatic liver biopsy with tract embolization

When a histological core of liver tissue is needed and coagulopathy or marked ascites preclude standard percutaneous liver biopsy, embolization of the needle tract within the liver can prevent bleeding from the liver capsule puncture site. Embolization of the tract is performed with a Gianturco coil [153] or with gelatin sponge plugs. The occluding materials may be introduced through the outer part of a Tru-Cut-type needle after the inner obturator and specimen have been removed, or through a 4-Fr (1.3-mm diameter) vascular sheath fitted over the needle before biopsy [154]. Introducing the embolus through the vascular sheath is useful because the sheath is much more flexible than the needle cannula and is less likely to cause injury while the patient breathes and the liver moves. The potential disadvantage of using the sheath is that a larger hole is made in the liver capsule than would be made by the needle alone.

Plugged biopsy is faster and usually less costly, and it does not require the same level of technical skill and experience required for transvenous biopsy. Plugged biopsy can be performed with imaging guidance to obtain a core sample of a focal lesion. Transvenous biopsy is not useful for most focal hepatic lesions because of the inability to steer the transvenous needle precisely. The published experience with plugged liver biopsy is too small to allow an accurate comparison of the risks of plugged liver biopsy with transvenous biopsy. Transvenous biopsy is considered safer for patients with severe coagulation disorders.

Percutaneous abscess and fluid collection drainage

Percutaneous abscess drainage (PAD) is effective in treating abdominal abscesses and fluid collections [155]. Percutaneous needle aspiration is helpful in determining the nature of any intraabdominal fluid collections, including abscess, biloma, lymphocele, seroma, loculated ascites, hematoma, and urinoma. Percutaneous catheter drainage is indicated for the treatment of infected fluid collections (e.g., hepatic and diverticular abscesses) and symptomatic fluid collections (e.g., pancreatic pseudocyst and lymphocele). Contraindications include absence of a safe access route to the fluid collection and coagulopathy.

Technique

Percutaneous needle aspiration and catheter drainage usually require CT or US guidance. Real-time US is most useful if the fluid collection is easily seen and a safe access route can be found, such as retroperitoneal, hepatic, or splenic drainage. C-arm-supported CT fluoroscopy is useful in percutaneous abscess drainage procedures [156]. Computed tomography guidance is preferred for drainage of deep fluid collections, and is helpful in differentiating bowel loops from abscess. All patients undergoing abscess drainage receive intravenous broad-spectrum antibiotics prior to the catheter placement, and in anticipation of possible drain placement, bleeding diatheses are corrected.

The methods in general use for percutaneous drainage of the intraabdominal abscesses include the Seldinger method using guidewires, dilators, and a drainage catheter; and the trocar method using a drainage catheter with an inner stiffener and central pointed trocar. The trocar catheter is advanced in a single pass, parallel to the initial needle, and to the same depth. The trocar technique obviates guidewire exchange and tract dilation, and also theoretically reduces the risk for leakage of pus into a contaminated space during guidewire exchange. When the acceptable window of access is narrow, the Seldinger technique may be preferred, so as to avoid unintentional passage of the trocar catheter into a vital structure.

Single- or double-lumen (sump) catheters (8–16 Fr) may be used. Single-lumen catheters are connected to gravity drainage. Sump catheters may be left to gravity or low suction. The catheter is flushed with 10 mL of saline every 4–6 h for the first day and once daily after the first day. The effectiveness of the drainage should be assessed with a repeat scan. The determination of successful therapy is made on the basis of abatement of symptoms and signs of infection and less than 10 mL/day of drainage, radiographic evidence of cavity closure with contrast injection, and absence of fluid collection by a repeat scan.

Hepatic cysts and abscess

Congenital cysts may be solitary or multiple, and can be associated with polycystic kidney disease. Cysts that cause symptoms such as pain or jaundice may require treatment. Percutaneous drainage and injection of sclerosing agent into the cyst is an effective alternative to surgical treatment [157,158]. The technique consists of percutaneous puncture of the cyst under US guidance and insertion of a 5-Fr pigtail catheter into the cyst using the Seldinger technique. After complete aspiration of the cyst, the cyst is filled with 95% ethanol in a volume of 30% of the cystic fluid aspirated. After 20 min of sclerosis with changes of the patient's position, the residual cystic fluid is aspirated.

Hepatic abscesses may be bacterial, echinococcal, or amebic in origin. When the diagnosis of pyogenic abscess is established, parenteral broad-spectrum antibiotic coverage is required 1 h before percutaneous aspiration or catheter drainage. Sedation and use of analgesia with appropriate monitoring of vital signs are required during the procedure. Percutaneous drainage is safe and succeeds in about 90% of patients [155]. Effective drainage can be achieved in a loculated hepatic abscess. Computed tomography or US is required for accurate puncture of the lesion. The pleural reflection extends to the 10th intercostal space laterally. To avoid transgression of the pleural space, an angled approach, guided by US and CT, should be used for drainage of high lesions.

The traditional treatment of hydatid cysts has been surgical because of the risk for percutaneous puncture (e.g., peritoneal seeding and anaphylaxis). Although hydatid cysts were previously considered a contraindication to percutaneous aspiration, safe and successful drainage has been achieved with the use of transhepatic puncture and injection of alcohol or hypertonic saline into the cyst after aspiration [159,160].

The role of percutaneous aspiration or catheter drainage for the treatment of hepatic amebic abscess remains controversial. Nearly all hepatic amebic abscesses can be cured by antimicrobial drugs alone, although percutaneous drainage may be useful for patients with abscesses of more than 6 cm and those who have failed one course of medical therapy. After a drainage catheter is placed, the catheter is irrigated with normal saline every 8 h. The volume of irrigating saline is about 25% of the volume of the original cavity. Excessive amounts of fluid should be avoided to prevent rupture of the cavity and leakage of the fluid. Follow-up imaging of the abscess is performed at 5–7 days to evaluate for the effectiveness of the drainage and communication with bile ducts or bowel. When the patient is afebrile with a normal white blood cell count, the 24-h drainage volume is less than 10 mL, and a cavity has no communication with a bile duct, the tube is removed. The patients should receive antibiotics for 2–6 weeks.

Pancreatic abscess and fluid collections

Pseudocysts, whether infected or not, are cured by percutaneous drainage in 70%–90% of patients [161–164]. The response rate may be higher in infected than in noninfected pseudocysts [163]. Indications for percutaneous drainage include pseudocyst infection, pain associated with a pseudocyst larger than 4–5 cm, and a pseudocyst causing bile duct or gastric outlet obstruction. An asymptomatic pseudocyst larger than 10 cm also warrants percutaneous drainage to avoid serious complications. Somatostatin analogues reduce output from pseudocyst drainage catheters and may prove useful in reducing the duration of catheter drainage. The technique for percutaneous drainage of pancreatic pseudocysts is the same as that for other intraabdominal fluid collections. Various access routes to pseudocysts have been used, including transgastric, transhepatic, transsplenic, and transhepatic–transduodenal approaches.

Long-term external drainage is often required for percutaneous transgastric decompression of large pancreatic pseudocysts. The initial external catheter can be converted to internal drainage by placing an internal double-mushroom stent after 14 days, eliminating the need for an external catheter [165]. When early catheter occlusion occurs, replacement or insertion of a second internal stent is done through the gastrostomy tract. When the cyst has resolved, the internal stent is retrieved by endoscopic snare.

The technique for the percutaneous cystogastrostomy involves insertion of a nasogastric tube, percutaneous transgastric puncture of the pancreatic fluid collection under CT guidance, and placement of a 10-Fr percutaneous transgastric catheter through an 11-Fr peel-away sheath into the cyst. The percutaneous gastrostomy is left to gravity drainage for 2–3 days and, when no leakage is seen with injection of contrast medium, the tube is capped. After 14 days of internal drainage, the percutaneous drainage is converted to internal drainage with placement of a stent between the cyst and the stomach under lateral fluoroscopy. Initial results in 19 patients show low complication and recurrence rates [165].

Diverticular abscess

Percutaneous abscess drainage plays an important role in treating certain patients with complications of diverticulitis [166,167]. Patients with phlegmonous changes around the colon can be managed medically. Patients with small pericolic abscesses can be treated with en bloc resection at the time of their colectomy, and patients with peritonitis require a two-stage operation. Patients who have larger pericolic, pelvic, or retroperitoneal abscesses may benefit from PAD. This subset of patients would require staged operations if PAD were not available. Percutaneous abscess drainage provides for resolution of septic complications and healing of the abscess such that a delayed single-stage operation can be performed. As with all cases of PAD, if signs of sepsis do not improve within 24–48 h of PAD and intravenous antibiotics, immediate operation should be undertaken unless catheter repositioning or replacement has a high likelihood of effecting improvement.

Abscesses with fistulae

The identification of fistulae associated with an abdominal or pelvic abscess frequently is not made on imaging studies before drainage or even at the time of drainage [168]. After several days, if the quantity of drainage remains more than 50 mL/day or if the character of the drainage changes and visually or chemically resembles stool, small bowel secretions, pancreatic juice, bile, or urine, then identification of the fistula can be attempted by injecting contrast medium into the abscess cavity under fluoroscopic observation. If this is unsuccessful, an attempt can be made to identify the fistula from its other end by filling the suspected organ of origin with contrast medium; for example, a barium enema is performed if a colonic origin is suspected, or a PTC or ERCP if biliary communication is present.

The presence of a fistula does not preclude definitive PAD in most circumstances. If a downstream stenosis is present in the hollow viscus or if a foreign body or neoplasm is present at the site of perforation, then closure of the fistula will not occur without surgical intervention [169]. Low-output fistulae of less than 200 mL/day appear to be more likely to heal than high-output fistulae. High-output fistulae may be treated more effectively by converting them to low-output

fistulae with nasoenteric intubation and suction, total parenteral nutrition, and histamine H_2-receptor blocker therapy. Catheterization of the fistula itself and advancement of a drainage catheter into the viscus is extremely useful in diverting drainage from the fistulous tract and allowing resolution [170].

When a fistula is present in association with a percutaneously drained abscess, the duration of catheter drainage usually is longer than if no fistula is present. Drainage for several months may be necessary; however, most of these patients can be managed as outpatients. If a patient's social situation precludes outpatient treatment, operative treatment should be considered to avoid the costs and risks associated with prolonged hospitalization.

Abscesses and Crohn's disease

The role of PAD in Crohn's disease has been debated [171], but several points are clear. Postoperative abscesses with or without fistulae, and hepatic abscesses in patients with Crohn's disease respond well to PAD [172,173]. Abscesses in association with transmural disease of the bowel but without visible fistulae also appear to respond [174]. It is unclear what the response rate is for abscesses with fistulae from transmural disease. Nevertheless, these patients may benefit from palliation with PAD before definitive operation. Percutaneous abscess drainage may control septic complications and allow improvement of nutritional status with a course of parenteral nutrition before operation. As in treatment of diverticular disease, PAD may allow conversion of a two-stage operation into a single-stage operation.

Percutaneous gastrointestinal intervention

Both endoscopic and interventional radiology techniques are used for gastrostomy, gastrojejunostomy, and direct jejunostomy placement. Morbidity is low and the success rate is high with both approaches; hence, the choice between techniques depends on local expertise and availability.

Percutaneous, radiologically guided ostomy formation is performed in both adults and children with use of conscious sedation and local anesthesia. General anesthesia is required in uncooperative patients. The procedure is performed on a C-arm fluoroscopic table. Before gastrostomy tube placement, US may be used to identify the liver and spleen.

Percutaneous gastrostomy and gastrojejunostomy

Indications for percutaneous radiological gastrostomy (Fig. 136.19) and gastrojejunostomy (Fig. 136.20) include:

- inadequate oral intake due to esophageal obstruction or neurological disorders
- decreased gastric motility (for gastrojejunostomy)
- decompression in chronic small bowel obstruction.

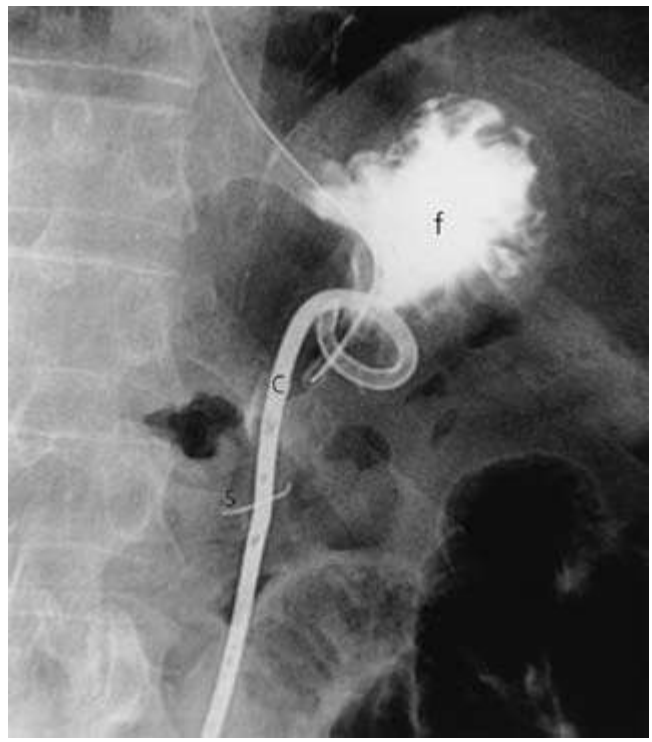

Figure 136.19 Percutaneous gastrostomy. A 12-Fr Cope loop gastrostomy tube (c) was placed following placement of a Cope suture anchor (s), and injection of contrast medium confirms the catheter loop in the fundus of the stomach (f). The nasogastric tube has been introduced into the stomach for air insufflation during puncture of the stomach.

The contraindications for gastrostomy or gastrojejunostomy tube placement include:

- uncorrectable bleeding diathesis
- inaccessible stomach from prior gastric pull-up, total gastrectomy, or partial gastrectomy
- clinical instability
- limited life expectancy
- presence of a ventriculoperitoneal shunt.

Ascites has been considered a contraindication to gastrostomy, although successful placement in patients with ascites has been reported [175]. Pericatheter ascitic leak may be avoided with preprocedural paracentesis and, if necessary, postprocedural paracentesis to promote skin healing. Gastropexy sutures are used in patients with marked ascites to avoid catheter dislodgment by preventing increasing amounts of ascites from displacing the stomach from the anterior abdominal wall. Two to three suture anchors may be placed before tract dilation. The suture may be left in place for 1–2 weeks, or the suture may be cut after placement of a gastrostomy tube. Bacterial seeding of the ascitic fluid remains a potential problem.

Technique

A nasogastric tube is placed the evening before the procedure, or, if a nasoenteric feeding tube is present, it is left in place. The patient is given nothing by mouth or through the

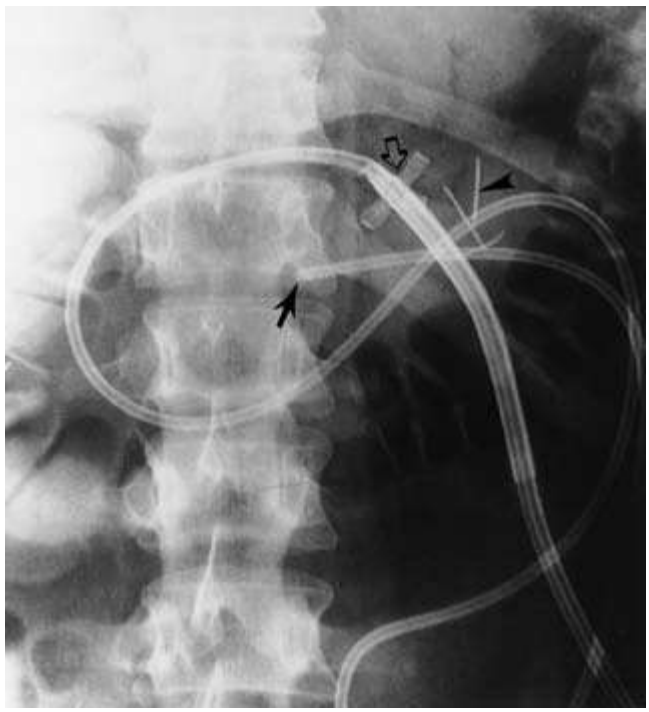

Figure 136.20 Percutaneous gastrojejunostomy. After gastrostomy, the pylorus was crossed using a guidewire and catheter. The tract was dilated and a 16.5-Fr Carey–Alzate–Coons gastrojejunostomy catheter was introduced through a peel-away sheath. The distal catheter tip is positioned in the jejunum (arrow) beyond the ligament of Treitz, allowing enteral feeding immediately following tube placement. Three anchor sutures (arrowhead) have been placed in the stomach before tract dilation. The friction-lock Malecot tip (open arrow) prevents tube dislodgment.

nasogastric tube (except for medications), beginning at midnight before the procedure. Glucagon is administered immediately before the needle puncture of the stomach to reduce the egress of air from the stomach. Distention of the stomach brings its anterior wall closer to the anterior abdominal wall, displaces the small and large bowel, and brings the stomach out from under the costal margin to facilitate puncture. Inflation also allows fluoroscopic visualization of the stomach. If no nasoenteric tube can be passed blindly because of esophageal obstruction, in nearly all cases a small-bore tube or catheter can be placed through the obstruction using standard angiographic techniques. For patients who cannot be transported to the angiography suite or who are unable to remain in supine position, percutaneous gastrostomy can be performed at bedside under portable real-time US guidance [176].

The radiological technique in general use for ostomy formation is the Seldinger method, using a guidewire, needle, dilators, and catheters. The puncture site is chosen fluoroscopically so that the needle enters the body of the stomach away from the greater curvature, avoiding the gastroepiploic vessels, epigastric vessels, the colon, and the left lobe of the liver. Oblique fluoroscopy is useful to confirm that the stomach abuts the anterior abdominal wall without intervening structures at the puncture site. The chosen puncture site is anesthetized with lidocaine, and a skin incision, large enough to admit the selected tube, is made. Gastropexy sutures may be placed with a modified 18-gauge needle [177].

Under fluoroscopic guidance, an 18-gauge needle attached to a 10-mL syringe half-filled with water-soluble contrast medium is advanced into the stomach with a brisk motion during aspiration with the syringe. Entry into the stomach is observed by free aspiration of air and is confirmed by injection of contrast medium and visualization of rugal folds. A 0.038-inch (0.97-mm) guidewire is advanced into the stomach and the tract is dilated. If a gastrojejunostomy tube is to be placed, the catheter and a long torqueable guidewire are used to traverse the pylorus and advance the guidewire through the duodenum into the proximal jejunum. The gastrojejunostomy catheter then is advanced over the guidewire into the jejunum through a peel-away sheath.

Catheters from 2.64 to 8.58 mm (8–26-Fr) are used for gastrostomy, with the smallest catheters used in the pediatric population for feeding, and the largest catheters used in adults for gastric decompression. Retention devices include balloons, Cope loops, and Malecot tips. Injection of contrast medium confirms the final position of the gastrostomy or gastrojejunostomy tube. Large-bore gastrostomy tubes and endoscopic-type gastrostomy tubes may be safely placed using the same radiological technique [178].

The gastrostomy or gastrojejunostomy tube is secured at the skin with a Molnar disk or friction fitting to stoma adhesive. If for any reason there is a high risk of catheter dislodgment, the tube may be sutured to the skin. The patient is observed for 6 h for signs of bleeding or peritoneal irritation. If a gastrostomy tube has been placed, it is left open to gravity drainage overnight and tube feedings begin the following morning. If a gastrojejunostomy has been placed, tube feedings may begin immediately.

The stitches (and gastropexy fasteners, if used) are removed after 10 days. The tract usually is mature enough by 7–10 days so that, if the tube is accidentally dislodged, the tract can be recatheterized and a de novo gastrostomy avoided if replacement is performed within 24 h.

Feeding gastrostomy versus feeding gastrojejunostomy

Because adequate data are not available, radiologists remain divided into two camps: those who place gastrostomy tubes in the majority of patients and gastrojejunostomy tubes only when gastroesophageal reflux is proven, and those who place gastrojejunostomy tubes in all patients. The most serious complication of tube feedings is aspiration pneumonia. Some evidence exists that surgical gastrostomies induce reflux; however, percutaneous radiological gastrostomy does not induce reflux. No study has demonstrated that endoscopic or radiological percutaneous gastrojejunostomy results in less aspiration than percutaneous gastrostomy.

Gastrostomy tubes are superior for the majority of patients. Most of the aspiration in these patients is due to oropharyngeal aspiration. Gastrojejunostomy tubes require greater maintenance than do gastrostomy tubes (Fig. 136.20). Gastrojejunostomy tubes have occluded more frequently than gastrostomy tubes because the jejunostomy portion of the tubes has been limited in size to 3.3–3.96 mm (10–12 Fr). Poorly crushed pill fragments or concretions of tube feedings may block the smaller tube and necessitate tube replacement. The greater length of gastrojejunostomy tubes may also contribute to this problem. Gastrojejunostomy tubes are harder to manage at home or at chronic-care facilities because they require mechanical pump infusion to achieve controlled infusion rates in the small intestine. In contrast, gastrostomy tubes can be infused with intermittent boluses or by gravity drips.

If gastroesophageal reflux and aspiration occur in a patient with a gastrojejunostomy tube, or in a patient with intractable gastroparesis, a better result may be achieved with two tubes – one placed into the jejunum for feeding and one placed into the gastric fundus for decompression.

Complications and results

A compilation of four major published series of radiological gastrostomy and gastrojejunostomy tube placements [179] in a total of 635 patients revealed a procedure-related mortality rate of 1% and a major complication rate of 5%. Major complications included peritonitis requiring laparotomy, bleeding requiring transfusion, external leakage, aspiration, gastric or duodenal perforation, and deep abdominal wall infection. Minor complications occur in 5% of patients.

A comparison of radiological gastrostomy with endoscopic gastrostomy and surgical gastrostomy revealed that radiological gastrostomy is associated with a higher success rate than is percutaneous endoscopic gastrostomy (PEG) and with less morbidity than either PEG or surgery [180]. Patients were not randomized in this study, however, making comparisons difficult. Percutaneous radiological gastrostomy or gastrojejunostomy can be performed in essentially all patients in whom the procedure is not contraindicated. Large-bore 20–24-Fr gastrostomy and gastrojejunostomy tubes can be placed under fluoroscopy. The technical success, morbidity, and mortality rates are similar to those of tubes placed surgically or endoscopically [181].

In pediatric patients with neurological or oropharyngeal impairment, fluoroscopically guided gastrostomy provides a safe and effective means for enteral nutrition and gastric decompression. Colonic interposition, microgastria, and hepatosplenomegaly are the causes of access failure of 1.2% [182]. The procedure can be performed with use of sedation and local anesthesia in nearly 90% of children.

Percutaneous jejunostomy

When percutaneous gastrostomy is not possible because of previous gastrectomy or an abnormal stomach position, direct percutaneous jejunostomy can be performed for enteral feeding [183,184]. Under fluoroscopic guidance, a nasogastric tube is passed into the stomach and through the pylorus. One milligram of glucagon is administered intravenously to decrease peristalsis. The small bowel is then filled with room air. Using a C-arm fluoroscope, a loop of bowel adjacent to the anterior abdominal wall is identified and a 21-gauge needle is inserted into the jejunal lumen; injection of contrast medium confirms the needle position within the jejunal lumen. A 0.018-inch (0.46-mm) guidewire is inserted and a 6.3-Fr introducer catheter is advanced into the jejunum. Over a 0.038-inch (0.97-mm) guidewire, the tract is dilated and an 8-Fr Cope loop nephrostomy catheter is placed in the jejunal loop. Pericatheter leakage is the main complication. The use of Cope suture anchors facilitates a feeding tube insertion by securing the jejunal loop to the anterior abdominal wall.

In the absence of a previous surgical jejunostomy scar, this procedure is considered risky and is not widely performed. In patients who have undergone esophagectomy and a previous surgical jejunostomy, the jejunal loop that has been surgically fixed to the anterior abdominal wall can be punctured using the metal clips as a guide [185]. The skin mark or a dimple at the site of the previous surgical jejunostomy is used to guide the needle puncture into the bowel loop.

Percutaneous cecostomy

Percutaneous cecostomy is an alternative to surgical and endoscopic decompression of the cecum in cases of colonic obstruction and pseudoobstruction (Ogilvie syndrome) [186,187]. Small 2.31–2.97-mm (7–9-Fr) catheters can be placed through the peritoneum with a Seldinger or trocar technique for decompression of the colon, and large 7.92–9.9-mm (24–30-Fr) catheters are placed for drainage of liquid stool after placement of anchoring sutures as used for gastrostomy. This technique is applicable for patients with Ogilvie syndrome in whom endoscopic decompression fails, and in patients with colonic obstruction whose medical condition precludes operation.

Balloon dilation and stent placement for gastrointestinal obstruction

Balloon dilation or metallic stents may be used as alternatives to surgery for malignant and benign strictures in the esophagus and GI tract (stomach, pylorus, duodenum, colon, and rectum) using radiological or endoscopic techniques [188]. Generally balloon dilation is used for benign strictures whereas stents are reserved for patients with malignant strictures.

The radiology-guided technique is similar to that used for percutaneous translumenal angioplasty. It can be performed on outpatients under sedation and local anesthetic. The strictured site is identified by injection of contrast medium or endoscopy. After placing a 0.035-inch (0.89-mm) guidewire across the stricture, an angioplasty balloon catheter is

advanced over the guidewire, placed across the stricture, and inflated two to three times for 3–5 min. Water-soluble contrast medium should be injected after dilation to rule out any perforation.

Metallic stents have been used for treatment of esophageal obstruction, gastric outlet stenosis, duodenal stenosis, and malignant colorectal stricture [189–195]. The technique for stent placement is similar to that used for angioplasty. Use of metallic stents in patients with colonic obstruction caused by malignant neoplasms eliminates the need for emergency surgical intervention on unprepared bowel, reducing mortality and morbidity [196]. The procedure can be performed on an outpatient basis or with minimal hospitalization, permitting single-stage surgery. The procedural steps for colonic stent placement are as follows: the patient is placed in the supine position on a fluoroscopic table and the combination of a 0.038-inch (0.97-mm) stiff-angled hydrophilic guidewire and a catheter are advanced through the rectosigmoid colon under fluoroscopy to the area of obstruction. After identification of the obstruction by injecting water-soluble contrast material, the catheter and guidewire are advanced through the lesion. The length of the obstruction is measured and a self-expanding WALLSTENT is deployed over a guidewire or through an endoscope if desired. The correct position of the stent and its patency are assessed by a barium examination. Complications occur in 10% of patients, including perforation, migration, hemorrhage, and sepsis.

Malignant tracheoesophageal fistula

A fistula may develop between the esophagus and the tracheobronchial tree from invasion of mediastinal structures by esophageal carcinoma. This may lead to pneumonia, lung abscess, and death. Covered esophageal stents can provide effective palliation of symptoms caused by the tracheoesophageal fistula. Simultaneous placement of a tracheal stent may be required for tracheal compression by the stent and tumor invasion [197,198]. Although radiological placement has been reported, the majority of these stents are placed endoscopically.

General principles of gastrointestinal biopsy interpretation

The key principle of gastrointestinal (GI) biopsy interpretation is that the GI tract has a limited repertoire of responses to a host of injuries, and diagnosing the type of injury in any given biopsy often requires correlation with clinical details. When dealing with mucosal biopsies of the GI tract, it should also be noted that they only display the mucosa (and possibly a small amount of submucosa), a feature that is obvious but sometimes forgotten by endoscopists and pathologists alike. Of course, mucosal biopsies should not include muscularis propria. When they do, it is good practice for the pathologist to contact the endoscopist and discuss the possibility of endoscopic perforation. A discussion of every entity that can be encountered on mucosal biopsies is beyond the scope of this chapter, but we attempt to describe those most commonly encountered and certain classical conditions.

Overview of the gastrointestinal tract

The innermost layer of the GI tract is the mucosa, which consists of three components.

- Epithelium: protective, secretory, or absorptive properties.
- Lamina propria: this is a loose connective tissue zone supporting the avascular epithelium. In the esophagus, stomach and small bowel, it is rich in lymphatics whereas it is less so in the lower tract. This is of clinical significance in evaluating carcinomas as they can attain lymphatic access with minimal invasion in the upper tract but not in the colon. In the upper tract there are few immune cells (lymphoid and plasma cells) in the lamina propria, whereas in the small bowel and colon lamina propria lymphocytes and plasma cells are more abundant. Neutrophils are abnormal when found in either the lamina propria or the epithelium. Eosinophils are a normal constituent of the lamina propria but mucosal biopsies from all sites must be assessed for prominence of normal inflammatory components.
- Muscularis mucosae: this is a slender double layer of smooth muscle separating the mucosa from the submucosa. It has an inner circular and outer longitudinal arrangement and in this respect can be regarded as a miniaturized muscularis propria.

The submucosa is composed of connective tissue and houses the Meissner nerve plexus as well as large-caliber vessels. The muscularis propria is the main wall of the GI tract and is composed of an inner circular and outer longitudinal layer of smooth muscle. Between these layers is the Auerbach nerve plexus. The outermost component is either adventitia or serosa. The former lacks a mesothelial membrane lining.

Parasympathetic ganglion cells are found in both the Meissner and Auerbach nerve plexuses but the submucosal Meissner plexus contains neuronal cell bodies of the intrinsic sympathetic nervous system that function on local areas of the gut. These are the neurons that have chemoreceptors and mechanoreceptors. They synapse on both other ganglion cells and muscle or secretory cells.

In assessing any biopsy from the GI tract, the pathologist should note the gender, age, and race/ethnicity (if known) of the patient and the site of the biopsy. This information is useful in directing interpretation and the endoscopist should provide these details as well as a brief synopsis of the indications for the biopsy and the clinical concerns. Examples of the utility of mentioning simple demographics include celiac disease, which is found in about 1% of all Americans but

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

virtually never in Southeast Asians, and collagenous colitis, which is typically a disease of older women. Assessments of all biopsies from infants should include a systematic review of each compartment of the tissue. For example, the epithelial surface is reviewed with an eye to malabsorptive diseases (such as microvillous inclusion disease in the small intestine), the lamina propria is scanned for the presence of plasma cells (their absence suggests common variable immunodeficiency), and the muscularis mucosae is assessed for eosinophils (which should be absent).

The type of mucosa in the biopsy is compared with the recorded biopsy site to address metaplasias (or "switched" specimens) and the normal architectural structures are noted, such as villous contours of the small intestine. Before making a diagnosis, the features are compared with the history to assure that the interpretation makes sense in light of the clinical information. If the information is scant but required for or inconsistent with the microscopic findings, this too must be addressed.

With a consistent approach, the pathologist interpreting GI biopsies can provide important information that can occasionally be life-saving (in certain instances of ischemic disease) and can often be reassuring to the ever-increasing group of patients undergoing GI tract mucosal biopsies. The gastroenterologist who remembers that diseases have many overlapping histological features will be better served by supplying clinical details to increase the possibility of the most accurate interpretation.

Sampling

The most important sampling issues concern sampling error and knowing where to biopsy. Whenever feasible, jumbo forceps provide better information than smaller ones. There are certain general principles that apply to many settings. For example, when sampling an ulcer where there is clinical suspicion of cytomegalovirus (CMV) infection, it is prudent to sample areas expected to harbor granulation tissue since the cytopathic effect of CMV is usually found in endothelial cells. In contrast, if the cytopathic effect of herpes simplex virus (HSV) is sought, intact epithelium must be present on the slides for review. Consequently both types of tissue should be sampled when assessing for viral lesions in erosions or ulcers in immunosuppressed patients. Similarly, in attempting to establish a cancer diagnosis in an ulcerated zone, it is essential to obtain more rather than fewer biopsies as sampling error is often a factor. With regard to celiac disease, biopsies should be obtained from beyond the bulb, as the bulb is prone to villous blunting from chronic damage by gastric contents. When obtaining biopsies to address the possibility of microscopic colitis, it is important to remember that inflammation is best seen in the right and transverse colon; a negative rectal biopsy does not exclude microscopic colitis. Lastly, gastric polyps (other than fundic gland polyps) seldom occur in isolation but rather in the context of gastric pathology in the surrounding flat mucosa, so it is helpful to sample this when investigating a polyp in the stomach, especially if the polyp is in the antrum [1,2]. Of course, this contrasts with the colon, where polyps are usually isolated findings; sampling the background flat mucosa is only necessary in the setting of inflammatory bowel disease (IBD).

Esophagus

Nonneoplastic conditions

Inlet patch (cervical gastric heterotopia)

Inlet patches are believed to be embryological vestiges from early gestation when the esophagus is lined by columnar epithelium. They are found in about 1% of patients undergoing upper endoscopy assessed retrospectively through biopsy records, but incidences of up to 10% have been recorded [3,4]. They are found in the cervical esophagus and are usually asymptomatic. However, there are occasional complications: local injury (webs, strictures, ulcers, fistulae) can result in symptoms (pain and dysphagia). Rarely, carcinomas complicate inlet patches.

Inlet patches range in size from 0.2–0.3 cm up to about 4 cm. They typically consist of oxyntic gastric-type mucosa (containing parietal cells), although a transitional or cardiac pattern (lacking oxyntic glands and negative for gastrin on immunohistochemistry) may also be found. Lesions are often inflamed and may occasionally harbor *Helicobacter pylori*. Intestinal metaplasia in inlet patches is occasionally found. Some studies have explored a link between inlet patches and Barrett esophagus and indeed these conditions are found together more than coincidence would suggest. Of course some studies are difficult to interpret since the criteria for Barrett esophagus have changed with the recent requirement for intestinal metaplasia to diagnose lesions as Barrett esophagus (see section on Barrett esophagus). Pancreatic tissue may also be a component of inlet patch.

Glycogenic acanthosis

Glycogenic acanthosis of the esophagus is a common benign entity [5–19] found in up to 15% of esophagi (but overall probably closer to 3% [19]). It is characterized by single or multiple plaques of hyperplastic squamous epithelium with abundant intracellular glycogen deposits. Lesions appear as slightly raised grey-white plaques that are usually 2–10 mm in diameter and which may be confluent. They cause a finely nodular or cobblestone mucosal pattern demonstrable on double-contrast views of the well-distended esophagus. The findings are not associated with mucosal ulcerations, lumenal narrowing, or mobility disturbance, although some patients may have coexistent hiatal hernia and gastroesophageal reflux. There is also an association between glycogenic acan-

thosis and Cowden disease. Glycogenic acanthosis does not appear to be linked with diabetes and does not regress with acid suppression when associated with reflux disease. In one Japanese study, it was commonly found in adjacent nonneoplastic mucosa in patients with squamous cell carcinoma of the esophagus [12].

In general, it is essentially an incidental finding. The endoscopist notes a white plaque and a biopsy displays prominent intraepithelial glycogen extending to within one cell layer of the basement membrane with just a single row (or two) of basal cells between the glycogenized squamous cells and the basement membrane. For the endoscopist, the differential diagnosis is with *Candida* esophagitis, whereas pathologists often do not notice glycogenic acanthosis. However, probably the most important reason for the pathologist to diagnose patients with glycogenic acanthosis is to provide the endoscopist with an explanation for the abnormal gross appearance of the biopsied lesion.

Findings in mechanical/anatomical disorders (webs, rings, achalasia)

Typically, biopsies from webs, rings, and from the squamous mucosa in patients with achalasia display normal squamous mucosa unless the condition has resulted in long-term reflux. There may be parakeratosis, a response to the process of food passing over the protuberant ring or the constricted segment, or erosions may appear where retained food presses on the static segment proximal to the attenuated lumen.

Reflux disease

Gastroesophageal reflux disease (GERD) is the costliest GI disorder affecting citizens of the USA. In 2002, the direct cost of GERD was estimated at over $9 billion [20] so, not surprisingly, many patients undergo endoscopic biopsies in the course of evaluation for reflux symptoms. Findings in these can range anywhere from classical reflux changes (basal cell hyperplasia, elongation of vascular papillae, and intraepithelial eosinophils), to ulcers, intraepithelial lymphocytosis (which correlates poorly with pH studies), or balloon cells (which appear distended and have pale abundant pink cytoplasm).

Reflux esophagitis is an example of an "-itis" that often lacks a prominent component of inflammation. The pathology reflects injury to the squamous epithelium, followed by attempts of the epithelium to regenerate. Mild features of cellular injury include balloon cells (squamous cells with ballooned cytoplasm from accumulation of plasma proteins) and vascular lakes (dilated small blood vessels in the mucosa, often seen endoscopically as erythema or redness). Severe injury can result in mucosal sloughing with erosions or ulcers. Regenerative changes include hyperplasia of the basal zone to greater than 15%–20% of the epithelial thickness and elongation of the vascular papillae to greater than two-thirds of the epithelial thickness. Inflammation is typically mild and

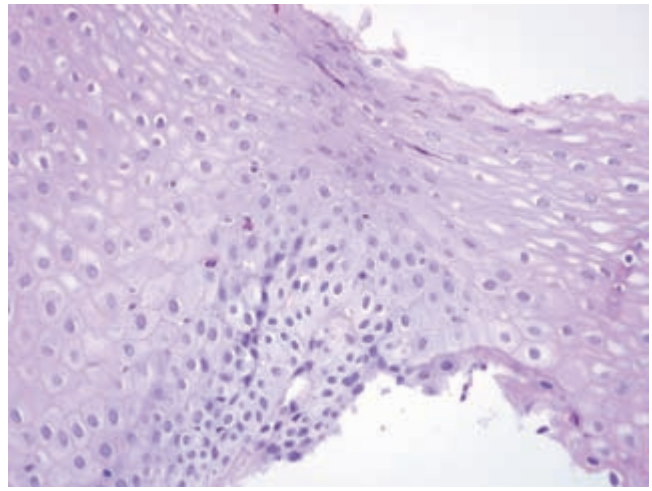

Figure 137.1 Reflux esophagitis.

includes scattered eosinophils (Fig. 137.1). Less commonly, scattered neutrophils are present; neutrophils can be more prominent in cases with more severe injury including erosions and ulcers.

The severity and extent of the histological changes on biopsy do not necessarily correlate well with the severity of the patient's symptoms. Severe complications of GERD are unusual. These include ulcer, hemorrhage, and stricture formation. The complication of Barrett esophagus occurs in approximately 10% of patients with symptomatic reflux.

Injury caused by chemical or physical agents

A few agents result in injury that leaves a footprint that can be recognized on biopsies, although often there is no microscopic clue.

Iron

In our patient population, in which inpatients are well represented, mucosal iron (ferrous sulfate) is found in about 1% of patients undergoing upper tract endoscopic biopsies. Iron is well known for its capacity to cause corrosive injury in the esophagus. While it can be argued that such a phenomenon is a result of a prior injury in which an iron tablet becomes embedded, the corrosive and toxic nature of iron itself suggests that the iron pill has caused the injury. Abraham and colleagues [21] studied the clinical and histological features of 36 upper GI tract biopsies from 33 patients (24 gastric, 9 esophageal, 1 gastroesophageal junction, 2 duodenal) containing characteristic brown crystalline iron material, and evaluated the amount and tissue distribution of the iron. The biopsies typically displayed lumenal crystalline iron adjacent to the surface epithelium or admixed with lumenal fibrinoinflammatory exudates (Fig. 137.2). Most biopsies (83%) showed crystalline iron deposition in the lamina propria, either covered by an intact epithelium, subjacent to small superficial erosions, or admixed with granulation tissue. Three

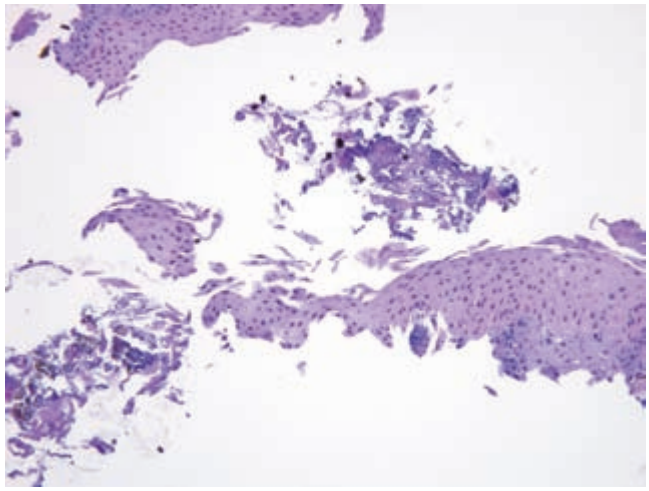

Figure 137.2 Iron pill esophagitis. The brown material in the image is iron pigment. The associated squamous epithelium shows reparative features.

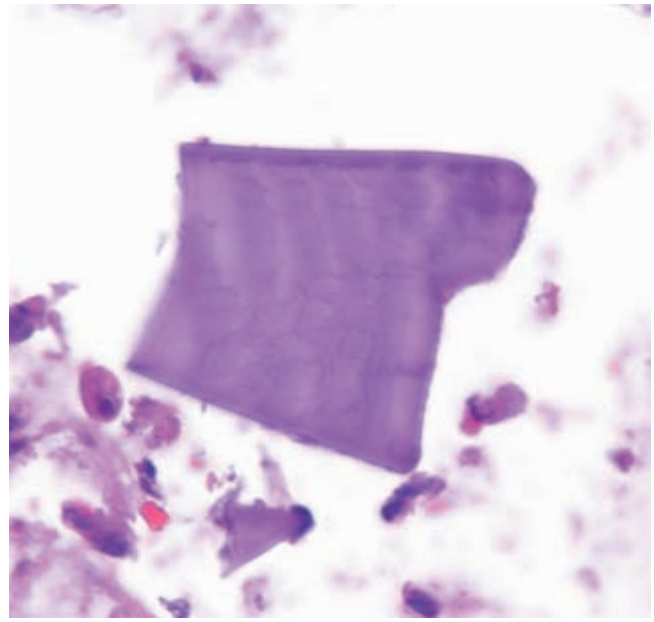

Figure 137.3 Kayexalate (sodium polystyrene sulfonate). Note the fish scale-like appearance of the crystalline material.

biopsies (8%) demonstrated iron-containing thrombi in mucosal blood vessels. Erosive or ulcerative mucosal injury was present in the majority of biopsies (83%). The amount of iron accumulation in cases with mucosal injury was greater than in cases without mucosal injury. Iron medication (usually ferrous sulfate) was confirmed in 25 of 33 patients (76%). However, as an argument for iron causing injury as a secondary event, half of the patients (17 of 33) also had underlying infectious, mechanical, toxic, or systemic medical conditions that could have initiated or exacerbated tissue injury.

Kayexalate

The use of Kayexalate (sodium polystyrene sulfonate) for the management of hyperkalemia was approved for use in the USA in 1975. It is a cation-exchange resin that can be instilled into the lower GI tract as an enema preparation or into the upper GI tract either orally or by nasogastric tube. When administered orally or by nasogastric tube, sodium cations are first released from the resin and exchanged for hydrogen ions in the acidic milieu of the stomach. As the resin passes through the intestines, hydrogen is exchanged for potassium, which is then eliminated in the feces along with the remainder of the altered resin, thereby lowering the serum potassium concentration.

During the early use of Kayexalate, the resin was administered as a suspension in water. Although generally well tolerated, some patients were reported to develop gastric and bowel opacifications as a result of concretions of resin. It therefore became increasingly popular to administer Kayexalate in a suspension with hypertonic sorbitol, which reduces the frequency of bezoar formation and colonic impaction by promoting an osmotic diarrhea. Subsequently, Lillemoe and colleagues reported five uremic patients who developed colonic necrosis temporally associated with the use of Kayexalate in sorbitol that contributed to death in four of them [22]. This study also provided experimental (murine) evidence implicating sorbitol as the agent responsible for colonic necrosis.

It has become apparent that Kayexalate can be associated with severe mucosal injury in the upper GI tract as well [23]. In most instances, the medication is easy to recognize in endoscopic biopsies (Fig. 137.3). Kayexalate crystals are lightly basophilic on hematoxylin and eosin (H & E) stain, red on periodic acid–Schiff (PAS)/Alcian blue and acid-fast stains, and blue on Diff-Quik staining. Crystals display a characteristic crystalline mosaic pattern resembling fish scales. It is this mosaic pattern that allows the distinction between Kayexalate crystals and histologically similar cholestyramine crystals. Kayexalate crystals are refractile but not polarizable.

Taxol and colchicine

Taxol, an antineoplastic agent with a novel mechanism of action, can cause striking mitotic arrest (Fig. 137.4) associated with epithelial necrosis and ulceration of the esophagus [24]. The mitotic arrest is associated with bundling of intermediate filaments secondary to accumulation of polymerized microtubules. Thus the histological correlate is the presence of arrested mitoses with ring forms. With taxol, the findings tend to be striking in the esophagus, whereas in colchicine toxicity, which has similar histological findings, the small bowel is more likely to be severely altered.

Fosamax

The bisphosphonates prevent osteoclast-mediated bone resorption and have therefore been found effective in the treatment of osteoporosis, Paget disease, and the hypercalcemia of malignancy [25].

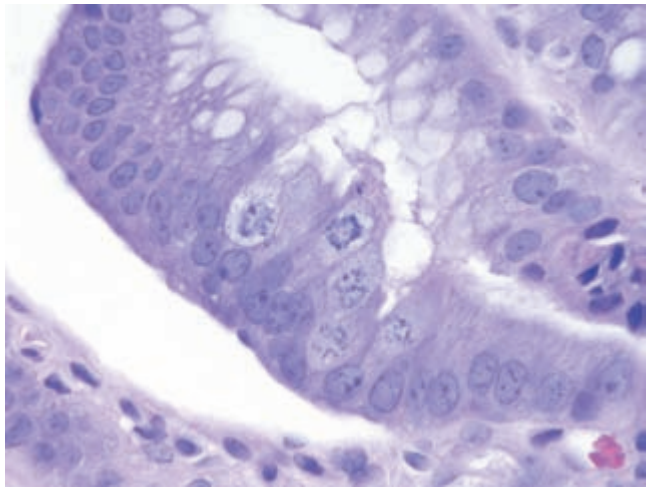

Figure 137.4 Taxol effect. This process involves metaplastic columnar mucosa in the esophagus. The ring mitoses are an indication of mitotic arrest.

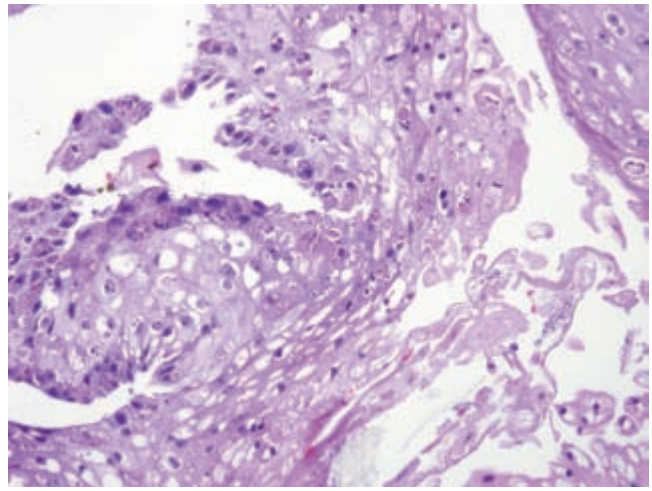

Figure 137.5 Graft-versus-host disease. There is extensive squamous epithelial apoptosis such that nuclei resemble specks of dust.

Ingestion of alendronate sodium (Fosamax) and related medications by osteoporotic patients has been associated with esophagitis and esophageal ulcer. Alendronate can damage the esophagus both by toxicity from the medication itself and by nonspecific irritation secondary to contact between the pill and the esophageal mucosa (pill esophagitis). Biopsies show inflammatory exudate and inflamed granulation tissue as characteristic of any ulcer site [26]. Polarizable crystalline foreign material is often found. There is no specific histological finding but it is worthwhile to be aware of this complication. However, it is now known that modifications in dosing schedules of this medication [27] can reduce mucosal injury and it is less likely to be encountered in practice.

These agents should be avoided in patients with achalasia and other motility disorders of the esophagus, esophageal stricture, or preexisting severe reflux esophagitis. However, patients with reflux disease can probably be treated with a proton pump inhibitor (PPI) and then safely undergo bisphosphonate therapy.

Corrosive ingestion (e.g., lye, bleach)

Like the esophageal injury associated with Fosamax, corrosive injury does not result in a specific pattern of injury (although saponification may accompany lye ingestion) and cannot be identified directly (like iron or Kayexalate). However, it can usually be correlated with an ingestion history in a pediatric or psychiatric patient. Endoscopically, severe ulceration is seen and endoscopists have described a strong bleach-like odor even when the patient has ingested lye. Microscopically, extensive necrosis is found. Those who survive are likely to have severe stricturing disease with all its complications. Such patients require lifetime follow-up based on their proclivity to develop squamous cell carcinoma [28].

Graft-versus-host disease

Esophageal biopsies from patients with graft-versus-host disease (GVHD) show intraepithelial lymphocytosis, basilar vacuolization, epithelial apoptosis (Fig. 137.5), and necrosis in severe disease. Many patients manifest a characteristic endoscopic appearance [29–37], and a bullous presentation akin to that of bullous pemphigoid is one of the possible presentations. Probably the most important goal in patients in whom GVHD is a clinical consideration is to exclude infectious etiologies since generally such patients are empirically treated with steroids.

Dermatological disease affecting the esophagus

Dermatological conditions that are well known to involve the esophagus include pemphigus vulgaris, mucous membrane bullous pemphigoid, epidermolysis bullosa, lichen sclerosis, lichen planus, and toxic epidermal necrolysis. Esophageal involvement by cutaneous diseases is not well recognized by pathologists or clinicians, resulting in delayed diagnosis and continued esophageal inflammation. In the case of lichen planus for example, dysphagia and esophageal strictures are frequently initially attributed to reflux disease.

Lichen planus

Lichen planus [38] is a subacute to chronic mucocutaneous disorder of unknown etiology. It can involve the skin, nails, and mucosal surfaces. Lichen planus of the skin affects both genders with equal frequency at any age, but most patients are middle-aged adults. Cutaneous lichen planus is characterized by eruptions of violaceous scaling papules and plaques. These plaques typically are intensely pruritic and most commonly localized to the extensor surfaces of the forearms and legs. Mucosal lichen planus may affect the perineum, oral mucosa, and pharynx. Unlike cutaneous disease,

mucosal lichen planus predominantly affects middle-aged women. Oral involvement in particular coexists with skin lesions in approximately 30%–50% of patients, but can be the only manifestation.

Esophageal lichen planus is a rarely described manifestation. It is an important diagnosis because of its tendency to cause persistent dysphagia resulting from esophagitis and stricture formation. Further trauma resulting from therapeutic dilation can lead to exacerbation of oral lichen planus in a Koebner-like phenomenon.

The pathological features of esophageal lichen planus differ from those in skin. The epidermal reaction in cutaneous lichen planus typically includes hypergranulosis, hyperorthokeratosis, acanthosis, and saw-tooth elongation of the rete pegs. In contrast, the esophageal epithelium, which does not normally contain orthokeratin or a granular layer, frequently shows parakeratosis rather than orthohyperkeratosis and frequently lacks hypergranulosis. In addition, the epithelium may be atrophic. The histological features therefore more closely resemble those of oral rather than cutaneous lichen planus. All sites of involvement reveal the typical band-like inflammatory infiltrate with a predominance of mature T cells and basal layer degeneration, including characteristic Civatte bodies (Fig. 137.6).

Lymphocytic infiltration alone is not diagnostic of esophageal lichen planus. Medications (gold, thiazides, antimalarials) can induce lichen planus-like lesions and must be excluded by clinical history. Nonspecific lymphocytic infiltrates can appear adjacent to esophageal ulcer sites from other causes and a lymphocytic esophagitis pattern is often a feature of esophageal Crohn's disease. Although infectious agents are usually easily excluded on biopsy material, exclusion of esophagitis due to pill ingestion or caustic substances requires clinical correlation. In addition, lymphocytic infiltrates are occasionally prominent, although often focal, in patients with gastroesophageal reflux. Reflux can usually be excluded on the basis of other criteria such as the lack of clinical symptoms, the results of pH probe studies, and the failure of the inflammatory condition to respond to intensive antireflux therapy. Other histological criteria for gastroesophageal reflux, including intraepithelial eosinophils, are also usually absent. Furthermore, the typical upper or middle esophageal location of the pathological findings and stricture sites would be unusual in GERD. However, it is difficult to positively diagnose lichen planus on histology; it can only be suggested and correlated with other features. Systemic treatment is usually required to forestall stricturing disease, whereas topical treatment is often sufficient for oral lesions.

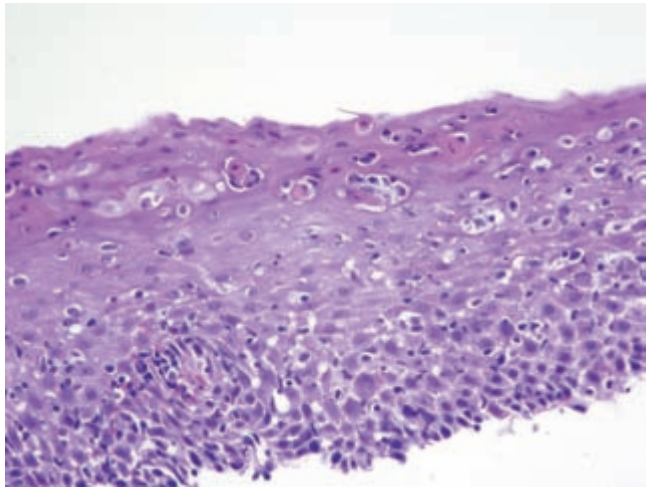

Figure 137.6 Lichen planus involving the esophagus. This field shows prominent intraepithelial lymphocytosis and necrotic squamous cells.

Bullous diseases

The bullous diseases are similarly challenging to diagnose specifically in the esophagus and must also be correlated with clinical findings. When esophageal biopsies show bullae, in the absence of an infectious explanation, additional biopsies can be submitted fresh for immunofluorescence studies to arrive at a more specific diagnosis.

Pemphigus vulgaris (PV), the most common form of pemphigus, affects the sexes equally, most commonly during the fourth and fifth decades. Skin and mucous membrane involvement are typical. Although any mucosal surface can be involved, oral lesions are the hallmark; these occur in almost every case and are the presenting sign in half of affected patients.

There are a few reports of esophageal involvement in PV, which was believed to be rare in early literature but is found in most patients if sought [39]. Because patients with esophageal involvement may be asymptomatic, such involvement has been under-recognized. Although esophageal involvement may be frequent in active mucocutaneous PV, its occurrence in the absence of other manifestations of the disease is rare [40].

Odynophagia and dysphagia are the usual symptoms of esophageal PV, as with other mucosal blistering diseases, including herpetic or esophageal candidiasis. Endoscopy is required for diagnosis; it allows evaluation of the appearance of the lesions and tissue sampling. Essentially normal esophageal mucosa may be seen on initial passage of the endoscope, followed by the appearance of erosions and sheets of sloughed mucosa on withdrawal of the instrument. Histopathological findings of suprabasal clefting, tombstone cells, and acantholysis are features of PV; immunofluorescence shows intercellular deposition of IgG and C3. Indirect immunofluorescence detects pemphigus antibodies in about 75% of cases; a negative result can occur if the disease is in remission or in an early localized stage.

Bullous pemphigoid (BP) affects the esophagus more rarely than other skin diseases [41,42]. It is a chronic, autoimmune, subepidermal, blistering skin disease that rarely involves mucous membranes. It primarily affects elderly individuals

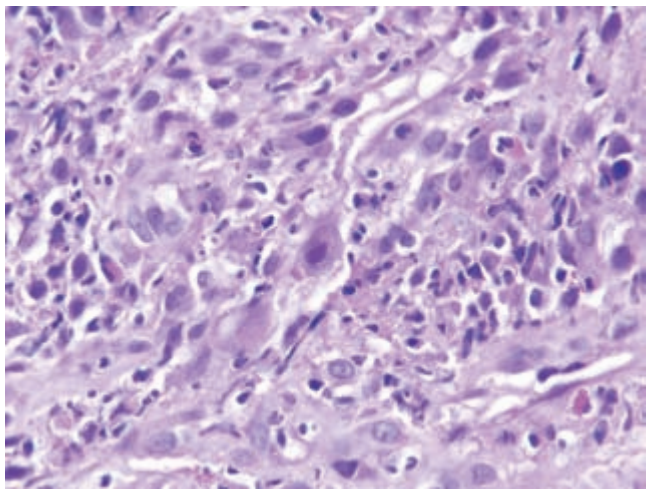

Figure 137.7 Cytomegalovirus esophagitis. An endothelial cell in the center of the field is affected. There is a large intranuclear inclusion.

in the fifth through seventh decades of life (average age at onset 65 years). In France and Germany, the reported incidence is 6.6 per million per year. In Europe, BP was identified as the most common subepidermal autoimmune blistering disease. The mucosa is affected in 10%–25% of patients.

Bullous pemphigoid is characterized by IgG autoantibodies specific for the hemidesmosomal BP antigens BP230 (BPAg1) and BP180 (BPAg2). IgG autoantibodies bind to the epithelial basement membrane and activate complement and inflammatory mediators. Eosinophils are characteristically found in bullae, although their presence is not an absolute diagnostic criterion. Serum levels of autoantibodies against BPAg2 correlate with disease activity in some studies.

Esophagitis caused by infectious agents

When an infectious etiology is suspected in erosive esophagitis, the endoscopist should biopsy the base of the erosion/ulcer to detect CMV (Fig. 137.7) whereas the epithelium is more likely to demonstrate HSV (Fig. 137.8). Greenson and colleagues have demonstrated that a prominent mononuclear infiltrate adjacent to the infected epithelium often accompanies HSV esophagitis and should provoke a search for the organism [43], whereas the presence of macrophages in a perivascular distribution in granulation tissue should spur a search for CMV [44]. In the case of HSV, the background infiltrate may suggest the need to perform immunohistochemistry for HSV as the organism may not be apparent on routine H & E stains. Zones of parakeratosis, however small, are worth study at high magnification to exclude *Candida* (Fig. 137.9). Pseudohyphal forms must be sought since budding yeast alone might be a reflection of oral contamination or colonization. Bacterial esophagitis is poorly understood. Walsh and colleagues [45] proposed a definition of "histopathologically demonstrable bacterial invasion of esophageal mucosa or deeper layers with no concomitant fungal, viral, or neoplastic involvement or previous surgery of the esophagus." Bacterial esophagitis should be considered in immunocompromised patients presenting with odynophagia and may not be accompanied by an inflammatory response but simply by numerous bacterial forms seen embedded in the squamous mucosa. Apparently, bacterial esophagitis can be a source of occult sepsis [46].

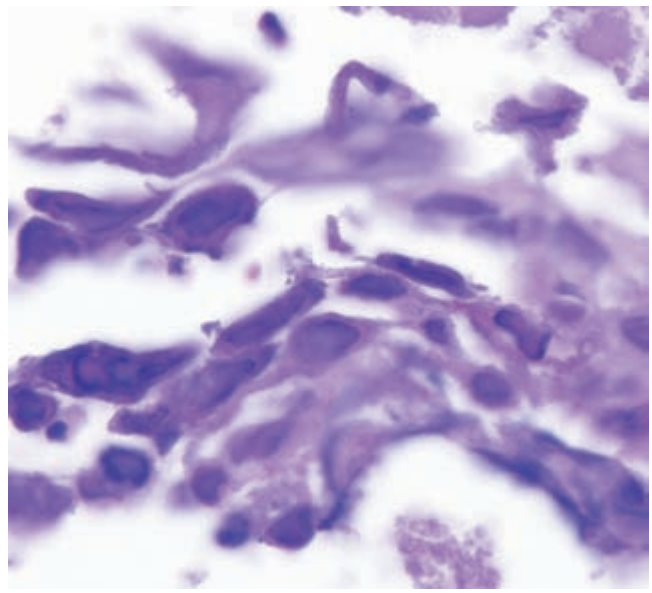

Figure 137.8 Herpes simplex virus esophagitis. The infected cells are multinucleated, with "smudged" nuclei.

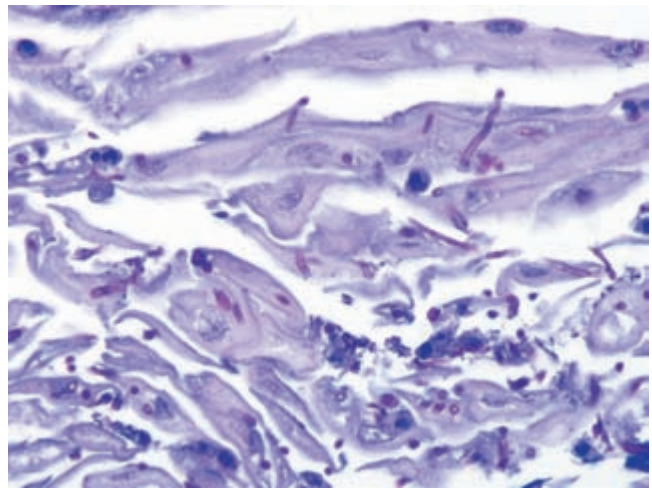

Figure 137.9 *Candida* esophagitis. This periodic acid–Schiff stain highlights pseudohyphal forms.

Allergic/eosinophilic esophagitis

Overall, eosinophilic esophagogastroenteritis is an uncommon benign inflammatory condition characterized by eosinophilic infiltration of the GI tract. The diagnostic criteria include GI symptoms, eosinophilic infiltration of the GI tract usually with intraepithelial eosinophils, and no evidence of parasitic infestation. Most patients (in addition to their GI involvement)

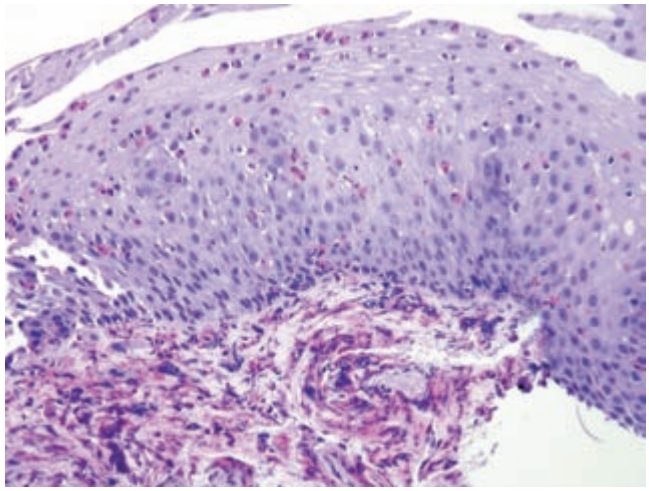

Figure 137.10 Eosinophilic esophagitis. Numerous eosinophils, some degranulating, are seen in both the epithelium and the lamina propria. Far fewer eosinophils are seen in reflux esophagitis. Compare with image shown in Fig. 137.1.

also have a history of allergy, asthma, drug sensitivities, peripheral eosinophilia, and increased IgE levels. Although food intolerance has been postulated as an etiological factor, most cases lack a specific allergen and are attributed to multiple allergens. Eosinophilic esophagogastroenteritis predominantly affects patients in the third to sixth decades. However, 15%–20% of cases are seen in the pediatric age group and, in some cases, milk allergy may be demonstrated.

Any part of GI tract from the esophagus (Fig. 137.10) to the rectum can be involved; the stomach and small bowel are commonly involved. Eosinophilic esophagogastroenteritis can show preferential involvement of the mucosa, muscularis propria, or serosa. Symptoms depend on the site and extent of eosinophilic infiltration. Mucosal disease can present as diarrhea, malabsorption, and protein-losing enteropathy. Submucosal disease presents as obstruction and abdominal pain, and patients can develop eosinophilic ascites with serosal involvement. Rarely patients can present with an acute abdominal emergency necessitating emergency laparotomy.

Patients with eosinophilic esophagitis (limited to esophagus) present with dysphagia and strictures. The differential diagnosis is with reflux esophagitis. However, unlike in reflux esophagitis, the upper and mid esophagus are commonly affected with relative distal sparing. In striking cases, the esophagus can display rings on endoscopy, an appearance termed *feline esophagus* since this appearance resembles that seen in cats [47–48].

On histological examination, superficial epithelial clusters of eosinophils that slough into the lumen are more common in eosinophilic esophagitis and there may be infiltration deep in the esophageal wall and not just limited to the mucosa. The eosinophilic infiltrate can be patchy and multiple, localized or diffuse. In 10% of cases, mucosal biopsies can be nondiagnostic due to the patchy nature of the disease or mucosal sparing. In daily practice, there are cases in which a distinction between allergic/eosinophilic esophagitis and reflux esophagitis cannot be made on histological grounds and the diagnosis requires correlation with pH monitoring studies or with other stigmata of allergic disease. However, some have proposed that an estimate of the number of eosinophils is a helpful clue in some cases: fewer than eight eosinophils per 40× field favors a diagnosis of reflux esophagitis, whereas a count of more than 24 eosinophils per 40× field better supports eosinophilic esophagitis. For cases with intermediate eosinophilic counts, clinicopathological correlation is required. We avoid reporting counts in our practice routinely since they can be meaningless [49], but we do attempt to compare biopsies to previous ones and estimate whether more or fewer eosinophils are present to help assess response to treatment. The distinction between reflux and eosinophilic esophagitis is worth attempting as patients with eosinophilic esophagogastroenteritis show dramatic response to steroids.

Crohn's disease affecting the esophagus

Reports on the prevalence of esophageal Crohn's disease vary widely in both adults and children. Decker and colleagues [50] reported that only 20 of 9900 (0.2%) adults with Crohn's disease seen over a period of 22 years had esophageal involvement. A higher prevalence was reported by D'Haens and colleagues (11%) [51]. Both studies were retrospective and used only macroscopic endoscopic evidence that likely resulted in an underestimation of the prevalence. In contrast, a prospective study of esophageal Crohn's disease in adults yielded a prevalence of 5.1% [52]. There have been few pediatric studies. In one prospective study, endoscopy identified esophageal Crohn's disease in 2 of 40 (5%) children with Crohn's disease and a total of 17 of 40 (42.5%) had histological evidence of esophageal Crohn's disease [53]. In a large cohort of 210 children with Crohn's disease, the lowest estimate of prevalence for endoscopic esophageal Crohn's disease was 7.6% and the highest estimate 17.6% when including histology findings as diagnostic criteria [54]. These findings suggest that the prevalence of esophageal Crohn's disease in adults and children may be similar and is at least 5%. There is wide variability in the clinical manifestations of esophageal Crohn's disease and many patients do not have specific esophageal symptoms. Isolated esophageal Crohn's disease is uncommon.

Esophageal Crohn's disease is usually associated with advanced ileocolonic disease but upper GI tract symptoms do not always correlate well with endoscopic and biopsy findings. Cameron [54] reported that upper GI symptoms were present in only 15% of children with Crohn's disease but found that 42% had endoscopic lesions. Alcantara and colleagues found that 17% of 41 adults had upper GI symptoms but only 5% had endoscopic esophageal Crohn's disease [52]. In the pediatric age group, there is often an overlap

of symptoms (such as nausea, anorexia, and abdominal pain) between esophageal and small bowel Crohn's disease. It is therefore difficult to identify an upper GI site of disease based on clinical evaluation alone. Thus upper endoscopy and biopsies are important in the evaluation of pediatric IBD, even in the asymptomatic child.

The presence of histological abnormalities in radiologically and endoscopically normal mucosa is not ususual. Hence, endoscopy with biopsy is generally considered the gold standard for diagnosis of early asymptomatic lesions. The spectrum of esophageal injury in Crohn's disease varies from mild esophagitis with small erosions to transmural involvement with perforation and fistulization to adjacent organs. In addition to aphthous ulcers, other findings in esophageal Crohn's disease are erythema, ulceration, erythematous nodules, and polypoid lesions. Pseudomembrane formation and progressive esophageal narrowing resulting in strictures and formation of multiple mucosal bridges have been described in advanced stages.

Epithelioid granulomas in the correct clinical setting are considered diagnostic for Crohn's disease (Fig. 137.11). Focal infiltration with mononuclear cells and histiocytes into the lamina propria that extends to the muscular layer is in keeping with Crohn's esophagitis. Unfortunately, nonspecific upper tract lesions can also be found in pediatric patients with classic ulcerative colitis [55].

The clinical course of esophageal Crohn's disease has been described by D'Haens and colleagues [51], who showed that 8 of 14 (57%) patients had no recurrence of esophageal lesions or symptoms during subsequent disease exacerbations. None of the children in the study by Ramaswamy and colleagues [56] had repeat endoscopy for recurrence of upper GI symptoms. Considering the high prevalence of histological esophageal Crohn's disease in children and the low prevalence of endoscopic esophageal Crohn's disease in adults, it seems reasonable to suggest that esophageal involvement is unlikely to progress to a more overt disease over time.

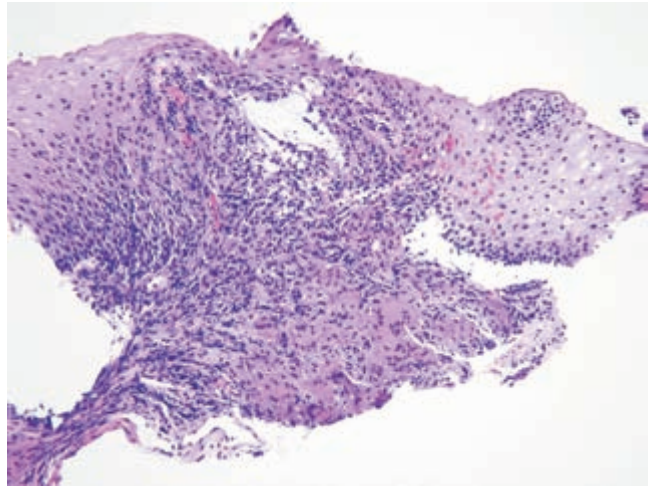

Figure 137.11 Crohn's disease involving the esophagus. There is a prominent lymphoplasmacytic infiltrate. A granuloma is seen in the lower center portion of the field.

Benign polyps

Fibrovascular polyps of the esophagus

These lesions are only rarely encountered in practice. Fibrovascular polyps are submucosal tumors of the esophagus. They have been classified as lipomas, fibromas, and fibrolipomatous polyps. There is only one example in the electronic surgical pathology files at the Johns Hopkins Hospital [57]. However, the dramatic presentation of these polyps has resulted in over 25 individual patient reports in the English literature since 1969, but the largest case series includes only 16 examples referred to the Armed Forces Institute of Pathology (AFIP) [58]. Most arise in middle-aged or elderly men. Presenting complaints include dysphagia, substernal discomfort, and sensation of a mass. In the AFIP series, all 16 patients with giant fibrovascular polyps were symptomatic; dysphagia was the most common complaint (present in 87%), followed by respiratory symptoms (25%) and regurgitation of the polyp into the pharynx or mouth (12%). This series did not include instances of asphyxiation, but it is a feared complication. In the AFIP series, the mean duration of symptoms was 17 months, and only 44% of the patients reported symptoms for 6 months or less.

Most fibrovascular polyps of the esophagus are giant lesions, some reaching 17 and 25 cm in length. They usually arise in the cervical esophagus, near the region of the cricopharyngeus muscle, which accounts for their tendency to prolapse into the mouth and their ability to impinge on the larynx. Chest radiography reveals a right-sided superior mediastinal mass or anterior tracheal bowing. Barium studies show smooth but variably lobulated intralumenal masses originating in the lower cervical esophagus with variable sizes and distal extension, with an average length of about 15 cm. Depending on the amount of fat and fibrovascular tissue in the lesion, computed tomography (CT) reveals a heterogeneous appearance in most cases with some lesions consisting of predominantly fat density and other of predominantly soft-tissue density.

Grossly, these are sausage-like pedunculated polyps arising from the wall of the esophagus. Their surface is covered by squamous mucosa and their cores consist of an admixture of grossly identifiable adipose tissue and firm whitish connective tissue.

Fibrovascular polyps are histologically rather uniform lesions composed of variable admixtures of mature adipose tissue lobules, collagenous and sometimes myxoid tissue, and prominent vasculature, all surrounded by mature squamous epithelium. Giant fibrovascular polyps of the esophagus are uniformly benign lesions that are cured by excision. Secondary tumors such as squamous cell carcinoma arising within a fibrovascular polyp are rare.

Squamous papillomas

These are uncommon lesions usually found incidentally at endoscopy. The largest series is of 25 patients [59,60]. All patients in whom race was known were white with a female predominance, and the majority of lesions occurred in the distal esophagus. Five patients had multiple lesions. Many cases showed endoscopic evidence of hiatal hernia, gastroesophageal reflux, or esophagitis. No examples of Barrett esophagus were found. In our own material from a busy gastroenterology practice, about 70 cases have been biopsied at our hospital in the past 20 years.

Squamous papillomas are seen as tiny polyps at endoscopy. On histological evaluation, they consist of bland polypoid squamous mucosa with fibrovascular cores (Fig. 137.12). Exceptional cases display viral cytopathic effects. Several studies have evaluated the presence of human papillomavirus (HPV) in these lesions by both immunohistochemistry and in situ hybridization [59–62]. They are negative in most cases and the possibility of polymerase chain reaction (PCR) contamination would seem likely in one of the studies [62]. However, a subset of patients with HPV-associated laryngeal papillomatosis has HPV-related squamous papillomas of the esophagus and occasional esophageal examples have been reported unassociated with laryngeal lesions.

Squamous papillomas of the esophagus do not appear to degenerate into esophageal malignancies, and no dysplasia is seen histologically. Evidence of recurrence is unusual, but synchronous or metachronous carcinomas of the ororespiratory tract have been described. Many reports suggest a role for mucosal injury and regeneration in the pathogenesis of these lesions. The association with other malignancies may be significant but, in our material, these have been incidental lesions.

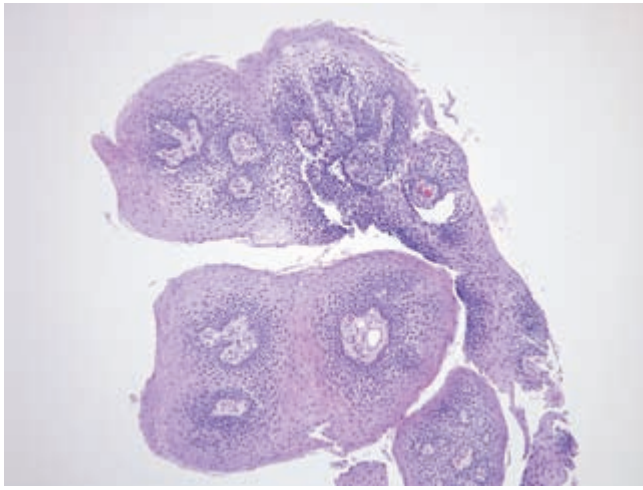

Figure 137.12 Squamous papilloma of the esophagus. Squamous mucosa coats fibrovascular cores.

Barrett esophagus

Since GERD has been shown on epidemiological grounds to be a strong risk factor for adenocarcinoma of the esophagus [63], evaluation of patients for the presence of histological precursor lesions (Barrett esophagus and columnar epithelial dysplasia in this setting) is best performed by a large number of upper endoscopic biopsies.

According to the American College of Gastroenterologists, Barrett esophagus is a change in the esophageal mucosa of any length that is visible at endoscopy and which contains intestinal metaplasia on biopsy [64]. Consequently, if an endoscopist is not certain whether a biopsy is from the esophagus, a pathologist cannot be sure whether the goblet cells found in it reflect cardiac intestinal metaplasia or Barrett esophagus. In the past, all columnar mucosa in the esophagus, whether of gastric cardiac type, oxyntic type or showing intestinal metaplasia, was diagnosed as Barrett esophagus. Currently, when biopsies are derived from the tubular esophagus and have columnar mucosa, the American College of Gastroenterologists requires the presence of unequivocal intestinal metaplasia in an endoscopically abnormal esophagus before an interpretation of Barrett esophagus is made [64]. However, it is well known that intestinal metaplasia can often be found at the gastroesophageal junction when no endoscopic lesion is apparent.

Endoscopically, Barrett mucosa appears as tongues and patches of reddish salmon-colored mucosa (in contrast to the normal pearly grey-pink color of the squamous epithelium) that extend from the gastroesophageal junction for varying distances up into the tubular esophagus. Short-segment Barrett esophagus is defined as less than 3 cm of metaplastic columnar epithelium and long-segment Barrett esophagus as more than 3 cm of metaplastic columnar epithelium.

Some authors have suggested immunophenotyping to separate cardiac intestinal metaplasia from true Barrett mucosa. Ormsby and colleagues evaluated cytokeratin (CK)7 and CK20 immunoreactivity patterns in resection specimens with long-segment Barrett esophagus and compared them to distal gastric resection specimens with intestinal metaplasia [65–67]. Virtually all cases with long-segment Barrett esophagus were characterized by superficial and deep CK7 immunoreactivity in the intestinalized mucosa with only superficial CK20 staining in the intestinalized zones. In contrast, distal gastric intestinal metaplasia was characterized by patchy superficial and deep CK20 staining in areas of incomplete intestinal metaplasia, strong superficial and deep CK20 staining in areas of complete intestinal metaplasia, and patchy or absent CK7 staining in either type of gastric intestinal metaplasia. As an extension of this work, this same group of researchers evaluated the utility of CK subsets in distinguishing intestinal metaplasia of the distal esophagus from that found in the gastric cardia in endoscopic biopsy specimens. Patients with intestinal metaplasia of the cardia all had

a normal-appearing squamocolumnar junction, and biopsies were obtained less than 5 mm from the esophagogastric junction with the endoscope in a retroflexed position. The Barrett CK7/CK20 pattern (described above) was found in all cases of Barrett esophagus but was absent in all 13 cases of cardiac intestinal metaplasia. However, other observers have questioned the utility of CK7/CK20 staining. CK7 is certainly the more useful of the two and it is key only to stain areas with a full gland profile with intestinal metaplasia. Piazuelo and colleagues found use of CK7 helpful in this distinction [68]. However, a study of carcinomas believed to arise in the esophagus and the cardia failed to find differences in CK7 and CK20 in these two types of cancers [69].

Use of MUC polypeptides has also been explored [68]. A significantly higher number of patients with Barrett esophagus ($P < 0.05$) showed goblet cell staining for MUC1 (55%) or MUC6 (32%) compared with patients with carditis with intestinal metaplasia (MUC1 14%, MUC6 7%) or antritis with intestinal metaplasia (MUC1 6%, MUC6 0%). Patients with Barrett esophagus also showed a higher frequency of MUC1 and MUC6 positivity in nongoblet columnar cells compared with carditis and antritis cases with intestinal metaplasia. Only cases of Barrett esophagus showed combined MUC1 and MUC6 staining (sensitivity 23%, specificity 100%). The sensitivity and specificity of MUC1 staining for Barrett esophagus are 55% and 96%, respectively, and for MUC6 staining 30% and 96%, respectively. Interestingly, normal gastric cardia mucosa also showed a significantly higher prevalence of MUC2 and MUC3 expression in glandular epithelium (29% and 38%, respectively) compared with the antrum (0% for both markers) ($P < 0.05$).

Das-1 antibody (named after one of the authors [70]) is also believed to stain Barrett metaplasia strongly, with less staining in gastric intestinal metaplasia.

Dysplasia in Barrett esophagus

Dysplasia refers to a neoplastic change in epithelium that remains confined to the neoplastic gland in which it arose. In other organ systems, the term *intraepithelial neoplasia* is usually applied, but old-fashioned terminology remains in place for the hollow viscus organs. Criteria in the esophagus were established at a consensus meeting held in 2001 [71].

Grading dysplasia in Barrett esophagus

Algorithm

The algorithm is based on four mucosal features in Barrett esophagus:

- surface maturation compared with underlying glands
- architecture of the glands
- cytological features
- inflammation and erosions/ulcers.

The algorithm presupposes that the biopsy is taken from the esophagus, that compatible endoscopic features of Barrett esophagus are found, and that intestinal metaplasia is found. Applying the algorithm, the classification of dysplasia is as follows.

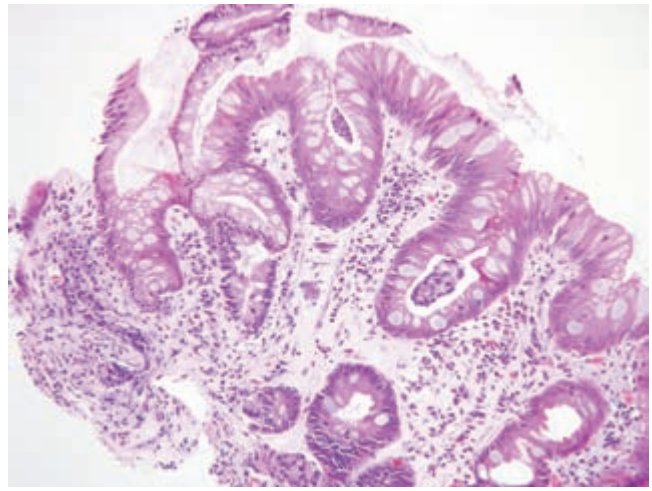

Figure 137.13 Barrett esophagus, negative for dysplasia. Note the goblet cells. There is surface maturation of the metaplastic cells and abundant lamina propria.

Barrett esophagus, negative for dysplasia

In Barrett esophagus without dysplasia (Fig. 137.13), the surface appears more mature than the underlying glands in that the nuclear-to-cytoplasmic ratio of surface cells is lower than that of the deeper glands. The architecture is normal, with abundant lamina propria between glands. The cytological features are normal, noting that mitoses may be present in deeper glands as well as nuclear stratification. The individual nuclei should have smooth nuclear membranes, and nucleoli, if present, should be small with smooth outlines. Nuclear polarity should be maintained in deep and superficial aspects of the biopsy. If inflammation is a component, reparative features may be present. In this setting, nuclear membranes should remain smooth, although the cells may display nuclear-to-cytoplasmic enlargement and nucleoli may become more prominent but retain smooth contours. The surface should show maturation compared with the deeper glands but there may be some loss of surface mucin.

Barrett esophagus, indefinite for dysplasia

Cases showing deeper cytological changes suggestive of dysplasia but with surface maturation are included in the indefinite category; other observers have used the indefinite category as a "wastecan" [72]. Cases in the indefinite category can show normal architecture or some degree of glandular crowding. On cytological evaluation, lesions can show hyperchromasia, nuclear membrane irregularities, and increased mitoses in the deeper aspects, and these mature to the surface. Loss of nuclear polarity is not a feature of the

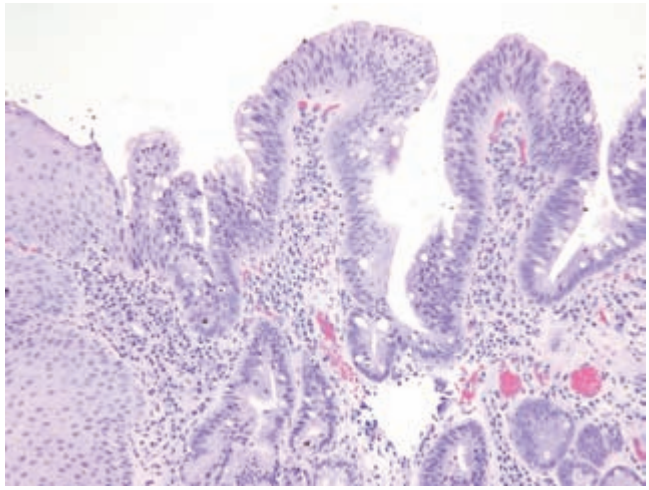

Figure 137.14 Low-grade dysplasia in Barrett esophagus. The epithelial changes are seen both in deep glands and on the surface but the nuclei are aligned perpendicularly to the basement membrane (maintained nuclear polarity).

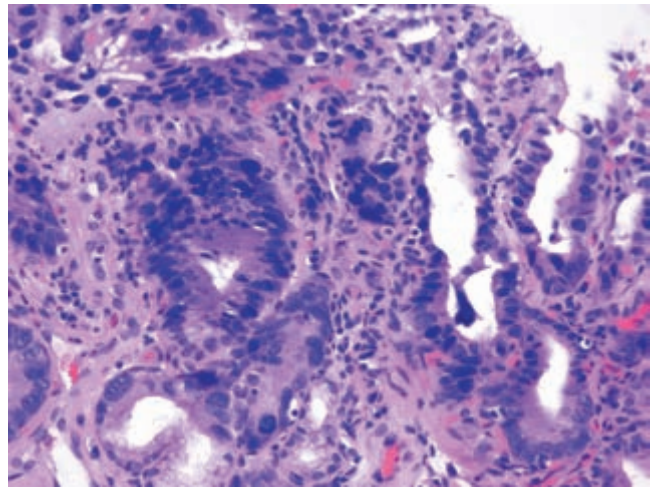

Figure 137.15 High-grade dysplasia and intramucosal carcinoma in Barrett esophagus. Hyperchromatic nuclei have lost their polarity (relation to the basement membrane).

indefinite category. In the presence of inflammation, more striking architectural abnormalities have been included in the indefinite category. This interpretation can also be applied when tangential embedding does not allow assessment between the glands and the surface. Some cases display peculiar morphology and it is unclear whether they are neoplastic or reparative. We often offer an explanation for resorting to this category when it is assigned.

Barrett esophagus, low-grade dysplasia

In Barrett esophagus with low-grade dysplasia (LGD) (Fig. 137.14), the surface appears similar to the underlying glands at low magnification or displays only slight maturation. The architecture may be mildly to markedly distorted with glandular crowding, although lamina propria should be identifiable between glands. The cytological features are important and the changes should extend at least focally to the surface. These include nuclear hyperchromasia with some chromatin clumping. The nuclei show nuclear membrane irregularities but not pronounced nuclear enlargement, although there may be focal marked enlargement if the other features support an interpretation of LGD. Nucleoli are not typically prominent in LGD. Loss of nuclear polarity is not a feature of LGD, although nuclear stratification similar to that seen in colonic adenomas is within the spectrum of LGD and may be present at the surface. Inflammation is typically minimal; cases with abundant inflammation and the other features of LGD are usually best classified in the indefinite category. If tangential embedding precludes evaluation of the surface, LGD can be diagnosed if there are dysplastic features in the deep aspects in the absence of inflammation provided that the features of high-grade dysplasia (see below) are lacking.

Barrett esophagus, high-grade dysplasia

As in LGD, surface maturation is lacking in high-grade dysplasia (HGD) (Fig. 137.15). The architecture may show crowding of cytologically abnormal glands or be markedly distorted with prominent glandular crowding and little intervening lamina propria. If the cytological features are sufficiently dysplastic, lesser architectural distortion is acceptable. Nuclei are hyperchromatic and nuclear membranes irregular. Most examples are similar to dysplasia in the uterine cervix in not displaying prominent nucleoli which, as in the cervix, tend to be present in either marked repair or when invasion has begun, both situations that are associated with ulcers. Cells may have either delicately clumped dark heterchromatin and inconspicuous nucleoli or prominent irregular nuclei with irregularly clumped chromatin and irregular nucleoli. Markedly enlarged hyperchromatic cells are a feature of HGD and these may extend to the surface. Loss of nuclear polarity is seen in HGD. Mitoses are readily identifiable. Inflammation is typically minimal. There is some evidence to suggest that HGD accompanied by an ulcer is a worrisome feature for an associated unsampled invasive carcinoma and we advise additional biopsies or endoscopic ultrasound when we see this pattern [73].

Intramucosal carcinoma

The distinction between HGD and the earliest intramucosal carcinoma (defined as invasion through the basement membrane into the lamina propria or muscularis mucosae but not beyond) remains difficult and observer variation between HGD and intramucosal carcinoma is not good. In general, these cases begin to demonstrate effacement of lamina propria architecture and a syncytial growth pattern, extensive back-to-back microglands, and an intermingling of single cells and small clusters within the lamina propria. Typically,

desmoplasia is absent or incompletely developed at this stage, and hence its recognition is difficult and subjective. In carcinoma which has invaded more deeply (into the submucosa), desmoplasia and a clearly infiltrative growth pattern become readily apparent, although tangentially embedded and scarred tissue can pose diagnostic problems. In the upper GI tract, invasion into the lamina propria is more significant than in the colon since the colon lamina propria lacks significant lymphatic access. In the colon, invasion into the lamina propria is biologically equivalent to HGD; in contrast, in the esophagus, invasion into the lamina propria can lead to metastatic disease.

Ancillary studies

Since the purpose of surveillance is to detect the earliest lesions, it is important for pathologists handling these biopsies to recognize them. Unfortunately, biopsy interpretation is plagued by problems with intraobserver and interobserver reproducibility [71,72], which probably accounts in part for the wide range of progression rates in various series, particularly at the lower ends of the spectrum. Among many surrogate markers explored to improve prognostication, flow cytometry and assessment of p53 may be useful adjuncts in identifying patients at highest risk [74] or even in identifying endoscopic foci of interest for follow-up in patients undergoing endoscopic mapping. Hopefully, newer technology will allow better clarification of high-risk patients and offer novel treatment options. However, pathologists do an excellent job in identifying high-risk lesions (HGDs) if these are biopsied. Sampling error and selection of the best patients to screen are probably more serious problems than diagnostic reproducibility in monitoring these patients. Despite substantial limitations inherent in interpretation of biopsies, grade of dysplasia correlates well with progression to invasive carcinoma, and it remains the foundation of clinical decision making. For example, in our series and others, grade on initial biopsy correlated significantly with progression to invasive carcinoma [75]. As a general rule, about half of patients with HGD ultimately progress to invasive carcinoma and no independently validated molecular test selects them. Estimates are poorer for LGD, but it results in progression rates of up to 15%.

Tumors

Adenocarcinoma

Since Barrett mucosa begins at the gastroesophageal junction and extends for varying distances into the tubular esophagus, adenocarcinomas are also most common in the distal third of the esophagus (in contrast to squamous cell carcinomas, which are most commonly found in the middle third).

Esophageal adenocarcinomas are seen at esophagectomy as firm whitish lesions usually involving the distal third. Often residual Barrett mucosa can be recognized by its salmon color and velvety appearance. When staging adenocarcinomas close to the esophagogastric junction, an attempt should be made to determine whether the tumor is esophageal or gastric [76]. The tumor is classified as esophageal if the epicenter is in the esophagus and gastric if the epicenter is in the stomach. The presence of Barrett mucosa is used as evidence that the tumor is of esophageal origin. This is of significance as esophageal carcinomas are staged as N0 or N1 whereas gastric ones are staged as N0, N1, or N2. It should also be noted that T1 includes tumors invading the lamina propria of the submucosa whereas T2 encompasses those invading the muscularis propria.

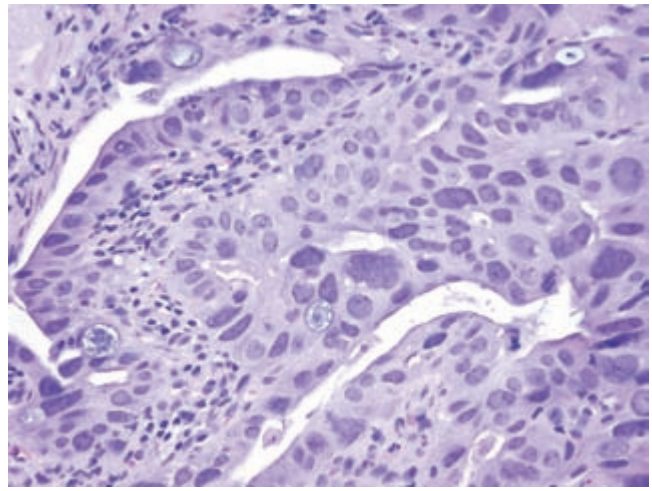

Figure 137.16 Esophageal adenocarcinoma. In this field, the adenocarcinoma undermines adjoining squamous mucosa.

Recognizing esophageal adenocarcinomas on biopsies is generally not a challenge and they appear as other adenocarcinomas, being composed of malignant cells with glandular differentiation either in the form of ductal structures or mucin production (Fig. 137.16). However, finding an in situ/HGD component is useful in assuring that the esophagus is indeed the primary site (rather than the lung). A subset of poorly differentiated carcinomas is essentially impossible to distinguish from high-grade lymphomas and requires immunohistochemistry for diagnosis. Poorly differentiated carcinomas may also assume spindle cell morphology (a more common scenario with squamous cell carcinomas) and, in the absence of an in situ component, an immunohistochemical panel is again advised.

Preoperative neoadjuvant chemotherapy and radiotherapy followed by esophagectomy is the preferred treatment; there is an especially poor prognosis when the patient presents with symptoms in the absence of surveillance for early detection.

Squamous cell carcinoma

Squamous carcinomas are most common in the middle third of the esophagus. On imaging studies, the presence of an esophageal mass in the middle third of the esophagus is in

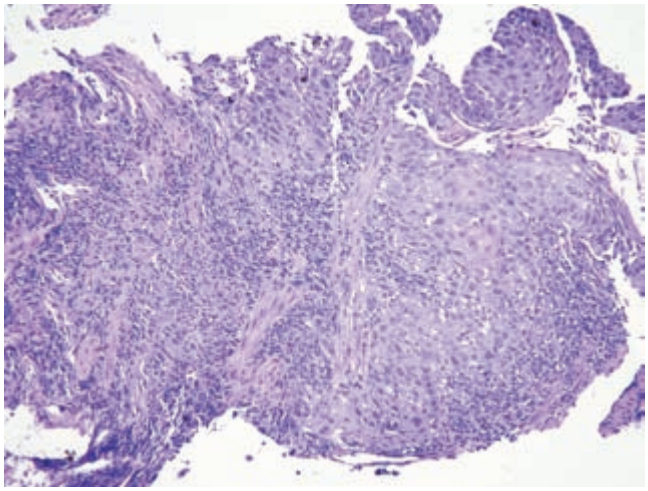

Figure 137.17 Esophageal squamous cell carcinoma. There is a squamous pearl toward the right of the field. In this biopsy, the lesion has invaded the muscularis mucosae, seen as slender pink strips.

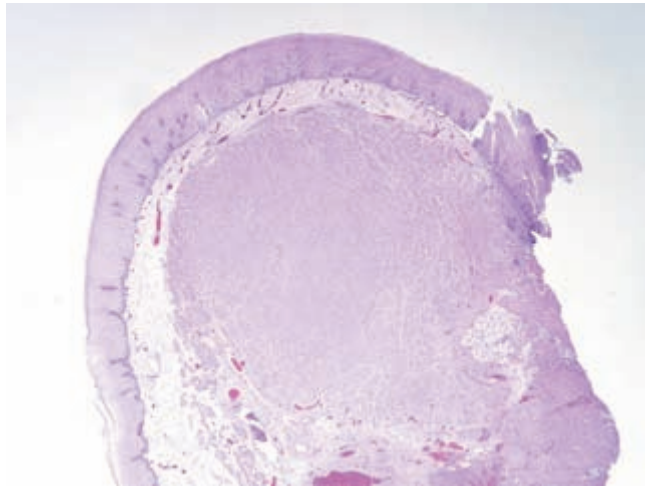

Figure 137.18 Granular cell tumor of the esophagus. At low magnification, a well-marginated nodule is seen in the lamina propria.

keeping with squamous cell carcinoma but there are no specific radiological features of this type of tumor.

On biopsies, squamous carcinoma of the esophagus appears similar to squamous carcinomas elsewhere (Fig. 137.17). They are usually well-differentiated squamous carcinoma with prominent keratinization. Background squamous epithelial dysplasia (intraepithelial neoplasia) including carcinoma in situ (HGD/intraepithelial neoplasia) is frequent at the periphery of invasive tumors. Dysplasia alone without invasion is uncommon. Some squamous carcinomas assume a prominent spindle cell appearance. This latter subtype tends to present as a polypoid mass. Short-term survival of such tumors is better than that for flat typical carcinomas owing to their exophytic growth, but long-term follow-up erases an apparent survival advantage. Squamous cell carcinomas of the esophagus, like squamous carcinomas elsewhere, express CK5/6 and a host of epithelial markers. Most examples are not a diagnostic problem. When spindled, melanoma and sarcomas must be excluded. The best way to do this is by sampling as much of the overlying squamous mucosa as possible in order to detect an in situ component.

Reported molecular genetic abnormalities include p53 mutations and deletion, deletion of Rb and p16, amplification of epidermal growth factor receptor, c-*myc*, int-2/hst-1 and cyclin D1, and overexpression of epidermal growth factor and insulin-like growth factor receptor-1. There is no important role for *ras* gene mutations.

Unfortunately, squamous carcinomas usually present late clinically, after extension into periesophageal soft tissue is already present. Esophageal obstruction, extension of carcinoma into mediastinal and intrathoracic structures (tracheobronchial tree, aorta, lung), and mediastinal lymph node metastases are more frequent clinical problems than distant metastases.

Radiotherapy or chemotherapy is the usual treatment, sometimes with esophagogectomy; this is usually palliative rather than curative. Esophageal squamous carcinoma has a dismal prognosis: the 5-year survival rate is 5%–10%.

Granular cell tumors

Granular cell tumors are generally rare. The most common sites are the tongue and skin [77]. A subset is multicentric and rare examples are malignant [78]. Granular cell tumors of the esophagus comprise about 1%–2% of all granular cell tumors and the esophagus is the most common GI site [79]. There are fewer than 100 reports of esophageal granular cell tumors in the literature. We have only encountered 12 esophageal granular cell tumors at our institution in the last 15 years. Most arise in the distal esophagus and about 5%–10% are multicentric. There is a female predominance and these tumors are relatively more common in African Americans than in whites. Rare malignant esophageal granular cell tumors have been reported [80,81]. Esophageal granular cell tumors are most likely to be identified incidentally at endoscopy but some patients are symptomatic. Most appear as well-marginated masses on imaging studies. Associated concentric narrowing can also be found.

On microscopic examination, tumors are centered in the submocosa with minor extensions into mucosa and muscularis propria and are well marginated but not encapsulated (Figs 137.18 and 137.19). They are composed of plump neoplastic cells with abundant lightly amphophilic granular cytoplasm which displays retention of PAS staining on diastase digestion. The cells are typically closely packed. Nuclei are small to pyknotic with occasional nucleoli. About half display squamous (pseudoepitheliomatous) hyperplasia in the overlying mucosa, which can raise the possibility of squamous cell carcinoma on superficial biopsies. Based on this hyperplastic squamous pattern, mucosal biopsies often

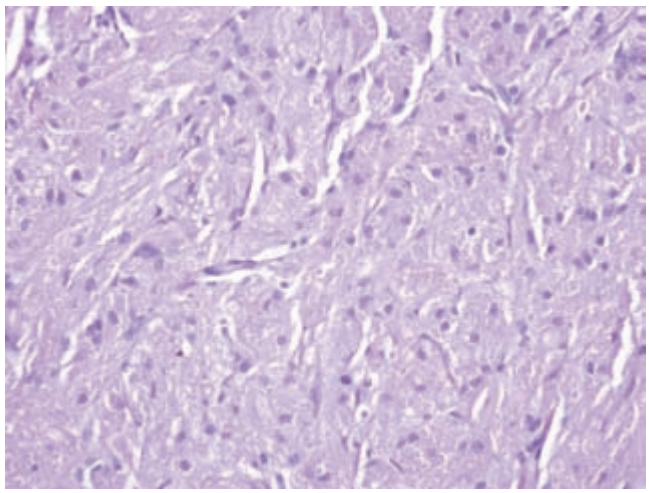

Figure 137.19 Granular cell tumor. Note the granular appearance of the eosinophilic proliferating cells.

contain predominantly the proliferated squamous epithelium and only a handful of lesional cells in the superficial lamina propria.

Granular cell tumors are reactive with S100 protein, calretinin, inhibin α, myelin basic protein, and CD68/Kp1 but lack muscle markers and melanoma markers.

The vast majority of granular cell tumors behave in a benign fashion. Those rare examples that have metastasized typically display prominent cytological alterations or mitotic activity.

Leiomyoma

This is the most common spindle cell tumor of the esophagus. It displays smooth muscle differentiation. Esophageal leiomyomas occur in a relatively young population (median age 35 years) [82] and there is a male predominance. Leiomyomas of the esophagus are, of course, benign. They show eosinophilic cytoplasm, and are positive for desmin and smooth muscle actin (SMA) and negative for CD117/c-kit and CD34. Rarely, leiomyosarcomas arise in the esophagus and are typically large high-grade tumors that show muscle cell markers but no CD117. These tumors are seldom encountered on biopsy as they tend to be intramural in location.

Gastrointestinal stromal tumors

Leiomyomas are the most common esophageal mesenchymal neoplasms even though they are distinctly uncommon in the remainder of the GI tract, despite the abundance of mural smooth muscle. In contrast, gastrointestinal stromal tumors (GISTs) predominate in the stomach and intestines but are truly rare in the esophagus. Using the files of the AFIP and the Haartman Institute of the University of Helsinki, Miettinen and colleagues were only able to accumulate 17 examples of esophageal GISTs [82]. The esophageal GISTs occurred in 12 men and five women with a median age of 63 years (range 49–75 years). All tumors were from the lowest third of the esophagus, and the most common complaint was dysphagia, whereas two tumors were detected incidentally. Histologically the tumors had the usual appearance of GISTs, displaying an overall basophilic appearance and combinations of solid, myxoid, and perivascular collar-like patterns with a spindle cell histology in 13 patients and epithelioid histology in four patients. All tumors were positive for CD117 and CD34, whereas two patients were also positive for α-SMA and three patients were positive for desmin. Nine patients died of disease, including all who had a tumor larger than 10 cm, and also one patient whose tumor showed five mitoses per 50 high-power fields.

Melanoma

Primary melanoma of the esophagus is quite rare, with fewer than 300 cases reported. The affected patients are adults, with a mean age of about 60 years [83–87]. They are more common in men than women but there is no racial predominance. Lesions predominate in the distal esophagus. At endoscopy, they are polypoid and pigmented in about 85% of cases. Imaging studies show bulky polypoid masses that bulge intralumenally without resultant obstruction. When biopsied, the findings in esophageal melanomas are similar to those elsewhere. Examples regarded as primary may display an in situ component. Obviously, finding this is extremely useful in establishing the esophagus as the primary site. Otherwise, cells are spindled to epithelioid with variable pigment, prominent nucleoli, and prominent intranuclear pseudoinclusions.

Primary esophageal melanomas have a dismal prognosis. Only rare patients whose tumors present early can be cured.

Stomach

The stomach has four main zones with divergent types of mucosa. The simplest way to consider the different parts of the stomach is that the ends (cardia and antrum) protect the esophagus and duodenum from acid and enzymes whereas the middle of the stomach (body and fundus) produces the acid and enzymes.

The empty stomach is thrown into rugae (folds). Tiny surface invaginations termed gastric pits are the conduits of secretions. Histologically the entire stomach has a surface of foveolar cells, which secrete neutral mucin that appears magenta to pink on PAS stain. In the isthmus region of the body and fundus, parietal cells (oxyntic cells) dominate but mucous neck cells are also present. Mucous neck cells are seen in the neck, and chief cells dominate in the base. Endocrine cells are in the deep isthmus towards the base. The cardia and antrum are simpler since the layers all predominantly produce mucin, although the antrum has G cells that produce gastrin. Gastrin is secreted by the antrum but not the body and fundus. The lamina propria of the stomach should

contain only a small population of lymphocytes, plasma cells, mast cells, and eosinophils, in contrast to the intestines, where these constituents are more abundant. Bacteria are usually not seen in the normal gastric mucus (in contrast to the colon, where they are normally present).

When pathologists consider biopsies from the stomach, features that help in diagnosis often involve correlation with clinical information. The endoscopist will be better served by providing information since the histological features of gastric diseases display considerable overlap. Even the gender and ethnicity can be of some value. For example, autoimmune metaplastic atrophic gastritis typically affects older white females and is unlikely (but not impossible) in African Americans. On a busy GI biopsy service, there are frequently many biopsies to review and time efficiency is critical so it is useful for the pathologist to have an idea which biopsies require the greatest attention. In gastric biopsies, the snake in the grass is signet cell carcinoma, which is often focal and subtle in mucosal biopsies. Any clinical concern (such as a stomach that distends poorly on insufflation by the endoscopist) merits a careful review of all biopsy fragments from gastric biopsies; this concern should be emphatically conveyed to the pathologist.

Inflammatory conditions

Acute hemorrhagic gastritis

Acute hemorrhagic gastritis is prototypically associated with alcohol abuse [88,89] but other agents that are injurious to the gastric mucosa can also be responsible [90,91]. In the early literature, it was difficult to separate the effects of *Helicobacter* gastritis from pure alcohol injury but we presently believe that the acute injury from alcohol is similar to a corrosive injury with little inflammation but with abundant edema, hemorrhage, and reactive epithelial changes.

Chemical gastritis/chemical gastropathy/reactive gastropathy

This type of injury, which is seen mostly in the antrum, is common as it is usually attributed to bile reflux and thus is usually seen in patients being evaluated for GERD (which in reality is duodenogastroesophageal reflux disease) [92,93]. Bile reflux is injurious to the gastric antrum as well as to the esophagus. In patients in whom the antrum has been removed, bile reflux injures the gastric body and contributes to the development of so-called "stump" cancers found in the postantrectomy setting. The other typical scenario for reactive gastropathy/chemical gastritis is seen in patients taking nonsteroidal antiinflammatory drugs (NSAIDs), a significant percentage of individuals. The general features of reactive gastropathy are foveolar hyperplasia, lamina propria edema, muscular stranding, and vascular ectasia (Fig. 137.20). Active and chronic inflammation are minimal, and hence some observers prefer the term *reactive gastropathy* rather than chemical gastritis.

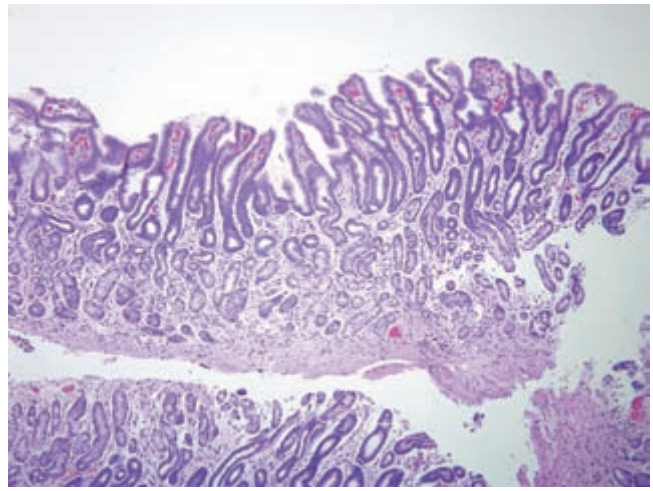

Figure 137.20 Chemical gastritis/reactive gastropathy. The antral mucosa has a villiform appearance and there is mucin loss in the epithelium. There is very little inflammation.

Mucosal calcinosis

Mucosal calcinosis is seen in some patients with renal failure and has been attributed to antacid use [94] but probably mostly reflects disorders of calcium metabolism that are typical in such patients [95]. Regardless, mucosal calcinosis seems to be of no significance in and of itself but an incidental finding in patients with renal failure.

Proton pump inhibitors

Proton pump inhibitors are commonly taken by patients having gastric biopsies. Examples of these include Prilosec (omeprazole), Prevacid (lansoprazole), and Nexium (esomeprazole). These medications reduce acid secretion by gastric parietal cells and have a morphological correlate of apocrine-like cytoplasmic swelling of parietal cells.

Injury due to chemical agents

Iron

Iron pill gastritis appears similar to iron pill esophagitis [21] as discussed above but is of particular note, since striking epithelial changes in the setting of iron pill gastritis sometimes mimic gastric carcinoma.

Kayexalate

Kayexalate can be found associated with gastric mucosa and gastric erosions/ulcerations just as in the esophagus. In the stomach, kayexalate bezoars may formed [23].

Colchicine

Colchicine is an alkaloid with antimitotic activity used to treat a variety of medical conditions, especially gout. Colchicine toxicity can result in multiorgan failure and death. If patients are taking colchicine at therapeutic doses, there are no abnormal biopsies. However, in patients who are colchicine

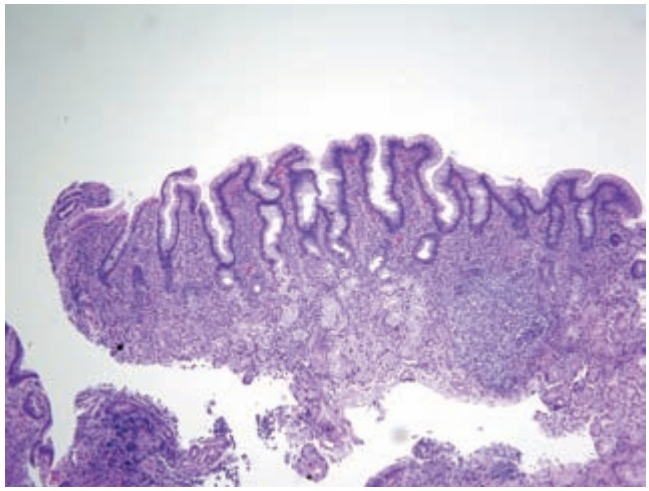

Figure 137.21 Active chronic *Helicobacter pylori* gastritis. Note the lymphoid follicles in this low-magnification field.

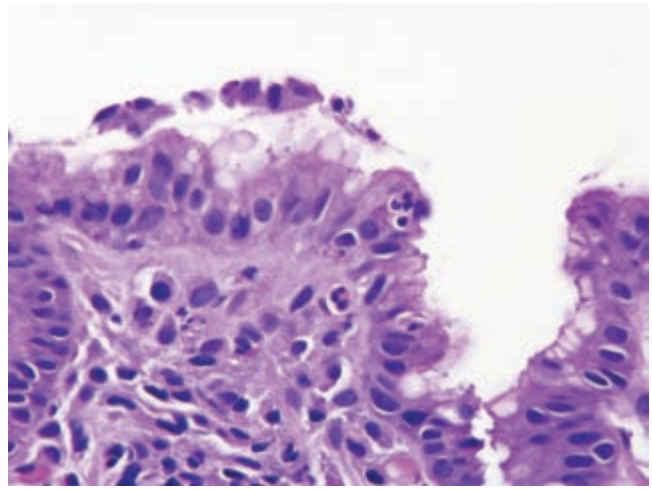

Figure 137.22 Active chronic *Helicobacter pylori* gastritis. At high magnification, neutrophils are seen in the epithelium. Organisms are easily identified on this hematoxylin and eosin stain but it is usually best to apply one of several other stains to detect them.

toxic (typically in the setting of renal insufficiency), distinct morphological changes (metaphase mitoses, epithelial pseudostratification, and loss of polarity, and abundant crypt apoptotic bodies) are seen in biopsy material [96]. These morphological features are best seen in biopsies from duodenum and gastric antrum, with relative sparing of the gastric body in the upper GI tract. Ki67 staining demonstrates an expansion of the proliferating region. Recognition of these features is important because colchicine toxicity can be fatal if undiagnosed clinically.

Helicobacter gastritis

Helicobacter gastritis has been a source of gastritis for years but was not recognized until Marshall and Warren identified the organism [97]. Marshall ultimately fulfilled Koch's postulates by swallowing a pure culture of the organism and acquiring gastritis [98]. There have been over 20 000 publications devoted to this organism in the ensuing 20 years and Marshall and Warren have been awarded a Nobel prize for their observations. *Helicobacter pylori* is now recognized as a curved flagellated Gram-negative rod that has variant forms (especially a coccoid form seen in treated patients) that is now known to be associated with both gastric carcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma. Another variant, *Helicobacter heilmannii*, is more tightly coiled and rare (< 1% of *Helicobacter* isolates) but cross-reacts with the immunohistochemical stain for *H. pylori* and is fully capable of producing gastritis and associating with MALT lymphoma and gastric adenocarcinoma. Like *H. pylori*, *H. heilmannii* produces antral-predominant gastritis but this gastritis is less severe than *H. pylori* gastritis [99]. *Helicobacter* gastritis was formerly known as diffuse antral gastritis, type B gastritis (Figs 137.21 and 137.22) (autoimmune gastritis was type A), and superficial gastritis. In the modern practice of pathology, all gastric biopsy reports should include a statement on *Helicobacter* status. At our hospital, all gastric biopsies are thus stained with Diff-Quik (Fig. 137.23) but any such stain is appropriate. Hematoxylin and eosin staining alone is not regarded as sufficient, although these organisms can certainly be recognized on routine H & E stains [100]. Immunohistochemistry is interesting in that it highlights organisms embedded in tissue, specifically in parietal cells. It is also of value in identifying small coccoid forms found in partially treated patients. We seldom use immunohistochemistry as it is not cost-effective in our practice (serology is less expensive) but some observers perform immunohistochemistry in every case, a practice that may reflect economic factors.

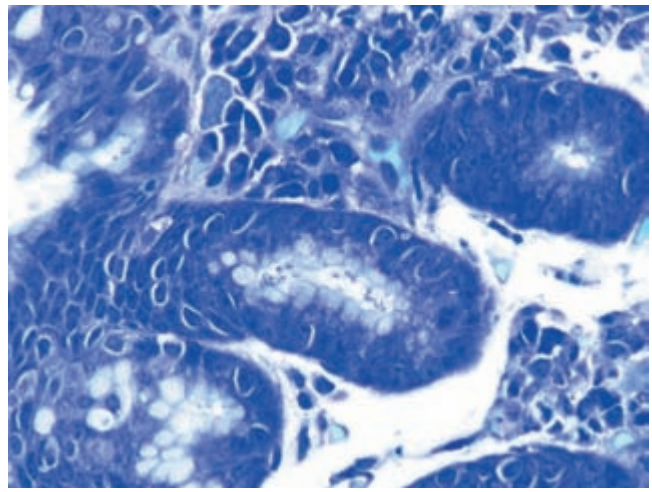

Figure 137.23 Active chronic *Helicobacter pylori* gastritis. A Diff-Quik stain highlights the organisms, seen as curved bacilli in the gland at the center of the field.

The endoscopic findings in *H. pylori* gastritis, and in assessing gastritis in general, correlate imperfectly with pathological findings, although some observers have learned to recognize a mamillated endoscopic corpus appearance and an abnormal antral appearance [101].

Histologically, *H. pylori* organisms are seen in gastric mucus and overlying surface and foveolar epithelium. They do not colonize nonsurface or foci of intestinal metaplasia. There is typically abundant lymphoplasmacytic chronic inflammation of the lamina propria with lymphoid follicles (MALT). There is often abundant active inflammation (neutrophils). The inflammation is concentrated in the upper mucosa, hence the old term of superficial gastritis. Following treatment, the active inflammatory component resolves but the chronic inflammatory component persists for months to years.

Helicobacter seems to have a particular preference for damaging D cells in the antrum, which secrete somatostatin. Since somatostatin usually keeps gastrin secretion in check, loss of these D cells causes excess gastrin secretion, which stimulates excess acid secretion in acutely infected patients. This is, in turn, responsible for the duodenal ulcers that often accompany *Helicobacter* gastritis [102].

Inactive chronic gastritis

There is an extensive literature on grading chronic gastritis, complete with published pictograms [103,104]. However, pictograms for chronic gastritis are seldom valued in daily practice but are a useful construct for standardization in research studies. Chronic gastritis is generally attributable to prior *Helicobacter* infection based on serological studies and is a common finding in biopsy material. However, the threshold for diagnosing it is not entirely clear. In a fashion that is more practical than evidence-based, we diagnose inactive chronic gastritis at 4× magnification and confirm at higher magnification. At low magnification, the lamina propria of the stomach should have only a few inflammatory cells, which appear as small dots. We essentially use a slight prominence in "dot density" as the criterion for low-magnification diagnosis of inactive chronic gastritis.

Metaplastic atrophic gastritis

Metaplastic atrophic gastritis occurs in two distinct types and, because of this, it is best if biopsies are obtained from both the gastric antrum and the body. Some authors have published studies with cartoons to be used as templates for grading the degree of inflammation and atrophy in gastritis but these are of little value in daily practice [103,104].

Autoimmune metaplastic atrophic gastritis

Autoimmune metaplastic atrophic gastritis (AMAG) was called type A gastritis in the past (before the role of *Helicobacter* was elucidated). This is a disease in which antibodies attack parietal cells. It is a disease typically affecting older women, usually with pale skin and blue eyes (e.g., Nordic ancestry). Patients have antibodies to parietal cells and to intrinsic factor (and thus are prone to severe vitamin B-12 deficiency/pernicious anemia). They are at threefold increased risk of developing gastric cancer but are not at risk for ulcers since their parietal cells are reduced in number or absent and thus little or no acid is produced. Since parietal cells are the type affected, the changes occur only in zones where parietal cells are found. Thus there is metaplasia and atrophy only in the body and fundus. An affected patient has no significant inflammatory disease in the antrum (hence the importance of taking biopsies from both the antrum and the fundus). Fundus biopsies show extensive loss of parietal cells and metaplasia. In some cases there are residual nests of parietal cells with chronic inflammatory cells (T cells) in the process of destroying them. In fact, the residual more normal mucosa sometimes appears as polyps to the endscopist in a sea of severe atrophy [105]. Metaplasia may be of the intestinal type or the pseudopyloric type. In pseudopyloric metaplasia, the oxyntic mucosa resembles antral mucosa in that it lacks parietal and chief cells (oxyntic glands) but differs from it by not secreting gastrin. Only the true antrum secretes gastrin. Thus, immunohistochemistry for gastrin in biopsies from the body lacks reactive cells, a finding that can be exploited to establish a diagnosis or exclude inaccurate sampling (i.e., the endoscopist has biopsied the antrum but labeled it "body"). In AMAG, there is no metaplasia in the antrum, which often shows hyperplastic features, possibly secondary to bile reflux (Figs 137.24 and 137.25). Since the patients are hypoacidic based on loss of parietal cell mass, a feedback loop causes antral G cells to produce abundant gastrin to stimulate acid secretion. As there are few or no parietal cells (Fig. 137.26), gastrin levels become progressively elevated in these patients and this stimulates proliferation of endocrine cells in the gastric body as a side effect. Thus chromogranin stains show linear and nodular endocrine cell hyperplasia (Fig. 137.27)

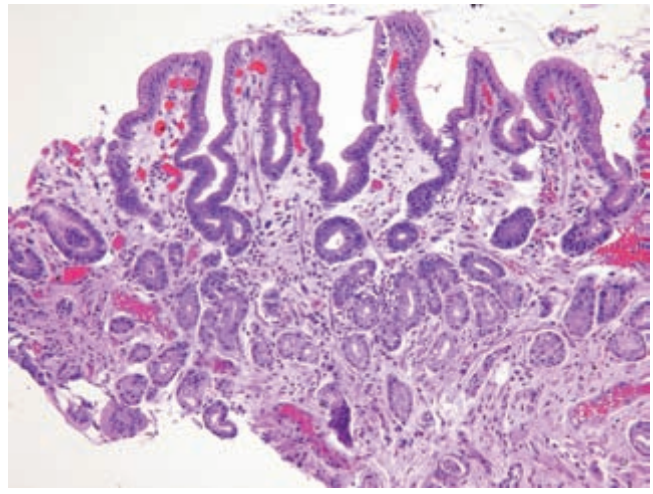

Figure 137.24 Autoimmune metaplastic atrophic gastritis. The antrum from this patient shows chemical gastritis. There are few inflammatory cells.

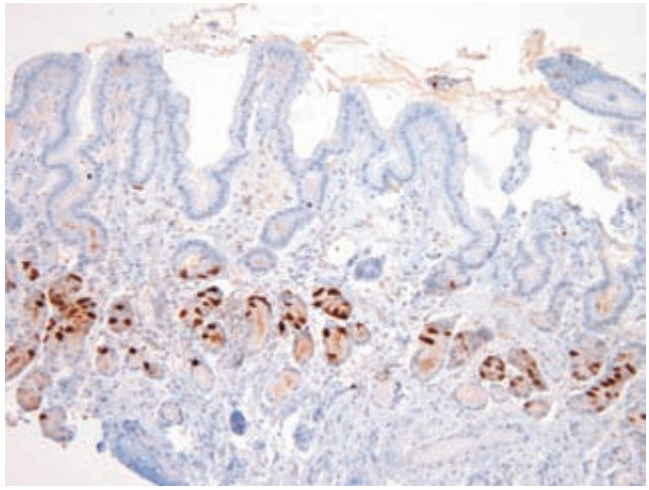

Figure 137.25 Autoimmune metaplastic atrophic gastritis. This is a gastrin stain from the field depicted in Fig. 137.24 There are many gastrin-producing cells. The patient was probably hypergastrinemic.

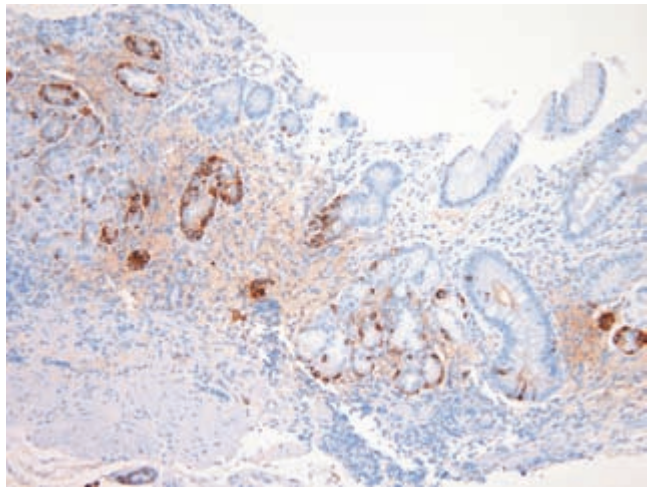

Figure 137.27 Autoimmune metaplastic atrophic gastritis. This chromogranin stain highlights endocrine cell hyperplasia in the area seen in Fig. 137.26 Such proliferation can lead to type 1 carcinoid tumors.

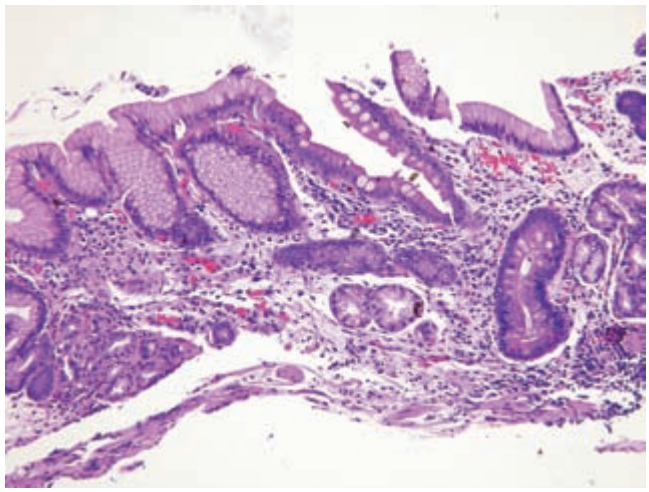

Figure 137.26 Autoimmune metaplastic atrophic gastritis. This biopsy is from the gastric body but there are no acid-producing cells. There is intestinal metaplasia in the center portion of the field (goblet cells).

in the body, none of which is attributable to G cells. If this condition persists, small indolent carcinoid tumors can result.

Environmental metaplastic atrophic gastritis

Helicobacter gastritis is probably the most important cause of environmental gastritis but is probably not the cause of all cases. Other associations include various dietary factors such as excessive salt, smoked foods (nitrites), paucity of green vegetables and fruits (lack of vitamins C and E, β-carotene, selenium), and nitrosamines. Nitrosamines can be produced from nitrites in the setting of colonization by anaerobic bacteria in a hypoacidic stomach. This type of gastritis has been called type B gastritis and multifocal atrophic gastritis.

The key feature is that environmental atrophic gastritis is most marked in the antrum. Multiple foci first appear in the transition zone between antrum and body at the area of the lesser curvature. Over time the entire antrum is affected but the body is relatively spared. There is less disease in the body, first in the distal body, but over many years affecting more of the body. The body can display pseudopyloric and intestinal metaplasia as in autoimmune gastritis, but of course the antrum is affected as well. These patients retain enough parietal cell mass that they seldom develop pernicious anemia. They can become hypochlorhydric but achlorhydria is rare. Their serum gastrin is usually normal and they can have ulcers and develop cancers. In the USA, it is usually seen in patients older than 50 years but in certain parts of the world atrophy appears in patients in their third or fourth decades (e.g., Japan, Andean South America).

Gastric antral vascular ectasia

Gastric antral vascular ectasia (*watermelon stomach*) was first described by Jabbari in 1984 and refers to an endoscopic appearance [106]. In this condition, longitudinal antral folds have visible reddened vessels radiating from the pylorus in a distribution resembling a watermelon rind. Patients present with iron deficiency secondary to chronic gastric bleeding. The typical patient is an elderly woman with achlorhydria, chronic liver disease, CREST syndrome, or lymphoma. Some cases are associated with scleroderma [107]. In some cases the endoscopic appearance is not prototypic but instead consists of diffuse gastric erythema. The etiology is not well known but is probably an acquired lesion. Some patients have antral prolapse [106].

Histological examination discloses features that reflect a mucosal prolapse component: there is foveolar hyperplasia with dilated mucosal capillaries, focal thrombi, and fibromuscular

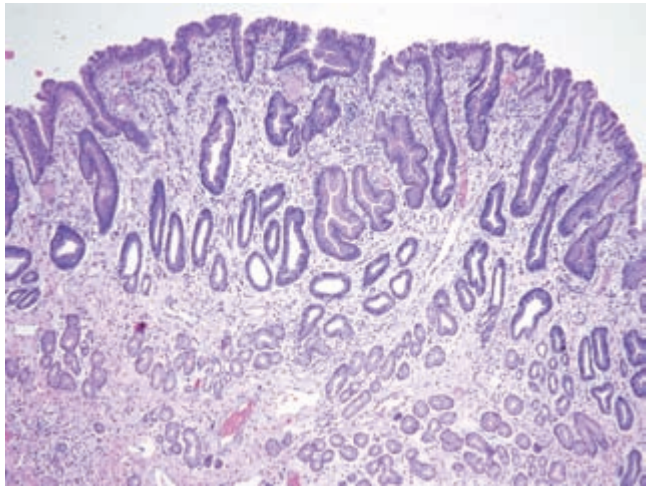

Figure 137.28 Gastric antral vascular ectasia (watermelon stomach). Even at low magnification, many vascular thrombi are apparent.

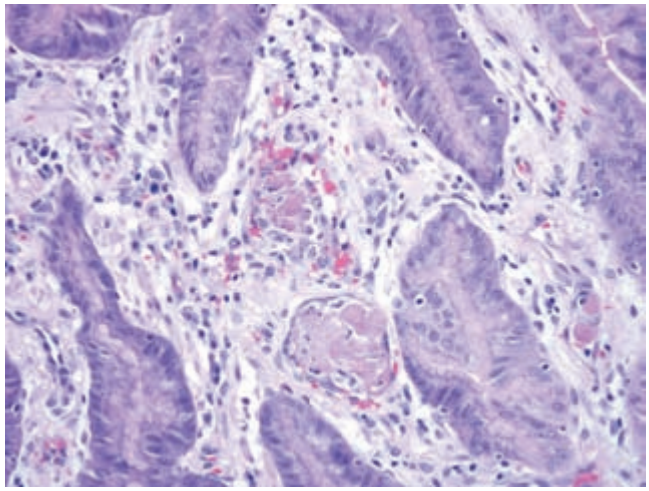

Figure 137.29 Gastric antral vascular ectasia (watermelon stomach). High magnification of fibrin thrombi.

hypertrophy [108] (Figs 137.28 and 137.29). Similar features may be seen in patients who have portal hypertension but the dilated capillaries in portal hypertension lack fibrin thrombi; however, patients with watermelon stomach may also have portal hypertension [109]. Treatment of watermelon stomach often entails mucosal ablation since patients have uncontrolled blood loss. Endoscopic therapy, including contact and noncontact thermal ablation of the ectatic vascular lesions, is the mainstay of conservative therapy. However, many patients fail endoscopic therapy and develop recurrent acute and chronic GI bleeding episodes. Surgical resection may be the only reliable method for achieving a cure and eliminating transfusion dependency. Traditionally, surgery was used only as a last resort after patients failed prolonged medical or endoscopic therapy. However, based on the experience garnered from the literature some authors have recommend a more aggressive surgical approach in patients who fail a short trial of endolumenal therapy [110].

Lymphocytic gastritis

Lymphocytic gastritis is a term that simply describes a pattern of inflammation rather than a specific etiology. It is yet another example of the limited repertoire of responses that the GI tract can mount to various types of injury. Lymphocytic gastritis is an uncommon form of chronic gastritis characterized by lymphocytosis of foveolar and surface epithelium. Lymphocytic gastritis is associated with celiac disease, *H. pylori* gastritis, and a varioliform gastritis pattern (an endoscopic form of gastropathy comprising enlarged folds, nodules and erosions, also called "octopus sucker" appearance [111]). Wu and Hamilton [112] studied 103 patients with lymphocytic gastritis classified according to the associated entities, including the distribution and severity of the gastritis in the 70 patients from whom biopsy specimens of both antrum and body were available. In 84 patients (82%), a distinct associated entity was identified, including 39 with celiac disease, 30 with *H. pylori* infection, four with varioliform gastritis, two each with inflammatory polyp, Crohn's disease, human immunodeficiency virus (HIV) infection, lymphoma, and esophageal carcinoma, and one with lymphocytic gastroenterocolitis. Lymphocytic gastritis was found in 33% of patients with celiac disease and 4.1% of histopathologically defined *H. pylori* gastritis. Lymphocytic colitis was common (5 of 13, 38%) in patients with celiac disease and lymphocytic gastritis. The authors concluded that lymphocytic gastritis most commonly occurs in celiac disease and *H. pylori* infection, but rarely with other entities. There is no need to count lymphocytes to arrive at a diagnosis of lymphocytic gastritis; they should simply be prominent and the diagnosis is made by pattern.

Collagenous gastritis

This describes a rare pattern of injury in which prominent subepithelial collagen, intraepithelial lymphocytosis, and surface damage is present in the stomach. It has been associated with lymphocytic and collagenous colitis and with celiac disease. There is a female predominance and the changes may be found throughout the stomach [113–121].

Gastric Crohn's disease

In the absence of granulomas, it is difficult to know in gastric biopsies whether inflammatory changes reflect unspecified gastritis or are a manifestation of the patient's systemic disease. However, some observers have used the term *focally enhanced gastritis* to refer to a pattern of gastritis seen in Crohn's disease [122]. This refers to a pattern in which most of the biopsy has little or no gastritis and only a single area displays a more striking inflammatory infiltrate. We have also found that identification of this pattern of focally enhanced gastritis is helpful in identifying upper tract Crohn's disease but it is not wholly specific, especially in children [123].

Granulomatous gastritis

Granulomatous gastritis is explained by Crohn's disease in about half of cases seen in Western populations and has been attributed to *Helicobacter* in populations with prevalent infection [124] but its etiology often remains unexplained and it seems to be of little clinical significance. In daily practice, when confronted with isolated granulomas in a gastric biopsy, we make an attempt to correlate with history or Crohn's disease or sarcoidosis and exclude infectious etiologies, including *Helicobacter* gastritis. Rare cases of granulomatous gastritis have been associated with adenocarcinoma, so this is always sought [125]. If a necrotizing appearance is present rather than isolated small granulomas, vasculitis is considered but we are reluctant to diagnose vasculitis definitively on any mucosal biopsy.

Other inflammatory conditions

A discussion of every cause of gastric inflammation is beyond the scope of this chapter, but some such conditions merit brief mention. Like the esophagus, the stomach can also be the center of GI tract allergic disease (eosinophilic gastritis) and prominent eosinophilia involving epithelium and muscularis is sought (since scattered eosinophils are a normal lamina propria constituent). Again, we do not count eosinophils but simply note whether they are prominent and suggest correlation with other stigmata of allergic disease.

CMV gastritis is not uncommon in inpatient material, where it can be found in both epithelial and endothelial cells. A pitfall in diagnosis can be the monocytic reaction it can invoke, which can be mistaken for lymphoma. This is also a potential pitfall with rare examples of Epstein–Barr virus (EBV) gastritis, which appears similar to large cell lymphoma in the manner that infectious mononucleosis simulates leukemia.

Gastric graft-versus-host disease

Gastric GVHD shows the same features as GVHD elsewhere in the GI tract, with epithelial apoptosis and ulcers/erosions to a varying degree [29]. We make an attempt to grade these changes as mild, moderate, and severe (where severe changes include ulcers/erosions) and to compare current biopsies with prior ones when possible to assess improvements (or lack thereof). Such biopsies are carefully studied for CMV inclusions as well.

Hyperplastic gastritis

A simplistic approach to hyperplastic gastritis (or *giant folds*) is to consider whether the cell type resulting in the thickened folds is foveolar hyperplasia or hyperplasia of oxyntic glands.

Foveolar hyperplasia

The syndrome of hypertrophic gastric folds, oxyntic gland loss (and thus achlorhydria), and protein loss is also termed Ménétrier disease [126–131]. However, this term often describes a phenotype rather than an etiology when used to encompass the host of lesions that can display hyperplastic mucosa [126–144]. When used this way, it is another example of the limited repertoire of mucosal response to a variety of insults and in fact the original cases reported by Ménétrier were probably not a single entity. However, some observers suggest isolating those cases that display massive diffuse foveolar hyperplasia in the absence of inflammation as the "true" disease (massive foveolar hyperplasia) [127]. The mucin in this condition has a profile that differs from the mucin extracted from normal stomachs, but this pattern does not explain the etiology [141].

Ménétrier disease is a rare disorder that has been described in adults as well as children (average fourth to sixth decades). It is three times more common in men than women. The course is usually chronic with an unfavorable prognosis. Patients present with hypoproteinemia and peripheral edema with loss of immunoglobulins, albumin, and transferrin. Symptoms appear insidiously and become progressive, consisting of epigastric pain, dyspepsia, anorexia, peripheral edema, hematemesis, and vomiting. The risk of developing carcinoma with Ménétrier disease is subject to debate. Approximately 15% of Ménétrier disease cases in the literature have been associated with carcinoma. In contrast to adults, children have a self-limited course for hyperplastic gastropathy, and CMV infection has been frequently implicated. Overexpression of transforming growth factor (TGF)-α has a possible role in the pathogenesis of Ménétrier disease. Transgenic mice that overproduce TGF-α in the stomach have many features of Ménétrier disease such as foveolar hyperplasia, increased mucin content, decreased parietal cell mass, and reduced acid production.

On mucosal biopsy, this condition appears no different from a gastric hyperplastic polyp, consisting of hyperplastic foveolar epithelium arranged in a disorderly fashion with loss of oxyntic mucosa in biopsies from the body or fundus (Fig. 137.30). Making a diagnosis of this sort of hyperplastic gastropathy on mucosal biopsies is impossible without correlation with the endoscopic and imaging findings.

Hyperplasia of oxyntic glands

Giant folds may be imparted by marked hyperplasia of the oxyntic component of the mucosa as well as by the surface component (Fig. 137.31). This happens in the setting of hypergastrinemia. Of course hypergastrinemia can result from an interrupted feedback loop when there is loss of oxyntic mucosa in autoimmune gastritis, but of course there cannot be hyperplasia of oxyntic mucosa if it has been destroyed by an autoimmune process. However, if there is intact gastric oxyntic mucosa, hypergastrinemia can be the result of a gastrin-producing neoplasm (gastrinoma) and the resultant hypertrophic gastropathy is referred to as a component of Zollinger–Ellison syndrome. Since the gastrin in Zollinger–Ellison syndrome also stimulates endocrine cells, endocrine cell hyperplasia is also a component of this

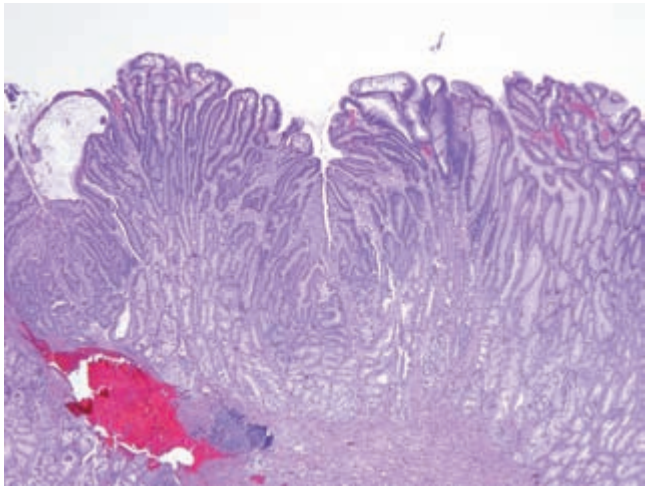

Figure 137.30 Hypertrophic gastropathy/Ménétrier disease. There is striking hyperplasia of foveolar (mucin-producing) cells.

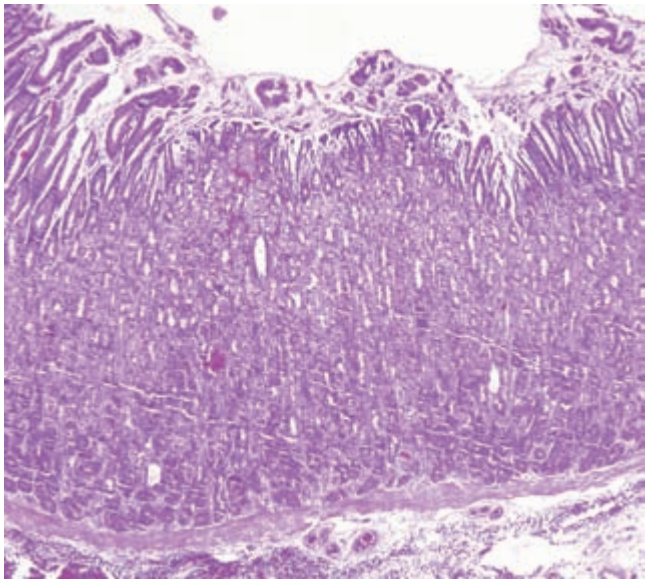

Figure 137.31 Gastric mucosa in Zollinger–Ellison syndrome. There is striking hyperplasia of parietal cells. Contrast this with the image in Fig. 137.30.

condition. On mucosal biopsy, the oxyntic component is markedly expanded and thick but the key feature is that parietal cells are seen insinuated in the epithelium nearly or even at the surface between residual foveolar cells instead of nested down deeper in the mucosa.

Nonneoplastic polyps

Endoscopically and pathologically, gastric polyps are defined simply as projections above the adjacent mucosal surface. The polyp itself may be reactive/inflammatory, hamartomatous, or neoplastic. Gastric polyps can arise from or be present in tissue anywhere in the layers of the stomach wall;

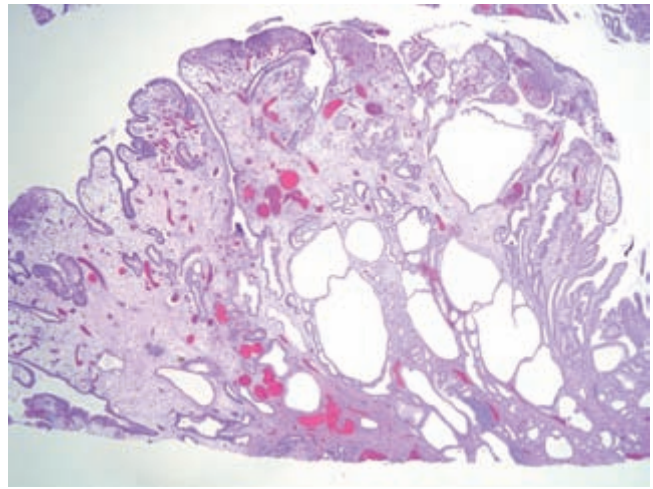

Figure 137.32 Gastric hyperplastic polyp. There is prominence of mucin-producing epithelium and cystically dilated glands. This lesion has overlap with hypertrophic gastropathy and diagnosis of either condition requires correlation with the endoscopic appearance.

however, polyps that are endoscopically biopsied are most commonly one of a wide variety of epithelial lesions.

The classification of gastric epithelial polyps can be challenging histologically, but has important consequences for clinical management of the polyp itself as well as implications about the remainder of the patient's gastric mucosa. Unlike colonic polyps (most of which are isolated findings in an otherwise normal background mucosa) many gastric polyps arise in association with either inflammatory/atrophic gastritides or inherited polyposis syndromes. Therefore, correct classification of gastric polyps, even innocuous-appearing polyps, may sometimes provide important clues about abnormalities in the surrounding stomach and patient.

Hyperplastic polyps

Hyperplastic polyps are one of the most common gastric epithelial polyps [145]. These polyps can range from a few millimeters to many centimeters in size, and as such may be mistaken endoscopically for carcinoma. They are composed of characteristic hyperplastic, elongated, and dilated foveolae within an edematous inflamed stroma (Figs 137.32 and 137.33). The lining of the hyperplastic foveolae is generally that of mature gastric mucin cells, but foci of intestinal metaplasia are found in about 15%. The lining cells can be markedly reactive in appearance (especially when surface erosions are present), but true dysplasia arising in hyperplastic polyps is uncommon [146,147]; in a review of 160 patients with gastric hyperplastic polyps biopsied at our hospital, dysplasia was found in only 4% [1]. Similarly, adenocarcinomas are occasionally reported to occur in these polyps but this is an unusual; Abraham and colleagues found adenocarcinoma within a hyperplastic polyp in only 1 of 160 (0.6%) patients [1].

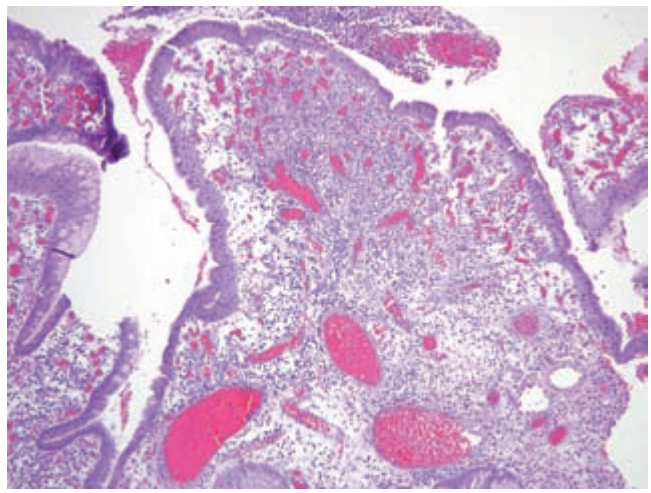

Figure 137.33 Gastric hyperplastic polyp. It is not uncommon for large hyperplastic polyps to display surface erosions/ulcers and reparative epithelial changes.

Hyperplastic polyps may arise anywhere in the stomach, with a slight preference for the antrum, and are multiple in approximately 20%. One of the major reasons for diagnosing hyperplastic polyps histologically is their significant association with a wide range of background gastric mucosal abnormalities. It is unusual for hyperplastic polyps to arise in normal stomachs. They are most strongly associated with atrophic gastritis of either autoimmune or environmental (e.g., *H. pylori*-associated) types, but many types of acute and chronic gastritides have been reported with hyperplastic polyps including the postantrectomy state, chemical/reactive gastropathy, and following therapy for gastric antral vascular ectasia (watermelon stomach). The frequent association between hyperplastic polyps and autoimmune gastritis has been extensively documented. Hyperplastic polyps are essentially a response to injuries. As a result, patients with hyperplastic polyps are at increased risk (approximately 6%) for synchronous or metachronous adenocarcinomas arising in the stomach outside of the polyp.

When we diagnose a hyperplastic polyp in a patient who has not had corresponding biopsies of the surrounding flat mucosa, we add a note in the report underscoring the relationship between hyperplastic polyps and background gastric atrophy or inflammatory gastritis, and indicate that biopsies of the flat antrum and body may be worthwhile.

The pathogenesis of hyperplastic polyps is not known, but they are thought to represent an exaggerated regenerative response to mucosal injury. The histological appearance of hyperplastic polyps overlaps significantly with conditions of generalized gastric mucosal hyperplasia (Ménétrier disease, Cronkhite–Canada syndrome) and with hamartomatous polyps and syndromes involving the stomach. As such, diagnosis requires correlation with the endoscopic findings and clinical history.

Hamartomatous polyps

Hamartomas are polypoid lesions formed from disorganized tissue elements native to that site. Hamartomatous syndromes that may involve the stomach include Peutz–Jeghers syndrome and juvenile polyposis, and less commonly Cowden disease. Peutz–Jeghers syndrome is an autosomal dominant condition caused by germline mutations in the *LBK1/STK11* gene on chromosome 19p13.3 and is characterized by polyposis and distinctive melanin pigmentation around the lips, buccal mucosa, and sometimes hands and eyelids. The pigment may fade after puberty and thus the syndrome is not excluded if it is absent in an adult presentation. The polyps of Peutz–Jeghers syndrome primarily occur in the small bowel (65%) and are slightly less common in the colon and stomach [148–152]. Importantly, unlike the small bowel polyps, which show prominent arborization of the muscularis mucosae, gastric Peutz–Jeghers polyps are composed mostly of dilated or branching mucus-filled pits and may have relatively inconspicuous smooth muscle. Occasional examples of gastric Peutz–Jeghers polyps have the classic arborizing architecture with strands of smooth muscle, but most have less specific features (but some degree of smooth muscle proliferation). Essentially they are best distinguished from hyperplastic polyps by correlation with the history. Dysplasia is rare in these polyps; however, patients with Peutz–Jeghers syndrome are at significant risk for gastric and other adenocarcinomas developing outside of the hamartomas [148].

Juvenile polyposis is a genetically heterogeneous condition in which some families have autosomal dominant germline mutations in the *DPC4* gene on chromosome 18q21. The polyps in juvenile polyposis can be limited to the colon or can be generalized, involving the colon, small bowel, and stomach. In addition, patients who appear to have juvenile polyposis predominantly confined to the stomach have been described. Juvenile polyps in the stomach frequently show a rounded surface contour with superficial mucosal erosions and an abundant, edematous, and inflamed lamina propria. The foveolae are frequently hyperplastic and dilated. Superimposed epithelial dysplasia or even mixed adenomatous/juvenile polyps occurs in up to one-third of juvenile polyps. Cowden disease is an autosomal dominant condition that is relatively poorly characterized, but some families have germline mutations in the *PTEN* gene on chromosome 10q22–23. The GI polyps in Cowden disease are usually a minor component of the syndrome (affected individuals typically show more prominent facial trichilemmomas and oral papillomas, as well as being at increased risk for breast and thyroid carcinomas). Detailed reports of the gastric polyps in Cowden disease have not been made, but they are reported to be histologically indistinguishable from small hyperplastic polyps [153]. Dysplasia is not reported in these polyps [151].

There are some clinical and pathological clues that help to distinguish between gastric hyperplastic polyps and hamartomatous polyps.

• The patient may have a previously characterized polyposis syndrome.
• Biopsies of the nonpolypoid gastric mucosa may show an atrophic or inflammatory gastropathy of the type associated with the development of hyperplastic polyps.
• Hyperplastic polyps frequently show a more lobulated or villiform surface compared with the often rounded surface of juvenile polyps.
• Hyperplastic polyps often contain a more prominent edematous inflamed lamina propria compared with Peutz–Jeghers polyps, which can sometimes but not always show smooth muscle arborization.

However, we do not believe that it is possible to distinguish between a hyperplastic or hamartomatous polyp based solely on the histological features of a polyp that is resected or biopsied. In the absence of clinical information and knowledge of the histology of the background gastric mucosa, we state in the diagnostic report that the polyp is histologically consistent with a hyperplastic polyp and give the differential diagnosis listed above.

Fundic gland polyps

Fundic gland polyps (FGPs) occur in two forms: sporadic and familial adenomatous polyposis (FAP) associated. FGPs were originally described in patients with FAP, believed to be a manifestation of that syndrome, but they are now recognized to be one of the most common gastric polyps (along with hyperplastic polyps) in individuals without FAP. Sporadic FGPs are found in 1%–2% of routine upper endoscopic examinations and are most common in middle-aged females. They are typically small (a few millimeters and only rarely more than 1 cm), sessile, and dome-shaped. Sporadic FGPs may be single but are commonly multiple (usually a few polyps). Rarely patients without FAP have numerous FGPs proliferating in a manner that resembles a polyposis syndrome. Unlike hyperplastic polyps, FGPs are not particularly associated with any type of inflammatory or atrophic background mucosal pathology and are essentially an incidental finding. However, some studies do indicate a temporal association between use of proton pump inhibitors and the development of FGPs [154]. This potential link is controversial and has not been demonstrated in any controlled prospective trial [155].

The morphology of FGPs overlaps considerably with that of proton pump inhibitor effects. An endoscopic nodule correlates with dilated oxyntic glands, some of which contain cells with apocrine-like snouts (Fig. 137.34). It is sometimes difficult to distinguish these two processes and the reality is that it is essentially done by correlation with the presence of an endoscopic lesion.

FGPs associated with FAP syndrome differ from sporadic FGPs on several epidemiological and clinicopathological points: FAP-associated FGPs occur in a majority of patients with FAP (reported frequencies range from 12.5% to 84% of FAP patients, depending on the age at endoscopy) and show a more equal gender distribution. They are more numerous than sporadic FGPs, and hence patients with FAP are more likely to have fundic gland "polyposis." They occur at younger ages, including children (FGPs are vanishingly rare in the non-FAP pediatric population). In addition, approximately 25% of FAP-associated FGPs demonstrate low-grade epithelial dysplasia [156]. Dysplasia in sporadic FGPs can occur but is distinctly unusual. A retrospective histological evaluation of several hundred sporadic FGPs at our hospital revealed fewer than 1% with low-grade dysplasia, and one of these cases was subsequently determined to be a member of an attenuated FAP family [156].

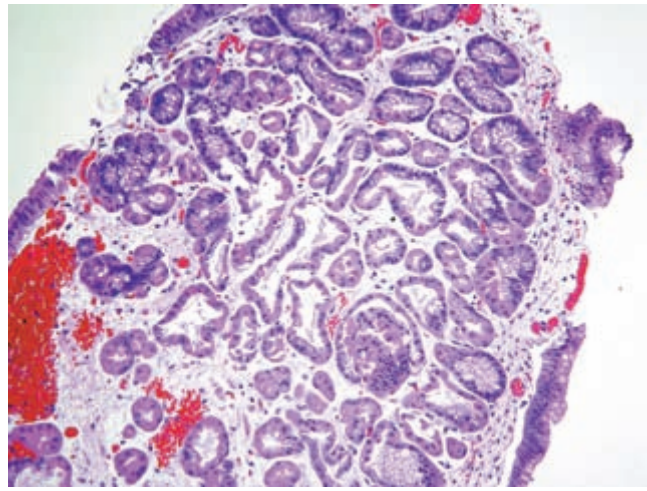

Figure 137.34 Fundic gland polyp. The cystically dilated oxyntic (fundic) glands are the key feature.

The natural history of FGPs is interesting because both sporadic and FAP-associated FGPs can increase, decrease, or remain constant in number when patients are followed with serial upper endoscopic examinations. Sporadic FGPs, even fundic gland polyposis, have never been reported to progress to gastric adenocarcinoma. Several cases of adenocarcinoma associated with fundic gland polyposis in patients with FAP exist, but this is a reportable occurrence [157,158]. Currently, upper endoscopic surveillance in patients with FAP is performed to address the increased risk for duodenal (> 300-fold) and particularly periampullary adenomas and adenocarcinomas [159] rather than to address gastric pathology. The presence of dysplastic or nondysplastic FGPs is regarded an incidental finding and would almost never require surgical resection. Even surveillance of dysplastic FGPs is controversial and we regard them as low-risk lesions.

As their name implies, FGPs develop only in the gastric body and fundus and not in the antrum. In patients with FAP, FGPs are more common than gastric adenomas, despite the fact that the colorectal and duodenal polyps in these patients are adenomas. When gastric adenomas do develop in the FAP setting, they are most frequently antral. Despite

the increased frequency of dysplastic FGPs and gastric adenomas in FAP, the risk of gastric adenocarcinoma is only slightly increased (approximately twofold in one study) and not statistically significantly increased in Western FAP patients [159]. This contrasts with studies of Asian patients with FAP, among whom the risk of gastric adenocarcinoma is increased approximately 10-fold. This low risk in Western FAP patients also contrasts with the much higher risk of gastric adenocarcinoma in non-FAP patients who have adenomas. This is most likely a reflection of the fact that germline mutations in the *APC* gene on chromosome 5q21 leading to FAP do not predispose patients to background gastritis or gastric atrophy. Most Western patients with FAP have normal gastric mucosa outside of any antral adenomas or body FGPs. In contrast, most patients with sporadic gastric adenomas have chronic atrophic gastritis (particularly *H. pylori*-mediated) that predisposes to gastric adenocarcinoma in the intestinalized background gastric mucosa outside of the adenomas.

Inflammatory fibroid polyps

These lesions were described first by Vaněk in the American Journal of Pathology in 1949 [160] although there were prior case reports. Helwig and Ranier coined the present term in the early 1950s [161] but these lesions have been called gastric submucosal granuloma with eosinophilic infiltration, eosinophilic granuloma, granuloblastoma, neurofibroma, and hemangiopericytoma. The vast majority arise in the stomach, accounting for about 3%–4% of all gastric polyps, but they have been reported throughout the GI tract [145,161–181]. In Stolte's large series, patients with gastric examples were typically 60–80 years old, but examples are recorded in young adults and the elderly. Most are found in the antrum, but other gastric sites are known. Their endoscopic appearance is that of a smooth submucosal lesion that can be pedunculated or sessile with surface ulceration/erosion in about one-third of cases. Presentation is site specific, in that small intestinal examples can lead to intussusception or obstruction and gastric examples are found in patients with pain and nausea and vomiting. Inflammatory fibroid polyps are probably reactive in nature, but an interesting family with these lesions in females for three generations has been reported (Devon polyposis) [164,165]. They lack alterations of a host of oncogenes [182]. These benign lesions seldom recur after excision. Japanese examples have been found in association with gastric dysplasia/carcinoma (presumably coincidence) [170] but not Western ones.

Histologically, these tumors are well marginated but nonencapsulated and affect the mucosa and submucosa. They are composed of uniform spindled cells, mixed inflammatory cells, and prominent vasculature. The spindle cells have amphophilic elongate cytoplasm and pale ovoid to spindle-shaped nuclei with variable collagen deposition. Most examples display a whorled "onion-skin" proliferation around vessels and all examples are punctuated by abundant background eosinophils, lymphocytes, and plasma cells (Figs 137.35 and 137.36). Mitoses are infrequent.

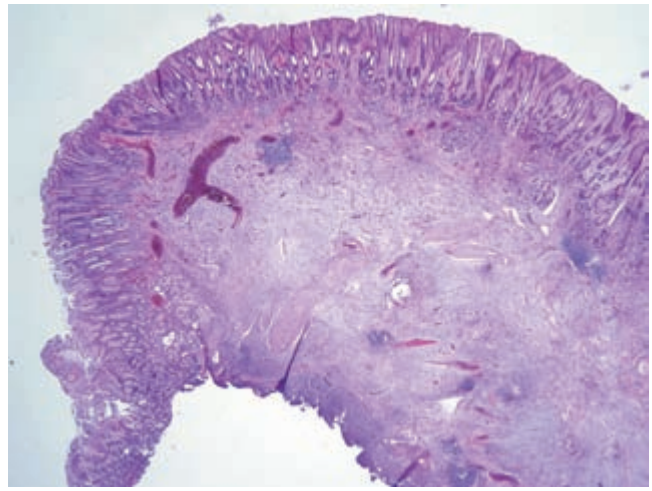

Figure 137.35 Inflammatory fibroid polyp. These tumors have their epicenters in the superficial submucosa.

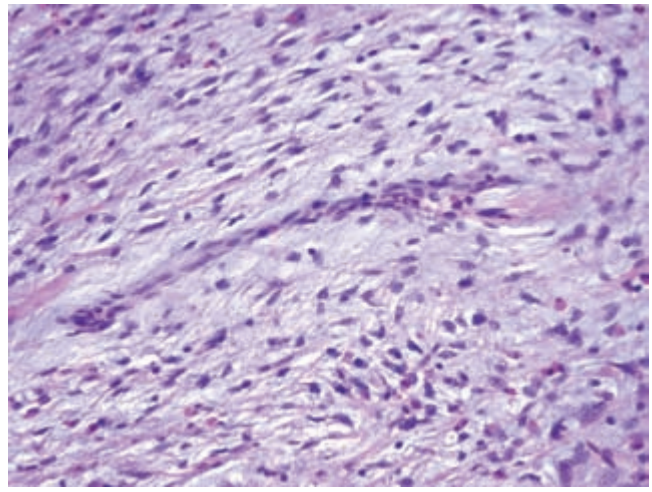

Figure 137.36 Inflammatory fibroid polyp. At higher magnification, there is a spindle cell lesion punctuated by many eosinophils.

The immunohistochemical and ultrastructural profile of the proliferating cells is that of modified fibroblasts/myofibroblasts, with variable actin but no S100 protein or epithelial markers [175,178]. Some authors believe that their consistent expression of cyclin D1 and fascin suggests that they are of dendritic cell origin [175] but their key feature is consistent CD34 reactivity in small tumors and less consistent staining in larger lesions [170]. This latter finding naturally raises the differential diagnostic consideration of GISTs, but the morphology is different and inflammatory fibroid polyps lack CD117/c-kit [175].

Pancreatic acinar cell metaplasia/heterotopia

In the esophagus this finding is generally incidental, and is in the stomach as well, but we have occasionally seen it

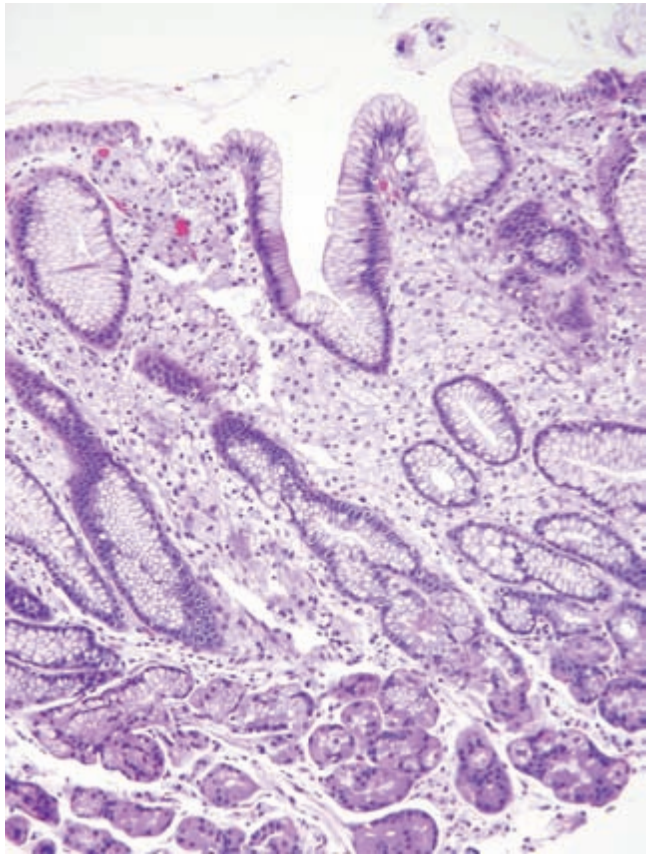

Figure 137.37 Gastric xanthoma. Numerous lipid-laden macrophages are seen in the lamina propria.

mistaken for carcinoid tumor and the pathologist is confused by the lack of expression of neuroendocrine markers. Occasionally, heterotopic pancreatic tissue can produce a symptomatic mass in the gastric antrum that results in gastric outlet obstruction [183–185]. Other than such occurrences, it is of little clinical significance. The heterotopic tissue may contain an admixture of pancreatic acinar tissue, ducts, and islet cells in varying proportion. Since the lesion is often submucosal, superficial biopsies containing only the overlying mucosa may be nondiagnostic.

Gastric xanthomas

Gastric xanthomas are pale yellow nodules or plaques, usually less than 3 mm in size, in the gastric mucosa. They are frequently found in groups, most often along the lesser curvature and pyloric regions. They consist of lipid-laden histiocytes in the lamina propria occasionally extending into the submucosa (Fig. 137.37). There is no correlation between gastric xanthomas and hypercholesterolemia. The lesion is of little significance, except that it may be misdiagnosed as carcinoma [186]. However, in any suspicious case, performing a keratin and CD68 stain can be reassuring. Some authors have associated gastric xanthomas with atrophic gastritis and *Helicobacter* gastritis [187].

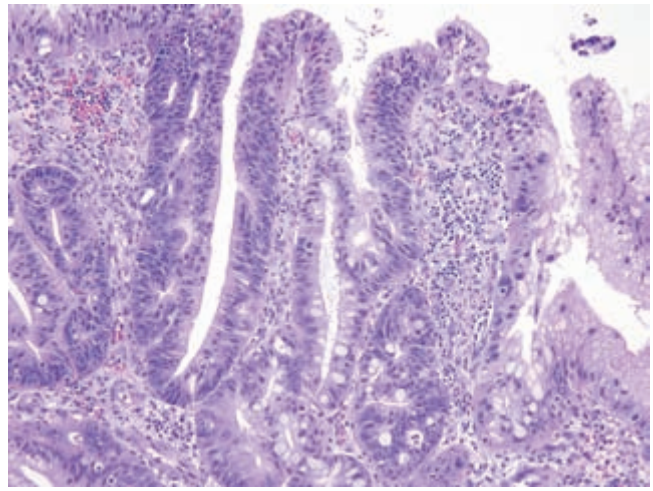

Figure 137.38 Gastric adenoma, intestinal type. This example shows both intestinal metaplasia and high-grade dysplasia.

Neoplasms

Gastric adenomas and gastric dysplasia

Literature in this area has been difficult to interpret in the past. There is massive experience with gastric cancer and its precursors in Japan but Japanese pathologists have applied different diagnostic criteria from Western pathologists. This was pointed out by Lauwers and colleagues in 1999 [188]. The observation that Japanese pathologists did not require invasion to diagnose carcinoma (and "invasion" was not listed as a criterion in the 1990 WHO classification) has presumably informed the far better cure rates in Japan for early carcinomas compared with results in Western countries. Based on these observations, an international panel convened in Vienna in 2000 and published consensus definitions of gastric epithelial neoplasia [189], which distinguished between noninvasive and invasive lesions.

Essentially, at present, if such a lesion appears as a polyp, it is referred to as an adenoma (Fig. 137.38) whereas flat lesions are termed dysplasia and are graded using criteria similar to those for the esophagus. This is not particularly scientific but is a convention based on practicality. Both types of lesions confer risk and both require mapping of the entire stomach to exclude invasive carcinoma. As in the case of gastric hyperplastic polyps, the background pathology is important. To illustrate this, Abraham and colleagues studied 61 gastric adenomas from 51 patients between 1985 and 2001 [2]. The adenomas were classified as intestinal type (containing at least focal goblet cells or Paneth cells) (Fig. 137.38), gastric type (Fig. 137.39), or indeterminate. The histological features of both the adenomas (location, multiplicity, degree of dysplasia, presence of adenocarcinoma within the polyp) and the surrounding gastric mucosa (presence of gastritis, intestinal metaplasia, and adenocarcinoma) were evaluated. Gastric adenomas were distributed equally throughout the stomach, were most frequently solitary (82%), and con-

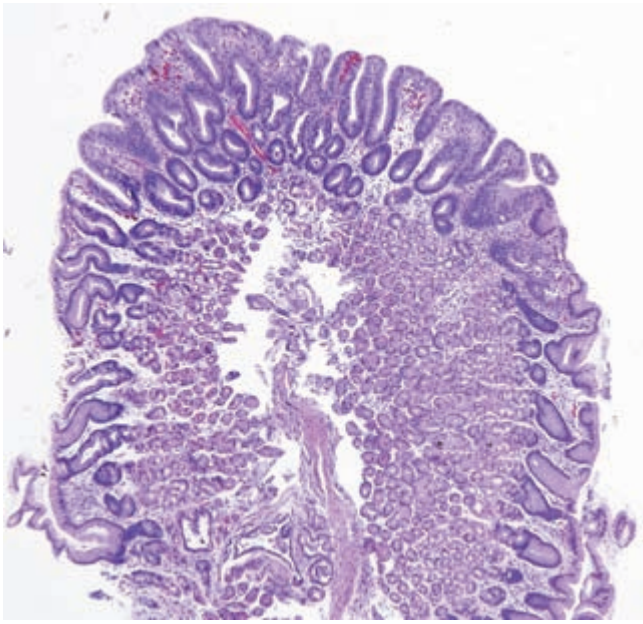

Figure 137.39 Gastric adenoma, gastric type. Such a lesion, arising in normal background mucosa, is a low-risk lesion unlikely to be associated with either high-grade dysplasia or invasive carcinoma.

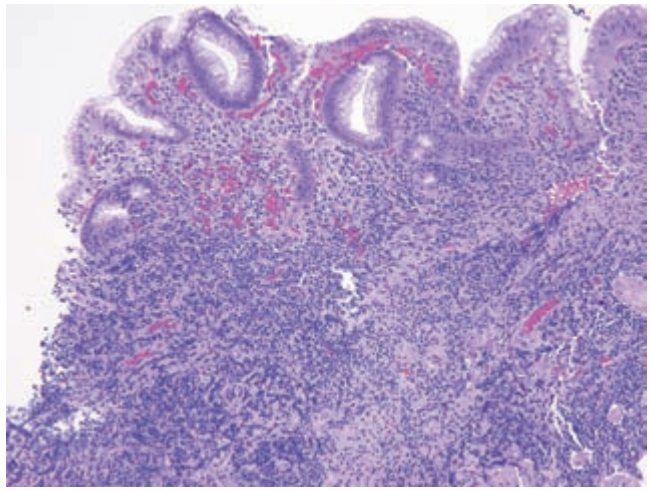

Figure 137.40 Mucosa-associated lymphoid tissue (MALT) lymphoma, also called extranodal marginal zone B cell lymphoma. Note the bottom-heavy distribution of the lymphoid infiltrate.

tained adenocarcinoma in nine cases (14.8%). There were 34 intestinal-type adenomas (56%) in 31 patients, 25 gastric-type adenomas (41%) in 18 patients (including 10 patients with FAP), and two of indeterminate type (3%). Intestinal-type adenomas were significantly more likely than gastric-type adenomas to show high-grade dysplasia ($P < 0.0001$), adenocarcinoma within the polyp ($P = 0.016$), intestinal metaplasia in the surrounding stomach ($P < 0.000001$), and gastritis ($P = 0.002$). Patients with intestinal-type adenomas were also more likely to have separate adenocarcinomas (five cases vs zero cases), although this did not reach statistical significance. Gastric adenomas are rarely truly sporadic lesions. In any individual patient, complete removal of the adenoma should be performed, and thorough biopsy of the surrounding gastric mucosa is essential to understand the clinicopathological context of the adenoma and exclude associated carcinoma. Similarly, when gastric flat dysplasia in the absence of a mass is found, the stomach should be mapped with multiple biopsies. Most cases are easily diagnosed, but some patients harbor unusual deceptively bland lesions.

MALT lymphoma

Low-grade B-cell lymphomas of MALT are believed to arise in organized lymphoid tissue in the gastric mucosa that is usually acquired in response to *H. pylori* infection. They are also termed extranodal marginal zone lymphomas. The close association between *H. pylori* and the lymphoma is further reflected by the demonstration that proliferation of the lymphoma cells can be driven by the presence of *H. pylori* organisms through a complex path of cellular interactions involving specific T cells [190–195]. From these observations it was suggested that removal of one of the proliferative drives to the neoplastic cells in the form of eradication of the organism might induce remission of the tumor [194]. Long-term remissions can indeed be induced in low-grade MALT lymphomas in 70%–80% of cases. The lymphomas that are most likely to respond to *H. pylori* eradication are those located superficially within the gastric mucosa. It has been suggested that certain genetic abnormalities, such as t(11;18) and the *Bcl-10* mutation, may be associated with lack of response to this therapy. Recurrences of low-grade lymphoma are encountered in patients treated by *H. pylori* eradication, but these appear to be infrequent and may be self-limiting and spontaneously regress without further therapy.

In assessing such a case at low magnification, the lamina propria is expanded with small uniform cells, some of which have a halo around them. We always assess the muscularis mucosae at low magnification (with confirmation at high magnification) as physiological lymphoid collections typically do not infiltrate the muscularis mucosae whereas MALT lymphomas do (Fig. 137.40). The classic lymphoepithelial lesion, in which lymphocytes are seen peppered in residual gland epithelium (Fig. 137.41), is not present in every case. At high magnification, before wasting resources on immunohistochemical stains, the cell composition is assessed: numerous plasma cells are more often an indicator of a reactive lesion (*Helicobacter* gastritis). We perform an abbreviated immunophenotyping panel consisting of CD20 (B-cell marker), CD3 (T-cell marker), and CD43 (normally found in T cells) and assess for CD20-reactive B cells that aberrantly express CD43. The CD3 stain is necessary since it is normal for T cells to express CD43 and the various stains must be compared. Unfortunately not every MALT lymphoma coexpresses CD43 (about half do) but the diagnosis can still be made on a

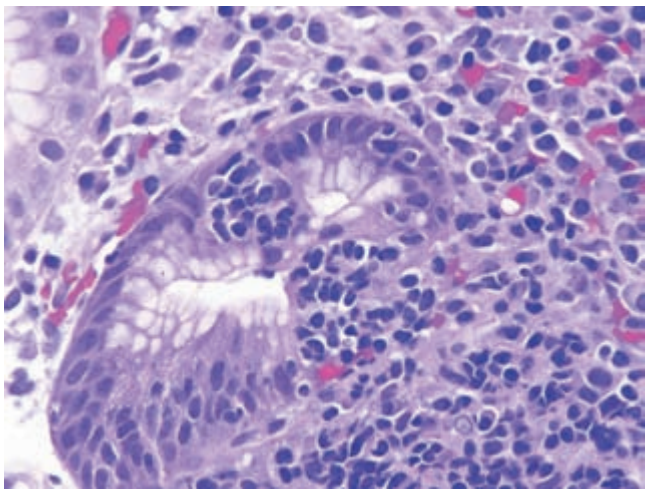

Figure 137.41 Mucosa-associated lymphoid tissue lymphoma. This field shows a lymphoepithelial lesion in which lymphoid cells proliferate in the epithelium itself.

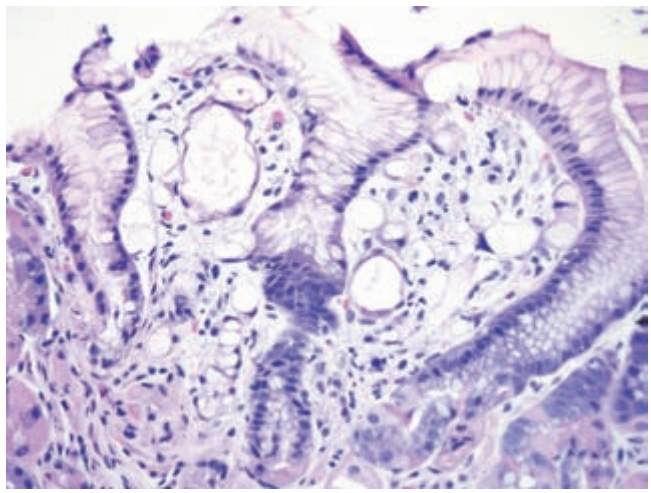

Figure 137.42 Gastric adenocarcinoma. This subtle early lesion is seen only in the lamina propria of the stomach (intramucosal carcinoma).

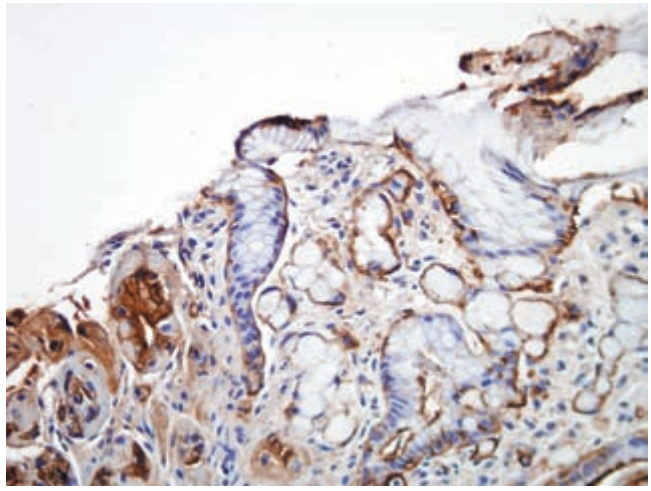

Figure 137.43 Gastric adenocarcinoma. A keratin stain highlights the cancer cells from the field seen in Fig. 137.42.

B-cell-rich infiltrate with typical morphology. The pathologist should always make an attempt to document the presence (or absence) of *Helicobacter*. It is most important for both the endoscopist and pathologist to remember that these lesions regress slowly over time on initiation of therapy and can linger for up to 18 months.

Adenocarcinoma

Gastric adenocarcinoma is the second leading cause of cancer death worldwide [196]. There are an estimated 21 500 new cases of gastric cancer annually in the USA, and about 10 880 of these patients will die of their disease [197]. Over the past several decades, the epidemiological and topographical profile of gastric cancer has changed dramatically. The incidence of gastric adenocarcinoma outside the gastric cardia is decreasing, but the incidence of gastric cardia adenocarcinoma is increasing [198].

Survival after resection of gastric adenocarcinoma has been studied in multiple series with patients stratified by stage of disease, Lauren tumor type (diffuse vs intestinal) [199,200], tumor location, time period, and administration of adjuvant therapy. All studies uniformly show an association between stage and survival. The Lauren classification correlates significantly with survival, in that intestinal-type tumors are associated with longer survival than diffuse-type tumors [201]. The Lauren classification, viewed simply, separates gastric cancers into those that have intestinal differentiation, form a large mass, and arise on a backdrop of intestinal metaplasia (intestinal type) and those that apparently arise de novo in otherwise unremarkable mucosa and diffusely infiltrate the tissues (diffuse type, subsuming signet ring carcinomas/linitis plastica). It is the diffuse type that causes problems on biopsies. According to some data analyses, tumor location is significantly associated with survival, tumors away from the gastric cardia having an improved prognosis over gastric cardia adenocarcinomas [198]. In many studies, both operative mortality and 5-year survival have improved over the past several decades [202]. Improved survival with adjuvant chemoradiotherapy has also been reported [203]. However, in our material, gastric carcinoma remains highly lethal and important to recognize in biopsy material [204].

Gastric carcinoma is often easy to recognize on biopsies but can also be extremely subtle (Figs 137.42 and 137.43). When there is a high index of suspicion, we examine each fragment carefully, concentrating on any focus that appears distinct or fibrotic at low magnification. Biopsies from patients who have undergone partial gastrectomy should be reviewed attentively as these are high-risk patients based on their continuous bile reflux. In doubtful cases, a keratin stain is helpful but should not be ordered in ulcerated cases as regenerative mucosa can give a false impression of a single cell

pattern. Carcinomas of the intestinal type can be extremely subtle on superficial biopsies but there is the correlate of a mass. Diffuse carcinomas are very difficult to spot on biopsies but there is the correlate of a stomach that does not distend on insufflation. It always behooves the endoscopist to provide information concerning these features. Some carcinomas are so poorly differentiated that they require keratin stains for diagnosis. Occasional gastric carcinomas have a clear cell pattern. Rare gastric carcinomas have squamous differentiation and still rarer ones have hepatoid differentiation. Some observers have suggested that carcinomas having parietal cell differentiation have an improved prognosis over other gastric carcinomas but this seems doubtful based on our material. We do not make an exercise of typing gastric carcinomas in our practice.

Mesenchymal tumors

Gastric stromal tumors

The stomach is the most common site for GISTs and they are occasionally diagnosed on mucosal biopsies. Typically, those diagnosed on biopsies are aggressive lesions that have invaded the mucosa. GISTs are mesenchymal tumors arising in the GI tract and occasionally within the abdomen with no GI connection. The earlier literature attempted to classify them as smooth muscle or nerve sheath tumors, but even in the benign tumors evidence for such differentiation was difficult to find. Mazur and Clark introduced the term *stromal tumor* in 1983 [205]. GISTs show differentiation toward (and supposedly arise from a precursor of) interstitial cells of Cajal, which are normally concerned with motility of the gut [206, 207]. The availability of specific antibodies and clarification of their immunohistochemical profile has facilitated diagnosis.

About 25% of GISTs (from all sites) are malignant, representing about 1% of all GI malignancies. They are most common in adults aged 50–60 years. These tumors vary in differentiation and prognosis according to their location within the GI tract. Esophageal GISTs are rare, but 50%–70% involve the stomach, 25%–40% the small intestine (of which 10%–20% arise in duodenum, 27%–37% in jejunum, 27%–53% in ileum), and less than 10% are colorectal (50% colonic, 50% rectal). They are rare in the esophagus (where true smooth muscle tumors are more usually found), colon and rectum. GIST-type tumors arising in omentum, peritoneum and retroperitoneum have been identified, comprising 6.7% of the large AFIP series of 1008 GISTs.

Malignant GIST are rare, with an incidence of about 5 per million (compared with 25 per million for soft tissue sarcomas). There is an increased incidence of GIST including multiple tumors in small intestine in patients with neurofibromatosis (NF)1, and GIST is occasionally familial (associated with a germline c-*kit* mutation). Some patients have second cancers, and some epithelioid gastric stromal tumors are associated with paraganglioma and pulmonary chondroma in Carney's triad.

About 20% of gastric GISTs are malignant. The consensus is that five mitoses per 50 high-power fields and size greater than 5 cm are adverse prognostic factors. The 5-year survival of gastric GISTs is about 40%, with improvement in completely resected cases. There is no evidence that radical surgery improves survival, so that the least extensive surgical procedure compatible with complete excision is advisable. Gastric GISTs are more frequent in males, but young patients, especially female, have an improved outcome.

Most GISTs are spindle cell tumors with variable palisading, peculiar paranuclear vacuoles, and collagen fibrils (Fig. 137.44). On a practical note, it is epithelioid GISTs (Fig. 137.45) that are most likely to cause diagnostic problems on mucosal biopsies as they are readily mistaken for a host of epithelioid and epithelial neoplasms. It is advisable to perform an immunohistochemical panel in assessing them to

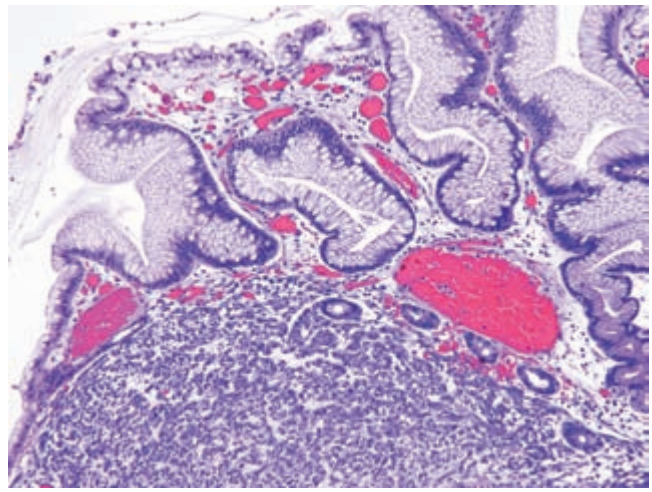

Figure 137.44 Gastrointestinal stromal tumor (GIST), spindle cell type. This lesion displays mucosal invasion, a feature of malignant GIST.

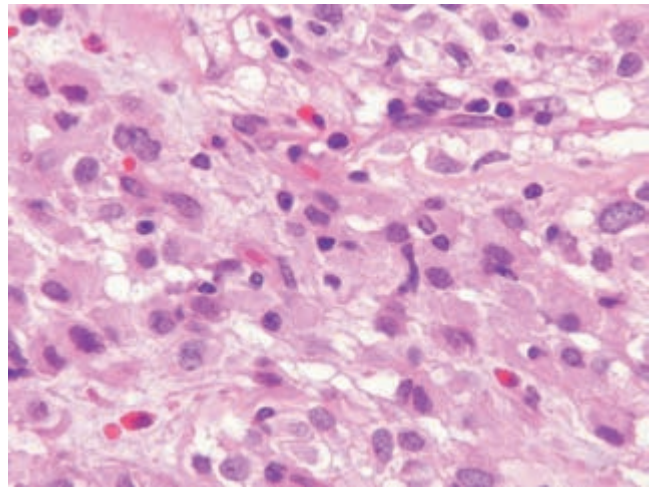

Figure 137.45 Gastrointestinal stromal tumor, epithelioid type. Note the eosinophilic appearance of the lesional cells. Such tumors were referred to as leiomyoblastoma in the past.

Table 137.1 Suggested prognostic criteria for resected gastrointestinal stromal tumors from all anatomical sites [211]

Risk assessment	Size (cm)	Mitotic counts per 50 high-power fields
Very low risk	< 2	< 5
Low risk	2–5	< 5
Intermediate risk	< 5	6–10
	5–10	< 5
High risk	> 5	> 5
	> 10	Any
	Any size	> 10

Table 137.2 Suggested prognostic criteria for resected gastrointestinal stromal tumors specific to stomach [214]

Risk assesment	Size (cm)	Mitotic counts per 50 high-power fields
Benign	No larger than 2	No more than 5
Probably benign	> 2, ≤ 5	No more than 5
	> 5, ≤ 10	No more than 5
Uncertain	No larger than 2	> 5
Low to moderate malignant	> 10	Not more than 5
potential	> 2, ≤ 5	> 5
High malignant potential	> 5, ≤ 10	> 5
	> 10	> 5

include CD117/c-kit, S100 protein (to address melanoma), and a cytokeratin stain to address signet cell carcinoma. The vast majority of GISTs have *kit* mutations and are CD117/c-kit stain positive, but about 5% lack *kit* mutations and many in the c-kit-negative subset have alternate mutations of platelet-derived growth factor α instead [208–210]. Since about 70% of GISTs express CD34, this can also be included in a diagnostic panel. On mucosal biopsies, it is difficult to assess tumor size and mitotic counts to prognosticate but it is possible to make a diagnosis in many cases and allow the patient to be scheduled for an operation to remove the tumor. Evaluation of resection specimens is not the focus of this book, but guidelines for this have been published [211] (Table 137.1). Some observers have taken issue with this as it assumes that all GISTs are potentially malignant and does not take site into account but is still a useful construct for attempting a prognosis. Trupiano and colleagues have published criteria that they believe allow separation of benign gastric stromal tumors from those they regard as not benign [212]. We have attempted to apply these to a series of gastric GISTs and had one outlier case [213] so we continue to add a note of caution to reports on large gastric stromal tumors that appear otherwise benign.

The AFIP group probably has the largest accumulated series of gastric stromal tumors, and have reported a large series of 1765 GISTs confined to the stomach with good follow-up information [214]. There was a slight male predominance (55%) and a median age of 63 years. Only 2.7% of tumors occurred before the age of 21 years and 9.1% before the age of 40 years. The tumors varied from 0.5 to 44 cm (median 6.0 cm) and most commonly presented with GI bleeding; 12% were incidentally detected. Histological variants recognized among the spindle cell tumors included sclerosing, palisaded/vacuolated, hypercellular, and sarcomatous and among the epithelioid tumors, sclerosing, dyscohesive, hypercellular, and sarcomatous. Outcome was strongly dependent on tumor size and mitotic activity. Only 2%–3% of tumors less than 10 cm in size and with less than five mitoses per 50 high-power fields metastasized, whereas 86% of tumors more than 10 cm in size and with more than five mitoses per 50 high-power fields metastasized. However, tumors more than 10 cm in size with less than five mitoses per 50 high-power fields and those less than 5 cm in size with more than five mitoses per 50 high-power fields had a relatively low metastatic rate (11% and 15%). A small number of patients survived intraabdominal metastasis for over 20 years. Tumor location in fundus or gastroesophageal junction, coagulative necrosis, ulceration, and mucosal invasion were all unfavorable factors ($P < 0.001$), whereas tumor location in antrum was favorable ($P < 0.001$). Probably the key feature of this very large series is that it allowed separation of a "benign" category of gastric GISTs based on large numbers of cases [214]. The AFIP group has proposed malignancy criteria specific to the stomach (Table 137.2). Another important feature of the AFIP study is that mucosal extension by gastric GISTs was evidence that the tumor would behave badly. This feature remained equivocal based on several earlier smaller studies (including our own [213]). However, based on these data from Miettinen and colleagues [214], if we encounter a gastric GIST on mucosal biopsy, it is likely malignant and we suggest this in our reports. Based on the large AFIP series of gastric GISTs, CD117/c-kit is found in 91% of gastric GISTs, CD34 in 82%, SMA in 18%, and desmin in 5%; the latter two tend to be focal.

Gastric neural tumors

These are not typically encountered on gastric mucosal biopsies. Most gastric nerve sheath tumors have been classified as schwannomas, although there is no reason that a patient with syndromic nerve sheath tumors (neurofibromas, neuromas, and ganglioneuromas) cannot manifest gastric lesions. Most GI schwannomas occur in the stomach involving submucosa and muscularis propria. They rarely arise in the esophagus or colon. They typically do not affect the mucosa but are surrounded by a lymphoid cuff, which is more likely to be biopsied than the underlying mesenchymal lesion.

GI tract schwannomas are not encapsulated, a feature that distinguishes them from schwannomas in the peripheral

nervous system [215]. They can also be plexiform. They have a lymphoid cuff with germinal centers, and intralesional lymphocytes can be seen. They are composed of interlacing bundles of spindle cells that are only loosely palisaded (in contrast to GISTs which, ironically, often display striking palisading). They appear quite similar to GISTs but the lymphoid cuff is a hint that these are Schwannian. These benign tumors are strongly S100 protein positive and lack muscle markers and CD117. They may have CD34 as well. The differential diagnosis is with GIST. The inflammatory backdrop is the key morphological feature that should prompt consideration of a nerve sheath tumor.

Other gastric mesenchymal tumors

Other gastric mesenchymal tumors include lipomas and glomus tumors. Glomus tumors are usually deep in the gastric muscularis propria and not encountered on mucosal biopsies. In the present era of better control of HIV disease, we seldom encounter Kaposi sarcoma in our GI material but when it is seen, there is a history of extreme immunosuppression and proliferation of CD34-reactive spindle cells. Antibodies to human herpesvirus 8 are also available to confirm this impression.

Carcinoid tumors

A tripartite classification system for gastric carcinoid tumors is now in common use:

- tumors associated with chronic atrophic gastritis with hypergastrinemia
- tumors associated with Zollinger–Ellison syndrome or multiple endocrine neoplasia (and thus with hypergastrinemia)
- sporadic lesions (without hypergastrinemia).

These subsets have been classified as types I, II, and III respectively. Gastric carcinoids associated with hypergastrinemia (types I and II) are relatively benign, while sporadic lesions require aggressive surgical management. However, gastric carcinoids can be managed initially by endoscopic excision of accessible tumors, with evaluation of the setting in which they have arisen, followed by regular endoscopic surveillance. Modlin and colleagues cite a striking increase in gastric carcinoids in the past 50 years, including an 800% increase in gastric carcinoids in white females [216,217]. Patients were not routinely endoscoped 50 years ago and tiny carcinoids are not uncommonly found in white women as a result of autoimmune gastritis if they are sought.

Essentially, in the two settings where the trophic effects of hypergastrinemia on gastric endocrine cells produce a tumor composed of these cells, the tumors are essentially a nuisance with negligible metastatic risk. Cutoffs for the minimal size that determines what is endocrine cell hyperplasia and what is neoplasia (often set at 5 mm but sometimes 0.5 mm) are of no clinical importance since these patients do not experience metastases. In our practice, we apply the term "carcinoid" when the endoscopist sees a nodule. It is more important to determine the source of the excess gastrin than to quibble about the size of the endocrine cell proliferation. This is done by attention to the background gastric changes: atrophy versus hyperplasia of the acid-producing cells. Hyperplasia of intact parietal cells is the hallmark of Zollinger–Ellison syndrome, in which there is a gastrin-secreting neoplasm, often in the pancreas. There are only a few large studies of the outcome of such tumors, but in one study it was noted that in patients having sporadic (type III) carcinoid tumors, size greater than 2 cm was a poor prognostic indicator [218].

Gastric carcinoids consist of small round proliferating cells and the diagnosis can be confirmed by performing endocrine stains (Figs 137.46–137.48). Some such tumors display cytological atypia and there are examples of gastric small-cell carcinoma, but experience with large numbers of these tumor types is lacking, as are good criteria for their separation from typical carcinoid tumors. It is worthwhile attempting to distinguish small-cell carcinomas, but those analogous to atypical carcinoids in the lung remain poorly characterized.

Metastatic neoplasms

Although theoretically any tumor might metastasize to the stomach, those seen in practice are metastatic lobular breast cancer, renal cell carcinoma, melanoma, and hepatobiliary carcinoma. These are best separated from de novo gastric primaries by history, but immunohistochemistry is important as well. Melanomas can be separated from gastric carcinomas by S100 staining. As a word of caution, melanomas can label with CD117 antibodies so a panel approach is warranted to exclude epithelioid GISTs. Breast cancers are separated by the identification of hormone receptors (estrogen/progesterone receptor) and gross cystic fluid disease protein since only rare gastric carcinomas express hormone receptors in material from the USA. Gastric cancers lack cytokeratin 34 β E12 (CK903) [219], whereas hepatobiliary cancers express it.

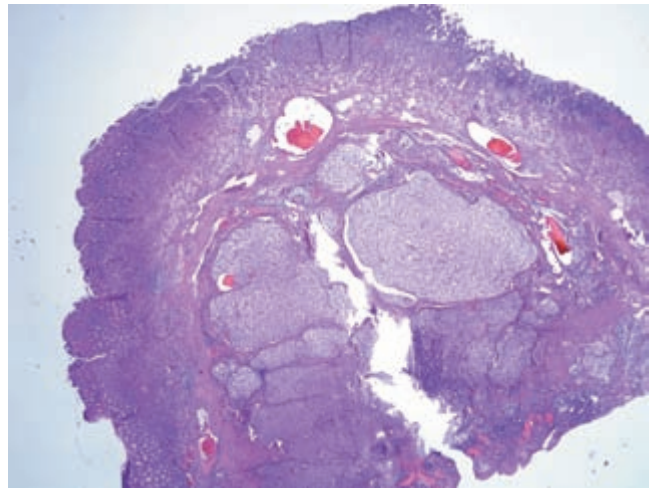

Figure 137.46 Gastric carcinoid tumor. This tumor is centered in the submucosa.

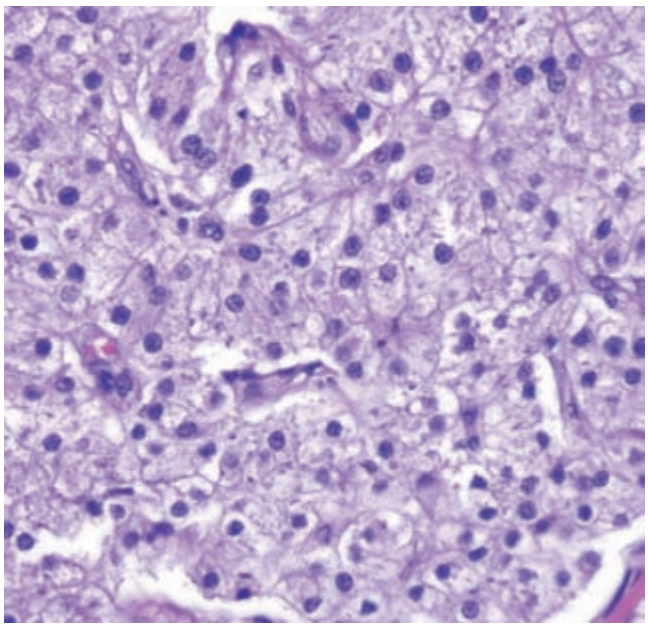

Figure 137.47 Gastric carcinoid tumor. Note the uniform nuclear features.

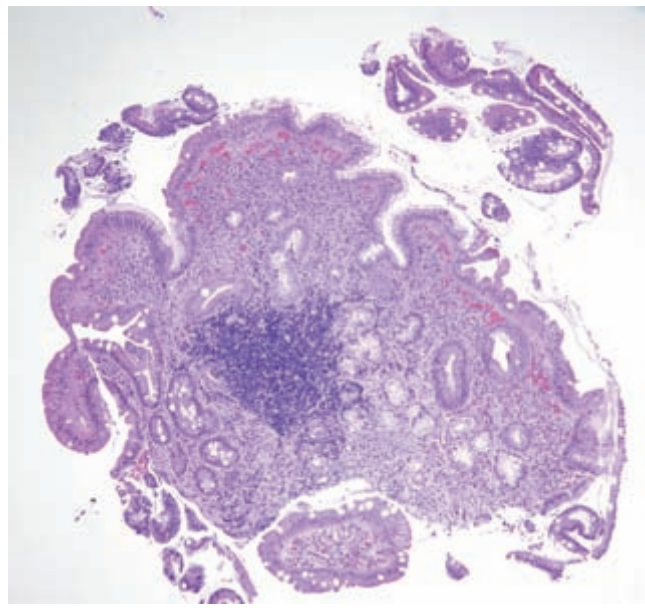

Figure 137.49 Chronic peptic duodenitis. At low magnification, normal duodenal mucosa is seen at the left (goblet cells are present) but the central portion shows gastric-type epithelium that is metaplastic.

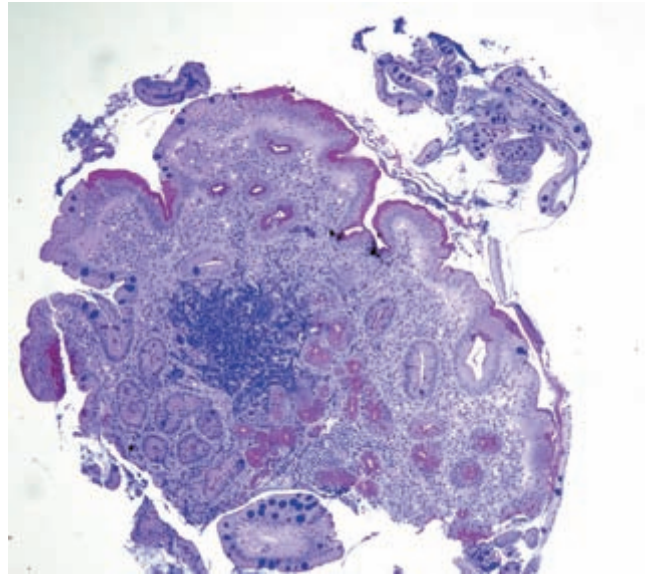

Figure 137.50 Chronic peptic duodenitis. Periodic acid–Schiff with Alcian blue shows the gastric metaplasia to advantage; it appears magenta.

Small bowel

Nonneoplastic conditions

Reactive lesions (gastric metaplasia of the duodenum)

When the esophagus and stomach are injured, metaplasia ensues, often of intestinal type. The duodenum can also undergo metaplasia when injured, but to gastric-type mucosa (Figs 137.49 and 137.50). *Helicobacter* gastritis was originally strongly associated with duodenal ulceration [97,220] since *H. pylori* infection up-regulates gastric acid secretion by damaging D cells that secrete somatostatin (somatostatin normally reduces gastric secretion). It is predominantly the bulb that is damaged. Gastric mucin cell metaplasia supervenes together with Brunner gland hyperplasia. In addition, the area

of metaplastic duodenum is then able to support *H. pylori*, which further stimulates ulceration in the duodenum. This cycle of events may attract inflammation and impart a nodular appearance to the duodenum (nodular peptic duodenitis) [142,221]. There may be striking reparative epithelial changes that are occasionally mistaken for adenomas. If PAS staining is done, these foci usually have at least some gastric mucin cell metaplasia as a clue that the process is reparative rather than neoplastic. In any doubtful case, repeat biopsy can be performed following treatment. Peptic duodenitis appears similar to gastric heterotopia, which occurs as a nodule in uninjured small bowel and often consists of oxyntic mucosa. It must be noted, however, that in some cases it is impossible to suggest whether the endoscopically noted nodule consists of a heterotopic or metaplastic process; fortunately both are benign.

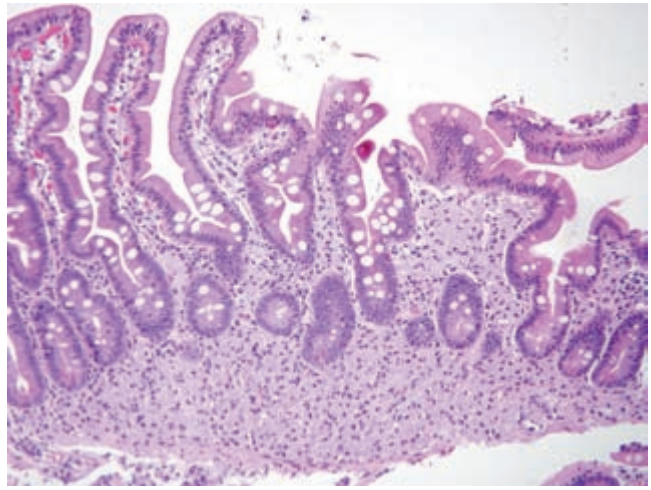

Figure 137.51 *Mycobacterium avium–intracellulare* duodenitis. The villi are expanded with macrophages.

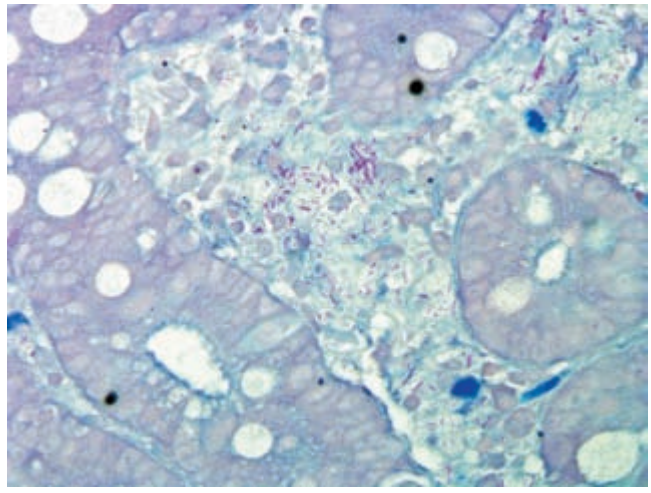

Figure 137.52 *Mycobacterium avium–intracellulare* duodenitis. This acid-fast stain highlights the organisms.

Infectious enteritis

A host of etiological agents may affect the small bowel mucosa. It is impossible to be exhaustive, but some merit comment.

Mycobacterium avium–intracellulare

In immunocompetent hosts, atypical mycobacteria show little virulence. However, *Mycobacterium avium–intracellulare* (MAI) is a significant cause of opportunistic infection in immunocompromised patients, especially patients with AIDS. Patients with $CD4^+$ cell counts of less than 100/μL are at risk of developing MAI. Symptoms include abdominal pain, fever, weight loss, chronic malabsorption, and diarrhea. Disseminated GI tract infection with MAI is common in AIDS patients. Clarithromycin or azithromycin are the preferred agents for MAI prophylaxis.

MAI usually affects both the small and large bowel. Endoscopically, the small bowel mucosa either appears normal or shows a coarse granularity without significant exudate (implying an attenuated local immunological response). The granular mucosa corresponds to massive infiltration of small intestinal villi by histiocytes loaded with acid-fast bacilli (Figs 137.51 and 137.52).

Unlike for *Mycobacterium tuberculosis*, well-defined granulomas are not a feature of MAI. Instead loose clusters of foamy histiocytes appear with little accompanying inflammation. Apart from the GI tract, MAI infection can affect a wide range of organs including lung, lymph nodes, spleen, liver, bone marrow, and brain.

Nematode infection

Strongyloides stercoralis is a nematodal infection with a worldwide distribution affecting 30–100 million people. It is endemic in Africa, Southeast Asia, South America and parts of the USA (e.g., Kentucky and eastern Tennessee).

The life cycle of this worm is as follows. The female lays eggs (and can do so without fertilization, i.e., parthenogenesis) in small intestinal crypts. The embryonated eggs hatch into rhabditiform larvae that pass into the lumen and are expelled with feces. The rhabditiform larvae develop into filariform larvae (infective form) that penetrate human skin, passing through blood vessels to the lungs and into the upper airways. The patient coughs and the larvae are swallowed and finally reach the small intestine where they mature into adult worms. The males are rapidly expelled after fertilizing the females. The female worms can remain in the intestine for decades, and in some cases have been known to be present for up to 30 years. In immunosuppressed patients, autoinfection is a major threat as internal rhabditiform larvae undergo transformation, penetrate intestinal mucosa and disseminate throughout the body. Autoinfection/hyperinfection carries a high mortality rate (up to 80%). Unlike hookworm infection, for which eggs are used for identification in stool examinations, eggs are not present in the

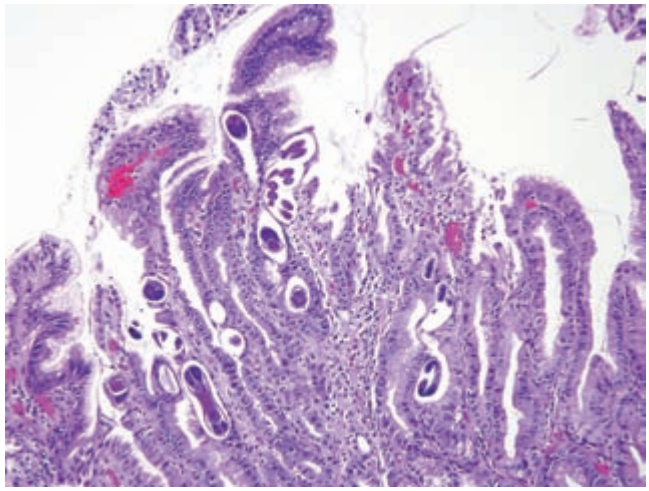

Figure 137.53 Strongyloidiasis. Multiple larval forms are seen in the small intestinal mucosa.

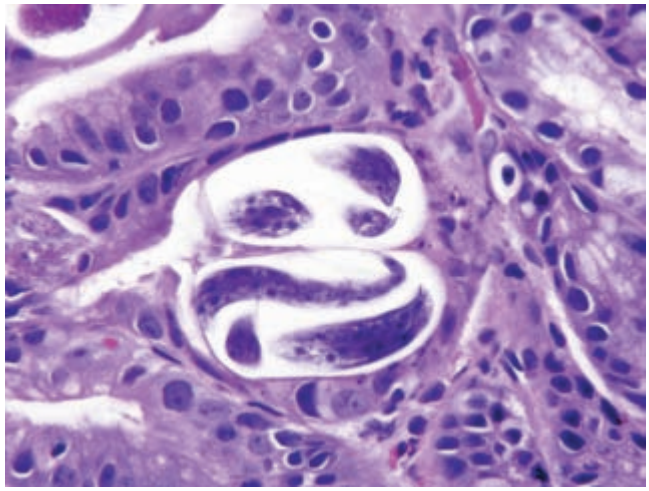

Figure 137.54 Strongyloidiasis. Higher magnification of Fig. 137.53.

stool in *Strongyloides* infection. Diagnosis is based most frequently on identification of rhabditiform larvae in stool. Intestinal biopsies are used less often for diagnosis. Characteristic findings in the biopsy are the presence of all stages of the worm embedded in mucosal crypts (Figs 137.53 and 137.54). Thus larvae, eggs and rarely adult worms (recognized by one intestinal tract and a pair of reproductive tubes) can all be seen. Additional changes include villous flattening, crypt hyperplasia, and an inflammatory reaction consisting of lymphocytes, plasma cells, and eosinophils. Finding a prominent eosinophilic infiltrate and Charcot–Leyden crystals should prompt a search for parasitic infestation. Treated worms invoke a brisk immunological response. The small intestine is the most common affected site but rarely stomach and colon can also be involved.

Patients can remain asymptomatic or present with nausea, vomiting, diarrhea, constipation, malabsorption, abdominal pain, and weight loss; the presentation can be varied depending on worm burden and site of infestation. Thiabendazole and more recently ivermectin (current drug of choice according to the WHO) are used to treat strongyloidiasis.

Whipple disease

Whipple disease is a rare systemic bacterial infection caused by *Tropheryma whippelii* (an actinomycete). Whipple disease was first described by Dr George Whipple at Johns Hopkins in 1907 as "intestinal lipodystrophy" due to the prominent accumulation of lipids in intestinal mucosa and lymph nodes. The bacterial etiology of this condition was confirmed by electron microscopy in 1961 [222,223]. There is a striking male predominance of 8–10 : 1, with white men aged between the fourth and fifth decades most commonly affected. Patients present with diarrhea, low-grade fever, weight loss, malabsorption, abdominal pain, arthralgia, anemia, lymphadenopathy (50%), and cardiac and central nervous system symptoms (10%). Most patients respond dramatically to antibiotics (trimethoprim and sulfamethoxazole). However, some patients can have a chronic relapsing course, with organisms persisting in affected tissues for a long time despite extended antibiotic treatment.

Whipple disease usually involves the postbulbar duodenum and jejunum. Thus biopsies should be taken both from proximal and distal duodenum and also jejunum. The characteristic appearance of small intestinal biopsy consists of blunted and rounded villi with distention of lamina propria by foamy pink macrophages. The macrophages contain PAS-positive, diastase-resistant, rod- or sickle-shaped bacterial inclusions. The bacterial inclusions can also be present in the extracellular space of lamina propria, and in epithelial cells, fibroblasts, endothelial cells, and smooth muscle. Lymphatic obstruction gives rise to dilated lacteals containing lipid deposits, a helpful feature which suggests the diagnosis of Whipple disease on H & E stain (Fig. 137.55). Endoscopically, the lesions can present as yellowish-white plaques or as pale yellow shaggy mucosa, or have an erythematous friable appearance. Thus the classic histological features of intensely PAS-positive foamy macrophages and dilated lacteals with large lipid droplets are characteristic of Whipple disease.

Apart from histology and special stains, it is now possible to detect the Whipple antigen by immunohistochemical analysis using a polyclonal rabbit antibody produced against a cultured strain of *T. whippelii* [224] (Fig. 137.56). The antigen is a component of the bacterial cell wall. This is a sensitive and specific method of detecting Whipple disease. Other tests consist of PCR assays for 16S ribosomal RNA genes of *T. whippelii*, and electron microscopy. The organism responsible has also been successfully grown in human fibroblast cell lines using shell-vial assays.

With electron microscopy, PAS stain, and Whipple immunostain it is still possible to see retained bacterial products months and even years after initiation of therapy despite

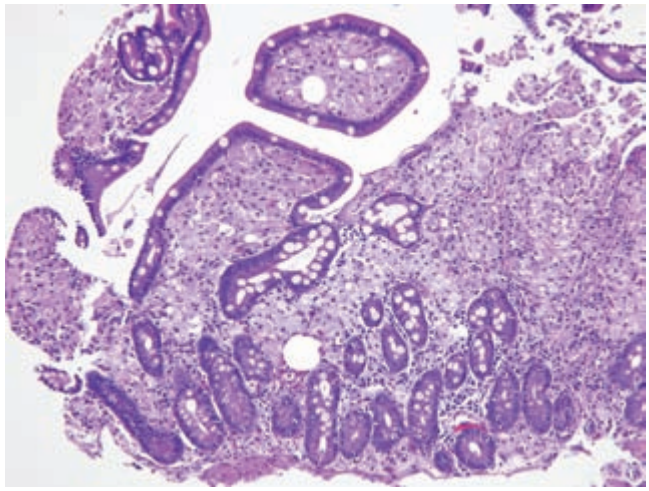

Figure 137.55 Whipple disease. Like Fig. 137.51, this image shows many foamy macrophages expanding the villi. In contrast, dilated lacteals are a feature of Whipple disease.

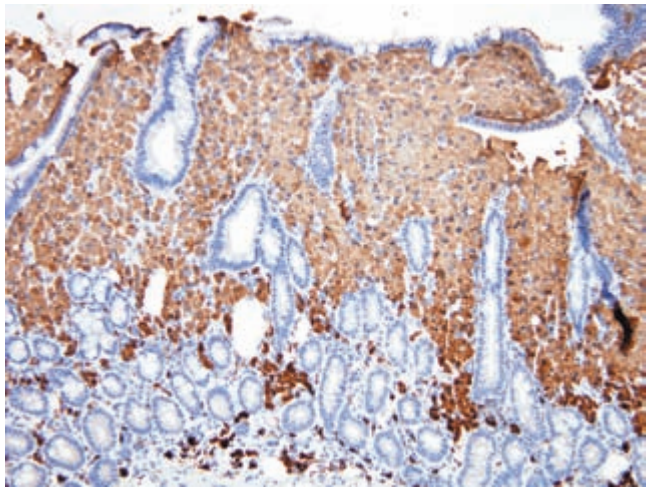

Figure 137.56 Whipple disease. This is an immunohistochemical preparation using an antibody directed against the organism.

clinical improvement. Thus, PCR may be a better tool to monitor treatment response as the bacterium has been shown to become undetectable shortly after initiation of antibiotic treatment.

Other infectious agents

Other infectious agents known to affect the small bowel include *Yersinia* spp., which produces necrotizing granulomas, and adenovirus, which results in marked lymphoid hyperplasia that can lead to obstruction or intussusception [225].

NSAID-associated injury

NSAIDs are well known to be associated with mucosal damage in the small intestine and may even lead to a peculiar form of strictures called *diaphragm disease* based on its macroscopic appearance [226–228]. The typical injury consists of ulcers which may lead to strictures. Unfortunately, the histological features of NSAID-associated ulcers are not specific, although they are usually not associated with abundant chronic inflammation.

Graft-versus-host disease

Patients with GVHD present with secretory diarrhea, abdominal pain and, at times, hemorrhage. There is a syndrome of upper GI GVHD that presents clinically as anorexia, dyspepsia, food intolerance, nausea, and vomiting. These syndromes were first recognized in the early 1990s [36,229,230] and endoscopic criteria for recognizing the lesions of GVHD are now available [29]. Of course patients who have had bone marrow transplants are prone to many infectious causes of enteritis, but many have upper tract GVHD. The original grading criteria were published by Snover and colleagues [229] and are summarized as follows: grade 1, increased crypt apoptosis; grade 2, apoptosis with crypt abscess; grade 3, individual crypt necrosis; grade 4, total denudation of areas of mucosa. These criteria are simple to apply and correlate well with clinical findings. Unfortunately, chronic GVHD results in nonspecific features of lamina propria fibrosis and mucosal atrophy. When confronted with such biopsies, we make an attempt to grade the active component and note the features of the chronic component. We also compare the biopsies to any prior ones. Papadimitriou and colleagues have reported a GVHD-like response to CellCept (mycophenolate mofetil) in colon biopsies [231]. This medication is widely used for maintenance immunosuppression in solid organ transplantation. Gastrointestinal toxicity, usually manifested as diarrhea, is its most common side effect. The authors reported findings in the colon, and we have seen them in the upper tract as well in our own material.

Common variable immunodeficiency

Daniels and colleagues have reported common GI complaints in patients with common variable immunodeficiency and related disorders [232]. Small bowel biopsies from these patients display villous atrophy and may have prominent intraepithelial lymphocytes as well as crypt apoptosis and even occasional granulomas, all features that suggest celiac disease or Crohn's disease. They differ from these other conditions by lacking plasma cells in about two-thirds of cases and being likely to harbor infectious agents (particularly *Giardia*). Of course, *Giardia* may be found in immunocompetent hosts as well; there are often fewer organisms.

Malabsorption

Celiac disease

Celiac disease is a relatively common (far more common than previously realized) systemic autoimmune disorder induced by gluten proteins found in wheat, barley, and rye. Injury to the small intestine is the hallmark of disease, but

Table 137.3 Schemes for assessment of biopsies in patients with celiac disease

Lesion category	Rostami modification [243,244]	Marsh classification [242]
Marsh 0	Same as original	Preinfiltrative: normal mucosal and villous architecture
Marsh I	Same as original	Infiltrative: normal mucosal and villous architecture; prominent intraepithelial lymphocytes
Marsh II	Same as original	Hyperplastic: same as infiltrative but also with enlarged crypts and increased crypt mitoses
Marsh III	Partial villous atrophy Subtotal villous atrophy Total villous atophy	Destructive lesion: flat mucosa (complete loss of villi); lymphocyte infiltration; enlarged hyperplastic crypts
Marsh IV	Same as original	Hypoplastic: total villous atrophy; normal intraepithelial lymphocyte count; believed to reflect severe malnutrition and be nonspecific

manifestations are systemic. Sites of extraintestinal injury include, but are not limited to, the skin (classically with dermatitis herpetiformis), joints, and uterus such that clinical presentations can be subtle and not GI tract-related. Certain HLA types confer the highest risk (HLA-DQ2 and HLA-DQ8) [233] and certain subsets of patients similarly are at high risk (e.g., family members of those with celiac disease, type 1 diabetics, children with Down syndrome [234], individuals with iron deficiency anemia). Prevalence of celiac disease has been reported as high as 1.5% in Finnish schoolchildren [235] and only slightly less in the general population of the USA [236] such that some observers suggest that there might be some utility in screening large numbers of individuals for this condition [237]. The incidence of celiac disease appears nil to low in Southeast Asians, but there are endemic populations in the Sahara with a high incidence of celiac disease [238]. In fact, pockets of prevalent celiac disease are found throughout the Middle East [239]. Undiagnosed celiac disease is responsible for growth retardation in some children [240] and has been associated with fetal wastage, infertility, and osteoporosis. An NIH conference was held on this topic and a statement from this is available at http://consensus.nih.gov and reported in 2005 [241].

When evaluating patients for celiac disease, it is worthwhile to remember that anti-gliadin tests are no longer recommended as they produce too many false positives. For example, patients with Crohn's disease may have both false-positive anti-gliadin tests as well as prominent intraepithelial lymphocytes, a combination likely to result in misdiagnosis. Presently, anti-tissue transglutaminase or anti-endomysial tests are recommended [241]. These are IgA-based tests in general so they yield false-negative results in IgA-deficient patients. IgG-based tests exist for this situation.

It is best to evaluate biopsies from beyond the bulb (first portion) since these are less prone to injury from gastric contents. Several biopsies should be obtained since characteristic features may be patchy. Review of these is easiest in well-oriented samples. There is a range of appearances in biopsies obtained from patients with celiac disease and the constellation of findings has been classified by Marsh [242] and further modified by Rostami and colleagues [243,244] (Table 137.3). What is important about these grading schemes is that they provide a framework for recognizing celiac disease lesions of that fall short of mucosal atrophy. Since these observers originally published their findings in the gastroenterology literature rather than the pathology literature, many pathologists have remained unaware of subtle findings that suggest celiac disease [245,246], although such findings are by no means specific [247,248]. Essentially, subtle or treated lesions display only intraepithelial lymphocytosis, similar in density or more prominent in the tips of the villi than the bases, where intraepithelial lymphocytes are physiological. As lesions progress, the lamina propria becomes expanded with numerous lymphocytes and plasma cells, the villi become progressively attenuated with epithelial damage, and the crypts become hyperplastic (Figs 137.57–137.59). The cells accounting for the infiltrate are T cells, and there is

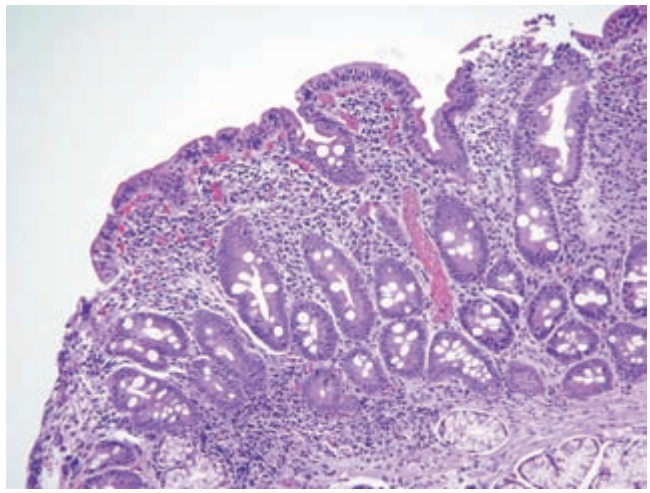

Figure 137.57 Celiac disease. The villi in this duodenal biopsy are wholly attenuated.

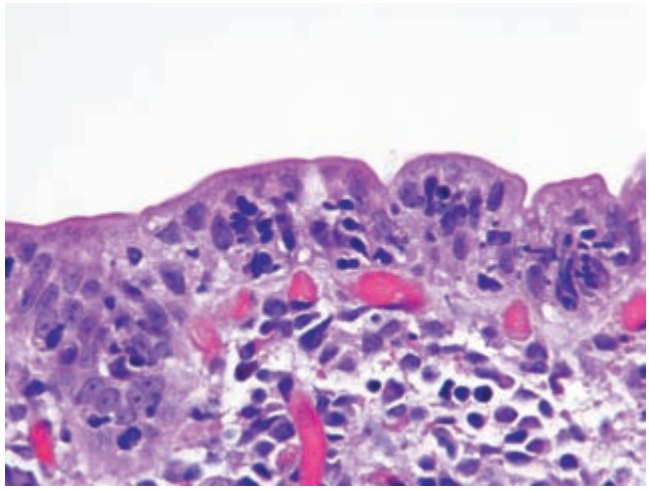

Figure 137.58 Celiac disease. Prominent intraepithelial lymphoctes are a key diagnostic feature.

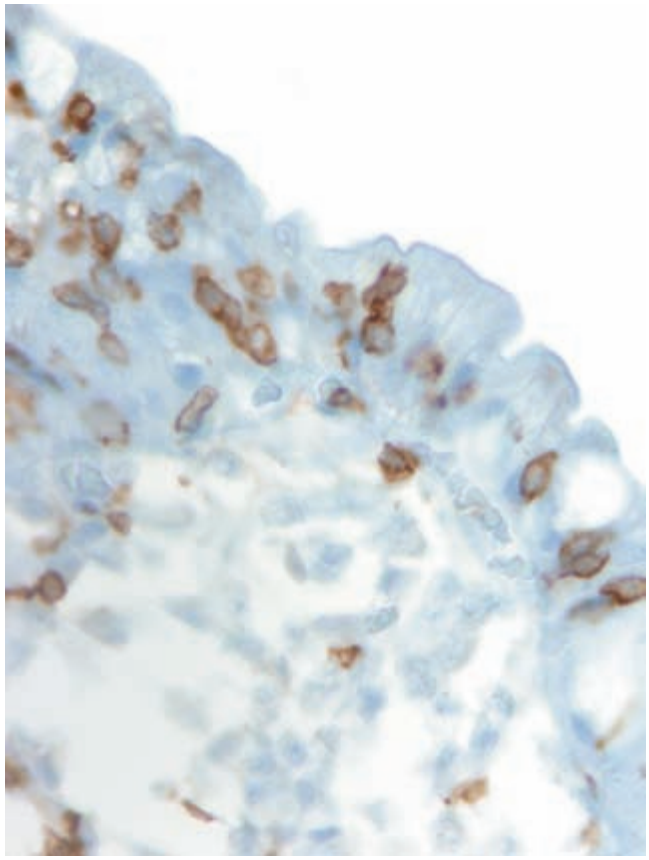

Figure 137.59 Celiac disease. This CD3 immunostain highlights the T cells in the epithelium.

extensive literature devoted to the phenotype of these T cells, most of which is of value only for research purposes.

Of course celiac disease is not unique in resulting in villous atrophy. Diseases that may produce villous atrophy include celiac disease and the related condition dermatitis herpetiformis, cows' milk protein intolerance (pediatric), giardiasis, peptic duodenitis, Crohn's disease, small bowel bacterial overgrowth (stasis and overgrowth usually of anaerobes), eosinophilic gastroenteritis, radiation enteritis, tropical sprue, severe malnutrition, lymphoma, GVHD, hypogammaglobulinemia/common variable immunodeficiency syndrome, and α-chain disease. A rule of thumb in considering atrophic enteritis is that neutrophils and histiocytes are not a typical inflammatory constituent in celiac disease and their presence should prompt other considerations, particularly bacterial overgrowth (stasis changes) and Crohn's disease. In reality, there are biopsies for which it is difficult to offer a precise etiology and in this situation a descriptive report is indicated together with dialogue with the endoscopist.

There remains a troubling subset of cases that defies current medical management and has a presentation resembling celiac disease and these are sometimes termed *refractory sprue* [249–251]. Robert and colleagues reported 10 cases of refractory sprue [252] and found that five of these patients ultimately developed collagenous sprue as a distinct histological marker of refractory disease. Additional distinctive findings in small bowel biopsies in the refractory group were subcryptal chronic inflammation (10 of 10) and marked mucosal thinning in three patients. Other nonspecific findings included acute inflammation and gastric metaplasia. One patient with collagenous sprue developed a B-cell lymphoma of the ileum, and in general collagenous sprue was associated with a poor prognosis. Two of five patients died whereas two others required total parenteral nutrition for survival. In other studies and in our experience, such cases may be clonal by gene rearrangement studies and related to T-cell lymphomas but these cases are also heterogeneous and rare so are difficult to study well [253]. Some patients respond to steroids but others are managed with antineoplastic regimens.

IgA deficiency

The incidence of IgA deficiency ranges from 1 in 400 to 1 in 3000 in healthy blood donors and most IgA-deficient individuals are healthy, although this condition is associated with protean manifestations [254]. It is believed that these people have a compensatory increase in secretory IgM. However, for the purposes of GI biopsy interpretation, disorders associated with IgA deficiency include giardiasis, nodular lymphoid hyperplasia, celiac disease (in around 2%), milk intolerance, and IBD. When reviewing biopsies from IgA-deficient individuals (serum IgA levels < 7 mg/dL), IgA-producing cells may be identified on immunohistochemistry but are usually reduced in number. It may be that, at least in some cases, the secretory (J chain) component is defective so that IgA-reactive cells are seen despite a lack of detectable serum IgA. However, since the number of IgA-labeled plasma cells is variable in any population of healthy individuals, the disease can only be suggested by the pathologist when the associated disorders are detected.

Tropical sprue and small bowel bacterial overgrowth

Aside from infectious intestinal diseases with known etiology, there is a group of GI disorders mainly affecting the small intestine of individuals living predominantly in, and less often visiting or returning from, the developing world, usually the tropics. These disorders range from asymptomatic structural or functional abnormalities of the GI mucosa (subclinical enteropathy) to a fully symptomatic condition highlighted by malabsorption of nutrients with associated nutritional deficiencies responsive to folate and broad-spectrum antibiotic treatment (tropical sprue). An infectious etiology is strongly suspected because of the occurrence of tropical sprue in epidemics, particularly in rural areas with poor sanitation, the susceptibility of visitors to endemic regions from developed countries, and its favorable response to treatment with antibiotics. In addition, patients with tropical sprue have also been associated with bacterial contamination of the small bowel. These patients have prolonged transit time through the small intestine, akin to that observed in obstruction [255], and evidence of bacterial overgrowth. The appearance of biopsies from these patients is very much like that in patients in Western countries with small bowel bacterial overgrowth. The findings are similar to those in celiac disease in terms of villous attenuation but with the addition of active inflammation and, at times, features of chronicity such as gastric mucin cell metaplasia and crypt distortion. Both conditions have overlapping features with upper tract Crohn's disease. Small bowel bacterial overgrowth is relatively common and occurs when small bowel motility is altered and patients present with diarrhea [256,257]. This alteration may be the result of underlying medical conditions such as diabetes or scleroderma (which results in sclerosis of the bowel wall) or from surgery. In addition, many patients with so-called irritable bowel syndrome are believed to have this condition. It is best diagnosed by small bowel aspirate and quantitative cultures and specific antibiotic therapy is determined by sensitivity testing of the cultured agents, which are generally anaerobes. A hydrogen breath test, which exploits hydrogen production from excess bacteria, is also effective in diagnosing this condition [258,259]. Sadly, the morphological features in small bowel bacterial overgrowth range from normal to Crohn's disease-like but usually do include a component of neutrophilic inflammation. The pathologist reviewing biopsies may be able to raise this possibility and suggest confirmation but it is difficult to diagnose in isolation of the clinical findings.

Microvillous inclusion disease

Microvillous inclusion disease is an uncommon congenital enteropathy that produces intractable secretory diarrhea in early infancy [260–267]. It is inherited as an autosomal recessive genetic trait. There are several synonyms used for this disease, including Davidson disease [261], familial microvillous atrophy, congenital microvillous atrophy, and intestinal microvillous dystrophy (a variant of microvillous inclusion disease). The outcome is typically poor, with most patients requiring small bowel transplantation. Rare cases have resolved.

Biopsies of duodenal mucosa show moderate villous blunting without active inflammatory reaction or intraepithelial lymphocytosis. The optimal specimen is a small intestinal biopsy; duodenal biopsy is most commonly used. (Rectal biopsy has been proposed as a simple and reliable method for early diagnosis although the findings may be subtle.) Architecturally, diffuse intestinal villous atrophy with no inflammatory reaction is a characteristic feature. Due to increased crypt cell apoptosis, either crypt hypoplasia or hyperplasia can be found. Subtle histological changes in the enterocytes are confined to the villous tips and distal villous lateral borders. Changes are difficult to discern at the base of the villus and in the crypt epithelium; indeed the enterocytes appear normal in these regions. Cytologically, a bubbly vacuolated appearance of the apical cytoplasm with extensive or patchy absence of the brush border is a specific diagnostic sign. Typical targetoid cytoplasmic inclusions are occasionally identified in the surface enterocytes.

Instead of a sharp linear brush border that stains with PAS or alkaline phosphatase histochemically, a bright apical cytoplasmic blush is present and is the most easily recognized change of microvillous inclusion disease. Brush border biomarkers, such as carcinoembryonic antigen (CEA) and particularly CD10 [264], are also useful in the diagnosis of microvillous inclusion disease. CEA and CD10 stains demonstrate the characteristic apical cytoplasmic staining pattern in the enterocytes. Ultrastructurally, identification of apical microvillous inclusions in surface enterocytes in intestinal tract biopsies makes a definitive diagnosis. A variant of this condition (possibly an incomplete form) is called *tufting enteropathy* or *intestinal epithelial dysplasia*; adhesion molecule defects have been implicated [260,266,267].

Colchicine toxicity

Colchicine is an alkaloid with antimitotic ability used to treat a variety of medical conditions. Iacobuzio-Donahue and colleagues reported findings in 21 GI mucosal biopsies from nine patients receiving oral colchicine therapy [96]. All patients had a history of gout. Four patients with chronic renal failure also had clinical evidence of colchicine toxicity, but the other five patients did not. Distinct morphological changes, seen as metaphase mitoses, epithelial pseudostratification, and loss of polarity, were seen in biopsy material from four of four (100%) patients with clinical colchicine toxicity. Three of these four cases (75%) also contained abundant crypt apoptotic bodies. These morphological features were best seen in the biopsies from duodenum (Figs 137.60 and 137.61) and gastric antrum, with relative sparing of the gastric body in the upper GI tract. Probably the most important finding in this study was that the distinctive mor-

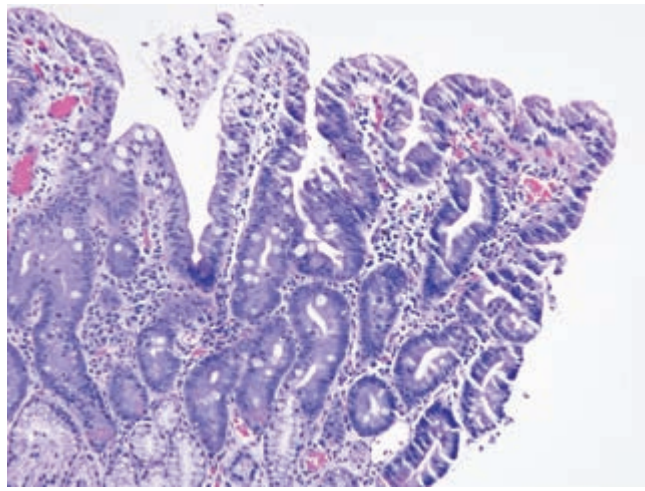

Figure 137.60 Colchicine toxicity. This duodenal biopsy shows attenuated villi and an expanded proliferative compartment. Mitotic arrest is seen as ring mitoses.

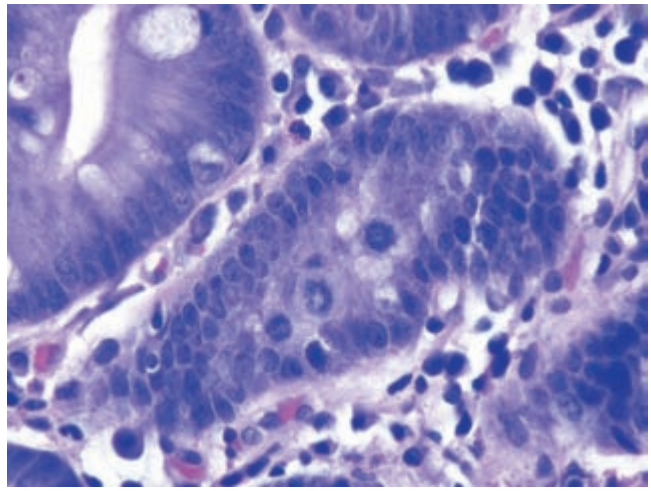

Figure 137.61 Colchicine toxicity. Higher magnification of arrested mitoses.

phological features were not seen in the five patients without clinical colchicine toxicity.

Lymphangiectasia

Primary intestinal lymphangiectasia is usually diagnosed before the age of 3 years. Most patients have growth retardation. Gastrointestinal complaints that vary in severity consist of diarrhea, vomiting, abdominal pain, and steatorrhea. If large segments of the gut are involved, secondary edema resulting from protein-losing enteropathy and malabsorption may occur. The edema is usually generalized, but asymmetric edema is not uncommon. Small biopsies taken in these patients may be nondiagnostic but they simply display multiple dilated lacteals, a finding easy for the pathologist to overlook without knowledge of an often dramatic CT appearance. The long-term course is variable, but is usually slow in progression with intermittent clinical remissions. The reported medical treatments for lymphangiectasia include a high-protein, low-fat diet with added medium-chain triglycerides. Octreotide has been reported to decrease intestinal protein losses.

Crohn's disease

The clinical features of Crohn's disease are well summarized elsewhere in this book. It is also referred to as regional enteritis, granulomatous enterocolitis, and terminal ileitis, and is a chronic relapsing and remitting inflammatory disease of unknown etiology that is often multifocal and can affect any portion of the GI tract. However, the classic disease site is the terminal ileum. It is typically characterized by foci of glandular destruction, aphthous erosions, serpiginous ulcers as well as areas of transmural inflammation, fibrosis and sometimes granulomas. Because of its transmural nature, fissures, sinuses, and fistulae may occur.

The gross endoscopic appearance of Crohn's disease is most consistently characterized as a multifocal process. Aphthous erosions (Greek *aphtha*, spot), longitudinal ulcers (tram-track or rake ulcers), and adjacent areas of erythematous or grossly unremarkable mucosa are hallmarks. Additional endoscopic findings include cobblestoning (irregular mucosa due to alternating ulcers and edematous mucosa), strictures, and fissures. The ileum typically shows focal or asymmetric involvement, which may include erosions, ulcers, or strictures. The rectum is often not involved (unlike in ulcerative colitis). Inflammatory polyps may be present. Rarely, Crohn's disease may become confluent, involving the entire bowel, which can be diagnostically difficult for the endoscopist. In both Crohn's disease and ulcerative colitis, the normal submucosal vascular network is lost in the involved areas, assisting the endoscopist in the diagnosis of chronic colitis. There is little correlation between the endoscopic appearance and the clinical symptoms of the patient.

Mucosal biopsies, although superficial, can show features suggestive of Crohn's disease (Fig. 137.62). Discrete foci of inflammation often associated with neutrophils within crypts (cryptitis) and adjacent to histologically normal crypts are common. Aphthous erosions or ulcers, characterized by focal surface epithelial necrosis associated with a mixed chronic inflammatory infiltrate, sometimes associated with underlying lymphoid aggregates are typical early lesions. Variability of inflammation within a single biopsy and among several biopsy fragments from the same anatomical location is also typical. The areas of inflammation show architectural changes of chronic crypt destructive colitis whereas adjacent crypts may appear totally normal. Granulomas are infrequently seen but when present are poorly formed and associated with chronic inflammation.

Terminal ileal involvement includes increased lamina propria inflammation, aphthous erosions, and flattened and broad

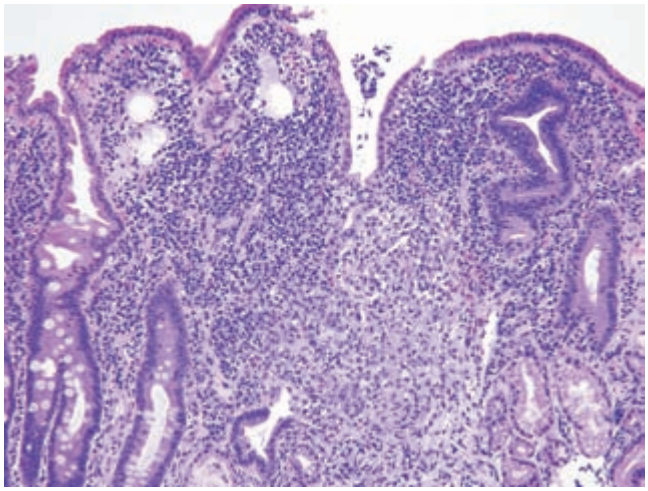

Figure 137.62 Crohn's disease. A granuloma is seen in the center of the field.

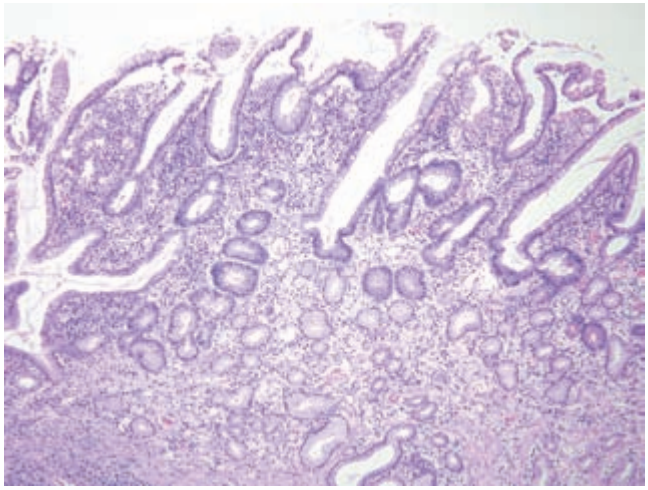

Figure 137.63 Crohn's disease. This ileal biopsy shows pyloric metaplasia: the metaplastic glands in the deep portion of the field lack goblet cells.

villi. Pyloric metaplasia (mucinous glands, reminiscent of the antral or pyloric mucosa) (Fig. 137.63) indicates repeated bouts of inflammation and repair. One must remember that focal acute ileitis is most commonly caused by medications, particularly NSAIDs, rather than Crohn's disease and finding the features of chronicity is critical; medication-induced injury is usually not associated with increased lamina propria inflammation or pyloric metaplasia. Submucosal fibrosis can also be a sequel to NSAID damage. Peyer patches are a normal component of the terminal ileum, particularly in young individuals, and should not be diagnosed as chronic inflammation. The mucosa over Peyer patches may be distorted with flattened villi due to underlying expansion of lymphoid nodules in nonspecific reactive hyperplasia. Yersiniosis can also result in prominent Peyer patches.

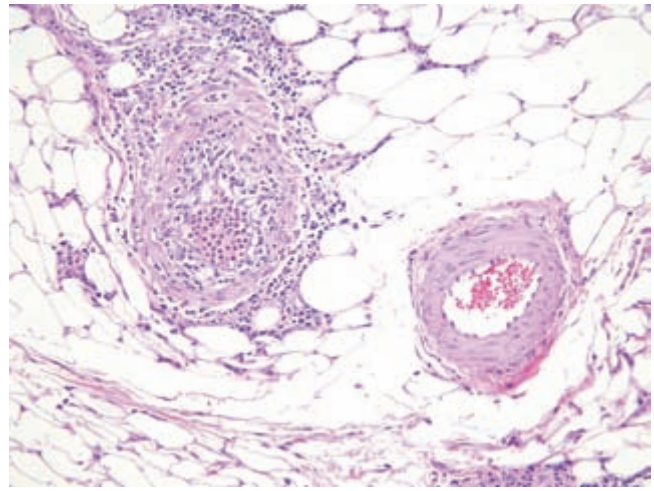

Figure 137.64 Behçet disease. Vasculitis primarily affecting mesenteric veins is the hallmark.

Behçet disease

Behçet disease is a systemic disorder consisting of oral ulceration plus any two of genital ulceration, typical defined eye lesions, typical defined skin lesions, or a positive pathergy test (an exaggerated response to a minor injury of skin) [268–270]. The GI tract may be affected anywhere, where deep penetrating ulcers lacking specific histological features are found, but the commonest sites are the terminal ileum and cecum. Establishing the diagnosis requires clinicopathological correlation and surgical management is often required. Vasculitis is one of the hallmarks, particularly involving veins (Fig. 137.64).

Small intestinal findings in ulcerative colitis

Generally the small intestine is unaffected by ulcerative colitis. Unfortunately, there is a subset of patients who have severe pancolitis that extends a short distance into the ileum as well, and the term *backwash ileitis* has been applied and used with some dissatisfaction by surgeons, gastroenterologists, and pathologists alike. It is associated with pouch complications in some studies [271] but not others [272] and is believed to reflect the severity of the ulcerative colitis. Backwash ileitis is sometimes described as active chronic and sometimes as minimal active but no real consensus exists. In daily practice we simply describe what is seen in the ileum. A group of patients with classic ulcerative colitis and severe confluent duodenitis has also been described [273]. These patients had otherwise classic ulcerative colitis and had a good clinical outcome with continent pouches and thus presumably had a rare form of ulcerative colitis with diffuse duodenal involvement rather than Crohn's disease. Whether these patients had a peculiar small bowel bacterial overgrowth complicating their ulcerative colitis was not clarified in the report.

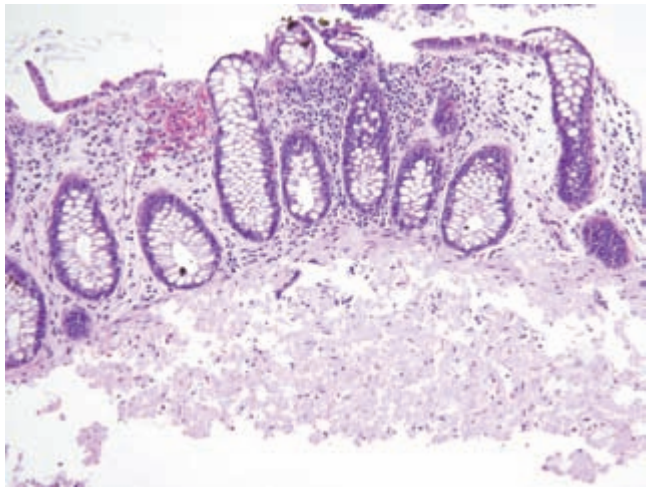

Figure 137.65 Amyloidosis. This field shows prominent submucosal deposits. This is from a colonic biopsy.

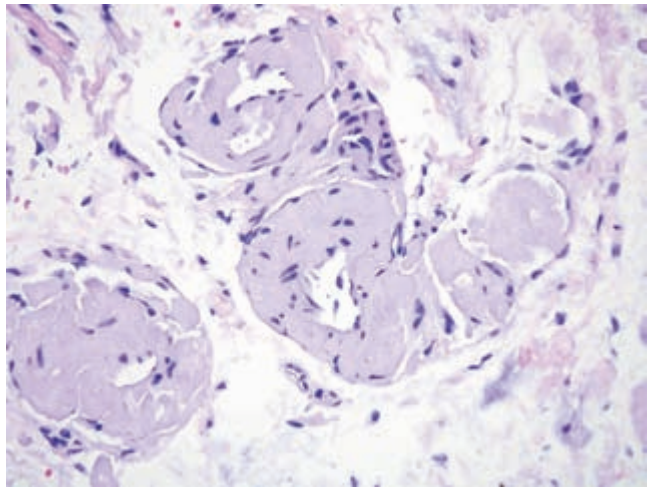

Figure 137.67 Amyloidosis. This vascular deposition was from a gastric biopsy.

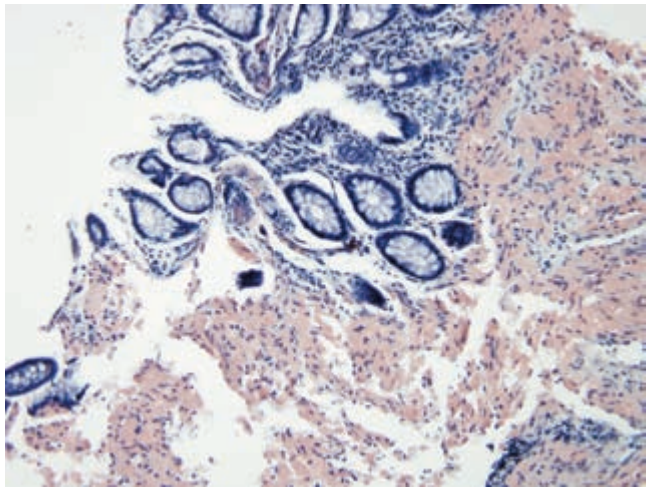

Figure 137.66 Amyloidosis. The Congo red preparation imparts an orange to brown color.

Amyloidosis

Gastrointestinal amyloidosis is an almost universal finding in systemic amyloidosis and consists of extracellular deposition of β-pleated protein sheets in the mucosa, submucosa, muscularis propria, or serosa (Figs 137.65–137.67).

The older classification divided amyloidosis into localized and generalized, or primary and secondary amyloidosis. Localized amyloidosis usually does not involve the GI tract. However, systemic amyloidosis almost universally involves the gut. Other common sites of amyloid deposition include heart, kidney, liver, and spleen, with restrictive cardiomyopathy, nephrotic syndrome, or hepatosplenomegaly depending on the site of amyloid deposition. The newer classification of amyloidosis is based on the biochemical composition of amyloid:

- AL amyloid (immunoglobulin light chain), associated with B-cell lymphoma, multiple myeloma, and Waldenström macroglobulinemia
- AA amyloid (serum amyloid-associated protein), seen in chronic illnesses such as rheumatoid arthritis, tuberculosis, bronchiectasis, Crohn's disease, and familial disease such as familial Mediterranean fever
- β_2-microglobulin, associated with renal failure and long-term hemodialysis
- β-precursor protein, associated with Alzheimer disease
- transthyretin (usually involves the heart).

Except for the familial forms, amyloidosis usually affects older adults in their sixties. Gastrointestinal manifestations consist of hemorrhage, nausea and vomiting, weight loss, malabsorption, gastric outlet obstruction, gastroparesis, stasis-related change such as bacterial overgrowth, or diarrhea. Amyloid deposits in blood vessels, which become fragile and leaky leading to hemorrhage. Deposits in the muscularis propria and nerve bundles cause impaired motility. Mucosal deposits lead to malabsorption and diarrhea. Rarely amyloid may present as a tumoral mass and can be mistaken for a carcinoma.

The endoscopic appearance is not specific, consisting of mucosal erosions, ulcers, thickened folds, or even a tumoral mass. Resection specimens with massive amyloid deposition have thick and rigid walls with a waxy appearance. Diagnosis is achieved through tissue biopsy of the GI tract, rectum and stomach being the preferred sites with a high yield. Biopsy samples must be adequate and deep enough to contain submucosal vessels in order to increase the diagnostic yield.

Biopsies often show intact and slender villi and few intramucosal Brunner glands. The lamina propria and muscularis mucosae contain extensive dense, eosinophilic, slightly globular extracellular deposits that produce the characteristic apple-green birefringence on Congo red stain, consistent

with amyloidosis. Amyloid deposits can also be seen in submucosal vessel walls.

The distribution of amyloid in the gut can be patchy or diffuse. Amyloid presents as dense, homogeneous, acellular, eosinophilic extracellular deposits in the lamina propria, submucosa, muscularis propria, nerve trunks, vascular intima and media. Amyloid deposits often show cracking with slit-like spaces as a result of tissue processing artifacts. Amyloid in the lamina propria often appears globular. Massive amyloid accumulation in the muscularis propria and submucosa is usually associated with AL amyloidosis.

Ultrastructurally, amyloid consists of nonbranching fibrils 7.5–10 nm in diameter. The fibrils are composed of β-pleated sheets of amyloid proteins. Cotton dyes such as Congo red, when polarized, impart a characteristic apple-green birefringence in the presence of amyloid. Other useful stains include Sirius red, Sirius supra scarlet and Thioflavin T (fluorescent dye). Immunolabeling for κ and λ chains is useful in AL amyloidosis, with the majority showing a λ restriction.

Arteriosclerosis of vessels with resulting hyalinization may be misdiagnosed as amyloid deposits. Systemic sclerosis can result in fibrosis of muscularis and submucosa which may be mistaken for amyloid. Ischemic injury resulting in lamina propria hyalinization and microcrypts can resemble amyloid. However, amyloid deposits in the lamina propria appear as globular deposits.

Polyps

Adenomas

Small intestinal adenomas are usually found in the duodenum and, like their colon counterparts, have three major histological types: tubular, tubulovillous, and villous. Adenomas in this site appear essentially the same as those in the colon. In patients with FAP, endocrine cells are often a prominent component. Most adenomas occur singly; the presence of multiple adenomas in the small intestine is unusual in the absence of FAP. In FAP patients, after colectomy, the main cause of death is upper GI malignancy [274]. The majority of patients with FAP also develop upper GI polyps. Those in the gastric antrum and duodenum are usually neoplastic. Therefore, surveillance of FAP patients through upper endoscopy plus biopsy is recommended. Because of their potential to undergo malignant transformation, adenomas should be removed via endoscopic polypectomy for pedunculated tumors and endoscopic mucosal resection or surgical resection for large sessile lesions.

Probably the biggest pitfall for pathologists in interpreting adenomas in the small bowel is the proclivity of reparative lesions to mimic them. When peptic duodenitis has a nodular configuration, it is easily confused with an adenoma. One clue is that peptic duodenitis often has surface gastric mucin cell metaplasia in the atypical focus and adenomas have their initiation point just beneath the surface epithelium [275] whereas reparative lesion have theirs at the base of the mucosa. Unfortunately, there are occasional cases in which it is impossible to distinguish adenomas from reparative processes and we designate them "indefinite for dysplasia" and additional samples are obtained. This distinction is not trivial in the small intestine, particularly in the area of the ampulla; there is a precedent for treating large ampullary adenomas with pancreatoduodenectomy based on their high likelihood of harboring an occult invasive carcinoma [276].

The ampulla itself is often a source of difficulty for pathologists since it normally has ampullary glands, with their features akin to biliary epithelium, interspersed with disorganized bundles of smooth muscle. When inflammation is a feature, great caution is advised. The ampulla is not typically biopsied without a compelling reason since pancreatitis may be a severe consequence of performing such biopsies.

When a clearly neoplastic small bowel lesion displays peculiar features, it is always important to consider that the process is a metastasis or extends directly from the pancreatobiliary tree.

Peutz–Jehgers polyps

The WHO has defined Peutz–Jeghers syndrome as an inherited cancer syndrome characterized by mucocutaneous melanin pigmentation and hamartomatous intestinal polyposis preferentially affecting the small intestine [277]. Extraintestinal neoplasms include those of the ovary (sex cord tumors with annular tubules), cervix (adenoma malignum), testis (Sertoli cell tumors), pancreas (carcinomas [278,279]), and breast (carcinomas). This syndrome is about one-tenth as common as FAP (incidence of FAP is between 1 in 7000 and 1 in 30 000). The diagnostic criteria include three or more histologically confirmed Peutz–Jeghers polyps; any number of Peutz–Jeghers polyps in an individual with this syndrome; appropriate melanin pigmentation in an individual with affected relatives; or any number of polyps with the appropriate mucocutaneous pigmentation. Since the pigmentation tends to fade with age, it may not be found in some adult patients with the syndrome. Recognition of the syndrome is important based on the associated 10–18-fold increase in cancers of both the intestines and extraintestinal sites [148,280]. This syndrome is an autosomal dominant trait with virtually 100% penetrance. Alterations in an involved gene, *LKB1/STK11* [281], are found in about half of affected patients, so doubtless there is more than one active locus that produces disease [282].

In their classical appearance, Peutz–Jeghers polyps are easy to recognize on endoscopic biopsies. They are hamartomas and thus display the type of mucosa typical for the site in which they are found. Thus, in the stomach they have gastric mucosa and in the small bowel they have small intestinal mucosa. The problems arise when biopsies are superficial or when ulceration distorts them. However, Peutz–Jeghers polyps in the small intestine are far more likely than those from the stomach to display the classic arborizing smooth

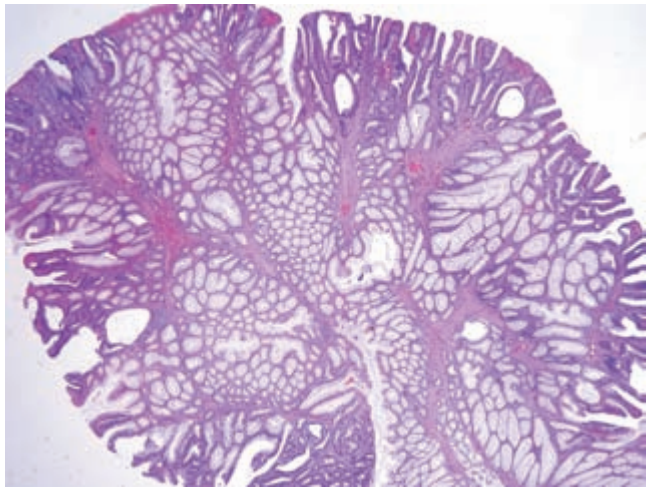

Figure 137.68 Peutz–Jehgers polyp. Note the striking muscular arborizing cores.

muscle cores from which the mucosa leafs out and must always be assessed for dysplasia (Fig. 137.68).

Neoplasms

Carcinoma

Adenocarcinomas are the most common malignancies of the small intestine (30%–50% of small bowel malignancies). However, primary adenocarcinomas are still rare lesions, accounting for only 2% of GI tract tumors or 1% of GI tract cancer deaths [274]. They present in older adults (median age 67 years), with a male predominance and are more common in African Americans than whites.

The majority are sporadic and share with sporadic colorectal adenocarcinomas both clinical risk factors and development from adenomatous polyps. The remaining minority of cases arise on a background of certain predisposing conditions, including several of the polyposis syndromes (primarily FAP but also hereditary nonpolyposis colon carcinoma syndrome, Peutz–Jeghers syndrome, and juvenile polyposis syndrome), Crohn's disease, gluten-sensitive enteropathy [283], ileostomy, and ileal conduits among others. The greatest risk of small intestinal adenocarcinomas is seen with FAP. In these patients, the relative risk of duodenal adenocarcinoma is striking (relative risk 330.82; 95% confidence limits 132.66 and 681.49; $P < 0.001$), as is that for ampullary adenocarcinoma (relative risk 123.72; 95% confidence limits 33.65 and 316.72; $P < 0.001$) [159]. As an aside, there seems to be no significant increased risk for gastric or nonduodenal small intestinal cancer in FAP patients. The risk of small intestinal carcinoma in Crohn's disease and celiac disease are each about 50–100-fold.

Lesions are most common in the duodenum, where 65% are periampullary, and their prevalence decreases progressively through the rest of the small intestine. An important exception to the proximal location occurs in patients with Crohn's disease, where 70% of adenocarcinomas are ileal, corresponding to the primary site of the inflammatory process.

Most adenocarcinomas are moderately differentiated, and one-third are poorly differentiated. Degree of differentiation and special histological subsets (mucinous, adenosquamous) have little bearing on prognosis and as such we mention them only as comments. The majority of small bowel adenocarcinomas have invaded through the bowel wall by the time of diagnosis.

Residual adenomatous epithelium is found with the majority of resected proximal tumors (those likely to be biopsied prior to resection), but often cannot be demonstrated in large distal small intestinal adenocarcinomas, presumably due to tumor overgrowth. Adenomatous epithelium can be mimicked by tumors metastatic to the GI mucosa. The main differential diagnostic consideration is metastatic disease, as the small intestine is the most common GI site for metastatic disease. Features favoring a metastatic tumor include the presence of multiple lesions, the absence of a precursor adenoma, a histological appearance of tumor being "bottom heavy" or encroaching from below, and lack of ulceration. Immunohistochemical studies are also helpful in most circumstances. Common metastatic lesions include colonic adenocarcinoma, melanoma, and breast and gynecological malignancies. Endometriosis is relatively common in the colon, but can also be seen in the small intestine and mimic metastatic adenocarcinoma.

Lymphomas

The GI tract houses more lymphoid tissue than any other anatomical site so it is not surprising that many lymphoid lesions are found here. In fact, the GI tract is the most common extranodal site of non-Hodgkin lymphoma. Secondary disease is common, especially in patients with advanced disease. Primary small intestinal lymphomas, in contrast to gastric lymphomas, are uncommon in the Western world, but still comprise 30%–50% of malignant tumors at this site. Primary GI tract lymphomas are defined as an extranodal lymphoma arising in the small bowel with the bulk of disease localized to this site and with the primary clinical manifestations and subsequent therapy related to this site. Lymphomas with a predilection for the small intestine include diffuse large B-cell lymphoma, followed by MALT lymphomas (usual and immunoproliferative small intestinal disease), secondary involvement by low-grade lymphomas (primarily mantle cell lymphoma and rarely follicular lymphoma), and enteropathy-like T-cell lymphoma. There is also evidence of rare follicular lymphomas primarily involving the duodenum. Hodgkin's disease can involve the GI tract primarily or secondarily but this is an exceedingly rare event [284].

Predisposing conditions include autoimmune diseases, immunodeficiency syndromes (e.g., AIDS), long-standing immunosuppressive therapy (e.g., post transplantation), Crohn's disease, and radiation therapy.

Marginal zone B-cell (MALT) lymphoma

Lymphomas of MALT are the most frequent primary lymphomas of the small intestine in the Western world but are much less frequent than gastric MALT lymphoma. There is a unique form of MALT lymphoma seen in Mediterranean areas and the Middle East referred to as immunoproliferative small intestinal disease (IPSID), which includes a spectrum of diseases including α heavy chain disease.

Small intestinal MALT-type lymphoma typically occurs in patients over the age of 50 years, with a slight male predominance. It is an indolent lymphoma; disease is often localized at diagnosis and may include mesenteric nodal involvement but typically no systemic spread. Long-term disease-free survival and cure are common. Unlike their gastric counterparts and IPSID, small intestinal MALT lymphomas have no clear infectious etiological associations. Presenting symptoms typically include abdominal pain and weight loss. Aggressive, diffuse, large B-cell lymphomas also develop in the intestine both as de novo lesions and through transformation from MALT lymphoma. Most of these large-cell lymphomas occur in older adults, but they can also rarely occur in children.

Small intestinal MALT lymphomas typically appear as ulcerated, exophytic, or annular mass lesions but rarely as small polyps. Deep mural invasion is typical although disease may be confined to the mucosa. The distal small intestine, particularly the ileocecal region, is the most frequent site but any part of the small intestine may be involved. The histology of small bowel MALT lymphoma is similar to that of gastric MALT lymphoma except lymphoepithelial lesions are often less prominent. The lesion typically progresses from an infiltrate between preexisting lymphoid follicles to one in which neoplastic cells erode and eventually overrun the lymphoid follicles, resulting in a vague nodularity or a completely diffuse infiltrate composed of marginal zone B cells that have a variable appearance even within the same tumor. They are intermediate size, with irregular nuclei and a rim of variable amounts of pale cytoplasm, giving them an overall appearance that ranges from a mature small B lymphocyte to a monocytoid appearance. Plasma cell differentiation is not uncommon and may be striking. The presence of moderate nuclear atypia, Dutcher bodies, and prominent lymphoepithelial lesions characterized by clusters of neoplastic cells infiltrating and destroying glands are features highly suggestive of lymphoma.

The presence of a large-cell component may represent transformation of a MALT lymphoma but criteria for diagnosing transformation to large-cell lymphoma are not well defined. When a large-cell component is prominent with clusters and sheets of large cells, a diagnosis of large-cell transformation or composite tumor has been suggested. When only focal large cells are present it should be noted in the report, but is a more dubious finding. If the tumor is composed exclusively of large cells, a diagnosis of extranodal diffuse large B-cell lymphoma should be made.

Immunohistochemistry is very useful in the diagnosis of MALT lymphoma; the labeling pattern is $CD20^{+}CD10^{-}CD5^{-}$. Coexpression of CD43 in CD20-reactive cells is a helpful finding when present but is only seen in about half of cases. The lesional cells express surface, and to a lesser extent cytoplasmic, immunoglobulin (usually IgM or IgA, rarely IgG) and show light chain restriction. Cytokeratin antibodies may highlight lymphoepithelial lesions, and follicular dendritic cell markers (CD21, CD23 ands CD35) help demonstrate the underlying follicular dendritic cell networks in those cases in which the lymphoid follicles have been obliterated by lymphoma. Ki-67 labeling index is low and can be useful for distinguishing from large-cell lymphoma.

Overall, long-term disease-free survival and cure are the norm. Primary therapy is en bloc resection of the bowel and contiguous lymph nodes in addition; radiation therapy and chemotherapy are often used postoperatively. Patients most likely to relapse include those with nodal involvement, extension beyond the bowel wall, and high-grade histology.

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (α heavy chain disease, Mediterranean lymphoma, and diffuse small intestinal lymphoma), a special form of MALT lymphoma restricted to a limited geographic distribution, is characterized by synthesis of α heavy-chain immunoglobulin. IPSID typically afflicts young adults and is slightly more common in males. It is seen almost exclusively in the Middle East and Mediterranean regions [285]. Common risk factors include low socioeconomic status, endemic parasitic infestation, poor sanitation, and infantile infectious enteritis. Some genetic factors have also been implicated. Presentation is typically severe, with malabsorption and chronic severe intermittent diarrhea and weight loss. α Heavy chain paraproteinemia (α heavy chain immunoglobulin without associated light chain) is present in up to 70% of IPSID cases; blood levels are at their highest early in the course and may diminish with progression of disease.

IPSID is generally a diffuse infiltrating lesion; initially the mucosa may appear normal then develop a cobblestone appearance and eventually may form lymphomatous masses. Mesenteric lymph node involvement occurs early in the course. The primary site of involvement is the proximal small intestine, but any part of or the entire small intestine may be affected. The stomach and colon can also be involved.

IPSID demonstrates a histological spectrum ranging from low- to high-grade histology, subclassified into stages A–C. All stages exhibit at least some features typical of other MALT lymphomas but usually with more striking plasma cell differentiation.

- Stage A is characterized by a lymphoplasmacytic infiltrate with features of a typical MALT lymphoma (reactive follicles with parafollicular clusters of clear cells and lymphoepithelial lesions) that is confined to the mucosa and which expands

the lamina propria causing broad villi, but may involve mesenteric lymph nodes.

• In stage B disease, the infiltrate becomes nodular, goes beyond the mucosa into the submucosa, and has mild cytological atypia. The macroscopic appearance at this stage is typically abnormal, with thickened mucosal folds. In MALT lymphoma with follicular colonization, the neoplastic cells may completely replace the follicle making distinction from a follicular lymphoma difficult.

• Stage C is characterized by the presence of large masses and transformation to large-cell lymphoma with numerous centroblasts and immunoblasts. Plasmacytoid differentiation is still evident but there is marked cell atypia including Reed–Sternberg cells. Mitotic activity is increased.

The lymphoma cells are $CD20^{+}CD5^{-}CD10^{-}CD23^{-}$. Immunoglobulin α heavy chains can be demonstrated in the cytoplasm of the infiltrating plasma cells, centrocytes and transformed blast cells.

The differential diagnostic considerations depend on the stage of IPSID. Early disease (stage A) may have a similar appearance to that of gluten-sensitive enteropathy (GSE). Unlike IPSID, GSE has prominent intraepithelial lymphocytes, true villous blunting, and crypt hyperplasia and clinically GSE is usually seen in northern Europeans and responds to a gluten-free diet. Intestinal T-cell lymphoma, while diffuse like IPSID, infiltrates the surface epithelium and is clearly is defined by immunohistochemistry ($CD3^{+}CD20^{-}$).

The nodular lesions of stage B disease require distinction from reactive follicular hyperplasia, and mantle cell and follicular lymphoma. Reactive follicular hyperplasia is unusual in the proximal small bowel and lacks prominent lymphoepithelial lesions and the typical MALT-type neoplastic cell of IPSID with pale/clear cytoplasm. Compared with other low-grade lymphomas, IPSID demonstrates monocytoid cells as well as plasmacytoid differentiation, and lymphoepithelial lesions and lacks the monotonous appearance of mantle cell lymphoma as well as the cleaved cells of follicular lymphoma. Immunohistochemical staining is very helpful in separating IPSID from the other low-grade lymphomas as IPSID is positive for α heavy chain and negative for CD5, CD10, and CD23.

The differential diagnosis of stage C disease is that of other high-grade malignancies, especially diffuse large B-cell lymphoma, but can be differentiated by the presence of residual MALT lymphoma with characteristic features and α heavy chain staining.

There is no well-established regimen for optimal treatment strategies. Early-stage disease responds to antibiotics. Later in the course as the tumor becomes more invasive and develops high-grade histology, radiation therapy or combination chemotherapy with nutritional support are typical treatments. Surgery is rarely indicated because intestinal involvement is generally diffuse. Prognosis has been traditionally considered poor but more recent studies note 5-year survival of 70%.

Mantle cell lymphoma

Mantle cell lymphoma (MCL) is a disease of older adults (mean age 55 years) with a male predominance (at least 2 : 1). Typically, it is a nodal-based disease but extranodal disease is common, particularly in the spleen and bone marrow. Gastrointestinal tract involvement is found in about one-third of MCL patients. Any part of the GI tract can be involved, but the ileum is favored.

When MCL involves the GI tract nearly all cases (~ 90%) have both distal small bowel and colon involvement. Involvement of the stomach and duodenum are also very common, seen in about half of patients [286]. Frequently MCL manifests as an isolated mass or small nodular polypoid tumors (2 mm to more than 2 cm in size), with or without normal intervening mucosa. The manifestation of multiple polypoid masses is termed *lymphomatous polyposis*. This pattern is most commonly associated with MCL but not specific for it. Mesenteric node involvement often accompanies GI tract disease.

The lymphoma cells are small to medium sized with scant cytoplasm; the nuclei have irregular outlines and indistinct nucleoli. Large transformed cells and proliferation centers are not typically present giving MCL a much more monotonous appearance than other low-grade lymphomas. Mitotic figures are easily identified. The most common architectural pattern is diffuse; however, both a nodular pattern and true mantle zone pattern can also be observed. Reactive germinal centers may be intermixed with and compressed by the lymphoma. Although displacement or obliteration of the glands may also be evident, lymphoepithelial lesions characteristic of MALT-type lymphomas are absent.

The tumor cells are mature B cells that express both CD19 and CD20, and aberrantly express CD5 and CD43. They lack CD10 and CD23. Cyclin D1 (BCL-1) is virtually always present. Surface light chains are present (usually IgM or IgD) and are typically λ restricted.

Although systemic chemotherapy is the treatment of choice, MCL is presently considered incurable, with a median survival of 3–5 years. Aggressive chemotherapy followed by autologous stem cell transplantation may benefit younger patients. Surgery has a relatively small role in the management of this disease, but may be necessary to relieve bowel obstruction.

Burkitt lymphoma

Burkitt lymphoma (BL) is a highly aggressive B-cell neoplasm that occurs in three major clinical forms: endemic, sporadic, and immunodeficiency associated [287–290]. All three types present primarily in extranodal sites including the GI tract.

Endemic BL is found primarily in Africa where it is the most common childhood malignancy and has a male predominance (male/female ratio 2 : 1). It typically presents with jaw, orbit or paraspinal lesions and is strongly associated

with EBV infection. It is unusual for African endemic BL to affect the GI tract. However, in other endemic regions (particularly the Middle East) BL frequently presents with intestinal obstruction or intussusception due to ileocecal involvement. Sporadic BL presents throughout the industrialized world, where it exhibits a wider age distribution. Half of cases involve children and the remainder occur in young adults but, as for endemic BL, the male to female ratio is about 2 : 1 and it is associated with EBV infection, particularly early in life. Sporadic BL frequently presents as an abdominal mass due to primary intestinal involvement (usually ileocecal), typically causing abdominal pain and obstructive symptoms. In adults, tumors can arise at any site in the GI system, but are most common in the ileocecal region and the rectum. Immunodeficiency-associated BL is primarily seen with HIV infection, often as the first manifestation of AIDS. EBV infection is found in up to half of cases. BL can be seen in other non-HIV immunodeficiency states, but not as often.

Gastrointestinal BLs of all clinical types have a predilection for the ileocecal region and less often rectum and stomach. They are bulky tumor masses that typically replace areas of involvement. They have a solid glistening white cut surface (fish flesh appearing) that is often associated with hemorrhage and necrosis. Lymph nodes are often surprisingly uninvolved but instead enveloped by tumor.

The morphology varies, with three common patterns: classic BL, BL with plasmacytoid differentiation, and atypical BL. The imprint morphology is distinct and well described, and thus touch preps and smears are helpful in the diagnosis. All the patterns share extremely high proliferation rates (manifest by numerous mitotic figures and very high Ki-67 labeling index) and high rates of spontaneous cell death (manifest by numerous macrophages with ingested apoptotic tumor cells, so-called "tingible body" macrophages). Classic BL morphology is seen in endemic BL and in most sporadic BL, and is characterized by a starry sky appearance, composed of diffuse monotonous pattern of infiltration of medium-sized cells (the "sky") admixed with frequent tingible body macrophages (the "stars"). The cells may have squared-off borders that make them appear cohesive at times. The nuclei are round with clumped chromatin and contain three to four centrally located small basophilic nucleoli. The cytoplasm is deeply basophilic and cytoplasmic lipid vacuoles are readily apparent. The atypical BL pattern has more pleomorphism than the monotonous classic BL morphology, and fewer but more prominent nucleoli. BL with plasmacytoid features has eccentric nuclei with only a single nucleolus; this morphology is more common in immunodeficiency-associated BL.

The tumors cells are positive for CD20 and CD10, and negative for CD5, BCL-2, and terminal deoxynucleotidyltransferase. Ki-67 labeling is seen in nearly 100% of cells. CD3-positive T cells are typically less common than the numbers seen infiltrating diffuse large B-cell lymphoma.

BL is a highly aggressive tumor but is potentially curable in the majority of patients. Prognosis depends on stage and is generally better in children. The mainstay of treatment is intensive combination chemotherapy regimens that result in 90% cure in low-stage disease and 60%–80% cure rate in advanced-stage disease. The prognosis for HIV-associated Burkitt-like lymphomas is related more to the underlying HIV syndrome than the lymphoma itself. Even Burkitt leukemia and those with central nervous system involvement can be cured. Surgical therapy has a role in treatment when debulking is required.

T-cell lymphoma

Intestinal T-cell lymphomas are far less common than those of B-cell origin. The majority of T-cell primary GI lymphomas occur in the setting of GSE and are specifically referred to as enteropathy-type T-cell lymphoma (ETL). ETL is rare (~ 5% of all GI tract lymphomas). Refractory GSE and particularly ulcerative enteritis (jejunitis) probably represent the first step toward ETL, although not all cases appear to progress to ETL [251]. The mean age of patients with ETL is 60 years with no gender predilection. The geographic distribution of ETL follows that of GSE, with the highest incidence in northern Europe. Immunodeficiency states are seldom associated with ETL. Since many patients presenting with ETL appear to have subclinical GSE, all patients with T-cell lymphoma of the gut should probably be tested for occult celiac disease.

ETL occurs most commonly in the jejunum, alone or in combination with other sites in the GI tract. The affected bowel segment is often dilated and edematous with large circumferential ulcers, ulcerated plaques and strictures with intervening areas of normal mucosa. Bulky exophytic or infiltrating masses are not typical but may be seen on occasion. Mesenteric lymph node involvement is common.

The histological appearance of ETL is quite variable between individual cases and between different sites in the same patient. Three basic types can be discerned, but transition between morphologies is common in the same case. The most common histological pattern is that of an infiltrate of pleomorphic medium to large cells followed by an anaplastic type with marked pleomorphism, both of which are associated with fibrosis and admixed inflammatory cells. The third type is composed of monomorphous small to medium-sized cells lacking background inflammation and fibrosis. The pleomorphic medium to large cell type is the most frequent morphology seen and is characterized by irregular nuclei with small nucleoli and moderate amounts of often pale cytoplasm. All the subtypes are associated with destruction of the overlying epithelium by the lymphoma cells. The areas of epithelium most affected are the upper and intermediate villous regions, or in the presence of villous atrophy the upper aspect of the crypts. In the majority of cases, endoscopically normal background mucosa shows changes

of GSE (intraepithelial lymphocytosis, villous blunting and crypt hyperplasia).

Most cases are positive for CD3 and CD7 and negative for CD4, CD8, CD5, and CD56 and express cytotoxic granule-associated protein TIA-1 often with granzyme B. CD56 has been used to describe two variants of ETL, type A ($CD56^-$) and type B ($CD56^+$ and $CD8^+$). The immunohistochemical labeling pattern of ETL correlates to some extent with the histological pattern. Both the medium to large pleomorphic and the anaplastic variants of ETL are usually type A ($CD56^-$) often with $CD30^+$, but are always negative for ALK1. Most of the type B ($CD56^+$) lymphomas are the small to medium-sized variant.

The prognosis is dismal, with a median survival of only 3 months and 5-year survival rates of approximately 10%. Patients suffer complications of peritonitis and malnutrition initially and later from progressive disease. A significant number of patients cannot tolerate chemotherapy due to underlying malabsorption. Factors associated with long-term survival include absence of a previous diagnosis of GSE and tolerance of a complete course of chemotherapy.

Carcinoid tumors

Carcinoid tumors (well-differentiated neuroendocrine tumors) of the small intestine account for about one-third of small intestine neoplasms. They seem to be overrepresented in African Americans [216,217,291]. Small intestinal carcinoids derive from two separate embryonic divisions of the alimentary tract, the foregut (duodenum) and the midgut (jejunum and ileum); these different origins correlate with distinct neuroendocrine differentiation and clinical behavior of these tumors.

Duodenal carcinoids are the second most common tumor in that site after adenocarcinomas and represent about 20% of GI tract carcinoids [292]. Overall, duodenal carcinoids are more common in men (male/female ratio 1.5 : 1) with a median age of 59 years (range 33–90 years). Two-thirds of duodenal carcinoids are gastrinomas (G-cell tumors); of the remaining one-third most are somatostatinomas (D-cell tumors) with a small percentage of undefined type. Only one-third of gastrinomas are functional and cause Zollinger–Ellison syndrome; these duodenal tumors account for half of cases of Zollinger–Ellison syndrome, the remainder being caused by pancreatic endocrine tumors. One-third of somatostatinomas are associated with von Recklinghausen disease. The somatostatinoma syndrome (diabetes mellitus, diarrhea, cholelithiasis), associated with pancreatic islet cell tumors, is virtually never seen in its entirety with these intestinal tumors. Proximal small intestinal carcinoids virtually never produce the carcinoid syndrome. Functional gastrinomas and somatostatinomas present in slightly younger patients than nonfunctioning gastrinomas and somatostatinomas are slightly more common in females. Nonfunctioning gastrinomas are usually located in the bulb, while their functional counterparts are found equally in all parts of the duodenum. Somatostatinomas are typically found in the periampullary region [293]. The carcinoid syndrome (watery diarrhea, flushing, endocardial fibrosis) is seen in 5%–7% of cases and jejunoileal carcinoids account for the majority of carcinoid syndrome cases overall. Nearly one-third of patients diagnosed with a small intestinal carcinoid have a synchronous or metachronous carcinoma (e.g., colon, stomach, lung, and breast).

Duodenal tumors can be readily biopsied and diagnosed by endoscopy. The location of jejunoileal tumors makes diagnosis more problematic as they are often not amenable to endoscopy and conventional imaging techniques (CT and barium contrast studies) are not particularly sensitive. In these circumstances, use of radiolabeled somatostatin analogues (octreotide and lanreotide) in scintigraphy studies has proven a sensitive detection method of both primary and metastatic lesions. This is also an area for which capsule endoscopy offers promise [294].

Duodenal carcinoids are typically small polypoid lesions less than 2 cm in size. They are submucosal lesions with an overlying mucosa that may be focally ulcerated. Infiltrative larger tumors can occur but are infrequent. Gastrinomas tend to be smaller than somatostatinomas. A minority (15%) are multicentric.

Jejunoileal carcinoids are twice as likely to be multicentric (30%), tend to be large (> 2 cm), and commonly are locally advanced, with deep bowel wall and mesenteric tumor involvement causing significant mesenteric fibrosis and subsequent obstruction and kinking of the bowel. Frank intestinal ischemia may also be seen due to tumor-induced angiopathy. Like duodenal carcinoids, jejunoileal tumors are typically centered in the deep mucosa or submucosa, and the overlying mucosa is typically intact or only slightly eroded.

The distinction between benign and malignant carcinoid is based on the presence or absence of metastasis rather than histology alone, since even clinically malignant tumors show little or no cellular pleomorphism, hyperchromasia, or increased mitotic activity. Carcinoids are characterized by a monotonous proliferation of small bland polygonal cells with moderate amounts of cytoplasm, and round regular nuclei with "salt and pepper" chromatin. Pleomorphism and significant mitotic activity are conspicuously uncommon. Morphological features of the cells do not differ by cell of origin (immunohistochemistry is required for this distinction). Carcinoids demonstrate variable architectural growth patterns. These do not have prognostic significance, but may be characteristic of certain carcinoid subtypes. The main architectural patterns are insular or nested (type A), trabecular (type B), and acinar (type C). These patterns often overlap and multiple patterns are typically seen within any single tumor. Since these categories offer no prognostic information, there is little to be gained by reporting them and many pathologists do not.

Duodenal G-cell tumors can manifest a variety of architectural growth patterns, whereas somatostatinomas often have characteristic features of prominent acinar growth pattern with frequent intraluminal psammoma bodies. Jejunoileal carcinoids, like G-cell tumors, do not display any consistent characteristic growth patterns. They typically display prominent nested growth, with more trabecular and acinar growth peripherally. These tumors are often larger and extend deeply into the bowel wall and can be associated with significant fibrosis.

Although carcinoid tumors can show immunohistochemical evidence of multiple hormone production, this information is typically not clinically significant. The vast majority of small intestinal carcinoids are positive for chromogranin and synaptophysin, and these markers are useful in confirming the diagnosis of carcinoid. Specific cell types (e.g., G-cells) can be identified by immunohistochemical labeling but the utility of this is limited as functional status correlates poorly with immunohistochemistry.

Duodenal carcinoids are generally indolent (overall 4% mortality); however, two-thirds of somatostatinomas and half of functional gastrinomas behave aggressively. Poor outcome in duodenal tumors is best predicted by invasion beyond the submucosa and lymph node or distant metastases. Jejunoileal carcinoids have a worse prognosis than those of the duodenum, with a 21% mortality rate. Survival has been negatively correlated with distant metastases (liver), tumor multiplicity, mitotic rate, invasion beyond submucosa, and female gender. Pathological features that have been associated with behavior are size, depth of invasion beyond submucosa, mitotic activity, and lymph node involvement.

Mesenchymal tumors

Gastrointestinal stromal tumors

Overall, GISTs of the small bowel should be regarded with caution compared with those in the stomach, which more often behave in a benign than malignant fashion [295,296]. They are not typically diagnosed on biopsies. When biopsies are evaluated, it is prudent to perform an immunohistochemical panel that includes CD117, CD34, SMA, desmin, keratin, and S100 protein.

Gangliocytic paraganglioma

These are rare and fascinating tumors, the vast majority of which are found in the duodenum in adult patients (average age about 54 years) [297–302]. The typical presentation involves abdominal pain, gastric outlet obstruction, or bleeding. There are isolated reports of an association with neurofibromatosis, but most cases are sporadic. These lesions typically have their epicenter in the submucosa with minor extensions into the mucosa that are occasionally biopsied. Excised tumors are 3–4 cm in size with a soft yellowish cut surface. They have infiltrative borders.

These tumors display a histological constellation of three cell types: spindle cells with the appearance of nerve sheath cells, ganglion-like cells, and epithelioid cells arranged in nests (endocrine pattern), trabeculae or papillary structures. The proportion of the cell types is variable and hence these lesions are prone to causing diagnostic problems.

On immunohistochemistry, the tumors are reactive with S100 protein in spindle and supporting/sustentacular cells, with synaptophysin in ganglion-like cells, and with neuron-specific enolase in all three cell types [297,300]. About half of cases display keratin in epithelioid cells. A variety of hormones can be demonstrated in various fractions of gangliocytic paragangliomas, including somatostatin, human pancreatic polypeptide, serotonin, gastrin, glucagon, insulin, and vasoactive intestinal peptide.

In lesions dominated by spindle cells, the differential diagnosis is with GISTs and nerve sheath tumors: positivity for S100 protein excludes GIST; finding the admixture of other cell types excludes nerve sheath tumors. Epithelioid lesions are distinguished from carcinoid tumors and carcinomas by the admixture of other cell types.

Gangliocytic paragangliomas are benign in the majority of cases. There are rare reports of regional metastases [298,299] but not of tumor-associated deaths.

Colon

Nonneoplastic conditions

In the USA, the most common cause of chronic diarrhea is irritable bowel syndrome (IBS), a condition with a prevalence of 6%–20% depending on inclusion criteria. Diagnosis is based on a set of criteria that include continuous or recurrent abdominal discomfort, bloating or distention, sometimes associated with a change in stool frequency or appearance. The American Gastroenterological Association advocates colonoscopy as part of the evaluation of patients with presumed IBS who are over 50 years old or in whom there are symptoms that might suggest another disease (diarrhea predominance or weight loss) [303]. Thus, most of the colonic biopsies reviewed as part of the evaluation for chronic diarrhea can be expected to have essentially normal histology and should be reported as such. This requires an understanding of the histological features of normal mucosa from all parts of the colon and rectum, as well as the ability to recognize histological "abnormalities" that can be ignored.

Normal histology in the colon reflects function of the specific site. Liquid stool from the small intestine enters the cecum and water is progressively absorbed such that the colonic contents has the consistency of feces by the time it has reached the descending colon. The colonic mucosa produces abundant mucus that lubricates the surface and facilitates the passage of fecal material. The differences in the normal histology of the right and left colonic mucosa reflect

these functions of absorption and lubrication. In the crypts of the right and transverse colon, absorptive cells predominate, although the larger goblet cells are more conspicuous. The lamina propria in these proximal segments of the colon is more cellular than that of the distal colon and rectum, and includes abundant plasma cells (involving the full thickness of the mucosa), lymphocytes, and eosinophils. Paneth cells may be found in the cecum and right colon. In contrast, goblet cells increase sharply in number, and absorptive cells are fewer in the left colon and rectum. The lamina propria is much less cellular, with fewer eosinophils. Plasma cells are present only beneath the surface epithelium more distally.

Lymphoid aggregates are normal and prominent intraepithelial lymphocytes are normally found over lymphoid aggregates. Macrophages are normally present, and play a role in the processing and presentation of antigens. They aggregate in the superficial lamina propria, where they phagocytose cellular debris from normal apoptosis of surface epithelial cells. Surface apoptosis is more prominent in the left colon and rectum than in the proximal colon.

Although eosinophils are present in the lamina propria of nearly all right colonic biopsies, their numbers vary greatly, particularly between geographic regions, being generally more numerous in warmer areas in the USA [304]. Paneth cells are abnormal outside of the right colon (although we accept them up to the splenic flexure); their presence in the left colon is metaplastic, usually in response to chronic inflammation or injury.

Effects of bowel preparation and other artifacts

Bowel preparation for sigmoidoscopy and colonoscopy may induce a number of mucosal injuries that must be recognized lest they be misinterpreted as pathological. Hypertonic enemas, generally used before sigmoidoscopy, may injure the mucosal surface, resulting in flattened or absent surface epithelium, loss of epithelial mucin, or slight neutrophilic inflammation. The lamina propria may be edematous or hemorrhagic [305].

The two most commonly used preparations for full colonoscopy are sodium phosphate and balanced electrolyte solutions containing polyethylene glycol (PEG). Sodium phosphate bowel preparations (e.g., Fleet enema) are preferred by many patients, and thus are currently the most common bowel preparation in adult patients, the exception being those who cannot tolerate the potential fluid and electrolyte shifts. Oral sodium phosphate preparations are strong osmotic laxatives that induce a number of endoscopic and histological changes. The most common endoscopic change is the presence of what appear to be small aphthous lesions: small foci of pale mucosa surrounded by erythematous rings that look like shallow erosions. These aphthous-like lesions have been described in up to one-fourth of patients after sodium phosphate bowel preparation. Histologically, these are usually large lymphoid aggregates, although some authors have described edema, hemorrhage, or acute inflammation [306–308]. The lesions disappear when colonoscopy is repeated with an alternate bowel preparation, and so are clinically unimportant. Oral sodium phosphate bowel preparation is also believed to induce foci of neutrophilic cryptitis (focal active colitis) in about 3% of patients. Whereas apoptosis is normal in the surface epithelium, scattered apoptotic bodies at the bases of crypts are found after sodium phosphate bowel preparation. These apoptotic bodies have been counted at about 1 per 10 well-oriented crypts [308].

Other endoscopic and biopsy-related artifacts

During the course of colonoscopy, gas is induced to insufflate the bowel for better visualization of the mucosa. Small amounts of this gas may infiltrate tissue and appear as small, clear, bubble-like spaces in the mucosa or superficial submucosa, often in or near lymphoid aggregates. Because these spaces resemble adipocytes, this phenomenon has been termed *pseudolipomatosis* [309]. Biopsy forceps can also induce tissue trauma, resulting in mucosal hemorrhage, crushing of epithelium that may resemble dysplasia, and an artifact in which the epithelium is squeezed entirely out of the crypts leaving empty crypts. This squeeze artifact is common on the edges of mucosal biopsies and usually readily recognized. However, when a large area is involved, it may be mistaken for ischemic injury.

Focal active colitis

Focal active colitis (FAC) is the term used to describe focal neutrophilic infiltration of colonic crypts. It may consist of one focus in a single biopsy, or multiple foci. Since focal inflammation is a feature of Crohn's disease, studies of FAC have examined whether it antedates subsequent development or diagnosis of Crohn's disease. In two studies of adult patients with FAC in colon biopsies, only a very few developed Crohn's disease [310,311]. Many seemed to have a clinical course that resembled infectious diarrhea, although this may have had no relationship to the FAC and may simply have reflected a common indication for endoscopy. However, in a group of pediatric patients with FAC, a higher proportion (27.6%) went on to develop Crohn's disease [123]. In Greenson's studies, no adult patient with FAC developed Crohn's disease and the only endoscopic abnormalities were aphthous or aphthous-like ulcers, possibly artifacts of bowel preparation. In contrast, in the pediatric group, 2 of 17 patients with normal colonoscopy developed Crohn's disease, compared with 6 of 11 with abnormal colonoscopy. Thus, it seems that in adult patients without history or endoscopic features suggestive of Crohn's disease, FAC can be safely ignored whereas it should probably be followed when it is found in pediatric biopsies.

Lamina propria macrophages

Macrophages are a normal constituent of the colonic lamina propria, where they serve roles in antigen processing and

phagocytosis of surface epithelial cells that have undergone apoptosis. CD68 immunostaining highlights a gradient in their distribution, with more macrophages in the upper lamina propria and fewer deeper [312]. Pigmented macrophages are referred to as melanosis coli and those containing mucin as muciphages.

When muciphages are present in otherwise normal biopsies, the usual gradient is reversed, as they tend to accumulate in the lower part of the mucosa. Muciphage aggregates are found associated with crypt rupture from any cause and so are seen in many settings [312]. Ultrastructural study supports degenerated epithelial cells as the source of the mucin [313]. Muciphages must be distinguished from the macrophages of Whipple disease and mycobacterial infection and from carcinoma, but it is not usually necessary to perform a full workup in any given case since aggregates of muciphages are very common in colorectal mucosa, present in 40% of otherwise normal rectal biopsies [314]. They are presumed to reflect occult and clinically unimportant epithelial injury, such as trauma related to stool passage, or subclinical infection.

The term melanosis coli is a misnomer. The brown pigment that accumulates in lamina propria macrophages in this condition is lipofuscin not melanin (Fig. 137.69). Although it is most often seen in right colonic biopsies, it can be found throughout the colorectum, appendix, and terminal ileum. It is extremely common and detected in the majority of elderly individuals. In one study of 200 patients, of men and women in the age group 20–54 years, 32% and 44% were affected; above the age of 75 years, 76% and 67% respectively were affected [315]. Lipofuscin accumulates by phagocytosis of apoptotic epithelial cells [316–318]. There is a strong association with anthraquinone and other laxatives because they induce apoptosis [319–321], but melanosis may be a result of any process associated with apoptosis, such as NSAID use.

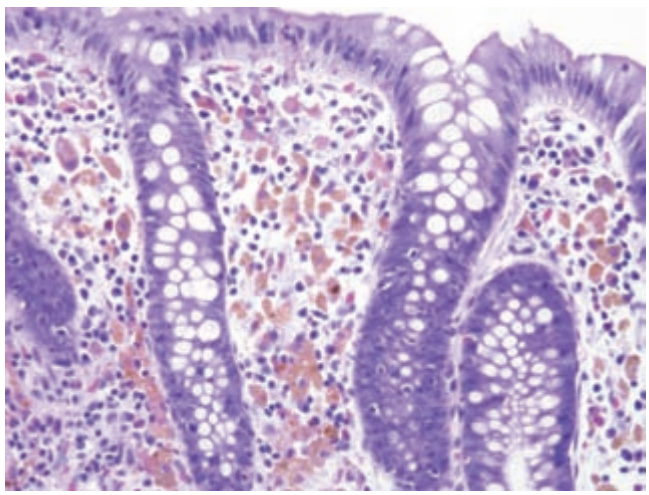

Figure 137.69 Melanosis coli. The pigment in the lamina propria macrophages is lipofuscin rather than melanin.

Many patients with melanosis have not used laxatives, including those with ulcerative colitis and Crohn's colitis [322].

Ulcerative colitis

As discussed in detail elsewhere in this text, ulcerative colitis is a chronic crypt-destructive inflammatory process of unknown cause characterized by predominantly mucosal-based disease and clinically associated with exacerbations and remissions of bloody diarrhea. The initial presentation may be indolent in onset or may be severe and acute presenting with toxic hemorrhagic colitis. In children, initial biopsies may be nondiagnostic since they are likely to be brought to medical attention before histological features of chronicity are evident (whereas adults wait until they have been symptomatic for months to years before seeking attention) [123,323,324].

The gross endoscopic appearance of ulcerative colitis varies with the degree of activity, duration of disease, and response to therapy. It is characterized by diffuse disease with rectal involvement extending proximally. In the more active phases the mucosa is typically erythematous, bloody, and friable with a granular appearance. Quiescent disease may appear granular with areas of punctate erythema. Pseudopolyps (mucosal remnants) and inflammatory polyps may be seen in active disease and postinflammatory polyps in active or quiescent disease. In all cases, the normal submucosal vascular network is lost and for the endoscopist is an important clue indicating chronic colitis. In patients who have had repeated bouts of colitis, the normal haustral folds may be absent. The transition between normal and abnormal mucosa is generally gradual but may be abrupt. Except for the occasional presence of focal cecal or periappendiceal involvement ("skip areas"), there is no loss of disease continuity and no skip lesions are seen in ulcerative colitis.

On biopsies, crypt architectural distortion and increased mucosal chronic inflammation are the two characteristic histological findings (Figs 137.70–137.72). Neutrophils, the hallmark of active disease, are located within crypt epithelium (cryptitis) and crypt lumina (crypt abscesses) with fewer within the lamina propria around the crypts. Architectural distortion results from prior mucosal destruction and imperfect repair, resulting in decreased numbers of crypts and branched, malformed, regenerated crypts (crypt-destructive colitis refers to the distortion of regenerated crypts rather than active destruction of crypts due to cryptitis). The chronic inflammatory constituents consist of variable numbers of plasma cells, eosinophils, and lymphocytes. Eosinophils may predominate. Lymphoid aggregates are commonly seen at the mucosal–submucosal interface. The regenerating epithelium is immature and as such does not contain mucin, typical of a mature goblet cell (mucin depletion). Biopsy fragments from the same topographic area typically show similar findings. Inflammation is usually more severe distally. Of course granulomas are lacking but occasionally a foreign-body re-

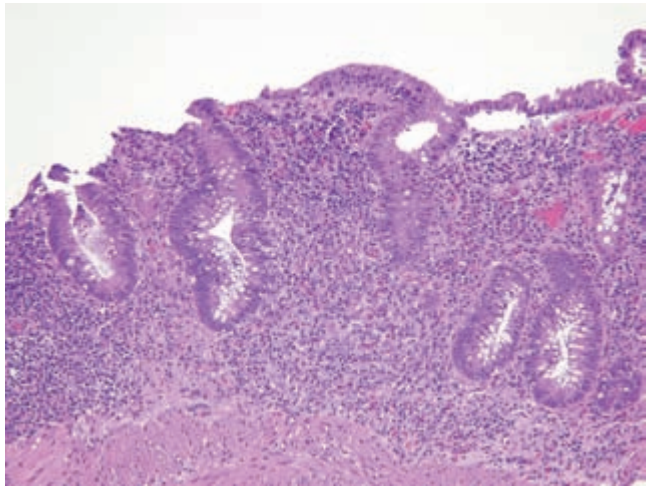

Figure 137.70 Ulcerative colitis. In this field, the crypts are distorted and do not reach the muscularis mucosae at the bottom of the field.

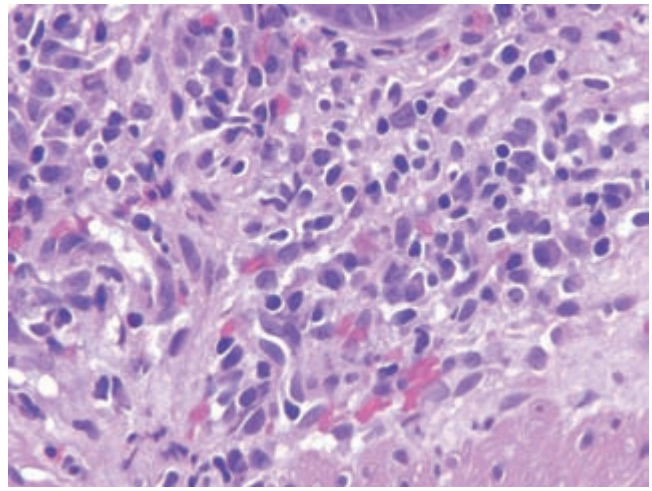

Figure 137.72 Ulcerative colitis. This field shows basal plasmacytosis, a feature of chronic injury. Plasma cells are seen between the base of the crypts and the top of the muscularis mucosae.

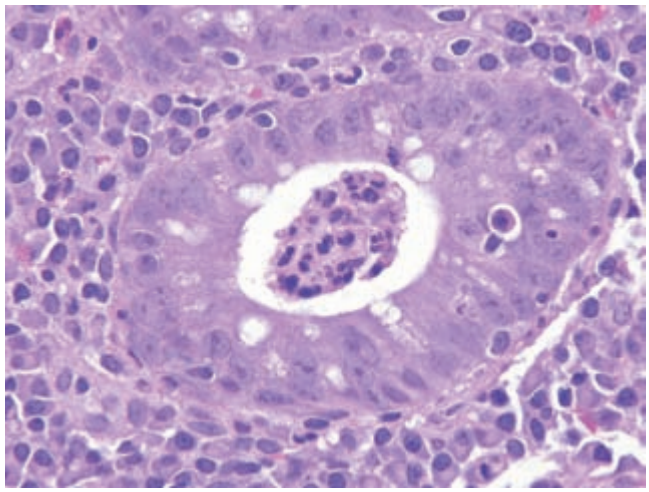

Figure 137.71 Ulcerative colitis. This field shows a crypt abscess (a collection of neutrophils within a crypt).

sponse to a ruptured crypt may be found. Usually the damaged crypt that has invoked a foreign body response can be found on additional sections. Pyloric metaplasia is not typical in ulcerative colitis but is occasionally found. Of course, knowledge of upper tract findings is important since ulcerative colitis theoretically involves only the colon and not the upper tract.

Ulcerative colitis must be distinguished from infectious colitis, medication-induced colitis, ischemic colitis, and Crohn's disease. Long-standing infectious colitis may display the features of ulcerative colitis including increased chronic inflammation, neutrophils, basal plasmacytosis, and diffuse colonic involvement. A predominance of neutrophils within the lamina propria rather than within the crypt epithelium and overall architectural preservation supports infectious over ulcerative colitis. The initial episode of ulcerative colitis may appear histologically similar to infectious colitis and thus infectious etiologies should be excluded prior to confirming a diagnosis of ulcerative colitis. Medications, particularly NSAIDs, may present with focal acute colitis or ulcers throughout the colon. Histologically, NSAID ulcers are typically abrupt with no significant inflammation in the adjacent mucosa and minimal chronic inflammation. Chronic ischemic colitis can be mistaken for ulcerative colitis particularly because ischemia due to low vascular flow often affects the left colon and because it may be intermittent. As such, abrupt episodes of ischemia can result in mucosal ulceration which, following reperfusion, may become inflamed and show all the architectural features of ulcerative colitis. Features that support ischemia include age of the patient, location, involvement of the muscularis propria and, importantly, the lack of neutrophils destroying crypt epithelium. Crohn's lesions characterized by crypt destruction are typically patchy, with areas that appear involved and uninvolved within single biopsies and among different fragments from one area. Crohn's colitis typically lacks the diffuse crypt destruction characteristic of ulcerative colitis.

Once a patient is treated, the characteristic distribution of ulcerative colitis may become altered. Thus, a patient may display iatrogenic rectal sparing, something that should be remembered by pathologists interpreting biopsies from treated patients (the usual case). Most patients have mild to moderately active disease that does not require colectomy.

Long-standing ulcerative colitis is associated with an increased risk of dysplasia (Fig. 137.73) and adenocarcinoma, even in patients with well-controlled quiescent disease. Periodic colonoscopic examinations are used to survey for dysplasia and adenocarcinoma. Routine surveillance with biopsies is recommended annually for patients with extensive disease of

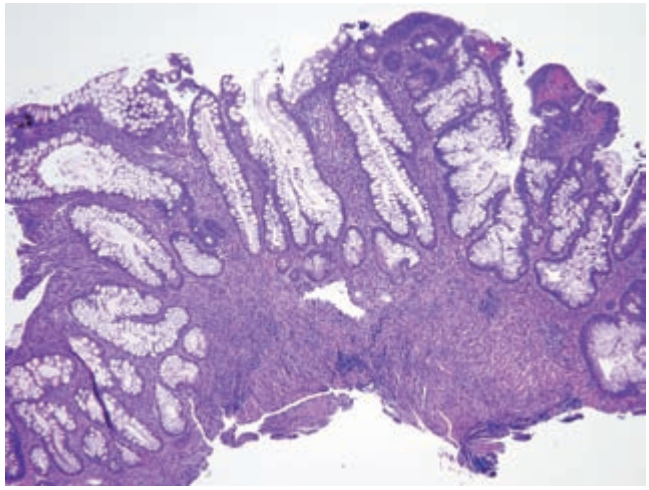

Figure 137.73 Ulcerative colitis. A zone of low-grade dysplasia is seen at the upper right portion of the field.

more than 8 years' duration because there is an increasing annual incidence of adenocarcinoma. Biopsies are generally taken from the cecum, ascending, splenic flexure, transverse, hepatic flexure, descending, and sigmoid colon, and rectum. The pathologist should record evidence of colitis, activity, and the presence or absence of dysplasia. As noted above, these surveillance biopsies often lack the typical distribution of ulcerative colitis but this should not prompt a diagnosis of Crohn's disease but rather of treated ulcerative colitis [325–327].

Crohn's disease

The biopsy features of Crohn's disease are addressed above as the small intestine is often the epicenter of disease, but Crohn's colitis is well known.

Mucosal biopsies, although superficial, can show features suggestive of Crohn's disease. Discrete foci of inflammation often associated with neutrophils within crypts (cryptitis) adjacent to histologically normal crypts are common. Aphthous erosions or ulcers, characterized by focal surface epithelial necrosis associated with a mixed chronic inflammatory infiltrate, sometimes associated with underlying lymphoid aggregates, are typical early lesions. Variability of inflammation within a single biopsy and among several biopsy fragments from the same anatomical location is also typical. The areas of inflammation show architectural changes of chronic crypt-destructive colitis while adjacent crypts may appear normal. Fissures may be apparent. Granulomas are infrequent but, when present, are usually poorly formed and associated with chronic inflammation.

If submucosa is present in the biopsy, there may be significant submucosal chronic inflammation while the overlying mucosa may be only slightly expanded by chronic inflammatory cells, a feature absent in infectious or ulcerative colitis. Pyloric metaplasia (mucinous glands, reminiscent of the antral or pyloric mucosa) indicates repeated bouts of inflammation and repair.

Crohn's colitis must be distinguished from infectious colitis, medication-associated colitis, and ulcerative colitis. The endoscopic finding of focal aphthous erosions of early Crohn's colitis may be similar to erosions caused by medications, bowel preparation, and infections. Erosions of Crohn's disease are associated with a chronic inflammatory infiltrate. Infectious colitis is characterized by a predominance of neutrophils rather than lymphocytes and plasma cells. Medication (NSAIDs and others)-induced erosions usually have negligible acute inflammation, typically only a few neutrophils in the area of erosion. The more advanced changes of Crohn's colitis, particularly discrete ulcers and masses seen endoscopically, must also be distinguished from those induced by medications and infection. NSAID ulcers may be multiple and deep. They tend to be on the top of mucosal folds and are circumferential rather than longitudinal. Biopsies often show fibrosis with only minimal inflammation. NSAID strictures may form; when these are circumferential, they are termed "diaphragms." Bowel wall thickening and heaped-up masses may be seen in *Yersinia* infection, particularly in the terminal ileum and right colon. The presence of marked inflammation histologically with numerous granulomas and the clinical information of a mass or stricture may lead to a diagnosis of Crohn's in a patient with yersiniosis or histoplasmosis. Features that suggest infection over Crohn's disease include numerous granulomas, granulomas centered in lymphoid follicles, and granulomas with central necrosis. Any specimen with numerous granulomas should suggest infection over Crohn's disease.

Fulminant Crohn's colitis is difficult or impossible to distinguish from ulcerative colitis in a mucosal biopsy specimen since many of the distinguishing features are deep to the mucosa. Furthermore, in fulminant (toxic) ulcerative colitis inflammation may become transmural. In resection specimens, the most important features are the presence of transmural lymphoid aggregates and the presence of occasional poorly formed granulomas at all levels of the bowel wall. The effects of treatment can also cause diagnostic difficulty as treated ulcerative colitis may show areas of involved and uninvolved mucosa and variable degrees of disease activity. It is important to ensure that there is re-review of original pretreatment material, if possible, to help distinguish between ulcerative and Crohn's colitis since patients with ulcerative colitis are candidates for ileal pouch anal anastomosis and those with Crohn's disease are not, because of the high risk of pouch failure due to anastomotic breakdown.

Pouchitis

Although technically pouchitis should be included under nonneoplastic small bowel conditions, it is included here because the continent pouch plays the role of a rectum. When Kock explained the creation of an ileal continent

pouch, he also described an inflammatory lesion that followed and this has been referred to as *pouchitis* [328–331]. Pouchitis is different from diversion colitis, which is found in blind pouches (Hartmann pouches) in contrast to continent ones such as Kock pouches or ileal pouch anal anastomosis. In a nutshell, the problem in pouchitis is that there really are no absolute criteria to determine whether the inflammation in a pouch is a reflection of the response of the ileal mucosa to serving as a rectum or a manifestation of recurrent inflammatory disease. When the pouch has been created after colectomy for a neoplasm rather than inflammatory disease, it is easier to dismiss the possibility of recurrent inflammatory disease but this is the minority of cases. In one study, pathological features that were associated with the subsequent development of pouchitis included the presence of severe colitis that extended into the cecum (severe pancolitis), early fissuring ulcers, active inflammation of the appendix, and appendiceal ulceration [272]. No significant differences in patient gender or age, depth or extent of ulceration, or the presence or absence of backwash ileitis were identified in patients with pouchitis compared with those without it. However, other observers have found an association between backwash ileitis and subsequent pouchitis [271].

The classic histological description includes neutrophilic inflammation in acute pouchitis and classic features of chronicity with villous atrophy in the chronic setting, all features that are identical to those of ulcerative colitis or Crohn's disease [332,333]. In fact, pyloric metaplasia is even seen in some examples and appears identical to that in the ileum in Crohn's disease [334–337]. However, these criteria certainly do not exclude infection or that the presumed ulcerative colitis patient actually has Crohn's disease. In some studies, pouchitis is classified as type A, B, or C:

- type A is defined as normal mucosa or mild villous atrophy with no or mild inflammation
- type B mucosa shows transient atrophy with temporary moderate inflammation followed by normalization of architecture
- type C mucosa is defined as a pattern of persistent atrophy with severe inflammation [338,339].

Some patients (type C) experience striking villous atrophy, and this may be the precursor to the small number of patients who develop dysplasia in their pouches [338–341]. In daily practice, we do not list response types as above but do make some attempt to report the degree of inflammation and the presence of extensive atrophy and allow our clinical colleagues to form the correlation with the endoscopic findings. A pouchitis activity disease index has been developed that combines clinical, endoscopic, and microscopic findings [342].

A more distressing concern in interpreting biopsies from patients believed to have ulcerative colitis at the time of resection involves the occasional patient who develops pouch complications that are indistinguishable from Crohn's disease. The conclusion of surgical and endoscopic colleagues is generally that the pathologist has misdiagnosed the resection specimen with ulcerative colitis when the patient in fact has Crohn's disease. In some instances this may be the case. Since patients with Crohn's disease in whom a continent pouch is attempted have terrible complications about half the time, most surgeons avoid creating continent pouches in these individuals (severe pouch complications are documented in about 20% of patients with indeterminate colitis and in about 8%–10% of those with ulcerative colitis). However, there is a small set of patients with classic ulcerative colitis in the view of all participating in their care who develop an idiosyncratic Crohn's-like disease in their continent pouch and it requires revision. This phenomenon was well described by Goldstein and occasionally it pays to be aware of this possibility [343].

Infectious colitis

The term acute self-limited colitis is used here to invoke features of colitis secondary to various bacteriological etiologies, with the exception of enterohemorrhagic *Escherichia coli* (mentioned below since it produces an ischemic colitis appearance). Such cases display neutrophils and crypt abscesses that tend to appear in the upper half of the mucosa and prominent neutrophils in the lamina propria [344]. The basal plasmacytosis seen in ulcerative colitis and Crohn's colitis is lacking [345]. Glandular architecture is preserved. Erosions and lamina propria edema may be seen. The course is self-limited and correlates with pertinent stool cultures. As acute self-limiting colitis heals (often when biopsies are taken), there are reactive epithelial changes but crypt architecture remains intact.

As for specific infectious agents affecting the colon, bacterial colitis is often a result of *Campylobacter* sp. or *Aeromonas* sp. but culture is required for precise typing. Of course, CMV infection may be encountered in many settings in which patients are immunosuppressed as can various parasites. The ova of schistosomes can be encountered (Figs 137.74 and 137.75) and *Strongyloides* is occasionally found on colon biopsies.

Colonic spirochetosis is a peculiar condition in which numerous unusual Warthin–Starry reactive organisms carpet the colon surface (Figs 137.76–137.78). It has been associated with abdominal pain, appendicitis, chronic diarrhea, and rectal bleeding in some cases, but in the majority of cases spirochetosis is an incidental finding with no clear clinical correlates. The anaerobic intestinal spirochetes *Brachyspira aalborgi* and *Brachyspira pilosicoli* seem to be responsible for most cases of spirochetosis. *Brachyspira pilosicoli* colonizes the intestinal tract of many animal species, especially pigs, and can be found in approximately 30% of feces from persons in developing countries. Koteish and colleagues have reported a retrospective analysis of colonic spirochetosis in 14 cases including four children and 10 adults seen at our hospital [346]. Two men had HIV infections. All children and both HIV-infected men had abdominal complaints, diarrhea, or

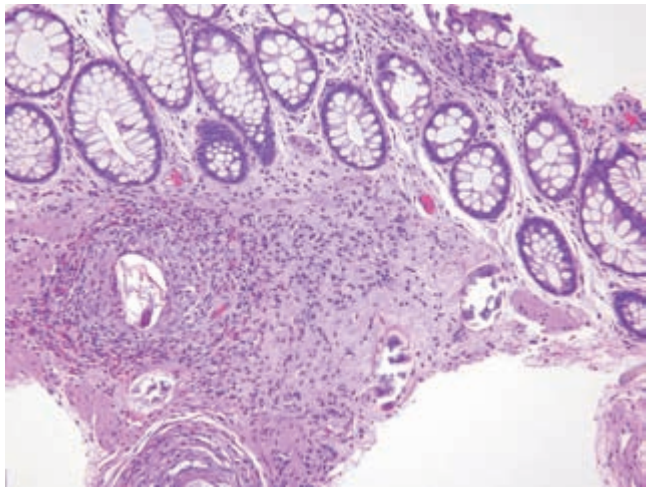

Figure 137.74 Schistosomiasis. Ova surrounded by eosinophils are seen in the submucosa.

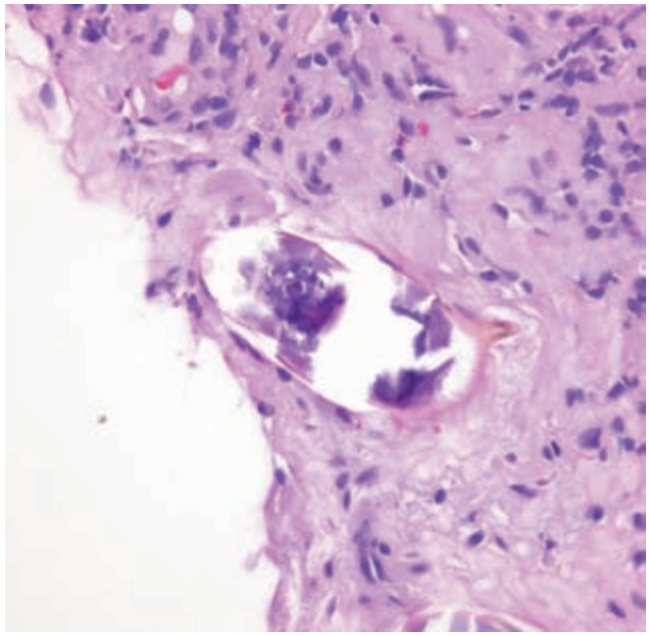

Figure 137.75 Schistosomiasis. The lateral spine of this ovum is in keeping with *Schistosoma mansoni*.

both. Most other adults underwent colonoscopy for polyp screening (four) or follow-up of Crohn's disease (one). Histologically, spirochetosis was identified in all parts of the colon and was not strongly associated with active inflammation, mucosal injury, or changes of chronicity. Genotype analysis of 13 cases showed that 11 resulted from *B. aalborgi* and two from *B. pilosicoli* infections. Only two patients were treated specifically with antibiotics, with complete resolution of abdominal symptoms in one patient with follow-up. Follow-up biopsy results were available for two patients who did not receive treatment; one showed persistent spirochetosis and the other was negative. Spirochetosis in this series

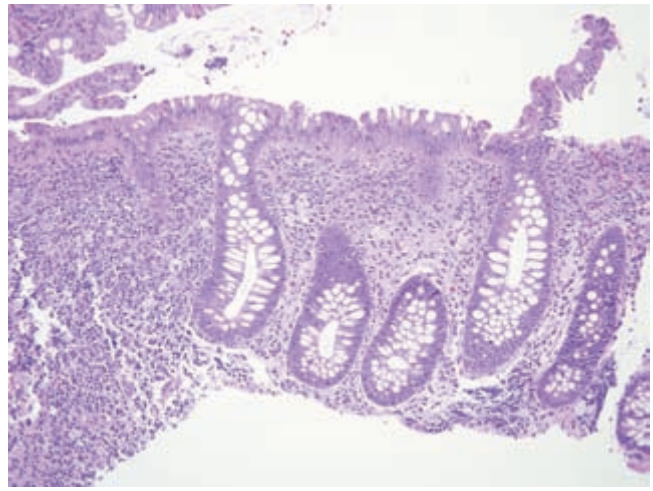

Figure 137.76 Spirochetosis. This biopsy was from an immunosupressed person with diarrhea. The biopsy shows features of acute self-limiting colitis in that there is cryptitis without crypt distortion.

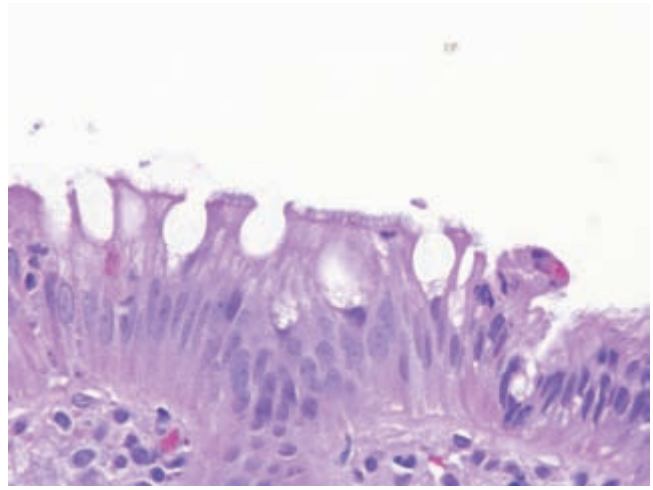

Figure 137.77 Spirochetosis. The hair-like structures emanating from the surface are the organisms.

had a male predominance, was generally caused by *B. aalborgi*, and occurred in two distinct clinical settings: children (who often have abdominal symptoms) and adults (who typically are asymptomatic). While treatment information remains limited, treatment seemed to ameliorate symptoms in some cases.

It is well known that a large number of infectious processes can mimic idiopathic inflammatory disease. Generally, the features of *Campylobacter*, *Salmonella*, and *Shigella* are distinguished from IBD by the proclivity of responding neutrophils to involve the lamina propria more than the glands and the lack of architectural distortion and basal plasmacytosis, but overlapping features do occur. Epithelioid granulomatous inflammation may accompany *Yersinia pseudotuberculosis* and aggregates of macrophages may accompany *Yersinia enterocolitica*. To the extent that the morphological features of pseudomembranous colitis (Fig. 137.79) and enterohemorrhagic *E. coli* colitis mimic IBD, these must also be considered (although these mimic ischemic effects more than they mimic IBD). The proclivity for GI histoplasmosis to mimic IBD has been emphasized by Lamps and colleagues [347] (Figs 137.80 and 137.81). The presentation of IBD and GI histoplasmosis can be identical (fever, malaise, GI bleeding, diarrhea, nausea and vomiting, ulcers, fissures, perforation, colitis) and the histological presence of granulomas and full-thickness inflammation can lead to an interpretation of Crohn's colitis. The disease may be seen in nonendemic areas and in immunocompetent hosts. Ulcerated areas should always be screened for the presence of *Entamoeba histolytica* and CMV. The former tends to appear in the exudate itself whereas the latter is found frequently in endothelial cells. Adenovirus may involve the bowel in immunocompetent individuals where it invokes an impressive lymphoid response, particularly in the terminal ileum, accompanied by loss of nuclear polarity and subtle intranuclear inclusions

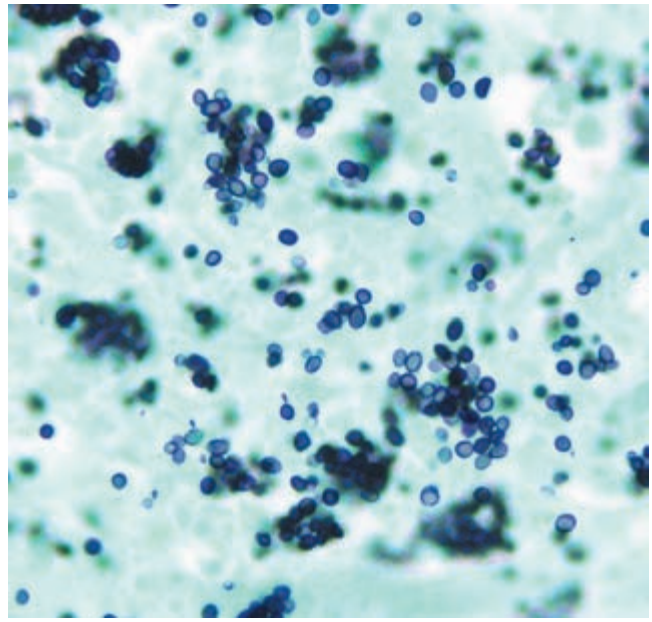

Figure 137.81 Histoplasmosis. Gomori–methenamine silver stain from the image seen in Fig. 137.80 shows budding yeast forms.

[225]. The necrotizing granulomas associated with *Yersinia* spp. are lacking in adenovirus infection. *Mycobacterium avium* complex and *Cryptosporidium* (Fig. 137.82) can be found in immunosuppressed hosts. We have also sometimes noted prominent lymphoid aggregates in biopsies from patients with a course clinically in keeping with viral gastroenteritis.

Of course malakoplakia, while usually in the genitourinary tract, can also be found in the GI tract and reflects a curious response to degenerating bacteria which assume a targetoid appearance when ingested by macrophages (Michaelis–Gutmann bodies).

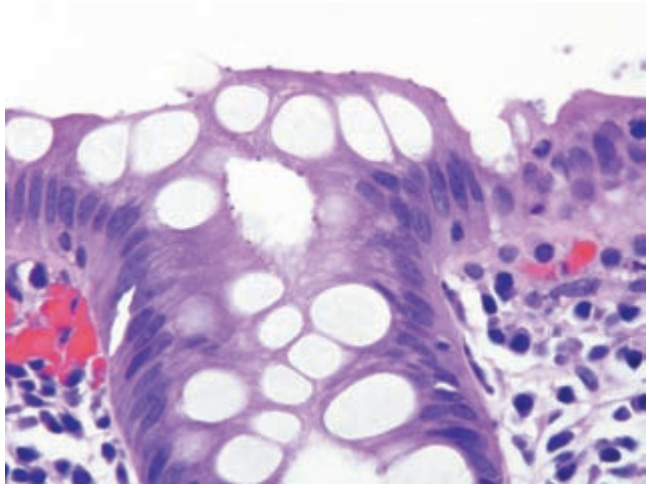

Figure 137.82 Cryptosporidiosis. Organisms appear as small beads at the epithelial surface.

Ischemic colitis

The biopsy features classically associated with ischemic colitis include marked surface injury, mucin loss in crypts, atrophic microcrypts, and hyalinization of the lamina propria such that the normal loose connective tissue punctuated with plasma cells, lymphocytes, and eosinophils is replaced with dense eosinophilic matrix and the residual glands become more closely spaced (lamina propria collapse) [348] (Fig. 137.83). In older patients, ischemic disease is typically attributable to atherosclerotic mesenteric vascular disease. In the setting of global hypoperfusion or splanchnic constriction the watershed zones are prone to vascular insufficiency. The classic watershed zone is at the splenic flexure, an area supplied by the most distal reaches of both the superior mesenteric artery and the inferior mesenteric artery but not by more proximal branches of either source. As such, any vascular compromise from hypovolemia or splanchnic shunting during exercise or global hypotension (such as after trauma) can affect this zone (point of Griffith) more substantially than others in the colon. A similar watershed zone is present in the ileocecal region (point of Sudeck) [349].

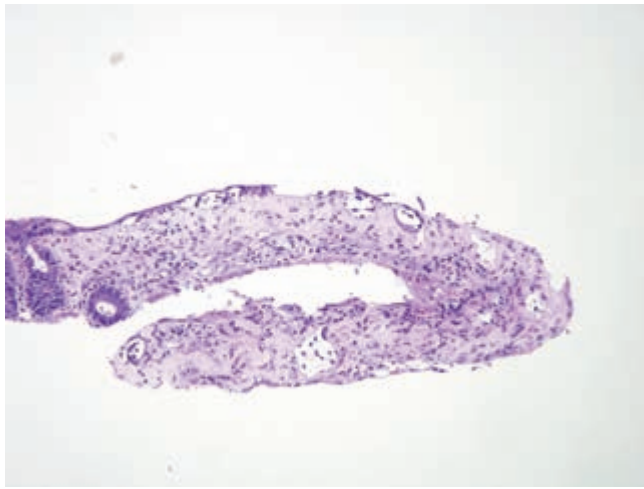

Figure 137.83 Ischemic colitis. This example is from an individual who was receiving Kayexalate but the features are similar regardless of etiology. This biopsy shows atrophic microcrypts and lamina propria hyalinization.

There are many etiologies for ischemic colitis. For example, distance running is known to be associated with varying degrees of colonic ischemia. It is known that about one-fourth of both male and female runners who previously lacked it have occult blood in their stool following participation in a marathon [350] and more extensively documented colonic ischemia has also been reported in such athletes [351–353]. In contrast to the effect of splanchnic constriction in athletic settings, however, ischemic colitis due to hypovolemia in young trauma patients is unusual [354].

Certain infectious agents are also known to produce an ischemic picture, classically enterohemorrhagic (verotoxin-producing) *E. coli* [355–371] and *Clostridium difficile*. The prototype infectious agent for producing ischemic colitis is *E. coli* 0157:H7, which first came to attention in the early 1980s [360,372]. It is a primary cause of severe hemorrhagic diarrhea and one of its complications, hemolytic–uremic syndrome, which develops in up to 20% of cases, is a serious consequence. Ground beef and other bovine products have been implicated as sources. The largest outbreak of this organism occurred in upstate New York in association with an agricultural fair [373]. Since *E. coli* is ubiquitous in stool, it must be specifically sought by stool cultures using sorbitol MacConkey medium from which sorbitol nonfermenting colonies are selected and assayed for the specific organism using either an enzyme immunoassay or a latex agglutination assay [374]. Unfortunately, about 3%–18% of toxin-producing *E. coli* are able to ferment sorbitol (and thus appear as ordinary *E. coli* on culture plates) and may also be responsible for outbreaks but are not detected by routine screening protocols for these organisms [361].

The key pathogenetic mechanism underlying the manifestations of enterohemorrhagic *E. coli* is its direct cytotoxic effect on endothelium [375], which results in GI manifestations if the process is limited but in hemolytic–uremic syndrome if it becomes systemic. Endoscopic biopsies taken from infected patients may display ischemic colitis features with prominent fibrin thrombi, findings that allow the pathologist to suggest pertinent laboratory evaluation [362] but which are by no means specific. An immunohistochemical test has been developed although there is limited experience with it in tissue diagnosis [365].

In younger patients with ischemic colitis, a variety of drug associations can be invoked, including illegal drugs (cocaine [376–381]), over-the-counter decongestant medications [382–385], oral contraceptives [386,387], NSAIDs [388,389], kayexalate (given for hyperkalemia in renal patients and suspended in a sorbitol solution that induces osmotic

ischemia) [390], the migraine headache medication sumatriptan [391,392], and alosetron (Lotronex) [393–401].

Other causes of ischemic intestinal disease in young adults include coagulopathies [402], anorexic behavior [403], and vasculitides (see below). A 2001 report from the Mayo Clinic of 39 young adults with ischemic bowel disease included 13 (of 25) women taking oral contraceptives, four patients with vascular thrombi, four taking vasoactive drugs, four with hypovolemia, and two with vasculitis. No etiology was demonstrated in the remaining 19 patients [404].

In older patients, the differential diagnosis is often between pseudomembranous and ischemic colitis. The diagnosis of ischemic colitis often requires careful clinicopathological correlation. The process may resolve spontaneously. Involvement is segmental and the splenic flexure area is particularly vulnerable. In early cases there is desquamation and necrosis of the mucosa, particularly the superficial mucosa. Pseudomembranes are often seen microscopically, although the endoscopic appearances of ischemia and pseudomembranous colitis differ. Hemorrhage and hemosiderin-laden macrophages are seen in the lamina propria. Fibrin thrombi may be seen as the process progresses. Chronicity is evidenced by crypt atrophy and hyalinized lamina propria. Dignan and Greenson have published helpful criteria to distinguish ischemic colitis and pseudomembranous colitis [348]. These criteria allow distinction of most but not all cases where this differential diagnosis arises. *Clostridium difficile* is often the etiological agent in pseudomembranous colitis, but not all pseudomembranes are caused by this bacterium and not all infestations with *C. difficile* result in pseudomembranes. Cases are typically associated with antibiotics.

Findings in systemic diseases

Scleroderma

This connective tissue disorder can result in hypomotility and intestinal pseudoobstruction, classically associated with sclerosis of the inner circular layer of the muscularis propria. Since the pathological process is mural, there are no specific biopsy changes. However, the stasis resulting from the obstruction can produce bacterial overgrowth.

Vasculitis

It is treacherous to attempt diagnosis of vasculitis on colonic biopsies since if ischemic ulcers are present, any inflammation in walls of small vessels may be secondary rather than primary. The systemic vasculitides are clinically diverse multisystem diseases and their signifying pathological feature is inflammation of blood vessel walls. Vasculitis may be categorized according to vessel size. Small-vessel vasculitides include systemic lupus erythematosus (SLE), microscopic polyangiitis, Wegener granulomatosis, Churg–Strauss syndrome, Henoch–Schönlein syndrome, Adamantiades–Behçet disease, and rheumatoid vasculitis. Medium-sized vessel vasculitides include SLE, polyarteritis nodosa (PAN), thromboangiitis obliterans, and Kawasaki disease, whereas large-vessel vasculitides include Takayasu arteritis and giant-cell arteritis. However, there may be considerable overlap among the various syndromes. In addition, both Crohn's disease and ulcerative colitis may result in vasculitis. The type of IBD most often associated with vasculitis is Crohn's disease, which usually affects arteries.

Intestinal vasculitis may accompany a variety of systemic vasculitides such as PAN, Churg–Strauss syndrome, Henoch–Schönlein purpura, lupus, and rheumatoid arthritis [404–409]. Among the angiitides, PAN, SLE, and Henoch–Schonlein syndrome are those most commonly accompanied by GI complications. Key features of the vasculitides affecting the GI tract are shown in Table 137.4.

Isolated venulitis of the GI tract has been reported using several different names: lymphocytic phlebitis, necrotizing and giant-cell granulomatous phlebitis, idiopathic myointimal hyperplasia of mesenteric veins, mesenteric inflammatory venoocclusive disease, intramural mesenteric venulitis, idiopathic colonic phlebitis [407,410]. The trouble with this entity, as is frequently the case in GI tract lesions, is it describes a pattern of injury but the etiology remains unknown.

On biopsies, vasculitis involving the GI tract vessels results in ischemic changes that cannot be distinguished from other causes of ischemia, and clinical correlation by working closely with the endscopist is crucial. For example, the angiographic features of PAN are characteristic and the diagnosis can be made prospectively by noting ischemic features on mucosal biopsy. If steroid therapy is promptly initiated, surgery can be avoided.

Amyloidosis

Amyloidosis can affect the colon just as much as the remainder of the GI tract (see Figs 137.65 and 137.66). Occasionally, since it imparts a thickened basement membrane, it may have overlapping features with collagenous colitis. In contrast to the latter, in which collagen is punctuated with nuclei of fibroblasts and entrapped endothelial cells, the thick basement membrane in amyloidosis contains no nuclei.

Common variable immunodeficiency

Common variable immunodeficiency is the second most common immunodeficiency syndrome after selective IgA deficiency. Manifestations in the colon are similar to those in the small bowel. The hallmark presentation is persistent sinonasal infections, but many such patients have GI tract complaints attributable to small intestinal atrophy, chronic giardiasis, pernicious anemia, and colitis. Such patients are at risk for development of small bowel lymphoma and gastric carcinoma. Since common variable immunodeficiency is a chronic disease, injury to the colon in patients with this condition is lifelong. As such, although they do not have plasma cells (Figs 137.84 and 137.85), other features of their disease mimic quiescent ulcerative colitis (they can display marked crypt distortion). Apoptosis is often a prominent feature, mimicking GVHD (Fig. 137.86), and these patients are prone

Table 137.4 Summary of the vasculitides affecting the gastrointestinal tract

Type	Definition	Vessel size typically affected	Microscopic features
Henoch–Schönlein syndrome (also called anaphylactoid purpura, Schönlein–Henoch syndrome)	Most common vasculitis in children characterized by purpuric skin eruption, fever, arthralgia, visceral symptoms. Seasonal incidence (peaks in winter). Renal involvement in up to half. Skin purpura, intestinal, renal, or pulmonary hemorrhage	Small	Necrotizing vasculitis (small vessel), histologically indistinguishable from small-vessel forms of polyarteritis. IgA immune deposits in vessel walls
Polyarteritis nodosa (also called periarteritis nodosa, polyarteritis)	Necrotizing vasculitis (medium- and small-sized arteries). Involvement of the aorta is unknown. Can involve any organ. In descending order: kidneys, muscles, nerves, viscera, heart. In children, heart most common site	Medium (arteries)	Focal segmental necrotizing arteritis with fibrinoid necrosis is hallmark of acute lesions, which have a proclivity for microaneurysm formation. Healing lesions have vessel wall sclerosis. Characteristic feature is coexisting acute and healing lesions with intervening segments of unaffected artery
Lupus vasculitis	Vasculitis affecting patients known to have lupus	Medium	Variable and nonspecific histology
Wegener vasculitis	Necrotizing granulomatous vasculitis that in classical form affects the lungs and kidneys. Most affected (75%) are c-ANCA (anti-neutrophil cytoplasmic antibody) positive	Small	Lesions have geographic necrosis, granuloma formation, and vasculitis. All three components are only found in 20%–30% of extrapulmonary cases, so diagnosis requires clinicopathological correlation
Churg–Strauss vasculitis (also called allergic granulomatosis, allergic granulomatous angiitis)	A subset or overlap syndrome of polyarteritis nodosa. The pathological diagnostic criteria require systemic and pulmonary necrotizing vasculitis with an eosinophilic infiltrate and extravascular granulomas. Clinical diagnostic triad: history of asthma/allergy, peripheral blood eosinophilia, and pulmonary and systemic vasculitis with eosinophilic infiltrate	Medium	Like polyarteritis nodosa with an eosinophilic infiltrate. When changes are limited to an isolated organ system, the condition is known as limited/isolated Churg–Strauss syndrome
Buerger disease (also called thromboangiitis obliterans)	Nonarteriosclerotic segmental inflammatory occlusive disease of medium-sized and small arteries and veins usually affecting limbs with occasional visceral involvement. Strong association with smoking, male sex (9 : 1). Usually in young men (< 40 years). Begins with Raynaud phenomenon	Medium	Diagnostic only in early stages with clinically evident thrombophlebitis. Inflammatory thrombi of arteries and veins with endovascular microabscesses with scattered giant cells. Later stages less diagnostic and organizing thrombi are seen. The end stage is nondiagnostic with fibrotic occluded vessels

to a host of infections. Common variable immunodeficiency is also associated with lymphocytic colitis.

Radiation colitis/proctitis

Radiation colitis may be acute or chronic. The acute phase occurs hours to days following irradiation and at endoscopy shows an edematous dusky pattern with loss of vascular pattern. On biopsy, nuclear pyknosis, karyorrhexis and enlarged nuclei are seen with diminished mitotic activity and mucin. These changes are reversible over 1–2 months. Chronic radiation colitis develops weeks to years after therapy. Hyalinized connective tissue is seen in any of the bowel wall layers accompanied by atypical fibroblasts, telangiectasia, vessel wall hyalinization, phlebosclerosis, and atrophy on the muscularis propria. The changes may be best seen in the submucosa and thus are not detected by mucosal biopsy [411–413]. Of course stromal changes may be striking and occasionally there may be epithelial changes [413]. We have noted an appearance where hyalinized vessels are seen aligned parallel to the surface epithelial basement membrane, a finding that is very common in rectal biopsies from men who have had irradiation for prostate cancer (Fig. 137.87).

Lymphocytic and collagenous colitis

The term *microscopic colitis* has been applied to biopsies of patients with symptomatic colitis in whom there are no endoscopic (gross) anomalies but in whom specific microscopic features are found. It was coined by Read in 1980 to describe patients who had chronic diarrhea, normal colonoscopy, normal barium enema, and mucosal inflammation in their

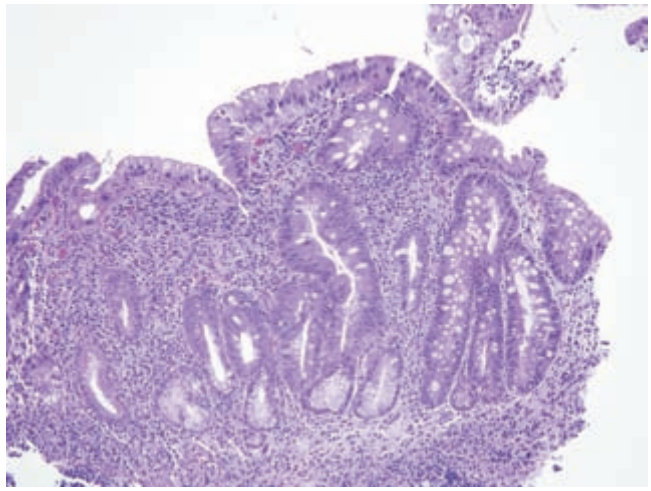

Figure 137.84 Common variable immunodeficiency. The features are similar to those of ulcerative colitis and it is easy for pathologists to make an incorrect diagnosis in such cases.

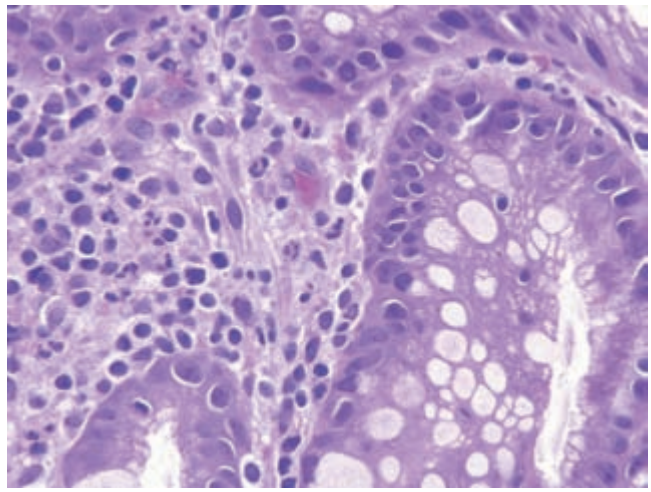

Figure 137.85 Common variable immunodeficiency. The key is the absence of plasma cells in the lamina propria; they would be a prominent constituent in the inflammatory backdrop of ulcerative colitis. The prominent lamina propria neutrophils in this biopsy are in keeping with an acute infection.

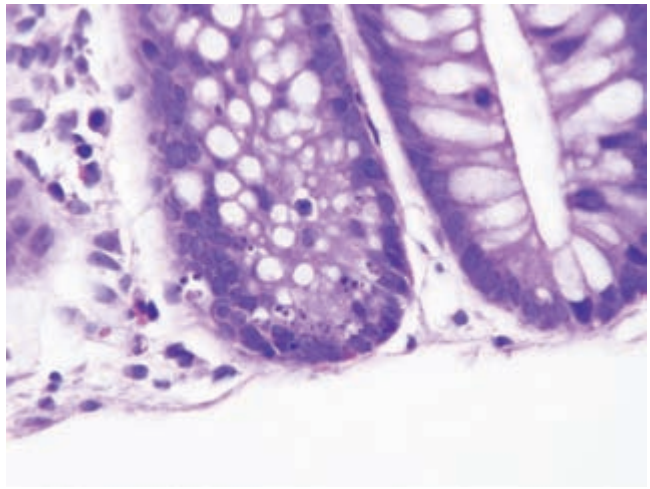

Figure 137.86 Graft-versus-host disease. Note the crypt apoptosis. Crypt apoptosis may also result from phosphasoda bowel preparation so this method is not advised if assessing for graft-versus-host disease.

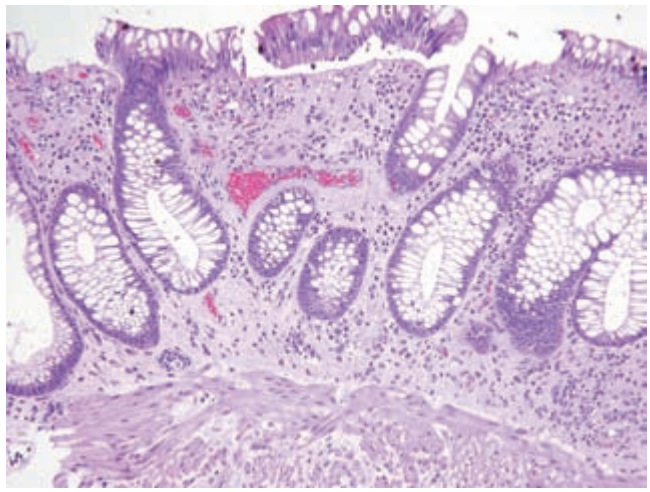

Figure 137.87 Radiation proctitis. Note the prominent vessel parallel to the epithelial surface.

colonic biopsies [414]. There are two types of microscopic colitis that account for most such patients: collagenous and lymphocytic colitis. Both entities feature an inflamed lamina propria and surface injury but seem to be distinct entities that differ in their demographics, disease associations, and clinical course.

Collagenous colitis was described in 1976 [415]. Patients have chronic watery diarrhea that may have an insidious onset or develop abruptly. In addition to diarrhea, many patients report abdominal pain, fatigue, or weight loss. Collagenous colitis is more common in women, with a female to male ratio of 6–8 : 1, and a median age at diagnosis of 55 years. However, the age range is broad, and many cases are diagnosed in patients under the age of 45 years. Associated disease is seen in 40% of patients. The most common of these include rheumatoid arthritis, thyroid disorders, celiac disease, and diabetes mellitus. There may also be an association with the use of NSAIDs [416–418].

Lymphocytic colitis was separated as a specific form of microscopic colitis by Lazenby and colleagues in 1989 [416,419]. Like those with collagenous colitis, patients with lymphocytic colitis have chronic watery diarrhea and normal colonoscopy. There is a broad age range at diagnosis, ranging from young adults to elderly patients, with a mean in the sixth to seventh decades. In sharp contrast to collagenous colitis, men and women are equally affected. Some patients report abdominal pain or weight loss. Lymphocytic colitis has a

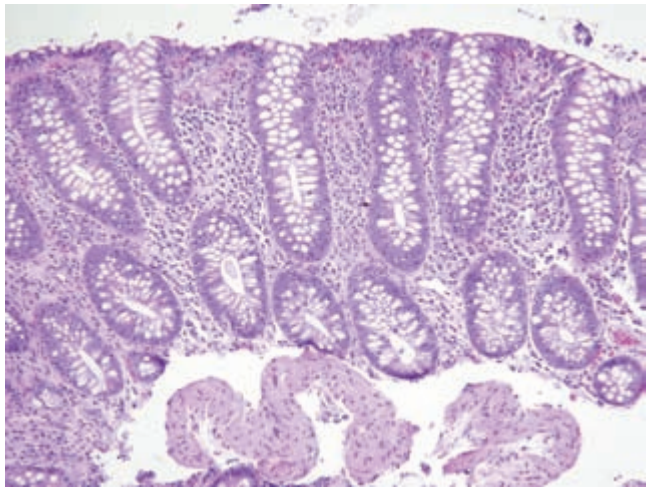

Figure 137.88 Lymphocytic colitis. Note the intraepithelial lymphocytosis.

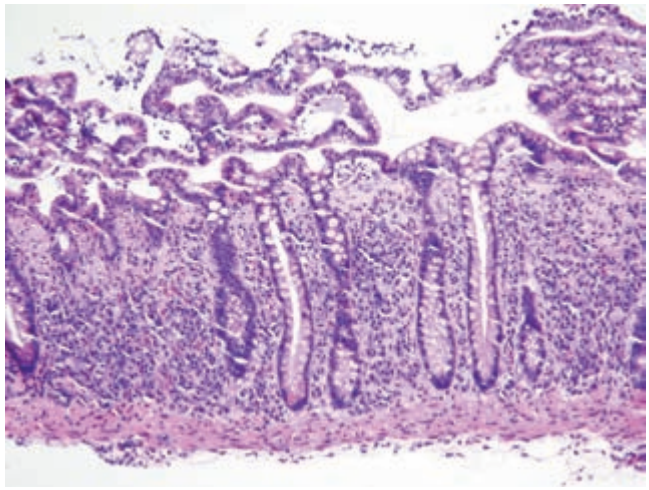

Figure 137.89 Collagenous colitis. Subepithelial collagen is the hallmark.

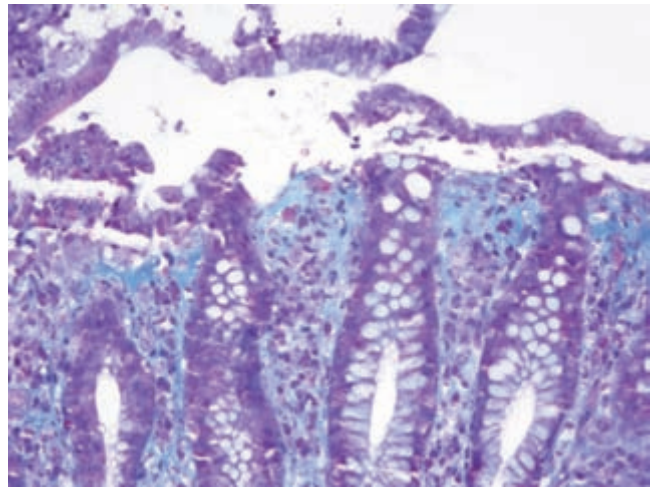

Figure 137.90 Collagneous colitis. This trichrome stain results in a blue color in the subepithelial collagen.

stronger association with celiac disease than collagenous colitis. Of patients with celiac disease, about one-third have histological features of lymphocytic colitis on biopsy. Of patients with lymphocytic colitis, as many as one-fourth may have celiac disease.

These two microscopic colitides share many histological features, including increased lamina propria cellularity, primarily attributable to plasma cells, but also lymphocytes and eosinophils (Figs 137.88–137.90). The crypts are not distorted or minimally distorted. There is surface epithelial injury associated with infiltration by lymphocytes, and degenerative features such as cytoplasmic vacuoles, loss of mucin, nuclear irregularity, pyknosis, and flattening.

The key diagnostic distinction between collagenous colitis and lymphocytic colitis is the deposition of an abnormal layer of collagen between the surface epithelium in the former. This can be variable, and tends to be more pronounced in the proximal colon and less so in the rectosigmoid. The lower border is irregular, with strands of collagen extending into the underlying lamina propria and incorporating dilated capillaries and fibroblast nuclei. Eosinophils are quite often prominent in collagenous colitis, both in the lamina propria and within surface and crypt epithelium [419]. Scattered neutrophils are often found in collagenous colitis but are not a feature of lymphocytic colitis. When neutrophils are prominent, it suggests superimposed infectious colitis. In collagenous colitis, the surface epithelium tends to separate from the basement membrane beneath, leaving stretches in which abnormal collagen is exposed on the surface. In lymphocytic colitis the surface lymphocytosis is usually more prominent, eosinophils are less common, and prominent crypt epithelial lymphocytosis is often a feature.

The abnormal subsurface collagen that is diagnostic of collagenous colitis is not always thick enough to be appreciated on routine H & E stain. There is no minimal thickness required for the diagnosis of collagenous colitis. In normal colonic mucosa, the trichrome stain marks the basement membrane lying at the base of the surface epithelium, forming a smooth thin line. When collagen is deposited beneath this epithelium, the trichrome stain has an irregular lower border, with strands of collagen extending into the adjacent lamina propria and trapping capillaries. It is this abnormal pattern rather than the absolute thickness of the collagen that is the key feature in collagenous colitis. There is no reason to measure the deposited collagen to diagnose collagenous colitis. The abnormal collagen deposition is not always evident on routine stains and we generally order a trichrome stain when we plan to diagnose lymphocytic colitis to detect subtle collagenous colitis. An abnormal collagen band alone is insufficient for the diagnosis of collagenous colitis, but must be present in the appropriate context. Occasionally, thick bands of collagen may be seen in the colonic mucosa as

a result of healed ischemia, radiation injury, ulcerative colitis, or mucosal prolapse [420].

Graft-versus-host disease

The features of GVHD of the colon are similar to those elsewhere, with varying degrees of apoptosis and crypt drop-out. It can be graded for comparison with prior biopsies (grade 1, increased crypt apoptosis (see Fig. 137.86); grade 2, apoptosis with crypt abscess; grade 3, individual crypt necrosis; grade 4, total denudation of areas of mucosa). Like GVHD elsewhere, it can have a chronic phase in which crypt distortion appears but it lacks the active inflammation and prominent basal plasmacytosis that characterize ulcerative and Crohn's colitis. It typically accompanies bone marrow rather than solid organ transplantation. Of course, GVHD is always diagnosed in the proper clinical setting so correlation with the clinical impression is critical. The differential diagnosis is with entities resulting in apoptosis, such as viral infection, autoimmune disease, NSAID use, and medications. For example, mycophenolate mofetil (CellCept) administered to recipients of solid organ transplants can result in colon biopsy findings that are identical to those of GVHD [231], and chemotherapy or other prolonged injury can produce similar features. The endoscopist should remember that phosphasoda bowel preparation itself can result in prominent apoptosis and this preparation should be avoided when GVHD is an issue.

Diversion colitis

Sometimes, when a segment of bowel is resected, the surgeon is forced to create an ileostomy or colostomy as there is simply too much inflammation (or tumor) to reanastomose the remaining bowel without clinical compromise. In this case the remaining bowel (often the rectum) has no passing fecal stream. If the rectum is left as a blind opening continuous with the anus, it is called a Hartmann pouch and the pathologist should consider that there might be diversion colitis. Colitis following diversion of the fecal stream is usually mild. However, in severe cases, the features may perfectly mimic both ulcerative and Crohn's colitis. Regression of the colitis generally follows restoration of the normal continuity of the fecal stream. Diversion colitis is common, occurring as subclinical disease in about 70% of diverted patients. Some authors have reported that lymphoid follicle hyperplasia is a typical finding, although others have reported variable histology [421–426]. If diverted colon is reconstructed into another anatomical structure (such as a neovagina), it is still prone to diversion colitis [427–429]. The hypothesis that the condition results from the absence of lumenal short-chain fatty acids (the preferred metabolic substrate of colonic epithelium) secondary to a change in the bacterial milieu is based on reversal of the condition in many cases on instillation of these compounds into the diverted segment [427,430].

Diverticular disease-associated conditions

In the early 1990s, clinicians became aware of a small subset of patients with diverticular disease (usually involving the sigmoid colon) who developed segmental colitis in the area of diverticular disease [431,432]. The pathological findings were subsequently described in detail and it was noted that cases sometimes perfectly mimicked ulcerative colitis [431] or Crohn's disease [433] and that there is a minority of patients who later manifest ulcerative colitis or Crohn's disease following their episode of diverticular disease-associated colitis. The key principle is that these cases may mimic either Crohn's disease or ulcerative colitis flawlessly and the pathologist is cautioned against diagnosing idiopathic inflammatory disease affecting only the sigmoid colon in patients with diverticular disease. Cases may display features of chronicity, including basal plasmacytosis and crypt distortion, although most show mild active colitis. Those cases of diverticular disease displaying granulomas may even have granulomas in resected lymph nodes [434]. In general, most patients with diverticular disease simply have "floppy" mucosa that is quite prone to prolapse changes [435,436] but one should always exercise caution when colitis is confined to the sigmoid colon. Patients with diverticular disease-associated colitis usually respond to antibiotics.

Polyps

Elastosis/elastofibromatous change

There is a subset of polyps of the GI tract in which the submucosa and muscularis mucosae exhibit a focal or diffuse increase of elastin fibers. This elastosis or elastofibromatous change most commonly manifests as a colonic polyp and is usually found during screening colonoscopy. Gastric and small intestinal cases are less frequent and associated with ulcers or an inflammatory process. Hobbs and colleagues [437] summarized the literature and found reports of 13 GI elastotic lesions with a topographic distribution similar to their own series of 13 cases. Histologically, elastosis appears as finely granular or fibrillar amphophilic material, sometimes with a fibrous component (elastofibromatous change) (Figs 137.91 and 137.92). The changes occasionally appear centered around blood vessels and are often mistaken for amyloid but are negative for Congo red stain and strongly positive for elastin stain. These lesions are probably incidental and of no clinical consequence.

Filiform polyps/postinflammatory polyps

Filiform polyps (also called postinflammatory polyps) are essentially a subtype of polyp associated with prior mucosal injury so they are not unusual in patients with IBD but can be found in patients who have had any type of prior ulceration. They consist of finger-like projections of submucosa covered by mucosa on all sides. They reflect healing of undermined mucosal and submucosal remnants and ulcers and are typically multiple. To the endoscopist, they appear

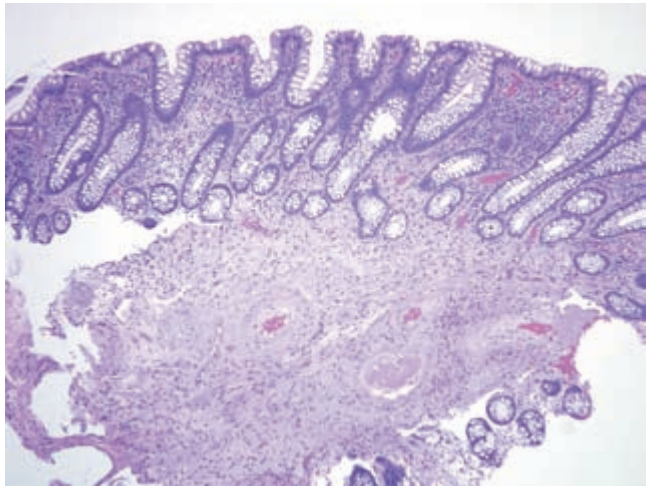

Figure 137.91 Elastosis. This process produced an incidental polyp.

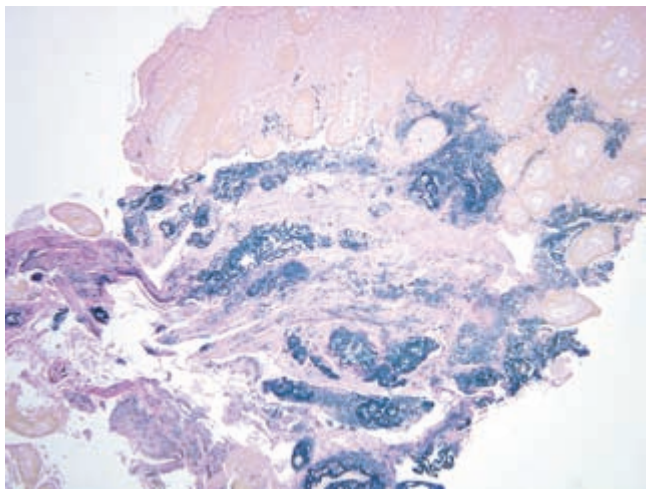

Figure 137.92 Elastosis. Elastic stain of the polyp seen in Fig. 137.91.

long and finger-like [438]. They are diagnosed by noting that they consist of two protruding layers of mucosa plastered together with only one intervening layer or no intervening layer of muscularis mucosae. This is because they reflect regrowth of mucosa over an area of ulcer that has damaged the muscularis mucosae.

Mucosal prolapse conditions

This category of lesion encompasses a host of processes in diverse GI tract sites, but prolapses often yield an endoscopic polyp when they occur in the colon. Well-defined colonic prolapse conditions include solitary rectal ulcer syndrome, localized colitis or proctitis cytstic profunda, inflammatory cloacogenic polyp, prolapsing folds associated with diverticular disease of the colon, and fibrin cap polyps of the colon. So-called myoglandular polyps are presumably part of the same spectrum [439,440]. In some GI sites, prolapse is virtually physiological. For example, the ileocecal valve is prone to prolapse and if there is abundant submucosal fat in the prolapsed area, this is termed lipoma of the ileocecal valve but is probably not neoplastic. These conditions are all benign and are all occasionally mistaken both clinically and microscopically for carcinomas.

Solitary rectal ulcer syndrome

Solitary rectal ulcer syndrome describes a pattern of mucosal changes (some of which are polyps without ulceration) localized to the terminal rectum and imparted by mucosal prolapse. It occurs at all ages, with a peak incidence between 20 and 40 years. The classic history is of a young woman who strains when defecating. There may be hematochezia, pain, tenesmus, and sometimes lower abdominal pain. Inability to evacuate the rectum or sensation of a foreign body is described. At endoscopy ulcers are seen in 20%–70% of patients, usually on the anterior or anterolateral rectal wall but a mass-like lesion can also be found, raising the possibility of a neoplasm. Sometimes defecation studies are used to evaluate these patients as they are believed to have difficulty coordinating the smooth muscle during the defecation process such that the puborectalis sling does not relax at the proper time.

The pathological changes on biopsy consist of hypertrophy of the muscularis propria with splaying of fibers which course into the mucosa and are seen throughout the lamina propria. The proliferated smooth muscle is accompanied by variable fibrosis and glands become entrapped and distorted. As the process continues, there is surface ulceration and glands can herniate into the submucosa, accompanied by wisps of lamina propria (a theme in adenomas as well) [441–445]. Thus lesions can have a polypoid phase or an ulcerated phase. Often crypts become diamond-shaped [446,447]. A caveat is that mucosal prolapse changes adjacent to carcinomas are the same as those of isolated mucosal prolapse, so we suggest multiple biopsies of large solitary rectal ulcers to exclude sampling error [448]. Colitis cystica profunda is part of the same spectrum of disease and implies that glands have prolapsed into the submucosa.

Inflammatory cloacogenic polyp

Inflammatory cloagogenic polyp refers to a mucosal prolapse polyp arising at the anorectal transition and thus has both squamous and columnar mucosa (Figs 137.93 and 137.94) [444,449]. Patients with such polyps present with hematochezia and the polyps are typically found on the anterior wall of the anal canal. These polyps display a tubulovillous growth and surface ulceration. Displaced clusters of glands are found in the submucosa, and abundant fibromuscular stroma extends into the mucosa.

Juvenile polyps

Juvenile polyps are the most commonly encountered colorectal polyps in children, and in one-third to half of instances more than one polyp is found [450–454]. Sporadic juvenile

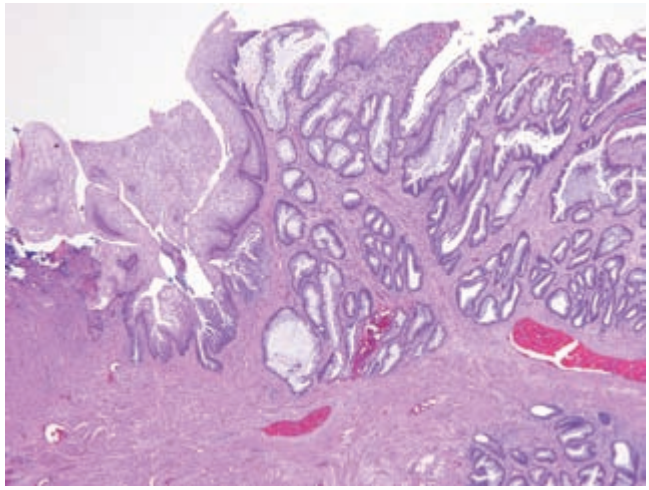

Figure 137.93 Inflammatory cloacogenic polyp. This prolapse lesion is found at the junction of anal squamous (left part of field) and rectal mucosa.

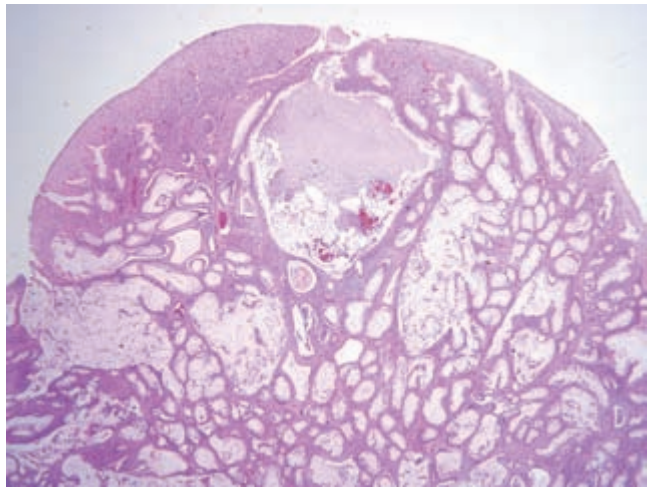

Figure 137.95 Juvenile polyp. This polyp features cystically dilated glands, an expanded lamina propria, and an eroded surface.

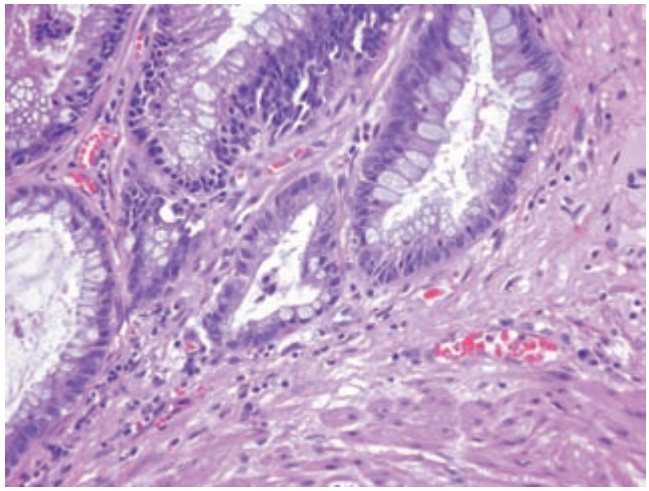

Figure 137.94 Inflammatory cloacogenic polyp. Diamond-shaped glands are a characteristic finding of colorectal prolapse lesions.

polyps usually have a spherical lobulated surface that is often eroded. These polyps are considered hamartomatous so in the colon they display colonic-type mucosa and have irregularly shaped and dilated glands accompanied by lamina propria that is expanded with edematous granulation tissue (Fig. 137.95). Dysplasia is rare in sporadic juvenile polyps.

Juvenile polyposis has been recognized since 1975 [455] and criteria for diagnosis include more than five juvenile polyps of the colorectum, juvenile polyps throughout the GI tract, or any number of juvenile polyps in a patient with a family history of juvenile polyposis. The incidence is about 0.5–1 per 100 000 in the West. The polyps may be found anywhere in the GI tract and the patients are at increased risk for colorectal, gastric, duodenal, and pancreatobiliary carcinomas. In addition, juvenile-type polyps are a component of several genetic syndromes [456–463], including classic juvenile polyposis, Cowden syndrome, and Bannayan–Riley–Ruvalcaba syndrome. Germline mutations in *MADH4* and *BMPR1A* predispose to juvenile polyposis, both genes being involved in TGF-β superfamily signaling pathways. In Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome, juvenile polyps are a less consistent feature. Cowden syndrome patients are at risk for breast and thyroid cancers. Mutations of the tumor suppressor gene *PTEN* have been found in the germline of patients with Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome. Despite different underlying genetic mechanisms, these and other syndromes share the same phenotypic feature of juvenile polyps. These syndromes are summarized in Table 137.5.

When juvenile polyps are biopsied from syndromic patients, smaller ones are identical to the typical sporadic ones. However, larger ones display an increase in the relative amount of epithelium compared with stroma, are multilobulated with rounded or finger-like lobes, and are more likely to display true dysplasia. Both types of juvenile polyp are prone to surface erosions with attendant reactive epithelial changes. In general, the pathologist is cautioned against diagnosing dysplasia when active inflammation and erosions are a feature.

Peutz–Jehgers polyps

Peutz–Jehgers polyps are most common in the small intestine. Their manifestations in the colon are similar to those in other sites in that they are characterized by site-specific (colonic) mucosa with arborizing smooth muscle. Unfortunately, since mucosal prolapse is so common in the colon, it is difficult to prospectively diagnose Peutz–Jehgers syndrome on the basis of a colonic polyp in isolation. When we encounter a colon polyp with features of a Peutz–Jehgers polyp we issue a descriptive diagnosis and suggest correlation with other stigmata of Peutz–Jehgers syndrome.

Table 137.5 Summary of syndromes associated with multiple juvenile polyps

Syndrome	Components	Genetic defect	Cancer risk
Juvenile polyposis	More than five colorectal juvenile polyps or juvenile polyps throughout the GI tract, or any juvenile polyp in a patient with family history of juvenile polyposis	Autosomal dominant: germline mutations in *SMAD4/DPC4* gastrointestinal	Colorectal, stomach, small intestine, pancreatobiliary
Cowden syndrome	Hamartomas involving organs from all three germ layers. Classic skin tumor (trichilemmoma), thyroid abnormalities, fibrocystic disease, juvenile polyps, uterine leiomyomas, macrocephaly, mental retardation, dysplastic gangliocytoma of the cerebellum	Autosomal dominant: germline mutations in *PTEN/MMAC1* gene	Breast and thyroid cancer
Bannayan–Riley–Ruvalcaba syndrome	Microcephaly, lipomatosis, hemangiomatosis, speckled penis, polyps. Overlap with Cowden syndrome	*PTEN* germline mutations	Presumed at risk

Cronkhite–Canada polyps

Unfortunately, this is a type of polyp that is virtually impossible to diagnose prospectively based on microscopic features. In 1955, Cronkhite and Canada reported a series of patients who had polyposis, pigmentation, alopecia, and onychotrophia [464]. There have been few subsequest reports of this condition (other than case reports), although Burke and Sobin [465] were able to amass polyps from nine patients from the consultation files of the AFIP for histological analysis, and Ward has provided excellent reviews of the literature [466–468].

Cronkhite–Canada syndrome is characterized by diffuse polyposis in patients with unusual ectodermal abnormalities, including alopecia, onychodystrophy, and skin hyperpigmentation. Europeans and Asians are most frequently affected, with a mean age at onset of 59 years. Several hundred cases of Cronkhite–Canada syndrome have been reported worldwide, with 75% of these reports originating from Japan. The male to female ratio is 3 : 2. Potentially fatal complications, such as malnutrition, GI bleeding and infection, often occur and the mortality rate has been reported to be as high as 60%. Neither a familial association nor a genetic defect is known.

The most common presenting symptoms include diarrhea, weight loss, nausea, vomiting, hypogeusia and anorexia. Paresthesias, seizures and tetany, apparently related to electrolyte abnormalities, have also been reported. Nail dystrophy (thinning, splitting and separation from the nail beds), essentially a reflection of protein loss, is one of the features. Both scalp and body hair alopecia may be present. Diffuse hyperpigmentation of the skin, manifested by light- to dark-brown macular lesions, is seen most frequently on the extremities, face, palms, soles and neck. Microscopic examination of biopsied skin reveals abnormally increased melanin deposition with or without increased melanocyte proliferation.

A number of complications may occur with Cronkhite–Canada syndrome and can contribute to poor outcomes in patients with this disease. These include potentially fatal GI bleeding, intussusception, and prolapse. Electrolyte abnormalities, dehydration, protein-losing enteropathy, and other nutritional deficiencies due to malabsorption can complicate the course of the disease. Cronkhite–Canada syndrome patients are prone to recurrent infections, but it is not known whether this is related to malnutrition or is a primary immunological deficiency.

Cronkhite–Canada syndrome is distinguished by the diffuse distribution of polyps throughout the entire GI tract, except for characteristic sparing of the esophagus. The question of whether polyps in Cronkhite–Canada syndrome possess malignant potential remains controversial. The Cronkhite–Canada polyp is characterized by its broad sessile base, expanded edematous lamina propria, and cystic glands [465] (Figs 137.96 and 137.97). Similar features are found in the lesions of

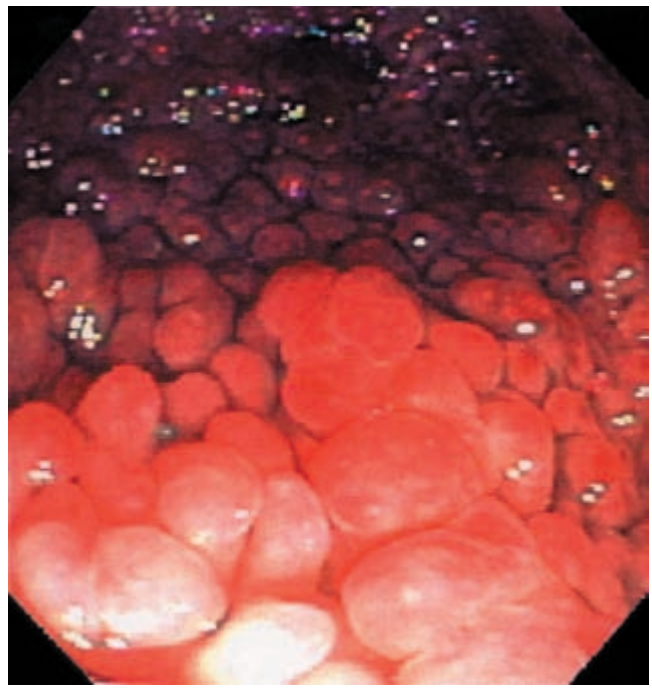

Figure 137.96 Cronkhite–Canada polyposis. This endoscopic image is from the patient's cecum. He had polyps throughout his gastrointestinal tract, sparing only his esophagus.

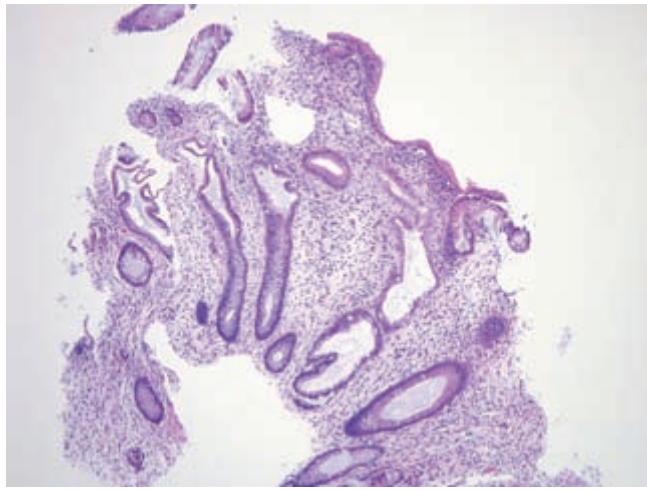

Figure 137.97 Cronkhite–Canada polyposis. This histological appearance of a colonic polyp is hardly specific: the polyp appears similar to a juvenile polyp. The distinction is made on clinicopathological grounds and by attention to the background flat mucosa, which is abnormal in Cronkhite–Canada polyposis but normal in juvenile polyposis.

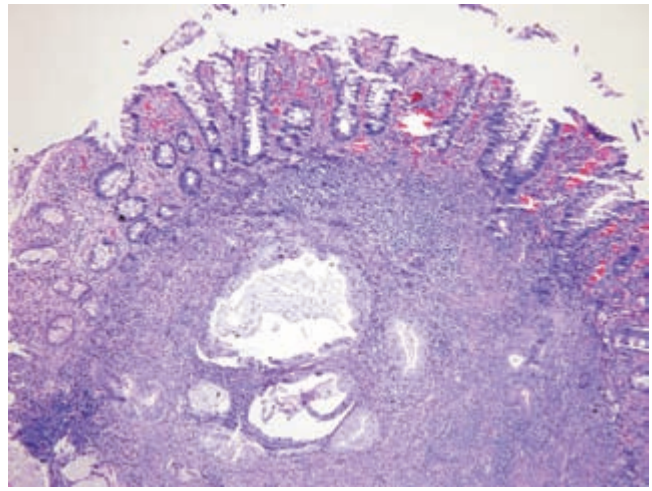

Figure 137.98 Colonic endometriosis. This is a diagnostic pitfall for endoscopists and pathologists alike. The key for the pathologist is to note the background stromal tissue accompanying the glands.

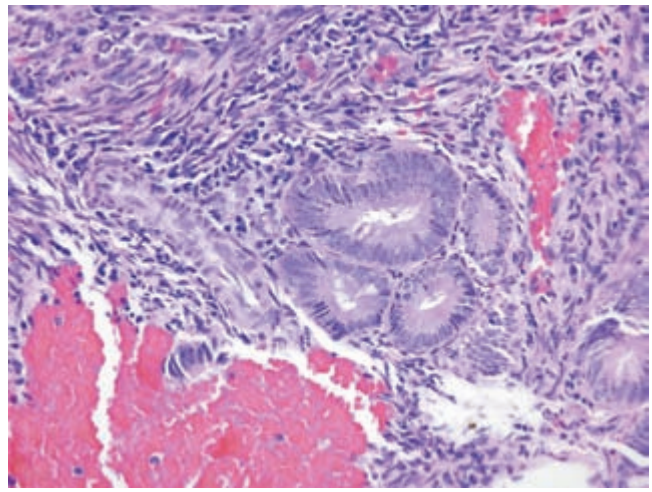

Figure 137.99 Colonic endometriosis. Higher magnification of the lesion seen in Fig. 137.98.

juvenile polyposis. The only distinguishing feature reported between Cronkhite–Canada and colonic juvenile polyposis was the pedunculated growth of the latter [465], a feature that did not hold for gastric lesions. Unlike Cronkhite–Canada polyps, juvenile polyps sometimes have areas of dysplasia, but this is not typical. Therefore the diagnosis of Cronkhite–Canada polyps (especially in the stomach) requires correlation with the presence of the ectodermal changes characteristic of this syndrome.

Other conditions

Endometriosis

Endometriosis is well known to present in a variety of sites and affects the GI tract in up to 40% of patients with pelvic endometriosis and about one-third of these patients have mucosal lesions amenable to biopsy [469]. The sigmoid colon is the most common site.

On gross examination, endometriosis appears as it does in other sites, as firm areas that may contain cysts filled with brown fluid. Most examples of endometriosis affect the serosa or muscularis propria and are accompanied by abundant fibrosis and adhesions, although submucosal examples are also reported. Endometriosis of the colon resembles examples found elsewhere, consisting of endometrial-type glands and stroma associated with hemosiderin deposition and a fibroblastic response (Figs 137.98 and 137.99). The endometrial-type epithelium changes with the menstrual cycle. A stromal decidual reaction may be found in endometriotic foci in pregnant patients.

Vascular lesions

As biopsy of vascular ectasias in not always a wise procedure, these are not often seen in biopsy material. When they bleed, they are managed with various obliterative techniques but not sampled for histology. However, there are a variety of vascular lesions occasionally encountered on colonic biopsies. In HIV patients, of course, Kaposi sarcoma is sometimes encountered. Other lesions occasionally seen include incidental hemangiomas and lymphangiomas, Dieulafoy lesions (usually found in the stomach but rarely in the colon), and vascular malformations. Angiosarcomas tend to be deeper and diagnosed on resections.

Neoplasms

Adenomas

It is estimated that over half the Western population will develop a benign colorectal tumor (adenomatous polyp) during their lifetime, and that about 10% of such tumors will

progress to malignancy [470]. Patients with FAP have germline defects in the adenomatous polyposis coli (*APC*) gene, the gatekeeper of colorectal neoplasia [470], and have hundreds to thousands of colon adenomas and essentially all develop colon cancers if no prophylactic colectomy is performed. Adenomas of the colorectum generally pose few diagnostic problems to the pathologist and endoscopists usually recognize and remove them readily [471]. The situations that can be difficult involve differential diagnosis between reparative conditions with epithelial changes simulating adenomas and adenomas themselves, and dysplasia in the setting of IBD.

Adenomas have dysplasia by definition. It is usually low grade with regular nuclei showing maintained nuclear polarity (their long axes are perpendicular to the basement membrane) (Fig. 137.100). When this is the case, we do not offer a grade of dysplasia but simply diagnose an adenoma and comment on cauterized margin status if the specimen is not tiny or fragmented. Typical adenomas display elongated pencillate nuclei that are similarly hyperchromatic throughout, in contrast to normal mucosa that shows reduced nuclear hyperchromasia at the surface. Adenomas may contain foci of clear cell change, squamous-like morules [472], and Paneth cell differentiation, none of which matter in an adenoma but which may inform some of the variation in the appearances of invasive carcinomas. Of course, small-cell carcinomas may arise in the background of ordinary-appearing adenomas but this is rare.

Adenomas have their initiation point near the surface of the mucosa such that tiny adenomas only affect the upper half of the mucosa, growing in a top-down fashion [275]. Genetically altered cells in the superficial portions of the mucosa spread laterally and downward to form new crypts that first connect to preexisting normal crypts and eventually replace them. This is a useful feature to remember in separating them from both reactive lesions and colitis-associated dysplasia, both of which seem to display bottom-up growth. Adenomas also usually display prominent apoptosis and may contain scattered neutrophils. The presence of prominent apoptosis can be a helpful diagnostic feature.

Adenomas may undergo striking mucosal prolapse changes, which can cause a host of diagnostic problems since neoplastic glands can herniate into the submucosa and, similarly, strands of muscularis mucosae can proliferate into the lamina propria and simulate submucosa. When neoplastic glands from adenomas prolapse into the submucosa, this can occasionally impart an appearance similar to that of invasive carcinoma, especially if the glands become obstructed and inspissated mucus dissects into the surrounding connective tissue, so-called *pseudoinvasion* [473]. The following clues are used to separate this artifact from true invasive carcinoma.

- In pseudoinvasion, lamina propria is dragged along with the neoplastic glands into the submucosa.
- There is often accompanying hemosiderin.
- The proliferation in the submucosa has the same cytoarchitectural features as that which can be recognized as adenoma only in the portion clearly in the mucosa; even high-grade dysplasia may be among these cytological features.

When an adenoma has high-grade dysplasia (Fig. 137.101), we mention this in our report but point out that the lesion still has no metastatic potential to forestall overly aggressive treatment in the event that the reader of the report is not familiar with this basic principle. When carcinomas arise in adenomas of the colon, invasion of the lamina propria is considered biologically equivalent to high-grade dysplasia (since the lamina propria of the colon is believed to lack lymphatic access). Intramucosal carcinoma in the colon is staged as Tis rather than T1 [474] so some observers do not report

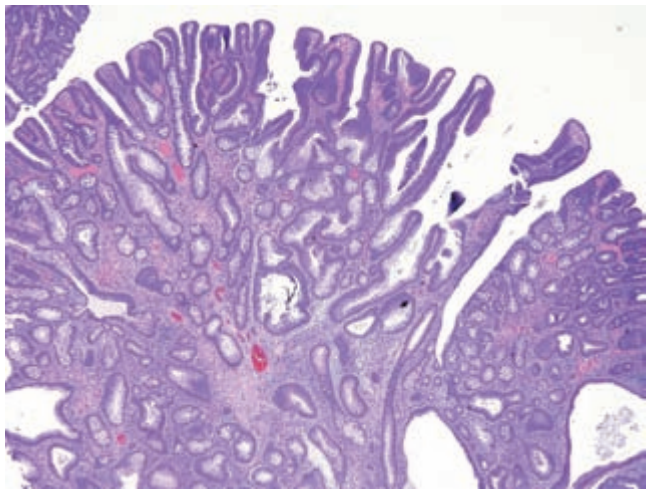

Figure 137.100 Tubular adenoma. By definition, the epithelium is dysplastic (neoplastic) but no invasive carcinoma is seen here.

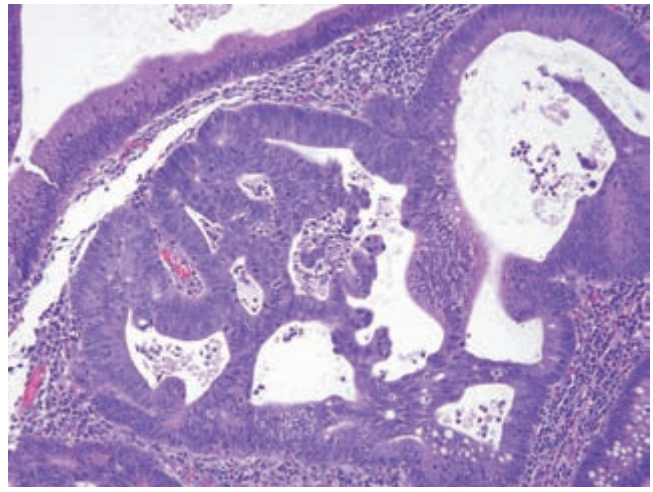

Figure 137.101 High-grade dysplasia in a tubular adenoma. The gland in the center is complex with a cribriform architecture. However, the basement membrane around it is intact.

this invasion. We do choose to report intramucosal carcinoma in adenomas as such but always include a note stating that it is biologically equivalent to high-grade dysplasia and that complete polypectomy should be curative. We provide this information as a precaution in the event that additional sampling might disclose deeper invasion.

Pathological evaluation of early colorectal cancers (pT1) diagnosed and treated by endoscopic polypectomy (malignant polyps)

Carcinomas develop in around 1 in 25 adenomas left in situ. When these are found in endoscopically removed polyps, a management decision must be made and the role of the pathologist is important. To justify colectomy, the risk of the patient having a metastasis must be higher than the risk to the patient of undergoing surgery to remove a segment of colon. Criteria to inform this decision have appeared in the literature [475,476] and have largely stood the test of time. Early studies indicated that there were levels of invasion akin to those in a melanoma [475] but other protocols have proved better.

The diagnosis and treatment of colorectal cancers by endoscopic polypectomy has become commonplace. Malignant polyps are adenomas that contain any amount of invasive carcinoma, which is defined as tumor that has penetrated the muscularis mucosae into the submucosa. They also include polypoid carcinomas, in which the entire polyp head is replaced by carcinoma. By definition, malignant polyps exclude adenomas containing intraepithelial carcinoma or intramucosal carcinoma because these polyps lack biological potential for metastasis. Polyps containing invasive carcinoma comprise about 5% of all adenomas. The chance that any given adenoma contains invasive carcinoma increases with polyp size, and the incidence of invasive carcinoma in adenomas greater than 2 cm in greatest dimension ranges from 35% to 53% [477]. Therefore, any polyp greater than 2 cm in diameter should be approached with suspicion that it might harbor an invasive cancer. When technically possible, these polyps are best removed intact rather than piecemeal, with as great a margin as possible at the base or stalk. Identification of the resection margin is necessary for determining both the adequacy of the excision and the closest approach of the tumor, a parameter that predicts the risk of tumor recurrence.

Malignant polyps often constitute a form of early carcinoma (pathological category pT1) curable by endoscopic polypectomy alone [478–480]. However, the incidence of an unfavorable outcome (lymph node metastasis or local recurrence from residual malignancy) for malignant polyps treated by polypectomy alone varies from about 10% to 20% [476,481–483]. Pathological evaluation is critical in defining polyps with an increased risk of residual or recurrent disease, and the subsequent clinical management of the patient may be based partly on the findings. The histopathological parameters that are known to be associated with a significantly increased risk of adverse outcome are listed below.

- High tumor grade (or histological type that is, by convention, always considered high grade, such as poorly differentiated adenocarcinoma, signet ring cell carcinoma, small-cell carcinoma, or undifferentiated carcinoma). It remains unclear in the literature whether poorly differentiated carcinomas apparently confined to the lamina propria have the biological potential to metastasize. In a limited series, patients with such tumors did well, but we would hesitate to suggest polypectomy alone for a poorly differentiated intramucosal carcinoma in a young patient [484].
- Tumor at or less than 1 mm from the resection margin (some authors advise 2 mm). We assess this by making two small dots (one at the leading edge of the tumor and the other at the nearest cauterized margin) and measuring the distance between them with a ruler. It is important to remember that cauterized tissue contracts, a process that can pull the normal tissue margins together, giving a false impression of positive margins.
- Small (thin-walled) vessel (presumed lymphatic) involvement by tumor (Figs 137.102 and 137.103).

In the presence of one or more of these features, the risk of an adverse outcome following polypectomy is estimated to be about 10%–25%. Therefore, if one or more of these high-risk features are found on pathological examination, further therapy may be indicated. Optimal management is decided on an individual basis, but segmental resection of the involved colonic segment, local excision (e.g., transanal disc excision for a low rectal lesion), or radiation therapy may be considered. In the absence of high-risk features, the chance

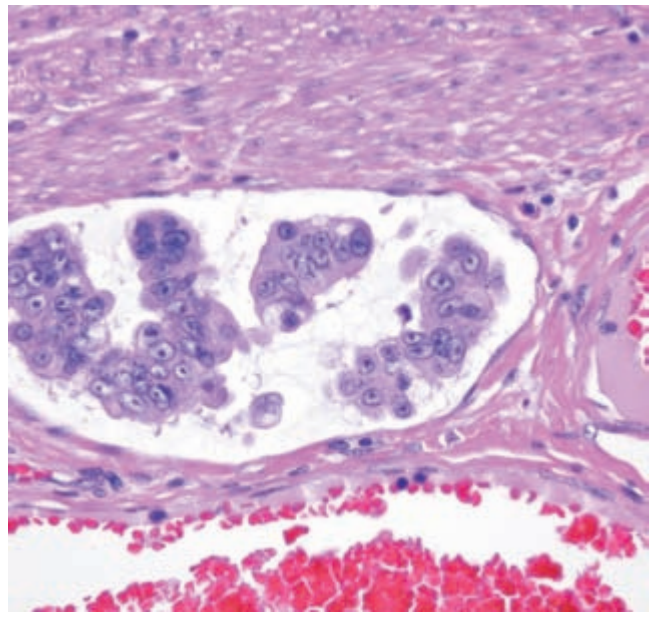

Figure 137.102 Carcinoma arising in association with an adenoma; vascular space invasion. This is a feature that most authors believe should prompt resection following diagnosis of cancer in a polyp.

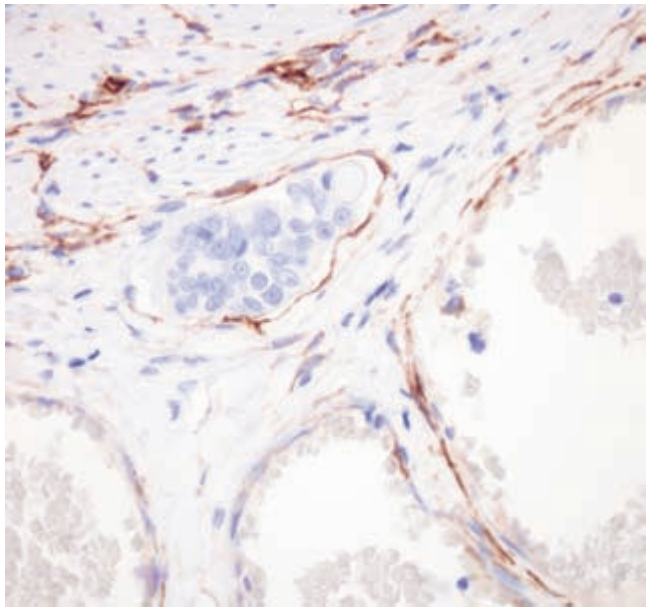

Figure 137.103 Carcinoma arising in association with an adenoma; vascular space invasion. This CD34 stain highlights endothelial cells lining the invaded vessel from the lesion seen in Fig. 137.102.

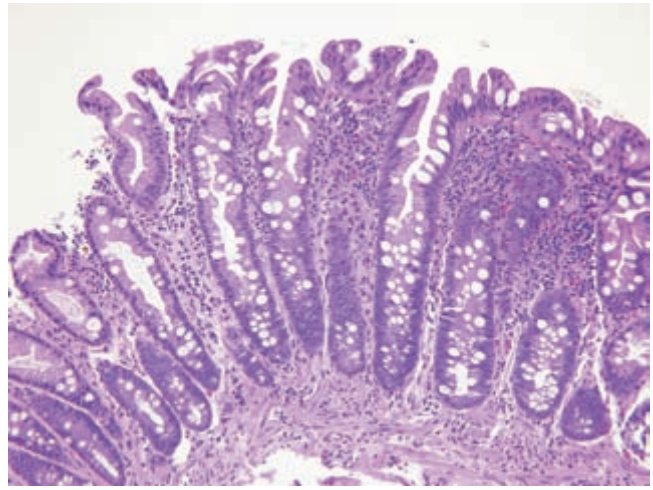

Figure 137.104 Hyperplastic polyp. This serrated polyp shows cells with eosinophilic cytoplasm. Note that the bases of the glands are narrow.

of adverse outcome is extremely small, and polypectomy alone is considered curative.

In the pathological evaluation of malignant polyps, assessment of small-vessel invasion can be difficult with interobserver variability [476]. In fact, small-vessel invasion may be impossible to diagnose definitively in some cases and ultimately may be judged as being indeterminate. An absolute diagnosis of vessel invasion is dependent on finding carcinoma cells within an endothelial-lined space. Contraction artifact in the tissue, tumor-induced stromal sclerosis, and extracellular pools of mucin secreted by tumor cells may all complicate the evaluation of vessel invasion. Examination of additional tissue levels of the specimen, review by a second observer, or immunohistochemical staining for endothelial markers may or may not resolve the dilemma. In published cases in which malignant polyps lacked definitive evidence of high-risk features but where the patients eventually died of their disease, lymphatic invasion had been judged (on blinded review) as indeterminate because of a lack of interobserver agreement [476]. This suggests that even the suspicion of small-vessel invasion on pathological examination should be considered as potentially important.

Small-cell carcinomas of the colon

These tumors are morphologically identical to those in the lung. They are typically found in the right colon where they are often associated with an ordinary adenoma or typical colorectal adenocarcinoma. They are not found associated with carcinoid tumors. The prognosis is poor and patients often have metastases at the time of surgery. The small-cell component usually proliferates off the lower portions of the lesion and is thus not detected on biopsies. Like small carcinomas in other sites, these express neuroendocrine markers (chromogranin and synaptophysin). Additionally, like small-cell cancers elsewhere in the body, about one-fourth stain using CD117/c-kit antibodies [485] but lack *kit* mutations. Carcinoid tumors and conventional colorectal cancers do not display CD117/c-kit labeling.

Serrated polyps (hyperplastic polyps, traditional serrated adenomas, sessile serrated adenomas)

For many years, physicians have believed that there was a simple set of polyps called hyperplastic polyps that could be ignored as they posed no risk. Pathologists recognized them by their serrated microscopic architecture. However, much new information has now been gained about a subset of polyps that superficially resemble hyperplastic polyps, but one with "teeth" among the serrations. The concept of a *serrated pathway* to colorectal neoplasia is very exciting but its effect on our daily practice remains unclear. We are now confronted with a new set of preneoplastic lesions to classify and manage.

Serrated polyps traditionally included hyperplastic polyps, mixed hyperplastic/adenomatous polyps, and serrated adenomas. It is now apparent that there are more groupings that need to be addressed, and an updated classification might include traditional left-sided hyperplastic polyps (Fig. 137.104), sessile serrated adenomas (Fig. 137.105), sessile serrated adenomas with superimposed dysplasia (formerly mixed adenomatous and hyperplastic polyps) (Figs 137.106 and 137.107), and traditional serrated adenomas (Fig. 137.108) [486]. It now appears that sessile serrated adenomas are the precursor to some colorectal cancers that exhibit high-level microsatellite instability (MSI-H) and which have unique genetic features (Table 137.6), including alterations in mis-

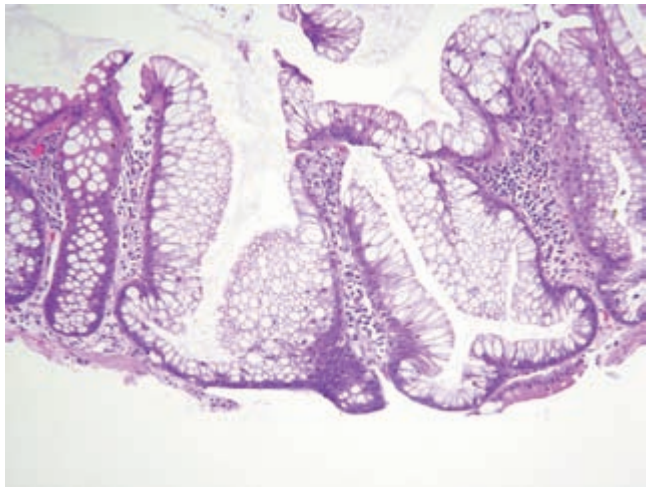

Figure 137.105 Sessile serrated adenoma. This lesion superficially resembles a hyperplastic polyp but differs by having broad-based glands (compare with Fig. 137.104). It lacks conventional dysplasia but is fully capable of progressing to invasive carcinoma.

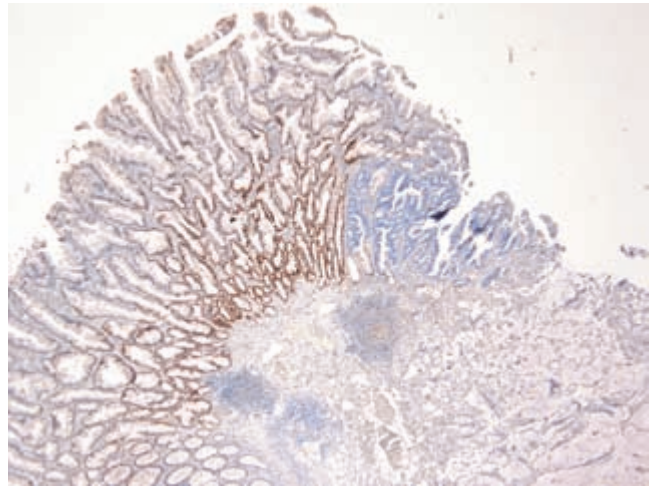

Figure 137.107 Sessile serrated adenoma with associated dysplasia and invasive carcinoma. In this immunohistochemical preparation for the mismatch repair protein MLH1, there is (nuclear) loss in the high-grade dysplasia and carcinoma component.

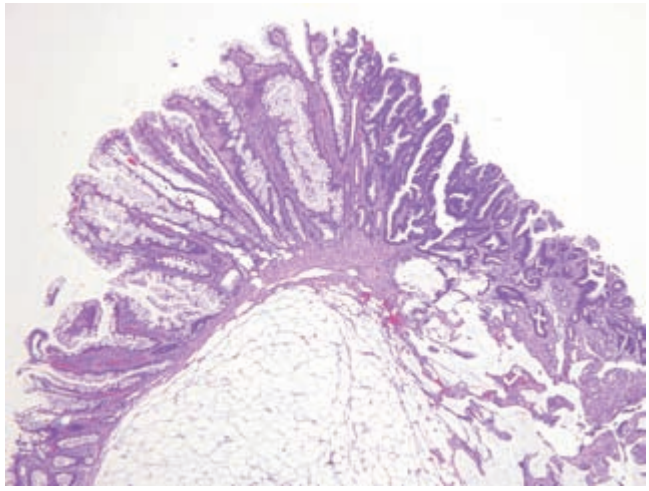

Figure 137.106 Sessile serrated adenoma with associated dysplasia and invasive carcinoma. The high-grade dysplasia and carcinoma component is at the right of the field.

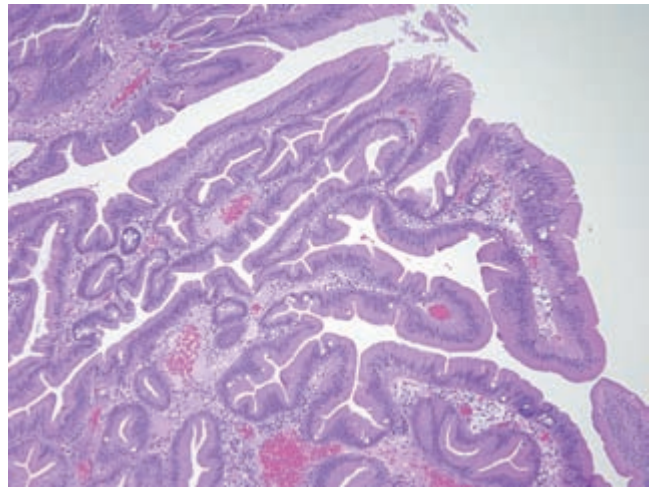

Figure 137.108 Traditional serrated adenoma. There is serrated architecture of the epithelial cells as well as traditional epithelial dysplasia like that of an ordinary adenoma.

match repair genes and *BRAF* alterations, both of which relate to MSI-H.

An important set of observations was published in the American Journal of Surgical Pathology that has set the stage for a radical change in how pathologists address colorectal polyps [487], although this paper had earlier underpinnings. Traditionally, the two global categories of colorectal epithelial polyps have been adenomatous and hyperplastic polyps. It is well recognized that adenomatous polyps are premalignant lesions. The molecular pathway most often seen in sporadic colorectal cancers but also in FAP is thus called the adenomatous polyposis coli (or APC) pathway. Subsequently, another molecular pathway to colorectal cancer, the MSI pathway, has also been described. Like the APC pathway, this can be seen in either sporadic colorectal adenocarcinomas or an inherited condition called hereditary nonpolyposis colon cancer (HNPCC). The key feature of this pathway is dysfunctional mismatch repair enzymes and subsequent accumulation of mutations. Colon cancers in these patients have a tendency to arise on the right side of the colon. In the work published by Torlakovic and colleagues [487], it was noted that there is a subset of polyps that tends to occur on the right side of the colon. These polyps superficially resemble hyperplastic polyps of the left colon but differ by larger size, a higher proliferative index, the presence of serrations extending to their bases, dilated architecture of the glands at

Table 137.6 *BRAF* mutations in polyps and cancers of the colorectum

Type of lesion	Morphology and anatomical location	Patients with *BRAF* mutations (%)[a]
Conventional hyperplastic polyp	Serrated architecture, crypts slender at bases with serrations in the superficial portions, many endocrine cells, left-sided location, small size	19
Sessile serrated polyp (also called sessile serrated adenoma)	Serrated architecture with serrations to the bases of polyps, higher proliferative index, loss of endocrine cells, usually right-sided location, larger size	75
Mixed hyperplastic/adenomatous polyp (sessile serrated polyp with dysplasia)	Similar to sessile serrated polyp but with foci of adenomatous change, namely surface hyperchromatic nuclei aligned in a pencillate fashion	89
Traditional serrated adenoma	Serrated architecture and adenomatous-type epithelium with hyperchromatic pencillate nuclei	20
Conventional adenoma	Tubular or tubulovillous architecture with dysplastic epithelium with pencillate nuclei and top-down neoplastic growth [275]	0
Sporadic MSI-H cancers	Poorly differentiated or mucinous appearance, often with prominent tumor-infiltrating lymphocytes, tendency for right side, reduced CK20 expression [570]	76
HNPCC cancers	Medullary or mucinous pattern, tendency to right side. Reduced CK20 expression [570]	0
Conventional MSS cancers	Moderately differentiated carcinomas with ample glandular lumenal necrosis, $CK20^{+}CK7^{-}$ keratin profile	9

a Mutations in *BRAF* have been linked with colorectal cancers showing high-level microsatellite instability.
HNPCC, hereditary nonpolyposis colorectal cancer; MSI-H, high-level microsatellite instability; MSS, microsatellite stable.

the bases, and a tendency to have mismatch repair defects. The authors had previously grouped such polyps with so-called serrated adenomas but this is somewhat unsatisfactory as the lesions lack the pencillate nuclei that typify traditional serrated adenomas [488]. Thus, although these polyps lack conventional dysplasia, they are regarded as adenomas.

Initially hyperplastic polyps were regarded as benign and metaplastic. However, there is now considerable evidence implicating at least a subset of what have traditionally been called hyperplastic polyps in the development of a subset of colorectal carcinomas [489–492]. Initially, reports and small series of adenocarcinomas associated with giant or large hyperplastic polyps (usually defined as > 1 cm) appeared [493,494]. It also became apparent that the presence of multiple hyperplastic polyps in the form of hyperplastic polyposis (also known as giant hyperplastic polyposis [495] or serrated adenomatous polyposis [496]) is clearly associated with the development of adenocarcinoma [495]. Even in patients lacking criteria for hyperplastic polyposis, some hyperplastic polyps are associated with colorectal cancers. Some patients with MSI colorectal cancers have an increase in serrated polyps (hyperplastic polyps and serrated adenomas) but not adenomas in the background mucosa [497]. A large series of more than 90 MSI colorectal cancers in which hyperplastic polyps had been diagnosed near the site of the colorectal cancer at earlier examination further implicates hyperplastic polyps in a subset of colorectal carcinoma [498].

Molecular data now provide convincing evidence for a pathway from hyperplastic polyps (or hyperplastic-like polyps) to colorectal carcinoma. As such, the serrated pathway to colorectal cancer is a hot topic in the GI pathology literature [486]. Our understanding of this pathway is under evolution. Early steps appear to involve reduced cell death (apoptosis) in serrated polyps leading to prolonged cell life, an increased concentration of epithelial cells resulting in a serrated appearance, and a presumed susceptibility to DNA methylation.

Thus, in summary, lesions that we have traditionally diagnosed as hyperplastic polyps are heterogeneous lesions, a subset of which is now regarded as the precursor of some colorectal cancers with MSI. Some authors have distinguished this subset from classic hyperplastic polyps and have introduced the term *sessile serrated adenoma*. These lesions frequently show *BRAF* mutations and DNA methylation [499–501]. It is estimated that around 25 hyperplastic polyps of the proximal colon exist for every colorectal cancer with MSI [502]. Further research is required to identify additional risk factors for hyperplastic polyps other than anatomical location. These may be demographic, clinical, morphological, or molecular.

The key practical issue is how to manage patients with the various serrated polyps, the main clinical decisions being how to address incompletely excised polyps, whether to perform pan-colonoscopy when index lesions are identified

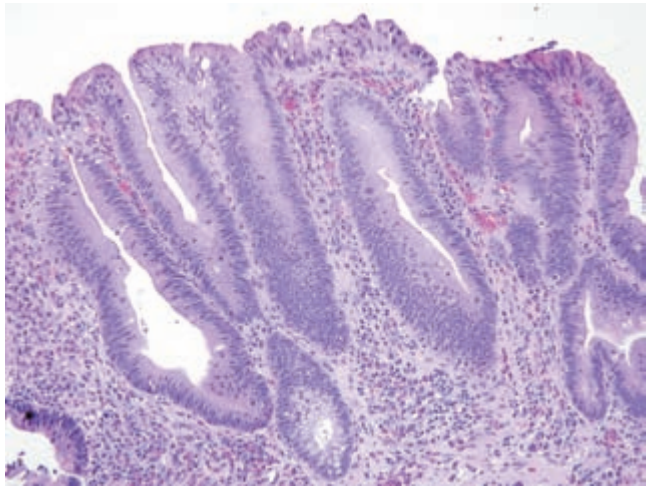

Figure 137.109 Dysplasia-associated lesion or mass. This lesion has low-grade dysplasia and presented as an elevated visible lesion.

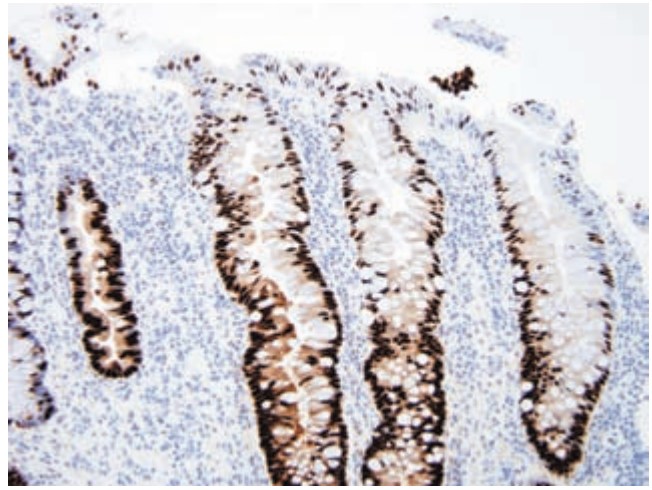

Figure 137.110 Dysplasia-associated lesion or mass (DALM). A p52 stain can be useful in confirming an impression of DALM.

on procotoscopy or sigmoidoscopy, and whether long-term endoscopic surveillance is needed. Currently, straightforward guidelines exist for the management of adenomatous polyps but guidelines for the serrated family of polyps are lacking. Snover and colleagues have suggested the following guidelines [486].

- Right-sided sessile serrated adenomas: complete endoscopic removal. If this is not feasible, additional sampling, probably at yearly intervals, to monitor for dysplasia. If this appears, surgical excision should be considered.
- Left-sided lesions: complete removal. If not feasible, additional sampling to monitor for dysplasia. A higher threshold for suggesting colectomy.
- The interval for surveillance remains unknown. It is probably reasonable to follow as per adenomas.

Colitis-associated dysplasia and colon carcinoma

Criteria for grading dysplasia in the setting of inflammatory disease were developed in 1983 [503] and remain useful. Dysplasia in ulcerative colitis is separated into low and high grades (Figs 137.109–137.111) and cases in which the findings are unclear are diagnosed as indefinite for dysplasia. The criteria for grading dysplasia in colitis are summarized in Table 137.7 [504]. Essentially, these are similar to other sites except that many patients have striking active inflammation, so it is difficult to make definitive diagnoses of low-grade dysplasia. A diagnosis of low-grade dysplasia requires nuclear alterations that extend onto the mucosal surface without loss of nuclear polarity whereas high-grade dysplasia displays surface loss of nuclear polarity. Some literature supports colectomy in the presence of any degree of dysplasia; others recommend resection only in the setting of high-grade dysplasia in flat mucosa. Dysplasia-associated lesion or mass (DALM) is typically irregularly shaped and raised, without a discrete stalk. The dysplasia may be found at any location

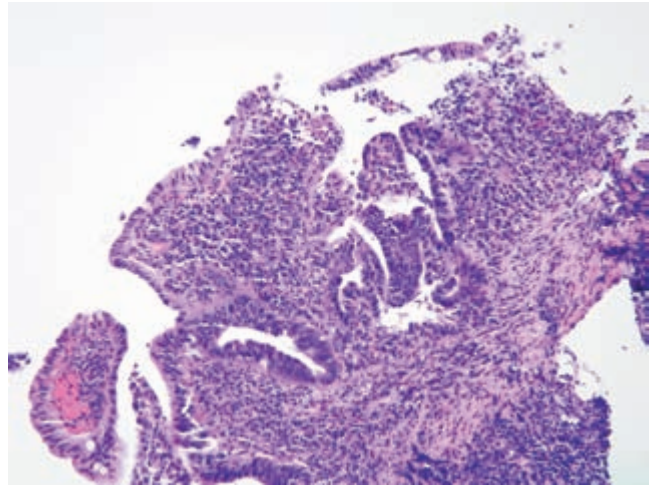

Figure 137.111 Dysplasia-associated lesion or mass. This area shows high-grade dysplasia.

in the crypt, a difference from an adenoma in which the dysplasia begins at the surface and moves down the crypt. Endoscopically, DALMs are often difficult to remove, in some instances because they are contiguous with an underlying invasive adenocarcinoma. Because sessile irregular DALMs are likely to harbor an adenocarcinoma, colectomy is sometimes recommended. While distinguishing between an adenoma and a DALM is important, in some cases this distinction is difficult to impossible. Happily, emerging evidence supports treating the lesion in the same fashion as a sporadic adenoma (i.e., polypectomy) if it is discrete and endoscopically adenoma-like [505]. Criteria that some observers have applied for distinguishing between colitis-associated dysplasia and adenomas are summarized in Table 137.8 but unfortunately there are no wholly reliable criteria for this distinction [506–509]. In daily practice, we report such lesions as

Table 137.7 Grading criteria[a] for ulcerative colitis

Feature	Negative	Indefinite	Low-grade dysplasia	High-grade dysplasia	Cancer
Surface maturation	+	Incomplete	–	–	–
Architecture	Intact	Intact or mild alteration[b]	Intact to mild alteration	Intact to marked alteration[c]	Desmoplasia with any architecture
Cytology	Normal or reactive[d] or reparative[e]	Mild or focal marked atypia[f] with inflammation/ulceration; marked atypia limited to crypts but with surface maturation; mild atypia that mostly matures	Mild to moderate atypia (more atypia than indefinite category), ranging from focal to diffuse but with maintained nuclear polarity[g]	Marked atypia (more than low-grade dysplasia), ranging from focal to diffuse; loss of nuclear polarity present in the majority	Mild or marked atypia
Other		Absent surface epithelium preventing assessment of surface maturation	Nuclei may fill the thickness of the epithelium and still be low grade	Nuclei do not have to extend above the halfway point of the epithelial thickness	

a General criteria applying to all grades: (1) biopsies that stand out as different from others, those with mucin loss or hypermucinous change, dystrophic goblet cells or endocrine cell hyperplasia tend to associate with dysplasia but not always; (2) in the case of discrepancy between cytology and architecture, cytology determines the grade; (3) in the presence of severe inflammation, with or without erosion/ulceration, assignment of unequivocal dysplasia is done only in very rare circumstances and the overwhelming majority of such biopsies should be classified as indefinite.
b Mild architectural alteration: glandular crowding, some degree of loss of parallel crypt arrangement.
c Marked architectural alteration: very crowded glands, back-to-back glands, fused or cribriform growth, dilated glands with lumenal necrosis, or zones of coagulative necrosis confined to mucosa.
d Reactive cytological alteration: basal proliferative glands with atypia that matures or slight nuclear atypia extending toward the surface in the presence of active inflammation; chromatin is often normal or open.
e Regenerative cytological alteration: single cell layer at surface repopulating eroded or ulcerated stroma usually devoid of glands or with gland loss; surface cells may have variably bizarre nuclei but they are limited to a single nonstratified pattern with abundant cytoplasm in addition.
f Cytological atypia: nuclear enlargement or hyperchromasia, or stratification, or irregular nuclear contours.
g Maintenance of nuclear polarity: nuclei whose longitudinal axes remain perpendicular to their basement membrane and the nuclei remain orderly and oriented to each other; loss of nuclear polarity refers to nuclei without a perpendicular orientation to the basement membrane and with a disorderly arrangement relative to each other.

Table 137.8 Distinction between polypoid colitis-associated dysplasia and sporadic adenomas arising in inflammatory disease

Feature	Adenoma	Colitis-associated dysplasia
Patient age (years)	Older (> 50)	Younger (< 50)
Disease activity	Active or inactive	Usually active
Disease duration (years)	Shorter (< 10)	Longer (> 10)
Endoscopic appearance	Well marginated	Irregular
Glands	Regular configuration	Irregular configuration
Surface	Homogeneous	Mixture of nonneoplastic and neoplastic glands
Distribution of mucin	Often near lumenal surface	Irregular
Dystrophic (upside-down) goblet cells	Rare	Frequent
Nuclei	Stratified, same level	Stratified, various levels
Stroma	Sparse	Variable
Demarcation from surrounding mucosa	Sharp	Gradual transition
Appearance of surrounding mucosa	Mildly distorted	Prominent architectural distortion
Prominent lamina propria mononuclear cells	No	Yes
Prominent lamina propria neutrophils	+/–	+
Prominent p53 immunohistochemistry	No	Yes (nuclear staining)
β-Catenin	Yes (nuclear staining)	No

"polypoid low-grade (or high-grade) dysplasia versus sporadic adenoma" and note why we favor one or the other (or why we are unable to favor one or the other). As a general rule, lesions arising in the field of inflammatory disease that have an unusual endoscopic appearance are probably best regarded as DALMs. In other words, the gross appearance probably yields more information than the microscopic one. In some cases, we perform p53 and β-catenin immunohistochemistry and find it useful but it does not always prove helpful, in which case we report it as noncontributory.

Adenocarcinomas detected during surveillance have a significantly better prognosis than those found in individuals with clinical symptoms. Total colectomy is then indicated. Resection with subsequent ileoanal anastomosis allows the patient to have relatively normal bowel function by maintaining the anal sphincter following colectomy.

There is an increased risk of adenocarcinoma in patients with Crohn's disease, estimated to be four to 20 times more than those without Crohn's disease. Adenocarcinomas may arise in morphologically normal bowel, in areas of stricture, and within fistula tracts, making diagnosis difficult. Multiple synchronous or metachronous adenocarcinomas may occur and involve the large and small intestines. Well-differentiated tumors can extend from fistula tracts and be misinterpreted as an adenoma. While survival may be good for patients with adenocarcinomas arising in fistula tracts, overall mortality for adenocarcinomas arising in Crohn's disease is high, approximately 80%. This may be due to the similarities between symptoms of Crohn's relapse and symptoms of developing cancer, resulting in delayed diagnosis. Dysplasia does occur in patients with Crohn's disease; however, no standard surveillance strategy has been advocated due to the technical difficulty in surveying the bowel. Unlike ulcerative colitis, resection is not advocated for dysplasia because of the risk of postoperative complications.

Mesenchymal tumors

Benign fibroblastic polyps

These are incidental lesions detected in adult patients undergoing screening colonoscopy. As such the mean age in the reported series was 61.5 years [510]. The present as small polyps at endoscopy (size range 0.2–1.5 cm). The polyps consist of an expansion of the lamina propria by a monomorphic spindle cell population lacking mitotic activity or necrosis (Fig. 137.112). Some are intimately admixed with hyperplastic polyps. Benign fibroblastic polyps are managed by simple polypectomy.

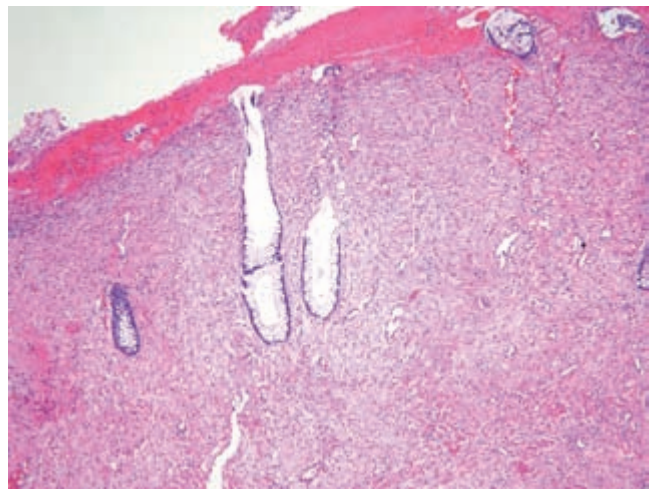

Figure 137.112 Benign fibroblastic polyp of the colon. The lamina propria is expanded by a benign spindle cell proliferation.

Leiomyomas

If a brightly eosinophilic spindle cell lesion with bland cytological features arises in association with the muscularis mucosae, it is in all likelihood an incidental leiomyoma, readily managed by simple polypectomy [511]. Of course most spindle cell tumors of the wall of the GI tract are GISTs (except in the esophagus where leiomyomas prodominate) but muscularis mucosae-associated tumors of the colorectum are usually leiomyomas. Miettinen and colleagues [511] studied 88 such tumors of the muscularis mucosae of the colon and rectum. The lesions, except one, were removed by snare polypectomy as incidental lesions at cancer or polyp surveillance; one small tumor was an incidental finding in the rectal resection specimen. The tumors had a significant male predominance (overall 2.4 : 1) and were found in adults (38–85 years, median 62 years). The lesions were typically small (range 1–22 mm, median 4 mm) and located predominantly in the rectum and sigmoid (72%). All were composed of well-differentiated eosinophilic smooth muscle cells that were seen immediately beneath the mucosa, obliterating the muscularis mucosae layer and merging with it. Two tumors had significant atypia (symplastic leiomyoma); mitotic activity was seen in one of these tumors but not in others. The lesional cells were uniformly positive for SMA and desmin and negative for CD34, CD117, and S100 protein, based on immunohistochemical studies of 20–24 cases with each marker. No GISTs were identified among the tumors of muscularis mucosae, and no CD117-positive cells, except mast cells, were seen in the muscularis mucosae layer. None of the patients had morbidity related to the tumor. Based on the authors' follow-up data on 29 patients, leiomyomas of muscularis mucosae are benign. In daily practice, we do not perform immunohistochemical stains on these lesions, but in any doubtful case a negative CD117 is reassuring.

Gastrointestinal stromal tumors

GISTs are most common in adults in the sixth decade and arise in the ascending and descending colon and usually present with pain or a mass. Except for small subserosal lesions, they are typically transmural tumors with intralumenal and outward-bulging components. Morphologically, they are

heterogeneous with spindle cells in fascicles, palisades or storiform arrangement, and sometimes an organoid patter; a minority has epithelioid cells in varying proportions.

Most (75%) colon GISTs are CD117 positive and 60% have CD34, with c-*kit* mutations in exon 11 in about one-third of cases. Some authors have taken a size of 5 cm and five mitoses per 10 high-power fields as thresholds for malignancy [512,513], but Miettinen and colleagues found lower levels [514]. In their series, tumors smaller than 1 cm did not recur, whereas in larger tumors 20% with minimal mitoses and all with more than five mitoses per 50 high-power fields metastasized or died of disease. Interestingly, the few cases with skeinoid fibers had a better prognosis. These tumors are not commonly encountered on mucosal biopsies as they are typically mural; when they are, performing an immunohistochemical panel is prudent.

Neural tumors

Ganglioneuromas occur in two general settings: as solitary isolated lesions, and syndromically as multiple lesions that either produce multiple exophytic polyps (ganglioneuromatous polyposis) or poorly demarcated transmural proliferations (ganglioneuromatosis) [515]. In solitary examples, there is no gender predominance and lesions have been detected in adults aged 20–90 years, with a peak incidence between the ages of 40 and 60 (mean age 48 years). The majority are found in the colon, usually on the left side. Most patients are asymptomatic and the lesions are detected during routine colonoscopy. Solitary lesions are not associated with genetic syndromes. In contrast, ganglioneuromatous polyposis is associated with FAP and diffuse ganglioneuromatosis with multiple endocrine neoplasia (MEN) type IIB and with NF1. Diffuse ganglioneuromatosis is found in virtually all patients with MEN IIb and often antedates the development of the endocrine neoplasms. Patients with MEN IIb and ganglioneuromatosis present with diverse GI symptoms that may include constipation, diarrhea, difficulty feeding, projectile vomiting, and crampy abdominal pain. Most syndromic GI tract ganglioneuromas are found in the colorectum and in younger patients than sporadic isolated ganglioneuromas (mean ages about 35 years).

Polypoid isolated ganglioneuromas are small sessile or pedunculated polyps that grossly resemble juvenile polyps or adenomas and are 1–2 cm in size. The polyps in ganglioneuromatous polyposis are multiple (20–40) and display greater variability than sporadic ones, ranging in size from 1 mm to over 2 cm. Some are filiform. Diffuse ganglioneuromatosis results in a poorly demarcated whitish thickening that may be transmural.

At low magnification, polypoid sporadic ganglioneuromas often resemble juvenile/inflammatory polyps in that they have disturbed crypt architecture and expanded lamina propria. At higher magnification, the lamina propria is expanded by collections of spindle cells within fibrillary matrix and

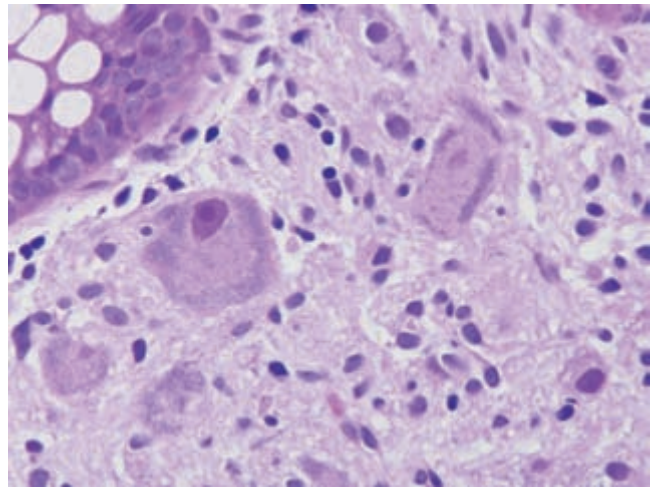

Figure 137.113 Ganglioneuroma. Aberrant ganglion cells and Schwann cells (bland spindled cells) proliferate in the colonic lamina propria. Most examples are isolated sporadic lesions.

irregular nests and groups of ganglion cells (Fig. 137.113). Sporadic examples may also have submucosal extension and a plexiform arrangement involving the submucosal nerve plexus such that they superficially resemble neurofibromas (differing by the presence of many ganglion cells). The ganglioneuromas in ganglioneuromatous polyposis show overlapping features with sporadic ganglioneuromas but tend to be more variable and have more numerous ganglion cells and filiform architecture. In diffuse ganglioneuromatosis, the process is centered around the myenteric plexus and is either diffusely intramural or transmural and consists of fusiform expansions or confluent transmural ganglioneuromatous proliferations.

Sporadic ganglioneuromas are treated by polypectomy and seldom recur. Patients with syndromic ganglioneuromas must be carefully followed based on their specific syndromes. Those with NF1 may develop other neural lesions, including malignant peripheral sheath tumors, and those with MEN IIb may develop endocrine neoplasms. Polypoid ganglioneuromas may herald Cowden disease, tuberous sclerosis, FAP, and juvenile polyposis whereas the diffuse type is most likely to be asociated with NF1 and MEN IIb. This type may cause strictures requiring resections but the ganglioneuromas are all themselves benign.

Schwannomas

Like gastric schwannomas, those of the colon differ from those encountered in the somatic soft tissues by lacking a capsule and having a prominent lymphoid cuff [516,517]. They consistently display strong diffuse S100 protein and lack CD117/c-kit. These tumors differ from conventional schwannomas genetically as well as they have no NF2 alterations whereas conventional schwannomas do [518] but share NF1 alterations with conventional schwannomas. We have

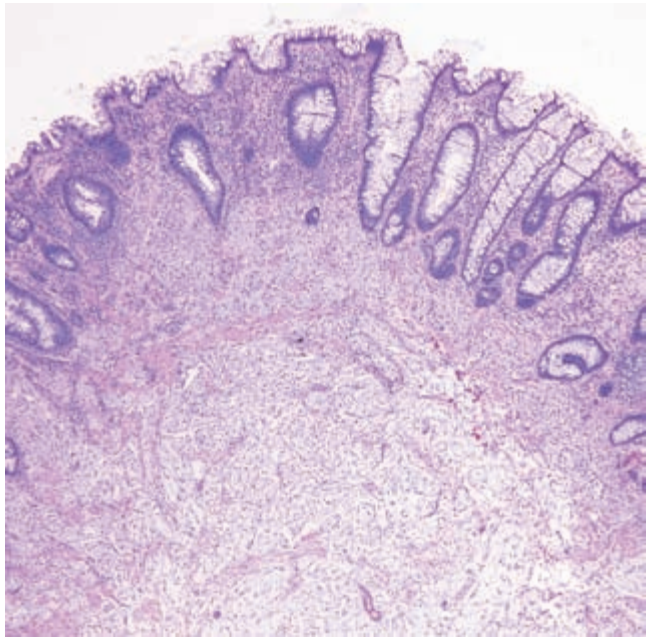

Figure 137.114 Benign epithelioid peripheral nerve sheath tumor. This lesion is centered around the lamina propria and superficial submucosa.

also seen a number of sporadic small epithelioid nerve sheath tumors in our practice that present as small polyps at endoscopy [519] (Fig. 137.114).

Granular cell tumor

Colon granular cell tumors are occasionally encountered in practice and are the second most commonly encountered GI tract granular cell tumor (after esophagus) but are still rare. In our in-house material, we have encountered only two colorectal granular cell tumors in a 20-year period, one of the cecum and the other of the rectum. They display the features of granular cell tumors elsewhere. There are rare reports of multicentric granular cell tumors of the colon [520]. Malignant examples arising in the colorectum were not identified by a PubMed search.

Lipomas

Multiple GI tract and cutaneous lipomas are known in patients with ganglioneuromas of the colon [515] but most lipomas of the colon are sporadic lesions centered around the submucosa. Of course, expanded adipose tissue at the ileocecal junction is sometimes referred to as a lipoma but is probably simply prolapsed submucosal fat. Colorectal lipomas are uncommon and mostly a curiosity (in one study of 5000 sigmoidoscopies, only one lipoma was removed) but those that have been present for some time can result in symptoms based on mechanical problems [521]. Colorectal lipomas are lesions of adulthood and thus are occasionally found at screening and usually recognized by endoscopists by their yellowish color (Fig. 137.115).

Figure 137.115 Colonic lipomas. Surgical specimen.

Carcinoid tumors

In contrast to carcinoid tumors in the stomach, which are often indolent tumors arising in the setting of atrophic gastritis (stimulated by hypergastrinemia), those in the colon arise sporadically. There is a body of literature suggesting a recent explosion in the incidence of such tumors, but one that fails to factor in the advent of colonoscopy and endoscopy during the studied time period [216,217]. Colorectal carcinoids are essentially limited to the rectum and sigmoid. They have a spectrum of appearances just like all carcinoids. A prognostic cutoff size of 2 cm has been suggested in the literature [522].

Other tumors

Prostate and bladder carcinomas can extend directly into the colorectum. Metastatic breast carcinoma can also be encountered, where it mimics primary colonic signet ring cell carcinoma. A host of lymphomas can also be found.

Anus

It is probably most important for pathologists to remember that a biopsy from the anatomical (clinical) anus can display glandular, transitional, or squamous mucosa and a biopsy labeled "anus" showing colonic-type mucosa is not necessarily labeled incorrectly or obtained ineptly. The anal canal, by definition, begins as the rectum enters the puborectalis sling (palpated as the anorectal ring on digital examination) and ends at the squamous mucocutaneous junction with the perianal skin [474]. The anal canal forms during weeks 4–7 of gestation and the upper two-thirds is endodermally derived whereas the lower one-third is ectodermally derived; the dentate or pectinate line is where these zones meet.

The anus can also be divided into the mucosa-lined anal canal and the more distal epidermis-covered anal margin. Where the skin meets the canal, apocrine glands may be prominent. Cancers arising in the anal margin are regarded as skin cancers and are treated with local excision. The anal

canal extends proximally from the anal verge to the rectal mucosa. Most of the anal canal is lined by squamous mucosa, which is present between the anal verge and the dentate (or pectinate) line. The dentate line is a visually identifiable border between the more distal squamous mucosa and a transitional area of squamous and nonsquamous mucosa. The adjacent nonsquamous lining can consist of either transitional (urothelium-like) or rectal glandular mucosa [523,524]. Anal ducts and glands are found at the transition zone and lymphatic spaces are often prominent in these zones.

Biopsies of the anal canal are less frequently performed than those from the remainder of the GI tract. Of course the length of the anus accounts for the minority of the GI tract. For example, in our material, colon biopsy accessions from about 5000 patients each year are sent for pathology and about 5000 from the upper tract, but only about 250 from the anus. We would probably have fewer were it not for a clinic in our hospital directed at detecting HPV-related intraepithelial lesions in high-risk individuals. Anal cancers are uncommon (estimated new cases for 2004 about 4000, in contrast to about 147 000 for colon and rectum [197]) and pilonidal disease, which is common, is seldom biopsied.

Of course the anus can be the site of a host of conditions affecting the skin, a topic beyond the scope of this manual, but, for example, various keratoses can be found in the anal area. When typical seborrheic keratoses present in this area, they raise the possibility of condyloma based on their site despite their lack of viral cytopathic changes. In patients who have been irradiated, the usual radiation-associated changes are seen [525], including hyalinized vessels and collagen.

Nonneoplastic conditions

Hidradenoma papilliferum

This cystic and papillary apocrine neoplasm generally arises in the perianal skin and vulva. The characteristic affected individual is a white woman over the age of 30. The typical sites include labia majora, perineum, and perianal skin [526–528], although extragenital sites appear as case reports. Rare reports of malignant change in these are often contested.

The lesion forms a large epithelial-lined cyst in the middermis that displays elaborate papillary infoldings formed by fibrovascular cores lined by two layers of cuboidal epithelium with foci of bridging and tuft formation (Fig. 137.116). The lesions lack inflammation and the superficial portions of the cyst are often lined by a flattened squamous layer. If the pathologist is concerned that this is a metatastasis, CK5/6 has a relatively limited expression profile, being relatively specific for mesothelium and other pavement-type epithelium such as squamous epithelium, and it stains these tumors [529], a helpful feature in excluding an adenocarcinoma. These lesions also express estrogen receptor [530], a potential problem if the pathologist is concerned that they are metastatic from the breast or female genital tract, although they lack a desmoplastic response and are well marginated.

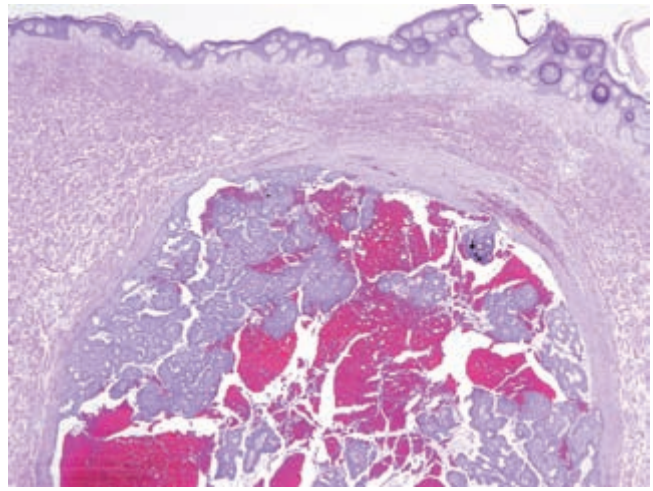

Figure 137.116 Hidradenoma papilliferum. This lesion shows differentiation along sweat gland lineage and is found in the perineum of females.

Hemorrhoids

Hemorrhoids are common and were the subject of both a review and a position statement by the American Gastroenterological Association in 2004 [531,532]. They were traditionally viewed as varicosities of submucosal veins but are now believed to reflect sagging or slippage of normal structures, probably exacerbated by straining at defecation. Hemorrhoids are normal anatomical structures found in the subepithelial space of the anal canal [533]. They consist of connective tissue cushions surrounding the direct arteriovenous communications between the terminal branches of the superior rectal arteries and the superior, inferior, and middle rectal veins. Anal subepithelial smooth muscle arises from the conjoined longitudinal muscle layer, passes through the internal anal sphincter, and inserts into the subepithelial vascular space. There, the smooth muscle suspends and contributes to the bulk of the hemorrhoidal cushions. The hemorrhoidal cushions serve as a "stopper" to ensure complete closure of the anal canal.

Hemorrhoidal vessels are usually located above the dentate line on the left lateral, right anterior, and right posterior aspects of the anal canal. Symptomatic hemorrhoids may be above (internal) or below (external) the dentate line. In some individuals, external hemorrhoids are actually prolapsed internal hemorrhoids.

When hemorrhoids are seen in excised material, they feature large ectatic vessels and the associated mucosa typically displays prolapse changes. Pagetoid dyskeratosis in overlying squamous mucosa, similar to that seen in prolapsed uterine cervices, is also observed [534]. However, we do not suggest reporting this peculiar pattern of dyskeratosis using such terminology (which might prompt excessive concern on the part of the surgeon) but recommend that it is not mistaken for the cytopathic changes of HPV.

Papillary endothelial hyperplasia/vegetant intravascular hemangioendothelioma

Papillary endothelial hyperplasia has been reported in all parts of the body [535–542] but the first report was in hemorrhoidal vessels, imparting a gross appearance that Masson likened to a cherry [543]. This benign reactive process is an unusually exuberant form of organizing vascular thrombus. Papillary endothelial hyperplasia may occur at any age and involve virtually any vessel, including those of neoplastic processes and vascular malformations. However, in its pure form, it typically presents as a solitary, superficial, firm, bluish or erythematous mass, involving the fingers, head and neck, or anorectal region.

Histologically, the lesion shows papillary fronds with a core of fibrin or hyalinized collagen, lined by a single layer of endothelial cells that may be plump or swollen but which lack significant atypia or mitotic activity. Occasionally the fronds appear to be free-floating within the vessel lumen. Extravascular extension may occasionally be seen, although it is usually not extensive.

Herpes simplex virus proctitis

HSV proctitis has the same viral cytopathic features as HSV elsewhere in the body. It is associated with the presence of genital lesions as well as with peno-anal intercourse [544–547]. Biopsies usually show characteristic multinucleated cells with smudged intranuclear inclusions in squamous epithelial cells at the edge of ulcers. Immunohistochemistry can be helpful in confirming an impression of HSV proctitis.

Crohn's disease

In 1978, Hughes proposed an anatomical and pathological classification for perianal Crohn's disease (Cardiff classification) in which each major manifestation of perianal Crohn's disease (ulceration, fistula, stricture) is graded on a scale of 0–2 (0, absent; 2, severe); fistulae are also classified as low (not extending above the dentate line) or high (extending above the dentate line, sometimes to the levator muscles). Other associated anal conditions, the intestinal location of other sites of Crohn's disease, and a global assessment of the activity of the perianal disease are also noted [548]. Despite its descriptive accuracy and comprehensiveness, the Cardiff classification system has never gained widespread acceptance because of the perception by clinicians that it is of limited clinical relevance [549,550].

In ulcerative colitis, involvement of the anal canal is typically nonspecific and unrelated to the inflammatory disease. In contrast, in Crohn's disease the anal canal itself is affected in about 25% of patients with classic small intestinal disease and in up to 80% of those with colonic involvement. Anal disease may be the initial manifestation in about one-third of patients with Crohn's disease. Biopsies may display a patchy active chronic inflammatory process but fissures, fistulae, and striking chronic inflammatory infiltrates are the hallmark. However, unless granulomas are detected, biopsy features are not specific and must be correlated with clinical ones. Anal biopsies are not commonly performed in Crohn's disease simply because they cause a certain amount of morbidity themselves. With anal Crohn's disease, the issue of treatment is far more compelling that than of biopsy interpretation [551].

Polyps

Fibroepithelial polyps

These lesions are also called anal tags and excising them is generally not suggested unless they are uncomfortable or interfere with personal hygiene since removing them may be extremely painful and, in the case of those associated with Crohn's disease, may result in poor healing and additional morbidity. They are essentially projections of anal mucosa and submucosa. When one arises at the leading edge of an anal ulcer or fissure, the term *sentinel tag* is applied. They are often submitted to the pathologist as hemorrhoids but lack vessels, features of hemorrhage, and organized thrombi. They are essentially the same lesion as skin tags (acrochordons).

Fibroepithelial polyps have received little attention in the pathology literature [552,553] but consist of myxoid or collagenous stroma covered by squamous epithelium (Fig. 137.117). Stromal cells with two or more nuclei are found in the majority of examples and large examples often harbor atypical stromal cells. Mast cells are frequent. The stromal cells in these polyps express vimentin, CD34, and sometimes desmin [552,553]. Electron microscopic examination shows fibroblastic and myofibroblastic features. Of interest is that subepithelial connective tissue from the normal anal mucosa shows bizarre multinucleated cells and mast cell infiltration so it has been assumed that fibroepithelial polyps reflect reactive hyperplasia of the subepithelial connective tissue of the anal mucosa.

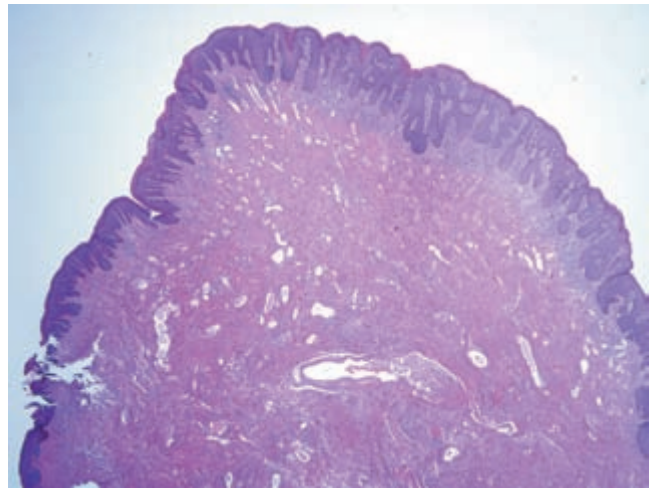

Figure 137.117 Anal fibroepithelial polyp. These appear similar to skin tags elsewhere.

Neoplasia

The bulk of anal neoplastic pathology encountered in daily practice revolves around the diagnosis of squamous carcinoma and its precursors even though such tumors are relatively rare. Resection specimens should be rarer still since most cancers are treated with radiation and chemotherapy. As such, biopsy diagnosis is particularly important. Resected anal specimens are handled differently from colorectal ones [524] and a key feature is that size rather than depth determines T status in anal cancers (T1, ≤ 2 cm; T2, 2–5 cm; T3, > 5 cm; T4, invasion into adjacent organs) [474].

Anal squamous intraepithelial neoplasia

The vast majority of such lesions, like those in the uterine cervix, are related to the various subtypes of sexually transmitted HPV infection, and these are presumed to be the precursors of invasive anal squamous cell carcinoma. The number of individuals in the population exposed to HPV is high; for example, 3% and 12% of US male and female blood donors respectively had positive serology for HPV16 in one study [554]. Since only about 4000 new anal and 10 000 new cervical cancers were reported in 2004 [197], this suggests a very low progression rate. However, it is known that HIV-infected individuals are extremely likely to have anal HPV lesions [555–557] so this is the group in whom screening is presently being evaluated, akin to mass cervical screening, and it is frequently from this population that pathologists receive anal biopsies to evaluate. At least half of the homosexual male HIV population have anal HPV lesions [555–557] and low-grade lesions progressed to high-grade lesions in about 20% of such patients in 2 years in one study [558], although it seems that very few of these in situ lesions progress to invasive carcinoma. However, the reason to treat that has been offered is the aggressive nature of invasive carcinomas in these individuals once invasion ensues. The effect of antiretroviral therapy on these lesions remains unclear but is not necessarily beneficial [559]. Anal intraepithelial lesions are summarized in Table 137.9. As noted above, their common denominator is HPV but the factors that determine whether any given infection manifests as, for example, Bowenoid papulosis versus invasive squamous cell carcinoma remain obscure.

Like the uterine cervix, the anal canal has a transformation zone. This zone cannot be visualized without the use of anoscopy, so a procedure is required even for cytological screening. In biopsies obtained from this area (anoscopically the dentate/pectinate line), it is typical to find fragments of rectal-type mucosa adjoining or separate from the lesions in question. The histology of anal squamous intraepithelial lesions is quite similar to that found in the uterine cervix and associated with the same HPV types as cervical lesions.

Such lesions had been classified as anal intraepithelial neoplasia (AIN) I, AIN II, and AIN III but, as for the cervix, most observers now prefer to separate low- and high-grade lesions, with AIN II subsumed under high grade (Figs 137.118 and 137.119). Variable degree of loss of nuclear stratification and polarity, nuclear pleomorphism and hyperchromatism with or without keratinization or HPV cytopathic changes, with

Table 137.9 Squamous precursor lesions encountered on anal area biopsies

Lesion	Gross appearance	HPV type	Microscopic features	Outcome
Condyloma acuminatum	Protuberant genital wart, cauliflower-like lesion	6, 11	Exophytic lesion with prominent surface viral cytopathic changes	Aggressive transformation, vanishingly rare
Bowenoid papulosis	Multiple brownish to reddish papules	16, 18, 33, 34	Histologically similar to Bowen disease (below, carcinoma in situ) but clinical presentation different (multiple papules vs plaque)	Sometimes resolves spontaneously, but can recur. Essentially never progresses to cancer
Anal intraepithelial neoplasia (AIN)	Inapparent or plaque-like in anal transition zone (area of dentate line). Likely in HIV population	16, 18, others	Variable degree of loss of nuclear stratification and polarity, nuclear pleomorphism and hyperchromatism with or without keratinization or HPV viral cytopathic changes, with increased mitoses high in the epithelium. A two-grade system is used (high and low), but formerly AIN I, II, and III were used. Observer reproducibility can be a problem	Risk of progression to cancer low but unknown. In HIV patients, progression from LSIL to HSIL about 20% in 2 years
Bowen disease (squamous dysplasia at the anal margin; carcinoma in situ)	Reddish-brown plaque of perianal skin, often extending into anal canal	16, 18, others	Full-thickness dysplasia with jumbled nuclei, disorderly maturation, mitoses at all levels and dyskeratosis, sometimes extending into skin appendages (pilosebaceous units)	Progression to cancer reported in 2%–6%

HIV, human immunodeficiency virus; HPV, human papillomavirus; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion.

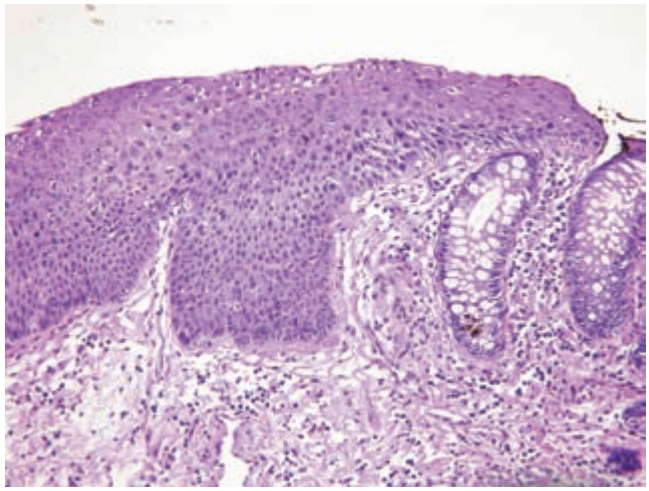

Figure 137.118 Anal intraepithelial neoplasia. This process often occurs at the anorectal transition.

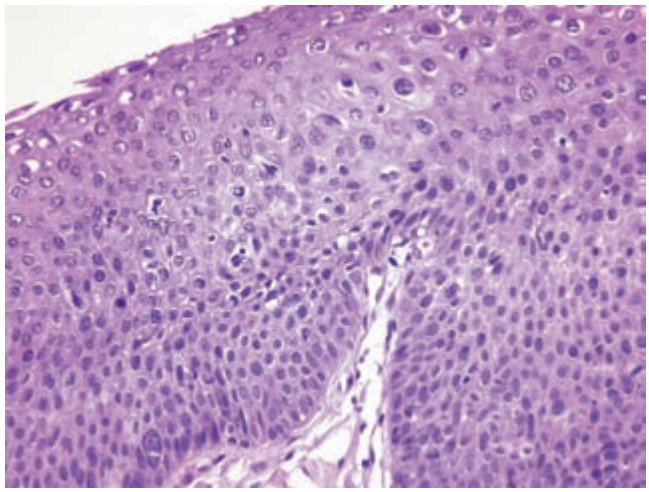

Figure 137.119 Anal intraepithelial neoplasia (AIN). The changes here are those of AIN 2 (moderate dysplasia) and would be subsumed under high-grade in situ lesions.

increased mitoses high in the epithelium are the constellation of findings sought on biopsy. HPV cytopathic changes alone, found in either exophytic or flat lesions, consisting of koilocytes and basal zone proliferation accounting for less than half of the epithelial thickness are classified as low-grade. Lesions with higher proliferation of hyperchromatic cells are regarded as high-grade lesions, as for the uterine cervix. As with the uterine cervix, there can be difficulty in separating AIN from reparative features. In these situations, p16 stains can sometimes be helpful. HPV infection is associated with overexpression of p16, a cyclin-dependent kinase inhibitor. Lu and colleagues studied 29 cases of squamous cell carcinoma of the anorectal region immunohistochemically for the expression of p16 [560]. The tumor cells exhibited a strong and diffuse nuclear stain (with some cytoplasmic positivity) for p16 in all 29 cases. HPV DNA was detected in every case (100%), with 25 cases (86%) harboring type 16. These observations indicate that overexpression of p16 is commonly associated with high-risk HPV infection, which may serve as a useful surrogate biomarker for identifying squamous cell lesions harboring HPV DNA. As such, in intraepithelial lesions, p16 can be a helpful adjunct in separating reactive from AIN lesions. Tandem Ki-67 stain can also be helpful.

Bowen disease is an eponymous term used for squamous carcinoma in situ at the anal margin (the outside part that can be seen by the clinician, in contrast to lesions seen at the transition zone inside the canal at the dentate line) where it presents macroscopically as a brownish plaque. Biopsies of Bowen disease display full-thickness dysplasia with jumbled nuclei, disorderly maturation, mitoses at all levels and dyskeratosis, sometimes extending into skin appendages (pilosebaceous units). Like AIN, it is strongly associated with HPV. It is more likely to progress to invasive cancer than AIN lesions but most cases still do not progress.

Bowenoid papulosis, first described in the penis [561], is a clinicopathological diagnosis. The patient presents with multiple papules, each of which has features of in situ carcinoma, but these essentially never progress to invasive carcinoma and sometimes resolve. These, too, are HPV lesions.

Anal squamous cell carcinoma

Carcinoma of the anal canal accounts for 1.5% of digestive-system cancers in the USA, with an estimated 4000 new cases in 2004 and about 580 disease-associated deaths [197]. The incidence of anal cancer is increasing but it is still uncommon [562]. Thirty years ago, anal cancer was believed to be caused by chronic local inflammation of the perianal area (such as from Crohn's disease). Treatment involved abdominoperineal resection, resulting in a permanent colostomy. However, it is now apparent that development of anal cancer is nearly invariably associated with infection by HPV, and usually sexually transmitted. Moreover, in the majority of patients, concurrent chemotherapy and radiotherapy is curative, without the need for surgery. Data from the Surveillance, Epidemiology, and End Results (SEER) program show similar incidence of anal cancer for men and women between 1994 and 2000 (2.04 per 100 000 and 2.06 per 100 000, respectively), the most recent period for which data are available, whereas men had lower rates than women between 1973 and 1979 (1.06 per 100 000 vs 1.39 per 100 000). In addition, black men had higher incidence rates than did other race-specific and gender-specific groups (2.71 per 100 000). From the earliest period for which data are available to the most recent one, relative 5-year survival improved from 59% to 73% among women, was unchanged among men (~ 60%), and decreased from 45% to 27% among black men; 18% of patients who had distant disease were alive at 5 years compared with 78% of patients who had localized disease [562].

Tumors arising within the anal canal distal to the dentate line are usually keratinizing squamous cell carcinomas, whereas those appearing in the transitional mucosa above the dentate line are frequently nonkeratinizing squamous cell carcinomas. The nonkeratinizing subtypes were once referred to as transitional cell and cloacogenic; however, they are now recognized as variants of squamous cell carcinoma that lack terminal differentiation. One type is composed of large cells and the other is characterized by small cells. The bladder and anus share a common embryological origin, thus giving rise to the similar (i.e., transitional or cloacogenic) morphology. The biology and prognosis of keratinizing and nonkeratinizing tumors of the anal canal are essentially the same, so prior concern about subclassification of anal tumors is probably not warranted (and we do not devote effort to this subclassification) [563,564]. Furthermore, pathologists do not always reproducibly separate the categories, further limiting their utility [565]. Adenocarcinomas of the anal canal are clinicopathologically like rectal cancer and are treated as such.

Lymphatic drainage of anal cancer depends on the location of the tumor. Above the dentate line, drainage flows to perirectal and paravertebral nodes (like rectal adenocarcinoma); below the dentate line, drainage is through inguinal and femoral nodes. Tumor size is the most important prognostic factor for patients with cancer of the anal canal. Mobile lesions less than 2 cm in diameter can be cured in approximately 80% of cases, whereas those 5 cm or more are cured in less than half the time. The probability of nodal involvement is also directly related to the size of the tumor.

Anal squamous carcinoma was classified in 1989 by WHO into the following types [566].

- Squamous cell (cloacogenic): large cell keratinizing; large cell nonkeratinizing (transitional); and basaloid.
- Giant condyloma (verrucous carcinoma).

In this classification, nonkeratinizing carcinomas were said to resemble transitional carcinomas of the urinary bladder (Fig. 137.120) and basaloid carcinoma was composed of solid sheets of small cells, often with peripheral palisading. Striking keratinization is unusual in lesions from the canal but not unknown. Most carcinomas do display the features of squamous carcinoma in other anatomical sites: striking nuclear alterations with nuclear pleomorphism and prominent mitotic activity and scattered squamous intercellular bridges. Anal squamous carcinomas can display the host of patterns found in other sites, including some with clear-cell features.

An exception to the usual striking epithelial changes is the rare verrucous carcinoma, which displays broad-based squamous papillae that are sheet-like in a sclerotic background and often accompanied by many neutrophils and a peculiar pattern of abnormal keratinization at all levels of the markedly thickened epithelial proliferation. Verrucous carcinoma has been termed *giant condyloma of Buschke–Löwenstein* and may involve the external genitalia and perianal skin.

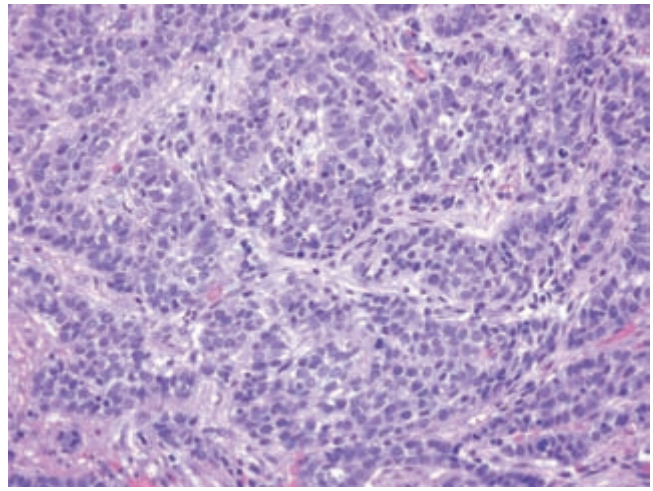

Figure 137.120 Anal squamous cell carcinoma. This example is basaloid (formerly cloacogenic).

It resembles a condyloma but is, if anything, cytologically blander with less striking viral cytopathic changes; koilocytes with nuclear cavities are not seen. Verrucous carcinoma lacks the true papillary configuration with fibrovascular cores seen in large condylomas. Metastases from verrucous carcinomas are vanishingly rare and the primary tumors are treated by local excision (which can be difficult since lesions can be quite large).

Since the reproducibility of diagnosing most of these subtypes is not particularly good [565] and since it bears little impact on outcome (with the exception of attempting to separate verrucous carcinoma), we do not devote much effort to separating anal squamous carcinoma into subtypes. Providing a diagnosis of invasive carcinoma is all that is clinically relevant and awareness of the subtypes is simply a construct to avoid misdiagnosis of squamous carcinoma variants as something else. As such, the 2000 WHO classification simply combined the subsets of squamous carcinoma [567].

Paget disease

Extramammary Paget disease typically affects apocrine gland-rich sites such as the perianal zone. It presents as a slowly growing erythematous eczematoid plaque that may extend internally to the dentate line. On biopsies, part or all of the squamous epithelial thickness is infiltrated by large pale cells, some of which may have signet cell features, and some of which may be large and pink (Figs 137.121 and 137.122). However, if the epithelium is crushed or altered in any way, it can be difficult to separate the Paget cells from atypical keratinocytes or from melanoma. Fortunately, an immunohistochemical panel resolves most doubtful examples. True Paget disease is a lesion with apocrine cell differentation, and the proliferating cells express Cam 5.2, CEA, gross cystic disease fluid protein (GCDFP), and CK7 and have mucin [568, 569]. Of course Merkel cells can also have CK7, a feature

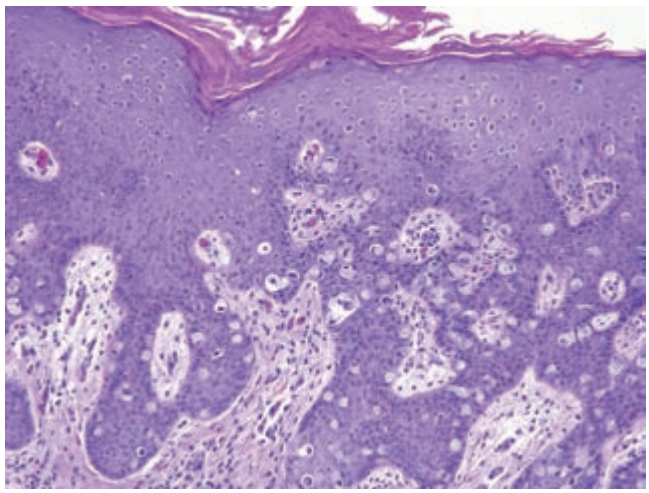

Figure 137.121 Anal Paget disease. Glandular cells proliferate in the squamous mucosa.

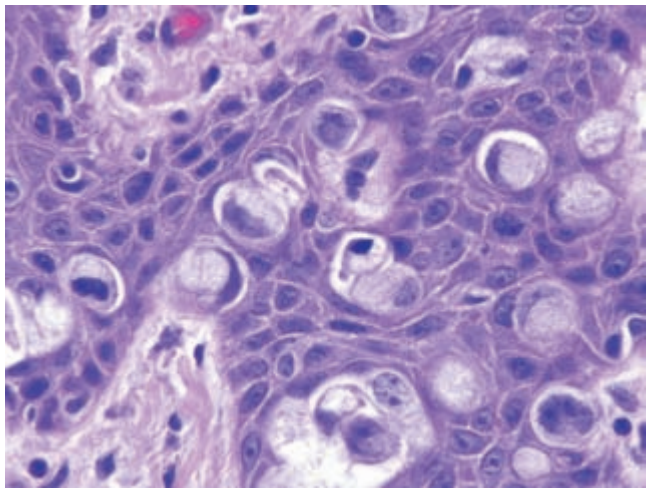

Figure 137.122 Anal Paget disease. At high magnification, intracellular mucin is apparent in these Paget cells.

the pathologist must consider when evaluating these stains. However, about half of cases showing adenocarcinoma cells in squamous mucosa reflect pagetoid extension of an underlying typical colorectal cancer into squamous epithelium and such lesions lack GCDFP and are often $CK20^{+}CK7^{-}$. However, the occasional MSI colorectal carcinoma may lack CK20 [570], although most such tumors are found in the right colon rather than the rectum. However, the best way to determine whether any case of anal Paget disease is associated with an invasive cancer is by a careful clinical examination.

The true Paget disease cases that are epidermotrophic apocrine neoplasms have a high local recurrence rate and can eventually become invasive. Those reflecting epidermotropism of ordinary adenocarcinomas behave and are managed as the associated cancers; thus stage is the primary prognostic marker.

Adenocarcinoma including anal gland adenocarcinomas

Most adenocarcinomas arising in the anus are of the rectal type and arise in the upper zone of the anus (which is normally lined by columnar mucosa). These are identical to true rectal carcinomas and are managed as such. On biopsies they appear identical to rectal adenocarcinomas and their immunohistochemical profile is similarly identical, namely CK20 positive and CK7 (usually) negative. These tumors are characterized by pencillate nuclei, abundant necrosis, and the usual overall pattern of colorectal carcinoma, with frequent association with an adenoma. Like rectal cancers, some are mucinous. These generally pose few diagnostic problems, although the differential diagnosis is with prolapse polyps (inflammatory cloacogenic polyps), which are distinguished by their diamond-shaped glands and blander cytology.

There is a rare subset of anal canal adenocarcinomas believed to arise in association with, or display differentiation toward, anal ducts/anal glands and these are called anal gland (duct) carcinomas. They are sufficiently rare that the AFIP was only able to amass seven convincing cases [571]. These tumors are composed of tubules originating from ducts that open onto the mucosal surface. They are intramural without a lumenal in situ component and they have variable overlying surface ulceration. On immunohistochemical staining they are typically $CK7^{+}$ and $CK20^{-}$ akin to the anal glands and ducts. When these tumors are found, they need to be distinguished from prostate cancer (which is negative for CK7 and CK20). These tumors lack prostate-specific antigen and prostatic acid phosphatase on the small number of tested cases. Many have behaved aggressively.

Gastrointestinal stromal tumors

True GISTs of the anus are rare. An AFIP series of over 100 anorectal GISTS included only three examples [514]. When found, they display the typical staining pattern of GISTs (remember, however, that about 40% of melanomas express CD117/c-kit, so be sure to add S100 protein to such immunohistochemical panels directed at diagnosing GISTs). Far more likely are small leiomyomas that appear similar to those found in the esophagus that tend to occur in women and express hormone receptors. Small leiomyomas may also arise from the muscularis mucosae in the upper part of the anus above the dentate line.

Melanoma

Anal melanoma is rare and usually affects white adults but, like subungual and esophageal lesions, individuals with pigmented skin can also be affected. Patients present with a mass and often with rectal bleeding, which is typically initially attributed to hemorrhoidal bleeding [572]. The lesions

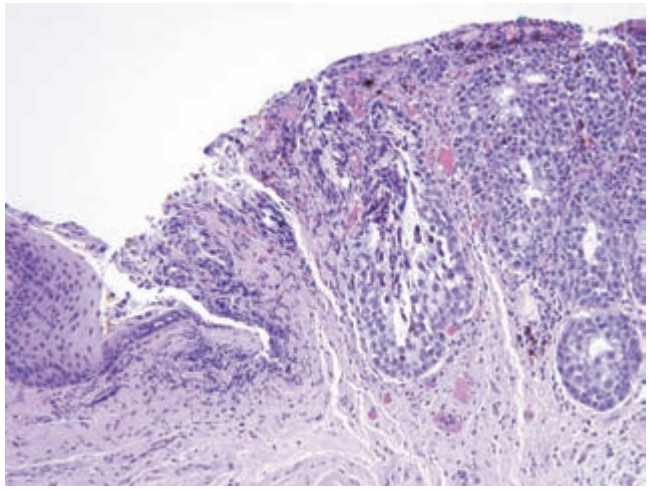

Figure 137.123 Anal melanoma. Note the melanin pigment.

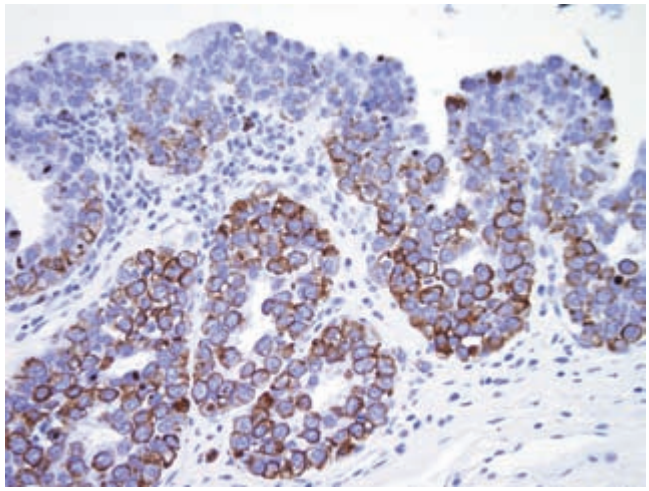

Figure 137.124 Anal melanoma. This immunohistochemical stain (HMB45) is for a relatively melanoma-specific antigen.

may be sessile or polypoid and, unless overt pigment is present (Fig. 137.123), a panel immunohistochemical approach (Fig. 137.124) is usually warranted to exclude poorly differentiated carcinomas and lymphomas. Confirmation that the lesion is primary is best accomplished by identification of an in situ component. The outcome is generally poor, with 5-year survival reported as 10%–45% [573–575]. Surgeons advocate sphincter-sparing surgery with adjuvant therapy rather than operations requiring colostomy [576].

D GASTROINTESTINAL FUNCTION STUDIES

138 Evaluation of gastrointestinal motility: emerging technologies

John W. Wiley, Chung Owyang

Background, 3393
Impedance planimetry, 3393
Endosonography for studying anatomy and motor function in the gastrointestinal tract, 3396
Assessment of gastric emptying, accommodation, and volume, 3402
Motility measurements of the pelvic floor, pelvic organs, and anorectum, 3404
Functional brain imaging in assessing visceral sensation in health and disease, 3407
Validation of new technologies, 3408

The methods available to evaluate gastrointestinal (GI) neuromuscular function are advancing rapidly. Conventional technologies often use water-perfused catheters, strain gauge catheters, or balloon devices that measure changes in pressure or volume but provide limited or no direct assessment of muscle tension and elastic properties of the gut wall. Direct assessment of these latter properties can provide more sensitive and specific information relevant to assessment of gut motility under physiological and pathophysiological conditions.

The objective of this chapter is to review selected emerging approaches for monitoring GI motility and visceral sensation. We include assessment of visceral sensation because abnormalities in visceral sensory pathways are thought to be involved in a number of functional GI motility disorders, such as the irritable bowel syndrome and nonulcer dyspepsia. Many of the emerging methods incorporate advances in volumetric measurements, endosonographic imaging technologies, and functional brain imaging to measure lumenal wall muscle structure and function and central nervous system (CNS) response to activation of sensory pathways innervating the viscera. The emerging methodologies to be discussed include:

- impedance planimetry
- intralumenal ultrasound applications to GI motility
- motility measurements of the stomach – scintigraphic emptying, volumetric assessment (e.g., single-photon emission computed tomography [SPECT], three-dimensional (3D) ultrasound, magnetic resonance [MR], and combined emptying volume measurements
- motility measurements of the pelvic floor, especially with MR imaging (MRI); and assessment of visceral sensation using functional brain imaging techniques
- assessment of regional activation in the brain using positron emission tomography (PET) and functional MRI (fMRI) in conjunction with visceral stimulation.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Background

Relatively few methods are well established for evaluating GI motor function *in vivo*. Manometry is the standard method for clinical motility testing, but in a number of motility disorders manometric results correlate poorly with organ dysfunction and symptoms [1]. Typically, manometry systems use water-perfused hydraulic-capillary systems where pressure at a sensor outside the body can be used accurately to measure pressure at a point along a catheter through a low-flow-rate perfused channel. This approach has been used extensively to measure force by a pressure measurement in lumens and in liquid-filled balloons. However, manometry is suboptimal in compartments where the lumenal diameter does not reach zero. Also, contractions may not be detected if the transducer is facing the lumen instead of the wall and manometric sensors do not directly capture relaxation [2]. Thus, measurement of lumenal pressure is a surrogate measure of changes in force generated by the surrounding tissues [3,4]. Other indirect measures of GI motor function include transit time studies, pH measurements in the esophagus, and radiographic methods using contrast agents.

Impedance planimetry

Since the late 1990s, tools have been developed for studying both the active (phasic and tonic contractions) and passive function using impedance planimetry before and during administration of drugs that effect GI motility [4–6].

Measurements of interest include tension, stress, and strain, because these endpoints give information about the elastic properties of the gut wall and mechanoreceptors respond more directly to these parameters than to pressure and volume [4]. Muscle function can be more accurately evaluated when force and tension are measured rather than the pressure generated by contractions [7,8]. The most commonly employed bag distention technique is the barostat, but techniques such as impedance planimetry and distention combined with imaging techniques give more detailed geometric information that more accurately represents the actual motility pattern. For example, rather than analyzing pressure–volume relationships based on the barostat, impedance planimetry generates data on the cross-sectional area (CSA) of the bag during distention. The CSA provides improved documentation of the dynamic changes in the alimentary lumen diameter during contraction and relaxation compared with volume measurements [6].

The principle of impedance planimetry

Impedance planimetry (IP) allows simultaneous measurement of intralumenal pressure and estimation of the CSA of a bag placed in a tube or hollow organ [9,10]. The CSA is determined from the impedance of fluid inside a bag using electrodes supplied with an alternating current to measure the potential difference between them. The CSA is calculated from the potential difference. The IP data are used to calculate the wall tension, a property that is often altered in a variety of GI motility disorders [6,11]. Specifically, Ohm's law describes the relationship between the potential difference, current, and electrical impedance: $V = IZ$, where V, I, and Z denote the potential difference, the current, and the electrical impedance. The impedance depends on the distance between the electrodes, the conductivity of the liquid in the bag, and the CSA of the bag between the electrodes. The size of the bag should be chosen based on the criteria of obtaining reliable measurements in the physiological range in the region of interest without stretching the bag wall. Before each study, pressures should be calibrated, for example, at 0 and 100 cmH_2O. The calibration curve for impedance planimetry is characteristically nonlinear [6]. Therefore, a multipoint calibration should be performed before each experiment. Also, impedance planimetry measurements are sensitive to temperature changes [7,9]. The fluid temperature should be kept constant at 38°C using a heating device. The coefficient of variation (CV) of the probe in each application should be assessed [12]. To minimize the risk of misattributing in vivo changes caused by variations within the measuring system, the operator should define the threshold for an event, for example, as a CSA deviation of 15% from baseline [12]. The pressure inside the bag can also be measured by a manometry system coupled to an external pressure transducer. Records of CSA and pressure are amplified, analog-to-digital converted, and stored on a computer for later analysis. Therefore, using distention protocols that combine manometry and impedance planimetry during bag distention, it is possible to differentiate phasic and tonic contractions and to obtain data on the force–velocity properties of the intestinal muscle in vivo.

In a typical recording session participants will be fasted for at least 6 h. The impedance planimetry probe is passed into the compartment of interest and the bag positioned using fluoroscopic guidance. The participant is rested for 15 min to adjust to the probe. Depending on whether the study objectives involve recording of fasting or fed motility patterns, a standardized meal may be given to the subjects. The volume-controlled ramp distentions are then initiated. Participants can report the sensation intensity using a validated visual analogue scale (VAS), typically from zero to 10. Prior to starting the study, participants should be trained how to use the VAS, for example, where 0 is no perception, 5 pain threshold, 7 moderate pain, and 10 unbearable pain [9,10,12]. If perception of pain is a primary or secondary endpoint, distentions should not exceed the volume that elicits a VAS value corresponding to moderate pain. The distentions are performed at a standardized infusion rate, for example 25 mL/min, for four times to precondition the tissue and to be used as learning sessions for the sensory ratings [6,10]. Two additional distentions are conducted at the same infusion rate and used for the analysis. Approximately 10 min after completing these distentions to obtain baseline data, they can be repeated during or after administration of a therapeutic intervention, for example, a drug of interest that is hypothesized to increase or inhibit distention-evoked smooth muscle contractions. Recordings should be performed while the effect of the therapeutic intervention is at steady state.

Applications of impedance planimetry to gastrointestinal motility

Impedance planimetry data provide more detailed information than conventional manometry regarding the contractile patterns in the compartment of interest, particular the elasticity of the gut wall. Changes in the elastic properties of the gut wall have been implicated in a variety of GI motility disorders. Some examples of how this technology has been employed to study disorders affecting GI motor function are provided below.

Systemic sclerosis (SS) is a connective tissue disease that affects the gastrointestinal (GI) tract. Previous studies have shown decreased and abnormal intestinal motility, dilation, and a stiffened wall. However, because of the limitations of conventional recording techniques, little is known about the underlying basis for altered muscle mechanics in this population. As discussed previously, impedance planimetry allows the study of several properties of muscle mechanics in vivo, including the wall stretch ratio, tension, shortening velocity, and muscle power, which can be calculated from pressure and CSA data. Patients with SS demonstrated increased wall

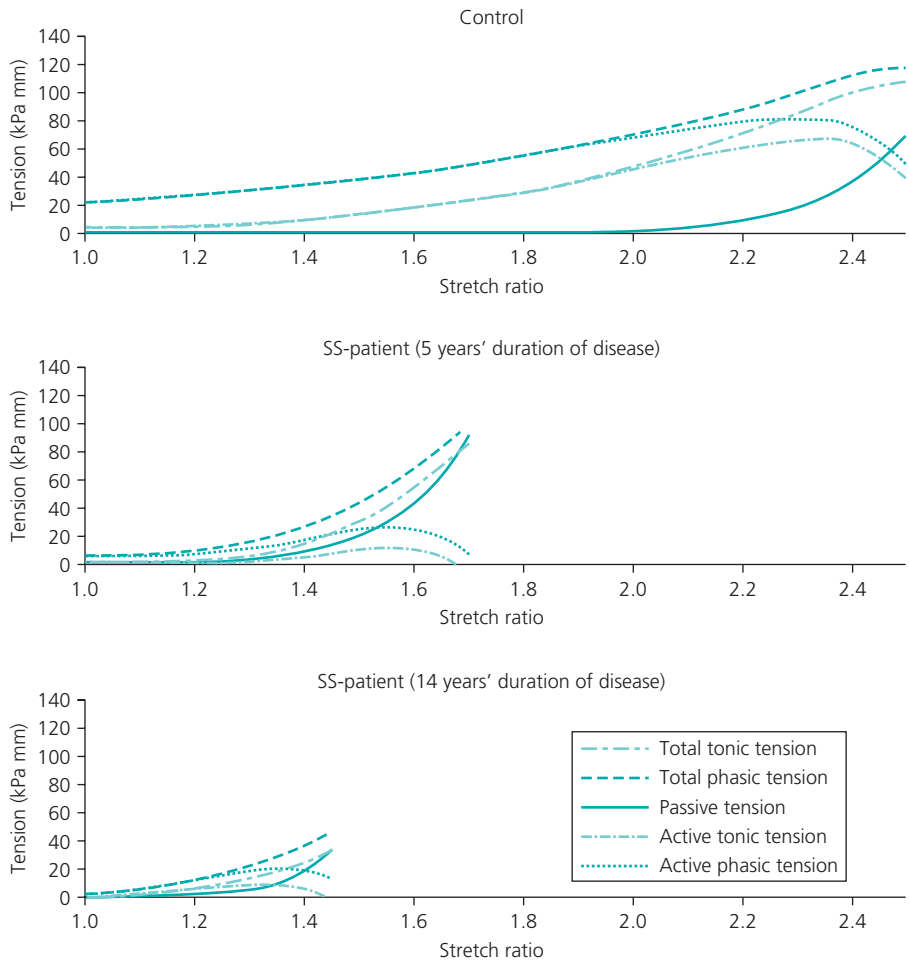

Figure 138.1 Representative length–tension curves, including total phasic tension, total tonic tension, active tonic tension, and passive tension. These data were obtained from a volunteer **(top)**, a patient with a duration of systemic sclerosis for 5 years **(middle)**, and a patient with a duration of systemic sclerosis for 14 years **(bottom)**. The key identifies the meaning of the different line patterns and it applies to all the panels. Reprinted with permission [13].

stiffness and impaired muscle dynamics including reduced power and decreased velocity of the duodenum, which correlated well with clinical symptoms (Fig. 138.1) [13]. The circumferential tension–stretch ratio diagrams showed a similar curve pattern for the controls and the SS patients. Thus, the passive tension curves were exponential and the active tonic and phasic tension curves showed an ascending leg, a local maximum, and the initial part of the descending leg in both the volunteers and patients. However, the tension and stretch ratio clearly decreased in the patients compared to the volunteers. By comparing the tracings in the middle and the bottom curves it appeared that the duration of disease was important. The translation to the left on the stretch ratio axis indicated that the intestine became stiffer in the patients and the low tension indicated that the muscle did not have the ability to contract with the same force as in the volunteers. Both in patients and in the volunteers, the active tonic and phasic tension curves appeared to peak at the same stretch ratio values. Impedance planimetry, however, does not provide information regarding whether the impaired muscle function may be due to reduced contractility of individual muscle cells, a reduced number of muscle cells, or increased stiffness of the matrix surrounding the muscle. In addition, the reduced contractility may also be influenced by lumenal dilation, causing a shift of the tension–stretch curves.

Impedance planimetry has also been used to examine the efficacy of potential therapeutic interventions. For example, theophylline has been proposed as a potentially effective treatment for noncardiac chest pain. The effects of intravenous theophylline or placebo were examined on esophageal sensorimotor function and chest pain, in patients with esophageal hypersensitivity, after intravenous theophylline or placebo [14]. The CSA of the esophagus increased significantly after theophylline compared with placebo. The tension–strain relationship shifted significantly to the right in the group of subjects who received intravenous theophylline but was unchanged in those who received placebo (Fig. 138.2). Based on these data, a second randomized 4-week crossover study was performed. Oral theophylline and placebo were administered to patients with esophageal hypersensitivity. Frequency, intensity, and duration of chest pain episodes were

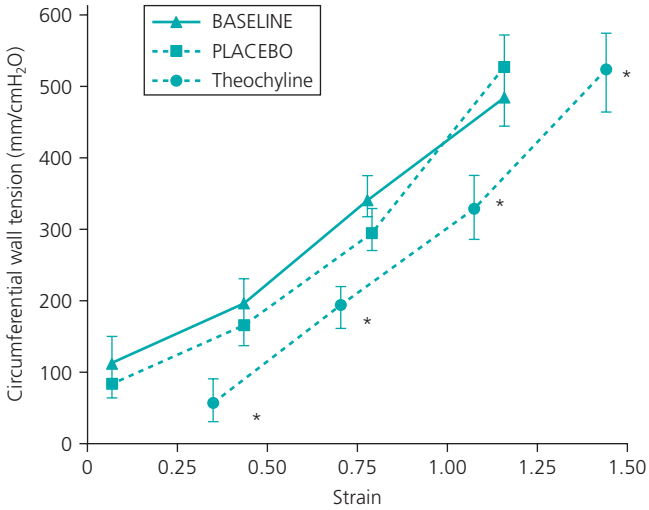

Figure 138.2 Effects of placebo and intravenous theophylline on circumferential wall tension/strain relationship. The curve in subjects that received theophylline (black circle dotted line) is significantly shifted to the right when compared with placebo (black squares, dotted line). These data suggest that the esophageal wall relaxed and became more deformable or more compliant after theophylline infusion (mean ± SEM). Reprinted with permission [14].

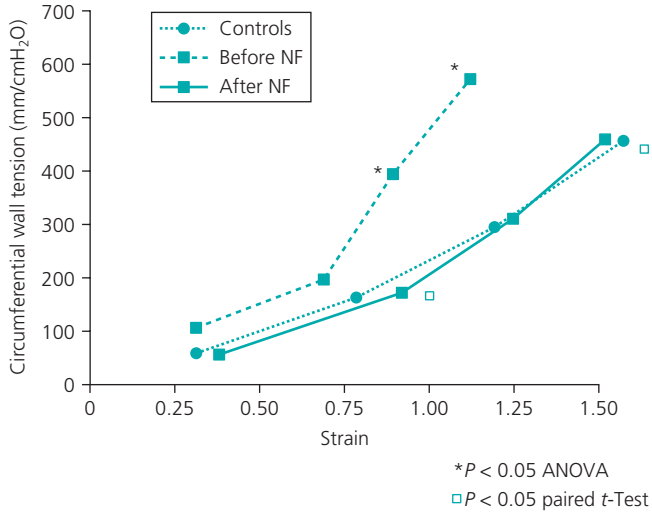

Figure 138.3 Relationship between circumferential wall tension and strain in response to graded balloon distention in control subjects and GERD patients before and after Nissen fundoplication (NF) (mean ± SEM). The curve in GERD patients before surgery significantly shifted to the left compared with control subjects. This suggests that for the same level of tension (force) the degree of strain or the deformability of the esophageal wall was less in GERD patients. However, after NF the curve shifted significantly to the right and was similar to control subjects, suggesting that the deformability of the esophageal wall had improved after NF. Reprinted with permission [15].

evaluated. Theophylline relaxed the esophageal wall, decreased hypersensitivity, and improved chest pain.

In another application, impedance planimetry was used to examine the sensory and biomechanical properties of the esophagus in patients with gastroesophageal reflux disease (GERD) before and after laparoscopic Nissen fundoplication compared with healthy controls [15]. The pathophysiology of persistent GERD symptoms after antireflux surgery is unclear. At baseline, GERD patients had lower thresholds for first perception, discomfort, and pain compared with controls. The esophagus was more reactive and less distensible in patients compared with controls. In GERD patients, before Nissen fundoplication, the curve that expresses the relationship between tension and strain shifted significantly to the left compared with controls (Fig. 138.3). This suggested that the esophageal wall was less distensible, or stiffer, in GERD patients. After Nissen fundoplication, in patients with persistent symptoms, the curve shifted to the right and was similar to controls, suggesting that the distensibility of the esophageal wall had improved. Of interest, some patients demonstrated persistent symptoms after Nissen fundoplication. In this population the sensory thresholds were unchanged but esophageal wall reactivity decreased, and distensibility improved. The authors concluded that laparoscopic Nissen fundoplication improves esophageal biomechanical dysfunction but not the underlying hypersensitivity. These observations highlight the application of this technology to identify and differentiate between abnormalities in the biomechanical properties of gut wall and primary sensory mechanisms.

Summary

Our understanding of the "mechanical" physiology of the GI tract is based on measurement techniques such as manometry. The objective of techniques such as impedance planimetry is to understand better the muscle properties of the gut wall and how they relate to mechanisms involved in symptom generation. The advantage of the impedance planimetric method is improved correlation of the measurements with lumenal wall elasticity based on assessment of changes in balloon CSA compared with changes in balloon volume. As an experimental tool for assessment of distention-induced responses, IP appears to be superior to other available distention techniques because the mechanoreceptors are most likely sensitive to mechanical parameters such as force, tension, and strain rather than to direct variation in pressure or volume. Direct comparisons with traditional barostat recording methods in specific patient populations in the absence and presence of interventions are required to establish the superiority of the impedance planimetric method in clinical research and before general acceptance of this approach as a diagnostic tool in the clinical setting. Similar to the barostat method, this approach is relatively invasive, requiring conscious sedation and intubation for positioning of the recording apparatus.

Endosonography for studying anatomy and motor function in the gastrointestinal tract

Background

Endosonography has emerged as a useful tool for studying the visceral wall and adjacent structures in detail [16]. This section focuses on the utility of endosonography to assess biomechanical and motor function of the gastrointestinal tract.

Echoendoscopes combine endoscopy with integrated ultrasound (US) transducers. They may have radial or curvilinear array transducers using frequencies between 7.5 and 30 MHz. Typically, higher frequencies provide more anatomical detail but less penetration. Small transducers or miniprobes have been developed with a diameter that allows the probe to be inserted through the biopsy channel of a conventional endoscope. The small-diameter probes can be passed into stenotic areas or areas with smaller lumenal diameters such as the biliary tree, not traversable with larger echoendoscopes. Ultrasound systems are available that combine linear compound scanning with mechanical sector scanning or M-mode. Doppler sonography can provide important information about vascular flow and separate vessels from other echo-poor structures [17].

Assessment of gastrointestinal motility and biomechanics

Endosonography has been employed in studies of the biomechanical function of the GI tract. Whereas motility considers active properties such as peristaltic contractions, biomechanics typically focuses on the active and passive forces and deformation of the tissue. Biomechanical alterations and abnormal motility in the GI tract are observed in several diseases that may involve the tract itself, the surrounding tissues, or other body systems. Lumenal manometry has so far been the most widely used method to study GI tract physiology. However, despite the development of high-resolution manometry systems problems remain in the investigation of GI motor function. The strength of a muscle contraction may vary considerably, resulting in suboptimal manometric data. Manometric data are also affected by respiration, aortic pulsation, and cardiac contractions.

The presence of probes in the GI lumen will influence physiology and biomechanical studies would, ideally, be performed without intralumenal devices. Miniprobes combine the advantages of high ultrasound frequencies with small transducers, allowing detailed images of GI wall layers to be obtained with less influence on the GI lumen than larger echoendoscopes in areas with narrower lumens such as the esophagus (Fig. 138.4). Echoendoscopes can be used to study motility in regions with wider lumens, such as the stomach. Echoendoscopes typically utilize lower ultrasound frequencies and larger ultrasound probes that allow examination of motility in adjacent GI structures (Fig. 138.5).

Correct interpretation of ultrasound images of the GI wall is essential when using this method. Anatomically, the GI wall consists of the mucosa, submucosa, muscularis propria, and adventitia/serosa. The muscularis propria has an inner circular and an outer longitudinal layer that is separated by the myenteric plexus. The normal GI wall is imaged by ultrasonography as a layered structure consisting of three to nine layers depending on the thickness and structure of different layers, ultrasound frequency, and applied pressure on the wall [18,19]. Generally, a five-layer structure of the wall can be demonstrated, as determined by the histological layers and the appearance of interface echoes (Fig. 138.6; see also Fig. 138.4). When the visceral wall is imaged with an endolumenal transducer, the interface between the lumenal contents and the mucosa accounts for the first, echo-rich layer. The rest of mucosa appears as a second, echo-poor layer. The third, echo-rich layer usually includes the interface between the lamina propria and muscularis mucosae, the submucosa, and the interface at the border of the muscularis propria. In a

five-layer structure, the rest of muscularis propria is imaged as an echo-poor fourth layer. The fifth, echogenic layer represents the outer wall delineation and is an interface echo at the serosa or adventitia level. Sometimes, the use of high-frequency ultrasound produces an interface echo between the different aspects of the muscularis propria, probably reflecting the connective tissue embedding the myenteric plexus. A thick muscularis mucosa may also be identified as an echo-poor layer dividing the third, echogenic layer. Hence, the ultrasonographic wall structure may consist of seven or even nine different layers [18,20].

Applications of endosonography in the clinical setting to study biomechanics and GI motility

Endosonography is regarded as a suitable tool for examination of the esophagus because this portion of the GI tract is a straight tube with a relatively small diameter. Studies of the high-pressure zone between the esophagus and stomach

(lower esophageal sphincter and extrinsic crural diaphragm) in normal subjects have been performed using a dual high-resolution endosonography-manometry catheter [21]. This catheter recorded simultaneously manometric pressures and corresponding ultrasound images while transiting the distal esophagus. Simultaneous high-resolution endolumenal sonography and pressure manometry could separate the two components of the high-pressure zone in the distal esophagus.

Endoscopic ultrasound studies suggest that an association exists between sustained contraction of the longitudinal layer in the esophageal body and chest pain of unknown origin [22]. The combination of manometry with a 20-MHz ultrasound transducer has been used to correlate wall thickness, lumenal diameter, and contractive activity in healthy volunteers [23]. An increase in muscle width detected by ultrasonography correlated with the increase in lumenal pressure by manometry. Hoff et al. [24] have described a multimodal device inserted into the esophagus that combines bag distention, manometry, high-frequency intralumenal ultrasound, laser Doppler flowmetry, and symptom registration. Preliminary results indicate that these modalities can be used in combination without significant technical influence on each other. Some specific applications of endosonography are discussed below.

Achalasia

Achalasia is a disorder in esophageal motility and is defined by its typical manometry pattern. The diagnosis can be supported by findings at barium radiography that may show delayed passage through the lower esophageal sphincter and dilation of the body of the esophagus. At manometry, achalasia is characterized primarily by aperistalsis of the esophageal body and incomplete relaxation of the lower esophageal sphincter. In autopsy studies of patients with achalasia, the thickness of the lower esophageal sphincter is increased. Using high-frequency ultrasound probes, it has been shown that the thickening of muscularis propria appears mainly in the inner circular portion (see Fig. 138.6). The available literature suggests that thickening of the circular layer of the muscularis propria at the gastric cardia may support the diagnosis of evolving achalasia [25–32]. A study of the esophageal wall in patients with newly diagnosed achalasia was performed using a sector scanning echoendoscope with 12-MHz transducer frequency. The endosonographic findings were correlated with manometric features and clinical symptoms, and suggested that in these patients an increase in thickness of the muscularis propria occurs at the level of the lower esophageal sphincter and the proximal 5 cm of the sphincter [25]. Miller et al. [30] used a 20-MHz radial ultrasound transducer to examine the width of the total muscularis propria, and the circular and longitudinal smooth muscles at the lower esophageal sphincter in patients with achalasia, comparing them with 19 normal subjects. They found that the mean width of these muscles was increased in patients with achalasia. However, because of overlap in muscle width thicknesses between these groups it was concluded that a thickened muscularis propria cannot be used to differentiate clinically between patients with achalasia and normal controls. Nevertheless, they found that the mean diameter of both the longitudinal and the circular smooth muscle layers at the lower esophageal sphincter were wider in patients with achalasia than in normal subjects. Trowers et al. [31] used a single crystal transendoscopic probe providing linear images and showed that achalasia patients have a four-fold increase in the thickness of the muscularis propria compared with controls.

Scleroderma

Patients suffering from systemic sclerosis frequently demonstrate clinical gastrointestinal manifestations such as swallowing problems. Endosonography can be useful to define morphological and physiological abnormalities of the esophagus in patients with scleroderma of the esophagus. Liu et al. [33] found that US images in patients with scleroderma correlated with established pathological descriptions like smooth muscle atrophy, variable fibrosis, and collagen deposition. Specifically, increased echogenicity and thinning of the muscularis propria, consistent with fibrosis and atrophy of the smooth muscle were observed. Miller et al. [34] used a 20-MHz ultrasound transducer to evaluate patients with systemic sclerosis and healthy subjects. Postmortem autopsy studies were also performed to compare histopathological abnormalities with sonographic findings in the esophagus. Hyperechoic abnormalities were observed ultrasonographically in the muscularis propria in patients with scleroderma but not in normal controls. These findings corresponded to fibrosis noted in histological examinations. A positive correlation between esophageal hyperechoic and manometric abnormalities was also observed.

Nutcracker esophagus

Patients with nutcracker esophagus (NE) experience dysphagia or chest pain due to strong peristaltic contractions. High-pressure amplitudes are found at manometry. Melzer et al. [35,36] used an echoendoscope to examine the thickness of the muscularis propria at the gastroesophageal junction and in the lower, middle, and upper esophagus in patients with nutcracker esophagus. The muscularis propria was thickened in one-third of the patients. This thickening, however, did not correspond to the location and magnitude of the manometric abnormality and did not correlate with the clinical presentation. They also reported a patient with nutcracker esophagus and esophageal pressures exceeding 800 mmHg in whom endoscopic ultrasonography demonstrated a markedly thickened esophageal muscularis propria. The hypertrophy of the muscularis propria extended from the gastroesophageal junction upward to the mid-esophagus.

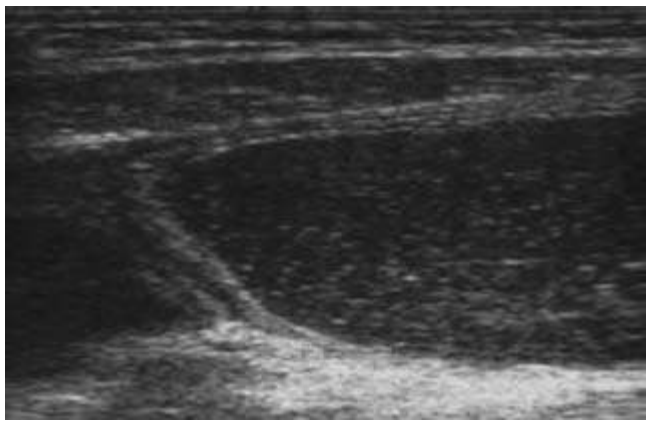

Figure 138.7 Ultrasonogram of the fluid-filled gastric antrum showing the different wall layers and a propagating contraction wave that occludes the lumen. From Gilja et al. [43], with permission.

Gastroduodenal motility

Ultrasonography can provide both qualitative and quantitative information about motility, both in a fasting state and after meal ingestion. Gastric contractions and propagation of waves can be visualized and evaluated by ultrasound [37–43]. Both frequency and amplitude can be monitored; the latter defined as the maximal reduction of antral area induced by a contraction, as a fraction of the relaxed area. High-resolution ultrasound using frequencies in the range 7–15 MHz enables detailed studies of gastric wall layer involvement during peristalsis (Fig. 138.7) [11]. Ultrasound is more sensitive than manometry in detecting antral contractions, particularly nonocclusive contractions [44].

Endosonography can be technically more challenging in wide and curved organs such as the stomach. Transabdominal ultrasound is applied in studying gastroduodenal motility, also in combination with intralumenal pressure devices. Mechanosensory properties in the human gastric antrum were evaluated using transabdominal ultrasound scanning during volume-controlled antral distention [45,46]. Furthermore, a device that combines endosonographic real-time imaging with intralumenal volume-controlled bag distentions has been developed also for use in large lumens. Thus, detailed images of GI wall layers corresponding to the area of bag pressure can be obtained. Arslan et al. [47] investigated the duodenum with high-frequency ultrasound to study wall layers and motility during allergenic provocation. A 20-MHz miniature ultrasound probe was inserted through a nasoduodenal tube and ultrasound examination was performed before and after provocation. Clinical symptoms were recorded and the thickness of mucosa, submucosa, and muscularis propria was measured directly on ultrasonographic images. Endosonographic changes (i.e., detectable wall thickening, contraction, or new echogenic layer) were observed in 75% of the patients. Mucosal thickening, changes in the number of wall layers, and sustained contractions of duodenum were observed in some patients after provocation. The mucosal thickening may represent mucosal edema in response to provocation manifesting in an allergic reaction. The clinical usefulness of endosonography in the investigation of gastroduodenal motility still remains to be determined.

Novel techniques and applications

Three-dimensional (3D) endoscopic ultrasonography (EUS) images are thought to be easier to understand and communicate than the mental reconstruction of 2D images. Three-dimensional techniques are under development for most imaging modalities and 3D-EUS may be applied for improved recognition of the GI anatomy and pathological lesions. Images acquired by echoendoscopes or miniprobes can be used in constructing 3D-EUS images. Typically, a pullback device has been employed to obtain parallel 2D images, which are reconstructed to create a 3D image. Acquired ultrasound images can be stored and digitized using frame grabbing, but direct digitizing of raw ultrasound data is being increasingly used in new scanners. Advanced software programs containing different rendering or other reconstruction algorithms are used for postprocessing and display of 3D ultrasound data, which can be studied using any plane slicing, segmentation, and volume calculation [48,49]. The advanced programs enable the import of image data that are acquired with both mechanical devices and magnetic position sensors as well as endosonographic acquisitions. Manual segmentation or semiautomatic rendering of structures in the 3D data set makes accurate volume estimation and reconstruction of organs or pathological tissue achievable. A representative display from a 3D ultrasound system is shown in Fig. 138.8. Additional information regarding 3D ultrasound systems is available in the literature [50–52].

Strain rate imaging

Strain rate imaging (SRI) is a technique to measure deformation of biological tissue. The technique is based on tissue velocity imaging, which is an ultrasound technique that provides quantitative information on velocities of deformation within a tissue. By color-coded tissue velocity imaging, velocity data from the whole field of view are available simultaneously [53]. This allows extraction of other parameters through spatial and temporal processing of the velocity data. Strain and strain rate are examples of such parameters. The methods have primarily been used in echocardiography, but other uses have also been reported, including measurements of gastric motor function [54]. For example, estimation of relative strain of the muscle layer of the gastric wall by Doppler ultrasonography is feasible (Fig. 138.9) and enables detailed mapping of local strain distribution [55,56]. Strain

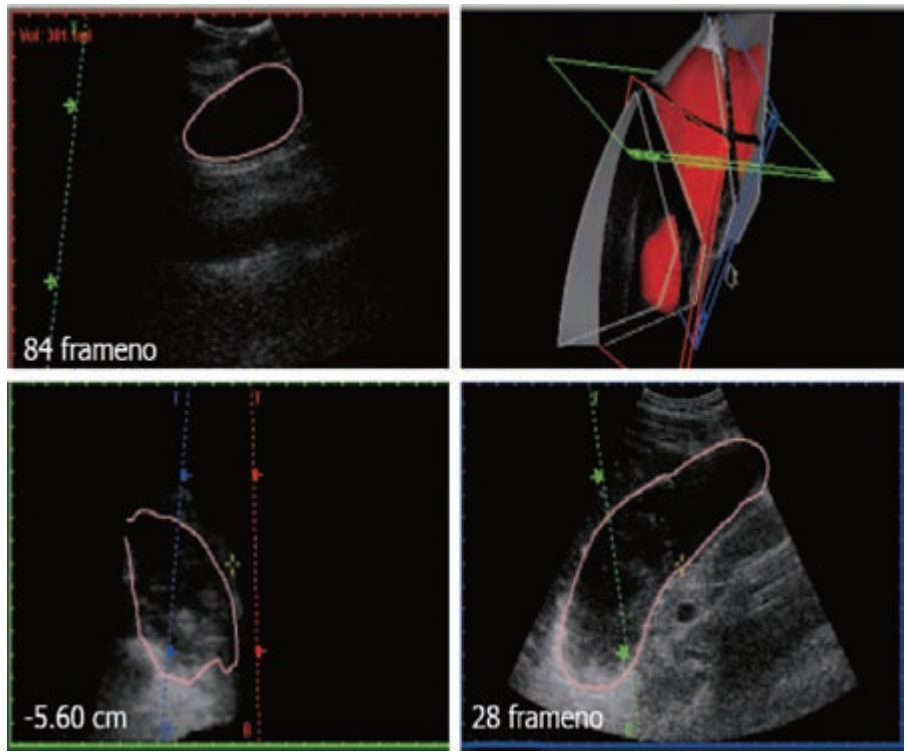

Figure 138.8 A three-dimensional reconstruction of the total stomach volume (red) in the upper left panel. The acquisition is based on magnetic scanhead tracking. Three orthogonal orientation planes are shown in red, green, and blue. The upper left panel is a volume reconstruction window for manual outlining of the structures. From Molin et al. [48], with permission.

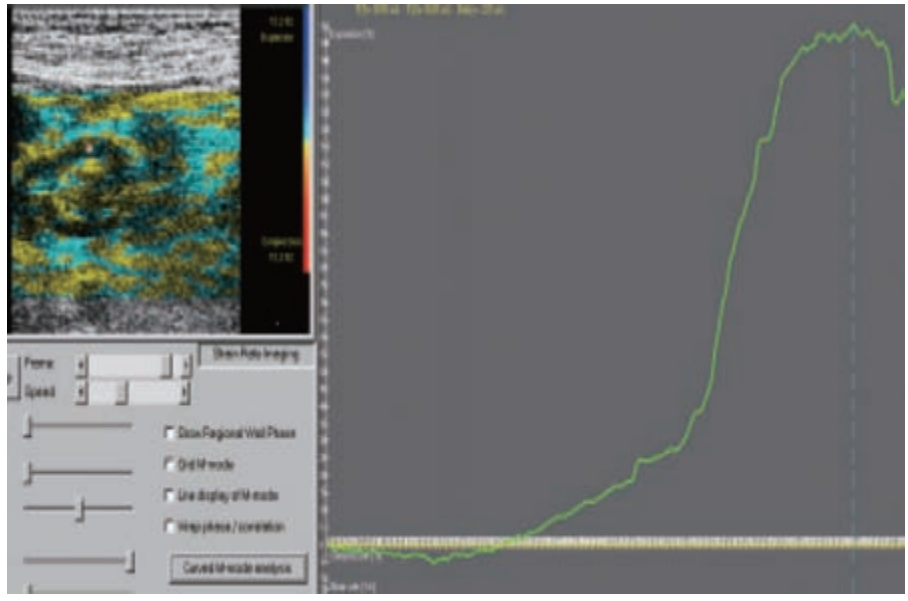

Figure 138.9 Graphics outlining the relative radial strain of the circular muscle layer of the antral wall. The exact sampling point in the gastric wall is denoted with a red marker in the color Doppler ultrasonogram **(left panel)**. **Right panel:** positive strain curve with a maximum of 150% radial elongation of the muscle layer. From Gilja et al. [54], with permission.

rate imaging can distinguish contractile activity of the longitudinal and circular muscle layers, although the two layers cannot be separated visually in the 2D images. It is anticipated that ongoing and future studies will determine whether SRI can be applied to evaluate the relation between symptoms and biomechanical factors in clinical disorders.

Further development of specialized EUS instruments will allow investigators to choose the most appropriate instruments for the specific tasks. Miniature probes, which are less costly and easier to operate, will likely be available in a majority of endoscopy units in the near future. We can anticipate that different modalities will be merged into new

multimodal devices making it possible to obtain multiple motility parameters in one procedure.

Assessment of gastric emptying, accommodation, and volume

Gastric scintigraphy

Assessment of gastric emptying of solids using scintigraphy has evolved over the years. Typically, scans are obtained at hourly intervals for 1–4 h. The longer scanning times potentially provide data on the gastric residuals at 4 h rather than a calculated $t_{1/2}$ (half emptying time for solids) value derived from a computer program-generated estimate of the gastric emptying curve based on 60-min or 90-min data. However, the added cost of extending the scanning time must be considered. Gastric scintigraphy has been standardized for practice and research (including multicenter studies) [57,58]. Interventions can then be evaluated based on documented abnormalities in gastric emptying rather than, for example, response to empirical therapy in patients with subjective symptoms such as postprandial fullness, nausea, bloating, or pain. A well-recognized problem with methods for assessing gastric emptying is that patients' symptoms correlate poorly with abnormal emptying; for example, symptoms are not sufficiently predictive of the nature (slow vs fast vs normal emptying) and the severity of the gastric emptying disorder. It is relevant that the coefficient of variation is lowest for the proportion of ingested food remaining in the stomach at 4 h [59]. Therefore, this time point appears to be a good index for diagnosis and a biomarker in pharmacodynamic studies.

Assessment of gastric accommodation and volume

The gold standard for the measurement of tone in hollow organs remains the barostat [60], which estimates changes in tone by the change of volume of air in a compliant bag maintained at a clamped or constant pressure. A related method is the tensostat [61,62], which corrects in real time for the changes in volume or diameter of the balloon to estimate lumenal wall tension based on the Laplace law. The barostat/tensostat techniques are unequalled for measuring colonic tone, such as in the assessment of megacolon [63] and suspected colonic inertia. It is also possible, for example, to measure tissue mechanical properties or symptoms during tone change, or to assess reflex responses to distention [64,65]. However, a limitation is that the barostat measures a volume within a balloon under constant pressure rather than true tone, volume, or tension. Also, these tests are invasive and unacceptable for some patients who are stressed and uncomfortable during these procedures, which may last over 3 h. These factors may introduce a measure of uncontrolled variation and may lead to erroneous results. Estimates of viscus tension based on the Laplace law are often approximations [66,67]. In addition, intubation and balloon distention under low constant or barostatic pressure may result in reflex relaxation of the stomach; therefore, a true baseline fasting volume cannot be estimated.

Given these concerns in the measurement of gastric accommodation and capacity, volume-based methods have been proposed to measure gastric capacity during fasting and postprandially. A liquid nutrient drink test was proposed as a surrogate for the barostat [68], but the accuracy relative to other volumetric measurements such as SPECT was poor [69]. Imaging-based volume methods include analysis of surface geometry of human stomach using real time 3D ultrasonography or 3D reconstruction of images acquired by ordinary ultrasonography assisted by magnetic scan-head tracking [70]. In an application of ultrasonography [71] an outline of the total stomach volume was visualized after ingestion of a soup meal that serves as a contrast medium.

Single-photon emission computed tomography imaging has been extensively validated in vitro, and for the measurement of gastric volumes during fasting and postprandially in vivo in comparison with the "gold standard," the barostat [72,73]. The effects of liquid and solid equicaloric meals on gastric volumes have been reported, and reproducibility of measurements of gastric volume with the same caloric liquid meal given an average of 9 months apart shows a coefficient of variation of approximately 10% [74]. Single-photon emission computed tomography has been applied to examine the effects of disease on postmeal change in gastric volume, a surrogate of gastric accommodation [75,76], and the effects of medications such as nitrates, erythromycin, glucagon-like peptide 1 (GLP-1) and octreotide [77,78] in health and in diseases such as diabetes [79]. In general, the effects of these interventions were similar to the results observed with the barostat in the published literature.

A novel method has been reported that measures gastric "accommodation" as the percentage change in planar (2D) gastric CSA using a left anterior oblique planar projection and the percentage change in total SPECT gastric voxel counts (by 3D imaging) compared with baseline fasting volume using National Institutes of Health (NIH) image software; see the NIH ImageJ website (http://rsb.info.nih.gov/ij/index.html). The procedure uses anterior and posterior images for estimation of gastric emptying, followed by SPECT imaging with a separate SPECT camera every 20 min [80]. This approach is potentially significant because it allows simultaneous measurements of gastric emptying and volume, thereby providing a means noninvasively to assess the pathophysiology of gastric motility disorders.

Other studies confirm the ability to measure the dynamics of gastric volume and emptying functions in health [81]. One

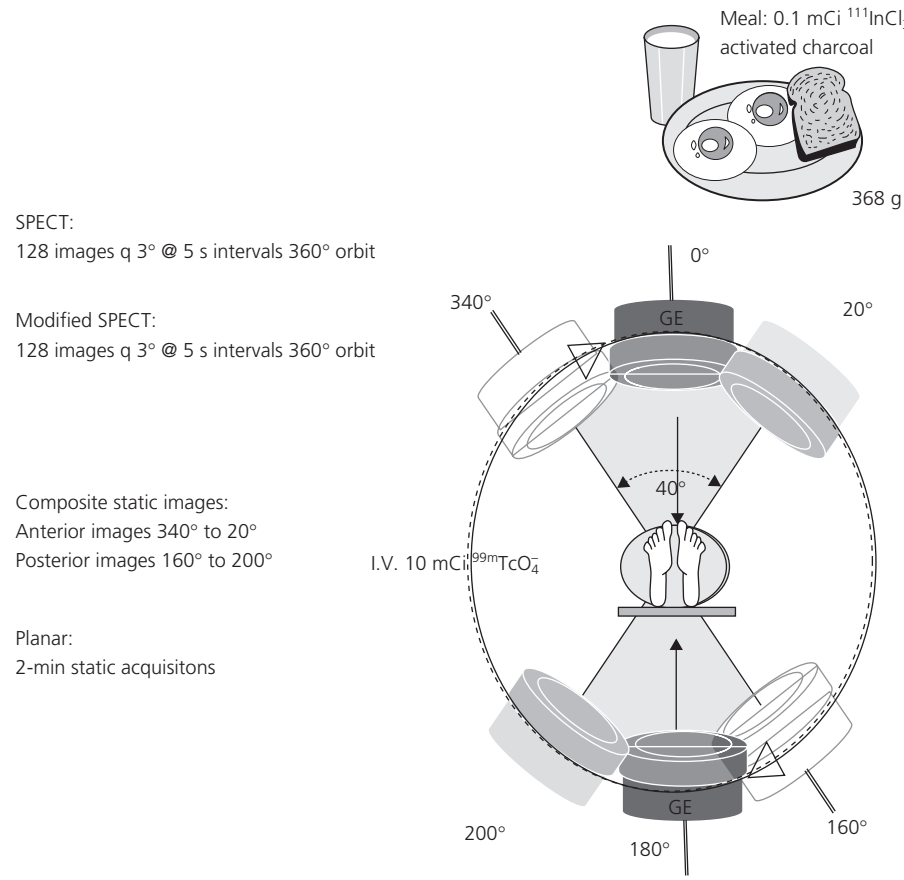

Figure 138.10 Method for combined measurements of gastric volume and emptying. SPECT, single photon emission computed tomography. Camilleri [80], with permission.

approach involves tomographic acquisition over 360° on a dual-head gamma camera SPECT (Fig. 138.10). Specialized software is used to acquire the required planar images from the tomographic data and integrate them into the gastric emptying study and to measure gastric accommodation (Fig. 138.11). The results suggest that the volume measured is not just the volume of the meal in the stomach.

Magnetic resonance imaging (MRI) of the stomach (Fig. 138.12) [82] has the potential of being a safe, noninvasive test that measures emptying, volume change, and wall motion as a surrogate of contractile activity without radiation exposure [83,84]. It is noteworthy that MRI has the ability to assess separately the emptying of fat and water from the stomach [85]. However, MRI of the stomach requires additional validation, such as comparison with barostat, including studies in disease and response to interventions including but not limited to the effects of nutrients and prokinetic drugs. The ability to resolve wall movement and to apply acquisition and projection algorithms developed for dynamic imaging in other indications, such as MR angiography, and the absence of radiation exposure make MRI of gastric function a potentially attractive technology, as long as it is affordable. Magnetic resonance imaging of the small intestine is in the developmental stages [86]. The resolution of abdominal organ imaging is enhanced with techniques such as respiratory gating and multiarray imaging using two surface MRI coils [87].

Motility measurements of the pelvic floor, pelvic organs, and anorectum

Distention-induced deformation of the intestinal wall activates mechanosensitive afferents in the mucosa, muscle layers, and serosa [88]. However, mechanoreceptors are not directly sensitive to volume or pressure [89–91]. Therefore, traditional distention data based on pressure–volume measurements may not be optimal [92–94]. The degree of tissue deformation (strain) and mechanical forces (stress) in the circumferential direction appear to determine activation of mechanoreceptors [95]. Analysis of the contractile state of the smooth muscle may be essential in understanding mechanosensory transduction [96]. As discussed previously, distention technology has been refined by the introduction

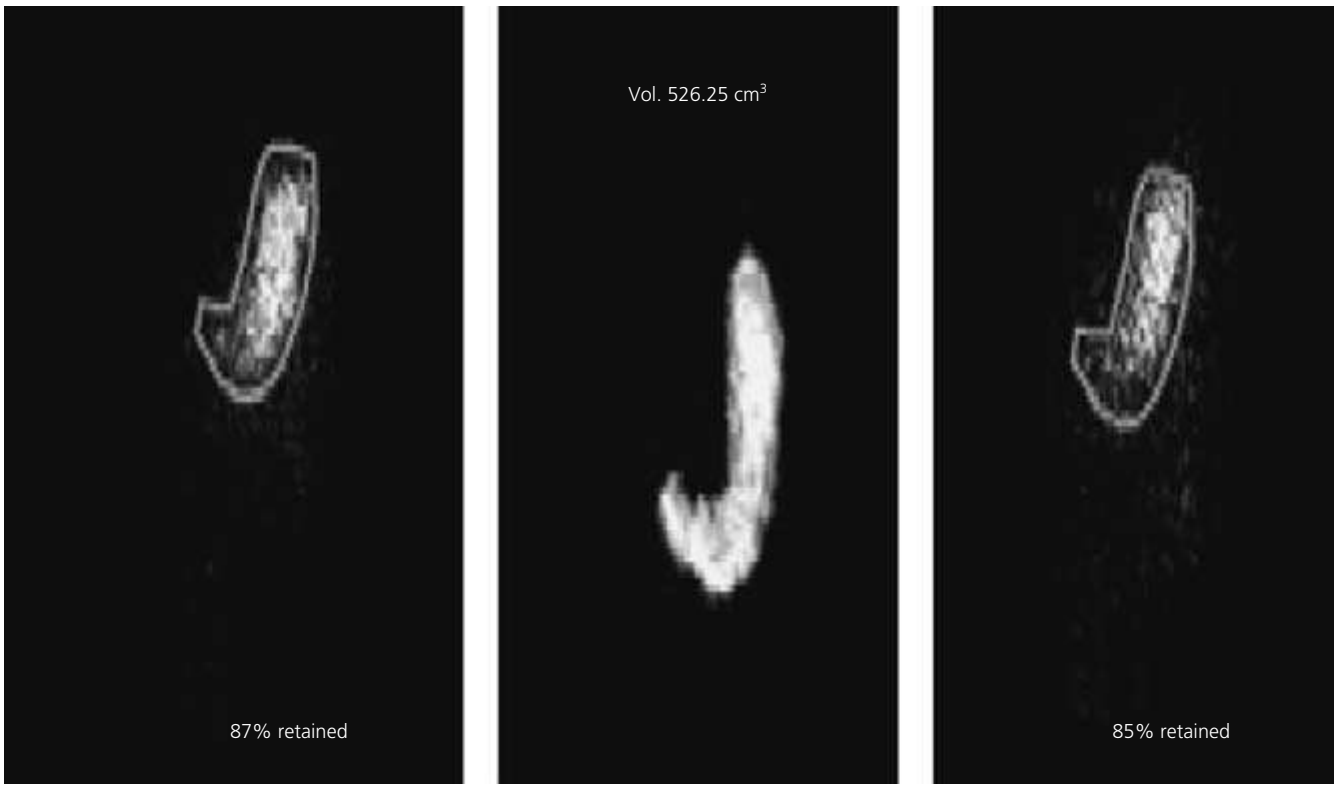

Figure 138.11 Images of the stomach by planar scans, single-photon emission computed tomography (SPECT), and composite SPECT acquisition to construct anterior image using the method described by Burton et al. [81]. Note that the amount of food retained in the stomach is similar when calculated using the traditional two-dimensional or planar anterior and posterior gamma camera images. The central image demonstrates the stomach volume simultaneously estimated using SPECT. From Camilleri [81], with permission.

of impedance planimetric techniques with assessment of circumferential strain, tension, and stiffness [97–104]. However, impedance planimetry using a single CSA measurement has limitations, making it difficult to characterize the biomechanical properties of regions such as the large bowel and rectum because of the complex and dynamic geometry of these segments. Therefore, methods based on cross-sectional imaging have been developed to assess the geometric variables in nontubular segments of the gut, that is, ultrasonography of the stomach and MRI of the gallbladder and rectum [105–108]. Magnetic resonance imaging has an outstanding safety profile and provides excellent soft tissue imaging capabilities. Also, MRI is well suited for studying the gastrointestinal geometry. It is possible to model the 3D geometry and mechanical properties of complex gastrointestinal segments, including multidirectional deformation and the spatial distribution of the 3D principal curvatures, radii of curvature, wall thickness, tension, and stress of the rectum [107]. Cross-sectional imaging and 3D analysis also allow assessment of the contribution and effect of the smooth muscle activity by studying the muscle relaxation during administration of stimulatory or inhibitory drugs.

Therefore, MRI of the pelvic floor has the potential to characterize several components of continence and defecation simultaneously. Dynamic imaging (Fig. 138.13) and the use of magnets that allow for studies in the seated position provide detailed information about structure and integration with function that was not possible using a combination of techniques such as barium defecography and endoanal ultrasound [109,110]. For example, a report demonstrates the occurrence of different phenotypes of obstructed defecation, abnormal structure and function of the pelvic floor and anal sphincters in people with incontinence, and physiological alterations associated with aging [111]. Frokjaer et al. [112] used a flexible PVC catheter equipped with a bag for gut distention and a radiopaque ring allowing proper positioning of the probe to examine sigmoid colon biomechanics in conjunction with MRI (Fig. 138.14). The geometry of the distended sigmoid colon was complex and varied considerably between the subjects, as depicted in Fig. 138.15. The

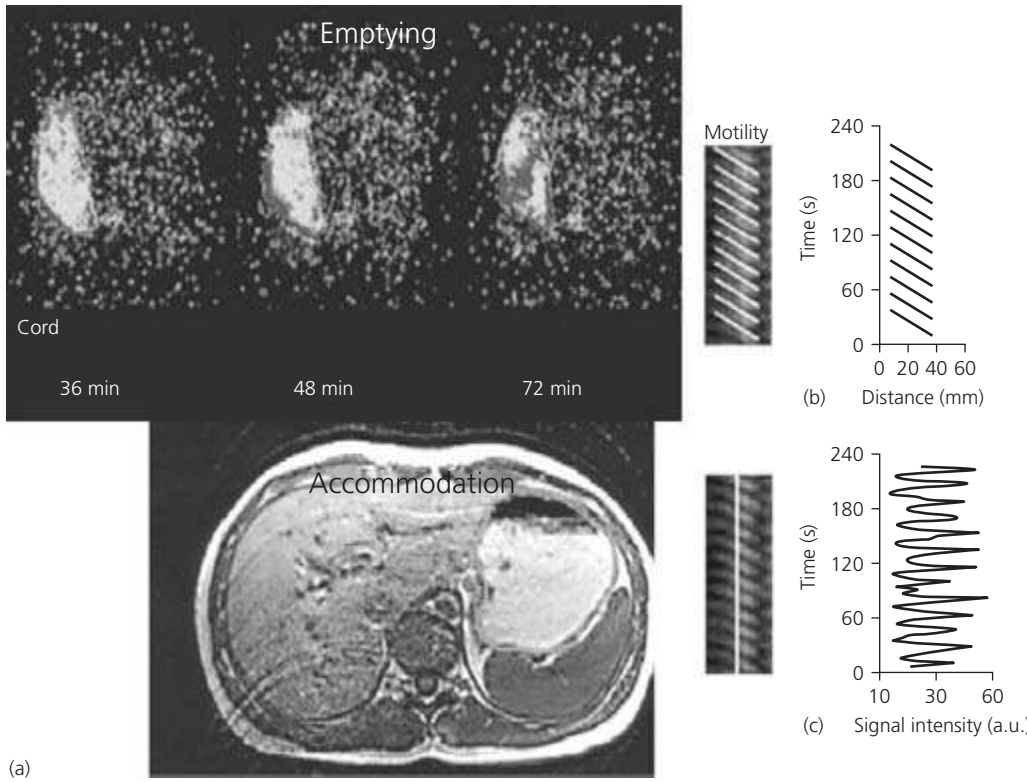

Figure 138.12 Magnetic resonance imaging provides the potential to estimate gastric emptying, accommodation, and wall motion in a noninvasive manner. From Camilleri [81], with permission.

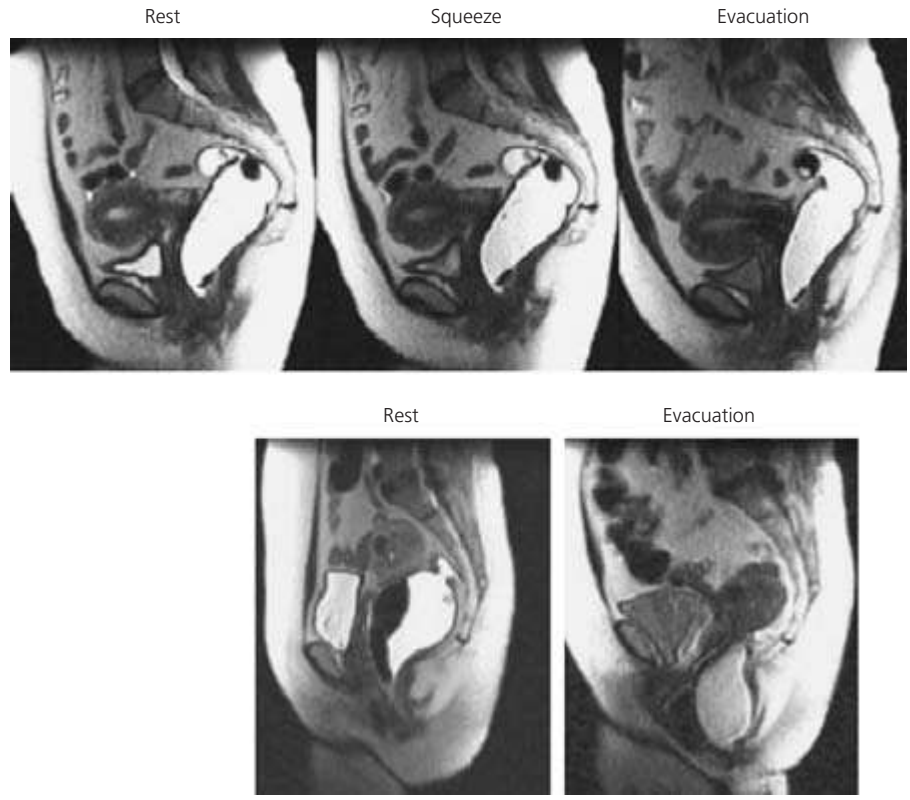

Figure 138.13 Defecation dynamics in patients with evacuation disorders due to immobile perineum **(upper)** or descending perineum syndrome **(lower)** using magnetic resonance imaging. From Bharucha et al. [109], with permission.

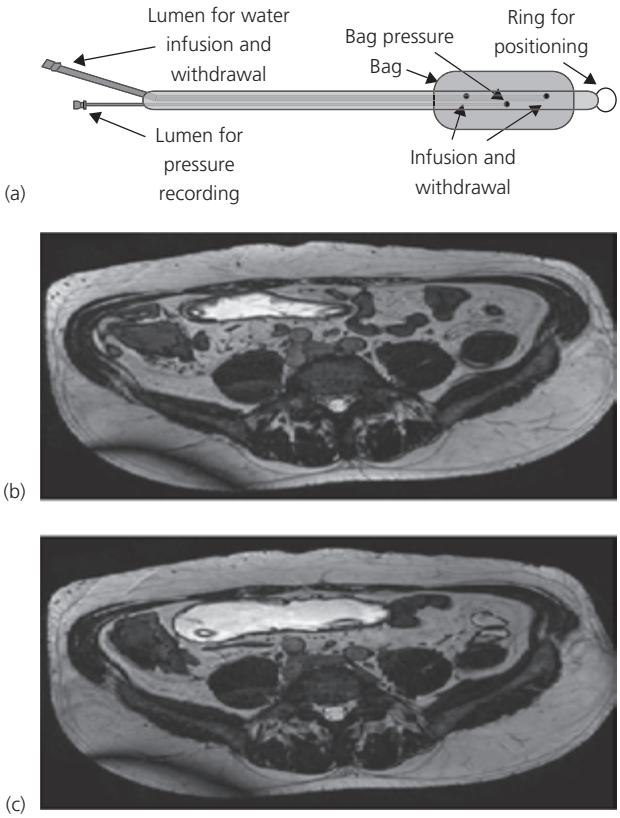

Figure 138.14 **(a)** The probe that allows bag distention and pressure measurements during magnetic resonance imaging (MRI). Transverse MRI shows the distended waterfilled bag (high signal intensity) in the sigmoid colon at 100 mL **(b)** and 300 mL **(c)**. From Frokjaer et al. [110], with permission.

circumferential radii of curvature increased, that is, increased in diameter, during the sigmoid distention but showed a highly inhomogeneous spatial distribution that was observed in all subjects. Histograms illustrating the distribution (frequency diagram) of the circumferential wall stress and wall thickness throughout the sigmoid wall are shown in Fig. 138.16. The histograms reveal "bell-shaped" distributions with an overall increase in wall stress and tendency to a decrease in peak wall thickness during the distention. The sensation induced by distention before and after administration of the muscarinic receptor antagonist butylscopolamine is shown in Fig. 138.17 as a function of bag volume, bag pressure, and the average values of the 3D distribution of the circumferential strain, circumferential wall tension, and stress. Administration of butylscopolamine did not affect the wall thickness, circumferential length, and strain. Bag pressure and wall stress were reduced by smooth muscle relaxation. Therefore, sensory response decreased as a function of circumferential strain, that is, right shift of the stimulus–response curves in the presence of butylscopolamine. The inhomogeneous and complex 3D sigmoid geometry suggest that this type of 3D modeling will likely be useful and provide reliable data for detailed studies of the biomechanical and mechanosensory properties. This technique may be useful in the clinical setting for understanding biomechanical properties and visceral perception in several hollow visceral organs.

Functional brain imaging in assessing visceral sensation in health and disease

We include a section on functional brain imaging because there is general acceptance that selective activation of brain regions occurs in response to regional distention of the gut in health, and emerging data support differential activation of brain regions in patients with functional bowel disorders (FBDs) such as the irritable bowel syndrome (IBS) and nonulcer dyspepsia [113]. For example, several reports of positron emission tomography (PET) or functional MRI (fMRI) suggest that the limbic and emotional motor system in the brain may be differentially activated in patients with functional gastrointestinal diseases [113,114]. However, brain imaging in FBDs requires additional technical and methodological advances to clarify the reported differences in regional brain activation and their relationship to stress, pain, and emotion [115]. The areas of activation often involve neural circuitry of several interacting regions of the brain, which is not addressed in some reports. For example, regions in the cerebellum can be activated during rectal distention without any clear rationale about why this occurs. Other unresolved issues include the imaging differences between PET and fMRI and differences in brain regions activated in males and females in response to painful rectal distention. Methodological concerns include:

- the confounding effects on imaging of the distention itself vs anticipation of the distention
- the potentially significant central effects of placebo controls
- inclusion of clinically heterogeneous patients (e.g., diagnosis and severity of disease)
- existence of comorbidities such as fibromyalgia [116,117].

For example, anterior cingulate cortex activation during somatic pain appears to reflect anticipation [118]. This was confirmed in patients with functional gastrointestinal disorders [116]. However, it has also been reported that actual and anticipated esophageal pain elicits similar cortical responses [119].

Other issues that influence the interpretation of imaging studies include the lack of instrument or protocol standardization, low "signal-to-noise" ratios, and limitations in measuring functionally heterogeneous regions, such as the cingulate and other brain regions. The time course of activa-

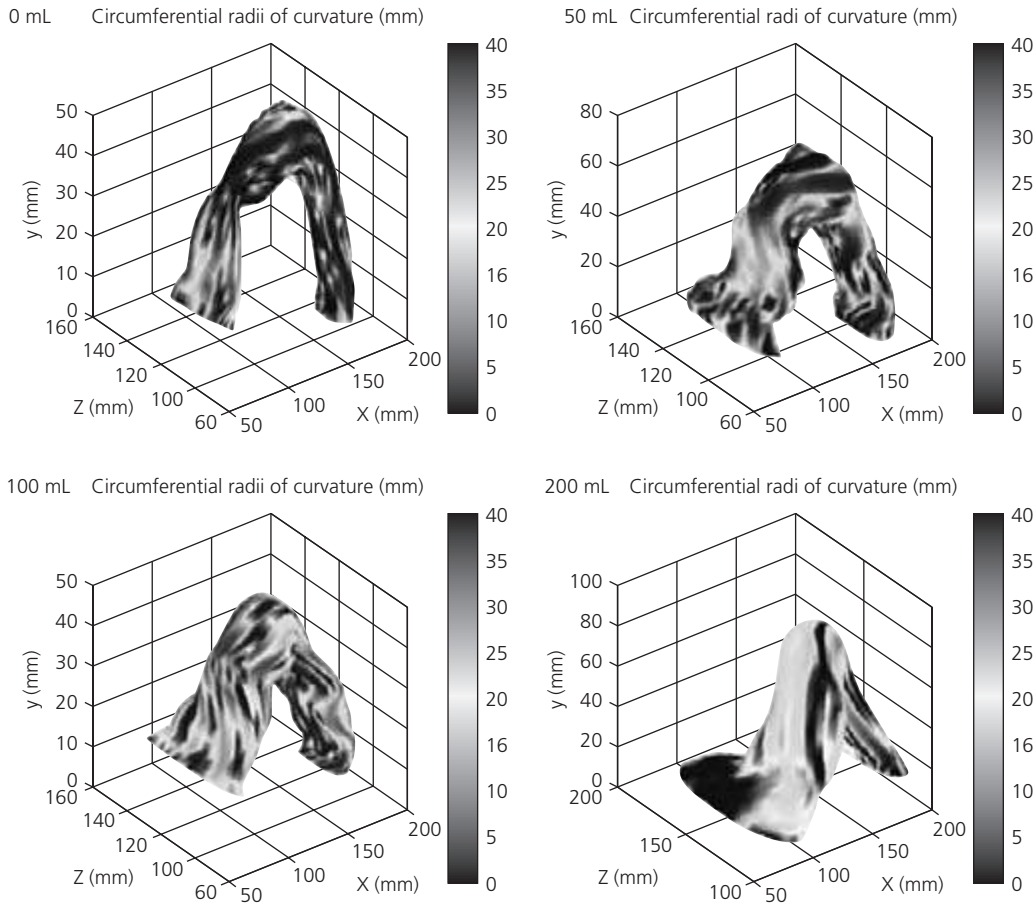

Figure 138.15 The three-dimensional distribution of circumferential principal radii of curvatures in one volunteer before administration of butylscopolamine at infused volumes of 0, 50, 100, and 200 mL. From Frokjaer et al. [110], with permission.

tion of different brain regions in response to stimulation has also resulted in relevant information. For example, cortical neural activity evoked by experimental esophageal pain is processed simultaneously in somatosensory and posterior insula regions. In contrast, activity in the anterior insula and cingulate brain regions that process the affective aspects of esophageal pain occurs significantly later than in the somatosensory regions, and no gender differences were observed with this experimental paradigm [120]. In addition, the timing and intensity of brain activation may be different in health and disease. For example, cortical activity associated with perceived and unperceived esophageal acid exposure in gastroesophageal reflux disease (GERD) patients and healthy controls, respectively, involves multiple brain regions, but it occurs more rapidly and with greater intensity in GERD patients than the activity in response to subliminal acid exposure in healthy controls [121]. Another marker of hypersensitivity in IBS may be detected by an enhanced response to subliminal stimuli [122]. Activity on fMRI was studied in IBS patients and age- and gender-matched healthy controls using a computerized barostat-controlled rectal distention device that generated equal subliminal distention pressures (e.g. 10, 15, and 20 mmHg) in both controls and patients. In all three distention levels, the fMRI activity in IBS patients was significantly greater than in controls, supporting the existence of hypersensitivity in this patient group irrespective of stimulus-related cognitive processes (Fig. 138.18).

In conclusion, the application of functional imaging techniques to neurogastroenterology research has resulted in significant advances in our understanding of the brain–gut axis in health and disease. Some of these methods are associated with significant radiation burden and would benefit from improvements in experimental design and standardization of methods. The experimental designs also suffer from limitations of statistical and experimental approaches to study circuits and networks simultaneously and sequentially

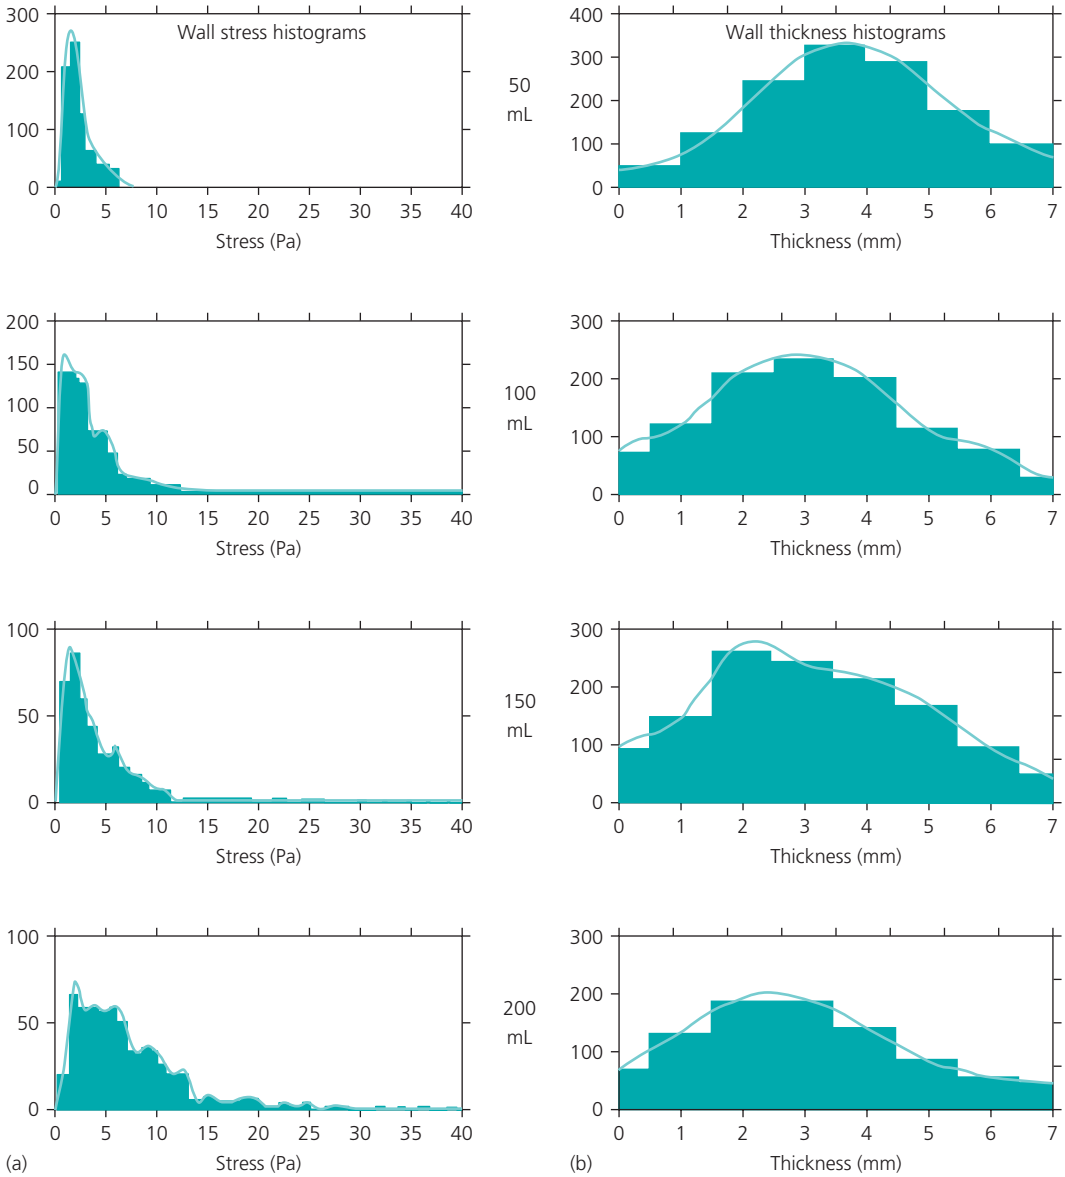

Figure 138.16 Histograms illustrating the distribution of **(a)** wall stress and **(b)** wall thickness before administration of butylscopolamine throughout the three-dimensional sigmoid surface in one subject. The y-axis indicates the number of surface squares. During distention, the distribution of stress clearly shifted to the right, whereas the distribution of wall thickness was not affected to the same degree. The same pattern was seen in all subjects. From Frokjaer et al. [110], with permission.

in "real-time." Advances in technology will likely resolve this problem in the future.

Validation of new technologies

Further validation of the emerging technologies discussed in this chapter is required for research purposes and before their routine application in clinical practice. Validation should include critical appraisal of:

- the internal validity (accurately drawing conclusions about the source population based on information from the study population) and external validity (independent, blind comparison with a reference standard)
- the technology's performance (in particular, reproducibility and coefficient of variation)

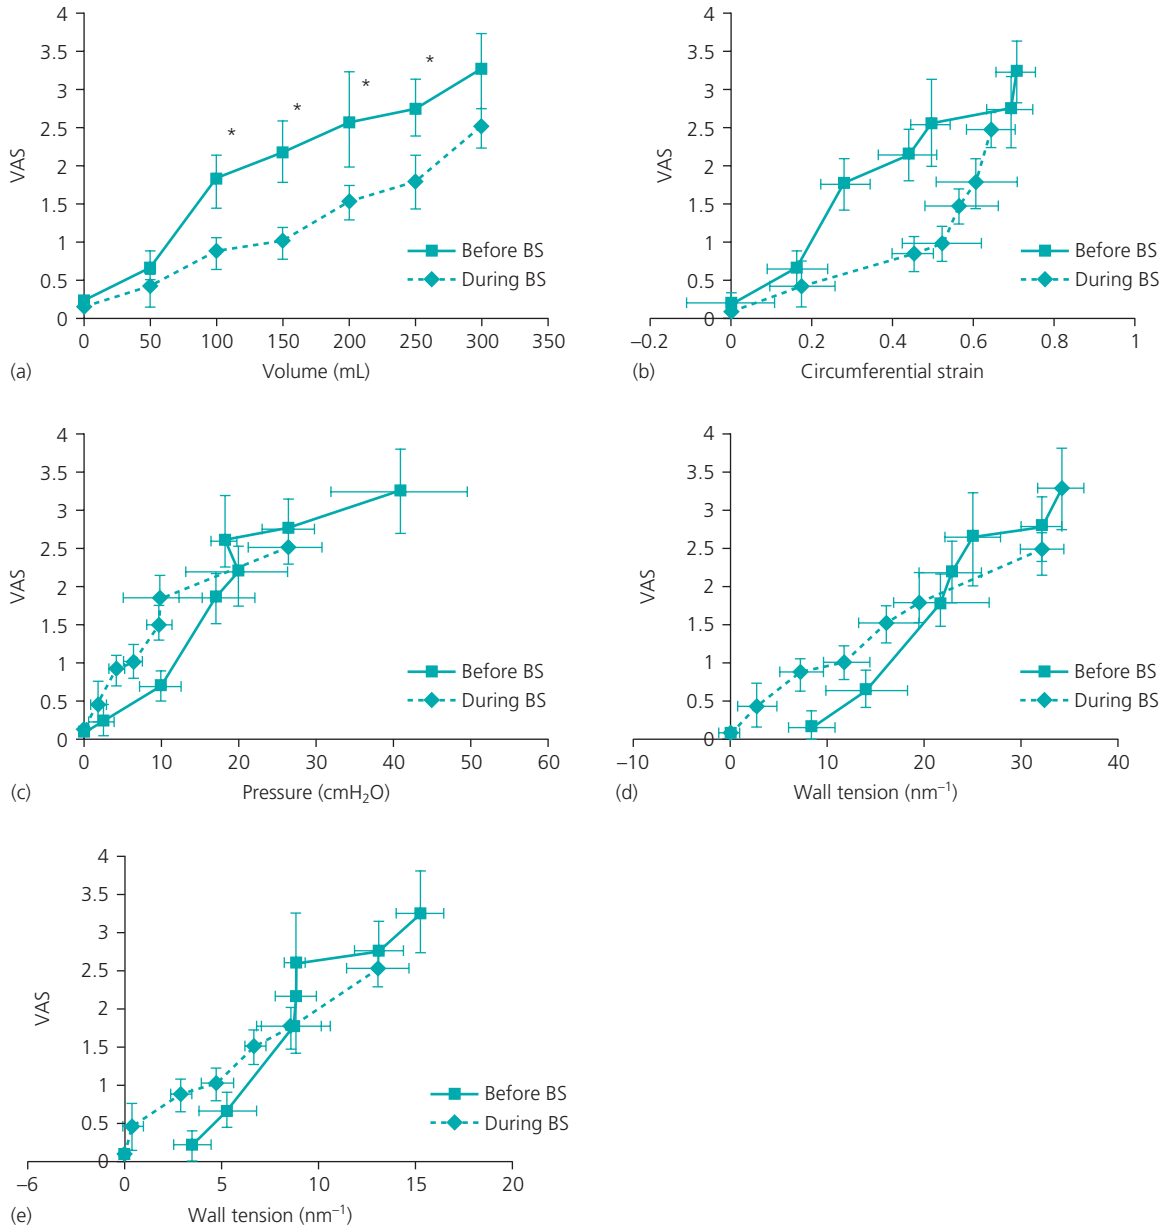

Figure 138.17 The sensory response rated on a visual analog scale (VAS) is illustrated as a function of infused bag volume **(a)**, average three-dimensional circumferential strain **(b)**, bag pressure **(c)**, circumferential tension **(d)**, and stress **(e)** before and after administration of butylscopolamine. Asterisk (*) indicates significant difference for the volume data. BS, butylscopolamine. The error bars indicate standard error of the mean (SEM). From Frokjaer et al. [112], with permission.

- the technology's sensitivity (proportion of true positives of all positives) and specificity (proportion of true negatives of all negatives)
- the likelihood ratios (i.e., the link between the pretest probability of the diagnosis of a disorder and the probability after the test)
- the responsiveness of the diagnostic test to change and the relationship between that change and a change in clinical outcome
- the cost–benefit of the technology either as a diagnostic tool or therapeutic intervention for acceptance in the clinical setting.

These are the standards to which diagnostic tests are held in other areas [123,124].

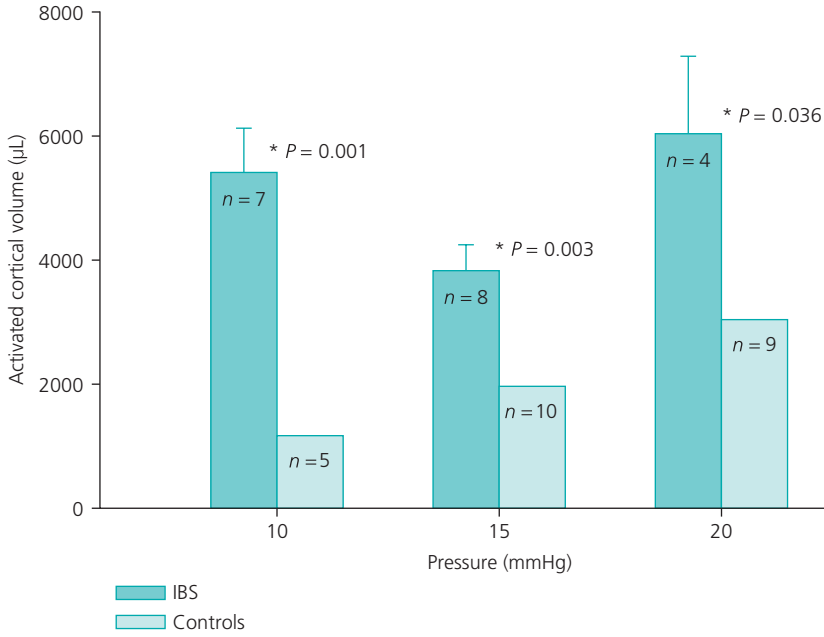

Figure 138.18 Total fMRI cortical activity volume response to three levels of subliminal rectal distention pressures in patients with irritable bowel syndrome and control subjects. In all three subliminal distention pressures the fMRI activity volumes in patients with IBS were significantly larger than those of control subjects. Furthermore, fMRI cortical activity volumes showed a stimulus intensity-dependent relationship in control subjects ($P < 0.001$), but not in patients with IBS for the three analyzed pressure levels. From Lawal et al. [120].

139 Tests of gastric and exocrine pancreatic function and absorption

William D. Chey, Matthew J. DiMagno, William Y. Chey

Tests of gastric secretory function, 3414
Tests of pancreatic exocrine function, 3419

In this chapter, we review the indications and currently available methods of assessing gastric secretory and pancreatic exocrine function. For a detailed review of the physiology of gastric secretory and pancreatic exocrine function, the reader is referred to Chapters 13 and 15.

Tests of gastric secretory function

The clinical applications of gastric acid analysis and prolonged intragastric pH monitoring are limited. However, these tests remain critical for better understanding the effects of various disease states and pharmaceuticals on gastric secretory function. Gastric acid analysis and prolonged intragastric pH monitoring have played a pivotal role in understanding the link between *Helicobacter pylori* infection and the changes in acid secretion documented in patients with peptic ulcer disease decades ago. As the *H. pylori* story has taught us, groundbreaking discoveries of the future will require ongoing reevaluation of our understanding of gastric secretory function. As such, the methodology and strengths and weaknesses of gastric acid analysis and prolonged intragastric pH monitoring continue to be worthy of review.

Gastric acid analysis

Indications

Traditionally, physicians have utilized gastric acid analysis to answer the following questions.

- Does the stomach produce acid?
- If so, what is the basal or unstimulated gastric acid secretion?
- How much acid is secreted in response to physiological or pharmacological stimulation?
- Is the vagal innervation to the stomach intact?

In recent years, the development of less invasive and less cumbersome diagnostic modalities for acid peptic disorders has decreased the relative importance of quantitative gastric acid analysis. In addition, the availability of proton pump inhibitors, which potently and reliably suppress gastric acid secretion, has decreased the number of circumstances in which quantitative gastric acid analysis is necessary. Nonetheless, gastric acid analysis remains the gold standard for evaluating gastric secretory function and is useful for the gastroenterologist or gastrointestinal surgeon in several clinical situations (Table 139.1).

Gastric analysis remains helpful in determining whether an elevated circulating gastrin level is physiological (achlorhydria) or pathological (acid hypersecretory states). Gastric analysis can establish that hypergastrinemia is an appropriate consequence of the inability to produce acid as seen in the setting of atrophy, pernicious anemia, or malignancy involving the body of the stomach [1]. On the other hand, hypergastrinemia can be seen in diseases of excessive acid secretion such as Zollinger–Ellison syndrome [2].

In the past, gastric acid analysis played a crucial role in the diagnosis of Zollinger–Ellison syndrome. However, the development of secretin stimulation testing and accurate imaging modalities such as high-resolution computed tomography (CT), magnetic resonance imaging (MRI), endoscopic ultrasound (EUS), and somatostatin receptor scintigraphy

Table 139.1 Indications for gastric acid analysis

Evaluate an elevated fasting plasma gastrin level
Physiological response (atrophic gastritis)
Pathological response (gastrinoma, ulcerogenic tumor syndrome with nongastrin secretagogue)
Assess the adequacy of proton pump inhibitor therapy in patients with diseases of gastric acid hypersecretion
Assessment of the patient with ulcer recurrence following surgical intervention for peptic ulcer disease
Exclude acid hypersecretion
Assess the completeness of vagotomy (sham feeding)

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

have relegated gastric acid analysis to an adjunctive role in the diagnosis of this disease [3,4]. Gastric analysis remains critical to the evaluation of the unusual patient with acid hypersecretion attributable to the ulcerogenic pancreatic tumor syndrome where circulating gastrin levels are typically normal [5,6]. Gastric analysis can be useful in determining the adequacy of acid suppressive therapy after the diagnosis of gastrinoma or the ulcerogenic pancreatic tumor syndrome has been established.

Gastric acid analysis can also be helpful in the evaluation of patients who develop recurrent ulcers following surgery for peptic ulcer disease. In this setting, gastric acid secretion can be quantified and hypersecretion excluded. In addition, the completeness of vagotomy can be determined by sham feeding that evaluates the vagally mediated cephalic phase of acid secretion.

In the age of *H. pylori* and proton pump inhibitors, however, the frequency for which gastric analysis is necessary for this indication is decreasing. Recent epidemiological data suggest that the prevalence of *H. pylori* and peptic ulcer disease in Western countries is declining [7–9]. Operative intervention for peptic ulcer disease has been decreasing in recent years, likely related to improvements in medical and endoscopic management options [10]. Further, most of the classic literature addressing postoperative ulcer recurrence was performed prior to the acceptance of *H. pylori* as one of the major pathogenic factors in the development of peptic ulcer disease [11]. It is likely that *H. pylori* eradication alters postoperative gastric acid secretion or decreases the likelihood of recurrent peptic ulceration following surgery. For these reasons, what was once a common reason to order gastric acid analysis is now an unusual indication for this procedure.

Gastric acid analysis remains an important means of better understanding the effect of various pharmaceuticals and disease states on gastric secretory function. For example, it has long been known that patients with duodenal ulcer have higher levels of basal acid secretion than controls [12,13]. Studies using gastric acid analysis have proven that this abnormality is related to *H. pylori* infection and that eradication of this infection leads to normalization of basal acid output (BAO). On the other hand, pentagastrin-stimulated maximal acid output (MAO) in patients with duodenal ulcer remains elevated even after successful *H. pylori* eradication. This suggests the presence of parietal cell hypersensitivity to gastrin or an increase in parietal cell mass that persists after eradication of *H. pylori* infection [14].

The utility of gastric acid analysis in patients with peptic ulcer disease, but without evidence of *H. pylori* infection or history of nonsteroidal antiinflammatory medication use, has yet to be determined. Other patient populations in whom gastric acid analysis might be useful include those with a nonhealing ulcer despite appropriate acid suppressive therapy and those with ulcer recurrence despite successful *H. pylori* eradication.

Methodology

The most widely practiced means of measuring acid secretion is the aspiration method in which gastric contents are withdrawn through a nasogastric tube at timed intervals under different test conditions. The hydrogen ion concentration in these samples can then be determined provided a quantitative assessment of basal and stimulated acid output and modified sham feeding (MSF) acid secretion.

A point worthy of consideration is the reliability of gastric acid analysis. A great deal of variability in test results has been observed in studies of healthy individuals. Both BAO and MAO tend to be higher in males than females. Patients with functional dyspepsia have similar acid secretion compared with healthy volunteers [12,13]. On the other hand, patients with duodenal ulcer tend to have greater acid secretion than healthy individuals (Fig. 139.1) [12–14]. Unfortunately, because of considerable overlap between populations, gastric analysis does not reliably discriminate between those with peptic ulcer disease and healthy volunteers. Even when Zollinger–Ellison syndrome is suspected, gastric analysis is

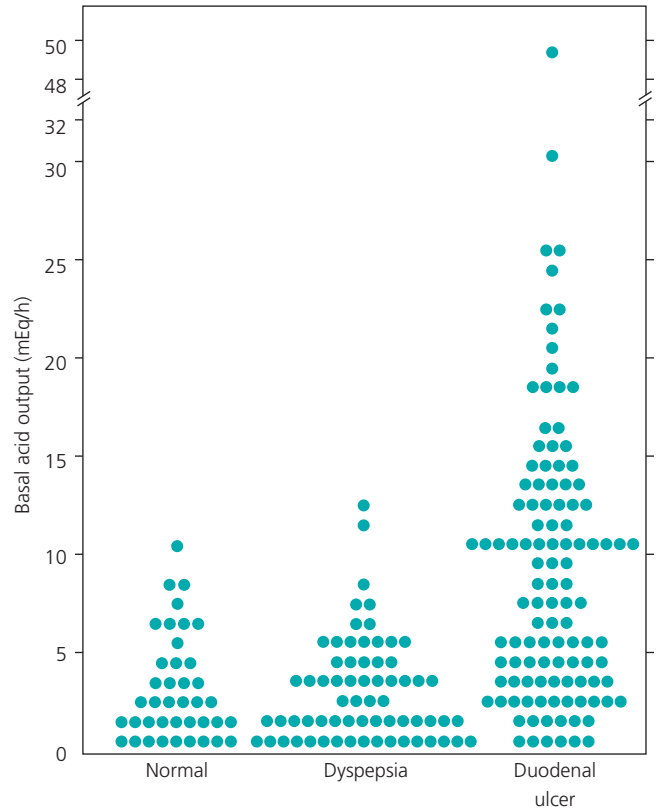

Figure 139.1 Basal acid output (BAO) in 40 healthy controls, 66 patients with nonulcer dyspepsia (NUD), and 114 patients with duodenal ulcer. There was no difference in mean BAO between normals (3.2 ± 2.7 mEq/h) and patients with NUD (2.9 ± 2.7 mEq/h). However, the mean BAO was significantly higher in patients with duodenal ulcer (9.1 ± 7.6 mEq/h) than in either normals or patients with NUD. From Collen and Loebenberg [12], with permission from Springer.

not always a reliable single diagnostic test because of the overlap in results yielded by patients and controls [1].

Aside from the considerable interindividual variability, there is also intraindividual variability when gastric acid analysis is performed on different days [15]. The reproducibility of this test depends on several variables including day-to-day variations in BAO, day-to-day variations in responsiveness of acid output to various secretagogues, and the completeness of gastric contents recovery. One study that evaluated several studies with intraindividual BAO data found the coefficient of variation to be rather poor [15]. This is likely related to the multiple factors (time of day, mental state, duodenal losses of gastric contents, neutralization of acid with swallowed saliva, and neurohormonal effectors of acid secretion) that influence acid secretion and its measurement in the basal state [16]. In contrast to basal acid secretion, acid secretion stimulated by histamine or pentagastrin is much more reproducible from day to day [15].

Recovery of gastric contents can be facilitated by proper tube placement and patient position. The aspiration tube should be of sufficient caliber to allow recovery of the gastric contents but not so large as to be intolerable to the patient. In general, tubes in the range 14–18Fr are best suited to these requirements. Testing should be performed in the seated or left lateral decubitus position. The tip of the tube should be placed into the most dependent portion of the stomach and proper placement is optimally confirmed with fluoroscopy. Even when test conditions are optimized, recovery of the gastric contents is often not complete [17].

The recovery of gastric contents during aspiration can be quantified by the infusion of a nonabsorbable marker such as polyethylene glycol (PEG) or radiolabeled chromic chloride ($^{51}CrCl_3$) [17,18]. Although this technique provides a means of assessing the completeness of gastric aspiration, the infusion and measurement of a nonabsorbable marker, particularly one that is radioactive, makes the procedure much more cumbersome and costly to perform. For these reasons, most centers including ours perform gastric acid analysis without the infusion of a nonabsorbable marker.

Basal acid output

On the evening prior to undergoing gastric acid analysis, patients should take a clear liquid dinner and consume nothing by mouth after midnight. Unless the purpose of the study is to assess the effect of a medication on acid secretion, dosing of agents that affect acid secretion should be modified prior to the test. Histamine (H_2)-receptor antagonists, antihistamines, anticholinergics, and cholinergic agonists should be discontinued at least 24 h before gastric acid analysis. Proton pump inhibitors inactivate the H^+,K^+-ATPase found on the parietal cell [19]. As such, proton pump inhibitors have prolonged effects on acid secretion [20] and should be withheld for at least 7 days before testing. For patients who suffer with recurrent symptoms once their proton pump inhibitor has been discontinued, an H_2-receptor antagonist may be used until 24 h before gastric acid analysis.

On the day of gastric acid analysis, the patient is intubated and tube placement is confirmed as described above. The study starts with a 30-min washout period during which all gastric contents are aspirated and discarded. After this washout period, samples are collected at 15-min intervals. Sample volume is recorded and an aliquot is used to determine the titratable acidity. Titratable acidity (mmol/L) is measured by titrating an aliquot of gastric juice to pH 7 with a base such as NaOH and then correcting this value for the size of the total timed sample. The following equations can be used to determine the titratable acidity:

(mL base to titrate to pH 7) × [concentration of the base] = millimoles H^+ per aliquot

Volume of sample × millimoles H^+ per aliquot

Volume of aliquot = millimoles H^+ per sample

BAO (mmol H^+ per hour) is the sum of the acid output from the four 15-min collections done in the unstimulated state. In healthy unoperated volunteers, BAO should be less than 15 mmol/h. In patients with Zollinger–Ellison (gastrinoma) syndrome or ulcerogenic pancreatic tumor syndrome without gastrinoma, BAO is greater than 15 mmol/h. A BAO of greater than 5 mmol/h is considered abnormal for a patient who has previously undergone partial gastrectomy or vagotomy [8]. In humans, BAO should be approximately 10% of the maximal secretory capacity of the stomach [15].

Alternative endoscopic means of assessing BAO have been described [21,22]. In a study involving 12 patients with gastrinoma, Oh and colleagues found that a 15-min endoscopic gastric acid collection yielded comparable acid concentration and acid output results to standard gastric acid analysis (Fig. 139.2). Volume of gastric contents collected between the two techniques showed poor agreement. For this procedure [22], patients received conscious sedation with meperidine or midazolam. Anticholinergic agents were not allowed prior to this procedure. All gastric contents were aspirated and discarded. This was followed by the collection of gastric contents for a period of 15 min. Hourly BAO was determined by multiplying the acid output of the 15-min sample by 4. Advantages of this technique include improved comfort over traditional gastric aspiration, targeted recovery of gastric contents, and the ability to perform both gastric acid analysis and traditional endoscopy with a single procedure. Further validation of this interesting new technique is eagerly awaited.

Maximal and peak acid output

MAO and peak acid output (PAO) indirectly assess functional parietal cell mass through the measurement of acid secretion following the administration of maximally effective doses of

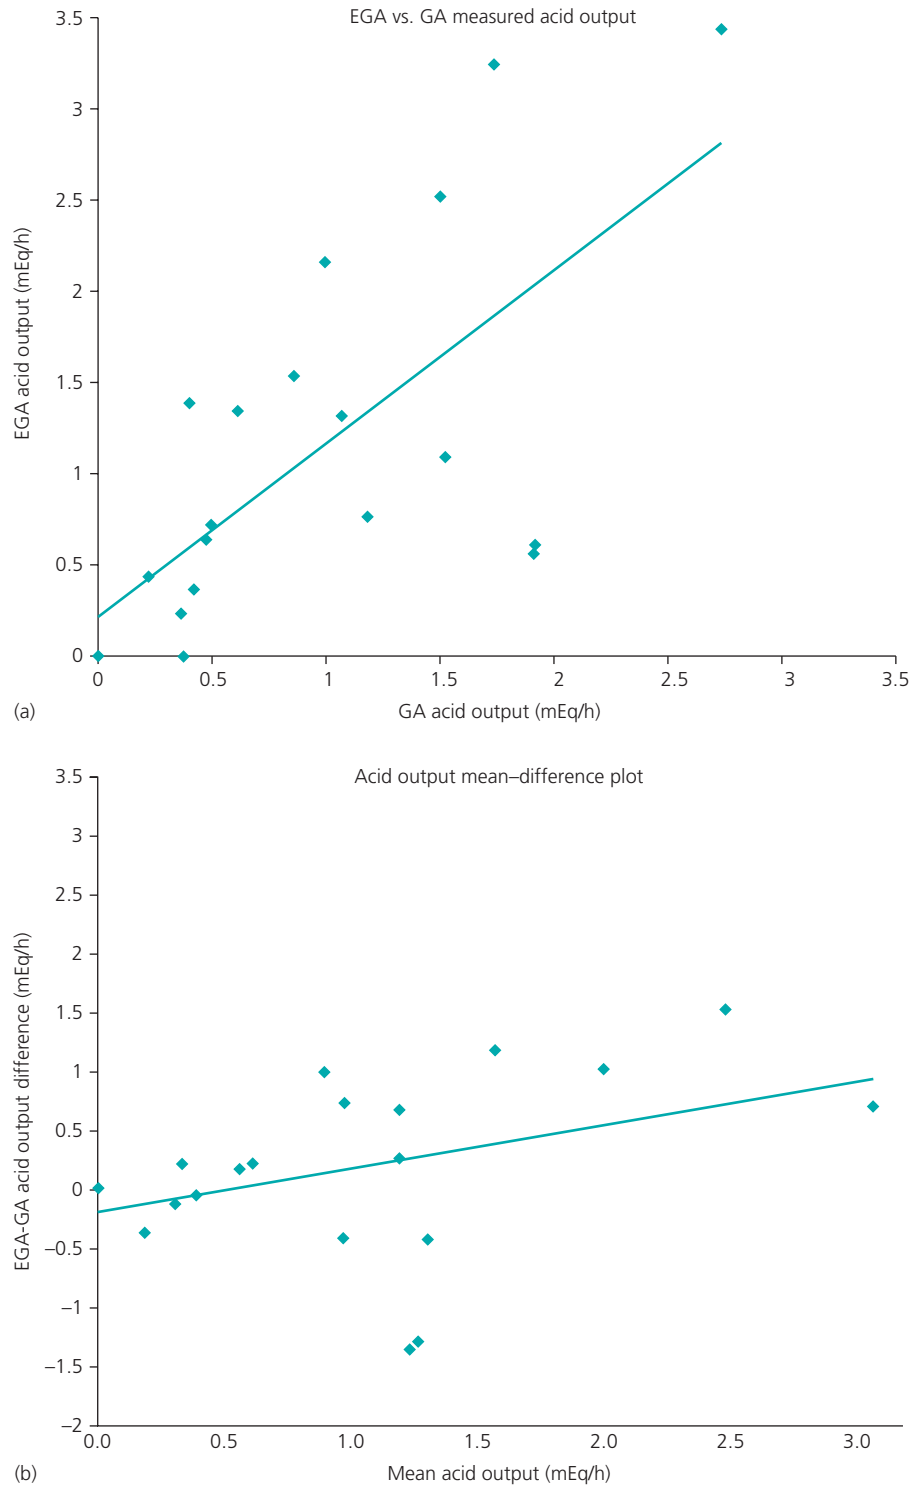

Figure 139.2 **(a)** Plot of endoscopic gastric analysis (EGA)-measured acid output against conventional gastric analysis (GA)-measured acid output with least-squares regression analysis. **(b)** Bland–Altman plot assessing agreement between EGA and GA acid concentration with least-squares regression analysis. The mean difference (horizontal solid line) is plotted. From Oh et al. [22], with permission from Elsevier.

agents that directly stimulate the parietal cell [23,24]. Such stimulants of acid secretion include pentagastrin, histamine, and histamine analogues such as 3-β-aminethylpyrazole. Pentagastrin is the most widely used agonist and is usually administered subcutaneously (6 μg/kg). Pentagastrin can also be given intramuscularly (6 μg/kg) or intravenously (1–6 μg/kg/h). After pentagastrin administration, gastric juice is collected every 15 min for 1–1.5 h. The titratable acidity (mmol H^+ per sample) is then determined for each of the four to six samples obtained after pentagastrin administration. MAO represents the greatest sum of the titratable acid from four consecutive samples (mmol H^+ per hour). PAO is the sum of

the two highest acid outputs multiplied by 2 to yield results in mmol H^+ per hour. MAO and PAO measurements vary widely in healthy subjects, ranging from 0 to 80 mmol/h. MAO is influenced by a number of variables including sex, age, and lean body mass [25]. MAO decreases by approximately 50% after truncal or proximal gastric vagotomy [26,27].

In conjunction with BAO, MAO measurement can suggest the presence of gastrinoma. As the presence of an abnormally elevated gastrin in plasma stimulates parietal cells to produce excessive gastric acid secretion in the basal state, patients with gastrinoma will typically have a BAO/MAO ratio of greater than 0.6 [1].

Another approach to the study of gastric secretory function is to administer gastrin-releasing peptide (GRP) rather than pentagastrin or histamine [14]. GRP leads to the release of gastrin from the antral G-cells and thereby indirectly stimulates gastric acid secretion by the parietal cell [28,29]. In addition, GRP influences the release of counterregulatory hormones such as cholecystokinin (CCK), secretin, gastric inhibitory peptide, vasoactive intestinal peptide, neurotensin, enteroglucagon, and somatostatin [30,31]. Therefore, unlike pentagastrin or histamine, which assesses only the parietal cell response to direct stimulation, GRP theoretically evaluates the sum of both stimulatory and inhibitory pathways responsible for the control of acid secretion. Investigators have used this approach to demonstrate abnormalities in the inhibitory control of acid secretion in patients with *H. pylori* infection and duodenal ulcer [14]. GRP is an interesting clinical investigative tool but is not currently considered part of routine gastric acid analysis.

Testing of vagally stimulated acid secretion

Since the turn of the 20th century, it has been known that the thought, sight, smell, and taste of food stimulate gastric acid secretion. Food-induced stimulation of the senses leads to activation of cerebral cortical sites resulting in increased gastric acid secretion. The so-called cephalic phase of gastric acid secretion is dependent on an intact vagus nerve and is cholinergically mediated [15].

The sham feeding test assesses vagally mediated acid secretion. Most commonly, this test is used to determine the completeness of vagotomy in patients with ulcer recurrence following surgery for peptic ulcer disease [32]. In humans, acid output response to sham feeding is 50%–65% of secretagogue-induced acid output [15]. In addition, some investigators have used this technique to assess the patency of vagal autonomic innervation to the stomach in the patients with diabetes mellitus [33].

During sham feeding, patients are allowed to see, smell, taste, and chew an appetizing meal. Food is then expectorated by the patient, thus avoiding the gastric phase of acid secretion. Gastric juice is collected via a nasogastric tube and the titratable acidity calculated as described above. Feldman and colleagues have shown that a sham acid output (SAO) to PAO ratio of less than 0.1 is abnormal in healthy volunteers. Therefore, an SAO/PAO ratio of more than 0.1 in a patient who has previously undergone peptic ulcer surgery suggests the presence of intact vagal innervation to the stomach [32].

Ambulatory intragastric pH monitoring

Indications

The role of ambulatory intragastric pH monitoring in clinical practice is limited. Like gastric acid analysis, however, the prolonged measurement of intragastric pH is useful in selected clinical and research situations. Prolonged intragastric pH monitoring has gained popularity as an investigative tool because it is better tolerated by patients and less cumbersome to perform than traditional gastric analysis using aspiration techniques. This technique has most often been used to evaluate the effects of duodenogastric reflux [34,35] and drugs that suppress acid secretion (e.g., H_2-receptor antagonists and proton pump inhibitors) on intragastric pH [36–39]. Intragastric pH monitoring can also help to establish a link between pH events and symptoms in patients with gastrointestinal symptoms [37,40,41].

Ambulatory intragastric pH monitoring has been used in a variety of other settings. For example, intragastric pH monitoring has been used to determine the relationship between suppression of gastric acid secretion and peptic ulcer healing [42]. This technique has also been used to define differences in intragastric pH between patients with duodenal ulcer associated with *H. pylori* infection and controls [43,44]. Intragastric pH monitoring has also been used to identify differences in the effectiveness of proton pump inhibitor therapy between those infected and not infected with *H. pylori* [45,46].

It is important to understand the differences in information yielded by gastric acid analysis and intragastric pH monitoring. While gastric acid analysis provides a quantitative measure of gastric secretory function, intragastric pH monitoring yields only qualitative information. As has already been discussed, gastric acid analysis quantitates basal and maximal acid secretion in response to the administration of a specific secretagogue. On the other hand, intragastric pH monitoring allows only the determination of pH, albeit in a more physiological setting than gastric acid analysis. How well results obtained with prolonged intragastric measurement correlate with traditional gastric acid analysis remains controversial. Several studies have reported a good correlation between data obtained from the two techniques [36,47]. However, studies have questioned the validity of drawing conclusions regarding overall intragastric pH solely on the basis of measurements obtained with a single electrode [35,48–50]. Intragastric pH recordings from the body and fundus yield similar results [51] (Fig. 139.3). Simultaneous recordings from the body and antrum have demonstrated significant differences in pH both in the interdigestive and postprandial periods [35,48–50]. In general, H^+ concentration

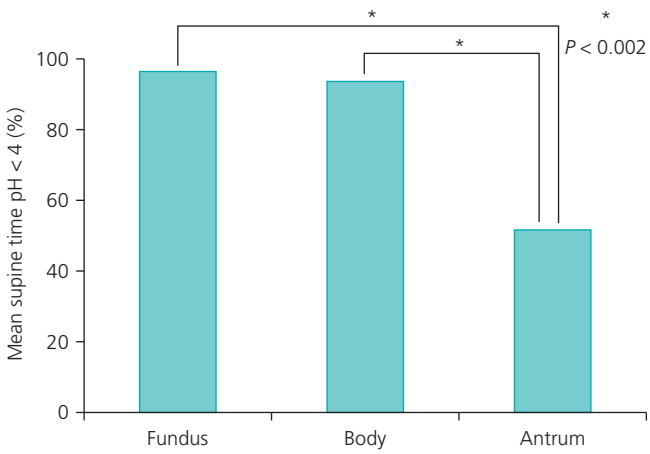

Figure 139.3 Mean percent time pH < 4 during supine periods for five healthy volunteers: comparison of fundus, body, and antrum. From Fackler et al. [51], with permission from Blackwell Publishing.

is higher when measured by intragastric pH monitoring compared with gastric acid analysis [49]. The precise reasons for these differences are not clear, but biophysical phenomena including environmental carbon dioxide concentration, temperature, and technical issues including electrode instability, artifact or interference may be contributory [49,52].

Methodology

There are a variety of ways to measure intragastric pH [51]. The most widely employed method has been to place a catheter containing a single electrode transnasally into the body of the stomach [53,54]. As mentioned above, recent literature has questioned the practice of using a single electrode as a sole means of evaluating intragastric pH. Obtaining pH measurements from more than one part of the stomach appears to yield more complete information. Whether this more complete information has practical relevance to the clinician or investigator remains to be determined. When a single pH electrode is used, recordings from the fundus (10 cm below the lower esophageal sphincter) appear to yield the most consistent and reproducible results [51]. Proper placement should be confirmed with manometry or fluoroscopy. Both antimony and glass pH electrodes have been used and although point-to-point variation in data has been noted, overall these techniques appear to give similar results [55,56]. The catheter is connected to any of a number of commercially available computerized modules that can digitally record changes in intragastric pH. Careful attention should be paid to proper calibration of the pH monitoring equipment prior to each study. The probes used for intragastric pH monitoring reportedly become less accurate with repeated use [52].

A catheterless capsule that can monitor pH events in the esophagus for up to 4 days has also become available [57,58]. Research suggests that this device can successfully record prolonged ambulatory intragastric pH in the cardia [59] and body [60]. Placement of the device in the gastric body can be facilitated by direct visualization via endoscopy [60]. Improved comfort and the ability to engage in daily activities makes this technique more physiological than traditional catheter-based monitoring techniques. Unfortunately, this technique is costly, requires endoscopy for placement, and does not resolve the issue of monitoring from only one location within the stomach. An orally ingested pH and motility capsule has also been evaluated [61]. This device can record intragastric pH until it is emptied from the stomach. An advantage of this technique is that it does not require endoscopy. Unfortunately, because this device is not fixed within the stomach, one cannot be sure from which part of the stomach pH data are being recorded. This device may prove useful as a means of grossly assessing intragastric pH as could be necessary in patients with an elevated fasting gastrin level or those with symptoms despite antisecretory therapy. This capsule has also been used to assess gastric acidification following a meal in patients with diabetic or idiopathic gastroparesis [62].

Data are often expressed as the percentage of time above or below a certain pH. This means of data presentation is simple and easy to understand. Unfortunately, this method of analysis only provides a gross estimation of intragastric acidity. For example, if one were assessing the effectiveness of a new acid-suppressive medication and used an end point of percent time intragastric pH > 4, a patient with a median pH of 4.5 over 6 h would yield identical results to an individual with a mean intragastric pH of 6 over 6 h. It is important to recall that pH is the inverse log of H^+ concentration so this form of analysis can be quite misleading. As such, it is more precise to express data from intragastric pH monitoring as H^+ concentration [49,63] or as integrated gastric acidity [64,65].

Tests of pancreatic exocrine function

Until the 1960s, short of radiological demonstration of pancreatic calcification or exploratory laparotomy, the presence of chronic pancreatic disease was extremely difficult to establish. The use of endoscopic retrograde pancreatography (ERP), CT, MRI, transcutaneous ultrasonography, and EUS has facilitated the diagnosis of chronic pancreatitis. Unfortunately, a definitive diagnosis may not be apparent despite evaluation with structural studies in a subset of patients with chronic pancreatitis. In addition, structural studies by these diagnostic modalities cannot precisely establish the severity of exocrine dysfunction. Although local expertise and availability influence the choice of diagnostic studies, this subset of patients sometimes benefits from functional testing which can uncover previously unidentified abnormalities or complement information yielded by structural studies.

Fat
Emerging tests of exocrine pancreatic function
Endoscopic pancreatic function tests
Secretin-stimulated magnetic resonance cholangiopancreatography

Tests of pancreatic exocrine function can be divided into several categories:

- tests that quantitate pancreatic exocrine secretion through gastroduodenal intubation
- studies that assess exocrine function indirectly by oral administration of various test substances
- tests that rely on the measurement of fat or pancreatic enzyme activity in feces
- emerging tests that combine more than one modality (Table 139.2).

As we begin this discussion of tests of pancreatic exocrine function, a very important point regarding the interpretation of the available literature deserves mention. Comparisons among tests for chronic pancreatitis are limited by the lack of availability of an accepted gold standard for the diagnosis of this condition. Histological data are rarely available because most patients do not require pancreatic surgery and there may be significant risk in performing core biopsies. Even when available, histological abnormalities are patchy, there is no consensus on grading histological severity, and the importance of fibrotic changes remains unclear in asymptomatic elderly and alcoholic patients without pancreatitis. Many studies comparing the accuracy of diagnostic tests are also limited by ascertainment bias (using the test being evaluated to identify patients for the study) or are confined to only patients with moderate to severe disease (populations in whom the diagnosis is typically not in question).

Tests requiring gastroduodenal intubation

These tests rely on the collection of pancreatic juice from the duodenum before and after intravenous administration of secretagogues including secretin or CCK or its analogues (e.g., CCK-8, cerulein). Compared with histology, tests that measure pancreatic secretion from duodenal contents provide an accurate, sensitive (67%–97%), and specific (78%–100%) means of assessing pancreatic exocrine function [66–75] (Table 139.3). These tests may be more sensitive in detecting pancreatic dysfunction than traditional imaging techniques including ERP but may be less sensitive than EUS. Although these tests are clearly superior to other pancreatic function tests, they are labor intensive and expensive. Moreover, they require specially trained personnel to perform properly. As such, these tests are typically only available at large referral centers and clinical research laboratories.

Secretin and cholecystokinin tests

The secretin test was developed in the early part of the 20th century [76,77] to measure exocrine pancreatic secretion in response to the intravenous injection of purified porcine secretin. The volume of aspirate as well as the concentration of bicarbonate and pancreatic amylase [77,78] are measured before and after the administration of secretin. To minimize contamination of the duodenal aspirate by gastric juice, a double-lumen tube should be used for the secretin test. Using fluoroscopic guidance, gastric aspiration ports are positioned in the antrum and body while duodenal aspiration ports lie in the first, second, and third portion of the duodenum (Fig. 139.4). Both gastric juice and duodenal contents are separately collected by continuous suction. Gastric contents are discarded while duodenal contents are retained for subsequent analysis.

Gastric aspiration is important as contamination of duodenal contents with gastric acid produces falsely low bicarbonate concentration and inaccurate volume measurements. Moreover, acid stimulates the release of secretin from the duodenal mucosa, which can also affect test results. The pH of uncontaminated duodenal fluid should be 7.5 or greater. In clinical conditions associated with gastric acid hypersecretion such as Zollinger–Ellison syndrome, the collection of uncontaminated duodenal fluid is often impossible.

Once the tube is properly placed, duodenal fluid is collected every 15 min for 1 h. Secretin in a dose of one clinical unit (approximately 0.3 μg) per kilogram of weight is then administered as a bolus intravenous injection and duodenal fluid is collected for an additional 1–1.5 h. The duodenal aspirate should lose its bile-stained appearance after secretin injection and become clear and colorless, except in patients with gallbladder dysfunction (e.g., chronic cholecystitis) or in those who have previously undergone cholecystectomy [79].

Normal values for duodenal fluid following secretin injection are provided in Table 139.4. Dreiling favored measuring bicarbonate concentration rather than total output evoked by secretin [80], but others have suggested that total bicarbonate output provides superior discriminant potential for diagnosing chronic pancreatitis compared with several measurements of juice constituents, including bicarbonate

Table 139.3 Subjects with laparotomy and histologically proven clinical pancreatitis

Heij, 1986 [75]	25	Chronic pancreatitis, 76% alcoholic	12	Secretin/CCK		Yes		88		N/A
Hayakawa, 1992 [66]	108	Chronic pancreatitis, 55% alcoholic pancreatic cyst	49	CCK			Yes	67	90	

a Chronic pancreatitis was established by tissue diagnosis (55/71), calcinosis (6/71), tissue diagnosis and calcinosis (5/71), cystic fibrosis (7/11), hemochromatosis (1/71), or by clinical history of repeated attacks of abdominal pain with elevated blood amylase, diarrhea, and diabetes (2/71).

b Chronic pancreatitis was diagnosed by a history of "long-standing attacks, with evidence of permanent glandular damage such as diabetes, steatorrhea, or calcification, and those in whom the surgeon noted a sufficient hardening in the gland to justify without doubt such a diagnosis."

c Chronic pancreatitis was established by tissue diagnosis (10/17) or by calcification on roentgenogram (7/17).

CCK, cholecystokinin; ERCP, endoscopic retrograde cholangiopancreatography; PFT, pancreatic function test.

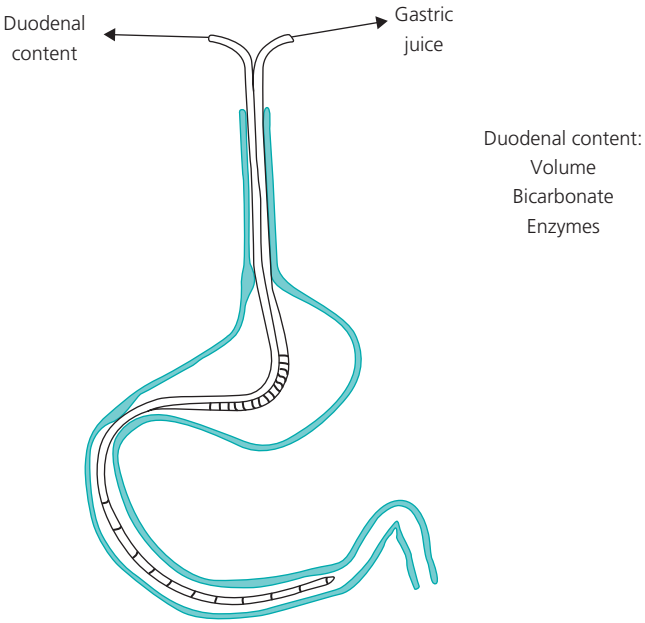

Figure 139.4 Schematic representation of the set-up for pancreatic function tests requiring gastroduodenal intubation. A double-lumen tube is placed into the stomach and duodenum with the assistance of fluoroscopy. Gastric and duodenal contents are then simultaneously aspirated during the basal state and following intravenous administration of pancreatic secretagogues including secretin, cholecystokinin octapeptide, or cerulein alone or in combination. Gastric contents are discarded, while duodenal contents are stored for subsequent analysis as described in the text.

Table 139.4 Normal ranges for results of pancreatic function tests requiring gastroduodenal intubation

Secretin test (mean ± 2SD)[a]
Volume: 107–223 mL/h
Bicarbonate concentration: 92–124 mEq/L
Bicarbonate output: 14–21 mmol/h
Amylase output: 174–1270 U/h
Secretin + CCK (lower limits of normal; mean ± 2SD)[b]
Volume: 151 mL/h
Bicarbonate concentration: 70 mmol/L
Bicarbonate output: 11.3 mmol/h
Amylase output: 131 U during 30 min of CCK
CCK test (range in 16 control subjects)[c]
Trypsin output: 25–54 KU/h
Lipase output: 77–322 KU/h
Lundh test (mean ± 2SD)[d]
Mean tryptic activity: 7–38 IU/L

concentration [75,81–83]. The sensitivity of bicarbonate concentration/output for diagnosing chronic pancreatitis may be affected by hypersecretion of fluid and bicarbonate, associated with hypertrophy and hyperplasia of the hepatic and pancreatic ductal systems, as seen during the early course of alcoholic chronic pancreatitis and in other conditions including cirrhosis, hemochromatosis, Zollinger–Ellison syndrome and alcoholism [80,83].

It is often difficult to judge the significance of an isolated abnormality in duodenal juice volume as the adequacy of aspiration is often unclear. To avoid this technical error, a nonabsorbable marker can be infused into the proximal duodenum during the course of the study. Quantification of the marker in the samples collected allows one to determine the completeness of duodenal aspiration [84]. When low volume is truly the only abnormality found, the clinician should consider the possibility of cancer in the head of the pancreas. When low values in all parameters including volume, bicarbonate concentration, and amylase output are present, patients virtually always exhibit signs of advanced pancreatic disease such as extensive calcification, steatorrhea, or pancreatic endocrine dysfunction [85]. The secretin test is sensitive enough to detect the presence of mild to moderate chronic pancreatitis. In such patients, low maximum bicarbonate concentration may be the only abnormality.

Using the basic technique described above, testing can be modified by adding or substituting the intravenous injection of CCK [69,79] or its analogue [86]. Whenever CCK is used, measurement of trypsin and lipase output is performed. Normal values for the secretin and CCK tests are given in Table 139.4.

CCK-evoked lipase output is superior to lipase concentration or other enzyme concentrations/outputs (trypsin, amylase) for diagnosing chronic pancreatitis [72,87]. Further, data from two studies that compared lipase and bicarbonate output evoked by CCK or secretin testing indicate that lipase output may be superior [72,87]. Using histology as the gold-standard diagnosis of chronic pancreatitis, CCK-evoked lipase and bicarbonate output had similar accuracy [72] but values for secretin-evoked bicarbonate output overlapped greatly among chronic pancreatitis, controls, pancreatic cancer and other cancer [72]. Burton and colleagues [69] provided early evidence that CCK-evoked enzyme output is the most sensitive indicator of impaired secretory function. Similarly, Bozkurt and colleagues [87] used the secretin/cerulein test and showed that lipase output is the earliest and most sensitive indicator of chronic pancreatitis; patients had dissociated reductions of volume, bicarbonate, amylase and lipase outputs but a reduction in any nonlipase parameter was always coupled to a reduction in lipase output. It is worth noting that administration of CCK by continuous intravenous infusion [72,87] greatly reduces variability of lipase output compared with bicarbonate output following a single injection of CCK [83].

Data from a small number of studies have found that results from these pancreatic function tests correlate well with pancreatic histology [66,75]. An additional study reported general concordance between histology and secretory function but also discordance in a subset of patients [74], perhaps related to nonuniform parenchymal damage. Importantly, some patients with mild histological pancreatitis may have severe pancreatic secretory dysfunction [74].

Lundh test

This test determines the pancreatic enzyme concentration of the duodenal contents in response to a test meal. After an overnight fast, a flexible tube is placed into the duodenum via the oral route with the assistance of fluoroscopy. As described by Lundh [88] the test subject ingests a standardized 300-mL meal composed of dried milk, vegetable oil, and dextrose. Duodenal contents are aspirated at set intervals for measurement of pancreatic enzyme concentration. When chymotrypsin is measured, a concentration below 12.6 IU suggests the presence of pancreatic exocrine insufficiency.

Because this test relies on endogenous secretin and CCK-stimulated pancreatic secretion and these hormones are released mainly from the mucosa of the duodenum and proximal jejunum, results of the Lundh test can be interpreted only in patients with intact gastroduodenal continuity and normal duodenojejunal mucosae [89,90]. Although this test is simpler and less expensive than the secretin test, it allows determination of enzyme concentration only. The sensitivity of this test ranges from 66% to 94% [91,92]. The secretin or CCK test appears to be more sensitive than the Lundh test, particularly in patients without steatorrhea [93,94].

Direct intraductal juice collection

The collection of pure pancreatic juice at the time of ERP is conceptually attractive. Unfortunately, the available data suggest that such collection of pancreatic juice has poor sensitivity and specificity for pancreatic exocrine insufficiency [66]. These findings were confirmed by a study that compared results of traditional secretin-based pancreatic function testing with intraductal secretin testing during ERP. This found that results yielded by intraductal secretin stimulation did not compare favorably with the results from traditional pancreatic function testing [95].

Tests that do not require gastroduodenal intubation

Short of the tests that require duodenal intubation, there are only a limited number of tests available for clinical use. These include the pancreolauryl test, bentiromide test, and tests for fecal pancreatic enzymes and fat.

Oral pancreatic function tests

The pancreolauryl and bentiromide tests are oral indirect tests of pancreatic exocrine function. Because of their limited availability in clinical practice, these tests are of more historical than practical interest. The pancreolauryl and bentiromide tests involve the ingestion of a cleavable test substrate (fluorescein dilaurate or *N*-benzoyl-L-tyrosyl-para-aminobenzoic acid [NBT-PABA] respectively) with or without a standardized meal. For the pancreolauryl test, fluorescein dilaurate is specifically hydrolyzed by pancreatic arylesterase to lauric acid and water-soluble free fluorescein, which is readily absorbed by the small intestine, conjugated in the liver, and excreted in the urine. For the bentiromide test, NBT-PABA, a synthetic peptide, is specifically cleaved by chymotrypsin to yield free PABA, which is absorbed in the small intestine, conjugated by the liver, and excreted in the urine. Fluorescein or PABA can be measured in the serum or urine. In general, serum measurement of both substrates has proven more reliable than urine measurement. These tests reportedly have a sensitivity of 37%–100% and a specificity of 39%–100% [96–104]. Perhaps the most important factor influencing the sensitivity and specificity of this test has been the severity of pancreatic disease in the patient population studied. For example, when data from several studies using the secretin/CCK test as a gold standard were pooled, the sensitivity of the NBT-PABA test with a 6-h urine collection was 71% in patients with severe pancreatic exocrine dysfunction but only 46% in those with mild to moderate exocrine insufficiency [96]. Thus, the utility of these tests appears rather limited in those with mild to moderate exocrine dysfunction. The accuracy of the test can be negatively influenced by previous gastrointestinal surgery, small bowel mucosal diseases (e.g., celiac disease, Crohn's disease), severe liver disease, or bacterial overgrowth.

Tests for fecal pancreatic enzyme output

Fecal pancreatic enzyme determination has been used to identify patients with severe chronic pancreatitis. The enzymes measured for this purpose include elastase, chymotrypsin, and lipase.

Elastase

Human pancreatic elastase 1, a member of the acidic elastase family, was detected by Sziegoleit as a new endoprotease and sterol-binding protein present in both human pancreatic secretion and feces [105]. Unlike chymotrypsin, quantitative studies using immunoelectrophoresis have shown that fecal elastase levels remain unaffected during intestinal transit. Unfortunately, fecal elastase-1 has poor sensitivity and specificity for diagnosing mild to moderate pancreatic insufficiency [106,107]. Hardt and colleagues [108] correlated fecal elastase levels with grades of pancreatitis (Cambridge classification) and showed a sensitivity of 45.3%, 57.4%, and 76.5% for grade 1, 2 and 3, respectively. Similarly, both the monoclonal and the polyclonal ELISA antibody fecal elastase-1 tests have also been shown to have unacceptably low sensitivity for diagnosing exocrine pancreatic insufficiency,

64% for severe disease and 40% for mild to moderate disease [109]. Therefore, if the diagnosis of chronic pancreatitis is in doubt, a direct test of pancreatic function is superior.

Low stool elastase values are not specific for reduced pancreatic exocrine function and occur in 25%–30% of patients with small bowel conditions [110–113] including celiac disease, Crohn's disease, cow milk protein enteropathy, bacterial overgrowth, short bowel syndromes, and enteritis [114]. Indeed, fecal elastase has been promoted as a marker of enteropathy regardless of cause [112]. Another cause of a low stool elastase is diabetes mellitus, a complication of chronic pancreatitis; the prevalence of low stool elastase is 46% in type I disease and 30% in type II disease [115–117]. Because low stool elastase may also be related to dilution of stool, individuals with diarrhea-predominant irritable bowel syndrome who have large-volume stools [118] may have a false-positive test. Thus, because of the poor sensitivity and specificity for exocrine pancreatic insufficiency, fecal elastase is a poor indicator of chronic pancreatitis in the clinic and in epidemiological studies.

Chymotrypsin

Fecal chymotrypsin determination has been used for many years to identify patients with chronic pancreatic disease. The test is typically performed on random stool samples, although prolonged collection may improve accuracy. Fecal chymotrypsin testing has a sensitivity of 45%–100% and specificity of 49%–90% [96,119–123]. A variety of factors including Billroth II gastrojejunostomy, severe hepatic disease, and gastrointestinal diseases that cause diarrhea or malabsorption can reduce the accuracy of this test [96]. Pancreatic enzyme supplementation can cause falsely normal results and should be discontinued 5 days before stool collection. As is the case with other forms of noninvasive pancreatic function testing, fecal chymotrypsin measurement is better able to identify those with advanced disease than those with mild to moderate disease [124]. The marginal performance characteristics of this test limit its usefulness as a screening tool for chronic pancreatitis.

Lipase

Fecal lipase has been measured by a sandwich enzyme immunoassay [125]. Abnormally low values were observed in 46% of patients with chronic pancreatitis, exocrine insufficiency and steatorrhea, and in 13% of patients without insufficiency. The overall sensitivity was a disappointing 34%.

Tests for fecal fat determination

Quantitative stool collection with fecal fat determination is the gold standard for detection of steatorrhea. For this study, patients should be instructed to ingest a diet containing 100 g of fat daily starting at least 3 days before the 48–72 h stool collection. Fecal fat excretion of more than 7 g per 24 h is consistent with steatorrhea [18]. If a patient is ingesting a proper diet, qualitative analysis of random stool samples with Sudan staining also sensitively and specifically detects steatorrhea. Steatocrit, a rapid gravimetric method for measuring stool fat, when performed on a 72-h stool collection is as sensitive and specific as a 72-h quantitative stool fat, and may be as accurate if performed on a 24-h stool collection [126] or random stool samples.

Unfortunately, less than 10% of normal lipase output must be present before fat maldigestion from pancreatic disease can be detected [70]. In addition, many other diseases of the gastrointestinal tract (e.g., Crohn's disease, celiac disease, Whipple disease) can cause steatorrhea. Consequently, the detection of steatorrhea by stool testing is neither sensitive nor specific for pancreatic disease. The specificity of fecal fat testing can be improved by performing a two-stage procedure where a repeat collection is done in conjunction with oral pancreatic enzyme replacement. A significant decrease in fecal fat excretion after enzyme replacement supports the presence of pancreatic exocrine dysfunction.

Comparison between pancreatic exocrine function tests and imaging studies in chronic pancreatic disease

ERP is currently felt to be the most sensitive method for detecting morphological change in the pancreatic duct. The major drawbacks of this procedure are its relative costliness and potential for significant adverse events such as pancreatitis. EUS is another invasive means of imaging the pancreas. High-resolution CT and MRI provide noninvasive, widely accessible means of evaluating the pancreatic parenchyma and duct. Unfortunately, none of the currently available structural or functional tests is always diagnostic in patients with suspected chronic pancreatitis. As such, a combination of structural and functional studies is sometimes required to achieve diagnostic certainty in patients with mild to moderate disease.

There are relatively few studies that have directly compared the ability of structural and functional tests to detect chronic pancreatitis [82,127–140]. The best-designed studies are those that evaluate functional or structural studies against a histological gold standard. For practical reasons, few such studies have been conducted [66,75,131]. When direct comparisons have been made, traditional pancreatic function testing has been found to more closely correlate with histological findings than ERP in patients with chronic pancreatitis [75,131].

A number of published protocols have used one or more structural studies or traditional pancreatic function testing as a gold standard, making meaningful direct comparisons difficult if not impossible. In one study that directly compared invasive pancreatic function testing (secretin/pancreozymin test) with ERP, Lankisch and colleagues found that in the majority of patients with chronic pancreatitis, there was good correlation between the two tests [127]. Of 202 pati-

ents, 129 (64%) had parallel secretin/pancreozymin and ERP test results; 21% had abnormal results on both tests but the degree of abnormalities observed were not consistent; 15% had discordant results with one test abnormal and one test normal. In the group with discordant results, all but one patient had an abnormal ERP but normal secretin/pancreozymin result. Others have also observed discordant ERP and traditional pancreatic function test results in 2%–29% [128–130]. There are several possible explanations for this observation. First, prior episodes of severe acute pancreatitis may have resulted in morphological abnormalities of the pancreatic duct without long-term consequence to pancreatic function [132]. Second, morphological changes of the pancreatic duct without corresponding changes in exocrine function are known to occur with aging [133]. Third, there are likely situations where ERP films are felt to demonstrate changes suggestive of mild chronic pancreatitis when in fact they do not. Finally, it may be that ERP is more sensitive than traditional pancreatic function testing or that traditional pancreatic function testing is falsely normal in some patients with discordant results. This possibility seems less likely based on a study by Lambiase and colleagues [130] which reported in abstract format that 8 of 52 (15%) patients had divergent functional and ERP test results. Six of eight patients had an abnormal traditional pancreatic function test but normal ERP. Of the six patients with an abnormal traditional pancreatic function test but normal ERP, five were subsequently found to have chronic pancreatitis. In contrast, neither of the two patients with an abnormal ERP and normal traditional pancreatic function test was later found to have chronic pancreatitis. This study would suggest that traditional pancreatic function testing may be better able to detect early chronic pancreatitis than ERP.

A number of studies [134–139] have evaluated EUS in the diagnosis of chronic pancreatitis and all but two [135,137] showed excellent accuracy of EUS using ERP or intraductal secretin testing as the gold standard for chronic pancreatitis. EUS and direct pancreatic function testing reach a similar finding in 75% of patients [140,141] and EUS and ERP reach the same diagnosis in 80%, although many patients enrolled in the available studies had advanced structural abnormalities [141]. Unfortunately, criteria for EUS parenchymal and ductal changes [134,136] have not been compared with histology. Most studies use three EUS features as a cutoff for diagnosing chronic pancreatitis [136,138,139]. The problem with these studies is that most patients had moderate to severe chronic pancreatitis and that the intraductal secretin test was used as the gold standard for diagnosis of chronic pancreatitis in three studies [134–136]. Indeed, EUS may be preferable to ERP because it is less expensive, exposes patients to less risk, and potentially allows earlier detection of subtle changes. Unfortunately, the specificity of EUS features for diagnosing early chronic pancreatitis is uncertain [139,142–146]. In one study, the correlation of EUS and ERP was good in advanced disease but poor in mild to moderate chronic pancreatitis [134]. Further, when Sahai and colleagues [138] focused on patients with unexplained abdominal pain without obvious chronic pancreatitis, they had difficulty choosing a cutoff to differentiate pancreatic disease in controls and patients with dyspepsia: EUS abnormalities were commonly seen in "normal" controls and dyspeptics. In addition, it has been reported that abnormal pancreatic EUS features can be identified in a variety of other settings [147], including 58% of asymptomatic alcoholics [144], 89% of alcoholic individuals with pancreatic-type pain [144], acute pancreatitis [134], and as a consequence of aging [146,148]. Further, EUS is operator dependent and suffers from variable degrees of interobserver variation [149]. From this information, it seems fair to conclude that EUS is quite sensitive but may lack specificity for mild chronic pancreatitis.

Emerging methods of assessing pancreatic exocrine function

Two new methods provide a potentially accurate, simple, less cumbersome, less expensive and perhaps better-tolerated method of assessing pancreatic exocrine function than the gold-standard direct pancreatic function test: the endoscopic pancreatic function test and secretin-stimulated magnetic resonance cholangiopancreatography.

Endoscopic pancreatic function test

Recently, a number of studies have assessed simpler, abbreviated, direct exocrine pancreatic function studies performed concurrently with upper endoscopy [150–153]. At the time of endoscopy, either secretin or CCK octapeptide is injected intravenously and pancreatic secretions are collected through the endoscope. In contrast to standard direct tests of pancreatic exocrine function, total pancreatic output of individual juice constituents cannot be quantified because perfusion of a nonabsorbable marker (PEG solution) is not performed.

It is questionable whether shorter collections of juice yield adequate sensitivity and specificity for pancreatic exocrine dysfunction. In a recent study in 412 patients who underwent endoscopic pancreatic function testing [154], collection of pancreatic juice was limited to 10 min after intravenous secretin. Bicarbonate concentrations were deemed unreliable. Although lipase concentrations were significantly lower in patients with chronic pancreatitis and pancreatic cancer compared with those with a normal pancreas, there was too much overlap between groups to be useful in clinical practice (positive predictive value 73%, negative predictive value 85%). These data have been confirmed by several other studies [155–157]. In 633 patients, data from the first 15-min collection of a secretin test had a specificity for chronic pancreatitis of 35%, positive predictive value of 44.0%, and accuracy of 57.3% [155,156]. The authors of another study concluded that endoscopic pancreatic function tests "using brief aspiration periods without marker perfusion or measures

of concentration greatly underestimate pancreatic secretory capacity and misclassify the clinical status of an unacceptably large number of patients [157]."

Whether endoscopic pancreatic function tests have better accuracy using a longer period of pancreatic juice collection remains unclear [153,158]. Preliminary data suggest that an 80-min duodenal collection period following secretin or CCK octapeptide infusion yields high sensitivity for the *peak* juice bicarbonate and lipase concentrations respectively, but is associated with overlap in bicarbonate and lipase values between individuals with and without chronic pancreatitis. Further, the long collection times detract from a major advantage of a short-duration endoscopic pancreatic function test.

Secretin-stimulated magnetic resonance cholangiopancreatography

Secretin-stimulated magnetic resonance cholangiopancreatography (SS-MRCP) is a promising noninvasive test of exocrine pancreatic function. Previously, investigators used semiquantitative measurements to assess pancreatic function, grading the duodenal filling of juice (0–3) based on the furthest downstream location [159–161]. More quantitative measures of pancreatic juice secretion involve translating magnetic resonance signal intensity of fluid in the duodenum and pancreas plotted against time into an actual juice flow rate [162–164]. Unfortunately, the clinical utility of this new procedure remains unclear because only a limited number of patients (nearly all with severe chronic pancreatitis) have been studied [162,164].

The latest modification, diffusion-weighted MRI (DW-MRI), is a calculation of the apparent diffusion coefficient (ADC), which integrates capillary perfusion and molecular diffusion [165]. The hypothesis is that movement of water molecules into the lumen increases during pancreatic secretion and manifests as signal loss on DW-MRI images and hence increased ADC values. Differences in pancreatic ADC values in chronic pancreatitis may be related to diminished blood vessel density [166] and impaired augmentation of pancreatic blood flow in response to secretagogues, described in experimental [167,168] and human [169,170] subjects with chronic pancreatitis. Erturk and colleagues [165] showed that following secretin stimulation, normal pancreatic function is characterized by an early ADC peak, whereas those with substantial alcohol consumption had a markedly delayed peak and those with chronic pancreatitis had no ADC peak. Using a cutoff value of 4 min for determining ADC peaks, the test proved 100% sensitive and 94.7% specific for discriminating the control group from the alcoholics with and without chronic pancreatitis. Although patients with mild to moderate chronic pancreatitis were not included, patients with substantial alcohol consumption and conceivably early chronic pancreatitis had a markedly delayed peak ADC.

Enthusiasm for application of DW-MRCP in clinical practice should be tempered by two major limitations. First, measurement of the ADC peak represents only an indirect assessment of pancreatic function. Secondly, because fewer than 10% of alcoholics develop chronic pancreatitis and reduced pancreatic exocrine function [171], the report that all alcoholics, including those without pancreatitis, had a delayed ADC peak raises questions about whether a low ADC peak truly represents abnormal pancreatic exocrine function. To address these limitations, future investigation of DW-MRCP should include comparative analyses of DW-MRCP with invasive secretagogue-stimulated pancreatic function tests, comparisons between groups of patients with alcoholic and nonalcoholic chronic pancreatitis, and comparisons of test accuracy for patients with mild to moderate and severe chronic pancreatitis.

D GASTROINTESTINAL FUNCTION STUDIES

140 Natural orifice translumenal endoscopic surgery (NOTES)

Samuel A. Giday, Anthony N. Kalloo

Potential benefits of NOTES over current surgical techniques, 3432
Risk of infection in NOTES, 3432
Closure of the gastrointestinal wall after NOTES, 3433
NOTES: current status, 3433
NOTES: human experience, 3436
Future applications of NOTES, 3437
NOTES: the road toward clinical applicability, 3439

The field of gastrointestinal endoscopy has witnessed major advances since the 1950s. From flexible endoscopy in the 1950s to endoscopic retrograde cholangiopancreatography in the 1970s and endoscopic ultrasound (EUS) in the 1980s, endoscopy has been transformed from a purely diagnostic method to one with significant therapeutic applications. A major advance is the notion of using the flexible endoscope, taking it beyond the beyond the confines of the gastrointestinal tract into the peritoneal and thoracic cavities. Natural orifice translumenal endoscopic surgery (NOTES) offers the exciting potential to be safer, less invasive, and possibly more cost-effective than either traditional open surgery or laparoscopy. The history and principles along with future implications are outlined in this chapter.

Since the first report by Gauderer and colleagues describing a tube-feeding gastrostomy without a laparotomy in 1980 [1], other endoscopic procedures using a transgastric approach have been described [2,3]. However, these procedures have targeted organs that are only in close anatomical relation to the gastric wall. Of the many transformations currently taking place in the field of endoscopy, NOTES stands out and represents a paradigm shift. The traditional view that gastroenterologists should not cause a breach in the integrity of the gastrointestinal wall is challenged by NOTES.

The first report of NOTES was made by Kalloo and colleagues from the Johns Hopkins Hospital in 2000 [4,5]. After standard upper endoscopy, the authors performed gastric wall puncture using a needle knife, extended the incision by balloon dilatation or a pull-type sphincterotome, and advanced a standard gastroscope into the peritoneal cavity in a live porcine model. Examination of the peritoneal cavity along with biopsy of the liver was successful. On completion of the procedure, closure of the gastric wall incision was performed using standard commercially available clips and long-term survival of the animal was successful without significant morbidity or mortality. This was this first study to demonstrate that the peroral transgastric approach to the peritoneal cavity was technically feasible and offered the potential for a wide array of diagnostic and therapeutic interventions.

Cautious but rapid momentum is being gained in the field of NOTES. Since the first publication, several more studies have been performed. Liver biopsy, tubal ligation, lymphadenectomy, gastrojejunostomy; cholecystectomy, and partial hysterectomy have been performed in animal models with successful survival [5–13]. Published nonsurvival studies include reports of splenectomy and abdominal herniorrhaphy [14]. There are also unpublished cases from India of transgastric appendectomy and tubal ligation [15]. Human NOTES procedures have also been performed under institutional review board (IRB)-approved protocols in different parts of the world.

The clinical practicality of NOTES is properly challenged by questions that surround the basic principle of NOTES, namely that access to the peritoneal cavity can be obtained by causing a breach in the gastrointestinal tract and not in the abdominal wall. Some of the critical questions being raised include the following.

- Why perform a perforation of the intact gastrointestinal tract when one can perform laparoscopy or minilaparotomy?
- What is the benefit of this type of surgery compared with currently available minimally invasive techniques?
- Can the procedure be performed without the introduction of gastrointestinal tract flora and hence under aseptic technique?
- Does it have problematic effects on the patient's physiology?
- Can one attain reliable closure of the gastric defect?
- Who will perform NOTES and how will training occur?
- Can it be applied to clinical practice at this stage?

Potential benefits of NOTES over current surgical techniques

NOTES enables intraperitoneal surgical interventions with the elimination of abdominal wall incisions, resulting in no remnant scars and obviating the possibility of abdominal wall infection and hernia formation. Theoretically, it also allows surgery that results in minimal pain and less potential for adhesion formation compared with currently available surgical approaches.

Several studies that compared laparoscopy to open surgery have demonstrated that laparoscopy results in a reduced neuroendocrine stress response and inflammatory response, as measured by levels of circulating cytokines, and a preserved immune response, as measured by delayed-type hypersensitivity [16–18]. The size of incision, extent of abdominal wall manipulation, and trauma all contribute to the immunosuppression. Laparoscopy also fares better when one evaluates the likelihood that it has an adverse effect on pulmonary function, which is one of the major morbidities that plague open surgery. Several studies have demonstrated that significant deterioration of pulmonary function and atelectasis occurs with open surgery compared with laparoscopy [19]. The conclusion reached from these studies is that smaller incisions and less peritoneal manipulation will result in better postoperative outcomes. Therefore, from a minimally invasive standpoint, there is a conjectural rationale for NOTES, since it would result in no abdominal wall incisions.

Open surgery leads to more damage to the peritoneum and hence more adhesions compared with laparoscopy [20,21]. Subsequent apposition of peritoneal surfaces with inadequate fibrinolytic activity, which is known to exist after surgery, leads to the formation of adhesions [22]. The major consequences of adhesions, such as infertility, chronic abdominal pain, and intestinal obstruction, lead to increased morbidity and also increase the difficulty and risk of repeat surgery. NOTES should result in no or minimal damage to the peritoneum and hence might have a lower likelihood of adhesion formation than open surgery or even, theoretically, laparoscopic surgery. Studies are needed to confirm this supposition.

Laparoscopic techniques were readily accepted by patients because it resulted in minimal scarring, rapid recovery time, and less cost [23,24]. Applying the same inference, the absence of abdominal wall incisions with subsequent reduced pain, less morbidity, faster rehabilitation, shorter hospital stay, and the economic benefit of returning to work earlier may also be more attractive to patients. Currently, advanced endoscopic procedures can be performed using deep sedation, which raises the possibility of NOTES being performed without general anesthesia and endotracheal intubation, unlike laparoscopic and open surgery.

In addition to the above-mentioned factors, the location of many peritoneal organs allows better access via the translumenal route and will thus make NOTES advantageous. Since the first description of transgastric peritoneoscopy, several investigators have confirmed the ease of attaining good intraabdominal visibility and manipulation of organs using currently available endoscopic accessories [8]. NOTES might also be beneficial in environments where performing abdominal wall incisions is less desirable, for example in underdeveloped countries, situations of acute abdominal trauma, and locations remote from health-care facilities. In these situations, NOTES can theoretically provide a safe approach to triage and allow immediate life-saving procedures, providing adequate sterility can be maintained.

Risk of infection in NOTES

The initial animal laboratory experiments resulted in occasional and insignificant intraperitoneal microabscesses [4]. This resulted in the implementation of sterile techniques, including gastric lavage with antiseptic solution, administration of prophylactic antibiotics, and use of sterile instruments. These measures appear to have resulted in better outcomes in subsequent translumenal endoscopic surgical experimental models. The study by Hazey and colleagues evaluated bacterial contamination of the peritoneal cavity after gastrotomy in patients undergoing laparoscopic gastric bypass. Despite the presence of bacteria in the peritoneal cavity after the gastrotomy (from zero colony-forming units [CFU] before gastrotomy to 24 720 CFU post procedure), no clinically evident peritonitis was seen in any of their patients. The authors concluded that the presence of peritoneal contamination after gastrostomy did not result in adverse clinical sequelae [25]. Another study in humans that involved the insertion of an endoscope into the peritoneal cavity along with liver biopsy did not result in any clinical infection in the participants [26]. Ongoing work evaluating the risk of infection and its prevention has demonstrated that the risk of infection depends on the site of access, type of access, and closure methods. When the transgastric access site has been used, the risk of infection has ranged between 0 and 40% [9,10]. These wide rates of infection are a result of a heterogeneous approach to sterilization and use of antibiotics. The transcolonic route has also been plagued with a high rate of infection due to leaks and local peritoneal contamination. In the study by Pai and colleagues, the rate of infection was found to be 20% [27].

The source of infection in NOTES will depend on the route of access and sterility of the accessories used. The transgastric route to the peritoneal cavity has potential for contamination from microorganisms in the buccal cavity, esophagus, gastric lumen, and refluxate from proximal small bowel. The transcolonic and transvaginal routes contain bacterial flora, which if introduced to the sterile peritoneal cavity can result in dire consequences. One study in a porcine model demonstrated that attaining maximal sterile conditions, including steriliza-

tion of equipment and accessories and use of combination systemic and local antibiotics, effectively prevented infection regardless of the closure method used during transgastric surgery [28]. The recommendation based on currently available studies is to attain maximally sterile preoperative conditions regardless of route of peritoneal entry, with secure closure of the access site.

Closure of the gastrointestinal wall after NOTES

In the existing literature, closure of the gastric wall has been performed with clips, endoloops, tags, bioabsorbable plugs, and stapling devices [27,29–32] (Figs 140.1 and 140.2). Kalloo and colleagues did not use any closure device after experiments with transgastric tubal ligation and found no adverse outcome [5]. This is in keeping with what is known about the closure rates of breaches in the gastric wall from various ailments. Studies that have examined closure rates for gastric ulcers randomized to surgery or conservative management in humans have shown that spontaneous closure does indeed take place, with no difference in morbidity or mortality between the two groups [33]. However, other investigators have found that use of closure methods resulted in better outcomes compared with spontaneous closure.

The use of clips as a method of closure of gastric perforations did not start with NOTES (Fig. 140.1). Several studies in humans have shown successful and complete closure of gastric perforations following endoscopic mucosal resection using endoscopic clips [34,35]. Interestingly, an ex-vivo study of leak tests on the different gastric closure methods for NOTES found that the closure afforded by clips was less secure than closure with a prototype full-thickness suturing device or hand-sutured gastric stoma [36].

Figure 140.1 T-bar closure of a gastrotomy.

Figure 140.2 Clip closure of gastrotomy.

Endoloops have also been used successfully as a method of attaining gastric closure (Fig. 140.2). Pai and colleagues first used endoloops as a method of closure following transcolonic peritoneal exploration experiments [27]. Subsequently, a simple variation of gastrotomy site closure using endoloops was reported by Katsarelias and colleagues [29]. These authors used one endoloop on either side of the incision site to create a fold. The two folds were then grasped using a forceps passed through an endoloop. The endoloop was deployed securing the two sides of the incision as one.

Tags and tissue-anchoring devices are gaining popularity for NOTES. This technique uses two sutures individually deployed transmurally and then secured with an anchoring system. This system is being currently refined and can now be deployed through a 2.8-mm accessory channel of an endoscope [30,37]. One downside of this system is that transmural placement of the tag is performed blindly and may lead to adjacent organ damage. The use of EUS for safe deployment of these tags has been described but more research is needed to evaluate the safety margin of this promising technique.

NOTES: current status

Leading figures from the American Society of Gastrointestinal Endoscopy (ASGE) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) convened in New York City in July 2005 to form a working group, the Natural Orifice Surgery Consortium for Assessment and Research (NOSCAR). At this meeting the group discussed issues for the further development of translumenal endoscopic surgery

and listed steps and guidelines needed. A summary of this meeting was jointly published by ASGE and SAGES in February 2006 as a "white paper" [15].

NOSCAR has made recommendations about the direction of future research and steps that need to be taken for the safe introduction of NOTES to clinical practice. Summarized below are significant published studies that address important aspects of NOTES.

Transgastric fallopian tube ligation

Fallopian tube ligation with survival in a porcine model has been performed successfully [6]. In this study of six pigs, tubal ligation was accomplished using an endoscopic detachable loop ligating device (Endoloops, Olympus Optical Ltd, Tokyo, Japan) applied via transgastric endoscopic access to the peritoneal cavity. Endoscopic visualization of pelvic anatomy was excellent. Orientation inside the peritoneal cavity and identification of pelvic structures was technically simple. There were no adverse effects or complications over a 2–3-week survival period. Postprocedure hysterosalpingograms demonstrated complete occlusion of the fallopian tube with histological evidence of obliteration of the lumen with chronic inflammation and no evidence of abscesses. During this experiment, a combination of high-level disinfection, gas sterilization of all equipment, topical and parenteral antibiotics, and a sterile overtube was utilized, resulting in no infectious complications. Furthermore, interventions in the pelvis via a transgastric approach was noted to be technically easier than in other parts of the peritoneal cavity because of the "straight shot" from the gastric wall incision toward the pelvis that eliminates the need for endoscope retroflexion.

Transgastric pelvic organ resection

Wagh and colleagues explored the peritoneal cavity and resected the pelvic organs in nine pigs [10]. They used glutaraldehyde-sterilized single- and double-channel gastroduodenoscopes and accessories and perioperative systemic antibiotics to minimize infection. Similar to our experiments, they applied Endoloops (Olympus Optical Ltd) to the mesentery and then resected the tube along with portions of the uterine horn and ovary. The authors reported no complications after surgery, with all animals tolerating the procedure well. Three animals that underwent survival surgery had no adverse outcome after 24 h.

The same group reported a similar transgastric oophorectomy and tubectomy with an extended survival period of 2 weeks. During this 2-week period there were no adverse clinical events in all animals. Necropsy with histopathological assessment of resected specimens confirmed oophorectomy and tubectomy [9].

Transgastric gastrojejunostomy

Several studies have described endoscopic gastrojejunostomy in a porcine model. The first successful creation of a per-oral endoscopic gastrojejunal anastomosis was published by Kantsevoy and colleagues in 2005 [7]. All procedures were performed with disinfected and gas-sterilized endoscopes and accessories under aseptic conditions. Systemic perioperative antibiotics and gastric lavage with antibiotic solution were used to minimize infection. An endoscopic needle-knife and pull-type sphincterotome were used to create a gastric incision. A small-bowel loop was grasped, pulled into the gastric lumen, and connected to the gastric wall by using a prototype endoscopic suturing device (Eagle Claw, Olympus Optical Ltd). Then, a 15-mm-long incision was made on the small bowel loop by using the needle-knife and the open ends of this incision were connected to the gastric wall with more sutures to complete the gastrojejunostomy. Two animals survived for 2 weeks. Postmortem examination 2 weeks after creation of the gastrojejunostomy revealed the gastrojejunal anastomosis on the border of the anterior abdominal wall and the greater curve of the stomach and normal-appearing small and large bowel and stomach (Fig. 140.3).

A second study by Bergstrom and colleagues published in 2006 confirmed the feasibility of fully endoscopically created transgastric gastrojejunostomy [11]. The authors performed 12 gastrojejunal anastomoses in a porcine model. Access to the peritoneal cavity was achieved in a similar manner to the

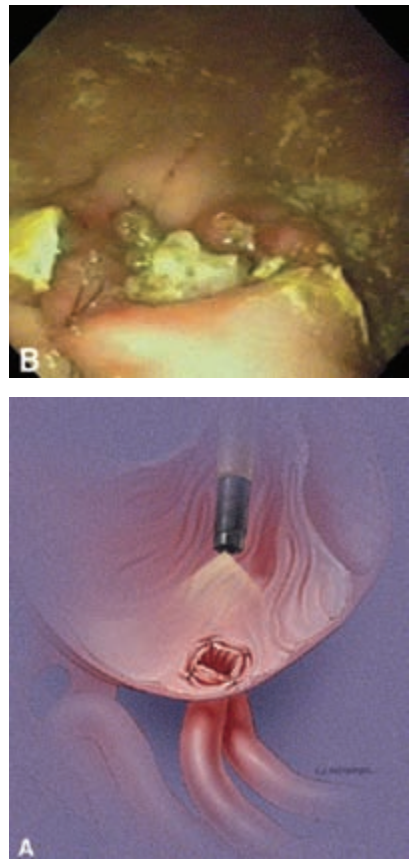

Figure 140.3 Endoscopic gastrojejunostomy.

one described by Kantsevoy and colleagues. The authors then used a snare-over-forceps method to retrieve a loop of small bowel into the gastric lumen for suturing. Incision of the small bowel was made with a needle-knife to open the anastomosis. Suturing was achieved using a new technique in which a metal tag attached to 3.0 polypropylene thread was placed into a 19G Echotip EUS needle, which was then placed into the tissue. The thread and metal tag were released from the needle into the tissue by advancing the stylet. Several (six to eight) placements of pairs of stitches were performed through the small bowel and the gastric wall, after which the pair was tied forming a secure gastrojejunostomy. Interestingly, anastomoses were placed either close to the cardioesophageal junction for bariatric purposes or in the antrum for pancreatic bypass. Survival studies in six pigs demonstrated patent anastomosis at 7–10 days following the procedure.

Biliary surgery

The first transgastric cholecystectomy and biliary anastomosis was published by Park and colleagues in 2005 [8]. They performed acute experiments in a porcine model that demonstrated the feasibility of transgastric cholecystectomy and biliary anastomosis. A single endoscope with percutaneously inserted grasping forceps or two flexible endoscopes were used. Successful cholecystectomies were performed in eight animals within a period of 40–150 min. Cholecystogastric anastomosis was performed successfully in three pigs. The authors accomplished biliary surgery using the transgastric route but emphasized the limitations of flexible endoscopes and instruments, including lack of adequate exposure of the biliary tree in a retroflexed position and reduced triangulation.

Pai and colleagues also reported a survival study that confirmed the feasibility of endoscopic translumenal cholecystectomy [27]. They performed five survival procedures. All pigs were prepared with tapwater enema and colonic antibiotic lavage with a Betadine rinse. The authors used a transcolonic approach to the peritoneal cavity that enabled a "straight shot" toward the gallbladder, making the procedure technically simple. After placement of a double-channel endoscope, an anterior incision was performed in the colon at 15–20 cm from the anus. Successful cholecystectomy was then performed using currently available endoscopic instruments. One animal (20%) developed peritonitis due to incomplete closure of the colonic incision. The authors not only concluded that the transcolonic approach provided a better approach to biliary surgery than the transgastric route but also emphasized the need to attain complete closure of the colonic incision for better outcome.

Transgastric splenectomy and hernia repair

A feasibility study to assess translumenal splenectomy was published by Kantsevoy and colleagues in 2006 [14]. A gastric wall puncture was made using a needle-knife and was extended with a pull-type sphincterotome to create a 1.5-cm incision. After entering the peritoneal cavity, dissection of the spleen from stomach and omentum was performed. Ligation of the splenic artery and vein was done using currently available endoscopic Endoloops and clips. The ligated blood vessels were then cut, freeing the spleen from its attachments. After the spleen was mobilized, the gastric incision was enlarged with the sphincterotome and the spleen was pulled into the stomach. It was found that not only can resection of a large organ be performed using this route but also adequate hemostasis is achievable during translumenal endoscopic procedures.

Using the idea that it may be easier to perform abdominal wall hernia repair using a transgastric approach, Jagannath and colleagues reported, in abstract form, acute experiments in a porcine model that evaluated the feasibility of a transgastric endoscopic approach for repair of abdominal wall hernias [38]. After gaining transgastric access to the peritoneal cavity, an anterior abdominal wall incision was made with a needle-knife to create an animal model of abdominal wall hernia. Using a prototype endoscopic suturing device (Eagle Claw, Olympus Optical Ltd), a 3-cm incision of the abdominal wall (hernia model) was closed without any difficulties. The authors concluded that transgastric endoscopic repair of abdominal wall hernias is feasible and may be technically easier than laparoscopic surgery.

Transesophageal mediastinoscopy

A group from the Mayo Clinic performed mediastinoscopy using a mucosal flap technique. The authors created a submucosal space by injecting high-pressure carbon dioxide that was then accessed using a cap-fitted endoscope. Access to the mediastinum was then gained at a place distant from the site of entry of the endoscope. After the procedure this flap acted as an additional safety barrier and the mucosal entry site was closed using clips [39] (Figs 140.4 and 140.5).

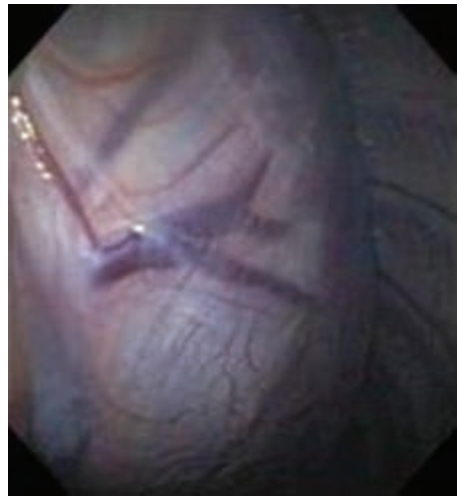

Figure 140.4 Endoscopic view of the heart.

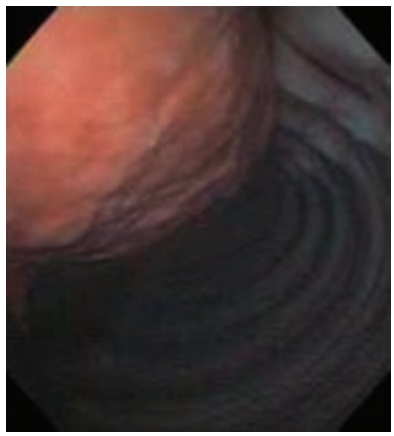

Figure 140.5 Endoscopic view of the hemithorax.

Nongastric translumenal access sites

Because of the limitations of the transgastric route for some procedures, various alternative access sites have been described. Lima and colleagues demonstrated that a different point of access could be used to facilitate entrance to the peritoneal cavity [13]. A ventral cystotomy was made using cystoscopic guidance. Under wire guidance, placement of an overtube followed by a cystoscope into the peritoneal cavity was performed. The authors were able to perform liver biopsy and peritoneoscopy in five survival swine models. Closure of the access site was not performed but the authors left a catheter to assist in decompression of the bladder and hence avoid urinary intraperitoneal leakage. Another study by the same authors demonstrated the feasibility and safety of transvesical thoracoscopy in an animal model. Thoracoscopy with pleural and lung biopsies was performed using a 9.8Fr ureteroscope [40]. The potential advantage of this method is mainly that the bladder is a sterile space and transvesical access may lead to less intraperitoneal infectious complications. Some of the drawbacks of this technique include limited robust accessories that can perform major surgical procedures.

The transcolonic access site is mainly used to obviate the limitation posed by the transgastric route during procedures on organs close to the gastric access site and in the upper abdominal quadrants. Even though results are encouraging, measures to avoid peritoneal contamination and achieve secure closure remain problematic. One study by Wilhelm and colleagues evaluated the use of a rigid sterile overtube to provide a contaminant-free conduit for the endoscope and secure closure [41]. The authors instilled an antibacterial solution into the peritoneal cavity to provide a preliminary hydroperitoneum using a percutaneously placed Veress needle. Postinstallation endoscopic ultrasonography was performed to assist in the identification of a site where there was no adjacent small bowel loops. This site was secured with a pursestring and used to "prolapse" the rectum. Breach of the wall was then achieved under direct visualization to attain a transcolonic route. After peritoneoscopy, closure was achieved using the preplaced pursestring in addition to a surgical stapler. This approach, though promising, needs to be corroborated by further studies.

NOTES: human experience

The first description of a human NOTES procedure, namely transgastric removal of an inflamed appendix, was reported by Rao and Reddy during Digestive Diseases Week in 2004. They performed transgastric peritoneoscopy on a patient using standard endoscope and accessories with no reported complications after the procedure. Following this procedure, NOSCAR has stressed the need for all human studies to be performed with local IRB approval and under a human trial registry. Taking this into consideration several human procedures, some of which are summarized below, are taking place under the auspices of an IRB.

Though not a clinical trial, Marks and colleasgues reported the rescue of a dislodged percutaneous endoscopic gastrostomy (PEG) tube by insertion of an endoscope into the peritoneal cavity and subsequently evacuating intraperitoneal fluid and repositioning the dislodged tube [42]. Subsequently, the first human trial was reported by Hazey and colleagues [43]. They performed peroral transgastric peritoneoscopy in 10 patients who were scheduled to undergo diagnostic laparoscopy. Furthermore, they compared diagnostic findings, operative time, and clinical course between the two modalities. All the patients underwent successful laparoscopy followed by transgastric peritoneoscopy, with a mean duration of 12.3 and 24.8 min, respectively. Closure of the gastric access site was performed by standard surgical and not endoscopic techniques. The authors concluded that human transgastric peritoneoscopy is safe and feasible, with the caveat that more instrumentation and technological innovations are needed before full clinical application.

Transvaginal cholecystectomy has been reported from several independent groups. Bessler and colleagues performed hybrid transvaginal and laparoscopic cholecystectomy on a 66-year-old patient with symptomatic gallstones [44]. Once the endoscope was placed in the peritoneal cavity with the aid of laparoscopy, a shape lock device was used to stabilize and fix the shaft of the endoscope while permitting controlled movement of the tip, allowing stability and precise dissection. In addition, standard laparoscopic clips were deployed through a trocar to ligate the cystic duct.

Marescaux and colleagues from IRCAD-EITS (Institute of Digestive Cancer Research/European Institute of TeleSurgery) performed a hybrid laparoscopic–endoscopic transvaginal cholecystectomy on a 30-year-old patient with symptomatic cholelithiasis [45]. Using a standard double-channel flexible

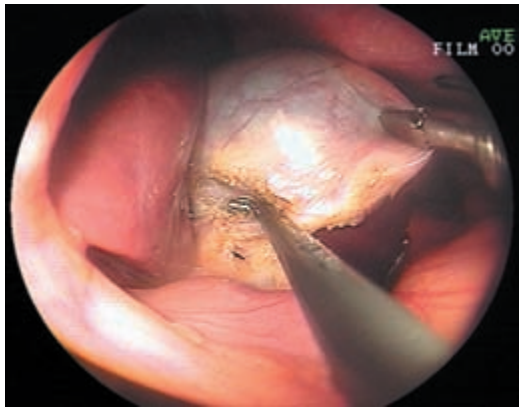

Figure 140.6 "Straight shot" to gallbladder during human transvaginal peritoneoscopy. Courtesy of Professor Ricardo Zorrón.

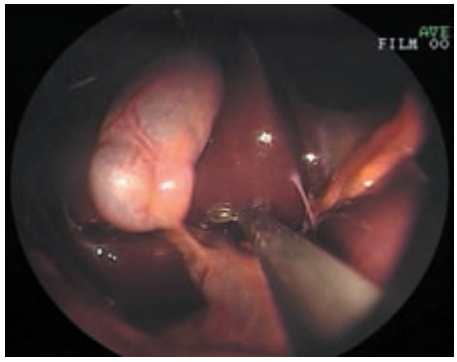

Figure 140.7 Successful human transvaginal cholecystectomy.

endoscope and standard endoscopic instruments along with a 2-mm laparoscopic needle port they performed a successful cholecystectomy using only the endoscope to perform gallbladder dissection. The laparoscopic port was used to give retraction and maintenance and monitoring of pneumoperitoneum. Other investigators have also performed a similar or modified version of transvaginal cholecystectomy with success, again proving the feasibility and safety of a hybrid transvaginal approach for gallbladder surgery [46,47] (Figs 140.6 and 140.7).

Experience with human NOTES has also expanded into other nongastroenterological fields such as urological surgery. A report by Branco and colleagues reported combined transvaginal and laparoscopic nephrectomy of a nonfunctioning kidney in a 23-year-old patient suffering from recurrent urinary tract infection and flank pain. The patient had an uneventful postoperative course and was discharged 12 h after the procedure [48].

All these important steps demonstrate that safe translumenal surgery can take place only if combined with laparoscopic techniques until further research and development provide robust and novel endoscopes and accessories.

Future applications of NOTES

Peritoneal interventions in the intensive care unit

Patients in the intensive-care setting have multiorgan dysfunction that precludes transportation and major surgical intervention. NOTES may avoid transportation to an operating room, allowing for bedside intervention. One example that has been described in the laboratory is diaphragmatic pacing for patients who are difficult to wean from ventilators [49]. NOTES may become a more practical approach for diagnosing ischemic bowel in the intensive-care patient who has contraindications for more definitive imaging such as computed tomography or magnetic resonance imaging [50].

Prehospital management of trauma

Prehospital management of critical patients has resulted in improved outcomes. This is mainly due to the proper resuscitation of patients and appropriate triage [51]. Despite these developments many patients with blunt or other urban-related injuries may not survive because of improper triage and stabilization. NOTES could become an integral and critical step in this setting since all instruments that are required are portable and can fit into current emergency care vehicles. Imagine a scenario where a patient involved in a motor vehicle accident with splenic trauma is given proper triage and hemostasis stabilization using NOTES before reaching the hospital, where traditional and more definitive surgical approaches can be performed. Of course, this could only be attained if there are appropriate tools to enable easy access and closure of the access site with minimal risk of infection and without adding time needed to transport the patient to the hospital.

Acute management of blunt trauma

The use of NOTES as a method for immediate assessment of organ injury and repair is theoretically possible. Its minimally invasive nature, due to the elimination of an abdominal incision and need for general anesthesia, makes NOTES an attractive approach in the prehospital trauma/disaster setting.

In a preliminary study performed at our laboratory we were able to demonstrate the feasibility of NOTES in the assessment of penetrating abdominal injury. We performed a controlled injury to intraabdominal organs (liver, spleen, kidney and small bowel loops) under laparoscopic guidance using laparoscopic shears. Transgastric peritoneal access was then attained using a PEG-like approach by an operator blinded to the sites of organ injury. The findings using NOTES were compared with those using laparoscopy. The peritoneal cavity in all animals was systematically examined, including the anterior abdominal wall, diaphragmatic dome, liver, spleen and both kidneys. The mean duration from time of entry to the peritoneum to identification of lesion was

11 min. Mean duration to identification of site of injury was 12 min for the liver, 15 min for the spleen, 17 min for the small bowel, and 6 min for the kidneys. The time required to identify anterior liver surface injury was significantly shorter than the time required for the identification of small bowel injury. Based on these results, we concluded that NOTES provides rapid and accurate identification of organ injury for penetrating wounds to the abdominal viscera [52].

Our group has also assessed the feasibility of achieving hemostasis after organ injury using nonthermal hemostatic mechanisms. In this study three nonthermal methods of achieving hemostasis were compared. The first group was randomized to QuikClot (QC; Z-Medica, Wallingford, CT), a granular zeolite powder with 1% residual moisture that, when placed on a bleeding wound, adsorbs water in an exothermic reaction, thereby concentrating platelets, erythrocytes, and clotting factors at the site of application. It has been tried on the battlefield with excellent success in achieving hemostasis. Several studies, including a swine liver injury model, have also shown its effectiveness as a hemostatic agent in life-threatening bleeding. The second group was randomized to oxidized regenerated cellulose (ORC), which is also used adjunctively in surgical procedures to assist in the control of capillary, venous, and small arterial hemorrhage when ligation or other conventional methods of control are impractical or ineffective. The third groups of animals was randomized to SHISH, a novel bioabsorbable hemostatic agent (Cook bioengineering prototype material).

The anterior liver surface was then lacerated using a laparoscopic shear to create a grade three (> 3 cm) liver laceration. Modified endoscopic delivery systems were used to deliver the hemostatic agents. The ORC was placed effectively, covering the site of injury in all animals. Delivery of QC granules to the site of bleeding was also straightforward. Accurate placement of the granules to the site of injury was achieved in all animals. In the third group of animals, SHISH was also able to be applied with resulting hemostasis in all animals. There was no statistically significant difference in the time to achievement of hemostasis between the QC and ORC group ($P = 0.33$). The conclusion from these studies is that intraperitoneal hemorrhage can be easily and quickly controlled with these novel endoscopic therapies [53].

NOTES: evolving beyond the traditional operating room

In today's world, where building future operating rooms is a multibillion dollar industry, NOTES maybe a cost-effective solution. Given that the development of accessories and other integral components of NOTES needs to take place, by keeping the focus of sterility to the gastrointestinal tract, instruments and accessories, the need for the sterile operating room environment could be eliminated. The potential cost reduction is staggering, since the cost of using an operating room is obviated as is the use of transportation staff, operating room energy, and operating costs. The fact that NOTES has the potential to be performed under deep sedation rather than general anesthesia will have a great impact in avoiding postoperative ventilator complications including ventilator dependency.

Robots for NOTES

The concept of deploying a mobile robot via NOTES into the peritoneal cavity may appear very futuristic. This limitation may be solved by using robotics and this technique has been shown to be feasible by Rentschler and colleagues [54]. A 12-mm-diameter in vivo robot was advanced into the gastric cavity using a sterile overtube and was able to traverse within the cavity under endoscopic guidance. Using its helical wheel the robot was able to navigate the gastric lumen with no apparent tissue injury. In the peritoneal cavity, the robot successfully navigated and maneuvered several organs, including the liver and small bowel. Development of an in vivo robot with camera and multipurpose arms capable of performing several tasks in addition to endoscopic imaging will enable performance of moderately complex surgery such as cholecystectomy. Furthermore, a robot with visual capabilities will help to overcome the problem of spatial orientation.

Intrauterine fetal interventions

Although transabdominal laparoscopic fetoscopy has proven to be a useful technique in human fetal surgery for such diseases as twin–twin transfusion syndrome and spinal meningomyelocele, it only allows anterior access to the uterine cavity and is limited by the use of rigid instrumentation. In addition, the performance of intraperitoneal procedures by the traditional percutaneous route can be followed by wound dehiscence and induce preterm labor. Theoretically, NOTES can provide unparalleled access to the uterine cavity because of its flexibility and because the transgastric route allows a "straight shot" toward the uterus. Moreover, the absence of abdominal wall incision and general anesthesia also provide an added benefit for NOTES. Based on these assumptions, our group have evaluated the feasibility of NOTES for uterine interventions in pregnant sheep. During this acute nonsurvival experiment NOTES allowed visualization of the anterior, posterior, and lateral walls of the uterus. In addition, all intraperitoneal organs could be identified and were easily accessible. Using EUS, the fetus, various body parts, and the placenta could be easily identified. Amniocentesis and intracardiac fetal interventions were technically feasible with the EUS scope in the peritoneal cavity [55].

Spinal procedures

Surgical spinal procedures most commonly include transthoracic and posterolateral percutaneous approaches. Open surgical techniques require separation of musculoskeletal structures and traction of nerve roots to create an opening large enough to accommodate surgical tools. The morbidities

associated with these surgical approaches include postsurgical neuralgia resulting from traction injuries to nerve roots, lacerations of the dura mater, scars from skin incisions, and muscular atrophy or trauma. Minimally invasive surgical techniques, including thoracoscopy and video-assisted thoracic spine surgery, have reduced the extent of percutaneous incisions and opening of the chest wall. Nevertheless, the consequences of percutaneous access are not totally avoided and complications such as lung atelectasis and retropleural effusions from single lung ventilation are additional morbidities [57].

NOTES provides direct anterior access to the vertebral column by transgastric and transesophageal approaches. In laboratory experiments with NOTES, we found that the proximity of the esophagus to the spine allowed immediate access to the posterior mediastinum and excellent visualization of the entire thoracic vertebrae and intervertebral spaces. This innovative approach to the anterior vertebral column allows the development of novel spinal interventions under direct endoscopic guidance, such as vertebroplasty and kyphoplasty for osteoporotic or pathological vertebral bone fractures, discectomies and interbody fusion for herniated discs, and release of the anterior ligament at different levels of the vertebral column in patients with severe scoliosis. In addition, the lumbosacral spine could also be approached for anterior endoscopic procedures via transgastric access. The advantages of NOTES for spinal interventions are similar to those for anterior laparoscopic spinal surgery but without the limitations of rigid instrumentation. These benefits include maintenance and ease of restoration of intervertebral disc height, avoidance of bone removal from the spine (an integral component of posterior spinal surgery), and preservation of normal spinal anatomy since this approach takes advantage of normal tissue planes with no removal of bone tissue. In addition the complications of posterior spinal surgery, such as injury and damage to nerves from manipulation and retraction of nerves and hematoma around nerves that may cause scarring and chronic pain, may be reduced [58].

NOTES: the road toward clinical applicability

For NOTES to evolve to clinical practice, it will require modification of current endoscopes and development of accessories to overcome the limitations of current endoscopes. The most noticeable limitations include stability of the instrument on retroflexion, small size of the instrument channel, and spatial incongruity [15]. Hybrid techniques combining laparoscopy with NOTES are currently the best solution. The hybrid approach can provide safe intraperitoneal access along with the essential triangulation and retraction. Once experience is gained, coupled with the development of new accessories, pure NOTES can then be tested against currently available techniques. Also important are issues of training, since acquiring advanced endoscopic skills are of paramount importance. Training physicians to perform NOTES will need to incorporate both surgical and advanced endoscopic training. This will result in development of hybrid surgical and endoscopic training programs that will blur the lines of delineation between specialties, challenging traditional training programs. It is equally important that gynecologists and urologists become familiar with NOTES in these early stages of development since successful NOTES may have implications to their routine practice.

In summary, NOTES offers the benefit of incisionless surgery, potentially leading to rapid recovery, less postoperative pain, no abdominal wall scar or hernia formation, and fewer adhesions. It will have definite advantages in situations where the transabdominal route is not optimal, such as in patients with marked obesity where the risk of postoperative wound complications is high and in patients with anterior abdominal wall infection or severe scarring. NOTES provides an exciting opportunity to improve peritoneal intervention using the skills, imagination, and ingenuities of gastrointestinal endoscopists and endoscopic surgeons.

cholecystokinin (CCK) 4, 6, 68, 70–1, 368
abdominal cramping 3230
acinar cell calcium ion levels 382, 383
actions 71
amylase secretion 379
bicarbonate ion secretion stimulation 375
cholescintigraphy 3230–1, 3233
chronic pancreatitis levels 1835
colonic motility 248
colonic response to eating 1134
delayed gastric emptying in chronic pancreatitis 912
duodenal phase 9–10
electrolyte absorption/secretion 355–6
endoscopic pancreatic function test 3425–6
enterochromaffin cell release 269, 273
enteroendocrine cell mediation 92
enterogastric reflex 248
extrapancreatic site action 375
fed motor pattern 242
feedback regulation 71
fluid secretion stimulation 375
food intake regulation 97, 2562, *2563*
gallbladder contraction 268, 1942–3
postprandial 268–9
gallbladder smooth muscle calcium handling 266–7
gastric emptying 221–2, 223
gastrocolonic response 245
growth/gene regulation 385–6, *387*
inhibition by somatostatin 387
intestinal adaptation 1299, 1300
measurement 71
mucosal receptor indirect activation 44–5
pancreatic exocrine function tests 3420, **3421**, 3422–3
pancreatic secretion regulation 10, 371, 374–5, 392, 1834
feedback 389–90
postprandial 376
pepsinogen secretion stimulation 312
peristaltic reflex 239
postprandial hyperemia 550
posttranslational modification 63
protein synthesis regulation 371
pylorus control 215
radioimmunoassays 59
release modulation 10, 389–90
response and gallstone formation 2565
satiety signals 47
secretion
jejunum removal 1297
stimulation 70
small intestinal motility 248
smooth muscle regulation 125
sphincter of Oddi 272–3
relaxation 1772, 1947, 2044
total parenteral nutrition 275
transient lower esophageal sphincter relaxation 203
vagal afferent neurons 95, *96*
vasovagal reflex 47
stimulation 95, *96*
water absorption/secretion 355–6
cholecystokinin (CCK) receptor 368
acinar cell 380
calcium ion release 382
gastric emptying 219–20
pancreatic secretion regulation 391
synergistic interaction with 5-HT receptors 376
type A 70, 71
ligand binding 70
vagal afferent neurons 90
vagus nerve 89–90
type B 69
ligand binding 70
vagal 375
cholecystokinin releasing factor (CCK-RF) 389–90
cholecystostomy, percutaneous 1969, 3283–4
choledochal cysts 1984, 2009–17
anomalous arrangement of the distal pancreaticobiliary tree 2010–11
anomalous pancreatic–biliary duct junction 2034
cholangiocarcinoma risk 2016, 2017, 2023
classification 2009–10, 2945
