Most infants with esophageal atresia and TEF undergo surgical repair with division of the fistula and primary esophageal anastamosis. In cases of atresia with wide separation of the proximal and distal esophageal remnants, esophageal lengthening procedures or interposition using small or large intestine is necessary. Gastrointestinal complications result from both the underlying congenital defect as well as surgical repair. Dysphagia is common and can result from anastamotic stricture formation as well as esophageal dysmotility and rarely from concomitant congenital esophageal stenosis. Abnormalities of the myenteric plexus have been described and may account for the dysmotility [50]. Gastroesophageal reflux and delayed gastric emptying have also been reported in a high proportion of patients.

Congenital esophageal stenosis

Congenital esophageal stenosis is rare, estimated to occur in 1 in 25 000 live births, and is thought to result from failure of the normal embryonic separation of trachea and esophagus that is frequently associated with esophageal atresia and TEF [51]. Stenoses caused by tracheobronchial remnants, and fibromuscular wall hypertrophy and membranous web formation have been described (Fig. 30.8) [52–55]. Unlike atresia and TEF, congenital stenosis is often not diagnosed until later in childhood, and several cases have been reported in adults [56,57,216]. Symptoms include regurgitation, prolonged eating time, and dysphagia with recurrent solid bolus impaction. An esophagram usually demonstrates a focal stenosis in the middle third of the esophagus. Endoscopic ultrasono-

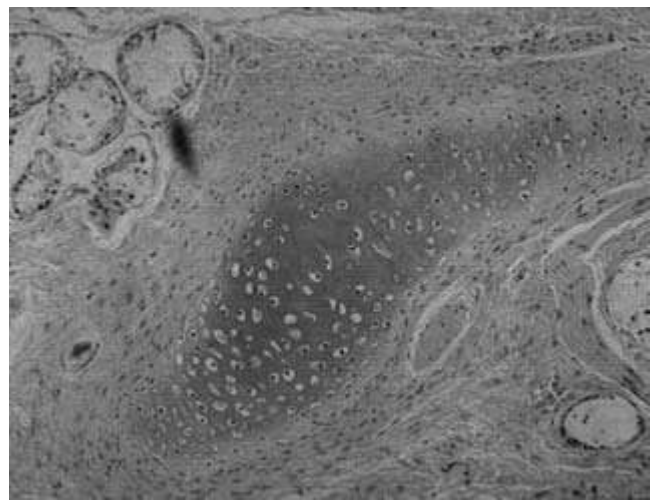

Figure 30.8 Histological section from the esophageal wall of a resected segment of congenital esophageal stenosis with cartilaginous tracheobronchial remnant. From Maeda et al. [58], with permission from Elsevier.

graphy can visualize the presence of tracheobronchial remnants. Surgical myotomy or segmental resection has been advocated for most symptomatic patients [58]. Esophageal dilation has been used in children and adults but perforation does occur [51,59]. Eosinophilic esophagitis can present with proximal esophageal focal strictures as well as concentric mucosal rings in both children and adults and is an important consideration in the evaluation of a patient with possible congenital esophageal stenosis. While the ringed appearance of eosinophilic esophagitis is sometimes referred to as *trachealization* of the esophagus, these are mucosal and not cartilaginous rings. Several reported cases of congenital esophageal stenosis were likely unrecognized cases of eosinophilic esophagitis.

Congenital esophageal duplication

Congenital esophageal duplications, tubular or cystic, represent about 15% of digestive duplications [60]. They develop in the third week of embryonic development as the result of failure of vacuoles to coalesce properly, interfering with normal recanalization of the esophageal lumen. As a result, a cyst or parallel tubular channel forms within the esophageal wall [61]. Duplications of the gastrointestinal tract have three common characteristics: they are contiguous with some segment of the gastrointestinal tract; they are lined by alimentary epithelium; and smooth muscle is present in their walls. Most patients present before 1 year of age, but as many as 25%–30% of cases are first diagnosed in adults [62]. The most common presenting symptom is dysphagia, but the diagnosis is often made as an incidental finding in patients studied for other indications [63].

Congenital duplication cysts constitute less than 3% of mediastinal masses. They are the second most common benign esophageal submucosal lesion, with gastrointestinal stromal tumors being the most common [64,65]. They are lined by squamous columnar, cuboid, pseudostratified, or ciliated epithelium [66,67]; 60% arise in the distal third of the esophagus, 17% in the middle third, and 23% in the upper third [60,68]. Cysts located posterior to the heart have been associated with cardiac arrhythmias [69]. Intraspinal cystic extensions can cause neurological deficits that may be the initial sign of these disorders [70]. In one report, intraspinal anomalies coexisted with mediastinal masses in almost 25% of patients [71]. Gastric cysts, inclusion cysts without a smooth muscle wall, bronchogenic cysts, and neuroenteric cysts are also rarely found in the esophageal wall [60].

Duplication cysts can be seen on chest radiographs as posterior or middle mediastinal masses. On barium esophagram, a smooth curved displacement of the esophagus is seen without the sharp step-like proximal and distal margin seen with a leiomyoma. Computed tomography (CT) can be helpful in determining the location, size, and anatomical relation to other organs [72,73]. At endoscopy, a soft compressible submucosal indentation into the esophageal lumen is apparent [74]. Endoscopic ultrasonography can define the structure of a duplication cyst [75]. Preoperative esophageal biopsies have been discouraged by surgeons because of potential for adhesions between the esophageal mucosa and cyst wall that may make surgical resection more difficult.

Tubular duplications are rare and may be associated with other congenital cardiac, spinal, pulmonary, and extremity abnormalities [63]. Tubular duplications may communicate at both ends with the esophageal lumen or be closed at one end, but more than 80% do not communicate with the lumen [76–78,217]. Spontaneous submucosal dissection of the esophagus has been reported and can radiographically present with a double-barrel esophagus that mimics a tubular duplication [79]. Surgical resection is usually recommended for definitive treatment and pathological diagnosis [80–82]. Both laparoscopic and thoracoscopic resection have been reported [83,84]. Marsupialization has been used for the treatment of large cysts, and needle aspiration has been used to relieve tracheal compression from a duplication cyst [85,86]. Although rare, both adenocarcinoma and squamous cell carcinoma within tubular or cystic duplications have been reported [87–89].

Bronchopulmonary foregut malformation

The term *bronchopulmonary foregut malformation* was proposed by Gerle in 1968 to include pulmonary developmental abnormalities both with and without communication to the gastrointestinal tract. Since then, confusion in the terminology has occurred because of the inclusion and exclusion of a number of gastrointestinal, pulmonary and vascular anomalies as well as attempts to histologically, pathogenetically and anatomically classify the varying presentations described largely in case reports and small series. Bronchopulmonary foregut malformations include a focus of pulmonary parenchyma or sequestration with a patent congenital communication to the upper gastrointestinal tract [90–92,218,219]. They are considered distinct from TEF, which result from initial foregut septation. Bronchopulmonary foregut malformations develop when cell rests with respiratory potential arise from the foregut caudal to the lung bud or when a portion of the lung bud arises from the dorsal esophagus rather than the ventral trachea [91]. The tract within the sequestered pulmonary lobe typically involutes because of outgrowth of its blood supply; incomplete involution of the tract leads to a gastrointestinal tract communication [92]. Bronchopulmonary foregut malformations are most commonly seen in the lower lobes [218]. Up to 40% of children with communicating bronchopulmonary foregut malformations have associated congenital anomalies. The clinical presentation in infants is respiratory distress that is exacerbated with feedings. In older children and adults, recurrent pneumonia, bronchiectasis, hemoptysis, gastrointestinal bleeding, and dysphagia may develop. Contrast esophagram, CT, and angiography are used for diagnosis and surgical planning.

Aortic arch vessel abnormalities

It has been estimated that 3% of the population have a congenital abnormality of the aortic arch vessels, but only rarely does this result in symptomatic compression of the esophagus [93]. In the embryo, the foregut is surrounded by vascular structures of the branchial arches. Normally, portions of the branchial arches obliterate to form the great vessels and aortic arch. Abnormalities in developmental obliteration of the branchial arches may lead to vascular compression of the trachea and esophagus [94].

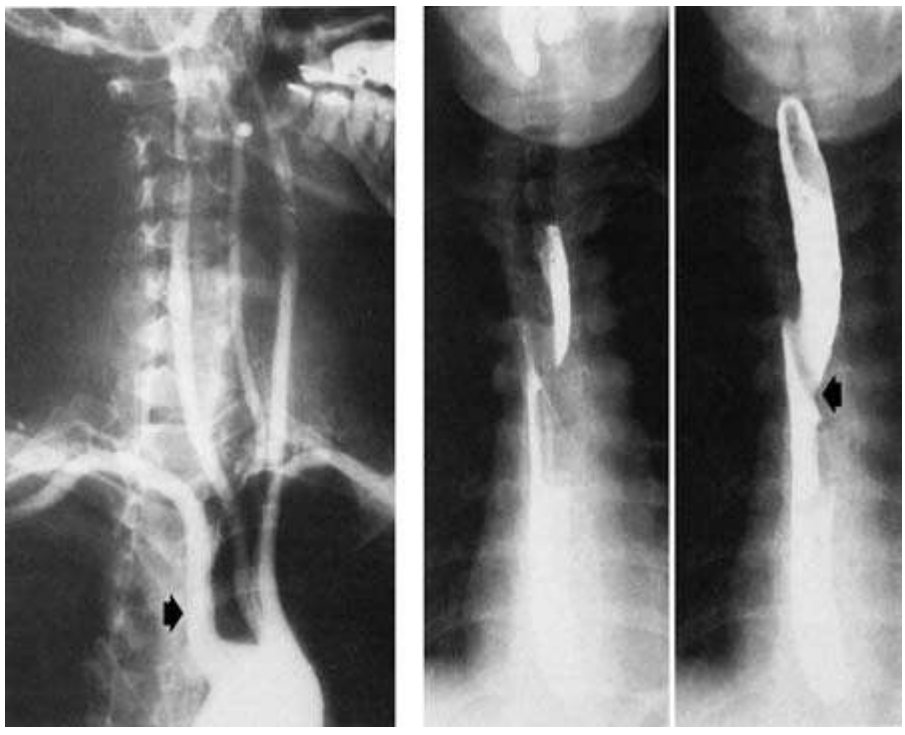
The term *dysphagia lusoria*, literally translated from the Latin *lusus naturae* (meaning trick or freak of nature), is used to describe symptomatic esophageal compression resulting from any vascular anomaly of the aortic arch. Most commonly, it results from an aberrant right subclavian artery [95]. The root of the aberrant artery often has a broad base referred to as Kommerell diverticulum. Symptoms of this anomaly may occur at the onset of semisolid feedings, later in childhood, or in adult life. With this anomaly, the right subclavian artery arises from the left side of the aortic arch and compresses the esophagus from the posterior aspect in an oblique manner (Fig. 30.9a). Based on autopsy studies, an aberrant right subclavian artery occurs in 0.7% of the general population, with only 10% of these affected individuals having symptoms related to compression [96]. During esophageal endosonography performed in 3334 patients, an aberrant right subclavian artery was identified in 12 (0.36%). None of the patients had symptoms from this entity [97]. While esophageal motility abnormalities have been observed, the patterns have been variable and nonspecific [98]. This vascular anomaly most typically causes symptoms later in life [99]. The reason for this is unclear but may be attributed to age-related changes to the vasculature.

Barium esophagram demonstrates an oblique filling defect just above the level of the aortic arch (Fig. 30.9b). Computed tomography and magnetic resonance imaging have largely replaced the need for angiography in the diagnosis. Endoscopy may demonstrate a posterolateral pulsatile compression of the lumen of the proximal esophagus. Correction is performed in children by division and ligation of the aberrant artery. In adults, reanastomosis to the ascending aorta is performed to avoid the development of a subclavian steal syndrome [100]. Surgery is not always needed because many adult patients can easily tolerate minor degrees of dysphagia by simply modifying their diet.

Esophageal compression by an anomalous vertebral artery and right aortic arch with constricting left ligamentum arteriosum has been reported in adults and can be successfully repaired surgically [101,102]. Other vascular anomalies are causes of tracheoesophageal compression in infants, and these require early surgical intervention [103,104].

Heterotopic gastric mucosa (inlet patch)

Heterotopic gastric mucosa, also know as an inlet patch, is a focus of gastric epithelium most commonly located in the cervical esophagus. An autopsy series of 1000 children



(a) (b)

Figure 30.9 **(a)** Angiography reveals an aberrant right subclavian artery (arrow) arising from the aortic arch. **(b)** Barium esophagram in the same patient reveals oblique esophageal compression (arrow) by the aberrant right subclavian artery posterior to the esophagus.

demonstrated the prevalence at 4.5% [105]. Endoscopic studies reported a prevalence of 0.1%–10% [106–109]. Most commonly, the inlet patch is situated immediately distal to the UES, making endoscopic detection difficult. Substantially higher prevalence frequencies are reported if microscopic foci of gastric tissue are included in the definition. Inlet patches have been reported to occur in 5.6% of patients with Barrett esophagus but in none with achalasia [110].

At endoscopy, these areas of gastric mucosa typically are well-circumscribed patches of reddish orange or salmon-colored mucosa that range in size from 2 mm to 4 cm [111]. The lesions can be unifocal, multifocal, or circumferential. Inlet patches can be dramatically demonstrated by injecting topical dilute iodine solution to stain the squamous mucosa around their margin. Histologically, the majority contain fundic-type gastric mucosa that includes parietal cells [106]. The inlet patch is generally considered to be a congenital abnormality that results from incomplete replacement of the early embryonic columnar epithelium with squamous epithelium. On the other hand, some investigators have reported that inlet patches share features with Barrett esophagus, suggesting that the former is an acquired condition associated with acid reflux [112–114]. *Helicobacter pylori* has been detected in mucosal biopsies of inlet patches [115,116].

Complications of heterotopic gastric mucosa include those secondary to acid production and neoplastic transformation. Acid secretion has been demonstrated in several reports [106,117–119]. While the majority of inlet patches are asymptomatic, symptoms of odynophagia, dysphagia and globus have been reported [120]. Cervical esophageal strictures or webs and even esophagotracheal fistula have been demonstrated [121–123]. Plummer–Vinson (or Paterson–Kelly) syndrome is characterized by dysphagia due to a cervical esophageal web with concomitant iron deficiency anemia. The anemia and strictures may be secondary to esophageal erosions produced by acid secretion. In terms of cancer risk, 30 cases of progression of heterotopic gastric mucosa to adenocarcinoma have been reported [124,125]. Given the high prevalence of inlet patches and low prevalence of cervical esophageal adenocarcinoma, both the absolute and relative risk of malignant transformation is quite low. In light of this, biopsies of endoscopically detected inlet patches are generally not performed.

Symptomatic inlet patches should respond to proton pump inhibition through the same mechanism by which gastric acid suppression is achieved. Complications of strictures and webs are amenable to standard esophageal dilation techniques, with the caveat that detection of such strictures can be more difficult given the location adjacent to the UES. Transendoscopic thermal ablation combined with high-dose omeprazole therapy and argon plasma ablation have been shown to allow replacement of the inlet patch by normal squamous mucosa, with resolution of related symptoms [126,127]. As most patients are asymptomatic and symptomatic patients should respond to acid inhibition or dilation, the role for ablation techniques is yet undefined.

Structural anomalies

Esophageal rings and webs

Lower esophageal mucosal ring (Schatzki ring)

The lower esophageal mucosal ring, or B-ring, was initially described by Templeton in 1944 [220]. In 1953, Ingelfinger and Kramer and Schatzki and Gary independently described the association of lower esophageal mucosal rings with dysphagia [128,129]. Schatzki and Gary attributed the symptoms to a fixed mucosal stricture at the squamocolumnar junction. Ingelfinger and Kramer, on the other hand, postulated that a contractile muscular ring at the gastroesophageal junction produced the symptoms. Ring-like narrowings at the esophagogastric junction are now differentiated into two types: the lower esophageal muscular ring, or A-ring, and lower esophageal mucosal ring, or B-ring.

Lower esophageal mucosal rings are located at the level of the squamocolumnar junction. These rings consist of mucosa and submucosa and are covered by squamous mucosa on the proximal aspect and either columnar mucosa or several millimeters of squamous mucosa on the distal or gastric aspect [130,131]. The lower esophageal mucosal ring is circumferential and 3 mm or less in thickness (Fig. 30.10). Based on an autopsy study of 100 subjects mucosal rings have a prevalence of 9%, and are detected in 4%–15% of radiographic studies [132]. The rings are likely acquired and may be a manifestation of reflux disease, although morphologically they are distinct from peptic strictures. The majority of patients with Schatzki rings have abnormal distal esophageal acid exposure on pH monitoring, although this does not prove causation [133]. A congenital origin and association with esophageal shortening have also been proposed [132].

Most patients with lower esophageal mucosal rings are asymptomatic; however, they are one of the most common causes of intermittent dysphagia and food impactions, typically presenting in patients older than 40 years of age [134,135]. The severity of symptoms depends on the inner diameter of the ring. Rings larger than 20 mm in diameter are usually asymptomatic, rings 13–20 mm in diameter cause variable degrees of dysphagia depending on type and size of bolus, and rings less than 13 mm in diameter frequently cause solid food dysphagia [136,137]. Serial esophagrams have demonstrated the development and progressive narrowing of lower esophageal mucosal rings, providing evidence that these are acquired and not congenital lesions [138–140]. Misunderstanding in the literature and in practice has resulted from confusing Schatzki rings with short annular peptic strictures and, more recently, eosinophilic esophagitis.

On esophagram, a lower esophageal mucosal ring appears as a thin (< 3.0 mm) transverse circumferential ridge above

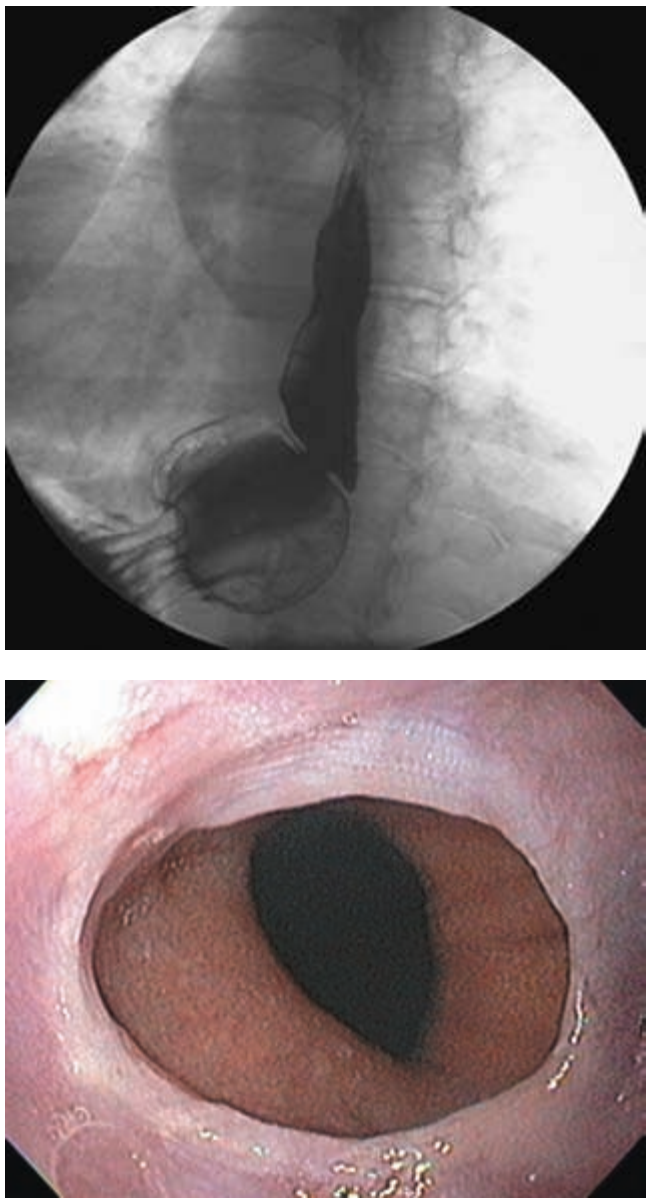


Figure 30.10 **(a)** Barium esophagram demonstrates a lower esophageal mucosal ring, also known as Schatzki or B-ring, at the proximal end of a hiatal hernia pouch. Constriction of the distal end of the hernia is secondary to the diaphragmatic hiatus. The ring is appreciated with both a distended (*left*) and undistended (*right*) hiatal hernia. **(b)** Endoscopic view of a Schatzki ring with hiatal hernia immediately below. The ring margin is smooth, less than 3 mm thick, and without inflammation or evidence of fibrosis.

the hiatus of the diaphragm. To visualize the ring either endoscopically or radiographically, the esophagogastric junction must be adequately distended (Fig. 30.10). By definition, a hiatal hernia is invariably present, although this may be related to a limited ability to visualize the ring when it is collapsed by constriction of the diaphragmatic hiatus. Lower esophageal mucosal rings are absent in patients with long segment Barrett esophagus. Barium esophagram with a prone full-column technique is more sensitive than double-contrast radiography or endoscopy in detecting lower esophageal mucosal rings [141]. Performing a Valsalva maneuver during the esophagram is helpful in demonstrating a ring [142]. The use of a barium tablet or marshmallow bolus may further improve the sensitivity of the barium esophagram to correlate dysphagia with the ring. The standard barium tablet has a diameter of 12.8 mm and will therefore ignore rings in the 13–20 mm category that may be clinically significant.

The endoscopic characteristics of lower esophageal rings and the associated findings are readily recognized (Fig. 30.10b) [143]. Symptomatic lower esophageal rings can be effectively treated with single passage of a 17–20 mm (51F–60F) Maloney or Savary dilator [144]. For very tight rings, some clinicians use the standard gradual sequential dilation technique rather than passage of a single large-diameter bougie. Hydrostatic balloon dilation is also effective. Disruption of the ring using four-quadrant mucosal biopsies and needle knife incision has been described [145,146]. While most patients achieve immediate relief of dysphagia following dilation, a follow-up study noted that 32% of patients had recurrent dysphagia at 1 year and 65% at 2 years [147]. Proton pump inhibitor therapy may reduce the occurrence of recurrent dysphagia, again pointing to a possible link with reflux disease. In a trial of patients with symptomatic Schatzki ring initially treated with dilation, recurrent dysphagia that required repeat dilation occurred in 7% of patients randomized to omeprazole compared with 47% of patients on placebo [148]. It should be kept in mind that Schatzki rings are common and may be an incidental finding when detected in a patient with dysphagia. For patients demonstrating a poor or short-duration response to esophageal dilation of a presumed symptomatic lower esophageal mucosal ring, other etiologies should be sought including motility disorders and eosinophilic esophagitis.

Lower esophageal muscular ring

In an autopsy series, lower esophageal muscular rings were found in 5% of an asymptomatic cohort of 100 patients [132]. The location proximal to the squamocolumnar junction makes it likely that the rings represent an exaggeration of the proximal aspect of the LES. Symptomatic muscular rings are unusual and typically present with dysphagia. Unlike the dysphagia that occurs with Schatzki rings, muscular rings present with intermittent dysphagia for both liquids and solids in the absence of food impaction. On barium esophagram, muscular rings are smooth symmetric narrowings that are several millimeters in axial extent with a lumenal aperture that varies during the course of fluoroscopic examination (Fig. 30.11). Endoscopically, the appearance is that of a constriction with intact overlying squamous mucosa situated 2–3 cm above the squamocolumnar junction. Unlike achalasia, the constriction is very focal and does not encompass the distal aspect of the esophagogastric junction. Lower esophageal muscular rings have been associated

Figure 30.11 Lower esophageal muscular ring (A-ring). Two views from the same patient show marked, 3-cm long constrictions in the distal esophagus proximal to a hiatal hernia (*left*). (*Right*) Partial relaxation of the A-ring with distention of the phrenic ampulla proximal to a concomitant Schatzki ring. The distended hiatal hernia is visible distal to the Schatzki ring.

with esophageal manometric abnormalities that include high-amplitude long-duration esophageal body contractions and esophageal spasm [149]. Esophageal dilation is often attempted but provides incomplete and short-lasting relief. Several case reports have noted significant improvement in dysphagia following injection of botulinum toxin [149–151]. Surgical myotomy has been described but is necessary in only rare instances [128,152–154].

Cervical esophageal and midesophageal webs

Esophageal webs are thin (1–2 mm) transverse membranes of squamous epithelium. They most commonly occur in the cervical esophagus and usually originate on the anterior wall. They are rarely circumferential but may be multiple. Because of their proximity to the UES, cervical webs are easily missed on upper endoscopy. Radiographic studies detected esophageal webs in 6%–12% of patients, with the higher prevalence reported in patients with symptoms of dysphagia [155,156]. Like Schatzki rings, most webs are asymptomatic. Intermittent solid food dysphagia is the usual complaint in symptomatic patients.

Cervical esophageal webs have been reported to occur in association with heterotopic gastric mucosa and in some instances may represent a form of peptic stricture related to local acid secretion [157]. Cervical webs should be distinguished from proximal, mucosal, web-like strictures secondary to a number of other conditions producing esophageal injury, including epidermolysis bullosa, cicatricial pemphigoid, pill esophagitis, chemotherapy-induced mucositis, graft-versus-host disease, radiation and eosinophilic esophagitis.

The association of postcricoid webs with iron deficiency anemia (i.e., Plummer–Vinson or Paterson–Kelly syndrome) is both infrequent and controversial [158,159]. The existence of the syndrome is debated, although some indirect evidence points to the possibility that iron deficiency could predispose to web formation. On the other hand, as discussed in a previous section of this chapter, acid secretion from heterotopic gastric mucosa could be a cause of blood loss from esophageal erosions as well as cervical webs.

Midesophageal webs are rare and typically present with dysphagia. They may be single or multiple and are believed to be of congenital origin [159–163]. In addition to midesophageal mucosal lesions resulting from the conditions causing esophageal injury noted above, they may also be confused with congenital esophageal stenosis. If symptomatic, they are best treated with bougienage. Treatment with transendoscopic incision or surgical resection has been reported but is rarely necessary [160–162,164,165].

Cricopharyngeal bar

Cricopharyngeal (CP) bar is a common radiographic finding, reported in anywhere from 5% to 19% of patients undergoing dynamic pharyngeal radiography [166,167]. It appears as a prominent and persistent posterior indentation at the level of the lower third of the cricoid cartilage (Fig. 30.12). The majority of patients with CP bar do not experience significant dysphagia. In one report, dysphagia was not statistically more prevalent in CP bar patients than in controls (13% vs. 8%) [168]. Symptomatic CP bars most commonly present in the elderly with dysphagia for solids and occasionally liquids as well. Studies have also shown histological changes similar to those found in patients with Zenker diverticulum that include muscle degeneration and fibrosis [169]. It is important to exclude other more common etiologies for

Figure 30.12 Barium swallow depicting a prominent cricopharyngeal bar in the cervical esophagus in a patient presenting with dysphagia.

dysphagia since a CP bar may be an incidental finding. Furthermore, CP bars may be secondary to neuromuscular causes, including central and peripheral nervous system abnormalities (multiple sclerosis, amyotrophic lateral sclerosis, syringomyelia, cerebral vascular disease), inflammatory myopathies, and myoneural junction disorders (myasthenia gravis, diphtheria, tetanus).

Early studies attributed the pathophysiology of CP bars to failed UES relaxation, UES spasm, and basal hypertension. It has subsequently been recognized that the radiographic appearance of a CP bar is neither associated with high basal UES pressure nor with incomplete sphincter relaxation. Moreover, one study found that neither peak pharyngeal pressure nor incoordination were predictors of outcome following cricopharyngeal disruption in a heterogeneous group of patients with oropharyngeal dysphagia [170]. Using simultaneous pharyngeal videoradiography and manometry, these investigators demonstrated that increased hypopharyngeal intrabolus pressure was a significant predictor of positive outcome following CP disruption. Similar to studies in patients with Zenker diverticulum, these authors suggested that increased intrabolus pressure implies impaired sphincter opening and may be an indirect measure of sphincter compliance, all of which predict response to CP disruption. An earlier study by Dantas and colleagues demonstrated significant impairment of cricopharyngeal opening in patients with a CP bar when compared with control subjects without a CP bar, which further supports the concept of sphincter dysfunction in the pathogenesis of CP bars [167].

Treatment options for symptomatic CP bar include esophageal dilation and surgical myotomy. Several small case series have described significant relief of dysphagia with a 1–2 year follow-up after dilation to 17–20 mm [170–173]. Esophageal dilation is an attractive alternative to surgery, especially in older patients with comorbidities.

Pharyngoesophageal and esophageal diverticula

Zenker diverticulum

Pharyngoesophageal diverticulum was first described by Ludlow in 1769 and critically reviewed a century later by the pathologists Zenker and Ziemssen [221]. Pharyngoesophageal or Zenker diverticulum represents an outpouching of the posterior hypopharyngeal mucosa proximal to the esophageal inlet. The site of origin of the diverticulum between the oblique fibers of the inferior pharyngeal constrictor and the transverse fibers of the cricopharyngeus was described by Killian in 1907 and is referred to as Killian dehiscence or the triangle of Killian.

A number of hypotheses have been proposed to explain the pathogenesis of Zenker diverticulum. The observation that both symptomatic and asymptomatic Zenker diverticula occur in the elderly population supports an acquired defect that is a consequence of aging. Early studies suggested that the UES failed to relax in this condition leading to the term *cricopharyngeal achalasia*. Subsequent combined manometric/fluoroscopic studies demonstrated complete UES relaxation but diminished opening [174,175]. As a result, hypopharyngeal pressures are increased and thought to lead to progressive protrusion through an area of relative mural weakness in the triangle of Killian. The limitation in UES opening is most likely a myogenic rather than neurogenic phenomenon. Histological studies of muscle biopsies taken during surgical treatment have demonstrated connective tissue replacement of skeletal muscle fibers and muscle fiber degeneration [175–177]. The cause of the muscle changes is unclear. Evidence linking gastroesophageal reflux disease with Zenker diverticulum is limited. Initial reports of UES hypertension and contraction in response to distal esophageal acid exposure have not been confirmed in subsequent studies [178,179]. Others have theorized that esophageal shortening induces mural weakness, allowing for mucosal herniation in patients with Zenker diverticulum [180].

The prevalence of Zenker diverticulum ranges from 0.01% to 0.11%, with the majority of patients being asymptomatic [181]. The median age is approximately 70 years with a male predominance, and presentation in a patient younger than 30 is unusual. The predominant symptoms are dysphagia and regurgitation. Throat pain, cough, aspiration, halitosis, and neck gurgling or mass are also reported. The diagnosis is apparent on esophagram but the fluoroscopic field needs to visualize the hypopharynx, which is not routinely included by all radiologists (Fig. 30.13). For reasons that are unclear, the majority of diverticula deviate to the left. Complications

Figure 30.13 Anterior view of barium-filled Zenker diverticulum deviating to the left of the esophageal axis.

include aspiration pneumonia, pill retention, ulceration, fistula, and bleeding. Squamous cell cancer was reported in 0.4% of 1249 patients with Zenker diverticulum over a 53-year period [182]. Spindle cell carcinoma and benign tumors have also been reported to arise in pharyngoesophageal diverticula [183,184]. Endoscopy is not essential to the management of symptomatic Zenker diverticulum and carries a risk of perforation. With direct visualization and awareness of the posterior location of the diverticular orifice, endoscopy is not contraindicated and may demonstrate concomitant esophageal pathology or secondary complications. Blind esophageal intubation with nasogastric tubes, manometric catheters, and transesophageal echocardiographic devices can lead to inadvertent perforation. A fluoroscopically placed guidewire and use of smaller, pediatric or transnasal endoscopes can facilitate esophageal intubation in cases with significant stenosis of the UES.

Patients with minimal or no symptoms can be followed clinically for potential progression. Symptomatic pharyngoesophageal diverticulum is managed by endoscopic or surgical approaches [185]. Early surgical reports of diverticulectomy alone were associated with a very high recurrence rate leading to the current recommendation for UES myotomy in most cases. For the open surgical approach, myotomy alone may suffice for small diverticula while a myotomy with either diverticulectomy or diverticulopexy is performed for larger diverticula. Notwithstanding the elderly population that is afflicted with this condition, operative mortality is less than 2% [186]. Reported morbidity is highly variable but approximates 5%–10% and includes esophageal leak, bleeding, mediastinal emphysema, fistula, nerve palsy, and mediastinitis.

The endoscopic approach to Zenker diverticulum dates back to 1917 but has become increasingly popular with advances in the use of electrical or laser cautery or endoscopic stapling devices. The technique involves dividing the common septum between the diverticulum and esophagus that is largely composed of the UES. As of 2006, well over 700 patients have been treated by this approach in the literature with outcomes, morbidity, and recurrence rates that are similar to the open surgical approach [187]. The procedure is often performed with monitored anesthesia care, although some surgeons still use general anesthesia. Advantages include shorter recovery and hospital stays. The technique is primarily being performed by thoracic surgeons and otorhinolaryngologists rather than gastroenterologists. An open surgical approach is generally favored for younger patients who are good surgical candidates and for large diverticula.

Killian–Jamieson diverticula

Killian–Jamieson diverticula are outpouchings arising from the proximal cervical esophagus immediately below the UES [188]. They are less common and less likely to present with dysphagia than Zenker diverticulum [189]. While more commonly unilateral with a left-sided predilection, bilateral diverticula occur in 25% and may coexist with Zenker diverticulum [189]. It is important to recognize these anatomical lesions since they can be confused with Zenker diverticulum. It is interesting to speculate on their pathogenesis given their location below the UES. An underlying esophageal motility disorder of the striated muscle of the cervical esophagus has neither been described nor looked for in these patients.

Midesophageal and epiphrenic diverticula

Diverticula may also occur in the middle or distal esophagus (Fig. 30.14). Prevalence estimates of less than 1% are based on retrospective reviews of radiographic studies but are affected by the indications for the radiographic examination. A century ago, midesophageal diverticula were described secondary to pulmonary tuberculosis. They were termed traction diverticula and felt to result from tethering on the outer aspect of the esophagus created by inflammation of adjacent mediastinal lymph nodes. Midesophageal diverticula have also been reported in cases of anthracosis, sarcoidosis, histoplasmosis, and lymphoma, all with a presumed similar pathogenesis [190]. Over the past 50 years, it has become recognized that the majority of both midesophageal and epiphrenic diverticula are seen in conjunction with esophageal dysmotility [191–195]. They are typically referred to as pulsion-type diverticula, caused by increased intralumenal pressure induced by high-amplitude or simultaneous esophageal body contractions or failed LES relaxation. The predominant associated manometric disorders are

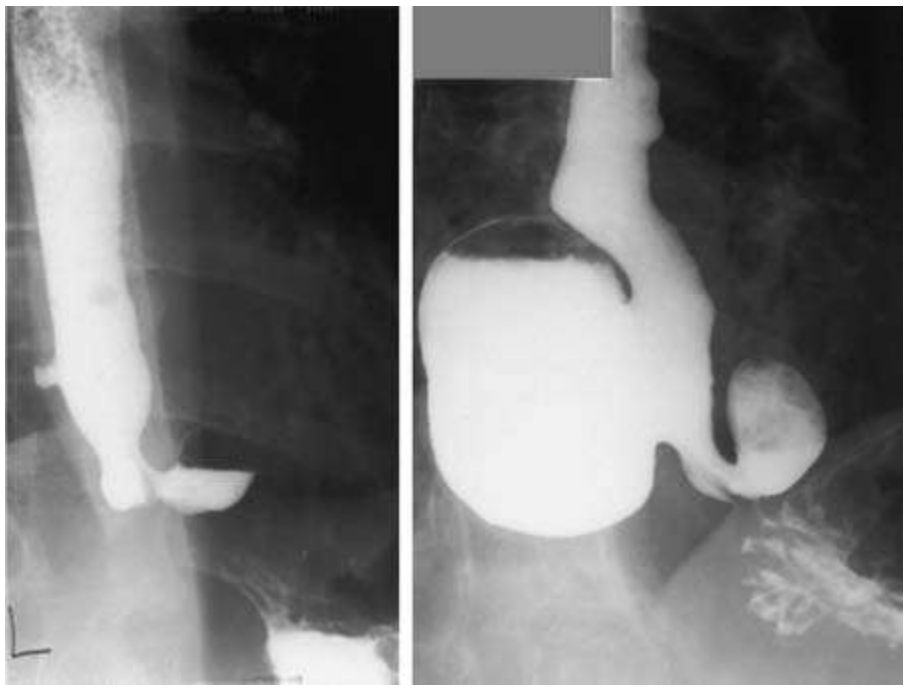

Figure 30.14 Barium radiograph depicting significant enlargement of epiphrenic diverticula in a patient on initial presentation (*left*) and 10 years later (*right*).

achalasia and diffuse esophageal spasm. However, diverticula are uncommon sequelae of either disorder. Cases of hypertensive LES, nutcracker esophagus, and nonspecific motility disorders have also been reported, although the causative nature of these diagnoses in the pathogenesis of diverticula is uncertain. They are manometrically defined conditions that even in the absence of diverticula have shown poor correlation with symptoms or esophageal functional abnormalities. A recent study utilizing high-frequency intralumenal ultrasonography reported temporal incoordination between circular and longitudinal muscle contractions in patients with nutcracker esophagus [196]. The investigators postulated that the asynchrony resulted in increased esophageal wall stress that could be a mechanism for diverticulum formation. Esophageal diverticula may also be secondary to esophageal wall anatomical weakening as in cases following Heller myotomy for achalasia or scleroderma [197].

Symptom presentation for esophageal diverticula closely mirrors that of the underlying esophageal motility disorders, making it difficult to discern whether a particular symptom is a direct result of the diverticulum. Dysphagia and regurgitation are the dominant presenting complaints with additional symptoms including chest pain, heartburn, weight loss, and respiratory symptoms [190]. In general, symptoms tend to correlate more closely with the motility disorder rather than the size of the diverticulum [190,194]. An exception to this are giant diverticula, which increase the retention of food and likely increase the risk of regurgitation and aspiration. Epiphrenic diverticula more commonly protrude from the right. Uncommon complications of esophageal diverticula include ulceration, hemorrhage, perforation, and fistulization. Rare cases of carcinoma arising from esophageal diverticula have been reported [198,199]. Many patients with esophageal diverticula are asymptomatic at the time of presentation with the finding incidentally noted on a radiographic or endoscopic procedure for another indication [190]. Natural history studies of untreated esophageal diverticula are few. In one radiologic series, enlargement of the diverticulum was noted in 16% over a 12-year period [200]. Clinical case series have noted the development or progression of symptoms in less than 10% with a follow-up of several years [190].

Surgery remains the primary means of therapy for symptomatic esophageal diverticula. Esophageal dilation over a guidewire under fluoroscopy provides partial and temporary symptom relief in some patients with diverticula. Botulinum toxin A injection of the LES has been effective in providing relief of dysphagia in a small series of patients with diverticula, although the moderate efficacy and durability of this approach limits its utility [201–203]. Recognizing the importance of underlying esophageal dysmotility, most surgical approaches combine a diverticulectomy with esophageal myotomy [190]. Several retrospective reports have noted a higher rate of postoperative esophageal leak and recurrent diverticula for diverticulectomy compared with diverticulectomy with myotomy. Even when combined with myotomy, esophageal leak is a major source of surgical morbidity and significantly more common than reported with myotomy alone in the treatment of achalasia without diverticula. A thorough presurgical evaluation, including barium esophagram, esophagoscopy and esophageal manometry, should be performed. The proximal extension of the myotomy into the esophageal body is considered in cases of esophageal spasm

and vigorous achalasia and can be guided by the proximal extent of the diverticula or hypercontractile manometric abnormalities. Divertulectomy, accompanied by LES myotomy plus some degree of fundoplication, has been successfully accomplished via the laparoscopic transhiatal approach [190].

Esophageal intramural pseudodiverticulosis

Esophageal intramural pseudodiverticulosis is a rare condition, detected in less than 1% of radiologic studies of the esophagus [204]. First described by Mendl and colleagues in 1960, multiple small diverticula form in the wall of the esophagus by dilation of the excretory ducts of the submucosal esophageal glands [205–207]. The diagnosis is best appreciated on barium studies where intramural tracking of contrast can also be appreciated in 50% of studies [208]. Thickening of the esophageal wall due to chronic submucosal inflammation and fibrosis can be appreciated on CT as well as endoscopic ultrasonography [209,210]. Most cases present after the sixth decade with chronic dysphagia. Esophageal strictures, typically proximal, are seen in 70%–90% of patients, and esophageal manometric abnormalities have been found in two-thirds of those studied [206,211,212]. Unlike the association between achalasia and esophageal spasm with esophageal diverticula, the reported abnormalities are most commonly nonspecific and may not be involved in the pathogenesis of intramural pseudodiverticulosis. Only one case of pseudodiverticulosis in achalasia has been reported [213]. The relation of corrosive injury of the esophagus to intramural pseudodiverticulosis has been reported [214]. A report of 14 cases of this entity in 59 patients with corrosive esophageal injury noted that an esophageal stricture was a constant association. No correlation was found between the length of the stricture and the number of diverticula, and the diverticula regressed in number or disappeared altogether after the stricture was dilated.

As opposed to the surgical management of other esophageal diverticula, esophageal intramural pseudodiverticulosis is managed medically. Dilation of strictures, antireflux therapy, antifungal therapy, and calcium channel blockers have been reported to relieve symptoms [209,214]. Esophageal candidiasis has been described in up to 50% of reported cases; however, its role in the development of esophageal intramural pseudodiverticulosis is unknown and is likely secondary to stasis. Rare complications include perforation, mediastinitis, fistula formation, and bleeding. An association between intramural pseudodiverticulosis and esophageal cancer has been reported but the cause and effect of this observation is unclear [215].

A ESOPHAGUS

31 Motility disorders of the esophagus

Peter J. Kahrilas, John E. Pandolfino

Oropharyngeal swallowing disorders, 740
Esophageal motility disorders, 747
Esophageal involvement in systemic disease, 766

Esophageal motility disorders can be categorized based on anatomical localization and muscle type involved. The oropharynx and proximal esophagus are composed of striated muscle and are under central nervous system control. In contrast, the distal esophagus is predominantly composed of smooth muscle controlled by the enteric nervous system and vagus nerve. Recognizing these morphological and functional differences, this chapter on motility disorders of the esophagus first considers oropharyngeal dysphagia, which includes most physiological aberrations of the upper esophageal sphincter and proximal esophagus, and then focuses on purely esophageal motor disorders, including considerations mainly relevant to the distal esophagus.

Oropharyngeal swallowing disorders

Oropharyngeal dysphagia is associated with high morbidity, mortality and cost. Estimates of the prevalence of dysphagia among individuals older than 50 years of age range from 16% to 22% [1,2]. Within health-care institutions it is estimated that up to 13% of hospitalized patients [3] and 60% of nursing home residents [4] have feeding problems, of which most are attributed to oropharyngeal dysfunction as opposed to esophageal dysfunction. The consequences of oropharyngeal dysphagia are severe: dehydration, malnutrition, aspiration, choking, pneumonia, and death. In fact, the mortality rate of nursing home residents with dysphagia and aspiration can be as high as 45% over 1 year [5]. As our population continues to age, oropharyngeal dysphagia will become an increasing problem associated with complex medical and ethical issues.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Evaluation and classification of oropharyngeal dysphagia

The evaluation of patients with presumed oropharyngeal dysphagia should focus on five fundamental questions:

1 Does the patient describe dysphagia as opposed to globus sensation or xerostomia?

2 Is dysphagia oropharyngeal or esophageal in origin?

3 Is the dysphagia secondary to a structural or functional disorder?

4 Is there an underlying related or causative disorder?

5 Should therapy be directed toward the underlying etiology or the dysphagia itself?

These questions can usually be answered with a careful history and physical exam. However, further diagnostic tests may be needed to determine both the cause of oropharyngeal dysphagia and the proper treatment.

The patient history is crucial in the evaluation of oropharyngeal dysphagia. Major objectives of the history are to differentiate oropharyngeal dysphagia from esophageal dysphagia, xerostomia, or globus sensation. Whereas patients almost invariably accurately recognize the locus and consequence of oropharyngeal dysphagia, they mistakenly identify the neck as the locus of bolus hang-up with esophageal dysphagia about 30% of the time. Therefore, elicitation of symptoms such as aspiration, coughing, nasopharyngeal regurgitation, or drooling is of great value in distinguishing oropharyngeal dysphagia from proximally referred esophageal dysphagia.

Distinguishing oropharyngeal dysphagia from globus sensation can be particularly vexing. Unlike dysphagia, which occurs only during swallowing, globus sensation is prominent between swallows. Patients relate the nearly constant sensation of having a lump in their throat or feeling a foreign object caught in their throat. In some instances globus is associated with reflux symptoms and in others with substantial anxiety; that anxiety is sometimes thought to be etiological (globus hystericus). Unfortunately, studies have failed to define an objective anatomical or physiological cause for globus and we are left with the crucial data being in

the history: globus sensation persists regardless of the act of swallowing.

Physical examination may help identify features of the underlying systemic or metabolic disorder or localize the anatomical level and severity of a causative neurological lesion. The patients general condition should be assessed to determine the degree that dysphagia is affecting fluid and nutritional status. Patients may initially require hydration and correction of electrolyte abnormalities. Examination of the oral cavity, head, and neck for masses, lymph nodes, goiter, and evidence of previous surgery or radiation therapy will help define structural abnormalities associated with dysphagia. Neurological examination may indicate cranial nerve dysfunction, neuromuscular disease, cerebellar dysfunction, or an underlying movement disorder. Of note, contrary to popular belief, the gag reflex is not predictive of pharyngeal swallowing efficiency or aspiration risk. The gag reflex is absent in 20%–40% of normal adults [6].

If the etiology of oropharyngeal dysphagia is not readily apparent after initial evaluation, further diagnostic studies are indicated. Because the management implications are so different, the first task in the evaluation of suspected oropharyngeal dysphagia is to distinguish between structural and functional etiologies. Structural abnormalities that may result from trauma, surgery, tumors, caustic injury, congenital anomalies, or acquired deformities are identified by endoscopic or radiographic examination. Functional abnormalities can be attributable to dysfunction of either intrinsic musculature, peripheral nerves, or central nervous system control mechanisms. Endoscopy may be performed either transorally or transanally to identify tumors, webs or hypopharyngeal diverticula. Barium studies may define areas of obstruction and hypopharyngeal diverticula, but add little structural information to endoscopic exams.

After structural defects have been excluded, videofluoroscopy is used for a functional evaluation of swallowing. Frequently referred to as a modified barium swallow, Logemann has described a protocol comprised of a series of swallow tasks [7]. Images are obtained in a lateral projection, framed to include the oropharynx, palate, proximal esophagus, and proximal airway. These images are then evaluated with respect to four major categories of oropharyngeal dysfunction:

1 inability or excessive delay in initiation of pharyngeal swallowing
2 aspiration
3 nasopharyngeal regurgitation
4 residue of the ingestate within the pharyngeal cavity after swallowing.

Furthermore, the procedure allows for evaluation of the efficacy of various compensatory dietary modifications, postures, and swallowing maneuvers in compensating for observed swallowing dysfunction.

Intralumenal manometry can quantify the strength of pharyngeal contraction, the completeness of upper esophageal sphincter (UES) relaxation, and the relative timing of these events. When coupled with concurrent videofluoroscopy it may provide useful complementary information regarding UES dysfunction. High intrabolus pressures may distinguish impaired UES opening from impaired UES relaxation as a cause of oropharyngeal dysphagia. Historically, a pitfall of UES manometry has been artifacts introduced by sphincter movement during swallowing. However, this limitation has recently been overcome with the introduction of high-resolution manometry that allows one to completely define the intralumenal pressure environment of the pharynx and esophagus without spatial gaps between recording sites and, consequently, with minimal movement-related recording artifacts. This can be very useful in discriminating between mechanical obstruction and weak musculature as potential causes of oropharyngeal dysphagia (Fig. 31.1).

Structural etiologies of oropharyngeal dysphagia

Implicit in the mechanical description of swallowing summarized above is that normal swallowing is associated with minimal outflow resistance from the oropharynx. Identification of obstructing lesions that cause dysphagia will lead to specific management in most cases. For example, cervical webs and pharyngeal or cricopharyngeal strictures or tumors are indications for surgery, dilation, antineoplastic therapy or some combination thereof. In the setting of benign strictures or postcricoid webs, simple dilation is safe and effective. Prominent cervical osteophytes can also cause obstructive dysphagia. As the posterior wall of the pharynx is so closely opposed to the anterior aspect of the cervical vertebrae, cervical osteophytes cause an anterior bulging into the hypopharynx that can impede passage of a normal-sized bolus [8]. The most common structural abnormalities of the hypopharynx associated with dysphagia are hypopharyngeal diverticula and cricopharyngeal bars. Given the interplay between structural and functional defects in these disorders, more detailed consideration is merited.

Hypopharyngeal diverticula and cricopharyngeal bars

Acquired hypopharyngeal diverticula occur most commonly in men after the age of 60. The most common type, Zenker diverticulum, originates in the midline posteriorly at Killian's dehiscence, a point of pharyngeal wall weakness between the oblique fibers of the inferior pharyngeal constrictor and the transverse cricopharyngeus muscle (Fig. 31.2) [9]. Other locations of acquired pharyngeal diverticula include the lateral slit separating the cricopharyngeus muscle from the fibers of the proximal end of the esophagus through which the recurrent laryngeal nerve and its accompanying vessels run to supply the larynx; at the penetration of the inferior thyroid artery into the hypopharynx; and at the junction of the middle and inferior constrictor muscles. The unifying theme of these locations is that they are sites of potential weakness of the muscular lining of the hypopharynx.

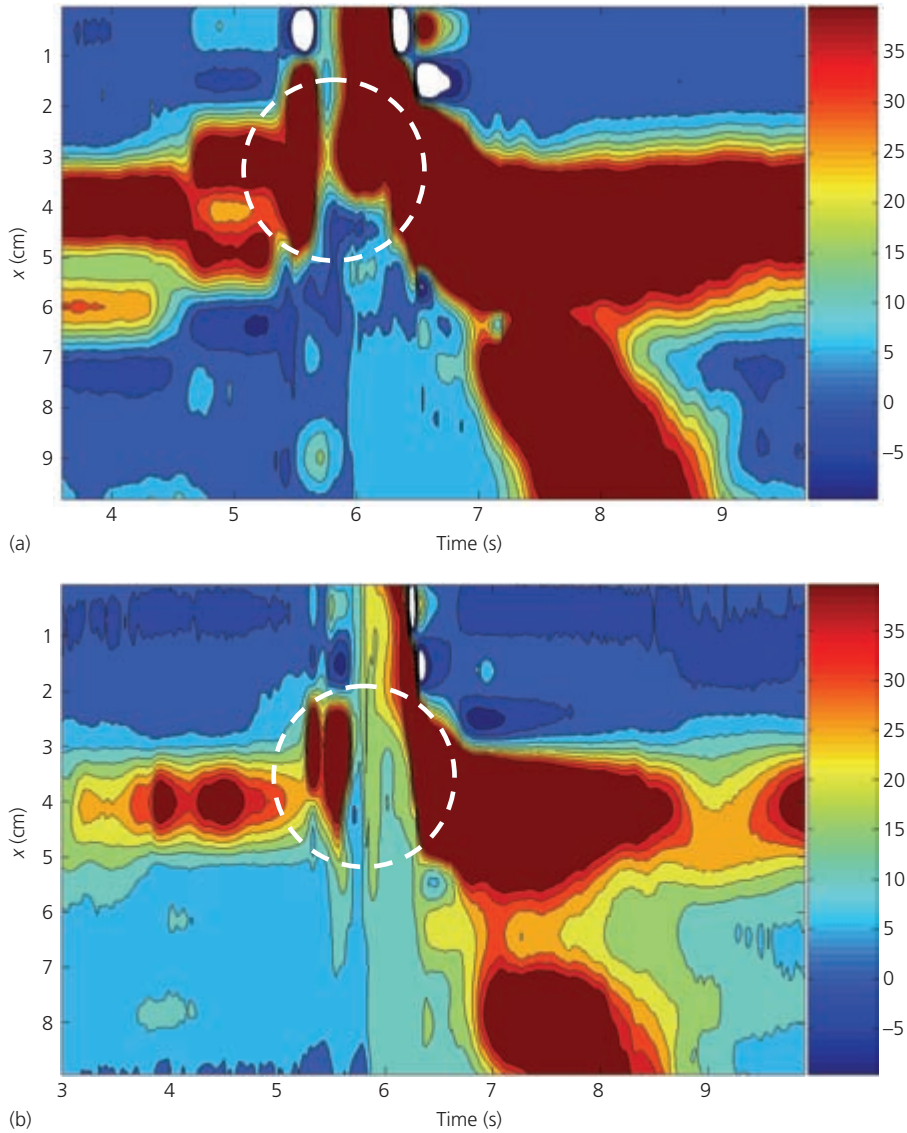

Figure 31.1 High-resolution manometry focused at the upper esophageal sphincter (UES) before and after dilation in a subject with a symptomatic cricopharyngeal bar. Isocontour plots before **(a)** and after dilation **(b)** reveal a decrease in intrabolus pressure and an increase in UES relaxation duration. Typical UES relaxation pressures are below 10 mmHg; however, in **(a)** the mean UES relaxation pressure is greater than 35 mmHg and the relaxation duration is extremely short. After dilation with an over-the-guidewire polyvinyl dilator **(b)** , the intrabolus pressure is substantially decreased and relaxation duration is adequate to allow for normal bolus transit through the UES.

Hypopharyngeal diverticula are often asymptomatic until they enlarge sufficiently to store a significant amount of food or liquid. In most instances, symptoms are of dysphagia, halitosis, post-swallow regurgitation, or even aspiration of material from the pharyngeal pouch.

Hypopharyngeal diverticula have been hypothesized to result from either delayed UES relaxation, failure of relaxation, or premature contraction [10]. However, little data and considerable contradiction accompany each of these hypotheses. A more plausible explanation for the development of diverticula is that they form as a result of a restrictive myopathy associated with diminished compliance of the cricopharyngeus muscle. Surgical specimens of cricopharyngeus muscle strips from 14 patients with hypopharyngeal diverticula demonstrated structural changes that would decrease UES compliance and opening [11]. The cricopharyngeus samples from these patients had "fibro-adipose tissue replacement and (muscle) fiber degeneration." Thus, although the muscle relaxes normally during a swallow, it cannot distend normally, resulting in the appearance of a cricopharyngeal indentation, or bar, during a barium swallow (Fig. 31.3). Diminished sphincter compliance necessitates increased hypopharyngeal intrabolus pressure to maintain trans-sphincteric flow through the smaller UES opening. The increased stress on the hypopharynx from the increased intrabolus pressure may ultimately result in diverticulum formation.

Management of structural oropharyngeal dysphagia

The treatment of hypopharyngeal diverticula is cricopharyngeal myotomy with or without a diverticulectomy. Cricopharyngeal myotomy reduces both the resting sphincter tone and resistance to flow across the UES. Resting UES tone is reduced to approximately 50% of baseline, suggesting that

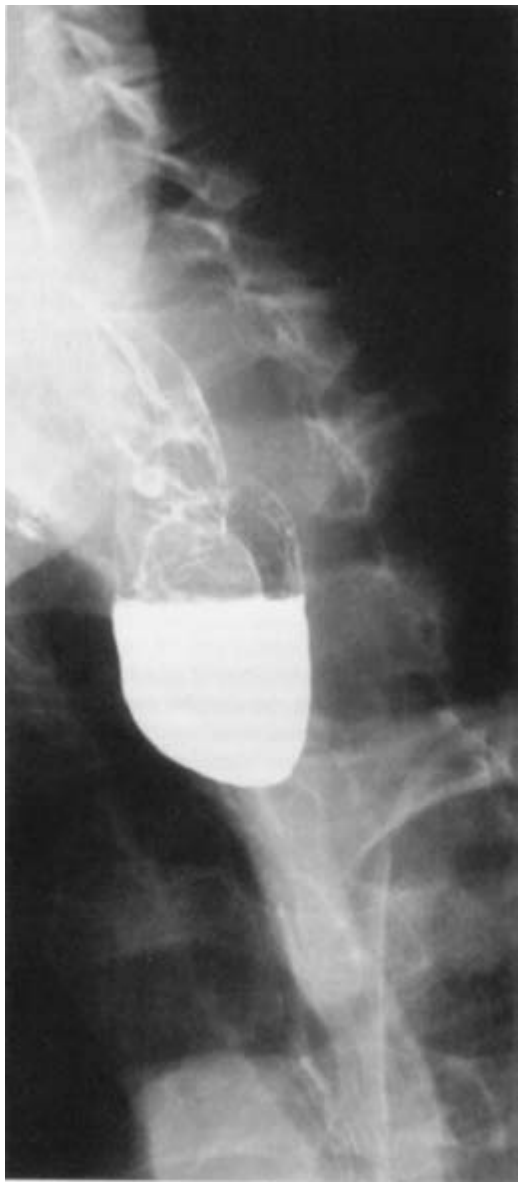

Figure 31.2 Radiograph of a large Zenker diverticulum partially filled with barium. Although the point of herniation is midline posterior, the diverticulum necessarily migrates laterally in the neck because there is no potential space between the posterior pharyngeal wall and the vertebral column.

the derived benefit is from increased compliance at the UES. A recent study found that the compliance of the sphincter following diverticulectomy with myotomy was restored to normal in five patients following surgery, as indicated by normal hypopharyngeal intrabolus pressure during swallowing [12]. Good or excellent results can be expected in 80%–100% of Zenker patients treated by transcervical myotomy combined with diverticulectomy or diverticulopexy [13]. There are instances in which a limited procedure would be adequate, but a definitive approach to the problem of

Figure 31.3 Cricopharyngeal bar in a patient with oropharyngeal dysphagia. The posterior indentation of the barium column is caused by a noncompliant cricopharyngeus muscle. Courtesy of Dr Richard Gore.

pulsion diverticula should involve both diverticulectomy and myotomy. Diverticulectomy alone risks recurrence because the underlying stenosis at the level of the cricopharyngeus is not remedied. Similarly, myotomy alone risks not solving the problem of food accumulation within the diverticula with attendant regurgitation and aspiration. Small diverticula may, however, disappear spontaneously following myotomy.

Whether or not a cricopharyngeal bar in the absence of a diverticula requires treatment is less clear. Certainly, if dysphagia exists and combined fluoroscopic/manometric analysis demonstrates reduced sphincter opening in conjunction with elevated upstream intrabolus pressure, there is good rationale for treatment. One recent uncontrolled series suggests that in this scenario dilation with a large caliber bougie may be efficacious in relieving dysphagia and this is certainly a reasonable treatment option prior to myotomy [14] (Fig. 31.1).

Functional etiologies of oropharyngeal dysphagia

Primary neurological or muscular diseases involving the oropharynx can be associated with dysphagia. Thus, whereas esophageal dysphagia usually results from esophageal diseases, oropharyngeal dysphagia is frequently the result of neurological or muscular diseases with oropharyngeal dysfunction being just one pathological manifestation. Although the specifics of the diseases vary, the net effect on swallowing

Table 31.1 Patterns and manifestations of oropharyngeal dysphagia

Mechanical element	Biomechanical mechanism	Evidence of dysfunction	Typical diseases
Nasopharyngeal closure	Soft palate elevation	Nasopharyngeal regurgitation, nasal voice	Myasthenia gravis
Laryngeal closure	Laryngeal elevation, arytenoid tilt, vocal fold closure	Aspiration during bolus transit	CVA, head trauma
UES opening	UES relaxation, laryngeal elevation, anterior hyoid traction, sphincter distension	Dysphagia, post-swallow residue/aspiration, diverticulum formation	Cricopharyngeal bar, CVA, Parkinson disease
Tongue loading and bolus propulsion	Lingual sensation and control	Sluggish, misdirected bolus	Parkinson disease, surgical defects, cerebral palsy
Pharyngeal clearance	Pharyngeal shortening, pharyngeal contraction, epiglottic flip	Post-swallow residue/aspiration	Polio, postpolio syndrome, oculopharyngeal dystrophy, CVA

CVA, cerebrovascular accident; UES, upper esophageal sphincter.

can be analyzed according to the mechanical description of the swallow outlined above. Table 31.1 summarizes the mechanical elements of the swallow along with the manifestations and consequences of dysfunction and representative pathological conditions in which they may be encountered. Some of the more distinct pathological entities are discussed below.

Neurological causes of oropharyngeal dysphagia

Neurological diseases can damage the neural structures necessary for either the afferent or efferent limbs of the oropharyngeal swallow. As there is nothing unique to neurons controlling swallowing, their involvement in disease processes is usually random. Furthermore, in most instances, functions mediated by adjacent neuronal structures are concurrently involved. Virtually any disease of the central nervous system can potentially cause dysphagia. The following discussion will focus on neuropathological processes with the best characterized patterns of dysphagia.

Cerebrovascular accidents

Aspiration pneumonia has been estimated to inflict a 20% death rate in the first year after a stroke, and 10%–15% each year thereafter [15]. It is usually not the first episode of aspiration pneumonia but the subsequent recurrences over a several-year period that eventually cause death [16]. The ultimate cause of aspiration pneumonia is dysphagia leading to aspiration, which can occur by a number of mechanisms: absence or severe delay in triggering the swallowing reflex (swallow apraxia), reduced lingual control, and unilateral or bilateral weakened laryngopharyngeal musculature [7]. Conceptually, these etiologies can be divided into motor or sensory impairments. Although sensory and motor impairment frequently co-occur, each will be addressed separately.

Cortical strokes are less likely to result in severe dysphagia than are brainstem strokes [17]. In a report of 100 consecutive patients, 37 of 86 (43%) who sustained an acute cerebral infarct experienced dysphagia when evaluated within 4 days of the event. However, 86% of these patients were able to swallow normally 2 weeks later [17]. Two-dimensional scalp topographical maps of the pharyngeal muscles obtained by transcranial magnetic stimulation suggest that recovery occurs as a result of contralateral areas taking over the lost function [18]. Thus, dysphagia is more prevalent among patients incurring larger strokes or patients who have had previous infarcts.

The sensory cues required for eliciting the pharyngeal swallow are unclear. In pathological circumstances in which one or the other neural substrate of the afferent signal has been damaged, patients may experience a relative inability to initiate a swallow. A study of sensory acuity in the supraglottic and pharyngeal regions [19] revealed either unilateral ($n = 9$) or bilateral ($n = 6$) sensory impairment of moderate to severe degree in all 15 stroke patients studied. Impaired sensation in these critical areas likely results in swallow apraxia. An interesting compensatory strategy for this sensory defect is to accentuate oropharyngeal stimulation during eating to facilitate achieving the threshold for triggering the medullary swallowing center [7]. Preliminary data suggest that the sour bolus is particularly effective in some patients with swallow apraxia providing some hope for the treatment of this disabling condition [7].

Poliomyelitis

Most cases of poliomyelitis involve only the spinal cord; however, the fatality rate from bulbar disease far exceeds that of spinal disease with the most common fatal complication being respiratory depression. In addition to its dreaded effect of respiratory depression, bulbar poliomyelitis is also associated with dysphagia. In one analysis of the persistent sequelae of bulbar poliomyelitis, 28 of 47 patients (60%) had recurrent or continued involvement of the pharynx 17 or more months after their acute illness [20]. Speech and

swallowing dysfunction are the result of weakness of the levator veli palatini muscle, pharyngeal constrictors, and hyolaryngeal elevators [20].

In recent years, neurologists have observed an increasing number of patients with new paretic symptoms traceable to their remote polio infection 30–40 years earlier. The new, slowly progressive postpolio muscular atrophy may occur in muscles that were clinically unaffected by the acute illness [21]. One investigation studied 13 patients with postpolio dysphagia and demonstrated palatal, pharyngeal, and laryngeal weakness [22]. Over half of the patients evaluated demonstrated silent aspiration suggesting that the clinician should maintain a low threshold for evaluating such patients with videofluoroscopy. Accumulating evidence suggests that at least some of these patients with postpolio syndrome respond to pyridostigmine bromide (Mestinon), a cholinomimetic agent.

Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive neurological disease characterized by degeneration of motoneurons in the brain, brainstem, and spinal cord. Specific symptoms are dependent upon the locations of affected motoneurons and the relative severity of involvement. When the degenerative process involves the cranial nerve nuclei, swallowing difficulties ensue. Oropharyngeal dysfunction characteristically begins with the tongue and progresses to involve the pharyngeal and laryngeal musculature. Patients experience choking attacks, become dehydrated or malnourished, and incur aspiration pneumonia. The decline in swallowing function is progressive and predictable, invariably leading to gastrostomy feeding. A number of patients die as a consequence of their swallowing dysfunction in conjunction with respiratory depression [23].

Parkinson disease

Although only 15%–20% of patients with Parkinson disease complain of swallowing problems, more than 95% have demonstrable defects videofluoroscopically [24]. The disparity between these numbers suggests that patients compensate effectively during the early stages of the disease and complain of dysphagia only when it becomes severe. Abnormalities of the oral phase of swallowing include repetitive lingual pumping before initiation of a pharyngeal swallow, piecemeal swallowing, and oral residue after the swallow [7,25]. Patients may also exhibit a delayed swallow response and a weak pharyngeal contraction, resulting in vallecular and pyriform sinus residue after each swallow [24]. Recent combined manometric and fluoroscopic data suggest that this is related to the combination of incomplete UES relaxation and a weakened pharyngeal contraction [24]. Although no controlled trials are available, dysphagic symptoms have improved following therapy with levodopa and carbidopa [25,26].

Tumors

Medullary or vagal tumors are potentially debilitating with respect to swallowing. Astrocytomas are the most common histological subtype affecting adults whereas medulloblastomas are the most common type encountered in children [27]. The relative inaccessibility of the medulla to surgery usually means that substantial morbidity is incurred during attempted resection or palliation.

Unilateral lesions of the vagus can result in hemiparesis of the soft palate and pharyngeal constrictors, as well as of the laryngeal musculature. Surgical manipulation of this region can even result in complete loss of the pharyngeal swallow response [28]. The recurrent laryngeal nerves can be injured as a result of thyroid surgery, polio, aortic aneurysms, pneumonectomy, primary malignancies of the mediastinum, or metastatic lesions to the mediastinum. Because of its more extensive loop into the chest, the left recurrent laryngeal nerve is more vulnerable to involvement with mediastinal node malignancy. Unilateral recurrent laryngeal nerve injury results in unilateral adductor paralysis of the vocal cords. This defect can result in aspiration during swallowing because of impaired laryngeal closure. Although some reports state the contrary [29], it is probably rare to have any primary pharyngeal dysfunction associated with recurrent laryngeal nerve injury.

Muscular diseases causing oropharyngeal dysphagia

Primary muscular diseases involving the oropharynx are associated with dysphagia, reflective of the pattern of involvement. Nasal voice and nasopharyngeal regurgitation indicate either weakness or paresis of the soft palate elevators, and tongue weakness can cause poor control of the bolus within the mouth. Post-swallow residue in the valleculae or hypopharynx reflects an ineffective, presumably weakened pharyngeal contraction. Aspiration suggests either weakened laryngeal elevators or post-swallow residue that is then aspirated after the swallow sequence is completed. As with neurological disorders, virtually any disorder affecting skeletal muscle can result in dysphagia. The following discussion focuses on a few of the better characterized entities.

Oculopharyngeal dystrophy

Oculopharyngeal muscular dystrophy, first described by Taylor in 1915 [30], is a syndrome characterized by progressive dysphagia and palpebral ptosis. Taylor noted that all of his afflicted patients reaching the age of 50 died of starvation resulting from pharyngeal paralysis. The disease is now known to be a form of muscular dystrophy inherited in an autosomal dominant fashion with occurrences clustered in families of French Canadian descent. Genetic studies of an afflicted family indicate linkage to chromosome 14, perhaps involving the region coding for cardiac α- or β-myosin heavy chains [31].

Oculopharyngeal dystrophy affects the striated pharyngeal

muscles and the levator palpebrae. Other forms of muscular dystrophy occasionally affect the pharyngeal constrictors but rarely, if ever, is this a dominant manifestation. The first symptom of oculopharyngeal dystrophy is usually ptosis, which develops slowly and eventually dominates the patient's appearance. Dysphagia may begin before the ptosis, but more often manifests simultaneously with it or a few years later. The dominant functional abnormalities are weak or absent pharyngeal contraction with hypopharyngeal stasis [32]. Dysphagia progresses slowly but may ultimately lead to starvation, aspiration pneumonia, or asphyxia.

Myotonic dystrophy

Myotonic dystrophy is a rare disorder characterized by prolonged contraction and difficulty in relaxation of involved skeletal musculature. Dysphagia is a common complaint among affected individuals. Early investigations suggested that the dysphagia was the result of myotonia of the cricopharyngeus with resultant overflow into the airway during attempted swallowing, but subsequent manometric and radiographic investigations have not confirmed this [33]. The experience in more recent investigations was that, even though only half of the patients studied complained of dysphagia, motor abnormalities could be demonstrated in every patient. The pattern of abnormality was of a weakened pharyngeal contraction, absent peristalsis in the striated muscle esophagus, and diminished or absent peristalsis in the smooth muscle portion of the esophagus. No study has demonstrated myotonia in any part of the esophagus. Thus, the consequences of the disease are identical to other forms of muscular dystrophy: poor pharyngeal clearance with risk of aspiration during the swallow if there is concurrent weakness of the laryngeal elevators or after the swallow when the substantial pharyngeal residue might fall into the reopened airway.

Myasthenia gravis

Myasthenia gravis is a progressive autoimmune disease characterized by high circulating levels of acetylcholine receptor antibody and destruction of acetylcholine receptors at neuromuscular junctions. Musculature controlled by the cranial nerves is almost always involved, particularly the ocular muscles. Dysphagia is prominent in more than one-third of myasthenia gravis cases and in unusual instances can be the initial manifestation of the disease [7]. In mild cases, dysphagia may not be evident until after 15–20 min of eating. Classically, manometric studies reveal a progressive deterioration in the amplitude of pharyngeal contractions with repeated swallows. Peristaltic amplitude recovers with rest or following the administration of 10 mg of edrophonium chloride. In more advanced cases the dysphagia can be profound and associated with nasopharyngeal regurgitation and nasality of the voice, even to the extent of being confused with bulbar ALS or brainstem stroke [34].

Management of oropharyngeal dysphagia

Management of oropharyngeal dysphagia begins with definition of the aberrant physiology along the lines summarized in Table 31.1. This is most easily accomplished with a videofluoroscopic swallowing study. Following definition of the patient's swallowing dysfunction, four specific issues pertaining to management of oropharyngeal dysphagia can be addressed:

1 identification of an underlying systemic disease
2 characterization of a disorder amenable to surgery or dilation
3 identification of a specific pattern of dysphagia amenable to swallowing therapy
4 assessment of aspiration risk.

Identifying underlying disease

A potential outcome of the swallowing evaluation is the identification of an underlying neuromuscular, neoplastic, or metabolic disorder that will dictate specific management. For example, dysphagia can be the presenting symptom in patients with myopathy, myasthenia, thyrotoxicosis, motor neuron disease, or Parkinson disease. In each instance, identification of the underlying disease will result in a specific treatment. Whether or not identification and treatment of the underlying disorder improves swallowing function depends on both the natural history of the disease and whether or not an effective treatment exists.

Disorders amenable to surgery

In marked contrast to the high efficacy observed with structural cricopharyngeal disorders, the efficacy of myotomy in neurogenic dysphagia is variable. Furthermore, most series evaluating the efficacy of myotomy in neurogenic dysphagia are uncontrolled without specific outcome measures. Thus, although an overall favorable response rate in excess of 60% is reported, there are currently no validated criteria for preoperative selection. Theoretically, the functional limitation in these circumstances is of pharyngeal propulsion and the potential benefit of myotomy is less obvious [35].

Specific patterns of dysphagia amenable to swallowing therapy

Following characterization of a patient's swallow dysfunction, the radiographic study should proceed to test selected compensatory or therapeutic treatment strategies. Compensatory treatments include postural changes, modifying food delivery or consistency, or the use of prosthetics. For instance, head turning can eliminate aspiration or pharyngeal residue by favoring the more functional side in patients with hemiparesis [7]. Similarly, diet modifications can reduce the "difficulty" of the swallow [7]. Therapeutic strategies are designed to alter the physiology of the swallow, usually by improving the range of motion of oral or pharyngeal structures using voluntary control of oropharyngeal movement during swallow. Depending on the severity of the

impairment, level of motivation, and global neurological intactness, defective elements of the swallow can be selectively rehabilitated. For a detailed description of the techniques and limitations of swallow therapy, the reader is referred to treatises on the topic [7,13].

Detection of severe aspiration

Oropharyngeal dysphagia associated with aspiration is responsible for an estimated 40 000 deaths a year as a result of aspiration pneumonia [19]. Videoflouroscopy is believed to be the most sensitive test for detecting aspiration, detecting instances not evident by bedside evaluation in 42%–60% of patients. However, despite the logical association between deglutitive aspiration and the subsequent development of pneumonia, this sequence is not inevitable. In fact, available data suggest that radiographic aspiration has a positive predictive value of only 19%–68% and a negative predictive value of 55%–97% for pneumonia [13]. Nonetheless, the balance of evidence suggests that the detection of aspiration is a predictor of pneumonia risk, and that its detection dictates that compensatory swallowing strategies, nonoral feeding or corrective surgery be instituted. Whether nonoral feeding eliminates the risk of aspiration is controversial. A provocative finding by Croghan et al. [5] was that, out of 22 patients with radiographic aspiration, pneumonia and death were more frequent among patients who received feeding tubes. This finding suggests that aspiration of oral secretions may be important in determining pneumonia risk and has led some to consider procedures such as tracheostomy to protect the airway.

Xerostomia

Although not an esophageal motility disorder, xerostomia (the subjective feeling of oral dryness) will be discussed briefly given its association with dysphagia. Xerostomia is usually associated with reduced salivary secretion. The normal, unstimulated salivary flow rate should be 0.3–0.5 mL/min, whereas flow rates of less than 0.1 mL/min are consistent with xerostomia. The most common etiologies of xerostomia are:

- drugs
- autoimmune diseases including Sjogren syndrome and rheumatoid arthritis
- radiation therapy.

Symptoms associated with xerostomia are:

- pain, burning, and soreness of the oral mucosa, especially the tongue
- difficulty in mastication, swallowing, and speech
- impairment of taste
- painful oral ulcers
- difficulty wearing dentures
- increased dental caries
- increased frequency or volume of fluid intake [36].

The dysphagia associated with xerostomia is primarily attributable to the absence of the lubricating properties of saliva. Therapy consists of attempts to increase secretion with sugarless gum or sour lozenges or with pharmacological agents such as pilocarpine and cholinergic agents. Individuals without a salivary response regardless of stimulation can try commercially available saliva substitutes.

Esophageal motility disorders

Neuromuscular function of the esophagus (motility) has the consistent objective of emptying the esophagus: primary esophageal peristalsis empties swallowed material from the esophagus; secondary peristalsis eliminates air or fluid refluxed from the stomach; the upper esophageal sphincter contracts during inspiration to exclude inspired air from the digestive tract; and elements of the esophagogastric junction (EGJ) contract during transient increases of intra-abdominal pressure, preventing gastroesophageal reflux. A basic characteristic of esophageal motility disorders is the failure to preserve esophageal emptiness. Retained material within the esophagus, or the excessive entry of material into the esophagus, is abnormal. Such dysfunction can be categorized as disorders of peristalsis or of sphincter competence. The main dysfunction of sphincter competence occurs with reflux disease, an entity covered elsewhere in this text. This discussion will focus on less common etiologies of sphincter dysfunction and on disorders of peristalsis.

Evaluation and classification of esophageal dysphagia

Dysphagia is a fundamental symptom of esophageal disorders. Esophageal as opposed to oropharyngeal dysphagia is suggested by the absence of associated aspiration, cough, nasopharyngeal regurgitation, dry mouth, pharyngeal residue following swallow, or co-occurring neuromuscular dysfunction. On the other hand, the associated conditions of heartburn, esophagopharyngeal regurgitation, chest pain, odynophagia, or intermittent esophageal obstruction suggest esophageal dysphagia. However, an important limitation of the patient history in esophageal dysphagia is that patient identification of the location of obstruction is of limited accuracy. Specifically, a distal esophageal obstruction caused by an esophageal ring or achalasia will often be sensed as cervical dysphagia such that patients correctly locate distal dysfunction only 60% of the time [37]. Because of this subjective difficulty in distinguishing proximal from distal lesions within the esophagus, an evaluation for cervical dysphagia should encompass the entire esophagus.

Another important consideration in patient management is that esophageal motility disorders are much less common than mechanical or inflammatory etiologies of dysphagia: tumors, strictures, rings, and peptic, pill, or infectious esophagitis. Historical points suggestive of a motor disorder are difficulty with both solids and liquids as opposed to only

solids, which is more suggestive of mechanical obstruction. However, as will become evident in the ensuing discussion, the functional consequences of mechanical or inflammatory disorders can exactly mimic those of primary motility disorders. Thus, as with oropharyngeal dysphagia, an esophageal motility disorder should be considered only after exclusion of these more common diagnoses by endoscopic or radiographic examination.

As outlined above, the physiological elements of esophageal peristalsis are the coordinated inhibition and excitation of the circular and longitudinal muscle layers of the esophagus. It follows that pathophysiological processes can involve dysfunction of deglutitive inhibition (including sphincter relaxation) or of the propagated contraction. Furthermore, because esophageal motor disorders are rarely diagnosed on histopathological grounds, diagnosis depends upon defining these functional aberrations. Table 31.2 illustrates an attempt at categorizing esophageal motility disorders on the basis of regional function of deglutitive inhibition and sequenced excitation. Examining Table 31.2, there are few well-defined esophageal motility disorders and, as one might predict, in some circumstances it can be very difficult to definitively choose between the diagnostic possibilities. However, such is the state of the art. Furthermore, in the instance of spastic disorders, there is considerable debate over the clinical significance of some manometric findings [38]. With these considerations in mind, the following discussion emphasizes disease entities with clear diagnostic or therapeutic implications rather than manometric phenomena of unproved significance. The exception is gastroesophageal reflux disease (GERD), which, although highly significant, is deferred to Chapter 32.

Diagnostic testing in esophageal disease

Endoscopy

Although upper endoscopy is an excellent tool for evaluating dysphagia, it has significant limitations in assessing extralumenal structures and abnormal esophageal motility. Upper endoscopy should be the first test ordered for evaluating new-onset dysphagia when structural causes requiring either dilation or biopsy are being considered. It has excellent specificity for strictures and tumors; however, it has the potential to miss subtle obstructing lesions, such as webs and rings. In addition, it will also provide very limited information regarding peristaltic function.

Contrast studies

Contrast studies of the oropharynx and esophagus are useful in assessing dysphagia if stricture or tumor is not suspected or upper endoscopy is not readily available. It has the added benefit of providing information regarding UES function, peristalsis, and bolus clearance through the EGJ. With good technique, normal peristalsis can be verified with 91%–95% specificity [39,40]. Peristalsis is best evaluated in the prone position so that clearance does not occur by gravity. In the prone position, the primary peristaltic wave manifests as an inverted "V" that represents the tail of the bolus leading the peristaltic wavefront (Fig. 31.4). Abnormalities of peristalsis are inferred by retrograde escape of the bolus through the peristaltic wavefront resulting in incomplete esophageal emptying. Normally the EGJ will become widely patent when the bolus reaches this area and impaired relaxation can be inferred when either a smooth tapering is noted at the EGJ or bolus transit across the EGJ is impeded.

Table 31.2 Patterns of esophageal dysmotility

	Esophageal region		
Functional impairment	**UES**	**Body**	**LES**
Inadequate deglutitive inhibition (or relaxation)	Parkinson disease, *cricopharyngeal bar*	Achalasia, diffuse esophageal spasm	Achalasia, *pseudoachalasia*
Impaired retrograde inhibition	Belch dysfunction, complicated achalasia	–	Gas bloat (postfundoplication)
Excess retrograde inhibition	–	–	GERD (tLESR)
Inadequate peristaltic excitation (or resting tone)	Oculopharyngeal dystrophy, mixed connective tissue disease	Scleroderma esophagus, advanced achalasia, GERD, nonspecific esophageal motor disorder, *obstruction*	Scleroderma esophagus, GERD
Excess peristaltic excitation (or resting tone)	–	DES, vigorous achalasia, nutcracker esophagus	Hypertensive LES, achalasia

Italics indicate structural abnormalities mimicking the findings of primary motor disorders.
DES, diffuse esophageal spasm; GERD, gastroesophageal reflux disease; LES, lower esophageal sphincter; tLESR, transient LES relaxation; UES, upper esophageal sphincter.

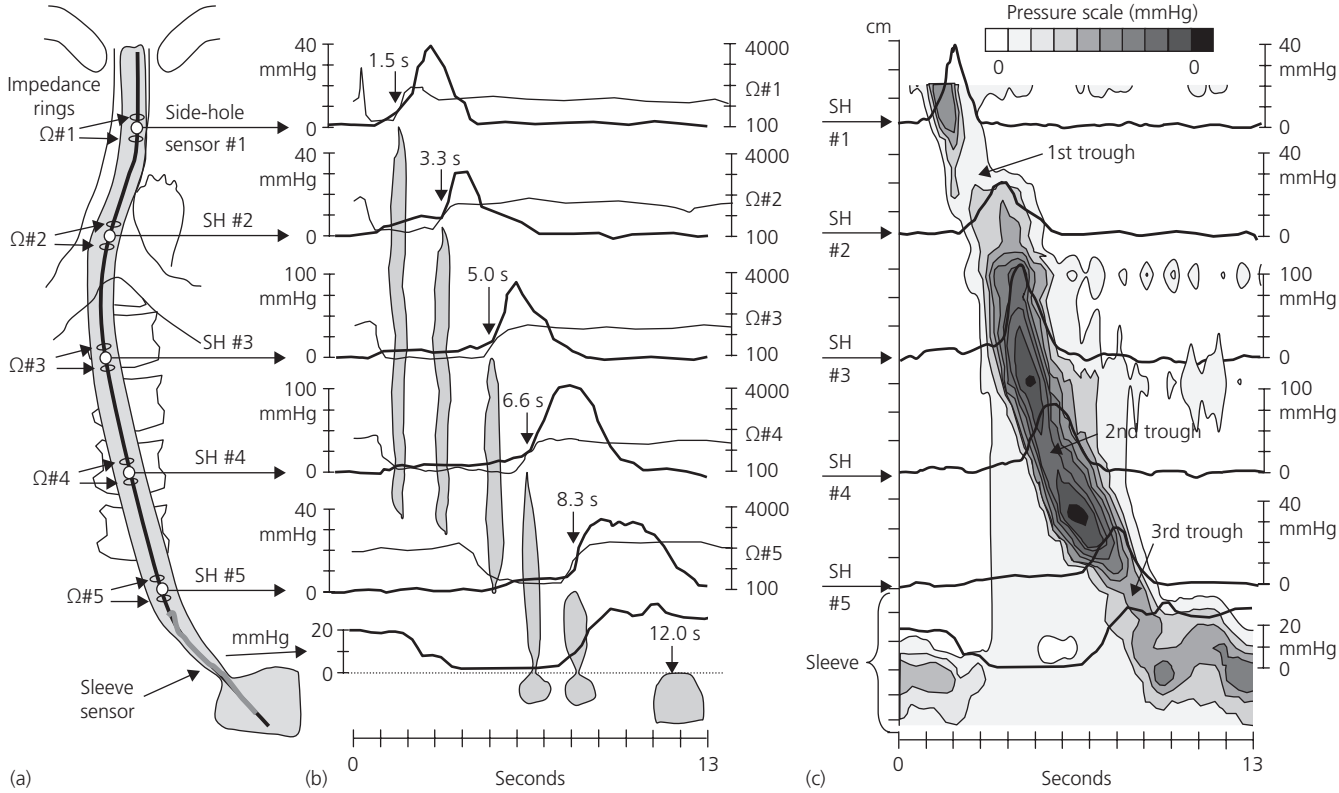

Figure 31.4 Representative physiological data, modified to illustrate the relationship between videofluoroscopic, manometric, impedance, and topographic representations of esophageal peristalsis. **(a)** Schematic drawing of placement of a combined manometry/intralumenal impedance monitoring system with five manometric side holes (SH) spaced 4 cm apart and a 6-cm sleeve sensor placed just distal to the last manometric port. The impedance rings (Ω) are also spaced 4 cm apart with the rings straddling the manometric ports. The arrows to part **(b)** point to the corresponding data tracings obtained from each combined manometry/impedance or sleeve recording site. **(b)** Concurrent videofluoroscopic, manometric, and multichannel intralumenal impedance recordings of a 5-mL renografin swallow that was completely cleared by one peristaltic sequence. Representative tracings from the videofluoroscopic sequence overlayed on the combined manometric/impedance tracing show the distribution of the bolus at the times indicated by the vertical arrows. At each recording site, the thick line intersecting the pressure scale (mmHg) on the left represents the manometric tracing and the fine line intersecting the impedance scale (Ω) on the right represents the impedance recording tracing. Bolus entry at each combined manometry/impedance recording site is signaled by a subtle increase in pressure (intrabolus pressure) and a greater than 50% decrease in impedance. In this example, the bolus propagates past Ω#4 rapidly, indicated by an abrupt reduction in impedance in Ω#2, Ω#3, and Ω#4 at time 1.5 s. Lumenal closure and hence the tail of the barium bolus is evident at each recording site by the upstroke of the peristaltic contraction and a 50% increase in recorded impedance. Hence, at 5.0 s, the peristaltic contraction was beginning at SH#3, corresponding to a 50% increase in impedance and the tail of the barium bolus at the same esophageal locus. Finally, after completion of the peristaltic contraction (time 12.0 s), all renograffin was in the stomach. **(c)** Comparison of conventional manometry obtained with a sleeve assembly as depicted in **(a)** and high-fidelity manometry with recording sites at 1-cm intervals displayed topographically as an isocontour plot. The standard manometric recordings are superimposed on the isocontour plot at axial locations corresponding to the equivalent portion of the high-fidelity manometry it represents. In the isocontour plot, deepening shades of gray indicate higher pressures, revealing four distinct pressure segments separated by three pressure troughs. Physiologically the first trough is at the junction between striated and smooth muscle, the second is within the smooth muscle segment and the third separates the peristaltic segment from the lower esophageal sphincter (LES). Note that LES relaxation is reliably recorded using either methodology, albeit somewhat differently. From the illustration one can see that the end of LES relaxation measured by the sleeve coincides with the peristaltic contraction contacting the proximal portion of the sleeve. In addition to measuring mean residual pressure, topographic analysis allows for more precise measurement of the transphincteric pressure gradient. Isocontour tracing courtesy of Ray Clouse. From Pandolfino & Kahrilas [204], with permission.

Manometry

Manometry is the only technique that can define the contractile characteristics of the esophagus in an attempt to identify pathological conditions. Manometric evaluation of the tubular esophagus assesses the integrity, rate of progression, and morphology of the contractile complex (amplitude, duration, repetitive contractions). Failed peristalsis is defined as the absence of contraction after a swallow, or a contraction that proceeds only part way down the esophagus and either disappears or ends with a simultaneous contraction. Each of

these outcomes results in incomplete esophageal emptying [41]. The progression rate of peristaltic contraction is measured by identifying the timing of the initial upstroke of contraction at adjacent recording sites and knowing the distance between these sites. Progression rates greater than 6.25 cm/s are associated with poor esophageal emptying and are considered simultaneous [42]. Contractile amplitude is considered hypotensive if it has an amplitude of less than 35 mmHg because this too can be associated with impaired esophageal emptying [41]. A typical convention for scoring hypertensive peristalsis is that the mean amplitude of contractile complexes exceeds 180 mmHg; however, this upper limit has varied among investigators. Repetitive contractions are multipeaked complexes. By convention, a contraction is scored as multipeaked if the valley between the peaks is at least 10 mmHg less than and at least 1 s after the preceding peak.

Both the magnitude of EGJ pressure and EGJ relaxation characteristics are measured with manometry. The three most widely used techniques are: (1) a stationary sleeve sensor; (2) a rapid pull-through of side-hole sensors across the EGJ during suspended respiration; or (3) a station pull-through of a side-hole sensor recording pressure activity for 30–60 s at 1 cm increments as the catheter is withdrawn. EGJ pressure varies by as much as 25 mmHg with the method of measurement and depending on whether mid-respiratory or end-expiratory EGJ pressure is reported. In addition to methodology, the minute-to-minute variations of EGJ pressure are attributable to normal physiological events, such as the migrating motor complex. Thus, normal EGJ pressure varies widely with normal values ranging from 15 ± 11 mmHg at end expiration to 40 ± 13 mmHg at end inspiration, even when measured from the same manometric tracings [43]. The most meaningful statement that can be made regarding isolated EGJ pressure measurements is that it is abnormal to find an extremely low value (≤ 5 mmHg).

The manometric evaluation of EGJ relaxation is arguably the most important measurement made during clinical esophageal manometry. Relaxation of the lower esophageal sphincter (LES) occurs with swallowing, esophageal distention, and transient LES relaxation (tLESR). Relaxation characteristics can be evaluated using a sleeve sensor, during a station pull-through, or after repositioning a side hole at the optimal position. Until recently, there was a paucity of quantitative data regarding EGJ relaxation. The deficiency was mostly attributable to the lack of standardized recording methodology and data interpretation. Recognizing this void, recent studies have quantified normal deglutitive EGJ relaxation with techniques suited to the study of a mobile anatomical zone: either a water-perfused sleeve sensor that spans the EGJ or high-resolution manometry with topographic data analysis. Shi and colleagues [44] used a standardized methodology of sleeve-sensor recording and computer-assisted data analysis and concluded that the best single assessment of EGJ relaxation was mean relaxation pressure (Table 31.3). Using the 95th percentile value of control subjects (12 mmHg) as the upper limit of normal, this parameter had a sensitivity and positive predictive value of 92% and 88%, respectively, for the diagnosis of achalasia. In another study aimed at defining the optimal criteria for incomplete EGJ relaxation, Staiano and Clouse [45] utilized high-resolution manometry with and without topographic analysis (Fig. 31.4) [45]. With topographic analysis, a transphincteric pressure gradient exceeding 5 mmHg had 94% sensitivity and 89% specificity for achalasia regardless of the presence or absence of peristalsis. Without topographic analysis, the 3-s mean residual EGJ pressure was most discriminative.

Impedance monitoring

Multichannel intralumenal impedance is a technique that was described more than a decade ago as a method to assess intralumenal bolus transit without fluoroscopy. The technique utilizes a catheter with multiple, closely spaced pairs of metal rings. An alternating current is applied across each pair of adjacent rings and the resultant current flow is dependent on the impedance between the rings. Impedance decreases when the electrodes are bridged by liquid and increases when they are surrounded by air, thereby providing data on the direction, content, and completeness of bolus transit. As illustrated in Figure 31.4, liquid bolus entry is indicated by a 50% drop in impedance, and return of the impedance tracing to 50% of baseline correlates with the passage of the tail of the bolus on fluoroscopy, also indicated by the contractile upstroke noted on manometry. Validation studies of multichannel intralumenal impedance against videofluoroscopy have shown excellent concordance in ascertaining bolus transit, reporting agreement in 97% (83/86) of swallows analyzed [46].

Multichannel intralumenal impedance has also recently been combined with manometry to assess the efficacy of esophageal emptying as a function of distal peristaltic amplitude. In a receiver operating characteristic (ROC) analysis of a large number of swallows, a 30 mmHg cutoff had 85% sensitivity and 66% specificity for identifying incomplete bolus transit [47]. With diminishing peristaltic amplitudes, the sensitivity progressively decreased and the specificity progressively increased (Fig. 31.5). This study illustrates the complementary nature of manometry and impedance testing in assessing esophageal function, which may potentially develop into a valuable clinical tool for the assessment of dysphagia.

Achalasia

Achalasia is the most easily recognized and best defined motor disorder of the esophagus. First recognized more than 300 years ago, the disorder was initially labeled cardiospasm reflecting the observation that it was caused by a functional obstruction of the esophagus at the cardiac sphincter with no

Table 31.3 Esophagogastric junction (EGJ) relaxation parameters and the detection of achalasia. Sensitivity and specificity values are in distinguishing achalasics from control subjects [85] or mixed subject groups [45]

Sleeve sensor **(Shi et al., 1998 [85])**

EGJ relaxation parameter	Threshold value	Sensitivity	Specificity
Basal pressure	> 41 mmHg	38%	93%
Mean relaxation pressure	> 12 mmHg	92%	93%
Percent relaxation	< 57%	88%	93%
Relaxation duration	< 2.2 s	31%	93%

High-resolution manometry with concurrent baseline (subjects with peristalsis) **(Staiano and Clouse, 2001 [45])**

EGJ relaxation parameter	Threshold value	Sensitivity	Specificity
Lowest residual pressure	≥ 4 mmHg	77%	92%
Lowest residual pressure over entire deglutitive period	≥ 4 mmHg	68%	98%
Lowest mean LES relaxation pressure in a 3-s postdeglutitive interval	> 10 mmHg	85%	92%

High-resolution manometry with concurrent baseline (subjects without peristalsis) **(Staiano and Clouse, 2001 [45])**

EGJ relaxation parameter	Threshold value	Sensitivity	Specificity
Lowest residual pressure	> 2 mmHg	81%	89%
Lowest residual pressure over entire deglutitive period	> 2 mmHg	77%	89%
Lowest mean LES relaxation pressure in a 3-s postdeglutitive interval	> 8 mmHg	87%	95%

High-resolution manometry with concurrent baseline (subjects with peristalsis or without peristalsis (in parentheses) **(Staiano and Clouse, 2001 [45])**

EGJ relaxation parameter	Threshold value	Sensitivity	Specificity
Transphincteric gradient	> 2 mmHg	100% (100%)	85% (100%)
	> 5 mmHg	94% (94%)	98% (100%)

LES, lower esophageal sphincter.

obstructing lesion evident in autopsy specimens. The first reported case was treated by passing a piece of carved whalebone with a sponge affixed to the distal end through the esophagus to facilitate esophageal emptying after meals [48]. That patient apparently sustained himself in this fashion for 15 years. During the next two centuries there were sporadic reports of cases similarly treated with crude ramrods or dilators. In 1937, Lendrum [49] proposed that the functional esophageal obstruction in this syndrome resulted from incomplete relaxation of the LES and renamed the disease achalasia ("failure to relax"), ushering in our current concept of the disease [49].

Epidemiology

Achalasia is a rare disease with an estimated incidence of 1/100 000 population per year in the United States and Europe [50,51]. The incidence in black Zimbabweans may be much lower, raising the issue of racial or environmental predisposition [52]. The disease affects both sexes equally and usually presents in adult life, being most common between the ages of 25 and 60 [53]. Because achalasia is a chronic condition, its prevalence greatly exceeds its incidence. Estimates of the prevalence of achalasia in Europe range from 7.1/100 000 in Wales to 13.4/100 000 in Ireland [54].

Reports of familial clustering of achalasia raise the possibility of genetic predisposition; however, the data on this are inconclusive. Achalasia has been reported in monozygotic twins [55], siblings [56], and children of affected parents [57]. However, other reports of the occurrence of achalasia in only one of a pair of monozygotic twins speaks against a strong genetic determinant [58]. Emphasizing this point, a survey of 1012 first-degree relatives of 159 achalasics

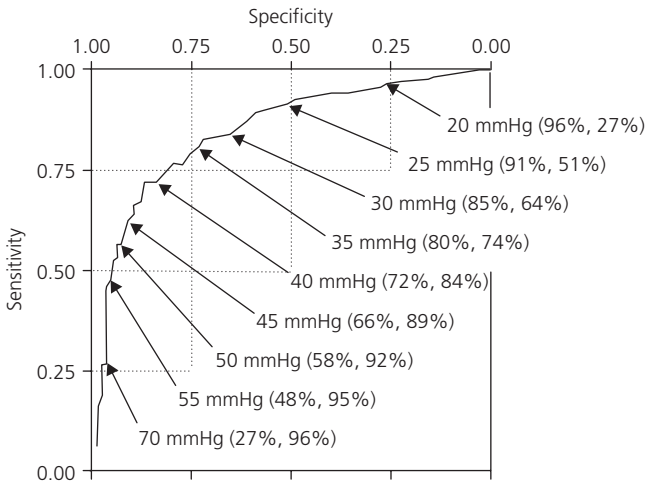

Figure 31.5 Receiver operating characteristic (ROC) curves describing the effectiveness of peristaltic contractions in achieving complete esophageal emptying for liquid swallows in subjects with hypotensive peristalsis. These data were generated from combined impedance and manometry studies of 700 swallows in 70 patients with the impedance/manometry segments under analysis positioned 5 and 10 cm above the lower esophageal sphincter (LES). The curves plot sensitivity against specificity of peristaltic amplitude as a predictor of complete bolus transit. The arrows indicate the position along the ROC curve of several discrete cutoff values of peristaltic amplitude with the corresponding sensitivity and specificity values (respectively) in parentheses. Evident from the curve, the peristaltic amplitude that achieves the optimal sensitivity and specificity is between 35 and 40 mmHg. Modified from Tutuian & Castell [137].

identified no affected relatives [59]. A rare genetic achalasia syndrome has also been described. Familial adrenal insufficiency with alacrima is inherited as an autosomal recessive disease that manifests itself with the childhood onset of autonomic nervous system dysfunction including achalasia, alacrima, sinoatrial dysfunction, abnormal pupillary responses to light, and delayed gastric emptying [60]. It is caused by mutations in the *AAAS* gene, which encodes a protein known as ALADIN.

Neuropathology

Achalasia is characterized by: (1) failure of the LES to relax completely with swallowing; and (2) aperistalsis in the smooth muscle esophagus. The resting LES pressure is elevated in about 60% of achalasia cases. If there are nonperistaltic, spasm-like contractions in the esophageal body, the disease is referred to as vigorous achalasia. These physiological alterations are thought to result from damage to the innervation of the smooth muscle esophagus (including the LES). Proposed neuroanatomical changes responsible for achalasia include loss of ganglion cells within the myenteric (Auerbach's) plexus, degeneration of the vagus nerve, and degeneration of the dorsal motor nucleus of the vagus. Of these possibilities, the loss of ganglion cells is best substantiated. Several observers report fewer ganglion cells and ganglion cells surrounded by mononuclear inflammatory cells in the smooth muscle esophagus of achalasics [61]. One report additionally noted ganglion cell degeneration extending into the proximal stomach in half of 34 specimens analyzed [62]. The degree of ganglion cell loss parallels the duration of disease such that ganglion cells are almost absent in patients afflicted for ≥ 10 years [63]. A morphological study of 42 esophagi resected from patients with advanced achalasia revealed diminished myenteric ganglion cells and inflammation within the myenteric plexus in all cases [64].

The ultimate cause of ganglion cell degeneration in achalasia is unknown; however, there is increasing evidence consistent with an immune-mediated process. Immunohistochemical analysis of the myenteric infiltrate in achalasia patients revealed that the majority of inflammatory cells are CD3/CD8-positive lymphocytes that express T-cell intracellular antigen-1 (TIA-1), indicating that these cells are either resting or activated cytotoxic T cells [65]. In addition to this histological support, there is also an association with the class II human leucocyte antigens (HLA) DQw1 [66] and DQb1 [67]. Achalasia may also be associated with degenerative neurological disorders such as Parkinson disease. Patients with both achalasia and Parkinson disease were noted to have Lewy bodies (intracytoplasmic hyaline or spherical eosinophilic inclusions) in the degenerating ganglion cells of the myenteric plexus [68].

Physiological studies also provide evidence of at least partial postganglionic denervation of esophageal smooth muscle in achalasia. Such damage can potentially affect excitatory (cholinergic) ganglionic neurons, inhibitory (nitric oxide ± vasoactive intestinal polypeptide [VIP]) ganglionic neurons, or both. Consider first the excitatory ganglionic neurons. Muscle strips from the circular layer of the esophageal body of achalasics contract when directly stimulated by acetylcholine but fail to respond to ganglionic stimulation by nicotine, indicating a postganglionic excitatory defect [69]. An in vivo demonstration of smooth muscle sensitivity to acetylcholine is the Mecholyl test in which the injection of this acetylcholine analogue evokes profound contraction of the otherwise flaccid achalasic esophagus [70]. This exaggerated response has been interpreted as a demonstration of Cannon's law of denervation supersensitivity. However, it is likely that loss of excitatory innervation is variable among achalasics. Partial preservation of the postganglionic cholinergic pathway is suggested by the observations that an achalasic's LES pressure increases after administration of the acetycholinesterase inhibitor edrophonium, and decreases after administration of the muscarinic antagonist atropine [71]. These observations are crucial to understanding why botulinum toxin may have therapeutic benefit in achalasia (see Botulinum toxin injection).

Regardless of excitatory ganglionic neuron impairment, it is clear that the inhibitory ganglionic neurons are necessarily impaired as an early manifestation of achalasia. Functionally,

these neurons are responsible for deglutitive inhibition (including LES relaxation) and for the timing of propagation of esophageal peristalsis; their absence offers a unifying hypothesis for the key physiological abnormalities of achalasia: impaired LES relaxation and aperistalsis. It is increasingly evident that the inhibitory ganglionic neurons utilize nitric oxide as a neurotransmitter [72]. In support of this conclusion, patients with achalasia have been shown to lack nitric oxide synthase in the EGJ [72]. Furthermore, VIP may be a cotransmitter in these neurons and immunohistochemical studies have demonstrated a marked reduction of VIP-staining neurons in achalasics [73].

A multitude of evidence supports impaired physiological function of postganglionic inhibitory innervation in the smooth muscle esophagus of achalasics. Muscle strips from the LES of achalasics do not relax in response to ganglionic stimulation as they do in normal control subjects [69]. Cholecystokinin octapeptide, which normally stimulates the inhibitory ganglionic neurons, thereby reducing LES pressure, paradoxically increases the LES pressure in achalasics [74]. Impaired inhibitory innervation of the tubular esophagus above the LES is more difficult to demonstrate than within the sphincter itself because of the absence of resting tone in this region. However, in a clever experiment, Sifrim and colleagues [75] utilized an intraesophageal balloon to create a high-pressure zone in the tubular esophagus that then relaxed with the onset of deglutitive inhibition. This deglutitive relaxation in the esophageal body was absent in early, nondilated cases of achalasia.

Clinical presentation

Clinical manifestations of achalasia may include dysphagia, regurgitation, chest pain, weight loss, and aspiration pneumonia. All patients have solid food dysphagia; the majority of patients also have variable degrees of liquid dysphagia. The onset of dysphagia is usually gradual with the duration of symptoms averaging 2 years at presentation [53]. Dysphagia severity fluctuates but eventually plateaus. Predictably, regurgitation occurs when large amounts of food are retained in the dilated esophagus. The regurgitant is often recognized as food that has been eaten hours, or even days, previously. It tends to be nonbilious, non-acid, and mixed with copious amounts of saliva. Chest pain is a frequent complaint early in the course of achalasia, occurring in approximately two-thirds of patients [76]. Its etiology is unknown but is speculated to be related to the occurrence of esophageal spasms or to the process of esophageal dilation associated with disease progression. Treatment of achalasia is less effective in relieving chest pain than it is in relieving dysphagia or regurgitation. However, unlike dysphagia or regurgitation, chest pain may improve or disappear over time [76].

An estimated 10% of achalasics have bronchopulmonary complications as a result of regurgitation; in some instances, it is these complications rather than dysphagia that prompts them to seek medical care [77]. Another interesting, but fortunately rare, symptom of achalasia is airway compromise and stridor as a result of the dilated esophagus compressing the trachea [78]. This is related to dysfunction of the belch reflex either because of neural degeneration or because esophageal dilation prevents activation of stretch receptors within the esophageal wall [79].

It is paradoxical that many achalasics complain of heartburn, even after the onset of dysphagia [80]. Although reflux may be a common sequela of the treatments for achalasia, it seems physiologically inconsistent to simultaneously have dysphagia from impaired LES relaxation and reflux from excessive LES relaxation. In support of this skepticism, ambulatory 24-h esophageal pH studies of achalasics have only shown periods of esophageal acidification caused by the bacterial fermentation of retained food in the esophagus rather than discrete gastroesophageal reflux events [81]. Furthermore, prolonged LES recordings have shown a nearly complete absence of transient LES relaxations in achalasics [82]. However, there are occasional exceptions to this, evident from a well-documented case of an achalasic patient with intact transient LES relaxation despite the absence of deglutitive LES relaxation [83].

Radiography

A barium swallow radiograph (Fig. 31.6) can demonstrate the physiological abnormalities of achalasia. The characteristic radiograph is of a dilated intrathoracic esophagus with impaired emptying, an air–fluid level, absence of a gastric air bubble, and an LES that tapers to a point giving the distal esophagus a beak-like appearance. Occasionally, an epiphrenic diverticulum, immediately proximal to the LES, is observed with achalasia [84]. With long-standing achalasia the esophagus may assume a sigmoid configuration, and in some instances an air–fluid level, mediastinal widening, and an outline of the dilated esophageal wall are even evident on a plain chest film. Note that the characteristic radiographic findings depend upon esophageal dilation; as dilation is not always present in achalasia, the sensitivity of the radiographic examination is limited [51].

Manometry

The defining manometric features of achalasia are aperistalsis and incomplete LES relaxation. In cases of achalasia that are established by all available clinical criteria, these features are present more than 90% of the time. Given that esophageal aperistalsis also occurs with disorders other than achalasia, including GERD, collagen vascular diseases, and diabetes, the diagnosis of achalasia is highly dependent on accurately detecting impaired LES relaxation. Assuming that the LES can be intubated, an inaccurate diagnosis of impaired relaxation may result from artifactual relaxation associated with inappropriate catheter design or from employing suboptimal diagnostic thresholds. Two studies utilizing assemblies that

control for the effect of axial movement (a sleeve sensor and high-resolution manometry with topographic analysis) were recently conducted to minimize such errors. The highlights of these studies are summarized in Table 31.3. With a sleeve sensor, the best single assessment of EGJ relaxation for a diagnosis of achalasia was mean relaxation pressure using the 95th percentile value of control subjects (12 mmHg) as the upper limit of normal [85]. Utilizing high-resolution manometry with topographic analysis, similar accuracy was achieved using a threshold value of 8–10 mmHg for the lowest mean residual pressure in a 3-s postdeglutitive interval [45]. However, the greatest accuracy was achieved utilizing a novel concept for assessing LES relaxation: the transphincteric pressure gradient during the 2- to 6-s post-swallow interval. Pressure gradients exceeding 5 mmHg had a sensitivity of 94% and specificity of 98% for detecting achalasia.

Although utilizing the methods and thresholds defined in Table 31.3 will maximize diagnostic accuracy, manometry remains an imperfect tool for detecting achalasia. Manometric variants exist in achalasia that can still confound the diagnosis [86–88]. Illustrative of this is a report describing four achalasia variants in a retrospective study of 58 patients with idiopathic achalasia [83]. Achalasia variants were characterized by:

1 high amplitude esophageal body contractions ("vigorous achalasia")

2 retained peristalsis in most of the esophagus with only a short segment of aperistalsis

3 retained deglutitive LES relaxation

4 impaired deglutitive relaxation but intact tLESRs (Fig. 31.7).

Despite utilizing state-of-the-art techniques, each of these achalasia variants had atypical features of either peristalsis or LES relaxation, confounding their diagnosis. Nonetheless, in each case the patient was symptomatically improved following Heller myotomy, and histopathological analysis subsequently confirmed inflammation and destruction of the myenteric plexus. In addition to the possibility of misdiagnosis, manometric criteria for achalasia are not 100% specific for either idiopathic achalasia or Chagas disease. Pseudoachalasia accounts for up to 5% of cases with manometric criteria typifying achalasia, being more common with progressive age [53].

Manometry is also useful in evaluating symptomatic patients after Heller myotomy or pneumatic dilation. Data suggest that relief of dysphagia is related to postprocedure EGJ pressure, with a value of less than 10 mmHg being optimal [89]. Identification of residual EGJ high pressure of more than 10 mmHg argues for further therapy targeting LES disruption. On the other hand, symptomatic subjects with basal LES pressures of less than 10 mmHg may not benefit from repeat dilation or surgery and should be evaluated with a timed barium swallow to assess emptying [90]. In instances in which a timed barium swallow demonstrates poor esophageal emptying despite an optimal reduction of EGJ pressure, esophageal resection with gastric pull-up or colon interposition may be indicated.

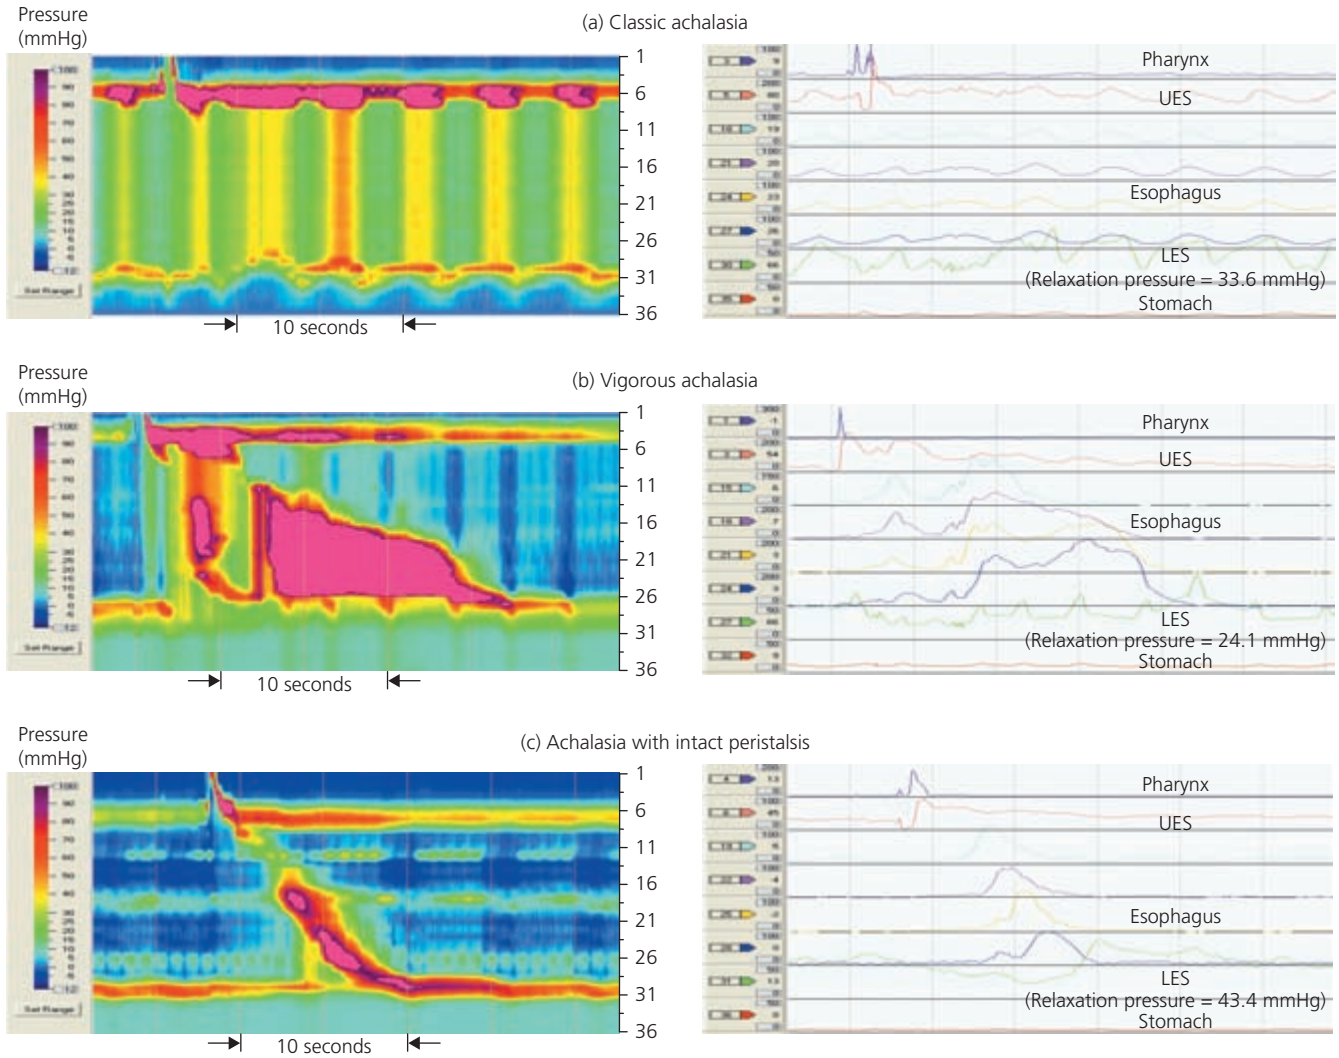

Figure 31.7 High-resolution manometric isocontour plots and conventional manometric recording in three patients with achalasia with varying peristaltic function. **(a)** Classic achalasia with aperistalsis and abnormal lower esophageal sphincter (LES) relaxation. Note the absence of the peristaltic activity and the common cavities with an abnormal increase in the esophagogastric pressure gradient. **(b)** A case of vigorous achalasia and a nondilated esophagus. Note the prolonged simultaneous contraction in the entire smooth muscle esophagus. LES relaxation is poor and the duration of relaxation is shortened as a result of the velocity of the simultaneous contraction reaching the distal esophagus. **(c)** A rare case of achalasia with intact peristalsis. Note that abnormal relaxation is associated with a normally propagating peristaltic wavefront with normal contractile pressures. Each of these patients responded to laparoscopic Heller myotomy.

Endoscopic findings

Endoscopy is relatively insensitive in the detection of achalasia with endoscopists prospectively suggesting the correct diagnosis in less than one-third of patients [51]. Typical endoscopic findings include retained food or saliva, dilation, and atony of the esophageal body. With progressive dilation and stasis, erythema, friability, and superficial ulcerations may be seen. Whitish plaques covering the epithelial surface may be seen as the result of *Candida* overgrowth; these are usually asymptomatic. The achalasic LES has a pinpoint appearance and does not open with air insufflation. Nonetheless, the instrument should pass easily through the sphincter into the stomach with minimal pressure. Resistance, or a feeling of stiffness as the endoscope crosses the EGJ, should immediately raise the suspicion of malignancy (see Pseudoachalasia). Equivocal mucosal abnormalities of the EGJ, evident on forward viewing or retroflexed inspection, should always be biopsied because of the possibility of pseudoachalasia.

Differential diagnosis

The differential diagnosis of achalasia includes both other esophageal motility disorders with functional attributes overlapping those of achalasia and diseases of distinct pathophysiology that duplicate the functional consequences of achalasia. With respect to other motility disorders, inspection of Table 31.2 suggests many similarities between esophageal

spasm and achalasia, especially vigorous achalasia. In fact, the only distinction between these entities is the demonstration of incomplete LES relaxation in vigorous achalasia. Thus, it has been speculated that in some instances esophageal spasm (and vigorous achalasia) may represent an early stage of achalasia and may evolve into full-fledged achalasia. Vantrappen and colleagues [86] first speculated on this relationship and reported several cases demonstrating just such an evolution. Recently, Khatami and colleagues [91] reported on a prospective cohort of patients diagnosed with esophageal spasm between 1992 and 2003. Review of their follow-up manometry by two independent interpreters revealed that achalasia was subsequently diagnosed in one of the twelve patients, suggesting this to be a rare occurrence. However, as will become evident later in this chapter, spastic disorders of the esophagus are a heterogeneous lot and only a small minority, at best, are part of the continuum with achalasia.

With respect to diseases of distinct pathophysiology that duplicate the functional consequences of achalasia, the main considerations are Chagas disease and pseudoachalasia. These disorders will be considered in some detail because they may resemble achalasia so closely that conventional diagnostic tests are misleading.

Chagas disease

Although achalasia is almost universally idiopathic in North America, the disease can be closely mimicked by esophageal involvement in Chagas disease, which is endemic in areas of central Brazil, Venezuela, and northern Argentina. Recently, cases have also been reported in south Texas. Chagas disease is spread by the bite of the reduviid (kissing) bug, which transmits the culprit protozoan, *Trypanosoma cruzi*. After infection, an acute septicemic phase of the illness develops, which varies in severity from being so mild as to go unnoticed to being so severe as to be fatal [92]. The chronic phase of the disease develops many years after infection and results from destruction of autonomic ganglion cells throughout the body, including the heart, gut, urinary tract, and respiratory tract. Chronic cardiomyopathy with conduction system disturbances and arrhythmias is the most common cause of death. The digestive tract organs most often affected are the esophagus, duodenum, and colon. The severity of esophageal dysfunction is directly proportional to the degree of intramural ganglion cell loss; abnormal peristalsis is first detectable after 50% of ganglion cells are destroyed and esophageal dilation only after 90% are destroyed [92]. Paralleling this, the initial dysfunction is confined to the esophageal body, with LES dysfunction occurring late in the course of the disease [92]. The most useful clinical distinction between idiopathic achalasia and esophageal involvement in Chagas disease is evidence of other tubular organ involvement (megaureter, cardiomyopathy, megaduodenum, megacolon, megarectum) in the latter. Otherwise, Chagas disease patients have the same clinical, radiographic, and manometric characteristics as those with idiopathic achalasia. The diagnosis of Chagas disease is confirmed by a serological test utilizing complement fixation or the polymerase chain reaction. The treatment of the achalasia syndrome in Chagas disease is similar to that for idiopathic achalasia. Treatment of the infection itself is of limited efficacy in the acute phase of the disease and of no proven efficacy with chronic disease.

Pseudoachalasia

It is important to emphasize that neither the radiographic nor the manometric features of achalasia are specific for idiopathic achalasia or achalasia associated with Chagas disease; tumor-related pseudoachalasia accounts for up to 5% of cases with manometrically defined achalasia. Pseudoachalasia is more likely with progressive age (> 50 years), abrupt onset of symptoms (< 1 year), and early weight loss in excess of 7 kg [53]. However, even though these criteria make pseudoachalasia more likely, they still have poor predictive value in individual cases [93]. Tumor infiltration (especially carcinoma in the gastric fundus) can completely mimic the functional impairment seen with idiopathic achalasia [94] (see Table 31.2). It is because of this potential pitfall that a thorough anatomical examination, including endoscopy, should be carried out as part of the diagnostic evaluation of every new case of achalasia. A clue to the presence of pseudoachalasia on endoscopic examination is of more than the slightest resistance of passage of the endoscope across the EGJ. In idiopathic achalasia, the endoscope should pop through with only gentle pressure required. If suspicion of pseudoachalasia persists, endoscopic biopsy, computed tomography, magnetic resonance imaging, or endoscopic ultrasound should be considered for further evaluation, depending upon the special circumstances.

Adenocarcinoma of the EGJ accounts for more than half of pseudoachalasia cases, with a myriad of tumors and miscellaneous conditions accounting for the remainder. Within the spectrum of malignancies, pancreatic, oat cell, hepatoma, bronchogenic, esophageal squamous cell, prostate, and lymphoma cases have been reported [53]. These tumors produce an achalasia syndrome by infiltrating the wall of the esophagus at the EGJ, in essence causing a malignant obstruction at the LES with proximal esophageal dilation [94]. Similarly, pseudoachalasia has also been reported to result from esophageal infiltration by amyloid [95], eosinophilic gastroenteritis [96], and sarcoidosis [97]. Although often speculated in the literature, it is less certain, and certainly much less common, that an achalasic syndrome occurs as a paraneoplastic syndrome without direct tumor stenosis of the EGJ [53].

Postfundoplication

Postfundoplication dysphagia is common in the early postoperative period and patients are often advised to consume soft diets for the first 2–4 weeks. Dysphagia that persists for longer than 2–4 weeks should be evaluated with upper

endoscopy or a barium esophagram to assess the integrity of the wrap and evaluate for possible paraesophageal hernia. Subjects without an overt mechanical disruption should be evaluated with manometry to assess peristaltic function, LES pressure, and LES relaxation to determine whether the wrap is too tight or an underlying motility disorder such as achalasia exists. Diagnosing achalasia in the context of fundoplication can be difficult as the manometric findings can be quite similar with both entities: aperistalsis and impaired LES relaxation. To distinguish mechanical obstruction due to a tight wrap or tight crural repair from a functional obstruction related to achalasia one can administer amyl nitrite during manometry and observe the effect on the EGJ high-pressure zone. The mechanical effect of a tight fundoplication should be less affected by the smooth-muscle relaxing effects of the amyl nitrite than the hypertensive sphincter of an achalasic [98].

Management

Because the underlying neuropathology cannot be corrected, treatment of achalasia is directed at compensating for the functional abnormalities and preventing complications. The main functional abnormality in achalasia is poor esophageal emptying, and this can be treated by reducing the LES pressure; with a reduced LES pressure, gravity promotes esophageal emptying. Peristalsis rarely returns with therapy. LES pressure can be reduced by pharmacological therapy, forceful dilation, or surgical myotomy. On the whole, pharmacological treatments are not very effective and are perhaps more indicated as temporizing maneuvers than definitive therapies. The definitive treatment of achalasia is still disruption of the LES either surgically (Heller myotomy) or with a pneumatic dilator. The optimal approach is an issue of debate given the lack of randomized controlled trials with accepted criteria for assessing efficacy. Thus, there is no alternative but to compare therapies based on the numerous uncontrolled series that have been published using a variety of qualitative endpoints as indications of efficacy. Table 31.4 summarizes the pooled estimate of response rate of medical and surgical treatment data in achalasia. Data in the table are uncontrolled and are consecutive series collected both prospectively and retrospectively. As there was no uniformity in assessment of efficacy among trials, the proportion with a good to excellent response was extracted from each study, regardless of criteria. Only studies including more than 10 patients and with a follow-up of 1 year were tabulated.

Pharmacological therapy

Smooth muscle relaxants such as nitrates or calcium channel blockers, administered sublingually immediately before eating, may offer partial relief of the dysphagia accompanying achalasia by reducing the resting sphincter pressure. Amyl nitrite [99], sublingual nitroglycerin [100], theophylline [100], and β2-agonists [100] have also been tried with variable results. The greatest reported experience has been with isosorbide dinitrate and nifedipine [101]. Isosorbide dinitrate (Isordil), 5–10 mg sublingually before meals, reduces the resting LES pressure by 66% for 90 min, with clinical efficacy paralleling the magnitude of LES response [102]. A 19-month trial of this therapy has been reported to provide marked or complete relief of dysphagia [102]. Side effects, particularly headache, are common. Placebo-controlled trials have not been reported.

Calcium channel blockers (diltiazem, nifedipine, verapamil) reduce the LES pressure by 30%–40% for more than an hour, with potential benefit in achalasia [102,103]. The greatest clinical experience has been with nifedipine (Procardia), which can be administered in a dose of 10–30 mg sublingually (capsules are crushed in the mouth) 30–45 min before meals. The benefit of nifedipine, 30–40 mg sublingually per day, was assessed in a group of 29 patients with early achalasia (before esophageal dilation) in a placebo-controlled trial. Nifedipine was significantly better than placebo (which had no significant benefit), yielding good to

Table 31.4 Pooled estimate of response rate of achalasia treatments across referenced studies. In calculating the weighted mean response for each treatment modality, studies were characterized by the number of subjects included (*n*) and the response rate for those subjects (*p*). excellent results in 70% of achalasics followed for 6–18 months [101]. However, subsequent placebo-controlled crossover trials have found only minimal clinical improvement with nifedipine [104]. Limiting side effects of nifedipine use are flushing, dizziness, headache, peripheral edema, and orthostasis.

Sildenafil is another smooth muscle relaxant that has been shown to decrease the LES pressure and deglutitive relaxation pressure in patients with achalasia by blocking phosphodiesterase type 5, the enzyme that destroys cyclic guanosine monophosphate induced by nitric oxide. A double-blind placebo-controlled trial revealed that 50 mg of sildenafil caused a significant decrease in LES pressure and relaxation pressure when compared with placebo [105]. The effect peaked at 15–20 min after administration and persisted for less than 1 h.

Botulinum toxin injection

Pasricha and colleagues [106] first reported the effects of botulinum toxin on the LES in achalasia patients in 1994. They found that intrasphincteric injection of botulinum toxin decreased LES pressure by 33% and improved dysphagia in 66% of patients for a 6-month period. Botulinum toxin works by irreversibly inhibiting the release of acetylcholine from presynaptic terminals, effectively eliminating the neurogenic component of LES pressure. However, as this effect is eventually reversed by the growth of new axons, it is not surprising that the effect of botulinum toxin is not long lasting. Although most patients initially experience a good response, there is minimal continued efficacy at 1 year (Table 31.4) [107–110]. The technique for administering botulinum toxin involves injecting a total of 80 units into four quadrants of the LES with a sclerotherapy catheter. Doses higher than 100 units have not been shown to be more effective [111]. Studies comparing botulinum toxin with pneumatic dilation suggest that the added expense of repeated injection outweighs the potential economic benefits of the added safety, unless life expectancy is 2 years or less [112]. Thus, this therapeutic option should be mainly reserved for elderly or frail individuals who are poor risks for more definitive treatments.

Pneumatic dilation

Therapeutic dilation for achalasia requires the forceful distension of the LES to a diameter of approximately 3 cm to partially disrupt the circular muscle of the sphincter and effect lasting reduction of LES pressure. Dilation with an endoscope or with standard bougies (up to 60F) provides very temporary benefit at best. Only balloon dilators specifically designed to treat achalasia achieve an adequate diameter for lasting effectiveness. The basic element of an achalasia dilator is a long, noncompliant, cylindrical balloon that can be positioned fluoroscopically (Rigiflex dilator) or endoscopically (Witzel dilator) across the LES and then inflated to a characteristic diameter in a controlled fashion using a hand-held manometer.

The technique of pneumatic dilation is variable among practitioners in terms of patient preparation, parameters of balloon inflation, and postdilation monitoring. There is general agreement that pneumatic dilation can be carried out in an outpatient setting with the patient under conscious sedation. In patients with substantial esophageal retention, it is useful to have them on a liquid diet for one or more days before the procedure. Reported balloon inflation pressures range from 360 mmHg (7 psi) to 775 mmHg (15 psi) with periods of inflation ranging from several seconds to 5 min [113]. Although there is minimal methodological consistency among authors, a cautious approach beginning with relatively low inflation pressures and/or a smaller diameter dilator (3.0–3.5 cm) is fairly universal.

The major complication of pneumatic dilation is esophageal perforation; mortality is very rare [114]. Most series report an incidence of esophageal perforation during pneumatic dilatation of between 1% and 5% [77,113]. Because most perforations are readily evident within a few hours of the procedure, patients should be observed closely for signs of an esophageal leak for 3–6 h after pneumatic dilation. Alternatively, some practitioners routinely obtain a fluoroscopic examination of the esophagus following pneumatic dilation to make sure that perforation has not occurred. Usually, water-soluble contrast is given first, followed by barium. If the perforation appears small and confined, or intramural, conservative management consisting of close observation while maintaining the patient nil per os (NPO) and administering intravenous antibiotics is appropriate [77]. If any substantial perforation has occurred, or if worsening pain and fever occur during observation of what was thought to be a small perforation, surgical repair should be pursued quickly. Patients with perforation from pneumatic dilation that is recognized and promptly treated surgically (within 6–8 h) have outcomes that are comparable to those of patients undergoing elective Heller myotomy [115].

The best predictor of efficacy following a pneumatic dilation is the postdilation LES pressure; neither sphincter relaxation nor peristaltic function is significantly changed. LES pressure values of less than 10 mmHg are associated with prolonged remission whereas values of more than 20 mmHg derive little benefit from the procedure [89]. It is neither unusual nor dangerous to repeat a pneumatic dilation 2–3 times in instances of an unsatisfactory result. The clinical efficacy of dilation has been reported to range from 32% to 98% (Table 31.4) [107]. Patients having a poor initial result or rapid recurrence of symptoms have a diminished likelihood of responding to additional dilations [107]. Subsequent response to surgical myotomy is not influenced by the history of previous dilations [116].

Heller myotomy

The surgical objectives in the treatment of achalasia are to reduce the LES pressure enough to eliminate dysphagia but

not so much as to allow gastroesophageal reflux. Current procedures are variations on the esophageal myotomy described by Heller in 1913 [107]. In Heller's operation, an anterior and posterior myotomy were performed through either a laparotomy or a thoracotomy. Although clearly efficacious, open Heller myotomy is associated with considerable morbidity related to thoracotomy, which led most patients to pursue pneumatic dilation as the initial intervention. However, adoption of the laparoscopic approach for achalasia surgery has led many practitioners to use surgery as an initial intervention because this technique offers similar efficacy to the open procedure and substantially reduced morbidity.

Surgical series of achalasics treated with myotomy report good to excellent results in 62%–100% of patients, with persistent dysphagia troubling less than 10% of patients overall (Table 31.4) [107]. The appeal of myotomy is that it offers a more predictable method of reducing LES pressure than pneumatic dilation [117]. Studies have suggested that laparoscopic and thoracoscopic approaches are associated with similar efficacy and reduced morbidity when compared with myotomy via thoracotomy or laparotomy [107,118–123]. Patti and colleagues [120] reported the clinical outcomes of 168 achalasic patients who underwent thoracoscopic myotomy (35 patients) or laparoscopic Heller myotomy accompanied by a partial fundoplication (133 patients). There were no deaths in this series and only eight patients required reoperation. Relief of dysphagia was obtained in 93% of the patients who underwent the laparoscopic Heller myotomy and 85% of those treated with thoracoscopic myotomy. Not only did the laparoscopic approach more effectively improve dysphagia, it was also associated with a shorter hospital stay and less postoperative gastroesophageal reflux. Historically, postmyotomy reflux in achalasics could be particularly severe [124]. However, with the availability of proton pump inhibitors, reflux is usually easily controlled, making these complications very unlikely. Thus, laparoscopic Heller myotomy combined with a partial fundoplication has become the preferred surgical procedure for achalasia.

Occasionally, patients fail to respond to dilation and myotomy and require more extensive surgical procedures. In extremely advanced or refractory cases of achalasia, esophageal resection with gastric pull-up or interposition of a segment of transverse colon or small bowel may be the only surgical option [125,126]. Indications for this intervention include unresolvable obstructive symptoms, cancer, and perforation during dilation. Although excellent long-term functional results can be achieved, the reported mortality rate of this surgery is about 4%, consistent with the mortality rate of esophagectomy carried out for other indications.

Medical versus surgical treatment

Although pharmacological therapy is simple and safe, it has become increasingly clear that this should be reserved for use as a temporizing measure while more definitive therapy is being considered. Thus, practically speaking, the choice is between pneumatic dilation and laparoscopic Heller myotomy as the primary therapy for achalasia. However, there are no prospective controlled trials comparing these treatments. One controlled trial exists comparing pneumatic dilation with myotomy via thoracotomy [127]. This study reported 95% symptom resolution with myotomy and 51% symptom resolution in the dilation group, but the study was criticized for the methodology of pneumatic dilation utilized. Most studies report symptom resolution in approximately 70% of patients after pneumatic dilation, substantially higher than the 51% reported in the controlled trial but still substantially lower than that reported in uncontrolled series of laparoscopic Heller myotomy (Table 31.4). Furthermore, although laparoscopic Heller myotomy is invasive, its morbidity rate is low. On the other hand, pneumatic dilation has a perforation rate that averages 3%. Even though these patients do well if the perforation is recognized and operated on promptly, they require a thoracotomy. Thus, it appears that, in expert hands, laparoscopic Heller myotomy is likely the optimal initial therapy when one considers both the safety and efficacy of the procedure.

Risk of squamous cell cancer

Numerous series report cases of squamous cell carcinoma developing in the achalasic esophagus [128,129], and the relative risk of developing squamous cell cancer has been estimated to be 33-fold higher than in the nonachalasic population [130]. The pathogenesis of the carcinoma is obscure, but stasis and mucosal irritation may be precipitating factors. The tumors develop many years after the diagnosis of achalasia. Because the tumors often arise in a greatly dilated esophagus, symptoms can be delayed and the neoplasms are large and advanced at the time of detection. These considerations raise the issue of surveillance endoscopy in achalasics to detect early squamous cell cancer. However, an elegant analysis by Sandler and colleagues [131] of a database encompassing the entire Swedish population of 1062 achalasics suggests that, after discounting incident carcinomas, the overall squamous cell cancer risk for achalasics is 17-fold higher than for age-matched control subjects, resulting in a 0.15% incidence of cancer among the achalasics [131]. The authors calculated that if surveillance endoscopy was carried out annually, 406 exams would need to be carried out in men and 2220 in women before one, potentially treatable tumor was found.

Spastic disorders

The concept of "esophageal spasm" is credited to Hamilton Osgood based on his 1889 description of six patients with episodic chest pain and dysphagia: "sudden and often intense constriction in the epigastrium . . . with an arrest of food at the cardiac orifice" [132]. From the time of that report,

further insights into the entity of esophageal spasm have paralleled the development of imaging or measurement technologies that might detect it. "Diffuse spasm of the lower part of the esophagus" was first described radiographically in 1934, and the first manometric descriptions of spasm came in the late 1950s. Introduction of the term "diffuse esophageal spasm" and our present concept of this entity followed Fleshler's 1967 description of a "clinical syndrome characterized by symptoms of substernal distress or dysphagia or both, the roentgenographic appearance of localized, nonprogressive waves (tertiary contractions), and an increased incidence of nonperistaltic contractions recorded by intralumenal manometry" [133].

In broad terms, diffuse esophageal spasm (DES) as described by Fleshler represents a disorder of peristalsis. However, the esophagus of the patient with DES usually retains its ability to propagate normal primary peristaltic waves for the majority of the time, suggesting that the responsible neuromuscular pathology must be subtler than with achalasia. Partly because of this fact, the criteria for diagnosing DES (which is the best accepted of the proposed disorders of peristalsis) remain variable and confusing [134]. Furthermore, along with the evolution of manometric techniques capable of accurately recording intralumenal esophageal contractile activity came the description of other minor aberrations of peristalsis (nutcracker esophagus, hypertensive LES, and nonspecific esophageal motor disorder) to which symptomatology, especially chest pain, might be attributed [135]. Despite this proliferation of literature, it remains controversial whether or not these entities have any clinical significance. The heterogeneity among patients, the absence of specific pathology, and the absence of well-defined clinical implications caution against considering them akin to achalasia. Strict criteria for defining a disease would stipulate that the peristaltic abnormality cause a major alteration of esophageal physiology demonstrable by both manometric and nonmanometric measures, and that it be temporally associated with symptoms, with correction resulting in symptomatic improvement [136]. If such criteria are applied to these aberrations of peristalsis, only severe DES would be judged significant [136]. Indicative of this, esophageal transit was recently assessed in a prospective cohort of 350 patients using multichannel intralumenal impedance [137]. Entities such as nutcracker esophagus and hypertensive LES exhibited normal bolus transit and only 50% of patients with esophageal spasm had abnormal bolus transit. Thus, even esophageal spasm is a heterogeneous group with varying degrees of functional compromise. With this caution in mind, consider what has been learned of spastic disorders of peristalsis.

Neuromuscular pathology

The esophageal muscularis propria and myenteric plexus are not readily accessible for biopsy, resulting in little material being available for histopathological examination. Furthermore, patients with spastic disorders of the esophagus rarely undergo esophageal surgery and the diseases are not fatal, making for a paucity of pathological specimens; the limited information that does exist pertains only to DES as opposed to the minor aberrations of peristalsis. The most striking reported pathological change is diffuse muscular hypertrophy or hyperplasia, mainly of the distal two-thirds of the esophagus. Muscular thickening of up to 2 cm has been reported in patients with clinical and manometric evidence of DES [138]. However, there are other well-documented cases of spasm in which esophageal muscular thickening was not found at thoracotomy [139], and still other instances of patients with muscular thickening not associated with DES symptoms [140]. Similarly, little evidence of neuropathology has been reported; diffuse fragmentation of vagal filaments, increased endoneural collagen, and mitochondrial fragmentation have been described but the significance of these findings is unclear [141].

Pathophysiology of spastic disorders of peristalsis

Esophageal spasm

Despite the absence of defined histopathology, physiological evidence implicates myenteric plexus neuronal dysfunction in spastic disorders of the esophagus. During peristalsis, vagal impulses reach the entire smooth muscle segment of the esophagus simultaneously and activate myenteric plexus neurons between the longitudinal and circular muscle layers [142]. Ganglionic neurons then intervene between the efferent vagal fibers and the smooth muscle, belonging to either an inhibitory population (using nitric oxide as a neurotransmitter) that hyperpolarizes the muscle cell membrane and inhibits contraction or an excitatory (cholinergic) population that depolarizes the membrane thereby prompting contraction. Thus, the instantaneous activity of the musculature at each esophageal locus is determined by the balance between these controlling influences from the myenteric plexus. Experimental evidence suggests heterogeneity among patients with spastic disorders such that some primarily exhibit a defect of inhibitory interneuron function, whereas in others the defect is of excess excitation.

Two in vivo experiments implicate a defect of myenteric plexus inhibitory interneuron function in the genesis of simultaneous contractions in the distal esophagus. Behar and Biancani [143] timed the propagation of a swallow-induced contraction in normal subjects and in a group of patients whose dominant manometric abnormality was of a simultaneous contraction in the distal 10 cm of the esophagus. Figure 31.8 illustrates the key finding of that work. Note that within the proximal (striated muscle) esophagus the two groups exhibited a similar contraction propagation, consistent with this timing being the result of the sequenced activation of motor units by vagal efferents programmed within the medullary swallowing center. However, once entering

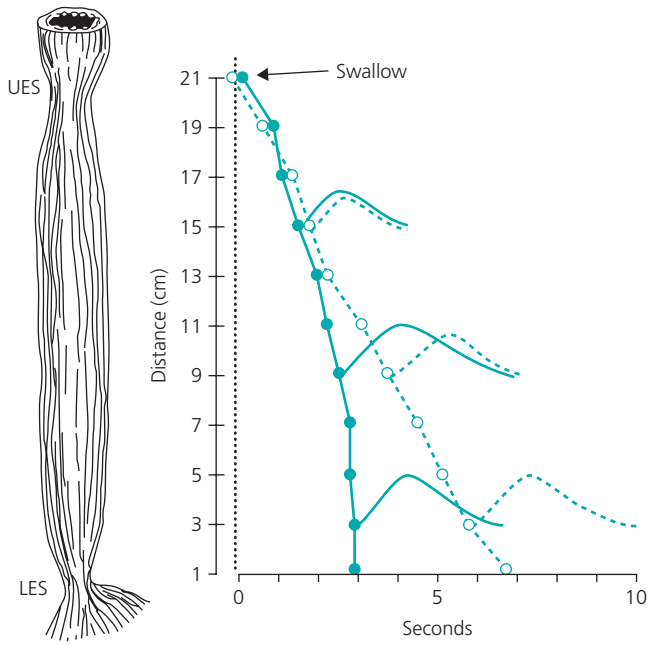

Figure 31.8 Rate of propagation of an esophageal contraction in individuals with normal peristalsis (open circles) and a group of patients with a motor disorder characterized by dysphagia and simultaneous contractions in the distal esophagus (filled circles). Note that the propagation is similar between the two groups in the proximal (striated muscle) esophagus but diverges in the distal (smooth muscle) esophagus. As the prolonged latency in the distal esophagus is believed to be a function of postganglionic inhibitory interneurons within the myenteric plexus, this suggests selective dysfunction of these cells. From Behar and Biancani [143], with permission.

the smooth muscle segment, the patients' contractions diverged from those of the normal subjects, resulting in a simultaneous contraction in the distal esophagus. The duration and amplitude of contraction at each esophageal locus was normal in patients, but the progressive delay of initiation of that contraction, a function attributable to the increasing influence of inhibitory interneurons in the distal esophagus, was absent. Furthermore, if these individuals swallowed twice within a 5-s interval, there was no deglutitive inhibition of the first peristaltic contraction within the smooth muscle esophagus as is observed in normal subjects. Another experiment demonstrating impaired deglutitive inhibition in DES comes from work using an artificial high-pressure zone within the distal esophagus. Patients with motor disorders characterized by rapidly propagating or simultaneous contractions exhibited only partial relaxation of the artificial high-pressure zone, proportional to the impairment of propagation velocity [75]. Taken together, these findings strongly suggest that one potential neuropathological process in DES is a selective, intermittent dysfunction of myenteric plexus inhibitory interneurons.

The above discussion suggests that the physiological abnormalities of patients with spastic disorders are heterogeneous, but all are characterized by an imbalance between the excitatory and inhibitory influences on the esophageal smooth muscle. The suggestion of an impairment of the pathway of deglutitive inhibition is particularly interesting in that it places DES in a pathophysiological continuum with achalasia, consistent with documented case reports of patients undergoing this evolution [86]. Furthermore there are marked similarities between vigorous achalasia and DES, both being characterized by simultaneous contractions of the esophageal body; the only differences are involvement of the LES and constancy of the disorder in vigorous achalasia. Similar to achalasia, the simultaneous contractions typifying diffuse esophageal spasm impair bolus transit through the esophagus, potentially explaining the associated dysphagia [144].

Nutcracker esophagus

Considerable attention has been focused on the clinical significance of the disorders of peristalsis other than DES described in Table 31.5, particularly "nutcracker esophagus." Esophageal bolus transit is normal in this condition [39,137] and no associated neuromuscular pathology is recognized. As outlined earlier, dysfunction of the excitatory population of interneurons within the myenteric plexus, or abnormal excitability of the muscle itself, can also cause an aberration of peristalsis. Several lines of evidence suggest instances of excess excitation in response to hormonal or cholinergic stimulation. Representative of such an abnormality is a second group of patients in the analysis of Behar and Biancani whose main manometric abnormality was of frequent spontaneous distal esophageal contractions. These patients had a normal propagation latency as defined by the parameters of Figure 31.8 but a significantly longer and higher amplitude contraction at each locus within the smooth muscle [143]. Examining the categorization of disorders of peristalsis outlined in Table 31.5, these individuals would be labeled as having nutcracker esophagus. Patients with peristaltic disorders characterized by excess excitation demonstrate heightened sensitivity to stimulation with cholinergic agents [70,145], the cholinesterase inhibitor edrophonium [146], pentagastrin [147], and ergonovine (ergometrine) [148]. An electromyographic correlate of this excitability is found from bipolar ring electrode recordings from the distal esophagus [149]. Whereas normal individuals uniformly exhibited spiking activity before each esophageal contraction, DES patients exhibited spike-independent spontaneous esophageal contractions.

A few instances in which nutcracker esophagus patients are subsequently diagnosed with achalasia have been reported [150,151], but considering the rarity of this observation and the high prevalence of nutcracker esophagus, the association is most likely explained by chance. No correlation has been shown between the severity of nonspecific peristaltic abnormalities and the severity of symptoms [152,153]. Long-term observation has shown neither a parallel

Table 31.5 Manometric criteria for disorders of peristalsis

Peristaltic disorder	Required finding	Associated finding
Diffuse esophageal spasm	Simultaneous contractions with > 30% of water swallows	Repetitive contractions (> 2 peaks); prolonged contractions (> 6 s); high-amplitude contractions (> 180 mmHg); spontaneous contractions, incomplete LES relaxation; increased LES pressure (> 40 mmHg)
Nutcracker esophagus	Mean distal esophageal peristaltic amplitude > 180 mmHg	Repetitive contractions (> 2 peaks); prolonged contractions (> 6 s); increased resting LES pressure (> 40 mmHg)
Hypertensive LES	Increased resting LES pressure (> 40 mmHg); normal LES relaxation	
Nonspecific esophageal motor disorder	Peristaltic abnormalities insufficient to establish any other diagnosis	Frequent nontransmitted contractions (> 20% water swallows); retrograde contractions; repetitive contractions (> 2 peaks); low-amplitude contractions (< 30 mmHg); prolonged contractions (> 6 s); high-amplitude contractions (> 180 mmHg); spontaneous contractions; incomplete LES relaxation

LES, lower esophageal sphincter.

in clinical course with manometric findings nor consistency in manometric diagnosis over time [154]. A therapeutic trial with nifedipine showed that a significant reduction of wave amplitude in nutcracker esophagus patients was not accompanied by a significant reduction in chest pain [155]. On the other hand, a controlled trial of trazodone produced significant symptomatic improvement but no change in manometric findings [156]. One controlled trial demonstrated an association of symptomatic and manometric improvement with diltiazem, but the correlation for individual subjects was not reported [157]. Finally, provocation of nonspecific motility abnormalities with cholinergic stimulation has not proven useful in detecting patients who are subsequently responsive to pharmacological treatment [158]. In summary, it has been difficult to determine a direct relevance of nonspecific motility disturbances to either symptoms or function, making their detection of no generalizable clinical value.

Epidemiology

No population-based studies exist on the incidence or prevalence of esophageal motility disorders other than achalasia. Thus, the only way to estimate the incidence or prevalence of spastic disorders is to examine the data on populations at risk and reference the observed frequency of spastic disorders to the incidence of achalasia, which, as detailed earlier, is about 1/100 000 population per year. Populations at risk for motility disorders are patients with chest pain and/or dysphagia, and so it is among these patients that extensive manometric data have been collected. As detailed in Table 31.6, summarizing representative studies of at least 30 subjects, manometric abnormalities are prevalent among these groups [128,135,159–168]. Asymptomatic volunteers (usually younger than the patients) were evaluated to define normal values in five of these studies [128,160,167–169]. The manometric pattern of achalasia was not detected in any of the volunteers. Similarly, although diffuse esophageal spasm is more variably defined than achalasia [134], simultaneous contractions following 30% or more of swallows were not found in any of the volunteers [167].

The majority of the manometric findings among the patients in Table 31.6 fall under the categories other than DES described in Table 31.5. Of this group, increased wave amplitude (nutcracker esophagus) is the most commonly detected pattern, accounting for a large proportion of the patients in the "nonspecific disorders" category. Variability in the prevalence values of the nonspecific disorders in Table 31.5 is partly attributable to a lack of uniform definitions of the motility disorders listed as well as to the inhomogeneity of patient populations studied.

Clinical presentation

The major symptoms of spastic disorders are dysphagia and chest pain; regurgitation is infrequent compared with achalasia. The prevalence of chest pain is constant among the spastic disorders listed in Table 31.5, but the prevalence and severity of dysphagia is greater with DES [153]. Among the individuals with chest pain as a dominant symptom, there is a high prevalence of psychiatric diagnosis, particularly anxiety and depression [170]. Evidence also exists suggesting a lower visceral pain threshold in this group; balloon distention and esophageal compliance studies reproduce esophageal pain at low distending volumes without corresponding motor changes [171,172]. Finally symptoms compatible with the irritable bowel syndrome may be seen in more than 50% of these patients [173].

Dysphagia for both liquids and solids is reported by 30%–60% of patients with spastic disorders [153,161]. Dysphagia

is usually intermittent in occurrence, sometimes related to swallowing specific substances or liquids at extreme temperature. Dysphagia is usually not progressive and weight loss is rare. In some instances, spasm patients experience episodes of esophageal obstruction while eating that persist until relieved by emesis; these instances are probably related to simultaneous prolonged DES-type contractions. More commonly, the dysphagia reported by patients with spastic disorders does not prevent or prolong eating.

Intermittent substernal chest pain is reported by 80%–90% of patients with spastic disorders [153,161]. Esophageal chest pain is very similar to angina, usually described as crushing or squeezing in character, often radiating to the neck, jaw, arms, or midline of the back. Pain episodes may last from minutes to hours, but swallowing is usually not impaired during these episodes. Severe pain episodes may require narcotics or nitroglycerin for relief, further confusing the distinction between esophageal and cardiac pain. The mechanism producing pain is poorly understood; transient ischemia, lumenal distension, and altered visceral sensitivity have all been hypothesized [171,174,175]. However, it is more likely that the mechanism responsible for esophageal pain is variable among individuals.

Radiographic, impedance, and manometric findings

Spastic motor disorders of the esophagus have no pathognomonic endoscopic features. However, endoscopy is useful in the evaluation of patients with dysphagia or suspected esophageal pain to identify either structural lesions or reflux esophagitis. Typically, spastic disorders are defined by manometry or barium radiography, the abnormal motor events are usually intermittent, and there are no uniform radiograpic or manometric definitions. Radiographically, a "corkscrew esophagus," "rosary bead esophagus," pseudodiverticula, or curling are indicative of DES (Fig. 31.9). It must be emphasized, however, that neither tertiary contractions (nonperistaltic, simultaneous esophageal contractions) on radiography nor an occasional simultaneous contraction on manometry are pathognomonic of esophageal spasm as both may be seen in asymptomatic individuals [135].

The manometric feature that is universal among proposed classification schemes for DES is the occurrence of simultaneous contractions [134]. However, beyond that there is little agreement as to how frequently such contractions need to occur or whether they must exceed a threshold amplitude to qualify [176]. With respect to frequency, the observation

Figure 31.9 Corkscrew esophagus on barium radiography in a patient with symptomatic diffuse esophageal spasm.

that simultaneous contractions with 30% or more of swallows have not been found in normal volunteers argues in favor of accepting that threshold. As for an appropriate threshold amplitude for what constitutes a "spastic" contraction, simultaneous low-amplitude contractions occur in scleroderma, amyloidosis, pseudo-obstruction, alcoholic neuropathies, and GERD, all entities from which DES should be distinguished. Recognizing that the functional significance of these low-amplitude pressure waves is different from that of high-amplitude contractions, Spechler and Castell [177] recently proposed adding a second necessary manometric criterion for DES that would incorporate a minimum amplitude of 30 mmHg for simultaneous contractions, based on functional studies assessing bolus transit. Although this new manometric criterion should improve the specificity of manometry in detecting clinically meaningful DES, it may still be too inclusive of insignificant contractile events and it remains to be seen how much of a difference it will make.

In the unequivocal case, nonperistaltic, high-amplitude, prolonged contractions are seen during esophageal manometry and these are associated with the patient experiencing pain (Fig. 31.10). These unequivocal cases are probably related to a defect in the neuronal architecture of the myenteric plexus, placing them along the continuum of vigorous achalasia and achalasia (Table 31.2) [75]. The LES typically functions normally. One hypothesized explanation for the limited sensitivity of esophageal manometry in detecting spasm is that abnormal motor events escape detection because of sampling error. As both chest pain and spasm are sporadic events, the likelihood of documenting both in a brief bedside study seems slim. This perception fostered the development of ambulatory esophageal manometry systems capable of longer recording intervals with the hope of correlating spontaneously occurring symptoms with abnormal esophageal motility. Unfortunately, despite multiple examinations of this technology, no consensus exists among investigators regarding scoring techniques or the utility of this technology in establishing abnormal esophageal motility as the cause of "noncardiac" chest pain. One report of combined ambulatory manometry and pH studies in a highly selected group of patients acutely hospitalized for attacks of chest pain showed that up to 43% of patients had pain associated with episodes of acid reflux, but there was little additional yield from the manometric data [178]. Thus, at present, ambulatory manometry remains an investigational technique, with scoring criteria and symptom-association criteria remaining to be established. The variability in results evident in published trials can easily be explained by differences in patient populations studied and analysis schemes utilized. Furthermore, the evolving picture suggests that motor abnormalities play a less significant role than previously suggested in chest pain and that reflux disease plays a much more significant role [179]. Bancewicz and colleagues [162] found that intensive antireflux therapy was the most useful therapy for a large group of symptomatic patients without a specific motor disorder. Similarly, Achem and colleagues [180] found that antireflux therapy benefited patients with unexplained chest pain, regardless of the presence or absence of nonspecific motor abnormalities.

Differential diagnosis

Although abnormal peristalsis can potentially cause dysphagia and chest pain, significant abnormalities are rare, as suggested by the data in Table 31.6. Furthermore, unlike angina pectoris, the pain of which it can closely mimic, esophageal dysmotility is not life threatening. Features suggesting an esophageal as opposed to a cardiac etiology include:

- pain that is nonexertional and prolonged
- pain that interrupts sleep
- pain that is meal-related
- pain relieved with antacids
- the presence of additional esophageal symptoms of heartburn, dysphagia, or regurgitation.

However, each of these characteristics still exhibits overlap with cardiac pain in some instances. Thus, an esophageal

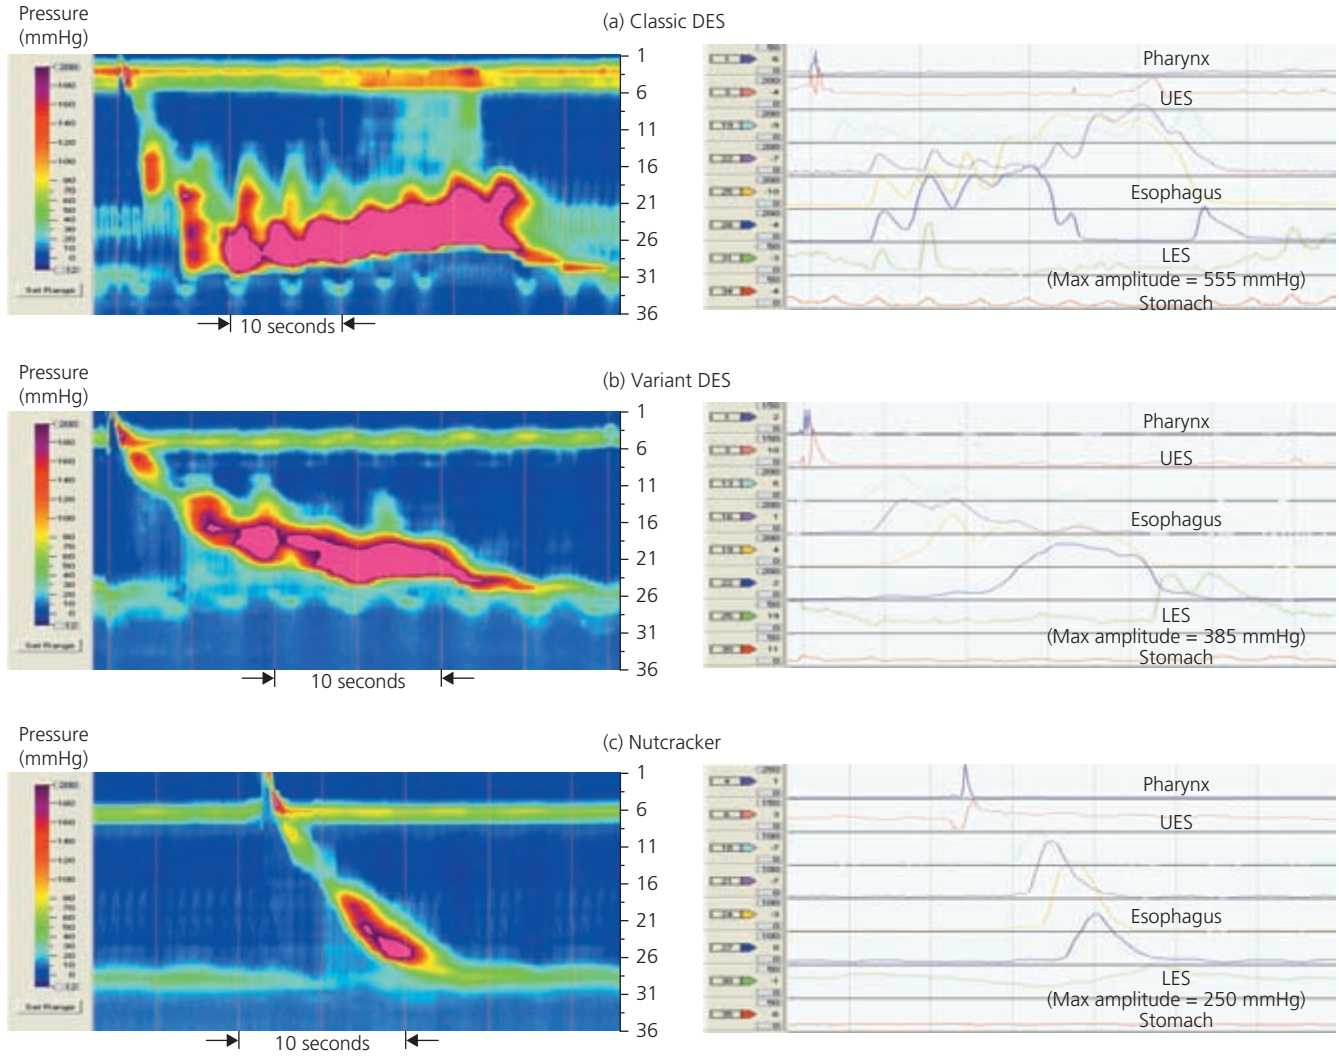

Figure 31.10 High-resolution manometric isocontour plots and conventional manometric recordings of three patients with varying spastic disorders of peristalsis. **(a)** Example of classic diffuse esophageal spasm (DES). This disorder is characterized by simultaneous contractile activity along the smooth muscle esophagus. The peristaltic amplitudes are elevated and the spastic event is prolonged. **(b)** Variant of esophageal spasm that has a normally propagating peristaltic wavefront; however, the peristaltic amplitudes are elevated and prolonged. This is different from **(c)**, representing classic "nutcracker esophagus," which has normal propagation of the peristaltic wavefront with elevated contractile amplitudes and normal contractile duration.

etiology of chest pain should be considered only after careful consideration and evaluation of potential cardiopulmonary etiologies. Furthermore, even within the spectrum of esophageal diseases, neither chest pain nor dysphagia is specific for a spastic disorder as both symptoms are also characteristic of common esophageal disorders, including peptic or infectious esophagitis. After these more common diagnostic possibilities have been excluded by appropriate radiographic evaluation, endoscopic evaluation, and, in some instances, a therapeutic trial of antisecretory medications, spastic disorders should be considered as the etiology of the still unexplained symptoms.

Treatment

Ironically, the medical therapies of esophageal spasm are similar to those of coronary artery disease, a disease with which it can be confused. However, despite the dogma of treatment with smooth muscle relaxants, there is a paucity of data on the medical treatment of esophageal spasm. Long-term outcome studies of the medical treatment of DES with smooth muscle relaxants are not available. Nitrates [181], calcium channel blockers [182], and hydralazine [183] have all been shown to be beneficial in small trials. In addition, botulinum toxin injected at the EGJ has also been used with some success in patients with nonachalasia esophageal

spasm [184]. The only double-blind placebo-controlled trial showing efficacy with medical therapy is in the case of the anxiolytic trazodone, suggesting that reassurance and control of anxiety are important therapeutic goals [156]. Consistent with this conclusion, successful management of symptoms associated with spastic motility disorders have also been reported using behavioral modification programs and biofeedback [185].

Although the rationale is unclear, esophageal dilation with standard mercury-filled dilators has also been suggested as a therapy for dysphagia or chest pain in patients with spastic disorders. However, in the only controlled trial of this therapy, dilation with an 8-mm ("placebo") dilator was as effective as an 18-mm dilator in producing transient symptom relief [186]. Alternatively, pneumatic dilation has been used in DES patients with severe dysphagia [77,187]. In one practitioner's experience, 45% of DES patients noted relief compared with 80% of achalasics [77]. In another series of nine patients with DES and LES dysfunction treated with pneumatic dilation, dysphagia but not chest pain improved during 37 months of observation [187]. However, it is not clear what distinguishes this group of patients from patients with vigorous achalasia, implying that patients likely to derive benefit from pneumatic dilation are those with mixed features of achalasia and DES as described by Vantrappen and colleagues [86].

If dysphagia becomes so severe that weight loss is observed or if pain becomes unbearable, surgical therapy consisting of a Heller myotomy across the LES with proximal extension of the incision to include the involved area of spasm should be considered [188,189]. However, there are no controlled studies of this treatment in well-defined DES patients and the indication for this procedure is extremely rare.

In summary, the therapy of esophageal spastic disorders is as poorly defined as are the spastic disorders themselves. Clearly, most esophageal pain is attributable to reflux, irrespective of the presence or absence of minor motility abnormalities, and antireflux therapy should be extensively pursued before attempting therapy of a spastic disorder. Within the range of motility disorders, achalasia stands alone as a well-defined disease. Partially overlapping achalasia is DES, a disorder characterized by a severe peristaltic defect with functional and symptomatic consequences in some cases. Interestingly, DES most likely responds to specific therapy when it exhibits characteristics indicative of vigorous achalasia, implying that it is part of a pathophysiological continuum in these cases (Fig. 31.11). Alternatively, episodic esophageal spasm may be a manifestation of GERD, a disorder for which very effective therapy exists.

With respect to other esophageal motility disorders (nutcracker esophagus, hypertensive LES, and nonspecific disorders), in extreme circumstances they may mimic DES in symptomatology and can exhibit profound esophageal hypercontractility; however, there are no significant controlled data suggesting that these patients benefit from antispasmotic therapy. In view of the unproven value of detecting these manometric aberrations, practice guidelines do not support pursuing them in the evaluation of chest pain patients. Rather, until the meaning of these aberrations of esophageal motility are clarified, we should not overlook therapy aimed at the most common esophageal disorder, GERD, or more global conditions such as depression or somatization neurosis that are coexistent in these patients (Fig. 31.11).

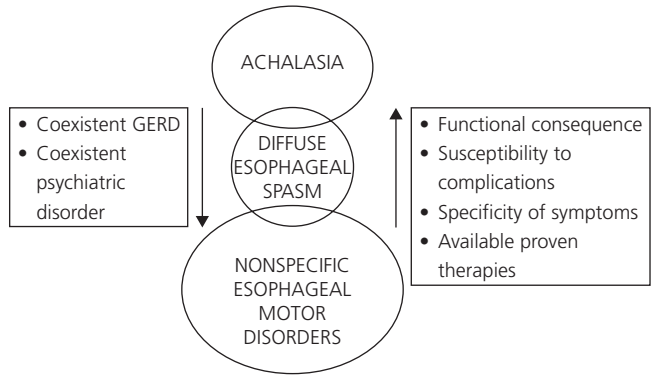

Figure 31.11 The range of esophageal motility disorders. Some overlap exists between adjacent entities as suggested by the Venn diagram. The attributes indicated on the left are increasingly relevant moving down the diagram whereas those on the right are increasingly applicable moving up the diagram. From Kahrilas PJ. Esophageal involvement in systemic disease

Esophageal dysmotility occurs as a manifestation of several disease processes with the potential to affect smooth muscle or the autonomic nervous system. Included are collagen vascular diseases, infiltrative diseases such as amyloidosis or malignancies, metabolic disorders such as thyrotoxicosis and diabetes, and caustic injury as occurs with gastroesophageal reflux. However, esophageal involvement is well characterized only with collagen vascular diseases, diabetes, and reflux disease. Dysmotility associated with reflux disease is discussed in Chapter 32; the following discussion focuses on esophageal involvement in the collagen vascular diseases and diabetes.

Scleroderma

Scleroderma causes diffuse fibrosis and degenerative changes in the skin and synovium. The disease also has the potential to involve the heart, kidneys, lungs, intestines, and esophagus. Caucasian women between 30 and 50 years of age are the most commonly afflicted. Two forms of scleroderma are recognized: progressive systemic sclerosis with diffuse

scleroderma (the more fulminant form with early involvement of internal organs) and the CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia). The basic disease process is of smooth muscle atrophy with subsequent fibrosis. With either form of scleroderma, the esophagus is involved in 75%–85% of cases [190,191]. Pathological changes are confined to the smooth muscle portion of the esophagus resulting in aperistalsis and atony of the LES [192].

The main clinical manifestations of scleroderma esophagus are dysphagia and heartburn. Symptomatic patients usually have Raynaud phenomenon, but the severity of the esophageal disease does not covary with the disease severity in other organs [193]. The prevalence of erosive esophagitis may be as high as 60%, with reported cases of Barrett metaplasia and Barrett adenocarcinoma [194,195]. Dysphagia may be attributable to poor peristalsis or to a stricture complicating the peptic esophagitis (seen in as many as one-third of patients) [195]. Radiographic findings typically consist of a slightly dilated aperistaltic esophagus and free reflux. Wide-mouth diverticula of the esophagus, similar to those described in intestines, have also been seen [191]. Manometric abnormalities consist of a hypotensive or absent LES pressure, hypotensive to absent distal esophageal peristalsis, and normal proximal esophageal peristalsis [190]. There is no specific treatment for the esophageal involvement in scleroderma. Gastroesophageal reflux should be identified and treated commensurate with its severity. Strictures may require frequent dilation and, in rare cases of intractable esophagitis, antireflux surgery may be required [196].

Other collagen vascular and connective tissue diseases

Esophageal symptoms are uncommon in systemic lupus erythematosus, although 25%–35% of unselected patients have the manometric findings of hypotensive peristalsis and a hypotensive LES [197,198]. Mixed connective tissue disease exhibits a mixture of the clinical features found in scleroderma, polymyositis, and systemic lupus erythematosus, and is characterized by high titers of a circulating antibody for a nuclear ribonucleoprotein antigen. More than 60% of patients with mixed connective tissue disease have esophageal involvement defined by cineradiography [199] and up to 82% of patients have manometric findings [197]. Abnormalities of both smooth and skeletal muscle are found. In the largest report to date [197], 5 of 17 patients had a manometric pattern consistent with scleroderma, and 10 patients had aperistalsis of the entire esophageal body along with low pressures in both the upper and lower sphincters.

Diabetes mellitus

More than 60% of diabetic patients with peripheral or autonomic neuropathy and an occasional patient without neuropathy have esophageal manometric abnormalities [200]. Reported manometric abnormalities associated with diabetes include hypotensive peristalsis, frequent failed peristalsis, hypotensive LES with impaired deglutitive relaxation, simultaneous contractions, and repetitive contractions [200,201]. The significance of these abnormalities is uncertain because most of these patients are asymptomatic [200]. Histological and pharmacological studies suggest that the esophageal abnormalities are secondary to the degenerative effects of diabetes mellitus on the autonomic nervous system rather than smooth muscle dysfunction.

Presbyesophagus

Manometric studies from the 1960s on men over the age of 80 suggested that aging was associated with failed peristalsis, decreased LES relaxation, and an increase in spontaneous contractions [202]. Symptoms correlated poorly with these findings leading to the introduction of the term "presbyesophagus" to describe incidental asymptomatic peristaltic abnormalities in the elderly. More recently, a study of patients over the age of 70, carefully screened to rule out diabetes or neurological disease, found no increased incidence of peristaltic abnormalities in the elderly compared with young control subjects [203]. The only difference found was decreased peristaltic amplitude in the elderly group suggesting that age in itself does not lead to peristaltic dysfunction. Thus, cases of "presbyesophagus" are likely related to comorbid conditions commonly encountered in the elderly.

Gastroesophageal reflux disease (GERD) results from the failure of the normal antireflux mechanism to protect against frequent and abnormal amounts of gastroesophageal reflux (GER), that is, the effortless movement of gastric contents from the stomach to the esophagus. GER is not itself a disease, but a normal physiological process. It occurs in virtually everyone, multiple times a day, especially after large meals, without producing either symptoms or signs of mucosal damage. In contrast, GERD is a spectrum of disease usually producing symptoms of heartburn and acid regurgitation. Most patients have no visible mucosal injury at the time of endoscopic examination (nonerosive GERD), whereas some have esophagitis, peptic strictures, Barrett esophagus, or evidence of extraesophageal diseases such as chest pain, pulmonary symptoms, or ear, nose, and throat symptoms. GERD is a multifactorial process, one of the most common human diseases, and of economic importance, contributing to the expenditure in the United States of US$4–5 billion per year for antacid medications.

Epidemiology

The prevalence of GERD differs depending on whether the analysis is based on symptoms (primarily heartburn) or signs (i.e., esophagitis) of disease. When based on symptoms, GERD is common in Western countries. For example, in a nationwide population-based study by the Gallup Organization in the United States [1], 44% of the population reported having heartburn at least once a month. More convincing data were obtained by Locke and colleagues [2], who mailed out 2200 validated self-report questionnaires to a predominantly white population residing in Olmsted County, Minnesota. The prevalence of heartburn and acid regurgitation in the previous 12 months were noted to be 42% and 45% respectively. Frequent symptoms (at least weekly) were reported by 20% of respondents, with an equal gender distribution across all ages. The majority reported that heartburn was of moderate severity and had a duration of 5 years or more, and only 5.4% reported a physician visit for reflux complaints within the previous year. More variable prevalence rates for symptomatic GERD have been reported from Europe, ranging from 5% in Switzerland to 27% in Finland [3].

Conversely, the true prevalence of esophagitis is very difficult to define because healthy persons rarely undergo endoscopic procedures. Studies suggest that 7% of persons in the United States have erosive esophagitis, whereas European studies identify prevalence rates ranging from 2% to 10% [4]. Analyses of the gender ratio of GERD show nearly equal proportions of affected men and women, but a male predominance occurs in esophagitis and Barrett esophagus [4]. Increasing age is an important factor in the prevalence of GERD complications, probably the result of cumulative acid injury to the esophagus over time [5].

In contrast, the prevalence of GERD and its complications is relatively low among residents of Africa and Asia. For example, a cross-sectional study in Singapore reported prevalence rates for reflux symptoms of 7.5% in Indian people, 0.8% in Chinese people, and 3.0% in Malay people [6]. Possible reasons for the lower prevalence of GERD include low dietary fat, lower body mass index, and lower maximal acid output related to infection with *Helicobacter pylori* [7,8].

The prevalence of GERD is increasing in Western countries. El-Serag and Sonnenberg [9] observed opposing time trends in the prevalence of peptic ulcer disease and GERD in the United States: rates of peptic ulcer disease and gastric cancer fell between 1970 and 1995, whereas the prevalence of GERD and esophageal adenocarcinoma rose significantly.

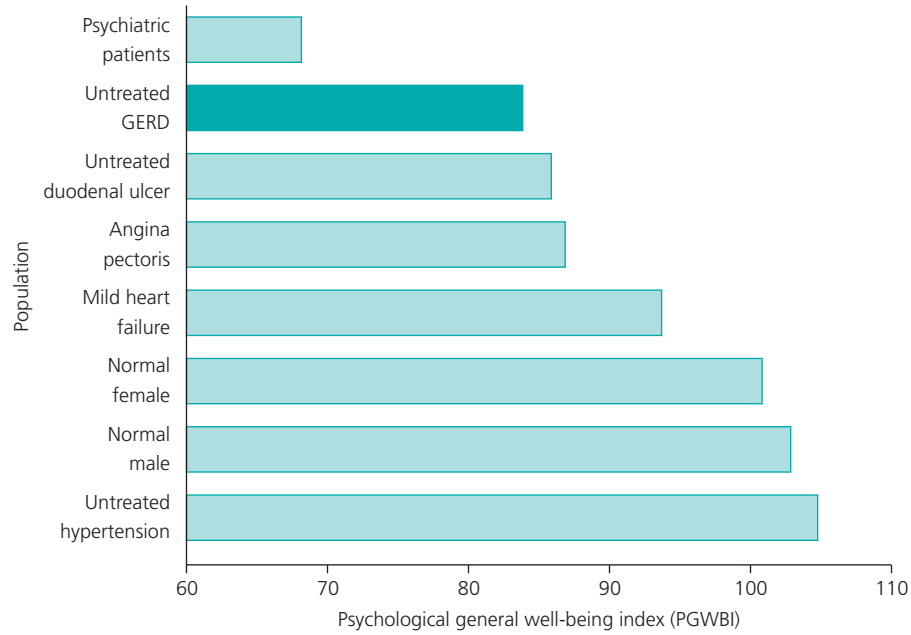

Figure 32.1 Gastroesophageal reflux disease (GERD) and quality of life. GERD has a greater negative impact on the sense of well-being than many common chronic diseases including hypertension and angina. The only illness that has a greater effect than GERD on quality of life is psychiatric disease. Adapted from Enck et al. [11].

The authors speculated that the decreasing prevalence of *H. pylori* may be playing a contributory role in the increasing prevalence of GERD. Data suggest that *H. pylori*-induced gastritis involves both the antrum and corpus, affecting the parietal cells and thus reducing acid secretion and elevating gastric pH [8]. This may have a protective influence on the esophageal mucosa in patients susceptible to GERD. Long-term epidemiological studies will be required to address this question more appropriately.

Other noteworthy epidemiological observations about GERD are that it is more common in white populations than in African American or Native American populations [4], family clustering has been reported [10], and it is rarely the cause of death [4]. GERD, however, is associated with considerable morbidity and with complications such as esophageal ulcerations (5%), peptic stricture (4%–20%), and Barrett esophagus (8%–20%). Furthermore, GERD as a chronic disease significantly impairs quality of life. Compared with other chronic medical conditions, the impairment of quality of life resulting from GERD is similar to, or even greater than, that resulting from arthritis, myocardial infarction, heart failure, or hypertension (Fig. 32.1) [11].

Pathophysiology

The pathophysiology of GERD is complex and results from an imbalance between defensive factors protecting the esophagus (antireflux barriers, esophageal acid clearance, tissue resistance) and aggressive factors from the stomach contents (gastric acidity and volume and duodenal contents). The intermittent nature of symptoms and esophagitis in many patients suggests that the aggressive and defensive forces are part of a delicately balanced system.

Antireflux barriers

The first tier of the three-tiered esophageal defense against acid damage consists of the *antireflux barriers.* This is an anatomically complex region that includes the intrinsic lower esophageal sphincter (LES), the diaphragmatic crura, the intraabdominal location of the LES, the phrenoesophageal ligaments, and the acute angle of His.

The LES is a tonically contracted segment of distal esophagus about 3.0–4.0 cm in length [12]. It is the major component of the antireflux barrier and is capable of preventing reflux even when it is completely displaced from the diaphragmatic crura because of a hiatus hernia [12]. The proximal margin of the LES is normally about 1.5–2.0 cm above the squamocolumnar junction, whereas the distal segment, about 2.0 cm in length, lies within the abdominal cavity [13]. This location of the distal LES contributes to the maintenance of gastroesophageal competence during intraabdominal pressure events. Resting LES pressure ranges between 10 and 30 mmHg and includes a generous reserve capacity, because a minimal basal LES pressure in the range of 5–10 mmHg usually prevents GER [14]. The LES maintains a high-pressure zone by the intrinsic tone of its muscle and by the action of cholinergic excitatory neurons [15]. There is considerable diurnal variation in basal LES pressure; it is lowest after meals and highest at night. It is also influenced by certain circulating peptides and hormones, foods (particularly fat), and numerous drugs, the most clinically relevant of which include theophylline, calcium channel blockers, estrogen/progesterone, and narcotics. During

swallowing, LES relaxation (LESR) occurs for 5–10 s, thus permitting esophageal peristalsis to sweep the swallowed bolus into the stomach.

Anatomically, the LES lies within the hiatus created by the right crus of the diaphragm, and it is anchored by the phrenoesophageal ligaments, which insert at about the level of the squamocolumnar junction [16]. Developmentally, the crural diaphragm arises from the dorsal mesentery of the esophagus and is innervated separately from the costal part of the diaphragm. It is inhibited by esophageal distention, during vomiting, and in association with transient LESRs, but not during swallowing. The crural diaphragm provides extrinsic squeeze to the intrinsic LES, contributing to resting pressure during inspiration and also augmenting LES pressure during periods of increased abdominal pressure such as coughing, sneezing, or bending [17]. Crural contractions impose rhythmic pressure increases of about 5–10 mmHg on the LES pressure recording [18]. During deep inspirations and some periods of increased abdominal straining, these changes may reach 50–150 mmHg [19].

The oblique entrance of the esophagus into the stomach creates a sharp angle on the greater curve aspect of the gastroesophageal junction, the angle of His. This angle has been shown in cadavers to create a flap valve effect that contributes to gastroesophageal junction competency [20].

Mechanisms of reflux

Transient lower esophageal sphincter relaxations

This is the most common mechanism underlying GER and also accounts for the reflux of gases during belching. Figure 32.2 illustrates an example of a transient LESR and highlights differences from swallow-induced LESRs: transient LESRs are not associated with antecedent pharyngeal contractions, are unaccompanied by esophageal peristalsis, persist for longer periods than swallow-induced LESRs (> 10 s), and are always accompanied by inhibition of the crural diaphragm [21]. Transient LESRs account for nearly all reflux episodes in healthy persons and for 50%–80% of episodes in patients with GERD, depending on the severity of associated esophagitis (Fig. 32.3) [22]. However, one study suggested that low basal LES pressure, rather than transient LESRs, may be the primary mechanism of GER in patients with nonreducible hernias [23]. Transient LESRs are not always associated with GER. In healthy persons, about 40%–60% of transient LESRs are accompanied by reflux episodes, compared with 60%–70% in patients with GERD [15,22,24,25]. The rate of transient LESRs is increased by gastric distention, whether by gas or a meal, by stress, and, to a lesser extent, by subthreshold (for swallowing) stimulation of the pharynx [26]. Under normal circumstances, meals are the major stimuli for transient LESRs, but the importance of specific foods is unknown [27]. Transient LESRs are inhibited by the supine position, sleep, general anesthesia, and vagal cooling [26]. Various drugs also impair transient

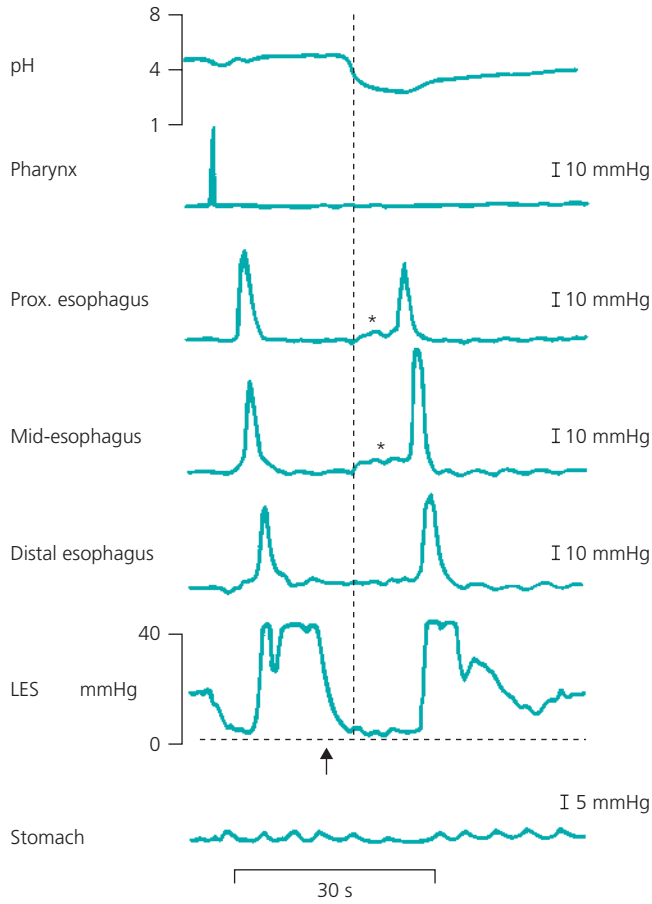

Figure 32.2 Transient lower esophageal sphincter (LES) relaxation (arrow) occurring immediately after the completion of a swallow-induced LES relaxation. Note the substantially longer duration of the transient LES relaxation (TLESR) compared with the preceding swallow-induced LES relaxation. A reflux episode (dotted line) associated with a common cavity (asterisk) occurs after complete LES relaxation has been achieved and is cleared by secondary peristalsis. From Mittal et al. [26], with permission from the American Gastroenterological Association.

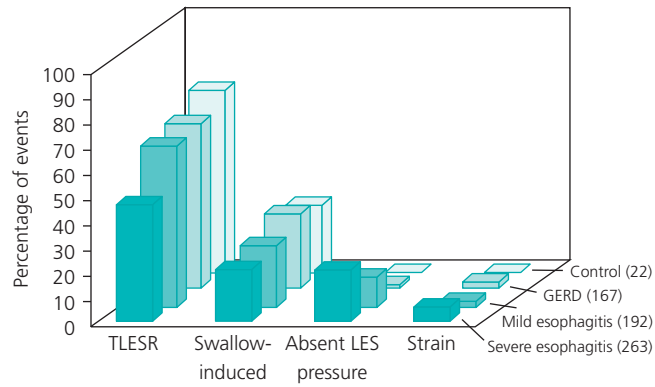

Figure 32.3 Proportion of reflux episodes in the spectrum of gastroesophageal reflux disease (GERD) occurring by the mechanisms of transient lower esophageal sphincter relaxation (TLESR), swallow-induced LES relaxation, absent basal LES pressure, and straining in the presence of low LES pressure. Adapted from Dent et al. [22].

LESRs including cholecystokinin A antagonists, anticholinergic drugs, morphine, somatostatin, nitric oxide inhibitors, 5-hydroxytryptamine 3 (5-HT_3) antagonists, and δ-aminobutyric acid B (GABA-B) agonists [28]. Current evidence indicates that transient LESRs are mediated through vagal pathways [26]. Gastric distention activates mechanoreceptors in the proximal stomach adjacent to the gastric cardia, which send signals to the brainstem center through vagal afferent pathways. The structured sequence of motor events including LESR, inhibition of the crural diaphragm, and contractions of the esophageal body suggest that this process occurs in a programmed manner, probably controlled by a pattern generator within the vagal nuclei. The motor arm is in the vagus nerve and shares common elements with swallow-induced LESRs [29].

Swallow-induced lower esophageal sphincter relaxations

About 5%–10% of reflux episodes occur during swallow-induced LESRs. Most of these episodes are associated with defective or incomplete peristalsis [22,30]. During a normal swallow-induced LESR associated with normal peristalsis, reflux is uncommon because of the absence of concomitant crural diaphragm relaxation, the relatively short duration of LES relaxation (5–10 s), and the prevention of reflux by the oncoming peristaltic wave (see Fig. 32.2). Reflux during a swallow-induced LESR is more common in the presence of a hiatus hernia because of pooling of gastric liquids in the hernia sac and the absence of any residual diaphragmatic support during the LESR [31].

Hypotensive lower esophageal sphincter pressure

Stress reflux and free reflux are two mechanisms by which GER can be associated with diminished LES pressure [14,22]. *Stress reflux* results when a relatively hypotensive LES is overcome and is "blown open" by an abrupt increase in intraabdominal pressure from coughing, straining, or bending. Stress reflux is unlikely when the LES pressure is greater than 10 mmHg. *Free reflux* is characterized by a fall in intraesophageal pH without an identifiable change in intragastric pressure, and it usually occurs when the LES pressure is 0–4 mmHg. Reflux as the result of low or absent LES pressure is uncommon. It is found mostly in patients with severe esophagitis, in whom it may account for up to 23% of reflux episodes (see Fig. 32.3), and rarely in patients without endoscopic evidence of esophagitis [14,22,24,25]. The mechanisms resulting in a low LES pressure are poorly understood. The presence of a hiatus hernia reduces LES pressure because the intrinsic support of the crural diaphragm is lost [12]. Some LES weakness may be secondary to impairment of the excitatory cholinergic pathways to the LES as a result of esophagitis. Induction of experimental esophagitis in cats affects the release of acetylcholine and lowers LES pressure, changes that are reversible on healing of the esophagitis [32]. However, healing of esophagitis in humans is rarely accompanied by an increase in LES pressure [33].

Hiatus hernia

The relationship between *hiatus hernia* and GERD remains controversial. Mainstream opinion has shifted widely from one that virtually equated hiatus hernia with GERD to one that denied it a causal role. Currently, both epidemiological and physiological data confirm the importance of the hiatus hernia in patients with more severe esophagitis, peptic stricture, or Barrett esophagus. Hiatus hernias, identified endoscopically or radiologically, are reported in 54%–94% of patients with reflux esophagitis, a rate that is strikingly higher than that in the healthy population [34].

The functional impact of the hiatus hernia has been clarified by elegant combined manometry and videofluoroscopic studies, which show that hiatus hernia impairs LES function through several mechanisms as well as impairing esophageal clearance (Fig. 32.4) [31,35,36]. Reflux is worse in patients who have a nonreducible as opposed to a reducible hiatus hernia. Nonreducing hernias are those in which the gastric rugal folds remain above the diaphragm between swallows [36]. Furthermore, statistical modeling has revealed a significant interaction between hiatus hernia and LES pressure, such that the likelihood of GER is increased as basal LES pressure decreases, an effect that is substantially amplified by the presence of a hiatus hernia and as hernia size increases [12].

Displacement of the LES from the crural diaphragm into the chest reduces basal LES pressure and shortens the length of the high-pressure zone primarily because of the loss of the intraabdominal LES segment [35]. Both of these effects are caused by the loss of the extrinsic support of the diaphragmatic crura resulting in increased GER [23]. Hiatus hernia virtually eliminates the increase in LES pressure that occurs during straining and may increase the triggering of transient LESRs during gastric insufflation with gas [35,37]. Large, nonreducible hernias also impair esophageal acid clearance because of an increased tendency for reflux to occur from the hernia sac during swallow-induced LESRs [31,36].

The origin of hiatus hernia remains unclear. Familial clustering of GERD [10] suggests the possibility of inherited muscle weakness in this area. Animal studies propose that reflux itself causes esophageal shortening, promoting the development of a hiatus hernia [38]. Other studies find an association with obesity [39] and lifting of heavy weights [40], raising the possibility that, over time, chronic intraabdominal stressors may weaken the esophageal hiatus and may cause the development of a hiatus hernia. This theory is attractive because it helps to reconcile the increased prevalence of hiatus hernias as the population ages [34].

Esophageal acid clearance

The second tier of the esophageal defense against reflux damage is *esophageal acid clearance.* Reflux events determine

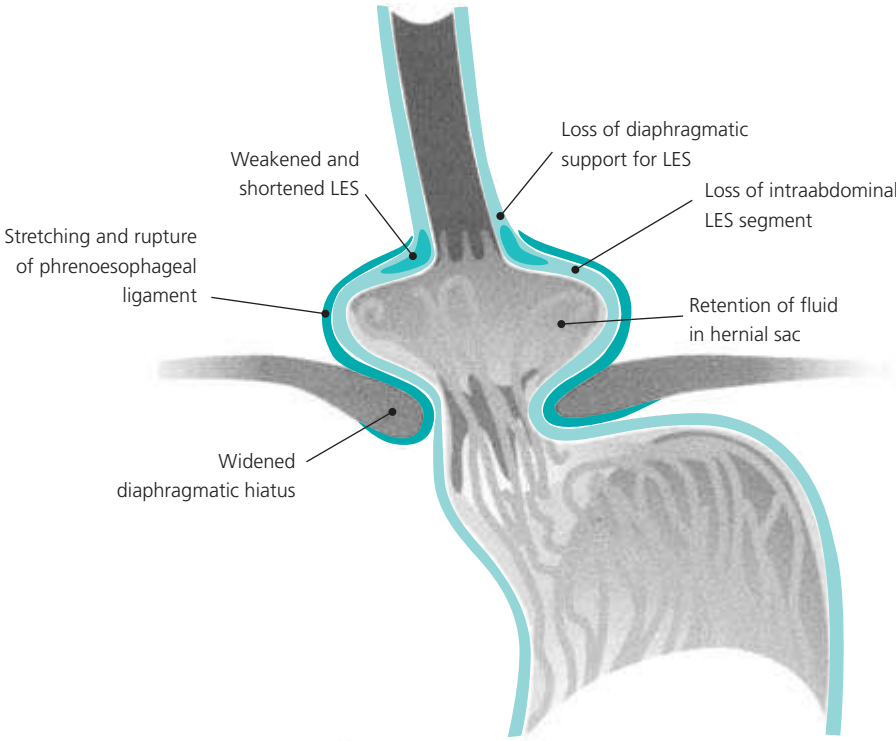

Figure 32.4 The impact of a hiatus hernia on the antireflux barrier. LES, lower esophageal sphincter. From Holloway [28], with permission from Elsevier.

the frequency with which and extent to which gastric contents enter the esophagus, but esophageal acid clearance time determines the duration that the mucosa is exposed to acid and probably the severity of acid damage. Esophageal acid clearance involves two related but separate processes: *volume clearance,* which is the actual removal of the reflux material from the esophagus, and *acid clearance,* which is the restoration of normal pH in the esophagus after acid exposure through titration with base, rather than true removal of the refluxed material.

Volume clearance

Esophageal peristalsis operates to clear the acid volume in both the upright and supine positions, but it is inoperative during deep rapid eye movement sleep [41]. Helm and colleagues [42] showed that one or two primary peristaltic contractions will completely clear a 15-mL fluid bolus from the esophagus. Primary peristalsis is elicited by swallowing, which occurs at a frequency of once per minute in awake subjects, regardless of whether reflux occurs. Secondary peristalsis, initiated by esophageal distention from acid reflux, is much less effective in promoting clearance of refluxate, thus offering only an ancillary protective role.

Peristaltic dysfunction, that is, failed peristaltic contractions and hypotensive (< 30 mmHg) peristaltic contractions that incompletely empty the esophagus, increases in frequency with the severity of esophagitis. Kahrilas and colleagues [43] found that the prevalence of peristaltic dysfunction rose from 25% in patients with mild esophagitis to more than 50% in patients with severe esophagitis (Fig. 32.5). Failed peristalsis results in very poor volume clearance because the foci of feeble contractions clear most, but not all, of the refluxate from the esophagus. Whether esophagitis leads to peristaltic dysfunction or whether an underlying motility disorder predisposes to the development of reflux disease is not clear. Animal studies find that esophageal dysmotility associated with active esophagitis is reversible, but that associated with stricture or extensive fibrosis is not [32]. Clinical observations suggest that impaired motor function does not revert to normal after either effective medical or effective surgical therapy [33].

Gravity contributes to bolus clearance when reflux occurs in the upright position. At night, when patients are supine, this mechanism is not operative unless the head of the bed is elevated. This time-honored treatment of GERD markedly improves acid clearance time and is most beneficial in those patients with aperistalsis (i.e., scleroderma) [44].

Salivary and esophageal gland secretions

Saliva is the second essential factor required for normal esophageal clearance of acid. Saliva has a pH of 6.4–7.8 and therefore is a weak base compared with the acidic gastric contents [45]. The high rate of spontaneous swallowing results in saliva production at a rate of approximately 0.5 mL/min. Although saliva is ineffective in neutralizing large volumes of acid (5–10 mL), it can neutralize small residual amounts of acid remaining in the esophagus after the volume of refluxed material has been cleared by several

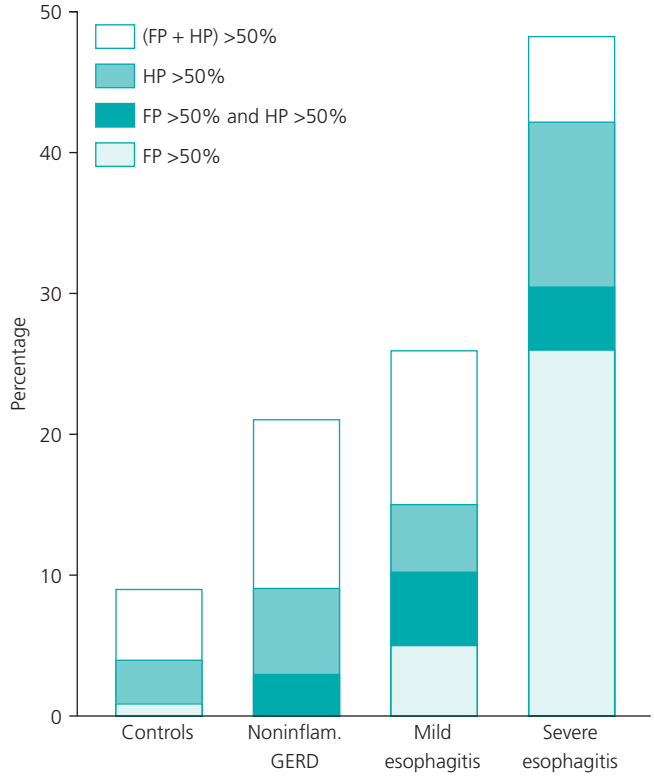

Figure 32.5 The prevalence of peristaltic dysfunction in control subjects and in patients with increasing severity of gastroesophageal reflux disease (GERD). Motility abnormality was defined as the occurrence of either failed, nontransmitted primary peristalsis (FP) or hypotensive peristalsis (< 30 mmHg) in the distal esophagus (HP) with more than half of the swallows. Note the increased prevalence of peristaltic dysfunction as the severity of GERD increases. From Kahrilas et al. [43], with permission from the American Gastroenterological Association.

peristaltic contractions [42]. The importance of swallowed saliva is supported by findings that increased salivation induced by oral lozenges or bethanechol is associated with a significant decrease in acid clearance time. In contrast, suction aspiration of saliva is accompanied by a marked prolongation of esophageal clearance, despite the presence of normal peristaltic contractions [45].

Physiological or pathological compromise of salivation may contribute to GERD. Diminished salivation during sleep explains why nocturnal reflux episodes are associated with markedly prolonged acid clearance times [41]. Similarly, chronic xerostomia is associated with prolonged esophageal acid exposure and esophagitis [46]. Cigarette smoking may promote GER. This was originally attributed to the effects of nicotine on lowering LES pressure, but more recent studies suggest that cigarette smokers have hyposalivation, which may also prolong esophageal acid clearance [47]. Finally, the esophagosalivary reflex may be impaired in patients with reflux esophagitis. This is a vasovagal reflex demonstrated by perfusing acid into the esophagus, thereby stimulating increased salivation [48]. This reflex may explain the symptoms of water brash (copious salivation) observed in some patients with reflux disease. The esophagosalivary reflex is very active in healthy persons, with a doubling or tripling of the salivary flow rate on exposure to acid. However, this reflex is diminished in patients with esophagitis and in those with strictures [48].

In addition to the role of saliva, dilution and neutralization of residual acid are achieved by the aqueous bicarbonate (HCO_3^-)-rich secretions of the esophageal submucosal glands. These glands have been identified in the opossum as well as in the human esophagus [49]. Reflux of acid into the esophageal lumen stimulates these glands and helps to neutralize the acid, even if swallowing does not occur [50].

Tissue resistance

Although clearance mechanisms minimize acid contact time with the epithelium, even healthy persons may have their esophagus exposed to acid for 1–2 h during the day and sometimes at night. Nevertheless, only a few persons experience symptomatic GER, and even fewer suffer GERD. This is the result of the third tier of esophageal defense, known as *tissue resistance*. Tissue resistance is not a single factor but a group of dynamic mucosal structures and functions that interact to minimize mucosal damage from the noxious gastric refluxate [51]. Conceptually, tissue resistance can be subdivided into preepithelial, epithelial, and postepithelial factors.

The preepithelial defense in the esophagus, in contrast to that in the stomach and duodenum, is poorly developed. There is neither a well-defined mucous layer nor a buffering capacity of the surface cells to secrete HCO_3^- into the unstirred water layer. This results in a lumen-to-surface pH gradient in the esophagus of 1:10, in contrast to the stomach and duodenum where the gradient can range from 1:1000 to 1:10 000 [52].

The epithelial defenses in the esophagus consist of both structural and functional components. Structural components include the cell membranes and intercellular junctional complexes of the esophageal mucosa. This structure is a 25- to 30-cell-thick, nonkeratinized squamous epithelium functionally divided into a proliferating basal cell layer (stratum basalis), a midzone layer of metabolically active squamous cells (stratum spinosum), and a 5- to 10-cell-thick layer of dead cells (stratum corneum). The esophageal mucosa is a relatively "tight" epithelium with resistance to ionic movement at the intercellular as well as the cellular level as a result of both tight junctions and the matrix of lipid-rich glucoconjugates in the intercellular space [53].

The functional components of epithelial tissue resistance include the ability of the esophageal epithelium to buffer and extrude H^+ ions. Intracellular buffering is accomplished by negatively charged phosphates and proteins, as well as HCO_3^-. When the buffering capacity of the cell is exceeded

and intracellular pH falls, the cell has the capacity to actively remove H^+ ions. This occurs possibly by the action of two transmembrane proteins, a Na^+/H^+ exchanger and a Na^+-dependent Cl^-/HCO_3^- exchanger [54,55]. After reflux-induced cell acidification, these transporters restore the intracellular pH to neutrality by exchanging H^+ for extracellular Na^+ or by exchanging Cl^- for extracellular HCO_3^- respectively. Additionally, esophageal cells contain a transmembrane Na^+-independent Cl^-/HCO_3^- exchanger that extrudes HCO_3^- from the cytoplasm when the intracellular pH is too high [54]. When the epithelial cells are no longer able to maintain intracellular pH, they lose their ability to regulate volume, edema occurs, and balloon cells develop.

The postepithelial defense is provided by the esophageal blood supply. Blood flow delivers oxygen, nutrients, and HCO_3^- and removes H^+ and carbon dioxide, thereby maintaining a normal tissue acid–base balance. Blood flow to the esophageal mucosa increases in response to the stress of lumenal acid [56]. Cellular injury also stimulates cell proliferation [57], which results in thickening of the basal cell layer of the epithelium. Unlike the stomach, in which superficial mucosal injury is repaired in hours, the esophagus repairs itself more slowly over days to weeks.

Gastric factors

Gastric factors (particularly gastric volume and certain aggressive factors found in the refluxate) are potentially important in the production of reflux esophagitis. Gastric volume is determined by the basal acid secretion rate, concomitant *H. pylori* infection, duodenogastric reflux, and the rate of gastric emptying. Increased gastric volume not only results in more gastric contents being available for reflux but also increases the rate of transient LESRs.

Gastric acid secretion

The primary importance of gastric acid in the production of reflux esophagitis is indisputable, but its mechanism of action may involve activation of pepsin rather than direct damage from acid alone. In animal studies, acid causes minimal injury at a pH of less than 3.0, primarily by protein denaturation. However, the combination of acid and even small amounts of pepsin disrupts the mucosal barrier resulting in increased H^+ ion permeability, histological changes, and gross hemorrhage [58]. Complementing the animal studies, a series of clinical reports showed that patients with various grades of esophagitis, including Barrett esophagus, have an increased frequency and duration of esophageal exposure to gastric refluxate of pH lower than 4.0 [59,60]. Conversely, perfusing the esophagus of animals with a pepsin solution of pH 7.5 produces minimal mucosal disruption or changes in permeability [58]. These observations are the cornerstone of acid suppressive therapy in the treatment of GERD.

Some studies have suggested that patients with reflux, especially those responding poorly to conventional antisecretory therapy, may have higher rates of acid secretion than control subjects [61]. However, most evidence finds no abnormality of gastric acid secretion in patients with GERD. For example, Hirschowitz [62] compared gastric secretion in 115 patients with esophagitis with that in 508 age-, gender-, and disease-matched control patients without esophagitis. Fasting basal or maximal secretion of either acid or pepsin was the same in both groups, and the severity of esophagitis was not related to any of these factors.

Factors that reduce gastric acid secretion naturally, for example concomitant infection with *H. pylori*, especially if it is the $cagA^+$ virulent strain, may protect from the development of severe esophagitis and Barrett esophagus [63,64]. *H. pylori*, particularly this virulent strain, is a biological *antisecretory agent* that lowers gastric acidity. It produces severe corpus gastritis and accelerates the progression to multifocal atrophic gastritis and intestinal metaplasia, with concomitant lower acid output (Fig. 32.6). In addition, the bacteria produce ammonia, which acts as a powerful neutralizing agent under elevated pH conditions [8,65]. The corpus mucosa returns to normal when the *H. pylori* infection is cured, increasing acid secretion and possibly contributing to the reports of esophagitis after successful treatment of *H. pylori* infection [66,67]. The consequences of long-term normalization of parietal cell function and return to higher intragastric acidity are unknown, but they could promote the development of more severe GERD, Barrett esophagus, and adenocarcinoma in Western populations [8].

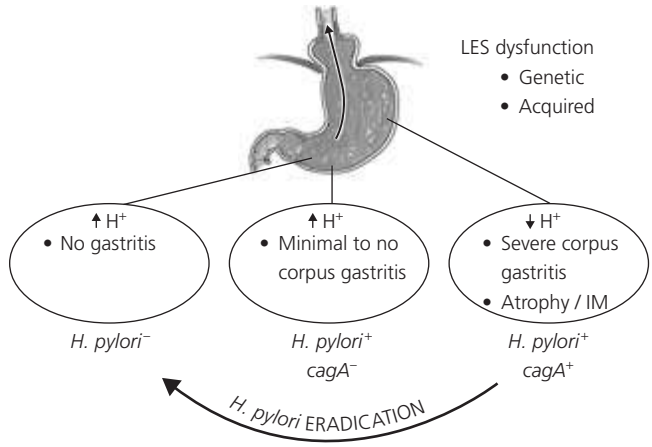

Figure 32.6 The acidity and volume of the gastric refluxate are modulated by the presence or absence of *Helicobacter pylori* and the $cagA^+$ virulence strain through the development of chronic corpus gastritis and gastric atrophy or intestinal metaplasia. Among persons susceptible to gastroesophageal reflux disease (GERD), the more acidic refluxate may increase the probability of esophagitis, Barrett esophagus, and adenocarcinoma, whereas the less acidic refluxate may protect against these complications of GERD. Conceivably, *H. pylori* eradication could shift this delicate balance and could increase the potential for the development of more severe forms of GERD. LES, lower esophageal sphincter. From Richter et al. [8], with permission from Blackwell Publishing.

Duodenogastric reflux

Bile acids have been implicated in the development of esophagitis, especially in the presence of increased *duodenogastric reflux*. Studies in animals demonstrate that conjugated bile acids produce their greatest injury in the presence of acid and pepsin, whereas trypsin, deconjugated bile salts, and the conjugated bile salt taurodeoxycholate are more damaging in the absence of acid [68]. Several surgical reports have suggested that duodenogastric reflux into the esophagus is frequent and may predispose to complications of GERD [59,69]. However, accurate measurement of duodenogastric reflux is difficult. Duodenogastric reflux may be indirectly estimated by ambulatory pH studies using an esophageal pH of less than 7.0 to indicate *alkaline reflux* [70]. However, the reliability of this indirect marker is now questioned by newer techniques, which either spectrophotometrically measure bilirubin, the most common pigment in bile [71], or measure esophageal impedance to the flow of liquids and gases independently of pH [72]. These studies show that acid reflux and bile reflux increase together across the spectrum of GERD, making it nearly impossible to incriminate one agent over the other in the development of esophagitis [73]. In addition, aggressive acid suppression with proton pump inhibitors (PPIs) decreases both acid and duodenogastric reflux, probably by decreasing the volume of gastric contents available to reflux into the esophagus [74]. Finally, the absence of membrane microvesiculation and intracellular bile deposits in human esophageal biopsies, two distinctive morphological features of experimental acid–bile salt injury, also argue against an important role for bile salts in GERD [75].

Delayed gastric emptying

The importance of *delayed gastric emptying* in the pathogenesis of GERD is controversial. Early studies observed a delay in the gastric emptying of solids in up to 50% of patients with reflux [76]. However, methodological problems with these studies including conducting them with the patients supine, scanning only in the anterior position, and the use of unstable radioisotopes may have influenced the results. More recent studies of patients in the upright position, in whom scanning was done both anteriorly and posteriorly, found only a 6%–38% rate of delayed gastric emptying, regardless of the severity of the esophagitis [77,78]. Nevertheless, delayed gastric emptying may be a major factor contributing to GERD in some groups, such as diabetic patients with autonomic peripheral neuropathy.

Associated conditions

Certain medical and surgical conditions can predispose a person to GERD. The most common is *pregnancy*: 30%–50% of pregnant women complain of heartburn, especially in the first trimester. Pregnancy increases the risk of reflux because of the relaxing effects of circulating estrogens and progesterones on LES pressure [79]. Although symptoms may be severe, esophagitis is uncommon, and this type of "situational" GERD is cured with childbirth.

Up to 90% of patients with *scleroderma* have GERD as the result of smooth muscle fibrosis causing low LES pressure and weak or absent peristalsis. Severe disease is common: up to 70% of patients have esophagitis, many have peptic strictures, and Barrett esophagus and carcinoma of the esophagus have been reported [80].

Unlike the previous two conditions, which are characterized by LES dysfunction, hypersecretion of acid and increased gastric volume are the major factors causing GERD in patients with the *Zollinger–Ellison syndrome*. In these patients, the esophagitis and complications may be more difficult to treat than the ulcer disease [81]. After Heller myotomy, 10%–20% of patients may develop GERD [82]. Finally, prolonged *nasogastric tube intubation* may contribute to the development of reflux esophagitis, in part because acid tracks orad along the tube and because the tube mechanically interferes with LES barrier function [83].

Clinical manifestations

Classical reflux symptoms

Heartburn is the classical symptom of GERD, with patients generally reporting a burning feeling, rising from the stomach or lower chest and radiating toward the neck, throat, and occasionally the back [84]. Usually it occurs postprandially, particularly after large meals or the consumption of spicy foods, citrus products, fats, chocolates, and alcohol. Recumbency and bending over may exacerbate heartburn. Nighttime heartburn interferes with restful sleeping and may impair next-day work performance. When heartburn dominates the patient's complaints, it has very high specificity (89%), but low sensitivity (38%), for GERD as diagnosed by abnormal 24-h esophageal pH testing [85]. The diagnosis of GERD is usually based on the occurrence of heartburn on 2 or more days a week, although less frequent symptoms do not preclude the disease [86]. Although this symptom is an aid to diagnosis, the frequency and severity of heartburn do not predict the degree of esophageal damage. Heartburn is caused by acid stimulation of sensory nerve endings in the deeper layers of the esophageal epithelium. These nerve endings are normally protected by a relatively impermeable epithelium but, with epithelial changes caused by reflux, they may be stimulated by H^+ ions or spicy foods [87].

Other common symptoms of GERD are acid regurgitation and dysphagia. The effortless regurgitation of acidic fluid, especially after meals and exacerbated by stooping or recumbency, is highly suggestive of GERD [85]. Among patients with daily regurgitation, the LES pressure usually is low, many have associated gastroparesis, and esophagitis is

common. For these reasons, acid regurgitation may be more difficult to control medically then classical heartburn complaints. Dysphagia is reported by more than 30% of patients with GERD [88]. It usually occurs in the setting of long-standing heartburn, with slowly progressive dysphagia primarily for solids. Weight loss is uncommon because patients have good appetites. The most common causes are a peptic stricture or Schatzki ring, but other causes include severe esophageal inflammation alone, peristaltic dysfunction, and esophageal cancer arising from Barrett esophagus.

Less common reflux-associated symptoms include water brash, odynophagia, burping, hiccups, nausea, and vomiting [89]. *Water brash* is the sudden appearance in the mouth of a slightly sour or salty fluid. It is not regurgitated fluid but rather secretions from the salivary glands in response to acid reflux [45]. *Odynophagia*, pain on swallowing, can occasionally be seen with severe ulcerative esophagitis. However, its presence should raise the suspicion of an alternative cause of esophagitis, especially infections (candidiasis, herpes) or pills (tetracycline, potassium chloride, quinine, vitamin C, alendronate).

In contrast to the previously described symptomatic presentations, some patients with GERD are asymptomatic. This is particularly true in elderly patients because of decreased acidity of the reflux material or decreased pain perception [5]. Many elderly patients present first with complications of GERD because of long-standing disease with minimal symptoms. For example, up to one-third of patients with Barrett esophagus are insensitive to acid at the time of presentation [90].

Extraesophageal manifestations

It has been suggested that GER may be the cause of a wide spectrum of conditions including noncardiac chest pain, asthma, posterior laryngitis, chronic cough, recurrent pneumonitis, and even dental erosion [91]. Some of these patients have classical reflux symptoms, but many are "silent refluxers," contributing to problems in making the diagnosis. Furthermore, it may be difficult to establish a causal relationship even if GER can be documented by testing (e.g., pH studies), because patients may simply have two common diseases without a cause-and-effect relationship.

Chest pain

GER-related *chest pain* may mimic angina pectoris. The chest pain is usually described as squeezing or burning, substernal in location, and radiating to the back, neck, jaw, or arm. It often is worse after meals, awakens the patient from sleep, and may worsen during periods of emotional stress. Heavy exercise, even treadmill testing, may provoke GER [92]. Reflux-related chest pain may last minutes to hours, often resolves spontaneously, and may be eased with antacids. Most patients with GERD-induced chest pain have heartburn symptoms [93].

Early studies suggested that spastic motility disorders were the most common esophageal cause of chest pain. However, studies using ambulatory esophageal pH and pressure monitoring suggest that about 25%–50% of patients with noncardiac chest pain have GERD [94]. Overall, these series of reports found that 41% of patients had abnormal 24-h pH test results, whereas 32% had chest pain that was clearly associated with acid reflux. Patients with coronary artery disease commonly have coexisting esophageal diseases, but the evidence that GER causes ischemic pain is controversial [95]. The mechanism for GERD-related chest pain is not clearly understood and probably is multifactorial, related to H^+ ion concentration, volume and duration of acid reflux, and secondary esophageal spasm.

Asthma and other pulmonary diseases

The association of GERD and *pulmonary diseases* was recognized by Sir William Osler [96], who recommended that asthmatic patients should "learn to take their large daily meal at noon to avoid nighttime asthma which occurred if they ate a full supper." More recent studies suggest the coexistence of the two diseases in up to 80% of asthmatic patients, irrespective of the use of bronchodilators [97,98]. GERD should be considered in asthmatic patients who present in adulthood, those without an intrinsic component, and those not responding to bronchodilators or steroids [99]. Up to 30% of patients with GERD-related asthma have no other esophageal complaints. Other pulmonary diseases associated with GERD include aspiration pneumonia, interstitial pulmonary fibrosis, chronic bronchitis, bronchiectasis, and possibly cystic fibrosis, neonatal bronchopulmonary dysplasia, and sudden infant death syndrome.

Proposed mechanisms of reflux-induced asthma are either aspiration of gastric contents into the lungs with secondary bronchospasm or activation of a vagal reflex from the esophagus to the lungs causing bronchoconstriction. Animal [100] and human [101] studies report bronchoconstriction after esophageal acidification, but the response tends to be mild and unpredictable. In contrast, intratracheal infusion of even small amounts of acid induces profound and reproducible bronchospasm in cats [100]. The reflux of acid into the trachea compared with the esophagus alone predictably caused marked changes in peak expiratory flow rates in asthmatic patients [102]. Although either mechanism may be responsible for reflux-induced asthma, most patients probably suffer from intermittent microaspiration.

Ear, nose, and throat diseases

GERD may be associated with a variety of laryngeal conditions and symptoms, of which *reflux laryngitis* is perhaps the most common [103,104]. These patients present with hoarseness, globus sensation, frequent throat clearing, recurrent sore throat, and prolonged voice warm-up. Ear, nose, and throat signs attributed to GERD include posterior laryn-

gitis with edema and redness, vocal cord ulcers and granulomas, leukoplakia, and even carcinoma. These changes usually are limited to the posterior third of the vocal cords and interarytenoid areas, both in close proximity to the upper esophageal sphincter. GERD is the third leading cause of chronic cough (after sinus problems and asthma), accounting for 20% of cases [105]. *Dental erosion,* defined as the loss of tooth structure by chemical processes not involving bacteria, can be caused by GER in healthy persons and in patients with bulimia [106].

Despite the association between ear, nose, and throat diseases and GERD, overt esophagitis usually is absent, and most patients have only mild reflux symptoms if any [103]. Microaspiration of gastric contents is the most likely cause of these complaints. Animal studies find that the combination of acid and pepsin is very injurious to the larynx [103]. Human studies report that proximal esophageal acid exposure, especially at night while sleeping, is significantly increased in patients with laryngeal symptoms and signs [107].

Table 32.1 Commonly used tests for assessing the presence, mechanism, and consequences of gastroesophageal reflux disease[a]

Tests for reflux
Intraesophageal pH/impedance monitoring
Ambulatory bilirubin monitoring
Radionuclide technetium 99m scintiscanning
Barium esophagram
Tests to assess symptoms
Empiric trial of acid suppression
Intraesophageal pH/impedance monitoring
Acid perfusion (Bernstein) test
Tests to assess esophageal damage
Endoscopy
Esophageal biopsy
Barium esophagram
Tests to assess pathogenesis
Esophageal manometry
Gastric analysis
Radionuclide technetium 99m scintiscanning

a Order of presentation represents the order of diagnostic usefulness.

Diagnostic evaluation

Many tests are available for evaluating patients with suspected GERD. These tests are often unnecessary because the classical symptoms of heartburn and acid regurgitation are sufficiently specific to identify reflux disease and to begin medical treatment. However, this may not always be the case, and the clinician must choose which test to use to arrive at a diagnosis in a reliable, timely, and cost-effective manner, depending on the information desired (Table 32.1).

Empiric trial of acid suppression

The simplest and most definitive method for diagnosing GERD and assessing its relationship to symptoms (either classical or atypical) is the empiric trial of acid suppression. Unlike other tests that only suggest an association (e.g., esophagitis at endoscopy or positive symptom index on pH testing), the response to antireflux therapy ensures a cause-and-effect relationship between GERD and symptoms. Therefore, it has become the first test used in patients with classical or atypical reflux symptoms without "alarm" complaints. The popularity of this approach was aided by the introduction of the PPIs, which, unlike the histamine type 2 receptor antagonists (H_2RAs), can drastically reduce the amount of acid reflux into the esophagus. Symptoms usually respond to a PPI trial within 7–14 days. If symptoms disappear with therapy and then return when the medication is stopped, GERD may be assumed.

In the reported empiric trials with heartburn, the initial dose of PPI was high (e.g., omeprazole 40–80 mg/day) and was given for not less than 14 days. A positive response was defined as at least 50% improvement in heartburn. Using this approach, the PPI empiric trial had a sensitivity of 68%–83% for determining the presence of GERD [108,109]. In noncardiac chest pain, Fass and colleagues [110] found that a 7-day trial of omeprazole, 40 mg in the morning and 20 mg at night, had a sensitivity of 78% and specificity of 86% for predicting GERD when compared with traditional tests. Likewise, Ours and colleagues [111] found omeprazole, 40 mg twice a day for 2 weeks, to be a very reliable method for identifying acid-related cough. Empiric trials using a 2- to 4-month regimen of PPIs taken twice a day are commonly used in patients with suspected GERD-associated asthma and GERD complaints related to the ear, nose and throat.

An empiric trial of PPIs for diagnosing GERD has many advantages. The test is office based, is easily performed, is relatively inexpensive, is available to all physicians, and avoids many needless procedures. For example, Fass and associates [110] showed a saving of more than US$570 per average patient because of a 59% reduction in the number of diagnostic tests performed for noncardiac chest pain. Disadvantages are few, including a placebo response and an uncertain symptomatic end point if symptoms do not resolve totally with extended treatment.

Endoscopy

Upper *endoscopy* is the current standard for documenting the presence of esophagitis and its extent and excluding other etiologies. However, only 40%–60% of patients with abnormal esophageal reflux by pH testing have endoscopic evidence of esophagitis. Thus, the sensitivity of endoscopy for

GERD is 60% at best, although it has excellent specificity, at 90%–95% [112].

The earliest endoscopic signs of acid reflux include edema and erythema. Neither finding is specific for GERD, and both are very dependent on the quality of the endoscopic visual images [112]. More reliable are the findings of friability, granularity, and red streaks. Friability (easy bleeding), occurring with gentle pressure on the mucosa, results from the development of enlarged capillaries near the mucosal surface in response to acid. Red streaks may extend upward from the esophagogastric junction along the ridges of the esophageal folds. In studies evaluating these stigmata, nearly all patients had GERD [113]. With progressive acid injury, erosions develop (Fig. 32.7a), characterized by shallow thinning of the mucosa associated with a white or yellow exudate surrounded by erythema. Commonly located just above the esophagogastric junction, erosions may be either single lesions or coalesced regions and occur along the tops of mucosal folds, areas most prone to acid exposure. Erosions may also be caused by nonsteroidal antiinflammatory drugs (NSAIDs), heavy smoking, and infectious esophagitis [113]. Ulcers reflect more severe esophageal damage. They penetrate the mucosa, tend to have either a white or yellow discolored base, and may be seen either isolated along a fold or surrounding the esophagogastric junction.

Multiple classification systems for esophagitis have been proposed; some are confusing and none has worldwide acceptance [114,115] (Table 32.2). In Europe, the most popular scheme is the Savary–Miller classification [114]. In the United States, the Hetzel [116] and Los Angeles [115] systems are most popular, with the latter gaining the most acceptance.

Most patients with GERD are treated initially without endoscopy. The important exception is the patient experiencing alarm symptoms: dysphagia, odynophagia, weight loss, and gastrointestinal bleeding. With such symptoms, endoscopy should be performed early to rule out other entities such as infections, ulcers, cancer, or varices. The role of endoscopy in GERD without alarm symptoms has changed dramatically in the PPI era. Previously, the degree of esophagitis helped direct management but this is less of an issue with PPIs, which effectively heal all grades of esophagitis. Currently, the most important reason for performing endoscopy in patients with GERD is to identify peptic strictures or Barrett esophagus. Using this rationale, most patients with chronic GERD need only one endoscopic examination while they are receiving therapy.

Esophageal biopsy

Similar to endoscopy, the role of esophageal biopsies in evaluating GERD has evolved over the years. Microscopic changes indicative of reflux may occur even when the mucosa appears normal endoscopically [117]. These classical findings are reactive epithelial changes characterized by an increase in the basal cell layer of greater than 15% of the epithelium thickness or papilla elongation into the upper third of the epithelium (see Fig. 32.7b), both changes representing increased epithelial turnover of the squamous mucosa. Unfortunately, these changes are also noted in up to 50% of healthy persons when biopsies are taken from the distal 2–3 cm of the esophagus [118]. Hence, the changes are sensitive markers for GERD but have poor specificity.

Acute inflammation characterized by the presence of neutrophils and eosinophils is very specific for esophagitis [118]; however, the sensitivity is low, in the range of 15%–40% [119]. Eosinophils are found more often on biopsy

(a)

(b)

Figure 32.7 Endoscopic and histological signs of esophagitis. **(a)** Two linear erosions extending proximally from the squamocolumnar junction at the proximal border of a hiatal hernia. This would be classified as grade II esophagitis by the Savary–Miller and Hetzel systems and as grade B on the Los Angeles scale. **(b)** Reparative changes secondary to reflux disease characterized by basal cell hyperplasia (dark cells crowding the papillae) and marked elongation of the rete pegs (pale papillae with finger-like projections).

Table 32.2 Endoscopic grading systems for esophagitis

	Savary–Miller classification	Hetzel classification
Grade 0	Not applicable	Normal-appearing mucosa
Grade I	Single erosive or exudative lesion on one longitudinal fold	Mucosal edema, hyperemia, or friability of mucosa
Grade II	Multiple erosions on more than one longitudinal fold	Superficial erosions involving < 10% of the mucosal surface of the last 5 cm of distal esophagus
Grade III	Circumferential erosions	Superficial erosions involving 10%–50% of distal esophagus
Grade IV	Ulcer, stricture, or short esophagus isolated or associated with grade I–III lesion	Deep ulceration or confluent erosions involving > 50% of distal esophagus
Grade V	Barrett esophagus ± grade I–III lesion	Not applicable

Los Angeles classification

Grade A	One or more mucosal breaks confined to folds, no longer than 5 mm
Grade B	One or more mucosal breaks of > 5 mm, confined to folds but not continuous between tops of mucosal folds
Grade C	Mucosal breaks continuous between tops of two or more mucosal folds but not circumferential
Grade D	Circumferential mucosal break

(19%–63% of subjects) but are less specific, present in up to 33% of healthy adults [120]. Interestingly, the sensitivity and specificity of eosinophils in children are much stronger, reflecting the lack of eosinophils in the juvenile inflammatory response [118,121].

In clinical practice, the primary indication for esophageal biopsy is to determine the presence of Barrett epithelium and possible eosinophilic esophagitis. When the former diagnosis is suspected, a biopsy is essential and should be carried out when all visual evidence of esophagitis is healed.

Esophageal pH monitoring

Ambulatory intraesophageal pH monitoring is the standard for establishing pathological reflux (see Chapter 137) [122,123]. The test is performed with a pH probe passed nasally, positioned 5 cm above the manometrically determined LES and connected to a battery-powered data logger capable of collecting pH values every 4–6 s. An event marker is activated by the subject in response to symptoms, meals, and body position changes. Patients are encouraged to eat normally and to pursue regular daily activities. Monitoring is carried out usually for 18–24 h. Reflux episodes are detected by a pH drop below 4.0. Commonly measured parameters include the percentage of total time that the pH is below 4.0, the percentage of time upright and time supine that the pH is below 4.0, the total number of reflux episodes, the duration of the longest reflux episode, and the number of episodes that last for longer than 5 min [122]. The total percentage of time that the pH is below 4.0 is the most reproducible measurement for GERD, with reported upper limits of normal ranging from 4% to 5.5% [123]. Ambulatory pH testing can discern positional variations in GER, meal- and sleep-related episodes, and help to relate symptoms to reflux events (Fig. 32.8). As the result of its reliability for measuring GER across normal activities, ambulatory pH testing has replaced other older studies such as the standard acid reflux (Tuttle) test and radionuclide scintigraphy.

One important problem with esophageal pH monitoring is that there exists no absolute threshold value that reliably identifies pathological GER. Validation studies comparing the presence of esophagitis with an abnormal pH test report sensitivities ranging from 77% to 100% with specificities of 85%–100% [123]. However, these patients rarely need pH testing; rather, patients with normal endoscopic findings and suspected reflux symptoms should benefit most from ambulatory pH monitoring. Unfortunately, the data are much less conclusive in this group, with considerable overlap between control subjects and patients with nonerosive reflux [123]. Other drawbacks of pH testing include possible equipment failure, the pH probe missing a reflux event because it is buried in a mucosal fold, and false-negative studies resulting from dietary or activity limitations because of poor tolerability of the nasal probe.

An important advantage of ambulatory esophageal pH monitoring is its ability to record and correlate symptoms with reflux episodes over extended periods. For this indication it has essentially replaced the shorter acid perfusion (Bernstein) test. Because only about 10%–20% of reflux episodes are associated with reported symptoms, different statistical analyses have evolved in an attempt to define a significant association between these two variables, including the symptom index, symptom sensitivity index, and symptom association probability [124]. However, one study found none of these statistical relationships to be superior to a high-dose trial of a PPI in establishing the causal relationship between symptoms and GER [124].

Definite clinical indications for ambulatory pH monitoring have been established [123]. Before fundoplication, pH

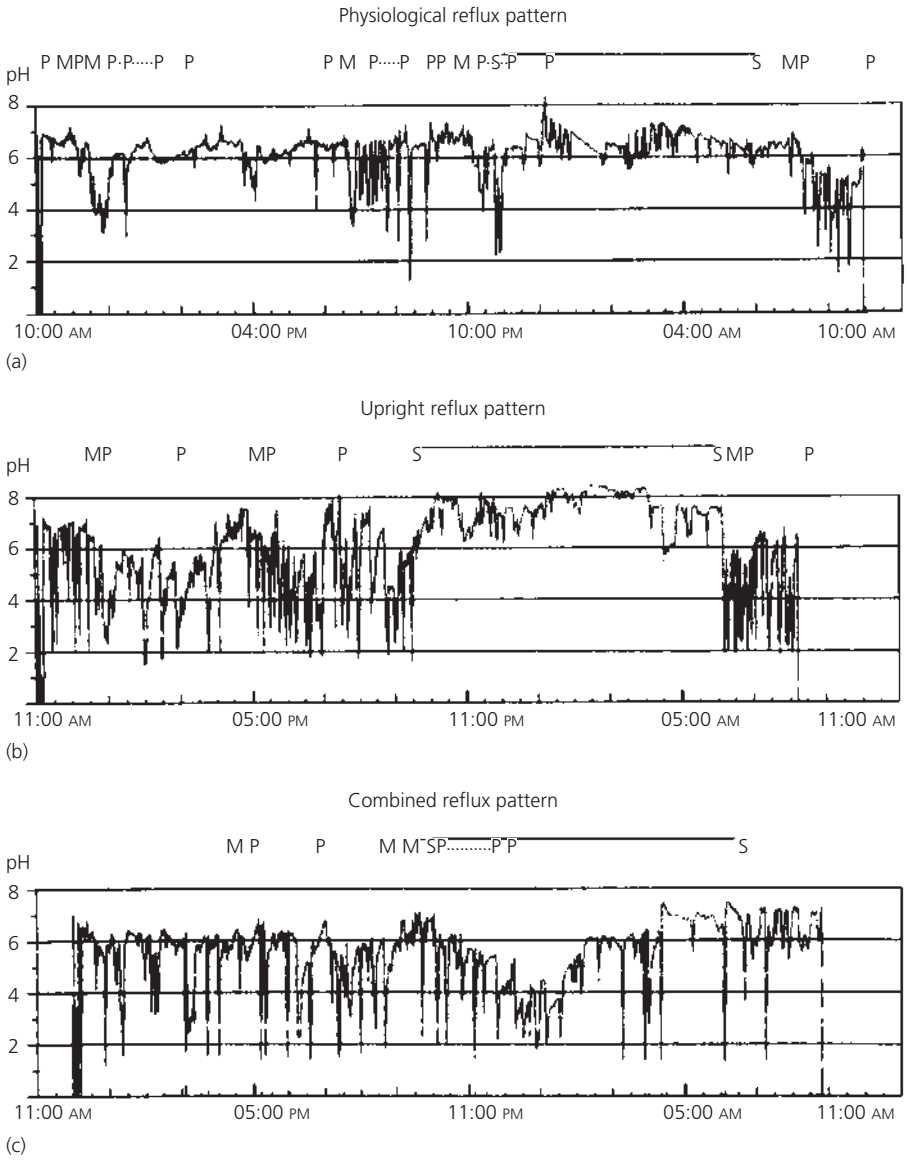

Figure 32.8 Common patterns of 24-h esophageal pH monitoring. MP, meal; P, postprandial; S, supine. **(a)** The physiological pattern of gastroesophageal reflux (GER) in healthy persons. Reflux is noted after meals (M) but not while asleep (S). A reflux episode is defined as a pH drop to less than 4.0. **(b)** Upright reflux pattern with extensive GER during the day but not at night. These patients have frequent symptoms but esophagitis is uncommon. **(c)** Combined pattern with GER during the day and at night (one episode lasted for 3 h). Most of these patients have esophagitis.

testing should be performed in patients with normal endoscopic findings to identify the presence of pathological reflux. If esophagitis is present, pH testing is not necessary because the disease has been established. After antireflux surgery, persistent or recurrent symptoms warrant repeat pH testing. In these situations, pH monitoring is performed with the patient discontinuing all antireflux medications (PPIs for 1 week, H_2RAs for 2 days). Esophageal pH testing is particularly helpful in the evaluation of patients with reflux symptoms resistant to treatment and with normal or equivocal endoscopic findings. For this indication, pH testing is usually also carried out in patients receiving therapy to define two populations: those with and those without continued abnormal esophageal acid exposure times. The group with persistent GER needs intensification of the medical regimen, whereas those patients with symptoms and adequate acid control have another cause of their complaints. Finally, ambulatory pH testing may help in defining patients with extraesophageal manifestations of GERD. In this situation, pH testing is usually carried out with additional pH probes placed in the proximal esophagus or pharynx [125]. Initially, most of these studies were carried out when patients were not taking antireflux medications, to confirm the coexistence of GERD; however, this does not guarantee symptom causality. Therefore, the current approach is to treat the patients aggressively with PPIs first and to reserve pH testing only for those patients not responding after 4–12 weeks of therapy [126].

Two advancements have made pH testing more user-friendly and capable of measuring nonacid reflux. The Bravo pH capsule is a tubeless method of acid monitoring that uses a radiotelemetry capsule attached directly to the esophageal

mucosa. This is more tolerable to the patient, allows 48 h of monitoring, and may improve test accuracy by allowing patients to more comfortably carry out their usual activities [127]. The second improvement combines impedance and pH testing, allowing the measurement of both acid and nonacid reflux. This test may be helpful in patients with regurgitation or those with persistent symptoms despite an adequate medical trial of a PPI [128].

Barium esophagram

The *barium esophagram* is an inexpensive, readily available, and noninvasive esophageal test (see Chapter 127). It is most useful in demonstrating structural narrowing of the esophagus and in assessing the presence and reducibility of a hiatal hernia. Schatzki rings, webs, or minimally narrowed peptic strictures are often seen only with an esophagram, being missed by endoscopy, which may not adequately distend the esophagus. Giving a 13-mm radiopaque pill or marshmallow along with the barium liquid can help to identify these subtle narrowings [129]. By giving the patient in the prone oblique position swallows of barium, the barium esophagram also allows good assessment of peristalsis and is helpful preoperatively in identifying a weak esophageal pump [130]. The ability of a barium esophagram to detect esophagitis varies considerably, with sensitivities of 79%–100% for moderate to severe esophagitis, with mild esophagitis usually missed [130]. Barium testing also falls short when addressing the presence of Barrett esophagus. The spontaneous reflux of barium into the proximal esophagus usually suggests reflux but is infrequent [129]. Provocative maneuvers such as leg lifting, coughing, the Valsalva maneuver, or the water-siphon test can be used to elicit stress reflux. Although these tests can improve the sensitivity of the barium esophagram, some argue that they also decrease its specificity [131,132].

Esophageal manometry

Esophageal manometry allows accurate assessment of LES pressure and relaxation, as well as peristaltic activity, including contraction amplitude, duration, and velocity (see Chapter 137). However, esophageal manometry is generally not indicated in the evaluation of patients with uncomplicated GERD because most of these patients have a normal resting LES pressure [43]. It is an integral component of pH testing to define the LES location accurately, a task poorly performed by endoscopy, fluoroscopy, or the pH pull-through technique. Esophageal manometry is traditionally recommended before antireflux surgery to document adequate esophageal peristalsis [133]. If ineffective peristalsis (low amplitude or frequent failed peristalsis) is identified [134], then a complete fundoplication may be contraindicated. However, several studies have challenged this physiological premise, finding that reflux control was better and dysphagia no more common in patients with weak peristalsis after a complete, compared with a partial, fundoplication [135]. Using impedance combined with traditional manometry, one study found that fewer than 50% of patients with manometric "ineffective" peristalsis have poor esophageal bolus clearance [136]. Thus, this new technology helps to better define a weak esophageal pump and limits the use of the less effective partial fundoplication.

Differential diagnosis

Symptoms associated with GERD may be mimicked by other esophageal and extraesophageal diseases including achalasia, Zenker diverticulum, gastroparesis, gallstones, peptic ulcer disease, functional dyspepsia, and angina pectoris. These disorders can usually be identified by their failure to respond to aggressive antisecretory therapy and by diagnostic tests such as endoscopy, barium esophagram, esophageal manometry, ultrasound, nuclear emptying studies, and various cardiac tests. Although GERD is the most common cause of esophagitis, other causes (pill injury, infections, or radiation esophagitis) need to be considered in cases that are difficult to manage and in older or immunocompromised patients.

Clinical course

The clinical course of reflux esophagitis depends to a great extent on whether the patient has *erosive* or *nonerosive GERD* on initial presentation. Furthermore, patients tend not to cross over from one group to another unless they are treated medically or surgically: in follow-up ranging from 6 months to more than 5 years, only 15% of patients with nonerosive disease evolved over time to having esophagitis or complications of GERD [137,138].

Nonerosive reflux disease

Although early studies from tertiary referral centers suggested that nearly half of patients with GERD had esophagitis [139], studies carried out in community practices reveal that up to 70% of the patients with GERD had a normal endoscopic examination [140,141]. Furthermore, another community-based study of antacid users found that 53% of patients with GERD had nonerosive disease, and two-thirds of the remaining had only minimal erosive changes at endoscopy [142]. Endoscopy-negative patients with GERD are more likely to be female, younger, thin, and without hiatal hernia. Despite their mild mucosal damage, these patients demonstrate a chronic pattern of symptoms with periods of exacerbation and remission [143]. Studies suggest that dilation of intercellular spaces is a histological marker of this disease, irrespective of esophageal acid exposure [144].

Nonerosive GERD is suspected by the presence of typical reflux symptoms with a normal endoscopic examination and is confirmed by the patient's response to antisecretory

therapy. When performed, 24-h esophageal pH monitoring identifies three distinct subsets of patients with nonerosive disease. First, there are the patients with abnormal acid exposure times who are usually responsive to antisecretory therapy. Second are the patients with normal reflux parameters but a good relationship between acid reflux episodes and symptoms. This group represents 30%–50% of patients with nonerosive GERD [145] and has "functional heartburn" [143]. These patients probably have heightened esophageal sensitivity to acid and are less likely to respond to antireflux therapy [146]. The third group is characterized by normal acid exposure times and poor symptom correlation. Despite sometimes having classical reflux symptoms, other diseases such as achalasia, gastroparesis, bile reflux, or functional dyspepsia are the cause of their symptoms. Overall, patients with nonerosive GERD do not respond to antireflux treatments as well as patients with erosive GERD, probably because these three subsets are not carefully defined before treatment [143].

Erosive reflux disease

The clinical course of patients with erosive esophagitis is more predictable and is associated with complications of GERD. Controlled studies have shown that, in the absence of ongoing maintenance therapy, up to 85% of patients with erosive GERD will have a relapse within 6 months, and the relapse rate is highest in those with the more severe grades of esophagitis [147,148]. This observation, however, should not prevent at least one attempt to withdraw medication, because 20% of patients remain in remission for up to 1 year, especially those with milder esophagitis grades. Although the natural history of untreated erosive GERD is well studied, two European studies suggest that these patients are more prone to reflux complications. In a Finnish study, 20 patients with erosive GERD treated with lifestyle changes, antacids, and prokinetic drugs were followed up for a median of 19 years. In total, 14 patients continued to have erosions, and six new cases of Barrett esophagus were detected [149]. Similarly, a large retrospective European study with 6.5 years of follow-up found a high rate of complications (21%) including 13 patients with esophageal ulcers, 15 with strictures, and 45 with Barrett epithelium [150]. However, these data must be contrasted with other studies, for example a 2-year trial in the United States [151] in which no patients with erosive esophagitis developed Barrett esophagus, and a study over a 12-year period of 3800 French patients [152] in whom the development of stricture was reported in only 0.26%.

Complications

Hemorrhage and perforation

Hemorrhage and esophageal perforation are rare complications of reflux esophagitis and are usually associated with deep esophageal ulcers or severe diffuse esophagitis. Clinically important hemorrhage has been reported in 7%–18% of patients with GERD [153]. Esophageal perforations are very rare in the PPI era, but they can result in mediastinitis and can be fatal if they are not rapidly recognized and treated.

Peptic esophageal strictures

Strictures occur in 7%–23% of patients with untreated reflux esophagitis, especially in older men [154]. They usually evolve over many years and may be linked to the long-term use of NSAIDs [155]. The mechanism of stricture formation is complex, starting as a reversible inflammatory process with edema, cellular infiltration, and vascular congestion, progressing to deposition of connective tissue and collagen, and ending in irreversible fibrosis. With the onset of dysphagia there is often less heartburn, reflecting the fact that the stricture is acting as a barrier to reflux. Dysphagia is usually limited to solids but it may progress to liquids. Unlike malignant strictures, patients with peptic strictures have a good appetite, alter their diet, and lose little weight.

Radiographically, peptic strictures are smooth-walled, tapered, circumferential narrowings in the lower esophagus; they are usually less than 1 cm long but can occasionally extend to 8 cm in length (Fig. 32.9). In these unusual cases the clinician should suspect a predisposing condition, such as the Zollinger–Ellison syndrome, superimposed pill esophagitis, or prolonged nasogastric intubation [154]. A stricture in the middle to upper esophagus should raise the suspicion of Barrett esophagus or malignant disease. Although once controversial, most data suggest that a Schatzki ring is a forme fruste of an early peptic stricture [156]. In all cases, the nature of a peptic stricture needs to be confirmed by endoscopy with biopsies because some patients may have Barrett esophagus or unsuspected cancer.

Barrett esophagus

In some patients with GERD, the squamous epithelium of the distal esophagus is replaced by specialized columnar epithelium resembling that of the intestine and containing goblet cells. Although Dr. Norman Barrett thought that this lesion was a congenitally shortened esophagus [157], studies consistently show that these patients have severe GERD with low LES pressures, poor esophageal motility, large hiatal hernias, and extensive acid and bile reflux [158]. Furthermore, most patients have had chronic reflux symptoms for at least 10 years [159]. Animal experiments show that, if the mucosal lining of the distal esophagus is excised in the setting of free acid reflux, columnar epithelium will regenerate in the area previously occupied by squamous epithelium [160]. If reflux is controlled, the mucosal lining will regenerate with squamous epithelium. Pluripotential stem cells derived from the stratified squamous epithelium are the origin of the specialized columnar epithelium [161].

Barrett esophagus was once considered an uncommon condition, but estimates of its frequency at autopsy (1 in 57 to

(a) (b)

The stricture occurred after prolonged nasogastric intubation following head and neck surgery.

1 in 105 cases), on general endoscopy survey (1 in 100 cases), and on endoscopic surveys of patients with GERD (10 in 100 to 15 in 100 cases) indicate that it is not uncommon and that it affects nearly 700 000 adults in the United States [157]. An autopsy series from Olmsted County, Minnesota found that most cases of Barrett esophagus go undetected during life and thus are not accessible for cancer surveillance programs [162]. Barrett esophagus is principally a disorder of white men; it is three times more frequent in men than in women and is rare in African American and Asian populations [163]. It is found predominantly in middle-aged and older adults; the mean age at diagnosis is approximately 55 years, but it has been reported in children older than 5 years of age [164]. The prevalence of Barrett esophagus increases with age, paralleling that of reflux esophagitis, but the length of the columnar-lined segment remains remarkably stable, even over years of endoscopic follow-up [163]. This finding suggests that it arises rapidly in the susceptible reflux-damaged esophagus and early in the course of disease. Families have been reported with multiple members having Barrett esophagus, some with cancer affecting more than one generation [10,165]. Although the columnar-lined esophagus in itself does not cause symptoms, most patients complain of heartburn and regurgitations. Approximately 25% of patients with Barrett esophagus discovered at endoscopy have no esophageal symptoms [90].

Barrett esophagus is suspected at endoscopy and is confirmed by biopsy and histological examination. The columnar epithelium of the stomach is reddish pink, and the junction between the glossy white squamous mucosa and the columnar mucosa (Z-line) is normally found at the lower end of the tubular esophagus, just above the proximal folds of a hiatal hernia if present. In Barrett esophagus, the distal esophagus is lined with columnar epithelium, extending upward for a variable distance, often 3–10 cm, but occasionally involving most of the esophagus (Fig. 32.10a). The

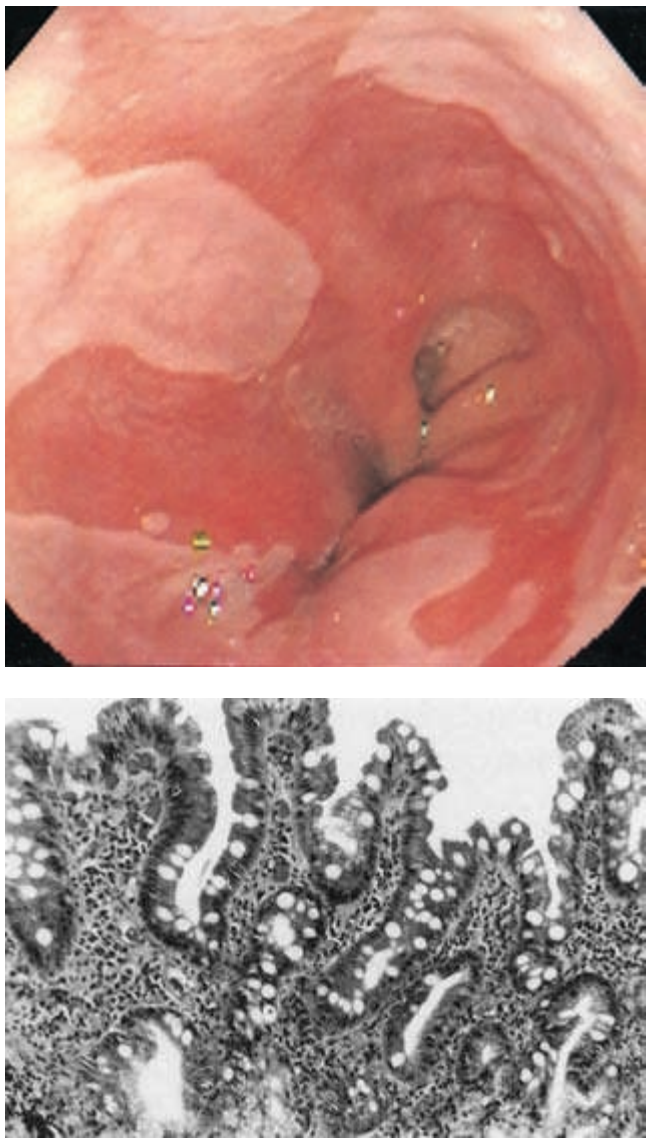

Figure 32.10 Barrett esophagus. **(a)** Reddish pink columnar mucosa with tongue-like projections 3–4 cm into the tubular esophagus. **(b)** Specialized intestinal metaplasia with glandular epithelium and characteristic goblet cells.

proximal margin may be horizontal or there may be irregular, often tongue-shaped upward extensions of columnar mucosa. Some patients have pale islands of regenerative or residual squamous epithelium, whereas others have punched-out benign ulcers in the columnar area. Strictures and esophagitis may be seen at the new squamocolumnar junction. The endoscopist should especially look for evidence of adenocarcinoma, such as nodularity or masses [166].

The characteristic histological finding in Barrett esophagus is a distinctive specialized intestinal epithelium. This is a glandular epithelium with mucin-type cells and the distinguishing presence of goblet cells (see Fig. 32.10b). These are easily seen on hematoxylin and eosin-stained sections and can be demonstrated more prominently in sections stained with Alcian blue. It occupies most or all of the columnar-lined area and is the type of epithelium in which adenocarcinoma arises [167]. Other types of epithelia seen with Barrett esophagus include gastric fundic and cardia-type epithelia, but these alone do not make the diagnosis of Barrett esophagus nor are they associated with adenocarcinoma.

There is some controversy over the classification of Barrett esophagus [157,166]. The classical or *long-segment Barrett esophagus* requires at least 3 cm of esophagus to be lined with columnar epithelium. This is the best-studied subset of Barrett esophagus, with traditional demographic features and a definite increased risk of becoming adenocarcinoma. *Short-segment Barrett esophagus* refers to shorter lengths or tongues of columnar epithelium, less than 3 cm, in the distal esophagus, with intestinal metaplasia on biopsy. This entity is three to five times more common than the long-segment variant, but, based on anecdotal reports, the risk of cancer appears to be lower [168]. *Intestinal metaplasia at the esophagogastric junction* refers to microscopic findings on biopsy but no visible columnar epithelium in the esophagus at endoscopy [157]. This finding has been reported in 10%–32% of biopsies from unselected patients, many of whom have no reflux symptoms [168]. The percentage of woman and African American people with this lesion is also higher than the percentage with either long- or short-segment Barrett esophagus. The cause is controversial; some investigators suggest that this is the earliest form of GERD [169], whereas others believe that these changes are secondary to *H. pylori* infection [170]. Cancer risk is minimal, if it exists at all.

Patients with long-segment Barrett esophagus have an estimated 30–125 times increased risk of developing esophageal cancer compared with the general population [171]. Early studies suggested that the median cancer incidence was 1 per 100 patient-years of follow-up [157], but subsequent studies with longer follow-up suggest a lower cancer incidence of 1 per 200–250 patient-years [172,173]. This represents an annual incidence of approximately 0.5%, with about 500 cases of adenocarcinoma diagnosed annually. However, since the early 1980s, the incidence of squamous cell carcinoma has stayed constant, whereas the incidence of adenocarcinoma of the esophagus and esophagogastric junction has risen fivefold – a growth rate exceeding that of any other cancer [174]. Adenocarcinoma accounts for more than half of all esophageal cancers in the United States. Despite this cancer risk, most patients with Barrett esophagus die of unrelated causes [173]. More than 95% of patients who develop cancer present with symptoms caused by the tumor itself and are unaware of their antecedent Barrett esophagus [175]. Epidemiological data suggest that the mean interval from developing Barrett esophagus to evolution of cancer may be 20–30 years [163].

Medical and surgical therapy

The rationale for GERD therapy depends on a careful definition of specific aims. In patients without esophagitis, the therapeutic goals are simply to relieve the acid-related symptoms and to prevent frequent symptomatic relapses. In patients with esophagitis, the goals are to relieve symptoms and to heal the esophagitis while attempting to prevent further relapses and the development of complications. These goals are set against a complex background: GERD is a chronic disease that may wax and wane in intensity, and relapses are common.

Nonprescription therapy

Although GERD is common in the United States, very few persons seek medical care for their complaints, instead choosing to change their lifestyles and self-medicate with over-the-counter (OTC) antacids and low doses of H_2RAs. These observations have led to the "iceberg" model of the GERD population. Most heartburn sufferers are invisible because they self-medicate and do not seek professional help; only those at the tip of the iceberg, typically patients with severe symptoms or reflux complications, are seen by physicians [176].

Lifestyle modifications

Sensible *changes in lifestyle*, especially if their rationale is explained to the patient, should be part of the initial management of all subjects. These include head of the bed elevation, avoidance of tight-fitting clothes, weight loss, restriction of alcohol consumption, elimination of smoking, dietary therapy, refraining from lying down after meals, and avoidance of evening snacks before bedtime. Physiological studies show that these maneuvers enhance esophageal acid clearance, minimize acid reflux-related events, or ease heartburn symptoms, but their therapeutic efficacy in controlled trials usually has not been evaluated [176,177]. The head of the bed can be elevated either by putting 6- to 8-inch blocks under the legs of the bed or by using a Styrofoam wedge under the mattress to elevate the upper torso. Eating several hours before retiring and avoiding evening snacks keep the stomach empty at bedtime, thereby decreasing the number of nocturnal reflux episodes. These three lifestyle changes are recommended for patients with nocturnal GERD symptoms or laryngeal complaints. One study found that head of the bed elevation was nearly as effective as ranitidine therapy in healing esophagitis [178]. Avoidance of tight-fitting clothes and weight loss are interventions aimed at reducing the incidence of reflux by the abdominal stress mechanism. Although obesity is now well established as a risk factor for GERD, esophagitis and esophageal adenocarcinoma, the efficacy of weight reduction is controversial [179]. Targeted weight loss may be helpful when discrete periods of weight gain can be associated with exacerbation of reflux symptoms. Cessation of smoking and elimination of alcohol are valuable because both agents lower LES pressure, reduce acid clearance, and impair intrinsic squamous epithelial protective functions [47,180,181]. Dietary changes include reducing the sizes of meals and the intake of fats, carminatives, and chocolate, to reduce the frequency of reflux by decreasing gastric distention and by reducing the episodes of transient LESRs, and avoiding foods that lower basal LES pressure [176,179]. Additionally, some patients complain of heartburn after consuming citrus drinks, spicy foods, tomato-based products, coffee, tea, or cola drinks. Stimulation of gastric acid secretion or esophageal sensitivity to low pH or hyperosmolar liquid solutions may account for these symptoms [145]. However, the indiscriminate prohibition of food products should be avoided; rather, to promote dietary compliance, prohibition should be tailored to those foods that bring on individual symptoms. Finally, if possible, patients should avoid drugs that lower LES pressure or which can promote localized esophagitis.

Over-the-counter medications

Over-the-counter antacids, Gaviscon, and H_2RAs are useful in treating mild and infrequent heartburn symptoms, especially when symptoms are brought on by lifestyle indiscretions. Antacids increase LES pressure but work primarily by buffering gastric acid in the esophagus and stomach, albeit for relatively short periods. Heartburn symptoms are rapidly relieved, but patients need to take antacids frequently, usually 1–3 h after meals and at bedtime, depending on symptom severity. Gaviscon, containing alginic acid and antacids, mixes with saliva to form a highly viscous solution that floats on the surface of the gastric pool and acts as a mechanical barrier. Both antacids [182] and Gaviscon [183] are more effective than placebo in relieving symptoms induced by a heartburn-promoting meal. However, these agents do not heal esophagitis, and long-term trials suggest effective symptom relief in only 20% of patients using antacids [184]. H_2RAs are available in an OTC form at doses that are usually one-half of the standard prescription dose. Although their onset of relief is not as rapid as that of antacids, the OTC H_2RAs have a longer duration of action, up to 6–10 h. Therefore, they are particularly useful when taken before a potentially refluxogenic activity, such as a heavy meal or exercise. Similar to antacids, the OTC H_2RAs are ineffective in healing esophagitis [185]. In the summer of 2003, the US Food and Drug Administration (FDA) approved omeprazole (20 mg) as the first OTC PPI. Drug labeling suggested daily use for only 2 weeks and recommended physician follow-up for persistent symptoms. Despite initial fears that patients might abuse this drug and not see a physician, early consumer data suggest that individuals accurately self-select if OTC omeprazole is appropriate to use, comply with a 2-week regimen, and seek physician care for long-term management of frequent heartburn [186].

Prescription medication therapy

Patients with frequent heartburn, esophagitis, or complications of GERD usually see a physician and receive prescription medications for their disease. Although prokinetic drugs attempt to correct the motility disorder associated with GERD, the most clinically effective medications for short- and long-term reflux treatment are the acid-suppressive drugs.

Prokinetic drugs

Until recently, three prokinetic drugs were available for the treatment of GERD: bethanechol, a cholinergic agonist; metoclopramide, a dopamine antagonist; and cisapride, a serotonin (5-HT_4) receptor agonist, which increases acetylcholine release in the myenteric plexus. These drugs improve reflux symptoms by increasing LES pressure, acid clearance, or gastric emptying [187]. However, none alters the frequency of transient LESRs, and their physiological activity decreases as the disease severity worsens [188]. Therefore, all of the current prokinetics provide modest benefit in controlling heartburn but they have little efficacy in healing esophagitis unless they are combined with an acid-inhibiting drug [187].

The use of prokinetic drugs is limited by their side-effect profiles. Bethanechol commonly causes flushing, blurred vision, headaches, abdominal cramps, and urinary frequency. Metoclopramide, which crosses the blood–brain barrier, has a 20%–50% incidence of fatigue, lethargy, anxiety, and restlessness, and rarely causes tremor, parkinsonism, or tardive dyskinesia. It is possible to decrease the frequency of these side effects by dose reduction, by increasing the dosing regimen to twice a day, by taking a larger single dose before dinner or at bedtime, or by using a sustained-release tablet. Although cisapride was the best prokinetic drug for treating GERD, with an excellent safety profile, it was withdrawn from the US market because of increased reports of serious cardiac arrhythmias (ventricular tachycardia, ventricular fibrillation, torsades de pointes, and QT prolongation), with associated cardiac arrest and deaths related to possible drug interactions [189].

Histamine type 2 receptor antagonists

Cimetidine, ranitidine, famotidine, and nizatidine reduce acid secretion by competing for histamine receptors on parietal cells. They are more effective in controlling nocturnal than meal-related acid secretion because parietal cells may also be stimulated postprandially by acetylcholine and gastrin [190]. All of the H_2RAs are equally effective when used in proper doses, usually twice a day before meals. Clinical GERD trials show that heartburn, both day and night, can be significantly decreased by H_2RAs compared with placebo, although symptoms are rarely abolished (Fig. 32.11a) [191]. Trials and a metaanalysis found that the overall esophagitis healing rates with H_2RAs rarely exceeded 60% after up to 12 weeks of treatment, even when higher than standard doses were used (see Fig. 32.11b) [191,192]. Healing rates differ in individual trials, depending primarily on the degree of esophagitis being treated: grade I and II esophagitis heals in 60%–90% of patients, whereas grade III and IV heals in 30%–50% of patients despite high-dose regimens [192].

Reflux symptoms associated with nocturnal gastric acid breakthrough during PPI therapy have been recognized [193]. At bedtime, H_2RAs successfully eliminated this problem, suggesting a new indication for H_2RAs in the PPI era [194]. However, this study used only a single evening dose and did not account for the tolerance that frequently develops to H_2RAs over weeks to months [195]. This may impair the ability of chronic long-term nocturnal dosing of H_2RAs to eliminate acid breakthrough symptoms [196], but it suggests an important clinical role as medications to be used on an

(b)

Figure 32.11 **(a)** Symptom relief–time curve expressed as the mean total heartburn relief for proton pump inhibitors (PPIs) or histamine type 2 receptor antagonists (H_2RA) corrected for patients free of heartburn at baseline and over 8 weeks. By week 2, more patients treated with PPIs are asymptomatic than patients treated with H_2RAs; this superior efficacy is maintained over the 6- to 8-week duration of these studies. **(b)** Esophagitis healing–time curve expressed as the mean total healing for PPIs, H_2RAs, and placebo over 12 weeks. By 4 weeks, PPIs healed esophagitis in more patients than the other two drug classes over 12 weeks, implying a substantial therapeutic gain. The number of studies is shown in parentheses. From Chiba et al. [192], with permission from the American Gastroenterological Association.

as-needed basis when lifestyle indiscretions may promote nocturnal symptoms.

The H_2RAs are very safe, with a side-effect rate (most of which are minor and reversible) of about 4% [190]. Serum concentrations of phenytoin, procainamide, theophylline, and warfarin are altered after the administration of cimetidine and, to a lesser degree, ranitidine, whereas this interaction is not reported with the other two H_2RAs. The concern that these agents could alter blood ethanol levels has been discounted [190].

Proton pump inhibitors

This class of drugs markedly diminishes gastric acid secretion by inhibiting the final common pathway of acid secretion, the H^+,K^+-ATPase pump. PPIs inhibit daytime, nocturnal, and meal-stimulated acid secretion to a significantly greater degree than H_2RAs [197], but they rarely make patients achlorhydric. Unlike H_2RAs, the degree of acid inhibition by PPIs does not correlate with plasma concentration, but is related to the concentration and duration (area under the curve). After oral ingestion, acid inhibition is delayed because PPIs need to accumulate in the secretory canaliculus of the parietal cell to bind irreversibly to actively secreting proton pumps [198]. Therefore, the slower a PPI is cleared from the plasma, the more of it is available for delivery to the proton pumps. PPIs are best taken before the first meal of the day, when most proton pumps are active. Because not all pumps are active at any given time, a single PPI dose does not inhibit all pumps. A second dose, if needed, can be taken before the evening meal.

The five available PPIs are omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole, the S-isomer of the racemic omeprazole. Their superior efficacy compared with H_2RAs is based on their ability to maintain an intragastric pH higher than 4.0 between 15 and 21 h daily compared with approximately 8 h daily for the H_2RAs [199]. PPIs are superior to H_2RAs in completely relieving heartburn symptoms in most patients with severe GERD, usually within 1–2 weeks (see Fig. 32.11a) [192]. Symptom relief is better in patients with erosive than nonerosive disease [200]. Controlled studies and a large metaanalysis report complete healing of even severe ulcerative esophagitis after 8 weeks in more than 80% of patients taking PPIs compared with 51% of patients taking H_2RAs and 28% receiving placebo (see Fig. 32.11b) [201–205]. In those patients not healing initially, prolonged therapy with the same dose or an increased dose usually resulted in 100% healing [206]. Therapeutic efficacy between PPIs was similar; however, large studies have found that the newest PPI, esomeprazole (40 mg), is superior to omeprazole (20 mg) and lansoprazole (30 mg) in healing esophagitis [207]. The therapeutic advantage is minimal with mild esophagitis (number to treat, 20–40 patients) and greatest with severe esophagitis (number to treat, 7–10 patients). This superiority is related to higher systemic bioavailability and less interpatient variability with esomeprazole. Several PPIs are now available in the United States for intravenous use.

All of the PPIs are well tolerated with headaches and diarrhea described as the most common side effects in clinical trials. Although increased gastrin levels are reported with all of the PPIs, the elevations generally do not exceed the normal range for gastrin and levels return to normal values within 1 week of stopping the drug. Omeprazole may decrease the clearance of diazepam and warfarin because of competition for the cytochrome P450 isoenzyme P2C19 [208]. The four newer PPIs have minimal or no important drug–drug interactions.

Maintenance therapy

GERD tends to be a chronic relapsing disease, especially in patients with low LES pressure, severe grades of esophagitis, and difficult to manage symptoms [185]. Although almost all patients with severe esophagitis can be healed with PPI treatment, recurrence can be anticipated in more than 80% of patients within 6 months of drug discontinuation [147]. The chronicity of less severe forms of GERD is less certain, but relapses probably occur in 15%–30% of patients over 6 months [209]. Therefore, maintenance therapy is needed for many patients.

One-year maintenance studies always find that the PPIs are superior to the H_2RAs or prokinetics, with remission rates higher than 75% [148,210,211]. H_2RAs and prokinetic drugs have lower overall remission rates (20%–50%) and are most useful in patients with mild or no esophagitis [148,212]. The FDA has approved all of the PPIs, sometimes at half the short-term dose, for maintenance therapy, but only ranitidine, 150 mg twice daily, has maintenance indications for mild esophagitis. Conversely, clinicians are now placing their patients with severe erosive esophagitis on long-term PPI therapy indefinitely. The efficacy of this approach is supported by open, compassionate use data, primarily from the Netherlands and Australia [213,214]. In a study of 230 patients with severe esophagitis healed initially with 40 mg of omeprazole, all subjects were kept in remission for up to 11 years. More than 60% were maintained on omeprazole, 20 mg a day, whereas higher doses of 60 mg or more were needed in only 12% of patients, suggesting a lack of tolerance to PPIs. Relapses were rare (1 per 9.4 years of follow-up), strictures did not occur, and Barrett esophagus did not progress [214].

There was concern about the long-term safety of PPIs because of their profound acid suppression. Evidence suggests that this fear is unjustified, as sufficient gastric acid is produced, allowing for normal protein and carbohydrate digestion, iron and calcium absorption, and the prevention of bacterial overgrowth. The clinical effect of omeprazole on vitamin B-12 absorption is controversial [215]. Therefore, it may be prudent to monitor vitamin B-12 levels in patients

receiving long-term PPI therapy, especially elderly patients or those with poor or unusual diets. The main concern over the long-term safety of PPIs stemmed from reports that omeprazole causes hypergastrinemia and gastric carcinoid tumors in rats, changes also subsequently demonstrated with long-term ranitidine therapy and subtotal resection of the gastric fundus [216]. However, the rat has a high density of enterochromaffin-like cells and an exaggerated response to achlorhydria; long-term omeprazole therapy in species with lower densities of enterochromaffin-like cells (mice, dogs, humans) has not caused carcinoid tumors. Furthermore, other groups with massive hypergastrinemia (five to ten times the gastrin values seen with omeprazole), such as patients with pernicious anemia or Zollinger–Ellison syndrome, rarely develop carcinoid tumors [216]. Finally, one study suggested that patients taking long-term omeprazole who are infected with *H. pylori* develop atrophic gastritis, a precursor to gastric adenocarcinoma, at a more rapid rate than noninfected patients [217]. Nevertheless, a subsequent FDA panel determined that the available data were insufficient for recommending screening and treatment of *H. pylori* infection in patients receiving long-term PPI therapy [218].

Treatment in elderly or pregnant patients

Older patients often complain of less severe reflux symptoms than their younger cohorts; however, because of prolonged acid exposure over many years, the elderly may have more complicated disease [5]. Treatment of older patients with GERD follows the same principles as treatment of other adults, although they may require more aggressive acid-suppression therapy [219]. Pill-induced esophagitis may complicate treatment. Metoclopramide must be used with caution because of frequent side effects in the elderly. H_2RAs can be associated with mental changes in older patients, and doses need to be decreased in patients with renal insufficiency. Fewer drug interactions are seen with famotidine and nizatidine. Alternative methods of administering PPIs may be necessary in debilitated older patients who cannot swallow intact omeprazole or lansoprazole capsules. Both capsules can be opened and the granules taken with water, a HCO_3^--based suspension, or apple or orange juice; alternatively, the granules can be sprinkled onto apple sauce or yogurt [220].

Teratogenicity or fetal harm from absorption of medications across the placenta is the foremost consideration in the treatment of GERD during pregnancy [221]. Lifestyle modifications and the use of antacids or Gaviscon remain the cornerstones of treatment, providing adequate relief to the majority of women with mild symptoms. Although rarely used in adults, sucralfate is a nonabsorbable mucosal binder that has been found to be superior to lifestyle changes in a controlled study in pregnant women [222]. Metoclopramide, H_2RAs, and most PPIs (except omeprazole) have a category B FDA safety profile for use during pregnancy, which is based on animal studies showing no risk, as well as on small case series and anecdotal human reports. Ranitidine is the only one of these drugs that has been shown to be effective during pregnancy [223]. PPIs may be safe for aspiration prophylaxis before anesthesia for elective cesarean sections. Antacids, sucralfate, and most H_2RAs (except nizatidine) are safe to use during lactation, even though H_2RAs are excreted in breast milk. PPIs are not recommended for use during breast-feeding, based on safety concerns in animal studies [221].

Treatment of complications

Extraesophageal presentations

Acid reflux-related chest pain is easily treated by H_2RAs or PPIs, with efficacy substantiated by placebo-controlled studies [224]. The efficacy of acid-suppression therapy in asthma, cough, and other pulmonary complications of GERD is more mixed [98]. Medical antireflux therapy improves asthma symptoms and reduces the need for asthma medications in more than 60% of patients, but objective improvement of peak expiratory flow rates is observed in only 25% of patients. Best results are found with higher doses of PPIs (usually twice-daily administration) given for 2–3 months. Potential positive predictors of PPI response include asthma that is difficult to control, associated acid regurgitation, proximal reflux on pH testing, and healing of esophagitis with antireflux therapy. Case studies report that 60%–96% of patients with suspected acid-related ear, nose, and throat symptoms and signs improve with acid suppression, but the results of placebo-controlled studies are inconsistent and much less encouraging [126]. Here again, PPIs are more effective than H_2RAs, and extended therapy for up to 3 months may be required. Predictors of response have not been identified, although patients with milder laryngeal signs show better symptom improvement. In all of these possible extraesophageal presentations of GERD, failure to respond to aggressive PPI therapy, confirmed by adequate acid control on pH testing, suggests a cause of these complaints other than acid.

Esophageal strictures

Dysphagia in patients with esophageal strictures is related to stricture diameter and severity of esophagitis [225]. When the esophageal lumen diameter is less than 13 mm, dysphagia is a major complaint and esophageal dilation is required. Simple short strictures can be dilated by blind peroral passage of rubber Hurst (round ends) or Maloney (tapered ends) mercury-filled dilators of increasing sizes (16–60 French, 3 French = 1 mm) to disrupt the fibrous bands producing the obstruction. Complicated longer, tighter, or more irregular strictures will require bougienage over a guidewire using hollow-centered Savary plastic-covered polyvinyl dilators or balloon (Gruentzig) dilators. The techniques of esophageal dilation are discussed in detail in Chapter 121 [226]. Before and after dilation, medical therapy with PPIs is indicated;

PPIs have been shown to be superior to H_2RAs in relieving symptoms and in reducing the need for repeat dilations [227]. Maintenance PPI therapy for patients with strictures has dramatically reduced the incidence of repeat esophageal dilations and the cost of treating these patients [154]. Recalcitrant strictures requiring surgery are now very uncommon and suggest another aggravating factor such as chronic pill injury.

Barrett esophagus

Esophagitis in the presence of Barrett esophagus can be easily healed with PPI therapy; however, regression of Barrett epithelium, except for small squamous islands, is rarely reported, even with high-dose PPI therapy [228]. Recent ex vivo studies [229] have suggested that intermittent "pulses" of acid enhance Barrett epithelial cell proliferation, possibly increasing the risk of dysplasia and cancer. The clinical relevance of this data is supported by a 20-year follow-up study of 236 veteran patients by a single endoscopist. In multivariate analysis, the use of PPIs after the diagnosis of Barrett esophagus was independently associated with a reduced risk of dysplasia (hazard ratio 0.25, 95% confidence interval 0.13–0.47) [230]. Therefore, all Barrett patients should be on chronic PPI therapy.

Esophageal resection of Barrett esophagus can prevent the progression to cancer; however, this requires a total esophagectomy, which has a high mortality rate except in selected surgical centers. Therefore, ablation of Barrett epithelium in the setting of strict PPI anacidity has been proposed. Photodynamic therapy, laser, multipolar electrocoagulation, argon plasma coagulation, and endoscopic mucosal resection have been used for this purpose [231]. In these studies, Barrett mucosa can be reversed completely in 70%–80% of patients, but intestinal metaplasia underlying the new squamous mucosa is reported in almost all series, with the occasional residual foci of metaplasia developing adenocarcinoma [232]. Adverse effects of ablation therapy have ranged from mild chest pain, sore throat, or odynophagia to esophageal perforation and death. The incidence of adenocarcinoma in patients with Barrett esophagus without dysplasia is probably so low that endoscopic ablation cannot be advocated outside of study protocols. Endoscopic therapy for patients with high-grade dysplasia or early cancer holds more promise, especially in the older patients with comorbid illnesses [233].

Because there is no way of eliminating the malignant risk of Barrett esophagus, regular endoscopic surveillance is recommended. Biopsies should be taken from each quadrant every 2 cm axially within the metaplastic tissue. The rationale is that dysplasia within Barrett epithelium is often multifocal, and obtaining fewer tissue samples increases the risk of missing dysplastic areas [234]. Brush cytology can complement endoscopic biopsies [235]. Biomarkers [236], such as p53, and flow cytometry [237] may augment the yield of histological examination of biopsy specimens. Although prospective studies are not available, case series confirm that esophageal adenocarcinomas detected by endoscopic surveillance are at an earlier stage and have a more favorable survival outcome than cancers detected at the time of diagnosis of Barrett esophagus, typically when patients present with dysphagia [238].

The appropriate surveillance interval for patients with Barrett esophagus has not been studied prospectively. However, current programs, such as proposed by the American College of Gastroenterology, are based on the grade of dysplasia (Table 32.3) [239]. In these recommendations, the management of high-grade dysplasia remains most controversial. Some groups suggest that high-grade dysplasia may regress to lesser grades, and that an intensive biopsy protocol every 3 months will differentiate high-grade dysplasia from cancer [240,241]. The surgical literature contrasts with this experience. Of 126 cases with high-grade dysplasia alone on endoscopic biopsy, 41% had cancer, although usually an early stage, at the time of esophagectomy [239]. Nevertheless, most patients with Barrett esophagus never progress to important degrees of dysplasia. Predictors of cancer progression at the initial diagnosis of Barrett esophagus are needed to define individual surveillance programs more appropriately. One study suggested that patients whose baseline biopsies are negative or show only low-grade dysplasia without increased 4N or aneuploidy on flow cytometry may have surveillance deferred for up to 5 years [241]. Another

Table 32.3 Barrett esophagus: grade of dysplasia and proposed follow-up

	Published data			
Dysplasia	**No. cancer cases/total no. patients**	**Percentage**	**Follow-up (years)**	**Proposed endoscopic follow-up**
None	5/150	3	3.4–10	After two negative biopsies, every 2–3 years
Low-grade	8/45	18	1.5–4.3	Every 6 months for 1 year, then every year
High-grade	21/61	34	0.2–4.5	Expert confirmation; esophageal resection, ablation therapy or endoscopic surveillance every 3 months

From Sampliner [239], with permission from Blackwell Publishing.

prospective multivariate analysis revealed that progression to high-grade dysplasia or cancer was significantly and independently associated with dysplasia at diagnosis or at any time during follow-up, hiatal hernia size, and Barrett esophagus length [242]. These patients may warrant more frequent surveillance programs.

Other unresolved issues in Barrett esophagus include the role of screening endoscopy and chemoprevention in dysplasia [243]. As the majority of Barrett patients remain undiagnosed, screening endoscopy has been recommended for older men with chronic long-standing heartburn [157]. A recent mathematical model [244] found that screening a 50-year-old man with GERD was cost-effective (US$10 000 per quality-adjusted life-year of survival gained) if follow-up endoscopies were carried out only in the subset of Barrett patients with dysplasia at initial biopsy. Two studies [244,245] of patients referred for colon cancer screening who agreed to upper endoscopy demonstrated Barrett esophagus (usually short segment) in 10%–25%, regardless of the presence of reflux symptoms, suggesting a practical method to address this issue. Chemoprevention is a rapidly emerging option that can be used to reduce the risk of developing adenocarcinoma in Barrett esophagus. A metaanalysis of previous cohort studies showed that low-dose aspirin and NSAIDs led to a significant risk reduction in esophageal cancer [246]. These drugs block the up-regulation of cyclooxygenase 2 (COX-2) enzyme activity, which is serially increased along the metaplasia–dysplasia–cancer cascade [247].

Surgical treatment

Antireflux surgery reduces GER by increasing basal LES pressure, decreasing episodes of transient LESR, and inhibiting complete LESR [248]. This is accomplished by reducing the hiatal hernia back into the abdomen and thereby restoring an adequate length of intraabdominal sphincter, reconstructing the diaphragmatic hiatus, and reinforcing the LES [249]. Since the advent of minimally invasive surgery, the two most popular operations are the Nissen fundoplication and the Toupet partial fundoplication (Fig. 32.12). The former is a superior operation with more long-term durability, but it has a higher frequency of postoperative dysphagia and gas bloat symptoms [250,251]. Both are now routinely performed laparoscopically through the abdomen. The hospital stay is 1–2 days, and many patients return to normal activity within 7–10 days. Patients with more severe disease and a short esophagus manifested by a large nonreducible hernia, a tight stricture, or a long-segment Barrett esophagus require a Collis lengthening procedure creating a 3- to 5-cm neoesophagus so that the fundoplication can be placed in the abdomen under minimal tension [252].

In the PPI era, the resolution of symptoms on treatment helps to predicate the success of antireflux surgery for both classical and atypical symptoms [253]. Antireflux surgery is a reasonable option in the following situations: (1) healthy patients with GERD well controlled on PPIs who want alternative therapy because of drug expense, poor medication compliance, or a fear of unknown long-term side effects; (2) patients with atypical GERD symptoms responding to PPIs; and (3) patients with volume regurgitation and aspiration symptoms not controlled on PPIs. Patients recalcitrant to PPI therapy need to be approached cautiously with surgery because there may be another cause of their disorder (i.e., pill esophagitis, gastroparesis, functional heartburn).

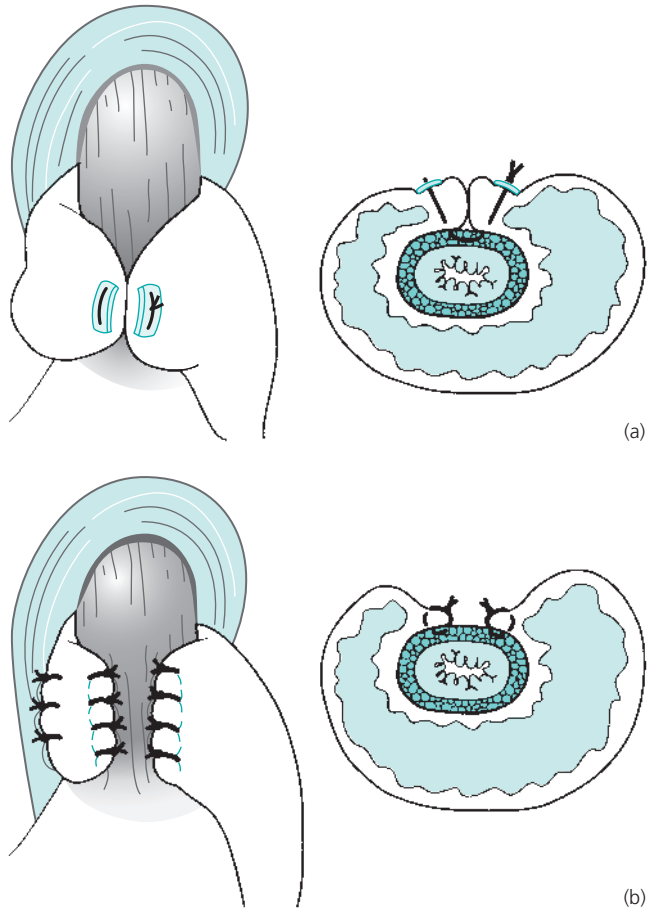

Figure 32.12 Appearance and cross-sectional views of the Nissen fundoplication, a full 360° wrap **(a)**, and the Toupet partial fundoplication **(b)**. These are the two most popular fundoplications used in laparoscopic antireflux surgery.

Extensive physiological testing should be carried out before antireflux surgery is performed. All patients need to undergo endoscopy to exclude strictures, Barrett esophagus, and dysplasia. A barium esophagram can help define a nonreducible hernia, shortened esophagus, and poor esophageal motility. Esophageal manometry combined with impedance testing will identify ineffective esophageal peristalsis and previously misdiagnosed achalasia or scleroderma. In addition, 24-h pH testing is needed in all patients with nonerosive GERD or in those with esophagitis not responding to PPI therapy. Gastric analysis and gastric emptying studies may be indicated in

selected patients. Careful testing will result in modification of the original operation or an alternative diagnosis in approximately 25% of patients [131].

Antireflux surgery relieves reflux symptoms and reduces the need for stricture dilation in more than 90% of patients [251], but Barrett esophagus rarely regresses and there is insufficient evidence that surgery reduces the risk of esophageal cancer [254]. Comparison studies have found that antireflux surgery is superior to lifestyle changes, the use of antacids, and H_2RA and prokinetic therapy [151,184], but not to PPI therapy, especially when dose titration is permitted [255]. Mortality is rare (< 1%) after antireflux surgery, but new postoperative complaints can occur in up to 25% of patients, including dysphagia, gas bloat, diarrhea, and increased flatus [256]. Most symptoms improve over a year, but persistent complaints suggest too tight a wrap, a displaced fundoplication, or inadvertent damage to the vagus nerve. Successful antireflux surgery, however, does not guarantee a permanent cure. The best surgical results are obtained by experienced surgeons in high-volume centers who report long-term symptom recurrence in only 10%–15% of patients [250]. However, most operations are performed by community or Veterans Affairs hospital surgeons. Here the results are not as good, with studies finding relapse of symptoms after 2 years in 32% of patients, with 7% requiring repeat surgery [257], and a return to regular use of antireflux medications in 62% of patients (one-half on PPIs) 10–15 years after fundoplication [258]. Potential factors contributing to these high relapse rates include inexperienced surgeons, low numbers of operations performed yearly per surgeon, and persistence of abdominal stressors (i.e., obesity, heavy isometric exercise or work) that gradually weaken the fundoplication. A suboptimal operation or severe symptom relapse may necessitate a second operation, which has less likelihood of a successful outcome [249]. Because optimal medical therapy is available to all patients with GERD, the risk and benefits of both long-term medical treatment and antireflux surgery must be carefully discussed with patients so that they can take part in this important decision.

New treatments

The future medical treatment of GERD involves drugs that interfere with transient LESRs but which do not cause dysphagia. Baclofen, a GABA-B agonist, has been shown to decrease reflux symptoms and to improve pH studies in healthy persons and in patients with GERD [259]. Newer endoscopic treatments of GERD have been approved by the FDA. These techniques include an endoscopic suturing system, radiofrequency energy delivery to the gastroesophageal junction, and the injection of nonabsorbable polymers into the submucosa surrounding the LES [260–262]. These procedures decrease the frequency of transient LESRs, but LES pressure is unchanged and less than 40% of patients have normal pH tests. To date, these techniques have been applied only to patients with small (< 2 cm) or no hernias and mild esophagitis. The results are encouraging, with improvement of symptoms and decreased medication requirements, but the cost-effectiveness and durability of the procedures is suspect (usually > 50% failure by 1–2 years) and reported complications include perforation, hemorrhage, pain, and death. Controlled studies using the radiofrequency energy delivery and injectable polymer techniques show consistent symptom improvement over the sham procedure, inconsistent reduction in the use of PPIs, and no significant improvement in LES pressure or pH profiles [263,264]. Serious adverse effects after using the injectable techniques, including several deaths, led to the voluntary withdrawal of Enteryx by the manufacturer in September 2005, and suspension of the Gatekeeper clinical program in 2005. An American Gastroenterological Association (AGA) Institute medical position statement recommended that "current data suggests that there are no definite indications for endoscopy therapy for GERD at this time" [265].

Since 2000 an increasing body of evidence has suggested that eosinophils are likely to play a key role in the pathogenesis of gastrointestinal diseases. In this time frame, eosinophilic esophagitis (EoE) has emerged as a distinct clinicopathological disease affecting both children and adults. Symptoms span a broad range in children but affected adults typically complain of dysphagia and often present with food impaction. These complaints are thought to be secondary to acute esophageal spasm resulting from chronic allergic inflammation with fibrotic stricture formation. Although the natural history of this disease remains uncertain, removal of dietary allergens and medical management with glucocorticoids have been shown to have clear benefit. This chapter will focus on pathogenetic mechanisms of eosinophilic inflammation and the clinicopathological features of EoE.

Eosinophil biology

Life cycle and regulation

Eosinophils are produced in the bone marrow from pluripotential stem cells under the regulation of the transcription factor GATA-1 [1] and the cytokines interleukin (IL)-3, IL-5, and GM-CSF [2]. IL-5 is the most specific to the eosinophil lineage and is responsible for the selective differentiation of eosinophils [3], their release from the bone marrow into the peripheral circulation [4], and their survival [5]. The critical role of IL-5 in the production of eosinophils is best demonstrated by genetic manipulation of mice. Overproduction of IL-5 by a variety of approaches, including transgenic overexpression in enterocytes, results in profound blood eosinophilia, whereas deletion of the IL-5 gene causes a marked reduction of eosinophils in the blood, lungs, and gastrointestinal tract after allergen challenge [6–9]. Based on these results, a humanized anti-IL-5 drug has been developed and tested in asthmatic individuals (as well as in patients with EoE [see section on pathogenesis]). Although this drug lowers the level of circulating eosinophils by 80%, it only reduces lung tissue levels by approximately 55% [10]. Early results with anti-IL-5 have not shown an improvement in airway function (e.g., forced expiratory volume in 1 s [FEV1]) [11], but it appears to induce a significant improvement in markers of remodeling (associated with decreases in transforming growth factor [TGF]-β1 levels) [12]. This suggests the importance of other molecules involved in eosinophil tissue accumulation as well as an important role for eosinophils in the inflammatory changes associated with chronic remodeling, a process that is likely to be important in EoE pathogenesis. Indeed, other products of T helper 2 (Th2) cells (e.g., IL-4 and IL-13) can affect eosinophils [13]. IL-4 and IL-13 induce eosinophil recruitment and survival. They mediate eosinophil function by inducing expression of critical adhesion molecules on the endothelium that bind to the β1- and β2-integrins on eosinophils (such as intercellular adhesion molecule 1 [ICAM-1] and vascular cell adhesion molecule 1 [VCAM-1]), as well as expression of eosinophil-active chemokines, such as the eotaxins, and other molecules that influence eosinophils (e.g., chitinases) [13,14]. IL-4 and IL-13 signal through a common receptor subunit, IL-4Rα, that utilizes the JAK-STAT6 pathway [15]. Mice with targeted deletion of STAT6 have impaired development of Th2-associated responses in the gastrointestinal tract [16,17]. Activated STAT6 dimers bind to specific promoter motifs located in a series of inflammatory genes, such as the eotaxin-1, eotaxin-2, and eotaxin-3 promoters [18–22]. IL-4 and IL-13 receptors are expressed by structural cells such as lung and intestinal epithelium [15,22,23]. In addition to promoting eotaxin production via STAT6-induced transcription, these cytokines promote increased eotaxin-1 mRNA stability by way of

stabilization motifs in the 3′ untranslated region of eotaxin-1 mRNA [24]. Although not yet studied in the esophagus, analysis of lung tissue from asthmatic patients has revealed expression of the eotaxin chemokines by epithelial cells [13,25]. Whether this also applies to esophageal epithelial cells has not been determined, but it is interesting to note that squamous epithelial cells in the skin produce the eotaxins in response to IL-13 treatment [26].

Chemotaxis – eotaxins and CCR3

Eotaxin was initially discovered using a biological assay in guinea pigs designed to identify the molecules responsible for allergen-induced eosinophil accumulation in the lungs [27]. Using an in vivo chemotaxis assay in guinea pig skin, the partial amino acid sequence of the protein responsible for eosinophil chemoattraction in the bronchoalveolar lavage fluid (BALF) in allergen-challenged guinea pigs was determined [27]. This sequence facilitated the genetic cloning of the genes and cDNA for guinea pig, murine, and human eotaxin, which led to the identification of eotaxin as a member of the CC chemokine family, being most homologous to the macrophage chemoattractant protein (MCP) subfamily [28–31]. Utilizing genomic analyses rather than biological assays, two additional genes have been identified in the human genome that encode CC chemokines with eosinophil-selective chemoattractant activity; these have been designated eotaxin-2 and eotaxin-3 [32–35]. It was subsequently determined that the mouse genome only contains eotaxin-1 and eotaxin-2 [19]; a putative mouse eotaxin-3 gene exists but it does not appear to be expressed [36]. Eotaxin-2 and eotaxin-3 are only distantly related to eotaxin-1 because they are only about 30% identical in sequence and are located in a different chromosomal position (human 7q11.23) [19,35,37]; however, they have a conserved structure [38,39] that allows them to specifically bind to the eotaxin receptor, CCR3, a seven transmembrane-spanning G protein-coupled receptor (GPCR), primarily expressed on eosinophils [31,40,41]. CCR3 is a genetically polymorphic receptor that undergoes ligand-induced internalization, a process that is required for eotaxin-induced cellular activation [42–44]. CCR3 is a promiscuous receptor. It interacts with multiple ligands including MCP-2, -3, -4, RANTES, and HCC-2 (MIP-5, leukotactin); however, the only ligands that signal exclusively through this receptor are the eotaxin chemokines, accounting for the cellular selectivity of the eotaxins [45]. Although all three eotaxin chemokines have been shown to selectively trigger CCR3 with potent binding affinities in the nanomolar range, their relative affinities are different. Eotaxin-1 appears to have a unique ability to weakly bind CCR2b and possibly CCR5 [46], whereas eotaxin-3 has been shown to antagonize CCR1, CCR2, and CCR5 [47,48]; this provides a potential mechanism to explain the nonredundant activity of the eotaxins. Indeed, gene targeting and antibody neutralization experiments have shown distinct and cooperative roles for each eotaxin in regulating baseline and allergen-induced eosinophil responses [36,49–51]. CCR3 appears to be the dominant eosinophil chemokine receptor as suggested by its relatively high level of expression and the ability of an anti-CCR3 reagent to block the activity of RANTES, a chemokine that can signal through CCR1 or CCR3 on eosinophils [52]. Interestingly, other cells involved in allergic responses (e.g., Th2 cells, basophils, mast cells, dendritic cells, and airway epithelial cells) also express CCR3 [53–55]; however, the significance of CCR3 expression on these cells has been less clearly demonstrated than on eosinophils. It is interesting to note that keratinocytes have been shown to express CCR3, raising the possibility that the esophageal epithelium may also have the capacity to express CCR3 [56].

There is now substantial preclinical evidence supporting a role for the eotaxins in human disease. Markedly increased levels of eotaxin-1 mRNA in the intestines of patients with inflammatory bowel disease (IBD) have been demonstrated [30]. Additionally, experimental induction of cutaneous and pulmonary late-phase responses in humans has revealed that the eotaxin chemokines are produced by tissue-resident cells (e.g., respiratory epithelial cells and skin fibroblasts) and allergen-induced infiltrative cells (e.g., macrophages and eosinophils) [13]. Following allergen challenge in the lung, eotaxin-1 is induced early (6 h) and correlates with early eosinophil recruitment; in contrast, eotaxin-2 and eotaxin-3 correlate with eosinophil accumulation at 24 h [57–59]. Collectively, these studies have provided the impetus for the development of therapeutic agents aimed at blocking the actions of eotaxins and CCR3. Indeed, small-molecule inhibitors of CCR3 and a humanized anti-human eotaxin-1 antibody have been developed [13,60,61]. The results of a phase I trial of humanized anti-eotaxin-1 antibody in patients with allergic rhinitis have shown no serious adverse responses when this drug is administered by intravenous or intranasal routes [60,62]. Notably, anti-eotaxin-1 antibody lowers levels of eosinophils in nasal washes and nasal biopsies, and improves nasal patency [60,62].

Gastrointestinal eosinophils

Eosinophils have been noted to be present at low levels in numerous tissues. When a large series of biopsy and autopsy specimens were analyzed, the only organs that demonstrated tissue eosinophils (at substantial levels) were the gastrointestinal tract, spleen, lymph nodes, and thymus [63]. Interestingly, eosinophil infiltrations were only associated with eosinophil degranulation in the gastrointestinal tract. Examination of eosinophils throughout the gastrointestinal tract of conventional healthy mice (untreated mice maintained under pathogen-free conditions) has revealed that eosinophils are normally present in the lamina propria of the stomach, small intestine, cecum, and colon [64]. Notably,

unlike intestinal lymphocytes and mast cells, eosinophils are not normally present in Peyer patches or intraepithelial locations, although they commonly infiltrate these regions in eosinophilic disorders [65]. Interestingly, prenatal mice have eosinophils located in similar regions and concentrations as observed in adult mice [64], providing evidence that eosinophil homing into the gastrointestinal tract occurs independently of endogenous flora. Indeed, germ-free mice and mice deficient in innate signaling responses (Myd88 deficient) have normal levels of gastrointestinal eosinophils (ref. 64 and unpublished findings). These data suggest that eosinophils respond to distinct stimuli compared with other intestinal leukocytes; indeed, constitutive expression of eotaxin-1 has been demonstrated to provide the unique signal that promotes localization of eosinophils into the gastrointestinal tract at baseline. The importance of eotaxin-1 in regulating the baseline level of eosinophils is reinforced by the observation that mice with the targeted deletion of eotaxin-1 or its receptor CCR3 (but not eotaxin-2-deficient mice) have a deficiency in gastrointestinal eosinophils [36,66].

Eosinophil-associated gastrointestinal disorders

Eosinophil accumulation in the gastrointestinal tract is a common feature of numerous gastrointestinal disorders including classic IgE-mediated food allergy [67–69], eosinophilic gastroenteritis [70,71], allergic colitis [72–74], EoE [75–77], IBD [78–80], and gastroesophageal reflux disease (GERD) [81–83] (Table 33.1). In IBD, eosinophils usually represent only a small percentage of the infiltrating leukocytes [80,84], but their level has been proposed to be a negative prognostic indicator [84,85]. Similarly, in GERD there are only low levels of esophageal eosinophils [81,86]. Primary eosinophil-associated gastrointestinal disorders (EGID; e.g., EoE, eosinophilic gastritis, eosinophilic gastroenteritis, eosinophilic enteritis, and eosinophilic colitis) are defined as disorders that primarily affect the gastrointestinal tract with eosinophil-rich inflammation in the absence of known causes of eosinophilia (e.g., drug reactions, parasitic infections, malignancy) [87]. Patients with EGID suffer from a variety of problems including failure to thrive, abdominal pain, irritability, gastric dysmotility, vomiting, diarrhea, and dysphagia [88–90]. Evidence is accumulating to support the concept that EGID arises secondary to the interplay of genetic and environmental factors. Notably, a large percentage (~10%) of patients suffering from EGID, especially EoE, have an immediate family member with EGID [91,92]. Additionally, several lines of evidence support an allergic etiology, including the finding that approximately 75% of patients with EGID are atopic [93–101], the common finding of mast cell degranulation in tissue specimens [102,103], and the finding that the severity of disease can sometimes be reversed by institution of an allergen-free diet [100,101,104]. Importantly, recent murine models of EGID support a potential allergic etiology for these disorders [105,106]. Interestingly, despite the common finding of food-specific IgE in patients with EGID, food-induced anaphylactic responses only occur in a minority of patients [87]. Thus, EGID have properties that fall between pure IgE-mediated food allergies and cellular-mediated hypersensitivity disorders (e.g., celiac disease) [69,87,107,108].

Table 33.1 Differential diagnosis for gastrointestinal eosinophilia

Gastroesophageal reflux disease

Toxic injury

Clinical features

EoE is a clinicopathological disease, predominantly affecting young males, that is often confused with GERD as it presents with symptoms of vomiting, dysphagia, heartburn, and food impaction. Features that help to distinguish it from peptic disease include the finding of large numbers of esophageal eosinophils, a history of other atopic diseases, peripheral eosinophilia, and the lack of response of these features to maximal acid suppression (Table 33.2). It is important to remember that the mere presence of esophageal eosinophils is not pathognomonic for a particular disorder as eosinophil infiltration in the esophagus occurs in a variety of states including EoE, eosinophilic gastroenteritis, GERD, parasitic and fungal infections, IBD, hypereosinophilic syndrome (HES), scleroderma, and drug injury [86,109,110]. Estimates suggest that peptic esophagitis is at least 10 times more common than EoE, emphasizing the fact that GERD must be ruled out before assigning a diagnosis of EoE.

All age groups are affected by EoE but the presentation in adults and children is different (Table 33.3). Commonly

Table 33.2 Differences between gastroesophageal reflux disease (GERD) and eosinophilic esophagitis (EoE)

	GERD	EoE
Prevalence	Common (~ 1:10)	Uncommon (~ 1:2000)
Sex preference	Males = females	Males > females
Food impaction	Uncommon	Common
Symptom response to PPI	Yes	No
Endoscopic appearance	Exudates, friability, ulceration	White exudates, furrowing, longitudinal shearing
Histology	Basal zone hyperplasia, papillary lengthening, distal eosinophilia	Increased basal zone hyperplasia, typically more eosinophils/hpf and eosinophils in proximal and distal region
pH probe analysis	Increased acid reflux	Normal
Treatment	Acid blockade, prokinetics	Elimination diet, elemental diet, corticosteroids (topical or systemic), dilation
Pathogenesis	Transient relaxation of the lower esophageal sphincter	IL-5-, IL-13-, and eotaxin-driven response
Complications	Distal stricture, Barrett esophagus	Proximal stricture, esophageal fragility

hpf, high-power field; PPI, proton pump inhibitors.

Table 33.3 Age-related differences in eosinophilic esophagitis

	Pediatric	Adult
Symptoms	Feeding refusal, vomiting, abdominal pain, GERD unresponsive to acid blockade	Dysphagia, food impaction, GERD unresponsive to acid blockade
Endoscopic findings	Whitish exudates, longitudinal furrows, fixed or transient rings, proximal strictures	Same as pediatric findings, small-caliber esophagus
Treatment	Dietary (elemental and food elimination), corticosteroids (systemic and topical)	Same as pediatric treatments plus esophageal dilation

GERD, gastroesophageal reflux disease.

reported symptoms include difficulty feeding, failure to thrive, vomiting, epigastric or chest pain, dysphagia, and food impaction [77,100,111,112]; in fact, these symptoms appear to occur in progressive order as they are the presenting symptoms from infancy into adulthood [92]. Indeed, the most common symptoms observed in adult patients are dysphagia and food impaction [113–115] whereas affected children typically seek evaluation for non-specific symptoms of vomiting, feeding refusal, failure to thrive, and epigastric and periumbilical abdominal pain. As longitudinal studies from childhood into adulthood are not yet available, it is unclear if childhood EoE evolves into adult EoE and whether adult EoE involves the same pathogenic mechanisms as pediatric EoE. Peripheral eosinophilia does not help as it is not a consistent finding.

Early studies described children who were thought to have recalcitrant GERD who underwent Nissen fundoplication. Because symptoms persisted postoperatively, endoscopy was repeated and showed large numbers of mucosal eosinophils in the esophagus. Esophageal narrowing is more commonly seen in teenage and adult patients than in the young child. Consistent with this finding is the fact that adult patients more often undergo treatment with esophageal dilation than children. Typically, children will respond to medical treatments that include dietary and corticosteroid approaches.

Unlike all other segments of the gastrointestinal tract, the esophagus is normally devoid of eosinophils and so the finding of esophageal eosinophils denotes pathology [65]. Presently, the exact number of eosinophils that define EoE is uncertain. Traditionally, fewer than six eosinophils/high-power field (hpf; 400 ×) has been thought to be most indicative of GERD, whereas more than 20–24 eosinophils/hpf appears to be most indicative of EoE [110,112,116]. The anatomical distribution of eosinophils in both the proximal

and distal esophagus typically denotes EoE whereas the accumulation of eosinophils mainly in the distal esophagus is likely to be more characteristic of GERD [76]. In one study [116], the level of eosinophils in the esophagus negatively correlated with the response to conventional anti-GERD therapy. For instance, esophageal eosinophil levels of more than 23/hpf correlated with lack of responsiveness to anti-GERD therapy. However, recent evidence suggests that large numbers of eosinophils (> 25/hpf) can also be seen in GERD in children (unpublished data). Patients with intermediate levels of eosinophils (7–20/hpf) often present a diagnostic dilemma for several reasons. First, the cutoff value of eosinophil concentration has not been vigorously determined. Second, EoE is often a patchy disease and diagnosis is dependent on the number of biopsies obtained; there may be great variability in the maximum level of eosinophils [77]. Other associated pathological findings suggestive of EoE include superficial layering of eosinophils and eosinophilic abscesses. Both gastric and duodenal biopsies are normal in this disease. Clearly, the detection of a molecular marker(s) for this disease would aid in disease diagnosis, as has occurred with celiac disease [117]. Endoscopic esophageal biopsy from a patient with EoE typically shows a high concentration of eosinophils, readily detectable eosinophil granule proteins in the extracellular regions, and the marked expansion of the basal layer (basal zone hyperplasia) (Fig. 33.1).

Radiographic studies from patients with EoE reveal proximal esophageal stricture, small-caliber esophagus, and Schatzki rings. Endoscopic analysis has shown a number of features including whitish papules or exudates consistent with eosinophilic desquamation. This finding can be confused with *Candida albicans* infection or use of topical anesthetic spray. Additional findings include longitudinal furrows, proximal strictures, and a fragile esophageal mucosa, which can occur when merely passing the endoscope across the esophageal epithelium and which can be quite painful [76,83,111,118,119]. Nearly 20% of patients with EoE have a normal endoscopic appearance [120], emphasizing the need for endoscopic biopsies.

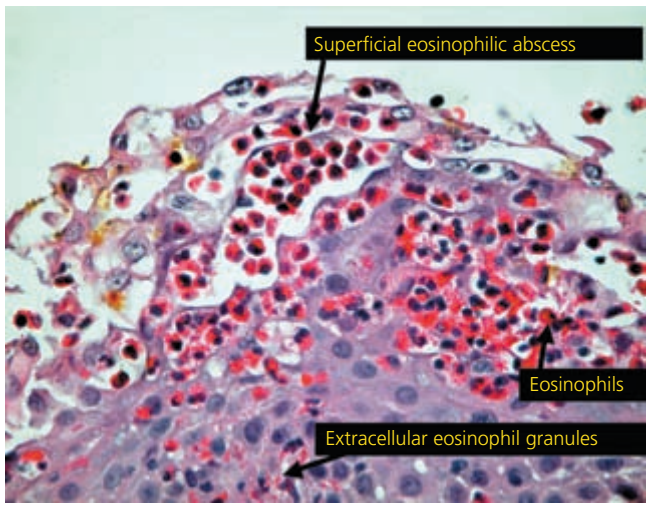

Figure 33.1 A representative microscopic image of eosinophilic esophagitis (EoE). This photomicrograph shows the classic findings of EoE following endoscopic biopsy and histological staining with hematoxylin and eosin. Note the characteristic abundant eosinophils (arrowhead), the readily detectable extracellular eosinophil granule constituents (arrow), and the eosinophilic microabscess near the surface (asterisk). Original magnification × 400.

Preliminary evidence suggests that symptoms associated with EoE result from esophageal dysmotility. Assessment of the esophageal wall with endoscopic ultrasound demonstrates significant submucosal and muscular inflammation in children with EoE compared with non-inflamed esophageal tissue. Although stationary esophageal manometric testing has revealed normal esophageal function, one preliminary study examining prolonged esophageal motility with 24-h ambulatory monitoring demonstrated increased isolated contractions compared with tracings derived from normal non-inflamed esophagi. Importantly, these contractions correlated with observed symptoms. Because food impaction is a primary complaint in EoE, one speculates that the esophagus can undergo intermittent non-fixed contractions leading to dysphagia with or without obstruction. The exact pathogenesis of the motor disturbances is unclear, but eosinophil activation and degranulation has been postulated as a possible etiology [121–123]. This is supported by the finding of increased deposition of the eosinophil granule protein, major basic protein (MBP), in the epithelium of patients affected by EoE with food impaction.

The assessment of EoE includes an extended allergy evaluation looking for food and aeroallergen sensitization, either by skin-prick or RAST (radioallergosorbent) testing, and the exclusion of GERD (typically by using anti-GERD therapy) as well as other causes of eosinophils in the esophagus [76,100,101]. A recent study has suggested that the evaluation of food protein sensitization by delayed skin-patch testing increases the identification of food allergy compared with skin-prick testing alone [101]. Of note, the presence of GERD does not exclude the diagnosis of EoE or food allergy, demonstrating the importance of a food allergy evaluation in these patients [75,86,124]. An essential question in understanding EoE is its relationship with other forms of esophagitis. In particular, it remains possible that the pathological level of eosinophils in the esophagus in patients with GERD and EoE represents a continuum. As such, the pathological processes in the esophagus of patients with EoE and GERD may be shared in part.

Epidemiology

EoE is a global health disease that has been reported in Australia [125], Brazil [124], England [123], Italy [126],

Japan [127], Spain [128,129], and Switzerland [130]. Although the incidence of primary EoE has not been rigorously calculated, a mini-epidemic has been noted over the last decade. Liacouras and his group [131] at the Children's Hospital of Philadelphia have found that 8%–10% of their pediatric patients with GERD-like symptoms unresponsive to acid blockade have EoE. Furuta and colleagues [76] at the Boston Children's Hospital have reported that 6% of their patients with esophagitis have EoE. Over a 16-year observation period, Straumann and Simon [132] have documented a prevalence of approximately 1:4000 adults in Switzerland. Croese and colleagues [125] have reported EoE to be present in 1:70 000 adults in an Australian provincial city. Finally, Rothenberg and colleagues have noted that EoE occurred in 1:2000 children in the Cincinnati metropolitan area over a 5-year time period (ref. 92 and unpublished findings).

Therapy

There is no uniformly agreed upon therapy for EoE, probably because of the lack of controlled clinical trials and studies on the natural history of the disorder [133,134]. At present, therapy for EoE is based on antigen elimination trials, antiinflammatory approaches, and physical dilation when strictures are present. The last approach, which has been the strategy reported for adults, temporarily reduces symptoms of dysphagia; however, it includes the significant risk of rupture and hemorrhage, needs to be repeated regularly, and does not improve the underlying inflammation [135]. An antigen elimination approach in sensitized individuals (e.g., aeroallergen avoidance and food elimination diets) is typically unsatisfactory or practically difficult (when patients are sensitized to many allergens), probably because the current allergen sensitization tests (skin-prick and patch tests, as well as antigen-specific plasma IgE levels) are not optimal for detecting sensitization. A diet consisting exclusively of an elemental (amino acid-based) formula frequently improves symptoms and normalizes esophageal pathology [104,111]. However, this approach is often not tolerated (especially in older individuals), frequently requires a surgically placed feeding tube, and can be financially costly (e.g., thousands of dollars per month). Glucocorticoids (systemic [83] or topical [136,137]) have been used with apparently satisfactory results. Systemic steroids are used for acute exacerbations, whereas topical glucocorticoids are used to provide long-term control. In particular, several studies have shown the usefulness of swallowed fluticasone (patients simply swallow fluticasone administered from a standard asthma inhaler). Fluticasone therapy is associated with normalization of esophageal eosinophilia, levels of CD3 and CD8 T cells, and epithelial hyperplasia, as assessed by staining for the proliferation nuclear antigen Ki-67 [138,139]. It is now appreciated that a significant fraction of patients are glucocorticoid resistant [139]. Swallowed fluticasone likely acts directly upon the esophageal tissue, but this has not yet been proven. Other antiinflammatory agents such as leukotriene receptor antagonists have been advocated, but they have not been shown to reverse esophageal pathology [140,141]. The mechanism by which any therapeutic intervention improves EoE has not been established and is under active investigation.

Pathogenesis

The etiology of EoE is poorly understood, but allergy has been implicated. In fact, the majority of patients have evidence of food and aeroallergen hypersensitivity as defined by skin-prick or RAST tests; however, only a minority have a history of food anaphylaxis [76], indicating distinct mechanisms compared with simple IgE-mediated mast cell/basophil activation. Substantial evidence is accumulating that EoE is associated with a Th2-type immune response. In particular, elevated levels of eosinophil-active Th2 cytokines (e.g., IL-4, IL-5, and IL-13) as well as mast cells are present in the esophagus of EoE patients [100,142]. In addition, experimental models of EoE can be induced in mice by allergen exposure, as well as by overexpression of Th2 cytokines [143,144]. In particular, repeated intranasal exposure to the aeroallergen *Aspergillus fumigatus* induces simultaneous eosinophilic airway and esophageal inflammation (without inducing gastrointestinal eosinophilia) [143]. Furthermore, intratracheal delivery of human or mouse IL-13 also induces experimental EoE [145], and this process can be blocked with a therapeutic anti-human IL-13 antibody [146].

More recently, epicutaneous allergen sensitization has been shown to potently prime for respiratory allergen-induced experimental EoE [147]. This finding may be particularly important for understanding EoE as a large fraction of EoE patients suffer from preceding allergic skin disease (atopic dermatitis) [100]. Collectively, these experimental systems demonstrate an intimate connection between the development of eosinophilic inflammation in the respiratory tract and esophagus and not only external allergic triggers but also intrinsic Th2 cytokines.

It is interesting to note that patients with EoE sometimes report seasonal variations in their symptoms; preliminary studies have recently documented seasonal changes in esophageal eosinophil levels [148]. Based on these results, as well as clinical observations, some investigators have referred to EoE as "asthma" of the esophagus [149].

Experimental modeling in mice has established that Th2 signaling is required for induction of experimental EoE. In particular, mice with the targeted deletion of STAT6 are protected from allergen- and IL-13-induced experimental EoE [145,147]. Furthermore, IL-13-deficient mice have impaired allergen-induced EoE [147]. As IL-13 is a potent inducer of

the eotaxins by a STAT6-dependent mechanism (based on studies primarily in the context of the lung) [13], it is interesting to speculate that IL-13 (and STAT6) may induce EoE by up-regulating the production of eotaxins in the esophagus. Indeed, the promoters of all three eotaxin chemokines contain STAT6 binding sites that have been shown to be operational in vitro [18–22]. However, the mechanism has remained elusive as the eotaxins have not yet been demonstrated to be overproduced in EoE, and eotaxin-1-deficient mice develop only a modest attenuation of experimental EoE [127,142,143].

A central role for IL-5 in EoE pathogenesis is emerging. Overexpression of IL-5 (by pharmacological or transgenic delivery) induces EoE, and neutralization of IL-5 (with antibodies or gene targeting) completely blocks allergen- or IL-13-induced EoE in mice [143–145]. Notably, in an early phase I/II trial designed to test humanized anti-IL-5 antibody therapy in hypereosinophilic patients, a remarkable response in the first treated EoE patient has been observed, with improved clinical symptoms and markedly reduced esophageal eosinophil levels [150].

Potential role of eosinophils in EoE

In vitro studies have shown that eosinophil granule constituents are toxic to a variety of tissues including intestinal epithelium [151]. Eosinophil granules contain a crystalloid core composed of MBP-1 (and MBP-2), and a matrix composed of eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO) [152]. These cationic proteins share certain proinflammatory properties but differ in other ways. For example, MBP, EPO, and ECP have cytotoxic effects on epithelium in concentrations similar to those found in biological fluids from patients with eosinophilia. Additionally, ECP and EDN belong to the ribonuclease A superfamily and possess antiviral and ribonuclease activity [153,154]. ECP can insert voltage-insensitive, ion-nonselective toxic pores into the membranes of target cells and these pores may facilitate the entry of other toxic molecules [155]. MBP directly increases smooth muscle reactivity by causing dysfunction of vagal muscarinic M_2 receptors [156]. MBP also triggers degranulation of mast cells and basophils [157]. Indeed, evidence is emerging that mast cells and eosinophils are both involved in EoE [142]. Triggering of eosinophils by engagement of receptors for cytokines, immunoglobulins, and complement can lead to the generation of a wide range of inflammatory cytokines including IL-1, -3, -4, -5, -13, GM-CSF, TGF-α/β, tissue necrosis factor (TNF)-α, RANTES, MIP-1α, and eotaxin-1, indicating that they have the potential to modulate multiple aspects of the immune response [158,159]. In fact, eosinophil-derived TGF-β is linked with epithelial growth, fibrosis, and tissue remodeling [160,161]; this may be particularly important in promoting the chronic inflammation and structural changes associated with EoE (e.g., fibrosis and strictures) [113]. Indeed, depletion of murine eosinophils with anti-IL-5 therapy abates allergen-induced epithelial hyperplasia in the esophagus [143], and the level of human esophageal eosinophils correlates with the degree of epithelial cell Ki-67 antigen staining [139]. Additionally, eosinophils can directly activate T cells by antigen presentation, which has been demonstrated in vitro and in vivo [162,163]. Further eosinophil-mediated damage is caused by toxic hydrogen peroxide and halide acids generated by EPO and by superoxide generated by the respiratory burst oxidase enzyme pathway in eosinophils. Eosinophils also generate large amounts of the cysteinyl leukotriene C4 (LTC4), which is metabolized to LTD4 and LTE4. These three lipid mediators increase vascular permeability and mucus secretion, and are potent stimulators of smooth muscle contraction [164]. Indeed, leukotriene modifiers appear to improve clinical symptoms in EoE patients [141].

Clinical investigations have demonstrated extracellular deposition of MBP in the esophagus of patients with EoE and other forms of EGID [71,165–169] and have shown a correlation between the level of eosinophils and disease severity [84]. Electron microscopy studies have revealed ultrastructural changes in the secondary granules (indicative of eosinophil degranulation and mediator release) in duodenal samples from patients with EGID [79,122]. Furthermore, Charcot–Leyden crystals, remnants of eosinophil degranulation, are found on microscopic examination of stools obtained from patients with eosinophilic gastroenteritis [95,170].

Summary and future directions

Eosinophilic esophagitis is a chronic allergic disease that can easily be confused with GERD. Although the exact pathophysiology of EoE has not been defined, it is likely that intermittent esophageal contraction or fibrotic narrowing leads to dysphagia and food impaction. The pathogenesis of EoE appears to be related to overexpression of IL-5, IL-13, and possibly eotaxins, which leads to chronic eosinophilic inflammation. Present studies have focused on clinicopathological features of EoE whereas future studies will likely define the natural history (e.g., the relationship between pediatric and adult EoE), the genetic basis of EoE including the role of particular single nucleotide polymorphisms, and non-invasive markers of disease activity. Whereas current therapy is primarily focused on anti-allergy therapy (including glucocorticoids), it is hopeful that molecular dissection of disease pathogenesis will lead to targeted therapy (such as anti-IL-5 and/or anti-CCR3 antibodies). This will lead to improved treatment guidelines and better care for the affected patients.

Because of the remarkable effectiveness of highly active antiretroviral therapy (HAART) and continued advancements in prophylaxis for opportunistic infections such as cytomegalovirus (CMV) in high-risk transplant patients, the prevalence of esophageal infections continues to fall in developed countries [1]. In contrast, the human immunodeficiency virus (HIV) epidemic continues unabated in developing countries where gastrointestinal disorders parallel what were seen in developed countries more than two decades ago [2]. Despite these advancements, there still remains a number of patients at risk for these diseases, particularly as our older population grows, immunosuppressive therapy becomes more widespread for a variety of indications, and the use of organ transplantation expands. Timely and accurate diagnosis of esophageal infections is critical because treatment is highly effective, results in rapid symptomatic improvement, and often yields a clinical cure. This chapter focuses on the specific causes of esophageal infections, in particular epidemiology, pathology, presentation, diagnosis, and therapy. Esophageal disorders associated with HIV infection and AIDS are also reviewed here.

Epidemiology and predisposing factors

Primary esophageal infection is rare in an otherwise healthy person in whom no permissive factor is present. In this setting, the most common pathogen is *Candida*, with herpes simplex virus (HSV) less commonly involved [3,4]. In general, immunocompetent patients who develop esophageal infection have conditions, either local or systemic, that weaken esophageal defense mechanisms, such as alteration of normal oroesophageal flora (e.g., antibiotics) or hampering of esophageal emptying (e.g., achalasia). Infection in adjacent structures may spread into and involve the esophagus secondarily.

More commonly, some form of humoral or cellular immunodeficiency, either iatrogenic, inherent, or a combination, leads to esophageal infection. Underlying conditions that predispose to infections include diabetes mellitus, alcoholism, malnutrition, malignant diseases, and advanced age. Transplantation predisposes to infections through variable mechanisms, most of which affect both B-cell and T-cell number and function, including the use of immunosuppressive agents, chemotherapy, and neutropenia. Episodes of rejection in recipients of solid organ transplants are also commonly complicated by infection because these patients are given more immunosuppression, including powerful agents such as antithymocyte globulin.

Without antimicrobial prophylaxis, infection after transplantation has a predictable time course. Bacterial and fungal infections are most common during the initial months after transplantation, because it is during this period that granulocyte number or function is most severely compromised. HSV infection also tends to occur early after transplantation, related to reactivation of disease, whereas CMV typically presents 2–6 months after transplantation at a time when neutropenia is common and T-cell function is most severely impaired. The development of opportunistic infections in HIV-infected patients reflects severe immunodeficiency; the risk for esophageal infections increases markedly when the CD4 lymphocyte count falls below 200/mm^3, with most infections occurring when the count is less than 100/mm^3 [5].

Fungal infections

Candida species

Epidemiology

Candida species are the most common esophageal pathogens, primarily *C. albicans* but occasionally *C. tropicalis, C. parapsilosis, C. glabrata*, and *C. dublinensis*. These organisms are normal components of the oral flora and their growth is kept in check by bacterial commensals. Conditions predisposing to *Candida* esophagitis in the "normal" host include antibiotic use, inhaled or ingested corticosteroids, antisecretory therapy (histamine H_2 receptor blockers, proton pump inhibitors), or hypochlorhydric states, diabetes mellitus, alcoholism, malnutrition, old age, head and neck radiotherapy, and esophageal motility disturbances. Alterations in cellular immunity lead to candidal colonization and superficial infection, whereas granulocytes function to prevent invasive disease and dissemination. The congenital immunodeficiency disorder chronic mucocutaneous candidiasis may also be complicated by *Candida* esophagitis. Improvements in immunosuppressive regimens, targeted prophylactic antifungal therapy, and empirical use of fluconazole in symptomatic patients have dramatically reduced the incidence of candidal infections in recipients of solid organ and bone marrow transplants [6]. Candidiasis remains the most common esophageal infection in patients with AIDS; it represents approximately 50% of esophageal infections and it frequently coexists with other esophageal diseases [7].

Pathology

The gross pathological appearance of esophageal candidiasis can range from a few white or yellow plaques on the mucosal surface to a dense, thick plaque that coats the esophageal mucosa (Fig. 34.1a). This plaque material is composed of desquamated squamous epithelial cells, admixed with fungal organisms, inflammatory cells, and bacteria [8] (Fig. 34.1b,c). In the absence of granulocytopenia or coinfection, true ulceration is infrequent (Table 34.1).

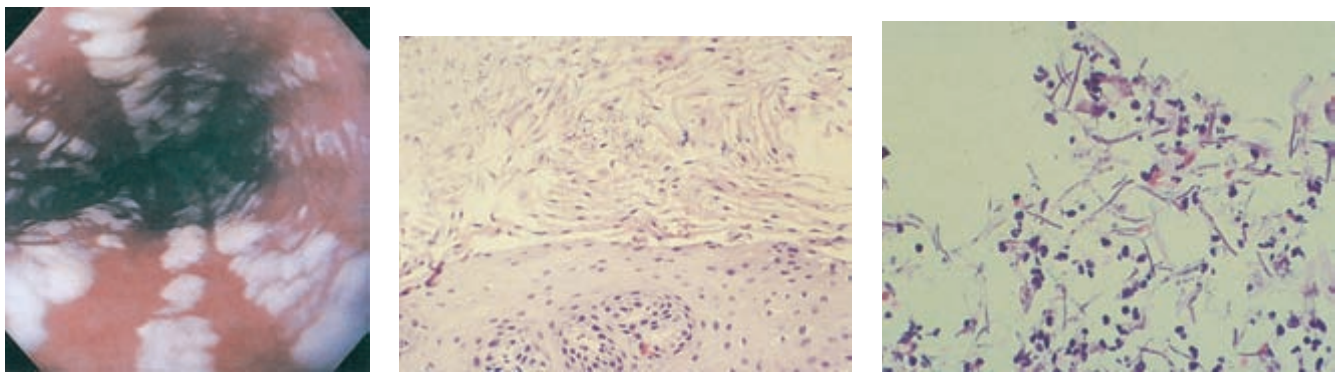
Clinical manifestations and complications

Although on occasion this infection is detected incidentally in an asymptomatic patient [3], the usual clinical presentation of esophageal candidiasis is dysphagia, with odynophagia less prominent (Table 34.2). Esophageal symptoms range from mild difficulty with swallowing to severe pain resulting in an inability to eat and secondary dehydration. When odynophagia is very severe, one must consider other causes or coinfections, particularly in patients with AIDS.

Physical examination may be helpful. Approximately two-thirds of patients with AIDS and esophageal candidiasis have oral candidiasis (thrush) [9]. Patients with chronic mucocutaneous candidiasis may have fungal involvement of various mucous membranes, hair, nails, and skin with a history of adrenal or parathyroid dysfunction. As the infection is generally superficial, complications of esophageal candidiasis are very rare.

Diagnosis

Esophageal candidiasis should be suspected in any patient at risk of esophageal infection who complains of dysphagia or odynophagia. The presence of thrush further supports this diagnosis, but the absence of oral involvement does not exclude esophageal disease. On a barium esophagram, *Candida* esophagitis is characteristically manifested by multiple plaque-like lesions, often in a linear configuration; when severe, these lesions become confluent to cause a "shaggy" appearance of the esophagus resembling ulcerations (see



(a) (b) (c)

Figure 34.1 *Candida* esophagitis. **(a)** Endoscopic photograph shows multiple raised plaques involving the esophagus with normal intervening mucosa. **(b)** Desquamated squamous epithelial cells admixed with fungi and inflammatory cells adherent to the mucosa. The underlying squamous epithelium appears normal. **(c)** Close-up view of the plaque material demonstrates mycelia and spores typical of *Candida*.

Fig. 34.1) [10]. A large, well-circumscribed ulceration should not be attributed to *Candida*. Importantly, a normal barium esophagram does not exclude esophageal candidiasis. The presence of severe odynophagia may limit the ability of the patient to drink barium and thus hampers the utility of barium studies.

Endoscopic examination of the esophagus is the most accurate method of diagnosing esophageal candidiasis. The gross endoscopic appearance of *Candida* esophagitis is usually diagnostic and may be graded according to published criteria [8]. During endoscopy, mucosal lesions can be brushed and submitted for cytological evaluation or examined by biopsy for histological diagnosis. Multiple biopsies are essential to exclude coexisting disorders when ulceration is identified endoscopically. The use of periodic acid–Schiff or Gomori methenamine silver stain helps to highlight the organisms. Cytological examination of esophageal brushings is more sensitive than histological examination of biopsy specimens because organisms may be washed off tissue surfaces in mild superficial candidiasis (i.e., grades 1 and 2) during processing of biopsy specimens. Rarely, positive cytology but negative histology indicates colonization rather than infection. Skin testing and serological tests for candidiasis play no role in the diagnosis of *Candida* esophagitis.

In patients with AIDS and thrush, the presence of dysphagia or odynophagia usually indicates *Candida* esophagitis [7]. Given the prevalence of *Candida* esophagitis in AIDS, in the symptomatic patient with associated thrush, an empirical trial of antifungal therapy may be instituted, reserving endoscopy for those patients who fail to respond. However, this symptom complex does not exclude coinfection with other pathogens, and one-third of patients with esophageal candidiasis do not have thrush. Following an empirical trial, further evaluation should not be delayed for longer than 1 week if severe symptoms persist, because the response to antifungal therapy is rapid, with substantial clinical improvement occurring in most patients within days [7]. When patients fail to improve with empirical antifungal therapy, endoscopy should be performed, given that disorders other than candidiasis are identified in most patients [11]. The role of empirical antifungal therapy in symptomatic immunosuppressed patients who do not have AIDS has not been well studied, although this approach is commonly practiced.

Treatment

Both oral and intravenous medications are available that are highly effective for the treatment of *Candida* esophagitis (Table 34.3). In general, oral therapies should be first initiated,

Table 34.3 Treatment regimens for common esophageal diseases in AIDS

Pathogen	Drug	Dosage	Route	Duration	Efficacy (%)
Candida	Ketoconazole	200–400 mg/day	p.o.	7–14 days	< 80
	Fluconazole	100 mg/day	p.o./i.v.	7–14 days	≈ 80
	Itraconazole	200 mg/day	p.o.	7–14 days	≈ 80
	Amphotericin B	0.5 mg/kg/day	p.o./i.v.	7 days	> 95
	Caspofungin	50 mg/day	i.v.	7 days	> 90
Cytomegalovirus	Ganciclovir	5 mg/kg b.i.d.	i.v.	2–4 weeks	≈ 75
	Foscarnet	90 mg/kg b.i.d.	i.v.	2–4 weeks	≈ 75
	Cidofovir	5 mg/kg weekly	i.v.	2–4 weeks	≈ 75
Herpes simplex virus	Acyclovir (aciclovir)	400 mg 5×/day	p.o./i.v.	14 days	> 90
	Valacyclovir (valaciclovir)	1 g t.i.d.	p.o.	14 days	> 90
	Famciclovir	500 mg t.i.d.	p.o.	14 days	> 90
	Foscarnet	90 mg/kg b.i.d.	i.v.	14 days	> 95
	Ganciclovir	5 mg/kg b.i.d.	i.v.	14 days	> 95
Idiopathic ulcer	Prednisone	40 mg/day taper	p.o.	4 weeks	> 90
	Thalidomide	200–300 mg/day	p.o.	4 weeks	> 90

reserving intravenous treatment for refractory disease or for patients who have contraindications to orally administered medication. Although candidal species other than *C. albicans* may cause esophagitis, speciation is not widely employed because reliable culturing and sensitivity testing are lacking at most centers and the treatment is generally the same. For those patients with mild disease, minimal immunocompromise, or readily reversible immunodeficiency, an abbreviated course of therapy with an oral azole should be given. Immunocompromised transplant recipients and patients with AIDS with *Candida* esophagitis are best treated with systemically absorbed agents (azoles). In addition, patients with granulocytopenia are at significant risk of disseminated candidal infection, thus warranting the use of systemically acting agents.

Orally administered systemic agents, all of which have efficacy for *Candida* esophagitis, include ketoconazole (Nizoral), fluconazole (Diflucan), and itraconazole (Sporanox). These agents, like other azoles, alter fungal cell membrane permeability by cytochrome P450-dependent interference with ergosterol biosynthesis resulting in fungal cell injury and death. The newer triazoles (itraconazole and fluconazole) have a greater affinity than the imidazoles (miconazole and ketoconazole) for fungal cytochrome P450 enzymes [12]. Although other agents such as clotrimazole and nystatin may be effective for oral candidiasis and for prophylaxis against esophageal involvement, these agents are much less effective as primary therapy for esophageal candidiasis.

Although ketoconazole therapy (200–400 mg/day) is effective for the treatment of esophageal candidiasis, its potent inducement of the P450 system has led to its replacement by newer azoles. Like ketoconazole, itraconazole absorption is reduced by increasing gastric pH [13]. Its half-life is 24–42 h and further dose increases lengthen the drug's half-life and improve efficacy [13].

Large randomized studies suggest that fluconazole (100 mg/day), the absorption of which does not depend on pH, has significantly greater efficacy for the treatment of *Candida* esophagitis in AIDS than ketoconazole (200 mg/day) [12] and itraconazole [14]. Both itraconazole and fluconazole are available in oral forms (both pill and solution) and fluconazole is also available in an intravenous preparation [15]. Fluconazole is minimally metabolized and is excreted unchanged in the urine. Unlike ketoconazole and itraconazole, fluconazole is highly water soluble, is minimally protein bound, and has a half-life of approximately 30 h if renal function is normal. The adverse effects of ketoconazole, fluconazole, and itraconazole are primarily dose dependent and include nausea, hepatotoxicity, and inhibition of steroid production. Minor increases in aminotransferases are common with these three agents but do not warrant drug discontinuation [16]. Finally, because of the effects on hepatic microsomal enzymes, all three azoles inhibit the metabolism of cyclosporine (ciclosporin) and result in an increase in cyclosporine blood levels, and this effect is most pronounced with ketoconazole.

Another major family of antifungal agents consists of the polyene antibiotics, represented by amphotericin and nystatin (see Table 34.3). These agents bind irreversibly to sterols in fungal cell membranes, thereby altering the permeability characteristics of the membrane and causing cell death. Nystatin is effective for treating thrush but much less so for esophageal disease. Although amphotericin B (Fungizone) is a highly effective treatment for systemic mycoses, its

severe side effects, coupled with the availability of effective alternative agents, have limited its use for the treatment of esophageal candidiasis.

The newest class of antifungal agents is the echinocandins. These agents have a novel mechanism of action as glucan synthase inhibitors, which inhibits fungal cell wall synthesis [17]. The first agent in this class, caspofungin, has activity against both *Aspergillus* and *Candida* species including non-*albicans* species. Prospective studies have shown it to be as efficacious and as well tolerated as fluconazole for AIDS patients with *Candida* esophagitis and as effective and better tolerated than amphotericin B for azole-resistant esophageal candidiasis [18,19].

Prophylaxis

The use of nystatin or azoles for the prevention of esophageal candidiasis in patients with cancer and in transplant recipients has yielded mixed results, and it can be problematic, especially for those receiving cyclosporine [20]. Primary prophylaxis has not been recommended in patients with AIDS, although the long-term use of fluconazole in AIDS has been associated with a reduction in cryptococcal disease [21].

Drug resistance

Because of widespread use, azole resistance has become a well-recognized problem in HIV-infected patients. This represents a less common clinical problem today with the widespread use of HAART. Both the cumulative dose of azole and severe immunodeficiency have been shown to be highly associated with the development of resistance [22]. In patients with AIDS, clinical resistance correlates with in vitro resistance. When resistance occurs, increasing the dose of azole, switching to another azole, or use of an oral solution of itraconazole may be tried, in higher doses because cross-resistance is often present. Intravenous amphotericin B, in doses of 10–20 mg/day, may be effective when high-dose (> 400 mg/day fluconazole) therapy fails; however, caspofungin is equally as efficacious as amphotericin B in these patients, and is better tolerated, making it the drug of choice in this setting [17,19]. Improvement in immune function with HAART is also an important component of the treatment of resistant candidiasis.

Other fungi

Epidemiology

Esophageal involvement with other fungi is rare [23]. Most instances of histoplasmosis and blastomycosis esophagitis represent secondary esophageal involvement from mediastinal lymph nodes rather than primary esophageal infection [24,25]. Although no particular geographical distribution within the United States has been reported for blastomycosis, histoplasmosis is endemic in the Midwestern states and the Mississippi Valley. Mucormycosis and aspergillosis esophagitis have also been described [26,27].

Pathology, clinical manifestations, and complications

Other than the development of fistula, there are no unique pathological features of these fungal infections (see Table 34.1).

Diagnosis

Histoplasmosis should be considered in endemic areas and if extraesophageal manifestations such as hilar adenopathy, calcification or atelectasis of adjacent pulmonary tissue, or splenic calcification are present. Esophageal blastomycosis should be considered in patients with skin involvement and dysphagia. Barium esophagraphy or endoscopy may show a focal area of extrinsic compression of the esophagus, usually in the region of the carina, ulcer, or fistula. As with other esophageal infections, the appearance of the abnormality at barium esophagram, the endoscopic appearance at endoscopy, and the use of endoscopic brushings and biopsies with appropriate culture and staining will establish the diagnosis. Serological tests are not useful because of the high prevalence of positive results in endemic areas. A urine antigen test is highly specific for the diagnosis of disseminated histoplasmosis [24].

Treatment

Although histoplasmosis may resolve without antifungal therapy in the normal host, therapy should be administered with an induction course of amphotericin B followed by maintenance itraconazole. Blastomycosis responds to itraconazole and amphotericin B. Systemic aspergillosis should be treated with a new azole agent voriconazole [28]. Surgery may be required for drainage of abscesses or excision of fistulae.

Viral infections

As with all esophageal infections, the prevalence of viral esophagitis has fallen in recent years. In the transplant setting, this reduction has resulted from targeted antiviral prophylaxis for herpesviruses in high-risk transplant recipients, the use of CMV-seronegative organs and blood products for seronegative recipients, and the use of leukocyte-depleted platelets for patients after bone marrow transplantation. A overall reduction in viral esophagitis attributable to the implementation of HAART has been also observed in HIV-infected patients [1]. Nevertheless, in patients who fail such therapy or for undiagnosed patients, viral esophagitis continues to be clinically relevant [5].

Herpes simplex virus

Epidemiology

HSV type 1 (HSV-1) is one of three herpesviruses that affect the esophagus, the others being CMV and varicella-zoster virus (see sections on cytomegalovirus and other viruses).

HSV-2 rarely involves the esophagus. After *Candida* species, HSV-1 is the next most frequent agent causing infectious esophagitis. Although well recognized as an esophageal pathogen in otherwise healthy people, HSV-1 esophagitis has been reported most often in patients with immunosuppression or other predisposing factors. After transplantation, HSV occurs as frequently as CMV as a cause of esophageal disease [23], whereas in patients with AIDS, HSV esophagitis is relatively uncommon and is much less frequent than CMV infection [29].

Pathology

HSV infection is generally limited to squamous mucosa, where the earliest manifestation is a vesicle. As these vesicles enlarge and ulcerate, they may coalesce to form larger lesions. Usually, the intervening mucosa between these lesions is normal. Microscopic examination of the squamous epithelial cells at the edge of the ulcers reveals multinucleation, ground-glass nuclei, and eosinophilic Cowdry type A inclusion bodies that may occupy half of the nuclear volume. These inclusion bodies may be surrounded by haloes and with time they become more basophilic, filling, enlarging, and deforming the nucleus.

Clinical manifestations and complications

HSV-1 esophageal infection commonly presents with the sudden onset of severe odynophagia, often resulting in an inability to swallow liquids or solids. Herpes labialis (i.e., cold sores) and oropharyngeal ulcers may frequently coexist, antedate, or develop during the esophageal infection, whereas skin infection is rare [9,29]. In untreated immunocompetent persons, spontaneous resolution of HSV-1 esophageal infection occurs 1–2 weeks after the onset of symptoms. Complications are rare and include bleeding, tracheoesophageal fistula, or dissemination [23].

Diagnosis

Esophageal disease caused by HSV-1 usually appears in radiographic studies as focal ulceration on a background of normal mucosa; vesicles are infrequently present (Fig. 34.2). These ulcers have been described as stellate or volcanic in appearance, with fewer propensities to form the longitudinal or linear lesions that are commonly seen in CMV infection [30]. Severe, diffuse herpetic esophagitis may result in a cobblestone or "shaggy" mucosal appearance resembling *Candida* esophagitis [30]. Although the radiographic appearance may be suggestive, definitive diagnosis of herpetic esophagitis requires endoscopic mucosal biopsies. The endoscopic appearance of herpetic esophagitis reflects the pathological changes (see Table 34.1), with discrete, usually small (< 2 cm), well-circumscribed ulcers [31], diffuse erosive esophagitis, or, rarely, vesicles. Small scattered lesions covered with exudates can mimic esophageal candidiasis. Given the pathophysiological mechanism of disease, deep ulcers, as seen with CMV, are very rare. Cytological or histological brushings or biopsies should be taken from the edge of an ulcer because the viral cytopathic effect is best identified here rather than in the granulation tissue in the ulcer bed (Fig. 34.3). Immunohistochemistry on biopsy samples using specific monoclonal antibodies to HSV will help to confirm the diagnosis when the viral cytopathic effect is infrequent. Viral culture may also help to establish a definitive diagnosis. As with other causes of infectious esophagitis, serological tests are unhelpful in establishing the diagnosis.

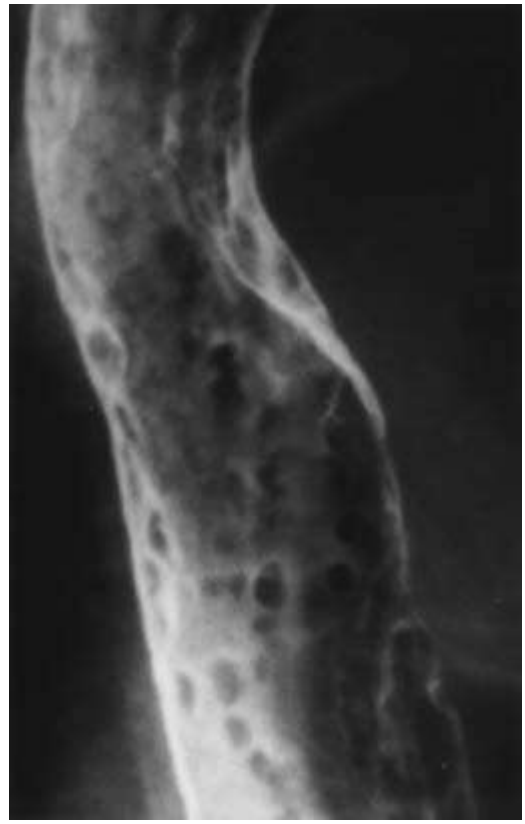

Figure 34.2 Herpes simplex virus esophagitis. Multiple vesicles and ulcers are present throughout the esophagus. Courtesy of Robert Koehler, MD.

Treatment

Uncontrolled trials and vast clinical experience in both immunocompetent and immunodeficient patients, including those with AIDS [32], suggest efficacy of acyclovir (aciclovir), a nucleoside analogue, for the therapy of esophageal disease [33]. Valacyclovir (valaciclovir), a prodrug of acyclovir, and famciclovir have largely replaced acyclovir as oral therapy given their longer half-lives. Although not studied for esophagitis, they have shown equivalency for genital HSV disease and, as with acyclovir, minimal toxicity.

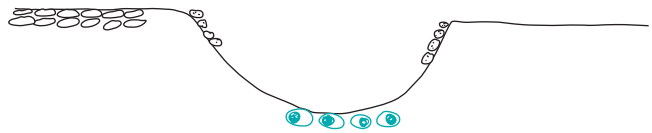

Figure 34.3 Location of viral cytopathic effect in esophageal ulceration.

Although spontaneous resolution of HSV-1 esophagitis is common in the immunologically normal host, because of its safety and efficacy, therapy is commonly instituted in all patients regardless of immune status. When oral intake is hampered by severe odynophagia or when there is a question of drug absorption, intravenous administration is required. Side effects of intravenous acyclovir therapy are few and appear limited to irritation of veins used for drug infusion and rash. Although rare, drug resistance should be suspected when there is clinical failure of acyclovir; in this setting, foscarnet (see Table 34.3) is the drug of choice and will lead to clinical cure in most patients [34]; cidofovir may also be used. Acyclovir is effective prophylaxis for HSV antibody-positive patients undergoing transplantation. Long-term secondary prophylaxis may be required when immunodeficiency persists because the relapse rate is high.

Cytomegalovirus

Epidemiology

CMV continues to dominate as one of the most common opportunistic infections across all risk groups. This frequency relates to the high background seropositivity rates in the general population with even higher rates in developing countries and homosexual men [35]. In transplant recipients who receive no antiviral prophylaxis, CMV and HSV are equally common esophageal pathogens [23]. In contrast, CMV is the most frequent cause of esophageal ulcer in patients with AIDS [29].

Pathology

The most prominent histological feature of CMV esophagitis is mucosal ulceration (see Table 34.1). Although there is variability, deep ulcers are very characteristic of disease in AIDS, whereas in immunosuppressed transplant recipients, lesions tend to remain more superficial. In contrast to HSV, the viral cytopathic effect of CMV is present in endothelial and mesenchymal cells in the granulation tissue of the ulcer base and not in the squamous epithelium. Inclusions are large (*cytomegalo*) and often have an eosinophilic appearance that may be present in the nucleus and cytoplasm (Fig. 34.4a). Because these inclusions may be atypical in appearance in patients with AIDS [36], immunohistochemical stains are useful in confirming the presence of CMV and often highlight more infected cells than can be appreciated on routine hematoxylin and eosin staining. As with other esophageal infections, CMV may coexist with HSV or *Candida*, especially in patients with AIDS. Whereas HSV leads to disease by a direct cytopathic effect on squamous epithelium, the pathogenesis of disease caused by CMV is not well understood. It has been speculated that CMV mucosal disease is the result of ischemia caused by endothelial cell involvement. Inflammatory cytokines, such as tumor necrosis factor-α, have also been suggested to play an etiological role [37].

Clinical manifestations and complications

In contrast to HSV esophagitis, CMV esophagitis has very rarely been documented in immunocompetent persons [38]. Odynophagia is almost uniformly present and is typically severe (see Table 34.2). A previous or coexistent diagnosis of CMV infection in other organs (e.g., retinitis or colitis) is not infrequent. Although rare in transplant recipients, retinitis may be observed in approximately 15% of patients with AIDS at the time of diagnosis of gastrointestinal disease [39]. Complications include gastrointestinal bleeding (~ 5% of patients) and, rarely, strictures [40] or fistulae to the tracheobronchial tree [41].

Diagnosis

Like HSV-1, the radiological appearance of CMV esophagitis is that of either focal or extensive ulceration and is dependent in large part on the epidemiological setting. Barium esophagraphy of CMV esophagitis may reveal thickening of mucosal folds or more typically ulcers; these ulcers may be vertical, linear with central umbilication, solitary, and deep, or occasionally they may manifest as diffuse superficial ulceration (see Fig. 34.4b) [30]. In patients with AIDS, these ulcers are often large and deep and may exceed 2 cm in size. Rarely, the exuberant inflammatory response mimics a malignant disease. The endoscopic appearance of CMV esophagitis is variable, ranging from multiple shallow ulcers, to solitary giant ulcers, to diffuse superficial esophagitis (see Fig. 34.4c) [42]. Given the high rate of previous exposure to CMV, serological testing is not helpful. In addition, some immunosuppressed transplant recipients fail to develop a brisk antibody response. Blood antigenemia is often present at the time of diagnosis and its presence may predict the subsequent development of end-organ disease [43].

Identification of viral cytopathic effect in mucosal biopsies is the best diagnostic method. Multiple biopsies (up to 10) may be required to establish the diagnosis in patients with AIDS and should be taken from the ulcer base because the viral cytopathic effect is found here [44] (Fig. 34.3). Viral culture of mucosal biopsies is less sensitive and specific than histology and cytological brushings are not helpful [45] The identification of an isolated inclusion found by immunohistochemical staining should not be considered CMV disease but rather infection, and other causes of mucosal disease should be sought. Because retinitis may coexist with gastrointestinal disease, and, when present, alters the duration of antiviral therapy, a diagnosis of CMV gastrointestinal disease in any patient with AIDS warrants ophthalmological examination.

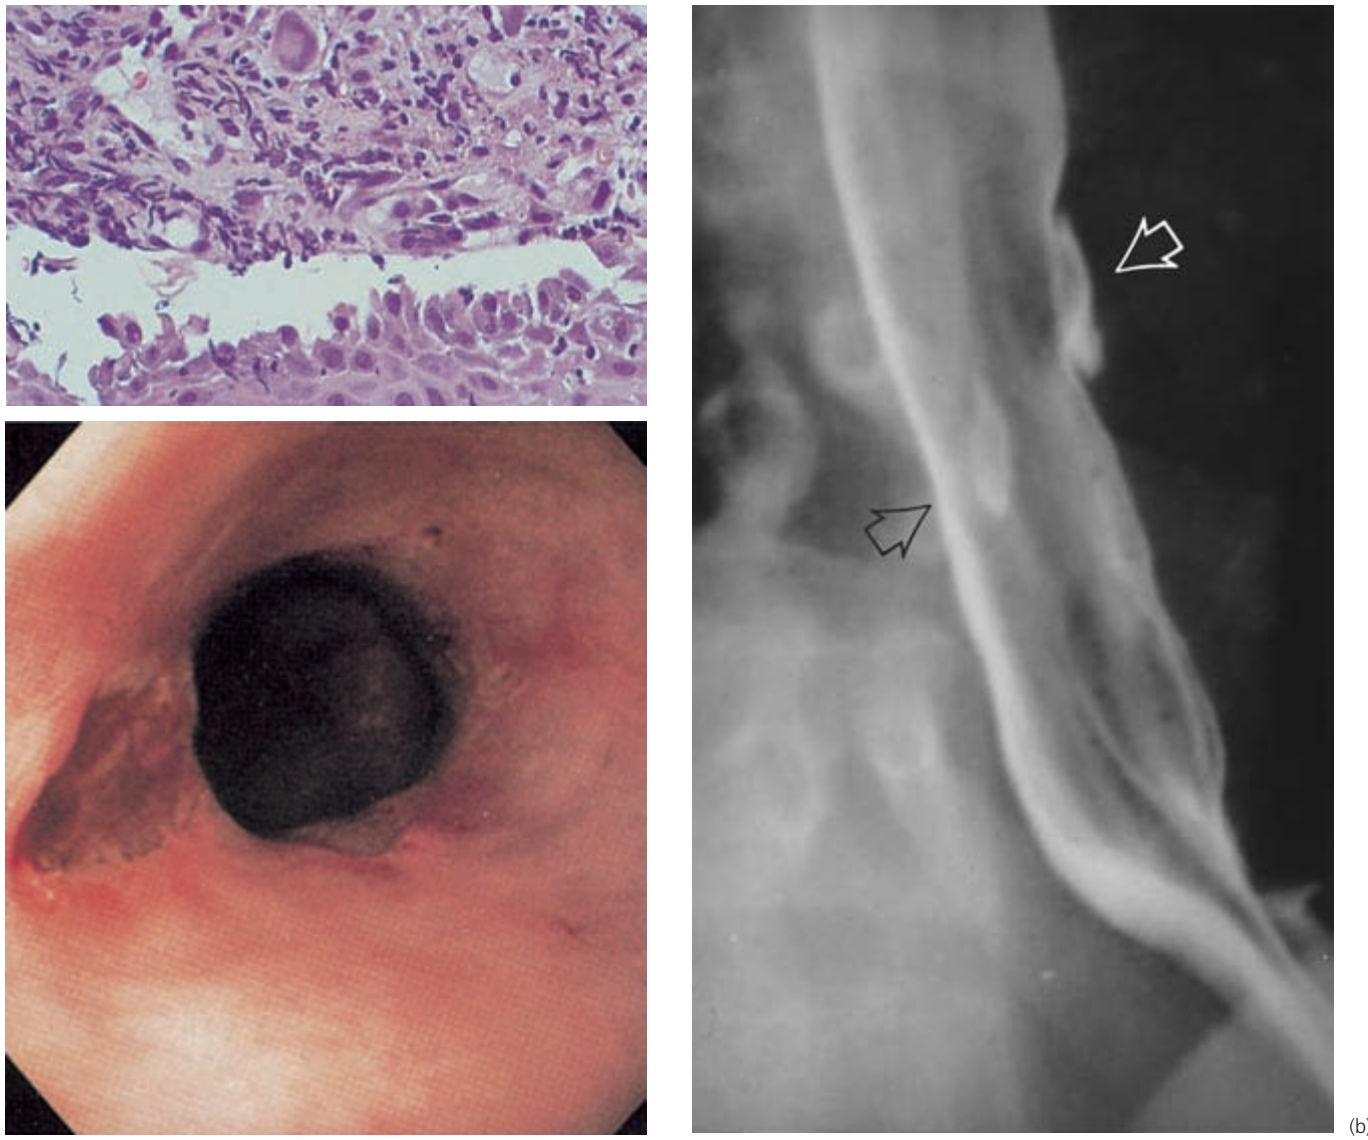

Figure 34.4 Cytomegalovirus esophagitis. **(a)** Biopsy from an ulcer base demonstrates granulation tissue with a large cell with intranuclear and intracytoplasmic inclusions diagnostic for cytomegalovirus. **(b)** Barium swallow demonstrates two well-circumscribed ulcers in the distal esophagus (arrows). **(c)** Endoscopic photograph shows the two ulcers, which are well circumscribed and have some depth; the surrounding mucosa is normal.

Treatment

The therapies available for the treatment of CMV disease generally require intravenous administration and include ganciclovir, foscarnet, and cidofovir. The most widely used therapy, ganciclovir, is an acyclovir derivative. A large prospective open-label trial of ganciclovir in 35 patients with AIDS documented clinical and endoscopic improvement in 77% [39]. The time course of the clinical response to ganciclovir is variable; a week of therapy may be required before there is symptomatic improvement. The total treatment duration should be based on the clinical and endoscopic response, and a 2- to 4-week treatment course is usually adequate. If retinitis is absent and there has been a complete response, the patient may be followed closely without maintenance therapy, especially if immune function can be optimized with HAART. Because of low bioavailability (< 10%), oral ganciclovir is not effective for the treatment of active infections including those of the gastrointestinal tract. After acute CMV disease in transplant recipients, treatment with ganciclovir should be given for approximately 1–2 months until the immunosuppressive regimen is either discontinued (bone marrow transplant) or significantly reduced (solid organ transplant). Ganciclovir is well tolerated with its major side effect being myelosuppression, which may be severe when

other bone marrow suppressive drugs are coadministered. Clinical and virological resistance has been documented, usually in patients receiving prolonged therapy. In this setting, foscarnet is often effective [46].

Valganciclovir, an orally administered prodrug that is rapidly hydrolyzed to ganciclovir, achieves high blood levels that are equivalent to those achieved with intravenous administration of ganciclovir [47]. Given its favorable pharmacokinetics, it has been used successfully for induction therapy for CMV retinitis in AIDS patients, as well as for prophylaxis in high-risk solid organ transplant recipients, such as those who are donor positive/recipient negative (D^+/R^-), and preemptively for those who develop CMV antigenemia [48,49]. Although potentially effective for treatment of end-organ disease such as esophagitis, trials have not been performed and intravenous ganciclovir remains the treatment of choice. Long-term prophylaxis with this agent following successful therapy is a reasonable option for those in whom severe immunodeficiency persists, and long-term use has rarely been associated with the development of resistance [50].

Foscarnet is a pyrophosphate analog that inhibits viral DNA polymerase and reverse transcriptase. A randomized trial comparing ganciclovir with foscarnet in patients with AIDS and gastrointestinal disease found clinical improvement in more than 80%; there was no significant difference in efficacy between the two agents [51]. There are fewer data on its use in immunosuppressed patients who do not have AIDS. Because of its recognized toxicity (reversible renal insufficiency and electrolyte disturbances), foscarnet has been most frequently used when there is clinical resistance or intolerance to ganciclovir. All drugs used for the therapy of herpesviruses only inhibit viral replication; thus, relapse is frequent when therapy is discontinued. The relapse rate for transplant recipients also remains high until immunosuppressive therapy is reduced.

Cidofovir, the newest systemic agent available for the therapy of CMV, has undergone evaluation for the treatment of retinitis in AIDS [52] and less so in other immunocompromised patients. Its long half-life provides the opportunity for once-weekly administration. Like foscarnet, however, this drug is associated with renal insufficiency; probenecid pretreatment is used to decrease this complication. Because of its significant expense, it has been used most often for CMV resistance (ganciclovir, foscarnet) as well as for other DNA viruses in patients with AIDS.

The relapse rate of CMV esophagitis is approximately 50% and is similar for HSV [32,39,51]. Initiation of HAART, when associated with significant improvement in CD4 count, may abrogate the need for long-term maintenance therapy [21].

Prophylaxis

Antiviral prophylaxis will reduce CMV disease and associated mortality in transplant patients [53]. Oral ganciclovir is recommended to reduce the incidence of CMV disease in solid organ transplant patients. Oral ganciclovir is also used preemptively in patients who develop CMV viremia. However, in high-risk patients, such as bone marrow transplant patients and solid organ transplant recipients, valganciclovir is the drug of choice [48,49]. Intravenous ganciclovir prophylaxis may be appropriate in very high-risk patients such as D^+/R^+ transplant recipients. Oral ganciclovir has shown efficacy for prophylaxis for CMV retinitis in AIDS, but HAART represents the ideal choice.

Other viruses

The frequency of esophageal involvement caused by varicella-zoster during the course of chickenpox or herpes zoster infections is unknown but clinically uncommon [23]. Papillomavirus may infect the esophagus and may cause small polypoid lesions. Esophageal ulcers have reportedly been caused by papovavirus and Epstein–Barr virus in patients with AIDS [23].

Mycobacterial infections

Epidemiology

Mycobacterial involvement of the esophagus is very rare, even in immunosuppressed patients. In developing countries the rate of tuberculosis (TB) is much higher, and extrapulmonary manifestations, including esophageal disease, are more common. The combination of the AIDS epidemic and the upsurge in reported cases of systemic TB have increased the incidence of esophageal infection in developed countries. *Mycobacterium avium* complex (MAC) remains primarily a small bowel pathogen with only rare cases of esophageal involvement reported [23].

Pathology

Most commonly, TB affects the middle third of the esophagus at the level of the carina [54]. Esophageal disease is caused by spread of infection from tuberculous-infected mediastinal lymph nodes by way of a draining fistula or obstructed lymphatics, often resulting in tracheoesophageal fistula. TB can also involve the upper third of the esophagus by direct extension from tuberculous pharyngitis or laryngitis. Primary esophageal TB in the absence of extraesophageal disease is exceedingly rare and found in patients from endemic areas.

Clinical manifestations and complications

The symptoms of esophageal TB depend on the degree and type of involvement [23]. Pulmonary complaints often predominate because of the common occurrence of fistula to the trachea, bronchus, or pleural space. Rarely, formation of long strictures or traction diverticula resulting from the fibrotic response cause dysphagia. Upper gastrointestinal

hemorrhage from tuberculous esophageal ulcers and tuberculous arterioesophageal fistulae has been reported [55].

Diagnosis

Esophageal TB should be suspected in patients with pulmonary or systemic TB who develop esophageal symptoms. Chest radiography is generally abnormal and CT scan may demonstrate mediastinal adenopathy [54]. Barium esophagram findings, including ulceration and stricture, are nonspecific. A sinus tract or fistulous connection to the bronchial tree or mediastinum is highly suggestive of TB but can also be seen with malignant disease or other infections; in this setting, the diagnosis may often be made by sputum staining and culture, or CT-guided or surgical biopsy [54]. Endoscopic findings include ulcers, which may be solitary and resemble a malignancy, fistulae or strictures [56,57]. Biopsies from the edges of the lesions may demonstrate granulomata or acid-fast bacilli, and biopsy material may be cultured for further confirmation of the diagnosis and determination of sensitivities to antimycobacterial agents.

Treatment

Regardless of the presence of immunodeficiency, a 9-month course of multidrug therapy (in the absence of drug resistance) will cure esophageal TB and will often close fistulae. If fistulae do not close with medical therapy, surgical intervention will be required. The prevalence of multidrug-resistant TB is an increasingly complex problem; thus, drug sensitivities to antituberculous therapy are essential to guide therapy. The most effective agents for the treatment of MAC are clarithromycin and ethambutol [58]. Although a clinical and bacteriological response is common, long-term therapy for MAC is required in AIDS unless HAART is effective [21].

Bacterial infections

Epidemiology

Bacterial esophagitis is a rare cause of esophageal disease in immunocompromised patients. It has been described almost exclusively in patients with hematological malignant disease complicated by severe granulocytopenia, occasionally after bone marrow transplantation and diabetic ketoacidosis or in those patients receiving radiation and chemotherapy [23,59,60]. For the most part the infecting pathogens are oral flora, particularly gram-positive organisms, including viridans streptococci, staphylococci, and other bacilli. It is likely that these pathogens colonize and then invade mucosa damaged by reflux disease, radiation, or chemotherapy, leading to local infection. Reports in patients with AIDS have broadened the etiological spectrum to include *Bartonella henselae*, the cause of catscratch disease [61], and *Nocardia* [23]. Actinomycosis causes ulcers, sinus tracts, and fistulas [60]. Although esophageal involvement by *Treponema pallidum* was well recognized many years ago, this disease is now only of historical interest [23].

Pathology

The gross pathological appearance of the esophagus in bacterial infection ranges from normal mucosa (colonization) to ulcers associated with erythema, plaques, pseudomembranes, sinus cavities or hemorrhage [59]. Microscopic examination reveals pseudomembranes and bacterial invasion that may be superficial and invade only the squamous epithelium or may be invasive and transmural with infiltration of blood vessels (i.e., phlegmonous esophagitis). *B. henselae* esophagitis causes multiple nodules of the esophagus resulting from a lobulated proliferation of capillary vessels lined by plump endothelial cells [61].

Clinical manifestations and complications

Bacterial esophagitis is usually found in a neutropenic patient with esophageal complaints who has undergone chemotherapy for a hematogenous malignant disease. Esophageal infection may serve as a focus for bacteremia and seeding of other organs, particularly in patients with granulocytopenia [59]. No unique complications have been reported.

Diagnosis

The diagnosis of bacterial esophagitis should be considered in the clinical setting described earlier. Radiographic findings are nonspecific, and endoscopic biopsy and culture are required to establish this diagnosis. Additional stains including Gram stain are required to identify the etiological bacteria. Positive blood cultures also pinpoint the bacterial pathogens and direct antimicrobial therapy.

Treatment

Broad-spectrum antibiotics that effectively treat both gram-positive and gram-negative oropharyngeal flora are required for treatment. Treatment of other bacterial infection found in these patients is similar to treatment of disease in other locations.

Protozoal infections

In developed countries, protozoal infections of the esophagus are very rare, occurring almost exclusively in patients with AIDS. In these patients, pathogens include *Pneumocystis carinii*, *Cryptosporidium parvum*, *Leishmania donovani*, and *Trichomonas* [23,62]. In immunologically normal hosts from endemic areas in South America, *Trypanosoma cruzi* may involve the myenteric plexus of the esophagus resulting in Chagas disease. This disease is indistinguishable clinically, radiographically, endoscopically, and manometrically from idiopathic achalasia. The diagnosis may be established by antibody testing [23].

Specific HIV-related esophageal disorders

In addition to the infections described earlier, certain unique disorders cause esophageal disease in HIV-positive patients.

Disorders associated with primary HIV infection

Although primary HIV infection is largely asymptomatic, in some patients a mononucleosis-like illness occurs around the time of infection consisting of fever, sore throat, and myalgias associated with a maculopapular rash [63]. Spontaneously resolving oropharyngeal and esophageal ulceration or candidal infection may also be observed during this seroconversion illness. Endoscopically, these esophageal ulcerations are multiple, small, and shallow. The diagnosis can be established at the time of presentation by the detection of HIV RNA in serum [63]. Antibody positivity to HIV occurs within 3–18 months after the illness.

Idiopathic esophageal ulcer

Epidemiology

Early in the AIDS epidemic, large esophageal ulcerations were recognized in which no specific cause could be identified despite extensive histopathological examination of ulcer tissue. These ulcers, termed idiopathic esophageal ulcers (IEU) or aphthous ulcers, are very common and were found in 41% of HIV-infected patients with esophageal ulcer in a large prospective study [29]. They are seen in the later stages of immunodeficiency when the CD4 lymphocyte count is less than 100/mm^3 [5,29]. Like all opportunistic disorders, their frequency has also fallen in the era of HAART [1].

Pathology

These ulcers are variable in size, may be large, and are uniformly well circumscribed; diffuse superficial esophagitis has not been described [64]. Ulcer tissue resembles that seen in CMV and HSV infection except that viral cytopathic effect is absent. The presence of a superficial candidal infection overlying a large well-circumscribed lesion with histopathological findings of granulation tissue without viral cytopathic effect should still lead to the diagnosis of IEU [65]. Although HIV has been suggested as the direct cause of these lesions, there is little histopathological evidence to support a direct cytopathic role for HIV [66].

Clinical manifestations and complications

IEU presents in a fashion indistinguishable from CMV esophagitis. Coexistent oropharyngeal aphthous ulcers are infrequent [9], whereas thrush is common, especially if the patient has not been given empirical antifungal therapy. Complications include bleeding and fistulae to the stomach but not to the tracheobronchial tree, and strictures [40].

Diagnosis

The findings of IEU on barium esophagram are typically large, well-circumscribed, and often deep ulcers [67]. Because of the similarity to CMV infection, a definitive diagnosis cannot be based on the radiographic appearance alone. Because IEU is a diagnosis of exclusion, endoscopy and biopsy are the only definitive diagnostic tests. These ulcers are variable in size and appearance, and larger ulcers are endoscopically indistinguishable from CMV infection [42,64]. Distal esophageal ulcer may suggest gastroesophageal reflux disease; the histopathological features alone also cannot distinguish IEU from gastroesophageal reflux disease. Pill-induced esophagitis must be excluded by history because the pathological findings of esophageal biopsies are similar. These ulcers respond rapidly to either prednisone or thalidomide, with clinical and endoscopic cure seen in more than 90% [29,68,69].

Neoplasms associated with AIDS

Kaposi sarcoma

With the advent of HAART, Kaposi sarcoma (KS), caused by human herpesvirus 8, has shown a sharp fall in frequency [70]. Gastrointestinal KS is common in those with cutaneous disease; clinical experience suggests that gastric or duodenal involvement is more common than esophageal disease, with esophageal lesions, like other areas of the gastrointestinal tract, being most frequently an incidental finding. Findings of KS on barium esophagram have not been well studied and small lesions can be easily missed. The endoscopic features of esophageal KS are characteristic and resemble their cutaneous appearance: violaceous macular or plaque-like lesions. These tumors typically involve the submucosa; therefore, mucosal biopsy must sample deeper tissue. Bleeding may occur when the tumor becomes large and ulcerated. Effective relatively nontoxic chemotherapy includes Doxil, a liposomal form of doxorubicin (Adriamycin). HAART therapy alone has been associated with lesion regression and apparent cure [71]. Radiation therapy is effective to treat local lesions of the head and neck including the oropharynx.

Non-Hodgkin lymphoma

Despite HAART, lymphoma remains an important opportunistic neoplasm. Although gastrointestinal involvement is common, esophageal disease remains rare [72]. Extraesophageal disease is common at the time of diagnosis [72]. The lesions appear radiographically as large ulcers or mass lesions typical of any carcinoma. The endoscopic appearance of these lesions has been described as an ulcerated polypoid mass, often with a central ulceration, a submucosal lesion or extensive disease resulting in lumenal narrowing resembling an adenocarcinoma, or a solitary ulcer [73]. Complications are rare and include bleeding. Multidrug chemotherapeutic regimens are usually given for non-Hodgkin lymphoma in AIDS, and complete remission may be realized in approximately 50% or more of patients. Radiation therapy may be a

potential option when the disease is localized. Complications are frequent because of chemotherapy-induced neutropenia. The median survival time for AIDS-associated non-Hodgkin lymphoma has been enhanced by HAART [74].

Miscellaneous neoplasms

Despite the profound immunodeficiency seen in these patients, there does not appear to be an increase in the incidence of other esophageal neoplasms including squamous cell cancer and adenocarcinoma [75].

Barrett esophagus is the condition in which the stratified squamous epithelium that normally lines the distal esophagus is replaced by an abnormal, columnar epithelium (Fig. 35.1) [1]. The condition is judged to be a consequence of gastroesophageal reflux disease (GERD), which both injures the esophageal squamous epithelium and provides the abnormal intraluminal milieu that leads to healing of the injury through the process of columnar metaplasia rather than through the regeneration of more squamous cells. For reasons that are poorly understood, the metaplastic columnar epithelium predisposes to esophageal adenocarcinoma. Indeed, GERD and Barrett esophagus are the major risk factors for esophageal adenocarcinoma, a tumor whose frequency has increased more than sixfold over the past few decades [2,3]. The history of Barrett esophagus has been one of intense controversy, and authorities continue to debate the pathogenesis, proper management, and the very definition of this common disorder.

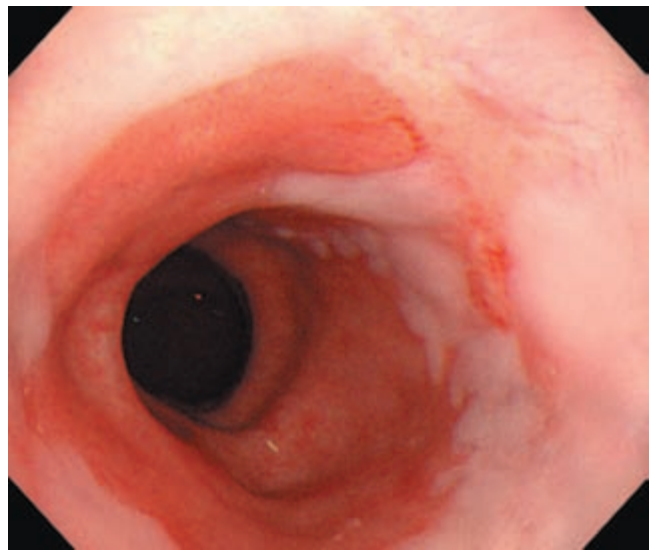

Figure 35.1 Endoscopic photograph of Barrett esophagus. Note the contrast between the pale, glossy squamous epithelium of the proximal esophagus and the red Barrett epithelium of the distal esophagus.

The history of Barrett esophagus – roots of the controversies

Barrett esophagus is named for Norman Rupert Barrett, an Australian surgeon who, in 1950, described a number of patients who had ulcerations in an organ that appeared to be the esophagus, but whose distal portion was lined by a "gastric type" of columnar epithelium [4]. Barrett originally contended that this condition was congenital in origin. In 1959, Moersch and colleagues [5] argued that the esophageal columnar lining was acquired as a result of reflux esophagitis and, since then, most investigators have agreed that Barrett esophagus is an acquired condition [6].

The histology of Barrett esophagus was a highly controversial issue until 1976, when Paull and colleagues [7] reported the results of a landmark study on 11 patients with Barrett's esophagus who had biopsy specimens obtained using manometric guidance to ensure that the specimens came from the esophagus. These patients were found to have one, or a combination, of three types of columnar epithelia lining the distal esophagus: (1) junctional-type epithelium (also known as

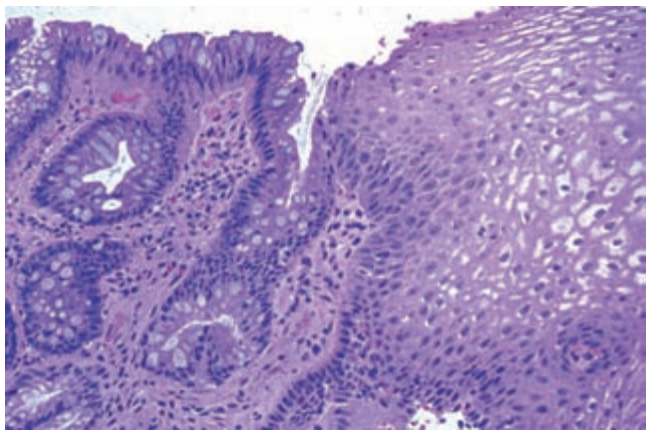

Figure 35.2 Photomicrograph showing the junction between stratified squamous epithelium (right) and specialized intestinal metaplasia (left). Note the numerous goblet cells characteristic of the intestinal-type epithelium.

cardiac epithelium) comprised almost exclusively of mucus-secreting cells; (2) gastric fundic-type epithelium (also called oxyntic epithelium) containing acid-secreting parietal cells; and (3) an incomplete form of intestinal metaplasia that the investigators called specialized columnar epithelium (now called specialized intestinal metaplasia). The three epithelial types were noted to occupy different zones in the esophagus, with specialized intestinal metaplasia found adjacent to squamous epithelium in the most proximal segment of the columnar lining (Fig. 35.2), followed by junctional-type epithelium and, most distally, by gastric fundic-type epithelium.

To recognize Barrett esophagus, endoscopists must identify the gastroesophageal junction (GEJ) and then ascertain that columnar epithelium extends proximal to it. Unfortunately, there are no universally accepted and clear-cut landmarks for the GEJ, a problem that can result in both false-positive and false-negative diagnoses of Barrett esophagus. Large hiatal hernias and severe reflux esophagitis can make it especially difficult to identify the GEJ. In the early 1980s, investigators intent on avoiding false-positive diagnoses established arbitrary criteria for the extent of esophageal columnar lining (ranging from 2 to 5 cm) needed to include patients in studies on Barrett esophagus [8]. Those arbitrary investigative criteria were embraced by clinicians and, as a result, endoscopists in the 1980s often dismissed columnar epithelium limited to the distal few centimeters of the esophagus as normal. In their efforts to avoid false-positive diagnoses, however, these investigators and clinicians had created a potentially larger problem of false-negative diagnoses.

In 1994, Spechler and colleagues [9] reported the results of a study in which patients undergoing elective endoscopic examinations in a general endoscopy unit had biopsy specimens taken at the squamocolumnar junction in the distal esophagus, irrespective of its appearance and location. Among 142 patients who had columnar epithelium involving 3 cm of the distal esophagus, 26 (18%) were found to have specialized intestinal metaplasia typical of Barrett esophagus. That metaplastic epithelium would have gone unrecognized if the study protocol had not mandated the procurement of biopsy specimens from a normal-appearing distal esophagus. A number of subsequent studies have confirmed this observation that intestinal metaplasia is present frequently in short segments of columnar epithelium in the distal esophagus, even in patients with no symptoms or endoscopic signs of GERD [10]. Since the description by Spechler, clinicians have called this condition "short-segment Barrett esophagus" [11].

The association between adenocarcinoma and Barrett esophagus had been well established by the 1970s [12]. By the late 1980s, it was recognized that intestinal metaplasia was the epithelial type that was especially associated with this cancer [13]. Because specialized intestinal metaplasia was the most frequent and distinctive of the epithelial types, the type that was clearly abnormal and the one most often associated with cancer, a number of investigators chose to define Barrett esophagus by the presence of intestinal metaplasia [14,15]. These investigators rejected the diagnosis of Barrett for patients with only junctional- and gastric fundic-type epithelia in the esophagus, arguing that it was too difficult to exclude the possibility that the endoscopist had inadvertently taken biopsy specimens from the stomach and that, without specialized intestinal metaplasia, the condition had no clinical importance anyway. This requirement for intestinal metaplasia to define Barrett esophagus, which was based more on practical than on scientific concerns, was also embraced by clinicians and adopted widely into clinical practice.

The definition of Barrett esophagus has undergone substantial evolution since the original report by Barrett in 1950. Some have argued that the very term "Barrett esophagus" should be discarded, because the condition has been defined so variably by different investigators who have imposed arbitrary criteria to fit their personal perspectives [6]. Nevertheless, the term is so firmly entrenched that it appears unlikely to be abandoned. For the past two decades, most studies on Barrett esophagus have included primarily or exclusively patients who had specialized intestinal metaplasia documented in their esophageal biopsy specimens. However, there remain substantial conceptual and practical problems with this practice.

Chandrasoma has suggested that cardiac (junctional) epithelium might not be a normal epithelial type at all, but rather a metaplastic epithelium acquired as a consequence of reflux esophagitis [16]. According to this hypothesis, reflux-damaged esophageal squamous epithelium is replaced first by cardiac epithelium, which later evolves into intestinal metaplasia. The British Society of Gastroenterology has defined Barrett as "an oesophagus in which any portion of the normal squamous lining has been replaced by a metaplastic columnar epithelium which is visible macroscopically" [17]. This definition, which does not require the presence of intestinal-type epithelium, is fine conceptually but problematic

practically because it is difficult to establish whether junctional- and gastric fundic-type epithelia found at the GEJ are metaplastic or normal. Today, more than half a century after the publication of Norman Barrett's seminal treatise, authorities continue to dispute the definition and nature of Barrett esophagus.

Diagnosis of Barrett esophagus

Endoscopic examination is required to diagnose Barrett esophagus, and most authorities insist on fulfillment of both of the following two diagnostic criteria: (1) the endoscopist must document that columnar epithelium extends above the GEJ to line the distal esophagus; and (2) histological examination of biopsy specimens from the esophageal columnar epithelium must reveal intestinal metaplasia. To document that columnar epithelium lines the esophagus, the endoscopist must identify both the squamocolumnar junction and the GEJ (Fig. 35.3). Columnar epithelium has a reddish color and coarse texture on endoscopic examination, whereas squamous epithelium has a pale, glossy appearance. The juxtaposition of these epithelia at the squamocolumnar junction forms a visible, typically jagged line called the Z-line. The GEJ is recognized endoscopically as the level of the most proximal extent of the gastric folds [8]. When the squamocolumnar junction is located proximal to the GEJ, then there is a columnar-lined segment of esophagus. When the squamocolumnar junction and the GEJ coincide (Fig. 35.4), then the entire esophagus is lined by squamous epithelium. If biopsy specimens from the columnar-lined esophagus show specialized intestinal metaplasia, then the patient has Barrett esophagus. Such a patient has long-segment Barrett esophagus if the distance between the Z-line and the GEJ is 3 cm or more, and short-segment Barrett esophagus if that distance is less than 3 cm (Fig. 35.5).

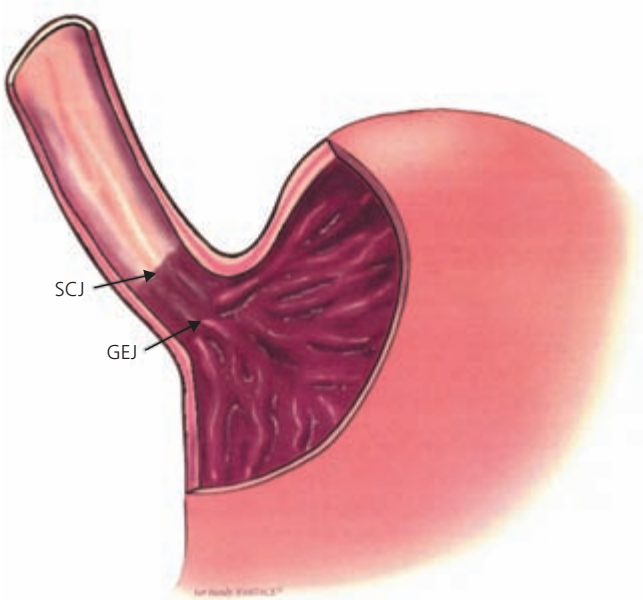

Figure 35.3 Landmarks at the gastroesophageal junction (GEJ) region. The squamocolumnar junction (SCJ, also called the Z-line) is the visible line formed by the juxtaposition of squamous and columnar epithelia. The GEJ is the imaginary line at which the esophagus ends and the stomach begins. The GEJ corresponds to the most proximal extent of the gastric folds. When the SCJ is located proximal to the GEJ, as it is in this figure, then the region between the two landmarks is a columnar-lined segment of esophagus.

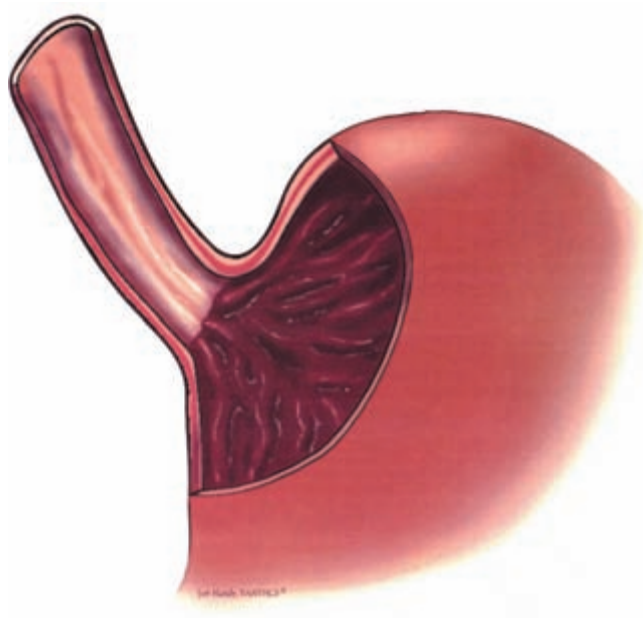

Figure 35.4 The squamocolumnar junction and gastroesophageal junction coincide. In this situation there is no columnar-lined esophagus (i.e., the entire esophagus is lined by squamous epithelium).

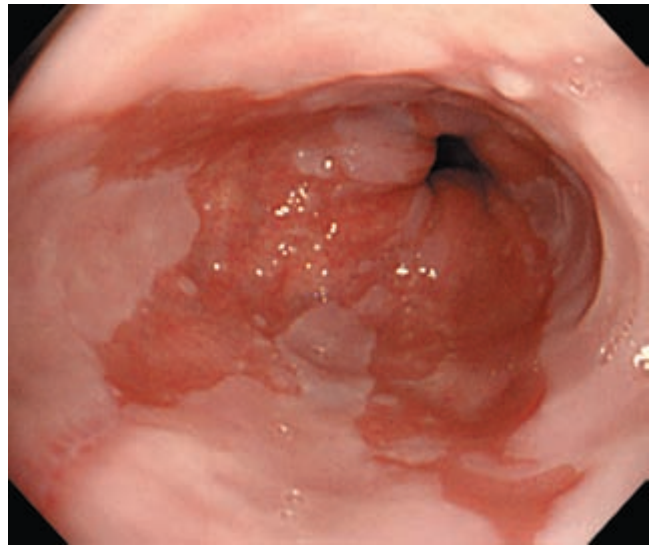

Figure 35.5 Endoscopic photograph of short-segment Barrett esophagus. Columnar epithelium extends for less than 3 cm above the gastroesophageal junction.

Recently, a new system called the "Prague C and M criteria" has been proposed for the endoscopic diagnosis and grading of Barrett esophagus [18]. This system evaluates both the circumferential (C) and the maximum (M) extent of Barrett metaplasia above the GEJ. The Prague C and M system has been found to have excellent reproducibility among endoscopists for a number of features of Barrett esophagus, with the notable exception of short-segment Barrett with metaplasia that extends for less than 1 cm above the GEJ, for which interobserver agreement is poor. However, it is not yet clear whether there is any clinical value to the Prague C and M criteria.

Intestinal metaplasia at the gastroesophageal junction

Chronic reflux esophagitis leads to the development of intestinal metaplasia in the esophagus. Intestinal metaplasia also occurs commonly in the stomach as a consequence of chronic gastritis caused by infection with *Helicobacter pylori* [19]. On histological examination, intestinal metaplasia in the stomach cannot be distinguished reliably from intestinal metaplasia in the esophagus. Because the GEJ cannot be identified with great precision, it can be difficult to determine whether short segments of intestinal metaplasia found in the GEJ region are lining the esophagus (i.e., short-segment Barrett esophagus) or the proximal stomach (i.e., intestinal metaplasia of the gastric cardia). The term "intestinal metaplasia at the GEJ" has been used to describe the condition in which intestinal metaplasia is found at a Z-line that appears to coincide precisely with the GEJ [20]. Rather than constituting an independent condition, however, intestinal metaplasia at the GEJ almost certainly represents either short-segment Barrett esophagus or intestinal metaplasia of the cardia. For technical reasons, it is difficult to distinguish these two conditions.

For clinical purposes, however, it may be important to distinguish short-segment Barrett esophagus from intestinal metaplasia of the gastric cardia because the former condition appears to have a substantially higher risk of malignancy. For example, one study found dysplasia (the precursor of malignancy) in 20 of 177 patients (11.3%) with short-segment Barrett esophagus, but in only 1 of 76 patients (1.3%) with intestinal metaplasia of the gastric cardia [21]. Authorities recommend endoscopic cancer surveillance routinely for patients with Barrett esophagus, but not for patients with intestinal metaplasia in the stomach [22,23]. Therefore, the distinction between the two conditions has implications for patient management. A number of histochemical and immunological biomarkers have been proposed to differentiate intestinal metaplasia of the cardia from short-segment Barrett esophagus (e.g., cytokeratin staining patterns, immunoreactivity for mAb Das-1, expression of colonic-type sulfomucins [24,25]). However, the utility of biomarkers in distinguishing short-segment Barrett esophagus from intestinal metaplasia of the gastric cardia has not been established [26]. For patients found to have intestinal metaplasia at the GEJ, one recommended approach is to assume that the condition is short-segment Barrett esophagus and to manage patients according to the guidelines for Barrett esophagus discussed below [20].

Epidemiology of Barrett esophagus and esophageal adenocarcinoma

Barrett esophagus is typically discovered in middle-aged and older adults, usually during endoscopic examinations performed for the evaluation of GERD symptoms [27]. The average age at the time of endoscopic diagnosis is approximately 55 years, but usually it is not possible to determine when the condition first developed. White men predominate in most series, and Barrett esophagus is decidedly uncommon in black and Asian populations [28]. Among patients who have had endoscopic examinations for the evaluation of GERD symptoms, long-segment Barrett esophagus has been found in 3%–5%, whereas 10%–20% have short-segment Barrett esophagus [1].

The prevalence of Barrett esophagus in the general adult population is not clear. In one study of 961 patients who were scheduled for elective colonoscopy and who agreed to have an upper gastrointestinal endoscopy performed for research purposes, Barrett esophagus (predominantly short-segment) was found in 6.8% [29]. In another study in which individuals in the general population of Sweden were invited to have endoscopic examinations, the prevalence of Barrett esophagus was found to be 1.6% [30].

The prevalence of Barrett esophagus in children is disputed. The condition appears to be very rare in children younger than 10 years of age and virtually non-existent in children younger than 5 years [31]. In a retrospective study of 6731 children who had upper gastrointestinal endoscopy in 12 pediatric facilities, only 17 (0.25%) had suspected Barrett esophagus, and only 9 of those had intestinal metaplasia confirmed by esophageal biopsy [32]. However, it has been proposed that this prevalence was spuriously low because pediatric gastroenterologists may not have recognized Barrett esophagus as readily as their adult counterparts. Another study from a pediatric group with a long-standing, special interest in Barrett esophagus found the condition (with histologically confirmed intestinal metaplasia) in 4.8% of 166 children who were receiving chronic proton pump inhibitor (PPI) therapy [33].

The epidemiology of esophageal adenocarcinoma is similar to that of Barrett esophagus. For example, GERD is a strong risk factor for adenocarcinoma of the esophagus [2], and this tumor affects white men predominantly [27]. In the

1960s, squamous cell cancers comprised well over 90% of all esophageal tumors in the United States, whereas adenocarcinoma of the esophagus was considered so uncommon that some authorities questioned its very existence. Since then, however, the frequency of adenocarcinoma of the esophagus has increased dramatically, to the point that adenocarcinoma surpassed squamous cell carcinoma in frequency in the 1990s [3,34,35]. Squamous cell carcinoma affects black people six times more frequently than white people, whereas adenocarcinoma is at least four times as common in white people [27].

Obesity has also been established as a strong risk factor for esophageal adenocarcinoma [36]. In the United States, the prevalence of obesity has increased substantially over the past three decades, paralleling the increase in the frequency of esophageal adenocarcinoma. The mechanism underlying the association between cancer of the esophagus and obesity is not known, but may be related to the fact that obesity predisposes to the development of GERD [37,38]. In addition, obesity is associated with increased serum levels of insulin-like growth factor 1 and leptin, hormones that can stimulate proliferation [39,40], and with decreased levels of adiponectin, a hormone that has antiproliferative effects [41]. Two studies have suggested that Barrett esophagus is associated with the presence of abdominal fat, not with body mass index (BMI) per se [42,43].

The frequency of infection with *H. pylori* has declined dramatically over the last century in the United States [44]. *H. pylori* is a well-established carcinogen for adenocarcinoma of the stomach, but some studies suggest that this infection may protect against the development and neoplastic progression of Barrett esophagus [45,46]. The mechanism of this alleged protective effect is not clear, but it has been proposed that *H. pylori* infections that cause pangastritis can decrease gastric acid secretion, thereby protecting against the development of GERD [47]. Thus, the declining frequency of *H. pylori* infection may be contributing to the rising frequency of esophageal adenocarcinoma.

In addition to *H. pylori* infection, factors that appear to protect against the development of esophageal adenocarcinoma include the use of aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) [48], and the consumption of a diet high in fruits and vegetables [49]. Although cigarette smoking and excessive alcohol consumption are very strong risk factors for squamous cell carcinoma of the esophagus, cigarette smoking only modestly increases the risk for esophageal adenocarcinoma and alcohol does not appear to affect that risk at all [50,51].

Cancer risk

Published estimates on the annual incidence of cancer in patients with long-segment Barrett esophagus have ranged from 0.2% to 2.9% [52]. In 2000, Shaheen and colleagues [52] presented compelling evidence that the cancer risk had been overestimated because of publication bias, the selective reporting of studies with positive or extreme results. A number of modern, larger studies, which may be less susceptible to sampling error, have suggested that the risk of cancer in Barrett esophagus is approximately 0.5% per year [53,54]. This estimate has become widely accepted among authorities.

It seems logical to assume that the risk of cancer in Barrett esophagus should vary with the extent of metaplastic epithelium, and data from a number of observational studies support this hypothesis [55,56]. However, there is yet no proof that the risk of cancer varies with the extent of the metaplastic lining. Furthermore, in one report of 235 patients with Barrett esophagus, the cancer risk was not found to vary significantly with the extent of metaplasia [57].

Pathogenesis of metaplasia in the esophagus

Metaplasia, the process in which one adult cell type replaces another, is a response to chronic inflammation in a number of organs [20,58]. Because the metaplastic cells may be more resistant to the factors inducing the inflammation than the native cells, metaplasia can be viewed teleologically as a protective mechanism. Unfortunately, metaplasia also may predispose to malignancy. In the esophagus, chronic inflammation due to GERD results in columnar metaplasia in which the acid-sensitive squamous epithelium is replaced by a columnar epithelium that may be more resistant to peptic injury.

A number of physiological abnormalities that predispose to severe GERD have been described in patients with long-segment Barrett esophagus. For example, gastric acid hypersecretion and duodenogastric reflux have been found in some patients [59,60]. Extreme hypotension of the lower esophageal sphincter, which predisposes to gastroesophageal reflux, is also common in patients with long-segment Barrett esophagus [61]. Manometric studies often reveal ineffective esophageal motility, an abnormality that may delay the clearance of refluxed material from the esophagus [62]. Some patients have diminished esophageal pain sensitivity [63]. If the reflux of caustic material does not induce the warning symptom of heartburn, then GERD may go untreated until a complication develops. Some patients have decreased salivary secretion of epidermal growth factor, a peptide that enhances the healing of peptic ulceration [64]. Individual patients may exhibit any, all, or none of these abnormalities, and their frequency in Barrett esophagus is disputed. For example, some investigators have found normal gastric acid secretion in their patients with long-segment Barrett esophagus [65]. Furthermore, many patients with short-segment Barrett esophagus have no GERD symptoms and no endoscopic signs of esophagitis [10].

Noxious factors that affect the most distal esophagus may play a role in the development of short-segment Barrett esophagus. Even in normal individuals, the environment of the GEJ appears to be especially hostile. After meals, there is a pocket of acid at the GEJ that escapes the buffering effects of ingested food [66]. This postprandial acid pocket has a mean length of approximately 2 cm, and may extend above the squamocolumnar junction to affect the distal esophagus. Studies have shown that the very distal esophagus (5–10 mm above the squamocolumnar junction) of healthy volunteers can be exposed to acid for more than 10% of the day [67,68]. This can result in acid peptic injury to the distal esophagus, and also in exposure to high concentrations of nitric oxide (NO), which is generated from dietary nitrate (NO_3^-) in green leafy vegetables. The ingested nitrate is absorbed by the small intestine, concentrated by the salivary glands, and secreted into the mouth where bacteria on the tongue reduce the nitrate to nitrite (NO_2^-). When swallowed nitrite encounters acidic gastric juice at the GEJ, the nitrite is converted rapidly to NO. After nitrate ingestion, high levels of NO can be found at the GEJ [69]. NO in these concentrations can be genotoxic and potentially carcinogenic. Thus, the GEJ is exposed repeatedly to acid, pepsin, NO, and other noxious agents in gastric juice. Chronic exposure to these agents may induce the injury and inflammation that results in the intestinal metaplasia of short-segment Barrett esophagus [70].

It is not known which cells give rise to the specialized intestinal metaplasia of Barrett esophagus. The prevailing hypothesis is that Barrett esophagus forms when GERD damages the superficial layers of the esophageal squamous epithelium, thereby exposing multipotential stem cells in the basal layers to gastric juice, which stimulates their abnormal differentiation [71]. Others have proposed that specialized intestinal metaplasia develops from progenitor cells located in the ducts of the esophageal mucosal glands [72]. In either case, the progenitor cells for Barrett esophagus have been assumed to reside within the esophagus itself.

One provocative study has suggested that bone marrow stem cells might contribute to the development of Barrett esophagus. In this study [73], female rats were given a lethal dose of radiation to destroy their native bone marrow cells, followed by a bone marrow transplant from male rat donors. The female rats then underwent esophagojejunostomy, a procedure that resulted in severe esophagitis and intestinal metaplasia histologically similar to human Barrett esophagus. Eight weeks after esophagojejunostomy, nuclear staining for Y chromosome was found in both squamous cells and metaplastic columnar cells in the esophagi of the female rats. These observations suggest that multipotential adult progenitor cells of bone marrow origin contribute to esophageal regeneration and metaplasia in this rat model of reflux esophagitis and Barrett esophagus, and raise the fascinating possibility that the progenitor cell for Barrett esophagus might be a circulating stem cell.

Although the identity of the progenitor cell for Barrett esophagus remains unclear, metaplasia must arise from changes in the gene expression of that cell. The protein products of key developmental genes are often transcription factors that regulate other genes and ultimately determine a cell's phenotype. The homeobox family of transcription factors includes those encoded by the *CDX* genes, which are known to mediate the differentiation of intestinal epithelial cells. Intestinal metaplasia in mouse stomach can be induced by forcing gastric epithelial cells to express either Cdx1 or Cdx2 [74,75]. Chronic acid exposure has been shown to activate the *Cdx2* gene promoter in cultures of mouse esophageal keratinocytes [76] and, in a rat model of Barrett esophagus, Cdx2 expression has been found in squamous cells of the basal layer prior to the development of specialized intestinal metaplasia [77]. In humans, CDX2 expression has been found in esophageal squamous epithelium from patients with Barrett esophagus [78], and biopsy specimens of specialized intestinal metaplasia have been shown to express both CDX1 and CDX2 [79,80]. These and other data suggest that gastroesophageal reflux may induce CDX expression by esophageal cells, which mediates their differentiation into the intestinal types characteristic of Barrett esophagus.

Bone morphogenetic protein (BMP)-4 also may be involved in the squamous-to-columnar metaplasia of Barrett esophagus. Early in embryonic development, the entire esophagus is lined by a columnar epithelium. In mice, a drop in levels of BMP-4 has been associated with the change from columnar epithelium to squamous epithelium in the embryonic esophagus [81]. In a rat model and in patients with GERD and Barrett esophagus, BMP-4 has been found by immunostaining in inflamed esophageal squamous epithelium and in specialized intestinal metaplasia, but not in normal esophageal squamous epithelium [82]. When cultures of human esophageal squamous cells are exposed to BMP-4, they express cytokeratins typical of columnar cells, and their gene expression patterns change to resemble those seen in Barrett epithelial cells [82]. These data suggest that reflux esophagitis may induce the esophageal squamous cells to express BMP-4, which mediates the change to the columnar cell types of Barrett esophagus.

Molecular biology of dysplasia and adenocarcinoma in Barrett esophagus

In 2000, Hanahan and Weinberg [83] proposed that, to become cancer cells, normal cells must acquire six essential physiological hallmarks which enable the cells to: (1) proliferate without exogenous stimulation; (2) resist growth-inhibitory signals; (3) avoid apoptosis; (4) resist cell senescence; (5) develop new vascular supplies (angiogenesis); and (6) invade and metastasize. This section will review what is known about how benign Barrett metaplastic cells

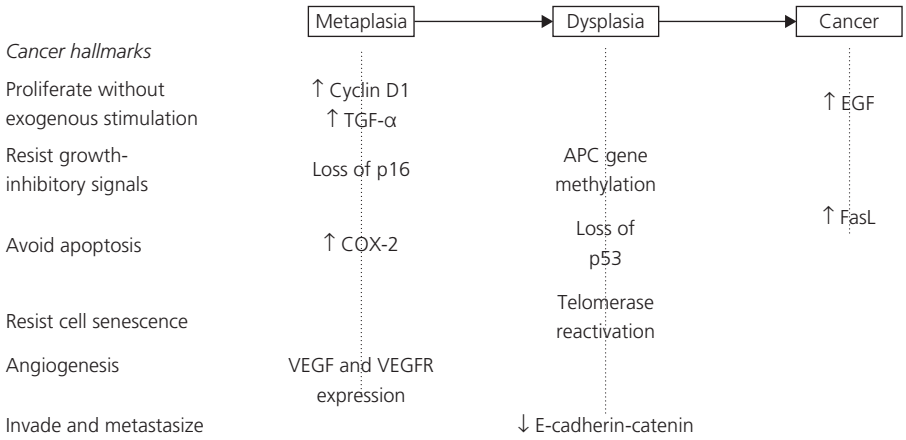

Figure 35.6 Molecular biology of dysplasia and cancer in Barrett esophagus. Some of the major genetic alterations recognized in Barrett esophagus that might allow the cells to acquire the six physiological hallmarks of cancer are shown. The histological stage at which each genetic change has been recognized is also depicted. APC, adenomatous polyposis coli; COX-2, cyclooxygenase 2; EGF, epidermal growth factor; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

acquire these abilities during the process of carcinogenesis [84,85]. The exact sequence and precise molecular changes necessary to produce esophageal adenocarcinoma remain incompletely understood. Some of the major genetic alterations that have been recognized in Barrett esophagus and which might allow the cells to acquire the six physiological hallmarks of cancer are shown in Figure 35.6.

Proliferation without exogenous stimulation

Oncogene expression is one mechanism whereby cells can proliferate without exogenous stimulation. Examples of oncogenes implicated in cancer progression of Barrett esophagus include cyclins D1, E, and B and c-*myc*. Increased nuclear expression of cyclin D1 protein has been found in 34% of biopsy specimens of Barrett specialized intestinal metaplasia [86]. Amplification of the chromosomal region of cyclin E or overexpression of cyclin E has been detected in Barrett esophagus with low- and high-grade dysplasia and in adenocarcinomas, but not in benign Barrett metaplasia [87,88]. Expression of cyclin B1 protein has been found to increase as the degree of dysplasia increases in Barrett epithelium [89]. Finally, up-regulation of c-Myc protein has been found in 50% of Barrett metaplasias and in 90% of adenocarcinomas [90,91].

Alterations in growth factors, growth factor receptors, and proproliferative signal transduction pathways are other ways in which Barrett cells may proliferate without exogenous stimulation. The Ras/Raf/mitogen-activated protein kinase (MAPK) pathway, which is activated by the binding of certain growth factors to their receptors, is one of the key proproliferative signaling cascades [92]. Data suggest that *KRAS* mutations occur as end-stage events in the process of carcinogenesis in Barrett esophagus [93]. Other studies have revealed genomic amplification or overexpression of the epidermal growth factor receptor (EGFR) and its ligand, transforming growth factor alpha (TGF-α), in biopsy samples of Barrett metaplasia [94]. Gastrin, a hormone that binds the CCK_2 receptor, has been shown to activate the MAPK pathways to induce proliferation in Barrett metaplasia and to prevent apoptosis in esophageal adenocarcinoma cells [95,96].

Acid exposure has been shown to activate the p38 MAPK pathway in metaplastic Barrett mucosa in vivo, and acid-mediated activation of the MAPK pathways has been associated with increased proliferation and decreased apoptosis in a human Barrett-associated adenocarcinoma cell line [97]. Exposure to glycochenodeoxycholic acid, a conjugated bile acid, also activates the MAPK pathways to increase proliferation in both nonneoplastic Barrett cells and in a Barrett-associated adenocarcinoma cell line [98]. Other growth factors and receptors that have been implicated in Barrett carcinogenesis include insulin-like growth factor 2, the insulin-like growth factor 1 receptor, and Met, a hepatocyte growth factor [99–101]. The role of *erb*B-2 (also called HER2 or Neu), an oncogenic form of EGFR, remains controversial [102,103].

Resistance to growth-inhibitory signals

Growth-inhibitory signals can exert their antiproliferative effects through the activation of tumor suppressor genes, and inactivation of these genes can result in hyperproliferation. There are at least three mechanisms by which tumor suppressor genes can be inactivated including mutation, loss of heterozygosity (LOH), and gene promoter methylation. Inactivation of the tumor suppressor genes p53, p16, p15, p27, and adenomatous polyposis coli (APC) has been implicated in the development of Barrett-associated adenocarcinomas.

The role of p53 in the neoplastic progression of Barrett esophagus has been studied extensively. LOH of 17p, the p53 locus, and p53 mutations have been found in nondysplastic cells of specialized intestinal metaplasia [104,105]. In fact, 17p LOH was found in diploid cells of specialized intestinal metaplasia prior to the development of aneuploidy, suggesting that p53 inactivation is an early step in the process of Barrett carcinogenesis [104]. Expression of mutant p53 has been found in nondysplastic Barrett metaplasia, and its levels increase as dysplasia progresses to cancer [106–108]. LOH of

17p and p53 mutations have been found in up to 90% of esophageal adenocarcinomas in Barrett esophagus [107–109].

LOH of 9p21, the chromosomal locus for p16 and p15, has been observed frequently in nondysplastic specialized intestinal metaplasia whose cells are aneuploid, and in Barrett-associated adenocarcinomas [110,111]. Mutations of the p16 and p15 genes are found far less frequently, however [110,112]. Recently, biopsy specimens of metaplastic Barrett esophagus demonstrated alterations of p16 via methylation, LOH, or mutation in 73%–87% of patients, suggesting that p16 alterations are a common and early event in the neoplastic progression of Barrett esophagus [111,113].

Loss of expression of p27, an inhibitor of cyclin E activity, has been found in 83% of esophageal adenocarcinomas, and has been correlated with aggressive tumor behavior and poor patient outcome [114]. LOH of 5q21, the APC locus, has been found in 20%–64% of esophageal adenocarcinomas, but only rarely have mutations been identified [115,116]. More common is APC inactivation by methylation, which has been found in 83%–92% of high-grade dysplasias and adenocarcinomas and in 40%–50% of Barrett metaplasias [117,118]. In one study, APC methylation was identified in the specialized intestinal metaplasia of 100% of patients who progressed to esophageal adenocarcinoma, compared with only 36% in patients who did not progress, suggesting that APC inactivation may be a predictive marker for neoplastic progression [118]. Furthermore, once adenocarcinoma develops, the finding of methylated APC DNA in the plasma may herald a poor survival [119].

Avoidance of apoptosis

Apoptosis is a tightly regulated, intrinsic form of programmed cell death that can occur in all normal cells. Normally, apoptosis is a beneficial process because it eliminates cells with DNA damage that, if perpetuated, might harm the organism [120]. Cancer cells must find ways to overcome apoptosis if they are to survive, albeit to the detriment of the organism. The apoptotic machinery comprises several death-commitment signaling pathways. These can be activated either by external stimuli that activate surface membrane death receptors or by intracellular stimuli including DNA damage and metabolic abnormalities that eventually converge on the caspase cascade, which ultimately leads to cell destruction [121].

The expression of death receptors that are members of the tumor necrosis factor (TNF) receptor superfamily has been investigated in the formation of Barrett-associated adenocarcinomas. Using immunohistochemistry and immunoblotting, one group of investigators has found enhanced expression of TNFR1 and its ligand, TNF-α, in the progression from Barrett metaplasia to adenocarcinoma [122]. Although this may seem counterintuitive, TNF-α binding to TNFR1 does not usually result in apoptosis, but rather in the up-regulation of antiapoptotic genes that promote cell survival [123,124]. Another death receptor–ligand pair implicated in Barrett carcinogenesis is Fas and Fas ligand (FasL). When FasL binds to Fas, apoptosis is induced in the Fas-expressing cells [125]. Therefore, one way for tumor cells to avoid apoptosis is to down-regulate Fas expression. Data on Fas expression in benign Barrett metaplasia as well as in esophageal adenocarcinoma are contradictory, with some studies detecting Fas expression and others finding undetectable or weak Fas staining [126–128]. Another way in which tumor cells can avoid apoptosis is by expressing FasL and mounting a "counterattack" against antitumor lymphocytes [129]. For example, in a study of esophageal adenocarcinoma, Younes et al. [130] found FasL expression in all 13 of the esophageal adenocarcinomas and their associated metastases, but none was detected in samples of normal squamous or metaplastic Barrett esophagus [130].

Intracellular stimuli that activate death-commitment pathways can also trigger apoptosis. Although the precise mechanisms are not known, the Bcl-2 family of proteins appears to be involved. The Bcl-2 protein family includes both proapoptotic members (e.g., Bax) and antiapoptotic members (e.g., Bcl-2 and Bcl-XL). Expression of Bcl-2 has been found in 72% of specimens with specialized intestinal metaplasia, 84%–100% with low-grade dysplasia, 0%–25% with high-grade dysplasia, and 0%–40% with adenocarcinoma [108,131]. Survival in patients whose tumors stained positive for Bcl-2 was significantly better than survival in those whose tumors were Bcl-2 negative [132]. Expression of the antiapoptotic protein Bcl-XL and the proapoptotic protein Bax has been found in nondysplastic specialized intestinal metaplasia, low- and high-grade dysplasia, and adenocarcinoma [100,132].

Other mechanisms for avoiding apoptosis have also been found in Barrett esophagus. For example, down-regulation of 15-lipoxygenase-1 (15-LOX-1), an enzyme involved in the formation of the apoptosis-inducing fatty acid 13-*S*-hydroxyoctadecadienoic acid (13-*S*-HODE), has been described in 75% of Barrett-associated esophageal adenocarcinomas [133]. Cyclooxygenase 2 (COX-2), an enzyme involved in the generation of prostaglandins from arachadonic acid, has been shown to reduce the rate of apoptosis in vitro [134]. Increased expression of COX-2 has been detected both in esophageal adenocarcinomas and in the metaplastic epithelium of Barrett esophagus compared with normal control subjects [135,136]. Souza et al. [137] found that, by inhibiting COX-2 with the selective inhibitor NS-398, apoptosis could be induced in Barrett adenocarcinoma cells, suggesting a potential role for COX-2 inhibition in patients with Barrett-associated cancers [137]. Expression of a transcription factor, nuclear factor-kappa B (NF-κB), that regulates the expression of a number of antiapoptotic genes has been detected in 40%–60% of Barrett specialized intestinal metaplasia and in 61%–80% of esophageal adenocarcinomas [138,139]. Finally, as discussed earlier, p53 inactivation

allows Barrett cancer cells to avoid apoptosis in response to DNA damage.

Resistance to cell senescence

Cellular senescence, a state of permanent growth arrest, is an autonomous, intrinsic mechanism that limits the proliferative capacity of normal cells. Cancer cells must overcome this limitation to maintain unlimited proliferative capacity and hence become immortal. Telomeres are long stretches of noncoding, DNA repeat sequences located on the ends of chromosomes [140]. With each successive round of cell replication, telomeric DNA repeats are lost. When telomere shortening reaches a critical level, the chromosomes becomes unstable, which triggers exit from the cell cycle into senescence. To maintain an unlimited proliferative capacity, therefore, cells must maintain their telomere lengths. Telomerase is the enzyme responsible for maintaining telomere length above the critical level [141]. Most normal human somatic cells do not produce this enzyme, but the large majority of cancer cells express active telomerase [142].

Weak levels of telomerase expression have been detected in benign metaplastic Barrett esophagus, and these levels increase progressively as dysplasia worsens, with the highest levels found in Barrett-associated adenocarcinomas [143,144]. With advances in our understanding of cellular senescence and telomerase, it has now become possible to use the expression of telomerase to immortalize normal, nontumorigenic cells in vitro, including the benign metaplastic cells of Barrett esophagus [145,146]. Shammas et al. [147] found that, by inhibiting telomerase with 2,6-bis[3-(N-Piperidino)propionamido]anthracene-9,10-dione (PPA), growth arrest and apoptosis could be induced in Barrett adenocarcinoma cells, suggesting a potential role for telomerase inhibitors in patients with Barrett-associated cancers.

Development of new vascular supplies (angiogenesis)

To continue to increase in size, tumors must form new blood vessels (angiogenesis) to enable essential nutrients and oxygen to be provided [148]. To do so, tumor cells secrete potent angiogenic factors such as vascular endothelial growth factor (VEGF). VEGF binds to its receptors (VEGFRs), which are located on the surface of endothelial cells, to stimulate the proliferation and migration of endothelial cells into the tumor [148,149].

Several groups have investigated neoangiogenesis and the expression of VEGFs and VEGFRs in Barrett esophagus. Compared with normal esophageal squamous mucosa, specialized intestinal Barrett metaplasia demonstrates an increase in the density of new, immature blood vessels, which increases further as dysplasia progresses to adenocarcinoma [150–153]. The Barrett epithelial cells have been found to express VEGF-A and -C, whereas the blood vessels supplying the metaplastic mucosa express the corresponding receptors VEGFR2 and -3 [150,154]. Investigators have speculated that this neovascularization is responsible for the salmon color characteristic of Barrett metaplasia on endoscopic examination [150]. VEGF-A and VEGF-C mRNA have been found in 100% and 74% of esophageal adenocarcinomas respectively [154]. Moreover, expression levels of VEGF mRNA and protein are higher in adenocarcinomas than in dysplastic and nonneoplastic Barrett metaplasia [150,155].

Invasion and metastasis

With loss of cell–cell anchoring mechanisms, tumor cells can break away from the primary lesion to metastasize and invade surrounding tissues [156]. Although the mechanisms of invasion and metastasis are poorly understood, abnormalities in cell adhesion molecules (cadherins) and their associated proteins (catenins) appear to play a central role. For tumor cells to invade they must disrupt cell–cell adhesion by altering the cadherins or the catenins. Membranous staining for E-cadherin and β-catenin has been found in normal esophageal squamous epithelium and in the nondysplastic, specialized intestinal metaplasia of Barrett esophagus and the intensity of this staining has been found to decreases as the metaplastic mucosa becomes increasingly dysplastic [157–160].

Disruption of the cadherin/catenin-based cell–cell interaction allows cancer cells to break free of the primary tumor. To invade the surrounding tissues and to metastasize through vascular structures, the free tumor cells must penetrate extracellular matrix barriers [161]. The matrix metalloproteinases (MMPs) are a family of zinc-dependent proteinases that can digest components of the extracellular matrix and other extracellular proteins including cell adhesion molecules [161,162]. MMP-9 expression is higher in the metaplastic mucosa than in normal esophageal squamous mucosa [150]. Using in situ hybridization, Salmela et al. [163] found MMP-7 to be the principal MMP in Barrett-associated adenocarcinomas and lymph node metastases, and up-regulation of MMP-7 was even found in the epithelial cells of nondysplastic specialized intestinal metaplasia. Moreover, this same group found that aggressiveness of the tumor, as determined by histological criteria, correlated with the expression of MMP-7 [163].

Dysplasia in Barrett esophagus

Cancers in Barrett esophagus develop through a series of genetic alterations that endow the affected cells with growth advantages. As the advantaged cells proliferate, they acquire more genetic damage until, eventually, an autonomous clone of cells emerges that no longer responds to normal growth controls. This autonomous condition is called neoplasia. Some of the same DNA changes that give the cells their growth advantages and autonomy also cause morphological changes that the pathologist recognizes as dysplasia.

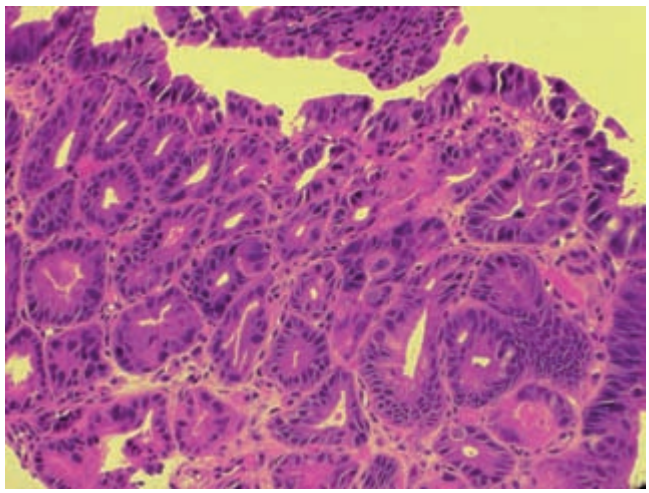

Figure 35.7 Photomicrograph showing high-grade dysplasia. Note that the nuclei are enlarged, pleomorphic, hyperchromatic, and stratified, and there are atypical mitoses.

Thus, dysplasia can be viewed as the histological expression of genetic alterations that favor cell growth and neoplasia [164]. Some prefer to use the term "intraepithelial neoplasia" instead of "dysplasia" to emphasize that the pathologist has judged the tissue to be neoplastic [165].

Pathologists diagnose dysplasia when they recognize a constellation of characteristic cytological and architectural abnormalities in tissue biopsy specimens including: (1) nuclear changes such as enlargement, pleomorphism, hyperchromatism, stratification, and atypical mitoses; (2) loss of cytoplasmic maturation; and (3) crowding of tubules and villiform surfaces (Fig. 35.7) [166]. Dysplasia is categorized as low-grade or high-grade depending on the degree of histological abnormalities, with more pronounced abnormalities assumed to reflect more severe genetic damage and greater potential for carcinogenesis.

Histological changes similar to those of low-grade dysplasia can be seen in nonneoplastic tissue that is regenerating in response to injury, and interobserver agreement among experienced pathologists for the diagnosis of low-grade dysplasia may be less than 50% [167–169]. Interobserver agreement is better (approximately 85%) for high-grade dysplasia, but far from perfect. There is also substantial interobserver disagreement when distinguishing high-grade dysplasia from intramucosal carcinoma [170].

Dysplasia in Barrett esophagus is often flat, inconspicuous, and patchy, both in extent and severity, factors contributing to the substantial problem of biopsy sampling error in identifying dysplasia [171,172]. Endoscopists use a random biopsy sampling system to find dysplasia in Barrett esophagus, and it is clear that this system can miss dysplastic areas. Furthermore, for patients who are found to have dysplasia, foci of invasive cancer can be missed because of sampling error. In a series of patients who had esophagectomies because endoscopic examination revealed high-grade dysplasia with no apparent tumor mass, invasive cancer has been found in 30%–40% of the resected esophagi [173]. Conversely, there are reports of patients whose preoperative biopsy specimens showed intramucosal carcinoma, but whose resected esophagi had no evidence of cancer [174].

Researchers have tried to develop endoscopic techniques for recognizing dysplasia in Barrett esophagus, and have tried to find alternative markers for cancer risk [175]. Techniques that have been proposed to identify areas of dysplasia for biopsy sampling during endoscopy include mucosal staining with vital dyes (chromoendoscopy), endosonography [176], optical coherence tomography [177], and Raman detection methods [178,179]. Some studies have shown that abnormalities in p53 and cyclin D1 expression [180,181], and abnormal cellular DNA content (aneuploidy) demonstrable by flow cytometry are associated with carcinogenesis in Barrett esophagus [182]. Presently, however, none of these tests and techniques has been shown to provide sufficient clinical information to justify its routine application for surveillance purposes. Endoscopy with random biopsy sampling for dysplasia, despite the many shortcomings, remains the clinical standard for managing patients with Barrett esophagus.

Although cancers in Barrett esophagus are thought to evolve from nonneoplastic metaplasia to low-grade dysplasia, to high-grade dysplasia, and to adenocarcinoma, this orderly sequence of progression is documented only infrequently. For patients with verified dysplasia, subsequent endoscopies often reveal no dysplastic epithelium, or patchy areas of dysplasia with varying severities [182,183]. Furthermore, adenocarcinomas have been found in patients whose previous surveillance biopsy specimens revealed only low-grade or even no dysplasia [184]. One recent study suggests that patients who have Barrett esophagus develop low-grade dysplasia at a rate of 4.3% per year, and high-grade dysplasia at a rate of 0.9% per year [54].

Few data are available on the natural history of low-grade dysplasia in Barrett esophagus. In a series of 48 patients with low-grade dysplasia followed for a mean duration of 41 months, five (10%) progressed to high-grade dysplasia (four patients) or adenocarcinoma (one patient) [185]. Another group described a 12% cumulative incidence of adenocarcinoma at 5 years for 43 patients with low-grade dysplasia on baseline endoscopy [182]. Skacel et al. [168] followed 25 patients with low-grade dysplasia for a mean duration of 26 months, during which seven (28%) progressed to high-grade dysplasia (five patients) or adenocarcinoma (two patients). In this series, agreement among pathologists in the diagnosis of low-grade dysplasia was associated with neoplastic progression. In total, seven of the 17 patients (41%) in whom at least two of the three study pathologists agreed on the diagnosis of low-grade dysplasia exhibited progression, whereas

progression was seen in four of the five patients (80%) for whom there was unanimous agreement among the study pathologists. In another study that included 156 patients with low-grade dysplasia, the incidence of cancer in these patients was 0.6% per year [54].

Relatively few studies provide meaningful data on the rate at which high-grade dysplasia in Barrett esophagus progresses to cancer, and reported estimates vary considerably. Hameeteman et al. [186] described eight patients with high-grade dysplasia in Barrett esophagus, five (63%) of whom were found to have adenocarcinoma on repeat endoscopic examination performed within 1 year [186]. Reid et al. [182] reported a 59% 5-year cumulative cancer incidence among 76 patients with high-grade dysplasia in Barrett esophagus [182]. However, Schnell et al. [183] observed a much lower cancer incidence in his 75 patients with high-grade dysplasia in Barrett esophagus, only 12 of whom (16%) developed adenocarcinoma during a mean follow-up period of 7.3 years. The reasons underlying the large disparities in the results of these three studies are not clear. In the series of Schnell et al. [183], it is possible that "overreading" of dysplastic changes contributed to the low incidence of adenocarcinoma [187]. In addition, the analysis of Schnell et al. [183] excluded patients who were found to have cancer within 1 year of the diagnosis of high-grade dysplasia, because the investigators considered these cancers to be prevalent (present at the first endoscopy but missed because of sampling error) rather than incident malignancies (developing during the period of follow-up). This elimination criterion would have excluded all of the five patients with cancer described by Hameeteman et al. [186], and would have reduced the 5-year cumulative cancer incidence in the series of Reid et al. [182] from 59% to 31% [22].

Buttar and colleagues [188] found that the extent of high-grade dysplasia in Barrett esophagus correlated with the risk for adenocarcinoma. In their report, high-grade dysplasia was defined as "focal" if the histological abnormalities were confined to a single focus involving up to five crypts, and as "diffuse" when these features were seen in more than five crypts or in multiple biopsy specimens. The cumulative cancer incidence at 3 years was 56% for the 67 patients with diffuse high-grade dysplasia, compared with only 14% for the 33 patients initially found to have focal high-grade dysplasia. However, the histological criteria for focal and diffuse dysplasia used in this study were arbitrary, and there is no clear consensus on this classification among gastrointestinal pathologists [189]. Furthermore, other investigators have not confirmed the observation that focal high-grade dysplasia is associated with such a low cancer risk [190].

In summary, it appears that patients with Barrett esophagus develop low-grade dysplasia at a rate of 4.3% per year, and high-grade dysplasia at a rate of 0.9% per year. The overall rate of cancer development in patients with Barrett esophagus is approximately 0.5%. Patients with low-grade dysplasia develop cancer at a rate of approximately 0.6% per year, but this estimate must be suspect because of the substantial problem of disagreement among pathologists in the identification of low-grade dysplasia. For patients with high-grade dysplasia, one review estimates that the rate of demonstrable cancer development is 4%–6% per year [164].

Management of patients with Barrett esophagus

The management of patients with Barrett esophagus involves three major components: (1) treatment of the associated GERD; (2) endoscopic surveillance to detect dysplasia; and (3) treatment of dysplasia. All three components are highly controversial.

Treatment of gastroesophageal reflux disease in Barrett esophagus

The general approach to the treatment of GERD in patients with Barrett esophagus is very similar to that recommended for patients who have GERD without Barrett esophagus [191]. One important difference, however, is that many modern authorities advocate initial and maintenance therapy with a PPI, rather than an incremental ("step up") therapeutic approach that is based upon symptom response. This practice is based on indirect evidence suggesting that acid reflux promotes carcinogenesis in specialized intestinal metaplasia, and that aggressive control of acid reflux may interfere with carcinogenesis.

The indirect evidence for acid promoting carcinogenesis in Barrett esophagus includes the observation that biopsy specimens of specialized intestinal metaplasia maintained in organ culture exhibit hyperproliferation and increased expression of COX-2 when exposed to acid [192,193]. In Barrett-associated adenocarcinoma cell lines, acid exposure has been shown to activate MAPK and protein kinase C pathways, to increase proliferation, and to decrease apoptosis [192,194]. Brief esophageal acid exposure in vivo also activates the MAPK pathways in Barrett esophagus [192]. In a clinical study in which esophageal biopsy specimens were taken from Barrett patients at baseline and after 6 months of antireflux therapy, the expression of PCNA (a proliferation marker) was decreased significantly in biopsy specimens from 24 patients in whom treatment had normalized esophageal acid exposure, but not in the 15 with persistently abnormal acid reflux [195]. Another group found no significant change in the proliferative activity of Barrett esophagus in 22 patients treated with a PPI for 2 years, whereas proliferative activity increased significantly in 23 patients treated for the same time with a histamine H_2 receptor antagonist [196]. During PPI therapy, most patients with Barrett esophagus develop partial regression of Barrett epithelium in the form of islands of squamous epithelium

[197]; however, it is not clear whether this partial regression reduces the cancer risk [198]. In a study of long-term follow-up of 236 patients with Barrett esophagus, the cumulative incidence of dysplasia at 10 years was 21% for the patients who received PPI therapy, compared with 58% for the patients not treated with PPIs [199]. All of these studies suggest that aggressive acid suppression might prevent the development of cancer in Barrett esophagus.

One study has challenged the notion that acid exposure exerts only damaging effects in Barrett esophagus [200]. The in vitro studies on this issue mentioned above involved cancer cell lines, which have extensive genetic abnormalities that might alter their responses to acid exposure, and tissue explants, which comprise numerous nonepithelial cell types that might mask the direct effects of acid on epithelial cells. Furthermore, in the clinical studies that suggest potential benefits for aggressive acid suppression, it is not possible to determine whether acid control decreased proliferation in Barrett epithelium directly, by removing an acid-triggered proliferation signal, or indirectly through the antiinflammatory effects of healing reflux esophagitis. Inflammation is well known to be a potent stimulus for proliferation and carcinogenesis in a number of organs. In cultures of a novel, nonneoplastic Barrett epithelial cell line that is immortalized but not transformed, Feagins et al. [200] found that acid exerts direct antiproliferative effects. If acid has beneficial direct effects on Barrett cells, then it is conceivable that the prescription of antisecretory medications in doses beyond those required to heal reflux esophagitis could have some detrimental effects.

For patients with Barrett esophagus, the elimination of heartburn by antisecretory therapy is no guarantee that acid reflux has normalized. A number of studies have shown that Barrett patients may be rendered asymptomatic by PPIs given in dosages that fail to normalize esophageal acid exposure [201–203]. In one study of 48 patients with Barrett esophagus, for example, 50% had persistently abnormal acid exposure documented by esophageal pH monitoring while they were receiving dosages of PPIs that abolished symptoms [203].

In patients with GERD who are treated with PPIs, lower healing rates of reflux esophagitis have been reported for those with Barrett esophagus than for those who have esophagitis of similar severity but without columnar metaplasia [204]. Thus, it has been suggested that patients with Barrett esophagus are unusually resistant to PPI treatment [203]. One study has suggested that this problem is not due to gastric resistance to the antisecretory effects of PPIs, because Barrett patients treated with high doses of esomeprazole exhibited gastric acid suppression to levels similar to those reported for normal individuals [205]. Despite the significant decrease in gastric acidity with the high dose of PPI, however, 16%–23% of the Barrett patients still had abnormal esophageal acid exposure. This suggests that the "PPI resistance" in patients with Barrett esophagus is a consequence of their profound propensity for reflux diathesis.

Some surgeons have proposed that fundoplication might be more effective than antisecretory therapy for preventing cancer in Barrett esophagus [206]; however, this proposal is based far more on speculation than on data. Some authorities have even proposed that antisecretory therapy might predispose to malignancy [207,208], and that the increasing use of antisecretory medications might underlie the rising frequency of esophageal adenocarcinoma in Western countries [209]. However, the limited studies that have addressed this issue directly have not found a significant association between esophageal adenocarcinoma and the use of antisecretory agents per se [210,211].

Although some observational studies have found fewer cases of dysplasia and cancer among patients with Barrett esophagus who had antireflux surgery than among those who had received medical treatment [212], a number of higher quality studies have refuted this observation. For example, during a 10- to 13-year follow-up of patients who had participated in a randomized trial of medical and surgical therapies for complicated GERD, four of 165 patients (2.4%) in the medical group and one of 82 (1.2%) in the surgical group developed an esophageal adenocarcinoma [213]. The difference between the treatment groups in the incidence of this tumor was not statistically significant but, with such a low observed rate of cancer development, the study did not have sufficient statistical power to detect small differences in the incidence of esophageal cancer. In addition, any potential cancer-preventive benefit of surgery was offset by an unexplained, but significant, decrease in survival for the surgical patients as a result of excess deaths from heart disease. Two studies using large patient databases [214,215] and two metaanalyses [216,217] also have found no significant cancer-preventive effect for antireflux surgery. These data suggest that antireflux surgery should not be advised with the expectation that the procedure will prevent esophageal cancer.

Endoscopic surveillance for dysplasia

Although a number of medical societies recommend endoscopic surveillance for patients with Barrett esophagus, there is no proof (in the form of a randomized control trial) that surveillance is beneficial. The unproved assumptions underlying endoscopic surveillance for patients with Barrett esophagus are outlined in Table 35.1.

A number of small studies have suggested that Barrett esophagus does not affect survival [218]. In these small series, survival for patients with Barrett esophagus did not appear to differ significantly from that for control subjects in the general population. However, small studies might not have the statistical power to demonstrate a small decrement in survival. In a large, population-based study comprising 7413 person-years of follow-up in 2373 patients with Barrett esophagus, Anderson et al. [219] found that overall mortality

Table 35.1 Unproved assumptions underlying endoscopic surveillance for patients with Barrett esophagus

1. Barrett esophagus decreases survival as the result of death from esophageal adenocarcinoma
2. Endoscopic surveillance reliably detects dysplasia in Barrett esophagus
3. Treatment of dysplasia found by surveillance prolongs survival by preventing deaths from esophageal cancer

in the Barrett patients was not increased above that of the general population of Northern Ireland. In contrast, Solaymani-Dodaran et al. [220] found that 1677 patients with Barrett esophagus had a 37% increase in mortality compared with a standard reference cohort of 13 416 individuals representing the general population of the United Kingdom. Approximately 45% of the excess mortality in the Barrett patients was due to esophageal cancer, with the remainder due to other causes, mostly cardiovascular disease.

On the basis of available data, one can conclude that the incidence of esophageal adenocarcinoma and the frequency of deaths due to esophageal cancer for patients with Barrett esophagus are increased significantly above those of the general population. Nevertheless, esophageal cancer is an uncommon cause of death in these patients. Older patients with Barrett esophagus succumb far more often to common illnesses such as coronary artery disease than to esophageal adenocarcinoma. Thus, overall mortality in patients with Barrett esophagus appears to be affected only slightly by their higher frequency of esophageal cancer.

Observational studies have shown that some patients with Barrett esophagus have had curable neoplasms detected by endoscopic surveillance, and that asymptomatic cancers discovered in surveillance programs are less advanced than those found when patients present to the hospital with cancer symptoms such as dysphagia and weight loss. For example, Corley et al. [221] reviewed the records of 589 patients who had adenocarcinomas at the GEJ, only 23 of whom were known to have had Barrett esophagus before the cancer was discovered. In total, 15 of those 23 patients had the cancer discovered during endoscopic surveillance for Barrett esophagus and 11 of those (73%) survived, whereas there were no survivors among eight patients who were not in surveillance and whose cancers were discovered when they presented with symptoms of dysphagia and weight loss. However, such observational studies are subject to a number of biases (e.g., healthy volunteer bias, lead-time bias, length-time bias) that might inflate the benefits of surveillance programs [222]. In addition, reports have documented the development of incurable esophageal malignancies in some patients despite their participation in endoscopic surveillance programs [223].

Surveillance programs seek to detect early neoplasia but, to prolong survival, there must be an effective treatment that prevents the progression to incurable cancer. Until recently, the only treatment available for dysplasia and early cancers was esophagectomy, a procedure associated with considerable morbidity and with mortality. For older patients with comorbidities, the risks of esophagectomy might exceed the benefits [224]. When the only treatment for dysplasia was esophagectomy, it made little sense to recommend endoscopic surveillance for any patient who was not fit enough to undergo that major operation. Now, however, there are less invasive treatments for dysplasia such as endoscopic ablative therapies (e.g., photodynamic therapy) and endoscopic mucosal resection (EMR), which are discussed below (see section on treatment of dysplasia in Barrett esophagus). Although studies have not yet proved that these less invasive therapies prolong life, the presence of these therapies has substantially expanded the population of patients who might benefit from surveillance. In other words, patients may no longer need to be fit enough to undergo esophagectomy to justify endoscopic surveillance.

A number of computer models have supported the practice of endoscopic screening and surveillance for Barrett esophagus [225–232]. Cost-efficacy studies often use a benchmark value of up to US$50 000 per life-year saved as something that society deems to be worthwhile. Provenzale et al. [225] estimated that surveillance performed at 5-year intervals would cost US$98 000 per quality-adjusted life-year. Although this exceeds the US$50 000 benchmark value, it remains within a range that might be considered reasonable. All other studies estimate that endoscopic screening and surveillance for patients with Barrett esophagus would cost less than US$50 000 per life-year saved. Unfortunately, the computer models are not definitive because they rely on numerous layers of soft data and questionable assumptions. Furthermore, the internal programs of the models are largely "black boxes," with no external means to validate their accuracy. Despite the problems and the apparent discrepancies in cost estimates among the various models, it is worthwhile to note that all of them have found that screening and surveillance for Barrett esophagus can be beneficial.

The major points of the arguments for and against endoscopic surveillance for Barrett esophagus are summarized in Table 35.2. The opponents argue that, in an era of shrinking financial resources, society can ill afford for physicians to practice the unproved, expensive, and potentially hazardous policy of performing endoscopic surveillance for Barrett esophagus. The proponents contend that it is ethically wrong for physicians to forgo the generally safe and potentially life-saving practice of endoscopic surveillance because of financial concerns or because they are awaiting the results of a definitive study that may never materialize. There have been numerous debates at medical meetings and in medical journals regarding the wisdom of surveillance for Barrett esophagus, with no clear winners.

Table 35.2 Arguments for and against endoscopic surveillance for patients with Barrett esophagus

Against surveillance
There is no proof (no randomized controlled trials) of efficacy
Endoscopy is expensive
Endoscopy has physical risks and potentially adverse, long-term emotional and financial consequences
Most patients derive no demonstrable benefit from surveillance
For surveillance
The rationale is reasonable
No proof of efficacy is likely in the near future
Most observational studies suggest benefit
All available computer models suggest benefit
No study has shown an overall survival disadvantage for patients in surveillance programs

Treatment of dysplasia in Barrett esophagus

When evaluating reports on treatments for dysplasia in Barrett esophagus, it is important to consider the issue of what constitutes adequate follow-up. Specifically, when can the patient treated for dysplasia be considered "cured?" Patients treated for carcinomas traditionally are deemed cured if there is no evidence of recurrence at 5 years, because it is assumed that any cancer cells that survived the treatment would have become clinically manifest within that time period. As discussed, however, it often takes considerably longer than 5 years for dysplasia to progress to invasive cancer. Consequently, it is not appropriate to conclude that the cancer risk has been eliminated in a patient who has survived for 5 years after treatment of dysplasia. Unfortunately, the follow-up duration in most reported studies on treatments for dysplasia in Barrett esophagus is considerably less than 5 years, and this factor severely limits the conclusions that can be drawn regarding the efficacy of therapy.

For patients with verified high-grade dysplasia in Barrett esophagus, there are generally four proposed management options: (1) esophagectomy; (2) endoscopic therapies that ablate the neoplastic tissue; (3) EMR (sometimes used in combination with ablative therapies); and (4) intensive endoscopic surveillance in which invasive therapies are withheld until biopsy specimens reveal adenocarcinoma. All four choices are associated with substantial risks and uncertain benefits.

Esophagectomy

Esophagectomy, which removes all of the abnormal esophageal epithelium in toto, is both the most definitive and the most risky (in terms of procedure-related morbidity and mortality) of the treatments for dysplasia in Barrett esophagus. Histological examination of the resected esophagus has revealed foci of cancer in 30%–40% of patients whose preoperative biopsies revealed only high-grade dysplasia in Barrett esophagus [173]. Studies on esophagectomy for high-grade dysplasia in Barrett esophagus typically have involved small numbers of patients from a single institution, and such reports are of limited value for estimating the morbidity and mortality of esophagectomy in this setting. Much larger series are available on the results of esophagectomy for esophageal cancer, but it may not be appropriate to extrapolate the results of surgery performed on patients with esophageal cancer, who often have substantial comorbidities and nutritional deficiencies, to otherwise healthy patients with precancerous lesions.

Mortality rates for esophagectomy among institutions are inversely related to the frequency with which the operation is performed. In one study of 340 esophagectomies performed at 25 different hospitals, the mortality rate was 3.0% for patients who had the operation at institutions that did five or more esophagectomies per year, compared with 12.2% for patients treated at institutions where the operation was performed less frequently [233]. In a study of data from the Dutch National Medical Registry, the mortality rates for esophagectomy were 12.1%, 7.5%, and 4.9% at centers performing 1–10, 11–20, and more than 50 esophagectomies per year respectively [234].

Esophagectomy has substantial operative morbidity. The average hospital stay for open esophagectomy is approximately 2 weeks, and 30%–50% of patients develop at least one serious postoperative complication such as pneumonia, arrhythmia, myocardial infarction, heart failure, wound infection, and anastomotic leaks [233–236]. Available data on minimally invasive techniques for esophagectomy are promising but limited, and it is not yet clear whether these approaches are preferable to the open procedure [237,238].

Esophagectomy can have substantial long-term morbidity including dysphagia, weight loss, gastroesophageal reflux, and dumping. However, the limited data available suggest that the impact of these symptoms on quality of life is surprisingly small. One group performed a utility assessment of patients who had esophagectomies at least 1 year earlier, and found that they rated their median quality of life at 0.97 on a scale of 0–1 (where 0 = death and 1 = perfect health) [225]. In another study of 53 patients who had esophagectomies for high-grade dysplasia in Barrett esophagus and who completed the MOS SF-36 Health Status Questionnaire, there appeared to be few important differences between the patients and a normal control population [239]. In another study in which quality of life questionnaires were administered to 199 patients before and after esophagectomy, quality of life was found to return to baseline values within 2 years [240].

The perception that the morbidity and mortality of esophagectomy is unacceptably high has prompted physicians to explore less invasive modalities to treat dysplasia in Barrett esophagus. However, it should be pointed out that,

unlike the alternative therapies discussed below, esophagectomy clearly eliminates the dysplasia and, if performed in a high-volume center on fit patients, should have a mortality rate substantially less than 5% with reasonable long-term morbidity. Thus, the esophagectomy option still warrants serious consideration, especially for young and fit patients.

Endoscopic ablative therapies

Endoscopic ablative therapies (e.g. KTP, argon, and Nd:YAG laser; multipolar electrocoagulation; argon plasma coagulation; photodynamic therapy; the HALO system) use thermal, photochemical or radiofrequency energy to ablate the abnormal epithelium in Barrett esophagus [241–244]. After the epithelium is ablated, patients are given potent antireflux therapy (usually PPIs) so that the injured mucosa heals with the growth of new squamous epithelium. The relative merits of the various endoscopic ablative therapies are disputed.

A major concern regarding endoscopic ablative therapies for dysplasia is that the procedures will leave dysplastic cells behind in the esophagus. Indeed, visible foci of metaplastic mucosa are found commonly after endoscopic ablation with all of the techniques available [241–244]. Partially ablated metaplastic mucosa can heal with an overlying layer of squamous epithelium that "buries" the metaplastic tissue and hides it from the endoscopist. There are reports of adenocarcinoma developing from buried metaplastic tissue [245]. Furthermore, partially ablated metaplastic epithelium can develop new abnormalities in the expression of proliferation markers and p53, raising the possibility that incomplete ablation of Barrett esophagus might even increase the risk of carcinogenesis [246]. Techniques to ablate the residual metaplasia are being studied, but limited data are available on their efficacy [247].

The conclusions that can be drawn from reports on ablative therapies for dysplasia in Barrett esophagus are limited because most studies are not randomized or controlled, involve small numbers of patients, and have short durations of follow-up. Photodynamic therapy (PDT) has been the most extensively studied of the ablative techniques. For PDT, patients are given a systemic dose of a light-activated chemical (usually a porphyrin or porphyrin precursor), which is taken up by the esophageal cells. The esophagus is then irradiated using a low-power laser that activates the chemical, which transfers the energy acquired from laser light to oxygen. This results in the formation of singlet oxygen, a toxic molecule that destroys the abnormal cells and their vasculature.

In a multicenter, randomized trial of PDT using porfimer sodium for ablation of high-grade dysplasia in Barrett esophagus, 138 patients were treated with PDT plus 20 mg of omeprazole b.i.d., and 70 received 20 mg of omeprazole b.i.d. alone (without PDT) [248,249]. No dysplasia was seen on repeat endoscopy in 77% of the patients treated with PDT and omeprazole, and in 39% of the patients who received omeprazole alone ($P < 0.0001$). During up to 5 years of follow-up, 15% of the PDT patients developed cancer, compared with 29% of those treated with omeprazole alone ($P = 0.027$). There was no procedure-related mortality, but 69% of the patients who received PDT developed photosensitivity reactions and 36% developed esophageal strictures that required one or more sessions of dilation therapy. Although these results show that PDT is clearly superior to omeprazole alone for eradicating dysplasia and preventing cancer in Barrett esophagus, the frequency of serious complications is disconcerting, as is the fact that 15% of the patients who received PDT developed cancer.

Although a number of reports have documented the feasibility of ablating neoplastic epithelium with endoscopic ablation, available studies have not established the overall benefits of the technique. Endoscopic ablation is expensive, and the treatments entail risks and inconvenience. Preliminary results of radiofrequency ablation for dysplasia in Barrett esophagus are promising, and this technique appears to have substantially fewer adverse effects than PDT [250]. Without histological examination of the resected esophagus or durations of follow-up well beyond 5 years, however, it is not possible to verify claims that dysplasia and cancer indeed are "eliminated" by endoscopic ablation. Residual foci of metaplasia remain in many patients after endoscopic ablation, and some of these foci may be buried under a superficial layer of squamous epithelium where they are invisible to the endoscopist.

Endoscopic mucosal resection

In EMR, a diathermy snare or endoscopic knife is used to remove a large segment of esophageal mucosa down to the submucosa [251,252]. Most centers have used a "suck and cut" method for EMR in which the endoscopist elevates the dysplastic area by injecting fluid into the submucosa, after which the elevated mucosa is suctioned into a cap that fits over the tip of the endoscope. A polypectomy snare is then deployed around the suctioned area to remove it. A recent variation on this technique involves the use of a ligating device, similar to that used for endoscopic variceal ligation, which deploys elastic bands around the suctioned mucosal segment [253]. Unlike the endoscopic ablative techniques, EMR provides large tissue specimens that can be examined by the pathologist to determine the character and extent of the lesion, and the adequacy of resection.

Although there is the theoretical potential for lymphatic dissemination of neoplastic cells that enter the esophageal lamina propria, limited data from surgical series suggest that fewer than 5% of patients with intramucosal adenocarcinoma in Barrett esophagus have lymph node metastases [254,255]. In contrast, for esophageal squamous cell carcinomas with a similar early T stage, lymphatic spread appears to be more common [256]. It has been proposed that the reflux esophagitis that often accompanies Barrett esophagus may

occlude mucosal lymphatic channels and thereby prevent lymphatic spread of early esophageal adenocarcinoma [255]. Once the tumor cells breach the muscularis mucosae to enter the submucosa, however, the frequency of lymph node metastases exceeds 20%, even for patients without bulky tumors [254,255]. The tissue specimens obtained by EMR allow histological examination to determine submucosal invasion. Therefore, EMR can be both diagnostic (revealing submucosal invasion that might not be apparent by less invasive techniques, which would require esophagectomy or other modalities for cure) and therapeutic (if there is no submucosal extension) [257].

Considering the depth and size of the mucosal specimens obtained by EMR, there have been surprisingly few reports of serious complications (bleeding, perforation, stricture) and virtually no procedure-related mortality [258–261]. The mean durations of follow-up in most reports are too short for meaningful conclusions to be made regarding the efficacy of EMR in decreasing the risk of cancer development. Furthermore, it appears that cap-assisted EMR leaves neoplastic cells behind in the large majority of cases. In one report, histological examination of EMR specimens obtained by the cap-assisted technique from 88 patients with high-grade dysplasia revealed dysplastic tissue at the margins of the specimens in 72 cases (82%) [262]. This suggests that EMR should be combined with an ablative procedure to eliminate the residual dysplastic epithelium.

The limited data that are available on long-term survival for patients with dysplasia and early cancers in Barrett esophagus who have been treated by EMR are impressive. For example, Ell et al. [260] performed EMR on 100 patients with early adenocarcinoma (i.e., tumor diameter < 20 mm, well-differentiated histology, no invasion of lymphatics or blood vessels, no metastases, no submucosal invasion) in Barrett esophagus. EMR resulted in no serious complications, and the calculated 5-year survival rate was an extraordinary 98%. However, recurrent or metachronous cancers were found in 11% of the patients during a mean follow-up period of 37 months. The recurrent tumors were treated successfully with more endoscopic therapy, but this high rate of recurrence shows that EMR often leaves behind cells with neoplastic potential. A retrospective study from the Mayo Clinic confirms this observation [261]. The investigators compared long-term survival in patients with high-grade dysplasia who were treated either with esophagectomy or with a combination of EMR and PDT. There was no statistically significant difference in overall long-term survival for patients treated with either of the therapies, even though 6.2% of the patients treated with PDT and EMR developed esophageal cancer during the follow-up period.

EMR for dysplasia and early cancers in Barrett esophagus appears to be safe in experienced hands, and limited data suggest that 5-year survival rates are excellent. However, recurrent neoplasms develop frequently, especially in patients with long-segment Barrett esophagus. Although the results so far are impressive, the clinician should appreciate that the data are still limited in duration and in scope. Most of the studies on EMR have come from only a handful of highly specialized centers, and it is not clear whether these results can be duplicated in a community hospital setting.

Intensive endoscopic surveillance

Some authorities recommend a program of expectant management with intensive endoscopic surveillance (i.e., endoscopic examinations every 3–6 months) for patients with high-grade dysplasia in Barrett esophagus, withholding invasive treatments until biopsy specimens reveal adenocarcinoma [174,183]. Although this practice has been endorsed as a management option by the American College of Gastroenterology [22], few published data directly support the safety and efficacy of intensive surveillance for high-grade dysplasia.

Schnell et al. [183] described 12 patients who developed adenocarcinoma during intensive endoscopic surveillance for high-grade dysplasia in Barrett esophagus. The cancers were deemed potentially curable at the time of detection in all 11 patients who were compliant with the surveillance program, but one patient who was lost to follow-up returned 10 years later with an unresectable tumor. In the series of Reid et al. [263] of 32 patients with high-grade dysplasia who developed adenocarcinoma during intensive endoscopic surveillance, only one patient (3%) had incurable disease (metastases) when the cancer was first detected on surveillance endoscopy. Weston et al. [190] performed intensive endoscopic surveillance in 15 patients with high-grade dysplasia for a mean duration of 36.8 months, during which four developed adenocarcinoma [190]. One of those four had metastatic disease. These studies show that intensive endoscopic surveillance generally is safe, but even patients who are compliant with intensive surveillance programs can develop incurable cancers.

Authorities have recommended that the treatment for patients with high-grade dysplasia in Barrett esophagus should be individualized based on considerations of age and comorbidities [264]. Is the patient a healthy 50 year old or a 90 year old with heart and kidney failure and an inordinate operative risk? Is the life expectancy 30 years or 30 days? What is the extent of the Barrett metaplasia? Is there short-segment Barrett with a single focus of dysplasia that can easily be removed endoscopically, or is there long-segment Barrett that involves the entire esophagus with multiple neoplastic areas that make endoscopic treatments untenable? And importantly, what is the patient's preference when the options are presented fairly?

Nonsteroidal antiinflammatory drugs

Epidemiological studies have shown that the use of aspirin and other NSAIDs, which inhibit COX, are associated with a

decreased risk for developing esophageal cancer; a metaanalysis of these studies suggests that the risk is decreased by approximately 40% [265]. The specialized intestinal metaplasia of Barrett esophagus exhibits increased expression of COX-2 [266], and inhibition of COX-2 has antiproliferative and proapoptotic effects in Barrett-associated esophageal adenocarcinoma cell lines [137]. Furthermore, COX-2 inhibitors have been found to prevent the development of esophageal adenocarcinoma in an animal model of Barrett esophagus [267]. Nevertheless, prospective clinical studies are needed before NSAIDs can be recommended routinely for chemoprevention for patients with Barrett esophagus. Even if efficacy in cancer prevention can be demonstrated, it is not at all clear that the cost and cardiovascular risks of NSAIDs will be justified for routine clinical use. Aspirin, an inexpensive, nonselective NSAID that can prevent cardiovascular as well as neoplastic complications, might be a very useful drug if its protective effects can be shown to outweigh its risk of gastrointestinal complications.

Management recommendations

Clinicians should appreciate that no management strategy for patients with Barrett esophagus has been verified by studies demonstrating that the strategy prolongs life. The bulk of the indirect evidence available suggests that acid suppression with PPIs may reduce the cancer risk in Barrett esophagus. We recommend that Barrett patients should be treated with a PPI using whatever dose is needed to control GERD symptoms and to maintain the healing of esophagitis. We do not routinely recommend esophageal pH monitoring to verify that esophageal acid exposure has been normalized by PPI therapy. We also feel that antireflux surgery should not be prescribed solely as a cancer preventive strategy. There may be other valid reasons to recommend this operation, but cancer prevention is not one of them. We also feel that it is appropriate to consider the prescription of low-dose aspirin, both for its cancer preventive and cardioprotective effects, especially for patients who are not at high risk for complications of NSAID treatment. Because patients will already be taking a PPI, the risks of aspirin causing serious gastrointestinal toxicity in average risk individuals should be minimal.

We endorse the management policy that has been recommended by the Practice Parameters Committee of the American College of Gastroenterology with some modifications as outlined in Table 35.3 [22]. We feel that esophagectomy may be the preferred management strategy for young patients with high-grade dysplasia. For patients with localized dysplasia, it may be reasonable to perform EMR, at least for the purposes of staging. If the EMR specimen shows no submucosal invasion and no dysplasia in the margins, the need for esophagectomy is highly controversial.

Table 35.3 Management of patients with Barrett esophagus recommended by the Practice Parameters Committee of the American College of Gastroenterology

- Patients found to have Barrett esophagus should have regular surveillance endoscopy to obtain esophageal biopsy specimens
  - o GERD should be treated aggressively before surveillance to minimize confusion caused by inflammation in the interpretation of dysplasia
- For patients who have had two consecutive endoscopies that show no dysplasia, surveillance endoscopy is recommended at an interval of every 3 years
- If dysplasia is noted, the finding should be verified by consultation with another expert pathologist:
  - o For patients with verified low-grade dysplasia after extensive biopsy sampling, yearly surveillance endoscopy is recommended
  - o For patients with verified high-grade dysplasia, the risks of esophagectomy must be weighed against those of intensive endoscopic surveillance, endoscopic ablative therapies, and endoscopic mucosal resection

Squamous cell carcinoma

Epidemiology and etiology

Esophageal *squamous cell carcinoma* (SCC) is the most common form of esophageal malignancy worldwide and is one of the leading causes of cancer mortality in men, especially African American men. The incidence of esophageal SCC varies according to geographical location, with a global range from 2.5 to 5.0 for men and from 1.5 to 2.5 for women per 100 000 population. High-incidence regions, where rates may exceed 100 per 100 000 population, include northern China, India, northern Iran, areas north and east of the Caspian Sea, and the Transkei area of South Africa [1–5]. Indeed, nearly 50% of all cancers are esophageal in southeastern South Africa [1]. In the United States, African Americans have a 4- to 5-fold increased risk compared with white people, especially African American men, in whom the risk is 15.1 per 100 000 compared with 2.9 per 100 000 in white men [6,7].

The geographical variation in esophageal SCC strongly hints at a contribution from environmental factors. An inherited predisposition to esophageal SCC is rare. The incidence of esophageal SCC is very low in those under 40 years of age, but it increases with each succeeding decade of life [7]. It is more common in men than in women, with a 2- to 3-fold higher risk, regardless of ethnicity and age [7]. However, there are some exceptions to this general finding. In northern Iran, the rate is 263 per 100 000 for women and 206 per 100 000 for men [8], and upper esophageal cancers in association with the Plummer–Vinson syndrome are found in women [9].

Tobacco and alcohol

Together, tobacco and alcohol constitute the largest risk factors for the development of esophageal SCC in North America and Western Europe [10–13]. Because tobacco and alcohol are commonly consumed together, their individual contribution may be difficult to ascertain. However, a comprehensive study of alcohol consumption in nonsmokers and tobacco use in nondrinkers found that each acts independently as a risk factor [14]. The relative risk was 2.0 for those who smoked fewer than 15 cigarettes per day, and 6.2 for those who smoked more than 25 cigarettes per day [14]. Not surprisingly, there is a documented substantial increase in risk in patients who consume both tobacco and alcohol, with the amount consumed and duration of use being pivotal factors [14–17,18]. Thus, smokers who have a large intake of beer and whiskey harbor a 10- to 25-fold increased risk of esophageal SCC compared with smokers who do not drink alcohol [18,19]. Additionally, the risk may be greater for pipe and cigar smokers than for cigarette smokers [18].

In a manner reminiscent of lung cancer, cessation of smoking does lead to a decreased risk of esophageal SCC after 10 years [18,20,21]. Although cigarette smoking is a key risk factor in North America and Western Europe, chewing tobacco, betel, or combinations of these with lime accounts for the high incidence of esophageal SCC in southern and Southeast Asia [22–24]. Tobacco tars and cigarette smoke contain various chemical carcinogens, such as aromatic amines, lactones, peroxy compounds, halo ethers, *N*-nitroso compounds, and polycyclic aromatic hydrocarbons [25–28], that individually or in combination likely lead to esophageal epithelial hyperproliferation and eventual malignant transformation.

The type of alcohol (beer, whiskey) and the fashion in which it is distilled, but not the duration of ingestion, are risk factors for esophageal cancer. Groups of people who do not consume alcohol have a substantially decreased risk. There are several factors underlying the contribution of alcohol to the pathogenesis of esophageal cancer, as well as other

cancers [29]. Alcoholic beverages may contain congeners or other ingredients, such as *N*-nitroso compounds, urethane, mycotoxins, tannins, pesticide residues, and asbestos products, that are directly or indirectly carcinogenic. Ethanol itself, because it is a solvent for fat-soluble compounds, may facilitate the absorption of other carcinogens. Carcinogens that are oxidants may increase the risk of DNA damage. Acetaldehyde, a metabolite of ethanol, can inhibit DNA methyltransferase activity [30]. Consequently, a state of methyl deficiency may ensue, which may potentiate the carcinogenic effect of a methyl-deficient diet.

Diet and nutrition

Vitamins and deficiencies, especially of vitamins A and C, folic acid, vitamins E and B-12, and riboflavin, are crucial risk factors [31–35]. Diets containing high amounts of green and yellow vegetables that are rich in β-carotene and citrus fruits that are high in vitamin C decrease the incidence of esophageal SCC [35]. Lower plasma levels of folic acid have been documented in patients with esophageal SCC [33]. Riboflavin deficiency manifested by cheilosis and glossitis is common in the Linxian province of China, where esophageal cancer is endemic [36]. It is likely that vitamins A, C, and E exert antioxidant effects; vitamins C and E are known to influence the formation of nitrosamines.

The levels of certain trace elements, such as selenium, molybdenum, and zinc, show an inverse association with mortality from esophageal cancer in high-incidence areas of the world [37–39]. Furthermore, in animal models, a significant increase in esophageal tumors is induced by *N*-nitrosomethylbenzylamine (NMBA) in rats with zinc-deficient diets. Mechanistically, zinc deficiency enhances the microsomal activation of NMBA to a methylating agent that yields *O*-6-methylguanine adducts in esophageal DNA [40]. As a component of superoxide dismutase, zinc also protects against oxygen-derived radical damage and free-radical formation [33]. Similarly, selenium has protective effects, in part mediated through the inhibition of lipid peroxidation of cell membranes through the actions of selenium-dependent glutathione peroxidase [32]. The Linxian and adjoining provinces in China have foodstuffs low in molybdenum and documented reduced levels of this trace element in patients' serum and urine. It is conceivable that molybdenum deficiency leads to the accumulation of nitrates that are precursors of nitrosamines because this trace element is a key constituent of nitrate reductase [24].

Achalasia

Patients with long-standing achalasia have a prevalence of esophageal SCC of 5% [41–46]. The interval from dysphagia, weight loss, and chest pain ascribable to achalasia to the development of cancer is approximately 17–20 years [46,47]. In a study of 195 consecutive patients with achalasia, the incidence of esophageal SCC was 3.4 per 1000 patients per year, representing a 33-fold increase when compared with age- and sex-matched controls [48]. A follow-up study of 146 of 147 patients with achalasia treated with myotomy revealed that 10 patients progressed to esophageal cancer, with a mean interval of 16.7 years; the predicted frequency was less than 1 [49]. Thus, the condition of achalasia eventually may lead to cancer; however, the exact risk and mechanism remain to be determined. Although endoscopic surveillance of patients with achalasia has been advocated, the frequency of examinations remains the subject of debate.

Head and neck squamous cell carcinoma

Reflecting the use of both alcohol and tobacco, patients with head and neck SCC are at an increased risk of developing esophageal cancer [50,51]. Either coexisting or sequential esophageal cancers may develop annually at a rate of 3%–7% [52–55]. As a result, endoscopic surveillance of the esophagus has been advocated in this setting. Toluidine blue staining has been demonstrated to enhance the detection of indolent esophageal cancers in patients with head and neck cancers [56]. Not surprisingly, survival of patients with head and neck cancers is adversely affected by the coexistence of esophageal cancer [57]. A reduction in the incidence of second primary tumors from 24% to 4% in patients with head and neck cancers has been observed with the use of isotretinoin, a chemopreventive agent that induces epithelial differentiation [58].

Tylosis

Although some studies from China have suggested familial aggregation of esophageal cancers [59], it is difficult to discriminate between a common environmental exposure and an actual genetic basis for these observations. However, a genetic predisposition to esophageal cancer is clear in *tylosis palmaris*, an autosomal dominant disorder manifested by hyperkeratosis of the palms and soles [60–66]. Approximately 50% of patients with tylosis palmaris will develop esophageal cancer by the age of 45 years, and perhaps 95% by the age of 65 years [61,62]. There is linkage between esophageal SCC and oropharyngeal leukoplakia. In endoscopic surveillance studies over a 5-year period, 4 of 29 patients were found to have dysplasia, and one patient had carcinoma in situ [67]. The gene responsible for tylosis has yet to be identified although chromosomal 17 linkage has been suggested; once identified, it may also provide insights into sporadic esophageal cancer.

Other factors

Lye ingestion, which results in stricture formation, has been postulated as a risk factor for esophageal cancer, mostly appearing at the level of the bronchial bifurcation [68–70]. Lye strictures constitute only a small proportion of esophageal cancer cases, and the progression to cancer after initial exposure requires 4–5 decades.

Other factors implicated in the pathogenesis of esophageal cancer include ionizing radiation [71,72], celiac sprue [72–75], human papillomavirus (HPV) [76–78], Plummer–Vinson syndrome [79], esophageal diverticula [80], and maté drinking [81,82]. Experimentally, induction of radiation injury is associated with cancer formation [83]. In patients who have undergone high-dose radiation treatments, esophageal cancer is the most frequently observed malignant disease [84–90]. DNA tumor viruses that have a tropism for squamous epithelial cells, such as HPV and Epstein–Barr virus, have been associated with esophageal SCC. Polymerase chain reaction techniques have demonstrated an association of the oncogenic variants of HPV, namely HPV-16 and HPV-18, as well as a novel HPV genotype with esophageal SCC [77,78]. The same has been observed with Epstein–Barr virus [91]. Both viruses infect squamous epithelial cells, replicate, and produce oncogenic proteins that contribute to hyperproliferation and malignant transformation.

Hot maté drinking is common in Uruguay and southern Brazil [81,82], and hot liquid ingestion is prevalent in China [92]. These findings suggest that thermal injury of the mucosa may increase the risk of esophageal cancer.

Biology and genetics

Based on the colon cancer paradigm, it is thought that the development of cancer results from the accumulation of alterations in oncogenes, tumor suppressor genes, and DNA mismatch repair genes. This is probably true for esophageal cancer as well. However, a genetic basis for the pathogenesis of esophageal cancer by no means precludes the importance of environmental factors; rather, it is likely that there is cooperativity among these factors. For example, some of the environmental factors injure the esophageal epithelium, which in turn may act to signal changes in key genes through point mutations or augmented gene expression.

Perhaps the most critical oncogene in esophageal SCC pathogenesis is cyclin D_1. Mammalian cyclins represent a large family of cell cycle regulatory proteins that associate, in turn, with their catalytic subunit partners, designated cyclin-dependent kinases or CDK. (The cell cycle is reviewed in the literature [93].) The activity of cyclin D_1 is restricted to the G1 phase, and it preferentially associates with cyclin-dependent kinase 4 or 6 (CDK4 or CDK6). The complex of cyclin D_1 and CDK4 or CDK6 then phosphorylates the retinoblastoma tumor suppressor gene product (pRb). This relieves the negative regulation of pRb in the G1 phase through the release of key transcriptional factors, such as E_2F. It has been shown that cyclin D_1 is overexpressed in more than 50% of esophageal SCCs and is associated with a poor prognosis [94–96]. A subset of esophageal cancers also show c-*myc* and epidermal growth factor receptor overexpression as a result of gene amplification [97]. Recent research suggests that retinoid receptor-induced gene-1 (RRIG1) plays a role in suppressing tumorigenesis [98].

Knowledge of the association of cyclin D_1 and esophageal cancer has been used to develop a transgenic mouse model in which one of the Epstein–Barr virus promoters has been used to target cyclin D_1 specifically to the oral–esophageal squamous epithelia, resulting in dysplasia and cell cycle abnormalities [99,100].

The key tumor suppressor gene *p53* has many functions, including cell cycle regulation, induction of apoptosis in response to environmental insults, transcriptional regulation of genes, and DNA replication. *p53* is mutated in up to 70% of esophageal cancers [101–104]. One of the functional consequences of *p53* mutation is the transcriptional downregulation of *p21,* a general CDK inhibitor. In addition, *p16,* also referred to as *INK4a* (designated $p16^{INK4a}$), is an inhibitor of CDK4. Located on chromosome 9p22–23, *p16* can be deleted, mutated, or hypermethylated, resulting in loss of its inhibitory function in esophageal cancer [105,106]. A paradigm that emerges in esophageal SCC is that either cyclin D_1 is overexpressed or *p16* is altered to accelerate the cell through the G1 phase. Loss of heterozygosity in other tumor suppressor gene loci, such as *pRb* (chromosome 11) and *APC* (adenomatous polyposis coli) (chromosome 5q), does not appear to occur in esophageal cancer [107], suggesting that other genes in proximity to *pRb* and *APC* are the key targets. Loss of function of E-cadherin and transforming growth factor-β receptor 2 have important implications for epithelial carcinogenesis in esophageal SCC [108].

Clinical manifestations

Early esophageal SCC may be asymptomatic or may be associated with only mild specific symptoms [109–113]. As the cancer grows, dysphagia occurs in nearly 90% and odynophagia in 50% of patients [114–116]. This is usually a reflection of partial or total lumenal obstruction. Anorexia and weight loss from malnourishment may be observed in about 75% of patients [116,117]. Retrosternal pain or radiation of pain to the back suggests mediastinal involvement by the cancer. Nausea, vomiting, and hematemesis may occur. Cough may reflect aspiration pneumonia or, rarely, tracheoesophageal fistula. Recurrent laryngeal nerve involvement may result in hoarseness. Skeletal metastases may cause bone pain. Physical examination may reveal cachexia, lymphadenopathy, hepatomegaly (if distant metastatic disease is present), and the presence of fecal occult blood.

Evaluation of dysphagia is imperative and is discussed in Chapter 31. The differential diagnosis may include peptic acid esophagitis with stricture, caustic ingestion resulting in stricture, malignant disease (either squamous or adenocarcinoma), and motility disorders such as achalasia or scleroderma.

Natural history and complications

Esophageal cancer in Western countries usually presents in an advanced stage and, consequently, nearly 75% of untreated patients succumb to the disease within 1 year [118].

Biologically, esophageal SCC is not a rapidly growing tumor, and there is a prolonged period of time between dysplasia and cancer [119,120]. The early stages of esophageal cancer have been shown to persist for more than two decades in China and Iran [121,122]. Additionally, balloon cytological examinations, used to monitor the natural history of esophageal squamous dysplasia in China, indicate that dysplasia may progress to cancer (26.6% of cases), but it may regress to mild dysplasia or a normal state (40.5% of cases). Furthermore, of the mild dysplastic cases, nearly 15% progressed to severe dysplasia and about 45% regressed [123]. Other studies in China indicate that early superficial cancers remain in this state in 58% of cases for a follow-up period of 19–78 months [120]. Patients with untreated early esophageal cancer in China have a median survival time of 75 months.

There are probably biological differences superimposed on environmental factors in the high-incidence areas compared with Western countries that may account for the apparently lengthy period from dysplasia to cancer in China and the good prognosis of resected early esophageal cancer with a 5-year survival rate approaching 90% [112]. Reminiscent of the high prevalence of early gastric cancer in Japan relative to Western countries, it is not entirely clear whether early esophageal cancer is prevalent in North America and Western Europe. Several nonbiological explanations can be evoked: the use and accuracy of balloon cytology in China, the definition of early esophageal cancer, and proper staging with aggressive therapy [124,125].

The average survival of untreated patients with advanced, symptomatic cancer is approximately 9.5 months [118,122]. Patients may develop aspiration pneumonia complications of esophageal cancer from extension into the tracheobronchial tree or other mediastinal structures [126]. Fistulae have a 4.5% prevalence and most often communicate with the trachea, the main stem bronchi, and the lung parenchyma. Fistulae carry a poor prognosis [127,128]. They may cause presenting symptoms, such as cough, chest pain, dyspnea, hoarseness, and hemoptysis, or may occur within 2 months of the initial diagnosis in untreated patients [127,129]. As a result of fistula formation, patients may develop pneumonia and sepsis. Direct extension of the esophageal cancer, as opposed to fistula formation, may involve the lung and tracheobronchial tree, aorta, pericardium, and upper abdomen. Hoarseness suggests recurrent laryngeal nerve involvement. Apart from direct extension or fistula formation, esophageal cancer may metastasize to lymph nodes, lung, and liver as frequent sites [130–134].

Diagnostic evaluation

Implicit in a diagnostic evaluation is a complete history and physical examination. A laboratory profile may reveal anemia, hypoalbuminemia, elevated prothrombin time reflecting vitamin K deficiency, and possibly elevated liver function tests if metastatic disease is present. Serological markers of cancer, such as carbohydrate antigen 72.4 in gastric cancer, carbohydrate antigen 19-9 in pancreatic cancer, carcinoembryonic antigen in colorectal cancer, and alpha-fetoprotein in hepatocellular carcinoma, have not proven to be of high sensitivity and specificity in esophageal SCC. Evaluation is driven by the establishment of tissue diagnosis through biopsy and cytology, followed by staging for prognosis and therapeutic planning. Initial diagnostic tests usually entail barium swallow supplemented with a tablet and flexible fiberoptic endoscopy. Staging requires computed tomography (CT), endoscopic ultrasound (EUS), and radionuclide bone scan. Bronchoscopy should be considered if tracheal invasion is suspected.

Endoscopy and barium esophagography

The diagnosis of esophageal cancer requires endoscopy with biopsy and cytology. Multiple biopsies increase the diagnostic yield to up to 96%; cytology identifies the remaining cases. For example, in a retrospective study of 155 patients with endoscopic biopsy and cytology of upper gastrointestinal lesions, 2 of 28 patients with malignant disease were diagnosed through cytology alone [135].

Because endoscopy may prove too costly in some regions of the world, barium esophagrams are advocated by some experts, especially in patients with dysphagia. Intrinsic advantages include reduction in cost, noninvasiveness, and reduced complication rate. Additionally, a barium study allows information to be obtained about motility as well as challenge with a solid bolus. Ultimately, endoscopy is a better diagnostic test for patients in whom one suspects esophageal cancer because of the ability to obtain tissue in one test and the greater positive predictive value of upper endoscopy: 100% for endoscopy and 33% for barium swallow [136].

The endoscopic appearance of early esophageal cancer includes superficial erosive ulcer, a raised plaque, a "congestive" lesion marked by red spots on the mucosa, and a small polypoid lesion. Vital staining dyes such as toluidine blue, aniline blue, or Lugol iodine may be used to enhance detection and simultaneously to discriminate early cancers from normal adjacent mucosa. In a study of 178 patients who underwent endoscopy and vital staining, nine esophageal cancers were found, of which seven were early cancers [137]. In contrast, endoscopy without vital staining only detected four of nine cancers. Limiting the usefulness of vital staining is its inability or failure to distinguish inflammation from dysplasia [138].

Advanced esophageal SCCs are typically exophytic, ulcerated, and even circumferential. Submucosal invasion may produce friable nodules or strictures. Whenever possible, the endoscope should be advanced through the stricture to determine the proximal–distal extent of tumor and any distal abnormalities. The majority of SCCs are found in the proximal esophagus to the midesophagus.

Radiologically, early esophageal cancer may have a granular mucosal appearance with single or multiple small ulcerations with tiny filling defects. Polypoid lesions are characterized by small intralumenal filling defects affecting one wall of the esophagus with ulcerations [139]. An infiltrative or an ulcerative appearance can be one of the defining features of advanced esophageal cancer, but the most common presentation of advanced esophageal carcinoma is that of a polypoid mass within the lumen produced by an exophytic cancer [140]. The mass may have the characteristic appearance of an "apple-core" lesion with circumferential involvement by the cancer (Fig. 36.1). Infiltrating carcinomas may result in diminished esophageal motility with or without stricture. Such a stricture may be symmetric or asymmetric and, in fact, can sometimes be difficult to distinguish from a benign stricture. The primary ulcerative type of esophageal cancer is rare, although ulceration can be a component of either polypoid or infiltrating cancer. Ulcerative cancers are characterized by a well-demarcated meniscoid ulcer with a thin rim of lucency representing neoplastic tissue [141].

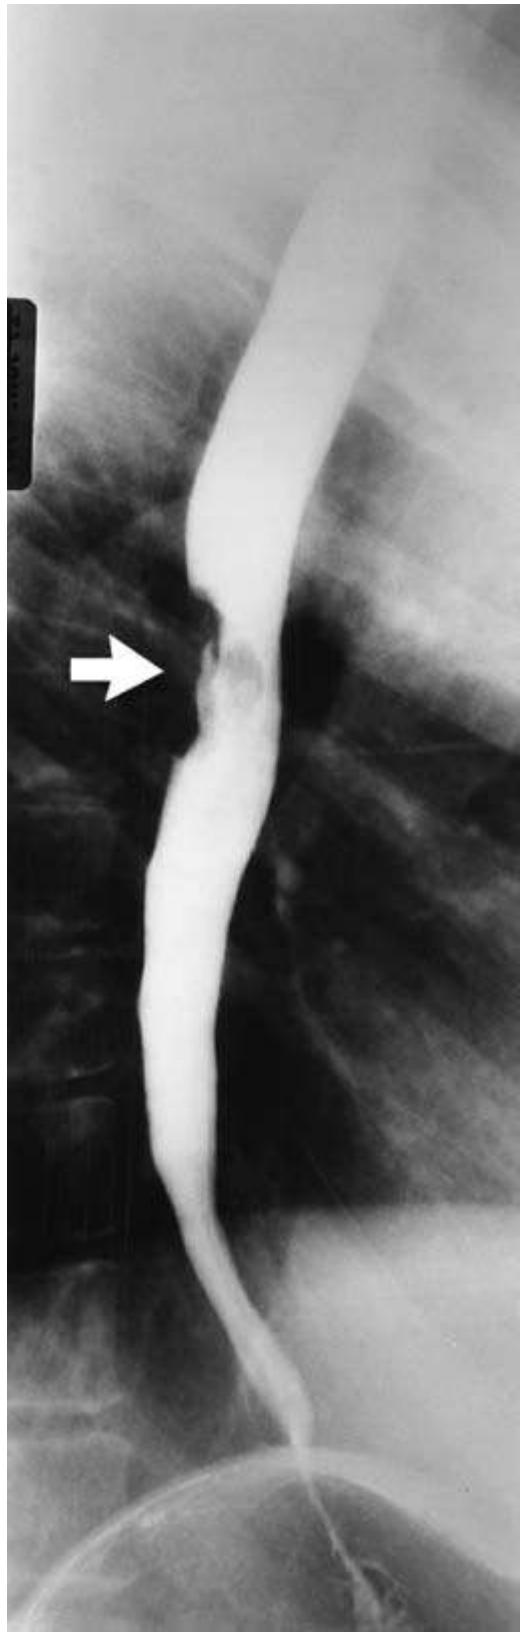

Figure 36.1 Advanced squamous cell carcinoma represented by an ulcerated mass (arrow) in the midesophagus. Courtesy of Deborah Hall, MD.

Screening

Endoscopic screening of the general population may be merited in high-incidence areas, such as in northern China. In China, 5-year survival was nearly 90% after operative resection for cancer cases detected through screening [142,143]. Surprisingly, nearly 80% of patients did not undergo therapy because of noncompliance, unavailability of medical resources, and coexisting medical illnesses [144]. Although balloon cytology has achieved success in China, its applications in US veterans did not prove very successful [145]. The reasons were the low prevalence of esophageal cancer and the low specificity of dysplasia because of a confounding factor such as inflammation resulting from reflux esophagitis. In this US veterans study, follow-up measures included biannual endoscopy with vital staining and biopsy, balloon cytology, laryngoscopy, and chest radiography [146]. However, false-positive results were obtained with cytology in more than 95% of screened patients. Thus, mass screening in the United States is probably not feasible for esophageal SCC, given the lack of cost-effectiveness. However, institution of screening and surveillance endoscopic programs may be applied to certain clinical situations, such as in patients with tylosis, achalasia, and head and neck cancer.

Ingestible esophageal capsule endoscopy (PillCam ESO)

An office-based noninvasive diagnostic approach (PillCam ESO) has been developed as an alternative to conventional endoscopy or other screening techniques to evaluate patients with esophageal abnormalities, especially those with Barrett esophagus and gastroesophageal reflux disease (GERD). A small plastic capsule with a tiny video camera glides down

the esophageal tract taking video images and transmitting these to a recording device. The disposable capsule is passed, usually within 24 h. A pilot study showed that the positive predictive value for any esophageal pathology was 92% and the negative predictive value was 100% [147]. However, large-scale studies are necessary to fully evaluate this novel diagnostic technology before widespread implementation.

Staging and staging systems

After establishment of the diagnosis of cancer, staging is necessary to optimize treatment options and management. This should ideally commence with CT scanning of the chest and abdomen and should be supplemented with EUS for esophageal wall and local lymph node involvement.

In a retrospective study [148], the critical determinants of survival in nearly 4000 surgical specimens from Japanese patients were depth of invasion, the presence or absence of lymph node metastases, and the presence or absence of distant metastases. Five-year survival was 46% with submucosal invasion, 29.5% with invasion of the muscularis propria, 21.7% with invasion into the muscularis propria, and 7% with involvement of adjacent tissues and organs [148]. Worsening survival rates (3.0%) are also correlated with involvement of distant lymph nodes and with metastasis to distant organs. Although several staging systems have been recommended for esophageal cancer, an overriding consideration is that surgical pathological staging is more accurate for predicting survival than pretreatment clinical staging.

Thus, staging involves clinical evaluation before therapy and then pathological staging of the surgically resected esophagus and dissected lymph nodes [149]. A staging system that is widely used because of its accuracy is depicted in Table 36.1.

Table 36.1 TNM staging system for cancer of the esophagus (American Joint Committee on Cancer criteria)

Primary tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria or submucosa		
T2	Tumor invades mucularis propria		
T3	Tumor invades adventitia		
T4	Tumor invades adjacent structures		
Regional lymph nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
Distant metastasis (M)			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
Stage grouping			
Stage 00	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
Stage III	T3	N1	M0
	T4	N1	M0
Stage IV	Any T	Any N	M1

Imaging studies: computed tomography and magnetic resonance imaging

CT scanning has proven useful in the preoperative staging of esophageal cancer [150–156], especially in defining lymph node, pulmonary, and hepatic involvement. The accuracy of CT staging has a broad range, from 39% to 100% [151,152,155,157]. Even documentation of aortic invasion, which precludes surgical resection, has a sensitivity of 80%–100% and a specificity of 50%–100% on CT scanning [151,152,155]. Tracheobronchial involvement is also discernible with CT scanning [149–151,153].

Comparisons between CT and magnetic resonance imaging (MRI) have shown little difference between the two modalities [158–161]. For example, sensitivity, specificity, and accuracy rates between CT scanning (100%, 80%, and 84%, respectively) and MRI (100%, 84%, and 87%, respectively) are comparable [158]. Early spread beyond the esophageal wall, regional lymph node involvement, and aortic invasion have led to problems with both false positivity and false negativity with both imaging modalities [151,152,154,155,157,159–161]. Thus, CT scanning remains the primary staging modality.

Endoscopic ultrasound

EUS has emerged as a key component of staging. It is particularly useful in gauging the depth of esophageal invasion and local lymph node involvement (Fig. 36.2). EUS is superior to CT scanning in the determination of the primary tumor (T) and regional lymph node (N) status of the staging classification scheme and has been compared with surgical–pathological and CT staging in several studies [162–165]. EUS accuracy in staging the depth of tumor invasion varies from 87% to 92%, making it more accurate than CT. The overall accuracy of EUS in detecting N status ranges from 80% to 88%. In these studies, EUS sensitivity varied from 92% to 95% and specificity varied from 50% to 54%, whereas CT accuracy ranged from 51% to 74%, with a sensitivity of 34% and specificity of

88%. EUS-fine needle aspiration (EUS-FNA) has improved the accuracy of EUS for N staging with confirmatory cytological material [166]. EUS-FNA has more than 90% accuracy in confirming celiac axis lymph node metastases, but only a limited role for staging distant metastases [167,168]. Therefore, it is generally recommended that CT or MRI be performed before EUS for detection of distant metastases. CT and EUS are usually considered to be complementary modalities for the staging of esophageal cancer.

EUS is useful in the assessment of resectability. It was able to predict resectability in 147 of 167 patients (89%), more accurately for adenocarcinoma (82%) than for SCC (64%) [169]. Lumenal stenosis, which prevents passage of the scope, portends a higher stage, either III or IV (older staging system), in nearly 90% of cases; conversely, 58% of cancers without stenosis were not stage III or IV [170]. Overstaging (T1 to T3) or understaging (T1 or T2) may be a problem with EUS; 73% of T2 lesions are overstaged, and 71% of T3 lesions are understaged [171]. Although EUS is superior to CT scanning for staging after preoperative chemotherapy and radiation, it is inaccurate, with a sensitivity of only 27%–52% for T2/T3 restaging and 48%–52% for N0/N1 disease. This is because of the inability to distinguish inflammation and fibrosis from residual cancer [172]. However, it has been found that more than a 50% decrease in tumor cross-sectional area or diameter correlates with treatment response [173]. Cost-effectiveness studies of EUS staging are needed.

Positron emission tomography

Positron emission tomography (PET) is a whole-body, metabolic-based imaging modality using fluorine 18-labeled deoxyglucose (FDG). There is an increased accumulation of the radiotracer in malignant tissues, which is believed to be the result of an increased expression of glucose transport enzymes in the tumor cell membranes together with an increased activity of the enzymes in the first steps of the glycolytic pathway. The degree of FDG accumulation in a lesion can be assessed semiquantitatively and expressed as a standard uptake value [174]. The results of a prospective study comparing the staging accuracy of FDG-PET with the standard combined use of CT and EUS showed that FDP-PET significantly improves the detection of stage IV disease [175]. Thus, FDG-PET has been documented as a highly accurate modality for the primary preoperative staging of patients with esophageal cancer. Other studies [176,177] also show that FDP-PET is a promising noninvasive tool for the assessment of preoperative (neoadjuvant) therapy. There is a good correlation between the clinical response evidenced via serial PET scans and the pathological response and survival. Recent studies suggest that PET with the nucleoside analogue

3′-deoxy-3′-(18)F-fluorothymidine (FLT) may be more accurate than FDG-PET in visualizing early changes in tumor proliferation. Using an experimental model of esophageal cancer (human xenographs), FLT-PET was more accurate than FDG-PET in detecting early changes in proliferation following docetaxel and radiation therapy, with a much stronger correlation with histological findings. Clinical studies are needed to determine whether FLT-PET can distinguish between degrees of response to neoadjuvant chemoradiation in patients with esophageal cancer [178].

Laparoscopy

Abdominal metastases are more common from distal esophageal tumors, and these subdiaphragmatic metastases may be confirmed by laparoscopy [179]. Nonetheless, laparoscopy is not common practice for the staging of esophageal cancer.

Therapy for esophageal cancer

The presentation of esophageal cancer at advanced stages mitigates against curative surgical resection on a consistent basis. In fact, although nearly 60% of patients may undergo surgical exploration, only two-thirds of such patients will undergo resection. Thus, more than 40% of patients will require palliative therapy. However, with better understanding of the disease and the development of new anticancer agents, the overall survival of patients with esophageal cancer has been improving. Based on Surveillance, Epidemiology, and End Results (SEER) information, the 5-year overall survival rate in the United States increased from 4.7% in 1976 to 14.9% in 2002 [180]. The following discussion is divided into categories of potential curative modalities as well as palliative measures.

Surgery

Surgery remains the mainstay of treatment of esophageal cancer with curative intent for respectable, local, and locoregional disease. Advances in surgical therapy, staging techniques, patient selection, and supportive care in recent years have resulted in a marked improvement in surgery-related mortality and morbidity. Even if cure is not accomplished, palliative surgical bypass procedures may also have some impact on patients with advanced unresectable disease, relieving symptoms and improving the quality of life.

There are various surgical approaches for esophageal cancer, including transthoracic, transhiatal, and radical en bloc resections. Despite the different advantages and disadvantages of each, and the controversies surrounding them, there is no evidence to suggest improved survival with any particular one [181]. Factors that may influence the decision of which particular technique to select include tumor location, depth of tumor invasion, status of lymph node involvement, overall performance status and body habitus of the patient, previous treatment (e.g., radiation or chemoradiation therapy), and the preferences and biases of the surgeon and institution.

In the 1940s, midesophageal tumors were approached through the left side of the chest. The benefits of a right-sided approach (Ivor Lewis) have been advocated since then and include enhanced accessibility to the upper two-thirds of the esophagus, location of the aorta as a barrier to the left pleural space, and visualization of the entire esophagus after division of the azygous vein. This approach has been applied as well for distal esophageal cancers, thus allowing for a longer segment of esophageal resection with a higher anastomosis. A cervical anastomosis has some inherent advantages, namely decreased morbidity and mortality, reduced reflux, and a better opportunity for postoperative radiation if pursued. The left thoracoabdominal approach may be used for distal esophageal and gastroesophageal cancers.

The early complications of transthoracic esophagectomy include anastomotic leak (0%–13%), pulmonary problems such as pneumonia, retained secretions, and pulmonary emboli (6%–50%), recurrent laryngeal nerve injury (1%–13%), and cardiac problems such as myocardial infarction, arrhythmia, and congestive heart failure (2%–27%). The mortality ranges from 1% to 13%, with a 5-year survival rate of 1%–35% [182–185].

Because of the high rates of morbidity and mortality linked to the thoracotomy associated with transthoracic esophagectomy, the transhiatal approach has also been advocated. The mortality rate ranges between 2% and 13%, and the 5-year survival rate ranges from 12% to 27% [186–192]. Although there are still some arguments about transhiatal esophagectomy (THE) without an en bloc mediastinal lymphadenectomy, THE has been used increasingly in the resection of benign and malignant disease with potential advantages over transthoracic esophagectomy, including significantly decreased respiratory complications and mediastinitis because of the avoidance of thoracotomy and intrathoracic anastomosis [193]. The en bloc resection of cancers of the distal esophagus and the cardia involves removal of 10 cm of the esophagus on either side of the tumor along with contiguous tissues, vascular supply, and lymph nodes. Various series report a 1.4%–11% operative mortality rate, with a 5-year survival rate of 18%–35% [194,195]. Histology cell type (squamous cell carcinoma vs adenocarcinoma) is considered important for the overall outcome after esophagectomy. Patients with squamous cell carcinoma have a poorer perioperative outcome than those with adenocarcinoma; however, in the longer term, squamous cell carcinoma appears to confer a significant survival advantage [196]. Other evidence has demonstrated that the most important determinants of survival appear to be the biological behavior of the tumor and

the stage at the time of resection rather than the operative approach, and esophageal carcinoma will likely require systemic therapy with pre- or postoperative chemotherapy and chemoradiation therapy for a cure.

An important consideration during surgery is the choice of esophageal replacement [197–202]. The stomach, by virtue of its rich blood supply, length, and muscular wall, is preferred, whereas the left colon, because of its similarity to the esophagus in caliber, can be used to replace the esophagus when the stomach cannot be used. Jejunal interposition may be used for reconstitution of the hypopharynx and the cervical esophagus. Overall, complications of esophageal replacement include anastomotic leaks (2%–5%), anastomotic stricture (9%–29%), gastric dysfunction, and chylothorax.

Analysis has demonstrated that, with modern surgical management, leak-associated mortality has markedly reduced and has no impact on long-term survival. Clinical decisions regarding the use of intrathoracic anastomoses should not be affected by concerns of increased mortality from leak [203].

Minimally invasive laparoscopic esophagectomy has been investigated in highly selected esophageal cancer patients with early disease. Limited information suggests that it is a feasible approach and can be safely performed by surgeons with extensive experience in that field. Advantages include less intraoperative blood loss, a smaller incision, and a potentially faster postoperative recovery [204]. Large prospective trials with longer follow up will be required to confirm any advantages of this approach over conventional approaches.

Unresectable esophageal cancer may warrant a bypass procedure using a portion of the stomach, jejunum, or colon as a conduit. However, bypass surgery is fraught with high morbidity and mortality rates, and it should be reserved for patients with a tracheoesophageal fistula or those in whom conservative medical measures have failed. Effective palliative resection of the cervical esophagus usually requires total laryngectomy and esophagectomy (transhiatal approach).

Radiation therapy

Radiation (external beam) alone

Radiation as a single modality is seldom used as either definitive or adjuvant therapy. It is limited to patients who are not candidates for surgical resection because of unresectable disease or patients who are medically unable to tolerate a surgical procedure and multimodality treatment [205–207]. Limited experience with patients treated with radiation therapy alone indicates a 1-year survival rate of 18% and a 5-year survival rate of 6%, reminiscent of survival data after surgical resection [208–210]. Favorable 5-year survival rates may be observed in women and in patients with cancers of less than 5 cm in length (22.4% and 17.7%, respectively) [205–210]. Radiation alone may lead to amelioration of dysphagia, with 50% of patients receiving relief for 2 months or more and 15% of patients for more than 1 year. In the acute setting, radiation-induced esophagitis may lead to dysphagia, and fibrotic strictures may form. Unusual complications of radiation therapy include pulmonary fibrosis, myelitis, and cutaneous burns.

Brachytherapy

Intralumenal radiation (brachytherapy) can ameliorate symptoms resulting from obstructing cancers. Higher doses of radiation can be delivered with this technique without inducing injury to pulmonary, cardiac, and mediastinal structures [211]. A cobalt 60 source is commonly used, either alone or after external beam radiation therapy, and treatment is typically administered over 2 weeks. Most patients experience a prompt subjective response to brachytherapy. Complications of brachytherapy include ulcers, strictures, and tracheoesophageal fistulae in up to 25% of patients [212,213]. Brachytherapy is commonly used for palliation of esophageal obstruction due to inoperable cancer. Studies show that brachytherapy delivers better long-term relief of dysphagia than metal stent placement and is also associated with fewer complications than stent placement [214].

Preoperative (neoadjuvant) and postoperative (adjuvant) radiation therapy

The potential advantages of neoadjuvant radiation therapy include increased resectability, decreased tumor seeding at the time of surgery, and increased radiosensitivity as a result of more oxygenated cells. Neoadjuvant radiation therapy has not been shown to improve the overall survival of patients with potentially resectable disease [215–219]. A metaanalysis [219] of 1147 patients from five randomized neoadjuvant radiation therapy trials (median follow up of 9 years) showed no statistically significant benefit in either the 2-year survival rate (34% vs 30%) or the 5-year survival rate (18% vs 15%). There was benefit demonstrated from radiation treatment, with an overall reduction in the risk of death of 11%.

Adjuvant radiation therapy provides the advantages of accurate pathological staging and the direction of treatment to areas with a high risk of disease recurrence. Postoperative radiation therapy is often given when the surgical margins are positive or the resection is incomplete. A slightly higher total dose range (4500–5500 cGy) than that administered in the neoadjuvant randomized trials has not yielded a survival advantage [220].

Chemotherapy

Because approximately 30% of patients present initially with metastatic disease and at least 50% of others present with stage II and III disease, chemotherapy holds promise for the local control of disease, increased survival, and the prevention of distant metastasis. Cisplatin and 5-fluorouracil (5FU) have been used as a standard regimen, and they have produced response rates of 35%–40% in advanced disease with

a median survival of 33 weeks and a 1-year survival of 38%. Other active agents are mitomycin and bleomycin, as well as many newer agents such as the taxanes (paclitaxel and docetaxel), irinotecan, gemcitabine, and oxaliplatin [221,222].

Neoadjuvant (preoperative) chemotherapy

The rationale of neoadjuvant chemotherapy is to eradicate occult metastases before surgery. No advantages of neoadjuvant therapy were demonstrated in the 1980s or 1990s [223–227]. The initial US intergroup trial 113 [227] did not show survival benefits in patients undergoing preoperative chemotherapy. However, data from a larger (802 patients), randomized, and well-controlled study of neoadjuvant chemotherapy in esophageal cancer conducted by the UK Medical Research Council (MRC) upper gastrointestinal tract cancer group [228] demonstrated that preoperative chemotherapy with 5FU and cisplatin can improve relapse rates, overall survival, and cure rate. Patients with esophageal cancer, 67% of whom had adenocarcinoma and 33% of whom had squamous cell carcinoma, were randomized to neoadjuvant chemotherapy before surgery or to surgery alone. Resectability was significantly higher in the treatment arm (78% vs 70%; $P < 0.001$), as was overall survival ($P = 0.003$). Two-year survival rates were 43% in the neoadjuvant chemotherapy arm vs 34% in the surgery-alone arm. Overall survival was superior in patients who received preoperative chemotherapy (hazard ratio [HR] 0.79; $P = 0.0004$). There was no increase in postoperative complications in patients receiving preoperative chemotherapy (40%–41%). Preoperative chemotherapy has become a standard in the UK and in much of Europe.

Adjuvant (postoperative) chemotherapy

A trial to evaluate the efficacy of postoperative chemotherapy in resectable lesions showed an advantage in disease-free survival in the treatment arm ($P = 0.05$), but there was no overall survival benefit [229]. Several clinical trials are ongoing to evaluate this approach further, using newer chemotherapy agents and regimens.

The MRC Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial was designed to determine whether perioperative chemotherapy could improve outcomes in patients with resectable gastric and lower esophageal adenocarcinomas. In total, 503 patients with operable disease were randomized to receive either three cycles of epirubicin, cisplatin, and 5FU (ECF) before and after surgery or surgery alone [230]. The resected tumors were significantly smaller and less advanced in patients who received perioperative chemotherapy. The perioperative chemotherapy patients also had higher overall survival, with a 5-year survival rate of 36.3% vs 23.0% ($P = 0.009$), and a statistically significant improved progression-free survival ($P < 0.001$). Postoperative complications and mortality were similar between the two groups.

Primary chemoradiation therapy

Cisplatin and 5FU combined with radiation therapy can substantially improve the 5-year survival in patients with esophageal cancer compared with radiation alone. Cisplatin and 5FU are radiosensitizers and improve the response to radiation therapy not only in the cancer cells but also unfortunately in normal tissues.

Definitive primary chemoradiation therapy for locoregional esophageal carcinoma is considered an alternative to surgical resection, although there are no large prospective randomized trials comparing it directly with surgery. The largest single-institution trial of primary chemoradiation was conducted by Coia [231] on 57 patients with stage T1 and T2 esophageal cancer. These patients were treated with 6000 cGy radiation and two cycles of 5FU delivered as a continuous 4-day infusion during the first and fifth week of radiation therapy, and a single bolus of mitomycin C on day 2. The median survival was 18 months, and 3-year and 5-year survival rates were 29% and 18% respectively.

A phase III multiple-institution randomized trial (RTOG 85-01) compared combination therapy with radiation therapy alone [232]. Patients randomized to combination therapy received a total dose of 5000 cGy radiation and 5FU for four consecutive days and cisplatin on day 1 in weeks 1, 5, 8, and 11. Patients in the radiation-alone group were given a total dose of 6400 cGy. This trial was stopped early after an interim analysis demonstrated a survival advantage for patients in the combination therapy group. The 5-year survival rate for patients who had chemoradiation was 26% vs 0% for those receiving radiation only ($P < 0.001$), with a median survival of 14.1 months vs 9.3 months respectively. There was no statistical difference in survival related to histology of the cancer (adenocarcinoma vs SCC). No further benefit but more treatment-related death was shown in a later study (RTOG 94-05) using a higher dose of radiation (6480 cGy) and the same chemoregimen [233].

Neoadjuvant chemoradiation therapy

Data from several nonrandomized studies suggest that neoadjuvant therapy with chemotherapy (5FU and cisplatin) plus radiation before surgery yielded complete response rates of 24%–42%, with a median survival of 12–23 months [220–222]. In a University of Michigan study [223], 100 patients (25 with SCC and 75 with adenocarcinoma) were randomized to either concurrent continuous infusion of 5FU, cisplatin, and vinblastine with 45 Gy radiation followed by surgery or surgery alone. In total, 28% of patients in the neoadjuvant chemoradiation arm achieved a pathological complete response. The 3-year survival rates were 30% in the combination therapy arm vs 16% in the surgery alone arm, but this difference was not statistically significant ($P = 0.15$). Median survivals were similar in both arms of the trial. A small-sized phase III trial in 113 patients with esophageal adenocarcinoma randomized to either 5FU infu-

sion and cisplatin with radiation (40 Gy) plus surgery or surgery alone suggested a survival benefit of combined therapy [224]. However, a trial of 297 patients with SCC randomized to either surgery alone or cisplatin with radiation followed by surgery was inconclusive [225]. Large randomized trials are needed to study this approach further. PET allows the early identification of patients not responding to chemoradiation and is probably helpful when making the decision as to whether a individual patient should continue with chemoradiation or undergo surgery [176,177].

Adjuvant chemoradiation therapy

Medical and radiation oncologists have also administered combined modality chemoradiation therapy postoperatively to patients with esophageal cancer, based on the proven benefit observed in other gastrointestinal malignancies, such as rectal cancer [234–239]. Several small or retrospective studies suggested a survival benefit of adjuvant chemoradiation for patients with esophageal and gastroesophageal junction cancer [240–243]. A large intergroup study from the United States demonstrated a survival benefit of adjuvant chemoradiation in such patients [244]. In total, 603 patients with complete resections, negative surgical margins, and no evidence of residual disease were randomized to receive surgery alone or surgery plus postoperative chemotherapy with 5FU and leucovorin and concurrent radiation therapy. The median survival was 36 months for patients in the adjuvant chemoradiation arm vs 26 months for patients in the surgery-only arm ($P = 0.005$). The 3-year overall survival rates were 50% vs 40% and disease-free survival rates were 48% vs 31% for the treatment group vs the observation group. The median disease-free survival rates were 30 months for chemoradiation-treated patients and 19 months for surgery-only patients ($P < 0.001$). The toxicities of the chemoradiation were acceptable, with hematological and gastrointestinal toxicities comprising the predominant adverse events. In total, three patients (1%) died as a result of toxicities. This study is the first large well-controlled study demonstrating an advantage of adjuvant therapy with respect to both disease-free survival and overall survival. Unfortunately, the study was not designed specifically for determining the role of adjuvant therapy in esophageal cancer. Although this study has been criticized for lack of standardized surgery, a subsequent analysis showed that the survival benefits of adjuvant chemoradiation therapy were retained in patients who had either a D0 (less than complete dissection of the N1 lymph nodes) or D1 dissection [245].

Summary

For patients with stage T1 and T2 lesions without any evidence of nodal involvement, surgery alone may be curative in more than 60%. For patients with locally advanced disease, the emerging recommendation entails perioperative chemotherapy and/or radiation therapy plus surgical resection. Perioperative chemotherapy or chemoradiation can be performed safely with an acceptable operative morbidity and a low operative mortality rate in patients with gastroesophageal cancer, with careful consideration of associated risks such as age and obesity [246]. Patients should be encouraged to enter large randomized clinical trials whenever possible, because definitive survival benefits of either neoadjuvant or adjuvant multimodality therapy with surgery need further study.

Palliation treatment

Local disease

Because fewer than 50% of patients are candidates for a curative approach after careful staging and preoperative assessment of comorbid disease, palliative approaches are essential. Because total esophagectomy is fraught with high mortality rates in palliative situations, bypass should be considered for those patients with an expected survival of more than 6 months. External beam radiation therapy (with or without chemotherapy) may be suitable for annular or nearly obstructive lesions, but radiation-induced esophagitis may be problematic. Lower doses may be an option. Brachytherapy should be considered for relief of symptoms (see Brachytherapy). Endoscopic esophageal interventions with various techniques including endoscopic dilation, photodynamic therapy, endoscopic lumen restoration, and self-expanding metal stents can be employed to relieve strictures and are associated with low complication rates [247,248]. Expandable metal stents are a good option to maintain patency; additionally, laser and bipolar electrocoagulation therapy may be helpful (see Chapter 121).

It is worth emphasizing the exciting potential of photodynamic therapy. An intravenously administered photosensitizer, porfimer sodium (approved by the Food and Drug Administration for use in the palliation of esophageal cancer), is administered, and then light of a specific wavelength (630 nm) is shone on the tumor. Cell toxicity is believed to occur through the release of singlet oxygen resulting in ischemia and eventually necrosis. The depth of destruction in photodynamic therapy is 2–5 mm, and it is preferred to laser treatment in tumors of longer than 8 cm (Fig. 36.3).

Metastatic disease

For distant metastatic disease, systemic chemotherapy with 5FU and cisplatin is the main modality for palliative care, although survival rates are not impressive. With newer agents such as paclitaxel, docetaxel, gemcitabine, irinotecan, and oxaliplatin, response rates have improved to 50%–60% and median survival has increased to 10–14 months, with gains in quality of life [249–254]. The combination of epirubicin, cisplatin, and 5FU is considered a standard treatment for esophageal and gastric adenocarcinoma in Europe. A large randomized phase III trial with a 2×2 factorial design

is testing whether oxaliplatin and capecitabine may replace cisplatin and 5FU. The preliminary results suggest that there are advantages to the combination of epirubicin, oxaliplatin, and capecitabine [255].

An emerging understanding of the molecular characteristics of cell growth, the cell cycle, apoptosis, angiogenesis, and signaling pathways has provided novel targets in cancer therapy including for esophageal cancer. Success has been demonstrated in the treatment of colorectal, breast, lung, and renal cell carcinomas. Preliminary data from esophageal cancer, while from small studies, are very encouraging [256–258].

Prognostic factors

It would be helpful to be able to identify patients a priori who would benefit from certain types of therapeutic modalities. Performance status, weight loss of more than 10% of body weight, the tumor stage, and lymph node involvement from the primary tumor are also very important [259,260].

The chances of curative surgical resection are optimal for lesions of less than 5 cm, confined to the mucosa, and without lymph node involvement. Poor prognosis is correlated with aneuploidy and histology. For those patients who achieve a pathological complete response to neoadjuvant chemotherapy, long-term survival is significantly improved [261]. Increased cyclin D_1 expression and reduced E-cadherin expression portend a less favorable outcome [262]. A high serum vascular endothelial growth factor (VEGF) level has been associated with tumor progression, poor treatment response, and poor survival in patients with SCC [263].

Patients with higher serum levels of C-reactive protein (CRP) may have a poorer response to chemoradiotherapy and worse overall disease-free survival rates [264]. It has also been suggested that high expression of BAX and $p16^{INK4a}$ are associated with a favorable prognosis [265]. Importantly, patients need to abstain from tobacco and alcohol consumption during treatment.

The extent of disease is an important prognostic factor for esophageal adenocarcinoma. After resection, negative surgical margins are important for improving prognosis; conversely, the development of distant metastasis during treatment portends a poor prognosis. The type of operation is not an independent prognostic factor, nor is ultrasound assessment after neoadjuvant therapy. Identification of micrometastatic disease in lymph nodes of patients with esophageal cancer may permit stratification to better or worse survival [266].

Benign epithelial tumors (squamous cell papilloma)

Squamous cell papillomas are usually discovered incidentally at endoscopy or radiography. Generally, they are small, sessile, and polypoid growths of normal or hyperplastic squamous epithelium covering a core of connective tissue [267,268]. On removal, they typically do not recur [269,270]. The average age of patients is 51.5 years, with a male-to-female ratio of 1.8:1. These tumors occur more frequently in Japan. Most are solitary and located in the distal one-third of the esophagus. Papillomas may result from chronic irritation from reflux esophagitis. Morphological features suggest that papillomas result from HPV infection, and HPV DNA has been found in a subset of papillomas. The actual development of cancer has not been documented in these tumors.

This may reflect the fact that the nononcogenic genotypes of HPV may be associated with esophageal papillomas, as in the skin. NMBA administered subcutaneously in rats leads to the development of esophageal squamous dysplasia and papillomas.

Malignant epithelial tumors

Squamous cell carcinoma with a spindle cell component

SCC with a spindle cell component is also referred to as carcinosarcoma, pseudosarcoma, spindle cell carcinoma, and polypoid carcinoma [271–277]. Originally, carcinosarcoma was believed to be malignant, whereas pseudosarcoma was designated benign without metastatic potential. Local and distant metastasis of spindle cells, however, has been reported.

Spindle cell carcinomas are either solitary or multiple and are large and polypoid. Histologically, the squamous component at the surface is associated with dysplasia or carcinoma in situ. One may also see adenocarcinoma or undifferentiated epithelial components. The spindle cell component may range from mild proliferation to marked proliferation with pleomorphism, giant cells, and mitoses. Differentiation into smooth or skeletal muscle, bone, or cartilage may be rarely observed. Immunohistochemical and electron microscopic analyses indicate that the spindle cells stem from mesenchymal metaplasia of malignant squamous cells. Although there are reports that spindle cells contain epithelial cell markers such as cytokeratins, suggesting multiclonality, most pathologists believe that spindle cell carcinomas arise from SCCs that produce a spindle cell component.

Clinically, men are affected more often than women, and most patients are middle aged or elderly. Located in the middle to distal esophagus, these cancers can produce obstruction and dysphagia by virtue of their large size. Most patients present with esophageal wall invasion and lymph node involvement.

Verrucous squamous cell carcinoma

Classically, *verrucous SCC* of the esophagus is a slow-growing malignant tumor that may be limited to local invasion but without distant metastasis [278,279]. Some, however, do metastasize to other organs, with resulting poor prognosis.

Adenocanthoma and adenosquamous carcinoma

These rare tumors feature adenocarcinoma with squamous metaplasia (*adenocanthoma*) or with squamous carcinoma (*adenosquamous carcinoma*) [280,281]. These lesions can arise in the setting of Barrett esophagus or de novo. It is likely that these tumors arise in the squamous epithelium, which has the ability to achieve squamous and glandular differentiation. Alternatively, squamous metaplasia or transformation within an adenocarcinoma may have occurred. Clinically, these tumors behave like adenocarcinomas.

Adenoid cystic carcinoma

This is a rare tumor that resembles salivary adenoid cystic carcinoma. Carrying a male predilection at an advanced age, these tumors are multilobulated or ulcerated and located in the midesophagus [282–287]. Histologically, *adenoid cystic carcinomas* contain many cystic spaces and are primarily submucosal.

Mucoepidermoid carcinoma

This cancer consists of glandular and squamous elements; however, the mixture is more pronounced than in adenosquamous carcinoma. Found in the middle to distal esophagus, *mucoepidermoid carcinomas* probably arise from submucosal glands or their ducts and carry a dismal prognosis.

Melanoma

Melanoma is a rare esophageal cancer that can be primary or metastatic, although the esophagus is less commonly a metastatic target than the stomach, small intestine, or colon [288–294]. The mean age of patients is 60 years, and there are more cases in Japan than in other countries. Melanomas are polypoid and may be multiple, with a propensity for lateral spread. Primary esophageal melanomas arise from melanocytes in the basal layer. There must not be evidence of melanoma in the skin or internal organs to call an esophageal melanoma a primary tumor. Additionally, in situ or junctional melanoma must be evident in the mucosa adjacent to the tumor. Some cases are amelanotic and may require confirmation with immunohistochemical demonstration of S100 protein or homatropine methylbromide 45; alternatively, electron microscopy may reveal premelanosomes. Overall, the prognosis of malignant melanoma is dismal; most patients succumb to the disease within 2 years.

Neuroendocrine tumors

Small cell carcinoma of the esophagus may include a small cell variant of SCC as well as oat cell carcinoma [295–298]. Oat cell carcinoma of the esophagus can be primary or secondary, but it is rare in either situation. A disease of the elderly, who present with dysphagia, primary small cell carcinoma of the esophagus (typically distal and sometimes multiple) carries a dismal prognosis, with an average survival of 4.7 months. These tumors may occasionally secrete ectopic antidiuretic hormone or calcium. Microscopically, this tumor is an anaplastic small cell carcinoma resembling what is observed in the lung, with solid sheets of small anaplastic cells with mitoses. There can be evidence of squamous or glandular differentiation. Neuroendocrine markers employed are chromogranin and synaptophysin, as well as electron microscopic evidence of neurosecretory granules.

Esophageal carcinoid tumors are rare [299–302], with most occurring at the gastroesophageal junction. Carcinoid syndrome has not been reported. There is little or no malignant potential and, consequently, prognosis is very good.

Choriocarcinoma of the esophagus is an exceedingly rare tumor that may be primary or an adenocarcinoma with trophoblastic differentiation [303,304]. Secretion of human chorionic gonadotropin has been reported.

Benign nonepithelial tumors

Leiomyoma

Leiomyomas are the most common benign esophageal tumors [305–310]. Men are affected more frequently than women, with a ratio of 2:1. These tumors typically are single, and most occur in the distal esophagus and in the inner circular layer of the muscularis propria. Typically, most leiomyomas are not associated with symptoms and are found incidentally. Symptoms, if present, include dysphagia and chest pain; gastrointestinal bleeding is rare.

The diagnosis is usually suggested by barium esophagography, which shows a smooth, round defect with sharp margins (Fig. 36.4), or endoscopy, in which there is a well-circumscribed, rounded mass with normal overlying mucosa. Biopsy is usually not necessary because of its nondiagnostic nature and also because of the potential for complications.

Granular cell tumor

Granular cell tumors are derived from neural or Schwann cell elements, as evidenced by positive staining for S100 protein and neuron-specific enolase. Endoscopically, granular cell tumor is characterized as a small, smooth, sessile polyp with overlying normal mucosa and intramural nodules or plaques [311]. Most tumors occur in the distal esophagus and may be single or sometimes multiple. Patients are typically asymptomatic. Malignant transformation is rare. Microscopically, there are sheets of monomorphic histiocyte-like cells.

Fibrovascular polyp

Intralumenal *fibrovascular polyps* of the esophagus are rare tumors that may grow and may prolapse into the larynx. Other symptoms include dysphagia, nausea, vomiting, and, occasionally, gastrointestinal bleeding from ulceration. The polyps are covered by a smooth mucosa and are composed of fibrous and vascular tissue, although adipose tissue may occasionally predominate, prompting the designation of a fibrolipoma or pedunculated lipoma. Fibrovascular polyps do not have any malignant potential.

Hemangioma

Hemangiomas are small, asymptomatic lesions found incidentally [312].

Figure 36.4 Leiomyoma of the esophagus represented by a smooth intramural mass (arrow) outlined with air-contrast barium. Courtesy of Deborah Hall, MD.

Lymphangioma

Lymphangiomas are rare, with the appearance of a translucent, easily compressed mass on endoscopy [313]. Histologically, they contain dilated endothelial spaces.

Lipoma and fibroma

Sessile submucosal nodules composed of adipose or fibrous tissue are called *lipomas* and *fibromas* respectively. Together, they constitute fewer than 5% of all benign esophageal tumors.

Malignant nonepithelial tumors

Leiomyosarcoma and other sarcomas

Leiomyosarcoma is an uncommon tumor of the esophagus [314–317]. These tumors may be polypoid or infiltrative, and they can occur in all segments of the esophagus. Other esophageal sarcomas include soft tissue sarcoma, rhabdomyosarcoma, neurogenic sarcoma, and Kaposi sarcoma.

Metastatic carcinoma

Metastatic carcinoma of the esophagus is unusual, representing 3% of esophageal malignancies in one autopsy series [318]. The most common metastatic tumor to the esophagus is melanoma, followed by breast cancer and, less commonly, gastric, renal, liver, prostate, testicular, bone, skin, lung, and head and neck cancer. Primary esophageal and head and neck squamous cancers may coexist or may develop sequentially. Metastatic carcinomas to the esophagus cause extrinsic compression. In this context, the esophageal stricture is extrinsic, without mucosal involvement.

Lymphoma

Primary esophageal *lymphoma* may be Hodgkin or non-Hodgkin lymphoma [319–322], although, clearly, primary gastrointestinal lymphomas more commonly affect the stomach and small intestine. Symptomatic esophageal lymphoma may be present in immunocompromised patients, as in those with acquired immunodeficiency syndrome. Alternatively, lymphoma of the esophagus may be attributable to disseminated disease or infiltration from adjacent lymph nodes.

Summary and future directions

Advances have been made in the pathobiology, diagnosis, prognosis, and therapy of both major subtypes of esophageal neoplasms, namely esophageal squamous cell carcinoma and esophageal adenocarcinoma. The development and characterization of in vitro and in vivo model systems will help to facilitate the discovery and implementation of novel approaches in diagnostics and therapeutics in the future. As the last 15 years have witnessed much progress, it is hoped that the next 15 years will mirror that growth and advance the field to new heights to allow more beneficial outcomes for these once deadly diseases.

A ESOPHAGUS

37 Miscellaneous diseases of the esophagus: foreign bodies, physical injury, and systemic and dermatological diseases

Dermatological diseases, 881

As the portal to the gastrointestinal tract, the esophagus is susceptible to insults from a variety of environmental exposures and to the effects of systemic and dermatological diseases. In this chapter we discuss myriad causes of esophageal injury not addressed elsewhere in this book. Although some of these diseases are rare it is important for the clinician to recognize them, because in many cases a delay in diagnosis of these diseases is the primary predictor of a poor outcome.

Esophageal foreign bodies

Epidemiology

A wide variety of objects can become lodged in the esophagus, the most common site of *foreign body impaction* in the gastrointestinal (GI) tract [1]. The type of object varies by age group. In the general population of adults, the annual incidence of food impaction is approximately 13 episodes per 100 000 people, with meat and bone impactions occurring commonly [2]. Special populations of adults at high risk include denture wearers, prisoners, the mentally challenged, substance abusers, and psychiatric patients, who swallow a panoply of implements [1,3–8]. In children, most cases occur between the ages of 6 months and 6 years, and small objects such as coins, toys, crayons, buttons, and batteries are commonly ingested [1,3–5,7].

Pathogenesis

Foreign body impaction can occur in areas of anatomical esophageal narrowing, such as the cervical esophagus, aortic arch, and gastroesophageal junction [7]. However, adults with food impaction often have an underlying structural esophageal disorder such as a peptic stricture or Schatzki ring (Fig. 37.1) [4]. Data suggest that a sizeable proportion may have eosinophilic esophagitis (see Chapter 33) [9].

Presentation

The clinical presentation is often straightforward. Many older children and adults are able to recognize the impaction when it occurs, and a history of prior impaction is common [1]. Patients may point to the level of the impaction, although this is not always reliable [10]. Dysphagia is the most common symptom and, if the esophagus is obstructed, odynophagia, choking, or drooling can be present [6]. These last few symptoms may be the only clue in young children or adults who cannot communicate. In children with foreign objects lodged proximally, 5%–15% may present with respiratory symptoms [3].

Complications usually depend on the characteristics of the impacted object, and may occur with a larger sized, irregularly shaped, or sharply pointed object [7]. If a foreign body perforates the esophagus, mediastinitis can result in abscess formation requiring drainage [11,12]. Fistulization to surrounding vasculature such as the aorta or innominate artery may lead to life-threatening hemorrhage [13,14]. Equally serious consequences can also occur with fistulization to the airway or pericardium [15,16]. Disk batteries pose a unique threat; leakage of alkali causes direct tissue damage, potentially leading to perforation or fistulization [17,18].

Diagnosis

An accurate history is crucial for diagnosis. Although little extra information is gained on the physical exam, signs of some complications may be detected. For example, proximal esophageal perforation is suggested with neck swelling,

erythema, tenderness, or crepitus. Imaging can confirm the diagnosis prior to an invasive procedure. Neck and chest radiographs show a radiopaque foreign object and, in the case of esophageal perforation, subcutaneous air [6,19,20]. Contrast esophagram should be avoided when obstruction is suspected because of the risk of aspiration. Barium is an opaque contrast agent that may coat both the foreign body and esophagus, hampering endoscopy and removal. Gastrografin is a transparent contrast agent but may cause severe pneumonitis if aspirated [7]. In children, metal detectors can be used to detect metallic foreign bodies [21].

Treatment

The management of an esophageal foreign body is determined by its physical characteristics, location, and length of time in place. In general, flexible endoscopy performed by an experienced endoscopist is the mainstay of therapy with a success rate of up to 98% and very low morbidity [1,7,22–25]. An exception is made for objects in the high cervical esophagus or pharynx, which may require rigid laryngoscopy for removal [4]. Blind bougienage carries a significant perforation risk and is not recommended [6]. As with all procedures, the risks of aspiration and airway obstruction should be minimized, and elective intubation may be necessary to manage an airway prior to endoscopic intervention.

The time frame for management varies. For disk batteries, sharp objects, and objects lodged in the proximal esophagus, immediate intervention is required [7]. Cases of complete esophageal obstruction in which patients have difficulty handling secretions should also be dealt with swiftly [1,6]. In contrast, it is safe to observe coins in the distal esophagus for up to 24 h to determine whether they will pass into the stomach [26]. If they do, they usually will pass through the remainder of the GI tract without incident [27]. Because of the increased risk of progressive mucosal damage and aspiration, frankly impacted objects should not be allowed to remain in the esophagus for more than 24 h, even if they are nonobstructing [6].

Nonendoscopic medical treatments are generally of limited value in esophageal foreign body impaction. Glucagon, given in a 1 mg intravenous bolus, can relax the esophagus to allow spontaneous passage of a food bolus or foreign body, but may only be successful in patients without a fixed esophageal obstruction, and is often not successful at all [28,29]. Effervescent agents are also of limited efficacy, carry a perforation risk, and interfere with subsequent endoscopy [30]. The use of enzymatic digestion of a meat bolus (with papain or another meat tenderizer) is not recommended; both perforation and death have been reported [31]. Even if a patient experiences medication-assisted passage of an object, subsequent esophageal examination is recommended to determine whether there is an underlying cause of mechanical obstruction.

To remove impacted esophageal foreign objects, a number of endoscopic instruments, including snares, nets, and multiple varieties of grasping forceps, are available (Fig. 37.2) [32,33]. Before the procedure, a practice session with a similar foreign body can identify the appropriate endoscopic

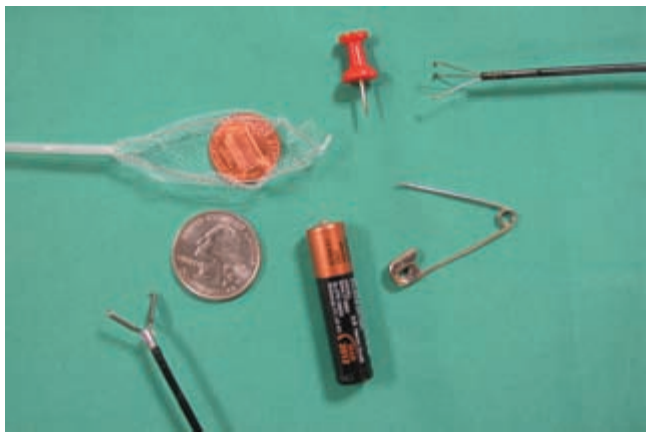

Figure 37.2 An example of the array of devices available for foreign body removal. From top left and proceeding clockwise, a Roth net (with a captured penny), a three-pronged grasping forceps, and a rat-tooth forceps are pictured. Objects that can potentially be impacted in the esophagus are shown for size comparison.

accessories for the actual removal and increase dexterity. An esophageal overtube can be used to protect the airway, but because of the risk of perforation should be used only by experienced personnel [34].

Coins can be removed with either a grasping forceps, net, or retrieval basket, depending on the size and whether the coin has a ridge [26,35]. Of note, special care should be taken when traversing the upper esophageal sphincter with a coin to prevent loss into the trachea. Disc batteries or other round objects are similarly captured in a net [32]. If a small (< 2.0 cm), smooth object can not be securely grasped in the esophagus, it is possible under direct visualization to gently advance it into the stomach where there is more room to maneuver. Sharp objects, however, are best removed where they lie with retrieval forceps or a polypectomy snare [32]. Orienting a sharp object with its point trailing during extraction can minimize mucosal injury, as does fitting a protector hood to the end of the endoscope [6,36]. Methods have been described for the closing of an open safety pin before extraction to minimize the risk of perforation [37].

Techniques for clearing a food impaction are similar. A bolus can often be gently advanced into the stomach under direct visualization with the tip of the endoscope [2,38]. Alternatively, the food bolus can be removed with snares, baskets, or forceps, although an esophageal overtube is usually required to prevent stray food particles from dropping into the airway [6]. A friction-fit adaptor, such as a variceal band ligator, placed on the end of the endoscope can be used as a suction device provided enough food is present to fill the cup and form an airtight seal [39].

After clearing an esophageal foreign body, the endoscopist must still assess for underlying structural abnormalities. If an esophageal stricture is found, it can be biopsied or dilated, provided that the foreign body removal was not delayed and severe esophagitis is not present [1,2,9,38]. Surgery is rarely needed to remove an impacted object or food bolus, and should be reserved for when endoscopic management has failed, an object is embedded in the esophageal wall or extraction carries a high risk of perforation, if a perforation has already occurred, or if endoscopic removal of the object poses an additional risk of systemic effects, such as in the case of ingested packets of illicit drugs [1,6,14].

Esophageal trauma

Mallory–Weiss syndrome

In 1929 Mallory and Weiss described a syndrome in alcoholics of retching and emesis followed by massive, and sometimes fatal, upper GI hemorrhage caused by linear lacerations at the gastroesophageal junction [40]. In subsequent retrospective series, these lacerations, termed *Mallory–Weiss tears*, account for 5%–15% of cases of upper GI bleeding [41,42]. These mucosal lacerations are generally 3–20 mm long, 2–3 mm wide, and parallel to the long axis of the esophagus (Fig. 37.3) [43].

The sudden rise in intraabdominal pressure during vomiting, retching, or coughing is thought to be the major pathogenic mechanism of a Mallory–Weiss tear. Accordingly, tears have been seen after ingestion of ipecac syrup or administration of chemotherapeutic agents, during diabetic ketoacidosis, seizures, hiccups, blunt trauma, straining at stool, asthma exacerbations, heavy lifting, cardiopulmonary resuscitation, or primal scream therapy, after abrupt changes in air pressure, and as a complication of carbon monoxide poisoning [41,44–47]. They can also occur during upper endoscopy, but this is rare (0.5% of all endoscopies) and only seen in patients with excessive retching during the procedure [48]. Hiatal hernias may also play a role in pathogenesis. When the gastroesophageal junction is located above the diaphragm, a large pressure gradient between the intragastric and intrathoracic compartments may result in sudden dilation and laceration of the mucosa at the gastroesophageal junction [43].

The "classic" presentation of a Mallory–Weiss tear is of repeated, violent retching, vomiting, or coughing followed by hematemesis. However, the presentation is often atypical: 40% of patients have no antecedent explanation for the tear, and 50% have hematemesis with the first episode of emesis [41,43]. The mean age at presentation is in the fifth decade, but the syndrome can occur at any age [43,49]. Male patients are affected more frequently (4:1) than female patients [41,43]. In total, 27% of patients have multiple lacerations and up to 77% have other associated upper GI lesions [41,42]. Although bleeding stops spontaneously in up to 90% of patients, blood transfusion may be needed and mortality may be as high as 12% [41,42]. Patients with portal hypertension and coagulation defects are at increased risk of bleeding from Mallory–Weiss tears [42,50]. Presentation

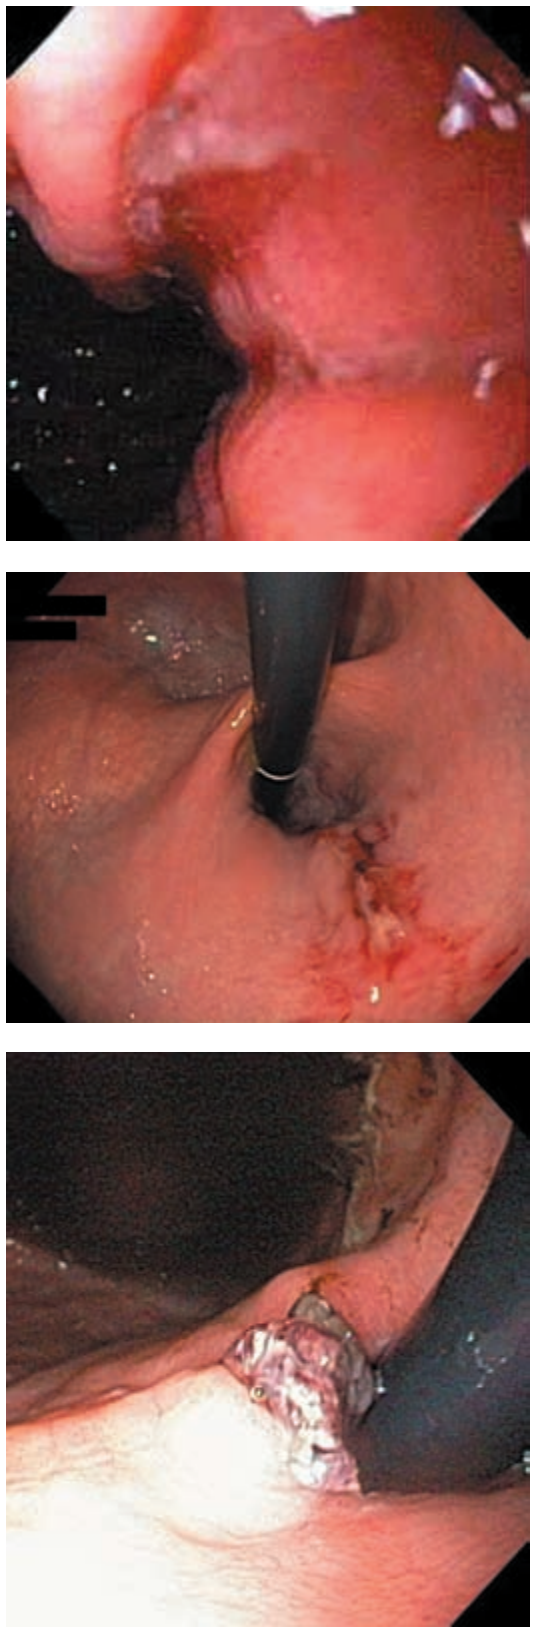

Figure 37.3 Examples of different morphologies of Mallory–Weiss tears in three different patients, seen in antegrade **(a)** and retroflexed **(b,c)** views in the proximity of the gastroesophageal junction.

with shock or ongoing active bleeding predicts recurrent bleeding episodes [51].

Endoscopy is commonly used to diagnose and treat Mallory–Weiss tears, but treatment is recommended only for lesions with active bleeding or stigmata of bleeding [52]. Endoscopic hemostasis has been achieved by the injection of anhydrous ethanol, polidocanol, or 1:10 000 epinephrine (adrenaline), cautery with a multipolar coagulation or heater probe, endoscopic band ligation, and application of hemoclips [41,53–60]. Endoscopic injection with epinephrine and polidocanol has been shown to reduce recurrent bleeding and decrease length of hospital stay [61]. Angiographic embolization has also been used with success, but typically is reserved for situations when endoscopic therapy fails [62]. Surgery may be required in rare instances when bleeding cannot be controlled by these methods [41].

Esophageal perforation and rupture

Injury to the esophagus resulting in perforation or rupture is life-threatening, and successful management depends on early diagnosis and prompt surgical intervention [63]. The most common cause of esophageal perforation, accounting for about 50% of cases, is medical instrumentation, including rigid and flexible endoscopy [64–66]. Therapeutic endoscopic stricture dilation by bougie or balloon caries a perforation risk, and in treatment of achalasia the perforation rate can be as high as 3%–4% [67–73]. Perforation has also been reported following nasogastric tube placement, inflation of a gastric variceal tamponade balloon in the esophagus, sclerotherapy, and insertion of an intragastric balloon for weight loss [66,74–76]. In addition to medical instrumentation, penetrating injury from knife and gunshot wounds or sword-swallowing, as well as blunt trauma to the neck, chest, and upper abdomen, may cause esophageal perforation [77–79]. The degree of blunt trauma may vary from grave, as in blast and crush injuries, to less severe, as in assault or the Heimlich maneuver [80–85].

In 1724 Herman Boerhaave described spontaneous transmural rupture of the esophagus in a patient, Baron von Wassenauer, who died suddenly after severe retching [86]. In total, 90% of cases of spontaneous rupture, or *Boerhaave syndrome*, occur in the distal esophagus, with more than two-thirds on the left side. This is likely due to an anatomical weakness of the left posterolateral aspect of the esophagus just above the diaphragm [87,88]. Most patients have antecedent retching and vomiting, although any maneuver that suddenly increases the intraabdominal pressure may result in rupture [87,89]. Interestingly, some patients with Boerhaave syndrome have been found to lack a muscularis mucosae, which may make them anatomically predisposed to rupture [90].

The etiology and severity of an esophageal rupture dictate the presentation. Chest pain, dysphagia, odynophagia, nausea, vomiting, hoarseness, or aphonia can be seen in an upper

esophageal perforation, whereas lower esophageal perforation manifests with abdominal pain, pneumothorax or hydropneumothorax, or pneumomediastinum. Hematemesis is rarely severe, but occurs in 55% of patients [66,87,89–92]. Of note, iatrogenic perforations often may remain asymptomatic for up to 8 h [66].

Physical examination reveals tachypnea, tachycardia, and sometimes fever. Subcutaneous emphysema is present in at least 30% of patients [93]. If present, Hamman sign (a mediastinal "crunch" appreciated with each heartbeat with patients in the left lateral decubitus position) suggests pneumomediastinum. With pleural involvement, there may be reduced or absent breath sounds on the side of the perforation. Signs of tension pneumothorax, hypotension, or shock are indicative of sudden massive esophageal rupture [94–96].

Early diagnosis and treatment are essential to avoid the high mortality rate (25%–75%) associated with presentation beyond 24 h from the rupture [92,95,97,98]. A high level of suspicion is also required, as misdiagnosis or treatment delay occur in more than 50% of patients [96,99]. After obtaining a history and performing the physical examination, radiographs of the chest and abdomen should be acquired. There are a range of findings, including subcutaneous emphysema, pneumomediastinum, mediastinal widening, mediastinal air–fluid levels, pleural effusion, pneumothorax, hydropneumothorax, or pneumoperitoneum [87,89]. A completely normal chest radiograph is present in fewer than 5% of patients [97]. The next step in evaluation is to perform an esophagram with water-soluble contrast; multidirectional views are diagnostic in most cases [66,87,89]. If this cannot be obtained, a noncontrast computed tomography (CT) scan may identify smalls quantities of air or oral contrast in the pleural space, and provides views of the mediastinum, pleura, and aorta [89,100]. Unfortunately, it does not always allow for localization of the perforation [101]. Flexible upper endoscopy is highly accurate and has been advocated for suspected blunt or penetrating esophageal trauma, but it does present the risk of extending the perforation [102].

Although infection is a common complication of esophageal perforation, until the patient develops fever, mediastinitis, pleural effusion, empyema, or sepsis, the diagnosis may be obscure. If examined, the pleural fluid is exudative, with a pH as low as 6.0 [103]. Because the pleural fluid is salivary in origin, the pleural fluid amylase may be elevated [104]. A wide range of community and nosocomial organisms cause empyema [105,106].

Surgical management is generally required for both spontaneous rupture and traumatic perforation [98,107]. Initially, all patients should take nothing by mouth, and broad-spectrum antibiotics should be administered. Specific therapy depends on the site and etiology of the rupture, the length of time between the perforation and the diagnosis, and the overall health status of the patient. Small perforations of the cervical esophagus can be treated conservatively with antibiotics and without surgery, or with localized drainage of the neck without esophageal repair [108,109]. Intrathoracic perforations, however, must be treated aggressively with debridement and irrigation of the mediastinum, followed by primary closure of the defect [110]. With early intervention, the mortality rate is less than 10%, but this rate triples if surgery is delayed for more than 24 h [64,98]. However, even in patients with a delayed diagnosis, primary esophageal repair remains the treatment of choice [64,110–113]. Esophagectomy is typically performed only when the diagnosis has been significantly delayed such that severe infection has developed [72,114]. Patients with perforation caused by endoscopy with dilation tend to have a good prognosis because of prompt diagnosis and treatment [115]. In addition, minimally invasive interventions are being used more commonly. Thorascopic repair of esophageal rupture and endoscopic repair of small dilation-induced perforations using hemoclips are emerging techniques [116–120]. Covered expandable metal stents have also been successfully deployed to seal immediately recognized esophageal perforations [121–124]. Because this type of stent is generally not removable, it should be reserved for inoperable patients with significant comorbidity (e.g., cancer). Recently, a removable expandable plastic stent has been developed that facilitates temporary stent placement in the case of esophageal perforation [125].

Esophageal intramural hematomas

An *esophageal intramural hematoma* is usually produced by local trauma [126–128]. It typically occurs in the setting of vomiting or retching, although spontaneous hematomas have been seen in patients with coagulopathies or those treated with anticoagulants or aspirin [126–133]. Iatrogenic hematomas have occurred after endoscopic sclerotherapy, cardioversion, thrombolysis, passage of a nasogastric tube, and endoscopic biopsy [134–139].

The pathogenesis is likely due to a mechanical injury of the esophageal wall. Potential causes include sudden or dramatic changes in internal esophageal pressure from blunt external trauma or from retching, coughing, or sneezing [127,128].

Patients typically present with an abrupt onset of substernal or epigastric pain followed by hematemesis. Hemorrhage is usually of small volume, although up to 10% of patients require blood transfusion [126,140]. Dysphagia and odynophagia are common, and in some cases the esophagus can be completely obstructed [132,134,140–142].

Patients presenting with hematemesis and substernal chest pain should immediately have a chest radiograph to rule out perforation. If negative, an esophagram with a water-soluble contrast agent should then be performed [141]. The most common abnormality seen on this test is a filling defect [143]. On endoscopy, a bluish or violet esophageal mass protruding into the lumen is seen, sometimes associated with a mucosal tear [127,144,145]. CT with contrast

or magnetic resonance imaging (MRI) can reveal a non-enhancing esophageal mass that has the density of blood [129,131,145,146]. Endoscopic ultrasound shows an intramural submucosal hypoechoic mass [145].

Most patients respond to conservative management with complete resolution within 2–3 weeks without long-term sequelae [133,138,140]. However, the development of fever or pleural effusions indicates that an esophageal perforation was not detected during the initial evaluation [138,143]. Endoscopic incision and drainage of the hematoma has been described [147,148]. Surgery is needed in 19% of cases to control bleeding or repair perforations [140].

Corrosive esophagitis

Epidemiology

Ingestion of corrosive substances occurs in more than 26 000 patients per year in the United States, approximately 17 000 of whom are children (half of whom are less than 4 years of age) [149]. Nearly half of caustic ingestions injure the esophagus severely enough to cause long-term sequelae, and ingestion of corrosive substances remains a leading cause of pediatric death [149,150]. Although corrosive esophageal injury usually represents accidental ingestion in children, in adolescents and adults most ingestions represent suicide attempts.

Caustic esophageal injury is also a risk factor for squamous cell cancer of the esophagus. One study found that this malignancy may be 1000 times more common in patients after caustic injury than in the general population, even though the mean time between ingestion and cancer is 50 years [149,151]. This association has prompted the recommendation for yearly endoscopic surveillance beginning 20 years after caustic esophageal injury [152].

Pathogenesis

The pathogenesis of corrosive esophagitis is due to direct tissue injury. Alkaline substances produce a deeper depth of injury than acidic substances because liquefaction necrosis occurs in seconds [149,153]. The pH required for esophageal damage is 12.5, but the severity is dependent on both the concentration of the alkaline agent and the mucosal contact time [149]. For example, one study found complications only in those ingesting strong alkaline agents such as lye, whereas detergent ingestion (a weak alkali) caused a complication in only a single case [154].

In contrast to alkaline agents, acidic corrosives cause coagulative necrosis and eschar formation, a mechanism felt to protect deeper esophageal layers from further injury [149]. As with alkalis, the concentration of the acidic agent determines the degree of injury, but the rapid clearance of acid by esophageal peristalsis and partial neutralization by swallowed salivary bicarbonate can limit esophageal injury [149].

The formulation of the corrosive agent is also important. Granular corrosives tend to cause less esophageal injury than liquids, because the granules adhere to the mucous membranes of the mouth rather than being carried into the esophagus [155].

Presentation

Some patients will present immediately after a volitional caustic esophageal injury, but others may not. Symptoms can last days to weeks and include abdominal pain, retrosternal chest pain, dysphagia, nausea, vomiting, and odynophagia. In children unable to describe their symptoms, refusal to drink and increased salivation might be noted.

The most common long-term consequences of severe or circumferential caustic ingestion injuries are esophageal strictures. These strictures are long and narrow, adversely affect distal esophageal peristalsis, and cause dysphagia or food impaction [156]. Strictures and subsequent dysmotility may also lead to decreased clearance of refluxate, esophagitis, and even peptic stricture.

Diagnosis

Most often, the diagnosis is suggested by an accurate history, but upper endoscopy is usually needed to confirm the diagnosis and grade the severity of the injury (Fig. 37.4) [149,153,154]. Injury can be classified as first degree (superficial injury manifest by erythema), second degree (deeper injury manifest by ulceration), or third degree (transmural injury manifest by necrosis). Although not yet widely used for this application, endoscopic ultrasound may provide a more accurate determination of depth of injury [157,158]. Other imaging modalities may also be helpful in the diagnostic evaluation. Plain abdominal or chest radiographs can show evidence of pleural fluid, mediastinitis, or frank perforation. If an esophageal perforation is found, upper endoscopy is relatively contraindicated. Barium swallow may demonstrate esophagitis, gastric abnormalities, or poor distention of the esophagus [159].

Treatment

Once a corrosive injury has occurred, there is no role for inducing emesis, lavaging the esophagus, or using a "neutralizing" agent because these modalities have the potential to cause further mucosal damage [149].

Although frequently recommended for palliation, the use of corticosteroids is somewhat controversial as there have been no placebo-controlled trials [160,161]. However, in a review of 13 publications of 361 patients [160], strictures were seen in 19% of those treated with steroids compared with 41% of those not treated with steroids. This effect was limited to patients who had either second- or third-degree burns; strictures were not seen in either of the treatment groups with first-degree esophageal burns. The timing of resuming oral feeding is not well established, but some

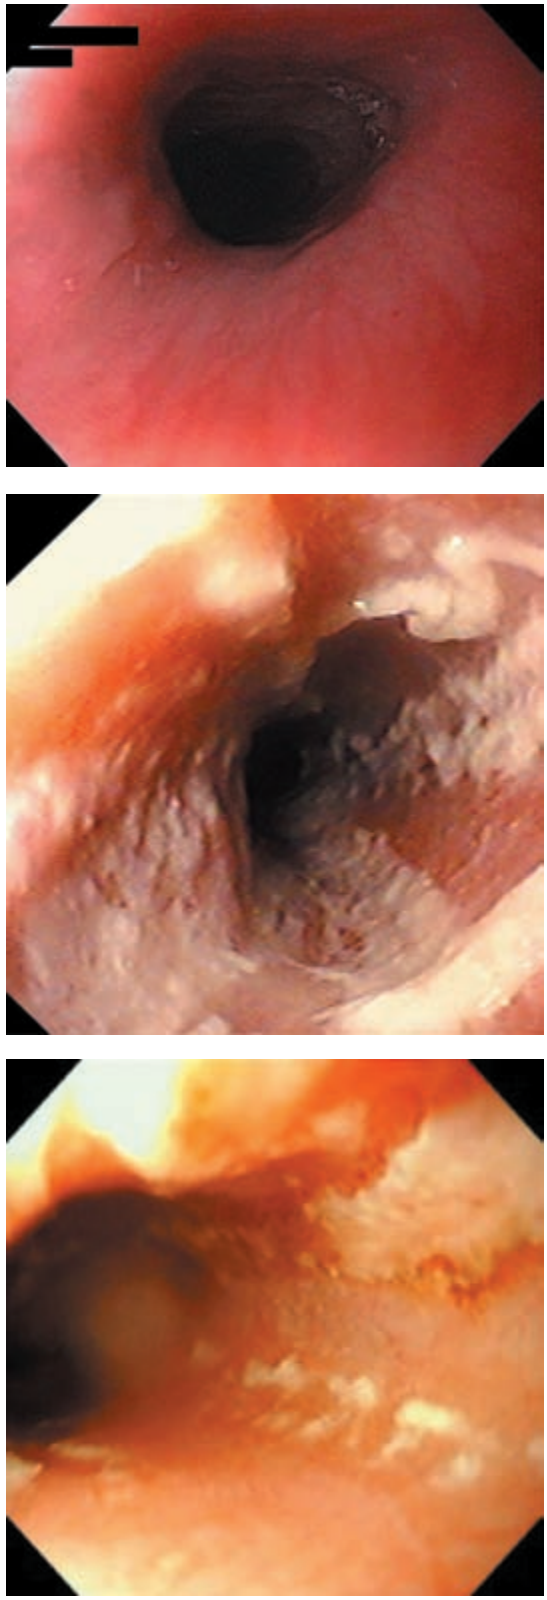

Figure 37.4 Examples of caustic esophageal injury in three pediatric patients after ingestion of a household alkali cleaning agent. First-degree injury is manifest by mucosal erythema **(a)**, whereas second-degree injury results in sloughing of the mucosa with ulceration **(b,c)**.

recommend giving patients nothing by mouth for at least 1 week in cases of severe esophageal burns [162]. Finally, given that concomitant reflux may also contribute to stricture formation, it is reasonable to prescribe antisecretory agents such as proton pump inhibitors [163].

When strictures secondary to caustic esophagitis do occur, endoscopic dilation is effective more than 50% of the time [164]. In recalcitrant cases, a gastrostomy has been placed to facilitate so-called endless-loop bougienage, in which a continuous string loop with plummets of progressively larger size is passed through the mouth and esophagus to the gastrostomy [165]. Patients with severe or dilation-refractory strictures require surgical resection, most commonly with a colonic interposition [166–168].

Pill esophagitis

Epidemiology

Pill esophagitis is widely reported in the literature. Although almost 100 different substances have been implicated in more than 700 cases (Table 37.1), the majority of cases are caused by tetracyclines, potassium chloride, nonsteroidal antiinflammatory drugs (NSAIDs), and quinidine [169–171]. The overall incidence of pill esophagitis has been estimated at 0.004% per year, but ranges from 0.04% for alendronate to as high as 20% for NSAIDs [171–174].

Because of the frequent use of high-risk medications, decreased salivation, and a higher prevalence of esophageal dysmotility, elderly patients are at increased risk for pill esophagitis [170,171]. Similarly, women are more likely to be treated with high-risk medications and are twice as likely than men to have pill esophagitis [170,171].

Pathogenesis

The development of pill esophagitis depends on a combination of patient, esophageal, and drug factors. Patients who lie down or swallow pills without adequate liquid intake may increase their risk of pill esophagitis. This risk is enhanced further by esophageal factors such as dysmotility or mechanical narrowing of the esophagus. Even without these conditions, esophageal transit of standard-sized medication tablets can take as long as 5 min [175,176]. The transit of capsules that adhere to the esophageal wall may also be slowed [169].

Most simply, however, pill esophagitis is caused by prolonged, direct contact of a caustic medication with the esophageal mucosa [171,177]. This is particularly typical of quinidine, potassium, and the bisphosphonates [173]. Tetracycline and ferrous sulfate, in contrast, injure the esophageal epithelium as a result of local pH changes or hyperosmolarity [178]. NSAIDs appear to be absorbed by the esophageal mucosa and cause injury from within, potentially as a result of prostaglandin inhibition [174].

Table 37.1 Selected medications implicated in pill esophagitis [169,171]

Antibiotics
Tetracycline
Tetracycline derivatives (doxycycline, erythromycin)
Penicillin
Penicillin derivatives (amoxicillin, ampicillin)
Trimethoprim
Clindamycin
Rifampin (rifampicin)
Zidovudine
Zalcitabine
Telithromycin

Nonsteroidal antiinflammatory drugs (NSAIDs)
Aspirin
Ibuprofen
Naproxen
Many others in class (e.g., indomethacin [indometacin], diclofenac)

Other drugs
Bisphosphonates (alendronate, pamidronate, etidronate)
Potassium chloride and potassium citrate
Quinidine
Emepronium
Ascorbic acid
Papain
Isotretinoin
Theophyllines
Oxybutynin
Iron preparations (ferrous sulfate)
Captopril
Nifedipine
Diltiazem
Warfarin
Valproic acid
Phenytoin
Phenobarbital
Cromolyn sodium
Chloral hydrate
Alprenolol
Corticosteroids

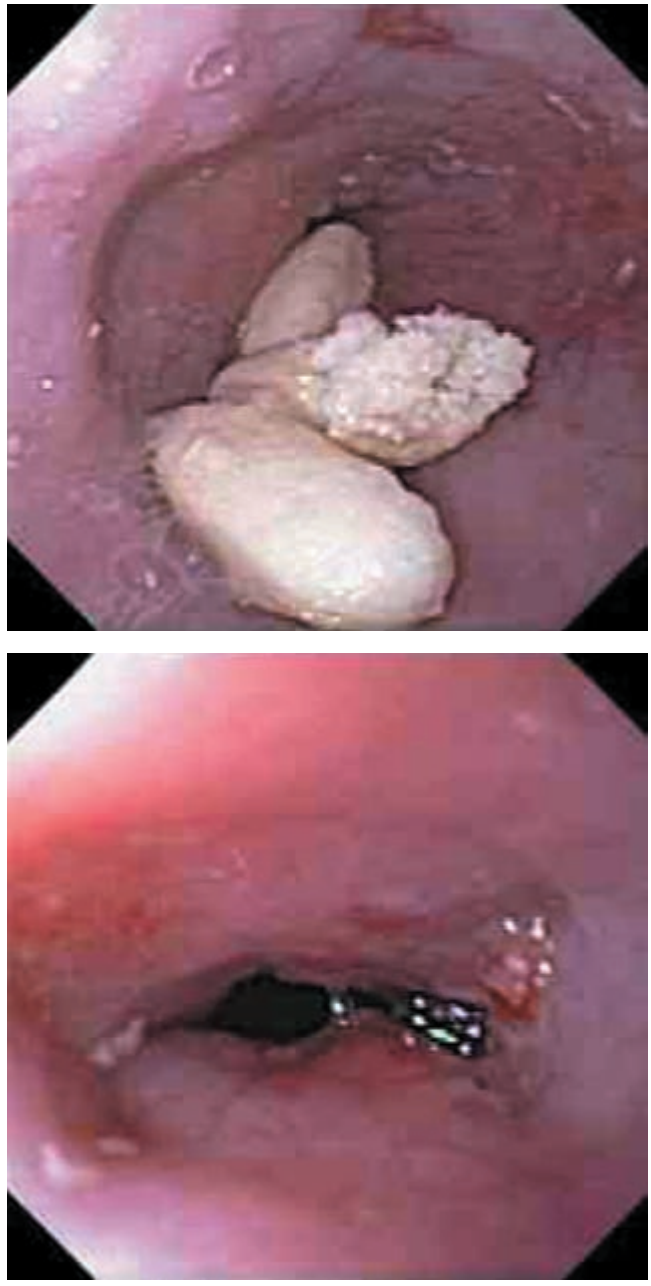
The mid- and distal esophagus are at highest risk for injury. Extrinsic compression by the left atrium or aortic arch may slow transit and increase contact time with the medication in the middle one-third of the esophagus. In the acid-exposed region of the distal esophagus, pill esophagitis may be worsened by concomitant acid reflux [179].

Presentation

Pain and odynophagia are the hallmarks of pill esophagitis, and these symptoms may be severe enough to inhibit adequate oral intake [178]. Retrosternal chest pain is also a frequent complaint. Dysphagia is less common and usually related to edema and ulceration rather than stricture. Rarely, patients may present with hematemesis or even perforation [170].

Diagnosis

Pill esophagitis should be suspected based on medication ingestion, risk factors, and symptoms elicited in a thorough history. Upper endoscopy typically demonstrates erosions or ulcers, usually in the middle or distal one-third of the esophagus, which are often circular or oval in nature. Rarely, the culprit medication is still in place (Fig. 37.5). Focal epithelial



(a) (b)

Figure 37.5 Three pill tablets (one partially dissolved) lodged in the midesophagus with nearby erosions **(a)**. After removal of the tablets, pill esophagitis and an underlying esophageal stricture are evident **(b)**.

damage that spares the majority of the distal esophagus is nearly pathognomonic of pill esophagitis, and effectively excludes reflux esophagitis. "Kissing" ulcers, or ulcers at the same level of the esophagus but on adjacent walls, can also be seen [180]. If a stricture is found, it more likely is the cause, rather than a result, of the esophagitis, and may be responsible for delayed transit of a pill. Finally, although nonspecific, barium esophagram can show discrete ulcers in the mid- or distal esophagus [181,182].

Treatment

Pill esophagitis can largely be prevented with appropriate patient education. Patients should be instructed to ingest medications in an upright position with at least 100 mL of fluid, and to remain upright for 30 min after ingestion. If possible, patients with known esophageal compression, stricture, or dysmotility, and those patients confined to a bed, should avoid medications most frequently associated with esophageal injury [170].

If pill esophagitis does occur, most mucosal lesions heal within days to weeks of withdrawal of the offending agent [169,171]. Occasionally, patients may have such severe symptoms that intravenous fluids or dietary modifications are needed to avoid dehydration. Antisecretory therapy with either an H_2-receptor antagonist or a proton pump inhibitor is usually prescribed to protect the esophageal mucosa from further injury related to reflux of gastric contents [171]. Similarly, agents that provide a protective coating over the esophagus, such as sucralfate, may be of benefit.

Systemic diseases

Sarcoidosis

In total, 10% of patients with known *sarcoidosis*, a systemic granulomatous disease, may have granulomata in the submucosa of their GI tracts, but associated symptoms are rare [183,184]. When symptoms do occur, dysphagia is the most common clinical manifestation of esophageal sarcoidosis. Causes of dysphagia include extrinsic compression from enlarged lymph nodes, an achalasia-like dysmotility syndrome, and granulomatous stricture formation [185–188]. Because granulomata are present in both diseases, esophageal sarcoidosis may be difficult to differentiate from Crohn's disease [188].

Medical therapy primarily targets the underlying systemic disease. Dysphagia may respond to steroid treatment, although endoscopic dilation of strictures may be required [186,187]. Esophageal surgery is very rarely needed [187].

Crohn's disease

Esophageal involvement in *Crohn's disease* is uncommon. The prevalence of esophageal disease in several series ranges from 0.3% to 2% [189,190]. This may be an underestimate because a large number of patients with esophageal involvement are asymptomatic: of 75 case reports of patients with esophageal Crohn's disease, only 55% presented with esophageal symptoms [191]. The prevalence may also be higher in children, although children undergo upper endoscopy more frequently during the evaluation of Crohn's disease than adults [190,192,193].

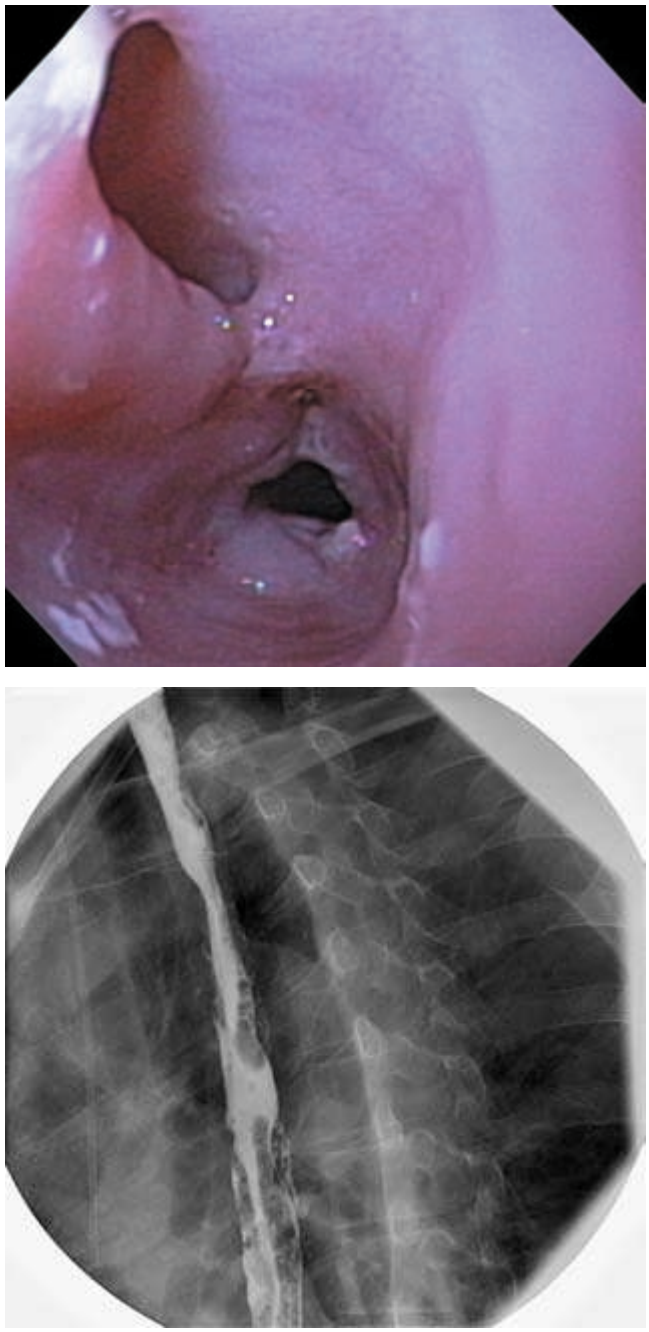
Patients with Crohn's esophagitis usually have active disease elsewhere in the GI tract, and the degree of inflammation typically parallels the activity in the other involved segments [194,195]. Rarely, dysphagia alone can be the presenting symptom of Crohn's disease, and isolated esophageal involvement has been reported [194,196–198]. Other symptoms include odynophagia, pyrosis, and substernal chest pain [189,194].

On upper endoscopy, aphthous ulceration can be seen early in the course of the disease, whereas cobblestoning and deep linear ulcerations may be present later, leading to decreased motility and distensibility (Fig. 37.6). Esophageal stricturing and the formation of sinus tracts, fistulae, or mucosal bridges have been reported [194,195,199]. In severe cases there is perforation and fistulization to the bronchi, mediastinum, pleura or stomach [190,198,200,201]. For diagnostic purposes, endoscopic mucosal biopsies can evaluate the degree of inflammation, but cannot demonstrate transmural inflammation; granulomata are rarely found [189,194,195]. The transmural nature of the inflammatory process may be better illustrated with endoscopic ultrasound, although this is not routine as of yet [202,203].

The tenets of treating Crohn's disease of the esophagus are the same as for the small or large intestine (see Chapter 57), with a focus on controlling systemic inflammation and local complications [190]. Of patients who respond to corticosteroids or other immunosuppressants, more than half will remain free of both esophageal lesions and upper GI symptoms, whereas the remainder will have either refractory lesions or recurrence [189,194,195]. For patients with fistulizing Crohn's disease of the esophagus, infliximab may have value [204]. Strictures may respond to both medical management and bougie dilation; extensive mucosal bridges may be endoscopically excised with a papillotomy needle knife [199]. In some patients, placement of a percutaneous endoscopic gastrostomy may be needed because of malnutrition [205]. Surgical resection is reserved for medically refractory fistulae, endoscopically refractory strictures, or when malignancy cannot be excluded [197].

Graft-versus-host disease

After bone marrow transplantation, the primary signs of *graft-versus-host disease* (GVHD) are a cutaneous rash, abnormal liver function tests, and diarrhea [206]. GVHD involving the esophagus is uncommon and, although isolated upper GI involvement may rarely occur, esophageal GVDH is usually seen in patients with severe multisystem chronic disease with both the upper and lower GI tracts affected [207–210].



(a)

(b)

Figure 37.6 An endoscopic view of Crohn's disease of the esophagus with diffuse esophageal narrowing, a prominent sinus tract, and exudative plaques **(a)**. A barium swallow from the same patient showing esophageal narrowing, mucosal irregularity, ulceration, and nodularity, and sinus tracts parallel to the esophagus **(b)**.

Symptoms of GVHD esophagitis include odynophagia, dysphagia, pyrosis, and retrosternal chest pain.

For diagnostic purposes CT is often normal, but a thickened distal esophagus may represent high-grade disease [211]. Because patients are immunosuppressed, upper endoscopy with biopsy and culture is the most sensitive way to differentiate GVHD esophagitis from opportunistic infections such as herpes simplex virus, cytomegalovirus, or *Candida* [212]. On visualization, the esophageal mucosa may appear erythematous and friable, and strictures, webs, bullae, or esophageal casts have been noted (Fig. 37.7) [207,208,213]. Recently, video capsule endoscopy has been used to image GVHD in the small intestine, but not the esophagus; however, this technique is limited because biopsies can not yet be obtained [214].

Therapy guided by hematologists specializing in bone marrow transplantation utilizes immunosuppressants such as prednisone, azathioprine, cyclosporine (ciclosporin), mycophenolate mofetil, and even infliximab [206,215,216]. Esophageal symptoms can respond to antireflux medications and to dilation of webs and strictures, although the risk of iatrogenic perforation may be increased in these patients [209].

Behçet syndrome

The constellation of oral and genital aphthous ulceration and ocular inflammation characterizes *Behçet syndrome*, which may rarely involve the esophagus [217]. It is most common in the eastern Mediterranean and in Middle Eastern and East Asian populations, primarily affecting young adults [218].

As with other esophageal processes, symptoms can include dysphagia, odynophagia, chest pain, and hematemesis. Upper endoscopy can reveal a range of findings including erosions, esophagitis, and esophageal strictures, most of which have been reported in the middle and distal esophagus [219–222]. Biopsies demonstrate ulceration with nonspecific inflammation and neutrophilic infiltration [217].

The clinical course is one of unpredictable remissions and exacerbations. Although dysphagia caused by esophageal ulcers may resolve spontaneously, corticosteroids have been reported to improve symptoms, and intestinal and esophageal ulcers have also responded to sulfasalazine and low-dose cyclosporine [217–220,223,224].

Miscellaneous autoimmune diseases

Rarely, the esophagus is involved in other systemic autoimmune diseases. Although more than half of patients with *Sjögren syndrome* complain of difficulty swallowing, dysphagia does not appear to correlate with the degree of xerostomia [225]. In up to 10% of affected patients, esophageal webs are responsible for dysphagia [226]. Data are mixed on whether dysphagia correlates with abnormalities on esophageal manometry, although heartburn is associated with reflux severity as measured by pH probe [227–229].

Primary or secondary *amyloidosis* may cause dysphagia because of amyloid deposition in the esophageal muscle or nerves. The resulting motility abnormalities can mimic achalasia [230–232]. In rare cases, amyloid deposition may predispose to spontaneous esophageal rupture [233].

The *anticardiolipin antibody syndrome* may present with esophageal vascular thrombosis and ischemic esophageal perforation or esophageal varices secondary to portal vein thrombosis [234–236].

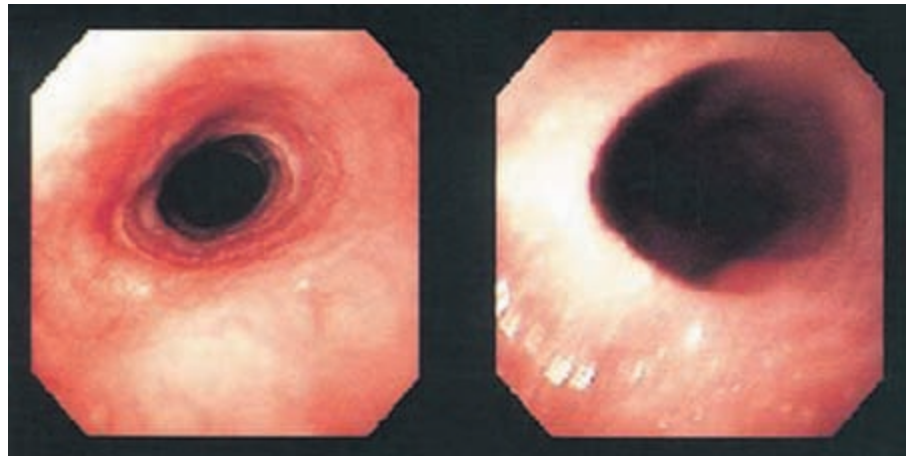


Figure 37.7 An endoscopic view of graft-versus-host disease showing multiple fine mucosal webs in the esophagus.

Dermatological diseases

Pemphigus vulgaris

The esophageal mucosa can be affected by diseases of the squamous epithelium of the skin. One example is *pemphigus vulgaris*, a chronic autoimmune blistering disease of older adults in which flaccid intraepidermal blisters and oral erosions are caused by IgG autoantibodies against desmoglein-3 in keratinocytes [237–239]. Patients may be asymptomatic, but the 50% who have esophageal involvement usually present with dysphagia or food impaction [240–242]. Isolated esophageal involvement without significant skin manifestations has rarely been reported [243,244]. On taking a history, the use of certain medications associated with pemphigus, such as thiol compounds (e.g., penicillamine), angiotensin-converting enzyme inhibitors, and antibiotics (e.g., penicillins, rifampin [rifampicin], cephalosporins), should be elicited [244].

Diagnosis requires upper endoscopy with biopsy [245]. On histopathological examination, immunohistochemistry cannot distinguish idiopathic pemphigus vulgaris from drug-induced or paraneoplastic pemphigus [239,246,247]. Therefore, serological testing for pemphigus antibodies and antidesmoglein-3 antibodies is also needed [248]. Although corticosteroids are the primary treatment modality in pemphigus vulgaris, other immunosuppressive drugs such as azathioprine, cyclophosphamide, cyclosporine, or methotrexate may be needed to induce a complete remission or to spare steroid use [239]. In severe cases, plasmapheresis has been successful [239].

Bullous pemphigoid

In contrast to pemphigus vulgaris, *bullous pemphigoid* is characterized by the presence of tense bullae on the skin of the flexor surfaces [239]. The disease is caused by IgG autoantibodies directed against the basement membrane of the squamous epithelium [239,249]. Although 20% of patients will have involvement of the oropharynx, the prevalence of esophageal bullous pemphigoid is unknown and may be underestimated because symptoms are infrequent [250]. Rarely, patients complain of dysphagia and odynophagia. Upper GI hemorrhage, scarring, mucosal sloughing, and hemorrhage are also rare [251]. Treatment with prednisone is highly effective, but azathioprine, cyclophosphamide, cyclosporine, or methotrexate have also been used [239].

Benign mucous membrane pemphigoid

Benign mucous membrane pemphigoid (BMMP), or cicatricial pemphigoid, is a chronic blistering disease of the conjunctivae, oral and genital mucosa, and adjacent areas of skin. In this disease, IgG or IgA autoantibodies are deposited in the basement membrane zone [239,252,253]. BMMP usually occurs after the sixth decade of life, producing tense blisters with scarring and strictures of the esophagus, trachea, anus, or vagina [254]. In total, 2–13% of affected patients have esophageal involvement, which can present up to 10 years into the course of disease as dysphagia, odynophagia, or chronic cough due to aspiration [255]. Rarely, patients have isolated esophageal BMMP with no other disease manifestations [256]. On endoscopy, esophageal webs or strictures may be seen (Fig. 37.8) [257]. In contrast, bullae are rarely seen endoscopically, although in one case endoscopy induced their formation [256]. Persistent dysphagia can be treated with dilation, although these patients may be at increased risk of esophageal injury [257,258]. In severe cases, BMMP requires prednisone, whereas milder cases often respond to dapsone [239,259]. Surgical treatment of strictures is rarely required [260].

Epidermolysis bullosa dystrophica

A final, and also rare, esophageal manifestation of dermatological disease is *epidermolysis bullosa dystrophica* (EBD), a blistering disease of the squamous epithelium caused by mutations in the collagen type VII gene (*COL7A1*) [261,262].

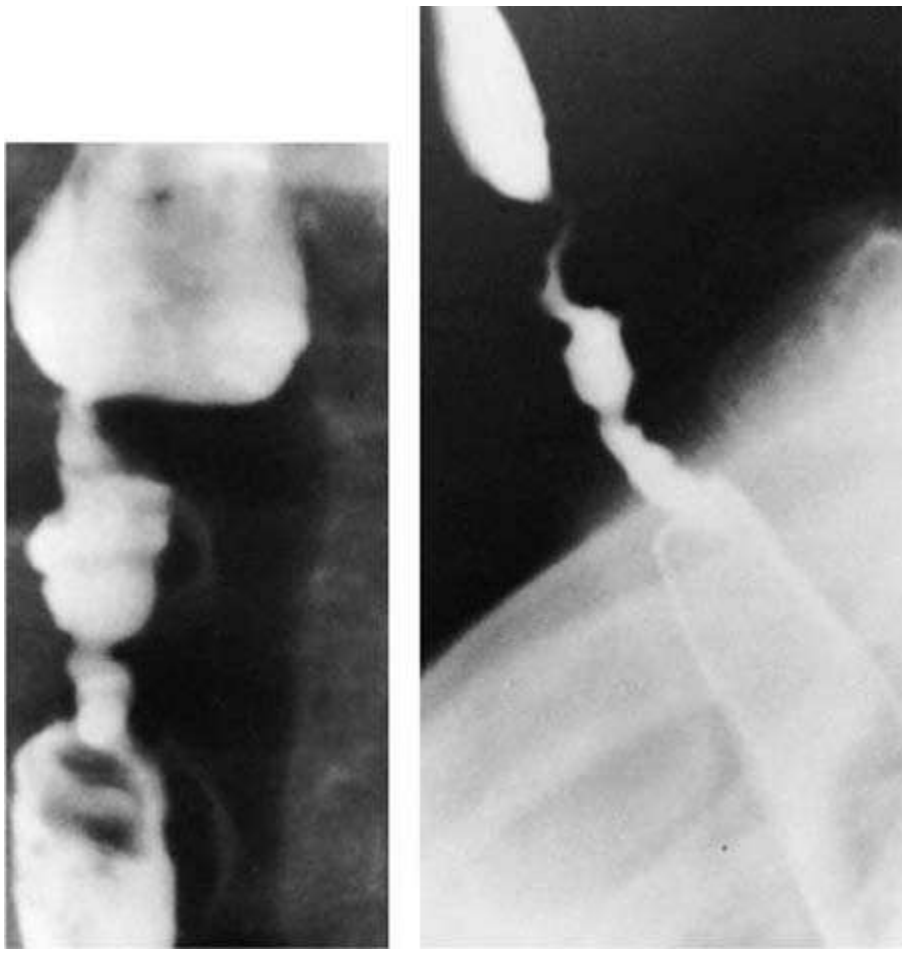

Figure 37.8 Benign mucous membrane pemphigoid. Postinflammatory scarring caused a long, irregular area of narrowing suggestive of a malignant process. From Eisenberg RL. Gastrointestinal Radiology: A Pattern Approach, 4th edn. Philadelphia, PA: Lippincott Williams & Wilkins, 2003.

Histopathologically, the basal lamina separates from the dermis because of a reduction or absence of the fibrils normally attaching these two layers [263]. Cutaneous bullae are evident beginning in early childhood and form at sites of minor trauma, especially in the hands and extremities. Over time, the cycle of chronic scarring and healing leads to contractures and syndactyly, a process termed *mummification*. Both dominant and recessive forms of this inherited disease exist, but esophageal involvement is only clinically important in the recessive form [264]. There is also an acquired form of the disease (*epidermolysis bullosa acquisita*), which causes nonscarring bullous lesions of the esophagus [265,266].

In the esophagus of patients with EBD, trauma from routine swallowing begins a cycle of bullae formation, healing, and scarring, leading to development of strictures, esophageal shortening, and dysmotility (Fig. 37.9) [267,268]. Clinically, these cause symptoms of dysphagia, odynophagia, and food impaction [267,268]. In younger patients, malnourishment is common and parenteral nutrition may be required. The constellation of esophageal symptoms and the prominent cutaneous manifestations suggest the diagnosis of epidermolysis bullosa dystrophica. In uncomplicated cases, the risk of traumatic bullae formation due to endoscopy outweighs the incremental diagnostic yield. If a diagnostic test is needed, barium esophagram can reveal strictures or webs [267,268]. Complications include esophageal perforation and occlusion due to scarring [267,268].

Treatments for EBD are limited, and when the esophagus is involved, the prognosis tends to be poor [268]. From a dietary standpoint, patients should avoid coarse or hot foods and use nutritional supplements to avoid malnutrition. Medical therapies lack efficacy, although corticosteroids or phenytoin have been used [267–269]. For endoscopic therapy of strictures, balloon dilators may be preferable to bougienage to avoid damage to friable mucosa, and a preprocedural barium swallow may help plan the procedure by assessing angulation within the stricture [270]. Because dilation carries an increased risk of esophageal trauma and perforation, fluoroscopy may be a valuable adjunct [268,271]. In patients with esophageal perforation or malnutrition from refractory esophageal stenosis, esophagectomy and conduit reconstruction may be necessary [268,269,272].

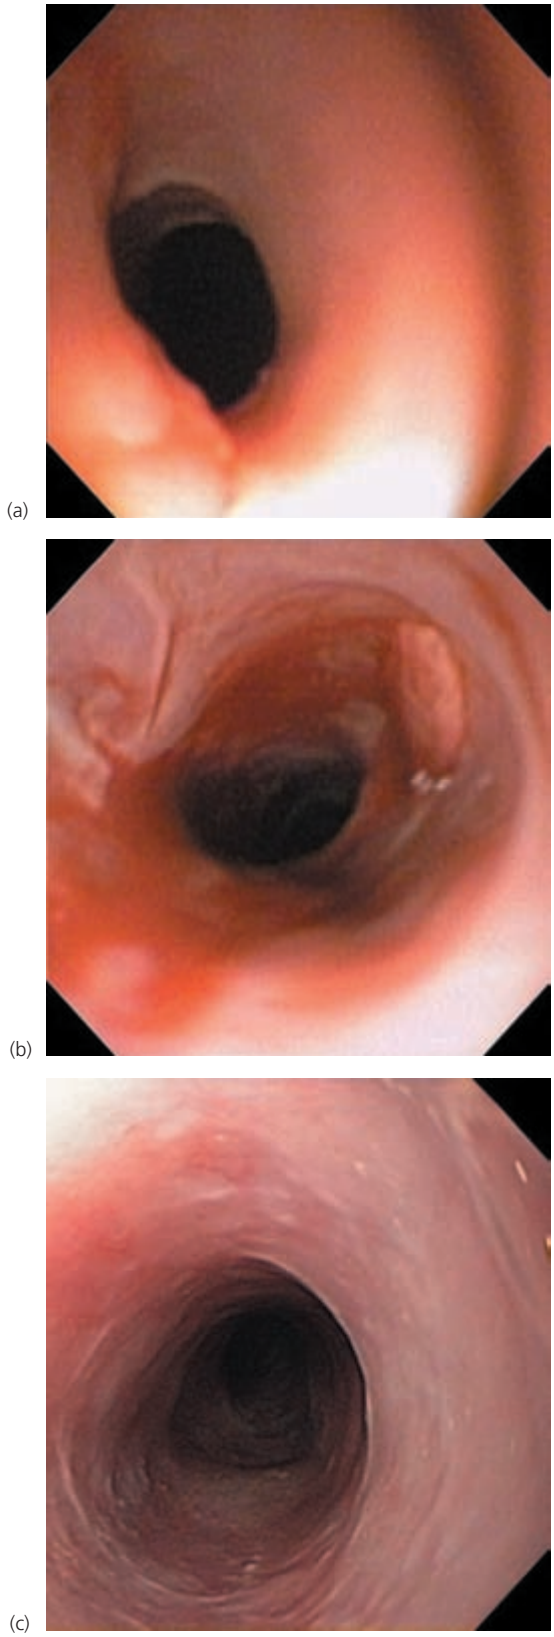

Figure 37.9 An endoscopic view of a tight esophageal stricture due to epidermolysis bullosa dystrophica before **(a)** and after **(b)** initial dilation. After multiple sessions of serial dilation, the stricture zone is much improved **(c)**.

38 Stomach and duodenum: anatomy and structural anomalies

Jean-Pierre Raufman, Eric Goldberg

Anatomy of the stomach and duodenum, 889
Embryology of the stomach and duodenum, 896
Congenital anomalies of the stomach, 896
Congenital anomalies of the duodenum, 898

Anatomy of the stomach and duodenum

The gross anatomy and microscopic anatomy of the stomach and duodenum are intrinsically linked to their functions of digestion and nutrition. The structure and organization of these organs facilitate sequential physiological events that promote the fragmentation, enzymatic digestion, and absorption of nutrients. Moreover, appropriately timed autocrine, paracrine, and hormonal secretions of gastric and duodenal endocrine cells recruit other cells and organs to aid in the digestive process. Despite advancements in our understanding of these complex integrated physiological events, which include secretory, peristaltic, and absorptive actions, much remains to be learned. In this chapter, the anatomy and structural anomalies of the stomach and duodenum are considered together because these organs are structurally and functionally related.

Gross anatomy

Anatomic relationships and divisions

The stomach, a large, distensible sac with the largest diameter of any part of the gastrointestinal tract, is located in the epigastrium, just inferior to the diaphragm (Fig. 38.1). The size and shape of the stomach vary greatly from person to person, depending on age, body habitus, posture, and interval since eating. The ability of the stomach to enlarge to accommodate meals is facilitated by its free mesentery, distensibility, and its location. Although fixed proximally to the esophagus and distally to the duodenum, and by the gastrocolic and gastrophrenic ligaments, the stomach has great latitude in distention and motion. When the stomach is nearly empty, gastric volume approximates a few hundred milliliters; when distended with food, the stomach can accommodate up to 2 L. With full distention, the stomach may extend from the diaphragm to the pelvic brim.

As a consequence of its size and central location in the abdomen, the stomach abuts many organs. These include the diaphragm superiorly, hepatobiliary organs to the right, the spleen to the left, and the pancreas and transverse colon posteriorly (Fig. 38.1). The anterior surface of the stomach abuts the abdominal wall. The stomach is separated from other abdominal organs by visceral peritoneal lining. The close proximity of the stomach to other abdominal organs such as the pancreas allows endolumenal imaging techniques such as endoscopic ultrasonography to evaluate intraabdominal viscera. Furthermore, because the anterior surface of the stomach is adjacent to the abdominal wall, percutaneous feeding tubes can be placed directly into the lumen of the stomach.

By convention, the somewhat J-shaped stomach is divided into the cardia, a 1- to 2-cm segment adjacent to the esophagogastric junction; the fundus, the superior portion of the stomach lying above and slightly posterior to the rest of the stomach; the body or corpus, the voluminous portion of the stomach below the fundus; the antrum, the distal region of the stomach; and, finally, the pylorus or pyloric channel, a narrow (1–2 cm) channel that connects the stomach to the duodenum (Fig. 38.2). The shorter right side of the stomach is the lesser curvature; the opposite, longer left side is the greater curvature. An intrusion, about two-thirds of the way along the distal lesser curvature, near the junction of the body and antrum, is designated the angular notch or incisura angularis.

The tubular, C-shaped duodenum, nestling the head of the pancreas, starts at the pylorus and extends to the ligament of Treitz, a landmark demarcating the fourth portion of the duodenum from the jejunum (Fig. 38.3). The word *duodenum* derives from its length, approximately the same as the breadth of 12 fingers (about 25–30 cm). The duodenum has no mesentery and, in contrast to the stomach, it is largely retroperitoneal and fixed in position.

Textbook of Gastroenterology, 5th edition Edited by Tadataka Yamada,

(b)

Figure 38.1 **(a)** Barium contrast radiograph of the stomach and duodenum. The pyloric channel can be seen connecting the antrum to the duodenal bulb. The second and third parts of the duodenum can be seen as well as the plicae circulares. F, fundus; B, body; A, antrum; D, duodenal bulb. **(b)** A computed tomogram of the abdomen shows the stomach in relation to adjacent organs. S, stomach; GB, gallbladder; L, liver; Sp, spleen. Courtesy of Drs Timothy Carter and Hemendra R. Shah, University of Arkansas for Medical Sciences, Little Rock, AR.

The first, or superior, part of the duodenum is about 5 cm long, starts at the pylorus, and passes posteriorly, upward, and to the right. The initial 2–3 cm of the first part is the duodenal bulb. In contrast to the rest of the duodenum, which is lined by circular folds (plicae circulares), the lining of the bulb is relatively flat. The second, or descending, part of the duodenum takes a sharp curve and descends along the head of the pancreas for 7–10 cm. The close proximity of the second portion of the duodenum to the head of the pancreas allows endoscopic ultrasonography and transduodenal biopsy of lesions in the head of the pancreas. The common bile and pancreatic ducts enter the second portion of the duodenum via the posteromedially located ampulla of Vater. The accessory pancreatic duct (Santorini) enters the duodenum approximately 2 cm proximal to the ampulla of Vater. The third, or horizontal, part of the duodenum passes from right to left across the spine, inclining upward about 5–8 cm. The fourth, or ascending part of the duodenum starts left of the spine, ascends leftward, and terminates at the ligament of Treitz, where the intestine angles anteriorly and downward as the jejunum.

Circulation

The gastric and duodenal blood supply are derived from the celiac artery and the superior mesenteric artery (SMA). Both of these vessels arise from the abdominal aorta. The short celiac artery branches to form the splenic, left gastric, and common hepatic arteries. A dense anastomotic network that encircles the stomach is formed by vessels that branch from these major arteries. These vessels include the left gastric artery, which feeds the anterior and superior portions of the stomach; the right gastric, gastroduodenal, and right gastroepiploic arteries, which arise from the hepatic artery and feed the lower right portion of the stomach and the lower greater curvature; and the short gastric and left gastroepiploic arteries, which arise from the splenic artery to feed the fundus and the upper greater curvature (Fig. 38.4). Because of the extensive anastomotic network surrounding the stomach, gastric ischemia is uncommon and generally occurs only when there are systemic aberrations in blood flow or there is gastric volvulus or previous gastric surgery.

The distal stomach, pylorus, and duodenum are supplied by the inferior pancreaticoduodenal branch of the SMA. The duodenum is also nourished by the right gastric and superior pancreaticoduodenal arteries that arise from the hepatic artery.

Venous drainage from the stomach and duodenum leads directly or indirectly to the portal vein. From the stomach, the left and right gastric veins drain the lesser curvature, and the right and left gastroepiploic and short gastric veins drain the greater curvature. From the duodenum, the anterior inferior and superior pancreaticoduodenal veins drain into the superior mesenteric vein. The posterior superior pancreaticoduodenal vein drains directly into the portal vein.

Lymphatics

The pattern of lymphatic drainage of the stomach is similar to that for its vasculature, with most lymph draining ultimately into celiac nodes. Submucosal, muscular, and serosal lymphatics join to drain into four major groups from the stomach and two from the duodenum. The first group of gastric

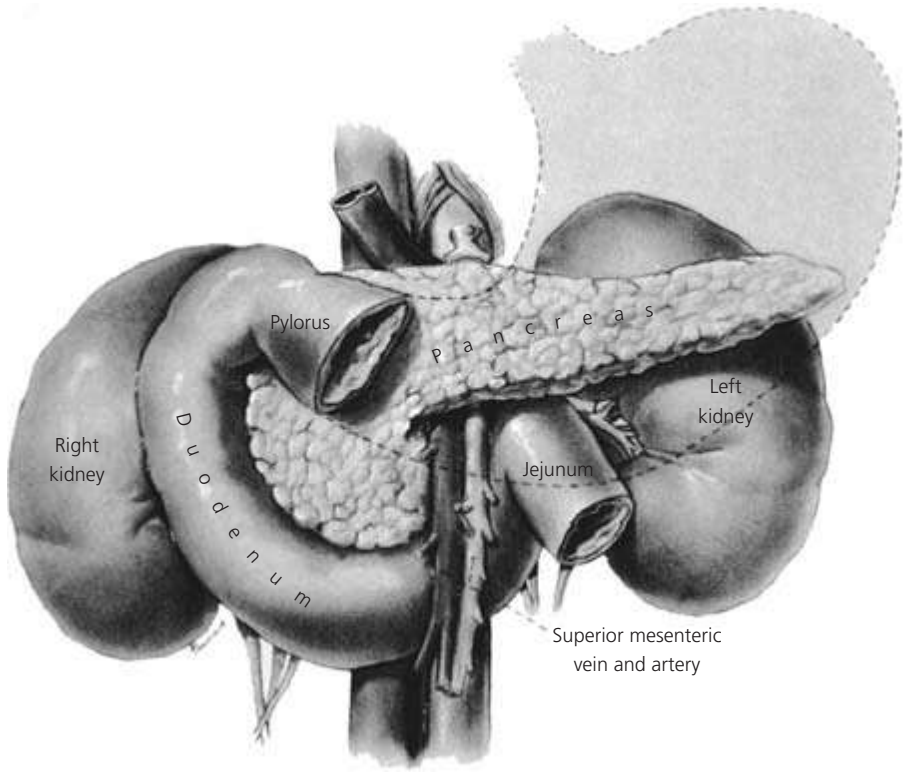

Figure 38.3 Anatomic relationships of the four parts of the duodenum to adjacent organs. The stomach is shown in outline. From Rosse C, Gaddum-Rosse P. Hollinshead's Textbook of Anatomy. Philadelphia, PA: Lippincott-Raven, 1997, with permission from Lippincott, Williams & Wilkins.

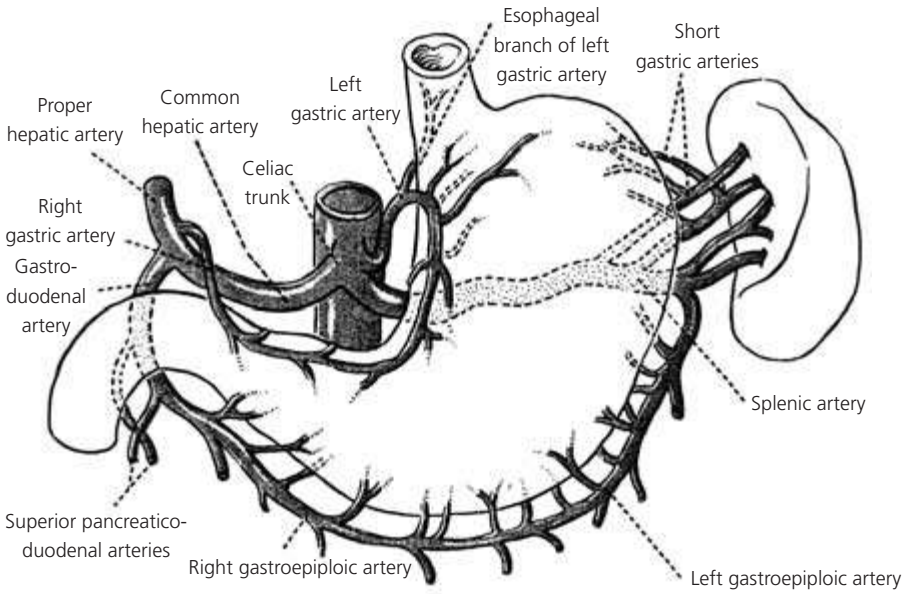

Figure 38.4 Illustration of the arterial supply of the stomach. From Rosse C, Gaddum-Rosse P. Hollinshead's Textbook of Anatomy. Philadelphia, PA: Lippincott-Raven, 1997, with permission from Lippincott, Williams & Wilkins.

lymphatics follows the left gastric artery, receives branches from the upper stomach, and ends in the superior gastric nodes surrounding the gastroesophageal junction. The second group drains the fundus and proximal stomach, follows the short gastric and left gastroepiploic arteries, and ends in the pancreaticolienal and splenic nodes, which drain into celiac nodes. The third group drains the distal greater curvature into inferior gastric nodes, which are connected to subpyloric nodes. The final group of gastric lymphatics drains the pyloric area into superior gastric, hepatic, and subpyloric nodes.

In the duodenum, anterior and posterior lymphatics drain into a series of small pancreaticoduodenal nodes near the boundary between the pancreas and duodenum. Efferents from these lymph nodes run superiorly and inferiorly to hepatic and pancreatic nodes, respectively, and to preaortic (superior mesenteric) nodes near the origin of the SMA.

Innervation

The stomach and duodenum are innervated by sympathetic and parasympathetic neurons of the autonomic nervous system. Sympathetic neuron cell bodies are located in the gray matter of the anterior columns of spinal thoracic segments T6–T12. Neural axons exit the spinal cord by the ventral roots and unite to form the greater and lesser splanchnic nerves that synapse in the celiac ganglia. Postganglionic fibers follow the hepatic, splenic, and left gastric arteries to the stomach, where they form perivascular intramural autonomic plexuses. Gastric afferent fibers follow the same course as efferent fibers; however, they pass through the celiac ganglia without synapsing, reaching cell bodies in dorsal root ganglia of the spinal cord. Afferent fibers transmit visceral pain sensation from the stomach and duodenum.

The vagus nerve, originating in the dorsal motor nucleus in the medulla, provides parasympathetic innervation to the stomach and duodenum. Vagal fibers course along the esophagus and enter the abdomen as the posterior and anterior vagal trunks. These neural trunks contain preganglionic efferent and visceral afferent fibers. Efferent fibers synapse with gastric cholinergic and peptidergic neurons in the wall of the stomach and duodenum, which innervate various cells directly. Although afferent vagal fibers predominate, little is known about their function.

After entering the abdomen at the esophageal hiatus of the diaphragm, the anterior vagal trunk divides almost immediately into anterior gastric and hepatic branches. The anterior branch innervates the cardia and provides a branch running to the right of the lesser curvature as the anterior nerve of Latarjet. The hepatic branch innervates the liver, gallbladder, pylorus, and proximal duodenum. The posterior vagal trunk divides into the celiac and posterior gastric branches. The former innervates the pancreas and other abdominal viscera. The posterior gastric branch innervates both surfaces of the stomach and forms the posterior nerve of Latarjet. The anterior and posterior nerves of Latarjet course along the lesser curvature, give off branches to the fundus and body, and terminate in a crow's foot neural distribution to the antrum and pylorus.

Preganglionic vagal fibers synapse with ganglia in the intrinsic plexuses of the gastric wall: the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus. Postganglionic fibers from these plexuses innervate secretory and muscle cells.

Microscopic anatomy

The stomach and duodenum have four tissue layers: mucosa, submucosa, muscularis propria, and serosa. The submucosa represents a connective tissue layer beneath the mucosa composed of a loose framework containing vasculature,

lymphatics, and nerves. The muscularis propria of the stomach consists of a series of three muscle layers between the submucosa and the serosa (Fig. 38.2). The oblique muscle layer overlies the submucosa. The more substantial circular muscle layer, which thickens at the pylorus to form the pyloric sphincter, is covered by an outer longitudinal muscle layer that is a feature of the muscularis propria of the entire gastrointestinal tract. The thin serosa, the outer layer of the stomach that serves as the visceral peritoneum, is composed of areolar tissue covered by a monolayer of squamous mesothelial cells.

Stomach

The gastric mucosa is divided into epithelium, lamina propria, and muscularis mucosae. At the gastroesophageal junction, the mucosal boundary between the stratified squamous epithelium of the esophagus and the glandular columnar epithelium of the stomach can be seen as an irregular line (Z-line) encircling the lumen. When the stomach is empty, the mucosa and submucosa contract into thick folds called *rugae* (see Fig. 38.2). As the stomach distends, the rugae flatten.

Gastric pits (foveolae gastricae), which serve as exit channels for underlying gastric glands, stud the gastric mucosal surface. This surface epithelium is lined by a single layer of columnar epithelial cells that extends into the gastric pits and glands. Differences in the cellular makeup of glands permits histological division of the gastric mucosa into three types, cardiac (junctional), fundic, and antral (pyloric), which differ in structure and function (Fig. 38.5). The lamina propria is an area of loose connective tissue containing strands of collagen and smooth muscle, lymphatics, blood vessels, nerves, and a variety of cells, including lymphocytes, plasma cells, mast cells, fibroblasts, macrophages, and eosinophils. The muscularis mucosae, a smooth muscle layer, forms the inferior margin of the mucosa and separates it from the submucosa, which contains dense connective tissue, arterioles, venules, lymphatics, and neural plexuses.

Proceeding from the surface epithelium into the pits, the following mucosal cells are considered in detail in the following subsections: mucous cells and mucous neck cells, which line the surface and extend into the pits, respectively; parietal cells, which secrete hydrochloric acid and intrinsic factor;

endocrine cells, which secrete a variety of hormonal mediators; and, toward the base of the pits, chief cells, which secrete pepsinogen (see Fig. 38.6) [1–3].

Mucous cells

The rectangular *mucous cells* are polarized (Fig. 38.7). Apically located mucous granules contain mucin, a neutral glycoprotein that can be stained with mucicarmine and periodic acid–Schiff. The mucous cell nucleus, Golgi complexes, and endoplasmic reticulum are located at the base of the cell. Like other columnar epithelial cells, mucous cells are attached at their apical margins by tight junction complexes and are connected by gap junctions and desmosomes at other cellular sites. Mucous neck cells are similar to the mucous cells just described, but they contain more rough endoplasmic reticulum and are found predominantly in the neck of glands and scattered deeper within glands. Because mucous neck cells contain acidic mucus (glycosaminoglycan), their granules are generally less dense than granules in surface mucous cells. Mucus is released by stimulated exocytosis; hence, the degree of granule filling depends on the stage of digestion.

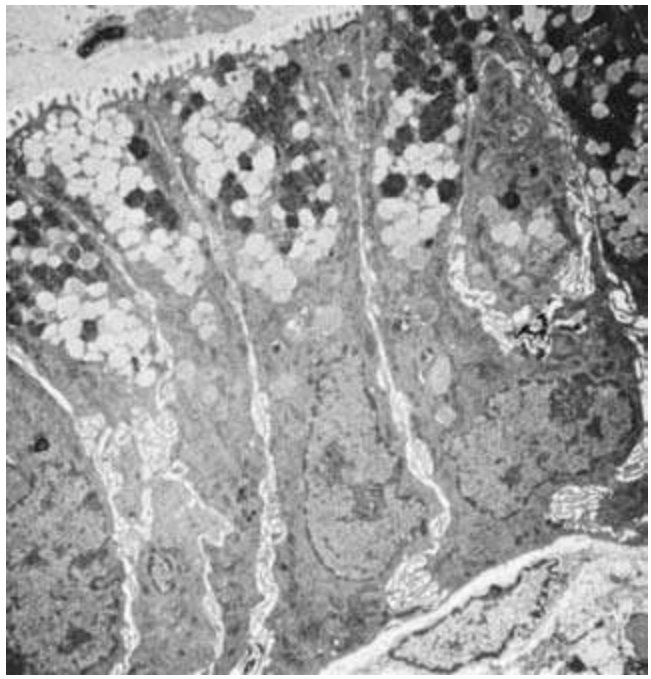

Figure 38.7 Electron micrograph (original magnification × 3200) of gastric mucous cells. Microvilli protrude from the apical surface, mucous granules fill the apical cytoplasm, and the nucleus lies near the base of the cell. From Misiewicz JJ, Forbes A, Price A, et al. Atlas of Clinical Gastroenterology. London: Wolfe, 1994, with permission from Elsevier.

Parietal (oxyntic) cells

Parietal cells, situated in the lower two-thirds of fundic-type glands, secrete hydrochloric acid and intrinsic factor (see Fig. 38.5). In glands of the fundus and body, these cells have a concentric nucleus and appear pyramidal, with the tubular apical end abutting the glandular lumen. Numerous mitochondria and tubulovesicles occupy much of the cytoplasm (Fig. 38.6a). When parietal cells are stimulated, tubulovesicles expand into microvillus-lined canaliculi that course through the cytoplasm and fuse with the apical membrane to connect with the lumen of the gastric gland (Fig. 38.6b) [4]. In unstimulated cells, H^+,K^+-ATPase, which mediates the electroneutral exchange of cytoplasmic hydronium ions for

potassium in the canalicular lumen, is found in the tubulovesicle membranes, whereas in stimulated cells this enzyme is relocated to canalicular membranes. Translocation of the proton pump and expansion of the canaliculi are necessary for the acid-secreting function of parietal cells.

Chief cells

Chief cells, found predominantly in the lower one-third of gastric glands (see Fig. 38.5), secrete the proenzyme pepsinogen, which is hydrolyzed in an acid environment to the acid protease pepsin. Chief cells are polar, with apically located dense pepsinogen-containing secretory granules. The basal pole contains granular endoplasmic reticulum, the nucleus, and prominent Golgi complexes (Fig. 38.8). When chief cells are stimulated, the zymogen granules migrate to the apical pole, fuse with the cell membrane, and release their contents into the lumen of the gastric gland by exocytosis.

Endocrine cells

Enterochromaffin-like (ECL) cells are small, irregularly shaped cells scattered near parietal cells in fundic-type gastric glands. ECL cells, which do not connect with the lumen of the glands, are packed with histamine-containing granules. Histamine release from ECL cells regulates parietal cell function [5].

G cells, located in the midportions of antral glands and in duodenal crypts, are characterized by a broad base resting against the basement membrane that runs beneath the epithelium [6]. Dense secretory granules containing gastrin cluster near the base. A narrow apex extends to the lumen of the gland. In response to stimuli associated with eating, such as vagal stimulation, antral distention, and the lumenal presence of aromatic amino acids, G cells secrete the hormone gastrin.

D cells, located in fundic and antral glands, contain the inhibitory peptide somatostatin. These cells have neuron-like extensions that terminate near other gastric mucosal cells, particularly G cells, ECL cells, parietal cells, and chief cells. Inhibitory actions of D cells are mediated by paracrine actions of somatostatin released from these extensions [7].

Duodenum

In the pylorus, the mucosal pattern changes from pits and glands (typical of gastric mucosa) to villi and crypts (typical of intestinal mucosa) [8]. From the proximal to distal duodenum, the villi become progressively taller and thinner until a ratio of villus to crypt of 4:1 or 5:1, characteristic of jejunal mucosa, is achieved. A monolayer of epithelial cells, consisting of absorptive, mucous, Paneth, and endocrine cells, covers the villi and lines the crypts. The lamina propria, composed of loose connective tissue, contains lymphatics (lacteals), blood vessels, nerves, and smooth muscle fibers, as well as varying numbers of plasma and mast cells, lymphocytes, fibroblasts, macrophages, and eosinophils. The muscularis mucosae lies below and perpendicular to the crypts.

The submucosa of the duodenum provides a connective tissue framework for blood vessels, lymphatics, and nerves, and contains Brunner glands that secrete alkaline mucus. Brunner glands extend through the muscularis mucosae, occupy part of the mucosa, and empty into the crypts. The muscularis propria consists of a layer of inner circular fibers surrounded by a layer of fibers arranged longitudinally. The myenteric plexus is located between these muscle layers.

Cellular interactions

The juxtaposition of secretory cells and neurons in the stomach and duodenum is crucial for their physiological interactions that regulate digestion. For example, in the fundus and body, ECL cells, D cells, and cholinergic neurons must be sufficiently close to parietal cells to allow paracrine secretory products, such as histamine, somatostatin, and acetylcholine, to reach receptors on the acid-secreting cells [5]. Likewise, in the antrum, the interplay among neurons containing gastrin-releasing peptide and vasoactive intestinal polypeptide, histamine-containing mast cells, somatostatin-containing D cells, and gastrin-containing G cells requires physical proximity [7].

Cellular renewal

Gastric and duodenal mucosal epithelial cells undergo continuous, rapid renewal, a process involving proliferation, migration, differentiation, senescence, and loss of epithelial cells [9]. To replace surface mucous cells, nascent cells migrate upward from the base of the gastric pits or duodenal crypts to the mucosal surface or villous tip. In humans, migration of basal cells to the surface takes 2–6 days [10,11]. In contrast, parietal and chief cells are replaced by cells in the upper proliferative zone of gastric glands, possibly mucous

neck cells, a process that takes weeks to months. Senescent gastric or duodenal mucosal cells are sloughed into the lumen.

Aspirin, indomethacin (indometacin), and ethanol stimulate epithelial proliferation, perhaps by causing mild injury [12–17]. Epithelial proliferation is also increased by chronic inflammation, as in chronic superficial gastritis caused by *Helicobacter pylori* infection, gastric atrophy associated with pernicious anemia, and other hypergastrinemic states, such as Zollinger–Ellison syndrome [18]. In these conditions, the zone of proliferating cells is expanded. In contrast, corticosteroids and physiological stress, such as water immersion and restraint in rats, suppress epithelial proliferation [15]. Prostaglandins appear to delay senescence and loss of epithelial cells [19]. The resulting mucosal thickening contributes to the cytoprotective effects of prostaglandins.

Embryology of the stomach and duodenum

The primitive stomach and proximal duodenum derive from the foregut caudal to the developing lung, whereas the duodenum distal to the ampulla of Vater derives from the cephalic end of the midgut [20,21]. After the fourth week of intrauterine development, the primitive stomach rotates 90° clockwise around its longitudinal axis, ending with the left side facing anteriorly and the right side posteriorly [22]. This accounts for the course of the left vagus along the anterior wall and the right vagus along the posterior wall. The left wall of the stomach grows faster than the right, resulting in the size difference between the curvatures. The dorsal mesentery, which attaches the stomach to the posterior body wall, forms the omental bursa, or lesser peritoneal sac. The ventral mesentery attaches the stomach and duodenum to the liver.

As the stomach grows and rotates, the cephalic end moves leftward and downward, forming the fundus and cardia. The caudal end moves upward and to the right, forming the antrum and pylorus. Hence, the long axis of the stomach runs from above left to below right.

The duodenum also grows rapidly, forms a C-loop projecting ventrally, rotates to the right, and becomes retroperitoneal. Because of rapid epithelial proliferation during the fifth and sixth gestational weeks, the duodenal lumen is temporarily obliterated. The duodenal lumen recanalizes over the ensuing weeks as some cells degenerate.

The epithelium and glands of the stomach and duodenum derive from the embryonic endoderm. The connective tissue, muscle, and serosa derive from the mesoderm.

Congenital anomalies of the stomach

Atresia

Gastric atresia results in a blind end in the antrum or pylorus. Atresia may involve only the mucosa and submucosa, with normal muscle and serosa, or it may involve the entire gastroduodenal wall. Atresia probably results from failure of the antrum and pylorus to recanalize after transient occlusion by epithelium during embryogenesis. Complete atresia is familial, with autosomal recessive transmission [23]. Complete pyloric atresia may be associated with junctional epidermolysis bullosa.

Symptoms of gastric atresia in the newborn include persistent, nonbilious vomiting, upper abdominal distention, dehydration, and hypochloremic, hypokalemic metabolic alkalosis. Gastric rupture may occur. Diagnostic abdominal radiographs demonstrate gaseous gastric distention without intestinal gas.

Initial therapy includes nasogastric suction and fluid resuscitation. Surgical treatment of a short atretic segment involving only the mucosa requires resection of the membrane and pyloroplasty. Extensive atretic segments require resection with gastroduodenostomy. Gastrojejunostomy should be avoided because, in the absence of vagotomy, peptic stomal ulceration may occur. Careful exploration must exclude unsuspected distal atresias.

Mucosal membranes

Congenital mucosal membranes, which are probably related to atresias, occur in the antrum or pylorus and generally encircle, but do not occlude, the lumen. The membrane may contain either squamous or columnar epithelium. Peptic ulceration can result in acquired membranes. Vomiting may occur in infancy, but symptoms usually develop in late childhood or adulthood.

Plain abdominal radiographs usually appear normal, but barium studies reveal a band-like defect in the prepyloric antrum. Gastric emptying may be slowed, and the antrum between the mucosal membrane and the pylorus may simulate a second duodenal bulb. Endoscopic lysis of membranes may be effective, thereby obviating surgical repair [24].

Gastric duplication

Gastric duplications, containing mucosa, submucosa, and muscle, usually involve the greater curvature and share a common wall, but they are separate from the main lumen of the stomach. They sometimes connect with the gastrointestinal tract, usually the stomach or pancreas. Gastric duplications vary tremendously in size, occur more commonly in girls, and may coexist with other duplications of the digestive tract.

Patients usually present in the first year of life. Symptoms depend on size, location, and the presence or absence of communication with the gastrointestinal tract. Small children may present with vomiting, failure to thrive, and weight loss. Projectile vomiting may mimic pyloric stenosis. In older children, epigastric pain, abdominal fullness or mass, gastrointestinal bleeding, or symptoms of gastric obstruction may occur. Rarely, peritonitis results from cyst perforation, hemoptysis results from fistulation to the lung, or cancer

develops in the duplication [25]. Barium radiography, ultrasonography, computed tomography (CT) or magnetic resonance imaging may demonstrate the anomaly. Complete surgical excision may not be feasible if a large part of the gastric wall is involved. Partial excision, partial gastrectomy, and cyst gastrostomy are options.

Microgastria

Microgastria represents a rare failure of the stomach to enlarge after its development from the foregut. The structure becomes tubular, with a small capacity. Esophageal dilation may provide some storage area, but patients with microgastria generally present soon after birth with vomiting, diarrhea, aspiration pneumonia, malnutrition, and anemia. Microgastria is associated with developmental cardiac abnormalities, upper limb and spinal deformities, micrognathia, and asplenia [26,27]. Many patients die within weeks to months. Supportive treatment requires frequent, small, high-caloric feedings and parenteral alimentation. If the child survives, surgical formation of a jejunal reservoir should be attempted, but anastomotic ulcers may occur [28].

Gastric teratoma

These congenital tumors contain all three primary embryonic germ layers. They can occur anywhere, but are rare in the stomach. *Gastric teratomas* may cause gastrointestinal bleeding, obstruction, or an upper abdominal mass, and occur almost exclusively in male patients. Although usually diagnosed in children, gastric teratomas may not be discovered until adulthood.

Plain abdominal radiographs may show calcified teeth or bone in the tumor, and barium contrast or CT studies confirm a gastric mass. The large size of these teratomas may require total gastrectomy and formation of a jejunal pouch [29]. Gastric teratomas are not associated with other congenital anomalies, and the prognosis is good [30].

Gastric diverticula

Congenital *gastric diverticula* are rare, comprise all layers of the gastric wall, and arise primarily from the posterior gastric wall near the gastroesophageal junction. Gastric diverticula may also be found in the antrum and pylorus. They may be associated with ectopic pancreatic tissue, hiatus hernia, and diverticula in another part of the gastrointestinal tract. Ectopic pancreatic tissue, or pancreatic rests, may occur in the mucosa or submucosa of the duodenum or stomach and may mimic tumors, or they may ulcerate and bleed. Acquired diverticula may result from the scarring and dilation that accompany peptic ulceration, intestinal obstruction, cancer, or gastric surgery.

Gastric diverticula are commonly asymptomatic and are discovered as incidental findings on endoscopy or imaging studies [31]. These must be distinguished from acquired false diverticula, peptic ulcers, ulcerated neoplasms, and prominent folds [32]. Occasionally, epigastric or chest pain, heartburn, and vomiting may be reported. Severe symptoms or, rarely, bleeding and perforation require surgical excision and closure of the defect.

Ectopic gastric mucosa

Rests of *ectopic gastric mucosa* can be found in any part of the gastrointestinal tract and may cause ulceration, obstruction, or bleeding. In the upper esophagus, this condition has been reported in as many as 5% of people [33]. In the small intestine, colon, and rectum, ectopic gastric mucosa may form bleeding masses resembling polyps [34,35]. Meckel diverticula in the distal ileum may contain gastric mucosa with acid-secreting parietal cells that cause ulceration and bleeding in children and young adults [36].

Hypertrophic pyloric stenosis

Neonates

In *neonatal hypertrophic pyloric stenosis*, a congenital condition, muscular hypertrophy and mucosal edema of the pylorus result in gastric outlet obstruction. This disorder, the most common indication for surgery during the first 6 months of life, is more frequent in boys (1 case per 150 births) than in girls (1 case per 750 births) [37]. It has a genetic basis, clusters in families, and is more common in white populations than in other races. Although the cause is unknown, lack of nitric oxide synthase in pyloric tissue may contribute to pylorospasm [38,39]. Cases cluster in families and can be associated with other disorders, including maternal myasthenia gravis, fetal rubella, phenylketonuria, Hirschsprung disease, Turner syndrome, Smith–Lemli–Opitz syndrome, Cornelia de Lange Amsterdam dwarf syndrome, and esophageal atresia [37].

Although the symptoms of pyloric stenosis, particularly regurgitation and nonbilious projectile vomiting, typically do not occur until 3–4 weeks after birth, up to 20% of infants may become symptomatic earlier [37]. Vomiting may occur immediately after eating or may be delayed until the stomach is full. The vomitus is classically nonbilious, but may contain blood. Despite vomiting, the infant remains hungry until malnutrition and weakness cause interest in feeding to wane. Decreased delivery of food and fluid to the intestines results in constipation, oliguria, and failure to thrive.

The baby generally appears thin, weak, and dehydrated. Abdominal examination is likely to reveal gastric dilation, visible gastric peristalsis, and a palpable pyloric mass. Whereas gastric dilation and visible peristalsis are more evident during feeding, the olive-like pyloric mass is more likely to be palpable immediately after vomiting, when the abdominal wall is more flaccid.

Typically, upright radiographs demonstrate a large gastric air bubble with little or no intestinal air. In most cases, the detection of an "olive" on physical examination in babies with typical symptoms is sufficient for diagnosis [40]. If

Figure 38.9 Barium contrast upper gastrointestinal series shows the long, narrow, double channel of the pylorus (arrows) in a patient with hypertrophic pyloric stenosis.

further testing is needed, barium radiography appears to be the most cost-effective [41]. It may show a long, narrow pyloric channel, giving the appearance of a double channel, and a mass effect that indents the prepyloric antrum and duodenal bulb (Fig. 38.9).

Initial therapy, before surgery is considered, requires replacement of fluid and electrolytes, as well as correction of the alkalosis resulting from repeated vomiting. Definitive therapy is surgical. The preferred operation is Ramstedt pyloromyotomy: longitudinal division of the anterior pyloric muscle from the serosa to the submucosa. Mild vomiting may persist, but symptoms usually disappear within several days. After surgical correction of the defect, growth and development are normal, and long-term results are excellent.

Adults

Rarely, congenital hypertrophic pyloric stenosis may not present until adulthood. In adults, however, most cases of pyloric stenosis are acquired and result from chronic peptic ulcer disease, severe gastritis, or cancer involving the pyloric area.

In adults with congenital pyloric stenosis, common symptoms, usually dating from infancy, include early satiety, nausea, vomiting, epigastric pain, weight loss, and anorexia. The diagnosis is generally delayed, in part because physical findings observed in infants, such as a pyloric mass, are not present. Imaging may reveal gastric dilation, delayed emptying, and a long, narrow pyloric channel. Endoscopic dilation or surgical pyloromyotomy may be therapeutic, but, to exclude a small focus of cancer, pyloric resection with gastroduodenostomy may be preferable [42].

Congenital anomalies of the duodenum

Atresias, stenosis, and membranes

The duodenal lumen is obliterated by epithelium during the fifth to sixth weeks of development. *Duodenal atresia, stenosis and membranes* likely result from subsequent failure of the lumen to recanalize. This rare cause of duodenal obstruction occurs distal to the ampulla in 80% of cases, has no sexual or racial predilection, and is frequently associated with other congenital anomalies, including Down syndrome, intestinal malrotation, tracheoesophageal fistula, annular pancreas, cardiac and renal anomalies, and anorectal malformations.

In newborns with compete obstruction caused by a duodenal membrane or atresia, vomiting develops within hours to days after birth. The vomitus is nonbilious if obstruction is proximal to the ampulla and generally indistinguishable from that associated with pyloric stenosis. With partial obstruction, symptoms may be delayed and less severe. Rarely, duodenal membranes that persist or develop in adulthood cause upper abdominal distention, vomiting, and weight loss.

When obstruction is distal to the duodenal bulb, plain abdominal radiography or ultrasonography shows a double bubble, caused by a distended stomach and duodenal bulb (Fig. 38.10) [43]. The absence of distal intestinal gas suggests complete obstruction.

Initial treatment consists of nasogastric suction, with fluid and electrolyte repletion. Definitive treatment is surgical, with gastrojejunostomy or duodenojejunostomy, depending on the level of obstruction [44]. At surgery, other correctable anomalies should be sought, as the prognosis usually depends on the outcome of associated anomalies. In adults, endoscopic lysis of duodenal membranes may be successful [45,46].

Annular pancreas

Annular pancreas is a rare condition that affects the sexes equally and may result in complete or partial obstruction of the second part of the duodenum [47]. The cause is unknown but probably involves incomplete migration of the ventral pancreatic bud during embryogenesis. This results in a pancreatic remnant within the duodenal wall or pancreatic encirclement of the duodenum. Annular pancreas is associated with intestinal malrotation, Down syndrome, facial cleft, imperforate anus, and cardiac and tracheoesophageal malformations [48].

Neonates present with intractable vomiting. Children or young adults have abdominal pain and distention with less

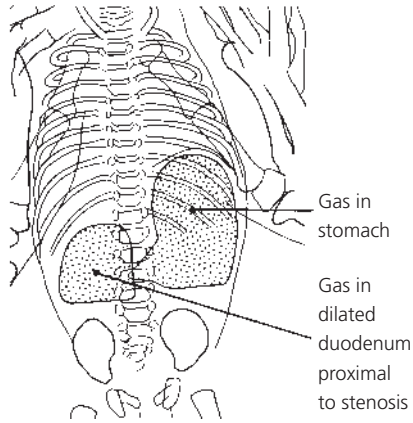

Figure 38.10 Plain abdominal radiograph in an infant with duodenal atresia shows the double bubble sign. The stomach and the proximal duodenum are distended with air. From Misiewicz JJ, Forbes A, Price A, et al. Atlas of Clinical Gastroenterology. London: Wolfe, 1994, with permission from Elsevier.

dramatic vomiting. The clinical presentation and plain abdominal radiographs are similar to those for duodenal obstruction caused by duodenal atresia, including a double bubble sign. Imaging and endoscopy confirm the level of duodenal obstruction and may establish the diagnosis (Fig. 38.11). In adults, endoscopic retrograde cholangiopancreatography can establish the diagnosis if the duct from the annular pancreas joins the main pancreatic duct. Endoscopic ultrasonography can also diagnose annular pancreas by identifying bands of pancreatic tissue encircling the duodenum [49]. Impaired pancreatic ductal flow may result in acute or chronic pancreatitis.

Treatment includes nasogastric decompression and correction of fluid and electrolyte disturbances. Resection or division of the annular pancreatic segment may cause pancreatitis or pancreatic fistula and should not be performed. Definitive therapy requires duodenostomy or duodenojejunostomy. Laparoscopic gastrojejunostomy has also been reported to treat annular pancreas in adults [50]. Surgical results are good, and long-term prognosis depends on the outcomes of associated anomalies.

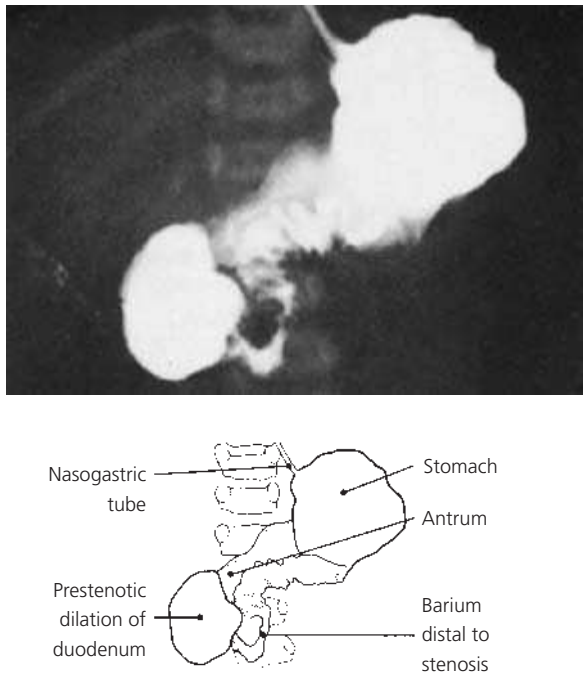

Figure 38.11 Barium contrast upper gastrointestinal series shows partial occlusion of the second part of the duodenum, consistent with annular pancreas, duodenal atresia, or other causes of duodenal obstruction. From Misiewicz JJ, Forbes A, Price A, et al. Atlas of Clinical Gastroenterology. London: Wolfe, 1994, with permission from Elsevier.

Duplication

Duplications are cystic or tubular malformations that contain all layers of the normal duodenum and which may communicate with the main lumen. Intestinal obstruction may occur secondary to compression by a mass effect with resulting symptoms of upper abdominal distention, early satiety, and vomiting. Duodenal duplications may ulcerate, bleed and, rarely, perforate into the head of the pancreas causing pancreatitis [51,52]. Diagnosis can be established by ultrasonography, contrast radiography, or CT. Treatment is surgical, and the approach depends on the relationship of the cyst to the biliary and pancreatic ducts, as well as the vasculature. If total resection is not possible, cystenterostomy may suffice.

Malrotation

In children, *intestinal malrotation* is the most common cause of duodenal obstruction [53]. This may occur in utero if the

duodenojejunal loop does not rotate normally around the SMA and the duodenum fails to complete its rotation. Consequently, the ligament of Treitz may be situated to the right, rather than to the left, of midline, thereby kinking the duodenum. If the cecum fails to rotate completely into the right lower abdomen or when the hepatic flexure lies medial to the duodenum, mesenteric bands may compress the second or third parts of the duodenum. Other developmental anomalies, such as duodenal atresia, annular pancreas, or Hirschsprung disease, are present in 30%–60% of patients with intestinal malrotation.

Patients with malrotation present within the first few weeks of life with bilious vomiting and abdominal distention. Intestinal peristalsis may be visible on the abdominal wall. Occasionally, lax mesentery results in intestinal or cecal volvulus. If the vasculature is twisted, intestinal ischemia can result in bleeding, perforation, peritonitis, and sepsis. A few patients with malrotation present later in life with weight loss, hypoproteinemia, chylous ascites, increased susceptibility to infection, intermittent postprandial vomiting, and abdominal distention.

Plain abdominal radiographs demonstrate a large gastric air bubble and distended duodenum proximal to the obstruction. An upper gastrointestinal series can confirm the obstruction and, if barium is able to pass this area, may identify the type and extent of malrotation. Ultrasonography may reveal obstruction or volvulus caused by malrotation in utero.

Treatment is surgical: division of obstructing bands, resection of infarcted bowel, and fixation of the cecum to prevent further episodes of volvulus. When extensive bowel resection is required, mortality approaches 20%, and survivors may develop short bowel syndrome with profound malabsorption requiring long-term parenteral alimentation.

Superior mesenteric artery syndrome

Rarely, the SMA obstructs the third portion of the duodenum by compressing it against fixed retroperitoneal structures, particularly the spine. Although *SMA syndrome* has been attributed to an acute angle between this vessel and the aorta, thereby trapping the duodenum, the exact cause is unknown. This syndrome has also been associated with rapid childhood growth, major weight loss in adults, immobilization in a cast that increases lordosis and accentuates the angle of the SMA with the aorta, abdominal surgery, and inflammatory diseases of the abdomen [54,55].

Symptoms are nonspecific, and documenting SMA compression of the duodenum as the cause is difficult. Symptoms, including episodic epigastric pain associated with vomiting, may be acute or chronic, sometimes lasting many years.

In adults, plain abdominal radiographs are usually unremarkable, but in children a double bubble sign may be seen (see Fig. 38.10). Upper gastrointestinal contrast studies may show dilation behind an abrupt cutoff in the third portion of the duodenum (see Fig. 38.11). On abdominal angiography, lateral views may show the narrowed angle of the SMA with the aorta. It is important to exclude other causes of abdominal pain before making this diagnosis.

Medical therapy includes small feedings or a liquid diet. Patients may benefit from lying prone or on their left side postprandially. In some cases, weight gain or removal of a body cast improves symptoms. Laparoscopic lysis of the ligament of Treitz has been reported to be beneficial in a few cases [56]. Duodenojejunostomy is required in refractory cases.

Preduodenal portal vein

A *preduodenal portal vein*, sometimes associated with a preduodenal common bile duct, can obstruct the duodenum. Only about 50 cases have been reported. In early embryonic life, both retroduodenal and preduodenal veins drain the primitive gut. The preduodenal vein usually atrophies, leaving a normal retroduodenal portal vein. When the retroduodenal branch atrophies, the preduodenal vein remains patent and may compress the duodenum. A preduodenal vein is

Figure 38.12 Barium contrast upper gastrointestinal series shows two large diverticula arising from the medial border of the descending duodenum. From Misiewicz JJ, Forbes A, Price A, et al. Atlas of Clinical Gastroenterology. London: Wolfe, 1994, with permission from Elsevier.

associated with other congenital malformations, such as duodenal stenosis or atresia, annular pancreas, intestinal malrotation, and biliary tract abnormalities [57].

Duodenal diverticula

Congenital *duodenal diverticula* occur within a few centimeters of the ampulla of Vater (Fig. 38.12) [58]. The ampulla may empty directly into the diverticulum. These diverticula are usually asymptomatic, incidental findings on imaging or endoscopy. Rarely, duodenal diverticula obstruct the common bile duct by external compression on the duct or distortion of its entry into the duodenum. Most cases of biliary obstruction associated with a duodenal diverticulum result from another cause, such as an obstructing common bile duct stone or neoplasm. A symptomatic diverticulum is best treated by choledochoduodenostomy or jejunostomy with Roux-en-Y anastomosis, rather than excision of the diverticulum.

39 Disorders of gastric emptying

Henry P. Parkman, Frank K. Friedenberg, Robert S. Fisher

Delayed gastric emptying (gastroparesis), 903
Disorders with rapid gastric emptying, 923
Functional dyspepsia, 925
Summary, 928

Gastric motility disorders include delayed gastric emptying (gastroparesis), rapid gastric emptying (as seen in dumping syndrome), and disorders with motor and sensory abnormalities (e.g., functional dyspepsia). Each disorder can present with a spectrum of symptoms that may be mild to severe and incapacitating. Evaluation of patients with possible gastric motility disorders may include gastric emptying scintigraphy, antroduodenal manometry, electrogastrography (EGG), and possibly tests of gastric accommodation or compliance (satiety testing). Evaluation may help to understand the underlying pathophysiology and guide treatment. Management of these patients requires an understanding of the pathophysiology, clinical tests, and treatment options.

Delayed gastric emptying (gastroparesis)

Symptoms and clinical presentation

Gastroparesis is a chronic motility disorder of the stomach characterized by symptoms of delayed gastric emptying in the absence of mechanical obstruction. The clinical presentation of gastroparesis may vary. Symptoms include nausea, vomiting, early satiety, bloating, and upper abdominal discomfort. Late postprandial vomiting of undigested food is typical. In 146 patients with gastroparesis, nausea was present in 92%, vomiting in 84%, abdominal bloating in 75%, early satiety in 60%, and abdominal pain in 46% [1]. These symptoms, however, are nonspecific and may mimic structural disorders such as ulcer disease, partial gastric or small bowel obstruction, gastric cancer, and gallbladder or pancreatic disorders [2]. At times, vomiting can be difficult to distinguish from the regurgitation of gastroesophageal reflux disease (GERD) or rumination syndrome.

There is an overlap of symptoms of gastroparesis and functional dyspepsia. Abdominal pain or discomfort is present to varying degrees in patients with gastroparesis, but it is not usually the predominant symptom. Abdominal pain is generally described as burning, vague, or crampy [3]. In diabetic gastroparesis, abdominal pain may represent a visceral equivalent of autonomic neuropathy. Pain in gastroparesis responds poorly to prokinetic agents and gastric electrical stimulation [3]. Visceral hypersensitivity to gastric distention has been suggested as a cause of pain in gastroparesis, analogous to that described in functional dyspepsia [4,5].

Symptoms that suggest delayed gastric emptying are primarily postprandial fullness, nausea, and vomiting [6,7]. In patients with diabetes, symptoms that have been associated with delayed gastric emptying are abdominal bloating/fullness and upper abdominal pain [8,9]. Some studies, however, have shown a poor correlation between gastric emptying and the severity of gastric symptoms [8–10].

Symptoms of gastroparesis may be quantified by a validated symptom questionnaire, the Gastroparesis Cardinal Symptom Index (GCSI) [11,12]. The GCSI is based on three subscales (postprandial fullness/early satiety, nausea/vomiting, and bloating) and represents a subset of the longer Patient Assessment of Upper Gastrointestinal Disorders–Symptoms (PAGI-SYM), which quantifies symptoms of gastroparesis, dyspepsia, and GERD [13].

Most gastroparetic patients are women. In the series of Soykan et al. [1], 82% of patients were female. Female gender and the luteal phase of the menstrual cycle have been associated with slower gastric emptying [14,15], thought to result from reduced gastric muscle contractility caused by female reproductive hormones, primarily progesterone. In the study by Stanghellini et al. [6] of functional dyspepsia, female gender was an independent risk factor for delayed gastric emptying.

Evaluation of patients with suspected gastroparesis

Gastroparesis is diagnosed by demonstrating delayed gastric emptying in a symptomatic patient after exclusion of mechanical obstruction by endoscopy or upper gastrointestinal (GI) series (Table 39.1).

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

Table 39.1 Evaluation of patients suspected to have gastroparesis

1 Initial investigation
a History and physical examination
b Blood tests
  i Complete blood count
  ii Complete metabolic profile including glucose, potassium, creatinine, total protein, albumin, calcium
  iii Amylase if abdominal pain is a significant symptom
  iv Pregnancy test if appropriate
c Abdominal obstruction series if vomiting or pain is acute or severe
2 Evaluate for organic disorders
a Upper endoscopy to evaluate for mechanical obstruction or mucosal lesions (alternative: barium upper gastrointestinal series, often with small bowel follow-through)
b Biliary ultrasound if abdominal pain is a significant symptom
3 Evaluate for delayed gastric emptying
a Solid phase gastric emptying test
b Screen for secondary causes of gastroparesis
  i Thyroid function tests
  ii Antinuclear antibody
  iii Glycosylated hemoglobin
4 Treatment trial with prokinetic agent or antiemetic agent
5 If no clinical response, consider further investigation
a Electrogastrography
b Antroduodenal manometry
c Small bowel evaluation with enteroclysis

The first step in the evaluation is taking a careful history. Understanding the patient's symptoms should lead to a clinical suspicion of gastroparesis. Typical symptoms in a young female patient may suggest idiopathic gastroparesis, just as typical symptoms in a patient with long-standing insulin-dependent diabetes should suggest diabetic gastroparesis. After abdominal surgery, patients can develop delayed gastric emptying, especially if the vagus nerve has been cut or damaged. On physical examination, a succussion splash, detected by auscultation over the epigastrium while moving the patient from side to side, indicates excessive fluid in the stomach from gastroparesis or mechanical gastric outlet obstruction [16]. Dehydration and weight loss suggest chronic and severe symptoms.

The second step in evaluating gastroparesis is to exclude mechanical obstruction or ulcers by performing an upper endoscopy or upper GI series. Endoscopy is more sensitive for detection of mucosal lesions [16]. Mechanical gastric outlet obstruction can be caused by pyloric stenosis, an active duodenal, pyloric channel, or prepyloric ulcer, scarring from previous ulcers, or neoplasia of the stomach. Gastroparesis is also suggested on endoscopy by the presence of food particles in the stomach after an overnight fast. In severe gastroparesis, bezoars may occur.

Double-contrast techniques have increased the sensitivity of radiological studies. When an upper GI series is ordered, a small bowel follow-through (SBFT) can look for small bowel lesions. The SBFT is accurate for detection of high-grade small bowel obstruction and usually provides an adequate assessment of the terminal ileum. However, it may fail to detect low-grade obstruction and smaller mucosal lesions. A SBFT may occasionally suggest superior mesenteric artery syndrome as a possible cause. Enteroclysis (small bowel enema) can be obtained after placement of a nasoduodenal or oroduodenal tube. Compared with SBFT, enteroclysis is more accurate in detecting small intestinal mucosal lesions, mild to intermediate grades of obstruction, and small bowel cancers [17]. Computed tomographic scanning with oral and intravenous contrast may also be useful for detection and localization of intestinal obstruction.

The third step is to obtain a gastric emptying scintigraphy using a radiolabeled solid meal. Patients should discontinue medications that may affect gastric emptying for 48 h before this test (Table 39.2). In general, the main medications that delay gastric emptying are narcotic analgesic agents and anticholinergic agents. The main medications that accelerate gastric emptying are the prokinetic agents used to treat

Table 39.2 Medications that affect gastric emptying

Medications that delay gastric emptying
Opiate analgesics
Anticholinergic agents
Tricyclic antidepressants
Calcium channel blockers
Progesterone
Octreotide
Pramlitide
Proton pump inhibitors
Histamine H_2 receptor antagonists
Interferon-α
L-Dopa
Fiber
Sucralfate
Aluminum hydroxide antacids
β-Adrenergic receptor agonists
Glucagon
Calcitonin
Dexfenfluramine
Diphenhydramine
Alcohol
Tobacco/nicotine
Tetrahydrocannabinol

Medications that accelerate gastric emptying
Prokinetic agents
  Metoclopramide
  Erythromycin and related antibiotics
  Cisapride
  Domperidone
β-Adrenergic receptor antagonists

gastroparesis. A delayed gastric emptying test suggests, but does not prove, that the symptoms are caused by gastroparesis. If gastric emptying is normal, other causes for symptoms should be sought. However, a gastric motility disorder should not be totally dismissed despite a normal gastric emptying test because localized motor dysfunction, such as impaired fundic relaxation or gastric dysrhythmias, may be associated with symptoms and normal gastric emptying [18].

Evaluation of a patient should not stop once delayed gastric emptying is demonstrated; an underlying cause should be sought. Other causes of gastroparesis besides diabetes and previous gastric surgery include smooth muscle, neurological, metabolic or endocrine disorders. Thyroid function tests should be obtained to evaluate for hypothyroidism. A glycosylated hemoglobin level evaluates long-term glycemic control; poor glucose control can worsen gastric emptying. Idiopathic gastroparesis is diagnosed after all other causes are excluded.

Evaluation of gastric emptying, motor function, myoelectric activity, and radiographic contrast techniques

The upper GI series is primarily helpful in detecting mucosal lesions and mechanical outlet obstruction. It is an insensitive method for measuring gastric emptying because it is difficult to quantitate, and barium is not a "physiological" meal (Table 39.3) [19]. Gastric retention may be suggested by poor emptying of barium from the stomach, gastric dilation, and the presence of retained food or a gastric bezoar. Little or no emptying of barium at 30 min and minimal barium remaining in the stomach at 6 h are suggestive of delayed gastric emptying [20].

Assessment of gastric emptying

Radionuclide gastric emptying scintigraphy

Gastric emptying scintigraphy remains the best current test for measuring gastric emptying because it is sensitive, quantitative, and physiological. It is used to confirm the presence of gastric stasis after excluding structural or mucosal disorders. However, the usefulness of emptying tests in directing therapy and predicting response is debated [21,22].

Measurement of gastric emptying of solids is more sensitive than measurement of gastric emptying of liquids for detection of symptomatic gastroparesis because emptying of liquids is often preserved until the disorder is advanced. In patients who have undergone gastric surgery, a dual solid and liquid emptying test may be indicated because symptoms may result from slow solid emptying or rapid liquid emptying.

The technetium 99m sulfur colloid radiolabeled meal consisting of the equivalent of two large eggs (Eggbeaters) plus two slices of bread with jam and water is suggested as the standardized test meal. Imaging is performed in the anterior and posterior projections at four time points (0, 1, 2, and 4 h)

Table 39.3 Tests to assess gastric motor and myoelectric function

Tests assessing gastric emptying	Advantages	Disadvantages
Upper gastrointestinal barium radiographic study	Assesses for mucosal lesions	Nonphysiological
Scintigraphy	Gold standard, noninvasive, solid and liquid phase	Radiation exposure minimum to moderate
Breath tests using ^{13}C	Noninvasive	Needs normal small intestinal absorption, liver metabolism, pulmonary excretion
Ultrasonography for serial changes in antral area	Noninvasive	Requires expertise for imaging and interpretation, primarily measures liquid emptying
Magnetic resonance imaging	Noninvasive	Expensive, time consuming, needs specialized centers and software
Tests assessing gastric contractile activity	**Advantages**	**Disadvantages**
Antroduodenal manometry	Assesses contractility in fasting and postprandial periods	Invasive, requires expertise to perform and interpret
Gastric barostat	Measures proximal stomach relaxation and contraction	Invasive, research technique
Tests assessing gastric myoelectrical activity	**Advantages**	**Disadvantages**
Electrogastrography	Noninvasive	Movement artifact may make recording difficult to interpret

Adapted from Hasler WL et al. [16], with permission from Elsevier.

[23]. The radiolabel needs to be cooked into the egg white so that the radioisotope binds to the solid phase, thus preventing elution of the radiotracer into the liquid phase with an erroneous measurement of the faster liquid phase of gastric emptying [24].

Imaging for gastric emptying up to 4 h increases the detection of delayed gastric emptying and is now suggested as the standard in all tests to obtain reliable results for the detection of gastroparesis [25,26]. When gastric scintigraphy is performed for shorter durations, the test is less reliable because of large variations in normal gastric emptying.

The simplest approach for interpreting gastric emptying studies is to report the percentage of retention at defined times after meal ingestion (usually 2 and 4 h) (Fig. 39.1).

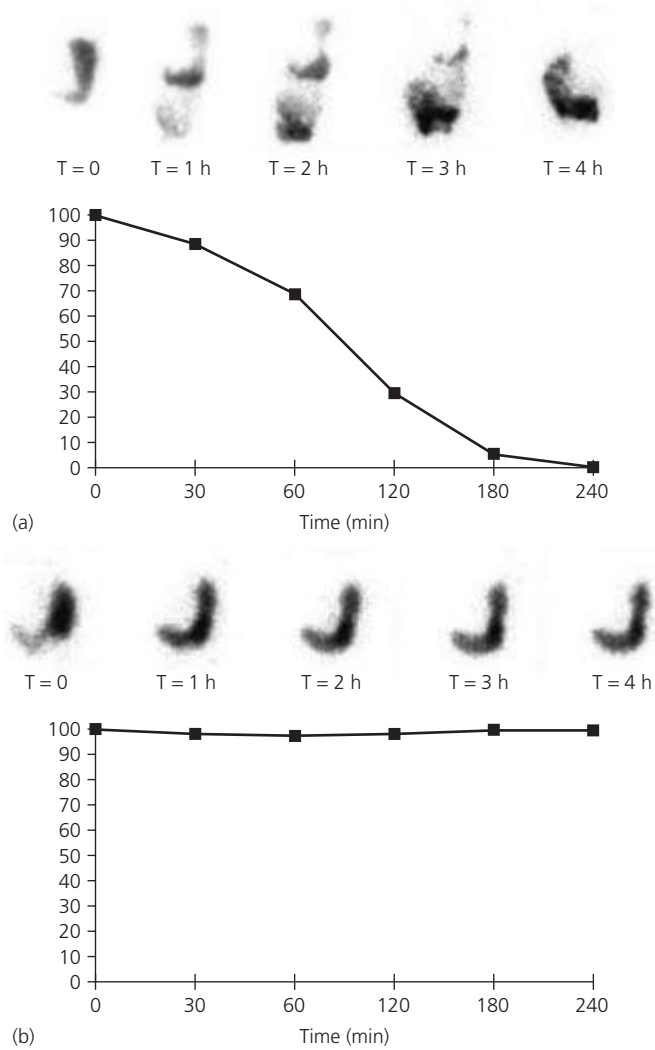

Figure 39.1 Gastric emptying scintigraphy using a technetium 99m-labeled egg sandwich. The percentages of gastric retention are shown at 0, 30, 60, 120, 180, and 240 min after meal ingestion. **(a)** Normal gastric emptying with only 30% retention at 2 h after meal ingestion (normal < 50%) and complete emptying at 4 h (normal < 10%). **(b)** Markedly delayed gastric emptying with little emptying at 4 h.

Curve-fitting techniques can calculate the half-emptying time, the time for half of the stomach contents to have emptied from the stomach. Extrapolation of the emptying curve to predict the half-emptying time may be unreliable if the emptying has not reached 50% during the actual imaging [27]. Other parameters of potential use are the lag phase for solids, which represents the time required for trituration of solid food into 1- to 2-mm particles that can then empty through the pylorus [28].

Advances in scintigraphy may provide information on fundic and antral abnormalities. Regional gastric emptying can assess intragastric meal distribution and transit from the proximal to distal portions of the stomach. Proximal retention may be seen in GERD, distal retention in functional dyspepsia, and global retention in gastroparesis (Fig. 39.2). Dynamic antral scintigraphy with frequent 1-s imaging can evaluate antral wall contractility [19].

Blood glucose, smoking, and gender are factors that affect gastric emptying. Premenopausal women empty the stomach more slowly than men [14,15]. Some investigators have advocated separate reference values for premenopausal women [29]. Marked hyperglycemia with serum glucose levels of 288 mg/dL or more significantly delays gastric emptying in diabetic patients when compared with euglycemia [30]. Blood glucose should be under reasonable control on the day of an emptying test to obtain a reliable measurement of gastric emptying. It is recommended that serum glucose be measured prior to the study, noted in the report, and if the blood glucose is greater than 275 mg/dL on the morning of the test, the glucose should be lowered with insulin to less than 275 mg/dL or the study should be rescheduled for another day when the blood glucose is under better control. Smoking during the test can delay gastric emptying.

SmartPill pH and pressure capsule to assess gastric emptying

The SmartPill is an ingestible capsule that measures pH, pressure, and temperature using miniaturized wireless sensor technology. The SmartPill capsule is swallowed by the patient and acidity and pressures are recorded as it travels through the gastrointestinal tract. From these measurements, gastric emptying and total gastrointestinal tract transit time can be obtained. In addition, the SmartPill capsule will characterize pressure patterns and provide motility indices for the stomach, small intestine, and colon. The gastric residence time of the SmartPill has a high correlation (85%) with the T-90% of gastric emptying scintigraphy suggesting that the gastric residence time of the SmartPill represents a time near the end of the emptying of a solid meal. The gastric residence time of the SmartPill is able to differentiate normal gastric emptying from delayed gastric emptying similarly to scintigraphy [31]. A SmartPill gastric residence cutoff time of 5 h was best in distinguishing between subjects with delayed and those with normal gastric emptying based on scintigraphy

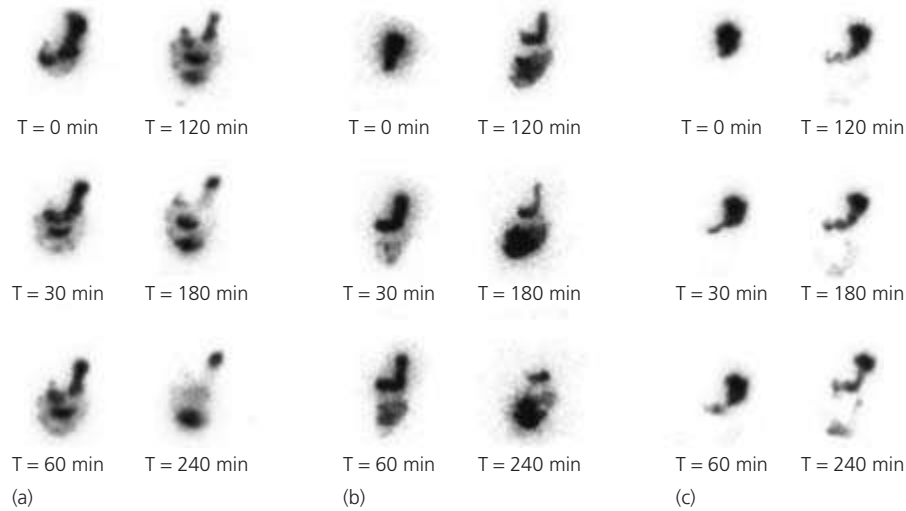

Figure 39.2 Regional gastric emptying abnormalities in gastroesophageal reflux disease, functional dyspepsia, and gastroparesis. **(a)** In patients with gastroesophageal reflux disease, there is retention of the radioactivity in the proximal portion of the stomach. **(b)** In patients with functional dyspepsia, there is retention of radioactivity in the distal portion of the stomach. **(c)** In patients with gastroparesis, there is a global retention throughout the whole stomach.

on the day of the test (83% sensitivity, 83% specificity) [32]. However, the utility of the SmartPill capsule in clinical settings remains to be determined.

There have been several reports of capsule endoscopy used to measure gastric emptying; this technique is able to visualize the capsule emptying from the stomach and thus measure gastric emptying of the capsule from the stomach. These studies have been limited by the need to perform this technique in the fasting stomach. How this relates to a physiological meal has not been determined.

Breath tests for gastric emptying

Breath testing can be used to measure gastric emptying. The nonradioactive isotope carbon 13 is used to label octanoate, a medium-chain triglyceride, which can be bound into a solid meal [33–35]. Studies have also been carried out using ^{13}C-labeled proteinaceous algae (*Spirulina*) [24]. After ingestion and emptying from the stomach, octanoate is absorbed by the small intestine. The octanoate is metabolized to carbon dioxide in the liver and the ^{13}C is excreted from the lungs during respiration. The rate-limiting step for excretion of ^{13}C is gastric emptying. By measuring ^{13}C in breath samples, gastric emptying can be indirectly determined. The octanoate breath test is reproducible, correlates with gastric emptying scintigraphy, and offers promise as a clinical test for gastric emptying. It does not use ionizing radiation, it can be used to study patients without access to gamma camera facilities in community doctors' offices or at the bedside, and breath samples can be shipped to a laboratory for analysis. The octanoate breath test has been used in clinical research and pharmaceutical studies. Validation of this test in patients with emphysema, cirrhosis, celiac sprue, and pancreatic insufficiency is needed, because it is not clear whether substrate metabolism in these disorders may also be a rate limiting step for $^{13}CO_2$ excretion.

Ultrasonography

Transabdominal ultrasonography can measure several parameters of gastric motility. Serial changes in antral cross-sectional area are measured as an index of gastric emptying; emptying is considered complete when the antral area returns to the fasting baseline [36]. Duplex sonography may be used to evaluate transpyloric flow of liquid gastric contents. Ultrasonography has also been employed to measure accommodation in the proximal and distal stomach [24]. Unfortunately, ultrasonography for gastric emptying is operator dependent and generally measures liquid emptying only. The test is suboptimal in obese people.

Assessment of gastric myoelectric activity with electrogastrography

EGG is the recording of gastric myoelectric activity using cutaneous electrodes on the abdomen overlying the stomach [37]. The dominant frequency of the EGG corresponds to the gastric electrical rhythm or frequency of the gastric slow wave. The normal gastric slow wave frequency is approximately 3 cycles/min (Fig. 39.3). Meal ingestion increases the amplitude of the EGG signal by increasing gastric electrical activity and contractility or by distention of the stomach. EGG measures the frequency and regularity of gastric myoelectric activity, detects abnormal rhythms of gastric myoelectric activity, and assesses the amplitude or power increase after a meal [27].

Gastric dysrhythmias (tachygastria, bradygastria) and decreased postprandial amplitude (or power) of the EGG have been described in idiopathic and diabetic gastroparesis [38] (Fig. 39.3). Gastric myoelectric abnormalities have also been described in patients with unexplained nausea and vomiting, motion sickness, and nausea and vomiting of pregnancy [27]. Studies have suggested a good correlation between delayed gastric emptying measured by scintigraphy

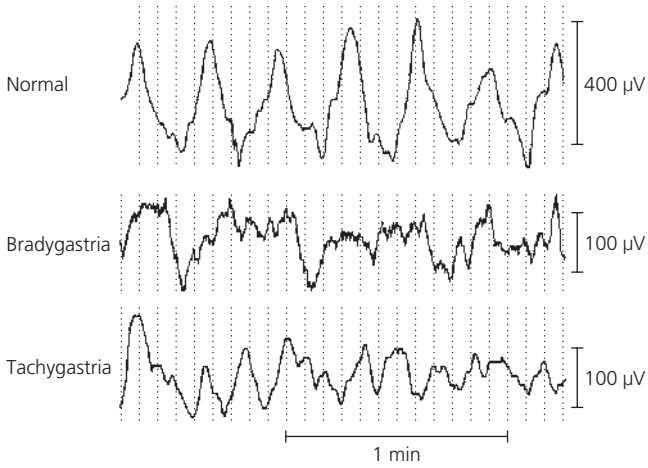

Figure 39.3 Gastric dysrhythmias recorded with electrogastrography (EGG). Representative raw EGG tracings showing normal 3 cycles/min rhythm, bradygastria, and tachygastria. From Parkman HP et al. [42], with permission from Blackwell Publishing.

and an abnormal EGG, particularly postprandial rhythm and amplitude abnormalities [38]. An abnormal EGG is present in 75% of patients with gastroparesis compared with only 25% of symptomatic patients with normal gastric emptying. Gastric dysrhythmias have been suggested to be better predictors of symptoms than delayed gastric emptying [39]. In diabetic patients, hyperglycemia may itself provoke dysrhythmias, primarily tachygastrias [40].

EGG is used to demonstrate gastric myoelectric abnormalities in patients with unexplained nausea and vomiting with abdominal discomfort or functional dyspepsia. The EGG is generally used as an adjunct to gastric emptying scintigraphy, as part of a comprehensive evaluation of patients with refractory symptoms suggestive of an upper GI motility disorder [27,41,42].

Antroduodenal manometry

Antroduodenal manometry provides information about the coordination of gastric and duodenal motor function in both fasting and postprandial periods [27]. The three main indications for antroduodenal manometry are to evaluate: (1) unexplained nausea and vomiting; (2) the cause of gastric or small bowel stasis (e.g., neuropathic or myopathic disorders); and (3) suspected chronic intestinal pseudoobstruction when the diagnosis is unclear [27].

Decreased antral contractility and phase III migrating motor complexes (MMCs) originating in the small intestine rather than in the stomach can be seen in gastroparesis. Occasionally, pylorospasm or irregular bursts of small intestinal contractions, which increase outflow resistance, can be observed. With an accurate stationary recording, a reduced postprandial distal antral motility index is correlated with impaired gastric emptying of solids [28]. An average of less than one antral contraction per minute postprandially has been suggested as a simple estimate of significant hypomotility [43]. Ambulatory studies, performed over 24 h using solid-state transducers, allow correlation of symptoms with abnormal motility but catheter migration in the stomach prevents quantitation of antral contractility.

Antroduodenal manometry may differentiate between neuropathic and myopathic motility disorders, and it may suggest unexpected small bowel obstruction or rumination syndrome [27,44]. Myopathic disorders, such as scleroderma or amyloidosis, have low-amplitude contractions with normal propagation. Neuropathic disorders have normal amplitude but abnormal propagative contractions, seen readily in the phase III MMC, such as bursts and sustained uncoordinated pressure activity, and a failure of a meal to induce the fed-type pattern. Occult mechanical obstruction of the small intestine is suggested by two types of pattern: postprandial clustered contractions for more than 30 min separated by quiescence, and simultaneous prolonged (> 8 s) or summated contractions suggesting a common cavity phenomenon from a dilated segment of intestine [45]. Antroduodenal manometry may demonstrate a characteristic pattern of rumination, with an increase in intraabdominal pressure at all levels of the upper gut (R waves), especially postprandially, indicating the act of rumination [46].

In pediatric studies, the absence of MMCs is an indicator of a poor response to prokinetic agents [47]. Some investigators perform the study with infusions of erythromycin or octreotide to predict the patient's response to treatment with these agents [48].

Gastroparesis and disorders with delayed gastric emptying

Gastroparesis occurs in many clinical settings (Table 39.4); the most common are diabetes mellitus, sequelae of gastric surgery, and idiopathic. In a series of 146 patients, gastroparesis was classified as being idiopathic in 36%, diabetic in 29%, and postsurgical in 13% [1].

Diabetic gastroparesis

Gastroparesis is a well-known complication of *diabetes,* most commonly associated with long-standing, insulin-dependent diabetes mellitus with other complications of retinopathy, nephropathy, and peripheral neuropathy. Frequently, it occurs with autonomic neuropathy as identified by orthostatic hypotension. Longitudinal studies suggest that delayed gastric emptying is present in 30%–40% of patients with long-standing type I diabetes and in 10%–20% of type II diabetics [43]. The prevalence of GI symptoms in insulin-dependent diabetes mellitus is greater in patients with poor glycemic control [49].

Diabetic gastroparesis is clinically important because it is associated with GI symptoms, alterations in glycemic control, and changes in oral drug absorption [50]. Symptoms of

Table 39.4 Etiology of gastroparesis (nonobstructive delayed gastric emptying)

Idiopathic
Endocrine or metabolic:
Diabetes mellitus
Thyroid disease
Renal insufficiency
After gastric surgery:
After resection
After vagotomy
Central nervous system disorders:
Brainstem lesions
Parkinson disease
Peripheral neuromuscular disorders:
Myotonia dystrophica
Duchenne muscular dystrophy
Connective tissue disorders:
Scleroderma
Polymyositis/dermatomyositis
Infiltrative disorders:
Lymphoma
Amyloidosis
Diffuse gastrointestinal motility disorder:
Chronic intestinal pseudoobstruction
Medication-induced (see Table 39.2)
Electrolyte imbalance: potassium, calcium, magnesium
Miscellaneous conditions:
Infections (especially viral)
Paraneoplastic syndrome
Ischemic conditions
Gastric ulcer

Adapted from Parkman HP et al. [19] from Blackwell Publishing.

diabetic gastroparesis primarily include nausea and vomiting, but also early satiety, fullness, and abdominal discomfort. The presence of abdominal bloating or fullness in particular appears to be associated with diabetic gastroparesis [51]. Symptom severity, however, does not necessarily correlate well with the degree of gastric stasis [52,53]. Patients with severe symptoms may have only a mild delay or even normal gastric emptying. One study examining the effect of the prokinetic agent domperidone in diabetic gastroparesis suggested that symptom improvement did not correlate with improvement in gastric emptying, but rather with resolution of dysrhythmias [50]. Diabetic gastroparesis has been considered to be associated with a poor prognosis; however, more recent studies suggest that this may be incorrect and that most patients with diabetic gastroparesis do not deteriorate over time [50].

The motor dysfunction is typically confined to the stomach (gastroparesis), but sometimes a diffuse GI motility disorder may be present. Gastric motor abnormalities include impaired fundic relaxation with antral dilation, gastric dysrhythmias, antroduodenal incoordination, antral hypomotility, and visceral hypersensitivity [4]; gastroparesis may be the end stage of gastric dysfunction. The term *gastropathy* has been used because symptoms do not predict delayed gastric emptying, and the symptomatic response to prokinetic treatment is not necessarily related to improvement in emptying.

Diabetic gastroparesis likely results from impaired neural control of gastric motor function, possibly resulting from a vagal neuropathy. Morphological abnormalities of the gastric myenteric plexus in diabetic patients have not been identified by conventional histology [54]. Abnormal neural innervation and neurotransmission of both inhibitory and excitatory neurotransmitters and underlying muscle dysfunction have been described in animal models of diabetes. Impairment of the inhibitory nitric oxide-containing nerves [55] and damage of the interstitial cells of Cajal [56], the electrical pacemaker cells, have been described in patients with diabetic gastroparesis [57].

Gastroparesis has also been described in type II diabetes mellitus [53]. However, it is also not uncommon for gastric emptying to be accelerated in type II diabetes [58]. Usually, this change occurs early in the disease. It may be related to a lack of a fundic receptive relaxation, a vagally mediated response [59].

Hyperglycemia itself may reversibly affect gastric motility. Hyperglycemia decreases antral contractility, decreases antral phase III MMC activity, increases pyloric contractions, causes gastric dysrhythmias (primarily tachygastria), and delays gastric emptying [40,60]. Normalization of serum glucose in hyperglycemic patients has been shown to improve gastric myoelectric activity, to improve gastric emptying, and to restore antral phase III MMC activity [61]. It is not clear how hyperglycemia adversely affects gastric motility. Hyperglycemia appears to cause a reversible impairment of vagal efferent function [62]. Glucose-responsive neurons have been identified in the central nervous system that may modify vagal efferent activity [63]. Prostaglandins may also be involved; indomethacin (indometacin) may reverse abnormal gastric electrical rhythms that occur during hyperglycemia [64].

Changes of gastric motility may also affect postprandial blood glucose concentrations. Delayed gastric emptying may contribute to poor glucose control because of unpredictable delivery of food into the duodenum [60]. Impaired gastric emptying with administration of exogenous insulin may produce hypoglycemia. Conversely, acceleration of emptying has been reported to cause hyperglycemia [58,65]. Problems with glucose control may be the first indication that a diabetic patient is developing gastroparesis [60]. Interestingly, gastroparetic symptoms may be mild or absent. Long-term oral administration of the prokinetic agents that accelerate gastric emptying have been shown to decrease plasma glucose and glycosylated hemoglobin (HbA_{1c}) levels in diabetic patients in some studies [66,67]. However, several other studies have not confirmed this.

Patients with insulin-dependent diabetes mellitus have an increased perception of gastric distention, with more nausea, fullness, and upper abdominal pain [4]. Hyperglycemia increases nausea and fullness during proximal gastric distention [60,68]. Increased sensitivity of the proximal stomach may be responsible for dyspeptic symptoms postprandially when the stomach is distended by a meal [4,68].

Postsurgical gastroparesis

Postsurgical gastroparesis has been classically described in the past occurring after peptic ulcer surgery [69], most commonly when a truncal vagotomy was performed. Vagal nerve stimulation causes both fundic relaxation and antral contractions; the effect of a total vagotomy is to delay emptying of solids while accelerating gastric emptying of liquids. A gastric drainage procedure such as a pyloroplasty or gastroenterostomy is usually performed in an attempt to offset the gastroparetic effects of vagotomy. In most patients, the net result is that vagotomy combined with a drainage procedure produces little alteration in gastric emptying. The results of different gastric surgical procedures on gastric emptying are shown in Table 39.5.

About 5% of patients undergoing vagotomy with antral resection and gastrojejunostomy develop severe postsurgical gastroparesis; the antrum is not present to triturate solids, and the proximal stomach is unable to generate sufficient pressure to empty solids [69]. Patients with gastric outlet obstruction undergoing surgery may also develop postsurgical gastric stasis; the chronic gastric dilation may have led to irreversible gastric muscle dysfunction.

The Roux-en-Y stasis syndrome is characterized by postprandial abdominal pain, bloating, nausea, and vomiting [69]. The combination of vagotomy, distal gastric resection, and Roux-en-Y gastrojejunostomy predisposes to gastric stasis, which results from both slow emptying from the gastric remnant and delayed small bowel transit in the Roux efferent limb [69]. Ectopic jejunal pacemakers may develop in the transected and reattached jejunal segment. In addition, myoelectric and motor activity in the Roux limb is slower than normal and may be retrograde, causing reverse peristalsis toward the stomach and allowing the Roux limb to cause a functional obstruction [70].

Gastroparesis is unusual in patients with a highly selective parietal cell vagotomy. Transient myoelectric abnormalities may occur, but they usually disappear with time [71]. Development of delayed gastric emptying after highly selective vagotomy may suggest inadvertent complete vagotomy [72].

Post-Nissen fundoplication gastric motor dysfunction

Mild acceleration of gastric emptying has been reported to occur after Nissen fundoplication [73,74]. Proximal gastric emptying after fundoplication is increased because of an increase in intragastric pressure resulting from the fundic wrap preventing receptive relaxation. This may lead to symptoms of early satiety [74]. In patients with GERD and delayed gastric emptying, there can be normalization of emptying after fundoplication [74]. However, this is not universally seen and, often, if Nissen fundoplication is performed in a patient with delayed gastric emptying, a pyloroplasty is sometimes performed.

Table 39.5 Gastric emptying alterations after different types of gastric surgery

Surgical procedure	Anatomic changes	Motility changes	Comments
Proximal gastric vagotomy or parietal cell vagotomy	Selective denervation of acid-producing parietal cells	Impaired receptive relaxation accommodation; accelerated liquid emptying, normal solid emptying	Early satiety is common
Truncal vagotomy with drainage procedure (pyloroplasty or gastroenterostomy)	Vagal denervation of entire stomach; ablation of pyloric sphincter	Same effects as proximal gastric vagotomy plus a significant decrease in antral contractility with delayed emptying of solids	Obligatory drainage procedure is needed to prevent stasis; as a result, larger solids, less suitable for intestinal digestion and absorption, pass directly into the small intestine
Partial gastrectomy	Proximal stomach resected	Impaired accommodation; accelerated liquid emptying	Decreased total reservoir capacity
Subtotal gastrectomy	Distal two-thirds of stomach resected	Decreased accommodation with decreased outlet resistance; rapid emptying into intestine	Usually performed with vagotomy, may account for dumping
Billroth I gastroduodenostomy or Billroth II gastroenterostomy	Antrectomy (distal one-third)		

Adapted from Parkman HP et al. [19], with permission from Blackwell Publishing.

Gas bloat syndrome refers to postoperative symptoms including an inability to belch, pain, and bloating. It is more common in patients with preoperative delayed gastric emptying [75].

Early satiety, postprandial fullness, nausea, and vomiting may develop after fundoplication [76]. In some of these patients, postprandial antral hypomotility or a delay in gastric emptying can be seen [77,78]. Delayed gastric emptying may have been present before surgery but not recognized because of the GERD symptoms of heartburn and regurgitation. The development of postoperative gastroparesis after an open or laparoscopic Nissen fundoplication may result in significant morbidity [78]. Vagal nerve injury has been reported in from 4% to as many as 40% of patients undergoing laparoscopic fundoplication [79,80].

Postbariatric surgery

Surgical therapy for morbid obesity has increased since the late 1990s. Several procedures are designed to restrict stomach size [81]. The most commonly performed surgical procedure is the Roux-en-Y gastric bypass. The stomach is partitioned into a small proximal fundic pouch and a bypassed distal stomach; a loop gastrojejunostomy through a small gastroenterostomy drains the proximal pouch [81]. Ingestion of large meals is prevented by early satiety resulting from the small gastric pouch. The gastrojejunostomy configuration produces a relatively malabsorptive state and can result in dumping if a high carbohydrate liquid meal is ingested. Solid emptying is slower and liquid emptying is faster after gastric bypass surgery [82]. Less commonly performed are gastric restrictive procedures including vertical banding gastroplasty and adjustable gastric banding [80]. Vomiting can occur in 21% of patients after vertical banding gastroplasty [83]; another study found that emptying from the proximal pouch was normal and could not explain the early satiety [84].

Idiopathic gastroparesis

Idiopathic gastroparesis refers to symptomatic gastroparesis in patients with no apparent primary underlying abnormality. In most series, idiopathic gastroparesis is the most common category for gastroparesis [1]. Symptoms may fluctuate, with episodes of pronounced symptoms interspersed with relatively symptom-free intervals.

Patients with idiopathic gastroparesis are typically young or middle-aged women. Even after adjusting for gender differences in gastric emptying, gastroparesis occurs more commonly in women [6]. A potential cause in some patients includes viral injury to the nerves or muscles of the stomach. Postviral gastroparesis was suspected in 23% of patients with idiopathic gastroparesis [85]. This clinical diagnosis is suggested in previously healthy persons with an acute onset of viral illness with nausea, vomiting, diarrhea, fever, and cramps who have persistence of symptoms (nausea, vomiting, early satiety) for more than 3 months with a delay in gastric emptying. Viruses suspected as potential causes are cytomegalovirus (CMV), Epstein–Barr virus, and herpes varicella-zoster. Symptoms of idiopathic gastroparesis after a presumed viral illness tend to be less severe than in gastroparesis from other causes. Overall, these patients appear to have a good prognosis, with many patients having a slow resolution of their symptoms [85].

Other disorders associated with delayed gastric emptying

Gastrointestinal disorders

Gastroesophageal reflux disease

Delayed gastric emptying can be seen in patients with GERD. Gastric stasis with proximal fundic distention may promote transient lower esophageal sphincter relaxation with subsequent gastroesophageal reflux [86]. Some investigators have found delayed emptying in 40% of patients with GERD [87]; others have not shown this high prevalence [88]. Studies suggest that slow emptying from the proximal stomach, but not from the overall stomach, may correlate with esophageal acid exposure [89].

Achalasia

Gastric emptying is difficult to study in achalasia because the ingested meal is often retained in the esophagus. Gastric emptying studies in these patients have given variable results; several reported no abnormalities in gastric emptying [90]. Studies delivering liquid meals into the stomach through a nasogastric tube have shown rapid emptying of liquids [91]. After successful pneumatic dilation, gastric emptying of solid meals was delayed in 50% of patients with achalasia [92]. These emptying abnormalities may be related to abnormalities of the vagus nerve and dorsal motor nuclei of the vagus, which have been reported in achalasia.

Gastric ulcer

Delayed gastric emptying has been reported in some patients with gastric ulcers. In some patients, the gastroparesis has resolved after ulcer healing. It may be difficult to determine whether the ulcer caused the gastric emptying delay or the gastric stasis caused the ulcer.

Atrophic gastritis

Atrophic gastritis is characterized by a decrease in gastric acid secretion, usually leading to hypergastrinemia through acid–gastrin feedback regulation. Atrophic gastritis may result from pernicious anemia or may occur on a nonautoimmune basis, such as in *H. pylori* infection. Delayed gastric emptying is present in two-thirds of patients with achlorhydric atrophic gastritis and in one-third of those with preserved acid secretion. Delayed gastric emptying in atrophic gastritis is associated with reduction of gastric acid output and hypergastrinemia, rather than with severity of mucosal atrophy [93].

Functional dyspepsia

See Functional dyspepsia later in the chapter.

Hypertrophic pyloric stenosis

Infantile hypertrophic pyloric stenosis (IHPS), occurring in up to 0.3% of births, is the most common disorder requiring abdominal surgery during the first 6 months of life. A typical infant begins to vomit within the first 4 weeks of life. Hypertrophy of the inner circular muscle of the pylorus produces pylorospasm or functional gastric outlet obstruction resulting in nonbilious vomiting, dehydration, and metabolic alkalosis. An enlarged pylorus (pyloric olive) can be palpated or detected radiologically. Pylorospasm occurs from a defect in pyloric sphincter relaxation and not from a true obstruction. A lack of inhibitory nerves of the pylorus, primarily nitric oxide-containing nerves, and interstitial cells of Cajal has been shown in IHPS [94,95]. Treatment with surgical pyloromyotomy is effective. Patients usually remain symptom free after surgical treatment; the muscle hypertrophy resolves. The abnormalities of nitric oxide-containing nerves and interstitial cells of Cajal partially reverse [96], although on manometry the pyloric tone is higher and the phasic pyloric pressure waves are less frequent than in physiologically normal infants [97]. Medical treatment with atropine has been suggested by European groups. IHPS has been associated with the use of erythromycin for pertussis prophylaxis in neonates [98].

IHPS in adults is rare [99]. Diagnostic criteria for adults have been variable. Early reported cases were related to local inflammation and fibrosis from previous gastric or duodenal ulcer. In the uncommon idiopathic form, there is hypertrophy of the smooth muscle without any underlying disease. A certain proportion of these primary cases may represent persistence of the juvenile form, presenting later in life. Endoscopic dilation and laparoscopic pyloroplasty have been used for treatment [100].

Celiac disease

Delayed gastric emptying is seen in 50% of patients with celiac disease, which normalizes with a gluten-free diet and recovery of small bowel mucosa. Delayed gastric emptying has been suggested to explain some of the dyspeptic symptoms in celiac disease [101,102].

Gallbladder disease

Delayed gastric emptying, in addition to delayed gallbladder emptying, may be present in cholelithiasis [103]. Some studies have reported delayed solid phase gastric emptying in 20%–42% of patients with gallstones [104], whereas others have not found alterations in liquid phase emptying [103]. Interestingly, cholecystectomy has been shown to normalize gastric emptying in some patients [104]. Many patients with gastroparesis have had a previous cholecystectomy, possibly with the thought that gallbladder dysfunction may be causing the nonspecific symptoms.

Chronic pancreatitis

Some patients with chronic pancreatitis have delayed gastric emptying [105]. This may explain some of the abdominal pain, nausea, and vomiting seen in this group of patients. This phenomenon may be related to the increased serum level of endogenous cholecystokinin (CCK) [105]. One study showed impaired gastric myoelectric activity in chronic pancreatitis [106]; this abnormality was restored toward normal with pancreatic enzyme replacement. Gastric emptying is variable in cystic fibrosis: early in the disease it may be rapid, whereas later in the disease it is delayed [107].

Liver disease

Abnormal gastric emptying has been reported in up to 78% of patients with cirrhosis of the liver [108]. The delay in gastric emptying is correlated with the severity of liver disease, as indicated by Child–Pugh status, bilirubin level, prothrombin time, and presence of esophageal varices [108]. Secretin and endothelin have been suggested to play a role in the gastric dysmotility seen in cirrhosis and portal hypertension [109,110]. Other studies have not shown significant changes in gastric emptying [111] and have even reported acceleration of liquid phase gastric emptying [112].

Interferon-α treatment may delay gastric emptying and may cause dyspeptic symptoms. In one study, interferon treatment delayed gastric emptying in 12 of 14 patients and was associated with development of anorexia and abdominal discomfort [113]. Prokinetic therapy improved gastric emptying and GI symptoms during interferon-α therapy.

Constipation

Delayed gastric emptying is not uncommonly observed in patients with constipation. The finding of delayed gastric emptying suggests the possibility of a diffuse GI disorder [114]. This has implications for treatment as patients with chronic severe constipation and proximal GI tract dysmotility often have poor responses to colectomy. Volitional suppression of defecation can delay gastric emptying, suggesting a "cologastric brake" or the effects of stress [115].

Diffuse gastrointestinal motor disorders

Gastroparesis can occur as a part of a diffuse GI motility disorder. *Chronic intestinal pseudoobstruction* is a syndrome with recurrent symptoms suggestive of intestinal obstruction in the absence of mechanical blockage. Symptoms are caused by ineffective peristalsis and include nausea, vomiting, and abdominal pain with abdominal distention. Radiological findings consist of air–fluid levels within the small intestine. The term *diffuse GI motility disorder* rather than chronic intestinal pseudoobstruction is often used if several portions of the GI tract have delayed transit but no air–fluid levels are seen on abdominal radiographs [19].

Chronic intestinal pseudoobstruction can be caused by several systemic diseases including scleroderma, amyloidosis,

myxedema, and long-standing diabetes mellitus. It is often idiopathic; the two main forms of idiopathic pseudoobstruction are myopathic and neuropathic. Small bowel manometry may help to differentiate between these two forms.

Nongastrointestinal disorders

Eating disorders: anorexia, bulimia, and rumination

Anorexia nervosa is a psychiatric disorder occurring primarily in adolescent and young adult women, characterized by distorted body image and fear of obesity with compulsive dieting and self-imposed starvation to maintain a profoundly low body weight. GI symptoms are common and include lack of appetite, early satiety, epigastric fullness, abdominal bloating, nausea, and vomiting [116,117]. Patients with anorexia nervosa often have delayed gastric emptying primarily for solids [117]. Interestingly, realimentation and maintenance of normal body weight improve gastric emptying and GI symptoms [116,118]. Prokinetic therapy had been suggested to improve gastric emptying and to facilitate refeeding [117]; other studies have not shown an effect on weight gain [119]. The pathogenesis of gastric dysfunction in anorexia is probably multifactorial; starvation and malnutrition with marked endocrine disturbances may play a role; others have suggested a central nervous system disturbance related to the psychiatric abnormality.

Bulimia nervosa is characterized by recurrent episodes of binge eating with a feeling of lack of control over the eating behavior during the binges, often followed by self-induced vomiting, the use of laxatives or diuretics, strict dieting or fasting, or vigorous exercise to prevent weight gain [120]. Self-induced vomiting allows bulimic patients to continue eating or to terminate the binge. In contrast to anorexia nervosa, concern about weight and body size does not lead to a fall in weight below normal. Symptoms of postprandial fullness, early satiety, bloating, nausea, and epigastric pain may occur [121]. Depression may be an important determinant of GI symptoms [121]. Gastric emptying studies in bulimia have yielded conflicting results; some bulimic patients (37%) appear to have delayed emptying [120].

Rumination syndrome is the effortless regurgitation of recently ingested food into the mouth with subsequent remastication and reswallowing or expectorating of food. Initially described in children and mentally retarded institutionalized persons, there is an increasing awareness of this disorder in adults of normal intelligence. Rumination can become a habit, often initiated by a belch, a swallow, or by stimulation of the palate with the tongue. Abdominal muscle contraction with lower esophageal sphincter relaxation in the early postprandial period is responsible for regurgitation [122]. Typically, the effortless repetitive regurgitation occurs within 15 min of starting a meal, in contrast to vomiting from gastroparesis, which occurs later in the postprandial period [46]. Symptoms often cease when regurgitated food becomes acidic to taste. Difficulty in diagnosis results from lack of awareness and the difficulty in differentiating rumination from vomiting caused by gastroparesis or regurgitation from GERD. Gastric emptying and esophageal pH monitoring are usually normal. Gastroduodenal manometry may show characteristic brief simultaneous increases in gastric and small bowel pressure (R waves) seen in all abdominal recording ports during the postprandial period. These represent abdominal wall contractions, and, if performed with esophageal pH monitoring, they are associated with a decrease in distal esophageal pH. These characteristic findings are seen in only one-third of patients with clinical symptoms of rumination [46]. Making the patient aware of this habit may be beneficial. Treatment involves behavioral modification and biofeedback therapy administered in a formal eating regulation program. Concentration on diaphragmatic breathing after eating may help. Biofeedback techniques help to teach patients to relax abdominal muscles during and after eating [123]. Chewing gum postprandially has been suggested to be helpful.

Cyclic vomiting syndrome

Cyclic vomiting syndrome refers to recurrent episodes of intense nausea and vomiting lasting hours to days separated by symptom-free periods of variable lengths. Typically, each episode is similar. Vomiting often starts abruptly, although a prodrome of nausea and abdominal pain can occur. The vomiting reaches its highest intensity during the first hours, diminishes thereafter, and ends rapidly. The duration of vomiting averages 3–4 days and can lead to marked dehydration. This disorder is well characterized in children, but it is now being described in adults [124,125]. In adults, the vomiting episodes are longer (3–5 days), less frequent (every 3–4 months), and triggering events are less evident [125]; there is usually a long delay in diagnosis. Abnormal upper GI motility can be demonstrated by gastric emptying scintigraphy, antroduodenal manometry, and EGG, even in the asymptomatic state; however, these tests are often normal [126]. Recently, gastric emptying has been reported to be rapid in the symptom-free period [127]. Precipitating events, identified in a few patients, include onset of menstrual periods and stress. Cyclic vomiting syndrome, also referred to as *abdominal migraine* or *abdominal epilepsy*, is associated with a history of migraine headaches in patients and other family members. The cause of this disorder is unknown; a mechanistic relationship to migraine, underlying hypothalamic–pituitary axis derangement, or an inappropriate activation of vomiting reflex has been suggested [124]. Mitochondrial disorders and dysfunction of corticotropin releasing factor (CRF) have been identified in some patients [128,129]. There is no standard management for this disorder. A quiet environment, sleep, intravenous fluids (generally dextrose 10% in normal saline [$D_{10}NS$]), and the use of antiemetics, such as ondansetron or metoclopramide, and benzodiazepines, such as lorazepam, may be effective in the acute episodes of vomiting [125,127]. Tricyclic antidepressants

(such as amitriptyline) in low doses [125,127] and β-blockers such as propranolol may prevent attacks. Antimigraine therapies such as the 5-HT_{1D} receptor agonist sumatriptan may reduce the severity of attacks. The use of nonsteroidal antiinflammatory drugs, such as indomethacin or ketorolac, given intramuscularly, has been reported to prevent or reduce the intensity of attacks if these drugs are given during the prodromal period [124]. These agents inhibit prostaglandin formation and may correct gastric dysrhythmias or act centrally.

Neurological disorders

Central nervous system causes of gastroparesis are rare. Any condition associated with increased intracranial pressure may produce emesis, with or without nausea, by activation of brainstem structures mediating vomiting [16]. Focal lesions including tumors, especially those involving the brainstem and posterior fossa, can cause nausea and vomiting and can even present with gastroparesis. Demyelinating diseases such as multiple sclerosis and other demyelinating disorders have been reported to cause gastroparesis [130]. An adult patient with vomiting from a central mass lesion usually has central nervous system symptoms or signs, such as headache, cranial nerve findings, long tract signs, or papilledema [131]. Rarely, objective neurological findings may be absent [132]. Magnetic resonance imaging is better than computed tomography for visualization of the posterior fossa.

Gastroparesis is common in Parkinson disease and has been reported in 70% of patients [133]. The stomach can be affected by the underlying Parkinsonian neurodegenerative pathology; Lewy bodies have been reported in the myenteric plexus of the stomach [134]. Medications used to treat Parkinson disease such as L-dopa can delay gastric emptying. Impaired gastric emptying with delayed levodopa absorption may be a reason for a poor response to medical therapy for Parkinson disease [133]. Domperidone may be a useful prokinetic agent in Parkinson disease; domperidone does not cross the blood-brain barrier and should not interfere with centrally acting antiparkinsonism medications [135].

Collagen vascular disorders

Scleroderma (systemic sclerosis) is a systemic inflammatory disorder affecting the skin and other organs. GI manifestations usually follow cutaneous and other systemic manifestations [136]. The esophagus is involved in about 75% of patients, especially when Raynaud phenomenon is present. Gastric involvement is less frequent than that of the esophagus, small intestine, or colon. Delayed gastric emptying has been reported in 10%–75% of patients [137], usually in those with esophageal involvement [138]. Watermelon stomach is also reported in scleroderma [137]. Antroduodenal manometry classically reveals very low amplitude antral and duodenal contractions with normal MMC propagation [136].

Polymyositis and dermatomyositis classically affect only skeletal muscle, as recognized on esophageal manometry with dysfunction of the upper esophageal sphincter and upper esophagus. However, polymyositis and dermatomyositis may be associated with other GI motor dysfunction. Gastric emptying was found to be delayed in 8 of 13 patients and correlated with the severity of the peripheral (skeletal) muscle weakness [139].

Systemic lupus erythematosus rarely affects gastric motility. Delayed gastric emptying has been reported in a patient with systemic lupus erythematosus; in some patients, functional gastric outlet obstruction with antral narrowing from thickened folds resolved with prednisone treatment [140].

Amyloid-associated GI dysmotility can manifest as intestinal pseudoobstruction, diarrhea, or achalasia [141]. GI symptoms typically include anorexia, difficulty with eating from macroglossia, and altered bowel habits. Nausea may occur in up to 40% of patients with amyloidosis [141]. Clinical gastroparesis occurs rarely in patients with amyloidosis; one study reported only three cases in 769 patients [142].

Endocrine and metabolic disorders: thyroid, parathyroid, and renal failure

Hypothyroidism should be excluded in all patients with gastroparesis. Although it represents only a small percentage of patients with gastroparesis, it is easily treated with thyroid supplementation. There is a poor correlation between the gastric emptying and the elevated thyroid-stimulating hormone level [143]. Intestinal pseudoobstruction has also been described in hypothyroidism. *Hyperthyroid* patients may be expected to have rapid gastric emptying; however, studies have reported normal, rapid, and delayed gastric emptying [138,139,144]. Delayed gastric emptying with gastric dysrhythmias has been reported; these resolve with treatment of the hyperthyroidism [145]. The delayed gastric emptying has been suggested to result from associated autonomic dysfunction [145].

In both hyperthyroidism and *hypoparathyroidism*, small intestine pseudoobstruction has been reported. Parathyroid hormone has been shown to relax gastric and other GI smooth muscle directly [146]. Whether it influences gastric emptying is not known.

GI symptoms, especially anorexia, nausea, and vomiting, are often present in *renal failure*. Symptoms may be from uremia, medications, gastric mucosal ulceration, or gastroparesis. Gastric emptying studies have yielded conflicting results. Delayed emptying has been seen in patients with symptomatic uremia [147]. Normal emptying is most commonly seen in patients undergoing hemodialysis. Delayed emptying has been reported to be associated with changes in nutritional status and autonomic neuropathy [148,149]. Using the octanoate breath test, delayed gastric emptying was present in 62% of patients undergoing long-term hemodialysis; delayed emptying was present in 91% of patients with

dyspeptic symptoms and in 40% of those without symptoms [150]. Chronic ambulatory peritoneal dialysis delays emptying, primarily when the abdomen contains the dialysate; emptying normalizes after the dialysate is emptied [151].

Gastric infections

Delayed gastric emptying can be seen during a variety of acute *viral infections* including herpes zoster and infections with Epstein–Barr virus, CMV, rotavirus, and parvoviruses [152]. Nausea and vomiting have been associated with altered gastric motor function [153]; this has been shown during acute viral gastroenteritis with parvovirus-like agents (Norwalk and Hawaii viruses). Delay in gastric emptying is usually transient and returns to normal with recovery from the viral infection. In rare patients, chronic symptoms and delayed gastric emptying may result [154,155]; this may be one cause of idiopathic gastroparesis.

Gastric CMV occurs often in immunosuppressed persons, particularly organ transplant recipients [156]. Upper GI CMV infection has been reported to occur in one-third of patients after liver transplantation, often associated with typical symptoms of gastroparesis including nausea and abdominal fullness. Endoscopy can show large antral folds, gastric inflammation including acute superficial gastritis, and duodenal erosions and ulcerations. Viral cultures of gastric biopsies and histological presence of CMV inclusions in the gastric mucosa are used for diagnosis [156]. The CMV infection can be treated with ganciclovir. GI infection with CMV is unusual in immunologically normal individuals. A case report documents acute CMV infection causing GI dysmotility in an immunocompetent patient; the disturbance in GI motor function persisted for years after viral infection had been eradicated [154].

Gastric emptying may be delayed in one-third of persons seropositive for human immunodeficiency virus (HIV) [157], particularly those with advanced disease evidenced by low CD4 counts, marked weight loss, and enteric infections [158]. In immunocompromised patients, the acute stage of gastritis and gastroparesis from viruses and other infectious agents, especially CMV and *Mycobacterium avium-intracellulare,* may persist for prolonged times. Some investigators have found delayed gastric emptying of solids with diminished postprandial antral motility but rapid emptying of liquids, suggesting an autonomic neuropathy that is common in HIV infection [159].

It had been speculated that *H. pylori* causes GI motor abnormalities. Although a few studies have shown an association [160], most conclude that *H. pylori* does not cause delayed gastric emptying or functional dyspepsia [161]. One study reported that chronic antral *H. pylori* gastritis was associated with a lower incidence of the phase III MMC starting in the antrum in dyspeptic patients [162]. Another study suggests that dyspeptic patients with *H. pylori* infection have a high prevalence of gastric dysrhythmias; eradication of *H. pylori* normalized gastric myoelectric activity and improved symptoms [163].

Chronic mesenteric ischemia (ischemic gastroparesis)

Gastric ischemia may occur in chronic *atherosclerotic disease*; the gastric ischemia is insidious and often is not recognized. Ischemic gastropathy secondary to atherosclerosis may present as gastritis, ulceration, or gastroparesis [164]. Angiography demonstrates arterial occlusion. Cases of chronic *mesenteric ischemia* with chronic gastric ischemia causing gastroparesis and gastric dysrhythmias have been reported [165]. Surgical revascularization may improve gastric emptying and corrects gastric dysrhythmias in selected patients.

Gastroparesis after lung and heart–lung transplantations

Gastroparesis has been reported after heart and lung transplantations [166,167]. After lung transplantation, gastroparesis may predispose to gastroesophageal reflux with microaspiration and subsequent pulmonary infection, which can have deleterious effects on the transplanted lungs. Symptomatic delayed gastric emptying was present in 25% of patients after single lung transplantation and in 50%–80% of patients after combined heart and lung transplantation [166,167]. Several causes including vagal nerve dysfunction, viral infection, and immunosuppressive medications may explain gastroparesis after heart and lung transplantation [166–168].

Gastroparesis secondary to malignant disease (tumor-associated gastroparesis)

Tumor-associated gastroparesis has been described with esophageal, gastric, pancreatic, breast, and lung carcinoma. The pathophysiology is unknown, but frequently it is attributed to paraneoplastic effects, neural invasion of the tumor, or the side effects of chemotherapy.

In *gastric cancers* that are nonobstructing, tumor infiltration into the stomach wall may disrupt smooth muscle or neural innervation. The symptoms and delay in gastric emptying can be responsive to prokinetic agents, including metoclopramide [169].

Small bowel tumors are rare and can be difficult to diagnose. Infrequently, patients initially diagnosed with gastroparesis are found on further evaluation to have a small bowel adenocarcinoma causing symptoms from partial obstruction [170]. These tumors can be missed on an SBFT examination. Enteroclysis provides a more detailed evaluation.

In *pancreatic cancer,* delayed gastric emptying has been reported in 40%–60% of patients without gastroduodenal invasion or obstruction. Usually, the gastroparesis is asymptomatic, but it may be responsible for the nausea, vomiting, and abdominal or back pain that occur [171]. Retroperitoneal nerve invasion of the tumor has been postulated as a cause of the gastroparesis, although gastroparesis can also occur with resectable cancers.

Pseudoobstruction with delayed gastric emptying may represent a paraneoplastic syndrome that occurs primarily with small cell lung carcinoma [172]. Intestinal dysmotility is suspected to have an autoimmune basis affecting the myenteric plexus. Pathological studies have shown degeneration of the myenteric plexus with infiltration by plasma cells and lymphocytes and markedly reduced numbers of neurons [173]. The onset of GI dysmotility not infrequently precedes the diagnosis of cancer [172]; patients may have a normal chest radiograph at presentation with subsequent diagnosis of cancer by computed tomography, magnetic resonance imaging, or bronchoscopy. Antroduodenal manometry may show neuropathic abnormalities with incoordination of contractions. Type 1 antineuronal nuclear antibody (ANNA-1 or anti-Hu) can often be detected in paraneoplastic pseudoobstruction from small cell lung carcinoma [172].

Delayed gastric emptying with nausea and vomiting can occur during treatment of malignant disease. Gastroparesis can occur after radiation therapy for treatment of tumors [174], during treatment with chemotherapeutic agents [175], after bone marrow transplantation [176], and after celiac plexus block for chronic pain from pancreatic cancer [177].

Medication-induced gastroparesis

Nausea and vomiting can be side effects of medications. Nausea and vomiting in response to a drug are likely to present early in its use; medications usually cause acute rather than chronic nausea and vomiting [16]. Many drugs including anticholinergics, narcotic analgesics, tricyclic antidepressants, and calcium channel blockers are known to delay gastric emptying (see Table 39.2). Several of the newer diabetic medications, including pramlintide, delay gastric emptying. Drug-induced gastroparesis may be asymptomatic, but it needs to be considered when delayed gastric emptying is found in a symptomatic patient. Gastric acid-suppressing agents, such as proton pump inhibitors and H_2 receptor antagonists, have been shown to delay gastric emptying [178]; however, these agents are unlikely to produce clinically significant gastroparesis. Some studies suggest that nizatidine, an H_2 receptor antagonist with cholinergic properties, may induce antral contractility and may promote gastric emptying [179].

Gastric emptying of solids is delayed in patients receiving total parenteral nutrition (TPN) [180]. It is suggested that if assessment of gastric emptying and motility is performed in a patient who is receiving TPN, the TPN should be converted to saline for the test [27]. Slowing of gastric emptying during TPN is correlated with an increase in blood glucose from the intravenous nutrients; hyperglycemia inhibits gastric emptying of solids. The inhibitory effect of hyperglycemia on gastric emptying may be mediated by the vagal–cholinergic system [180]. Oral ingestion of fat is well known to delay gastric emptying through intestinal feedback and release of CCK. Intravenous infusion of fat emulsions also delays gastric emptying [180,181]. The mechanism by which intravenous fat influences gastric motility is poorly understood [180,181].

Treatment of symptomatic gastroparesis

The general principles for treatment of symptomatic gastroparesis are as follows: first, to correct fluid, electrolyte, and nutritional deficiencies; second, to identify and treat the underlying cause of gastroparesis; and third, to reduce symptoms [16,182,183]. The specific treatment depends on the severity of symptoms and the underlying disorder. For mild gastroparetic symptoms, dietary modifications may be used. Medicines are reviewed to ensure that the patient is not taking an anticholinergic agent or narcotic analgesic that could delay gastric emptying or prevent the action of a prokinetic agent. For diabetic patients, blood glucose should be regulated carefully to prevent hyperglycemia. In severe cases of gastroparesis with vomiting, signs of dehydration, and poor glucose control, treatment may include hospitalization, intravenous hydration, nasogastric suction to decompress the stomach, regulation of blood glucose, and intravenous administration of antiemetic and prokinetic agents.

Dietary treatment

In gastroparesis, dietary modification is the initial treatment [184]. The diet may be modified to promote faster gastric emptying. Liquid nutrients in the diet should be increased, because emptying of liquids is usually less affected than solids. Because fat intake releases CCK, which can delay gastric emptying, low-fat meals with complex carbohydrates are suggested. Meals should be small to allow time for emptying to occur; gastric emptying of meals is regulated for a set number of calories to be emptied into the duodenum [185]. To compensate for small meals, patients may need to eat four or five times daily. A diet low in indigestible fiber and roughage will reduce the chance of bezoar formation.

Alcohol and carbonated beverages should be avoided. Even low doses of alcohol can decrease antral contractility and impair gastric emptying. Carbonated beverages release carbon dioxide gas, which can aggravate gastric distention.

Commercial or self-prepared liquid homogenized meals may be tolerated in small quantities; larger volumes needed to cover daily caloric needs are often not. Enteral alimentation may be needed in patients with refractory symptoms unable to maintain adequate nutrition and hydration. In some severe cases, TPN may be needed. This is not a long-term solution because of catheter-induced bacteremia, clot formation, and cost.

Glucose control

Diabetic patients with gastroparesis may have abnormally high glucose concentrations both after fasting and postprandially. Hyperglycemia itself has been shown to delay gastric emptying [60,61]. This slowing is associated with reduced antral contractility and increased pyloric pressure.

Hyperglycemia can inhibit the accelerating effects of prokinetic agents [186]. Improvement of glucose control can increase antral contractility, correct gastric dysrhythmias, and accelerate gastric emptying. Measures should include more aggressive glucose monitoring with frequent dosing of short-acting insulin preparations to prevent profound postprandial hyperglycemia. Prevention of wide fluctuations in serum glucose levels may be more important than maintenance of a given steady state blood sugar value from a gastric emptying perspective. For many type I diabetic patients, a long-acting preparation such as insulin glargine may be administered twice daily with preprandial injections of regular insulin formulas. However in patients with gastroparesis, postprandial hypoglycemic episodes can occur when the glucose-lowering effects of preprandial short-acting insulin precede delivery of nutrients into the small intestine for digestion and absorption. To this end, monitoring 2-h postprandial blood glucose levels may be useful.

Antiemetic agents

Nausea and vomiting are treated with antiemetic agents [16]. These include phenothiazines, antihistamines, anticholinergics, dopamine receptor antagonists, and serotonin receptor antagonists.

The actions of phenothiazine compounds are mediated primarily through a central antidopaminergic mechanism at the chemoreceptor trigger zone in the area postrema of the medulla oblongata [16]. Commonly used agents include prochlorperazine (Compazine), trimethobenzamide (Tigan), and promethazine (Phenergan). These agents are commonly used for severe episodes of nausea and vomiting and are available as tablets, capsules, liquid suspensions, and suppositories, and for injectable use. Sedation and extrapyramidal side effects may develop with these agents [187].

Antihistamines with H_1 receptor antagonistic properties have central antiemetic effects [16]. These include diphenhydramine (Benadryl), dimenhydrinate (Dramamine), and meclizine (Antivert). These agents exert antinausea effects by blocking H_1 receptors in the vestibular apparatus and the chemoreceptor trigger zone within the area postrema. In vection-induced motion sickness, dimenhydrinate reduced tachygastria, decreased symptoms, and caused drowsiness, suggesting that symptom improvement is by improvement of gastric myoelectric activity or depression of central nervous system activity [188].

Serotonin ($5\text{-}HT_3$) receptor antagonists, such as ondansetron (Zofran) and granisetron (Kytril), are useful in chemotherapy-induced nausea and vomiting. The primary site of action is likely the chemoreceptor trigger zone because of the high density of $5\text{-}HT_3$ receptors in the area postrema [16]. They may also act peripherally because $5\text{-}HT_3$ receptors are present in the GI tract [16]. They do not appear to affect gastric emptying [189]. If used, they are best given on an as needed basis because of the lack of evidence of prolonged efficacy and their expense. Benzodiazepines such as lorazepam and diazepam have been shown to be effective as adjunctive agents in the treatment of chemotherapy-related nausea and vomiting [16]. The most recently approved antiemetic agents for chemotherapy-induced nausea and vomiting are the neurokinin-3 receptor antagonists such as aprepitant [190].

Prokinetic agents

Prokinetic agents enhance contractility of the GI tract and accelerate the aboral movement of lumenal contents (Table 39.6). In general, prokinetic agents increase gastric antral contractility, correct gastric dysrhythmias, and improve antroduodenal coordination. Some of the prokinetic agents, metoclopramide and domperidone, also have antiemetic properties.

Table 39.6 Prokinetic agents for gastroparesis

Agent	Major mechanism of action	Comments
Metoclopramide (Reglan)	Dopamine receptor antagonist, central/peripheral	Only FDA-approved agent for gastroparesis Central nervous system side effects in 20%–30% Prokinetic and antiemetic properties
Erythromycin	Motilin receptor agonist	Gastrointestinal side effects in many: nausea, vomiting, abdominal pain Tachyphylaxis with long-term oral administration
Cisapride (Propulsid)	$5\text{-}HT_4$ receptor agonist, facilitates acetylcholine release	Taken off the market in March 2000 for prolonging QT interval Was approved only for nocturnal heartburn Currently not available in the United States
Domperidone (Motilium)	Dopamine receptor antagonist, peripheral	Prokinetic and antiemetic properties Available in Europe, Canada, and Mexico, but not in the United States
Bethanechol (Urecholine)	Muscarinic receptor agonist	Increases amplitude of contractions, not peristalsis Not a true prokinetic agent

Usually, prokinetic agents are administered 30 min before meals to maximize blood levels and gastric prokinetic effects at meal ingestion. In addition, a bedtime dose is often used so that indigestible solids can be emptied from the stomach. Medications with anticholinergic activity may block the effects of prokinetics that work by facilitating acetylcholine release.

In gastroparesis, pharmacological therapy with prokinetic agents is often needed on a prolonged basis. Because GI symptoms correlate poorly with gastric emptying, the response to treatment is usually judged clinically; repeating gastric emptying tests is not necessary.

Prokinetic therapeutic options are limited now that cisapride and tegaserod are not routinely available (see Table 39.6). Prokinetics available for clinical use in the United States are metoclopramide and erythromycin.

Metoclopramide

Metoclopramide (Reglan), a substituted benzamide structurally related to procainamide, has been used since the 1970s to treat gastroparesis [191]. Metoclopramide has both prokinetic and antiemetic effects. It releases acetylcholine from intrinsic cholinergic neurons and blocks peripheral dopamine receptors, where dopamine acts as an inhibitory agent of smooth muscle contraction. The prokinetic properties of metoclopramide are limited to the proximal GI tract. Metoclopramide increases amplitudes of esophageal contractions, resting lower esophageal sphincter pressure, and gastric fundic and antral contractions, and improves antropyloroduodenal coordination. It has antiemetic effects resulting both from dopamine antagonism in the chemoreceptor zone and from a central action at the vomiting center.

Metoclopramide is approved for use in diabetic gastroparesis and for prevention of postoperative and chemotherapy-induced nausea and vomiting. Controlled trials have shown that metoclopramide may provide symptomatic relief while accelerating gastric emptying of solids and liquids in patients with idiopathic, diabetic, and postvagotomy gastroparesis and in patients with GERD [192,193]. Metoclopramide has been reported to be effective in the short-term treatment of gastroparesis for up to several weeks [192,193]. Long-term efficacy for metoclopramide has not been clearly demonstrated; its effect on gastric emptying may diminish during long-term treatment [194]. In diabetic gastroparesis, acute administration of metoclopramide accelerates emptying, but not after 1 month of treatment [194]. However, metoclopramide may continue to relieve symptoms because of its antiemetic effects.

The usual starting dose of metoclopramide in adults is 10 mg 30 min before meals and at bedtime. In patients not responding, the dose can be increased to 20 mg. In severe gastroparesis, oral metoclopramide may not be adequately absorbed because of vomiting or delayed gastric emptying; metoclopramide administered intravenously may improve gastric emptying. Metoclopramide may also be administered subcutaneously, by suppository, or even intraperitoneally in patients undergoing peritoneal dialysis [195].

Side effects of metoclopramide, resulting from its antidopaminergic properties, may occur in up to 30% of patients and are the major factor restricting its use. Acute dystonic reactions including facial spasm, oculogyric crisis, trismus, and torticollis occur in 0.2%–6% of patients [196]. These effects are usually observed during the first 48 h of treatment and are more frequent with higher doses. Drowsiness, fatigue, and lassitude occur in 10% of patients. Mental depression may occur and may range from mild to severe. Metoclopramide can aggravate underlying depression. Other side effects may include restlessness, agitation, irritability, and akathisia. Increased prolactin release may result in breast engorgement, lactation, and menstrual irregularity.

Side effects of long-term use of metoclopramide are of concern. Prolonged treatment with metoclopramide may result in Parkinsonian-like symptoms, more commonly within the first 6 months after beginning treatment, but occasionally after longer periods [196]. These symptoms usually subside within 2–3 months after discontinuation of the drug. Patients with Parkinson disease should be given metoclopramide cautiously, if at all. Tardive dyskinesia, consisting of involuntary movements of the face, tongue, or extremities, may occur with prolonged use and may not reverse after stopping the medication. The prevalence of tardive dyskinesia may range from 0.02% to 2% when patients take metoclopramide for at least 3 months [196]. This study also reported a prevalence as high as 15% [196]. This effect is more common in elderly women. Possible side effects of metoclopramide should be discussed with the patient before starting this medication, and notation of this discussion should be documented in the patient's medical chart.

Erythromycin and motilides

Erythromycin has prokinetic effects because it is a motilin receptor agonist in addition to being an antibiotic [197]. Motilin, an endogenous GI peptide, plays a role in initiating the gastric phase III of the MMC and is a potent stimulator of antral contractility. Erythromycin binds to motilin receptors located on smooth muscle and on cholinergic neurons; the latter appear to be important for actions in vivo [197,198].

Erythromycin stimulates gastric emptying in diabetic, idiopathic, and postvagotomy gastroparesis. It is the most potent prokinetic agent in accelerating gastric emptying, which it achieves by increasing the amplitude and frequency of antral contractions. Interestingly, erythromycin has been reported to accelerate stomach emptying in postsurgical gastroparesis in which the antrum, the primary site of its motor effect, has been resected [199]. The prokinetic effect in this situation may result from a stimulatory effect on the fundus.

Erythromycin is reported to be most effective when it is used intravenously during acute exacerbations of gastroparesis

[200]. Intravenous infusion of erythromycin lactobionate (200 mg) accelerated emptying of solids in patients with diabetic gastroparesis [201]. In these same patients, after 4 weeks of oral erythromycin ethylsuccinate (250 mg orally three times daily, 30 min before meals), the magnitude of the acceleration was less than that observed in response to the single intravenous dose. Studies carried out over longer observation periods have reported a reduction of benefit over time with oral administration. Hyperglycemia attenuates the stimulation of antral contractility and gastric emptying by erythromycin [186]. The motilin receptor agonist ABT-229 was not efficacious in relief of postprandial dyspeptic symptoms in diabetic gastroparesis or functional dyspepsia [202]. This lack of efficacy has been attributed to motilin's propensity to increase fundic tone, impairing accommodation.

Oral administration of erythromycin should be initiated at low doses, such as 125–250 mg three times daily. Many physicians prefer using erythromycin suspension as it takes less time to reach peak concentrations and is easier to adjust dosages [203]. One center reports the use of intravenous erythromycin (100 mg every 8 h) for severe refractory gastroparesis [204]. Side effects of erythromycin include nausea, vomiting, and abdominal pain.

Domperidone

Domperidone (Motilium) is a benzimidazole derivative and is a specific dopamine type 2 receptor antagonist. The effects of domperidone in the upper GI tract are similar to those of metoclopramide. Domperidone stimulates upper GI motility by enhancing gastroduodenal contractions and coordination. It does not readily cross the blood–brain barrier; therefore, it is much less likely to cause extrapyramidal side effects than metoclopramide [205]. However, domperidone has antiemetic properties from its actions at the chemoreceptor trigger zone on the blood side of the blood–brain barrier.

Domperidone has been studied primarily in diabetic gastroparesis. It increases both solid and liquid emptying, especially in those patients with a severe delay in gastric emptying [206]. Symptomatic improvement may not correlate with improvement in emptying; symptom improvement may result from antiemetic effects. A symptomatic benefit of domperidone can occur in diabetic patients with normal gastric emptying [207].

The effect of long-term treatment with domperidone has been variable. In one study, at 6 weeks the effect of domperidone on solid phase gastric emptying was lost, whereas that on liquid gastric emptying was maintained [206]. Another study found that nausea and vomiting were improved compared with baseline values after 6 weeks of treatment, but there was no change in solid phase gastric emptying [207]. Other studies have suggested that improvements in gastric emptying and symptoms were still present after 1 year of treatment [135]. Double-blind studies examining the effects of long-term treatment with domperidone on chronic nausea and vomiting have revealed symptomatic benefit; these observations, however, have not been uniform [207].

Domperidone has been suggested for therapy of nausea and vomiting in Parkinson disease, symptoms that may be related to the use of dopaminergic agents (e.g., L-dopa), which may cause or worsen gastroparesis associated with the disorder [135]. Domperidone would work peripherally for GI dysmotility and symptoms, whereas L-dopa would still work centrally for the parkinsonian symptoms.

The side effects of domperidone are usually secondary to increased prolactin levels, and include breast engorgement and galactorrhea. Central nervous system side effects are minimal.

Domperidone has not been approved by the US Food and Drug Administration (FDA) and is not available by routine prescription in the United States. Physicans who would like to use domperidone for their patients can submit an Investigative New Drug (IND) application to the FDA and their Institutional Review Board (IRB); patients need to purchase the medication (US$50 per month for 10 mg orally four times a day).

Cisapride

Cisapride (Propulsid) is a serotonin (5-HT_4) agonist that facilitates the release of acetylcholine from cholinergic nerves in the myenteric plexus throughout the GI tract. Cisapride stimulates antral and duodenal contractions, improves antroduodenal coordination, and accelerates gastric emptying. Cisapride accelerates gastric emptying and decreases symptoms in patients with gastroparesis, an effect that may last for a year. It also increases esophageal contractions and resting lower esophageal sphincter pressure.

Cisapride was approved by the FDA for the treatment of nocturnal heartburn in patients with GERD. There have been rare instances of cardiac arrhythmias and sudden death after use of this drug [16,187]. These were not due to the 5-HT_4 agonist properties of cisapride, but rather were an effect of its molecular structure on cardiac potassium channels, prolonging the QT interval and predisposing to ventricular arrhythmias, particularly torsades de pointes. Cisapride is metabolized by the cytochrome P450 3A4 system; use of medications that interact with this enzyme system leads to increased cisapride blood levels and increased cardiac toxicity. Besides cardiac risks, side effects include diarrhea, lightheadedness, and abdominal cramps. In patients with a seizure focus, cisapride may rarely increase seizure activity. Cisapride is not available for routine clinical use in the United States; it can be obtained only through limited-access investigational study protocols.

Bethanechol

Bethanechol (Urecholine) is a nonspecific cholinergic muscarinic receptor agonist. It enhances the amplitude of contractions throughout the GI tract. Unfortunately, bethanechol does not coordinate contractions; gastric emptying and small

bowel transit are not necessarily accelerated. Thus, bethanechol is not a true prokinetic agent [187]. Occasionally, it may be helpful as adjuvant treatment in combination with other prokinetic agents. The typical dose is 25 mg orally four times daily. The direct cholinergic action of bethanechol may also stimulate secretion of gastric acid and saliva. Potential side effects of bethanechol include increased salivation, blurred vision, abdominal cramps, and bladder spasm.

Octreotide

Somatostatin has variable effects on GI tract motor activity. Somatostatin inhibits antral motor contractions. In the intestine, somatostatin initiates ectopic myoelectric and motor fronts under basal conditions but inhibits fed motility. Octreotide is a cyclic analog of somatostatin that is administered by subcutaneous injection and which induces small intestinal phase III-like contractile activity. Nocturnal dosing may improve small intestinal motor function in patients with scleroderma with small bowel involvement [208]. In patients with gastroparesis, octreotide initiates phase III activity, which originates in the small intestine and inhibits postprandial antral contractility [209]. Thus, octreotide delays gastric emptying and may worsen symptoms in patients with gastroparesis. Clinically, it may be used for small bowel dysmotility. In this case, prokinetic agents are administered before meals and octreotide is given at bedtime. Prolonged usage may result in gallstones from inhibition of gallbladder emptying.

Refractory gastroparesis

There is no uniform way to handle patients with refractory gastroparesis – patients not responding to standard antiemetic and prokinetic agents or with side effects preventing their use. In one study of 110 patients with "refractory" gastroparesis [1], 74% responded to use of another prokinetic agent and only 26% were refractory to all prokinetic agents. These truly refractory patients underwent enteral or parenteral feedings and gastric electrical stimulation, and some underwent gastrectomy. Poor responders to prokinetic agents include postgastrectomy patients, those with myopathic connective tissue disorders, type I diabetic patients with severely delayed gastric emptying, and patients with idiopathic gastroparesis with abdominal pain [1].

An initial approach to refractory gastroparesis includes ensuring that delayed gastric emptying is present, optimizing the patient's current therapy, and changing prokinetic agents [187]. Why some patients respond to one prokinetic agent and not another is uncertain. Different prokinetic agents have different mechanisms of action (see Table 39.6) and the efficacy of most prokinetic agents diminishes with prolonged use. A "drug holiday," as used for L-dopa in Parkinson disease, can be used for prokinetic agents.

In patients who remain refractory to treatment, one may consider placement of a venting gastrostomy or a feeding jejunostomy. Newer therapies might include gastric electrical stimulation and injection of botulinum toxin into the pylorus. TPN, if used, should be temporary because of the risk of infection and deep venous thrombosis. Surgical subtotal gastric resection, usually accompanied by a Roux-en-Y diversion, should generally be discouraged. Completion gastrectomy can be considered for selected patients with postsurgical gastroparesis.

Combination prokinetic therapy

Prokinetic agents use different mechanisms to enhance gastric emptying (see Table 39.6). Addition of a second prokinetic agent may augment the response of a first agent. Combination prokinetic therapy with two different agents may be useful to accelerate emptying and reduce symptoms in some refractory gastroparetic patients. The combination of the available prokinetic agents, metoclopramide with erythromycin, or domperidone with erythromycin have not been studied.

Newer prokinetic agents

Newer prokinetic agents being tested for gastroparesis include 5-HT_4 receptor agonists, dopamine receptor antagonists, CCK receptor antagonists, motilin receptor agonists, and, more recently, ghrelin receptor agonists.

Tegaserod, a partial 5-HT_4 receptor agonist, has been shown to accelerate gastric emptying in normal subjects and in patients with gastroparesis [210]. However, its effect on symptoms was marginal. Tegaserod was removed from the market in March 2007 because of cardiovascular side effects. Other 5-HT_4 receptor agonsts are being studied.

Clonidine, an α_2-adrenergic agonist, has been reported to decrease symptoms and to accelerate gastric emptying in patients with diabetic gastroparesis [211]. Other studies have shown that clonidine reduces dyspeptic symptoms by improving gastric accommodation [212]. Some studies report that clonidine delays gastric emptying [213]. A side effect is hypotension; clonidine should be used cautiously, especially in diabetic patients with autonomic dysfunction.

Acetylcholinesterase inhibitors, such as physostigmine and neostigmine, may stimulate GI contractility by increasing acetylcholine levels with subsequent muscarinic receptor activation. Anticholinesterase agents may increase gastric contractility, but they may not increase antroduodenal coordination; therefore, they may not increase emptying [214]. In animal studies, GI transit is affected in an inverted U-shaped dose–response curve with acceleration at lower doses but inhibition at higher doses [215]. This dual effect may be related to activation of different muscarinic receptor subtypes. Some H_2 receptor antagonists, such as ranitidine and nizatidine, have been reported to have anticholinesterase activity [178,179].

Psychotropic medications

Tricyclic antidepressants appear to be of some benefit in patients with functional vomiting and gastroparesis [215,216];

they may be helpful for the nausea, vomiting, or abdominal pain. They are used at lower doses (median 50 mg/day) than in the treatment of depression. Low doses may reduce afferent sensory transmission. Some of these agents, especially the tertiary amines such as amitriptyline (Elavil), have anticholinergic properties and may delay gastric emptying. In general, desipramine and nortriptyline are used in patients with gastroparesis because of their reduced anticholinergic effects. Future prospective controlled trials will define the role of this group of medications in the management of gastroparesis.

Botulinum toxin injection into the pyloric sphincter

Gastric emptying is a highly regulated process reflecting the integration of propulsive forces of proximal fundic tone and distal antral contractions with inhibitory forces of pyloric sphincter resistance. Few studies have been performed to see whether inhibition of the pyloric sphincter muscle accelerates gastric emptying. Early studies with surgical pyloromyotomy did not show benefit; more recent studies have shown a beneficial response in diabetic gastroparesis [217]. Pyloromyotomy may be helpful in preventing gastric stasis after truncal vagotomy.

Botulinum toxin is a potent inhibitor of neuromuscular transmission and has been used to treat spastic disorders of muscles by local injection into affected muscles. Injection of botulinum toxin directly into the lower esophageal sphincter reduces pressure and improves symptoms in patients with achalasia [218]. Initial case series included small numbers of patients with idiopathic and diabetic gastroparesis in whom botulinum toxin was injected into the pylorus in an attempt to reduce gastric outlet resistance and accelerate gastric emptying [219–221]. These series showed a mild improvement in gastric emptying and a modest improvement in symptoms after injection of botulinum toxin. A subsequent, much larger case series included 63 patients and demonstrated that approximately 40% of patients experienced clinical benefit from pyloric injection, which lasted a median of 5 months [222]. Results from placebo-controlled trials have shown that, although botulinum toxin injection into the pylorus may mildly accelerate gastric emptying, there is little difference in symptom improvement with botulinum toxin compared with placebo [223,224].

Alternative and unconventional medical therapy primarily for nausea and vomiting

Ginger, a traditional Chinese herbal remedy, is used to treat nausea and vomiting postoperatively [225] and nausea and vomiting during pregnancy [226]. Ginger reduces nausea and associated tachygastria caused by circular vection, an experimental model of motion sickness [227]. Ginger has also been shown to reduce hyperglycemia-induced gastric dysrhythmias and nausea [228].

Stimulation of the PC6 acupuncture point on the wrist with conventional acupuncture, electroacupuncture, or acupressure with a wrist band (e.g., Sea-band) may help to control postoperative nausea, chemotherapy-induced nausea, and nausea associated with morning sickness [229–231]. These studies also suggest that acupressure has similar efficacy to standard antiemetic therapy for postoperative nausea [229]. Another acupuncture point that has been used for influencing gastric motility is the Zusanli point (ST36) located on the leg below the patella [230]. Electroacupuncture reduces the severity of symptoms of vection-induced motion sickness while decreasing gastric tachyarrhythmias [231]. Animal studies suggest that electroacupuncture enhances gastric emptying by vagal stimulation. Electroacupuncture has been postulated to modulate the release of serotonin, substance P, and endogenous opiates in central nervous system pathways [232].

Venting gastrostomy and feeding jejunostomy tubes

In the treatment-refractory patient with severe nausea and vomiting, placement of a gastrostomy tube for intermittent decompression by venting or suctioning may provide relief to the patient who has prominent abdominal distention. The gastrostomy tube can be opened for drainage or aspirated to decompress the stomach; this can be employed when symptoms are distressing to alleviate nausea, pain, and bloating. Venting gastrostomy tubes may be placed by the endoscopist, surgeon, or interventional radiologist. In one series, six of eight patients were able to return to full-time work or school [232]. The percutaneous endoscopic gastrostomy tube can be converted to a button. Gastrostomy tubes are used much less now that refractory patients can be treated with gastric electrical stimulation; the gastrostomy tube may interfere with placement of the gastric stimulating electrodes.

Use of a gastrostomy tube for feeding may aggravate gastroparetic symptoms. A feeding jejunostomy is usually preferred. Although a J-tube extension can be placed through the gastrostomy, these often prolapse into the stomach. To prevent this, enteral feedings through a direct jejunostomy tube can be helpful. Jejunostomy tubes are effective for providing nutrition, fluids, and medications, provided that the small intestine is functioning [233,234]. Carefully regulated nutrient enteral infusion may allow better glucose control in diabetic patients whose glycemic control is otherwise poor because of vomiting and gastroparesis [234]. Jejunostomy tubes are usually inserted laparoscopically or at laparotomy [235]; in some centers they are placed endoscopically.

Gastric electrical stimulation

Gastric electrical stimulation is an emerging treatment for refractory gastroparesis. There are several techniques for stimulating the stomach. First, in gastric electrical pacing the goal is to entrain and pace the gastric slow waves with

low-frequency, high-energy, long-duration pulses. Pacing at 10% higher than the basal rate has been shown to accelerate gastric emptying and to improve dyspeptic symptoms [236]. Second, stimulation with high-frequency, low-energy, short-duration pulses has been shown to decrease symptoms with little effect on gastric emptying [237,238]; it may affect proximal stomach function and activate sensory afferent nerves to reduce symptoms. Third, sequential muscle stimulation using bursts of suprahigh-frequency stimulation to induce direct gastric muscle contractions in a peristaltic sequence has accelerated emptying in animal studies [239]. More recently, sequential gastric neurostimulation of the stomach has been used to entrain gastric slow waves.

High-frequency gastric electrical stimulation at 12 cycles/min has received FDA humanitarian approval for treatment of chronic, refractory nausea and vomiting secondary to diabetic or idiopathic gastroparesis. Stimulating wires are placed into the gastric muscle at the greater curvature during laparoscopy or laparotomy. These leads are attached to an electric stimulator ("pacemaker"), which is placed in a subcutaneous abdominal pouch. An initial study demonstrated effectiveness in 20 of 26 patients with a decrease in nausea and vomiting at 3 and 6 months; gastric emptying of liquids, but not solids, was improved [237]. In long-term follow-up, 3 of 24 patients underwent total gastrectomy because of unsatisfactory results, and three had the stimulator removed because of erosion or infection. A subsequent study reported on 33 patients with chronic gastroparesis [238]. After implantation, the electrical stimulator was turned on or off in a randomized, double-blind, crossover design. Patients felt better when the stimulator was on, although the decrease in vomiting that occurred was not statistically significant. Long-term follow-up over 1 year showed a decrease in the mean vomiting frequency from 25 to 6 times per week. In addition, there was an improvement in the overall quality-of-life score and a mild improvement in gastric emptying. Complications were infection in three patients and electrode penetration of the stomach wall in one patient. An open-label study in 25 patients reported an overall improvement from "severe" to "moderate" in symptoms of nausea and vomiting of 40% [240]. There was an infection rate of 15%, requiring removal of the stimulator. Carefully designed studies are needed to determine the overall effectiveness of gastric electrical stimulation, which type of patient will likely respond, and the optimal stimulation parameters. Preliminary studies suggest that the patients most likely to respond are those with diabetic gastroparesis, main symptoms of nausea and vomiting, and those not taking regular narcotic analgesic medications [241].

Surgical treatment

Surgical treatment of idiopathic and diabetic gastroparesis has generally been disappointing [16]. Surgery is performed only as a last resort. The procedure usually employed is a partial gastrectomy and Roux-en-Y gastrojejunostomy.

For selected patients with postsurgical gastroparesis in whom medical therapy has failed, further resection of the stomach may occasionally be considered. Usually, these patients have had a previous vagotomy. Postsurgical gastroparesis patients require radical surgery to eliminate hold-up in the atonic stomach and to enable the creation or revision of a Roux limb to prevent enterogastric reflux. The resection is performed as a completion of the gastrectomy or a near-total gastrectomy, rather than as a less extensive resection [242,243]. In near-total gastrectomy, only a small rim of proximal stomach (< 1 cm) is retained. Reconstruction is achieved by a Roux loop of at least 45 cm to the rim of the stomach. The extensive gastrectomy is to eliminate the gastroparetic stomach and to allow ingested nutrients to pass directly from the esophagus into the small intestine. The Roux-en-Y jejunal segment helps to prevent reflux of small intestinal contents into the remaining stomach and esophagus. This extensive surgery may lead to improvement in two-thirds of patients in specialized centers [242].

In a series of 62 patients who underwent completion gastrectomy for severe postvagotomy gastric stasis [244], good symptomatic improvement in nausea, vomiting, and postprandial abdominal pain was obtained in only 43%. There was no improvement in chronic pain. The combination of nausea, need for TPN, and retained food at endoscopy predicted a poor outcome.

In another series of 81 patients with severe postsurgical gastroparesis [245], near-complete gastrectomy with a 55-cm Roux-en-Y reconstruction was performed. Follow-up averaged 56 months for 52 patients; 78% reported improvement of their GI symptoms, 7% believed that there was no change, and 15% stated that their condition had worsened.

A subtotal (70%) gastrectomy with resection of the antrum and pylorus, closure of the duodenum, and restoration of GI continuity with a 60-cm Roux-en-Y jejunal loop was reported in four patients with insulin-dependent diabetes with intractable vomiting from gastroparesis [246]. In total, three of the four patients did well, eliminating frequent hospital admissions.

Pancreatic transplantation for diabetic gastroparesis

Pancreatic transplantation and simultaneous kidney and pancreatic transplantation are being performed more often for insulin-dependent diabetes mellitus. With successful pancreatic transplantation, postprandial hyperglycemia resolves, and insulin therapy can be discontinued [241]. Simultaneous pancreatic and kidney transplantation helps to correct both uremia and hyperglycemia. Pancreatic transplantation has been shown to halt progression and slightly improve diabetic polyneuropathy [240]. Improvement during the first year

after pancreatic transplantation may be primarily the result of correction of hyperglycemia, which affects nerve function. A relatively small degree of improvement in peripheral nerve function has been reported over time [247]. Gastric emptying may be improved in some patients after pancreatic transplantation, although the literature is sparse. One study reported an improvement in liquid emptying in six of eight patients with previously delayed emptying, but no improvement in solid phase emptying at 6 months after pancreatic transplantation [241]. Another study found that emptying was improved 1 year after pancreatic and kidney transplantation in 8 of 23 patients [248]. Despite limited improvement in gastric emptying, symptoms and gastric dysrhythmias improved in diabetic patients after organ transplantation [241,248].

Disorders with rapid gastric emptying

Postsurgical dumping syndrome

Description and clinical features

Rapid gastric emptying and its consequences are responsible for *dumping syndrome*, symptoms of which include postprandial sweating, weakness, orthostasis, tachycardia, and diarrhea. Dumping syndrome, especially of liquids, occurs almost exclusively after gastric surgery. It affects up to 20% of patients after gastrectomy (usually antrectomy) or truncal vagotomy with a drainage procedure (see Table 39.5). Postsurgical pathophysiological abnormalities causing the dumping syndrome include the following: (1) loss of proximal stomach receptive relaxation and accommodation secondary to vagotomy; (2) decreased gastric capacity after gastrectomy; (3) loss of controlled emptying from bypass or ablation of pyloric sphincter; (4) loss of duodenal feedback inhibition resulting from a bypassed duodenum from gastrojejunostomy [249,250].

Dumping symptoms are often characterized as early or late relative to their time course after meal ingestion. Early dumping symptoms occur in the first 30 min and result from accelerated early gastric emptying of liquids with rapid filling of the intestine with hypertonic fluid, leading to bloating, crampy abdominal pain, and explosive diarrhea. Rapid filling of the intestine is associated with osmotic fluid shifts into the gut lumen and reduction of plasma volume resulting in secondary release of vasoactive substances that cause vasomotor symptoms such as lightheadedness, sweating, flushing, and palpitations with tachycardia. Late dumping symptoms occur 2–3 h after a meal and are associated with reactive hypoglycemia (weakness, palpitations, and diaphoresis); these result from the hyperinsulinemic response to an overwhelming carbohydrate load [251]. Because of its relatively long half-life, increased serum concentrations of insulin and associated hypoglycemia persist for relatively long periods.

Rapid gastric emptying of solids has been demonstrated in some patients with unexplained nausea, vomiting, bloating, and fullness [252]. Enhanced emptying of gastric contents has also been reported in some patients with functional dyspepsia [253]. Rapid gastric emptying also occurs in some diabetic patients, particularly in the early stages of type II diabetes [254]. Many of these patients have symptoms that are indistinguishable from those of gastroparesis. Rapid movement of food from the stomach into the small bowel with small bowel distention may explain the pain and nausea, symptoms similar to those described in patients with delayed gastric emptying. Rapid emptying has been recently observed as an accompanying factor in adult patients with cyclic vomiting syndrome [255,256]. In one study, rapid gastric emptying was more common than delayed gastric emptying in symptomatic patients with autonomic dysfunction [257].

Diagnosis

Dumping syndrome is usually diagnosed clinically, based on the characteristic symptoms occurring in patients after gastric surgery. Another postsurgical disorder is postvagotomy diarrhea; in this disorder the diarrhea is not related to meals, and postprandial hypotension and hypoglycemia are not seen. Scintigraphic studies of both the solid and liquid phase can document rapid gastric emptying. The rapid emptying is most notable immediately after the meal, occurring in the first 15 min [257]. In patients with suspected dumping syndrome, gastric emptying of liquids may be the preferable measurement. Orocecal transit time may also be helpful.

Treatment

Postsurgical dumping symptoms may resolve over time with conservative management. Specific treatment of the dumping syndrome is aimed at slowing delivery of nutrients into the small intestine and minimizing release of endogenous vasoactive substances. Initial dietary recommendations are to eat small, dry, frequent meals, to increase protein and fat content in the diet, to reduce the intake of carbohydrates by avoiding simple sugars, and to minimize liquid intake [249]. Lying down in a supine position after drinking liquids may delay liquid emptying. Increasing the viscosity of liquid meals by adding gel-forming carbohydrates (pectin or guar gum) may delay transit time and may slow carbohydrate absorption. Late dumping symptoms from hypoglycemia are usually relieved by ingestion of simple carbohydrates.

Medical therapy has centered on delaying gastric emptying. Anticholinergic agents have been employed, but they are usually not beneficial. The somatostatin analog, octreotide, is the primary pharmaceutical agent used for treatment. Octreotide has a much longer half-life than somatostatin and is administered subcutaneously to prevent breakdown by gastric acid. Octreotide has effects on both GI transit and

GI peptide release. Octreotide delays gastric emptying and prevents the accelerated emptying seen in dumping syndrome [249]. Octreotide also inhibits the release of enteric hormones and insulin secretion; this may actually be the primary mechanism of its symptomatic benefit [251]. Octreotide, 50 μg subcutaneously 30 min before meals, reduces the symptoms (diarrhea, lightheadedness, and palpitations) and signs (orthostatic hypotension, tachygastria) and metabolic alterations (late hypoglycemia) seen with dumping syndrome [251]. The dose may be increased to 100 μg three times a day if needed. The side effects of octreotide when administered subcutaneously include injection site pain, iatrogenic diabetes, malabsorption with a worsening of diarrhea, and cholelithiasis. Two studies have reported the long-term utility of octreotide and use of the newer long-acting depot form of octreotide [258,259].

The fatty acid oleic acid, administered before a meal, may slow GI transit and may decrease diarrhea in patients with rapid GI transit including dumping syndrome. Oleic acid activates nutrient-triggered intestinal inhibitory feedback mechanisms (jejunal–ileal brake) [260].

Revisional gastric surgery is performed in a few patients with severe dumping symptoms, with the aim of delaying stomach emptying to alleviate symptoms [261]. The results are variable and often disappointing [249]. Because of the risk of causing severe gastric stasis, surgery is recommended only when other measures have failed. Surgical procedures include takedown of a previous gastrojejunostomy with conversion to Billroth I gastroduodenostomy. A commonly used surgical procedure is creating a Roux-en-Y diversion, which has been reported to slow gastric emptying [260]. Insertion of an antiperistaltic jejunal segment between the stomach and the small bowel has been performed to produce a functional delay of nutrient outflow from the stomach [260]. Pyloric reconstruction has also been attempted.

Other disorders with rapid gastric emptying

Type II diabetes mellitus

Accelerated gastric emptying has been reported in early *type II diabetes* and rarely in early type I diabetes [58,59]. Although this condition primarily applies to liquids, rapid emptying of a high-carbohydrate solid meal may occur. This may result from impaired fundic accommodation from vagal neuropathy with reduction of inhibitory nitric oxide nerves [56]. Accelerated gastric emptying may result in enhanced intestinal absorption of glucose and increased postprandial glucose levels, in part because of a mismatch between absorbed food and insulin release. Excessive hepatic glucose release also contributes to postprandial hyperglycemia [59].

Slowing gastric emptying has been suggested to improve control of postprandial glucose in type II diabetes [262]. This may be the means by which the addition of dietary soluble fiber has been shown to improve glucose control [263,264]. Agents that slow gastric emptying are being used to improve glucose tolerance in diabetic patients; these include amylin and its analog pramlintide, and glucagon-like peptide-1 [262].

Pancreatic exocrine insufficiency

In *pancreatic insufficiency*, accelerated gastric emptying of fatty meals has been reported [265]. Maldigestion and malabsorption of lipids may lead to the inability of unhydrolyzed fats to release CCK, which serves as a feedback inhibitor of gastric emptying. Pancreatic enzyme replacement slows the rapid gastric emptying [266]. Other studies report normal gastric emptying in pancreatic insufficiency [266]. Chronic pancreatitis has also been reported in association with delayed gastric emptying (see Chronic pancreatitis) [105].

Duodenal ulcer

Some patients with *duodenal ulcer* have rapid gastric emptying of liquids with increased acid secretion [267]. Rapid gastric emptying of acid may exceed the duodenal buffering capacity leading to mucosal injury. One study reported that enhanced gastric emptying was still present in patients with healed duodenal ulcers. Many of these studies were performed before the recognition that *H. pylori* is an important factor in ulcer disease and acid secretion.

Zollinger–Ellison syndrome

Patients with *Zollinger–Ellison syndrome*, characterized by hypergastrinemia and increased gastric acid secretion, can have duodenal ulcers, diarrhea, or marked esophagitis. The diarrhea is usually attributed to massive gastric acid secretion leading to an increased amount of liquids propelled into the small intestine. These patients may have accelerated gastric emptying of liquids. However, gastric acid suppression may not normalize the rapid gastric emptying, suggesting that the rapid emptying may not be related to gastric acid hypersecretion [268]. Pentagastrin administration also does not accelerate gastric emptying in physiologically normal subjects; instead, it seems to delay stomach emptying of solids [268].

Hyperthyroidism

Orocecal transit time is rapid in *hyperthyroidism* and may be a factor in hyperthyroid-associated diarrhea [269]. It returns to normal after reestablishment of the euthyroid state. Rapid gastric emptying and intestinal transit have been reported in hyperthyroidism [144]; however, most patients with hyperthyroidism appear to have normal gastric emptying [270] and some have delayed emptying [145].

Obesity

Morbidly obese patients may have accelerated gastric emptying [271]. Dieting with weight loss has been shown to decrease this accelerated gastric emptying to a near normal rate [271]. Gastric volumes are also larger than in normal-weight persons; this may result in satiety signals not being triggered in

response to meal ingestion and gastric distention. In addition, intestinal absorption of nutrients may be more efficient in obesity [272].

Functional dyspepsia

Definition

Dyspepsia refers to symptoms originating in the upper GI tract; the term is used to describe upper abdominal pain or discomfort often exacerbated with eating, early satiety, postprandial abdominal bloating or distention, and nausea [273]. Some examples of structural or biochemical disorders causing dyspepsia include gastroduodenal ulcer, gastritis, GERD, medication side effects, and gastric cancer. In many patients the cause of dyspepsia is idiopathic and it is otherwise termed functional or nonulcer dyspepsia. Recently, the Rome III criteria for functional dyspepsia were developed [274]. The committee developed a general definition of functional dyspepsia for the purposes of clinical management, which includes the following requirements:

1 The presence of one or more of the following: bothersome postprandial fullness, early satiation, epigastric pain, epigastric burning.

2 No evidence of structural disease (including at upper endoscopy) that is likely to explain the symptoms.

To satisfy the criteria for functional dyspepsia it is required that these features be fulfilled for the previous 3 months with symptom onset at least 6 months before diagnosis [274].

It should be emphasized that there may be a substantial overlap between patients categorized as having functional dyspepsia and the presence of gastroesophageal reflux disease (GERD). The use of validated reflux questionnaires as well as a trial of adequate acid suppression therapy may be useful to distinguish these two disorders [275]. In some patients, functional dyspepsia may coexist with GERD. This often becomes evident after relief of GERD symptoms with acid suppressive therapy. The following section will address the roles of gastric motility and sensory perception in functional dyspepsia.

Pathogenesis with emphasis on gastric dysmotility

Numerous mechanisms have been proposed for the pathogenesis of functional dyspepsia [276]. The *gastric acid* or *inflammation hypothesis* suggests that gastric acid or inflammation from acid, bile, or *H. pylori* infection is responsible for symptoms. This acid hypothesis also includes occult GERD. The *motor disorder hypothesis* suggests that gastric motility disorders such as gastroparesis, impaired fundic accommodation, antral distention, or gastric dysrhythmias are important. The *visceral hypersensitivity hypothesis* proposes exaggerated symptoms in response to physicochemical stimuli such as distention, contraction, acid, and bile. The *psychological* or *psychiatric hypothesis* proposes that symptoms are related to depression, anxiety, or a somatization disorder.

Gastrointestinal dysmotility

There are several pathophysiological alterations of gastric motility and sensation in functional dyspepsia. Delayed gastric emptying, impaired gastric accommodation to a meal, gastric dysrhythmias, and visceral hypersensitivity are important pathophysiological factors in functional dyspepsia. One or more of these factors may be detected in one-half to two-thirds of patients with functional dyspepsia [277].

Distinct pathophysiological abnormalities may be present in subgroups of patients, perhaps causing different symptoms, and may predict different responses to treatment. One study found that 23% of patients with functional dyspepsia had delayed gastric emptying with associated symptoms of nausea, vomiting, and postprandial fullness, 35% of patients had hypersensitivity to gastric distention associated with symptoms of pain, belching, and weight loss, and 40% had impaired accommodation associated with symptoms of early satiety and weight loss [277]. In total, 23% of patients had two or three of these abnormalities, whereas 26% had none, suggesting still another as yet unidentified mechanism of functional dyspepsia. Unfortunately, individual symptoms do not strongly predict underlying pathophysiology [277]. These disorders may be interrelated: reduced fundic accommodation may lead to increased wall tone in response to distention or meal ingestion and may lead to stimulation of visceral afferents and cerebral perception of gastric events/symptoms [278].

Delayed gastric emptying and antral hypomotility

Delayed gastric emptying is present in approximately 35% of patients with functional dyspepsia, with a range of 25%–80% [6,277]. Specific dyspeptic symptoms and their severity correlate poorly with the degree of gastric stasis [279–281]. However, in a series of 343 patients with functional dyspepsia, the severity of postprandial fullness and vomiting correlated with delayed gastric emptying, which was present in 34% of the dyspeptic patients [6].

Detection of delayed gastric emptying in functional dyspepsia may have prognostic importance because these patients may respond better to prokinetic agents than patients with normal emptying [21]. However, the role of prokinetic agents in improving gastric emptying and symptoms is inconsistent; in some cases both delayed emptying and symptoms may be improved by prokinetic therapy, whereas at other times either emptying or symptoms have improved but not both [21].

Antroduodenal manometry has been used to study patients with functional dyspepsia. The most common abnormality, present in about 50% of patients, is postprandial antral hypomotility [282]. Antral hypomotility correlates

with delayed gastric emptying. Several studies have suggested that small bowel motor dysfunction occurs in a large proportion of patients with nonulcer dyspepsia [282]; other investigators have reported small intestinal dysmotility in only a small percentage [283]. Small intestinal abnormalities may include retrograde, simultaneous, or reduced frequency of fasting MMC activity, as well as a reduced percentage of MMCs that start in the antrum. In the fed state, decreased or low-amplitude duodenal contractions may occur. In a study of 41 consecutive patients with severe chronic dyspepsia, a neuropathic disorder (contractions of normal amplitude but abnormal propagation) was present in 39%, myopathy (low-amplitude contractions with normal coordination) in 2%, and normal small bowel motility in 59% [284].

Regional gastric dysfunction: impaired fundic accommodation and antral distention

Regional gastric function abnormalities may be present in many dyspeptic patients and appear to correlate with dyspeptic symptoms. Normally, the stomach accommodates a meal by the relaxation of the gastric fundus and corpus, providing the meal with a reservoir and enabling a volume increase without a rise in intragastric pressure. Reduced postprandial fundic relaxation and accommodation were found in 40% of patients with functional dyspepsia [285]. Impaired proximal gastric accommodation was associated with early satiety and subsequent weight loss and may be related to a vagal defect. Other studies have not found a clear relationship between postprandial symptoms and proximal stomach function [286].

Scintigraphy and ultrasound studies have shown that, in functional dyspepsia, the intragastric distribution of the meal is characterized by rapid transit of ingested food from the proximal stomach to the distal stomach (Fig. 39.3) [287]. Rapid transit from the proximal stomach may result from poor receptive relaxation or accommodation of the proximal stomach. In a study of 25 patients with functional dyspepsia, rapid proximal gastric transit after ingestion caused abnormally large quantities of food to immediately enter the antrum and remain for a prolonged period [288]. Other studies have confirmed that early antral distention occurs in many dyspeptic patients [287,289]. The degree of postprandial abdominal discomfort has been related to the degree of impaired accommodation of the proximal stomach and antral distention [290].

Radionuclide imaging of the gastric wall with single photon emission computed tomography (SPECT) to calculate gastric volumes has been used as a noninvasive measure of gastric accommodation [278]. SPECT imaging in 32 patients with functional dyspepsia suggested that impaired gastric accommodation (41%) may occur more commonly than delayed emptying (9%) in dyspeptic patients referred to tertiary centers.

Satiety testing with water has been used as a noninvasive technique to evaluate impaired accommodation and sensation. For the water load test, subjects drink water until full (maximum tolerated volume) [291]. Functional dyspeptic patients consume a reduced volume even after adjustment for body mass index [292,293]. Another option for satiety testing is the use of a caloric drink (Nutridrink; NV Nutricia, Zoetermeer, The Netherlands) ingested at 15 mL/min [294]. The maximum tolerated volume consumed during the satiety test has been correlated with gastric accommodation to a meal, as measured by the barostat. Satiety tests therefore offer the potential to evaluate gastric accommodation in a noninvasive way. However, reduced maximum tolerated volume may reflect either impaired accommodation or hypersensitivity of the stomach [24] as there is a poor correlation between maximum tolerated volume and total gastric volume during fasting as measured by SPECT scanning [288,295].

Gastric myoelectric abnormalities

Gastric myoelectric abnormalities measured by EGG, such as tachygastria, bradygastria, and a decreased ratio of postprandial to fasting power, are found in about 40% of patients with functional dyspepsia [41,291,295,296]. The prevalence of EGG abnormalities is similar to that of delayed gastric emptying in functional dyspepsia. EGG and gastric emptying tests appear to complement each other in correlating symptoms to gastric dysmotility [41]. Multichannel EGG recording using electrodes placed at several positions overlying the stomach has been suggested to assess slow wave propagation and coupling. Indeed, patients with functional dyspepsia were frequently found to have inconsistencies in frequency and regularity of gastric slow waves suggesting impaired propagation and coupling [297]. At present, despite these advances, EGG studies are not performed at most centers, and have been a disappointing tool in the management of patients with dyspepsia.

Visceral hypersensitivity

Augmentation of visceral afferent sensation (nociception) may be a major cause of symptoms in functional dyspepsia. In total, 35%–50% of patients with functional dyspepsia have increased sensation to gastric and small intestinal distention [5,298]. When the stomach is stimulated by increasing volumes or increasing intragastric pressures, patients with functional dyspepsia experience symptoms at volumes that physiologically normal subjects do not (allodynia), and they have greater amounts of pain at levels when the physiologically normal subjects begin to have pain (hyperalgesia). The symptoms in functional dyspepsia may result from altered gastric perception with an exaggerated visceral sensory perception of normal physiological events. In addition to hypersensitivity to distention, some dyspeptic patients may be hypersensitive to intragastric or intraduodenal acid, bile salts, or even nutrients [299].

Brain activation by visceral stimulation with gastric distention is being studied in functional dyspepsia using positron emission tomography and functional magnetic resonance imaging [300]. In normal subjects, distal gastric distention produces symptoms of abdominal pain, nausea, and bloating, and it activates some of the same cortical and subcortical central nervous system regions implicated in processing somatic pain [300]. It is conceivable that patients with functional dyspepsia may have abnormal activation of these cortical and subcortical sites in response to gastric distention.

Treatment of functional dyspepsia

There is much literature available on the treatment of functional dyspepsia, although it is inconsistent. Methodological shortcomings are present in many studies including suboptimal study design, unclear inclusion criteria, unvalidated outcome measures, and a short duration of follow-up [301]. In addition, the placebo response in functional dyspepsia can be substantial, approximating 45% [302]. It has been hypothesized that the variability in the efficacy and safety of agents used for the treatment of functional dyspepsia may be due to genetic polymorphisms or differences in the activity of cytochrome P450 isoenzymes [303]. Treatment modalities that have been tested extensively include acid-suppressive agents, promotility compounds, nociceptive modulating compounds, and *H. pylori* eradication. The following sections discuss the therapeutic approach focusing on gastric dysmotility and nociception.

Treatment focusing on gastric dysmotility and nociception

Promotility agents

The relative lack of available promotility compounds limits this treatment modality. Promotility agents including metoclopramide, cisapride, and domperidone have improved dyspeptic symptoms more effectively than placebo in the majority of studies [304]; improvement in symptoms with promotility agents has been 40%–45% greater than with placebo [304]. The few studies that compare the effects of acid-suppressing and promotility agents on dyspeptic symptoms have favored the promotility agents [305].

Several metaanalyses of studies of prokinetic agents in functional dyspepsia have been published [304,306,307]. In a metaanalysis of 17 cisapride studies and four domperidone studies, both cisapride and domperidone seemed to be efficacious [307]. For cisapride, there were overall reductions in epigastric pain, early satiety, abdominal distention, and nausea [308].

Erythromycin and other motilin receptor agonists are potent stimulants of gastric motor function. Intravenous erythromycin significantly enhances solid and liquid gastric emptying; however, it does not reduce meal-related dyspepsia symptoms [309]. Similarly, other motilides have not demonstrated efficacy in functional dyspepsia. The motilin receptor agonist, ABT-229, was ineffective in dyspeptic patients with delayed gastric emptying [310]. It is speculated that, because motilin receptor agonists increase proximal gastric tone, they may aggravate the impaired fundic accommodation in functional dyspepsia, and this could explain the worsening of postprandial symptoms with ABT-229 [310].

Psychotropic medications, sensory modulators, and antinociceptive agents

Strategies to inhibit pain or symptom perception (sensory modulators) are receiving attention because of the augmented visceral hypersensitivity in dyspepsia.

Low-dose tricyclic antidepressants appear to have analgesic effects that are independent of psychological effects. The mechanism of action of these agents in functional bowel disorders is not known, but it may include a reduction in visceral sensitivity [311]. Tricyclic antidepressants have been beneficial in treating abdominal pain syndromes, noncardiac chest pain, and irritable bowel syndrome [312]. Several studies using low-dose tricyclic antidepressants for functional dyspepsia [313,314] have reported a decrease in dyspeptic symptoms, primarily abdominal pain.

In clinical practice, psychotropic medications have been suggested for patients with severe, intractable, refractory dyspeptic symptoms that interfere with daily activities. Dosages required for symptomatic improvement are usually lower than those used to treat psychiatric disorders [311]; the general approach is to start with a low dose, with gradual dose escalations in small increments if required. Typically, for amitriptyline, a starting dose is 10–25 mg at bedtime. If benefit is not observed after several weeks, doses are increased by 25-mg increments up to 75–100 mg. The positive effects are rapidly noticed by many patients, in contrast to the prolonged treatment needed to improve depression. Significant side effects of antidepressant agents are common and can interfere with management, leading to a change in medication in 25% of patients [311]. The sedative effects of many tricyclic compounds may be helpful for patients with difficulty in sleeping. Agents with strong anticholinergic properties, such as amitriptyline, may adversely affect gastric motility. The secondary amines, nortriptyline (Pamelor) and desipramine (Norpramin), have fewer side effects than amitriptyline (Elavil).

There are no published studies demonstrating the utility of the selective serotonin reuptake inhibitors for functional dyspepsia, although some studies have reported their use in irritable bowel syndrome [315]. Interestingly, paroxetine (Paxil) appears to enhance gastric accommodation rather than improve the visceral hypersensitivity [316].

Strategies to inhibit pain or symptom perception also include the use of κ-opioid agonists and 5-HT_3 receptor antagonists. Fedotozine, a κ-opioid agonist, was tested in patients with functional dyspepsia and irritable bowel syndrome.

Concern was expressed on the fairly modest symptom improvement and the exact mechanism of action. Other κ-opioid agonists are now being studied.

5-HT_3 receptors are located on vagal afferents and dorsal root ganglion neurons. In normal subjects, the 5-HT_3 receptor antagonist, alosetron (Lotronex), reduced postprandial nausea and vomiting in response to a dyspepsia-inducing meal, without affecting gastric accommodation or the amount of ingested food [317]. Preliminary studies suggest that alosetron may be mildly effective in decreasing symptoms of functional dyspepsia [318]. Alosetron was FDA approved for treating irritable bowel syndrome. It was withdrawn because of reports of cases of ischemic colitis and is currently available for clinical use in the United States under controlled protocols for patients with diarrhea-predominant irritable bowel syndrome.

Fundic relaxing agents

Agents that relax the fundus and improve the accommodation response may be helpful in some patients with functional dyspepsia, perhaps those with early satiety. 5-HT_1 agonists (sumatriptan, buspirone), α-adrenergic receptor agonists (clonidine), and nitric oxide donors (glyceryl trinitrate) have been tried in several small series [212].

The 5-HT_1 agonists, such as sumatriptan, induce relaxation of the gastric fundus through a nitric oxide-mediated pathway. Sumatriptan allows larger volumes to be accommodated before perception or discomfort is reached, and it improves meal-induced satiety in patients with functional dyspepsia [319]. It is administered by injection, and recently became available orally. Buspirone (Buspar), an oral 5-HT_1 agonist, may have effects similar to those of sumatriptan. It also has anxiolytic properties.

The α-adrenergic agonist clonidine reduces proximal gastric tone and pain perception during gastric distention in healthy subjects [212]. Thus, clonidine has the potential to reduce gastric sensation or increase gastric compliance without altering other physiological motor functions. Some studies have suggested that clonidine may delay gastric emptying [213].

Sildenafil (Viagra) has been shown to increase gastric accommodation [320]. In animal models, it also relaxes the pylorus and improves gastric emptying [321]. In humans, however, it slows gastric emptying [319].

Summary

In this chapter, gastric motility disorders have been reviewed, focusing primarily on the pathophysiology, diagnosis, and treatment of gastroparesis, dumping syndrome, and the gastric dysmotility seen in functional dyspepsia. Refractory symptoms may lead to a comprehensive evaluation including gastric emptying scintigraphy, antroduodenal manometry, EGG, and possibly tests of gastric accommodation or compliance. This evaluation may guide treatments that target the underlying pathophysiological mechanisms.

Introduction

Peptic ulcers are defects in the gastrointestinal mucosa extending through the muscularis mucosae, which persist and are generally dependent on the acid–peptic activity of gastric juice. The major causes are infection with *Helicobacter pylori* (Hp) and consumption of nonsteroidal antiinflammatory drugs (NSAIDs), including aspirin (Table 40.1). Although the incidence of Hp ulcers has rapidly declined in developed countries and treatment has been greatly facilitated by potent antisecretory agents, peptic ulcer remains a major challenge to patients, clinicians, investigators, and payors.

Etiology and pathophysiology of peptic ulcer

Normal mucosal defense and healing

The regulation of acid–pepsin secretion reflects an intricate balance between inputs from neural, endocrine, paracrine, and autocrine pathways and involves both stimulatory and inhibitory mechanisms. The normal gastroduodenal mucosa has a remarkable ability to defend itself against injury and to rapidly repair injury when it does occur (Fig. 40.1). Chronic ulcer disease only occurs when these repair and healing mechanisms fail.

Ulcer pathogenesis

Considering the aggressive nature of the acid–peptic environment and the noxious agents we ingest, ulcer disease is surprisingly uncommon. Even among individuals at high risk, such as those with Hp infection, the yearly incidence of new clinical ulcer disease is only about 1%. No pathogenic mechanisms have been identified distinguishing the small subset who develop ulcers from those who do not, and there are not good explanations for the focal distribution of ulcers nor for their intermittent and recurring course.

Pathogenesis is multifactorial. Duodenal, but not gastric, ulcers are associated with a high duodenal acid load, and acid secretion is also typically high-normal or high. Duodenal ulcer (DU) is also associated with decreased duodenal defenses, manifest by the presence of duodenal inflammation and the related decreased duodenal bicarbonate secretion [1] (Fig. 40.2). Although environmental factors such as smoking and stress affect the duodenal acid load (e.g., smoking inhibits duodenal bicarbonate secretion), they also have other effects such that their impact on pathogenesis remains incompletely understood.

Pathology of peptic ulcers

Erosions are superficial mucosal defects. In contrast, the defect in ulcers extends through the muscularis mucosa into the submucosa or muscularis propria. Acute lesions, such as those occurring with aspirin injury, are generally multiple and shallow, with minimal surrounding inflammation or fibrosis, and generally heal rapidly. In contrast, chronic ulcers are usually single and surrounded by inflammation and fibrosis. They heal slowly and tend to recur in the same location. Gastric ulcers (GU) typically occur on the lesser curvature near the angularis at the transition of oxyntic and antral mucosa [2,3]. More proximal gastric ulcers are typically located at the junction of the atrophic border as Hp gastritis encroaches on the acid-secreting oxyntic mucosa [4]. Ulcers in the gastric cardia or in a hiatal hernia pouch have been hypothesized to be a distinct entity [5], and in some series they account for up to 10% of GU. Cameron ulcers, initially described in association with anemia, occur on the tips of folds in the region of a hiatal hernia [6].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Table 40.1 Etiologies and disease associations for peptic ulcer

Ulcers due to defined mechanisms

Infection:
- *Helicobacter pylori*
- HSV
- CMV
- *H. heilmannii*

Other rare infectious causes: e.g., tuberculosis, syphilis

Drug exposure:
- NSAIDs and aspirin
- Corticosteroids (when combined with NSAIDs)
- Bisphosphonates
- Clopidogrel
- Mycophenolate mofetil
- Potassium chloride
- Chemotherapy (e.g., hepatic infusion with 5-fluorouracil)

Hormonal or mediator-induced, including acid hypersecretory states:
- Gastrinoma (Zollinger–Ellison syndrome)
- Systemic mastocytosis
- Basophilia in myeloproliferative disease
- Antral G-cell hyperfunction (existence independent of *H. pylori* is controversial)

Vascular insufficiency including crack cocaine use

Mechanical: duodenal obstruction (e.g., annular pancreas)

Radiation therapy

Infiltrating disease: sarcoidosis, Crohn's disease

Idiopathic peptic ulcer

Idiopathic hypersecretory (*H. pylori*-negative) duodenal ulcer

Non-*H. pylori*, non-NSAID familial peptic ulcer

Non-*H. pylori*, non-NSAID peptic ulcer

Comorbid ulcers associated with decompensated chronic disease or acute multisystem failure

Stress (ICU) ulcers

Chronic obstructive pulmonary disease

Cirrhosis

Renal failure

Organ transplantation

Other comorbidity, such as cardiovascular disease

CMV, cytomegalovirus; HSV, herpes simplex virus; ICU, intensive care unit; NSAIDs, nonsteroidal antiinflammatory drugs.

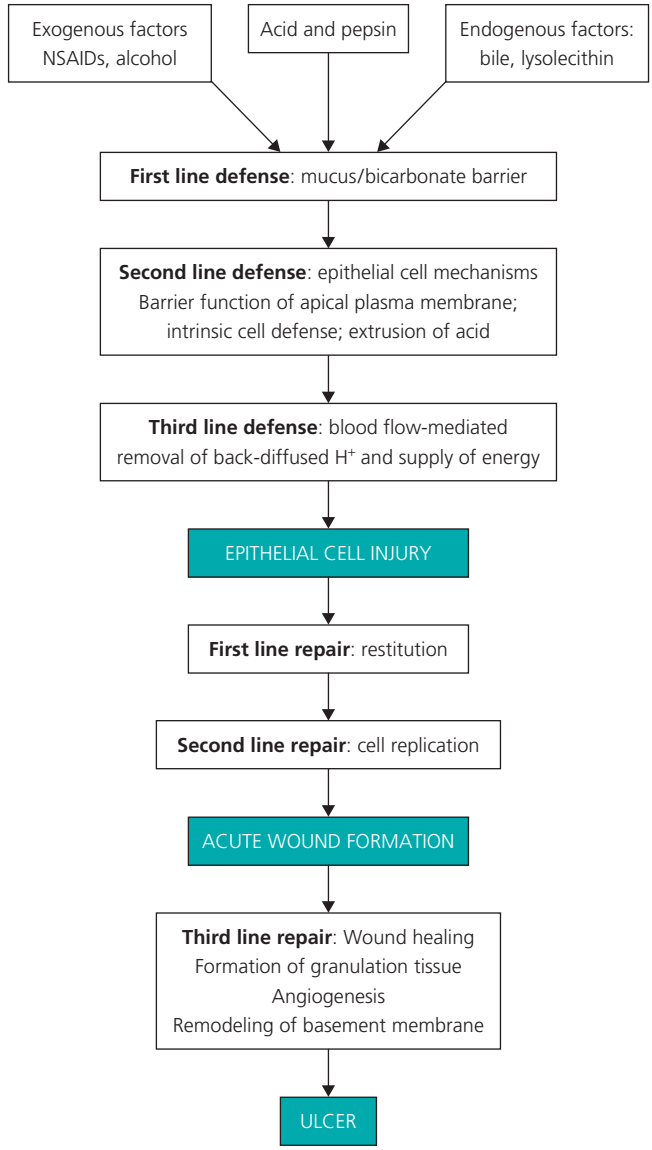

Figure 40.1 Cascade of mucosal defense and repair mechanisms. Damaging effects on epithelial cells of exogenous and endogenous factors are amplified by acid peptic activity. If the three sets of lines of defense mechanisms fail, epithelial cell injury occurs, which will be repaired by restitution and cell replication. If these repair mechanisms fail, an acute wound forms. Ulcers form when these normal defense and repair mechanisms fail or are overwhelmed. NSAIDs, nonsteroidal antiinflammatory drugs.

Helicobacter pylori and peptic ulcer

It is well accepted that, worldwide, Hp and NSAIDs account for the large majority of cases of peptic ulcer disease (PUD). However, the proportions associated with these specific causes vary greatly with demographics and are changing rapidly over time, especially in developed countries. Several studies in the United States have demonstrated rates of Hp infection of less than 75% in those with DU not associated with the use of NSAIDs. Studies from Rochester, New York, for example, found that, after excluding NSAID use, only 61% of DU and 63% of GU were Hp positive [7]. Only 52% of white people with DU were Hp positive, compared to 85% of nonwhite people, underscoring the differences in Hp prevalence in different populations.

Helicobacter pylori, gastritis, and peptic ulcer

Hp is a gram-negative spiral bacteria whose niche is the human stomach (see Chapter 42). The infection causes progressive gastric inflammation and has been etiologically related to gastritis, PUD, gastric adenocarcinoma, and primary

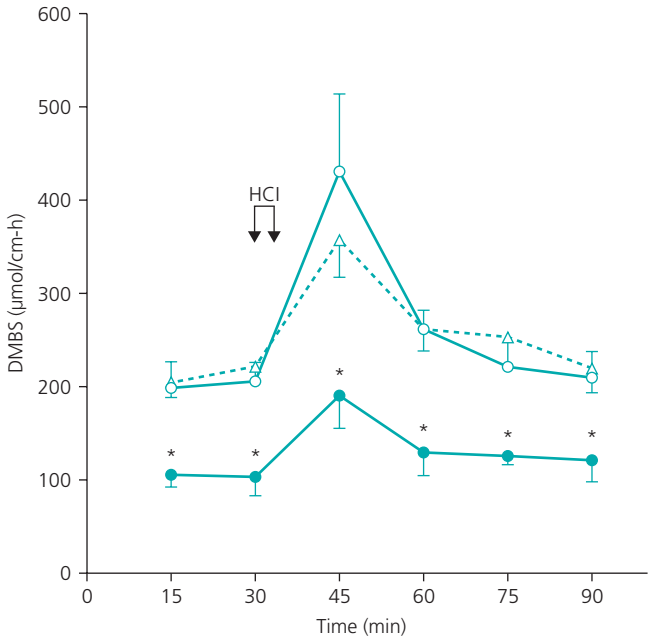

Figure 40.2 Duodenal bicarbonate output in response to cure of *Helicobacter pylori* (Hp) infection. Proximal duodenal bicarbonate secretion (DMBS) is shown for normal subjects (open circles), Hp-positive duodenal ulcer (DU) subjects before antibiotic treatment (solid circles), and DU subjects after successful Hp cure (open triangles). Data are mean (± SE) for basal bicarbonate output (15 and 30 min) and in response to acid stimulation. Redrawn from Hogan et al. [1], with permission from Elsevier.

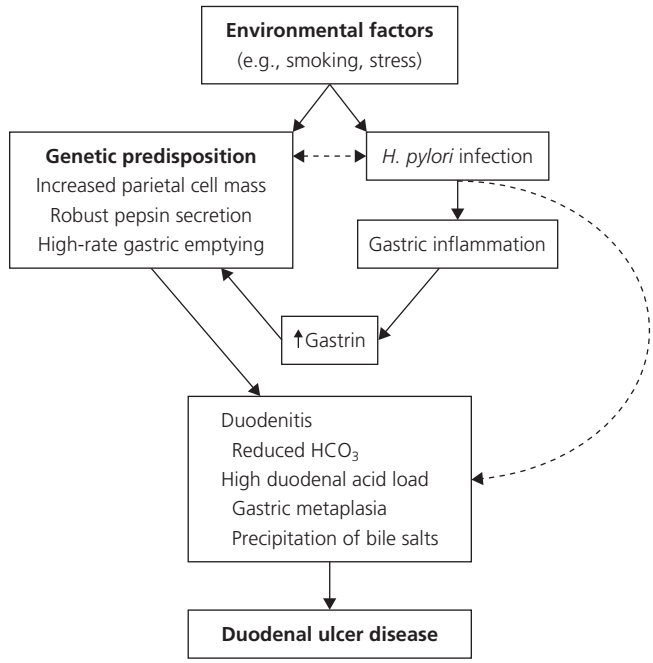

Figure 40.3 Hypothesis regarding the pathogenesis of duodenal ulcer disease showing the interaction of environmental, host, and *Helicobacter pylori* factors leading to an increased duodenal acid load, increased gastric metaplasia in the duodenum, and infection of that metaplastic epithelium, resulting in a duodenal ulcer. Redrawn from Graham [8], with permission from Elsevier.

gastric B-cell lymphoma. Other forms of peptic ulcer (e.g., NSAID, gastrinoma, or stress ulcer) occur without gastritis in the surrounding mucosa. Hp-associated DU is associated with gastric inflammation largely restricted to the antrum, thereby sparing the acid-secreting body of the stomach and allowing robust acid secretion. In contrast, GU are associated with antral and corpus gastritis and, as noted above, typically occur just proximal to the line of demarcation between the advancing atrophic border and the oxyntic mucosa. The natural history of Hp gastritis is to progress into the oxyntic mucosa leading to hyposecretion of acid and pepsin and eventually to atrophy. In contrast, oxyntic mucosal inflammation usually progresses slowly, or not at all, in DU subjects. However, inhibition of acid secretion with either vagotomy or antisecretory therapy releases this block and promotes progression of oxyntic gastritis, which may lead to gastric atrophy [8–11].

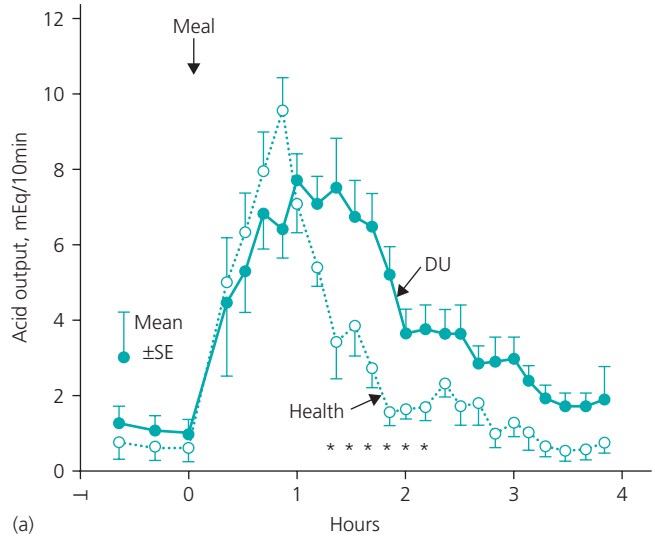
Helicobacter pylori, duodenitis, acid secretion, and gastric metaplasia in duodenal ulcer

Acid causes duodenal damage in DU and gastrinoma resulting in an increase in gastric metaplasia. Hp is trophic for gastric epithelium and, when Hp is found in the duodenum, it is exclusively localized over gastric-type epithelial cells [12–14]. Therefore, Hp-related DU is actually a "gastric mucosal" ulcer occurring in the duodenum. The complex relationship (Fig. 40.3) has additional elements. For example, bile salts inhibit Hp but are precipitated at low pH. Thus, Hp may thrive in the duodenum in individuals where robust acid secretion, usually coupled with low duodenal bicarbonate secretion, lowers duodenal pH, thereby precipitating bile salts and removing their Hp-inhibitory effects [15,16].

Acid secretion

"Peptic" ulcers are by definition dependent upon the acid and peptic activity in gastric juice. An adequate level of acid secretion (12–15 mEq/h) is necessary for DU [17,18], and inhibition of acid secretion promotes healing of both duodenal and gastric ulcers. When ulcers occur in the absence of acid, other factors deserve consideration, including NSAID use, neoplasia, and infection other than Hp [19–21]. However, GU may occur in the face of very low acid concentrations.

The average maximal acid secretory response to stimulation, which reflects an increased parietal cells mass, is greater in DU patients than in normal subjects [22–27]. Gastrin is an important trophic factor for oxyntic mucosa, stimulating oxyntic mucosal growth and clearly accounting for increased secretory mass in gastrinoma patients (see Chapter 41). However, eradication of Hp reverses Hp-associated hypergastrinemia without a significant reduction in parietal cell mass [28].



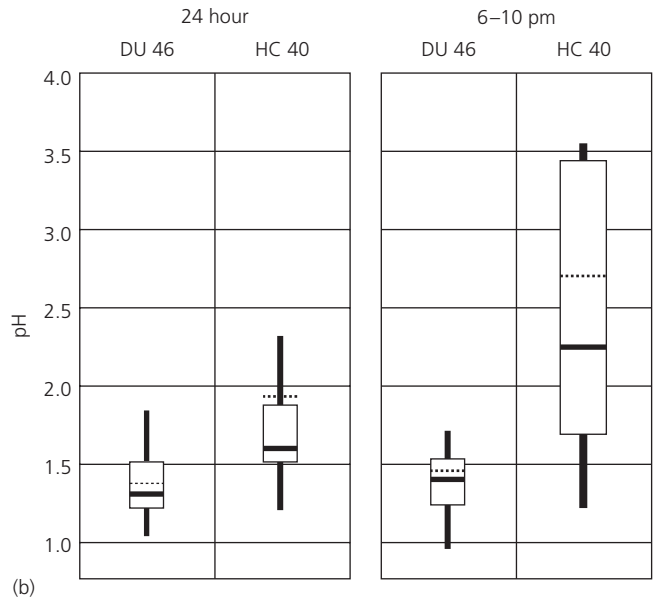


Figure 40.4 **(a)** Acid secretion in response to a meal, comparing duodenal ulcer (DU) and normal subjects. The consistent difference is not the peak acid secretory response, but a more sustained response in DU subjects. This difference is more pronounced in the evening hours, presumably due to circadian rhythm. (From Malagelada et al. [385], with permission from Elsevier.) **(b)** pH in duodenal ulcer: 24-h (left panel) and nocturnal (right panel). Box plots illustrate the median intragastric pH for DU patients and healthy controls (HC). On the left are data for the 24-h period and on the right are data for the evening hours from 6 to 10 PM. Dotted lines show the mean and the solid line the median of the individual values. The box contains the interquartile range and the whiskers stretch to the furthest value within one interquartile distance from the first and third quartiles. The data illustrate the considerably increased difference in gastric pH in DU that is most evident in the evening postprandial period. From Merki et al. [32], with permission.

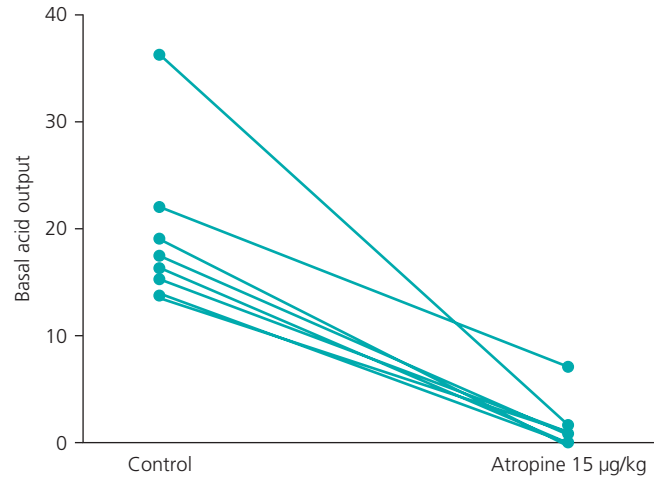

Figure 40.5 Inhibition of basal acid hypersecretion in a subset of duodenal ulcer (DU) patients by intravenous atropine. DU subjects with basal acid hypersecretion were evaluated before and after administration of atropine (15 μg/kg). Marked inhibition was noted in all of these subjects. Data redrawn from Kirkpatrick and Hirschowitz [40].

A number of perturbations of gastric physiology have been hypothesized to underlie acid hypersecretion in DU, including enhanced and prolonged meal-stimulated gastric acid secretion (Fig. 40.4a) and impaired inhibitory mechanisms [24,29–31]. The result of these abnormalities is that the acid secretory response persists long after the food buffer has emptied. The difference in acid secretion or gastric pH is most evident in the evening or night-time hours [32] (Fig. 40.4b). Although the pathogenesis of these abnormalities is incompletely understood, most have all proved to be reversible following eradication of Hp infection [33,34]. The major exception is the acid hypersecretion that persists in a small subset of subjects.

Hypersecretion in Hp-positive DU occurs in at least two subsets: those with hypergastrinemia that is Hp-dependent (reversed with antibiotics, i.e., Hp-positive antral G-cell hyperfunction) and those with acid hypersecretion that appears to be independent of Hp [35–37]. Sometimes the Hp-independent acid hypersecretion is modest, but it can on occasion mimic gastrinoma [39]. Vagal hyperactivity has been hypothesized as an underlying mechanism. In a group of DU subjects with basal acid hypersecretion, atropine was found to inhibit basal acid secretion [40] (Fig. 40.5), implicating the importance of cholinergic pathways. A rare patient may have hypergastrinemia in the absence of gastrinoma and Hp.

Proximal GU, in contrast to GU in the distal antrum, are usually associated with low acid secretion, reflecting a low or low-normal parietal cell mass and the presence of corpus inflammation [3,17,22]. These findings correspond to the encroachment of oxyntic mucosa by advancing antritis and

oxyntic gland atrophy [4,41]. In contrast to proximal GU, patients with distal antral GU or GU associated with DU have normal or even increased levels of acid secretion.

Pepsin and peptic ulcer

Despite the fact that ulcers of the stomach and duodenum are referred to as "peptic," pepsin and peptic activity have received little attention. Acid plus pepsin is much more ulcerogenic than acid alone [42], leaving little question that the "peptic" in peptic ulcer appropriately reflects the critical pathogenic role of proteolytic activity in gastric juice. Peptic activity is closely linked to gastric pH for two reasons. First, the precursor pepsinogen is converted into the active protease at low pH. Second, pepsin is inactivated when the pH is elevated above 4. This pH dependence probably accounts for the healing of refractory ulcers when the pH is elevated above 4. Hp infection is largely responsible for the hyperpepsinogenemia that occurs in peptic ulcer. The degree of hyperpepsinogenemia reflects acid secretion and has been used to help predict the risk for peptic ulcer in Hp-infected subjects [43].

Abnormalities of mucosal defense and healing in peptic ulcer

Impaired healing of mucosal breaks and ulcers appears to be the factor that differentiates patients with chronic ulcer disease from those exposed to the same risk factors (Hp, NSAIDs, or elevated acid secretion) who do not develop ulcers. However, there is no evidence implicating any primary derangement in epithelial repair, ulcer healing, or key mechanisms of mucosal defense in ulcer pathophysiology (Fig. 40.1).

Defense mechanisms are compromised by the presence of Hp and Hp-induced inflammation, and by the NSAID-induced reduction in mucosal prostaglandin synthesis. However, the abnormalities associated with Hp or NSAIDs do not in themselves explain ulcer pathogenesis because they are present throughout the mucosa and in the many subjects who do not develop focal peptic ulcers.

Ulcers tend to recur locally. Wyatt and others have hypothesized that the gastric metaplasia in the duodenum explains the localization of both Hp-induced inflammation and ulcer formation [8,13]. However, there is no good explanation for the localization of ulcers in the stomach. A hypothesis that we consider attractive is that dense fibrosis occurs at the site of ulceration in predisposed subjects and this fibrosis prevents complete healing and mucosal remodeling and predisposes to local recurrence.

Impaired mucosal blood flow is clearly an important factor in ulcer formation, at least in a subset of subjects. Blood flow through normal mucosa removes acid that has diffused across an overwhelmed or injured epithelium and delivers the metabolic energy necessary to support transport and other functions. Maintaining mucosal blood flow at adequate levels for these demands is critical for mucosal integrity. Using reflectance spectrophotometry, mucosal blood volume was found to be decreased in patients with active gastric ulceration compared with those with healing or healed ulcers [44]. However, as with other potential mechanisms, changes were generalized in the antrum and body and not limited to the region or margin of the ulcer. Of interest, when healing had commenced, blood volume at the margins of healing ulcers increased compared with measurements at a distance from the crater.

There is little doubt that the initiation of ulcer healing is marked by an ingrowth of new blood vessels (angiogenesis) into the granulation tissue in the ulcer bed. Pathologically, chronic ulcers are surrounded by fibrinoid necrosis and fibrosis; this is the zone accounting for the decrease in blood flow around nonhealing ulcers [45]. The increase in blood flow at the edge of a healing ulcer probably reflects angiogenesis, and the failure of blood flow to increase probably reflects the failure of normal angiogenesis. Ulcer persistence is thus marked by failure of blood vessel ingrowth into this granulation tissue and, conversely, ulcer healing commences with angiogenesis in the granulation tissue and an increase in blood flow at the ulcer margin [45].

Ulcers from NSAIDs and platelet-active agents

Superficial damage, endoscopic ulcers, and clinical ulcers

NSAID-induced mucosal damage is categorized as either superficial damage consisting of petechiae (intramucosal hemorrhages appearing like "blood under plastic wrap" [46]), erosions, and small, shallow ulcers, or "clinical" ulcers, which can be defined either by presentation in a clinical setting with or without complications or by having a size and depth to clearly be of clinical relevance. Cross-sectional studies of individuals chronically consuming full-dose NSAIDs reveal normal endoscopic appearances in about 35%, erosions or petechiae in about 50%, and endoscopic ulcers in 5%–30% (depending upon defining criteria) [47,48]. In chronic cases, ulcers frequently are present in the absence of superficial injury.

Many studies of the natural history of NSAID-induced mucosal damage and of preventive strategies have focused only on acute superficial injury and erosions or small acute ulcers. Such lesions are especially amenable to "prevention" with acid-suppressive therapies and are not good surrogates for clinical ulcers with respect to natural history or response to therapy. It behooves clinicians to remain skeptical of "marketing" claims based on such surrogate markers (see Prevention of NSAID ulcers).

Mechanisms of NSAID injury

Petechiae and superficial erosions reflect topical mucosal injury in which, in the acidic environment of gastric juice, weak acids are not ionized and freely penetrate the gastric barrier to become concentrated in mucosal cells, thus

amplifying potential damaging effects. Superficial lesions may cause occult bleeding and rarely can cause chronic iron-deficient anemia. Superficial lesions rarely, if ever, cause clinically significant acute GI bleeding.

Clinical NSAID ulcers are related to the systemic effects of NSAID administration. Such damage occurs irrespective of the route of administration of the NSAID (e.g., oral, rectal, or parenteral) and can occur even in patients with achlorhydria. The leading hypothesis is that the systemic action of NSAIDs that produces ulcers is the reduction of mucosal prostaglandin production, which limits the ability of the mucosa to defend itself against injury from superimposed factors.

Helicobacter pylori, NSAIDs, and the peptic ulcer diathesis

The interaction between NSAIDs and Hp is controversial and complex. The confusion is not surprising because Hp causes a spectrum of gastric consequences ranging from antral-predominant gastritis with robust acid secretion, which predisposes to duodenal ulcer formation, to pangastritis with achlorhydria, in which the Hp peptic ulcer risk is nil. Patients with Hp and low acid secretion may even be partially protected from NSAID ulceration, whereas the subset with active or subclinical ulcer disease would be at high risk from NSAID complications. As noted below, 1%–4% of asymptomatic Hp-positive subjects without an ulcer history have silent peptic ulcers evident at surveillance endoscopy; presumably this is the group that would be at the highest risk with exposure to NSAIDs.

The most convincing evidence for the Hp exacerbation of gastrointestinal complications from NSAIDs comes from two controlled trials in which patients who were Hp positive and NSAID-naïve were randomized to Hp eradication treatment or placebo [49,50]. Hp cure lowered the incidence of endoscopic ulcer formation, clinical ulcer development, and complications. The second trial entered a higher risk group with a history of dyspepsia or previous ulcer and followed them for 6 months on NSAIDs; complicated ulcers were reduced from 27% in the control group to 4% in the eradication group.

In patient populations other than those naïve to NSAIDs, the relation to Hp and the benefits of eradication are less clear. A metaanalysis examining observational studies found synergism between Hp and NSAIDs in producing both peptic ulcer and ulcer bleeding [51]. However, there are negative studies that point against a causal relation between Hp and NSAID ulcer risk. Some of these studies were carried out with low-risk patients who had previously been on NSAIDs or examined only endoscopy end points [52], so these conclusions are without much weight [53].

One point is critical. In patients with a history of previous NSAID-induced complications, even if Hp is found and eradicated, the risk of complications on subsequent NSAID therapy is very high. The one exception may be low-dose aspirin treatment. In one controlled trial [54], Hp-positive patients resuming conventional NSAIDs plus placebo after Hp eradication had a 6-month ulcer recurrence rate of 24% compared with 4% in patients treated with NSAIDs plus a proton pump inhibitor (PPI). It should not be surprising that, if an ulcer is caused by Hp, failure to eradicate Hp is associated with a high rate of recurrence. Similarly, if one has an NSAID-induced ulcer and restarts NSAIDs, one should not be surprised that the ulcer recurs. In fact, one would be amazed if eradication of Hp entirely prevented recurrent NSAID ulcers. Aspirin use appears to be different from the use of other NSAIDs; patients who resumed low-dose aspirin after Hp eradication had a recurrence rate at 6 months of only 1.9% compared with 0.9% for those who resumed aspirin after being treated with a PPI without antibiotics [54].

We advise testing and treating Hp infection before starting NSAIDs in naïve users, in patients with a history of a previous ulcer or ulcer complications, and in those who will receive PPI cotherapy. As there are other potential benefits to curing Hp infection, we favor at least offering patients Hp testing and treatment before initiating NSAIDs.

Aspirin vs NSAIDs: platelet vs gastric and intestinal mucosal effects

Aspirin, even at low doses, increases the risks of ulcer complications and GI bleeding [55]. Although it is clear that aspirin can cause peptic ulcers, many bleeding complications and even perforation from aspirin occur at sites other than the stomach and duodenum [56]. Bleeding from these sites most likely reflects the effects of aspirin on platelet function and bleeding time. It is of interest that a subset of patients with a history of bleeding induced by aspirin have markedly prolonged bleeding times on aspirin [57], suggesting a predisposing factor that has received little attention from clinicians or investigators. Other NSAIDs vary in their effects on platelet function and bleeding time. It is important to keep in mind that other NSAIDs also cause small intestinal and colonic damage, which can result in clinical complications.

COX-1 vs COX-2 inhibition

Factors that may determine NSAID propensity for mucosal damage and ulcer formation include relative potency for inhibiting gastric cyclooxygenase 1 (COX-1) compared with COX-2, duration of action, solubility of the NSAID in gastric juice, the gastric absorption of NSAIDs that are soluble in gastric juice, and the concentration by pH partition of weak acid NSAIDs in gastric mucosa. Potency, duration of action, and relative COX inhibition appear to be the most important factors.

Controlled trials with COX-2-selective inhibitors (coxibs) have demonstrated a reduction in risk of clinical peptic ulcers and their complications [58]. Valdecoxib and rofecoxib were removed from the market by the US Food and Drug Administration (FDA) because of data indicating increased risk of thrombotic cardiovascular disease. Although there are

concerns about the cardiovascular risks of celecoxib, especially at higher doses, it remains on the market at present. However, the benefit of celecoxib in reducing the risk of ulcer complications compared with nonselective NSAIDs is less clear than with valdecoxib and rofecoxib. It is also suspected that traditional NSAIDS, with the possible exception of naproxen, also share the propensity for myocardial infarction [59,60].

Although there is evidence that coxibs have a lower complication rate for average-risk patients taking NSAIDs, coxibs may impair ulcer healing [61]. There is no evidence that coxibs have advantages over other NSAIDs for high-risk patients with unhealed clinical ulcers or with a history of previous complications, although there is some evidence that the combination of a coxib and a PPI has a lower rate of recurrent ulceration and/or complications than a PPI plus a traditional NSAID [62].

Platelet-active agents

The antiplatelet agent clopidogrel appears to have a very high risk of complications when used in patients with previous GI complications. Clopidogrel was associated with a 12-month rebleeding rate of 8.6% compared with 0.7% with aspirin plus a PPI [63]. Thus, clopidigrel may be contraindicated in high-risk patients when used alone or in combination with NSAIDs. Any antiplatelet agent should be approached with caution, especially in patients at increased risk for ulcer complications. The mechanism of action has not been established but may be related to the role that platelets play in ulcer healing and in angiogenesis in particular [64].

Risk factors for NSAID ulcers

A large number of individuals consume NSAIDs but only a very few go on to develop clinical ulcers or complications. Several risk factors have been identified that have a major impact on patient outcomes. Risk stratification is essential to make the use of NSAIDs as rational and safe as possible.

Age

Many early studies have demonstrated an increased risk of ulcer complications (hospitalization, operation, and death) from NSAIDs in elderly individuals [65–68], which has been confirmed in more recent controlled trials. Age greater than about 70 years is a factor because older individuals frequently use NSAIDs and they have comorbid diseases that compromise tolerance to complications. However, controlled studies [69,70] provide evidence that age is also an independent risk factor.

Previous history of ulcers or complications

A previous history of ulcers, especially if complicated, has the greatest impact on NSAID ulcer risk. Presumably this group is at risk because of permissive levels of acid secretion, but defects in mucosal defense and healing are also possible. Although there are no firm data available, it is likely that a high risk would be imparted by either a previous history of Hp ulcers or of "virgin" NSAID ulcers.

Duration of therapy

The risk of ulcer complications begins to emerge within the first week of therapy and the absolute risk is greatest within the first month of therapy and then remains constant [71]. Adaptation is the phenomenon by which acute injury resolves despite continued therapy [72]. However, adaptation fails to occur in the 10%–20% who develop endoscopic ulcers and in the few who develop clinically significant ulcers. The mechanisms accounting for adaptation or its failure remain unclear.

Dose and duration of action and use of multiple NSAIDs

In clinical studies, ulcer complications with NSAIDs appear to be dose dependent. However, the threshold for conventional NSAIDs, as well as for aspirin as noted above, appears to be quite low for continuous use [71]. Risk appears to be related to the potency and duration of action of suppression of prostaglandin synthesis; NSAIDs with high COX-1 antiinflammatory activity and duration of action are associated with greater risk than those whose significant antiinflammatory activity requires multiple tablets of the drug (e.g., piroxicam compared with ibuprofen). Simultaneous use of multiple NSAIDs also appears to increase the risk of complications.

Dyspepsia

Previously, it appeared that little relation existed between dyspepsia induced by NSAIDs and clinical ulcer formation. This conclusion is probably valid in unselected subjects in whom there is no predictive value of dyspepsia for either acute mucosal damage or clinical ulcer risk. However, in a controlled study, the development of new dyspepsia did predict ulcer recurrence [73,74]. Therefore, it behooves the clinician to ask patients taking NSAIDs about symptoms and to pay particular attention to changes in symptoms.

NSAIDs plus low-dose aspirin

Aspirin was observed to impair the beneficial effects of celecoxib on reducing the rate of ulcer complications [75]. Subsequent studies have further indicated that the addition of aspirin to coxibs increases the risks of complications and obviates or reduces any ulcer-sparing benefit. Presumably, the addition of aspirin will also exacerbate the risks with nonselective NSAIDs. There is also evidence that the coadministration of NSAIDs (e.g., ibuprofen) may also reduce the antiplatelet effects of aspirin [76].

Cotherapy with corticosteroids

In early studies, the impact of corticosteroids on the risk of peptic ulcer was controversial. However, the relative risk for upper gastrointestinal hemorrhage of adding steroids to

NSAIDs is 10.6-fold above that found with NSAIDs alone [77]. Steroids alone impart insignificant ulcer risk, but these agents potentiate the ulcer risk from NSAIDs. These data argue for avoiding the combination of steroids with NSAIDs whenever possible, particularly in elderly patients. There are no controlled studies indicating that cotherapy with antisecretory agents prevents complications in the face of NSAIDs plus corticosteroids, and so extreme caution is necessary.

Cotherapy with other drugs

In addition to steroids, aspirin, and platelet-active agents, interactions of NSAIDs with other drugs also increase the complication risk. Anticoagulants [78] and alendronate both dramatically increase the complication risk. Any agent that interferes with platelet function or bleeding time or with mucosa integrity or repair deserves caution until proved safe.

Comorbidity

Comorbidity also increases the risk of ulcer complications from NSAIDs [70]. It is unclear if this is a specific effect for NSAIDs or part of the general effect of comorbidity on ulcer formation (see Comorbid ulcers – Disease associations).

Other forms of peptic ulcer (non-Hp, non-NSAID)

Other specific causes of peptic ulcer have been elucidated in addition to Hp and NSAIDs, such as gastrinoma or viral infections (Table 40.1). It remains unclear whether non-Hp, non-NSAID ulcers are becoming more prevalent or are becoming more apparent as the prevalence of Hp and Hp ulcers has fallen. Although one could argue that the defined secondary forms should be listed in the differential diagnosis section, we have listed them here if they present and require treatment as peptic ulcers. However, it is important to keep in mind that several secondary forms of PUD also require specific forms of treatment.

Infections other than *Helicobacter pylori*

Herpes simplex virus type 1

Antibodies to herpes simplex virus type 1 (HSV-1) have been reported to be increased in DU patients. As herpesvirus can reside in vagal ganglia it is possible that some ulcers may represent reactivation of latent HSV infections [79]. HSV-1 DNA and viral proteins have been detected in the mucosa of the margins of a low percentage of ulcers by immunocytochemistry, in situ hybridization, and polymerase chain reaction with sequence confirmation [79]. In one report, four patients with HSV-1 markers had antral or prepyloric ulcers and none had systemic disease or were immunocompromised. A second study reported HSV-1 at the margins of 10% of GU [80]. A recent study using PCR to identify HSV-1 and a rapid urease test and histology to identify Hp found HSV-1 in 30% and 32% of DU and GU respectively [81]. HSV-1 was found more frequently in the absence of Hp. In all three studies, HSV-1 was only present in the margins of ulcers and was absent in gastric mucosa distant from the ulcer and in controls, consistent with a role for HSV-1 in ulcer pathogenesis.

Cytomegalovirus

Although the number of reports is limited, cytomegalovirus (CMV) is a well-documented cause of gastroduodenal ulcers in immunocompromised subjects and it is a common cause of ulceration in HIV patients with low CD4 counts [82]. CMV ulcers occasionally complicate, causing bleeding, perforation, or pyloric stenosis [83]. Although much more common in immunocompromised hosts, CMV can also cause ulceration in immunocompetent subjects [83]. The ulcers are frequently large and multiple.

Drug exposures

A number of drugs besides NSAIDs are probably also capable of causing or complicating peptic ulceration. Platelet-active agents, steroids, and anticoagulants were discussed above. Sirolimus has been associated with aggressive ulcer disease in patients undergoing transplantation [84]. Sirolimus is known to inhibit wound healing and has been associated with small bowel ulceration [85], so this connection is convincing and warrants cautious use of this agent in patients with a history of PUD as well as aggressive management of patients on the drug who develop symptoms or complications suggestive of PUD.

The relation of alendronate to clinically significant GU is more controversial. Damage and acute ulceration have been observed [86], but the proportion that go onto clinically significant events appears limited [87]. An impressive interaction between NSAIDs and alendronate [88] prompts caution in coadministration of these agents.

Hormonal- or mediator-induced ulcers associated with acid hypersecretion

Gastrinoma

See Chapter 41.

Systemic mastocytosis

Systemic mastocytosis is characterized by mast cell infiltration of many tissues. Symptoms include flushing, maculopapular rash, pruritus, abdominal pain, and diarrhea [89]. Dyspepsia, DU, and severe duodenitis occur in 30%–50% of these patients, typically in association with basal acid hypersecretion and elevated serum histamine levels [89,90], suggesting that circulating histamine contributes to the basal acid hypersecretion. Dyspeptic symptoms and the duodenal disease are readily treated by antisecretory drug therapy. Histamine H_2 receptor antagonists (H2RAs) and PPIs have been used with success; no comparative studies are available to guide management.

Basophilia associated with myeloproliferative disorders

Basophilic leukemia and chronic myelogenous leukemia with marked basophilia have been associated with increased acid secretion, increased serum or urine histamine concentrations, and DU [91]. Acid hypersecretion may require a threshold level of basophilia [91]. Polycythemia vera has also been associated with peptic disease [92]. It has been hypothesized that ulcers result from alterations in mucosal blood flow due to increased blood viscosity.

Antral G-cell hyperfunction

Antral G-cell hyperfunction most often occurs as an exaggerated response to Hp infection and responds rapidly to Hp eradication. However, an Hp-independent form has also been reported.

Idiopathic hypersecretory (Hp-negative) duodenal ulcer

As noted (see Laboratory evaluation – Acid secretion), gastric acid hypersecretion occurs in non-Hp, non-NSAID DU. Some cases have acid secretory rates that approach those found in gastrinoma [38]. Mechanisms of acid hypersecretion have not been established; vagal cholinergic mechanisms are a possibility that deserve further study in Hp-negative hypersecretory DU patients (Fig. 40.5). After Hp, NSAIDs, and gastrinoma have been confidently excluded, management is conservative using a PPI [93]. Occasionally it is necessary to titrate PPI dosage, as in gastrinoma.

Vascular insufficiency including crack cocaine use

Mucosal blood flow is critical to mucosal integrity and vascular insufficiency syndromes involving the arterial supply can present with gastric and also duodenal ulcers [94–96]. These ulcers often fail PPI therapy but will respond to revascularization. For example, gastric ulceration associated with stenosis of the inferior mesenteric artery responded to stenting of the inferior mesenteric artery [96]. Large ulcers and perforation of gastroduodenal ulcers has also been described with crack cocaine use, presumably secondary to mucosal vasoconstriction [97,98].

Enterocolic lymphocytic phlebitis is a rare cause of gastrointestinal ischemia apparently due to inflammation and has been reported with gastric and duodenal involvement associated with chronic nonhealing antral ulcer [99].

Mechanical: duodenal obstruction

Unusual cases of DU have been linked to a variety of duodenal abnormalities, including congenital duodenal webs, hypertrophic pyloric stenosis, annular pancreas, and preduodenal portal vein. Although DU in this setting may present in infancy or childhood, presentation in adolescence or adulthood also occurs [100]. Although annular pancreas may present at birth with high-grade duodenal obstruction, it more commonly presents in the second to seventh decades with the peak incidence in the fourth decade [100,101]. Ulcers with annular pancreas are sometimes postbulbar and have been associated with basal acid hypersecretion. The mechanisms linking these various "obstructing" lesions of the pylorus and duodenum to acid hypersecretion and ulcer disease remain undefined.

Other uncommon forms

Unusual secondary forms of ulcer include postradiation therapy, infiltrating disease, connective tissue disease, and unusual neoplastic conditions. Inflammatory conditions include Crohn's disease, Wegener granulomatosis [102], and Behçet disease [103]. Neoplastic conditions that mimic peptic ulcer include lymphomatous gastric ulcers [104], primary gastric [105] and metastatic malignant melanoma [106], and metastatic renal cell carcinoma [107].

Childhood peptic ulcer

Duodenal ulcer occurring in the first two decades often presents with nocturnal pain, and one-third of patients present with hemorrhage [108]. Diagnosis is often delayed because of the low level of suspicion. Hp is responsible for most DU in children (e.g., 82%) [109–111]. However, DU in childhood may occur in the absence of Hp [110,112].

Risk factors for peptic ulcer

Cigarette smoking

Strong evidence implicates smoking as a major risk factor associated with the occurrence, persistence, recurrence, and complications of Hp-associated peptic ulcer. Epidemiological studies have shown that smokers are at increased risk for both duodenal and gastric ulcers and that the risk is proportional to the amount smoked [113–117]. Smoking impairs ulcer healing, promotes recurrences, and increases the risk of complications and the need for surgery. Of interest, following Hp eradication, smoking ceases to be an important variable related to recurrent duodenal ulcer [118,119].

There are several candidate mechanisms by which smoking exacerbates the ulcer diathesis, including increased duodenal acid load by increasing gastric acid secretion and impairing duodenal and pancreatic bicarbonate secretion [16,120].

Alcohol

Alcohol in high concentrations damages the gastric mucosal barrier to hydrogen ions and is associated with acute gastric mucosal lesions characterized by mucosal hemorrhages. Alcohol itself stimulates acid secretion [121], and the contents of alcoholic beverages other than alcohol also stimulate acid secretion. Despite these acute effects, there is no evidence that alcohol intake causes or exacerbates chronic PUD [122,123]. Modest alcohol consumption is associated with

enhanced ulcer healing [124,125]. However, alcohol misuse interferes with patient compliance and ulcer healing [126]. Furthermore, cirrhosis, regardless of etiology, is associated with increased risk of peptic ulcer (see Disease associations).

Psychological factors

The importance of psychodynamic factors in the genesis of peptic ulcer remains controversial despite decades of study [127]. Investigation of the psychodynamic aspects of ulcer disease has been hampered for a variety of reasons including:

1 It is difficult to define ulcer occurrence and recurrence and to achieve adequate sampling and blinding. Many retrospective studies are based on self-report about the ulcer history, which could lead to bias favoring association with psychosocial factors.

2 Psychological stress is difficult to measure. Stressful events are only part of the picture; the level of distress also reflects the patient's perception of the stressful event, interpretation of implications, and coping mechanisms.

3 As the pathogenesis of ulcer disease is multifactorial, psychodynamic factors need to be correlated with known pathophysiological factors, such as infection with Hp, adequate acid secretory mass, smoking, and NSAID use.

4 Psychodynamic factors are likely to play a role only in a subset of ulcer patients, which remains undefined.

Keeping these limitations in mind, two lines of evidence strongly implicate psychosocial factors in ulcer pathogenesis. First, several recent studies have used a prospective design to address methodological limitations [127]. The most useful approach has been to track ulcer incidence (new ulcers) or ulcer recurrence in a defined epidemiological cohort. Using this type of approach, studies over the last 15 years have painted a consistent picture about the importance of several forms of psychological stress as predictors of de novo ulcer incidence or ulcer recurrence. As an example, poorly tolerated stress or depressive symptoms at baseline increased the risk of ulcer development over the next 9–15 years (Fig. 40.6) [127]. Other psychosocial factors, such as work-related stress, social problems, and posttraumatic stress disorders (PTSD), were also predictive of subsequent ulcer disease. Second, several studies have established that peptic ulcer complications are more prevalent during periods of natural disaster or societal catastrophe. The first such study was the demonstration of a dramatically increased rate of ulcer perforation during the German bombardment of London [128]. Several other studies have shown similar findings following other such horrific events [127].

Stress, anxiety, and depression have been observed to impair endoscopic healing and to promote relapse of endoscopically diagnosed ulcers [127,129]. The effects of stress seem to be reversible; patients who develop an ulcer following traumatic life events, but who are psychologically stable, tend to do well after the stress has resolved. The pathophysiological mechanisms accounting for the effects of stress on ulcer formation have not been defined. These effects could be mediated by both altered behaviors and by altered physiology. Pathogenic mechanisms for peptic ulcer are multifactorial, a fact that confounds unraveling the link between psychosocial factors and ulcerogenesis. For example, stress increases acid secretion and the effects are more prominent in patients with DU than in control subjects [130]. As a result, one must consider not only the stressor, but the individual's physiological and psychosocial response to the stress. Lastly, finding a relationship between psychosocial factors and ulcer disease does not establish causality. One study found that anxiety and neuroticism were high in a group of DU patients at the outset, but normalized in relapse-free patients at the end of a 10-year follow-up period [131]. In some cases, psychological features may be the result and not the cause of the disease process in susceptible hosts.

The genetics of peptic ulcer disease

Studies from the pre-Hp era recognized familial aggregation of PUD in a pattern suggesting polygenic inheritance. The familial aggregation of both DU and GU appeared distinct: first-degree relatives of patients with DU had a threefold increased prevalence of DU but not GU; in contrast, relatives of patients with GU had a threefold increased prevalence of GU but not DU [132]. Hyperpepsinogenemia was proposed as a marker of autosomal dominant inheritance of predisposition to peptic ulcer. Subsequent follow up of these same subjects revealed that this pattern of hyperpepsinogenemia

was in fact due to familial clustering of Hp infection [133]. Although hyperpepsinogenemia may generally be related to Hp infection, Italian investigators have identified a family in whom peptic ulcer was linked to elevated serum pepsinogen group A in the absence of Hp infection [134].

Questions were reframed for the Hp era: First, are genetic factors involved in predisposing to Hp infection or in predisposing to certain disease outcomes in infected individuals? Second, are there genetic factors that operate independently of Hp? Host factors appear to be important in predisposing to Hp infection and to disease outcomes such as DU and gastric cancer. In the setting of Hp infection, polymorphisms involving the cytokine IL-1-β [135,136], but not IL-6 [137], appear linked to DU, probably related to the effects of Hp-associated inflammation and acid secretion.

Twin studies also provide evidence for a clear genetic predisposition to PUD that is independent of any predisposition to Hp infection. An illustrative report found high concordance of a self-reported ulcer history in monozygotic compared with dizygotic twins, regardless of whether they were reared apart or together [138]. Cross-twin, cross-trait correlations for monozygotic and dizygotic twins indicated that the genetic effects for peptic ulcer were independent of the genetic influences for Hp. Another twin study also concluded that genetic factors were linked to DU independently of environmental variables [139].

There are a few rare inherited syndromes associated with PUD, such as genetic forms of gastrinoma and mastocytosis. There are other scattered reports of peptic ulcer linked to inherited syndromes, but many of these reports are dated and not well investigated and familial clustering of Hp has not been excluded.

Epidemiology of peptic ulcer

Estimates of ulcer prevalence

Prevalence is defined as the proportion of the population with a given disease at a single point in time, over a period of time, or over a lifetime. Results from the pre-Hp era are difficult to link to the current situation, in which the prevalence of Hp has markedly decreased. The prevalence of PUD must be defined as a function of Hp status and of NSAID and aspirin use. Prevalence estimates from endoscopic studies of adult volunteers indicate a prevalence rate of 1%–6% in patients who were Hp positive by at least one screening test [140], with a lifetime risk of about 10%–20% in those with Hp infection [140]. The prevalence of PUD in the subpopulation who are neither Hp infected nor NSAID users is unknown but is probably very low.

DU was infrequently recognized before the end of the nineteenth century, after which the incidence appeared to steadily increase until 1960 and then to decrease [141]. Although the pathogenesis of this phenomenon is unknown, this was also the time in history when there were marked improvements in diet, sanitation, standards of living, and household hygiene. Together these events were associated with a change in the pattern of transmission of many infectious diseases including Hp infection. The prevalence of Hp infection in 20 year olds in the United States has declined to less than 15%, which has resulted in Hp-related PUD becoming an increasingly uncommon disease. DU requires a normal or near-normal gastric corpus capable of secreting sufficient acid (e.g., 12 mmol/h) to sustain the ulcer disease. In contrast, gastric cancer and GU are associated with corpus gastritis and reduced acid secretion. It appears likely that the change in diet with increased availability of fresh fruits and vegetables, fortification of foods, and a reduction in the frequency of childhood febrile illnesses all combined to produce changes in the pattern of gastritis, which underlies the observed pattern of the appearance of DU as a "new" disease and the decline in the prevalence of gastric cancer [141,142]. The decline in Hp ulcers occurred at the same time that NSAID and aspirin use was increasing, and the current data are consistent with the notion that the rates of ulcer disease are decreasing in young subjects but are increasing in older subjects related to both residual Hp infection and use of NSAIDs and aspirin. These trends were evident in data collected in the United States from 1970 to 1990, and similar trends are also evident in data from the UK, the Netherlands, and Denmark (Fig. 40.7a,b) [143–145].

A complete understanding of the incidence and time trends in ulcer occurrence requires a detailed understanding of a number of important environmental variables including the prevalence of Hp infection, NSAID use, and cigarette smoking, all of which influence the occurrence of ulcer in an age-dependent fashion (see Etiology and pathophysiology of peptic ulcer). In addition, the epidemiological assessment of ulcer prevalence and incidence is challenging as different results may reflect different scenarios such as:

- the mode of ulcer detection (symptoms, radiography, endoscopy, hospitalization, complications, surgery, or death)
- the period assessed (the disease is intermittent)
- the care with which DU and GU are differentiated from other disorders (e.g., other peptic disorders such as esophagitis, nonulcer dyspepsia, and other causes of GI bleeding)
- the dramatic shift to outpatient management
- improved medical therapy
- changes in the criteria and coding system for mortality and hospitalization data [146].

Comorbid ulcers

Disease associations

There has been a long-standing suspicion that peptic ulcer is associated with other medical conditions [92]. However, the existence, mechanisms, and implications of these putative

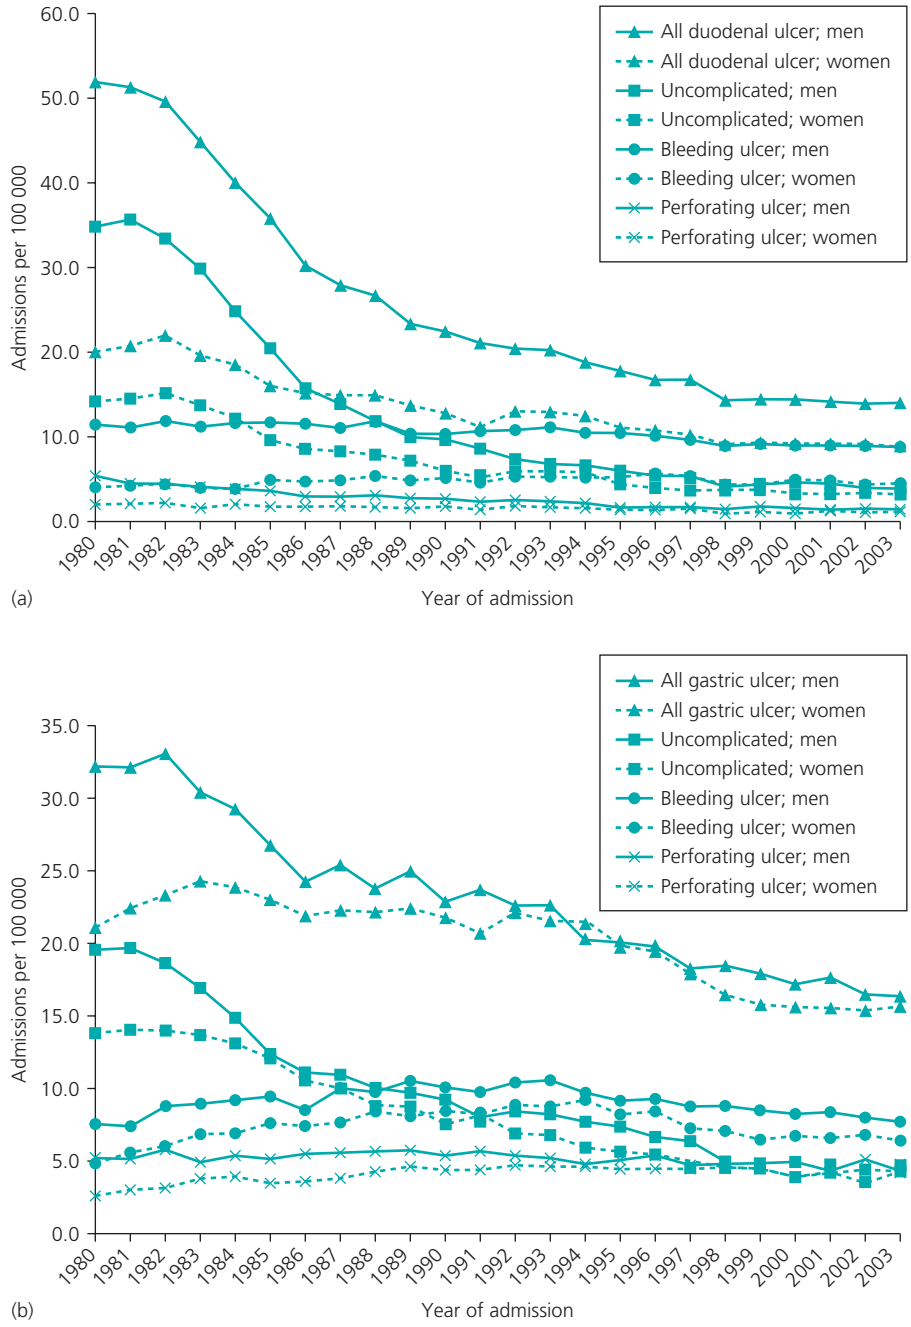

Figure 40.7 Trends in hospital admission rates in the Netherlands: **(a)** duodenal ulcer; **(b)** gastric ulcer. Data show a dramatic fall in rates of uncomplicated duodenal ulcer and gastric ulcer in men, and to a lesser extent in women. In contrast, rates of complications are relatively stable over this period. From Post et al. [145], with permission from Blackwell Publishing.

associations remain unclear and many such apparent associations may be spurious. Berkson recognized the fallacy of apparent disease association due to referral and selection bias among patients referred for a given disease [147]; studies with a hospital or referral population are likely to indicate a greater prevalence of a given disease than examining a random population sample for both diseases, alone and in combination. Furthermore, patients presenting for evaluation are more likely to be examined for other medical problems.

Any study of disease associations must also take into account known ulcer risk factors, such as Hp, NSAID use, and smoking. However, reliable detection of these factors outside of prospective studies is difficult. False-negative results for Hp are common in patients with PUD, especially if only a single test is done, and NSAID use is difficult to uncover, even with direct questioning. Furthermore, simply the presence of Hp does not guarantee that it caused the ulcer disease.

Intensive care unit stress, medical comorbidity, and peptic ulcer

The association between medical comorbidity and peptic ulcer is generally accepted for "stress ulcers" that occur in an

ICU setting. Superficial mucosal lesions are present in the majority of seriously ill patients within 18 h of admission to an ICU [148]; this finding has been called stress-related mucosal damage. However, although stress-related mucosal damage can cause low-grade GI bleeding, it rarely causes clinically significant bleeding in the absence of severe coagulopathy. Serious complications result from discrete ulcers that erode into sizable blood vessels or perforate.

The incidence of ICU stress ulcers has dramatically fallen in recent years. For example, studies of patients with severe burns three or four decades ago reported ulcer complications in more than 20% of patients, whereas the ulcer complication rate today in state-of-the-art burn units is very low. Presumably, most of this improvement is due to improved medical care, which primarily reduces pulmonary, septic, and renal complications and improves nutritional balance. These factors are probably much more important than antiulcer therapy per se. This point underlines the most important element of management of stress ulcers: treat the underlying medical condition.

The medical comorbidity of relevance to peptic ulcer occurs in two forms: chronic medical comorbidity and acute multisystem organ failure. The latter is obviously more relevant in the ICU, but we anticipate that serious medical comorbidity occurring outside of the ICU is also a very important factor in peptic ulcer pathogenesis, as considered below. We will refer to "comorbid ulcers" as those associated with either form of comorbidity. We hypothesize that comorbid ulcers are a distinct subgroup that should not be confused with idiopathic, non-Hp, non-NSAID ulcers; the epidemiology, pathogenesis, and management are likely to be very different.

There is little understanding of the epidemiology, mechanisms, and natural history of comorbid ulcers. We speculate that the most important factors are generic rather than disease specific. Probably the most important generic factors are malnutrition and a catabolic state with negative nitrogen balance interfering with tissue integrity and repair and tissue hypoperfusion and oxygenation due to hypovolemia, anemia, low vascular oncotic pressure, vasoconstriction, and poor oxygen delivery. These factors, in addition to multisystem organ failure, can be acute or subacute. As mucosal damage is very common in seriously ill patients, the impairment of tissue repair and healing may be the most critical factor in patients who make enough gastric acid and pepsin to be at risk for developing comorbid ulcers. Disease-specific factors may also be important in a subset of patients with comorbid ulcers but, with the exception, possibly, of cirrhosis, such factors have not been identified, (see section on cirrhosis).

Two recent studies of ulcer complications have observed an association with medical comorbidity that was more evident in patients with non-Hp, non-NSAID ulcers [73,149]. Hung and coworkers from Hong Kong [73] made an important observation that 16% of bleeding ulcers presenting as outpatients were Hp negative; in contrast, 42% of bleeding ulcers presenting as inpatients were Hp negative. Patients who develop ulcer bleeding as inpatients are much more likely to have serious medical comorbidity. Another study from Hong Kong also found that Hp-negative ulcers were more likely to occur in older subjects who had concomitant medical problems, malignancy, recent surgery, or sepsis [149]. We cannot answer the question of how many of these ulcers should be considered ICU ulcers related to stress of acute cormorbid disease; neither study discriminated among ulcers associated with acute organ failure, ICU admission, or stable or decompensated chronic comorbidity.

Hp-negative ulcers have been observed to have poor outcomes when compared with Hp-positive ulcers [73,149,150]. However, it is unclear whether these poor outcomes are due to the ulcer disease per se or to the medical comorbidity, which may be causing both the ulcers and the poor outcomes. Although it is certainly true that some patients die with comorbid conditions from ulcer complications for which they are probably more susceptible, we anticipate that mortality is largely due to the underlying comorbid conditions.

As noted above, studies have reported that Hp is less common in ulcers presenting in hospitalized patients than in those presenting in outpatients [73]. It is quite likely that Hp does play a role in a small number of patients, as preexisting, often clinically silent ulcers or ulcer scars may exist in a few percent of an asymptomatic Hp-positive population, especially if elderly. Such preexisting ulcers might be exacerbated with the stress of acute illness. However, we suspect that a sizable portion of patients presenting with comorbid ulcers will be Hp negative.

The following sections list several chronic conditions that have been linked to PUD. The strongest association is noted between cirrhosis and PUD, which appears to be mediated by a disease-specific mechanism. For other conditions it is unclear whether the association reflects an undiscovered disease-specific mechanism or the more generic mechanisms mentioned above. Most of the studies of this topic have only correlated the presence or absence of a given disease, rather than attempting to quantify the number and severity of comorbid conditions and overall nutritional status. Obviously, prospective studies are needed; we strongly encourage future investigators to include a more comprehensive approach to capturing comorbidity and overall status.

Chronic obstructive pulmonary disease

An association between chronic obstructive pulmonary disease (COPD) and peptic ulcers has been suspected for many years. The frequency of chronic lung disease in patients with peptic ulcer is increased 2- to 3-fold over the general population and peptic ulcers, both gastric and duodenal, occur in up to 30% of patients with chronic lung disease [92,115,151].

The association between these diseases is not influenced by the clinical severity or therapy of the lung disease. It appears

likely that the major factor underlying the association is the impact of cigarette smoking on both diseases. In one series of Japanese men living in Hawaii, cigarette smoking was associated with an increased risk of gastric and duodenal ulcer, but showed a dose–response in pack-years only for gastric ulcer [115].

Cirrhosis

The prevalence of peptic ulcer is significantly increased in patients with cirrhosis [83,152,153], with prevalence estimates ranging from 10% to 49% [154,155]. The annual incidence has been estimated to be 4.3% [153]. The ulcers are often asymptomatic but are associated with a high rate of complications and frequent recurrences.

The mechanism of this association is unknown. Alcohol ingestion is not an explanation. Although Hp has been reported to be associated with ulcers in cirrhotic patients [154,156], other studies have not found any striking association [155]. Investigators who treated Hp with antibiotics found that the high ulcer recurrence rate was not apparently different amongst the Hp-cured, persisting Hp-positive, and Hp-negative subjects [155]. The Child–Pugh class is a risk factor [154] suggesting that the severity of the cirrhosis is important.

The yearly recurrence rates are about 50%, underlining the importance of careful follow-up for patients with cirrhosis and PUD [155]. Although many of the recurrences are asymptomatic, the risk of complications is sufficiently high to warrant consideration of maintenance antisecretory therapy.

Renal failure

Earlier studies described an increased incidence of peptic ulcer in patients with chronic renal failure. However, subsequent studies have yielded conflicting data regarding the prevalence of PUD in patients with chronic renal failure [157,158]. The role of Hp eradication in the apparent change in epidemiology is unknown.

Organ transplantation

Peptic ulcer disease has been a significant cause of morbidity posttransplantation, in part because of immunosuppression, the administration of corticosteroids, and CMV infection. The use of cyclosporine (ciclosporin), antiviral therapy, and early diagnosis and treatment appear to have had beneficial effects, although the incidence of PUD remains increased and peptic ulcers are still an important source of morbidity in this population [159,160]. As noted above, some of these ulcers are stress ulcers associated with multisystem failure; the improvement reflects a general improvement in status and nutrition. Chen et al. [161] observed two risk factors for peptic ulcer in transplant patients: methylprednisolone pulse therapy and a pretransplantation history of PUD. The value of pretransplant screening is controversial and antiulcer prophylaxis is routine in most centers [162].

Clinical presentation and diagnosis of peptic ulcer

Peptic ulcer classically presents with symptoms of acid dyspepsia, which appears to reflect gastroduodenal sensitization to hydrogen ions. However, it can also present with other symptoms (Table 40.2) [163–165].

"Acid dyspepsia:" the classic ulcer symptom

In the era of classic diseases, DU was thought to be easy to diagnose [166]. The classic symptom of ulcer is characterized as a burning epigastric "hunger" pain or discomfort that tends to occur when acid is secreted in the absence of a food buffer (e.g., 2–3 h after meals) and at night, usually between 11 PM and 2 AM, when the circadian stimulation of acid secretion is maximal. Pain rarely occurs before breakfast. Alkali, food, and antisecretory agents produce relief such that "classic" patients tend to "feed" their ulcers. However, the classic presentation proved not to be specific for PUD as it occurs in nonulcer dyspepsia; in addition, many ulcer patients have "atypical" symptoms [163–165,167,168]. Despite these qualifications, food relief is more likely to occur with peptic ulcer, whereas food provocation of symptoms (postprandial pain or food intolerance) and nausea have negative predictive value for underlying PUD [169]. GU is less likely than DU to be relieved by antacids or food and more likely to display food provocation.

The discomfort occurs in the epigastrium in about two-thirds of symptomatic ulcer patients, but may occasionally localize in the right or left upper quadrants or hypochondrium [163]. Radiation of the pain to the back may also occur, but primary back pain is atypical. Clusters of pain lasting a few weeks followed by symptom-free periods of weeks or months is a pattern that is characteristic of classic DU. However, the classic symptoms of acid dyspepsia with food relief, described above, occur in only about 50% of DU patients (Table 40.2).

Unencumbered by placebo controls, Palmer [170] demonstrated that aspiration of gastric contents relieved pain and that reinfusion of the acidic (but not neutralized) gastric juice precipitated pain, supporting the concept that acid bathing an ulcer crater caused symptoms. In a double-blind protocol duodenal infusion of acid, but not saline, induced pain in about 40% of patients with active duodenal ulcers [171], whereas infusion of saline produced pain in only 10%. Pain was not produced by infusions in control subjects. Thus, in at least a portion of DU patients, symptoms are provoked by acid bathing the ulcer.

Data from numerous controlled endoscopic trials, largely in the pre-Hp era, have shown that symptoms and mucosal pathology are frequently dissociated such that ulcer healing does not guarantee disappearance of symptoms. Conversely, ulcers may also be present without producing symptoms;

Table 40.2 Symptoms of gastric and duodenal ulcers and nonulcer dyspepsia [163–165]

Symptom	Gastric ulcer (%)	Duodenal ulcer (%)	Nonulcer dyspepsia (%)
Pain/discomfort	100	100	100
Features of the pain:			
Primary pain			
Epigastric	67	61–86	52–73
Right hypochondrium	6	7–17	4
Left hypochondrium	6	3–5	5
Frequently severe	68	53	37
Within 30 min of food	20	5	32
Gnawing pain	13	16	6
Increased by food	24	10–40	45
Clusters (episodic)	16	56	35
Relieved by alkali	36–87	39–86	26–75
Food relief	2–48	20–63	4–32
Occurs at night	32–43	50–88	24–32
Not related to food or variable	22–53	21–49	22–65
Radiation to back	34	20–31	24–28
Increased appetite		19	
Anorexia	46–57	25–36	26–36
Weight loss	24–61	19–45	18–32
Nausea	54–70	49–59	43–60
Vomiting	38–73	25–57	26–34
Heartburn	19	27–59	28
Nondyspeptic symptoms	2	8	18
Fatty food intolerance		41–72	53
Bloating	55	49	52
Belching	48	59	60

15%–44% of ulcer patients who become symptom free during therapy still have an ulcer crater at endoscopy. Thus, in a largely Hp-positive group of ulcer patients, resolution of symptoms with antiulcer, but not anti-Hp, therapy does not predict ulcer healing. Complete resolution of dyspeptic symptoms may have different implications when Hp is being treated; complete symptom resolution at 3 months had a 98% positive predictive value for successful eradication of Hp infection [172]. In contrast, persisting symptoms had only a 25% positive predictive value for persisting Hp infection [172]. The presence or absence of persisting dyspepsia is an inadequate measure of Hp status posttherapy and emphasizes the need for post-Hp eradication testing (see Confirmation of *Helicobacter pylori* cure).

The dissociation between ulcers and symptoms is also evident from the impact of Hp eradication on the long-term symptomatic outcomes. In one study [173], 1–3 years after successful eradication of Hp in Hp-positive ulcer patients, 55% had resolution of their dyspeptic symptoms compared with only 18% of those with failed eradication. Although Hp cure clearly reduces symptoms in ulcer patients, excluding patients with preexisting gastroesophageal reflux disease (GERD), approximately one-third of Hp-positive ulcer patients can be expected to have persisting symptoms 1–3 years after successful cure of the Hp infection. The pathogenesis of these symptoms remains unclear. However, it is clear that the symptoms experienced by ulcer patients reflect factors more complex than simply acid bathing an ulcer crater. Symptoms may relate in part to sensitization of afferent nerves in response to tissue injury (i.e., visceral somatic hypersensitivity) [174,175]. Dyspepsia may result in an exaggerated response to superimposed chemical, mechanical, infectious, or inflammatory insults, and the gastroduodenitis associated with Hp or the inflammatory response to the peptic ulcer itself may produce this sensitization.

Gastroesophageal reflux, duodenal ulcer, *Helicobacter pylori*, and acid secretion

Gastroesophageal reflux disease evident by heartburn, acid reflux, or esophagitis occurs in 20%–60% of DU patients (Table 40.2) [173]. Both are common disorders and Berkson's fallacy deserves consideration [147] (see section on diseases associated with peptic ulcer). However, the association is strong and has a clear pathophysiological basis. With acid hypersecretion from gastrinoma or idiopathic PUD defined as basal acid output of more than 15 mmol/h, GERD was found

in 80% (65% with grade 2 or greater esophagitis and 15% with heartburn only) [176]. Furthermore, patients with esophagitis had a median lower esophageal sphincter pressure (LESP) of 15.5 mmHg compared with 23 mmHg in those without symptoms. Frequent vomiting and obesity were also identified as risk factors for esophagitis, whereas Hp was a strong negative predictor (odds ratio, 0.16) [176]. Therefore, GERD in an ulcer patient should be one clue to an underlying acid hypersecretory disorder.

This association between GERD and PUD has important implications for management. Hp-positive ulcer patients with prominent GERD symptoms are more likely to have persisting symptoms after Hp eradication [173]. In contrast, treatment of Hp in GERD patients either has no effect on requirements for therapy or is associated with an improvement [173,177].

History and physical examination

Clinical evaluation should accomplish three goals. The first is to elicit a history and findings that help discriminate between common and uncommon disorders that overlap with, obscure, or mimic ulcer disease. The second is to evaluate the severity of underlying disease if present. The third goal is to evaluate the psychosocial dimensions, including patient questions and concerns about the diagnosis, process, and prognosis. Clues to more severe forms of PUD, such as gastrinoma, include the presence of multiple duodenal ulcers, ulcers occurring distal to the duodenal bulb, a strong family history, ulcers that are refractory to medical therapy, and ulcers that recur after surgery. Additional clues to Zollinger–Ellison syndrome (gastrinoma) are peptic ulcers in Hp-negative, NSAID-negative subjects, an association with diarrhea, steatorrhea, or weight loss, and an association with hypercalcemia and renal stones.

Presentation of ulcer complications

Complications, especially in the absence of NSAID use, are usually associated with chronic peptic ulcers and are often heralded by the development of ulcer symptoms or a change in symptom pattern. However, in approximately 25% of cases in the absence of NSAID use and 50% in the presence of NSAIDs, complications are the presenting symptom of an ulcer that was otherwise clinically silent [178,179]. However, in controlled trials the new development of symptoms appears to herald ulcer formation in some patients [73,74,180]. Classically, penetrating ulcers present with a shift from the typical, vague visceral discomfort to a more localized and intense pain that radiates to the back; the expected relief from food or antacids is also diminished. A sudden development of severe, diffuse abdominal pain may indicate perforation. Vomiting is the cardinal feature present in most cases of pyloric outlet obstruction. Hemorrhage may be heralded by nausea, hematemesis, melena, or dizziness.

Unusual complications may also herald the presentation of peptic ulcer. Massive hemorrhage can occur with erosion into a major artery. Posterior perforation is usually characterized by the insidious onset of upper abdominal pain due to a sealed perforation, localized retroperitoneal abscess, or generalized contamination of the lesser sac and peritoneal cavity [181]. Pneumoperitoneum on chest roentgenogram or computed tomography (CT) is a critical diagnostic clue. Valentino syndrome is a DU presenting with retroperitoneal perforation and right lower quadrant pain. The veiled right kidney sign (retroperitoneal air obscuring the right kidney) can be a clue [182]. Penetrating ulcers can also result in fistulae. Gastrocolonic fistulae occur with anterior GU and present with halitosis, feculent vomiting, postprandial diarrhea, dyspepsia, and weight loss [183]. An apparent double pylorus has been observed to develop by endoscopy due to erosion of a GU into the duodenum [184]. Hepatic penetration has been observed with large DU or GU [185].

Laboratory evaluation

Routine laboratory studies are typically normal. Screening studies should include a complete blood count, liver chemistries, serum creatinine, and serum calcium. A fasting serum gastrin level is indicated in ulcers refractory to therapy, with a positive family history, or in cases requiring surgery. Serum salicylate levels can reveal unsuspected aspirin abuse, and are indicated in refractory and complicated cases. Surreptitious use of aspirin and NSAIDs can also be detected by testing for platelet COX activity [186].

Acid secretion

Formal gastric analysis has fallen into disfavor, exacerbated by the fact that pentagastrin is largely unavailable. However, one can easily assess basal gastric acid secretion using traditional techniques and one can measure the acid concentration in gastric fluid, including that obtained at the time of endoscopy. The presence of an elevated gastrin level should always prompt measurement of gastric acidity to exclude achlorhydria as the cause. A fasting hydrogen ion concentration of approximately 100 mmol/L or more is highly suggestive of a hypersecretory state.

Helicobacter pylori testing

Patients with peptic ulcers have high pretest probabilities for the presence of Hp. This high pretest probability means that a positive test, whether it be the presence of anti-Hp IgG antibody, a carbon 13 or carbon 14 urea breath test (UBT), or a stool antigen test, is strong evidence of the presence of infection and treatment can be initiated. In contrast, especially in the setting of ulcer disease, a negative test has a reasonably high probability of being a false-negative result, and thus negative tests must be confirmed by a second test (e.g., one designed to identify the presence of active infection such as a UBT or stool antigen test). One caveat is that the use of PPIs, bismuth, or antibiotics all reduce the bacterial load and

will result in an increased risk of a false-negative UBT, stool antigen test, histology, rapid urease test, and culture. If the patient is receiving a PPI, it should be stopped for approximately 2 weeks and an H2RA substituted before testing as it does not reduce bacterial load. Culture of Hp is generally not available nor necessary, except for antibiotic susceptibility testing in refractory cases. Another caveat is that, although experienced pathologists can diagnose Hp using hematoxylin and eosin staining, false negatives are frequent, especially when the number of organisms is low. Special stains are recommended, especially when chronic gastritis is present. As histology is more expensive than biopsy or rapid urease testing, at endoscopy it is reasonable to obtain biopsies from normal-appearing mucosa for both tests and then to discard histology specimens if the urease test is positive. Biopsies for histological testing for Hp should always include sampling of both the antrum and corpus.

Upper gastrointestinal radiography

A definitive radiographic diagnosis of peptic ulcer requires demonstration of barium within an ulcer niche, which is generally round or oval and may be surrounded by a smooth mound of edema [187,188]. Secondary changes include folds radiating to the crater, and deformities in the region secondary to spasm, edema, and scarring. The incisura found encircling a GU reflects secondary spasm of circular muscle. Secondary signs of DU include deformity of the duodenal bulb, which may be evidenced by flattening of the superior or inferior fornices, eccentricity of the pyloric channel, pseudodiverticulum, or exaggerated outpouching of recesses at the base of the bulb [187]. In the presence of deformity of the duodenal bulb, edema of the folds, or postoperative deformity, ulcer craters become much more difficult to detect. False-positive results occur when barium is trapped between folds. Although endoscopy has replaced radiology as the technique of choice for the evaluation of upper GI complaints in general and detection of cancer in particular, radiology can occasionally be useful. Radiographic signs suggesting gastric malignancy include: (1) an ulcer within a definitive mass; (2) effaced, interrupted, fused, or nodular mucosal folds as they approach the margin of the crater; and (3) negative, irregular filling defects in the ulcer crater.

Endoscopy

Endoscopy provides a sensitive, specific, and safe method for diagnosing peptic ulcers, allowing direct inspection and biopsy. Benign ulcers have smooth, regular, rounded edges, with a flat, smooth ulcer base often filled with exudate. Malignancy [189] is associated with an ulcerated mass that protrudes into the lumen; surrounding folds that are nodular, clubbed, fused, or stop short of the ulcer margin; or margins that are overhanging, irregular, or thickened. The gold standard for determining whether an ulcer is benign or malignant is biopsy. Biopsy should be performed even for gastric lesions with a benign endoscopic appearance, as benign-appearing ulcers may harbor malignancy [190]. The proper number of biopsies has been debated and depends upon technique. Four jumbo biopsies of the ulcer margin are equivalent to 6–7 adequate, regular-sized biopsies, the number shown to detect nearly all cancers. The description "adequate" biopsy warrants emphasis, because biopsies that do not provide a good sample of the lesion are useless at best and misleading at worst.

In addition to direct endoscopic inspection and biopsy, repeat endoscopy to confirm healing of gastric ulcers may be required for confirmation of benignity. Until recently, follow-up endoscopy was the rule for gastric ulcers. Currently, management is individualized based on the clinical situation, endoscopic findings, and the adequacy of initial biopsy. For example, an obviously benign ulcer in a young, NSAID user without Hp infection and with adequate initial biopsies that were negative would not mandate follow-up endoscopy to rule out malignancy. However, a large, endoscopically indeterminate ulcer in the body of the stomach of an elderly subject generally warrants repeat endoscopy and biopsy.

Computed tomography

Despite very limited data, CT is clearly the most valuable test if a penetrating or perforated ulcer is suspected. Furthermore, the much higher resolution of the newer spiral and multislice CT techniques makes them more valuable for assessing the sometimes subtle findings of complicated ulcers. Advanced CT is clearly more effective than an upright chest radiograph in detecting free air, with positive findings in all 14 consecutive patients with perforation in one surgical series [191]. In total, 10 of these 14 patients also had fluid collections and 5 had inflammatory changes in surrounding soft tissues [191]. Extravasation or sinus tracks with intralumenal contrast material, discontinuity of the bowel wall, and mucosal thickening can also be useful findings localizing the site of perforation or penetration, but these findings only appear to be reliable with the highest resolution scanning equipment [192,193]. Use of oral contrast is controversial, but also appears to be valuable with higher resolution equipment [192].

Recommendations regarding evaluation and follow-up

The goal in evaluating a patient with upper gastrointestinal symptoms is to expeditiously arrive at a definitive diagnosis without unnecessarily exposing patients to costly and potentially risky diagnostic procedures. These decisions fall within the realm of "good clinical judgment;" there is no gold standard for decisions that are both cost-effective and appropriately cautious. However, decisions must be made and data interpreted in light of specific patient characteristics and diagnosis, such as patient age, socioeconomic background, index event, "ulcer" history, and previous workup. Decisions would be very different for a 25-year-old graduate student

with uninvestigated dyspepsia compared with a 70-year-old patient with previously documented ulcer complications. Decisions would also be very different in patients with a firm recent endoscopic diagnosis of ulcer but no Hp testing compared with a remote "ulcer" diagnosis on clinical grounds.

Complicated gastric or duodenal ulcer with unknown *Helicobacter pylori* status

With all ulcers, the question is "Hp, NSAIDs, neither, or both." As noted, testing for Hp is relatively straightforward provided that the caveats for false-negative results are taken into account. The goals include healing the ulcer and preventing its recurrence. If Hp is present it should be treated and, at a suitable time (e.g., 4 weeks) after the end of therapy, cure should be confirmed (see *Helicobacter pylori* and ulcer therapy – Confirmation of Hp cure). Patients with a history of ulcer complications are at a markedly increased risk for future life-threatening events. Hp eradication essentially removes that risk, whereas a return to NSAID use is associated with a recurrent risk of a new complication.

Helicobacter pylori-negative ulcers

In ulcers that test negative for Hp, alternative etiologies (Table 40.1) deserve consideration. However, the most common etiologies for Hp-negative ulcers are false-negative testing for Hp and undiscovered consumption of NSAIDs. Once Hp and NSAID use have been firmly excluded, then alternate etiologies deserve consideration, especially for complicated or troublesome ulcers.

Atypical ulcers

Giant ulcers

Giant ulcers commonly occur in association with NSAID consumption [194]. Giant duodenal or prepyloric ulcers have also been reported in association with end-stage renal failure [195]. Giant GU may also carry an increased risk of harboring carcinoma. Crohn's and other disease processes can present with giant ulcers [196].

Atypical duodenal ulcers

Duodenal carcinoma and invading pancreatic carcinoma typically present as masses but may produce benign-appearing ulcers. Because of the very low yield, routine DU biopsies cannot be recommended unless the clinical condition warrants it, such as a refractory DU or an atypical endoscopic appearance.

Postbulbar ulcers

Generally, ulcers in the duodenum are located within 2–3 cm of the pylorus. Postbulbar ulcers are uncommon and suggest the presence of gastrinoma and other hypersecretory states. Differential diagnosis should include diverticula, adhesive bands, annular pancreas, and neoplasia of the pancreas and duodenum.

Natural history of peptic ulcer

The natural history of Hp-related DU and GU is to recur. Bardhan [197], following patients for 12 months after documented DU healing, observed that without medical treatment 26% of patients remained symptom free and 74% relapsed; 33% had one relapse, 24% had two recurrences, and 17% experienced three or more recurrences. The placebo-treated control groups drawn from numerous clinical trials of maintenance therapy indicate a similar 50%–80% recurrence rate during the 6–12 months following initial ulcer healing [198,199]. These recurrences can produce symptoms, but asymptomatic ulcers are frequently found at surveillance endoscopy. A number of factors influence the highly variable rate at which ulcers heal and recur (see Medical treatment of active peptic ulcer disease – Factors influencing healing). Successful eradication of Hp markedly changes the natural history and markedly reduces recurrences. However, after Hp eradication, erosions may occur in the duodenum that spontaneously heal and do not produce any clinical problems [200,201]. Such post-eradication erosions were likely responsible for post hoc subgroup analysis of patients participating in a US anti-Hp treatment trial reporting an unexpectedly high rate of "ulcer" recurrence after successful eradication of Hp [202].

The natural history of NSAID ulcers has not been formally studied in patients who continue on NSAIDs without ulcer treatment. It is clear that when NSAIDs are stopped, associated ulcers heal unless an independent cause of ulceration exists. As NSAIDs impair healing, it is possible that such ulcers are more persistent than Hp ulcers.

The limited data that exist for non-HP, non-NSAID ulcers also suggests that they may persist. Persistence of the ulcer diathesis is also expected for hypersecretory, idiopathic PUD [93].

Antiulcer pharmacology

Antisecretory agents

Antisecretory agents accelerate the healing of ulcers regardless of the etiology. They also relieve ulcer-associated dyspepsia. Continued use retards the rate of ulcer recurrence and reduces the risk of complications.

H_2 receptor antagonists

H_2 receptor antagonists are competitive reversible inhibitors of histamine at H_2 receptors on parietal cells. These drugs are equally efficacious and safe and differ primarily in potency. Available drugs include cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid). These drugs are also licensed for sale over the counter at reduced dosages, including Tagamet HB, Zantac 75, Pepcid AC, and

Axid. H_2 receptor antagonists have no antibacterial activity against Hp.

H_2 receptor antagonists are well absorbed after oral dosing; absorption is inhibited by 10%–20% by concomitant antacids, but not by food. Peak serum concentrations occur 1–3 h after oral dosing. All four drugs cross the blood–brain and placental barrier and are excreted in breast milk [203]. The distribution of cimetidine in cerebral spinal fluid appears to be increased in liver failure [203].

Cimetidine is the least potent of the H2RAs and has the highest incidence of side effects and drug–drug interactions. As such, it has largely fallen into disfavor. H_2 receptor antagonists have largely been replaced by PPIs for the treatment of PUD because of their increased potency and lack of tachyphylaxis (tolerance). The only advantage of H2RAs is cost, but as PPIs come off patent, this is less of a consideration.

Proton pump inhibitors

Proton pump inhibitors block acid secretion at the hydrogen–potassium adenosine triphosphatase (H^+,K^+-ATPase) pump located on the lumenal border of the gastric parietal cell. This pump exchanges hydrogen ions for potassium ions across the parietal cell microvillus membrane, secreting hydrogen ions into the gastric lumen and creating the low pH environment characteristic of gastric secretions. Proton pump inhibitors bind to and irreversibly inhibit the ATPase. Proton pump inhibitors are the most effective antisecretory agents currently available, achieving better pH control than that provided by H2RAs. Available agents include omeprazole (Prilosec), lansoprazole (Prevacid), pantoprazole (Protonix), rabeprazole (Aciphex), and esomeprazole (Nexium). Of note, although PPIs have some direct antibacterial activity against Hp in vitro, used alone they do not cure the infection. As noted in the section on diagnosis, PPI therapy reduces the Hp load in the stomach and can result in false-negative diagnostic tests.

PPI are acid labile and are inactivated if permitted to dissolve in acidic gastric juice. Therefore, enteric coated granules that dissolve at pH6 or above or sodium bicarbonate are used to protect the drug during transit through the stomach. When given with sodium bicarbonate buffer to fasting patients, PPIs are rapidly absorbed and peak plasma levels are reached in 30 min. With the enteric coated granules the peak concentration occurs 1–3 h after dosing and the drug is detectable in serum for about 6 h (Fig. 40.8a) [204]. The effectiveness of PPIs when given by oral administration relates closely to the AUC (area under the plasma concentration–time curve) rather than to peak plasma drug levels (Fig. 40.8b) [204–209]. The prolonged duration of PPI antisecretory action reflects irreversible inactivation of the parietal cell H^+,K^+-ATPase, rather than a prolonged serum half-life. Administering PPIs with food delays absorption but does not alter the AUC [210]. Although PPIs differ slightly in metabolism and potency, clinically they are completely interchangeable and cost should be the primary consideration when choosing which to prescribe. Drug metabolism, as evident by the AUC [211], occurs via P450 (see Drug interactions via cytochrome P450), and is prolonged with liver but not renal disease (Fig. 40.8c). Delayed metabolism is also observed with genetic P450 polymorphism and in the elderly. However, in light of the wide safety margin with these drugs and the apparent absence of accumulation, there are no current recommendations to alter dose in the elderly or in the face of hepatic failure.

The dose and time dependencies of inhibition of acid secretion by PPIs are characterized as follows:

1 *A time lag* in the onset of antisecretory effectiveness is noted over the first 4–7 days of therapy, probably reflecting progressive inhibition of the H^+,K^+-ATPase and possibly increases in drug bioavailability. This lag period is inversely related to dose.

2 There is *variability in antisecretory effectiveness*, probably due to variability in absorption and clearance, as reflected in the AUC. For example, after 7 days of therapy on a dose of 10 mg omeprazole, some subjects have minimal inhibition whereas others have more than 90% inhibition [212]. At 20 mg, inhibition is less variable [213] (Fig. 40.9), with a mean inhibition of acidity (hydrogen ion concentration) of about 90% [214]. Therefore, more consistent inhibition of acid secretion is observed at higher doses (Fig. 40.9). A PPI given twice daily produces better inhibition of secretion than one given once daily.

3 *PPIs maximally inhibit stimulated parietal cells.* As PPIs must be concentrated and activated in the acidic compartments of the parietal cell, they will only inactivate the H^+,K^+-ATPase present in actively secreting membrane compartments. PPI effectiveness therefore depends on the degree of activation of acid secretion at the time of drug administration. Omeprazole action is reduced, for example, if administered while secretion is inhibited by H2RA [215], as efficacy varies depending upon whether the patient is fasting, has recently taken an H2RA, or has secretion activated by food, gastrin or vagal pathways during the time that the prodrug is circulating. PPIs are effective when taken shortly before meals.

4 *Rapid control of acid secretion* can be achieved using higher doses of PPI or more frequent administration (i.e., three or four doses of 20 mg of omeprazole in the first 24 h).

5 The *bioavailability* of PPIs administered via nasogastric tube or parenterally is comparable to that of oral dosing [15,216]. Intravenous formulations of esomeprazole and pantoprazole are available; the pharmacodynamics, duration of action, and effectiveness are essentially identical to those of oral administration. In an ICU setting with fasting patients, intravenous PPIs are most effective when given by continuous infusion of 8–10 mg/h after a bolus loading dose [217,218].

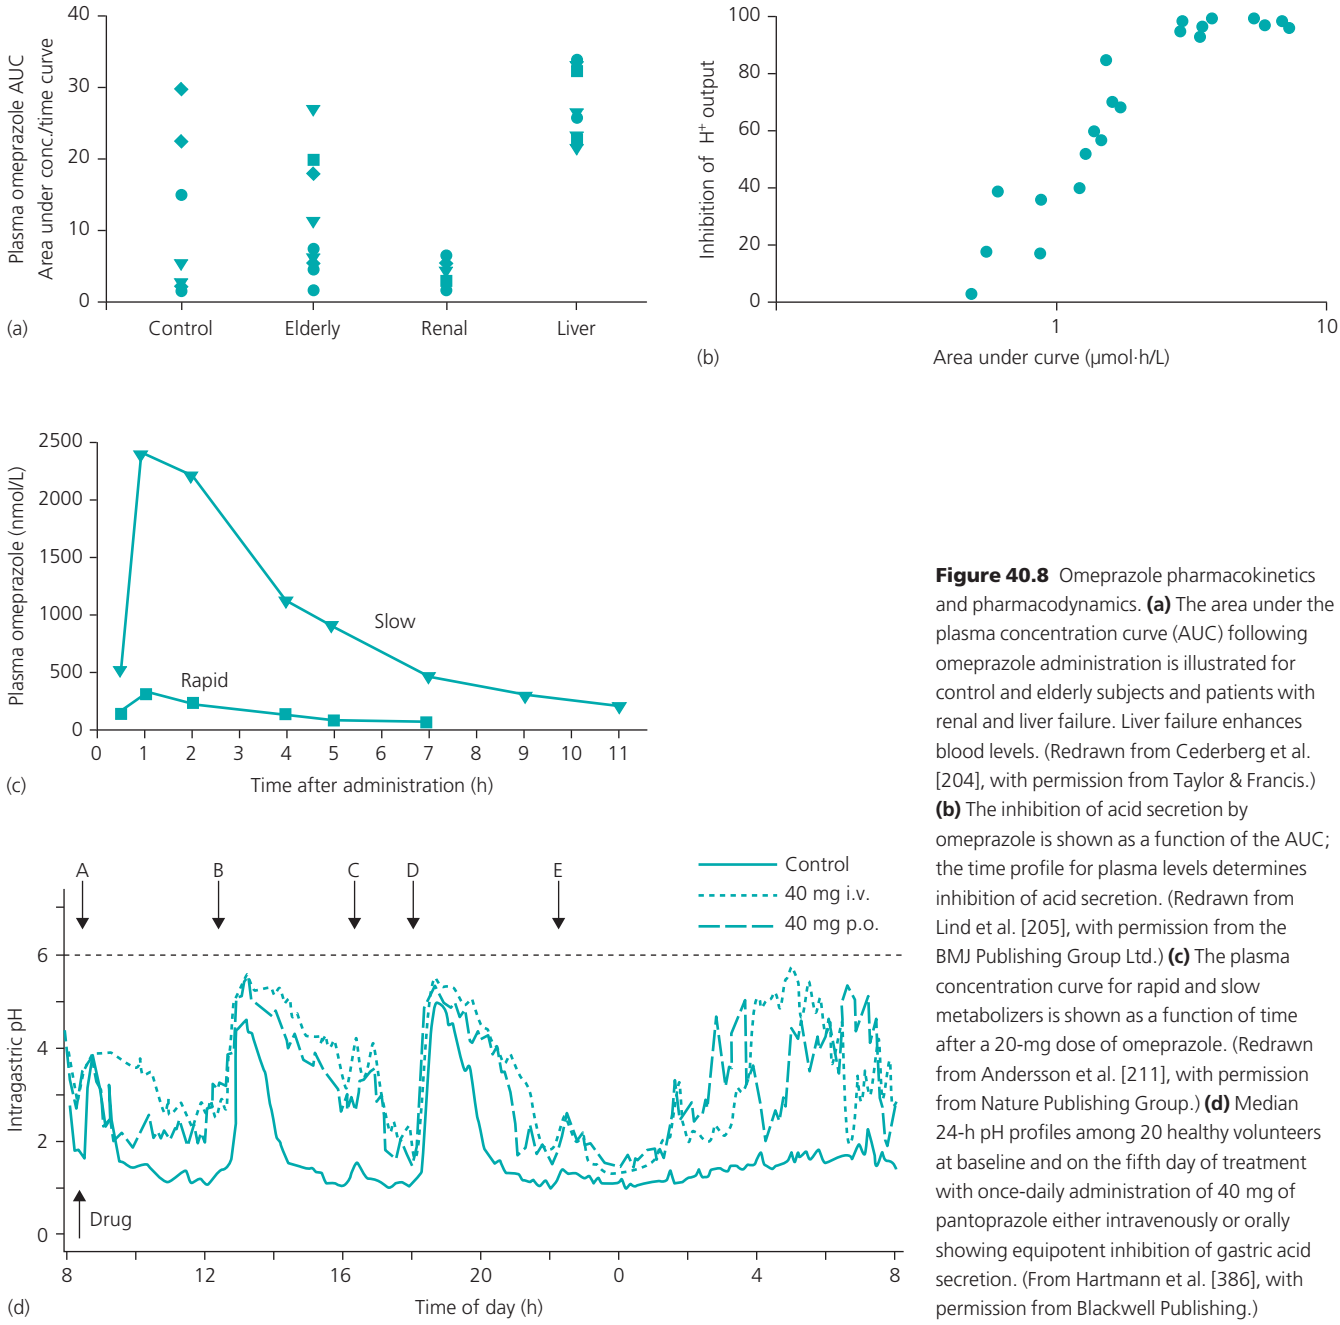

Figure 40.8 Omeprazole pharmacokinetics and pharmacodynamics. **(a)** The area under the plasma concentration curve (AUC) following omeprazole administration is illustrated for control and elderly subjects and patients with renal and liver failure. Liver failure enhances blood levels. (Redrawn from Cederberg et al. [204], with permission from Taylor & Francis.) **(b)** The inhibition of acid secretion by omeprazole is shown as a function of the AUC; the time profile for plasma levels determines inhibition of acid secretion. (Redrawn from Lind et al. [205], with permission from the BMJ Publishing Group Ltd.) **(c)** The plasma concentration curve for rapid and slow metabolizers is shown as a function of time after a 20-mg dose of omeprazole. (Redrawn from Andersson et al. [211], with permission from Nature Publishing Group.) **(d)** Median 24-h pH profiles among 20 healthy volunteers at baseline and on the fifth day of treatment with once-daily administration of 40 mg of pantoprazole either intravenously or orally showing equipotent inhibition of gastric acid secretion. (From Hartmann et al. [386], with permission from Blackwell Publishing.)

Anticholinergics

Anticholinergic medicines have weak antisecretory ability and no antibacterial activity against Hp and should be considered obsolete for treatment of ulcer disease. These agents may have some place in Hp-negative, NSAID-negative PUD.

Prostaglandins

Misoprostol (Cytotec) is a 15-deoxy-15-hydroxy-16-methyl analogue of prostaglandin E_1. It shares the properties of other E-type prostaglandins, displaying moderate inhibition of basal and food-stimulated acid secretion in humans [219]. Topical action appears critical in prostaglandin action; oral

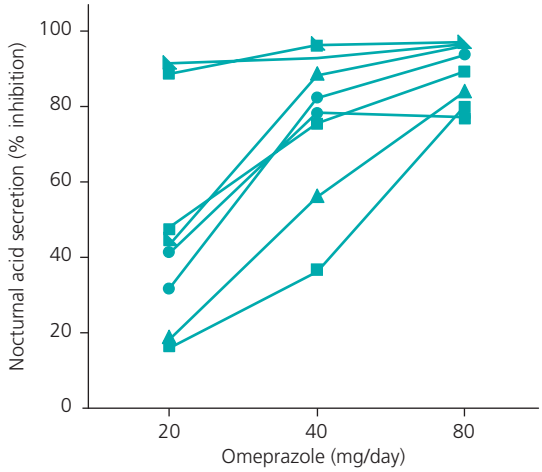

Figure 40.9 Dose–response curves for omeprazole inhibition of nocturnal acid secretion. Acid secretion was determined during four night-time sessions for seven patients with duodenal ulcer. Single doses of placebo or omeprazole (20, 40, or 80 mg) were given at 8AM. Acid secretion was then determined between 9PM and 6AM, with the data expressed as a percentage of control secretion. This study illustrates the high variability of inhibition with low but not high doses of proton pump inhibitors. Data from Shearman et al. [213].

administration gives greater antisecretory efficacy and fewer side effects than systemic administration [220] Misoprostol has no antimicrobial activity against Hp. The primary adverse effects are crampy abdominal pain and diarrhea, which are dose-dependent effects [221,222]. Diarrhea occurred in 3%–39% of patients on the 200 μg four times daily dose of misoprostol, with the range reflecting trial design and the definition of diarrhea [221,222], Diarrhea is often mild and transient, and may respond to a temporary reduction in dose. In clinical trials, usually less than 20% of subjects drop out because of diarrhea, such that the majority can take the drug without problems. The prevalence and significance of side effects have been heavily marketed by producers of antisecretory drugs competing for the same market (chronic NSAID users). In clinical trials, misoprostol, even when given at half dose, has proven superior to PPIs for the healing of endoscopic gastric ulcers and prevention of ulcer relapse among patients without concomitant Hp infections (see Prostaglandins) [223,224]. Prostaglandins of the E group are generally uterotropic and are contraindicated in women of childbearing potential who are not receiving contraception. All patients should be informed of this risk, to minimize the drug being inadvertently given by the patient to a pregnant woman.

Sucralfate

Sucralfate is a topical antiulcer drug. Sucralfate is the aluminum hydroxide salt of sulfated sucrose and has the main activity of coating ulcer sites, leading to slightly increased rates of ulcer healing. It does have an effect on Hp adherence in vitro but has not demonstrated any convincing anti-Hp effect in vitro. It is now generally considered as obsolete for the treatment of ulcer disease.

Antacids

Antacids neutralize gastric acid and have a long history in the therapy of peptic ulcer. However, they are inconvenient, requiring multiple doses per day and are outmoded for PUD.

Antimicrobials

Hp causes a bacterial infection of a mucosal surface. As with other bacterial infections, the mainstay of therapy is use of antimicrobials to which the bacterium is susceptible. Because the infection is inside the stomach, but outside the stomach body, there may be a place for topical therapy. In fact, because of the hostile acid environment of the stomach, topical therapy may greatly enhance overall effectiveness. It is not clear how much of the effectiveness of current therapies is related to the topical action of the drugs and how much is due to a systemic action, but both are probably important. There is considerable evidence that Hp also invade surface epithelial cells and thus the combination of topical and systemic actions may be best.

Topical agents

Bismuth salts have been used to treat 'gastritis' and peptic ulcers for over 200 years. Bismuth is directly bactericidal to Hp and leads to bacterial lysis. Upon ingesting bismuth, there is an immediate and marked reduction in bacterial numbers, thereby reducing the chances that an antimicrobial-resistant subpopulation will survive.

Bismuth has an excellent safety record with the most problematic side effect being temporary discoloration of the tongue and development of black stools. There is a hypothetical concern about systemic absorption of bismuth leading to bismuth toxicity but this has not proved to be a clinical problem when it is used for short duration therapies. Of note, if the common subsalicylate form of bismuth is used, a significant salicylate ingestion will occur. Each tablet of Pepto-Bismol, for example, has 225 mg of salicylate and the majority is absorbed. Patients receiving salicylate therapy should have their doses modified and patients who should avoid salicylates (e.g., children under the age of 16 years) should consider an alternate form of bismuth. In the United States bismuth is primarily available as bismuth subsalicylate (Pepto-Bismol) although bismuth citrate has become available as part of a combination therapy.

Traditional antimicrobials

Hp is susceptible to many different antibiotics and a variety of antibiotics and antibiotic combinations have been tried. The antibiotics that have proven effective include clarithromycin,

amoxicillin, metronidazole/tinidazole, tetracycline, furazolidone, fluoroquinolones, and rifabutin.

Clarithromycin

Clarithromycin (Biaxin) is a macrolide that binds to bacterial ribosomes and disrupts protein synthesis, leading to bacterial cell death. Clarithromycin is the most acid stable of the macrolides and has the lowest minimal inhibitory concentration. The major metabolite of clarithromycin is also active against Hp. Clarithromycin is generally well tolerated. Reported side effects include an altered sense of taste, frequently described as metallic, nausea, vomiting, and headache. Clarithromycin resistance is increasing; resistance predicts treatment failure.

Amoxicillin

Amoxicillin is an acid-stable semisynthetic penicillin that is bactericidal in vivo. The antimicrobial activity of amoxicillin is pH dependent with the minimal inhibitory concentration decreasing as the pH increases. Resistance to amoxicillin is rare but has recently been reported and may in part be responsible for the markedly variable success of the dual combination of a PPI and amoxicillin. Amoxicillin concentrations are highest in the antral mucosa with lower levels achieved in the corpus mucosa or the mucus layer. Overall, results with combination therapy that includes amoxicillin have been good, suggesting that sufficient levels are achieved and that it is an effective anti-Hp agent when used as part of a combination therapy.

Metronidazole/tinidazole

Metronidazole (Flagyl, Protostat) and the very similar tinidazole are nitroimidazoles that are selectively toxic to microaerophilic microorganisms. A chemically reactive, reduced form of the drug leads to generation of cytotoxic products and destruction of microorganisms. The activity of metronidazole is pH independent making it theoretically an ideal drug for the gastric environment. Unfortunately, Hp rapidly develops resistance to metronidazole and the widespread use of this drug has resulted in a high rate of primary resistance. Metronidazole resistance identified in vitro does not always predict resistance in vivo, such that this agent may remain useful despite a high level of resistance in a population or even in an individual (see Antibiotic resistance).

Tetracycline

Tetracycline hydrochloride was used in the first effective therapies against Hp and remains an important antibiotic. The activity of tetracycline is independent of gastric acidity making it a potentially very useful drug. Tetracycline is also inexpensive and resistance is rare. Success has been reported with tetracycline hydrochloride and with oxytetracycline, whereas doxycycline has produced inferior results. Tetracyclines are contraindicated in children because of the abnormal pigmentation of permanent dentition that occurs when the drug is used while teeth are being calcified.

Fluoroquinolones

Fluoroquinolones have been used increasingly for Hp eradication; they act by blocking DNA gyrase and DNA synthesis in Hp. Resistance to fluoroquinolones develops rapidly and previous use of these medications is associated with a high rate of resistance.

Furazolidone

Furazolidone is a monoamine oxidase inhibitor with broad antibacterial activity based on interference of bacterial enzymes; it has proven to be an effective part of triple therapy. Resistance to Hp is rare such that furazolidone is currently an underutilized antimicrobial.

Rifabutin

Rifabutin is a semisynthetic ansamycin antibiotic with a low minimal inhibitory concentration (MIC) level for Hp. Rifabutin use is becoming increasingly common, primarily in combination with a PPI and amoxicillin as a rescue therapy.

Drug interactions with antiulcer drugs

Altered absorption

As a result of intralumenal binding, antacids and sucralfate decrease absorption of a number of drugs [225,226] and it is best to advise separation of consumption of antacids and other drugs by an hour (Table 40.3). Bismuth may have the same effect, but data are limited and bismuth is generally given along with the other drugs used in the treatment regimen [227]. Antisecretory agents, by increasing intralumenal pH, can alter drug absorption. For example, the effect of antisecretory agents on reducing absorption of food-bound vitamin B-12 can be quite dramatic [228,229]. The effect appears to be mediated by the increase in pH and resultant decrease in peptic activity, rather than by inhibition of intrinsic factor secretion [230]. The absorption of iron and calcium can also be compromised and there is increasing evidence of an association between antisecretory drug use, especially PPIs, and the risk of hip fracture [231]. It is not clear whether this is a consequence of the effect on calcium absorption, effects on osteoclast function, or both. There is also evidence that thyroxine absorption is markedly suppressed by either the use of PPIs or in cases of Hp gastritis, requiring adjustment of the thyroxine dose [232].

The dissolution of some drugs, particularly weak bases, will be decreased with gastric neutralization. The consequences depend on the specific drug and its preparation. For example, decreased dissolution of ketoconazole, a weak base, significantly decreases absorption [203]. Alternatively, the absorption of bismuth from colloidal bismuth subcitrate is increased, presumably because decreased gastric acidity increases free

Table 40.3 Impact of acid peptic therapy on nutrient absorption and drug interactions

General mechanism	Acid peptic therapeutic agent	Drug or nutrient	Consequences
Intralumenal binding	Sucralfate, antacids, ?bismuth	Potentially binds several drugs in gastric lumen	Prevents absorption, producing lower blood levels
Decreased acid secretion	PPI,[a] H2RA	Vitamin B-12	Anemia
		Iron	Anemia
		Calcium	Osteoporosis, pathological fractures
		Thyroxine	Decreased T4 and increased TSH
		Ketoconazole, cefpodoxime, cefuroxime, protease inhibitors (atazanavir and indinavir)	Decreased absorption, particularly of drugs that are weak bases
		Aspirin	Another weak base for which gastric absorption is decreased at high pH[b]
		Colloidal bismuth	Increases bismuth absorption
P450 drug interactions	Cimetidine	Alfentanil, amiodarone, nifedipine, carbamazepine, cyclosporine (ciclosporin), citalopram, sulfonylureas, warfarin, and CYP substrates, such as 1A2 (theophylline, trifluoperazine), 2C19 (citalopram, phenytoin, propranolol, sertraline), 3A4[c]	Altered metabolism increases blood levels. Significant consequences may result when the therapeutic margin is small. Consequences are minimal for others, such as diazepam, because of the wide therapeutic margin
	Omeprazole, other PPI[d]	Carbamazepine, CYP2C9 substrates (amiodarone, fluoxetine, phenytoin, sertraline, warfarin), CYP2C19 substrates (citalopram, propranolol)[e]	Same type of impact as noted for cimetidine
	PPI in slow metabolizers	Antibiotics	Enhanced cure of *Helicobacter pylori*
	PPI in slow metabolizers or PPI in combination with multiple other drugs that share CYP sites of metabolism, especially 3A4 (e.g., omeprazole plus clarithromycin and carbamazepine)[f]	Any drug metabolized by CYP3A4[c] or possibly other CYP sites	Delayed clearance with significantly increased levels of drugs metabolized by 3A4

a Effects will be exaggerated in slow metabolizers because of genetic polymorphism at the CYP2C19 pathway.
b Decreased absorption may decrease superficial mucosal damage, but clinical consequences are minimal because intestinal absorption is so much more important and aspirin and NSAIDs have systemic actions resulting in ulcers.
c Many drugs interact with 3A4, including carbamazepine, cisapride, nifedipine, macrolide antibiotics, azole antifungals, antitumor agents, tacrolimus, psychotropics, diclofenac, doxycycline, imatinib, isoniazid, nefazodone, nicardipine, propofol, protease inhibitors, quinidine, telithromycin, and verapamil.
d Although omeprazole has been implicated for these interactions, in vitro studies suggest that lansoprazole and pantoprazole are potent in vitro inhibitors of CYP2C19 and CYP2C9 respectively [387]. Therefore, caution is appropriate and interactions may become important for other PPI, especially if combined with other factors, such as in patients who are homozygous slow metabolizers, who are taking multiple drugs that amplify interactions, and who have illnesses that impair hepatic metabolism or renal excretion.
e To the extent that these interactions are mediated at CYP2C19, they are *not* more pronounced in slow PPI metabolizers, presumably because the point of interaction is itself defective or absent.
f There may be some differences among PPI in that such effects may be less prominent with rabeprazole [388], but data are so limited that no firm conclusions can be reached.
H2RA, histamine H_2 receptor antagonist; NSAIDs, nonsteroidal antiinflammatory drugs; PPI, proton pump inhibitor, T4, thyroxine, TSH, thyroid-stimulation hormone.

bismuth concentrations [233]. Acid secretory inhibition can decrease the absorption of weak acids from the stomach and increase absorption of weak bases. For example, secretory inhibitors will reduce uptake into gastric mucosa of weak acid NSAIDs, such as aspirin, and decrease superficial damage. However, gastric absorption is usually modest compared to intestinal absorption, and systemic effects override this sparing of gastric mucosa.

Drug interactions via cytochrome P450

To some extent, all of the nine PPIs and H2RAs available in the United States for acid inhibition undergo hepatic metabolism and interact with members of the cytochrome P450 (CYP) superfamily of mixed function oxidases. This topic is inherently complex as the CYP superfamily is complex, composed of three major families (CYP1–3), a varying number of subfamilies (e.g., CYP2A–E), and numerous specific members or isoforms within these subfamilies (e.g., CYP2C1–19). For the antisecretory agents, these interactions with the CYP superfamily generally carry little clinical significance. However, there are specific circumstances in which they can become critical and potentially life-threatening (Table 40.3). These serious events are rare and occur in seriously ill subjects with impaired hepatic function and drug metabolism, often confounded by multiple (more than 2) interacting drugs and genetic polymorphism of the CYP metabolic pathways. Such factors will not be detected in routine pharmacokinetic studies in young, healthy volunteers with usually undefined CYP genetic backgrounds; therefore, such studies carry little negative predictive value for excluding uncommon, serious interactions encountered in the treatment of complex cases in practice.

Several features of P450 metabolism are important with respect to the antisecretory drugs; this list has been adapted from previous reviews [230,234]:

1 *Time and dose dependence*. Drug metabolism and drug interactions undergo dose- and time-dependent changes over the first several days of therapy. Generally, 3–5 days are needed to reach maximal inhibition of drug metabolism, although maximal effects can be further delayed in some instances.

2 *The therapeutic margin*. Drug interactions are of greatest relevance when the drugs have a narrow therapeutic range. For example, cimetidine may potentially produce significant effects with R-warfarin, theophylline, phenytoin, and nifedipine [203,230].

3 *Genetic polymorphism of drug metabolism and interactions*. Genetic polymorphism is particularly important for the PPIs, for which the CYP2C19 pathway is a primary metabolic step in degradation. Because of the wide safety margin of PPIs, the major clinical implication is that acid secretory inhibition will be modest in rapid metabolizers and exaggerated in slow metabolizers, as the degree of acid inhibition reflects the AUC. The impact in many situations is modest. For example, healing of GU is more rapid at 2 weeks in slow metabolizers, with comparable healing found at 8 weeks in rapid metabolizers [235]. In contrast, cure of Hp with omeprazole plus amoxicillin is highly dependent on CYP2C19 metabolism: slow metabolizers had a 100% cure rate, rapid metabolizers a 29% cure rate, and heterozygotes a 60% cure rate [236]. CYP2C19 is also the site of interaction between diazepam and either omeprazole or cimetidine; however, with the wide therapeutic range for diazepam and marginal effects of the interactions, clinical implications are minimal [210,237]. Omeprazole does not further delay clearance of diazepam or S-mephenytoin in slow metabolizers, probably because the point of interaction is defective or absent [234,238]. However, in slow metabolizers, delayed PPI clearance increases the potential for interactions at other CYP sites, such as 3A4 or 2C8. For example, although pharmacokinetic studies indicated that lansoprazole had only minimal P450 drug interactions, in a patient with a CYP2C19 mutation, lansoprazole caused significant increases in tacrolimus levels. These levels returned to normal after replacing lanxoprazole with famotidine [239]. Drug interactions may only show up in slow metabolizers who shift metabolism to 3A4.

4 *Variability among individuals*. In addition to genetic polymorphism, other factors can also underlie the variability of drug interactions among individuals. Age can be important on both ends of the spectrum. Elderly subjects are much more likely to have impaired drug metabolism. Infants and very young children tend to have rapid metabolism, underlying the use of higher PPI doses in the very young [240]. The relative impact of slow metabolizers is comparable in very young subjects.

5 *Multidrug (beyond 2-way) interactions*. Three-way drug interactions can produce unexpected results. All of the PPIs are metabolized by CYP3A4 and, therefore, potential interactions with other drugs metabolized by this pathway warrant consideration, particularly for drugs with a narrow therapeutic margin. Omeprazole and clarithromycin interact at 3A4 [241] with the result being an increased AUC for both. Both drugs have a wide therapeutic window and this interaction may even enhance cure of Hp infection. However, the omeprazole–clarithromycin combination considerably increases carbamazepine (Tegretol) levels [242]. Other drugs metabolized at CYP3A4 should also be used cautiously during combination therapy with a PPI and clarithromycin. Drugs interacting at CPY3A4 include drugs related to cisapride, ketoconazole, macrolide antibiotics, antitumor agents, and several psychotropics.

6 Whether interactions produce relevant effects depends upon whether alternate pathways exist for drug metabolism.

7 The antisecretory drugs interact with multiple CYP sites. Furthermore, a drug may be a substrate for and, thus, be metabolized by one or several CYP sites, or it may induce or inhibit a CYP site.

Medical treatment of active peptic ulcer disease

Factors influencing healing

Several factors potentially influence the rate of ulcer healing and the tendency for recurrence. Reversible factors should be identified and addressed, particularly Hp infection, NSAID use, and cigarette smoking.

Ulcer size influences the time to healing. Large and small GU heal at the same rate and, although effective medical

therapy results in more rapid healing, larger ulcers will still require more time to heal [243–245].

Conventional ulcer therapy

The superior potency and duration of action of PPIs have resulted in PPI therapy becoming the therapy of choice with regard to rapid relief of ulcer symptoms and acceleration of ulcer healing. Numerous marketing studies have attempted to demonstrate differences among the available PPIs. However, when the results are corrected for differences in dose, it becomes clear that the best PPI is the cheapest one (i.e., a PPI is a PPI). It is important to remember that parietal cell hyperplasia and rebound acid hypersecretion follow discontinuation of prolonged PPI therapy [246–249]. Although the rebound acid secretory response is generally small and transient, this hypersecretion may underlie transient exacerbation of acid peptic disease (e.g., the development of duodenal erosions noted above) and GERD symptoms.

Recommendations

Treatment decisions are based on the situation (e.g., presentation, complicating issues, sense of urgency) and etiology of the ulcer disease. Clearly, in the presence of a complicated ulcer (e.g., major upper GI bleeding), diagnosis of the cause can wait until the crisis has passed. For routine symptomatic ulcers, diagnosis and treatment can occur concomitantly. Symptomatic ulcers, regardless of cause, typically respond well to antisecretory drug therapy and most physicians would consider the least expensive PPI as the treatment of choice. There is no place for the routine use of antacids, sucralfate, or prostaglandins for DU, and certainly not for GU. If the ulcer is diagnosed by endoscopy, one would expect that the endoscopist would have obtained samples to diagnose or exclude Hp infection. There is no urgency to diagnosis Hp, and diagnosis or confirmation of the diagnosis can certainly be delayed until it is convenient for the patient and physician. However, as antisecretory drug therapy is typically part of anti-Hp therapy, there may be cost savings to do both together. For an uncomplicated, small, Hp-related DU, both treatment of the infection and the ulcer can be carried out in the same time frame (e.g., 2 weeks) (see next section). Treatment of large and complicated ulcers will need to be individualized. The only instance in which antiulcer therapy is required beyond the antibiotic treatment period is for larger or complicated ulcers (e.g., bleeding ulcers) or in the setting of sustained NSAID use, as considered in the following sections.

Helicobacter pylori and ulcer therapy

Drug combinations used to treat *Helicobacter pylori*-associated ulcers

Treatment of Hp infection results in acceleration of ulcer healing, prevention of ulcer relapse, and prevention of ulcer complications (Fig. 40.10) [250,251]. Successful eradication of Hp will also reduce the rate of development of gastric cancer in high-risk groups [252,253]. If the infection is cured before significant atrophy develops, it is likely that gastric cancer can be completely prevented [254]. In developed countries Hp eradication is rarely followed by reinfection. In developing countries where hygiene may be poor, reinfection is common and this remains a major problem for future worldwide eradication programs [255,256].

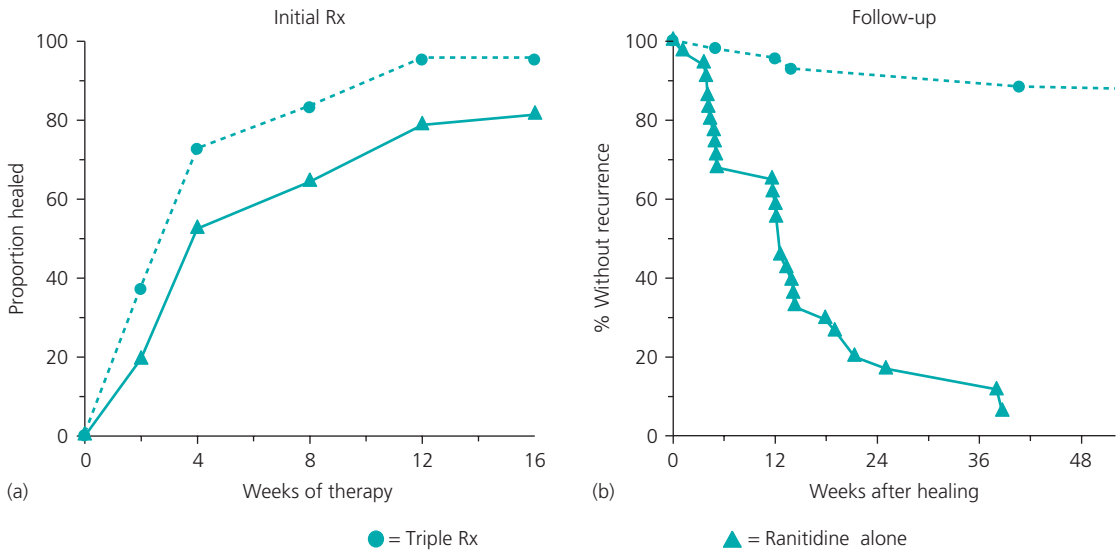

Figure 40.10 **(a)** Patients with duodenal ulcer disease received either triple therapy with ranitidine (closed circles) or ranitidine alone (closed triangles) until the ulcer was healed. **(b)** After ulcer healing patients were followed with regular endoscopic evaluation of the ulcer site. *Helicobacter pylori* (Hp) therapy resulted in enhanced ulcer healing and a reduction in ulcer recurrence. All ulcer recurrences in the antibiotic-treated group were related to failed Hp therapy, use of nonsteroidal antiinflammatory drugs, or both [250,251].

Although there are a number of drug combinations that are approved for use, none is ideal and many are outdated. A number of studies have shown that subtle changes in protocol, such as changes in drugs, drug formulation, dosing interval, dosing in relation to meals, and duration of therapy, may have profound effects on outcome [257,258]. There are a number of practical issues to be considered when selecting a regimen for treatment of Hp infection, including cost, simplicity, effectiveness, side effects, the rate of antibiotic resistance in the community, dose, duration, number of administrations per day, whether to administer with meals or fasting, and whether control of pH is needed [257,258]. None of these issues has been adequately evaluated in a systematic way and recent studies with sequential therapy have definitely shown that the outcome of therapy can be improved. The lack of such studies is possibly part of the legacy of Hp infection being a disease studied by gastroenterologists rather than infectious disease specialists, who by their training and experience are less likely to have declared "victory" or "success" at eradication rates considered unacceptable for other serious infectious diseases. The approach for other infectious diseases has been to identify a therapy that is universally effective and then to attempt to simplify it. With Hp, the approach was to simplify only partially effective therapies. To remain competitive the pharmaceutical industry did the minimum required to obtain approval and, in the absence of clear FDA-defined requirements for high eradication rates, attempted to gain marketing advantages by using shorter duration and less frequent administrations instead of attempting to identify regimens with very high and reliable cure rates. This has resulted in a number of approved but only partially effective regimens.

An evidence-based choice of the best treatment regimen is nearly impossible because large randomized trials comparing the most effective regimens have rarely been done. Metaanalyses have shown that the most commonly used therapies produce cure rates that are typically less than acceptable [259–263]. Although metaanalysis is usually a powerful tool to help understand the overall effectiveness of treatment, it is less helpful in choosing the best therapy because of the presence of considerable heterogeneity in the data, including absence of crucial data such as the presence or absence of pretreatment antimicrobial resistance. There are few head-to-head comparisons of different antibiotic dosages or therapy durations, leaving the influence of these parameters on treatment success unknown. Finally, and unexpectedly based on the responses to treatments of other infectious diseases, the cure rates often differ greatly in different countries despite using the same regimes [262,264]. All of the PPIs appear to be equally as effective as the clarithromycin–amoxicillin or metronidazole triple therapies, and they can be used interchangeably depending on local availability and cost [265]. H2RAs are approximately equally effective with the only benefit being a slight reduction in cost of therapy [266]. Healing rates and time to pain relief are better with PPIs and they are generally preferred.

Large population-based trials have also shown that the high rates of success expected from the pharmaceutical company-sponsored trials are often unobtainable in clinical practice. Part of this difference is likely to be related to patient selection. Pharmaceutical company-sponsored trials typically study patients with duodenal ulcer disease in which the cure rates are typically higher than among patients without ulcers [263,267–269]. Fundamentally, Hp is a serious chronic transmissible infectious disease that causes damage to gastric structure and function and which is a major cause of morbidity and mortality worldwide. As noted above, therapies for bacterial infectious diseases are expected to yield cure rates of nearly 100%. Although Hp proved more difficult than some, by 1989 a successful therapy for Hp had been defined as one that cured more than 80% of patients [270]. By 1995 it seemed that a 90% cure rate was achievable [271] and that 95% or greater cure rates were just around the corner. However, such cure rates have not been achieved, in part because of the failure to learn from the successes of the previous decade. Here we will use the Maastricht consensus conference definition of a useful therapy as being one with an intention to treat (ITT) cure rate of greater than 80% (i.e., those with cure rates of 80% or less would be unacceptable) [272].

Legacy-approved triple therapy (e.g., a PPI plus amoxicillin and clarithromycin) now yields unacceptably low eradication rates in Europe and the United States, typically below the minimally acceptable 80% success rate (Fig. 40.11a; Table 40.4) [268,269,273–296]. These results indicate that traditional triple therapy should no longer be considered initial therapy in Western populations unless pretreatment susceptibility is confirmed, in which case it should be used for 14 days [264,297,298].

Better *Helicobacter pylori* therapies

Because most antibiotics are more effective when given with an antisecretory drug, an antisecretory drug, typically a PPI, is used along with three or four antimicrobials. The original formulas used a PPI plus two antibiotics chosen from amoxicillin, clarithromycin, and metronidazole/tinidazole (i.e., triple therapy) or four drugs consisting of bismuth, tetracycline, metronidazole/tinidazole, and a PPI (i.e., quadruple therapy). These were administered for 7–14 days; as a longer duration of treatment generally provided higher cure rates, 14 days was the preferred treatment time. Searches for new therapies have followed two basic formulas. One was to start with a PPI plus amoxicillin and add a new drug or drugs. The other was to replace the metronidazole/tinidazole in quadruple therapy with another drug. Although triple therapy generally provides unacceptably low cure rates, cure rates with quadruple therapy have largely been maintained. In quadruple therapy, including either bismuth subcitrate or subsalicylate, tetracycline hydrochloride, metronidazole/

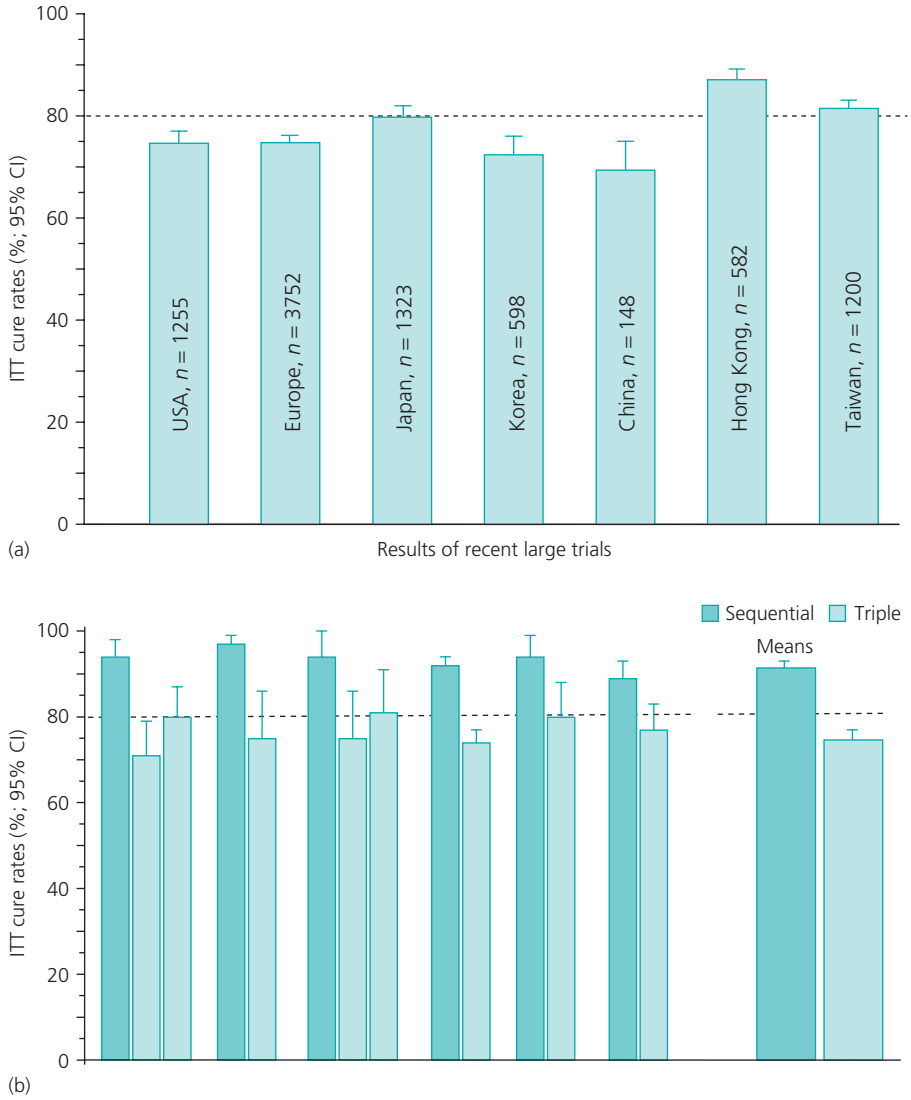

Figure 40.11 **(a)** The mean pooled results as intention-to-cure (ITT) rates and 95% confidence interval (CI) of recent large studies using a proton pump inhibitor (PPI) plus clarithromycin and amoxicillin to treat *Helicobacter pylori* (Hp) infections [268,269,273–278,280,281,283–296]. The 80% or minimally acceptable cure rate is also shown (dotted line). As seen, in the majority of areas the results are unacceptably low suggesting that this therapy should not be utilized unless clarithromycin-susceptible strains are definitely present. **(b)** The six direct comparisons of triple therapy consisting of a PPI plus clarithromycin and amoxicillin with sequential therapy. The pooled results of all of the comparisons are shown on the right. The mean cure rate (ITT) for sequential therapy was only 90.5% (95% CI = 89%–92%) suggesting that additional experiments are needed to further improve the efficacy.

Table 40.4 Regimens for the initial therapy of *Helicobacter pylori* infection

Regimen	Antisecretory adjunct	Antibiotics	Duration	Comments
Quadruple therapy	PPI b.i.d.	Tetracycline HCl, metronidazole, and bismuth	14 days	Higher doses help surmount metronidazole resistance
Sequential therapy	PPI b.i.d.	Amoxicillin	5 days	Cure rates low with dual resistance to metronidazole and clarithromycin
		Clarithromycin and metronidazole[a]	5 days	
Triple therapy	PPI b.i.d.	Clarithromycin plus metronidazole or amoxicillin	7–14 days	Avoid where clarithromycin resistance is high; 14-day treatment increased cure by 12%

a Metronidazole can be replaced by tinidazole.
b.i.d., twice a day; PPI, proton pump inhibitor.

tinidazole, and a PPI, the antimicrobials are effective in an acid environment. Effectiveness requires that the regimen be given at appropriate doses and durations (e.g., a minimum of 1500 mg of tetracycline HCl and 1200–1500 mg of metronidazole/tinidazole, and six or eight tablets of bismuth given in divided doses (e.g., three or four times daily) for 14 days.

New antibiotic combinations

Quinolones (e.g., ciprofloxacin) were tried in the early phases of searching for effective anti-Hp therapies but were abandoned because of the rapid development of resistance. Fluoroquinolones have seen a renaissance as a replacement for clarithromycin in triple therapy. However, as with legacy triple therapy, 7-day duration therapy provides an unacceptably low cure rate, which is improved by longer treatment duration [299]. However, the widespread use of these drugs for other indications has led to a rapid increase in fluoroquinolone resistance in many communities, such that it usefulness will likely be short-lived [300]. Furazolidone is an old but effective drug that can be substituted for metronidazole or clarithromycin in either legacy triple or quadruple therapy. Unfortunately, it has become difficult to obtain in the United States as the company that sold it no longer does; it is, however, easily available in Mexico. Despite the issues related to its role as a monoamine oxidase inhibitor, it is probably one of the best choices for difficult cases. Rifibutin is also commonly used as a substitution drug and, again, longer duration of treatment provides better outcomes. None of these approaches is universally satisfactory and clearly new drugs are needed.

Sequential therapies

Rather than abandoning triple therapy, Italian investigators decided to provide the drugs sequentially. In this approach a PPI and amoxicillin are given for 5 days followed by the PPI plus clarithromycin (250 or 500 mg) and tinidazole (500 mg) for an additional 5 days [282,286]. This approach has repeatedly proven to be superior to legacy triple therapy in both adults and children (Fig. 40.11b) [276,279,282,283,301,302]. Sequential administration of antibiotics has traditionally been avoided because of concern that it would promote drug resistance rather than result in increased eradication; however, this sequential therapy starts with drugs against which development of resistance is rare. This approach markedly reduces bacterial load, making the development of resistant organisms less likely [257,303]. The addition of the third or third and fourth drug would then kill the few remaining organisms. The high rate of success (e.g., reliably ~ 90% ITT) suggests that sequential therapy should supplant triple therapy in regions where the success rates have become unacceptable. However, success of sequential therapy is reduced in the face of dual resistance (clarithromycin and metronidazole) [283]. Sequential therapy can likely be improved by altering the dose, duration, frequency of administration, or order of administration (e.g., similar effects have been reported when all four drugs are given nonsequentially) [304–306].

Recommendations for therapy

In areas where legacy triple therapy no longer provides adequate cure rates (e.g., the United States, most of Europe, and much of developed Asia), one should use sequential therapy as described or add a fourth drug to legacy triple therapy (e.g., metronidazole or tinidazole to the PPI–clarithromycin–amoxicillin combination). Studies are needed to confirm that sequential therapy can be improved by changes in the dose, duration, or drugs utilized. The alternative is to use traditional quadruple therapy with a PPI, bismuth, tetracycline, and metronidazole/tinidazole (Table 40.4).

Other approaches for areas with high rates of antimicrobial resistance

Dual therapy with a PPI and amoxicillin was an early attempt at therapy but was soon abandoned because of low and variable eradication rates. In Germany this therapy is still used clinically, but with a high-dose PPI and high-dose amoxicillin (e.g., 40 mg of omeprazole and 750 mg of amoxicillin given three times daily for 14 days). Reported eradication rates range from 67% to 91% [307–309]. Our recent experience with the high-dose approach has yielded a cure rate in the range of 70%–75%, and this high-dose dual therapy has formed the basis of our approach to sequential therapy for patients who have proven, difficult-to-cure infections. Our approach has been to use 40 mg of omeprazole or esomeprazole and 1 g of amoxicillin three times daily for 5 days, followed by the addition of a third antibiotic or third and fourth antibiotics on day 6, continuing as a triple or quadruple therapy for a total of 12–14 days (e.g., ref. 300). The third and fourth antibiotics should be ones that the patient has not used before (such as tetracycline, levofloxacin, furazolidone, or rifibutin). However, therapy is best guided by pretreatment antibiotic susceptibility testing.

Probiotics and nonantibiotic additions

Probiotics are live, nonpathogenic microbial feed or food supplements that can affect the host in a beneficial manner. The best-studied probiotics are the lactic acid-producing bacteria, particularly *Lactobacillus* spp. and *Bifidobacterium* spp. Probiotics are thought to play a role in keeping the gut microbial ecosystem stable by restoring resident microflora after antibiotic treatment [310,311]. Some strains of *Lactobacillus* spp. and *Bifidobacterium* spp. have shown in vitro bactericidal effects against Hp and a protective effect has been confirmed in some animal models [312]. Clinical trials however indicate that probiotics generally do not cure Hp but may decrease the density of colonization and may decrease the mucosal gastroduodenal inflammation. Metaanalyses have suggested a slight but not dramatic improvement in cure rates by the addition of probiotics [313].

In addition to probiotics, many plant or dairy foodstuffs have been evaluated for gastroprotective and anti-Hp properties [314,315]. Turmeric, cumin, ginger, chili, borage, broccoli sprouts, black caraway, oregano, and liquorices have antimicrobial activities in vitro [316,317]. No data justify the therapeutic use of these agents, but further investigation would be of interest. Mucolytics such as *N*-acetylcysteine [318] and the proteolytic enzyme pronase [319] have additive effects to triple therapy, possibly as a result of reducing the mucosal surface gel layer and improving local antibiotic delivery.

Improving compliance with probiotics

Probiotic cotherapy with antibiotics decreases diarrhea and taste disturbances [320,321]. Additional studies are needed to determine whether such cotherapy improves the poor compliance seen with antibiotic regimens, which is a major reason for ineffective therapy.

Treatment failures

The best results after initial therapy has failed are obtained when susceptibility testing guides the choice of antibiotics. Generally, such testing is unavailable, and choices must be based on drugs that have not been administered previously [322,323]. Clearly, one should avoid drugs (e.g., clarithromycin) where resistance eliminates effectiveness during subsequent therapy. Resistance can be expected if fluoroquinolones have been given previously for any other reason. Quadruple therapy is generally recommended after triple therapies have failed [257,258,324] as this combination is effective even with metronidazole resistance [325,326]. Despite the large number of tablets and the frequent drug administrations, dropout rates and compliance of quadruple therapy in most clinical trials have been comparable to those of twice-daily triple therapy regimens. Furazolidone is often the drug of choice for multiple treatment failures (a salvage therapy).

Explanations for failure of Hp therapy include inappropriate choice of initial therapy (e.g., use of doxycycline instead of tetracycline, or erythromycin instead of clarithromycin), poor compliance with the regimen, and antibiotic resistance. Resistance is the major problem. Compliance can be improved if the patient is counseled regarding the need to continue the regimen for the prescribed duration even when symptoms have disappeared. Compliance is reduced when side effects occur.

Side effects of therapy

Side effects occur in 20%–30% of patients and are generally mild and transient. Severe side effects are rare. The most common side effect is nausea, which can result from most drugs. Clarithromycin given in doses greater than 1 g a day typically causes a taste disturbance and patients should be warned to expect it. Patients treated with bismuth salts will have dark stools and they must be warned that this is not blood [327]. Diarrhea is relatively common with antibiotic therapy, and pseudomembranous colitis is rare but does occur. Candida vaginitis may occur in women, especially following treatment with tetracycline. Alcoholic beverages should not be consumed during metronidazole therapy and for at least 1 day afterward because of an Antabuse-like reaction with abdominal cramps, nausea, vomiting, headaches, and flushing.

Antibiotic resistance

Acquired resistance has been demonstrated with all of the antimicrobial agents used to treat Hp infection, especially with nitroimidazoles, macrolides, fluoroquinolones, and rifampins (rifampicins). Resistance to tetracycline and amoxicillin has been demonstrated but is uncommon. Resistance to metronidazole in the United States is in the range of 25% and rates of metronidazole resistance in excess of 60% have been documented in some developing countries. Increasing the metronidazole dose partially overcomes acquired resistance, but high-dose quadruple therapy is more effective. Hp resistance to clarithromycin has steadily increased, especially in locations where clarithromycin use is high (e.g., Japan and in children in Western countries) [323,328]. Clarithromycin and fluoroquinolone resistance cannot be overcome by increasing the dosage [260,263,323].

Patient education

Poor compliance is the most controllable factor resulting in treatment failure. An informed, motivated patient is important for success. Patients should be instructed about dose, duration, possible side effects, and the necessity of completing the entire course of therapy, rather than stopping when they feel better [327]. Patients who use tobacco should be educated about the benefits of stopping [263]. Written instructions about how to take the pills are helpful. Gastric distress from the drugs can be reduced by instructing the patient to take them with food. Many pharmacists routinely label tetracycline to not be taken with food. We administer all drugs with food, because this greatly simplifies the treatment regimen, is not associated with a reduction in cure rate, reduces nausea, and improves mixing and retention in the stomach. This requires education of both the patient and the pharmacist, who may resist giving tetracycline or bismuth with meals.

Confirmation of *Helicobacter pylori* cure

Confirmation of cure is now the standard of care, particularly because poor outcomes accompany persisting infection and because cure rates are often below 80%. Failure to cure the infection in an ulcer patient causes recurrent ulcer disease, continuing risk of ulcer complications, and the need for more testing and treatment. The infected patient also remains a reservoir for transmission to others, especially family members.

Noninvasive, inexpensive, and widely available urea breath or stool antigen tests are typically sufficient for confirmation of cure. Whichever test is used, it is important to wait a sufficient time after stopping antibiotics to ensure

that residual Hp have multiplied to detectable levels. The data suggest that a 4-week hiatus is preferable for histology, culture, or urea breath testing. Approximately 8 weeks is required for the stool antigen test. Proton pump inhibitors should be preferably stopped for 2 weeks to avoid false-negative results for the tests that require actively growing Hp, including urea breath, rapid urease, and stool antigen tests; culture; and histology. A positive test at any time after therapy indicates treatment failure, but a negative test is difficult to interpret as long as prolonged suppression is possible. If confirmation of cure is critical, then endoscopy with biopsy or a urea breath test should be performed 8–12 weeks posttherapy.

Serological testing is not useful for confirming the outcome of therapy because antibody levels can remain elevated for a long time. A negative test correlates with cure but is unusual within 2 years after therapy. Recurrent infection is associated with a return of test positivity.

Treatment of NSAID ulcers

There are two critical steps in treating NSAID-associated ulcers. First, whenever possible discontinue or at least reduce the NSAID dose. Second, search for and cure Hp infection. If NSAIDs can be discontinued, ulcers will generally readily heal with adequate antisecretory drug therapy, although PPIs are preferred, especially for complicated or large ulcers. Continuing NSAIDs, including COX-2-selective agents, may interfere with ulcer healing; they should be continued only with great caution and with explicit and documented patient consent. The necessity and duration of cessation of low-dose aspirin in patients at high cardiac or cerebrovascular risk has been controversial. A recent controlled trial of patients randomized after endoscopic hemostasis for ulcer bleeding reported that discontinuing low-dose aspirin for 8 weeks led to significantly increased mortality compared with continuing aspirin [329]. Both groups were treated with intravenous and then oral PPI; there was no increase in recurrent GI bleeding in the aspirin-treated group. Although preliminary, this study was well carried out, statistically significant, and indicates that ulcers in high vascular risk patients should be treated aggressively with PPIs without discontinuing low-dose aspirin.

PPIs are preferred for ulcer healing in the presence of ongoing NSAIDs. However, even double-dose PPIs will fail in some patients and recurrences and complications will occur. There are inadequate data from controlled trials to guide treatment decisions in this setting, other than discontinuing NSAIDs. Patient preferences should be included in any decision to continue NSAIDs and we advise documenting that the patient has elected to continue NSAIDs despite being warned of the consequences.

Misoprostol is generally not a good alternative for the healing of NSAID ulcers; it has only been studied for prevention (see Prevention of NSAID ulcers – Prostaglandins). H2RAs, sucralfate, and antacids are inadequate for treatment of NSAID ulcers, especially if NSAIDs will be continued.

Prevention of NSAID ulcers

Earlier studies on the prevention of NSAID ulcer complications were largely short-term trials in normal subjects or patients free of active ulcer disease and well enough to qualify for study. As noted previously, "endoscopic" ulcers, defined by arbitrary size criteria that may or may not require visible depth, are found at surveillance endoscopy in 5%–25% of subjects taking NSAIDs. In contrast, "clinical" ulcers present with complications at a rate of 0.5%–2% per patient-year of NSAID use. Valid recommendations are those based on preventing complications [70] rather than "endoscopic" ulcers, most of which remain clinically silent.

Determining cost-effective prevention of NSAID ulcer complications is difficult with the available data. Although the frequency of ulcer complications from NSAIDs is very low, these drugs are widely used and so the number of patients at risk is high. Several factors impart increased risk for complications (see Risk factors for NSAID ulcers); these factors should be taken into account when deciding whether to offer a more costly regimen to reduce ulcer risk. NSAIDs carry a black box warning label regarding ulcer complications; patients should be informed of this risk and whether they are in a high-risk category and this discussion should be documented.

Prostaglandins

Misoprostol (200 mg four times daily) is approved for prevention of NSAID-induced GU and DU [222,330]. Diarrhea and abdominal cramps limit patient compliance, but these side effects are often transient and may be reduced by starting therapy with lower doses. The low-dose regimen is less effective in preventing "endoscopic" ulcers, suggesting that the higher dose is preferable if tolerated [222]. However, in clinical trials with Hp-negative NSAID users, low-dose misoprostol was superior to omeprazole for both endoscopic gastric ulcer healing and ulcer prevention [223]. Data from a randomized clinical trial with about 9000 patients indicated that misoprostol (200 mg four times daily) reduced NSAID ulcer complications by about 40% [70]. Although patients with active ulcer disease were excluded, misoprostol suppression of complications was evident in the subgroup with history of previous peptic ulcer [70]. Unfortunately, the numbers were small and, most importantly, Hp status was not determined so that it is unknown how well misoprostol works for prevention of clinical complications in Hp-negative subjects vs Hp-positive subjects.

Antisecretory agents: proton pump inhibitors

There are no approved regimens for the prevention of ulcer complications in patients who cannot tolerate or who fail misoprostol. Data from two randomized clinical trials indicate that standard doses of H2RAs do not prevent NSAID-induced

"endoscopic" GU [331,332]. One caveat is that the early studies were carried out in patients of unknown Hp status. Subsequent studies have shown a marked difference between the outcome of those with and without Hp infections [223]. PPIs were remarkably less effective in those without active Hp infection. Interestingly, misoprostol, even at a dose of 400 μg/day, was superior to PPIs for the healing of endoscopic GU and preventing ulcer relapse, and PPIs were also only marginally superior to low-dose ranitidine [223]. The superiority of misoprostol was confirmed in a separate study of full-dose misoprostol vs full-dose lansoprazole [224]. Epidemiological studies have also shown reduced mortality with the fixed combination of diclofenac and misoprostol (Arthrotec) compared with traditional NSAIDs [333,334]. It is likely that misoprostol is under utilized.

There are few data available regarding H2RA or PPI prevention of ulcer complications, particularly in Hp-negative subjects, either naturally or after Hp eradication. There are data, however, regarding the highest risk group (i.e., patients who have experienced an upper gastrointestinal bleed and who have restarted NSAIDs). In this high-risk group, the addition of a PPI to traditional NSAID therapy produced very disappointing results, showing rebleeding rates of 12.8% and 22.2% (annualized) [50,335]. The expected rate is between 24% and 36% per year, suggesting that the benefit was probably in the range of 50% protection. In contrast, the combination of a PPI and the coxib Celebrex appeared effective in preventing rebleeding, whereas the coxib alone did not [62].

Overall, PPIs do not appear to be very effective in preventing clinically important NSAID-associated upper gastrointestinal events. As was so elegantly described for gabapentin, medical opinion can be swayed via the use of marketing studies with surrogate end points, opinion leaders speakers bureaus, and regular consensus conferences, despite the lack of data [336]. As noted above, one should probably not expect more than a 50% reduction in serious events with PPI cotherapy. Importantly, there are no data suggesting a dose–response effect (i.e., the lowest PPI doses have proven equally as effective as higher doses for the prevention of endoscopic ulcers), such that the lowest dose of the least expensive PPI is probably sufficient. No data support the use of sucralfate, antacids or bismuth for the prevention or treatment of NSAID-induced ulceration.

Age alone and age plus symptoms markedly influence the baseline risk of NSAID ulcer complications [68]. The issues have become complicated by recent data suggesting that many traditional NSAIDs have significant cardiovascular risks [59,60], making the choice of therapy among the elderly even more difficult. This has led to rethinking of the role of non-drug therapy [337].

The ulcer risk with different NSAIDs

The choice of agent is dependent on the therapeutic goal. If analgesia is the primary aim, then in most cases a trial of full-strength non-NSAID pain relievers should be initiated first. As with NSAIDs, one should strive for the lowest effective dose. If the patient fails this first-line therapy (e.g., acetaminophen [paracetamol] prescribed at regular intervals for the pain of osteoarthritis or other noninflammatory conditions), the cost, safety, and efficacy of individual NSAIDs should be considered before prescription of NSAIDs.

In general, one should choose NSAID agents with the shortest half-lives for the temporary treatment of acute painful states. The dental pain model suggests that both aspirin and acetaminophen at 650 mg are equally effective as analgesics. The maximum analgesic dose of aspirin or acetaminophen is approximately 650 mg, which is equivalent to 200 mg of ibuprofen. The maximum analgesic dose of ibuprofen is 400 mg. Thus, there is no reason to give more drug when analgesia is the goal, as it only increases the risk with no additional benefits. As noted above, the issue of the cardiovascular risk of selective and nonselective NSAIDs also needs to be taken into account. The decisions regarding which NSAID for which indication are continuing to evolve.

Refractory and recurrent ulcers

With the advances made since the beginning of the 1980s, most peptic ulcers now respond to antimicrobial therapy for Hp or withdrawal of NSAIDs, or heal with usual doses of potent antisecretory drugs. However, occasional ulcers are either refractory to treatment or recur following initial healing. Careful clinical and endoscopic evaluation is essential to ensure that refractory or recurrent symptoms in fact reflect peptic ulceration and to evaluate potential causes (Table 40.5).

Ulcers are considered refractory if unhealed after 8–12 weeks of treatment. However, bigger ulcers take longer to heal. Obviously, the nature of the therapy has a big impact; patients with ulcers refractory to standard doses of H2RAs, for example, represent a different population from the much smaller number refractory to twice-daily PPIs.

Symptoms and recurrent and refractory ulceration

It is essential to differentiate between refractory symptoms and refractory ulcers. Endoscopy discriminates those patients who have intractable symptoms associated with unhealed ulcers from those without active ulceration. Persistent symptoms in the absence of active ulceration suggest that other etiologies for the symptoms should be sought.

Two lines of evidence suggest that symptoms in patients with refractory peptic ulcer often reflect more than acid bathing an unhealed ulcer crater. First, patients with refractory ulcers frequently have a return of symptoms after their ulcers have healed. This was illustrated in a surgical series of patients who underwent highly selective vagotomy for refractory ulcers that did not respond to medical management; only 3% patients developed an ulcer recurrence,

Table 40.5 Causes of refractory and recurrent ulceration

Persisting* Helicobacter pylori *infection
Poor compliance
Resistant organism
Inadequate *H. pylori* regimen
Persisting or recurrent ulcer, no apparent* H. pylori *infection
False-negative *H. pylori* testing
Continued or undiscovered NSAID use
Delayed healing:
Dense fibrosis or deformity
Heavy smoking
Giant ulcer
Serious comorbidity
Inadequate inhibition of acid secretion:
H2RA tolerance or PPI resistance (rapid metabolism)
Hypersecretory states: gastrinoma, idiopathic hypersecretory DU
Uncommon forms of peptic ulcer (see Table 40.1)
Non-peptic ulcer: cancer, Crohn's disease, other infections
Persisting symptoms, no ulcer
Another diagnosis
Irritable gut

DU, duodenal ulcer; H2RA, histamine H_2 receptor antagonist; NSAID, nonsteroidal antiinflammatory drug; PPI, proton pump inhibitor.

whereas 41% returned for recurrent symptoms [338]. In contrast, the patients who underwent surgery for recurrent, but not refractory, ulcers had a 5% ulcer recurrence rate and an 11% symptom recurrence rate.

The second line of evidence is that symptoms in DU patients often include more than classic acid dyspepsia (hunger pain with relief occurring when acid is buffered with food or antacids or inhibited by antisecretory agents) (see Table 40.2). Ulcer patients also frequently complain of symptoms of acid reflux or an irritable stomach (causing indigestion-like symptoms). There can also be considerable overlap with irritable bowel syndrome (IBS). Although complete systematic surveys of ulcer patients are limited, approximately 30%–50% experience symptoms in addition to or other than classic acid dyspepsia (Table 40.2).

On the other hand, the absence of symptoms does not exclude the presence of a persisting ulcer crater. At least 25% of refractory and recurrent ulcers are asymptomatic [339].

Etiology of refractory and recurrent ulcers

For both refractory and recurrent ulcers, the most important step in management is to consider the several elements that may influence natural history. Factors that perpetuate the ulcer itself can also retard healing and predispose to recurrence. These factors are considered in the following sections. This evaluation should exclude diseases mimicking peptic ulcer (e.g., gastric cancer mimicking GU), and causes of peptic ulcer that require specific therapy, such as Hp infection, NSAID use, and gastrinoma (Table 40.5).

Persistent *Helicobacter pylori* infection

Hp infection may have been missed because of a false-negative test or infection may not have been successfully eradicated. The latter situation occurs most frequently as a result of selection of an inappropriate antibiotic regimen, antibiotic resistance, or poor patient compliance.

Nonsteroidal antiinflammatory drugs

Continuing NSAID use is a critical factor underlying a surprising number of troublesome ulcers. Patients may not admit to the use of aspirin and NSAIDs, even after experiencing ulcer recurrences or a refractory course, or undergoing surgery [340–342]. More than 40% of NSAID use associated with refractory ulceration was initially not reported by the patient. It is essential to confidently exclude NSAID use or abuse in all patients with refractory or recurrent ulcers. This evaluation should include measurement of serum salicylate levels, platelet adhesiveness, and taking a history with family members.

Giant ulcers

Large and small GU heal at the same rate on antacids, approximately 3 mm per week [343]. Thus, larger ulcers will require more time to heal. Ulcer size also influences healing rates for DU.

Smoking

Effective antiulcer therapy usually compensates for the deleterious effects of smoking on ulcer healing. However, cigarette smoking, particularly if heavy, may contribute to impaired healing and recurrences [245]. Effects of smoking on ulcer have only been defined for Hp ulcers before eradication (see Risk factors for peptic ulcer – Cigarette smoking).

Impaired healing, scarring, and deformity

It is likely that general factors (severe comorbidity or catabolism) and local factors (dense scarring) impair healing. Specific mechanisms have not been defined, but low mucosal blood flow, which would impair angiogenesis and tissue repair, is one attractive candidate.

Duodenal deformity, probably resulting from dense scarring, has been associated with poor healing [344–346]. Local inflammation, an absence of glandular structure, and blunt or absent villi are markers of poor histological restoration and healing, which also predispose to ulcer recurrence [347].

Acid hypersecretory states

Obviously, refractory and recurrent DU can be due to gastrinoma [348]. It is not surprising that in nongastrinoma patients the degree of healing inversely reflects acid output.

In one study 55 patients with complete healing of their DU had a mean basal acid output of 6.6 mEq/h, whereas 20 patients with nonhealing DUs had a mean basal acid output of 20 mEq/h [349]. Following Hp treatment, occasional recurrences have been associated with continued high pentagastrin-stimulated peak acid output, rather than reinfection with Hp [35]. Once identified, maintenance antisecretory treatment may be necessary to prevent relapse in this subset of patients.

Impaired response to antisecretory agents

Tolerance to H2RAs that develops during sustained therapy has been hypothesized to contribute to some cases of refractory ulcers in response to these agents. Tolerance does not seem to develop with PPIs. Occasional patients fail to respond to standard doses of PPI; double doses are effective in inducing and maintaining healing in many of these individuals [350].

Diagnostic approach for refractory or recurrent ulceration

A careful clinical evaluation is needed to assess the etiology of symptoms. For DU, fasting serum gastrin should be measured to exclude gastrinoma [348], but caution is necessary because both PPI and Hp can raise gastrin levels. Endoscopy is necessary to determine if symptoms are linked to refractory or recurrent ulceration. Edema, spasm, or a deformed duodenal bulb can impair the accuracy of endoscopy, especially in inexperienced hands. If ulceration is found, biopsies of the antrum and body are indicated to assess Hp status. The presence of gastritis suggests false-negative Hp testing (see Laboratory evaluation – *Helicobacter pylori* testing). Refractory ulcers in the absence of antral gastritis are usually the result of NSAID use.

With refractory ulcers, particularly in the absence of Hp or NSAID use, endoscopic biopsy of the ulcer should be considered to exclude other benign (e.g., infectious causes) and malignant diseases that can present with ulceration. In some instances endoscopic ultrasound may be helpful, especially for the diagnosis of ulcerated smooth muscle tumors.

Refractory or recurrent GU require multiple biopsies of the ulcer margin and base to exclude neoplasia. Nonhealing GUs must be considered cancer until proven otherwise. Gastric ulceration in the presence of severe body gastritis or atrophy should heighten concern about malignancy.

Treatment of refractory ulcers

The presence of a refractory ulcer should always prompt the clinician to reconsider the diagnosis and management to date, focusing on three points. First, confirm that the patient is compliant with an adequate PPI regimen, now the mainstay of treatment. Second, ensure that continued use of gastrotoxic drugs (e.g., NSAIDs) has been confidently excluded by assessing platelet function, measuring salicylate levels, and taking a history from family members. Third, either confirm that Hp has been confidently excluded using a second, sensitive test or confirm that it has been successfully cured. Judging the appropriate length of continued therapy is an empirical process for refractory ulcers, which must be adapted to the individual patient. If the underlying cause can be reversed, then treatment usually becomes easy. However, particularly for large or densely scarred ulcers, an extended treatment period may be necessary to prevent recurrences and allow mucosal remodeling to take place.

Surgery is only rarely required for refractory or recurrent ulceration. Unless emergent, surgery should be approached very cautiously and only after carefully excluding reversible causes and allowing adequate time for healing on PPIs, assuming patient compliance can be ensured. Truly refractive ulcers are sufficiently rare that one should consider referral, especially of difficult cases, to individuals with extensive experience.

Prevention of ulcer recurrence

Maintenance therapy is indicated to prevent recurrence in high-risk subgroups, defined by a history of complications, frequent recurrences, or refractory, giant, or severely fibrosed ulcers. In patients in the high-risk subgroup who are infected with Hp, maintenance therapy should be continued at least until cure of the infection has been confirmed. Maintenance therapy is also indicated in high-risk patients who fail Hp eradication or who have Hp-negative ulcers. In the Hp–NSAID era, maintenance has received little study, except for the prevention of NSAID ulcers during continued NSAID treatment (see Prevention of NSAID ulcers). PPI therapy appears to be effective for the small set of hypersecretory, non-Hp DU [93]. When maintenance is indicated, standard doses of PPIs are reasonable choices, unless the patient has previously failed such a regimen and requires higher doses.

Complications of peptic ulcer

The complications of ulceration include hemorrhage, perforation, penetration, and obstruction, and occur with all types of ulcers. In one study the annualized incidence of complications of NSAIDs per year of NSAID use were 1% for hemorrhage, 0.3% for perforation, and 0.1% for obstruction [70]. Complications for largely Hp-positive ulcers occur at a rate of about 1%–2% per patient-year of follow-up [351].

The pathophysiological factors that distinguish patients predisposed to complications or recurrence of complications are unclear. However, it is clear that patients with complicated ulcers represent a distinct subset who are more prone to experiencing another complication than are patients without history of previous complications [351–353]. Another common feature is that most complicated ulcers are chronic and densely fibrosed ulcers, penetrating deeply into the wall to form a dense fibrotic scar that is slow to heal, involves blood vessels, or reaches the serosa. A prolonged ulcer history is also common among complicated ulcers; however,

some patients have few or no symptoms until complications develop, despite an obviously scarred, chronic ulcer. In contrast, some complicated ulcers, especially when linked to NSAID use or developing in hospitalized patients (stress ulcers), are acute and occur without dense fibrosis, previous symptoms, or ulcer history; they can develop and complicate within days.

Gastric outlet obstruction

Pathophysiology and epidemiology

Gastric outlet obstruction is the least frequent ulcer complication. Most cases are associated with duodenal or pyloric channel ulceration; gastric ulceration accounts for only 5% of cases (Table 40.6) [353]. Several elements can contribute to gastric outlet obstruction. Rapidly reversible elements include spasm, edema inflammation, and pyloric dysmotility related to the ulcer or inflammatory changes. Fibrosis, scarring, and deformity underlie slowly reversible or irreversible obstruction. Gastric atony, developing after prolonged obstruction, contributes to gastric retention.

Table 40.6 Differential diagnosis of gastric retention

Gastric outlet obstruction
Peptic ulcer: DU and channel ulcers greater than GU
Neoplasia:
Gastric carcinoma
Pancreatic cancer
Lymphoma
Benign adenomatous polyp
Inflammation:
Cholecystitis
Acute pancreatitis
Crohn's disease
Eosinophilic gastroenteritis
Miscellaneous causes:
Adult hypertrophic pyloric stenosis
Postsurgical stenosis
Pyloric, antral, and duodenal webs/diaphragms
Duodenal bands
Annular/ectopic pancreas
Caustic stricture
Gastric dysmotility (see Chapter 39)
Idiopathic
Drugs: atropine, opioids, high-dose tricyclics, etc.
Neuromuscular:
Diabetic gastroparesis
Gastric atony from prolonged obstruction
Previous gastric surgery: vagotomy, antrectomy
Collagen vascular disorders, e.g., scleroderma
Pseudoobstruction
Inflammatory: contiguous inflammation, peritoneal disease
Miscellaneous anorexia nervosa

DU, duodenal ulcer; GU, gastric ulcer.

There are few good data available regarding the frequency and natural history of obstruction. Most data come from venerable surgical series. Obstruction had accounted for 10%–30% [353,354] of patients undergoing ulcer surgery, but this number is dropping as medical and endoscopic management have become more effective and underlying causes have been identified and treated. Although there are no good statistics, it appears that obstruction from peptic ulcer has become less frequent than bleeding and perforation. Obstruction presenting in a medical setting is likely to be different from surgical data, but data are limited [70,355,356]. In a medical setting, partial outlet obstruction that resolves with medical management is more likely. Reflecting the apparent drop in obstruction due to peptic ulcer, malignancy has emerged as a prominent cause of obstruction [355,357].

Webs in the antrum [358] and to a lesser extent in the duodenum [359] can occur either as a congenital abnormality or as a sequelae of peptic or inflammatory disease. Surprisingly, symptoms can be intermittent with these lesions and in some cases it is difficult to determine if they are obstructing.

Both Hp and NSAIDs can clearly cause obstructing ulcers. As with other complications, the rate of Hp infection in patients not consuming NSAIDs is controversial [360,361]. Regardless, the bottom line is clear; both factors must be diligently excluded.

Clinical presentation

Symptoms of gastric retention include early satiety, bloating, indigestion, anorexia, nausea, vomiting, epigastric pain, and weight loss (Table 40.7) [353,356]. Although commonly absent, the presence of recognizable food more than 8–12 h after eating is indicative of gastric retention. The average duration of symptoms is 1 month, although one-third of patients have symptoms for longer than 3 months. Although these patterns are useful, they are drawn from surgical series, and presentation in a medical setting may be different. Important variables include the patient's response to these symptoms, age, comorbid conditions, and general health status. A subset of patients with chronic organic disease – and peptic ulcer in particular – have visceral hyposensitization; in these patients, high-grade outlet obstruction may be present without perceived gastric distress. Appetite and food intake may be preserved in association with delayed, large-volume vomiting of undigested food. Pain, nausea, and bloating are variable with gastric retention (Table 40.7). Conversely, other patients may have minimal or intermittent obstruction, but complain of considerable pain and indigestion.

Diagnosis and differential diagnosis

It is first important to determine whether the symptoms are due to gastric retention and whether outlet obstruction is the explanation. Clinical assessment may provide helpful clues to the presence of gastric retention [353] (Table 40.7). A high

Table 40.7 Manifestations of gastric retention

History	Vomiting (80%–90%), especially with stale food ingested > 4 h previously; projectile or nocturnal Abdominal pain (87%) Weight loss (65%) Early satiety (60%) Nausea (40%)
Physical examination	Visible gastric peristalsis Succussion splash > 4 h after eating (25%)
Gastric aspirate	Gastric residual volume > 300 mL 4 h after eating Overnight fasting gastric residual volume > 200 mL
Radiography	Retention of barium > 50% at 4 h Large, atonic stomach; retained food
Special studies	Saline load (see Table 40.8)
External scanning technique – radionuclide gastric emptying	Liquid phase: fractional emptying rate < 10% per min Solid phase: fractional emptying rate < 0.5% per min
Barium burger	Barium residue after 6 h in intact stomach and after 3 h in resected stomach

Table 40.8 Saline load test

Procedure

Place a No. 16 French nasogastric sump tube into the stomach
Position the tip 65 cm from the nares
Empty the stomach
Place patient right side down to enhance gastric emptying
Infuse 750 mL of 0.9% NaCl into the tube over 3–5 min
After 30 min use a syringe to aspirate and measure gastric residual volume

Interpretation of gastric residual volume

> 400 mL: definite gastric outlet obstruction
300–400 mL: probable gastric outlet obstruction
200–300 mL: indeterminate
< 200 mL: normal

volume of residual gastric fluid is expected and obstruction is unlikely if it is not present. After gastric decompression, the saline load is helpful to evaluate mechanical outlet obstruction [353] (Table 40.8). If gastric residual volume is found and the saline load is positive, then several days of gastric decompression are indicated, as considered below.

Definitive diagnosis of gastric pathology must await gastric cleansing, decompression, and restoration of fluid and electrolyte abnormalities (see Medical management). Endoscopic inspection and biopsy are indicated in suspected cases of outlet obstruction and usually provide definitive diagnosis of underlying pathology. Although conventional upper GI radiography can provide useful information [362], it is rarely definitive and the stomach is left with a large amount of barium residue that interferes with visualization during endoscopy.

Malignancy must be excluded in all cases of obstruction; obstruction should be assumed to be neoplastic until proven otherwise (Table 40.7). About 50% of cases of outlet obstruction are due to malignancy [355,357]. Patients with malignancy tend to be older and typically do not have a history of peptic ulcer or use NSAIDs [355]. Importantly, in about 10% of obstructed patients undergoing endoscopy and biopsy, malignancy was not suspected before operation [355,357]. Endoscopy should include careful inspection and multiple, jumbo biopsies. Endoscopic ultrasound with biopsy or needle aspiration should be considered in persisting obstruction. CT with oral and intravenous contrast may also be useful in detecting malignancy, although a negative study does not rule out malignancy.

Other causes of delayed gastric emptying require consideration (Table 40.7). Diagnosis of obstruction due to peptic ulcer has been delayed when confused with various conditions, including vomiting in pregnancy [363] or a presentation suggesting anorexia nervosa [364].

Medical management

Especially in a surgical setting, obstruction is often accompanied by severe, long-standing ulcer disease [353]. Furthermore, in the era before definitive treatment of the underlying cause was possible, obstruction frequently recurred and a large majority of cases underwent surgery within a 3-year period [365]. Although no formal trials or hard data are available, management has undergone a dramatic evolution since the mid-1990s.

In patients with severe and long-standing obstruction, the initial steps in management are to resuscitate the patient and to confirm the diagnosis, including emptying and decompressing the stomach. Depending on the condition of the patient, the diagnosis of gastric retention can be confirmed at endoscopy or by using a saline load test. If gastric retention is confirmed, the nasogastric tube should be replaced by a large-bore (e.g., Ewald) tube and the stomach lavaged to remove debris. The nasogastric tube should then be replaced, good placement and function of the tube confirmed, and intermittent suction continued for 3–5 days to decompress the stomach while intravenous fluid and electrolytes are administered. In some cases, prolonged vomiting and poor fluid intake cause prerenal azotemia, hyponatremia, or a hypokalemic metabolic alkalosis (the loss of HCl and volume leads to renal conservation of Na and loss of K). In these cases, after intravenous saline has restored volume status and urine output, K can be administered. Only in rare cases will alkalosis require direct correction with intravenous HCl. Intravenous H2RA or PPI therapy is useful to reduce volume requirements, facilitate control of gastric pH, and heal the ulcer. Careful assessment of nutritional status is required and intravenous hyperalimentation deserves consideration in malnourished patients. Repeating the saline load test (Table 40.6) can gauge progress; residual volume of less than 200 mL indicates resolution of obstruction. About half of the cases of chronic obstruction will respond to this regimen [366].

In the current era, most patients do not have chronic obstruction but rather have symptoms due to spasm, edema, inflammation, or associated pyloric dysmotility rather than to malignancy or dense scarring. Such patients respond rapidly to intravenous H2RA or PPI therapy. Some start anti-Hp therapy immediately [367] but in our experience the rapid response is actually related to the antisecretory drug therapy and not to the antibiotics and we prefer a more measured approach including endoscopy and biopsy to exclude malignancy, diagnose ulcer disease, and determine if Hp is present.

Although there are no controlled studies, obstruction definitively occurs with Hp ulcers, and case reports indicate that, as expected in the absence of dense fibrosis, cure of Hp infection is associated with resolution of the obstruction [367,368]. Since deformities of the duodenum appear to resolve slowly following cure of Hp infection, complete resolution may take considerable time following cure of Hp infection.

Although controversial in the past, NSAID ulcers also cause gastric outlet obstruction. The MUCOSA trial had three cases among 4500 NSAID users over 6 months of observation [70]. In 119 consecutive elderly patients undergoing endoscopy for peptic ulcer, 12 cases with obstruction were found and 11 were consuming NSAIDs [369]. Most importantly, these cases responded to medical management, possibly suggesting a different natural history from ordinary peptic ulcer presenting with obstruction.

Medical management should include antisecretory therapy, and full-dose intravenous antisecretory therapy is warranted during gastric decompression. After the patient resumes oral intake and the stomach is emptying adequately, oral PPI treatment can be started. If Hp is present we recommend deferring antibiotic therapy until adequate gastric emptying can be ensured. Full-dose antisecretory medication should probably be continued until successful Hp cure has been confirmed and until any antroduodenal deformity has resolved. It is reasonable to assume that the combination of curing Hp infection and continued antisecretory therapy will eventually reverse antroduodenal deformity and the tendency for recurrent obstruction.

For patients who do not respond to medical therapy alone, endoscopic balloon dilation can provide lasting benefit [356], although repeated sessions are necessary in some cases. Dilation can be accomplished at endoscopy with a through-the-scope balloon or by using a balloon placed over a guidewire positioned under fluoroscopic guidance. Advancing the wire well past the stricture and use of 6- to 8-cm balloons stabilizes balloon placement during dilation [353]. Balloon dilation should be monitored by pressure gauge, sustained for 1 min, and repeated 3–4 times. Successful dilation is usually confirmed by pulling the balloon through the strictured segment, although failure to accomplish this test does not preclude a successful procedure. Balloon dilation using dilute contrast medium allows progress to be followed fluoroscopically; a waist forms initially during dilation but is effaced during balloon distention in successful dilation. Long duodenal strictures are the most difficult to dilate. In one series of 30 patients [356], dilation to 18 mm produced perforation in two patients, who did well after prompt surgery. Although no controlled studies are available, stepwise dilation for tight obstruction will probably lower the risk of perforation. Symptoms are usually improved with successful dilation to 12 mm [353] and there may be advantages to postponing dilation beyond 15 mm until after a period of time and medical management. With the finite risk of perforation, patients should be appropriately prepared for surgery before dilation and monitored closely after dilation before resuming oral intake. A postprocedure oral contrast study will generally detect perforation in a timely fashion.

Peptic ulcer hemorrhage

The presentation and management of ulcer hemorrhage is detailed elsewhere (see Chapter 124). Key elements in management are outlined below.

Clinical assessment at triage is essential: Is bleeding life-threatening? The aggressiveness of intervention should be scaled to the severity and rapidity of bleeding. Appropriate, cost-effective management requires triage by experienced clinicians. Several factors influence prognosis: age older than 60 years, hematemesis, hematochezia from an upper GI source, shock, requirement for multiple transfusions, and

the presence of comorbid disease, particularly of cardiorespiratory, hepatic, or malignant origin. Mortality is not usually due to exsanguination but to either comorbid disease or to the surgical procedure performed to stop the bleeding. Appropriate global assessment of patient status is critical at the outset and periodically during care.

Endoscopic diagnosis and assessment of risk for continued bleeding or rebleeding has become the focal point of initial management. However, first the patient must be stabilized and the general status assessed. Then, upper endoscopy is indicated, both for acute upper GI bleeding and also for acute lower GI bleeding. Hematochezia is a trap for the uninitiated; about 10% of apparent acute lower GI bleeding is due to an upper source, most frequently duodenal ulcer. When peptic ulcer is found, endoscopic findings have been firmly established as useful indicators for the risk of recurrent bleeding (active bleeding, visible vessel, and adherent clot).

Intravenously administered high-dose PPIs along with endoscopic management are indicated for actively bleeding or high-risk lesions (visible vessel or occasionally adherent clot) [370].

Surgical intervention remains an important option for carefully selected cases (see Chapter 44). Although emergency surgery usually carries a high risk, controlled studies have indicated an excellent outcome when surgical intervention is used early in the course of management for rapid or recurrent bleeding that is not controlled by expert endoscopic intervention. Surgical risk is much higher when surgery is delayed, awaiting multiple endoscopic or radiological interventions. Optimal management entails endoscopic intervention by endoscopists experienced in management of acute bleeding; this expertise is evident by rapid and effective intervention coupled with timely hand-off to surgery in cases in which active or recurrent bleeding is not readily controlled by endoscopic intervention. The experienced endoscopist knows when to quit and send the patient to surgery. Outcomes are best when patients are managed by a team that includes experienced endoscopists and surgeons.

Without definitive treatment, the risk of recurrent bleeding is 10%–36% per patient-year [351,352,371]. Every effort should be made to identify underlying causes; eradication of Hp, if present, and discontinuation of NSAID use dramatically decrease subsequent recurrent hemorrhage. Diagnosis of Hp is more difficult in bleeding patients, in part because of obvious factors such as the reluctance to perform biopsies for definitive tests at the time of bleeding and also because of the use of Hp suppressant therapy (PPI, bismuth, and many antibiotics) [372]. In addition, active bleeding appears to cause false-negative tests dependent on Hp urease activity [189,373,374] as well as false-negative Hp stool antigen tests [375]. The UBT is typically still accurate. Because of the high pretest prevalence of Hp, negative serology or urease testing should be confirmed with histology to accurately exclude inflammation and organisms. An extra effort to exclude Hp infection can be justified in this high-risk subset of patients. It is critical to detect NSAID and aspirin use; as noted previously, surreptitious use is easily missed and must be sought. There should actually be no rush to make a definitive diagnosis as treatment of an Hp infection can be safely delayed until after the acute episode has passed and even until after the ulcer causing the bleed has healed.

Data indicate that early treatment with high-dose continuous intravenous PPIs coupled with endoscopic hemostatic therapy has a beneficial impact on ulcer rebleeding rates; decision analysis suggests that administering PPIs for the treatment of bleeding ulcers is cost-effective [376,377].

Ulcer perforation (see Chapter 44)

Duodenal, antral, and gastric body ulcers account for 60%, 20%, and 20% of perforations respectively [353,378]. One-third to one-half of perforated ulcers are NSAID associated [378], usually in elderly patients [379]. Hp infection probably accounts for the large majority of other cases but data are limited and rates of Hp infection vary considerably among available studies [380,381]. As with bleeding ulcers, surreptitious NSAID use and false Hp testing should be kept in mind, but it appears that there are other explanations for a subset of these cases. Although perforation occurs in patients without an ulcer history, when a detailed history is taken after recovery, the majority of patients report having ulcer symptoms before the perforation [382]. However, older patients who experience perforation in association with NSAID use frequently deny any preceding ulcer symptoms.

As with many acute conditions, the challenge is to consider perforation in the differential diagnosis. The highest mortality rates occur when presentation to the hospital or recognition of the problem is delayed. High mortality rates also occur when hospitalized patients suffer perforation. Perforation presenting in "inpatients" is probably due to stress ulcers. This presentation will be blurred and outcome impaired by comorbid disease. Perforation should be included among the conditions considered in the evaluation of shock and sepsis.

As detailed elsewhere (see Chapter 44), surgical management has changed since the mid-1980s; sealing the perforation with an omental patch and performing a parietal cell vagotomy is a highly effective approach with low rates of recurrence and morbidity [381]. However, simple closure followed by Hp eradication appears adequate, especially for perforated DU [383]. Nonoperative management (intravenous fluids, antibiotics, nasogastric suction) is also an alternative in cases in which the leak seals quickly in response to medical management [384]. Conservative management becomes particularly attractive because the underlying cause can be reversed by either discontinuing NSAID use or curing Hp infection.

In the past, patients with a history of ulcer perforation who received an omental patch without definitive ulcer operation had a high likelihood of experiencing another ulcer com-

plication [353]. Although no firm data are available, it is reasonable to assume that definitive therapy (cure of Hp infection or removal of NSAID exposure) will prevent the recurrences of ulcers due to these causes. It is also likely that maintenance therapy with antisecretory agents will reduce, but not eliminate, recurrence of ulcer complications. Therefore, patients with a history of ulcer perforation should be offered definitive management, as outlined previously. Patients with a history of Hp should be maintained on full dose antisecretory therapy until successful cure of Hp has been confirmed.

"Fortunate indeed is the surgical service that does not have one or more problem cases of recurrent marginal ulceration despite the adequacy of the surgical attack," noted the opening sentence of Zollinger and Ellison's landmark description of the syndrome that today bears their names [1]. Benign ulceration of the upper jejunum associated with extremely high gastric acid secretion and the presence of a non-β-cell adenoma of the pancreas was the triad of clinical findings described in two patients who eventually required total gastrectomy for relief of their severe ulcer disease. Although earlier reports [2,3] described a similar clinical situation, it was Zollinger and Ellison who hypothesized that the components of this clinical triad were intimately related and were produced by a humoral agent that induced gastric acid hypersecretion and its sequelae. This hypothesis was confirmed by Gregory and colleagues [4,5], when they established that the tumor extract from a patient with Zollinger–Ellison syndrome contained a substance that was chemically and physiologically indistinguishable from the antral hormone gastrin.

Subsequent development of a sensitive and specific radioimmunoassay for gastrin [6,7] facilitated the measurement of this peptide in the sera of patients with Zollinger–Ellison syndrome and confirmed that their circulating gastrin concentrations exceeded by several-fold the plasma levels found in a normal control population. This sensitive assay also permitted earlier tumor detection, which has led to a steady increase in the number of patients described with gastrinoma. Potent inhibitors of gastric acid secretion and sophisticated preoperative and intraoperative diagnostic procedures have transformed Zollinger–Ellison syndrome from an illness for which total gastrectomy and tumor progression were the normal course to a condition for which a cure is feasible in many patients. Moreover, new molecular tools are leading to an improved understanding of disease pathogenesis at the cellular level, potential new markers for prognostication and novel therapeutic approaches for advanced disease.

Epidemiology

The true incidence and prevalence of Zollinger–Ellison syndrome are unknown. Estimates of incidence have ranged from 0.1% to 1% of patients who present with peptic ulcer disease in the United States [8]. The heterogeneous clinical manifestations, the widespread use of proton pump inhibitors (PPIs) for the treatment of acid peptic disease and its sequelae [9], and the high incidence of silent pancreatic endocrine neoplasms [10] have all contributed to an underestimation of the incidence and prevalence of Zollinger–Ellison syndrome. The age range of affected persons has varied from 7 to 90 years, with the majority of patients diagnosed between the age of 30 and 50 years. The disorder is found more often in men than women, with ratios varying from 2:1 to 3:2 [8,11,12].

Gastrinomas can be subdivided into tumors that are sporadic [13] and those that are genetically transmitted and associated with *multiple endocrine neoplasia type 1* (MEN1) [14]. Sporadic gastrinomas, the more common of the two types, frequently behave as malignant tumors. Zollinger–Ellison tumors associated with MEN1 occur at a younger age than the sporadic tumors and have been characterized by some investigators as following a more benign course. These two subtypes have various distinguishing features, as discussed later in this chapter.

Pathophysiology

Gastric acid hypersecretion and severe peptic ulcer diathesis secondary to unbridled release of gastrin from a non-β-cell endocrine neoplasm are the essential elements leading to Zollinger–Ellison syndrome. The neoplastic pancreatic cells secreting gastrin are thought to arise from the ductular epithelium and not from cells of the islets of Langerhans,

despite the appellation of gastrinomas as "islet cell tumors" [1]. Normally, the adult pancreas does not secrete gastrin, but the fetal pancreas contains large quantities of this peptide [15]. After birth, the gastrin-secreting cells in the pancreas disappear and are not seen again, except as benign or malignant neoplasms in Zollinger–Ellison syndrome. The hypergastrinemia that results from the release of peptide from an endocrine neoplasm free of the usual regulatory restraints has two synergistic effects: overstimulation of gastric parietal cells to secrete acid and increased mass of parietal cells susceptible to overstimulation. The enhanced gastric acid hypersecretion that results is presumably the cause of the clinical manifestations (i.e., acid peptic disease and diarrhea) of the gastrinoma syndrome.

In contrast to many of the common malignant diseases, such as those originating in the pancreas, colon, or breast, gastrinomas are not associated with alterations in classic oncogenes such as *ras*, *myc*, *fos*, and *src* or with tumor suppressor genes such as *p53* or the retinoblastoma susceptibility gene (*Rb*) [16]. Despite this observation, studies reveal that 16%–40% of sporadic gastrointestinal neuroendocrine tumors express mutations in the *MEN1* gene, which is found to be defective in patients with MEN1. This is a 10-exon gene found on chromosome 11q13 [17–20], as further described later in this chapter.

Goebel and colleagues [21] attempted to correlate mutations of the *MEN1* gene with clinical characteristics in 51 patients with sporadic gastrinoma. This study revealed that 31% of the tumors had a mutated *MEN1* gene. Of interest, mutations are clustered within a fairly narrow region (amino acids 61–166), a finding different from that seen in MEN1-related gastrinomas, in which the mutations occur throughout the gene. The presence of a mutation in the *MEN1* gene did not appear to be useful as a marker at an early stage of disease for predicting patient outcome.

Additional studies have demonstrated a series of genetic alterations in gastrinomas including methylation and deletion of the *p16/MTS1* tumor suppressor gene [22], amplification of the *HER-2/neu* protooncogene [23], amplification of chromosome 9q [24], and deletion of chromosome 1 [25,26] or 3p [24–27]. Yu and colleagues [27] performed a detailed survey of genetic alterations in eight sporadic gastrinomas. Although the number of tumors was small, these investigators concluded that important molecular features of gastrinomas include defects in chromosome 1, aneuploidy, and mismatch repair defects and deletions in the *MEN1* gene. Serrano and colleagues [28] determined that alterations (hypermethylation of the promoter) in the tumor suppressor gene *p16INK4aCDKN2A* were present in more than 50% of gastrinomas, independent of tumor extent. This genetic alteration is the most common one found in gastrinomas to date and suggests that changes in this gene may be an early event in its development. Subsequent attempts at characterizing the molecular fingerprint of pancreatic endocrine tumors using microarray technology will be discussed later in the chapter. Although posttranslational processing variants of gastrin have been described in patients with gastrinoma [29–32], the clinical relevance of this finding has not been established.

Tumor distribution

More than 80% of gastrinomas have been localized in the anatomical area known as the *gastrinoma triangle* [33]. The boundaries of this triangle include the confluence of the cystic and common bile ducts superiorly, the junction of the second and third portions of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially. The most common extrapancreatic site is the duodenum [34], wherein up to 40%–50% of sporadic gastrinomas arise [35–37]. Other less common extrapancreatic sites include the stomach, bones, ovaries, liver, heart, and lymph nodes, which together account for fewer than 10% of gastrinomas [38–40]. More than 50% of gastrinomas are considered to be malignant. Solitary pancreatic lesions were found in fewer than 30% of the earliest reported patients with gastrinoma [11]. With the trend toward earlier measurement of serum gastrin and exploratory surgery [41], the incidence of metastatic disease at the time of operation has decreased. Nevertheless, multiple tumors or metastatic lesions are still observed in 30%–55% of patients at the time of diagnosis [35,37].

The morphology of the neoplastic cells in gastrinomas is heterogeneous [42,43]. The gastrin-producing cells are generally well differentiated and contain histological markers characteristic of endocrine neoplasms in general; that is, they contain chromogranin, neuron-specific enolase, synaptophysin, and tyrosine hydroxylase. The degree of malignancy does not appear to correlate with a gastrinoma's histological appearance; however, this observation must be tempered by the knowledge that tumor aggressiveness is usually determined retrospectively.

As in the case with other endocrine neoplasms, gastrinomas have been found to express a variety of neuroendocrine peptides besides gastrin, including somatostatin, pancreatic polypeptide, adrenocorticotrophic hormone, and vasoactive intestinal polypeptide. Although the clinical manifestations are generally associated with overproduction of one hormone, case reports illustrating combined syndromes have been described [44–48]. Of these, Cushing syndrome in association with gastrinoma is the mixed syndrome most frequently described [49,50].

Clinical manifestations

More than 90% of patients with gastrinoma develop ulcers in the upper gastrointestinal tract at some point during the

disease [11–13]. Presenting ulcer symptoms are indistinguishable from those associated with benign peptic ulcer disease, but frequently they are less responsive to standard therapy. As in benign peptic ulcer disease, ulcers in patients with Zollinger–Ellison syndrome occur most frequently in the first portion of the duodenum (75%), and they are usually solitary. However, ulcers in patients with gastrinoma also may occur in the second, third, and fourth portions of the duodenum (14%), and in the jejunum (11%) [12]. The ulcers are usually less than 1 cm in diameter but can occasionally present as giant lesions. Peptic ulcer disease refractory to standard medical therapy, recurrent ulcers after prior gastric surgery, diarrhea in patients with ulcers, or peptic disease presenting with complications such as obstruction, perforation, or bleeding suggest a possible diagnosis of Zollinger–Ellison syndrome. Esophageal symptoms caused by acid reflux are seen in up to two-thirds of patients with Zollinger–Ellison syndrome [51,52]. The disease found in the esophagus may range from mild to severe esophagitis complicated by stricture formation and Barrett mucosa.

Diarrhea is the other common feature of Zollinger–Ellison syndrome; it may be present in more than half of patients, and can precede the diagnosis by many years and occur in the absence of peptic ulcer symptoms [11,13,53,54]. The pathogenesis of diarrhea is likely multifactorial, but its dependence on acid hypersecretion is demonstrated by amelioration of symptoms on continuous nasogastric suction or inhibition of acid secretion [8,55]. Added features of the diarrhea are steatorrhea and maldigestion [56,57], which result from the inactivity of pancreatic enzymes at the low pH of the duodenum caused by the excessive acid load. The acidic pH of the small bowel also may lead to damage of the intestinal mucosa, resulting in a sprue-like state, with flattened intestinal villi and accompanying malabsorption [58]. Bile acids are poorly soluble in an acid milieu; thus, Zollinger–Ellison syndrome may result in decreased micelle formation and subsequent malabsorption of vitamin B-12 and other lipid-soluble nutrients and vitamins [56]. It is possible that in the presence of markedly high serum gastrin levels, gastrin itself may increase secretion of potassium and may reduce absorption of sodium and water by the small intestine [59,60], thus potentially leading to secretory diarrhea. Secretory diarrhea also may occur in Zollinger–Ellison syndrome in association with the secretion of another hormone besides gastrin, such as vasoactive intestinal polypeptide.

Twenty-five percent of patients with gastrinoma have MEN1 syndrome [14]. The primary sites of organ involvement in this autosomal dominant genetic disorder include the parathyroid, pancreas, pituitary, and, less commonly, adrenal cortex and thyroid. In a large series by Ballard and colleagues [61], 87% of 85 patients with MEN1 had involvement of the parathyroid glands, 81% had disorders of the endocrine pancreas, and 65% had pituitary involvement. Trump and colleagues [62], reporting on their findings in 220 patients with MEN1, observed different rates of organ system involvement, with 95%, 41%, and 30% of patients having parathyroid, pancreatic, and pituitary neoplasms, respectively. This latter study also confirmed that in 87% of patients parathyroid lesions were the first indication of this genetic disorder. The clinical features of Zollinger–Ellison syndrome (ulcer complications, gastric or pancreatic surgery) account for the major morbidity and mortality related to MEN1 [63]. In up to one-third of patients, the first clinical manifestation of MEN1 may be Zollinger–Ellison syndrome, which suggests that patients with the presumptive diagnosis of sporadic Zollinger–Ellison syndrome should be monitored biochemically and, when feasible, genetically screened for evidence of MEN1 [64]. Others recommend an oral calcium tolerance test to exclude early evidence of hyperparathyroidism and MEN1 [65].

The genetic defect in patients with MEN1 has been mapped to the long arm of chromosome 11 (11q11–q13) by analysis of restriction fragment length polymorphisms in affected families [62,63]. As outlined earlier, the *MEN1* gene consists of 10 exons and encodes the protein menin. Menin is a nuclear protein of 610 amino acids that is expressed widely throughout the body and functions as a tumor suppressor [66]. It interacts with Jun D, an AP-1 transcription factor, and with a protein involved in cell growth, SMAD-3 (SMAD, small mothers against decapentaplegic) [67,68]. Subsequent work has demonstrated that menin may be involved in methylating histone H3 and enhance gene transcription [69]. In addition, studies with genetically modified mouse models suggest that the critical consequence of MEN1 mutations may be deregulation of the cell cycle, which in turn may play a central role in the pathogenesis of neuroendocrine tumors (NETs).

Hyperparathyroidism and the associated hypercalcemia have direct bearing on the gastric acid hypersecretory state found in patients with Zollinger–Ellison syndrome and MEN1. Intravenous infusion of calcium in healthy human volunteers induces gastric acid hypersecretion, and calcium has been shown both in vivo and in vitro [70] to stimulate gastrin release directly from gastrinomas. Moreover, gastrinomas express the calcium-sensing receptor [71], thus providing the mechanism by which elevated calcium levels cause gastrin release from these tumors. Indeed, previous reports [72,73] have demonstrated that resolution of hypercalcemia by parathyroidectomy reduces basal acid output (BAO) and fasting serum gastrin concentrations in patients with gastrinoma with MEN1.

One consequence of prolonged hypergastrinemia in patients with Zollinger–Ellison syndrome with MEN1 is the development of primary gastric carcinoid tumors. In a review of data from the National Institutes of Health (NIH), Jensen [74] reported that 13% of patients with Zollinger–Ellison tumors with MEN1 developed gastric carcinoids. Similar tumors have been noted previously in patients with achlorhydria and

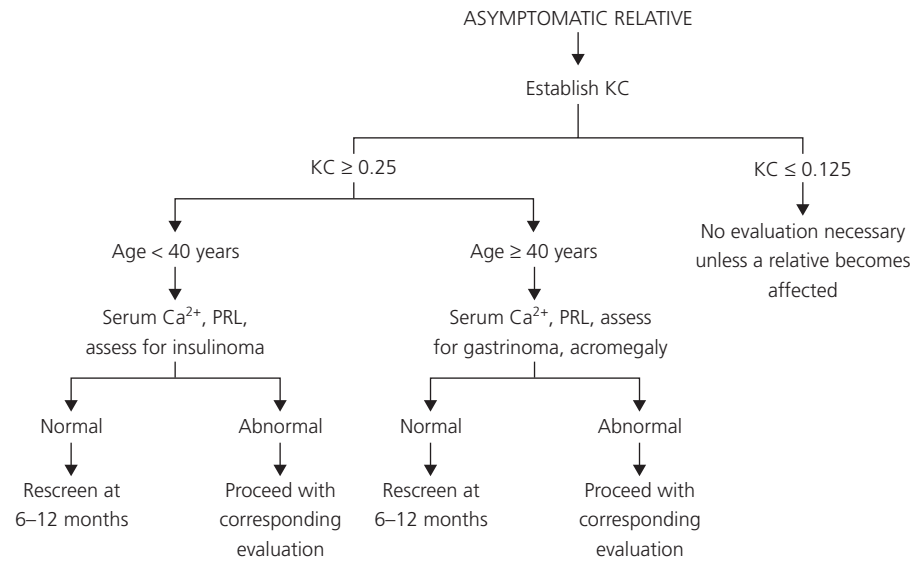

Figure 41.1 Screening protocol for relatives of patients with multiple endocrine neoplasia type 1. KC refers to the coefficient of kinship, in which known affected individuals were assigned a KC of 1.0. Asymptomatic first-degree relatives (siblings, children) were assigned a KC of 0.5, and asymptomatic second-degree relatives (grandchildren, nephews, nieces) were assigned a KC of 0.25. Spouses were also screened and were assigned a KC of 0. Adapted from Trump et al. [62].

hypergastrinemia [75], and in rats made hypochlorhydric and hypergastrinemic with potent antisecretory agents such as omeprazole. These findings presumably arise from the action of gastrin in inducing cellular proliferation. However, gastrin may not be the only cause of the carcinoids, inasmuch as in Jensen's NIH series [74] only 0.6% of patients with sporadic Zollinger–Ellison tumors developed carcinoids. In support of the hypothesis that hypergastrinemia alone is not sufficient to promote the development of gastric carcinoid tumors with enterochromaffin-like cells, it was observed that 75% (15 of 20 patients) of Zollinger–Ellison syndrome-related gastric carcinoid tumors had loss of heterozygosity at the *MEN1* gene locus (11q13) [76]. Therefore, it is postulated that the enterochromaffin-like-cell carcinoid is a tumor type independent of MEN1 but sharing a similar pathogenesis by inactivation of the *MEN1* gene.

Once a secretory endocrine tumor is diagnosed, patients with MEN1 should be evaluated carefully for the presence of other endocrinopathies. A thorough medical and family history must be obtained. Diagnostic studies should include evaluation of visual fields, fasting blood glucose, serum calcium, and prolactin levels. If there is suspicion of a pituitary lesion, a computed tomography (CT) or magnetic resonance imaging (MRI) scan of the head should be considered. The inheritance of MEN1 is autosomal dominant, with a high degree of penetrance. Children of these patients have an approximately 50% risk of developing this disorder by 20 years of age [77]; thus, genetic counseling and screening of family members are imperative. In a study evaluating a large kindred (221 members) of patients with MEN1, elevated albumin-adjusted calcium, parathyroid hormone, gastrin, and prolactin (in girls and women) were the most frequently encountered laboratory abnormalities among presumed carriers of the *MEN1* gene [78]. Trump and colleagues [62] evaluated 709 members of 62 families with MEN1 and developed a screening program based on their observations (Fig. 41.1). The genetic defect in MEN1 can be used to develop predictive testing for this syndrome [66,79,80] and may eventually serve as the basis for informed genetic counseling in families with MEN1.

A consensus statement for genetic screening and follow-up of patients with MEN1 and their family members has been published [81]. These authors recommended that mutation analysis of the *MEN1* gene be performed in patients meeting the following criteria:

- newly diagnosed neuroendocrine tumor typically found in MEN1 (primary hyperparathyroidism, pancreatic endocrine tumor, or pituitary adenoma)
- age less than 40 years
- positive family history
- recurrent or multifocal neoplasia
- involvement of two or more organ systems.

It is also recommended that genetic screening be performed in early adolescence of first-degree relatives of patients with MEN1. Persons carrying the *MEN1* mutation should undergo annual biochemical screening, as outlined earlier.

Differential diagnosis and diagnostic studies

The various clinical circumstances in which a serum gastrin level should be obtained because of a suspected gastrinoma are outlined in Table 41.1. Fasting serum gastrin levels in healthy persons and in patients with routine peptic ulcer disease are usually less than 150 pg/mL [82]. The degree of hypergastrinemia in patients with Zollinger–Ellison syndrome varies greatly. Although occasional reports of normal

Table 41.1 When to obtain a serum gastrin determination in patients with peptic ulcer

Multiple ulcers
Ulcers in unusual locations
Ulcers associated with severe esophagitis
Ulcers resistant to therapy, with frequent recurrences
Ulcer patients awaiting surgery
Extensive family history of peptic ulcer disease
Postoperative ulcer recurrence
Basal hyperchlorhydria
Unexplained diarrhea or steatorrhea
Hypercalcemia
Family history of pancreatic islet, pituitary, or parathyroid tumor
Prominent gastric or duodenal folds

Table 41.2 Hypergastrinemia: differential diagnosis

Hypochlorhydria or achlorhydria with or without pernicious anemia

Massive small bowel resection
Gastric outlet obstruction
Other conditions (rheumatoid arthritis, vitiligo, diabetes, pheochromocytoma)

levels [83,84], and values that vary from day to day [85,86], have been described, virtually all patients with gastrinoma have fasting levels greater than 150 pg/mL, with levels exceeding 100 000 pg/mL in some patients. A serum gastrin level greater than ten times normal is highly suggestive of Zollinger–Ellison syndrome. Two-thirds of patients will have fasting gastrin levels that overlap with levels found in the more common disorders outlined in Table 41.2 [87].

Chromogranin A is a 49-amino-acid glycoprotein constituent of the secretory granules found in many neuroendocrine cells [88], and as such it has been used as a histological and serological marker for neuroendocrine tumors [88–90]. Although serum gastrin and chromogranin A were found to be sensitive indicators for the presence of a gastrinoma, the latter had a relatively low specificity (67%) [90]. Moreover, neither of the markers correlated with tumor growth or extent [91]. It is also important to remember that chromogranin levels may also be elevated in patients with chronic atrophic gastritis (CAG), which is a common disorder in the differential diagnosis for hypergastrinemia. Campana and colleagues examined this issue further by comparing chromogranin A levels in 238 patients with NETs vs 42 patients with CAG and 48 normal volunteers [92]. Although overlap occurred amongst these groups, the highest levels were seen in NET patients. Accordingly, it is necessary to use specific cutoffs to maximize sensitivity and specificity of this marker. It appears that the best cutoff level to distinguish NET patients from normal volunteers was 19 U/L (sensitivity 75.3%; specificity 84.2%). More importantly, it is necessary to use a cutoff of 84–87 U/L to differentiate between NET patients and individuals with elevated chromogranin levels caused by nonneoplastic disorders such as CAG (sensitivity 55%; specificity 95%). This study was, however, performed with one particular commercial assay. There may be variability in results across centers because of the lack of international standardization for the different kits used for measuring chromogranin [48].

With the ever-increasing use of potent antisecretory agents such as long-acting histamine H_2 receptor antagonists and PPIs, drug-induced hypergastrinemia [93] must be excluded before proceeding with an extensive diagnostic evaluation for Zollinger–Ellison syndrome. The level of hypergastrinemia is usually less than 1.5–2 times normal levels and is reversible with drug cessation. Many patients with *Helicobacter pylori* infection and peptic disease develop hypergastrinemia and gastric acid hypersecretion [94], which are reversible with eradication of the organism. The potential for *H. pylori* infection to mimic the clinical and biochemical picture of Zollinger–Ellison syndrome was illustrated in a report [95]; thus, careful search and eradication of *H. pylori* are mandatory in any patient with peptic ulcer disease before one considers a diagnosis of gastrinoma.

The most common cause of hypergastrinemia is gastric atrophy [96]. Gastric acid is the primary inhibitor of gastrin release; therefore, its absence leads to uninhibited secretion of the hormone with concomitant hyperplasia of antral G cells and hypergastrinemia as observed in pernicious anemia [95–99]. Up to 75% of patients with pernicious anemia have substantial hypergastrinemia. The gastrin levels in these patients can approximate those found in patients with gastrinoma, reaching values greater than 1000 pg/mL. Chronic atrophic gastritis and gastric carcinoma are two other conditions associated with hypochlorhydria or achlorhydria and hypergastrinemia. Additional important causes of hypergastrinemia are outlined in Table 41.2.

To differentiate among the many causes of hypergastrinemia, various provocative tests [100–108] have been developed (Table 41.3). The *secretin test*, initially developed by Isenberg and associates [102], has proved to be the easiest and most reliable study to perform. Secretin can induce a significant early (albeit low) increase of serum gastrin levels in a few healthy persons and in patients with common duodenal ulcer disease [107], but rarely in persons with achlorhydria [108]. The mechanism by which secretin stimulates release of gastrin from endocrine neoplasms is unclear [70,109,110].

Although naturally occurring purified porcine secretin is no longer available in the United States, human synthetic secretin has been synthesized and approved by the US Food

Table 41.3 Gastrin provocative testing

Disorder	Calcium infusion	Secretin injection	Test meal
Gastrinoma	Increase in serum gastrin by > 400 pg/mL	Increase is usually > 200 pg/mL	Increase is < 50%
Antral G-cell hyperfunction	May or may not elicit increase in serum gastrin > 400 pg/mL	Decrease, no change, or slight increase in serum gastrin	Increase by > 200%
Common duodenal ulcer	Small increase in serum gastrin	Increase in serum gastrin is < 200 pg/mL	Moderate increase

and Drug Administration for clinical use. A randomized controlled crossover study of six patients with confirmed gastrinoma showed that the synthetic secretin preparations could be used to confirm the presence of a gastrinoma [111]. Based on several studies involving small numbers of patients, various criteria for establishing the positivity of a secretin provocative test have been proposed, including increases in serum gastrin of 100 pg/mL, 200 pg/mL, or 50% above basal levels. Frucht and colleagues [112] observed that the secretin test was positive in 87%–93% of all patients with Zollinger–Ellison syndrome (80 patients) and appeared to be more advantageous than the calcium infusion study (see later) because of its greater sensitivity, shorter sampling time, ease of performance, and lack of side effects. An increase in serum gastrin of 200 pg/mL or greater is highly suggestive of Zollinger–Ellison syndrome. Berna and colleagues [113] reported their results on a prospective study of gastrin provocative testing in 293 gastrinoma patients and compared their findings with the published literature (537 gastrinoma patients and 462 non-gastrinoma patients). They compared secretin stimulation with calcium infusion and meal testing. The authors confirmed the overall value of secretin stimulation above the calcium and meal studies. Secretin stimulation appears to be much more sensitive and specific than calcium infusion (94% vs 62%). Moreover, after a systematic analysis of the sensitivity and specificity of multiple criteria for a positive provocative test (secretin and calcium) the authors observed that a rise in gastrin of 120 pg/mL above baseline after secretin infusion has a sensitivity and specificity of 94% and 100%, respectively.

Calcium infusion study is a less commonly employed provocative test. More than 80% of patients with gastrinoma demonstrate an increase in gastrin levels of more than 395 pg/mL during the third hour of calcium infusion. As outlined earlier, lack of specificity, diminished sensitivity, and the potential adverse effects of administering intravenous calcium have made this provocative test less useful than the secretin test in diagnosing Zollinger–Ellison syndrome. It is usually reserved for patients with a negative secretin test in the presence of gastric acid hypersecretion and a strong clinical suspicion of gastrinoma [112,113]. False negative secretin testing is occasionally observed in a small subgroup of gastrinoma patients. Ding and colleagues suggested that certain gastrinomas expressed an abnormal secretin receptor, leading to a negative response to secretin [114]. Long and colleagues examined this question in 54 patients with Zollinger–Ellison syndrome and concluded that the variation in responsiveness to secretin was more a function of total receptor density than structurally variant receptors [115].

Standard meal studies have been employed to distinguish hypergastrinemia of gastric origin (as in G-cell hyperplasia or hyperfunction) from that of pancreatic origin (gastrinoma) [116]. Patients with Zollinger–Ellison syndrome may have less than a 50% increase in serum gastrin in response to a meal, and a postprandial increase in serum gastrin of more than 100% is characteristic of G-cell hyperplasia or hyperfunction. However, the studies of Frucht and associates [116] suggest that 50% of patients with Zollinger–Ellison syndrome have a greater than 50% postprandial increase in serum gastrin, and work by Berna and colleagues confirm the limited usefulness, if any, of meal testing in the evaluation of patients with hypergastrinemia [113].

The net effect of hypergastrinemia is increased gastric acid secretion; thus, it is not surprising that a BAO of 15 mEq/h or greater is found in as many as 90% of patients with gastrinoma [54,86,117–119]. However, 12% of patients with common duodenal ulcer disease can have similar levels of acid secretion. A BAO of greater than 5 mEq/h is found in 55% of patients with Zollinger–Ellison syndrome after surgery [117]. The widespread use of potent antisecretory agents such as the PPIs complicates the interpretation of acid secretory studies. A study by Corleto and colleagues [9] suggests that the use of PPIs may mask Zollinger–Ellison syndrome, thus leading to delay in establishing this diagnosis. To enhance the sensitivity of the gastric secretory studies, *maximal acid output* (MAO) values may also be measured. Patients with gastrinoma are presumed to have near-maximal secretion of gastric acid even under basal conditions; thus, the acid secretory response to exogenously administered secretagogue (pentagastrin) is diminished. Accordingly, a ratio of BAO to MAO greater than 0.6 is highly suggestive of Zollinger–Ellison syndrome [8], although a ratio of less than 0.6 does not exclude the diagnosis [53,86,117]. Unfortunately, pentagastrin is no longer available in the United States, making measurement of MAO virtually impossible. The other secretagogue used in gastric secretory studies was Histalog,

which has been off the market for several years. Metz and Starr [120] observed that measurement of MAO had a small but significant benefit compared with measuring BAO alone.

There has been controversy over the utility of gastric acid analysis in view of the sensitivity and specificity of serum gastrin values with or without secretin stimulation. Investigators at the NIH performed the most exhaustive analysis to date of the role of gastric secretory studies in Zollinger–Ellison syndrome [121]. They prospectively examined 235 patients and reviewed 984 cases in the literature in an effort to delineate the potential role of gastric secretory studies in the diagnosis, clinical expression, and extent of tumor growth. These authors observed that diarrhea, esophageal stricture, and pyloric scarring were associated with a higher BAO. The level of acid hypersecretion did not appear to correlate with other clinical characteristics including tumor extent or size, primary tumor location, or other signs and symptoms in patients with gastrinoma. A summary of the recommendations made for measurement of gastric acid secretion in patients with Zollinger–Ellison syndrome is presented in Table 41.4. Under optimal circumstances, acid secretory studies should be part of the diagnostic evaluation in patients suspected of having gastrinomas. If the equipment needed for this test is not available, a simple determination of basal gastric pH of greater than 3 essentially rules out the diagnosis of Zollinger–Ellison syndrome. Oh and colleagues have validated a novel endoscopic method of performing gastric analysis [122]. Although the method shows promise, further validation and cost analysis are needed.

In summary, no single diagnostic test has a sensitivity or specificity of 100% in evaluating patients for Zollinger–Ellison syndrome. A fasting gastrin level greater than 10 times normal and a BAO greater than 15 mEq/h in a patient with recalcitrant peptic ulcer is virtually diagnostic of Zollinger–Ellison syndrome. In the absence of this triad of findings, provocative testing may be required. Of these, the secretin stimulation test offers the greatest sensitivity and specificity.

Table 41.4 Recommendations for measurement of gastric acid secretion for the diagnosis of Zollinger–Ellison syndrome[a]

1. Secretory criteria for patients with no prior gastric acid-reducing surgery
1.1 BAO ≥ 15 mEq/h
1.2 BAO ≥ 18 mEq/h, in patients with known sporadic form
1.3 No pH criterion useful for diagnosis
1.4 BAC/MAC ratio ≥ 0.6
1.5 Basal gastric volume > 160 mL/h
1.6 No MAO criterion useful
2. Patients with prior gastric acid-reducing surgery
2.1 BAO ≥ 5 mEq/h
2.2 No pH criteria useful for diagnosis
2.3 BAC/MAC ratio ≥ 0.6
2.4 BAO/MAO ratio > 0.6
2.5 Basal gastric volume > 140 mL/h
2.6 No MAO criterion alone useful
3. In hypergastrinemic patients, if pH > 2, patient rarely has ZES
4. Acid measurements required only for 30 min

a All values refer to acid measurements made by nasogastric secretion with the patient not taking any gastric antisecretory medications (off proton pump inhibitors ≥ 1 week; oral histamine H_2-receptor antagonists ≥ 48 h; intravenous histamine H_2-receptor antagonists ≥ 12 h).
BAC, basal acid H^+ concentration; BAO, basal acid output; MAC, maximal acid H^+ concentration; MAO, maximal acid output; ZES, Zollinger–Ellison syndrome.

Tumor localization

Gastrinomas are notoriously difficult to localize. Case series of patients who eventually underwent surgery for Zollinger–Ellison syndrome before the 1990s noted the inability to identify the tumor in approximately 30%–50% of patients, with more than 20% having metastatic disease at laparotomy [35,123–127]. Subsequent series, perhaps reflecting improvements in preoperative imaging modalities, have localized tumor in 85% of cases, although metastatic disease is frequently present (~50% of patients). Early intervention with resection of a localized tumor presents the only opportunity to cure this disease [127–129]. In addition, preoperative detection of metastatic disease will prevent unnecessary surgery. Accordingly, every effort should be made to localize the tumor preoperatively. A diagnostic plan for localizing gastrinomas in patients with Zollinger–Ellison syndrome is depicted in Fig. 41.2.

Many approaches have been used for the purpose of localizing gastrinomas. These include abdominal ultrasonography [130,131], CT scanning [131–135], abdominal arteriography [136–139], selective portal venous sampling for gastrin [138, 140–143], selective arterial stimulation with secretin (SASI) [144–147], endoscopic ultrasonography (EUS) [148–154], and somatostatin receptor scintigraphy (SRS) with the somatostatin analog octreotide [155–158]. The latest additions to the imaging techniques, SRS and EUS, have emerged as most useful in preoperative staging algorithms (see Fig. 41.2). The sensitivity of these modalities in localizing primary and metastatic gastrinomas is outlined in Table 41.5.

Ultrasonography: transcutaneous, endoscopic, and intraoperative

In general, transcutaneous abdominal ultrasonography is not considered useful for the diagnosis of gastrinomas. Most

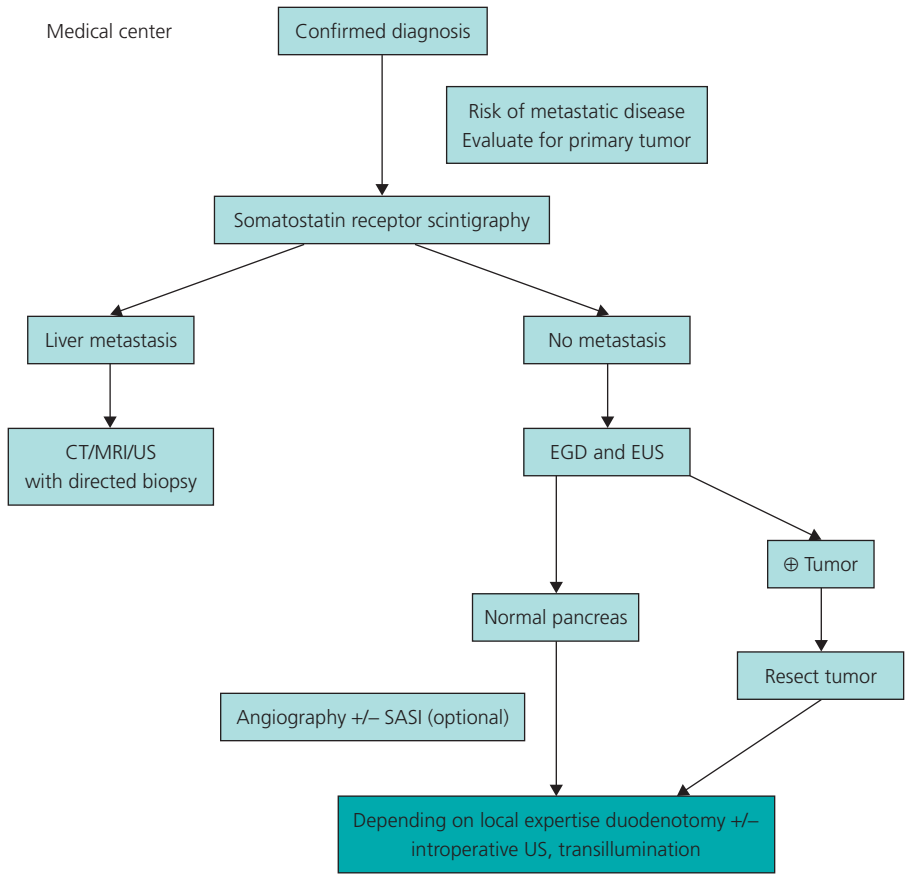

Figure 41.2 Diagnostic plan for localizing gastrinomas in patients with Zollinger–Ellison syndrome. CT, computed tomography; MRI, magnetic resonance imaging; EUS, endoscopic ultrasound; EGD, esophagogastroduodenoscopy; R/O, rule out; SASI, selective arterial secretin stimulation.

gastrinomas are small; therefore, sensitivity of this test is low, as demonstrated in a prospective study [159] in which transcutaneous ultrasonography could localize tumors in only 20% of patients later shown by surgery to have gastrinomas. Nevertheless, if a lesion is seen, it is likely to represent gastrinoma; thus, the specificity of ultrasonography was 90%–100% in this prospective series.

High-resolution imaging of the pancreas has been facilitated by EUS, permitting delineation of structures smaller than 5 mm. Because the accuracy of this procedure in diagnosing small pancreatic carcinomas approaches 100% [160,161] it is not surprising that this diagnostic modality is also useful in localizing small neuroendocrine tumors of the pancreas [148–154]. Rösch and associates [151] examined 37 patients with surgically confirmed endocrine neoplasms of the pancreas (39 tumors), in whom preoperative ultrasonography and CT scan of the abdomen yielded negative findings. Thirty-two of the tumors were diagnosed by EUS (82% sensitivity), with a specificity of 95%. Tumors varied in diameter between 0.5 and 2.5 cm. However, all seven of the gastrinomas

Table 41.5 Sensitivity of imaging studies in Zollinger–Ellison syndrome

	Sensitivity (%)	
Study	**Primary gastrinoma**	**Metastatic gastrinoma**
Ultrasound	21–28	14
Computed tomography	35–59	35–72
Selective angiography	35–68	33–86
Portal venous sampling	70–90	N/A
Selective arterial stimulation of secretin	55–78	41
Magnetic resonance imaging	30–60	71
OctreoScan	67–86	80–100
Endoscopic ultrasound	80–100	N/A

in this series were located in the pancreas, and none was located in extrapancreatic sites, such as the duodenum.

The University of Michigan group used EUS as a primary diagnostic tool to localize neuroendocrine tumors and evaluated more than 82 patients in a prospective study [162]. In their initial prospective study of 16 patients, Thompson and colleagues [153] observed that the sensitivity of a negative EUS result in predicting an extrapancreatic gastrinoma was 100%. Subsequently, their series was expanded to include 75 patients with neuroendocrine tumors with operative confirmation of the EUS findings. In 36 patients with suspected gastrinoma, these investigators confirmed a 100% accuracy in localizing pancreatic lesions and guiding the surgeon to an extrapancreatic primary tumor, findings supporting the contention that EUS was invaluable in the preoperative evaluation of the patient with Zollinger–Ellison syndrome [162]. An early EUS localization strategy was found to be highly cost-effective (and cost-saving) when this group compared this approach with that employed before the introduction of EUS, which primarily used angiographic and venous sampling techniques [163].

The sensitivity of EUS in detecting gastrinomas has been noted by other investigators [154]. In a study of 22 patients with Zollinger–Ellison syndrome, the sensitivity of EUS was 50% for duodenal wall tumors, 75% for pancreatic tumors, and 62.5% for tumor-bearing lymph nodes. These investigators observed that conventional endoscopy had a sensitivity of 40% for detecting duodenal wall lesions; thus, EUS has a small advantage over endoscopy in localizing duodenal wall lesions. Zimmer and colleagues [164] reported a similar experience, with EUS localizing 11 of 14 (79%) of all gastrinomas in 10 patients with Zollinger–Ellison syndrome. Of note, EUS localized 89% of the pancreatic lesions, and the results of conventional endoscopy are not reported. At the University of Michigan, a routine endoscopy (with a pediatric colonoscope) is performed to look for duodenal submucosal tumors, and EUS is primarily used to examine the pancreas. This strategy is based on the findings that EUS has limited value in the detection of duodenal wall lesions, with overall detection rates of 43% [165]. The advent of somatostatin receptor scintigraphy, improved CT/MRI techniques, coupled with the low sensitivity of EUS in finding duodenal wall lesions have led others to recommend the use of EUS in the preoperative evaluation of a patient suspected of having Zollinger–Ellison syndrome (sporadic) only after the octreotide and CT scan have been performed and are negative [165]. A study by Kann et al. indicated that the finding of a pancreatic nodule by EUS in a patient suspected of having neuroendocrine tumor should be interpreted with great caution [166]. In general, it is believed that EUS has greater benefit as part of the preoperative evaluation in patients with MEN1, in view of its ability to map the pancreatic lesions, which are often multiple in this subgroup of patients [167].

Other centers without EUS experience have reported the utility of intraoperative ultrasonography, which appears to be useful in the localization of small gastrinomas [168–170]. Tumors not detected by the surgeon through manual inspection may be imaged using this technique, which can achieve a sensitivity of 95% in the hands of experienced operators [170].

Intraoperative transillumination

Frucht and associates [171] prospectively examined the efficacy of intraoperative endoscopic transillumination for detecting duodenal gastrinomas in 26 patients. These investigators detected duodenal gastrinomas with 83% sensitivity, which compares well with the sensitivity of the combined preoperative studies (25%) or intraoperative ultrasonography and surgical palpation (42%). This technique remains part of surgical protocols for the management of Zollinger–Ellison syndrome [37].

Computed tomography

The diagnostic accuracy of CT scanning reflects continued innovation in techniques and instrumentation. A prospective study [135] examined the value of CT in localizing tumors in 61 consecutive patients with gastrinoma. For extrahepatic gastrinoma, CT scanning with intravenous contrast had a specificity of 95%, a sensitivity of 59%, a positive predictive value of 96%, and a negative predictive value of 54%. For gastrinomas metastatic to liver, CT scanning had a specificity of 98%, a sensitivity of 72%, a positive predictive value of 93%, and a negative predictive value of 90%. Tumor size and location appear to be the key determinants in the successful diagnosis of gastrinoma by CT scanning. Approximately 80% of tumors in the pancreas and tumors larger than 3 cm are detected. Only 40% of extrapancreatic lesions and no tumors measuring less than 1 cm in diameter are detectable by CT scanning. The sensitivity and specificity of CT do not appear to be enhanced by performing dynamic studies. Whether helical techniques have led to improved sensitivity remains uncertain, although one study (requiring further comparative study) has reported 82% sensitivity for tumor localization [172].

A study by Panzuto and colleagues suggests that helical CT was more sensitive than OctreoScan for detecting duodenal lesions [173], but this result requires confirmation.

Angiography

Diagnostic innovations have limited angiography to selected patients for whom imaging by SRS or EUS has proved unsuccessful. Maton and colleagues [139] prospectively examined the role of selective angiography in the diagnosis of 20 consecutive patients with gastrinoma. For hepatic gastrinoma, angiography had a specificity of 100% and a sensitivity of 86%, with a positive predictive value of 97% and a negative predictive value of 53%. In combination with CT scanning,

100% of the hepatic tumors were detected. Extrahepatic lesions were not as easily detected, inasmuch as CT scanning detected only 57%, angiography 70%, and the combination 73%, with a false-positive rate of 7%. This study suggests that after a CT scan, selective abdominal angiography will detect an additional 28% of patients with liver lesions and an incremental 16% of patients with extrahepatic tumors. Unfortunately, 24% of the extrahepatic lesions will be missed even when both tests are used. Nevertheless, angiography was found to be a useful adjunct to CT scanning in patients with Zollinger–Ellison syndrome who undergo surgery. This same group [174] subsequently reported less enthusiastic experience with CT (31% sensitivity for primary tumors, 42% for liver lesions) and angiography (28% and 62%, respectively). The reduced sensitivity likely reflects both increased numbers of patients referred with negative outside CT scans and angiograms and the ability of newer imaging modalities such as SRS to detect small lesions that would have been missed in the past.

Portal venous sampling

Before SRS and EUS, under the best circumstances the combination of ultrasonography, CT scanning, and angiography failed to localize tumors in up to 50% of the patients with biochemical evidence of Zollinger–Ellison syndrome. Thus, percutaneous transhepatic selective portal venous sampling for gastrin was developed as a means to improve the diagnostic yield [138,140–143]. There is general agreement on the relative sensitivity of this test in identifying the presence of gastrinomas (70%–90%), but considerable debate over its specificity, with values ranging from 33% to 90%, depending on the series. Despite the potential usefulness of the selective venous sampling technique, its complexity and invasiveness limit its availability to only a few specialized centers, where it has largely been replaced by selective arterial secretin injection (SASI); thus, it is not recommended for the evaluation of Zollinger–Ellison syndrome on a routine basis.

Selective arterial secretin injection (SASI)

Selective arterial secretin injection (SASI) has been added to the growing list of modalities used for localizing gastrinomas [145–148]. As initially described by Imamura and colleagues [144], secretin (30 U) is injected selectively into the celiac, proximal splenic, gastroduodenal, proper hepatic, and superior mesenteric arteries, and blood samples for gastrin measurement are obtained simultaneously from the hepatic vein at short intervals (30, 60, 120, and 210 seconds). Given the results of emerging imaging modalities such as EUS and SRS, it appears that SASI will be employed infrequently and will be most helpful when imaging data are conflicting [175].

Magnetic resonance imaging (MRI)

Magnetic resonance imaging [176,177] has been evaluated for the detection of both primary and metastatic gastrinoma, and initial results appear similar to those of CT scanning. In a prospective study, the NIH group found that MRI, using short-time inversion-inversion recovery sequences, was superior to CT for the detection of liver metastases (sensitivity 71% vs 42%). In the detection of primary lesions MRI was equivalent to CT, leading this group to suggest that it should replace CT as the cross-sectional imaging test of choice. For most medical centers the choice between CT and MRI for detecting liver metastases depends on the availability and local expertise. There might be instances where CT and MRI can be complementary in the evaluation of a patient with positron emission tomography (PET) [178]. For example, MRI may be used to confirm a finding noted on CT scan.

Somatostatin receptor scintigraphy (SRS)

Many gastrinomas express somatostatin receptors. Therefore, targeted nuclear scanning after injection of an isotopic analogue of somatostatin – either ^{123}I-labeled Tyr3-octreotide (Tyr3, tyrosine 3) or ^{111}In-labeled diethylenetriamine pentaacetic acid-Dphe^{1}-octreotide (Dphe^{1}, D-phenylalanine-1) [155–158,164,174,179] – has emerged as a readily available, noninvasive test to localize gastrinomas, with sensitivity and specificity of greater than 75%. The indium analogue (^{111}In-pentetreotide) is marketed as OctreoScan 111 (Mallinckrodt, St Louis, MO). In prospective studies [177], the NIH group found that the scan was more sensitive than transcutaneous ultrasonography, CT, MRI, and angiography for localizing both primary and metastatic lesions, with a sensitivity of 58% and 92%, respectively. The efficacy of EUS and SASI was not directly compared with SRS with regard to the ability to localize primary lesions. Cadiot and colleagues [179] observed that OctreoScan 111 scintigraphy was useful in detecting small duodenal lesions (3 mm) and peripancreatic lymph nodes. It also appears that the addition of single photon emission computed tomography (SPECT) enhances the sensitivity of OctreoScan over planar imaging [180,181]. In a review of 122 patients who underwent SRS to localize primary and metastatic gastrinoma lesions, the NIH group noted that SRS altered management in 47% of patients, with its greatest impact in the detection of liver metastases [182]. These investigators concluded that SRS should become the initial imaging modality for patients with gastrinoma. However, it should be noted that a study examining 64 patients for metastatic NET to the liver using a MRI, CT scan and OctreoScan suggested MRI was superior to CT scan and somatostatin scintigraphy [183]. However, a number of issues may compromise the validity of this observation: (i) only a small number of the patients evaluated had elevated gastrin levels (1/64); and (ii) 12 of the patients studied had been treated with somatostatin analogue, which may in turn have led to a false-negative OctreoScan, although this latter issue is somewhat controversial. Therefore, based on the available literature, it remains reasonable to consider somatostatin scintigraphy as the most sensitive imaging modality

for detecting metastatic gastrinomas. Among patients undergoing surgery for cure at the NIH, SRS was the most accurate preoperative imaging study, yet it still missed one-third of all lesions found at surgery [184]. The ability of SRS to detect tumors was related to size, because only 30% of tumors 1.1 cm or smaller were imaged, compared with 64% of those 1.1–2.2 cm and 96% of those larger than 2 cm. Duodenal primary tumors were most commonly missed by SRS. Because of these shortcomings, OctreoScan does not seem to change surgical cure rates [165]. This same group also noted the limitations of SRS with regard to specificity; false-positive results occurred in up to 10% of cases [185]. Knowledge of the clinical situations leading to false-positive results is essential for optimal interpretation of the OctreoScan 111 technique.

Novel nuclear imaging modalities based on positron emission tomography (PET) are being explored in the evaluation of patients with NETs in general [186]. This is based on the observation that most neuroendocrine cells have the ability to take up amine precursors and decarboxylate them (i.e., amine precursor uptake and decarboxylation, or APUD, cells). The ^{18}F and ^{11}C-labeled amine precursor L-dihydroxyphenylalanine and 5-hydroxy-L-tryptophan (5-HTP) have been used for PET imaging of NETs. Early studies suggest that ^{11}C-labeled 5-HTP-PET is promising for the detection of NETs, but studies with gastrinomas are needed.

In summary, surgical cure of Zollinger–Ellison syndrome requires accurate tumor localization. To avoid unnecessary laparotomy, OctreoScan 111 in combination with CT or MRI should be used to exclude metastatic disease. If no metastatic disease is found, the approach to localize disease in the peripancreatic region is governed by local expertise and surgical experience. Endoscopic ultrasonography (with upper gastrointestinal endoscopy to evaluate for duodenal tumors) appears to be the most cost-effective modality to evaluate the pancreas and duodenum, whereas SASI remains an alternative if EUS is not available. Occult metastasis can also be detected using SASI, which may assist in the interpretation of equivocal examinations. In other medical centers, the endocrine surgeon may go directly to exploration with intraoperative ultrasonography or transillumination. In the management of Zollinger–Ellison syndrome, it is clear that a team approach to localization and surgical exploration is essential to ensure curative resection.

Therapy

When considering the therapy of patients with Zollinger–Ellison syndrome, it is important to entertain two objectives: control of gastric acid hypersecretion and treatment of the malignant neoplasm. The emphasis placed on each of these objectives has shifted since the 1970s. Initially, total gastrectomy seemed the only option for effective treatment of the potentially lethal ulcer disease, and less attention was directed at tumor excision because many of these patients died of ulcer complications long before their tumors became problematic. The availability of highly effective antisecretory therapy such as histamine H_2 blockers and H^+,K^+-ATPase antagonists led to a significant reduction in mortality related to the complication of acid peptic disease. The major cause of morbidity and mortality in Zollinger–Ellison syndrome is widespread metastatic disease [187]; thus, early tumor detection and excision have assumed primary importance.

Medical therapy

The primary aim of medical therapy in Zollinger–Ellison syndrome is control of gastric acid hypersecretion. The development of histamine H_2-receptor antagonists was a major breakthrough toward this aim. Cimetidine, the first of these agents, proved efficacious in controlling acid hypersecretion and prompted ulcer healing and symptom improvement in more than 80% of patients with Zollinger–Ellison syndrome treated on a short-term basis [188]. However, over a longer term, these patients often required progressive increases in the frequency and dose of medication. Although H_2-receptor antagonists with greater potency and duration of action have been useful in treating patients with gastrinoma [189–191], an important newer class of drugs made available for the treatment of Zollinger–Ellison syndrome are the proton pump inhibitors (PPIs), of which omeprazole was the first of its class [192]. The efficacy of these agents in inhibiting acid secretion, relieving dyspeptic symptoms, and promoting ulcer healing in patients with gastrinoma has been established [193–196].

Although earlier studies suggested that the doses of omeprazole required for effective inhibition of acid secretion in patients with gastrinoma were significantly higher than in patients with standard peptic ulcers (Table 41.6), a study by Metz and associates [197] suggests that the recommended maintenance dose of omeprazole (~ 60 mg/day) used in these patients is too high. Accordingly, a gradual reduction of omeprazole dose is recommended once the initial dose required for adequate control of gastric acid hypersecretion (as described earlier) has been achieved. The NIH group has

Table 41.6 Median dose of antisecretory agents used in patients with gastrinoma

Agent	Median doses g/day (range)
H_2-receptor antagonists	
Cimetidine	3.6 (1.2–12.6)
Ranitidine	1.2 (0.45–6)
Famotidine	0.25 (0.05–0.8)
H^+,K^+-ATPase inhibitors	
Omeprazole	60 mg/day
Lansoprazole	60–90 mg/day

prospectively examined the effectiveness of low doses of omeprazole (20 mg/day) as initial therapy in patients with gastrinoma [198], and based on their results, the investigators continue to recommend initiating omeprazole therapy at a dose of 60 mg/day. This dose allows rapid control of gastric acid secretion, thus minimizing complications related to peptic diathesis. Once an adequate maintenance dose is achieved, tapering the medication is then indicated while following symptoms and acid output. Lansoprazole has also been found to be safe and effective in the treatment, for up to 10 years, of patients with gastrinoma [196]. Tachyphylaxis is observed less frequently with PPIs than with H_2-receptor antagonists. One concern with long-term omeprazole therapy has been its potential for inducing enterochromaffin cell hyperplasia. A prospective study following 40 patients with Zollinger–Ellison syndrome who were treated with omeprazole for a mean of 29 months (6–51 months) reported no evidence of hematological, biochemical, or gastric toxicity [199,200]. Their marked potency, prolonged duration of action, and safety profile make PPIs the treatment of choice for peptic disease in patients with Zollinger–Ellison syndrome. However, long-term hypochlorhydria or achlorhydria may lead to vitamin B-12 and iron deficiency, thus these micronutrients should be monitored in patients on long-term PPIs. The intravenous formulation of pantoprazole has become available and appears to be effective in the treatment of patients with Zollinger–Ellison syndrome [201].

Somatostatin is a known peptide inhibitor of gastric acid secretion [202] and gastrin release [203]. The two biochemically stable analogues of somatostatin in clinical use are octreotide and lanreotide. The former has been used with varying success in patients with gastrinomas [204–206]. At present, however, these compounds are available only in injectable form; thus, they are rarely used as first-line agents in the treatment of patients with Zollinger–Ellison syndrome, especially considering the overall efficacy of PPIs in this group of patients. The long-acting depot formulation of octreotide has become available and shown in preliminary studies to be beneficial in the treatment of neuroendocrine tumors of the gut [207]. Future studies will clarify the role of these compounds in the therapy of patients with gastrinoma. Side effects from somatostatin analogues are mild and usually include bloating, abdominal discomfort, and mild steatorrhea, all of which tend to subside within the first several weeks of therapy [208].

Surgical therapy

Before the advent of potent antisecretory agents, total gastrectomy was the treatment of choice in patients with gastrinoma. Although initial operative mortality was high (15%–20%) [209], total gastrectomy offered better long-term survival than more conservative approaches [11]. Increased experience and earlier diagnostic testing have reduced the operative mortality rate associated with total gastrectomy to less than 5% [210]. Nevertheless, the newer gastric antisecretory agents have greatly reduced the need for total gastrectomy, and at present this procedure should be considered only in the rare patient with nonresectable gastrinoma in whom aggressive medical therapy has failed or in those patients who cannot take oral medications.

Another operation applied in the past as an adjunct to medical therapy in patients with Zollinger–Ellison syndrome is proximal gastric vagotomy [211,212]. The rationale for this operation was the high failure rate with H_2-receptor antagonists. The advent of PPIs may obviate the need for the routine use of this procedure although some still advocate parietal cell vagotomy as part of the surgical approach in an individual who is being considered for surgical cure [165].

As discussed earlier in this chapter, the hypercalcemia found in patients with MEN1 may be associated with a gastric acid hypersecretory state that is refractory to medical therapy. A report [213] demonstrated that in addition to lowering both BAO and fasting hypergastrinemia, parathyroidectomy facilitates the management of peptic disease with H_2-receptor antagonists. Although the availability of H^+,K^+-ATPase inhibitors may make this operation unnecessary, parathyroidectomy may be a surgical option for treatment of patients with gastrinoma with MEN1 and hyperparathyroidism who are refractory to medical management.

Clearly, the appropriate surgical approach for therapy of Zollinger–Ellison syndrome is curative resection of the neoplasm. Although initial series reported a cure rate of less than 10% after tumor resection, present data indicate that cure may be possible in as many as 30% of cases. Norton and colleagues [36] published the largest experience of surgical intervention in patients with gastrinoma. This group followed 151 consecutive patients (123 with sporadic cases, 28 with MEN1) who underwent surgery between 1981 and 1998. Thirty-four percent of patients with sporadic gastrinoma were free of disease at 10 years. Unfortunately, none of the patients with MEN1 was disease free at the 10-year mark. Moreover, the overall 10-year survival observed in these patients was 94%. This same group reported a more extensive follow-up on 160 patients with Zollinger–Ellison syndrome (sporadic and MEN1) who underwent surgery, and the disease-free survival at 15 years was 98% [214]. These authors concluded that all patients with Zollinger–Ellison syndrome who do not have metastatic disease or MEN1 should be offered surgical intervention for possible cure. Improved diagnostic capabilities have led not only to a reduction in unnecessary surgery on patients with metastatic disease, but also to the identification of extrapancreatic neoplasms with increasing frequency [33,34,126,127,213–217]. Studies have reported the incidence of extrapancreatic lesions to be as high as 66% and resection of these lesions is associated with a high likelihood of long-term cure [125,218].

Patients with gastrinoma with MEN1 represent a particularly difficult problem to the surgeon. Because of the

multicentric nature and extrapancreatic location of tumors in MEN1 syndrome [219–224], curative resection is virtually impossible [142,187,210,225,226]. Moreover, studies suggest that the vast majority of gastrinomas in MEN1 patients are localized in the duodenum, which may impact the surgical approach in these patients [37]. Some surgeons advocate an aggressive approach whereby all patients without evidence of hepatic metastasis are explored, with removal of all duodenal lesions found by duodenotomy, enucleation of all tumors found in the head of the pancreas, and distal pancreatectomy [221,224]. The rationale for this approach is to effect a potential cure and, failing that, to prevent the development of future pancreatic neoplasms. The value of such an aggressive approach remains to be established. If a single tumor is found during the preoperative evaluation, an attempt at surgical resection should be undertaken [227] because larger tumors may be associated with a greater likelihood of metastasis. The role of surgery in patients with gastrinoma and MEN1 was explored in 81 consecutive patients [228]. All patients with limited disease (single tumor between 2.5 and 6 cm, $n = 17$) and advanced disease (two or more lesions > 6 cm, $n = 31$) underwent exploratory laparotomy with tumor enucleation or resection. Patients with tumors smaller than 2.5 cm ($n = 17$) and those with liver metastases ($n = 8$) were observed. Approximately 40% of patients had advanced disease without metastases. Duodenal lesions were found in 80% of patients with Zollinger–Ellison syndrome and MEN1. The authors observed that tumors could be removed in patients with advanced disease with no mortality and a complication rate similar to that observed in patients with limited disease. An additional important observation was that patients with advanced tumor who underwent resection had the same survival rate as patients with limited disease and those without identifiable tumor. As a group (nonresected and resected), 15-year survival was between 89% and 100%, whereas for patients with metastatic disease, it was only 52%. The authors of this study concluded that surgical resection should be performed in patients with gastrinoma and MEN1, even with advanced localized disease. This study, however, did not address the ideal type of operation for this group of patients. Although a subgroup of patients with gastrinoma may follow an aggressive course warranting a Whipple procedure, the tools to predict this subgroup of patients have not been developed (see later). Work by Bartsch and colleagues supports a more aggressive approach in which surgery should be provided for patients with MEN1 and pancreatic endocrine tumors greater than 1 cm without evidence of distant metastasis [229]. They examined 26 genetically confirmed MEN1 patients, 11 of whom had Zollinger–Ellison syndrome. After a median of 83 months, 7/11 patients with Zollinger–Ellison syndrome were biochemically cured. This group noted that the procedure of choice is a pylorus-sparing pancreaticoduodenectomy. A subsequent study by Tonelli and colleagues also supports the notion that a more aggressive surgical approach in MEN1 patients is warranted, adding intraoperative gastrin measurement as a tool to assess surgical cure [230].

Although laparoscopic sugery has been used successfully by some in resecting certain NETs, such as insulinoma, the experience with gastrinomas is limited. Moreover, because many gastrinomas are within the duodenum and these lesions tend to be more advanced, a laparoscopic approach is not recommended in Zollinger–Ellison syndrome patients [165].

Operative management of Zollinger–Ellison syndrome requires careful and detailed mobilization and exploration of the entire pancreas and duodenum (duodenotomy) and surrounding areas [217,221,224]. Any tumors found in the region of the pancreatic head should be enucleated, and tumors located elsewhere should be resected with great care. If a tumor is not found at surgery, distal pancreatectomy should be avoided because more than 80% of the gastrinomas are located within the gastrinoma triangle [33]. If a lesion is found in the head of the pancreas, a Whipple procedure should be considered, albeit with great care because the mortality of this surgical procedure may outweigh its potential benefits. Nevertheless, in some cases the Whipple procedure may be the only option if complete tumor excision is not possible by a less invasive procedure [231].

Pisegna and colleagues [232] examined the effects of curative gastrinoma resection on gastric secretory function. They observed that the trophic effects of long-standing hypergastrinemia are largely reversible within a short period, with a 50% and 75% decrease in MAO and BAO, respectively, within 3–6 months after curative resection. However, these observations also indicate that acid secretion must be monitored even after curative resection because as many as 55% of patients at 3–6 months and up to 67% at 4 years after gastrinoma resection remained mild hypersecretors requiring low doses of antisecretory drug.

Therapy for metastatic gastrinoma

Metastatic disease occurs in 25%–40% of patients with gastrinoma and is the most common source of morbidity and mortality in this disease. One major difficulty in evaluating the effectiveness of the various therapeutic regimens is that most clinical trials have involved small numbers of patients. The overall value of chemotherapy in gastrinomas and NETs in general remains somewhat controversial. Cytotoxic chemotherapy has been of limited usefulness in Zollinger–Ellison syndrome, because gastrinomas are less responsive than the other pancreatic NETs examined [233]. Combined treatment with streptozotocin, 5-fluorouracil (5-FU), and doxorubicin (adriamycin) has provided the most promising results. In one series of 42 patients with metastatic islet tumors of various types [234], initial response rates of 63% and complete response rates of 33% were reported with this regimen. However, gastrinomas comprised a small percentage of the cases studied, and the response to chemotherapy

may vary according to the cell type of the tumor. In another study using a similar treatment regimen, Bonfils and colleagues [235] reported the disappearance of the gastrinoma, as assessed by imaging studies, in 20% of their patients with Zollinger–Ellison syndrome with metastatic tumors. Other agents evaluated in a limited number of patients include cisplatin/etoposide and temozolomide [233].

These encouraging results of earlier studies were not confirmed in later trials. A prospective study [236] by the investigators at the NIH provided a sobering perspective on treatment of metastatic gastrinoma with chemotherapy. Ten consecutive patients with gastrinomas were treated with a regimen of streptozotocin, 5-FU, and doxorubicin, and although a modest objective response was observed initially in four patients, the response lasted for less than 10 months. All the patients were considered as treatment failures thereafter, with no significant change in short-term survival, and experienced many side effects of the therapy, including nausea and vomiting (100%), alopecia (80%), proteinuria (40%), and leukemia (20%). At 10 months after initiation of therapy, all patients had evidence of tumor growth over the preceding 6 months. The question when to treat patients having metastatic gastrinoma with chemotherapy remains unanswered. Although an occasional patient with metastatic disease may survive up to 20 years, it appears that most will die within 5 years. Two approaches to treating these patients are to begin chemotherapy when the patient is symptomatic [234], or to reassess the patient 3–6 months after initial presentation and to use chemotherapy if the metastases are increasing in size [237]. Both approaches are based on studies mostly involving relatively small numbers of patients; thus, additional data are needed before firm recommendations can be given.

In view of the limited success of chemotherapy in the treatment of metastatic gastrinomas and neuroendocrine tumors of the pancreas in general (see Chapter 000), alternative therapeutic modalities have been explored. As in the case of assessing the value of chemotherapy in patients with gastrinoma, the rarity of the disease coupled with the heterogeneous group of patients studied and the variable natural history of these malignancies make the available data somewhat difficult to interpret.

Therapy with biological agents such as the stable somatostatin analogues octreotide and lanreotide has been attempted in metastatic gastrinoma [238,239]. Although early reports suggested a significant decrease in tumor size in response to octreotide [240], subsequent studies have not been as encouraging [241,242]. Tumor stabilization may be achievable in some of the NETs, but this is unclear in the case of patients with gastrinoma.

A novel and exciting therapeutic alternative for the treatment of neuroendocrine tumors is peptide receptor radionuclide therapy [243,244]. Therapy with radiolabeled somatostatin analogues appears promising, because many NETs express a high density of somatostatin receptors (predominantly subtype 2). Several nuclides being explored with some success include indium-111, yttrium-90, and lutetium-177. Early reports have demonstrated an approximate 25% rate of tumor shrinkage of greater than 50% in a heterogeneous group of tumor types. Although this option is in the early stages of development, future studies may prove it beneficial for patients with metastatic disease.

Leukocyte interferon is another biological agent that also has been used in the therapy of neuroendocrine tumors with reported success [245,246]. Unfortunately, these encouraging results were not observed by Pisegna and associates [247] after examining the effect of human recombinant interferon-α in patients with Zollinger–Ellison syndrome. Smaller trials examining the efficacy of combining interferon with octreotide or 5-FU have been published [208,248,249], but the limited number of patients evaluated makes these data difficult to interpret. In addition, there was a substantial increase in drug toxicity when interferon was combined with 5-FU, making it a less desirable treatment option [208,249].

Vascular occlusive therapy (hepatic artery embolization [HAE] with particles and chemoembolization [HACE]) of metastatic NETs to the liver is based on the principle that these lesions receive the majority of their blood supply from the hepatic artery. By contrast, normal hepatic tissue receives its blood supply mainly from the portal vein. Ruszniewski and associates [250] examined the efficacy of chemoembolization with doxorubicin in 24 patients with metastatic tumors (five patients with gastrinoma), and tumor stabilization was observed in three patients. Subsequently, Gupta and colleagues performed a retrospective analysis comparing HAE and HACE in 69 patients with metastatic carcinoid tumor and 54 patients with metastatic NETs of the pancreas (nine gastrinomas) [251]. The authors observed that carcinoid patients did better overall and that, in addition, they appeared to have a better response to HAE compared with NET patients (who had a better outcome with HACE), with initial response rates of 67% and 35%, respectively, and overall median survival of 34 months and 23 months. Attempts at combination therapy have also produced marginal results. Moertel and colleagues [252] treated 111 patients (with carcinoid and pancreatic endocrine tumors) with systemic chemotherapy in addition to chemoembolization, and achieved an overall response rate of 80%. In view of the limited data available in patients with gastrinoma and the potential complications (10%–17%) related to HAE and HACE, including abdominal pain, fever, nausea, and even death (< 5%) [253,254], these treatment modalities should be reserved for treatment-refractory patients until further data are available.

Several other ablative treatments have been examined to a limited extent in patients with metastatic NETs. These include percutaneous ethanol injection, cryotherapy, and radiofrequency ablation [255–261]. Although initial reports

suggest these treatment options may be promising, more data are needed.

Aggressive surgical resection (debulking) [165,262–265] has been performed successfully, with 5-year survival achieved in more than 75% of patients whose tumors were amenable to complete resection [263]. Elias and colleagues reviewed their experience in 47 patients who underwent aggressive resection with intent to cure and observed that resection was curative in only 53% of the patients, despite having removed as much as 97% of tumor in each of the patients [265]. Morbidity and mortality for surgery were 45% and 5%, respectively, and median survival was 91 months, with overall survival rates at 5 and 10 years being 71% and 35%, respectively. These authors concluded that surgery for liver metastases from well-differentiated endocrine neoplasms is indicated when all visible intrahepatic and extrahepatic lesions can be resected safely. These data suggest a potential benefit of an aggressive surgical approach, and some advocate this approach in patients in whom at least 90% of the tumor can be resected based on imaging studies [165].

Orthotopic liver transplantation also has been attempted as a therapeutic option in patients with hepatic metastases. The finding that these tumors are slow growing and are often unresponsive to aggressive medical management has served as the driving force behind this treatment modality [266–268]. Unfortunately, the 4-year survival rate in patients with pancreatic neuroendocrine tumors following liver transplantation was only 8% in the largest sample of patients examined [268]. Thus, orthotopic liver transplantation is not an attractive option for these unfortunate patients.

Despite the strides made in the therapy of these rare neoplasms, the treatment of recurrent or metastatic disease leaves much to be desired. Better understanding of the basic molecular and cell biology of these rare tumors may offer new therapeutic options. Studies have demonstrated the biological importance of angiogenesis and angiogenic growth factors such as vascular endothelial growth factor (VEGF) and its receptor, insulin-like growth factor 1 (IGF-1) and its receptor, the platelet-derived growth factor receptor (PDGFR), epidermal growth factor receptor (EGFR), and the mammalian target of rapamycin (mTOR) signaling pathways. Phase II–III clinical studies in patients with NETs of agents that target various of these pathways have shown initial promising results for bevacizumab (VEGF monoclonal antibody) and everolimus (mTOR inhibitor) [269]. Larger-scale studies focusing on the use of these agents in the treatment of different subtypes of NETs are pending.

Prognosis

Zollinger–Ellison tumors can be classified as either benign or malignant [35,270] based on a series of clinical characteristics. Of these characteristics, tumor extent and rate of tumor growth are the most important prognostic indicators for patients with gastrinoma. As reviewed by Maton and colleagues [227], 5-year survival rates for all patients with gastrinoma vary between 62% and 75%, and 10-year survival rates vary between 47% and 53%. If one segregates the survival data according to extent of tumor at the time of diagnosis, patients who have a negative laparotomy or who have all their tumor removed surgically have 5- and 10-year survival rates greater than 90%. By contrast, patients with tumors that were incompletely resected have 5- and 10-year survival rates of 43% and 25%, respectively. Weber and associates [35] critically evaluated 185 consecutive patients with Zollinger–Ellison syndrome and identified the criteria that determined metastatic rate and survival in these patients. These investigators confirmed that both benign and malignant categories of gastrinomas exist. The overall 10-year survival rates were 93% for patients with MEN1 and 74% for patients without MEN1, somewhat better than rates reported previously [227], but similar to results reported by Eriksson and colleagues [271]. It was also found by these investigators that there was no difference in survival for the following groups of patients: those rendered disease free at surgery; those with residual tumor after surgery; and those with disease and negative exploratory laparotomy results. A poor clinical outcome is seen in female patients, in patients without MEN1, in patients with high serum gastrin levels, in patients with a large pancreatic tumor, and in patients with hepatic metastasis.

A detailed prospective analysis of the clinical course of 212 patients with Zollinger–Ellison syndrome [272] observed for a mean period of 15 years (range 0.1–31 years) was published. Thirty-two percent of patients died (none of acid-related complications); 50% of them had gastrinoma-related causes of death, which are outlined in Table 41.7, with the most common being progressive cachexia associated with hepatic metastases (67%). Gastrinoma-related causes of death were more commonly observed in patients with the following characteristics: shorter disease duration; higher gastrin levels; pancreatic primary and large tumor; metastatic disease to lymph nodes, liver, or bones; and ectopic Cushing

Table 41.7 Causes of death related to Zollinger–Ellison syndrome

Cause of death	Number	Percentage
Liver metastases with progressive inanition	22	67
Secondary PET syndrome	10	30
Liver metastases causing hepatic failure	4	12
Tumor-related embolism	2	6
Postoperative complications	1	3
Cardiac gastrinoma with arrhythmia	1	3

PET, pancreatic endocrine tumor.

syndrome. When considering patients with hepatic metastases, tumor-related Cushing syndrome and development of metastases to bone were independent predictors of decreased survival time (Fig. 41.3). Besides the extent of hepatic metastases, the rate at which they developed was an independent indicator of poor prognosis. From this and other studies [35], it appears that roughly 25% of patients with gastrinoma follow an aggressive pattern, with 10-year survival approaching 30%, whereas the remaining patients follow a more indolent course, with a 10-year survival of 95%.

Gibril and colleagues [273] performed a similar type of prospective study on the natural history of gastrinoma in 57 patients with MEN1. These patients were followed-up for a mean period of 8 years, with 23% having or developing liver metastases and 14% having a tumor with aggressive growth, defined as tumor growth of 25% volume increase or more per month or the appearance of any new lesion. In terms of survival, 5% of the study group, 23% of patients with hepatic metastases, and 38% of patients with aggressive tumor growth died during the study period. Factors predictive of aggressive gastrinoma growth were identified by the authors and are summarized in Table 41.8. Ultimately, further elucidation of the molecular determinants important in tumor development in MEN1 coupled with recognition of clinical features predictive of poor outcome may allow earlier identification and intervention in patients prone to developing aggressive disease.

Table 41.8 Factors predictive of aggressive growth of gastrinomas in patients with multiple endocrine neoplasia type 1

Clinical
Age at MEN1 diagnosis (years) < 35 ($P = 0.021$)
Age at ZES onset (years) ≤ 27 ($P = 0.043$)
Age at ZES diagnosis (years) ≤ 33 ($P = 0.032$)
Duration of ZES before diagnosis (years) < 2.1 ($P = 0.021$)
Laboratory
Fasting gastrin levels ≥ 10 000 pg/mL ($P < 0.0001$)
Tumor characteristics
Pancreatic tumor size > 3 cm ($P < 0.0001$)[a]
Presence of liver metastases ($P < 0.00001$)
Presence of bone metastases ($P = 0.0019$)
Presence of gastric carcinoid ($P = 0.024$)

a Data from 41 patients who underwent abdominal exploration.
MEN1, multiple endocrine neoplasia type 1; ZES, Zollinger–Ellison syndrome.

Advances in elucidating the molecular makeup or fingerprint of gastrinomas, and NETs of the gut in general, will lead to further insights into predicting not only the clinical outcome of tumor types but also potentially shed light on

optimization of treatment for these often refractory neoplasms once they are metastatic. Modern molecular tools have begun to help in this regard. For example, studies using surgically resected specimens suggest that genetic alterations accumulate during malignant transformation [274]. Specific changes noted include the loss of chromosome 1 and 11q and gain of 9q early in pancreatic endocrine tumor development, which occur with smaller more indolent tumors. By contrast, loss of chromosomal arms 3p, 6pq, and 10pq, and gains of 5q, 12q, 18q, and 20q occur with the development of a malignant phenotype [275–277]. The utilization of EUS-guided sampling of these lesions combined with modern molecular techniques has also led to several interesting observations concerning NETs that may help to understand the natural course of gastrinomas. Nodit and colleagues performed a broad panel microsatellite loss analysis of fine-needle aspirate (FNA) samples obtained by EUS and could differentiate between benign and malignant pancreatic endocrine tumors [278]. Another exciting development is the potential to perform gene expression profiling using complementary DNA microarray analysis on EUS-obtained FNA samples to identify potential therapeutic targets. Couvelard and colleagues [279] found that 72 gene transcripts were upregulated and 51 downregulated in malignant tumors. In metastatic (vs nonmetastatic tumors) they observed selective expression of CD34, E-selectin (endothelial adhesion molecule 1), MKK4 (map kinase kinase 4) and MDR1, genes involved in angiogenesis and remodeling (CD34, cadherin-5, E-selectin, semaphorin E, and fibrillin), in signal transduction through tyrosine kinases (tyrosine kinase-2), platelet-derived growth factor Rb (receptor beta), MKKR (map kinase kinase receptor), and discoidin domain receptor 1), and in calcium-dependent cell signaling. Although the number of gastrinomas studied was relatively small, future work may confirm these findings in gastrinproducing tumors. This type of biological profiling of NETs may shed light on prognosis and assist in the development of effective molecularly targeted therapy.

Gastritis of the cardia, 1020

Gastritis is defined as microscopic inflammation of the stomach and represents a histological not a clinical entity, as the majority of persons with gastric inflammation are completely asymptomatic. A myriad of etiological agents can induce gastritis, but the most common cause is infection by *Helicobacter pylori*, a bacterium that resides in the mucus gel layer overlying the gastric mucosa [1,2]. Barry Marshall and Robin Warren were awarded the Nobel Prize in Medicine in 2005 as the investigators who in 1983 first identified and cultured these spiral bacilli from gastric epithelium of patients with chronic gastritis [3,4]. Since that time, a strong link has been established between *H. pylori* and a diverse spectrum of gastroduodenal diseases, including gastric and duodenal ulceration, gastric adenocarcinoma, mucosa-associated lymphoid tumor (MALToma), and non-Hodgkin lymphoma of the stomach (Fig. 42.1) [1,2,5–28]. *H. pylori* colonizes the stomach for years or decades, not days or weeks, as is usually the case for bacterial pathogens, and this organism virtually always induces chronic gastritis; however, only a fraction of *H. pylori*-colonized individuals ever develop disease. Identification of mechanisms that regulate *H. pylori*–host interactions will not only improve diagnostic and therapeutic modalities, but also may provide insights into other diseases that arise within the context of pathogen-initiated inflammatory states, such as chronic viral hepatitis and hepatocellular carcinoma. In addition to *H. pylori*, the other pathogens and exogenous agents that induce gastric inflammation and mucosal injury, gastritis, and gastropathy will also be discussed in this chapter.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Classification of gastritis using the Sydney system

The most widely used method for classification of gastritis and reporting of nonneoplastic gastric biopsies in the research setting is the updated Sydney system [29], which classifies chronic gastritis based on topography, morphology, and etiology (Table 42.1).

Biopsy protocol

The Sydney system requires histological sampling with separate submission of biopsies from five locations in the stomach: the greater and lesser curvature in the antrum, the greater and lesser curvature of the corpus, and the incisura. The incisura is a typical site for atrophy, intestinal metaplasia, and dysplasia [29], although data suggest that biopsies from endoscopically normal incisura add little additional clinical information [30]. Histological features assessed on a 0–4+ scale include *H. pylori* density, neutrophil infiltration, mononuclear cell infiltration, atrophy, and intestinal metaplasia. A series of cartoons illustrating the scoring is available to assist in standardizing histopathological grading [29]. Additional features assessed as present or absent and not otherwise graded are surface epithelial damage, lymphoid follicles, and foveolar hyperplasia. Additional findings such as granulomas are noted when present. The final diagnosis represents a synthesis of individual histological findings, topographical location, and available clinical information. Although the Sydney system is useful for research purposes, in clinical practice, failure to obtain the specified numbers of biopsies from the various regions of the stomach and the complexity of the scoring system limit its widespread use.

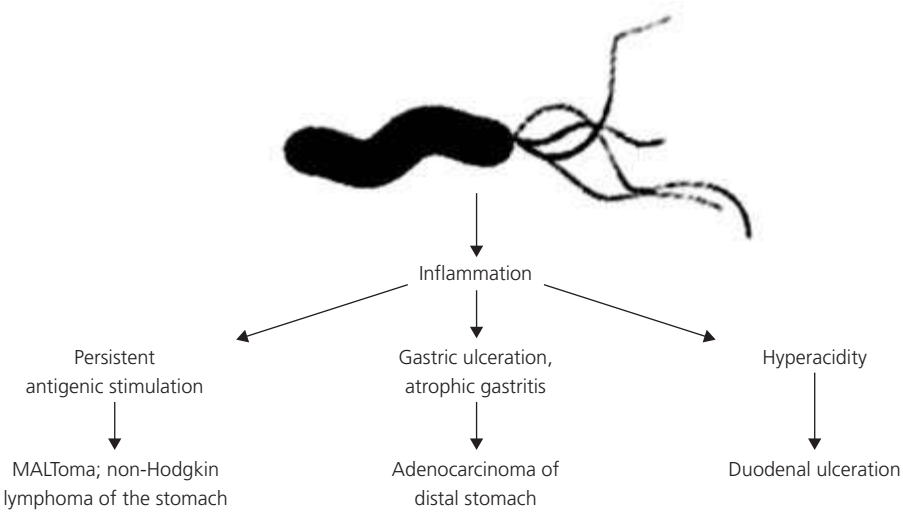

Figure 42.1 Disease outcomes that develop within the context of *H. pylori*-induced gastric inflammation.

Table 42.1 Classification of chronic gastritis based on topography, morphology, and etiology (updated Sydney system)

Type of gastritis	Etiology	Synonymous terms
Nonatrophic chronic gastritis	*H. pylori* ?Other factors	Chronic superficial gastritis Diffuse antral gastritis Chronic antral gastritis Type B gastritis
Atrophic gastritis		
Autoimmune gastritis	Autoimmunity ?*H. pylori*	Type A gastritis Diffuse corporal gastritis Pernicious anemia-associated gastritis
Multifocal atrophic gastritis	*H. pylori* Environmental factors	Type B or type AB gastritis Atrophic pangastritis
Special forms of gastritis		
Chemical gastropathy	NSAIDs Bile reflux Other chemical irritation	Reactive gastropathy Reflux gastropathy
Radiation	Radiation injury	
Lymphocytic	?Gluten ?Autoimmune mechanisms Drugs ?*H. pylori* ?Idiopathic	Celiac disease-associated Varioliform
Noninfectious granulomatous gastritis	Crohn's disease Sarcoidosis Foreign substances ?Idiopathic	Isolated granulomatous gastritis
Eosinophilic gastritis	Food sensitivity ?Other allergies	Allergic
Other infectious gastritides	Bacteria other than *H. pylori* Viruses Fungi Parasites	Phlegmonous gastritis Emphysematous gastritis Cytomegalovirus Anisakiasis

NSAIDs, nonsteroidal antiinflammatory drugs.

Histological features of chronic gastritis

Three patterns of chronic nonspecific gastritis are recognized:
- diffuse antral gastritis (nonatrophic gastritis in the Sydney system), which is associated with *H. pylori* infection
- multifocal atrophic gastritis, which is also highly associated with *H. pylori*
- diffuse corporal atrophic gastritis (autoimmune gastritis).

Nonatrophic chronic gastritis

In the nonatrophic chronic gastritis associated with *H. pylori* infection, a diffuse chronic inflammatory infiltrate composed of lymphocytes, plasma cells, and scattered eosinophils and mast cells is present in the lamina propria. The density of this infiltrate is variable and tends to be sparser in atrophic gastritis. The presence of lymphoid aggregates (Fig. 42.2), especially with germinal centers, is greatly associated with *H. pylori* infection and may persist after eradication of the organism. The presence of neutrophils indicates an "active" gastritis and is often associated with the presence of *H. pylori* organisms in the nearby superficial epithelium. Neutrophils infiltrate gastric glandular epithelium, typically in the neck area of the gland, and may form "pit abscesses" (Fig. 42.3). The foveolar epithelium often shows degenerative changes, and superficial erosions may be seen. Mucosal edema and hyperemia are common but nonspecific findings. *H. pylori* organisms

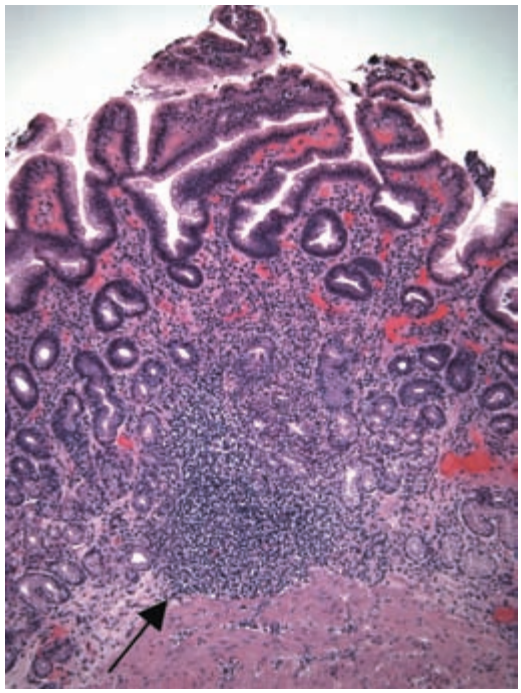

Figure 42.2 Lymphoid aggregates (arrow) are common findings in *H. pylori*-associated gastritis. The lamina propria contains a mixed inflammatory infiltrate of plasma cells, lymphocytes, neutrophils, and eosinophils.

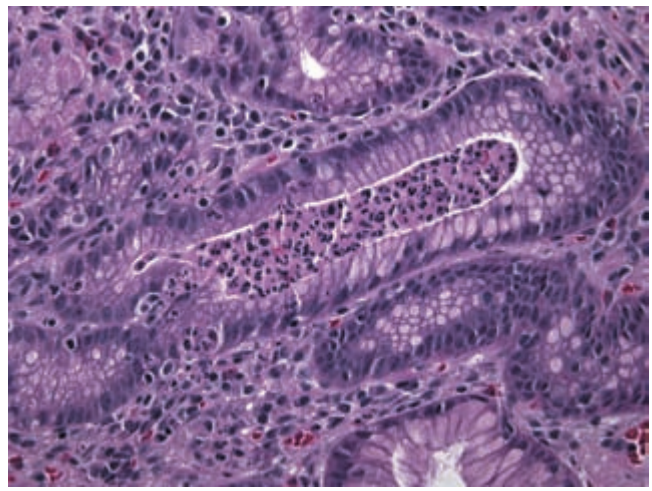

Figure 42.3 Neutrophils infiltrating in the lamina propria and foveolar epithelium and forming pit abscesses are characteristic of *H. pylori* gastritis.

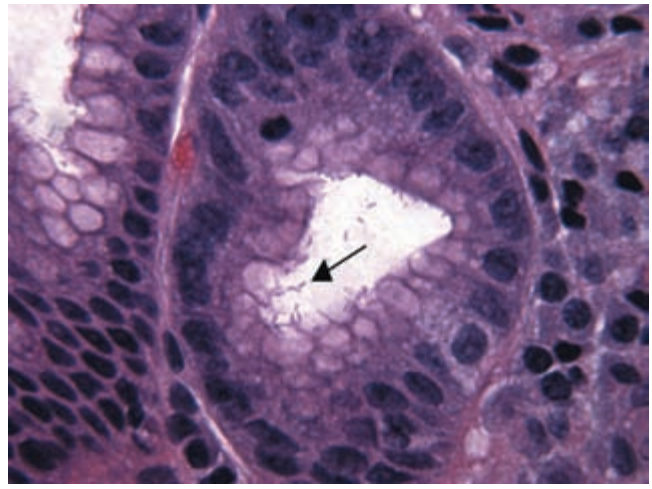

Figure 42.4 *Helicobacter pylori* organisms (arrow) are found in the surface mucous layer and extending into the lumen of the gastric pits.

are generally readily identifiable on routine hematoxylin–eosin-stained slides in the superficial mucus layer and extending into the lumen of the gastric pits (Fig. 42.4).

Multifocal atrophic gastritis

In atrophic gastritis, the specialized glands, such as chief and parietal cells in the gastric corpus and deep mucinous glands in the antrum, are lost and replaced by metaplastic epithelium or by fibrous tissue. Multifocal atrophic gastritis involves the gastric antrum and corpus and is generally patchy in distribution. Intestinal metaplasia, in which the gastric mucosa is replaced by mucosa resembling the small bowel, is common (Fig. 42.5). Pseudopyloric metaplasia, in which the oxyntic glands of the corpus are replaced by mucinous glands resembling antral mucosa, may be difficult to distinguish from gastric antral mucosa. Endocrine cell hyperplasia secondary

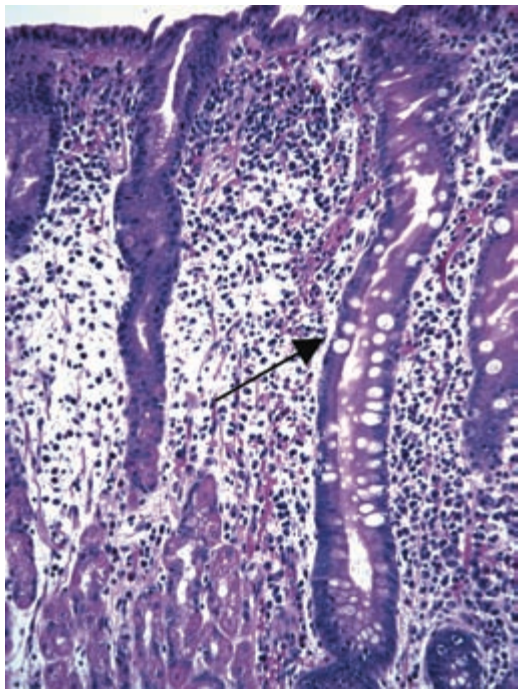

Figure 42.5 Multifocal atrophic gastritis involving the gastric corpus, showing patchy loss of oxyntic glands and intestinal metaplasia (arrow).

to hypergastrinemia is common. Because gastric acid production falls in atrophic gastritis, *H. pylori* organisms colonize more sparsely and are more difficult to detect.

Diffuse corporal atrophic gastritis (autoimmune gastritis)

The hallmark of this pattern of gastritis is the destruction of oxyntic glands. Atrophic gastritis is confined to the corpus and involves the antrum only minimally (see Autoimmune gastritis).

Helicobacter pylori-induced gastritis

H. pylori colonizes the stomachs of at least half the world's population, and persons in all geographical zones have been shown to carry the bacteria. Infection is usually acquired in childhood and, when left untreated, persists for the lifetime of the host [27,31]. The prevalence of *H. pylori* is greater in developing than developed countries [27,31,32]. In the United States, *H. pylori* is present in 10%–15% of children aged under 12 years, compared with 50%–60% of people older than 60 years [31–33]. The rate of acquisition of new *H. pylori* infections among adults in developed countries is less than 1% per year [32], and most carriers in the United States acquired *H. pylori* during childhood. Since the 1960s, however, progressively fewer children have been shown to carry *H. pylori* [1]. Risk factors for *H. pylori* acquisition include lower socioeconomic status and household crowding, and colonization rates reflect country of origin and ethnicity [31,34]. Colonization is related to intrafamilial clustering, but not to the presence of nonprimate reservoirs, favoring person-to-person transmission as the mode of infection. Experimental induction of regurgitation and catharsis increases *H. pylori* culture positivity rates from vomitus and diarrheal specimens [35], suggesting that *H. pylori* transmission may increase during childhood episodes of gastroenteritis.

Gastric colonization

H. pylori has evolved several mechanisms for eluding primary host defenses such as gastric acidity and peristalsis, to establish persistent infection within the stomach. One pH-altering mechanism is production of urease [36–38], and *H. pylori* isolates that cannot produce urease fail to colonize rodent models of infection [39,40], indicating that urease is a necessary factor for establishment of infection. To facilitate locomotion within gastric mucus and to counteract peristalsis, *H. pylori* possesses five or six polar flagella [41]. Like urease production, bacterial motility is required for persistent infection [42]. Approximately 20% of the *H. pylori* population in the stomach binds to gastric epithelial cells in vivo, and adhesion is important for acquisition of nutrients from the host and for resistance to shedding of the mucus gel layer. Several *H. pylori* and host ligands have been identified, including an *H. pylori* hemagglutinin encoded by *hpa* that binds to sialic acid-containing components of erythrocyte membranes [43], an exoenzyme S-like protein that binds phosphatidylethanolamine and gangliotetraosylceramide [44–46], and two outer membrane proteins (BabA and SabA) that bind the human blood group antigens Lewis^b and sialyl-Lewis^x, respectively [47–51].

Histopathological studies in human subjects have shown that *H. pylori* binds to specific regions of gastric epithelium, and that bacterial density is greatest in the upper portion of the gastric glands. This pattern of colonization mirrors the distribution of trefoil factor 1 (TFF1), and because *H. pylori* binds avidly to TFF1 in vitro [52], this molecule likely functions as a receptor for *H. pylori* in vivo. A specific component of gastric mucin (α1,4-linked *N*-acetylglucosamine *O*-glycan), which is confined to deep glandular regions rarely colonized by *H. pylori,* has been shown to exert antimicrobial effects against *H. pylori* by inhibiting the synthesis of cholesteryl-D-glucopyranoside, a major *H. pylori* cell wall component [53]. Thus, the host seems to have evolved mechanisms to restrict *H. pylori* to certain microniches within the gastric mucosa.

H. pylori can also limit the bactericidal effects of proinflammatory molecules, such as nitric oxide [54]. *H. pylori* expresses an enzyme called arginase, which siphons the nitric oxide substrate L-arginine away from inducible nitric oxide synthase (iNOS), limiting the production of iNOS-generated nitric oxide [54]. Another level of host defense circumvented by *H. pylori* is innate immunity. Toll-like receptors (TLRs) are a conserved family of host-cell receptors that function in innate

immunity by recognition of invariant regions in bacterial molecules termed pathogen- or microbe-associated molecular patterns [55–57]. *H. pylori* can avoid global activation of this system because *H. pylori* lipopolysaccharide and flagellin are relatively anergic compared with LPS and flagellins of other enteric bacteria [58–62]. *H. pylori* can also actively suppress the adaptive immune response [63–65] and survive within epithelial cells and macrophages [66–68]. However, despite these strategies for persistence, substantial immune activation still occurs, as evidenced by proinflammatory cytokine release, infiltration of the mucosa by inflammatory cells, and cellular and humoral recognition of *H. pylori* antigens [59].

Development of *H. pylori*-induced gastric inflammation

The gastric inflammatory response induced by *H. pylori* consists of neutrophils, lymphocytes, plasma cells, and macrophages, along with varying degrees of epithelial cell degeneration and injury (Figs 42.2 and 42.3), and the most distinctive feature of *H. pylori*-induced gastritis is infiltration of the gastric epithelium by neutrophils. Within the lamina propria, polymorphonuclear cells are admixed with lymphocytes, lymphoid follicles, plasma cells, and eosinophils, and the severity of gastritis is greatest in the superficial portions of the lamina propria. *H. pylori* colonization also induces an exuberant systemic and mucosal humoral response directed at multiple antigens [33,69–73]; however, antibody production does not result in eradication. Experimental mouse models have demonstrated that the inflammatory response to *H. pylori* is strongly dependent on the presence of T cells [74]. $CD4^+$ T lymphocytes can be broadly divided into two functional subsets, type 1 (Th1) and type 2 (Th2) T-helper cells, each of which are defined by distinct patterns of cytokine secretion. Th1 cells produce interleukin-2 (IL-2) and γ-interferon (IFN-γ) and promote cell-mediated immune responses, whereas Th2 cells secrete IL-4, IL-5, IL-6, and IL-10 and induce B-cell activation and differentiation. The type of immune response to a particular microbial agent is governed by preferential expansion of one T-helper cell subset accompanied by a relative downregulation of the other. Intracellular bacteria classically induce Th1 responses, whereas extracellular pathogens stimulate Th2-type responses. However, the majority of *H. pylori*-specific T-cell clones produce greater levels of IFN-γ than IL-4 [75], and IL-12, a cytokine that promotes Th1 differentiation [76]. These data are consistent with a model in which an inappropriate host T-cell response towards an extracellular pathogen, *H. pylori*, facilitates the development and chronicity of gastric inflammation.

Patterns of *H. pylori*-induced gastritis and disease outcome

There is a distinct dichotomy between *H. pylori*-induced duodenal ulceration and gastric cancer [77], and this depends on the topography of inflammation within the stomach. In the majority of infected persons residing in developed countries, *H. pylori*-induced gastritis is more severe in the gastric antrum, with only minimal involvement of the corpus, a pattern termed "diffuse antral gastritis" or "nonatrophic chronic gastritis" [78,79]. Gastric atrophy and intestinal metaplasia are typically absent in this type of gastritis. Persons with such corpus-sparing inflammation are at increased risk for duodenal ulcer disease, and gastric acid production in this population is either normal or increased [78,79]. By contrast, persons who progress to gastric ulcer disease and distal gastric adenocarcinoma have a different pattern of gastritis: there is involvement not only of the antrum but also the acid-secreting corpus and, as predicted, patients with pangastritis tend to have reduced acid outputs [15,80]. Corpus gastritis is often accompanied by gastric atrophy and intestinal metaplasia both in the antrum and the corpus. This pattern of gastric inflammation is most common among infected persons residing in Southeast Asia, South America, and certain regions of central, eastern, and southern Europe [81].

H. pylori virulence factors and gastric injury

H. pylori strains from different individuals are extremely diverse [82–85], and genetically unique derivatives of a single strain are present simultaneously within any individual human host [86]. The most well-studied strain-specific virulence determinant is the *cag* pathogenicity island, a 27-gene locus that is present in approximately 60% of US strains [82,83,87,88]. Although all *H. pylori* strains induce gastritis, the presence of cag^+ strains augments the risk for severe gastritis, peptic ulcer disease, and gastric cancer compared with that posed by cag^- strains [1,2,71,72,89–99]. Gene products of the *cag* island form a secretion system that functions as a molecular syringe to export proteins, and the product of the terminal gene in the island (CagA) is translocated into host epithelial cells following bacterial attachment (Fig. 42.6) [1,100–104]. Epithelial cell responses induced by the *cag* island include morphological alterations that are reminiscent of unrestrained cellular stimulation by growth factors, and production of the proinflammatory cytokine IL-8 (Fig. 42.6) [100–103,105–119].

Another *H. pylori* locus linked with disease outcome is *vacA*, which encodes a secreted bacterial toxin (VacA) [120–125]. Unlike the *cag* island, *vacA* is present in virtually all *H. pylori* strains [121,125]; however, strains vary in cytotoxin activity because of variations in *vacA* gene structure. The regions of greatest diversity are localized near the 5′ end of *vacA* (allele types s1a, s1b, s1c, or s2) and in the midregion of *vacA* (allele types m1 or m2) [125–127]. *H. pylori* strains that possess both type s1 and m1 *vacA* alleles are associated with an increased risk of peptic ulcer disease and gastric cancer [47,128–130] and enhanced gastric epithelial cell injury [131,132] compared with *vacA* s2/m2 strains. VacA also actively suppresses both T-cell proliferation and activation [63–65], which may contribute to the longevity of *H. pylori* colonization.

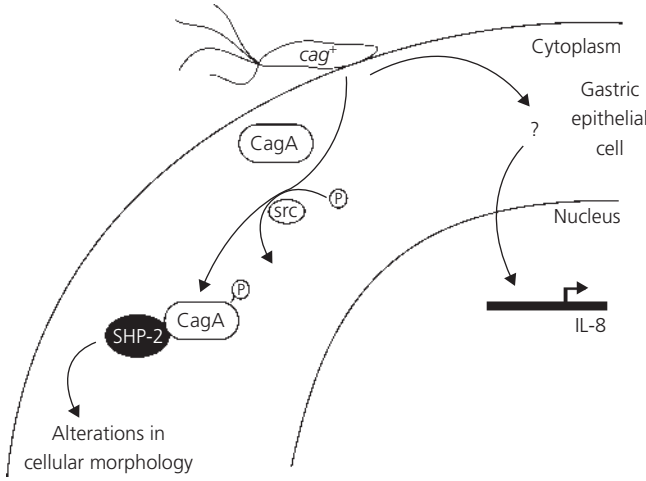

Figure 42.6 *Helicobacter pylori* affects multiple pathways in gastric epithelial cells that induce alterations in cellular morphology or production of interleukin-8 (IL-8). CagA is translocated into host cells, where it becomes phosphorylated by Src kinases, binds to a host phosphatase (SHP-2), and alters cellular morphology. An undefined factor is also translocated into host cells by the *H. pylori cag* secretion system leading to increased IL-8 expression.

Sequence analysis of the genomes from the two completely sequenced *H. pylori* strains, 26695 and J99, has revealed that an unusually high proportion of identified genes encode outer membrane proteins (OMPs) [49,51,82,83]. BabA is a membrane-bound OMP encoded by the strain-selective gene *babA2* and binds the blood-group antigen Lewis^b present on gastric epithelial cell membranes [47,48]. *H. pylori* strains possessing *babA2* are associated with an increased risk for gastric adenocarcinoma [47]. Sialyl-Lewis^x glycosphingolipid also functions as a receptor for *H. pylori* [50], and the bacterial adhesin required for binding is the OMP SabA. Sialyl-Lewis^x antigens are established tumor antigens and markers of gastric dysplasia that are upregulated by chronic gastric inflammation. Another *H. pylori* OMP is a proinflammatory protein encoded by *oipA* [133], and *H. pylori* strains that contain a functional copy of *oipA* induce more severe gastric inflammation, enhanced mucosal levels of IL-8, and duodenal ulcer disease [134]. These studies emphasize the pivotal role of *H. pylori* adherence in the induction of gastric inflammation and injury.

Human genetic polymorphisms and development of disease among *H. pylori*-infected persons

Most persons colonized with disease-associated *H. pylori* strains remain asymptomatic. *H. pylori cag*$^+$ toxigenic strains are related to both duodenal ulcer disease and distal gastric cancer, considered to be two mutually exclusive disease outcomes. The inability of bacterial virulence components completely to account for pathological outcomes has highlighted the need to explore host factors that may influence disease, particularly gastric cancer.

The cytokine IL-1β is a proinflammatory molecule whose concentration is increased within *H. pylori*-colonized gastric mucosa [135]. Interleukin-1β amplifies host inflammatory responses and potently inhibits acid secretion by parietal cells (100-fold more potent than proton pump inhibitors) [136]. These effects are biologically significant because inflammation that involves the acid-secreting gastric corpus (e.g., pangastritis) increases the risk of gastric adenocarcinoma, perhaps by inducing hypochlorhydria and atrophic gastritis leading to bacterial overgrowth [1,137]. The IL-1β gene cluster contains a number of functionally relevant polymorphisms that are associated with either increased or decreased IL-1β production, which has permitted the performing of case-control studies that relate host genotypes and disease. El-Omar and colleagues demonstrated that *H. pylori*-colonized persons with high-expression IL-1β alleles have a significantly increased risk for hypochlorhydria, gastric atrophy, and distal gastric adenocarcinoma than persons with genotypes that limit IL-1β expression (Table 42.2) [138]. These relationships, subsequently replicated in geographically distinct regions

Table 42.2 Human genetic polymorphisms that influence the development of distal gastric cancer

Genetic locus	Function of expressed protein	Genotype associated with enhanced risk
IL-1β	Induces expression of inflammatory cytokines; potently inhibits acid secretion from parietal cells	–31 C/C –511 T/T
IL-1RN	Receptor for IL-1β	Pentaallelic 86-bp tandem repeat in intron 2
TNF-α	Activates intracellular signaling pathways related to inflammation and apoptosis; inhibits acid secretion from parietal cells	–308 A/A
IL-10	Inhibits production of proinflammatory cytokines	–592 ATA/ATA –819 ATA/ATA –1082 ATA/ATA

IL, interleukin; IL-1RN, IL-1 receptor; TNF, tumor necrosis factor.

of the world, were only present among *H. pylori*-colonized persons, emphasizing the importance of host–environment interactions and inflammation in the progression to gastric cancer [139,140].

Similar to IL-1β, tumor necrosis factor α (TNF-α) is a proinflammatory, acid-suppressive cytokine that is increased within *H. pylori*-colonized mucosa [141]. Polymorphisms of the TNF-α gene that increase TNF-α expression are also associated with an increased risk of gastric cancer and its precursors (Table 42.2) [142]. Conversely, polymorphisms that reduce the production of antiinflammatory cytokines such as IL-10 increase the risk for gastric cancer (Table 42.2) [142]. The relative risk for distal gastric cancer increases progressively with an increasing number of proinflammatory polymorphisms, to the point that three polymorphisms increase the risk of cancer 27-fold over baseline [142]. *H. pylori* virulence factors synergize with host genotype to augment further the risk of cancer. In persons with high-expression *IL1B* alleles that are colonized by *H. pylori vacA* s1 strains, the relative risk for gastric cancer is 87-fold over baseline [143]. Combined bacterial and host genotyping may identify individuals at extremely high risk for gastric cancer.

Diagnosis of *H. pylori* infection

The presence of *H. pylori* should only be determined if such results will affect clinical decisions. The only persons for whom a clear indication for *H. pylori* testing exists are those with peptic ulcer disease, MALToma, prolonged use of nonsteroidal antiinflammatory drugs (NSAIDs), and possibly those with a strong family history of distal gastric cancer [144,145]. Techniques to diagnose *H. pylori* can be classified as either invasive (requiring endoscopy) or noninvasive (requiring breath tests, body fluid, or stool) (Table 42.3) [146,147]. Invasive methods require endoscopy with biopsy and include histology, rapid urease tests, culture, or polymerase chain reaction [146,147]. Although none of the available diagnostic tests is completely reliable because of heterogeneity in colonization density, most are sufficiently accurate to permit their widespread use, either for initial diagnosis or confirmation of cure (Table 42.3).

Histological detection of *H. pylori*

The presence of *H. pylori* within biopsy specimens can be determined histologically with or without the use of special stains that enhance bacterial visibility such as Warthin–Starry, Giemsa, Diff Quick, Genta, and el-Zimaity stains. The last two techniques offer an additional advantage by permitting simultaneous visualization of *H. pylori* and coexisting features of gastritis or damage, such as intestinal metaplasia. Advantages of histological diagnosis include direct visualization of the organism, assessment of the severity of gastritis, identification of more severe gastric lesions such as atrophic gastritis, intestinal metaplasia, adenocarcinoma, or lymphoproliferative disease, and accuracy for both initial diagnosis and confirmation of cure [146,147]. Although histology is considered by many to be the gold standard, its reliability depends on the number and sites of biopsy harvest, staining technique, and the experience of the histopathologist [148,149]. Evaluation of 3–5 biopsy specimens in total obtained from the greater or lesser curvature of the antrum and the corpus, respectively, in addition to the angularis, reliably distinguish infected from uninfected mucosa [149].

Rapid urease tests

Rapid urease tests take advantage of the robust production of urease by *H. pylori*. The most widely used form consists of a gel tablet containing urea and a pH indicator [146,147]. When an infected biopsy is placed into the gel, urea is converted to ammonia by urease, the pH within the tablet increases, and the pH indicator undergoes a color change (typically from yellow to red), often within 30 minutes. Additional forms of rapid urease tests have been developed,

Table 42.3 Diagnostic tests for *Helicobacter pylori*

Test	Clinical utility for:		Detects viable bacteria
	Primary diagnosis	Confirmation of cure	
Invasive			
Histology	+	+	–
Rapid urease testing	+	+	+
Culture	±	±	+
Polymerase chain reaction	–	–	–
Noninvasive			
Urea breath testing	+	+	+
Serology	+	–	–
Stool antigen tests	+	+	–

including paper and tablet tests, but their superiority to gel forms has not been established.

The advantages of rapid urease testing include ease of use, cost-effectiveness, and rapid acquisition of results, and they can be used for both initial diagnosis and follow-up of therapy. Sensitivities of rapid urease tests range from 93% to 97%, with specificities of approximately 98%; however, biological conditions can affect their accuracy [146,147]. Achlorhydria that develops as a consequence of atrophy or medication use (i.e., proton pump inhibitors) can lead to both false-positive (bacterial overgrowth with urease-producing organisms such as *Proteus*) and false-negative (decreased *H. pylori* colonization density) results [150]. False-positive results may also occur when non-*H. pylori Helicobacter* species, such as *H. heilmanni*, colonize the stomach. Heterogeneity in sites of colonization can alter the accuracy of biopsy-based rapid urease tests. For these reasons, it is recommended to wait at least 4 weeks following completion of anti-*H. pylori* therapy and at least 1 week after discontinuing proton pump inhibitors before performing a rapid urease test [146,147].

H. pylori culture

H. pylori can be grown directly from gastric tissue either by gently rubbing a biopsy specimen onto selective or nonselective media or by homogenizing gastric tissue in sterile saline and plating serial dilutions of homogenate [89]. Samples are then incubated for up to 10 days at 37°C in an environment containing 5%–12% CO_2. Similar to rapid urease testing, medications such as antibiotics or acid-suppressive drugs that alter bacterial colonization patterns in vivo may affect culture sensitivity. Despite significant advances over the past two decades, microbiological culture has not been widely accepted as a practical means to diagnose *H. pylori*, primarily due to cost, the special conditions required for specimen transport and growth, and the long interval between specimen harvest and test results, which delays treatment decisions. *H. pylori* culture is advantageous, however, if antimicrobial susceptibility patterns for specific isolates need to be determined.

Detection of *H. pylori*-specific DNA sequences in vivo

H. pylori DNA can be successfully detected in gastric tissue by the polymerase chain reaction (PCR). Using specific primers, PCR amplifies DNA sequences specific for *H. pylori* and can yield high levels of sensitivity (93%) and specificity (100%) by detecting as few as 10 *H. pylori* colony-forming units (CFU). *H. pylori* DNA has also been amplified from gastric juice, saliva, dental plaque, and stool [146,147,151–155]. Disadvantages of this technique include a high rate of false-positive results as a result of contamination, either within the clinical setting (i.e., contaminated or improperly cleaned endoscopes) or laboratory setting. Because PCR is only detecting DNA, a positive result cannot be equated with the presence of viable organisms. False-negative results can occur due to the presence of PCR inhibitors within gastric tissue, extremely low numbers of organisms, or DNA damage that occurs during specimen processing. For these reasons, plus the availability of other diagnostic techniques with comparable levels of sensitivity and specificity, PCR is still considered a research technique.

Urea breath tests

A noninvasive technique that also capitalizes on urease production is urea breath testing [146,147]. When urea labeled with either carbon-13 or carbon-14 is ingested by a patient with active *H. pylori* infection, gastric urease hydrolyzes labeled urea to ammonia and labeled CO_2, which is quickly absorbed into the bloodstream and can be detected in expired breath samples [146,147]. Urea breath tests accurately ascertain the presence of active infection, unlike PCR or serological methods, and allow a more global assessment of *H. pylori* within the stomach than can be provided by biopsy-based techniques. Breath tests also are effective for detection of *H. pylori* post-therapy, and on account of their noninvasive nature and high levels of sensitivity and specificity, they represent the gold standard for confirmation of cure.

Serological testing for *H. pylori*

The production of antibodies against *H. pylori* does not result in eradication of the infection; however, quantitating levels of anti-*H. pylori* immunoglobulins is an effective technique for primary diagnosis. A variety of serological methods have been developed, which include bacterial agglutination, complement fixation, hemagglutination, enzyme-linked immunosorbent assay (ELISA), immunofluorescence, radioimmunoassay, and latex agglutination [146,147]. Patient samples range from blood obtained by venipuncture or finger-stick, to saliva. As a rule, whole-blood tests are less accurate than serum-based tests due to the presence of chylomicrons within whole blood, and finger-stick tests have reduced sensitivity and specificity compared with venipuncture tests. Levels of anti-*H. pylori* antibodies in saliva are much more variable than in blood, and thus saliva-based tests are inferior to serum-based tests. Commercially available serology kits provide an extremely accurate means to diagnose *H. pylori* in patients who have not been previously treated, and levels of sensitivity are comparable with those obtained by histology, culture, and urea breath testing [146,147]. Additionally, there are clinical situations in which serology may be preferable to other techniques, for example with patients who present with an actively bleeding ulcer. Newer tests for detecting antibodies directed against *H. pylori* include urine assays, and sensitivities range from 82% to 94%, with specificities of 68%–92%, depending on the population under study [146,147,156–158].

The most significant limitation of serological testing is its inability reliably to confirm cure. Following treatment, anti-*H. pylori* antibody levels decrease slowly, and often 6 months

or more elapse before serum antibody concentrations decrease below the cutoff value for positivity [159,160]. In addition, serology is not cost-effective for confirming eradication in clinical practice because of the potential for multiple patient return visits and tests, and the requirement for storing pre-therapy samples as a standard against which post-therapy antibody levels must be compared. The availability, accuracy, and simplicity of urea breath tests also preclude using serology as a practical means to confirm cure.

An interesting area for future investigation is to assess the presence of *H. pylori* virulence characteristics by serology and segregate infected persons on the basis of differing levels of disease risk, such as risk for gastric cancer. CagA serology is simple to perform and reliable [161]. However, there is no convincing evidence to suggest that treatment of patients harboring $CagA^+$ strains decreases the risk for either premalignant or malignant gastric lesions. Another concern is that disease risk in *H. pylori*$^+$ $CagA^-$ subjects has not yet been established to be equivalent to that seen among uninfected persons [94]. If the prevalence of $CagA^+$ strains in a particular patient population is exceedingly high (i.e., East Asia), then screening for CagA may not be relevant. Finally, differences in serological recognition of CagA among clinical populations may not only reflect variation in the overall prevalence of *cagA*$^+$ strains, but also reflect the particular CagA antigen used in the assay, a limitation of serological tests designed to detect responses against *H. pylori* whole-cell antigens.

H. pylori stool antigen tests

An enzymatic immunoassay (HpSA, Meridian Diagnostics) that detects the presence of bacterial antigens in feces was also developed as a noninvasive diagnostic technique for *H. pylori* [162]. This test was originally formulated as a sandwich ELISA in which polyclonal anti-*H. pylori* antibody is bound to microtiter wells. Stool samples are then added and *H. pylori* antigens (if present) are "captured" by the bound antibody. A secondary antibody is then added followed by the addition of substrate, and bound *H. pylori* antigens are detected by a color change [162]. This assay has subsequently been modified into an immunocard [146].

The *H. pylori* stool antigen test is both sensitive and specific [146,147], and the US Food and Drug Administration (FDA) has approved HpSA for initial diagnosis and for monitoring post-therapy responses in *H. pylori*-infected adults [162]. Several trials have reported the sensitivity of HpSA to range from 91% to 96%, and specificities were also 91%–96% [147,162]. Concomitant use of proton pump inhibitors does not affect the accuracy of detecting *H. pylori* antigens in stool, in contrast to urea breath tests or biopsy-based techniques [162]. Following successful treatment of *H. pylori*, stool antigen levels rapidly decline, and in the majority of patients are undetectable by 5 days post-treatment [162]. Stool samples can be stored for prolonged periods of time, and multiple samples can be assayed at once. HpSA testing is safe and accurate in pediatric patients infected with *H. pylori* [162]. Finally, testing stool for *H. pylori* antigens is cost-effective. These data indicate that the *H. pylori* stool antigen test is a highly accurate technique that can identify the presence of *H. pylori* prior to and shortly following initiation of antimicrobial therapy. Its place in the *H. pylori* diagnostic armamentarium in the United States remains to be determined, especially given US patients' reluctance to obtain stool samples.

Treatment of *H. pylori* infection

The goal of *H. pylori* therapy is to eliminate the organism from the stomach, and successful eradication is defined as a negative test for the bacterium ≥ 4 weeks after the completion of therapy [145]. Treatment regimens should be straightforward, well tolerated, and cost-effective [163]. There are several different options for effectively treating *H. pylori* infections, and selection of a particular therapy is dependent on many factors, including drug availability, antmicrobial resistance patterns, and cost. First-line anti-*H. pylori* regimens may consist of a proton pump inhibitor (PPI) or ranitidine bismuth citrate (RBC), in combination with clarithromycin and either amoxicillin or metronidazole (triple therapy), for at least 7, but preferably 10 days (Table 42.4) [145,146,163–166]. There are no consistent advantages to using a particular PPI for *H. pylori* eradication [165,167]; therefore, any agent in this class can be used as a component of triple therapy. The prevalence of antimicrobial resistance in *H. pylori* is increasing, particularly for metronidazole, which reduces treatment efficacy [168]. Because the most effective second-line regimens contain metronidazole (Table 42.4), it is advisable to use clarithromycin and amoxicillin instead of clarithromycin and metronidazole in first-line regimens to optimize results should subsequent therapy be required [164,165].

Sequential therapies against *H. pylori* have also been tested [146,166]. In a randomized trial, over 1000 *H. pylori*-infected patients received either standard triple therapy for 7 days or a 10-day sequential therapy regimen consisting of a PPI daily plus amoxicillin 1 g twice a day for the first 5 days, followed by PPI therapy plus clarithromycin 500 mg and tinidazole 500 mg, each twice a day, for the remaining 5 days [146,166,169]. Higher eradication rates were found with the sequential regimen, whereas compliance rates and side-effect profiles were similar.

Second-line (rescue) therapies should be used if first-line regimens fail to eliminate *H. pylori*. The most effective salvage regimen is quadruple therapy using a PPI, bismuth subsalicylate, metronidazole, and tetracycline for 14 days (Table 42.4) [145,146,163–166]. This regimen is so effective that some experts have advocated it as first-line therapy (see Chapter 40, Peptic ulcer disease). If this regimen is used as first-line treatment, an appropriate second-line therapy would consist of a PPI, clarithromycin, and amoxicillin for 14 days [164].

Table 42.4 Treatment regimens for *Helicobacter pylori*

Therapy	Drug	Dosage	Duration (days)
First-line	Proton pump inhibitor (PPI)[a]	Twice a day[b]	7–10
	and		
	Clarithromycin	250 or 500 mg twice a day	7–10
	and		
	Amoxicillin	1000 mg twice a day	7–10
	or		
	Metronidazole	500 mg twice a day	7–10
Second-line	PPI	Twice a day[b]	14
	and		
	Bismuth subsalicylate	120 mg four times a day	14
	and		
	Tetracycline	500 mg four times a day	14
	and		
	Metronidazole	500 mg three times a day	14

a PPIs can be used interchangeably.
b Dose depends on individual PPI.

Anti-*H. pylori* therapies are also available as prepackaged formulations, such as Prevpac (lansoprazole 30 mg, clarithromycin 500 mg, amoxicillin 500 mg; each taken twice a day for 7 days) and Helidac (bismuth subsalicylate 262.4 mg, metronidazole 250 mg, tetracycline 500 mg; each taken four times a day for 14 days). Although these may be more convenient, they are not cost-effective, and the shorter duration (7 days) and lower dose of amoxicillin (500 mg) in Prevpac compared with standard triple therapy (Table 42.4), in addition to the need for combination therapy with a PPI (Helidac), preclude recommending these formulations as optimal first-line anti-*H. pylori* therapies [145].

Although eradication rates in controlled trials frequently exceed 90%, efficacy in clinical practice is often lower [145,146,166,170], primarily because of differences in patient populations, the genetic composition of infecting *H. pylori* isolates, or antibiotic resistance patterns of strains in a particular geographic locale. Because of the availability of accurate noninvasive diagnostic tests for *H. pylori*, it is recommended that urea breath testing or stool antigen tests be performed post-intervention to confirm successful cure [165].

Infectious gastritis (excluding *H. pylori*)

Bacteria

Bacterial colonization of the achlorhydric [171] or dysmotile stomach does not elicit an inflammatory response, and is generally asymptomatic. True bacterial infections of the stomach, excluding *H. pylori* gastritis, are exceedingly rare. Acute suppurative gastritis, or *phlegmonous gastritis*, is a life-threatening condition caused by infection of the submucosa and muscularis propria of the stomach by pyogenic bacteria, most often α-hemolytic streptococci. Immunocompromised patients, the elderly, and alcoholics are at greatest risk [172], and iatrogenic causes include endoscopic mucosal resection [173] and polypectomy [174]. Patients typically present with acute abdominal pain, peritonitis, fever, and hypotension. When gas-forming bacteria such as *Clostridium* species invade the stomach wall, the term *emphysematous gastritis* is used [175]. Surgical intervention with gastrectomy may be necessary, and mortality is high for both conditions. Other rare causes of gastric bacterial infections include syphilis, which may cause ulcerated lesions [176] and nodular masses [177], and *Mycobacterium tuberculosis* [178], which may present as gastric outlet obstruction. In gastric tuberculosis, biopsies show necrotizing granulomas, with acid-fast bacilli demonstrated on appropriate stains.

Viruses

Although enteric viruses cause a clinical picture of acute gastritis, biopsy is rarely performed in such cases and no distinctive findings have been reported. The most common viral infection identified in gastric biopsies is cytomegalovirus (CMV), usually seen in immunocompromised patients as part of disseminated infection, although it is occasionally found in elderly apparently immunocompetent patients [179]. Clinically, gastric involvement by CMV may be manifested by nausea and upper abdominal pain [180] or occasionally by gastric outlet obstruction [181] or hemorrhage. Endoscopically, erosions, ulcers, hypertrophic folds, and edema are identified. In children, cytomegalovirus gastritis causes massive foveolar

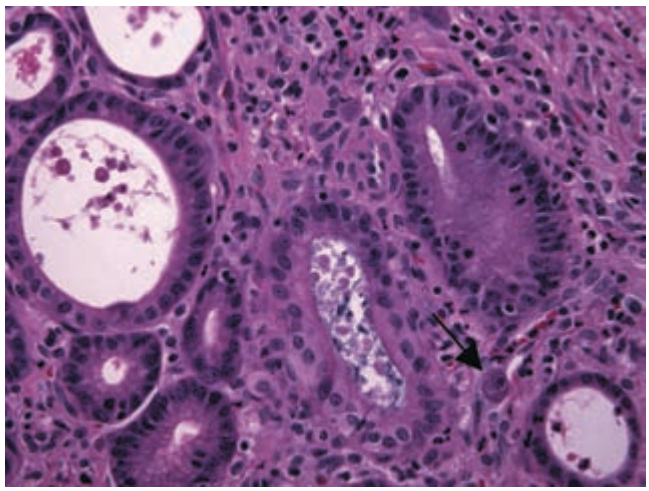

Figure 42.7 In cytomegalovirus gastritis, the inflammatory infiltrate is variable; characteristic nuclear viral inclusions may be seen in endothelial cells (arrow), stromal cells, epithelium, and smooth muscle.

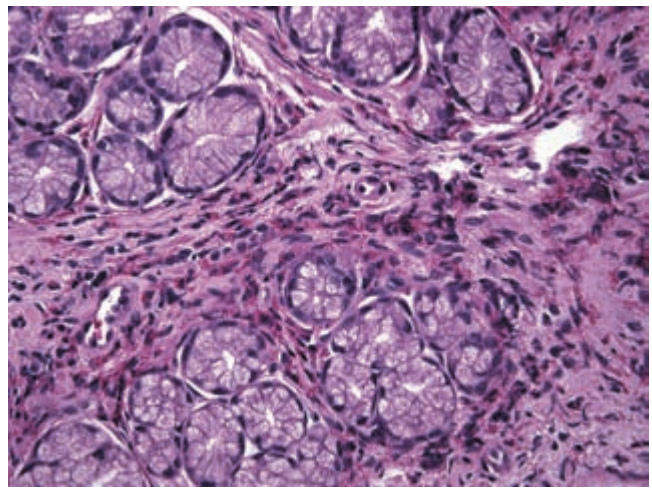

Figure 42.8 Eosinophilic gastritis is characterized by a dense but irregularly distributed infiltrate of eosinophils in the lamina propria or deeper layers of the stomach.

hyperplasia that is indistinguishable from Ménétrier disease. Nuclear cytomegalovirus inclusions may be found in enlarged epithelial, endothelial, smooth muscle, and stromal cells and range in number from numerous to undetectable on routine histology. The inflammatory response is variable; in some cases, patchy acute inflammatory infiltrates often centered about small vessels in the lamina propria and submucosa may be seen. Diagnosis is established by demonstration of the characteristic viral inclusions (Fig. 42.7), highlighted by immunohistochemical or in situ hybridization techniques. Treatment is with ganciclovir.

Fungi

Fungal colonization of gastric ulcers by *Candida* species is relatively common [182] but is of little clinical consequence. Invasive or disseminated fungal infections with *Histoplasma capsulatum* [183], *Cryptococcus neoformans* [184], and Zygomycetes species [185] (among others) involving the stomach have been reported in immunocompromised patients.

Parasites

Although involvement of the stomach by parasitic infestation is rare in Western countries, many cases of invasive anisakiasis have been reported in Japan, where raw marine fish is commonly consumed. Nematode larvae of the genus *Anisakis* may migrate into the gastric wall and cause sporadic epigastric pain. Multiple gastric erosions are a typical finding on endoscopy, and microscopically an eosinophilic granulomatous inflammatory infiltrate with abscess formation and granulation tissue is seen [186]. A small worm may be identified in some cases. Other parasites occasionally found in gastric mucosa, primarily in immunocompromised patients, include *Cryptosporidium* species [187], *Giardia intestinalis* [188], and *Strongyloides stercoralis* [189].

Eosinophilic gastritis

Small numbers of eosinophils are normally found in the gastric lamina propria, and eosinophils are a typical component of the inflammatory infiltrate in a wide range of inflammatory diseases involving the stomach. Eosinophilic gastritis, the gastric component of eosinophilic gastroenteritis, should only be diagnosed when numerous eosinophils disproportionate to the other components of the inflammatory infiltrate are present (Fig. 42.8). Eosinophilic gastroenteritis is considered a polygenic allergic disorder [190]; in the majority of cases, serum immunoglobulin E (IgE) is elevated and peripheral eosinophilia is present. Endoscopic findings are nonspecific and include friability, erythema, erosions, and enlarged gastric folds, particularly in the antrum; the endoscopic appearance may be normal even when the gastric mucosa is heavily infiltrated by eosinophils. Biopsy diagnosis may be difficult, as selective involvement of the deeper layers of the gastric wall may be seen, with minimal or only patchy mucosal collections of eosinophils [191]. Eosinophilic gastritis has also been described in the setting of collagen vascular disease [192] and parasitic infection by the fish parasite *Anisaka simplex* [193]. In noninfectious cases, the disease often responds to corticosteroid therapy [190].

Granulomatous gastritis

Granulomas may be found in the gastric mucosa in a wide variety of infectious and noninfectious inflammatory disorders. Clinical and endoscopic findings generally reflect the underlying disease, but the gastric mucosa may also appear entirely normal on endoscopy; small erosions and ulcers are common [194]. Although in most cases of granulomatous gastritis a specific diagnosis can be made by integrating histological findings with clinical data [195], in a small number of cases, termed idiopathic, no etiology can be identified.

Infectious causes of granulomatous gastritis include acid-fast bacilli (*Mycobacterium tuberculosis*), fungi (*Histoplasma capsulatum*), bacteria (*H. pylori*), and parasites (*Anisaka simplex*). Granulomas associated with *H. pylori* gastritis are generally found in the superficial mucosa in the antrum near injured gastric glands [194]. Foreign bodies such as sutures may also give rise to a granulomatous reaction. Rarely, a granulomatous response to tumor antigens may be seen in nonneoplastic mucosa or perigastric lymph nodes in patients with gastric adenocarcinomas [194,196] or gastric lymphomas [197,198].

In most series, Crohn's disease, followed by sarcoidosis, are the most common disorders associated with granulomatous gastritis [195,199], with over half of all cases identified in retrospective series attributed to upper GI involvement by Crohn's disease. A prevalence of 10%–15% for gastric granulomas (Fig. 42.9) and up to 70% for "focally enhanced gastritis" (characterized by focal periglandular mononuclear inflammatory infiltrates composed of T cells and $CD68^+$ histiocytes) has been reported in these patients [200]. It should be noted that focally enhanced gastritis has also been reported in children and adults with ulcerative colitis [201,202]. In unselected gastric biopsies, this pattern of gastric inflammation is relatively rare, and has a low positive predictive value for inflammatory bowel disease [203]. In many cases, involvement of the stomach by Crohn's disease is an incidental finding; however, severe involvement, with strictures and fistulas refractory to medical management, also occurs [204,205]. Gastrointestinal involvement by sarcoidosis is generally an incidental finding and rarely has clinical importance. In severe cases, scarring and ulcers [206] are seen; these may mimic gastric carcinoma or cause gastric outlet obstruction.

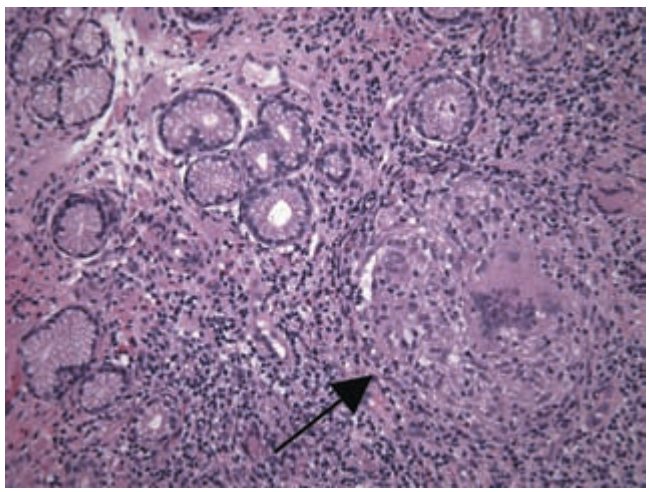

Figure 42.9 Nonnecrotizing granulomas (arrow) composed of epithelioid histiocytes with occasional giant cells are found in up to 15% of gastric biopsies from patients with Crohn's disease.

Autoimmune gastritis

Autoimmune gastritis is a chronic atrophic gastritis restricted to the body of the stomach and associated with circulating anti-parietal cell and anti-intrinsic factor antibodies, with resulting deficiency of intrinsic factor. Only a small subset of patients with autoimmune gastritis will have classic pernicious anemia.

Clinical features and pathogenesis

Patients with autoimmune gastritis may be clinically asymptomatic for many years, until parietal cell mass has decreased to the point that hypochlorhydria or achlorhydria results. Achlorhydric patients have hypergastrinemia, and injury to the chief cells results in reduced pepsin activity. Achlorhydria results in iron deficiency anemia in roughly 15% of patients [207] as a result of lack of absorption of nonheme iron. Patients who present with pernicious anemia may complain of anorexia, weight loss, sore tongue, and neurological disturbances including numbness and paresthesias in the extremities, weakness, and ataxia.

Patients with autoimmune gastritis may have other autoimmune diseases such as Graves disease, idiopathic adrenocortical insufficiency, and vitiligo. It has been hypothesized that *H. pylori* infection may trigger autoimmune gastritis in a genetically susceptible individual as a consequence of molecular mimicry between *H. pylori* and gastric mucosal antigens; this is supported by evidence that up to 80% of patients with *H. pylori* may have autoantibodies with H^+,K^+-ATPase specificity directed against the canalicular membranes of parietal cells, the same target autoantigen as occurs in autoimmune gastritis [208]. However, additional evidence is needed before concluding that *H. pylori* is the causative agent for autoimmune gastritis.

Endoscopic appearance

Progressive thinning of the mucosa in atrophic gastritis results in loss of gastric folds and increased visibility of fine submucosal vessels. The antrum is endoscopically normal in most cases of autoimmune gastritis. Multiple hyperplastic polyps may develop in advanced stages of the disease.

Pathological features

The corpus of the stomach is most severely affected in autoimmune gastritis. Characteristic histological findings include a diffuse, chronic, atrophic gastritis with variable degrees of intestinal metaplasia (Fig. 42.10). Typical features early in the disease are deep or diffuse lymphoplasmacytic infiltrates in the lamina propria with foci of epithelial infiltration and damage, intestinal or pyloric metaplasia, and linear enterochromaffin-like cell hyperplasia [209]. Pyloric metaplasia tends to predominate over intestinal metaplasia in the early

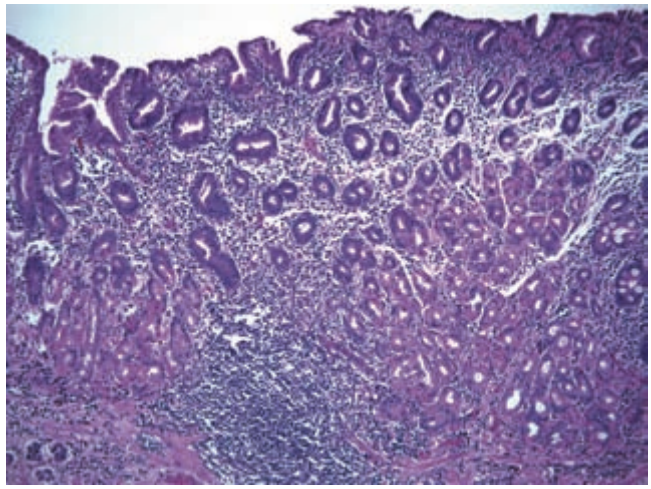

Figure 42.10 In autoimmune gastritis, loss of oxyntic glands results in atrophic gastritis primarily affecting the gastric corpus. A diffuse lymphoplasmacytic infiltrate is common.

stages. In late-stage disease, the oxyntic mucosa is largely destroyed, with replacement of chief and parietal cells by metaplastic cells; at this stage, the inflammatory infiltrate is minimal. Extreme degrees of ECL cell hyperplasia often lead to the formation of multiple microcarcinoids secondary to hypergastrinemia. The antrum may show mild chronic inflammation with intestinal metaplasia, and hyperplasia of gastric cells may be seen.

Management

The mucosal changes in autoimmune gastritis are irreversible. Although patients with multiple hyperplastic polyps and extensive metaplasia may be at increased risk for gastric adenocarcinoma, there are no standards for frequency of endoscopic surveillance. Most abnormalities resulting from cobalamin deficiency are reversible with replacement therapy, except for the neurological manifestations.

Lymphocytic gastritis

Lymphocytic gastritis is characterized by large numbers of mature lymphocytes infiltrating the surface and foveolar epithelium (i.e., intraepithelial lymphocytes in contrast to lamina propria lymphocytes). It occurs most commonly in patients with celiac disease, with up to 45% of celiac disease patients [210] showing evidence of lymphocytic gastritis on biopsy. Approximately 4% of patients with *H. pylori* gastritis [211] also have increased numbers of lymphocytes in surface epithelium, but this feature may be obscured by the presence of active inflammation. The pathogenesis of lymphocytic gastritis is unknown, but given its association with celiac disease it likely represents a response to persistent antigens.

Clinical and endoscopic features

Patients with lymphocytic gastritis may be asymptomatic, and the condition is discovered by random biopsy of endoscopically normal mucosa. In more severe disease, there may be scattered erosions and enlarged mucosal folds resembling Ménétrier disease and accompanied by anemia and hypoalbuminemia (hypertrophic lymphocytic gastritis).

Pathological features

The minimal number of lymphocytes considered diagnostic for lymphocytic gastritis is 25 per 100 epithelial cells [211]; counts of up to 65 lymphocytes per 100 epithelial cells are not uncommon. Virtually all of the lymphocytes are of T-cell origin. Lymphocytes are distributed singly (Fig. 42.11), but rarely small clusters resembling lymphoepithelial lesions may be seen. The antrum is more severely involved in patients with celiac disease compared with patients with *H. pylori* gastritis [211], in which the lymphocytic gastritis pattern is more likely to be corpus-predominant and to show concomitant infiltration of the mucosa by neutrophils. The intraepithelial lymphocytes are more numerous in hypertrophic forms of lymphocytic gastritis.

Therapy

Treatment of lymphocytic gastritis is aimed at treatment of the underlying *H. pylori* gastritis or celiac disease; for patients with lymphocytic gastritis not associated with these diseases, therapy has largely consisted of proton pump inhibitors [212].

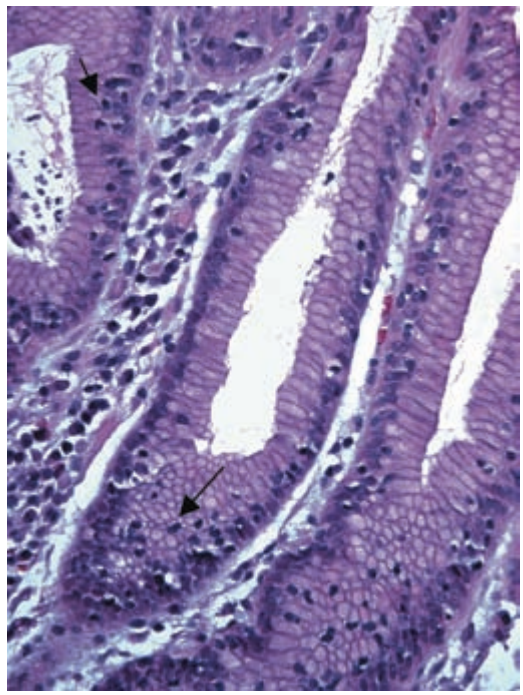

Figure 42.11 Numerous intraepithelial lymphocytes (arrows) are found in the mucosa in lymphocytic gastritis.

Collagenous gastritis

Collagenous gastritis is a rare but histologically distinctive disorder characterized by thickening of the subepithelial collagen layer in the gastric mucosa. It has been reported in association with collagenous colitis in older adults [213] and celiac disease [214]. In children and young adults, collagenous gastritis may present with disease limited to the gastric mucosa and showing a nodular pattern on endoscopy [213]. On biopsy, in addition to the markedly thickened and irregular subepithelial collagen band, the mucosa contains a variable chronic inflammatory infiltrate, and the surface epithelium shows degenerative changes and infiltration by lymphocytes and eosinophils.

Chemical (reactive) gastropathy (NSAID and bile reflux)

Chemical gastropathy (also variously referred to as reflux gastritis or gastropathy, chemical gastritis, or reactive gastritis) is a distinctive constellation of endoscopic and microscopic findings first described in the setting of bile reflux in stomachs subjected to gastric surgery, most commonly Bilroth II gastrojejunostomy. Subsequently it has been recognized that bile reflux in the intact stomach may lead to chemical gastropathy. Most cases, however, are associated with use of nonsteroidal antiinflammatory drugs (NSAIDs), with an estimated prevalence of chemical gastropathy of up to 45% in this group [215].

Clinical manifestations and pathogenesis

Chemical gastropathy may be seen in three clinical settings: postgastrectomy alkaline reflux; bile reflux secondary to gastroduodenal dysmotility; and aspirin or NSAID ingestion. Patients with bile reflux complain of burning midepigastric pain unresponsive to antacids; bilious vomiting may occur. In persons ingesting aspirin or NSAIDs on a regular basis, epigastric pain is common, but no relationship has been established between the mucosal appearance and the presence or severity of symptoms. Unless complicating erosions or ulcers are present, chemical gastropathy may be an asymptomatic lesion.

Disruption of the mucus barrier of the antrum and direct damage to surface epithelium, either from reflux of alkaline duodenal contents or reduced prostaglandin synthesis secondary to NSAID use, is a major factor in the pathogenesis of chemical gastropathy. Cyclooxygenase- and prostaglandin-independent mechanisms may also be involved in NSAID-induced gastric injury, perhaps through systemic release of TNF-α [216]. The gastric injury induced by NSAIDS is exacerbated by acid, and use of potent acid suppression therapy is a common approach to reducing NSAID-related complications.

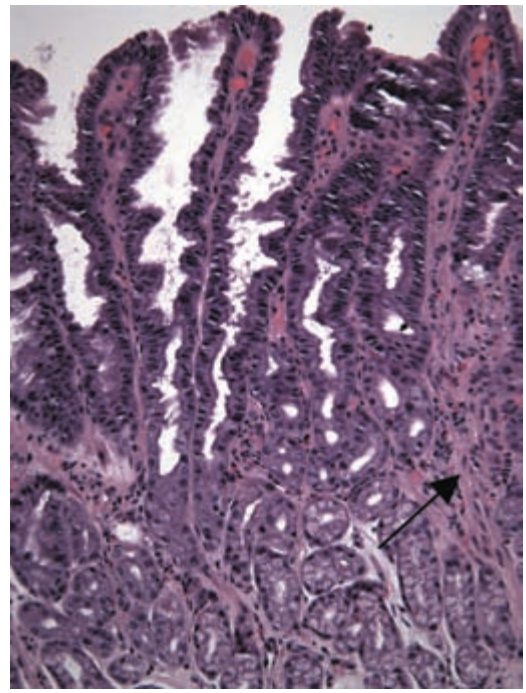

Figure 42.12 Chemical gastropathy is characterized by reactive epithelial changes out of proportion to the sparse inflammatory infiltrate, foveolar hyperplasia with corkscrew appearance to the superficial mucosa, and increased lamina propria smooth muscle fibers (arrow).

Endoscopic appearance

In patients with nonoperated stomachs, the mucosa in chemical gastropathy may show edema, vascular congestion and erythema, and erosions. In the operated stomach, the mucosa shows similar features, often primarily involving the anastomotic site. Superficial erosions may be seen in this setting but are not specific for chemical gastropathy.

Histological features

The characteristic histopathological features of chemical gastropathy are best seen in the antrum and include foveolar hyperplasia imparting a corkscrew appearance to the superficial mucosa, reactive epithelial changes (nuclear enlargement and loss of cytoplasmic mucin), increased lamina propria smooth muscle fibers, and edema of the lamina propria (Fig. 42.12). Acute and chronic inflammatory cells are typically sparse.

Hemorrhagic gastropathy

Hemorrhagic gastropathies are a multifactorial group of conditions characterized by mucosal hemorrhages and erosions. The major etiological factors are NSAID use, major physical stress, and ingestion of large quantities of alcohol. Hemorrhagic gastropathy has also been reported in the setting of crack cocaine use [217]. The most severe examples of hemorrhagic gastropathy are *stress ulcers*, originally described by Dr Thomas

Curling in 1842 [218] and therefore sometimes referred to as Curling ulcers, seen in patients who suffer major physical or thermal trauma, shock, sepsis, or head injury. Respiratory failure requiring mechanical ventilation for more than 48 hours and coagulopathy are independent risk factors for the development of bleeding from hemorrhagic gastropathy [219]. The pathogenesis of hemorrhagic gastropathy is related to disruption of the mucosal protective mechanisms secondary to compromise of gastric mucosal microcirculation in some cases; gastric acid secretion likely contributes to the injury [219], and *H. pylori* infection has been implicated as a contributing factor in some cases [220].

In hemorrhagic gastropathy, the mucosal lesions are multiple, superficial, and nontransmural. Microscopically, the superficial mucosa is eroded and edematous; a neutrophilic inflammatory response may be seen, but mononuclear inflammation is not present unless there is concomitant chronic mucosal injury, as in *H. pylori* infection. Hemorrhagic gastropathy usually produces no symptoms and blood loss is minor. However, because of the increased mortality associated with gastrointestinal bleeding in critically ill patients, prophylactic treatment with proton pump inhibitors is advocated by some investigators [219].

Vascular gastropathy

Vascular gastropathies are the result of alterations in gastric circulation; the most common are gastric antral vascular ectasia ("watermelon stomach"), and portal hypertensive gastropathy (see Chapters 111 and 123). Congestive heart failure may also cause a congestive gastropathy [221] that endoscopically resembles portal hypertensive gastropathy. Frank ischemic necrosis of gastric mucosa is rarely seen, but occasionally occurs in patients with severe atherosclerotic disease.

Portal hypertensive gastropathy

Clinical manifestations and pathogenesis

Portal hypertensive gastropathy (PHG) produces characteristic mucosal changes recognizable at endoscopy, and is a common finding in patients with portal hypertension, both with and without underlying liver disease. Although the development of PHG correlates with duration and severity of liver disease [222] and presence and size of gastroesophageal varices, the severity and presence of portal hypertensive gastropathy does not correlate in a linear fashion with severity of portal hypertension, and measurements of gastric blood flow to the stomach have shown variable results [223]. Overall, the incidence of acute bleeding is low, and blood loss is usually mild and rarely life threatening [222].

Endoscopic appearance

Portal hypertensive gastropathy is more prominent in the body and fundus of the stomach and is rare in the gastric antrum. Characteristic patterns on endoscopy are a mosaic or snakeskin pattern, scarlatina rash, and cherry-red spots or black-brown spots (or both). Endoscopic grading schemes have been proposed [224], with more severe scores correlating with increased risk for bleeding; in general, prominent mosaic pattern and confluent red marks are considered indicative of more severe changes.

Histopathology

Small veins in the mucosa and submucosa show dilation, tortuosity, and thickened walls [225] (Fig. 42.13). The mucosa is otherwise generally normal in appearance, with neither erosions, nor significant inflammation, nor thrombi. Correlation of histological findings with the endoscopic impression of PHG is poor, because the vascular changes are more pronounced in submucosal vessels, and small mucosal biopsies may not show diagnostic changes.

Management

Because clinically significant bleeding is rare, most patients require no specific treatment for PHG. Nonselective β-blockers, such as propranolol or nadalol, may be used to lower portal pressure and gastric mucosal blood flow. Endoscopic intervention is of limited value because of the mild and diffuse nature of the bleeding in most cases. Transjugular intrahepatic portosystemic shunt (TIPS) and shunt surgery have been used to treat PHG hemorrhage in refractory cases, but are generally considered a last resort [223].

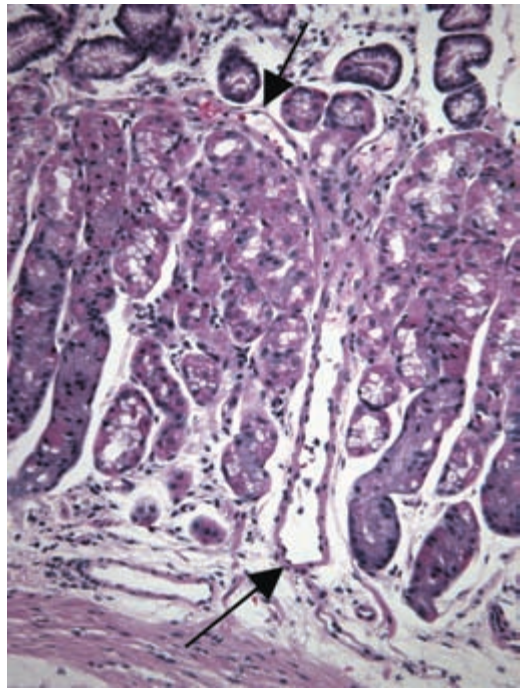

Figure 42.13 In portal hypertensive gastropathy, dilated small veins are found in the submucosa and lamina propria (arrows).

Hypertrophic gastropathy

Hypertrophic gastropathy is characterized by diffuse macroscopic enlargement of the gastric folds, primarily in the body of the stomach. These markedly enlarged folds follow the normal rugal pattern of the stomach, and may resemble cerebral convolutions at endoscopy. Three main types are recognized, according to which mucosal compartment is hyperplastic:

- foveolar hyperplasia (Ménétrier disease), usually accompanied by atrophy of oxyntic glands
- hyperplasia of oxyntic glands, without foveolar hyperplasia (Zollinger–Ellison syndrome; see Chapter 41)
- mixed foveolar/oxyntic hyperplasia, seen in a diverse group of conditions (see above), including *H. pylori* infection, cytomegalovirus gastritis in children, lymphocytic gastritis, sarcoidosis, and Cronkhite–Canada syndrome (see Chapter 55).

Ménétrier disease

Whereas enlarged gastric folds may be associated with a wide variety of inflammatory conditions, classic Ménétrier disease is rare, affecting primarily men in their 50s and 60s. Patients may present with weight loss, abdominal pain, nausea, and vomiting. Histologically, the enlarged folds in Ménétrier disease show massive expansion of the foveolar compartment, with normal or reduced numbers of chief and parietal cells (Fig. 42.14). The foveolae are tortuous and dilated, and cystic glands may be seen. Inflammation is not typically a feature, although the enlarged folds are subject to erosion, and may thus show secondary inflammatory changes in the superficial mucosa. In well-developed Ménétrier disease, severe protein loss from the abnormal gastric mucosa leads to hypoalbuminemia; low acid secretion is the result of loss of parietal cell mass.

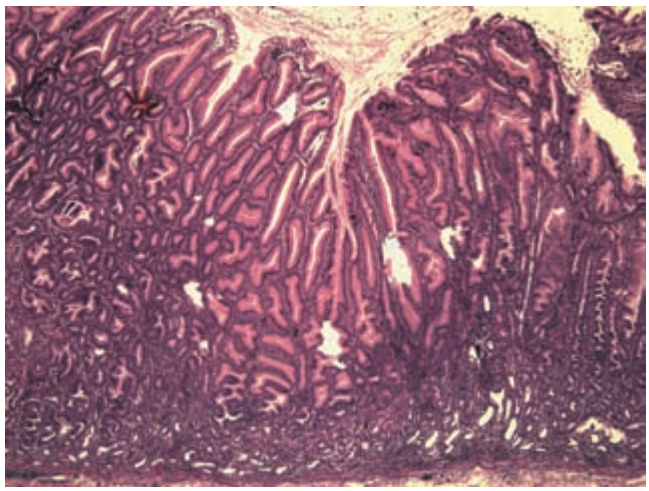

Figure 42.14 The enlarged folds in Ménétrier disease are composed of massively expanded foveolar epithelium, leading to protein loss and hypoalbuminemia.

Transient forms of hypertrophic gastropathy resembling Ménétrier disease are seen in children and are almost always associated with cytomegalovirus gastritis [226] although cow's milk protein allergy [227] and other inflammatory disorders have also been implicated. Cytomegalovirus-associated Ménétrier disease has also been reported in adults [228]. The pathogenesis of the classic form of the disorder is unknown, although overexpression of transforming growth factor-α (TGF-α), which stimulates epithelial cell proliferation and inhibits gastric acid secretion, among other functions, has been implicated [229]. Medical treatments for Ménétrier disease include antacids, corticosteroids, and proton pump inhibitors, but they have been inconsistently effective; treatment with a monoclonal antibody directed against the epidermal growth factor receptor has proven effective in a few patients treated on an experimental basis [229].

Gastritis of the cardia

The cardia is an ill-defined anatomical zone of the stomach extending 10–20 mm distal to the lower end of the esophagus. Given the rising incidence of adenocarcinoma of the proximal stomach and gastroesophageal junction, pathological changes in this region have generated intense interest. Histologically, cardiac mucosa resembles antral mucosa in that it lacks oxyntic glands. Inflammation of the cardia ("carditis") may be seen in the setting of pangastritis due to *H. pylori* infection [230]; its intensity parallels that of antral inflammation [231]. Similarly, the presence of intestinal metaplasia in the cardia is associated with multifocal atrophic gastritis in the remainder of the stomach [232]. Carditis is also reported in *H. pylori*-negative patients with reflux esophagitis and without significant inflammation elsewhere in the stomach [233], with an estimated prevalence of 23% [230]. Intestinal metaplasia of the cardia is present in roughly 3% of patients in this group [234], raising the issue of whether this finding represents short-segment Barrett esophagus. Although a distinction of gastric cardiac intestinal metaplasia vs Barrett esophagus has been proposed based on differential expression of cytokeratins 7 and 20 [235], others have reported inconsistent results [236,237]; hence no histological markers differentiate between these entities in a reliable and reproducible fashion.

43 Tumors of the stomach

Wai K. Leung, Enders K.W. Ng, Joseph J.Y. Sung

Gastric adenocarcinoma, 1026 Other gastric tumors, 1044

Gastric cancer is the second most common cause of cancer-related mortality worldwide [1]. Although relatively uncommon in the United States, gastric cancer is the commonest cancer in many Asian countries. With the rapid changes in economy and improvement in sanitary conditions, the incidence of gastric cancer is declining globally.

Because the majority of gastric tumors are adenocarcinomas, this chapter will focus on this type of cancer. Other less common gastric malignancies, such as lymphoma, mesenchymal tumors, and endocrine tumors, will be discussed briefly.

Gastric adenocarcinoma

Epidemiology

Gastric carcinoma is the second commonest malignancy, causing over 700 000 deaths per year in the world (Fig. 43.1) [1]. In 2002 it was estimated that in the United States 21 860 new cases of gastric cancer were diagnosed and 11 550 patients died from this disease [2]. In most countries, the incidence of gastric cancer has been declining over the past few decades (Fig. 43.2). Nonetheless, due to the rapidly growing populations in developing countries with high background incidence rates for gastric cancer, the total number of gastric cancer cases in the world has actually remained static [1]. Murray and Lopez projected that the annual number of new cases will continue to rise in the developing world over the next few decades as a result of population growth [3].

The overall reduction in gastric cancer incidence largely reflects a decline in incidence of cancers of the distal stomach, mostly of the intestinal type. However, since the mid-1970s there has been a steady rise in the incidence of adenocarcinoma of the proximal stomach and the gastroesophageal junction [4,5]. According to the US National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database, the annual increase in proximal gastric lesions is estimated to be 3.6%–5.6% [4]. The rise in proximal gastric cancer is alarming because on a percentage basis the increase is greater than that of lung cancer or melanoma, and proximal gastric cancer is associated with a worse prognosis than distal gastric cancer. This increase is paralleled by a rising hospitalization rate for gastroesophageal reflux disease, as noted in the US Department of Veterans Affairs database [6].

There are marked geographical variations in the incidence of gastric cancer (Table 43.1). The highest rates are observed in east Asia, where gastric cancer is still the most frequent cancer in men. The age-adjusted standardized rates in Japan and China are 62 and 41 per 100 000, respectively [1]. The corresponding rates in North America and Western Europe are 7.4 and 12.8 per 100 000, respectively. Apart from geographical variations, variations in cancer incidence and mortality can also be observed between different ethnic groups. In the United States, African Americans, Hispanic Americans and Native Americans are 1.5–2.5 times more likely to have gastric carcinoma than whites [7]. Similarly, the incidence of gastric cancer in Singapore Chinese is about twice that of Indians and five times greater than that of Malays [8]. The reason for this discrepancy is unclear, but factors including differences in socioeconomic status, and dietary and environmental conditions have been suggested. In Japan and China, there appears to be a dichotomized distribution of gastric cancers in which both incidence and mortality are higher in the northern parts than in the southern parts of the countries [9,10].

Gastric cancer has a predilection for elderly patients, with incidence peaks in the seventh decade. Men are more commonly affected than women, with male incidence rates double those for females. Besides gender differences, the incidence of gastric cancer also appears to be inversely related to social class. Rates are higher in unskilled laborers (class V) and lower in professional groups (class I) [11].

Etiology

With the global contrasts in the incidence of gastric carcinoma, tremendous effort has been made to identify the cause

for this malignancy. It is generally believed that gastric cancer has multiple etiological factors including diet, exogenous chemicals, intragastric synthesis of carcinogens, infectious agents, and the genetic make-up of the host (Table 43.2). Among various factors, *Helicobacter pylori* infection is the one most frequently examined.

Helicobacter pylori

Helicobacter pylori is a Gram-negative spiral-shaped bacterium found in the mucus layer of the human stomach. It was first successfully cultured by Marshall and Warren in 1984 [12]. This discovery dramatically revolutionized our understanding of gastroduodenal diseases, and earned Marshall and Warren the 2005 Nobel Prize in Medicine or Physiology.

Based on several large-scale epidemiological cohort studies that linked *H. pylori* to gastric carcinoma [13–16], the International Agency for Research on Cancer (IARC) classified *H. pylori* as a group 1 carcinogen in 1994 [17]. Data from 19 case–control studies have been summarized in a metaanalysis and show that the combined odds ratio (OR) for gastric cancer in *H. pylori*-infected subjects is 1.92 [95% confidence interval (CI), 1.32–2.78] [18]. Moreover, *H. pylori* infection is linked to both intestinal and diffuse-type cancers. The association between gastric cancer and *H. pylori* is found to be

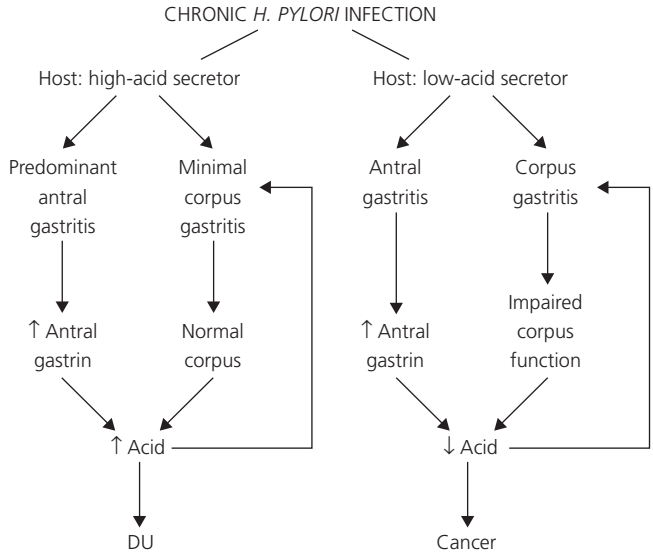

Figure 43.4 Divergent host response to *Helicobacter pylori* infection. Based on data from McColl KE, et al. *Helicobacter pylori* gastritis and gastric acid secretory function – an integrated approach. In: Hunt RH, Tytgat GN (eds). Basic mechanisms to clinical cure. Kluwer Academic Publishers, Dordrecht, the Netherlands, 1996. Copyright © 1996, Axcan Pharma Inc.

restricted to noncardiac cancers, and is stronger when blood samples for *H. pylori* serology are collected more than 10 years before cancer diagnosis (OR, 5.9). Because elderly patients with severe atrophic gastritis may have spontaneous remission of infection, the association between *H. pylori* and gastric cancer is particularly strong in young infected subjects. The OR increased from 1.05 at age ≥ 70 years to 9.29 at age ≤ 29 years (Fig. 43.3).

There are several genotypic variations among different *H. pylori* strains. For example, strains that express the cytotoxin-associated gene A (*cagA*) and secrete high amounts of the vacuolating cytotoxin (VacA) are more frequently found in patients with peptic ulcer and gastric carcinoma [19,20]. Possession of the *cagA* and *vacA* s1 genotype is therefore sometimes termed the type I strain. Moreover, strains that carry the *babA2*$^{+}$ gene are considered to be potentially more virulent [21].

In addition to epidemiological study, the causative role of *H. pylori* infection in gastric carcinogenesis was confirmed by experimental animal studies. In the absence of exogenous mutagens, Japanese investigators demonstrated that Mongolian gerbils infected with *H. pylori* developed severe active chronic gastritis, ulcers, and intestinal metaplasia within 6 months of infection [22]. Adenocarcinoma was detected in the stomach of one-third of the gerbils after 1 year of infection.

Although *H. pylori* infection is associated with noncardiac gastric cancers, there are data to suggest an inverse association between *H. pylori* infection and proximal gastric carcinoma [23]. It is believed that *H. pylori* infection leads to suppressed acid output, which paradoxically protects infected individuals from gastroesophageal reflux and hence Barrett esophagus, the precursor of adenocarcinoma of distal esophagus and proximal stomach. [24,25].

It is important to note that not all *H. pylori*-infected individuals will develop gastric cancer in their lifetime. In a large Swedish cohort study, the risk of gastric cancer among patients with duodenal ulcer was in fact significantly reduced (OR, 0.6; 95% CI, 0.4–0.7) [26]. Thus, *H. pylori* infection appears to produce two distinct phenotypes, namely duodenal ulcer or gastric ulcer/cancer [27,28]. The duodenal ulcer phenotype is characterized by the antral-predominant nonatrophic type of gastritis whereas gastric cancer patients tend to have multifocal or extensive corpus atrophic gastritis (Fig. 43.4). This hypothesis was confirmed by a prospective study in Japan showing that subjects with pangastritis and corpus-predominant gastritis have, respectively, a 16- and 35-fold increase in risk of gastric cancer compared with those with antral-predominant gastritis [29].

Interestingly, the incidence of gastric cancer is unexpectedly low in African countries despite the high prevalence of *H. pylori* infection [30]. It was found that concurrent helminth and *H. pylori* infection converts the T-helper cell type 1 (Th1) responses, which normally promote cell-mediated immune responses and tissue injury, to a less damaging Th2 response [31]. Thus, the progression of *Helicobacter*-associated gastric atrophy, a premalignant lesion, is attenuated. This finding illustrates the potential interaction between *H. pylori* infection and environmental factors that may partly explain the "African enigma."

Epstein–Barr virus

The virus being most extensively studied as an etiological factor for gastric cancer is Epstein–Barr virus (EBV). This is an icosahedral herpevirus containing linear double-stranded DNA, and is ubiquitous in all human populations. It has been

estimated that about 10% of gastric carcinomas worldwide show monoclonal proliferation of EBV-infected cancer cells [32]. In contrast to Burkitt lymphoma and nasopharyngeal carcinoma, which are endemic in Africa and southeast Asia, EBV-positive gastric carcinoma is a nonendemic disease.

Although EBV has been detected in all types of gastric cancer, it is closely linked to a form of undifferentiated gastric carcinoma called the lymphoepithelioma-like carcinoma. Histologically, these tumors resemble nasopharyngeal carcinomas. The presence of lymphoid stroma, proximal location, and predominance in males are characteristics of EBV-positive gastric carcinomas [33]. They also tend to be of diffuse histological types and have a lower frequency of lymph node metastasis [34]. The prevalence of *H. pylori* infection with this tumor is also lower than with non-lymphoepithelioma-like carcinomas [35].

Dietary factors

Dietary factors have long been suspected as an important cause of gastric cancer. However, most studies were based on retrospective data collection, which are readily subject to recall bias. In spite of these caveats, many case–control studies have shown a consistent inverse association between gastric cancer and consumption of fresh fruits or vegetables [36–40]. This observation may be partly related to the presence of vitamins such as vitamins C and E, carotenoids, and flavonoids in fruits and vegetables. These vitamins may act through various mechanisms, including antioxidant effects, inhibition of nitrosamine formation [41], and dilution or binding of carcinogens. An epidemiological study from China demonstrated that the risk of progression to gastric dysplasia and carcinoma was reduced by 80% (95% CI, 30%–90%) in subjects with high baseline ascorbic acid levels [42].

By contrast, food substances that are rich in nitrates, nitrites, and secondary amines, which combine to form *N*-nitroso compounds (NOC), are known mutagens or carcinogens. Nitrates and nitrites were used in food preservation before the era of refrigeration. Consumption of preserved meat and vegetables is consistently linked to the development of gastric cancer [37,43]. Humans are exposed not only to preformed NOCs, but also to a wide range of precursors and nitrosating agents, which can react in vivo to form potentially carcinogenic NOC. This process is facilitated in the presence of nitrate-reducing bacteria of the digestive tract. With the advent of refrigeration and the growth of the frozen food industry, consumption of preserved meats and vegetables has declined in most developed countries. This has been postulated to be a crucial factor for the reduction of gastric cancer incidence in North America and Western Europe [44].

A high-salt diet in humans and experimental animals is associated with an elevated risk of atrophic gastritis, a preneoplastic lesion [45,46]. Salt also enhances the colonization of *H. pylori* in mice and may therefore perpetuate the development of gastritis and glandular atrophy [47]. In Japan, a significant correlation was found between the amount of salt excreted in urine and stomach cancer mortality [48]. A study from 65 Chinese counties also demonstrated a significant positive association between stomach cancer mortality and consumption of salted vegetables [49]. In addition, consumption of a carbohydrate-rich diet was found to have a positive association with gastric cancer. A study from Shanghai showed a 1.5- to 1.9-fold increase in the risk of gastric cancer for the highest quartile of carbohydrate intake [40]. However, this association was not confirmed in other studies [50] and the possible role of carbohydrate in gastric carcinogenesis remains poorly defined.

The polyphenols in green tea have been postulated to have anticarcinogenic effects. Several case–control studies suggested an inverse association between consumption of green tea and the risk of gastric cancer [51]. However, the anticarcinogenic effect of green tea is refuted by a large-scale population-based prospective cohort study in Japan, which involved more than 26 000 residents [52].

Apart from case–control studies of dietary ingredients, migrant studies also provide invaluable information on the role of diet in gastric carcinogenesis. Migration is accompanied by change in lifestyle, especially diets. It is found that Japanese people who migrate to the United States have a significant reduction in mortality from stomach cancer when compared with native Japanese [53]. This observation implicates environmental factors in the pathogenesis of gastric cancer, with diet being the most likely cause.

Tobacco and alcohol

Although several studies have shown a 1.5- to 3.0-fold increase in the risk of gastric cancer among smokers, a clear–dose response relation cannot be demonstrated [54]. Moreover, smoking may be more related to cancer in the cardia than in the distal stomach. Given the rapid rise in the incidence of lung cancer and the progressive fall in stomach cancer incidence worldwide (Fig. 43.2), tobacco use is unlikely to be an important etiological factor for gastric cancer. Moreover, epidemiological studies have failed to show any significant correlation between alcohol use and stomach cancer [38,39].

Previous gastric resection

Many studies have suggested an increased incidence of gastric cancer in the stump remaining after gastrectomy. An annual incidence of 3% has been reported [55]. Rates of gastric cancer appear to remain low for 15–20 years after resection of the distal stomach and increase substantially thereafter [56,57]. Notably, Billroth II gastrectomy was associated with higher risk than Billroth I gastrectomy. The increase in cancer risk may be explained by changes in the gastric environment after acid-reducing surgery. As gastric surgery reduces acid production in the stomach and causes neutralization of the gastric milieu, the luminal bacterial content increases. Of particular interest is the presence of anaerobic bacteria in the

gastric remnant; these could convert dietary nitrates into nitrites, a potential gastric carcinogen. In addition, bile reflux after gastric surgery promotes gastric epithelial proliferation in the stomach remnant and possibly favors cancer development [58].

Genetic predisposition

Familial clustering of gastric cancer suggested a genetic basic for this malignancy. Case–control studies showed that first-degree relative of patients with gastric cancer have a two- to three-fold increase in the risk of gastric cancer [59]. However, true hereditary gastric cancer is rare except in patients suffering from germ-line mutation in the E-cadherin (*CDH1*) gene. This mutation was first identified in a large family from New Zealand with early-onset diffuse-type gastric cancer [60]. Screening for the *CDH1* mutation is recommended to patients with hereditary diffuse gastric cancer (HDGC) or even isolated cases of early-onset diffuse gastric cancer (< 35 years) [61]. It has been suggested that prophylactic gastrectomy may be indicated in young asymptomatic carriers of germ-line *CDH1* mutations because superficial infiltrates of malignant signet-ring cells are frequently found in these subjects [62]. Hereditary gastric cancers are also uncommonly seen in kindreds of hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, familial adenomatous polyposis and Peutz–Jeghers syndrome.

However, familial clustering of gastric cancers may be explained by common exposure to various environmental factors, particularly diet and *H. pylori* infection [63,64] among family members. It has also been shown that gastric atrophy and intestinal metaplasia are more common in relatives of gastric cancer patients than in control populations [65,66].

The increased prevalence of gastric atrophy among family members may be related to a polymorphism in the interleukin-1β (IL-1β) gene [67]. Although IL-1β is a proinflammatory cytokine and a potent inhibitor of gastric acid secretion, inheritance of the proinflammatory polymorphism trait is associated with increased risk of gastric cancer and of gastric atrophy in different populations [67,68]. Moreover, polymorphisms in a number of other inflammatory genes, for example IL-10 and tumor necrosis factor-α (TNF-α), are found to increase the risk of gastric adenocarcinoma [69]. The combination of *H. pylori* virulent factors and proinflammatory gene polymorphism may further increase the risk of development of cancer and premalignant gastric lesions [70].

The cascade of gastric carcinogenesis

Based on extensive observational studies in populations with high incidences of the disease, gastric cancer is generally believed to be a multistep progression from chronic gastritis to gastric atrophy, intestinal metaplasia, dysplasia, and cancer [71]. This is dubbed Correa's model of gastric carcinogenesis, which is usually triggered by *H. pylori* infection [72] (Fig. 43.5).

In this context, gastric atrophy and intestinal metaplasia are regarded as preneoplastic gastric lesions, particularly for intestinal-type cancer. Gastric atrophy usually predates the development of intestinal metaplasia and can be detected in 80%–90% of patients with gastric cancer. It has been estimated that 10% of individuals with chronic atrophic gastritis will develop gastric carcinoma in a 15-year follow-up period [73]. Apart from endoscopic methods, evaluation of serum pepsinogen I/II ratios may also help to identify individuals with gastric atrophy. In a prospective study from Japan, it was found that individuals with atrophic gastritis with elevated serum pepsinogen and negative serology for *H. pylori* had the greatest risk of gastric cancer development (hazard ratio, 8.2; 95% CI, 3.2–21.5) [74]. In addition, patients with type A or autoimmune atrophic gastritis, which typically

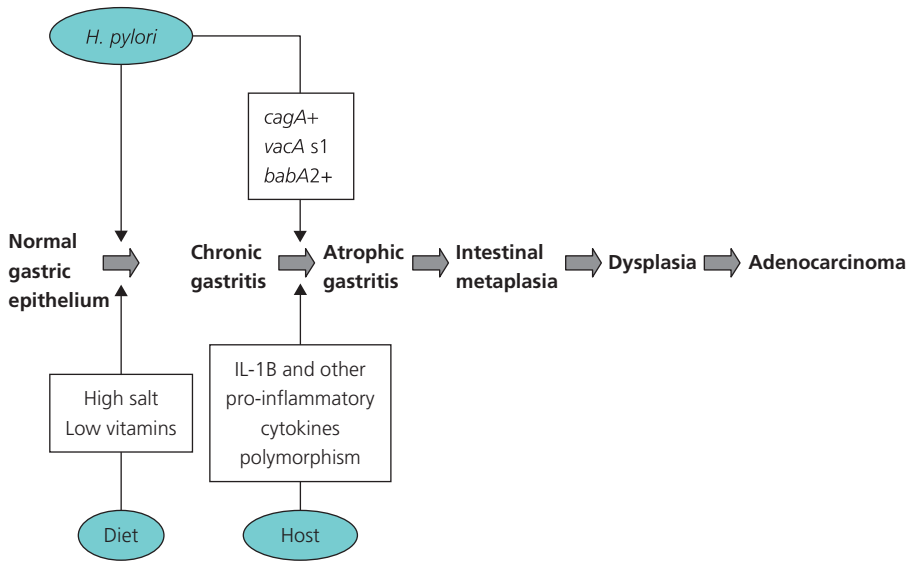

Figure 43.5 Multistep gastric carcinogenesis: the role of *Helicobacter pylori* genotypes, host proinflammatory cytokine polymorphism, and diet on the gastric carcinogenesis model.

affects the corpus, have a two- to three-fold increased risk of stomach cancer [75].

Intestinal metaplasia (IM) is recognized by the presence of goblet cells, absorptive cells, and cells resembling colonocytes or by the mucin content of the colonocyte-resembling cells. Intestinal metaplasia can be further divided into small intestinal and colonic types, or complete and incomplete types, on the basis of morphology and enzyme histochemistry [76]. Type I (complete) refers to the presence of goblet cells containing sialomucins interspersed between nonsecretory absorptive cells with well-delineated brush borders. Type II (incomplete) indicates the presence of sialomucin-containing goblet cells scattered among gastric-type cells containing either neutral mucin or sialomucins. Type III (incomplete or colonic type) is diagnosed when there are tortuous and branched crypts lined by tall columnar cells containing abundant sulfomucins. Sulfomucins can be differentiated from sialomucins by using high-iron diamine (HID)–alcian blue staining (Fig. 43.6). Complete, or type I, IM is generally believed to carry the lowest risk of gastric cancer, whereas type III (colonic) has the strongest association [77]. Although the real clinical significance of IM typing remains controversial, there is unequivocal evidence that individuals harboring IM have an increased cancer risk. In a cohort study from Shandong Province, China, involving more than 3000 subjects with a follow-up of 4–5 years, the odds ratio of progression from intestinal metaplasia to gastric cancer varied from 17 to 29. The risk was particularly high for those with more advanced baseline histological lesions, such as the presence of dysplasia [78]. Another prospective study from Japan further showed that individuals with IM had at least a sixfold increase in risk of gastric cancer [29].

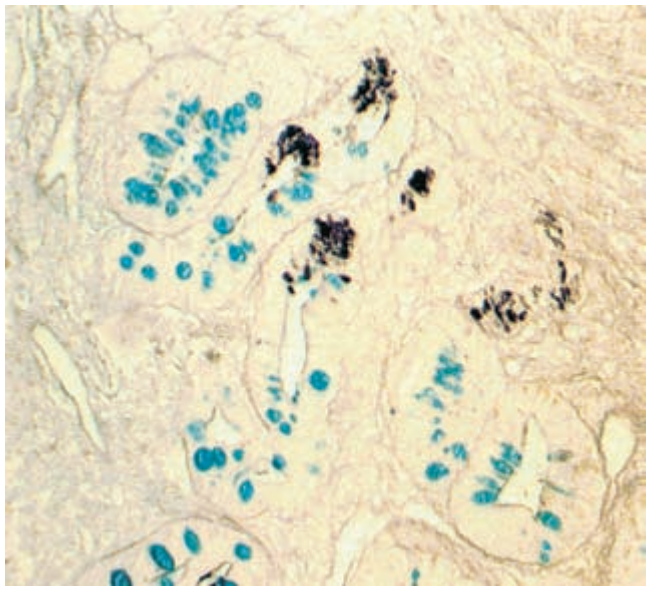

Figure 43.6 Type III intestinal metaplasia of stomach. The presence of sulfomucin in type III intestinal metaplasia is illustrated by the high iron diamine (HID)/alcian blue staining.

Molecular changes associated with gastric carcinogenesis

The molecular changes associated with gastric carcinogenesis are poorly characterized, in contrast to those of colorectal cancer. A number of genetic alterations have been identified but many are detected at a relatively low frequency [79]. Mutations in p53 are observed in up to 45% of intestinal-type cancers, with a lower frequency in diffuse-type cancer (0%–21%). Mutations in the *APC* gene are detected in more than 50% of well-differentiated gastric cancers, but not in any poorly differentiated gastric cancers [80]. Unlike hereditary diffuse gastric cancer, somatic mutations of E-cadherin are detected at a lower frequency in sporadic diffuse-type gastric cancer than in hereditary diffuse gastric cancer [81]. The *RUNX3* gene has been identified as another potential tumor suppressor gene in gastric cancer [82]. Activation of protooncogenes such as *ras* and *c-myc* is infrequently detected in gastric cancer [83].

Microsatellite instability (MSI), a form of genomic instability and a manifestation of cellular defects in DNA mismatch repair, is present in 17%–48% of gastric cancer [84,85]. Gastric cancers with MSI phenotypes tend to have specific clinicopathological characteristics, including intestinal type, prominent lymphocyte infiltration, and antral location, and are associated with a better prognosis [85,86]. Microsatellite instability can also be detected in gastric intestinal metaplasia, a preneoplastic lesion, in patients without gastric cancer [87]. In contrast to hereditary forms of colorectal cancers with MSI phenotypes, germ-line mutations of DNA mismatch repair genes are infrequent in MSI-positive gastric cancer. Instead, epigenetic inactivation of *hMLH1*, a DNA mismatch repair gene, by promoter hypermethylation was found to be the major mechanism underlying the gene silencing [88]. The E-cadherin gene is also frequently silenced by promoter hypermethylation. A second hit of promotor hypermethylation of E-cadherin in carriers of germline E-cadherin mutations leads to cancer development [89]. Gastric cancer frequently demonstrates concordant methylation in multiple tumor-related genes [90]; cancers with methylation in several specific loci are also called the CpG island methylator phenotype (CIMP) [91].

Cyclooxygenase-2 (COX-2) is an inducible form of prostaglandin synthase responsible for the conversion of arachidonic acid to prostanoids. Upregulation of the COX-2 gene and overexpression of the COX-2 enzyme are detected in approximately 70% of human gastric cancers [92–94]. Gastric carcinomas with COX-2 overexpression tend to have enhanced angiogenesis [95] and are associated with a worse prognosis [96]. Interestingly, there are overwhelming experimental data to support the potential use of COX-2 inhibitors in chemoprevention and treatment of gastric cancer. The use of celecoxib, a specific COX-2 inhibitor, has been shown significantly to reduce gastric cancer development in rats treated with mutagen [97]. Inhibition of COX-2 also was found to inhibit the growth [98] and angiogenesis [99] of gastric cancer cells.

Expression of COX-2 is also detected in *H. pylori*-associated gastritis and intestinal metaplasia [94,100], suggesting their early involvement in the gastric carcinogenesis pathway.

Chemoprevention of gastric cancer

Chemoprevention, as defined by the International Agency for Research on Cancer (IARC), refers to interventions with pharmaceuticals, vitamins, minerals, or other chemicals (natural or synthetic) at any of the multiple stages of carcinogenesis to reduce cancer incidence. Chemoprevention of gastric cancer focuses on the effect of *H. pylori* eradication or supplementary antioxidants.

Despite the strong etiological link between *H. pylori* infection and gastric cancer, it remains elusive whether eradication of *H. pylori* could prevent gastric cancer development. These chemoprevention studies are extremely difficult to perform due to the long cancer development process, which typically takes a few decades. To determine the potential benefits of *H. pylori* eradication, most studies were designed to examine the regression of presumed preneoplastic lesions – atrophy and intestinal metaplasia – as the surrogate end point of treatment success. Results of two large-scale randomized controlled studies performed in China and Colombia showed marginal benefits of *H. pylori* eradication in preventing regression of intestinal metaplasia at the end of 5–6 years [101–103]. Another study performed in southern China, which used gastric cancer incidence as primary end point, failed to show any significant benefits of *H. pylori* eradication [104]. It was only in subgroup analysis that individuals with no precancerous gastric lesions at baseline were found to have a marginally lower risk of gastric cancer development after *H. pylori* eradication.

The Colombian study by Correa et al. also examined the long-term effects of vitamin supplementation on changes in atrophy and intestinal metaplasia [102]. It was found that both β-carotene and ascorbic acid resulted in significant regression of both atrophy and intestinal metaplasia. However, there was no additional benefit of combination treatment with vitamins or *H. pylori* eradication. It remains unknown whether these findings could translate into real reductions in gastric cancer incidence.

Pathological features

Macroscopically, gastric tumors can be broadly categorized by their locations and appearances. Categorization of tumors into proximal (cardia) and distal (including body and antrum) cancers has major clinical significance in terms of etiology and prognosis. Distal cancers are more common in areas with a high incidence of gastric cancer, whereas cardia cancers are more prevalent in Caucasians with a low background gastric cancer incidence. Distal cancer is closely related to chronic *H. pylori* infection whereas cardia cancer is often the consequence of chronic gastroesophageal reflux disease and Barrett esophagus.

The macroscopic appearance of gastric cancer has been classified by Borrmann into four types (Fig. 43.7). Type I represents polypoid lesions without necrosis or ulceration; type II encompasses fungating cancers, which may contain superficial ulceration; type III represents ulcerated lesions infiltrating the gastric wall; and type IV are diffusely infiltrating tumors or linitis plastica lesions. There is considerable overlap between the different types, and this typing system does not appear to correlate with histological typing. Around

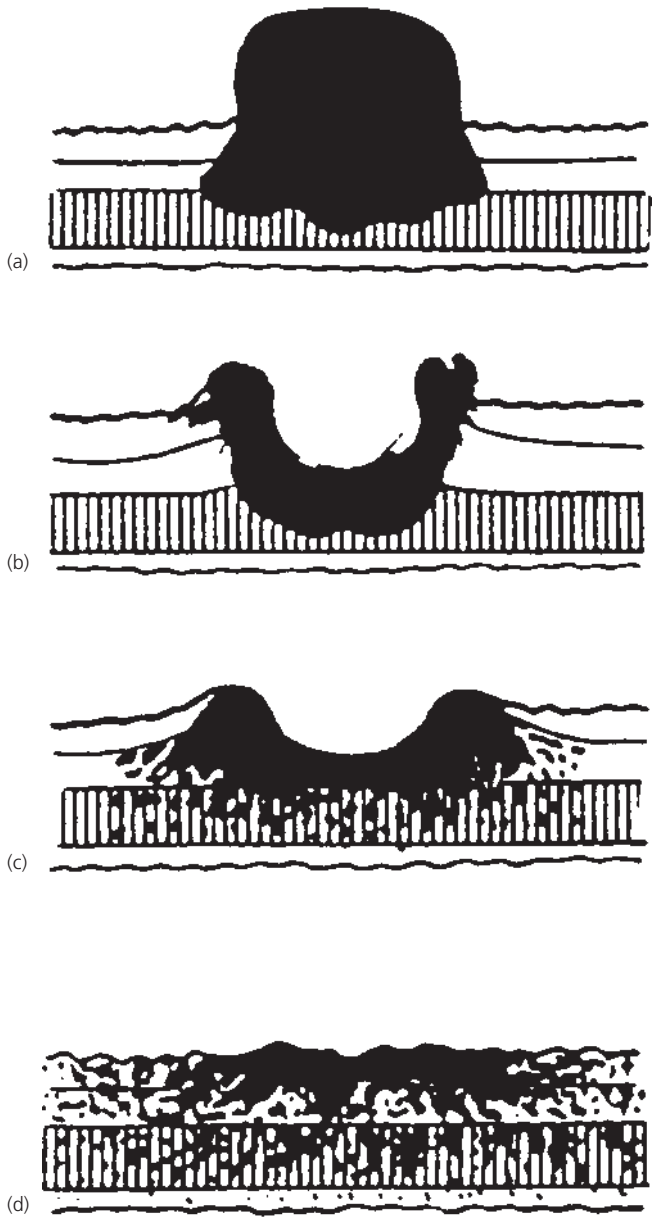

Figure 43.7 Macroscopic appearance of tumor as classified by Borrmann. **(a)** Polypoid; **(b)** fungating with surface ulceration and hemorrhage; **(c)** ulcerated without major lumen component; **(d)** infiltrative. From Borrmann R. Geshwulste des Magen und Duodenums. In: Henke F, Lunbarsch O (eds). Handbuch der Speziellen Pathologischen Anatomie und Histologie, vol. 4. Berlin: Julius Springer, 1926:812.

40%–50% of tumors are fungating or polypoid in appearance, and a similar proportion of tumors are ulcerative in nature. Linitis plastica is an aggressive infiltrating tumor consisting of high-grade tumor cells accompanied by a marked desmoplastic reaction that results in the rigid, leather-bottle-like stomach. This form of tumor spreads through the submucosa and is associated with a worse prognosis.

Adenocarcinoma accounts for 95% of the stomach cancers, whereas squamous cell carcinoma, carcinoid tumors, leiomyosarcoma, and lymphoma constitute the rest of the gastric tumors. Microscopically, there are several histological classifications for gastric adenocarcinoma. The most widely used classification was proposed by Lauren [105]; this broadly divides gastric cancer into diffuse and intestinal types (Fig. 43.8). Despite its simplicity, this classification categorizes tumors into two distinct types with contrasting epidemiology, etiology, and prognosis. The intestinal type is named by its histological morphology, and the diffuse type is characterized by its biological behavior. Intestinal-type cancer is characterized by cohesive neoplastic cells forming glandular tubular structures whereas diffuse-type cancer comprises sheets of epithelial cells or cells scattered in a stromal matrix without evidence of gland formation. Diffuse cancers may contain signet-ring cells. Intestinal-type cancer is more common in the distal stomach and is often preceded by preneoplastic stages such as intestinal metaplasia. It is more prevalent in regions with a high background incidence of gastric cancer and is generally associated with a better surgical outcome than the diffuse type. Approximately 5%–10% of tumors remain unclassified and are called "mixed type." These unclassified tumors are usually regarded as diffuse type during clinicopathological evaluations.

Another classification system proposed by the World Health Organization (WHO) divides gastric tumors into 10 types (Table 43.3) [106]. This classification is highly reproducible and is useful for routine pathological diagnosis of gastric cancer. Based on the degree of differentiation at architectural and cellular levels, gastric tumors can be divided into well-, moderately, or poorly differentiated types. Tubular adenocarcinoma, in which the glands form branching tubules, is the most common type of gastric adenocarcinoma. In papillary tumors there are prominent intraglandular foldings and projections, with cuboidal to high-columnar carcinoma cells lining the narrow bands of interstitial tissue in an arborizing pattern. Both types contain absorptive cell type and tend to form polypoid or fungating masses macroscopically. Signet-ring cell carcinomas are named because of the shape of the tumor cells, which contain abundant intracytoplasmic mucus. There is minimal gland formation, and this type of tumor tends to infiltrate. Mucinous adenocarcinoma, also called mucoid or colloid carcinoma, is diagnosed when mucus occupies more than 50% of tumor mass [107].

There have been some controversies concerning the diagnosis of well-differentiated carcinoma between pathologists in the West and the East. According to Western criteria, diagnosis of adenocarcinoma is based on evidence of invasion. By contrast, Japanese pathologists diagnose gastric carcinoma on the nuclear and structural criteria even in the absence of invasion. Thus, dysplasia according to Western pathologists was frequently interpreted as early carcinoma in Japan [108]. In this regard, the Western policy runs the risk of overlooking cancers whereas the Japanese policy may overtreat "nonmalignant" lesions.

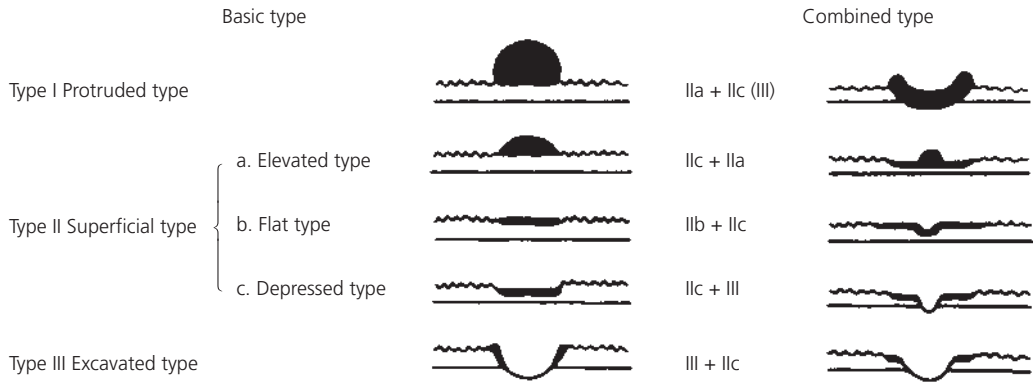

Figure 43.9 Classification of early gastric cancer by the Japanese Gastroenterological Endoscopy Society. From Japanese Research Society for Gastric Cancer. The general rules for the gastric cancer. Jpn J Surg 1973;3:61.

Early gastric cancer

Early gastric cancer (EGC) refers to tumor confined to the mucosa or submucosa, regardless of the presence or absence of metastasis. This disease is particularly prevalent in Japan, where mass screening for gastric cancer is performed. It is estimated that up to 65% of gastric cancers diagnosed in Japan belong to this entity. The prognosis for EGC is extremely good, with a more than 90% 5-year survival rate [109].

The Japanese Research Society for Gastric Cancer classified EGC into three types based on the macroscopic appearances [110] (Fig. 43.9). Type I is an exophytic lesion, type II is flat (or superficial), and type III is an ulcerated or depressed lesion. Type II is further divided into three subtypes depending on whether the lesion is elevated (IIa), flat (IIb), or depressed (IIc). In addition, combined types have been defined to include complex configurations. The protruded-type (type I and IIa), with a diameter of less than 25 mm, and the excavated type (type IIc), with a diameter less than 20 mm, seldom produce lymph node metastasis. The incidence of nodal metastasis of intramucosal and submucosal cancer is reported to be 3% and 20%, respectively [111]. Other parameters that may determine the rate of lymph node metastases are the size of the tumors and the presence of ulcerations. Distant metastasis is uncommon in EGC.

Many argue that EGC is not a genuine malignant condition because of the diagnostic criteria for cancer adopted by Japanese pathologists [112]. Tsukuma et al. reported their long-term follow-up of 56 patients with EGC diagnosed by endoscopy and confirmed by histology, and in whom surgical resection was delayed or not carried out [113]. Over a period of 6–137 months, 36 (64%) patients progressed to the advanced stage. The cumulative risk for progression to advanced cancer in 5 years was 63%, suggesting that EGC progresses at a relatively slow pace.

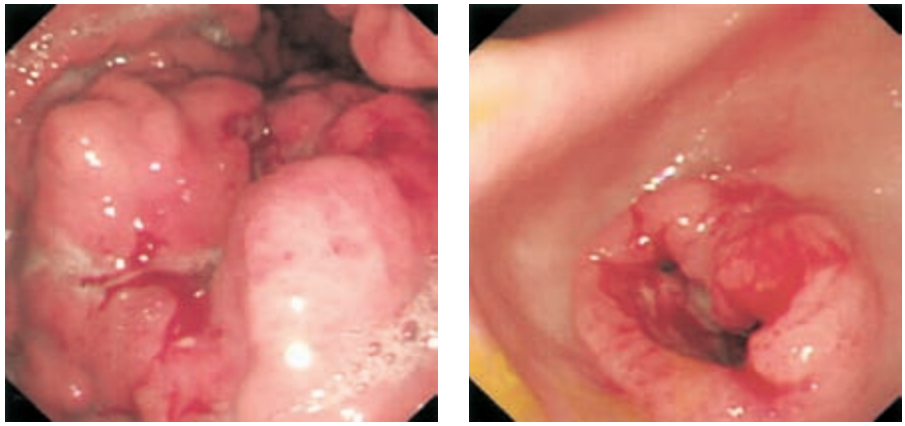
Clinical features

Early gastric cancer typically is asymptomatic and only patients with advanced disease will notice discomfort. Frequent symptoms are weight loss and abdominal pain [114]. Persistent vomiting can occur in antral tumors obstructing the gastric outlet. Dysphagia may be present with tumors obstructing the gastroesophageal junction. Early satiety, although not a common presentation of gastric cancer, may suggest a diffusely infiltrative tumor resulting in loss of distensibility of the stomach. Gastrointestinal bleeding has been reported in about 10%–15% of patients but frank bleeding is rare. Overt massive upper gastrointestinal bleeding may be more common in gastric stromal tumors.

Physical signs are usually absent in gastric carcinomas except in metastatic diseases. Palpable abdominal mass is rare before regional extension of the tumor. Gastric carcinomas spread by local extension to adjacent structures or metastasize by lymphatic, peritoneal, and hematogenous routes. Tumor may penetrate the gastric wall and directly invade omentum, pancreas, kidney, colon, spleen, and liver. Gastrocolic fistula is uncommon but may result in vomiting of fecolith materials or passage of recently ingested food into stool. Lymphatic metastasis occurs early and local lymph nodes are usually the first to be involved. Metastasis to left supraclavicular lymph node produces the so-called Virchow node. Tumor spreading along the peritoneal surfaces may result in a periumbilical nodule (Sister Mary Joseph node), ovarian mass (Krukenberg tumor), or tumor mass in the cul-de-sac (Blumer shelf). Peritoneal seeding of tumor may produce malignant ascites. Hematogenous spread usually involves the liver and occasionally the lung, bone, or brain. Patients with gastric cancer occasionally present with paraneoplastic syndromes, such as acanthosis nigricans, membranous glomerulonephritis, microangiographic hemolytic anemia, arterial and venous thrombi (Trousseau syndrome), seborrheic dermatitis (Leser–Trélat sign), and dermatomyositis.

Diagnosis

Barium meal was once the investigation of choice for all upper gastrointestinal symptoms. With the use of double-contrast techniques, better visualization of mucosal detail



(a) (b)

Figure 43.10 Endoscopic appearance of gastric cancer.

can be obtained. Malignant ulcer typically has an asymmetric ulcer crater eccentrically located in an irregular mass with distortion or obliteration of the normal mucosal fold surrounding the ulcer. Other features such as nodularity, clubbing, fusion, or amputation of radiating folds also suggest malignancy. However, false-negative rates of up to 25% have been reported in lesions between 5 mm and 10 mm in diameter [115]. Use of barium meal and radiography in the diagnosis of gastric cancer is currently limited to mass population screening.

Since its introduction in the 1960s, upper gastrointestinal endoscopy and biopsy has become the gold standard for the diagnosis of gastric cancer. However, endoscopic appearance alone is insufficient for the diagnosis of stomach cancer (Fig. 43.10). Diagnostic accuracy was reported to be 95% [115–117] and this can be further improved by increasing the number of biopsies [118]. Biopsies should be taken from the edge and the base of a malignant ulcer [119]. The additional use of brush cytology may further increase the sensitivity of endoscopic diagnosis. Identification of two of the three cytological features makes the diagnosis of gastric cancer more likely: (1) single atypical cells with intact cytoplasm; (2) eccentric nuclei; and (3) atypical naked nuclei [120]. Diagnosis of early gastric cancer can be difficult as lesions may not be conspicuous. Endeavors to improve the diagnostic accuracy of endoscopy have led to the development of new technologies. The use of a magnifying endoscope has enabled visualization of the microvascular architecture of the stomach. It was shown that the well-differentiated carcinoma may demonstrate the following findings:

- a demarcation line between the cancerous and the non-cancerous mucosa
- the disappearance of the regular subepithelial capillary network pattern
- the presence of an irregular microvascular pattern [121].

Light-induced fluorescence endoscopy (LIFE-GI) is another new technique that detects the autofluorescence from tissues after irradiation with blue or violet light. Characteristically, gastric tumors emit a different fluorescence from that of normal tissues, and this can be used as an adjunctive technique for the evaluation of presumptive neoplastic tissue [122,123].

Screening for gastric cancer

Screening for gastric cancer in asymptomatic individuals may increase the chance of detecting early cancer and hence improve overall survival. It is widely practiced in Japan. The early screening programs used double-contrast radiography [124], which has been largely replaced by endoscopy. It is estimated that 40%–60% of cancers diagnosed by the screening program are early cancer with no lymphatic metastasis [125], and that about 25% of gastric cancers in Japan are diagnosed by screening procedures [79]. Although screening is regarded as the main reason for the decline in stomach cancer mortality in Japan, a formal randomized study to evaluate the effectiveness of the screening program is lacking. Given the low incidence of gastric carcinoma in most developed countries, it is unlikely that a similar population-based screening program can be adopted. In areas with a low incidence of gastric cancer, screening may have to be targeted to high-risk individuals only, such as those with family history of gastric cancer, chronic atrophic gastritis, previous gastric surgery, or pernicious anemia.

Apart from contrast study and endoscopy, biochemical markers have been used to identify those at risk of developing gastric carcinoma. A low level of serum pepsinogen I, which correlates with corpus atrophy, has been found to be significantly associated with gastric cancer [126]. Kitahara et al. showed that a pepsinogen I concentration of less than 70 ng/mL, and a ratio of pepsinogen I:pepsinogen II of less than 3, are useful indicators, with a sensitivity of 84.6% and a specificity of 73.5% for detecting gastric cancer [127]. In this context, an elevated serum gastrin level has also been used in the screening for severe atrophic gastritis [128]. Although an elevated gastrin level of greater than 200 ng/L

appears to be specific, the sensitivity is low (30%), which precludes its use as a screening tool. The use of molecular screening techniques, such as serum protein profiling, may also help to identify patients with gastric cancer [129].

Staging

The staging of gastric carcinoma is of paramount importance for the planning of therapy, besides its prognostic implications. The most widely used staging system in most countries is the TNM (tumor, node, metastasis) classification devised by the International Union against Cancer (UICC) and American Joint Committee on Cancer (AJCC). The system used in Japan is the Japanese Classification of Gastric Carcinoma, and the second English edition was published in 1998 [110].

The acronym TNM stands for tumor invasion (T; Fig. 43.11), lymph node involvement (N), and the presence of metastasis to other organ(s) (M). The classification has been constantly revised, and the sixth edition of the TNM classification was published in 2002 [130] (Table 43.4). The lymph node staging system underwent major revision in the fifth edition, being based on the number of regional lymph nodes involved rather than the anatomical site or the distance of metastatic lymph nodes from the primary tumor, as used in the Japanese Classification (Fig. 43.12). This revised classification is easier to follow than the previous sophisticated localization of lymph nodes around the stomach, and reduces the problems involved in lymph node retrieval.

The Japanese Research Society for Gastric Cancer uses a more meticulous classification system including four categories of findings: clinical, surgical, pathological, and final [110]. In addition to TNM, the presence of hepatic metastases (H) and peritoneal metastases (P) is documented. Another important difference from the UICC/AJCC classification lies in the lymph node staging. In the Japanese classification, the regional lymph nodes, each labeled with a different station number (numbers 1–20 and 110–112), are classified into three groups depending on the location of the primary tumor. Hence, patients with N1 staging have the group 1 lymph node involved only whereas patients with N3 staging have group 3 lymph node metastasis as well.

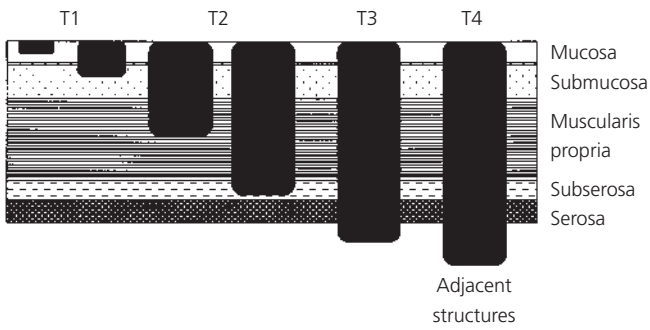


Figure 43.11 T-classification of gastric carcinoma (TNM staging system).

Table 43.4 Summary of the UICC (International Union Against Cancer) TNM classification of gastric cancer, sixth edition

T Primary tumor	
Tis	Carcinoma in situ; intraepithelial tumor without invasion of lamina propria
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria or subserosa
T2a	Tumor invades muscularis propria
T2b	Tumor invades subserosa
T3	Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures
T4	Tumor invades adjacent structures
N Regional lymph node	
N0	No regional lymph node metastasis
N1	Metastasis in 1–6 regional lymph nodes
N2	Metastasis in 7–15 lymph nodes
N3	Metastasis in more than 15 regional lymph nodes
M Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

Stage grouping

Stage	T	N	M
0	Tis	N0	M0
IA	T1	N0	M0
IB	T1	N1	M0
	T2a/b	N0	M0
II	T1	N2	M0
	T2a/b	N1	M0
	T3	N0	M0
IIIA	T2a/b	N2	M0
	T3	N1	M0
	T4	N0	M0
IIIB	T3	N2	M0
IV	T4	N1–3	M0
	T1–3	N3	M0
	Any T	Any N	M1

Preoperative staging

In general, no single imaging technique is accurate enough in the preoperative staging of gastric cancer. The use of multiple test modalities is therefore necessary for accurate preoperative staging. However, 25% of metastatic nodes measure 5 mm or less and are undetectable by most imaging techniques [131].

Ultrasonography (US) is a noninvasive, relatively inexpensive, and easily available imaging technique for intraabdominal malignancy. In experienced hands, US can be a useful

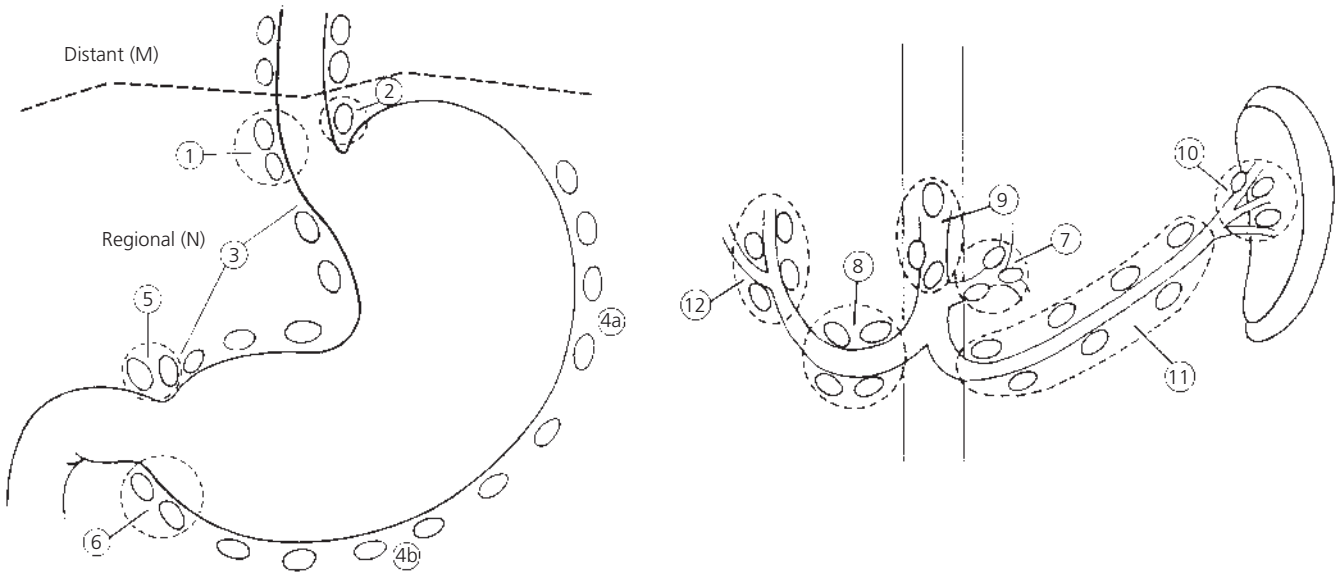

Figure 43.12 Regional lymph node stations as proposed by the Japanese Research Society for Gastric Cancer. From Hermanek P, Huttter RVP, Sobin LH, et al. (eds). TNM atlas, 4th edn. Berlin, Heidelberg: Springer-Verlag, 1997:82.

preoperative investigation for screening of solid organ metastases, enlarged paraaortic and portal lymph nodes, ascites, and pelvic deposits such as Krukenberg tumors of the ovary. Computed tomography (CT) is widely used for preoperative staging of stomach cancer [132]. Although it is sensitive in detecting direct invasion of the tumor into adjacent organs and liver metastasis [133,134], one of the major limitations of CT is its inability to differentiate between different structural layers of the gastric wall and hence to define the T stage accurately. The use of multidetector row CT gastrography with multiplanar reformation and virtual endoscopy may help to improve the accuracy of preoperative T staging [135].

For lymphatic metastasis, the sensitivity of CT varies from 48% to 91% [136,137]. The sensitivity of CT in detecting a distant metastasis is about 57% [138] but false positives are not uncommon. Finally, it is generally recognized that CT is poor in the visualization of small peritoneal nodules except in the presence of ascites. Overall, CT scan tends to understage gastric cancer and may be more useful in identifying advanced stage disease.

The role of magnetic resonance imaging (MRI) in the preoperative staging of gastric cancer has yet to be defined. It is superior to CT scan in delineating the structural layers of the stomach wall and may be used in predicting the depth of tumor invasion (T staging) [54]. However, MRI requires a longer scan time and is prone to artifact caused by breathing and bowel movements.

Positron emission tomography (PET) with ^{18}F-deoxyglucose (FDG) is being increasingly used in the evaluation of gastrointestinal malignancy. The preferential accumulation of positron-emitting FDG by tumor cells has been used in the detection of human cancers. It has been shown that PET combined with CT is more accurate for preoperative staging than either modality alone, particularly in lymph node staging [139].

Endoscopic ultrasonography (EUS) is an important preoperative staging tool for gastric cancer. With the use of a medium- to high-frequency ultrasound probe (7.5–30 MHz), the gastrointestinal tract is clearly delineated as a five-layered structure by EUS. The ability of EUS to distinguish between mucosa, submucosa, and muscularis mucosa makes it the best imaging modality to assess the depth of tumor invasion (Fig. 43.13). It is superior to conventional CT scan, with reported accuracy ranging from 71% to 92% for T-staging, and 55% to 87% for N-staging [140]. The presence of ascitic fluid on EUS may also predict the presence of peritoneal metastasis [141]. However, the presence of metastases within a normal-sized lymph node may be missed and EUS is generally unsuitable for the assessment of distant metastases due to the low penetration of high-frequency ultrasound.

Although transcelomic spread occurs in about 40% of tumors with serosal involvement (stage T3 or above), the inability of CT scan to diagnose peritoneal and omental metastases may lead to understaging of the tumors. Preoperative staging laparoscopy often detects unexpected peritoneal or liver metastases that may not be identified by other imaging techniques (Fig. 43.14). The overall rate of detecting peritoneal and liver metastasis by laparoscopy ranged from 3% to 37% and from 2% to 25%, respectively [142]. The addition of laparoscopy has modified the management plan of 25%–40% of patients who were otherwise deemed to be

curable by radical surgery according to other preoperative staging investigations [143,144]. The use of laparoscopy may therefore be particularly useful in patients with locally advanced disease that may benefit from preoperative multimodality treatment [145].

Treatment

Surgery was long the mainstay of treatment for gastric cancer. Conventional treatment comprises resection of the primary tumor and control of lymph node metastasis. However, with the increasing recognition of EGC and improvement in techniques, endoscopic treatment is widely used in removing cancer confined to the mucosa.

Endoscopic therapy

Therapeutic endoscopy has three roles in gastric cancer treatment:

- to remove or obliterate the cancer
- to palliate obstruction
- to control bleeding.

Due to the low incidence of lymph node and distant metastasis (3% for intramucosal and 20% for submucosal tumors), surgical resection of the stomach for EGC (T1 cancer) is sometimes considered unnecessary. Endoscopic mucosal resection (EMR), or strip biopsy, was first described by Tada and colleagues in Japan [146], and is the standard treatment for EGC in Japan. It involves injection of saline into the submucosa beneath the lesion to lift the mucosal and submucosal layer from the muscle to avoid perforation. Methylene blue may be added to the saline to demarcate the plane of separation. The endoscope is fitted with a suction cap at its tip. The lesion is sucked into the chamber and resected by EMR snare (Fig. 43.15). Resection of the mucosa may then be achieved by using a cap-fit device at the tip of the endoscope and a mucosectomy snare. The malignant tissue can be removed en bloc or by piecemeal resection. Muscle fibers can be seen at the base of the resected area. Reepithelialization usually occurs within weeks. In contrast to ablation by laser or argon plasma, EMR can provide the original resected specimens for histological evaluation. The major complications of EMR are bleeding and perforation together occurs at a rate of about 5% [147]. According to the Japanese Gastric Cancer Association treatment guidelines [148], EMR is indicated for patients with a small mucosal cancer with no lymph node metastasis. Specifically, an intestinal-type mucosal cancer less than 2 cm in diameter is the best tumor type for EMR. In a review of the 11-year results of EMR performed at the National Cancer Center Hospital of Japan, which included 479 cancer patients, 69% of tumors were resected with clear margin and a total of 17 local recurrences were detected during subsequent follow-up [147]. There were no gastric cancer-related deaths during the follow-up period (3–120 months). Bleeding and perforation occurred in 5% of cases.

A more extensive endoscopic resection technique has been introduced in Japan, involving the use of a new device called the insulation-tipped (IT) needle knife [149]. The procedure is called endoscopic submucosal dissection (ESD), to indicate the potential depth of resection. The advantage of this procedure over EMR is the provision of a large en bloc specimen for histological staging and a greater potential to prevent recurrent disease. Bleeding (7%) and perforation (4%) are more commonly encountered after this procedure than after EMR [150].

For advanced inoperable gastric cancer with obstruction, laser or argon plasma coagulation therapy and endoscopic stenting procedures can be considered. Laser ablation of tumors requires expensive equipment, and thus argon plasma coagulation is preferred by most gastroenterologists. With the advent of self-expanding metallic stents, the palliation of malignant stricture can be achieved with minimal complications. It is particularly useful in the palliation of proximal gastric cancer as well as gastric outlet obstruction. In addition, any fistula or perforations can be sealed by the covered stent. Endoscopic stenting can also be used to relieve obstruction caused by tumor recurrence at an anastomosis after partial or total gastrectomy (Fig. 43.16). Tumor ingrowth, stent

migration, and gastroesophageal reflux remain problems of endoscopic stenting. Various covered stents are available to overcome the problem of tumor ingrowth, and antireflux mechanisms have been devised to avoid gastroesophageal reflux.

Surgery

Surgery can achieve the best locoregional control of gastric tumors, and it remains the standard treatment for such tumors other than EGC. It has been shown that the completeness of surgical resection is an important factor for survival [151]. Hence, patients with an R0 resection (i.e., no residual disease and clear margins) have a better survival than R1 (microscopic residual disease) or R2 (gross macroscopic residual disease). There are, however, considerable differences in the extent of gastric resection and lymph node dissection performed by Asian surgeons and Western surgeons. In the Japanese Gastric Cancer Association guidelines [148], the extent of surgical resection and lymph node dissection is dictated by the clinical staging of the patients (Fig. 43.17). By contrast, there is no similar guideline in the West.

Removal of the primary tumor

Total gastrectomy was, at one time, the recommended surgery for cancers of the stomach regardless of their location. Although the procedure is expected to provide better locoregional control of the primary tumor and remove all the remaining at-risk gastric mucosa, the resulting functional disturbance can be disabling. However, there is an increasing tendency to perform a proximal or distal gastrectomy, depending on the size and location of the tumor, instead of total gastrectomy. Two randomized trials conducted in the 1980s showed that the overall survival of patients with antral cancers after subtotal gastrectomy was not inferior to that after total gastrectomy [152,153]. A subsequent randomized trial by the Italian Gastrointestinal Tumor Study Group showed that patients with subtotal gastrectomy had a similar survival probability (65.3%) when compared with those undergoing total gastrectomy (62.4%) [154]. Subtotal gastrectomy should therefore be considered in patients with distally located tumor of intestinal differentiation. For a sizable tumor of diffuse subtype or more proximally located lesions, a total gastrectomy is advisable. Tumors involving the esophagogastric junction are better treated with esophagogastrectomy by a left thoracoabdominal approach.

Apart from curative resection, palliative surgery may still be considered in circumstances such as tumor obstruction, perforation, and bleeding. There is a reduction in the incidence of debilitating ascites after palliative gastrectomy [155]. If gastrectomy is performed, gross disease immediately adjacent

to the stomach should be removed. Leaving behind a primary tumor mass in the stomach not only invites bleeding and perforation but also diminishes the likelihood of response to subsequent palliative chemotherapy. Alternatively, a bypass procedure or gastrojejunostomy can be performed, although this is associated with a significantly shorter palliation period compared with gastric resection [156]. There is also no signficant difference in terms of operation-related morbidity and mortality. However, gastric resection is not indicated in patients with a poor chance of survival, and the final decision is usually dictated by the overall clinical conditions of the patients.

Lymph node dissection

There is significant controversy about the extent of lymph node dissection, particularly between Western and Japanese surgeons. Japanese surgeons first advocated the use of extended lymphadenectomy in the 1960s in the hope that it might reduce the chance of nodal recurrence and improve survival. All intraabdominal lymph nodes are placed, according to location of the tumor, into groups 1, 2, or 3 [110]. In Japan, the standard practice for stage II or above cancers is standard gastrectomy with D2 dissection (removal of all group 1 and group 2 nodes). D1 dissection (removal of group 1 nodes only) is generally reserved for T1 tumors with N0 or N1 lymph node status. Although this practice is considered to be the major reason for the better outcome of Japanese cancer patients, results from two prospective randomized controlled trials performed in Western countries comparing D1 with D2 lymphadenectomy failed to demonstrate any survival benefit of the more aggressive approach using D2 dissection [157–159]. Both the British Medical Research Council (MRC) trial and the Dutch Gastric Cancer Group trial showed a significantly higher short-term morbidity and hospital mortality among patients undergoing D2 dissection. The high initial complication rate of D2 gastrectomy has been attributed to pancreaticosplenectomy and the unfamiliarity of the surgeons with this operation. In the MRC trial, participant institutes were criticized for their low case volume and lack of formal training on D2 resection [157,158]. Another controversial issue relating to these two trials was the high rate of noncompliance with either D1 or D2 gastrectomy, which may interfere with the final outcome. A Cochrane Database systemic review summarizing all trials published after 1970 with 5-year survival data [160] concluded that there was no survival benefit for extended lymph node dissection (risk ratio [RR] 0.95, 95% CI, 0.83–1.09). Extended lymph node dissection with spleen and pancreas resection significantly increased postoperative mortality associated with spleen and pancreas resection (RR, 2.23; 95% CI, 1.45–3.45). Even in experienced Japanese centers, the morbidity associated with D2 lymphadenectomy was as high as 21% [161]. However, subgroup analysis showed an apparent benefit in patients with N2 staging. To complicate the issue, an analysis of the Surveillance, Epidemiology, and End Results (SEER) database of the United States [162] showed that the overall survival was highly dependent on the number of lymph nodes examined in all stages. For every 10 extra lymph nodes dissected, there was a survival benefit of 6%–11%, which favored extended lymph node dissection. Thus, the debate is likely to continue until results from better designed and controlled clinical trials are available.

Open vs laparoscopic surgery

Laparoscopic surgery has been increasingly employed for gastric resection. Most reports of laparoscopic gastrectomy have been confined to cases of early disease for which there is no demand for extended lymphadenectomy [163,164]. Laparoscopic gastrectomy takes significantly longer in operating time but results in less wound pain in the postoperative period. However, there is no difference in the overall hospital stay and complication rate when compared with the conventional open approach.

In a small randomized study from Italy, it was suggested that the early and 5-year survival rates of open and laparoscopic-assisted radical subtotal gastrectomy were comparable [165]. More experience has subsequently been gained for laparoscopic extraperigastric lymph node dissection [166], although the long-term results are yet to be determined.

Chemotherapy

Chemotherapy can be given preoperatively (neoadjuvant), intraoperatively, or postoperatively to reduce the chance of local or systemic recurrence. The ultimate aim of giving systemic chemotherapy is to decrease the chance of tumor recurrence and increase the overall survival rate of patients.

Adjuvant chemotherapy

Adjuvant chemotherapy is generally considered as an additional treatment for patients who have already undergone potentially curative surgical procedures. Numerous chemotherapeutic agents, either given alone or in combination, have been used with variable success [167]. 5-Fluorouracil (5-FU) is the most frequently used agent, with responses ranging from 20% to 30% if given alone. Differences in effect and toxicity profile are the reasons for its application as continuous infusion in many modern protocols. Mitomycin C (MMC), commonly used in Japan, has an overall objective response rate of 30%. Other agents, with reported response rates of 19% to 26%, include epirubicin, doxorubicin, cisplatin, and hydroxyurea. In addition, a variety of combinations such as FAM (5-FU, adriamycin, mitomycin C), FAMTX (5-FU, adriamycin, methotrexate), FEP (5-FU, etoposide, cisplatin), FAP (5-FU, adriamycin, cisplatin), and ECF (epirubicin, cisplatin, infusional form of 5-FU) have been used in various studies [168]. Combination chemotherapy is the accepted standard in Europe and the United States whereas in Japan it remains unclear as to whether a single agent or combination therapy achieves better results [169].

Despite a large number of different single-agent or combination chemotherapy regimes, neither single-agent nor combination chemotherapy can be considered as an internationally accepted standard of care. A number of metaanalyses have been published since the mid-1980s addressing the role of postoperative chemotherapy [170–174]. Most of these reviews showed a small benefit in favor of chemotherapy. However, the benefits may be limited to trials conducted in Asia [174]. The controversy was summarized in the Cochrane systematic review of controlled trials [169]. When compared with patients receiving supportive care, ones receiving chemotherapy were found to have a better overall survival rate (hazard ratio [HR], 0.39; 95% CI, 0.28–0.52). Combination chemotherapy was also shown to have a survival benefit over single-agent chemotherapy (HR, 0.85; 95% CI, 0.76–0.96) but incurred increased toxicity. Among various combinations of chemotherapy regimes studied, the best survival results are achieved with regimes containing 5-FU, anthracyclines, and cisplatin.

In addition to the systemic route, antitumor drugs can be delivered intraperitoneally. The potential benefit of intraperitoneal chemotherapy lies in the ability to control local-regional recurrence after curative resection. Hagiwara evaluated the use of intraperitoneal mitomycin C adsorbed to activated charcoal, in high-risk patients following curative resection [175]. There was a highly significant difference in the 2-year survival rate (68.6% vs 26.9%) favoring the use of this regime. A prospective randomized trial of early postoperative intraperitoneal chemotherapy as an adjuvant therapy for resectable gastric cancer also showed significant improvement in the 5-year survival rate in a subset of patients with stage III disease [176].

Preoperative chemotherapy

For patients with locally advanced cancer, complete surgical resection may not be feasible. Hence, the use of neoadjuvant (preoperative) chemotherapy may reduce the size of large tumors to enable an R0 resection or reduce the chance of occult micrometastatic disease before surgery. Numerous trials have been conducted and it appears that neoadjuvant chemotherapy does not increase the postoperative morbidity and mortality [177]. Several phase II studies with neoadjuvant treatment have shown low toxicity and increased R0 resection rates for advanced disease [178,179]. However, data regarding long-term survival with the combination of neoadjuvant chemotherapy and surgery are still lacking.

Radiotherapy

Gastric carcinoma is relatively resistant to radiotherapy, including both external beam and intraoperative radiation. The British Stomach Cancer Group found that postoperative radiotherapy in addition to surgery did not confer any benefit for survival [180]. However, intraoperative radiotherapy is frequently used in Japan [181]. Although data suggest it may prolong survival for patients with stage II and III disease, this therapy needs further evaluation.

Chemoirradiation

There has been intense interest in the use of a combination of radiation for local control and chemotherapy to prevent systemic micrometastases in the postoperative treatment of gastric cancer, although early studies were largely inconclusive.

The Gastrointestinal Cancer Intergroup Trial (INT0116) [182] randomized 566 patients with resectable adenocarcinoma of the stomach or gastroesophageal junction to receive surgery alone or surgery plus postoperative chemoradiotherapy consisting of bolus 5-FU/leucovorin and irradiation. The median overall survival in the surgery-only group was 27 months, compared with 36 months in the chemoradiotherapy group. The HRs for death and relapse were 1.35 (95% CI, 1.09–1.66) and 1.52 (95% CI, 1.23–1.86), respectively. Despite the superior results, grade 4 toxicities occurred in 32% of patients receiving chemoradiotherapy. Moreover, the quality and extent of surgical resection was criticized: 54% of patients underwent a less than D1 dissection and only 10% of patients underwent a D2 resection. In subgroup analysis, there was no difference in the overall survival or disease-free survival in the D2 group of patients. It is therefore argued that the enhanced survival observed in the chemoradiotherapy group may be due to a compensatory effect for the inadequate surgical resection.

The feasibility of preoperative chemoradiotherapy has been evaluated in patients with potentially resectable gastric carcinoma [183]. In this small nonrandomized trial, the R0 resection rate was 70% and the median survival of these patients was 33.7 months. Further results of randomized controlled trials are needed to clarify the role of preoperative chemoradiotherapy.

Prognosis

The stage of the disease and completeness of surgical resection are important factors underlying patients' survival. Despite many advances in surgical techniques and chemotherapy, the mortality rate of gastric cancer in many parts of the world has not changed over the past few decades. A review from the National Cancer Data Base revealed that the overall 5-year and 10-year survival rates of patients diagnosed to have gastric cancer between 1985 and 1996 were 28% and 20%, respectively [184] (Fig. 43.18). By contrast, the overall survival rate of Asian patients, particularly in Japan and Korea, is higher than that in most Western countries. This is largely related to the use of screening procedures that detect early lesions with an excellent prognosis. However, even stage-stratified survival tends to be higher in these Asian countries [151,185]. The reasons for this discrepancy may be attributed to the more extensive lymph node dissection, which results in better locoregional control, and more precise staging of lymph node status.

In general, stage-stratified survival analysis suggests that males have a poorer prognosis than females, and proximal cancer is associated with a worse prognosis than distal cancer. Difficulty in attaining an adequate proximal resection margin and the close proximity to paraaortic lymph nodes around the hiatus may be reasons for the worse outcome in proximal gastric tumors. The predominance of distal cancer may also account for the better outcome of Asian patients [184].

Other gastric tumors

Gastric lymphoma

The gastrointestinal tract is the most common site of extranodal lymphoma, accounting for 30%–50% of cases. Although primary gastric lymphoma is a rare malignancy, which accounts for less than 5% of all gastric malignancies, it is the commonest form of gastrointestinal lymphoma. In the WHO classification, primary gastric lymphomas are defined as lymphomas originating from the stomach and contiguous lymph nodes [186]. Lymphomas at this site are considered primary if the main bulk of disease is located in the stomach. The majority (80%) of primary gastric lymphomas are B-cell non-Hodgkin lymphoma, either low-grade mucosa-associated lymphoid tissue (MALT) lymphoma or a high-grade, diffuse, large-cell lymphoma (Table 43.5). Gastric lymphoma has a worldwide distribution. Most patients are over 50 years at presentation.

MALT lymphomas tend to arise as a polyclonal proliferation in chronically inflamed tissues, either of autoimmune or

infectious origin. Compelling epidemiological and pathological evidence suggests a link between chronic *H. pylori* infection and gastric MALT lymphoma [187,188]. More than 90% of low-grade gastric MALT lymphoma shows evidence of *H. pylori* infection, and this disease is more prevalent in regions with a high prevalence of *H. pylori* infection [189].

MALT lymphoma is characterized by the presence of plasma cells, reactive follicles, and centrocyte-like cells that tend to invade mucosal epithelium and form characteristic lymphoepithelial lesions (Fig. 43.19). The use of immunostaining for cytokeratin enhances the visibility of lymphoepithelial lesions. The detection of monoclonal rearrangements of the immunoglobulin heavy chain gene by polymerase chain reaction (PCR) or Southern blotting suggests the presence of lymphoma. The immunophenotypes of low-grade MALT lymphomas overlap with those of B cells.

Symptoms of gastric lymphoma are nonspecific, and most frequently include abdominal pain, weight loss, nausea, vomiting, and anorexia. Bleeding occurs in about 20% of cases [190]. Gastric lymphoma can be polypoid, fungating, infiltrating, or even ulcerative in appearance. Most lymphomas spread by submucosal infiltration and the muscular layer is usually spared until the late stage of the disease. Further spread to local and regional lymph nodes then follows.

Although upper gastrointestinal endoscopy is widely used in the diagnosis of gastric lymphoma, multiple and deep gastric biopsies are usually required for accurate histological diagnosis. The Musshoff modified Ann Arbor staging system is widely used for staging of gastric lymphoma (Table 43.6) [191]. Stage IE_1 refers to infiltration of the mucosa and submucosa only, whereas IE_2 lymphomas extend beyond the submucosa. Staging of disease can be done by CT scan and EUS. The latter is reliable in delineating the depth of

Table 43.6 Musshoff's modification of the Ann Arbor staging system for gastric lymphoma

Stage	Description
IE	Localized involvement of one or more gastrointestinal sites on the same side of the diaphragm without lymph node involvement
IE_1	Confined to the mucosa and submucosa
IE_2	Extending beyond submucosa
IIE	Stage IE with lymph node involvement; penetration of lymphoma through the gut wall
IIE_1	Regional lymph node involvement
IIE_2	Lymph node infiltration beyond the regional wall
IIIE	Involvement of the gastrointestinal tract or lymph nodes (or both) on both sides of the diaphragm
IVE	Diffuse or disseminated involvement of nongastrointestinal tract organs or tissues

tumor involvement and is superior to CT in distinguishing stage IE from stage IIE_1 disease [192]. To differentiate primary gastric lymphoma from systemic lymphoma with gastric involvement, other investigations, such as peripheral blood smear, bone marrow biopsy, and radiological imaging, may be required.

Eradication of *H. pylori* infection results in long-term cure of the majority of low-grade gastric MALT lymphomas [193–195]. The overall success of antibiotics in achieving complete remission in stage IE1 lymphomas is about 80%, with an annual recurrence rate of about 5% [194]. However, the time for complete tumor remission varies, and regression may not be apparent until several months after clearance of the organism [195]. Monoclonal B cells, as detected by PCR, may persist for up to several years after cure of *H. pylori* infection or complete histological and endoscopic remission [196,197]. Staging by EUS might predict the response of gastric MALT lymphoma to anti-*H. pylori* treatment. Patients with stage IE1 disease (confined to mucosa and submucosa) are more likely to have complete regression of the MALT lymphoma after anti-*H. pylori* therapy [198,199]. Patients should be followed by endoscopic examination every 6 months for the first 2 years and then yearly to monitor histological regressions. Other factors associated with a nonresponse to antibacterial therapy include *H. pylori* negativity and the presence of high-grade lymphoma features. The presence of t(11;18), which results in a chimeric transcript between the *API2* and *MLT* genes, may also predict resistance to antibiotic treatment [200]. For patients who fail *H. pylori* eradication, there is little consensus on the most appropriate management. Various treatment modalities, including expectant management, surgery, irradiation, and chemotherapy, have been used. Rituximab, a monoclonal antibody against cell surface CD20 on B cells, has been shown to result in complete pathological and clinical remission in 46% of patients with gastric MALT lymphoma resistant to or ineligible for anti-*H. pylori* therapy [201].

The emergence of clusters of large transformed "blastic" B cells reflects transformation to high-grade lymphoma. Treatment options for localized high-grade lymphoma remain controversial. Although surgery is particularly useful for local control of disease, there is an increasing tendency toward an organ-preserving approach. Surgery is associated with a favorable 5-year survival rate of 85%–100%, particularly in early-stage diseases [197]. However, aggressive surgery with radical excision is associated with high morbidity and mortality, and the extent of resection remains poorly defined. Data suggest that chemotherapy alone may be as effective as surgery plus chemotherapy in patients with localized disease [202,203]. In the prospective nonrandomized German Multicenter Study [204], patients were treated with either surgery plus radiation–chemotherapy or chemotherapy–radiation therapy alone. The 5-year survival and complete remission rates were comparable in the two groups. For chemotherapy, the combination of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) is the standard regime used in the treatment of gastric lymphoma. One argument against nonsurgical therapy is the risk of perforation and hemorrhage. However, the overall risks of perforation and bleeding in those treated without surgery are 1.7% and 2.1%, respectively, which is not significantly different from those treated with surgery (0.9% and 2.1%) [204].

Patients with advanced stage disease (stages III and IV) are best treated with systemic chemotherapy or combination treatment. Radiotherapy is usually used as an adjuvant to surgery or chemotherapy, or to both. However, radiotherapy alone has been shown to have a reasonable outcome [205,206].

Mesenchymal tumors of the stomach

Most gastrointestinal mesenchymal neoplasms are gastrointestinal stromal tumors (GIST) or smooth muscle types. The term GIST, originally used to describe tumors that were neither leiomyomas nor schwannomas, denotes a specific group of tumors comprising the majority of gastrointestinal mesenchymal tumors including those previously called leiomyoma, cellular leiomyoma, leiomyoblastoma, and leiomyosarcoma. Approximately 60%–70% of GISTs occur in the stomach [207].

The precise cellular origin of GISTs has been proposed to be the interstitial cell of Cajal, an intestinal pacemaker cell [208,209]. This is supported by the sharing of morphological, immunohistochemical, and ultrastructural features between GIST and interstitial cells of Cajal. Mutations of c-*kit* that cause constitutive activation of the tyrosine kinase function of KIT are detectable in most GISTs and appear to play a pivotal role in the pathogenesis of these tumors [210]. The c-*kit* protooncogene encodes a type III tyrosine kinase growth factor receptor, which can be detected by immunohistochemistry for CD117. Immunoreactivity against CD117 is expressed in 80%–100% of GISTs and may be more sensitive and specific than the CD34, which is present in 60%–70% of cases [211]. In addition, a subset of GISTs contain mutations in the homologous kinase platelet-derived growth factor receptor-α (PDGFRA) [212].

GIST is an uncommon disease. The Finnish Cancer Registry estimated an annual incidence of 4 cases per million, which may be an underestimation [213]. In a review performed by the Memorial Sloan-Kettering Cancer Center, there had been only 200 patients with GIST treated during the previous 16 years [214]. The most frequent site affected is the stomach, which accounts for about 70% of the cases [215]. The peak incidence is found in adults during the fifth and sixth decades, and it is uncommon under the age of 40. Both genders are affected. Etiological agents have not been identified.

Many of these tumors are asymptomatic and are discovered incidentally but the clinical courses are highly variable.

Patients can present with nausea, vomiting, abdominal pain, gastrointestinal bleeding, and even metastatic disease. Bleeding is considered the most common presentation. Malignant tumors can metastasize to liver and peritoneum, and rarely to lymph nodes, bone, and lung [214]. Abdominal CT scan is useful in the evaluation of primary tumor and distant metastases. A GIST is usually demonstrated by intense uptake on a PET scan. The use of EUS may also help in differentiating benign and malignant tumors. Tumors less than 30 mm in diameter with regular margins and a homogeneous echo pattern are usually benign in nature [216]. Percutaneous biopsy is usually inadequate for making a proper histological diagnosis, and carries a theoretical risk of peritoneal seeding and tumor rupture.

The distinction between benign and malignant GIST is difficult. Conventionally, various parameters have been used to predict the biological behavior, including mitotic activity (> 10/high-power field), tumor size (> 5 cm), tumor necrosis, histological type/pattern, immunohistochemical profile, staining for proliferation antigens, and ploidy status [213]. Among these, mitotic activity and tumor size appear to be more reliable in categorizing tumors into benign, borderline, and malignant, but there is no agreed cutoff point for these values.

Surgical resection of the tumor was once the most important treatment for GIST. In general, a limited dissection is known to achieve comparable results to extended resection [217]. Lymphadenectomy is not routinely practiced due to the low incidence of lymph node metastasis. The availability of imatinib (formerly STI 571), a selective and competitive inhibitor of ABL tyrosine kinases, has revolutionized the treatment of GIST. Imatinib is reported to produce a partial tumor response in 45% of patients and stable disease in approximately 30% [218–220]. The role of adjuvant imatinib after complete resection of GIST is being investigated. Primary resistance to imatinib occurs in less than 15% of patients. Acquired resistance typically occurs after more than 1 year of therapy and is often due to secondary *KIT* mutation in novel sites including exons 13, 14, and 17 [221,222]. Before the era of imatinib, the median survival of recurrent GIST was only 15 months [223]. The 2-year survival of patients with metastatic disease is now about 70% [220].

Apart from GISTs, other gastric mesenchymal tumors include gastrointestinal autonomic nerve tumor (GANT), leiomyoma, glomus tumors, schwannomas, lipoma, and granular cell tumor.

Endocrine tumors of the stomach

Gastric carcinoid tumors are uncommon and account for only about 3% of all carcinoids [224]. Reviews, however, suggest that the incidence of gastric carcinoid is rising, from 3.8% in the 1970s to 8.9% in 1990s, according to the SEER database [225]. Whether this increase is the result of an increase in endoscopic detection or the use of acid suppressive therapy resulting in hypergastrinemia remains unknown at this stage.

Three distinct types of gastric carcinoid tumors with characteristic biological behavior and prognosis have been identified. Type I are the most frequent form (about 65%) of gastric neuroendocrine tumors and are localized in the oxyntic mucosa at the fundus and body. Patients usually have chronic atrophic gastritis, achlorhydria, and pernicious anemia. They often have elevated basal gastrin levels and are highly sensitive to trophic stimulus of gastrin. Type I tumors tend to be small (less than 100 mm) and multiple. They are considered to be the most benign of the three forms of carcinoid tumors, with a relatively low frequency (9%–23%) of metastasis [226–229]. Type II tumors are associated with the gastrin-producing neoplasms in Zollinger–Ellison syndrome as part of the multiple endocrine neoplasia type 1 (MEN1) syndrome. This type of carcinoid has intermediate metastatic potential. Enterochromaffin-like (ECL) cells are the main endocrine cell types in types I and II tumors. By contrast, type III, or sporadic, carcinoid lesions are encountered less frequently. They are not associated with hypergastrinemia and are frequently solitary large lesions in nonatrophic mucosa. This type of tumor behaves more aggressively, with a strong tendency for advanced local invasion and metastasis [230].

The clinical presentations of gastric carcinoids are usually nonspecific and variable, including pain, vomiting, anemia, and bleeding, or they can be discovered incidentally during endoscopy for other reasons. Presentation with the typical carcinoid syndrome of flushing, diarrhea, cutaneous edema, and bronchoconstriction is uncommon [230,231]. This is related to the secretion of histamine instead of substance P, serotonin, or 5-hydroxyindoleacetic acid. In a review of the cases identified by the SEER program from 1973 to 1991, 52.9% of the gastric carcinoids were localized disease, 10.3% regionalized, and 20.6% with distant metastasis [224].

Upper gastrointestinal endoscopy is the most useful diagnostic tool, and the typical lesions are small, rounded, submucosal masses that often are yellow [232]. There is no definite histological criterion for establishing the degree of malignant potential, and the best indicator is still the demonstration of invasive growth and presence of regional or distant metastases [224]. Indium-111 pentetreotide (OctreoScan) is increasingly used for identification of metastatic disease. The overall sensitivity is approximately 80%–90%, and it is particularly useful for lesions not apparent by conventional imaging techniques [233].

It is generally believed that endoscopic removal is appropriate for hypergastrinemia-associated lesions less than 1 cm in size and fewer than 3–5 in number [234]. Local excision, either antrectomy or fundic resection, should be considered for large and multiple lesions [231]. Antrectomy reduces the serum gastrin levels, resulting in regression of ECL cell carcinoids [226]. Fundic resection, however, removes all

ECL cells and carcinoids, which eliminates the chance of local recurrence. Surveillance endoscopy is recommended at 6-month intervals after endoscopic or surgical removal. However, a more radical approach is necessary for type III carcinoids due to their high malignant potential and strong tendency for metastasis. Complete or partial gastrectomy with regional lymph node dissection is recommended [227]. The use of long-acting somatostatin analogues has been reported to be efficacious in diminishing tumor load and decreasing ECL cell density [228]. The prognosis of gastric carcinoids is dependent on both the subtype of lesion and the extent of the disease. In general, patients with localized disease have a better survival than those with distant metastasis. The overall 5-year survival for gastric carcinoid ranges from 63% to 80% [225,229,235].

Gastric polyps

Gastric polyps are uncommon. The estimated incidence is less than 1% in autopsy or radiological survey [236]. However, up to 50% of gastric polyps are discovered incidentally during endoscopy for unrelated symptoms [237]. They may be solitary or multiple, and occasionally associated with other polyposis syndromes such as familial adenomatous polyposis, Peutz–Jeghers syndrome, Cowden syndrome and Cronkhite–Canada syndrome.

Hyperplastic polyps are among the commonest gastric polyps [236]. Hyperplastic or regenerative polyp frequently occurs in association with gastritis, particularly *H. pylori*-associated gastritis. In general, the malignant potential of hyperplastic polyps is minimal (1.5%–3%) [238,239].

Adenomas are circumscribed lesions comprising tubular or villous structures (or both) showing intraepithelial dysplasia. Adenomatous polyps account for about 10% of gastric polyps [240] and are more prevalent in areas with high incidences of gastric cancer. This type of polyp is associated with a greater risk of malignant transformation, and this risk is size dependent [241]: the risk is approximately 40%–50% in lesions greater than 2 cm.

Fundic gland polyp, also known as fundic gland hyperplasia or glandular cyst, is recognized as the most frequent type of gastric polyp in Western populations [240]. These lesions are composed of fundic glands lined with increased numbers of normal-appearing parietal and chief cells, and with a variable degree of cystic dilation. They are located exclusively in the acid-producing mucosa and thus are not found in the antrum. They are associated with the long-term use of proton pump inhibitors and with familial adenomatous polyposis syndrome.

Occasionally, misplaced gastric glands can present as a polypoid mass in the stomach. These heterotopic polyps are composed of tissue from the neighboring pancreas or duodenum. Heterotopic pancreas is frequently found in the prepyloric region and presents as a submucosal, nipple-like lesion, composed of mainly exocrine glands and ducts.

In the American Society for Gastrointestinal Endoscopy review, all polyps causing symptoms, such as bleeding and obstruction, and those greater than 2 cm, should be removed [242]. Polyps smaller than 2 cm can be initially biopsied and excised. If biopsies reveal adenomatous change, endoscopic excision should be considered. Most gastric polyps can be safely removed by snare polypectomy. Complications such as bleeding, perforation, and abdominal pain are rare. Surveillance endoscopy is only recommended in adenomatous gastric polyps 1 year after removal to assess for recurrence, or development of new polyps.

44 Surgery for peptic ulcer disease and postgastrectomy syndromes

Robert E. Glasgow, Sean J. Mulvihill

Surgical treatment of peptic ulcer disease, 1054 Postgastrectomy syndromes, 1060

The current scope of gastric surgery encompasses four main indications: peptic ulcer disease, gastroesophageal reflux disease, neoplasms, and operations for morbid obesity. Formerly, peptic ulcer disease was the most common indication for gastric surgery; however, the introduction of antisecretory agents, the development of endoscopic therapy for complications of ulcer disease, and the recognition of the importance of *Helicobacter pylori* in the pathogenesis of peptic ulcer disease have significantly changed the spectrum of gastric surgery. These improvements in medical management have dramatically reduced the frequency of hospitalizations and operations for uncomplicated ulcer disease. However, the incidence of complications of peptic ulcer disease is unchanged, especially in the elderly population.

The changes in normal gastroduodenal anatomy and physiology resulting from gastric surgery are usually well tolerated and have no clinically relevant sequelae. However, approximately one-fourth of patients develop significant postoperative symptoms, which are severe enough in 1%–3% of patients to warrant remedial surgery [1]. In some patients the postoperative symptoms are vague or ill-defined, whereas other patients describe a more clear-cut constellation of symptoms. Collectively, these disorders of gastrointestinal function following gastric surgery are termed postgastrectomy syndromes. Although some of these postgastrectomy disorders are mechanical in origin and require surgical intervention, the majority result from functional changes in normal physiology. In the latter group, remedial surgery is reserved for patients who fail conservative measures. The goal of this chapter is to provide an overview of concepts in surgical treatment of peptic ulcer disease and management of postgastrectomy syndromes.

Surgical treatment of peptic ulcer disease

Duodenal ulcer

Intractability

Surgical treatment of peptic ulcer disease is indicated for intractability, perforation, bleeding, and obstruction (Table 44.1). Intractability is generally defined as the failure of an ulcer to heal after 8–12 weeks of therapy or when relapse follows discontinuation of therapy. Elective definitive surgical treatment of peptic ulcer disease is rarely required today, but should be considered in the patient with intractable symptoms of duodenal ulcer despite optimal medical treatment including the eradication of *H. pylori* infection [2]. Additional indications for elective surgery may include suspicion of malignancy, intolerance to or noncompliance with medical therapy, patients at high risk for ulcer complications (transplant recipients, steroid or nonsteroidal antiinflammatory

Patient preference

a Most common indications for surgery.
NSAID, nonsteroidal antiinflammatory drug.

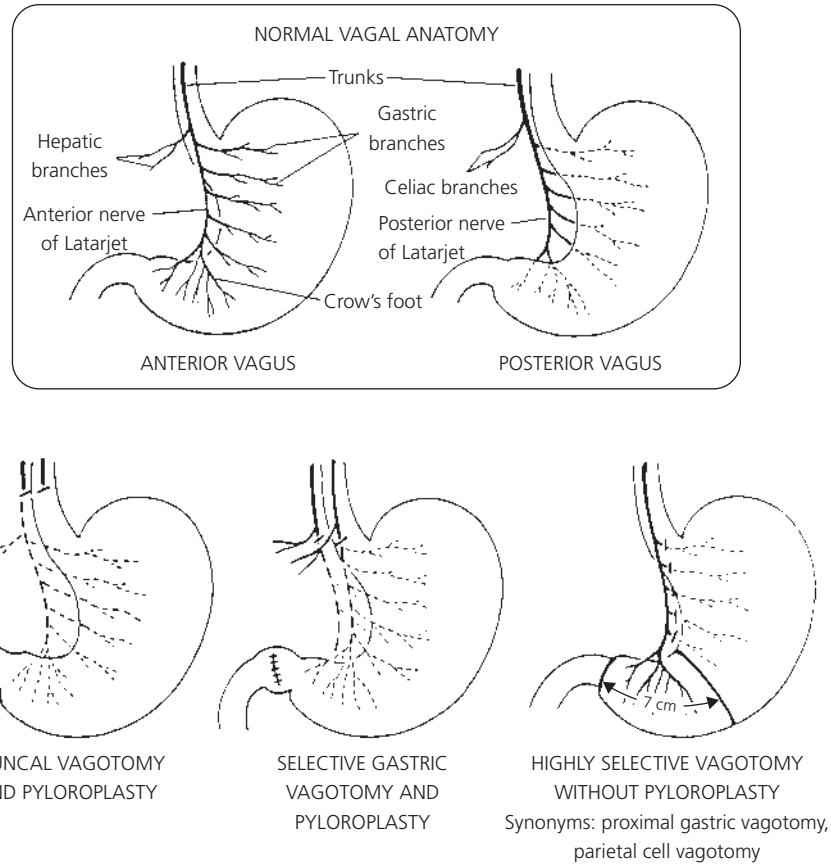

Figure 44.1 Normal vagal anatomy and types of vagotomy. Truncal and selective vagotomies are shown with a gastric drainage procedure (pyloroplasty). During truncal vagotomy, nerve trunks are divided above the celiac and hepatic branches. During selective vagotomy, the anterior and posterior nerves are divided distal to the celiac and hepatic branches, thus preserving extragastric innervation to the gastrointestinal tract. During highly selective vagotomy, individual branches of the anterior and posterior nerves of Latarjet to the body of the stomach are divided, sparing the branches to the antrum and pylorus ("crow's foot"). Pyloroantral motor function is preserved and, therefore, a drainage procedure is not indicated.

drug [NSAID] dependency, giant ulcers), a strong ulcer diathesis, patient preference, and failure of nonoperative management of an ulcer complication. The cost of long-term antisecretory therapy may also be considered when deciding on a course of antiulcer surgery. Regardless of the indication for surgery, the fundamental goals of surgical therapy are to permit ulcer healing, prevent or treat ulcer complications, address the underlying ulcer diathesis, and minimize postoperative digestive sequelae.

Surgery for peptic ulcer disease consists of two elements: vagotomy to decrease gastric acid secretion and drainage of the stomach. Three versions of vagotomy have been described: truncal, selective, and highly selective or parietal cell vagotomy. These are shown in Figure 44.1. When performing truncal or selective vagotomy, gastric emptying is impaired because of a loss of coordination of the antral mill and pyloric sphincter mechanism. Therefore, a drainage procedure is indicated. Drainage options include antrectomy, pyloroplasty, and gastrojejunostomy. The most effective operation for duodenal ulcer is truncal vagotomy with antrectomy. This operation inhibits both the cephalic and gastric phases of acid secretion, including the gastrin drive, and results in a greater decrease in acid production compared with vagotomy with pyloroplasty or gastrojejunostomy. Vagotomy with antrectomy and Billroth I or Billroth II reconstruction is shown in Figure 44.2 and vagotomy with pyloroplasty is shown in Figure 44.3.

Before the introduction of proton pump inhibitors (PPIs), several prospective trials demonstrated that vagotomy with antrectomy is superior to vagotomy and pyloroplasty, with ulcer recurrence rates of 1%–2% vs 10% respectively [3–7]. The impact of antisecretory therapy on recurrence rates following each of these procedures is not well defined. Because truncal vagotomy sacrifices vagal innervation to the pancreas, small intestine, proximal colon, and hepatobiliary tree, in addition to the stomach, a selective vagotomy was developed. Selective vagotomy spares the hepatic and celiac branches. However, compared with truncal vagotomy and drainage, selective vagotomy is inferior with regard to recurrence, dumping symptoms, diarrhea, pain, and dyspepsia, and has fallen out of favor.

Highly selective vagotomy (HSV), also known as parietal cell vagotomy or proximal gastric vagotomy, selectively eliminates the vagal innervation to acid-producing parietal cells and pepsin-producing chief cells of the fundus and body of the stomach while preserving innervation to the antrum and pylorus as well as the liver, pancreas, gallbladder, and bowel. A drainage procedure is unnecessary because the integrity of the antral mill and pyloric sphincter mechanism is preserved. Prospective randomized trials have demonstrated lower

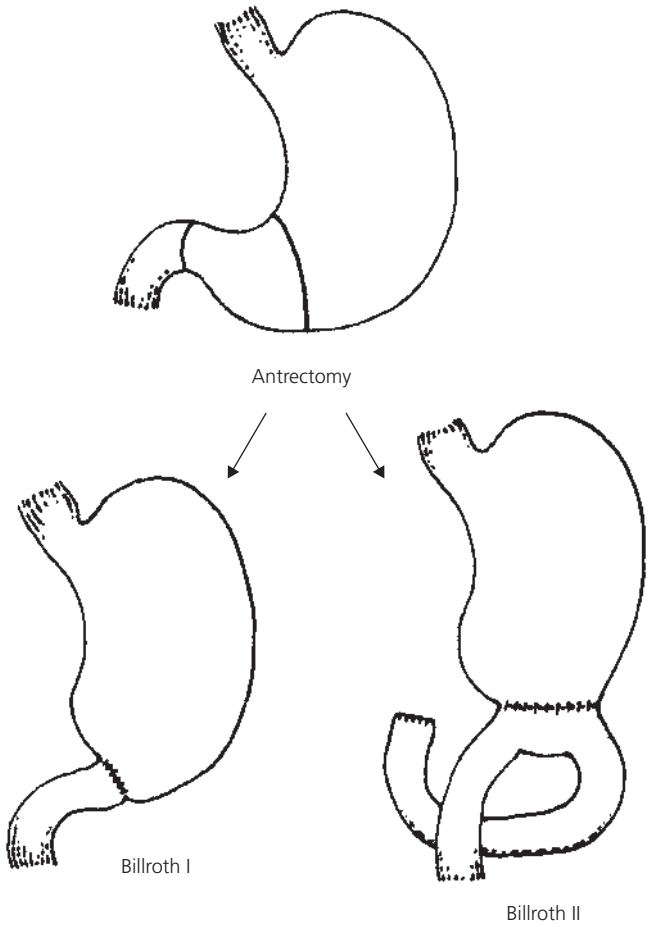

Figure 44.2 Reconstruction after gastrectomy. Billroth I gastroduodenostomy and Billroth II gastrojejunostomy.

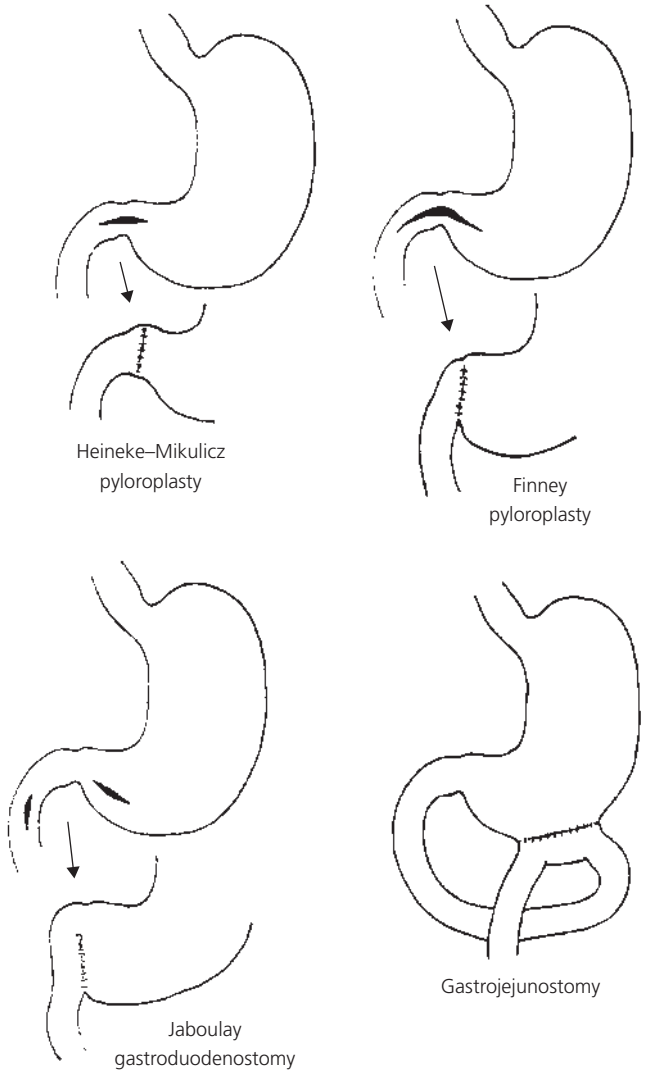

Figure 44.3 Methods of gastric drainage. The Heineke–Mikulicz pyloroplasty is most frequently used. The pylorus is opened in a longitudinal fashion and closed transversely to open and distract the edges of the pyloric sphincter. The Finney and Jaboulay gastroduodenostomy are used when the duodenal bulb is severely deformed from chronic ulcer. They are rarely indicated. A gastrojejunostomy is used when access to the duodenal area is limited.

postoperative morbidity related to postvagotomy symptoms when HSV is compared with both truncal and selective vagotomy [8,9]; however, although postoperative morbidity rates are lower following HSV, ulcer recurrence rates are higher. Studies have reported ulcer recurrence rates that range from 13% at 5 years [10] to 22% at 12 years [11]. The differences between the various ulcer operations with regard to recurrence and morbidity are summarized in Table 44.2 [12].

Laparoscopy has emerged as a surgical option not only for elective ulcer surgery but also for emergent complications of peptic ulcer disease. All of these surgical procedures, including parietal cell vagotomy and anterior seromyotomy with posterior truncal vagotomy, have been performed laparoscopically in the elective setting with patients experiencing low recurrence rates and shorter hospital stays.

Perforation

The clinical presentation of a perforated duodenal ulcer may vary according to the location of the ulcer. Posterior penetrating ulcers present with bleeding whereas anterior duodenal perforations cause the acute onset of severe, diffuse abdominal pain from free perforation into the peritoneal cavity. Patients with "kissing ulcers" of the duodenum present with both bleeding and perforation. When an anterior perforation occurs, air escapes into the abdominal cavity and may be detected by plain or upright radiographs of the abdomen and chest in approximately 70% of cases [13]. Most patients who experience a perforation will have a history of peptic ulcer disease or symptoms suggesting the diagnosis of peptic ulcer disease. However, chronically ill, elderly patients may be an exception to this presentation with vague, poorly localized abdominal pain that has developed over days to weeks.

Table 44.2 Results of duodenal ulcer surgery

	Highly selective vagotomy	Truncal vagotomy with pyloroplasty	Truncal vagotomy with antrectomy
Mortality rate (%)	0	0.5–1	2
Ulcer recurrence (%)	10–15	10	1–2
Gastric emptying			
Liquids	Accelerated	Accelerated	Accelerated
Solids	No change	Accelerated	Slowed
Dumping (%)			
Mild	< 5	10	10–15
Severe	0	1	1–2
Diarrhea (%)			
Mild	< 5	25	20
Severe	0	2	1–2

Duodenal ulcer perforation usually involves the anterior wall of the duodenal bulb whereas the lesser curvature is commonly the sight of gastric ulcer perforation [14]. The two major causes of perforated duodenal ulcers are *H. pylori* infection and NSAID use. Perforated ulcers are associated with NSAID use in one-third to one-half of patients [15,16] and more commonly occur in elderly patients. Smoking has also been implicated in peptic ulcer perforation, especially in younger patients [17].

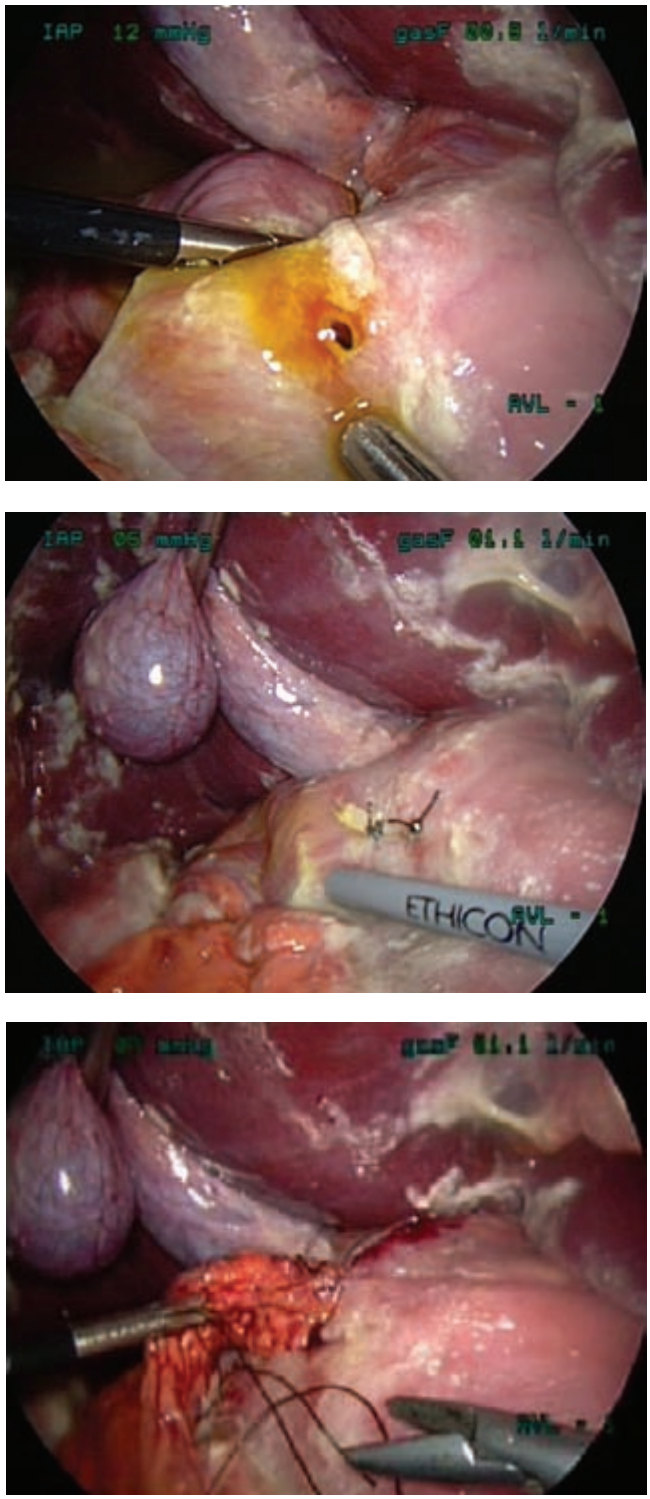
A perforated duodenal ulcer is a surgical emergency. It is most commonly managed with an omental patch (Graham patch) or truncal vagotomy with pyloroplasty, which incorporates the perforation. Simple patch closure (Fig. 44.4) is appropriate in patients who have not been previously treated for peptic ulcer disease and who can take PPIs and antibiotics for *H. pylori* infection [18,19]. Vagotomy is not necessary. Perforations related to NSAID use may also be treated with patch closure if the drug can be discontinued. Simple closure of perforated peptic ulcer has been compared with truncal vagotomy and pyloroplasty and vagotomy and antrectomy in randomized clinical trials prior to the *H. pylori* era [20–22]. Ulcer recurrence rates were 61% following simple closure compared with 6% following a definitive operation [2]. However, recurrent ulcer disease after peptic ulcer perforation occurs mainly in patients infected with *H. pylori* [23]. This is supported by several studies that demonstrated low recurrence rates following simple closure of the ulcer with *H. pylori* eradication [19,24–26]. Therefore, patients presenting with perforated duodenal ulcers should be tested for *H. pylori* and if found to be positive treated with eradication therapy. In a study by Ng et al. [19] of patients presenting with perforation, 81% were shown to be infected by *H. pylori*. Although initial ulcer healing rates were similar between patients treated for *H. pylori* compared with those treated with omeprazole, recurrence rates at 1 year were far less in the *H. pylori*-treated group (4.8% vs 38.1% respectively).

Definitive ulcer surgery in the form of vagotomy and pyloroplasty or antrectomy should be considered in patients who will require continued use of nonselective NSAIDs, who fail optimal medical treatment, or in whom compliance with *H. pylori* therapy is in doubt. One study that followed patients for more than 10 years after truncal vagotomy and pyloroplasty for perforated duodenal ulcer reported a mortality rate of 5.5% with a recurrence rate of 8.8%. Operative mortality rates from perforated duodenal ulcers range from 5% [20] to more than 30% in the elderly [27,28]. Risk factors that increase mortality include a severe comorbidity, the presence of shock on admission, and a presentation delay of more than 24 h [20,28].

The laparoscopic treatment of perforated peptic ulcers with an omental patch has been compared with open repair in randomized clinical trials [29,30]. The laparoscopic approach offers comparable efficacy, morbidity, and mortality to open surgery with a shorter hospital stay, lower analgesic requirements, and a shorter overall recovery time to normal function. The laparoscopic repair was also associated with shorter operative times. Additionally, laparoscopy has been advocated as a diagnostic technique when the diagnosis of duodenal ulcer perforation is in doubt.

Hemorrhage

Hemorrhage from a duodenal ulcer typically involves a penetrating posterior ulcer in the duodenal bulb in close proximity to the gastroduodenal artery. Bleeding from a peptic ulcer stops spontaneously in approximately 80% of cases [31]. Several stigmata predicting a higher than average risk of recurrent bleeding may be identified endoscopically. These include an actively bleeding ulcer, a nonbleeding visible vessel, and an adherent clot at the base of the ulcer. The rebleeding rate for each of these findings is 90%–100%, 40%–50%, and 20%–30% respectively [32]. The mainstay of treatment of a bleeding duodenal ulcer is endoscopic, with hemostasis



(a)

(c)

Figure 44.4 Modified Graham patch (omental) closure of a perforated duodenal ulcer. **(a)** Laparoscopic view of perforated anterior duodenal bulb ulcer. **(b)** Suture closure of the perforation. **(c)** Omental patch reinforcement of the perforation.

Table 44.3 Indications for surgical treatment of bleeding duodenal ulcer

1. Hemodynamic instability despite aggressive resuscitation (> 3 units transfused)
2. Failed endoscopic therapy
3. Recurrent hemorrhage after initial endoscopic hemostasis
4. Continued slow bleeding requiring > 3 units per day of transfusion

achieved in more than 90% of cases [33]. Thermal coagulation, injection therapy, hemostatic clips, fibrin sealant, argon plasma coagulation, and combination therapy have all been successfully used. The most commonly used endoscopic therapy is a combined modality with injection of an epinephrine (adrenaline)-containing solution followed by thermocoagulation. Patients should receive antisecretory therapy and be tested and treated for *H. pylori* infection. In patients who rebleed after endoscopic therapy the decision becomes one of repeat endoscopy or surgery. In one controlled trial, patients were randomized to repeat endoscopic therapy or surgery. Repeat endoscopy achieved long-term hemostasis in 73% of patients with similar mortality rates and lower morbidity rates compared with surgical intervention [34].

Surgery for peptic ulcer bleeding is indicated in the following scenarios: hemodynamic instability despite aggressive resuscitation (> 3 units transfused), failed endoscopic therapy, recurrent hemorrhage after initial endoscopic hemostasis, and continued slow bleeding requiring greater than 3 units per day of transfusion (Table 44.3). Surgical control of a bleeding duodenal ulcer consists of a longitudinal duodenotomy, usually encompassing the pylorus. Direct pressure is placed on the bleeding ulcer to allow resuscitation of the patient. The ulcer is then oversewn at three separate sites: cephalad and caudad to the ulcer to ligate the gastroduodenal

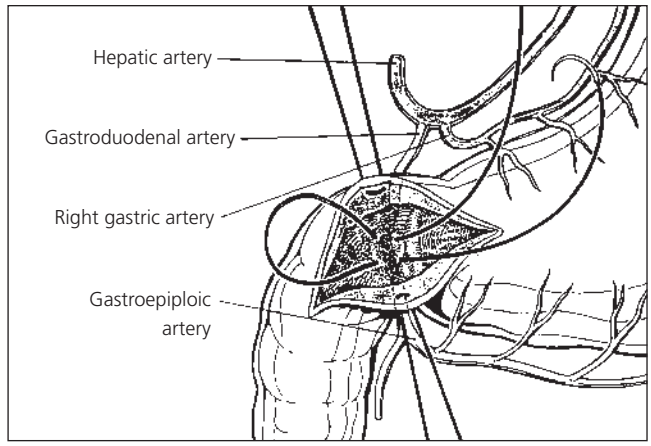

Figure 44.5 Suture closure of a posterior bleeding duodenal ulcer. Exposure is through a longitudinal gastroduodenotomy. The bleeding point within the ulcer is oversewn with monofilament sutures. Additional sutures are used above and below the ulcer to secure the gastroduodenal artery. From Seymour NE, Gastroenterology and Hepatology: The Comprehensive Visual Reference. Philadelphia, PA: Current Medicine, 1996.

artery and a U-stitch placed through the base of the ulcer to ligate the transverse pancreatic artery. This is demonstrated in Figure 44.5. Once the bleeding is controlled by these suture ligatures, a truncal vagotomy and pyloroplasty using the Heineke–Mikulicz technique should be performed [35]. The use of vagotomy in this circumstance is not universally supported, however [36]. A randomized controlled trial by Millat et al. [37] concluded that patients undergoing emergency surgery for massive, persistent bleeding or recurrent bleeding from a duodenal ulcer should undergo distal gastric resection because of a lower postoperative recurrent bleeding rate compared with oversewing the ulcer and vagotomy.

Gastric outlet obstruction

Patients with gastric outlet obstruction due to peptic ulcer disease typically present with nausea, vomiting, early satiety, bloating, indigestion, reflux symptoms, epigastric pain, and weight loss. Often patients have a hypochloremic, hypokalemic metabolic alkalosis as a result of chronic vomiting. Initial management of these patients includes nasogastric tube decompression, fluid resuscitation and correction of electrolyte abnormalities, and intravenous antisecretory agents. Approximately one-half of patients may initially respond to this regimen [38].

Two underlying mechanisms have been proposed for gastric outlet obstruction. The first is related to the inflammation, edema, and muscular spasm that may accompany an acute ulceration. The second mechanism of obstruction is the scarring and fibrosis of chronic ulceration [39,40]. Upper gastrointestinal radiography can provide useful information although endoscopic inspection is warranted for both diagnosis and to rule out malignancy. Malignant obstruction has been reported in as many as 66% of patients. Patients presenting with malignant obstruction tend to be older and do not have a history of peptic ulcers or NSAID use [41].

Patients who present with a gastric outlet obstruction secondary to peptic ulcer disease are commonly infected with *H. pylori* [42–44]. Reversal of gastric outlet obstruction has been reported following the eradication of *H. pylori* infection [45,46]; however, the time span from eradication of *H. pylori* to resolution of gastric outlet obstruction ranges from weeks to months [44]. In patients who fail to respond to initial medical therapy and in whom malignancy has been ruled out, endoscopic balloon dilation may be useful [47,48]. Patients may require multiple endoscopic sessions [49] but when *H. pylori* can be eradicated and NSAID use discontinued a good long-term result may be achieved.

Surgery is generally indicated if obstruction fails to resolve after nonoperative management [50]. These patients usually require vagotomy and antrectomy to relieve the obstruction and to rule out malignancy. A randomized controlled trial was performed to examine the outcomes of 90 consecutive patients with gastric outlet obstruction secondary to a duodenal ulcer [51]. The three operations tested were selective vagotomy with antrectomy, highly selective vagotomy with gastrojejunostomy, and highly selective vagotomy with Jaboulay (gastroduodenostomy) anastomosis. Postoperative gastric acid secretion was similar among the groups. Overall, results were best with the highly selective vagotomy and gastrojejunostomy whereas Jaboulay patients did the worst. Laparoscopic management of gastric outlet obstruction due to duodenal ulceration has also been described. In one small series of 12 patients, truncal vagotomy and gastroenterostomy was performed, with patients experiencing good results with a median follow-up of 6 months [52].

Gastric ulcer

Similar to duodenal ulcer, gastric ulcer can present with intractability, bleeding, perforation, and, less commonly, obstruction. However, fundamental differences exist between these two entities, which affect medical and surgical therapy. Only 70% of gastric ulcers are associated with *H. pylori* infection compared with 90% of duodenal ulcers [53]. In addition, reduced gastric acid secretion in gastric ulcer patients is more common, compared with normal or increased acid secretion in duodenal ulcer patients [54].

Malignant ulcers are more common in the stomach than in the duodenum and, therefore, all gastric ulcers must be excised or biopsied. Furthermore, gastric ulcers tend to affect older individuals, which may increase perioperative morbidity and mortality rates.

Gastric ulcers have been divided into five types depending on their location and specific etiology. These are summarized in Figure 44.6. Type I gastric ulcers are the most common and occur along the lesser curvature at the junction of the fundic and antral mucosa. This type of ulceration is generally associated with acid hyposecretion and can be treated with distal gastrectomy incorporating the ulcer and Billroth I or II reconstruction. A reasonable alternative is vagotomy, pyloroplasty, and local excision of the ulcer. Type I gastric ulcers are generally the consequence of inadequate mucosal defense rather than acid hypersecretion, and previous trials have shown no substantial advantage to the addition of vagotomy over distal gastrectomy alone. However, agreement has not been reached on this recommendation and, in practice, vagotomy has commonly been performed for gastric ulcer. For example, the Cleveland Clinic reviewed their experience with 349 patients operated upon between 1950 and 1979 with a mean follow-up of 11.8 years. In total, 55% of the patients had a gastric resection without vagotomy; 19.8% had gastric resection with vagotomy; and 20.3% had vagotomy, pyloroplasty, and wedge excision or biopsy of the ulcer. Operations were selected based on the type of ulcer, whether the surgeon suspected cancer preoperatively, whether the operation was elective or an emergency, and the age and general health of the patient (presence of significant comorbid disease). Long-term results were equivalent with an ulcer recurrence rate of 4% [55].

Type	Location	Symptom	Acid secretion
I	Gastric body on lesser curvature	Penetration	Normal or low
II	Gastric body and duodenal ulcer	Hemorrhage Obstruction Perforation	Elevated
III	Prepyloric	Hemorrhage Perforation	Elevated
IV	High on lesser curvature	Hemorrhage	Low
V	Anywhere on stomach		NSAID use

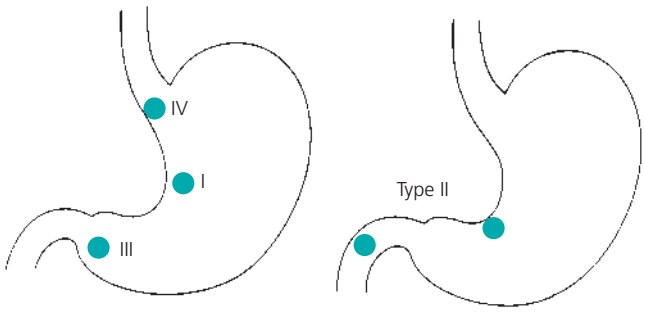

Figure 44.6 Classification of gastric ulcers according to location, symptoms, and acid secretion.

Type II gastric ulcers are found in the body of the stomach in conjunction with a duodenal ulcer whereas type III gastric ulcers occur in the prepyloric region. Types II and III are associated with increased acid secretion and should be managed similarly to duodenal ulcer with vagotomy and antrectomy. Type IV gastric ulcers are similar to type I gastric ulcers in that they tend to occur in the setting of acid hyposecretion. Type IV ulcers are located high on the lesser curve in close proximity to the gastroesophageal junction and may represent a migration of the junction of the fundic and antral mucosa to this location. Subtotal gastric resection for type IV ulcers is considered optimal and reconstruction with a Roux-en-Y esophagogastrojejunostomy (Csendes' procedure) is recommended [56]. Type V gastric ulcers are associated with NSAID use and can occur anywhere in the stomach. Operations for benign gastric ulcers are shown in Figure 44.7.

Perforation of a gastric ulcer is a morbid event as patients tend to be elderly with significant comorbidities. Mortality rates following gastric perforation range from 10% to 40% in reported series [29,57–59]. The preferred surgical treatment is distal gastrectomy incorporating the ulcer, as the risk of a malignant ulcer is high in this situation. If the patient has severe comorbid conditions or becomes unstable intraoperatively, the ulcer should be excised or biopsied and oversewn to rule out malignancy [60]. Depending on the intraoperative condition of the patient, truncal vagotomy and pyloroplasty may be added if the frozen section analysis of the ulcer biopsies shows no malignancy.

Laparoscopic repair of perforated peptic ulcers with an omental patch has been compared with open repair in randomized clinical trials [29,30]. In general, patients treated with the laparoscopic approach had decreased analgesic requirements, experienced shorter hospital stays, returned to normal activity earlier, and had no significant differences in morbidity, reoperation rates, or mortality compared with the open approach.

As with perforation, bleeding from a gastric ulcer raises the suspicion of malignancy. Hemodynamically stable patients with bleeding should undergo a definitive ulcer operation, particularly if the need for continued ulcerogenic medication such as NSAIDs is predicted. A distal gastrectomy incorporating the ulcer is preferred, with Billroth I or II reconstruction. Truncal vagotomy may be added. An acceptable alternative is excision of the ulcer, truncal vagotomy, and pyloroplasty. The unstable patient with a bleeding gastric ulcer requires ulcer excision or oversewing of the ulcer with biopsy. Excision of the ulcer is performed from within the gastric lumen through an anterior gastrostomy. In patients with a type IV bleeding gastric ulcer, the left gastric artery may be ligated and the ulcer biopsied and oversewn through a high anterior gastrostomy [61].

Postgastrectomy syndromes

Dumping syndrome

The dumping syndrome is one of the most common causes of morbidity following gastric surgery. Of all patients who undergo gastric surgery, 25%–50% have some symptoms of dumping, but these are disabling in only 1%–5%. The incidence of dumping symptoms varies according to the procedure performed. Significant dumping occurs in 5%–15% of patients following truncal vagotomy and drainage, 15%–20% of patients following partial gastrectomy, but less than 2% following highly selective vagotomy [1].

The dumping syndrome has two forms, early and late, based on the onset of symptoms. The early form occurs within 10–30 min of a meal and is characterized by both gastrointestinal and vasomotor symptoms. Gastrointestinal symptoms include postprandial fullness, crampy abdominal pain, nausea, and explosive diarrhea. Vasomotor symptoms include diaphoresis, weakness, dizziness, flushing, palpitations, and an intense desire to lie down. Expression of these symptoms is variable among patients. Most, however, exhibit both gastrointestinal and vasomotor manifestations. In the late form of dumping, symptoms arise 2–3 h following a meal and are typical of hypoglycemia. These differences are summarized in Table 44.4. Approximately 75% of patients with dumping syndrome have symptoms of early dumping and about 25% of patients have late symptoms. A few patients have both early and late dumping symptoms.

Pathophysiology

Dumping symptoms may occur following any gastric operation. The central factor responsible for the development of

Table 44.4 Forms of dumping syndrome

	Early dumping	Late dumping
Postprandial onset	10–30 min	2–3 h
Typical symptoms	Postprandial fullness	Diaphoresis
	Crampy abdominal pain	Weakness
	Nausea	Palpitations
	Explosive diarrhea	Flushing
	Diaphoresis	Dizziness
	Weakness	
	Palpitations	
	Flushing	
	Dizziness	

dumping appears to be the disruption of the normal regulation of gastric emptying. The emptying of the solid components of a meal is regulated by the coordination of antral grinding and pyloric relaxation, whereas liquid emptying is largely controlled by the pressure differential between the fundus of the stomach and duodenum. Gastric resection reduces fundic volume with a secondary increase in basal fundic tone. Vagotomy increases gastric fundic tone and limits accommodation to a meal. These operations result in more rapid emptying of liquids. Similarly, operations in which the pylorus is removed, bypassed, or destroyed increase the rate of gastric emptying of solids, both through loss of coordinated antropyloric motility and loss of duodenal feedback inhibition of gastric emptying.

Early dumping

Early dumping is thought to result from rapid emptying of hyperosmolar chyme into the small bowel. This leads to fluid shifts from the intravascular space into the intestinal lumen, resulting in small bowel distention and an increase in both the amplitude and frequency of bowel contractions. This results in bloating, crampy abdominal pain, and diarrhea. Sequestration of fluid into the bowel depletes circulating blood volume, causing hypovolemia with tachycardia and lightheadedness.

Several gut hormones have been implicated in the pathogenesis of early dumping. The postprandial concentrations of enteroglucagon, glucose-dependent insulinotropic peptide (GIP), pancreatic polypeptide, vasoactive intestinal polypeptide, gastrin-releasing peptide, serotonin, bradykinin, motilin, and neurotensin are all increased in dumping patients compared with asymptomatic patients following gastric surgery. Of these, neurotensin is the most likely agent involved in the pathogenesis of dumping. It has been shown to have both vasomotor and gastrointestinal actions that mimic those seen in early dumping. However, proof that neurotensin or other peptides cause dumping symptoms is lacking.

Late dumping

Late dumping most likely results from rapid gastric emptying leading to delivery of unusually high carbohydrate concentrations to the proximal small bowel. The carbohydrates are rapidly absorbed, resulting in hyperglycemia and excessive insulin release. The cause of this increased insulin release is unclear, but is thought to be related to the rapid absorption of lumenal carbohydrates or to an enhanced incretin effect. Several peptides may play a role in mediating this incretin effect. These include cholecystokinin, enteroglucagon, GIP, and glucagon-like peptide (GLP). The increased insulin release causes a postprandial hypoglycemia approximately 2–3 h following the meal. This reactive hypoglycemia leads to vasomotor symptoms characteristic of an insulin reaction.

Diagnosis

The diagnosis of dumping is based mainly on clinical history. A scoring system has been developed to assist in the differentiation of dumping from other postgastrectomy complications (Table 44.5). Any patient with a history of gastric surgery who develops symptoms consistent with dumping warrants further evaluation. Despite the characteristic symptomatology, other postgastrectomy complications may mimic the presentation of dumping. Patients should undergo an upper gastrointestinal contrast study to exclude stomal obstruction or afferent loop syndrome. Upper endoscopy should also be carried out to exclude recurrent ulcer, reflux alkaline gastritis, or gastric remnant carcinoma. A radionuclide-labeled gastric emptying study should be performed to document rapid gastric emptying and exclude gastric stasis. Falsely normal

Table 44.5 Sigstad clinical dumping score

Symptom	Score[a]
Preshock, shock	+5
"Almost fainting", syncope, unconsciousness	+4
Desire to lie or sit down	+4
Breathlessness, dyspnea	+3
Weakness, exhaustion	+3
Sleepiness, drowsiness, yawning, apathy, falling asleep	+3
Palpitations	+3
Restlessness	+2
Dizziness	+2

Eructation	–1
Vomiting	–4

a A score of +7 or more suggests dumping; indices of +4 or less suggest other diagnoses.

gastric emptying as measured by radionuclide scanning may be observed if the test meal is of insufficient volume to reproduce the patient's symptoms.

Treatment

Prevention

As with other postgastrectomy syndromes, prevention is the best form of treatment for dumping. Of the surgical options for patients with peptic ulcer disease, highly selective vagotomy has the lowest risk of postoperative dumping syndrome. Although the long-term ulcer recurrence rate after highly selective vagotomy is higher than that after truncal vagotomy and antrectomy, management of recurrent ulcer is less problematic than management of dumping. If resection is required, some surgeons have advocated the use of Roux-en-Y gastrojejunostomy as the drainage procedure of choice to minimize the risk of dumping symptoms. Roux-en-Y gastrojejunostomy clearly decreases the rate of gastric emptying compared with pyloroplasty or loop gastrojejunostomy. However, Roux-en-Y reconstruction has its own set of problems, including Roux stasis syndrome and obstruction. When feasible, Billroth I gastroduodenostomy is the preferred reconstruction after antrectomy, as it most closely restores normal anatomy.

Medical therapy

The majority of patients with dumping syndrome have relatively mild symptoms that improve with time. Dietary modification is the mainstay of therapy and most patients intuitively modify their diet appropriately to minimize their dumping symptoms. The best diet avoids simple carbohydrates and favors complex carbohydrates and dietary fiber. The patient should eat frequent, small meals and avoid liquids during a meal. Liquids may be taken an hour or later following the "dry" meal. For severe vasomotor symptoms, lying supine for 30 min postprandially may slow gastric emptying and increase venous return, thereby minimizing the likelihood of syncope.

Octreotide acetate, a long-acting somatostatin analogue, is the most effective agent for the treatment of severe dumping symptoms. Octreotide ameliorates dumping by slowing gastric emptying, inhibiting insulin release, and decreasing enteric peptide secretion. Both anecdotal reports and randomized trials have documented the short-term efficacy of octreotide treatment in patients with severe dumping symptoms [62–65]. In general, octreotide improves the symptoms in over 90% of patients with severe dumping unresponsive to other medical therapy. In all studies, acute octreotide therapy significantly decreased the symptom score, pulse rate, and plasma insulin level compared with placebo. Long-term follow-up of patients treated with octreotide for dumping has not been reported. Steatorrhea is common with octreotide therapy because of inhibition of pancreatic exocrine secretion. This responds to oral pancreatic enzyme replacement. Other complications of octreotide treatment include hyper- or hypoglycemia, injection site pain, and cholelithiasis.

Surgical therapy

For patients with debilitating dumping unresponsive to medical therapy or patients unwilling to continue medical therapy, remedial surgery may be considered. A conservative approach is warranted, however, because most patients with dumping improve with time and remedial surgery does not cure all patients. Many remedial operations for dumping syndrome have been described, including pyloric reconstruction, jejunal interpositions, conversion of Billroth II anastomosis to Billroth I gastroduodenostomy, and conversion to Roux-en-Y gastrojejunostomy. No controlled trials comparing the relative efficacy of these operations exist. Analysis of their efficacy is difficult, as many of the procedures have good early results but are long-term failures.

For patients with dumping following pyloroplasty, pyloric reconstruction is the optimal remedial approach. In this operation, the pyloroplasty scar is identified and opened along its length. The sphincter muscle is identified and reapproximated. The incision is then closed longitudinally. This procedure has the advantages of simplicity and low risk. Interestingly, gastric stasis is unusual following pyloric reconstruction [66].

Several types of small bowel segment interposition for dumping syndrome have been described. These include an isoperistaltic jejunal segment interposed between the stomach and duodenum, creation of a 10-cm reversed jejunal segment interposed between the stomach and duodenum, and insertion of an antiperistaltic jejunal segment in the efferent limb of a Billroth II gastrojejunostomy or in a Roux-en-Y limb. Mixed results have been reported with this remedial operation, with generally favorable improvement of dumping symptoms but development of gastric outlet obstruction symptoms in some patients. It is clear that the reversed segment must be tailored to an appropriate length. Segments that are too short do not resolve the dumping symptoms, but segments constructed too long result in gastric retention. A 10-cm length appears ideal. Care must be taken to rotate the interposed segment only 180° and to avoid undue torsion of the mesentery. Mesenteric defects should be securely closed to avoid internal herniation.

Conversion of a Billroth II anastomosis to a Billroth I gastroduodenostomy improves dumping symptoms in about 75% of patients. The main advantage of this procedure is the restoration of the normal physiological delivery of a meal into the duodenum. This operation, however, is occasionally technically difficult and fails to alleviate symptoms in a substantial minority of patients. Overall, conversion of a Billroth II to a Billroth I has been eclipsed by the relative simplicity of Roux-en-Y conversion.

There is support in the literature for conversion of a Billroth I or a Billroth II to a Roux-en-Y gastrojejunostomy as

a remedial operation for dumping syndrome. In patients with previous Billroth I or Billroth II gastrectomy and medically resistant dumping, 85%–90% have favorable outcomes with Roux-en-Y conversion. In one of the larger series, Vogel et al. [67] reported that 19 of 22 patients treated with Roux-en-Y conversion had a good result. Of the three failures, only one was due to persistent dumping symptoms whereas the other two were due to the development of Roux stasis syndrome. This procedure has the advantage of simplicity when compared with jejunal interpositions, and it appears to have fewer undesirable long-term complications.

To summarize, remedial surgery for dumping syndrome should be considered for patients with medically unresponsive, severe symptoms. For patients with previous pyloroplasty, pyloric reconstruction is preferred. For patients with previous Billroth I or Billroth II gastrectomy, Roux-en-Y conversion is a simple and effective corrective operation. For patients who have previously undergone Roux-en-Y gastrojejunostomy, the best approach is construction of a 10 cm antiperistaltic jejunal segment within the Roux limb. These recommendations are summarized in Figure 44.8.

Postvagotomy diarrhea

Up to 20% of patients undergoing truncal vagotomy complain of postoperative diarrhea and it is debilitating in 1%–2% [1]. Its severe form is characterized by frequent, watery stools, which are occasionally explosive. The diarrhea may be postprandial or continuous. In some patients, nocturnal diarrhea is problematic. It is important to recognize that diarrhea following gastric surgery most commonly results from causes other than vagotomy. Thus, patients with early postoperative diarrhea should be initially investigated for causes such as bacterial overgrowth, pseudomembranous colitis, obstruction, inflammatory bowel disease, intestinal parasites, and malabsorption. The appropriate initial diagnostic tests should include fecal white blood cell count, stool culture, fecal *Clostridium difficile* titer, and, occasionally, sigmoidoscopy. For patients with persistent diarrhea, further studies should be performed to exclude steatorrhea, partial intestinal obstruction, and inflammatory bowel disease. Appropriate diagnostic studies include 3-day fecal fat quantification, colonoscopy, upper gastrointestinal barium contrast series with small bowel follow through, and barium enema. Consideration should also be given to the possibility of laxative abuse. If this is suspected, measurement of stool pH and magnesium concentration may be useful. If the workup is unrevealing, the diarrhea may be due to dumping syndrome or vagotomy. These last conditions are diagnoses of exclusion. No specific tests are available to confirm that the diarrhea is, indeed, due to the gastric surgery.

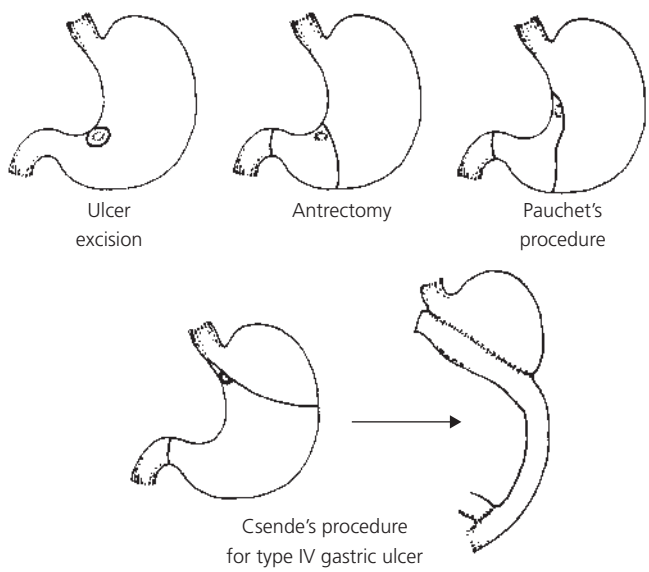

Figure 44.7 Operations for benign gastric ulcer.

Pathophysiology

The pathophysiology of postvagotomy diarrhea is unclear. Although there is no direct evidence, the most likely explanation is that truncal vagotomy interferes with central nervous system modulation of enteric nervous system control of gut motility and secretion. Rapid gastric emptying is often associated with the diarrhea but normalization of gastric emptying by remedial surgery does not always correct the problem. Impaired gallbladder emptying and increased excretion of bile salts may be involved. Supportive evidence includes the finding of higher levels of fecal bile salts in patients with postvagotomy diarrhea compared with control subjects and the beneficial effect of cholestyramine, a bile acid-binding agent, in many patients.

Treatment

Medical therapy

The medical treatment of postvagotomy diarrhea is similar to that recommended for patients with the dumping syndrome. Simple dietary changes including small, frequent, dry meals and increased dietary fiber may slow intestinal transit and therefore improve diarrhea. Opiates are beneficial through their inhibitory effect on intestinal transit. Cholestyramine improves diarrhea in the majority of patients. For patients unresponsive to these measures, octreotide, a long-acting somatostatin analogue, may be tried. Octreotide, however, has had limited success in controlling severe postvagotomy diarrhea as it may exacerbate the diarrhea by inducing steatorrhea.

Surgical therapy

For severe postvagotomy diarrhea unresponsive to medical therapy, remedial surgery may be considered. Although rapid gastric emptying is associated with the diarrhea, operations that slow gastric emptying are not usually curative. The most effective surgical strategies have focused on slowing small

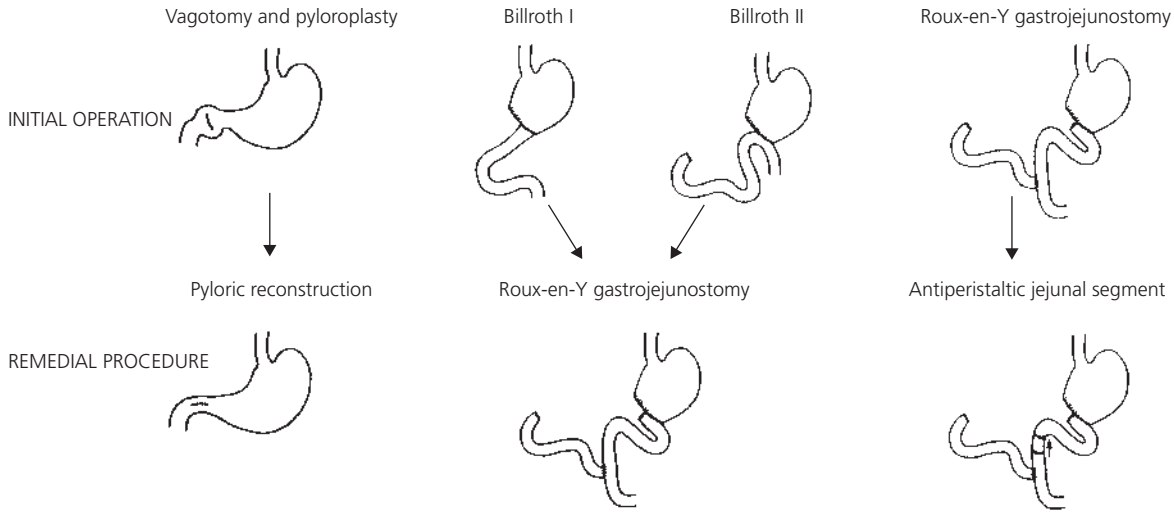

Figure 44.8 Remedial operations for dumping syndrome following gastric surgery. Although many options exist, for each initial operation, a reasonable remedial procedure is proposed. From Glasgow & Mulvihill [1].

bowel transit. Construction of a 10-cm antiperistaltic jejunal segment located 100 cm from the ligament of Treitz is effective in about two-thirds of patients. This is shown in Figure 44.9. Sawyers et al. [68], for example, reported a series of 16 patients undergoing this procedure in whom 14 had successful outcomes. On the other hand, Cuschieri [69] has reported that 12 of 13 patients in whom he performed this procedure had relief of diarrhea, but 10 required reoperation for pain and obstruction. The most important lesson learned regarding the treatment of postvagotomy diarrhea is that, like dumping, prevention is much simpler than treatment. Highly selective vagotomy minimizes the risk of postvagotomy diarrhea and should be performed when possible in lieu of truncal vagotomy for this reason.

Alkaline reflux gastritis

Alkaline reflux gastritis can occur in patients who have undergone removal, bypass, or destruction of the pyloric sphincter mechanism. Loss of pyloric function causes reflux of duodenal contents into the stomach, which may result in gastritis. Although some degree of reflux is seen in all patients without significant sequelae following gastric surgery, approximately 3% develop severe alkaline reflux gastritis. The majority of patients have a previous history of Billroth II reconstruction. However, Billroth I gastroduodenostomy and pyloroplasty are also associated with this syndrome.

Patients typically complain of persistent, burning, epigastric abdominal pain and nausea that are exacerbated by meal ingestion. Bilious emesis, often mixed with incompletely digested food, does not relieve the symptoms of pain and nausea. This feature distinguishes this condition from afferent loop syndrome in which bilious emesis, void of foodstuff, relieves the patient's discomfort. Patients develop an avoidance to food, resulting in significant weight loss. In addition, chronic low-grade gastritis results in anemia, a common finding in these patients. Alkaline reflux gastritis is the most common postgastrectomy syndrome for which remedial surgery is performed.

Pathophysiology

Patients with alkaline reflux gastritis have extensive gastritis involving the entire gastric remnant on gross examination. The gastric mucosa has an erythematous, friable, inflamed, ulcerated appearance on endoscopic examination, usually with visible pooling of bile and duodenogastric reflux. Histologically, the mucosa is void of parietal cells, hemorrhagic, and superficially ulcerated. The former observation is responsible for the achlorhydria or hypochlorhydria seen in patients with alkaline gastritis. Intestinalization of gastric glands, an increase in mucin cells, and a chronic inflammatory infiltrate are commonly observed.

Although the association between duodenogastric reflux and the symptoms of alkaline reflux gastritis is clearly established, the exact pathogenesis of the gastritis is not clear. Some degree of reflux is seen in all patients following gastric surgery; however, only a small minority develop gastritis. Several reports have suggested that patients with alkaline gastritis have increased concentrations of bile acids in the refluxed duodenal juice, increased volume and frequency of reflux, increased concentration of specific bile acids such as deoxycholic acid, or altered composition of bile acids and pancreatic enzymes. Others have suggested that prolonged mucosal exposure to bile acids resulting from gastric dysmotility may play a role in the pathogenesis. Likewise, prolonged gastritis may exacerbate gastric hypomotility. Nevertheless, it appears that the mucosal injury is most likely

caused by bile acids. Contact of bile acids with gastric mucosa results in breakdown of gastric mucosal barrier function, resulting in back-diffusion of hydrogen ions. This causes mast cell disruption with release of serotonin, histamine, and other vasoactive amines, which trigger the inflammatory changes characteristic of this condition.

Diagnosis

The diagnosis of alkaline reflux gastritis is based on a careful clinical history and endoscopic evidence of gastritis by gross and histological appearance. Radiographic studies should be performed to exclude mechanical causes of epigastric pain, nausea, and vomiting, including recurrent ulcer and afferent loop syndrome. An analysis of gastric fluid to document the presence of hypo- or achlorhydria should be performed. If hyperchlorhydria is encountered, hypergastrinemia from an undiagnosed Zollinger–Ellison syndrome, retained antrum, or incomplete vagotomy should be excluded. Bile acid composition and concentration should be determined. Technetium scintigraphy with and without cholecystokinin stimulation can be used to quantify duodenogastric reflux. Provocative testing with alkaline solutions and bile acids may reproduce symptoms in afflicted patients and serve to identify patients who may benefit from remedial surgery. In patients being considered for surgery, a solid-phase gastric emptying study should be performed to exclude significant concomitant gastric dysmotility.

Treatment

Medical therapy

The mainstays of medical therapy for alkaline reflux gastritis are prokinetic agents to improve gastric emptying and coating agents such as sucralfate to enhance gastric mucosal defense. No specific dietary or behavioral therapy is reliably successful. Attempts at binding bile acids with cholestyramine or aluminum-containing antacids have been unsuccessful.

Surgical therapy

The goal of remedial surgery in patients with alkaline reflux gastritis is to prevent pancreaticobiliary secretions from refluxing into the gastric remnant. For patients with a previous history of Billroth I or Billroth II anastomosis, the best remedial choice is conversion to a Roux-en-Y gastrojejunostomy with a Roux limb of sufficient length to prevent retrograde reflux, usually 45–60 cm. This procedure is 75%–85% effective in treating reflux symptoms [70]. However, Roux-en-Y gastrojejunostomy has two major potential complications. First, Roux-en-Y gastrojejunostomy is ulcerogenic, and therefore a vagotomy must be performed if not done so in the initial operation. Second, approximately one-fourth of patients with alkaline reflux gastritis who undergo Roux conversion will develop the Roux stasis syndrome. This underscores the importance of adequate preoperative assessment of gastric emptying in patients with alkaline reflux gastritis. If significant preoperative gastroparesis is encountered, a 90%–95% near-total gastrectomy should be performed with the Roux-en-Y gastrojejunostomy. Others have advocated a Braun enteroenterostomy in patients at risk for Roux failure. In this procedure, the afferent and efferent limbs are anastomosed 30–60 cm away from the gastroenterostomy in patients with a Billroth II anastomosis. Although the results with this procedure appear promising, it requires the presence of a long afferent limb.

For patients with reflux gastritis following truncal vagotomy and drainage, antrectomy with Roux-en-Y gastrojejunostomy should be performed. Antrectomy is necessary to minimize the risk of ulcer formation. For patients with a previous history of Billroth I gastroduodenostomy, a Roux-en-Y conversion should also be considered. Another option in this case is the Henley procedure, in which an isoperistaltic segment of jejunum is interposed between the gastric remnant and the duodenum. However, the results with this procedure have not been favorable. The duodenal switch operation described by DeMeester has also been proposed in the treatment of patients with alkaline reflux gastritis. In this operation, the duodenum is divided 5–7 cm beyond the pylorus. The distal end is oversewn and the proximal end anastomosed end to end to a Roux-en-Y limb. Long-term results with this procedure are not available, but short-term results appear promising. Remedial operations for alkaline reflux gastritis are shown in Figure 44.10.

Stasis syndromes

Stasis syndromes, including gastroparesis and the Roux syndrome, are well-recognized complications of gastric surgery. Postsurgical gastroparesis can occur following vagotomy or gastric resection. Two forms of postoperative delayed gastric emptying have been identified: an early form occurring in

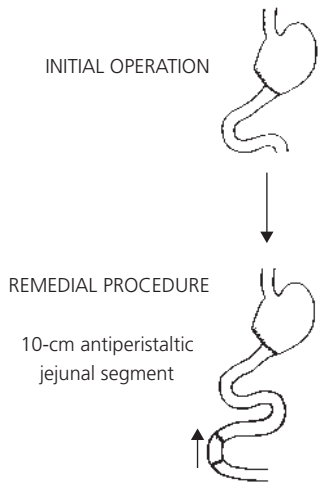

Figure 44.9 Remedial operations for postvagotomy diarrhea include construction of a 10-cm antiperistaltic jejunal segment located 100 cm from the ligament of Treitz. From Glasgow & Mulvihill [1].

the immediate postoperative period and a late form occurring from weeks to years following surgery. The incidence of gastric atony varies with the indication for surgery and type of procedure initially performed. In patients operated on for gastric outlet obstruction, for example, the incidence of postsurgical gastroparesis is as high as 27%–50%. Gastroparesis is seen in 1.4% of patients following vagotomy and drainage, in 2.4%–9% of patients after vagotomy and antrectomy, and in 3% of patients following subtotal gastrectomy without vagotomy. Overall, the incidence of postsurgical gastroparesis is 2%–3% [1].

In patients who have previously undergone Roux-en-Y reconstruction, gastroparesis or stasis in the Roux limb are termed the Roux syndrome. The incidence of this syndrome has been reported to be as high as 25%–30%. The incidence in patients who undergo Roux-en-Y diversion as a means of treating alkaline reflux gastritis is 10%–50%.

Patients with postsurgical stasis syndromes present with postprandial epigastric fullness or bloating, early satiety, epigastric pain, nausea, and vomiting of incompletely digested food. Some patients develop bezoars. Patients may attempt to compensate for their condition by consuming only soft, semisolid foods or liquids. Weight loss and nutritional deficiencies often result.

The diagnosis of postsurgical stasis syndromes is one of exclusion, as symptoms mirror those of other postgastrectomy syndromes. These include mechanical problems such as stomal obstruction from edema, kinking, or stricture, recurrent ulcer, and gastric stump carcinoma. In addition, symptoms may be confused with those of afferent or efferent limb syndrome or postoperative small bowel obstruction. Functional problems, such as gastroparesis related to diabetes mellitus, may be confused with a postoperative complication. These conditions must be excluded before instituting therapy for presumed postsurgical stasis. When surgery is necessary, a near-total gastrectomy is indicated with good long-term results [71,72].

Afferent limb syndrome

The afferent limb syndrome occurs in rare patients following Billroth II gastrojejunostomy. In this condition, the limb of duodenum and jejunum responsible for proximal intestinal, biliary, and pancreatic drainage becomes partially or completely obstructed proximal to the gastric anastomosis. The cause of this obstruction is mechanical and is usually related to excessive length. When the limb is too long, internal small bowel herniation, kinking from redundancy or adhesions, loop volvulus, and intussusception can occur. In addition, obstruction at the gastrojejunostomy from recurrent ulceration, stricture formation, and carcinoma may cause the afferent limb syndrome.

Two forms of afferent limb syndrome have been described: acute and chronic. Acute afferent limb syndrome occurs in the early postoperative period, usually within the first week. Obstruction of the afferent limb leads to accumulation of intestinal, pancreatic, and biliary secretions within the proximal jejunal lumen. As lumenal pressure increases, venous pressures are quickly exceeded, resulting in ischemia and pressure necrosis of the intestinal mucosa. Obstruction of pancreatic and biliary outflow may arise if lumenal pressures are sufficiently elevated. Disruption of the duodenal stump may result.

The symptoms of acute afferent limb syndrome are abrupt in onset. Severe epigastric pain, nausea, nonbilious vomiting, tachycardia, and fever are uniformly present. Abdominal tenderness and fullness are usually present. If uncorrected, shock may ensue. Elevated serum amylase and liver function tests often confuse the clinician into believing postoperative pancreatitis or biliary pathology is the cause of the patient's deterioration. This leads to delay in appropriate surgical management. The diagnosis is confirmed by ultrasound or computed tomography scan, which reveals a fluid-filled mass in the epigastrium. Acute afferent limb syndrome is a form of closed loop obstruction and, as such, is a surgical emergency. Mortality rates associated with acute afferent limb syndrome approach 50% [1].

Chronic afferent limb syndrome may occur at any point in time after the initial surgery. It results from intermittent, partial mechanical obstruction of the afferent limb. Patients typically present with postprandial epigastric discomfort, pain, and fullness. This results from the rapid accumulation of pancreatic, biliary, and duodenojejunal secretions within the limb in response to a meal. As intralumenal pressure exceeds the resistance to outflow caused by the obstruction, the patient experiences explosive bilious vomiting, usually void of foodstuff. This emesis relieves the patient of symptoms. These last two features distinguish chronic afferent limb syndrome from alkaline reflux gastritis, in which emesis usually contains undigested food and does not relieve the discomfort. A minority of patients develop bacterial overgrowth in the partially obstructed afferent limb, resulting in a blind loop syndrome. Plain abdominal radiographs are usually nondiagnostic. Ultrasound or computed tomography is the test of choice. Endoscopy should be performed to exclude the presence of alkaline gastritis, recurrent ulcer, anastomotic stricture, and anastomotic carcinoma.

Patients with afferent limb syndrome require remedial surgery. In the average patient, this is best accomplished via conversion to a Roux-en-Y gastrojejunostomy as seen in Figure 44.11. Alternatively, a Braun enteroenterostomy between the afferent and efferent limbs is effective in decompressing the obstructed afferent limb. In severely ill patients with acute obstruction, the afferent limb and duodenal stump must be examined for viability. In the rare patient with necrosis of the afferent limb, resection of the devitalized tissue, reconstruction of the afferent limb, bypass of the obstruction, and drainage of the duodenal stump is indicated. If extensive necrosis exists, pancreaticoduodenectomy may

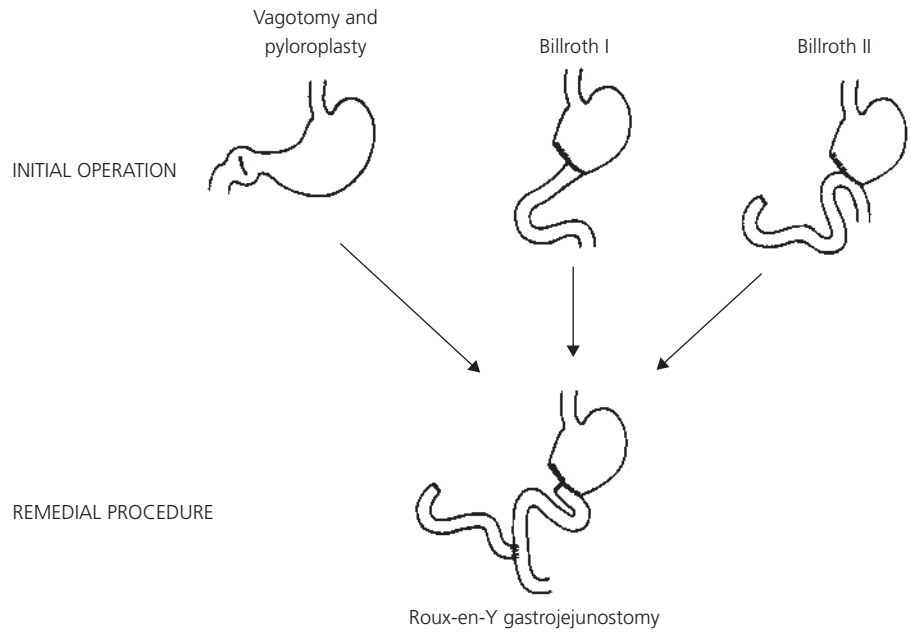

Figure 44.10 Remedial operation for alkaline reflux gastritis involves conversion to Roux-en-Y gastrojejunostomy, regardless of the initial operation. From Glasgow & Mulvihill [1].

be necessary. Afferent limb syndrome can be prevented by creation of a retrocolic gastrojejunostomy with a short (5–15 cm) afferent limb. All defects in the mesocolon or small bowel mesentery should be closed. The gastrojejunostomy should lie in a horizontal plain without kinks.

Efferent limb syndrome

In patients treated with Billroth II gastrectomy, obstruction of the gastrojejunostomy distal to the anastomosis is termed the efferent limb syndrome. Efferent limb syndrome is less common than afferent limb syndrome and is synonymous with postoperative small bowel obstruction. Efferent limb obstruction can be intermittent, partial, or complete. It can occur soon after the original surgery or years later. The causes of obstruction include postoperative adhesions, internal herniation, and jejunogastric intussusception. The last condition typically presents years after the initial surgery and results from intussusception of the efferent limb into the stomach. Less common causes include recurrent or marginal ulcer, gastric stump carcinoma, and lumenal obstruction from passage of undigested food or bezoar through the gastrojejunostomy.

Patients present with symptoms suggestive of small bowel obstruction. These include colicky abdominal pain, distension, diffuse tenderness, and frequent bilious emesis. The diagnosis is confirmed by either barium swallow or computed tomography scan with oral contrast. Upper endoscopy should be performed when recurrent ulcer, gastric stump carcinoma, or intussusception are suspected.

Most cases of efferent limb syndrome require remedial surgery. For patients with obstruction secondary to adhesions or internal hernia, lysis of adhesions, reduction of the internal hernia, and closure of the offending mesenteric defect, if present, should be performed. Anchoring the efferent limb to the anterior abdominal wall in the case of an antecolic reconstruction or to the transverse mesocolon in the case of a retrocolic gastroenterostomy may prevent recurrent herniation, kinking, or twisting of the gastroenterostomy. Most patients with jejunogastric intussusception may be managed nonoperatively. In patients failing conservative therapy, reduction of the intussusception and anchoring of the gastroenterostomy to the abdominal wall or mesocolon should be performed. Resection and revision of the gastroenterostomy or conversion to a gastroduodenostomy is occasionally needed.

Nutritional and metabolic consequences of gastrectomy

Several metabolic and nutritional abnormalities have been attributed to gastric surgery. In general, these result from alterations in the normal digestive and absorptive mechanisms responsible for nutrient uptake. Although weight loss is common following gastric resection, it is typically short-lived and seldom of significance in terms of effects on nutritional and metabolic homeostasis. However, in a minority of patients, considerable weight loss is encountered as a consequence of inadequate food intake and disabling concurrent gastrointestinal symptoms resulting from the resection. Although uncommon, the malabsorption of fat is occasionally seen following gastric resection. The normal mixing of bile acids and pancreatic lipase is disrupted following duodenal bypass in Billroth II gastrectomies or Roux gastrojejunostomies. This fat malabsorption results in steatorrhea. Other causes of fat malabsorption following gastric surgery include bacterial overgrowth or stasis of the afferent limb, pancreatic insufficiency, or intestinal mucosal dysfunction.

Deficiencies of specific nutrients are often encountered in these patients. Iron-deficiency anemia is seen in 30%–50% of patients at long-term follow-up. The cause appears to be the failure to liberate and absorb iron bound in organic molecules in food. When these patients are encountered, marginal or anastomotic ulcer and bleeding from occult gastrointestinal neoplasia must be excluded. Megaloblastic anemia following gastrectomy results from either folate or vitamin B-12 malabsorption. Intrinsic factor, required for vitamin B-12 absorption, is secreted by gastric parietal cells. Vitamin B-12 deficiency may follow gastric resection or occur because of gastric atrophy from gastritis or loss of trophic stimuli such as gastrin. Vitamin B-12 malabsorption may also result from blind loop syndrome with bacterial overgrowth. Osteomalacia from impaired calcium and vitamin D absorption has also been reported. Nutritional and metabolic deficiencies are usually best treated by replacement therapy and rarely require remedial surgery. Recommendations for postgastrectomy vitamin and mineral replacement are shown in Table 44.6.

Gastric remnant carcinoma

Several reports have suggested an association between previous gastric resection for benign disease and the development of gastric remnant carcinoma. Patients undergoing antrectomy with Billroth II reconstruction appear to have a two- to sixfold increased risk of developing gastric remnant carcinoma. However, this increased risk appears to be a late phenomenon, appearing 15–20 years after the initial surgery [73]. Patients with gastric remnant carcinomas tend to present late in their course, with more advanced disease, and tend to be elderly. Reports have suggested similar outcomes to primary gastric cancers, despite the late presentations [73]. These observations have led some authors to recommend screening following gastric resection, with radiographic or endoscopic surveillance beginning 15–20 years after the original resection, especially if the patient experiences new symptoms. However, this recommendation has not been universally endorsed. The low incidence of gastric cancer in the general population and in patients with a previous history of gastric surgery, the lack of evidence supporting a progression of gastric remnant dysplasia to cancer, and the operative risk of total gastrectomy in these high-risk patients argue against routine use of endoscopic surveillance [74,75]. Gastric remnant carcinoma usually requires completion gastrectomy with Roux-en-Y reconstruction.

Recurrent ulcer

Recurrent ulceration following acid-reduction surgery for peptic ulcer disease is an uncommon complication. The incidence varies according to the type of surgery originally performed. Patients undergoing vagotomy and antrectomy or subtotal gastrectomy have a 1%–4% recurrence rate. In contrast, this rate increases to 10% in patients undergoing truncal vagotomy and drainage and 15% or greater in patients undergoing parietal cell vagotomy [1]. Recurrence rates are higher in patients who smoke, and in those with combined duodenal and prepyloric ulcers.

Symptoms may be pain typical of ulcer, or obstructive in nature, related to anastomotic recurrence and stricture. Most commonly, patients complain of episodic midabdominal pain and burning that is often exacerbated by eating and alleviated by antacids. About one-third of patients present with upper gastrointestinal hemorrhage. Perforation is less common, occurring in fewer than 5% of patients. An unusual complication is erosion of a marginal ulcer into a neighboring viscus such as the colon, resulting in a gastrojejunocolic fistula. In this condition, severe diarrhea, weight loss, feculent emesis, fluid and electrolyte disturbances, and malnutrition accompany ulcer pain. Barium enema is the best diagnostic tool, as the fistula is often missed by barium swallow or endoscopy.

The main causes of recurrent ulcers are an inadequate initial operation, continued exposure to environmental ulcerogens, or the Zollinger–Ellison syndrome. Technical features typical of an inadequate initial operation include incomplete vagotomy, retained gastric antrum, or anastomotic stricture. Incomplete vagotomy can be confirmed with the sham feeding test, in which basal and cephalic phase gastric secretions are measured. Retained antrum and the Zollinger–Ellison syndrome can be diagnosed with serum gastrin measurements, with and without secretin stimulation. All patients with suspected recurrent ulcer should undergo gastroscopy. Whenever possible a complete diagnostic evaluation should be undertaken, so that the pathophysiology of ulcer recurrence in a given patient is completely understood.

Table 44.6 Nutrient replacement following gastric resection

Nutrient	Monitor	Sign or symptom	Replacement
Vitamin B-12	B-12	Megaloblastic anemia	Intramuscular, subcutaneous, or intranasal vitamin B-12
Folate	Red blood cell folate	Megaloblastic anemia	Oral folate
Iron	Ferritin	Microcytic anemia	Oral iron supplements
Calcium	Bone mineral density	Osteomalacia	Oral calcium supplements
Fat malabsorption	Qualitative or quantitative fecal fat	Steatorrhea	Pancreatic enzymes

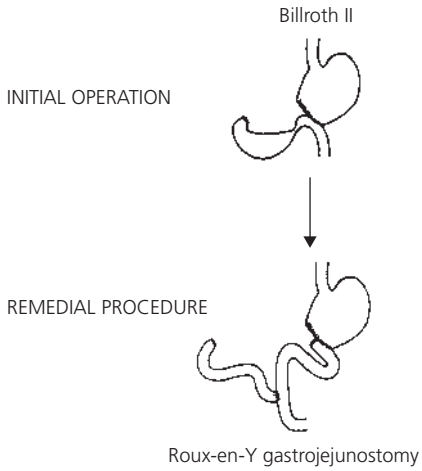

Figure 44.11 Remedial operations for afferent limb syndrome include resection of the obstructed gastrojejunostomy with Roux-en-Y reconstruction. From Glasgow & Mulvihill [1].

The initial management of patients with recurrent ulcer includes a trial of H_2 receptor or proton pump antagonists. Antibiotics are warranted if *H. pylori* infection is suspected. The majority of patients respond initially to medical therapy. Surgery is reserved for patients who fail conservative medical management, those with gastrinoma, and those who develop complications including hemorrhage, perforation, obstruction, or fistulas. Surgical planning should begin with a review of the patient's previous surgical and pathological record to help evaluate the possibility of retained gastric antrum or incomplete vagotomy. Patients with documented incomplete vagotomy can be managed with thoracoscopic truncal vagotomy with minimal morbidity. If the initial procedure was parietal cell vagotomy, reoperation should include truncal vagotomy and antrectomy. For patients previously treated with vagotomy and antrectomy or drainage, a search should be made for residual vagal trunks. In addition, a 50% distal gastric resection with gastrojejunostomy should be performed. If the problem is retained antrum, resection of the tissue at the duodenal stump down to the gastroduodenal artery is indicated. Gastrinoma is best dealt with via resection of the tumor. Results of reoperation are generally good with low rates of rerecurrence.

Hiatal hernias

Under normal circumstances, the stomach is held in position by the gastrophrenic, gastrohepatic, gastroduodenal, and gastrosplenic ligaments. Furthermore, the phrenoesophageal membrane helps to prevent herniation through the diaphragmatic hiatus. This membrane attaches near the squamocolumnar junction and extends approximately 1 cm above this. During swallowing and longitudinal esophageal muscle contraction, there is "physiological" herniation of the gastric cardia through the diaphragmatic hiatus. The phrenoesophageal membrane has a recoil action to pull the squamocolumnar junction back into its normal anatomical position. When these mechanisms are defective, true herniation can develop.

Type I hernias

The most common type of hernia is the sliding, or type I, hernia, with a prevalence of 10%–80% depending on age. In one retrospective analysis, hiatal hernias were identified in 29% of patients with noncardiac chest pain and in 45% of gastroesophageal reflux disease (GERD) patients [1]. Predisposing factors include a widened hiatal tunnel and laxity of the phrenoesophageal membrane, resulting in passage of the gastric cardia into the posterior mediastinum. This herniation is often transient and asymptomatic, but larger hernias (typically defined as greater than 3 cm in length) are often nonreducing and predispose to gastroesophageal reflux. One study has suggested that patients with hiatal hernias are more than twice as likely as patients without hiatal hernias to have inguinal hernias as well [2]. Obesity was also cited as a risk factor for inguinal hernias, and the authors concluded that increased intraabdominal pressure predisposes patients to both types of herniation.

The sliding hernia is an acquired condition with a peak prevalence in the fifth decade of life [3]. Factors such as pregnancy, obesity, deep inspiration, vomiting, coughing, and the Valsalva maneuver, which cause a positive peritoneopleural pressure gradient, predispose to this type of hernia. Longstanding gastroesophageal reflux may also result in a hiatal hernia because of esophageal shortening consequent to acid-induced tonic longitudinal muscle contraction within the esophagus. Age-related degeneration of the phrenoesophageal membrane likely increases vulnerability toward herniation as well. Endoscopically, a sliding hiatal hernia results in cephalad displacement of the squamocolumnar junction above the diaphragm and widening of the angle of His [4]. The cardia, identified by gastric folds, will be seen extending above the diaphragmatic impression. While in gastric retroflexion, this herniation can be seen through the diaphragmatic hiatus because the lower esophageal sphincter has been displaced (Fig. 45.1). As a result of disruption of the antireflux barrier (which is composed of the diaphragmatic crura, phrenoesophageal membrane, and lower esophageal sphincter in anatomical unity), the distal esophagus can also be clearly seen in gastric retroflexion.

Normally, the squamocolumnar junction is located 0.5 cm below the diaphragmatic hiatus, and the gastroesophageal junction high-pressure zone extends about 1 cm distal to this [5]. With a hiatal hernia, two high-pressure zones can be found manometrically because of disruption of the antireflux barrier, one corresponding to the lower esophageal sphincter and one corresponding to the diaphragmatic hiatus. The distal high-pressure zone (at the level of the diaphragm) is augmented by inspiration and abdominal compression. With regard to gastroesophageal reflux, patients with large hernias (over 3 cm long) have weaker and shorter lower esophageal sphincters than do patients with smaller or no hernias; also, distal esophageal peristalsis and acid clearance are less effective [6]. Although esophagitis is more common in patients

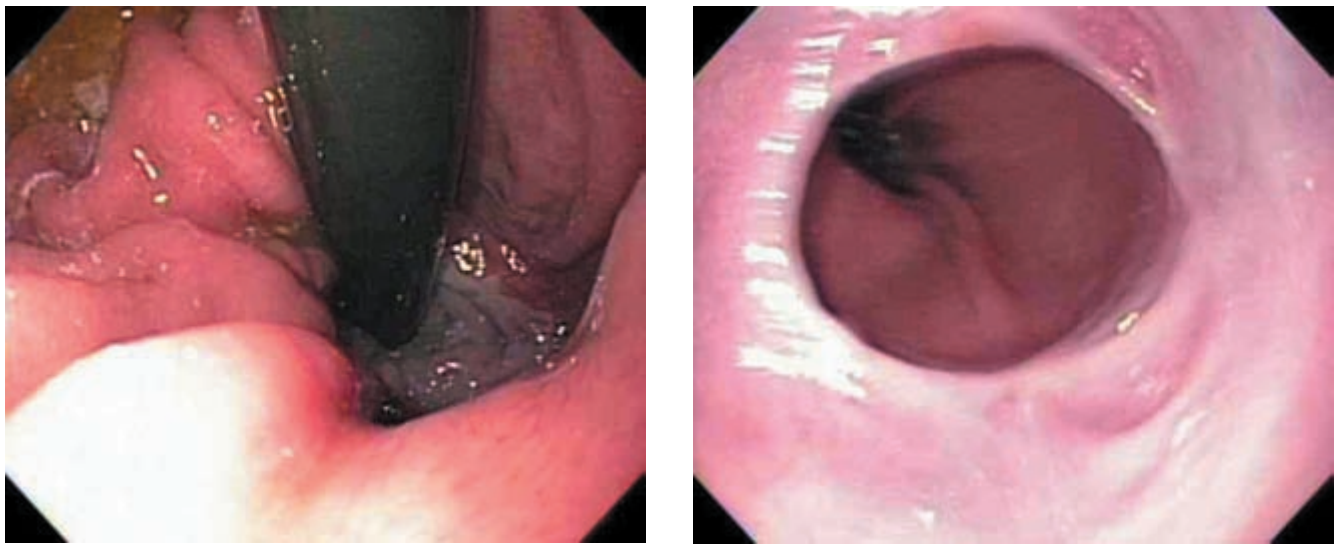

Figure 45.1 Hiatal hernia in retroflexed view.

with a hiatal hernia of any size, it is often more severe in patients with large hernias. Not surprisingly, given the correlation between GERD and Barrett esophagus, hiatal hernias are also associated with Barrett esophagus. In one series, 96% of patients with long-segment and 72% of patients with short-segment Barrett esophagus had a hiatal hernia of at least 2 cm in size, compared with 42% of controls without Barrett esophagus [7]. The mean length of the hernia in patients with Barrett esophagus was nearly 4 cm. In patients with esophagitis but no specialized columnar epithelium, 71% had a hiatal hernia as well. Gastroesophageal reflux disease and Barrett esophagus are discussed in greater detail elsewhere, but their association with gastric herniation is important to note.

Type II to IV hernias

Approximately 5% of hiatal hernias are of types II–IV, the paraesophageal hernias [8]. Unlike type I hernias, these hernias are associated with fundic herniation into the thoracic cavity (i.e., alongside the gastroesophageal junction), whereas the gastroesophageal junction may or may not be displaced as well. Although relatively uncommon, these hernias are associated with severe complications such as gastric volvulus and strangulation. They frequently develop after surgical procedures in the region of the hiatus, such as fundoplication and splenectomy. In an era where laparoscopic Nissen fundoplications are becoming more prevalent, it is important to realize that postoperative paraesophageal hernias develop in 1%–6% of cases [9–12].

In type II hernias there is a localized phrenoesophageal membrane defect allowing the gastric fundus to become the lead point of a herniation. The gastroesophageal junction is still in proper anatomical attachment to preaortic fascia and the phrenoesophageal membrane (Figs 45.2 and 45.3). As more fundus herniates into the thoracic cavity, in part because of gastrocolic and gastrosplenic ligament laxity, gastric rotation can develop along the longitudinal axis of the stomach. This organoaxial volvulus results in the greater curve lying anterior to the lesser curve. Type II hernias can also result in a mesenteroaxial volvulus where rotation is along the transverse axis, but this is much less common. Type

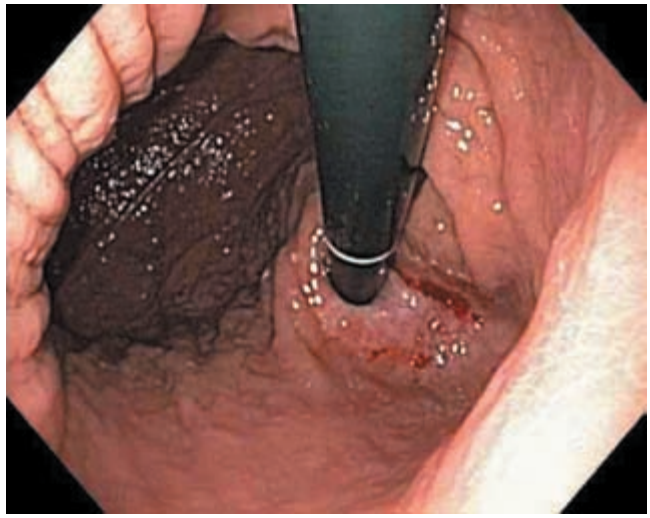

Figure 45.2 Hiatal hernia in standard view.

Figure 45.3 Radiographic view of a type II paraesophageal hernia. The arrow denotes the gastroesophageal junction, which remains below the diaphragm. There is an associated gastric volvulus with a portion of the stomach within the hernia sac.

Figure 45.4 A type III, or mixed, paraesophageal hernia where the gastroesophageal junction is markedly elevated due to gastric herniation. The leading gastric edge has also herniated through the phrenoesophageal membrane and hence is the paraesophageal component of the hernia.

III hernias are a combination of types I and II; the fundus herniates through the hiatus, but stretching of the phrenoesophageal membrane results in displacement of the gastroesophageal junction above the diaphragm as well (Fig. 45.4). Type IV hernias are rare and require a massive hiatal defect that results in herniation of abdominal organs (colon, small bowel, spleen, and pancreas) into the thoracic cavity.

Common symptoms of the paraesophageal hernias include epigastric and substernal pain, postprandial fullness, nausea, pyrosis, dysphagia, and nonproductive retching [13]. A "floppy" fundus, defined by the location of the fundus below the superior portion of herniated gastric body, has been proposed to be an indicator for hernia-related symptoms [14]. Acute bleeding from gastritis or ulceration is rare, but up to one-third of these patients may have iron deficiency anemia resulting from erosions (Cameron ulcers) or venous dilation and engorgement from hiatal constriction and ischemia [15,16] Similar to type I hernias, these hernias are also associated with a hypotensive lower esophageal sphincter, shortened intraabdominal lower eosophageal sphincter (LES) length, distal esophageal dysmotility, and impaired acid clearance [17,18]. Because of the vague nature of many complaints, the true prevalence of paraesophageal hernias is unclear. Nonetheless, up to 20% of such patients may present with acute gastric strangulation or perforation, with associated mortality rates of 50% [19,20].

As a general rule, surgical repair of paraesophageal hernias is indicated only in patients with symptoms [17,21]. Perhaps one exception to this rule is the immediate repair of paraesophageal hernias that develop after routine fundoplication. Many authors recommend obtaining routine barium esophagrams in the first week after fundoplication to rule out the development of a hernia, which is more easily repaired in the immediate postoperative period, even in asymptomatic patients [10,12]. This approach is not unreasonable because these patients are considered to have a failed surgical procedure with persistent gastroesophageal junction derangements and a high likelihood of recurrent symptoms at some point.

The risks associated with paraesophageal hernia repair include bleeding, pneumothorax, vagal injury, early satiety and bloating, diarrhea, and nausea. Up to 20% of patients will have dysphagia initially, and 6% will have chronic dysphagia [17,22]. In addition to hernia reduction and repair of the diaphragmatic defect, fundoplication is routinely performed given the gastroesophageal junction abnormalities associated with paraesophageal hernias. Swanstrom and colleagues followed 52 patients after surgery for paraesophageal

hernias, most of whom had Nissen fundoplications rather than Toupet or Collis–Nissen procedures [22]. Preoperatively, 59% of these patients had pyrosis, 50% had dysphagia, and 26% had esophageal body dysmotility. Postoperatively, pyrosis was reduced to 10%, dysphagia to 6%, and esophageal dysmotility to 13% after a mean follow-up of 18 months. In addition, more than 60% of patients had improved LES pressure after surgery, but 8% developed recurrent herniation. Laparoscopic surgery is feasible in most patients; conversion to an open procedure is necessary about 5% of the time [23]. A study of patients who had undergone laparoscopic hernia repair demonstrated a good or excellent outcome in 80% of patients based on symptoms [24]. It should be noted that the same study had a hernia recurrence rate of 30% and that one-third of the patients with recurrent hernias were asymptomatic. In a Mayo Clinic series comparing open with laparoscopic approaches to hernia repair, there was an overall rate of 17% intraoperative and 19% postoperative complications [25]. In this series, there was only a 2% incidence of hernia recurrence over 14 months.

Although there are no prospective trials with long-term efficacy data that compare open vs laparoscopic repair of paraesophageal hernias, one study has shown that the laparoscopic approach is associated with decreased operative blood loss, decreased rates of ileus, and decreased intensive care and total hospital stays [26]. Patient selection is certainly important because complication rates reportedly increase from 17% to 28% when comparing patients below the age of 65 with those over the age of 75 [27]. Interestingly, this same series reported a hernia recurrence rate of approximately 27% with no difference between various age groups. New approaches have been proposed to improve long-term outcomes. For example, one German group reports only a 1.8% hernia recurrence rate at 6 months by tailoring the type of crural closure (to include the selective use of mesh) to the size of the diaphragmatic defect [28].

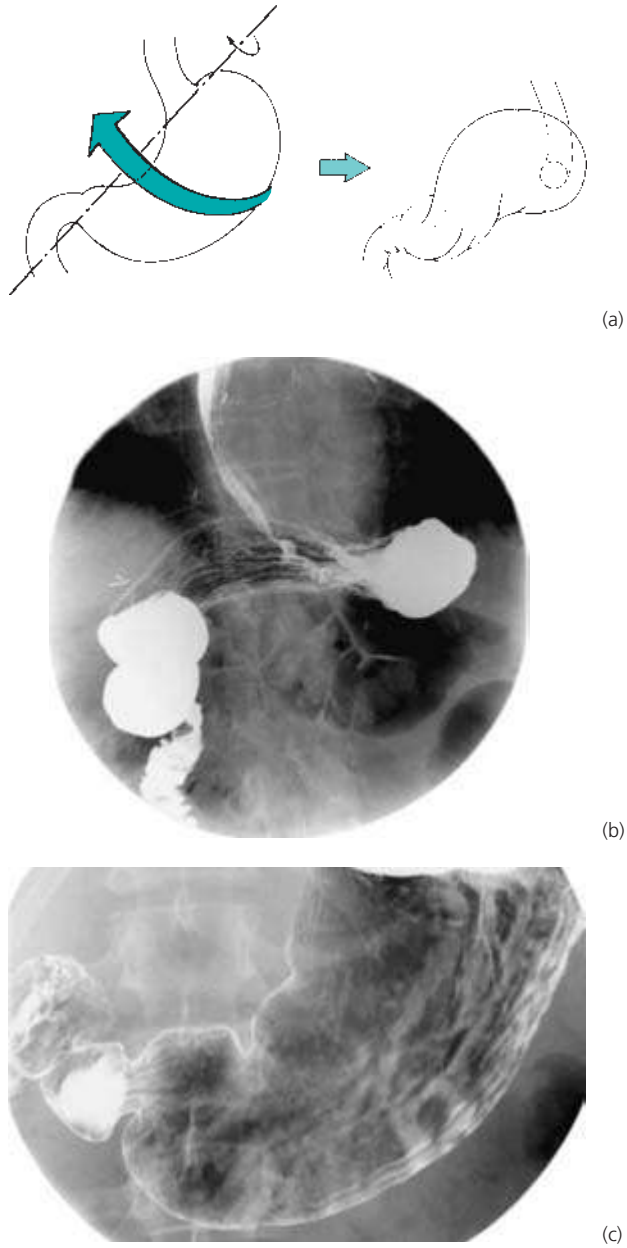

Figure 45.5 **(a)** Schematic representation of an organoaxial volvulus. **(b)** Large organoaxial volvulus with much of the stomach trapped within a hiatal hernia. **(c)** After spontaneous resolution of organoaxial volvulus.

Gastric volvulus

A volvulus of the stomach occurs when one portion of the stomach twists around another. If the twist occurs around an imaginary line between the pylorus and the gastroesophageal junction, it is an organoaxial volvulus (Fig. 45.5). Typically, the greater curve spins upward such that the stomach appears "upside-down" with the true posterior wall lying anteriorly. The antrum rotates anteriorly and superiorly while the fundus is displaced posteriorly and inferiorly. Alternatively, a mesenteroaxial volvulus develops when the distal stomach twists around an imaginary line between the center of the greater curve and the porta hepatis (Fig. 45.6). The antrum and distal body twist to the right (anteriorly and superiorly) such that the posterior wall again becomes anterior in placement; occasionally, the antrum rotates posteriorly in a mesenteroaxial volvulus, although this is rare. Approximately 60% of cases are organoaxial, 30% are mesenteroaxial, and the remainder are either mixed or unclassified [29]. There is no clear prognostic value in defining the type of volvulus, although defining the degree of the volvulus is important [30]. A volvulus may be partial with no symptoms and

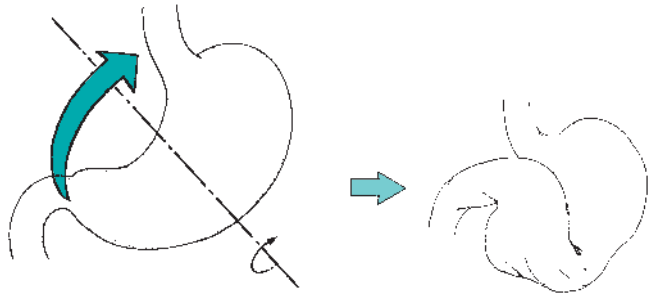

Figure 45.6 Schematic representation of a mesenteroaxial volvulus.

spontaneous resolution, but a complete volvulus can result in vascular compromise, ischemia, and gastric infarction.

The peak incidence of gastric volvulus is in the fifth decade with no clear gender predomination, but 20% of cases may occur in children, usually in the first year of life [29,31]. Predisposing factors include paraesophageal hernias (in up to 76% of cases), abnormal ligament fixation (of the gastrophrenic, gastrohepatic, gastrosplenic, gastroduodenal, and gastrocolic ligaments), prior trauma, and phrenic nerve injury [30,32–34]. Abdominal surgery is another risk factor, largely due to adhesions, but specific procedures such as Nissen fundoplications and gastrostomies are also frequently associated with gastric volvulus [35–37]. In children, ligamentous laxity, splenic mobility, congenital diaphragmatic defects, and hiatal hernias are predisposing factors [31].

Acute gastric volvulus

The acute presentation of gastric volvulus includes substernal or epigastric pain that frequently radiates to the neck and arms and may be confused with a myocardial infarction. Patients may have minimally productive emesis or dry heaves. Hematemesis is rare but suggests mucosal ischemia or tears. The upper abdomen may become tense and distended whereas the lower abdomen is soft. Tympany is not uncommon, and abdominal tenderness may not be impressive. Organoaxial rotations are much more likely than mesenteroaxial rotations to cause an acute volvulus. If the volvulus is complete, it may not be possible to place a nasogastric tube. The Borchardt triad, associated with an acute and complete volvulus, is characterized by abdominal pain, violent retching, and the inability to place a nasogastric tube [38]. In organoaxial volvulus, vascular compromise and gastric infarction occur in 5%–25% of cases, and there is a 15%–20% overall mortality rate with an acute volvulus [35]. In cases of intrathoracic volvulus resulting from a hiatal hernia, emergent surgical mortality rates are 40% but approach 60% if there is gastric strangulation [32,39].

The diagnosis is suggested by the presence of a large gas-filled viscus in the chest or upper abdomen on routine radiography, with the appropriate clinical symptoms. Plain films, however, may be difficult to interpret with an organoaxial volvulus because the stomach still lies in a horizontal position with a single air–fluid level. A nasogastric tube should be placed if possible, although this is unlikely to untwist the volvulus. Although surgery is still considered standard therapy, some have proposed endoscopic reduction as a temporary maneuver in patients where vascular compromise is not suspected. There are case reports of volvulus reduction where the endoscope tip is placed just beyond the torsion, dials are locked, and the scope is rotated 180° to untwist the volvulus [40–42]. Eventually, if not emergently, surgery should be pursued to untwist and repair the volvulus with either anterior gastropexy (where the greater curve is fixed to the anterior abdominal wall) or tube gastrostomy. A subtotal or even complete gastrectomy may be necessary in cases of necrosis. Anatomical defects that might have predisposed to the volvulus can be repaired at the same time. Laparoscopic surgery may be a viable option in many volvulus patients, although this may be a better option in cases of chronic volvulus [43,44]. Given the risk of ischemic strangulation, perforation, and death with acute volvulus, immediate surgical intervention should probably remain the initial treatment of choice, especially as endoscopic reduction does not prevent volvulus recurrence [29].

Chronic gastric volvulus

Unlike the acute volvulus, a chronic volvulus is far more likely to involve a mesenteroaxial rotation. Because this volvulus is usually incomplete and intermittent, patients are more likely to present with chronic and vague symptoms. Abdominal discomfort, dysphagia, pyrosis, fullness, bloating, and postprandial borborygmi are the primary symptoms of a chronic volvulus. Such symptoms are usually worsened after a large meal, and patients may report that changes in body position or self-induced vomiting help to alleviate the symptoms [30]. The diagnosis is often made incidentally on a chest radiograph or barium study. In a mesenteroaxial volvulus, plain films demonstrate a spherical stomach with two air–fluid levels in the upright position; the upper level reflects the antrum whereas the lower level reflects the fundus. The mortality of chronic gastric volvulus is 0%–13% [30,45]. Although surgery is again considered the mainstay of treatment for the chronic and relapsing volvulus, the endoscopic reduction of chronic gastric volvulus and placement of percutaneous gastrostomy tubes (in the body and antrum) has been reported in poor surgical candidates [40–42,46,47]. The need to pursue surgical or endoscopic procedures is unclear in patients with an asymptomatic volvulus or in those with only mild symptoms attributable to the volvulus. In such cases, the risks of surgery or endoscopy must be weighed against the risk of an untreated volvulus.

Gastric rupture

Nontraumatic tears of the gastric wall are relatively rare, but the true incidence is not well defined. In one autopsy study, 0.12% of more than 5100 patients were found to have a spontaneous gastric rupture [48]. Those affected are generally in the fourth decade of life, and women are more commonly affected than men [49]. Gastric ruptures may be as large as 15 cm, and the affected muscle may demonstrate edema and hemorrhage without an inflammatory infiltrate [50]. Initially, there is a mucosal tear followed by dissection of the deeper muscle layers and serosa.

Numerous etiologies may result in gastric rupture. Intragastric pressure and overdistention may play a role in many ruptures, especially if there are pyloric or gastroesophageal junction obstructions to prevent gastric decompression. Normally, the gastric musculature will relax in response to distention, and it has been suggested that distention does not lead to rupture until the intragastric volume is about 4 L [50,51]. Mechanical outlet obstruction, preventing decompression at either the gastroesophageal junction or the pylorus, may develop as a consequence of tumors of the esophagus, pancreas, distal stomach, or duodenum, of complicated peptic ulcer disease, of congenital duodenal obstruction, or of fundoplication [52–54]. There can also be functional obstruction at either gastric orifice. For example, increased intragastric pressure will normally result in a tightened lower esophageal sphincter and an accentuated angulation of the esophagus against the right diaphragmatic crus, both of which tend to prevent gastroesophageal reflux and gastric decompression [49,53,55]. Similarly, a distended stomach may cause angulation and obstruction at the pylorus [56]. Other causes of gastric distention and rupture include gastric lavage in the setting of balloon tamponade for bleeding varices, mouth-to-mouth resuscitation with external cardiac compressions, aerophagia, oxygen administration from nasal cannulation, gastric insufflation during general anesthesia, and fermentation of retained gastric food with associated gas production [53,57–61]. Rapid decompression in diving accidents has also resulted in profound gastric distention and rupture [62–64]. Excessive dosing of sodium bicarbonate for indigestion in the setting of existing overdistention has been reported to cause rupture, although large volumes of sodium bicarbonate would be necessary to generate significant carbon dioxide gas [51,65,66]. Spontaneous rupture of a gastrointestinal stromal tumor (GIST) has also been reported as a cause of gastric rupture [67]. Finally, neonates may be at increased risk for gastric perforation for unknown reasons; in a series of 13 newborns with gastric rupture, 45% were preterm, and mortality was 54% [68].

Trauma and vomiting can also result in gastric rupture. Surprisingly, gastric rupture from blunt abdominal trauma occurs in less than 2% of trauma cases, in part because the stomach is somewhat protected by the ribs and liver [69]. Examples of trauma-induced ruptures include coughing, grand mal seizures, exertion during heavy lifting, the Heimlich maneuver, and motor vehicle accidents with seat-belt compression of the stomach on the vertebrae [58,70–76]. Endoscopic procedures, especially when cautery or laser therapies are involved, can result in a traumatic rupture. Violent vomiting that results in a gastric tear may be seen in peripartum and postpartum emesis, in retching from pyloric stenosis, and in vomiting induced by ipecac [77–79].

In cases of gastric distention, 60% of ruptures occur along the lesser curve near the cardia or at the fundus [50]. It is much less common for such ruptures to occur along the greater curve, on the anterior or posterior walls, or near the pylorus. However, ruptures induced by vomiting typically occur on the greater curve and fundus because violent emesis results in herniation of the stomach into the chest [80]. Symptom onset is immediate, and patients frequently report a history of recent overeating and emesis [50]. Severe pain, abdominal distention, and dyspnea are typical. Shock may develop from peritonitis, blood loss, and tension pneumoperitoneum (which causes inferior vena cava compression with reduced blood return to the heart and hypotension) [56]. Subcutaneous emphysema, where abdominal free air traverses the retroperitoneum and mediastinum to the neck, has also been reported [55]. These symptoms and findings can mimic other intraabdominal catastrophes, such as ulcer perforation, pancreatitis, appendicitis, neoplastic perforation, and splenic rupture. Plain radiographs will typically demonstrate the pneumoperitoneum. Other imaging modalities are of questionable benefit because the clinical scenario typically necessitates immediate surgical attention.

Gastric rupture has a 100% mortality rate without intervention [49]. Death is caused by sepsis, bleeding, respiratory failure, and air embolism [56]. Mediastinitis may also develop with similar end reults [70]. With surgical intervention, mortality rates still exceed 60%. Larger tears, reflecting increased peritoneal contamination, contribute to the high mortality. Perforated ulcers typically have a small tear (i.e., less than 2 cm) and a better outcome, whereas gastric ruptures usually measure 5 cm or greater, and have a poorer outcome [65]. If abdominal pressure is excessive and compromises the patient's cardiorespiratory status, a decompressive paracentesis may be necessary prior to surgical correction [57]. Surgery consists of resection of necrotic gastric tissue, correction of any predisposing obstructive lesions, and peritoneal lavage. Broad-spectrum antibiotics against aerobic and anaerobic organisms are warranted perioperatively. There are case reports of treating gastric perforations with endoclip placement, although this approach is likely only feasible with small or incomplete tears [81,82]. This approach requires

further study and should not be considered the standard approach in the United States.

Foreign bodies

Foreign objects are frequently swallowed, either intentionally or accidentally; in the United States approximately 1500 persons die each year from either swallowing or aspirating foreign bodies [83]. In children, small toys are common, but coins clearly account for most accidental ingestions [84]. In adults, items may be accidentally swallowed as a result of carelessness, poor vision, or alcohol intoxication [85,86]. Such items may be articles that are frequently placed in the mouth, such as toothbrushes, dental prostheses, or nails. Patients with dementia or psychological disease are most likely to intentionally ingest a foreign body, but patients with bulimia may inadvertently swallow objects while trying to induce emesis [87–89]. Incarcerated criminals may swallow objects for secondary gain (hospitalization), whereas drug traffickers may be "body-packers," who intentionally ingest small packets of illicit drugs [85,90].

The vast majority of foreign bodies will traverse the stomach without causing gastric symptoms; symptoms induced by a gastric foreign body suggest mucosal penetration or perforation, peritonitis, or obstruction [85,87]. Mucosal tears, ulceration, perforation, abscess formation, hemorrhage, and fistula formation may all develop as a result of a retained foreign object [85,86]. Sharp objects such as splinters or animal bones are more likely to induce a perforation. When to remove foreign bodies from the stomach is a clinical uncertainty. Objects more than 2 cm in diameter or 5 cm in length should strongly be considered for removal because such items may lead to duodenal obstruction [91]. Due to the risk of perforation, sharp objects should also be removed promptly. If a sharp object is too large to reasonably retrieve endoscopically, a laparoscopic gastrostomy or other surgical methods may be necessary [92]. Blunt objects that are less than 2 cm in diameter or 5 cm in length may be followed with serial radiographs. If the object remains in the stomach for 3 weeks or if the patient develops symptoms of mucosal irritation, endoscopic retrieval of the foreign body should be pursued.

Before attempting endoscopic removal, the patient should be placed in the left lateral decubitus position, and glucagon may be administered to limit motility (although this is more likely to be beneficial for objects in the duodenum than ones in the stomach). Although there is some risk of perforation, a protective overtube may be placed in the esophagus for sharp or difficult-to-grab objects to prevent the possibility of aspiration or esophagopharyngeal trauma [93,94]. Standard biopsy forceps or snares may be used, but larger forceps are available specifically for foreign body removal. Oval or round objects may be trapped within a basket or net. Surgery should be considered before endoscopy for large, jagged objects, and for "body-packers" where there is a significant risk of death from the endoscopic rupture of a packet containing illicit drugs. With the use of commercially available forceps, snares, baskets, and nets, endoscopic retrieval of foreign bodies is successful in 94%–98% of cases [95,96].

The accidental ingestion of button batteries deserves special mention. These batteries contain alkaline compounds such as sodium or potassium hydroxide. Damage to the stomach may occur as a result of low-voltage burns, pressure necrosis, or direct corrosion [84]. Batteries lodged within the esophagus should be removed immediately by endoscopy. If the plain radiograph demonstrates the battery within the stomach and the patient is asymptomatic, the patient can be followed with serial radiographs. Endoscopic removal is warranted if the battery remains in the stomach at 48 hours, if it is greater than 15 mm in diameter, if it is a mercury-based battery, or if the patient is symptomatic with localized abdominal pain, hematemesis, or melena [97]. Ipecac syrup should never be administered in cases of battery ingestion because it has not been shown to be effective and may result in esophageal impaction of the battery [97]. If there is battery disruption, heavy metal levels (dependent on the type of battery) in the blood and urine should be measured.

Caustic ingestion injury

Often more dangerous and damaging than foreign bodies is the ingestion of caustic materials. Common household cleansers and chemicals may contain compounds such as sodium or potassium hydroxide, sodium carbonate, aluminum hydroxide, and bleaches like hydrogen peroxide. Acids tend to cause immediate pain and are quickly expelled by the patient, even in the setting of an intentional ingestion. However, alkali agents are often odorless and tasteless, leading to more significant ingestions. Furthermore, alkali agents penetrate tissue more rapidly than acidic agents because of their solvent action on lipoproteins [98]. Acute manifestations of a caustic ingestion include persistent salivation, odynophagia or even a complete inability to swallow, and the development of palatal or pharyngeal ulcers and white plaques [99,100]. Hoarseness, stridor, and hematemesis may also develop. In a series of 378 patients with acid ingestions, 3% developed massive upper gastrointestinal bleeding between 9 and 21 days after the ingestion [101]. The majority of these hemorrhages were from the stomach rather than the duodenum, and 90% of gastric bleeds required surgical intervention. The presence of peritonitis or mediastinitis suggests a perforation. Acute and chronic manifestations of a caustic ingestion are more commonly seen in the oropharynx and esophagus, but gastric damage may result in late manifestations such as early satiety, weight loss, and vomiting

(symptoms of a possible outlet obstruction). A reasonable approach to the patient with caustic ingestion should begin with abdominal and chest radiographs.

These radiographs are most useful to exclude the presence of free air or esophageal and gastric distention, which are commonly seen after caustic ingestions. If there is no free air but perforation is still suspected, barium studies or a computed tomography (CT) scan can be pursued. The patient may be sent home if there is no free air on plain films, if there are no symptoms, and if the ingestion was accidental. Obviously, admission and surgical consultation are warranted if there is evidence of perforation. If the patient has respiratory or gastrointestinal symptoms or if the ingestion was intentional, hospital admission is necessary. The patient should ingest nothing by mouth initially, and psychiatric consultation should be considered. If the patient has significant respiratory complaints, laryngoscopy may be justified to determine the need for intubation or tracheostomy. Endoscopy is warranted in all cases, but the timing of an endoscopic examination is unclear. Although some authors recommend immediate endoscopy, most recommend an examination at 24–72 hours better to define the extent of injury [99,100]. An endoscopic grading system has been proposed:

- grade I: erythema and edema
- grade II: hemorrhage, erosions, blisters, and superficial ulcers (IIA, linear; IIB, circumferential)
- grade III: multiple, deep, brown-black or gray ulcers
- grade IV: full perforation.

For grade I–IIA damage, liquids can be started with dietary advancement as tolerated. Grade IIB or III patients should have a nasogastric tube placed for gastric decompression, and acid suppression should be employed. Oral liquids may be started approximately 48 hours after endoscopy if the patient is swallowing well. Immediate surgery is warranted in patients with grade IV damage.

Acid neutralizers have been used to limit caustic damage in the past, but these are no longer recommended because heat production from the neutralization process has been shown to worsen tissue injury [102]. Owing to the risk of esophageal strictures and antral stenosis, some investigators have proposed administering oral corticosteroids, based on animal or anecdotal data only. The only randomized controlled trial performed suggested that steroids did little to prevent or limit esophageal strictures, and routine steroid use is not recommended by all clinicians [103].

In the long term, caustic gastric injury may lead to antral stenosis within 3–6 weeks of the ingestion, or it may be delayed for many years. It is not unreasonable to perform an upper gastrointestinal series at 3–6 weeks to look for this complication. Some cases of antral or pyloric stenosis may respond well to endoscopic balloon dilation, but most patients will eventually require a surgical pyloroplasty or distal gastrectomy. In patients with prior caustic injury who are undergoing endoscopy for other reasons, antral hyalinization has been reported and may mimic gastric Crohn's disease or malignant disease [104]. Corrosive damage may increase the risk for subsequent gastric cancer, but such reports are isolated. Endoscopic surveillance is not warranted, based on the available literature [105].

Gastric bezoars

Bezoars are concretions of foreign material that are retained most frequently within the stomach but have also been found in the esophagus and rectum [100]. Such matter may include plant and vegetable debris (phytobezoar), hair (trichobezoar), medications (pharmacobezoar), and persimmons (disopyrobezoar). The true prevalence of bezoars is uncertain because many patients are asymptomatic, but bezoars are uncommon in the intact stomach, with a reported prevalence of 0.4%. However, 10%–25% of patients with prior antrectomies have been found to have symptomatic bezoars [106,107].

The formation of bezoars is likely multifactorial. Altered gastric motility and emptying are the primary causes, but size and digestibility of swallowed material are factors as well. Inadequate mastication, missing teeth, and poorly fitting dentures may also contribute to bezoar formation [108,109]. Prior gastric surgery, whether it be a pyloroplasty, antrectomy, Roux-en-Y gastric bypass, or partial gastrectomy, clearly places patients at risk for phytobezoar or fungus ball formation [110,111]. Surgery can induce gastric atony and dysmotility, but outlet obstruction from stenosis and decreased secretion of acid and pepsin also play a role in bezoar formation. Furthermore, many postsurgical patients develop chronic gastropathy that leads to increased mucus production, and this mucus may act like cement for developing concretions [112]. In an era of antiobesity surgeries, Roux-en-Y gastric bypass and even laparoscopic adjustable gastric banding have been associated with bezoar formation [111,113]. In addition to surgery, gastric stasis and bezoars have been linked to diabetic gastroparesis, mixed connective tissue disease, hypothyroidism, and myotonic dystrophy [114–117].

Phytobezoars commonly comprise apples, grapes, oranges, cherries, raisins, bran, oats, cabbage, potato peels, peanuts, and celery [108,118]. Bezoars may also be composed of nonfood items such as plastic, paper, string, or Styrofoam. Disopyrobezoars develop when unripe persimmon material comes into contact with gastric acid; a tannin in the fruit forms a coagulum that acts as a base for bezoar formation. Trichobezoars may be large, depending on the amount of hair consumed. Medications have reportedly been trapped within hair fibers, and drug toxicity has been attributed to altered drug metabolism [119]. Trichobezoars may also contain food material and fat. Fungus balls, also termed yeast bezoars, are associated with prior gastric surgery and fre-

quently resolve without therapy. For symptomatic fungus balls, gastric lavage, antimycotics, and gastric outlet reconstruction have all been used [120,121].

Concretions are typically hard bezoars. Shellac, furniture polish, and concrete are classic components of such bezoars, and surgery may be necessary to remove concretions because other therapies are generally ineffective. Pharmacobezoars may develop in patients with normal or abnormal gastric physiology. Aluminum hydroxide antacids have caused bezoars in patients with renal failure, and the cellulose-based coating of enteric coated aspirin has been problematic in other patients [122,123]. In patients with achlorhydria, calcium and magnesium carbonate preparations may not dissolve normally. Sucralfate will occasionally form concretions at normal doses and in patients with gastric outlet obstruction, so this agent should be avoided in patients with outlet obstruction or significant dysmotility [124]. Other drugs with capsules that do not digest (such as certain nifedipine or mesalamine preparations) should also be avoided in patients with gastric outlet narrowing [125].

Many patients with bezoars are asymptomatic, but epigastric pain, early satiety, nausea, and vomiting are common manifestations of a bezoar [100,108]. Bloating, malaise, and weight loss may also be reported. In some patients, these symptoms may persist despite bezoar resolution; in such cases, the nonspecific symptoms may be more reflective of the gastric dysmotility than of the actual presence of a bezoar. In patients at risk for bezoar formation, symptoms of a small bowel obstruction may reflect the passage of a bezoar into the small bowel, although this is rare [126]. Gastric outlet obstruction and gastric bleeding (hematemesis or melena) can also be complications of bezoars. Given the nonspecific nature of the symptoms, the patient's history may suggest other causes such as peptic ulcer disease, gastric cancer, or many other intraabdominal processes. On physical exam, potential findings include abdominal tenderness, a palpable mass, and a succussion splash [100]. Plain radiographs may demonstrate an air shadow or a mottled-appearing mass in the stomach. Barium studies are much more likely to demonstrate a bezoar; trichobezoars "absorb" barium and have a mottled appearance whereas phytobezoars and concretions are typically impermeable to barium (Fig. 45.7). Radiographic studies may miss a bezoar, and endoscopy remains the test of choice. Although other studies such as ultrasound or CT may demonstrate a bezoar, endoscopy is best for determining the type of bezoar, for excluding cancer, and for evaluating the mucosa for associated ulceration or outlet obstruction.

Figure 45.7 Gastric bezoar on upper endoscopy examination.

Enzyme therapy

Because many bezoars contain cellulose, protein, and mucus, enzymatic degradation of phytobezoars may be possible. For bezoars containing fibrous material, papain may be a useful proteolytic enzyme. Although this enzyme can be individually purchased, papain can be obtained more cheaply by using Adolph's Meat Tenderizer [1 teaspoon in 115 mL (4 ounces) of water before each meal] [100,118]. Some caution should be used with the latter salt-containing preparation (1800 mg per tablespoon) because hypernatremia is a potential problem. Cellulase may be used for phytobezoars as well. The cellulase tablets are frequently crushed and given after each meal, or 2 L of cellulase solution may be consumed over the course of 2 days (20 g cellulase in 2 L of water) [118,127]. Biochemical supply companies can provide papain and cellulase preparations. Because many phytobezoars contain mucus as well, the mucolytic agent acetylcysteine may also be used. This agent has been reported to be effective at a dose of 15 mL in 50 mL of saline administered through a nasogastric tube two times per day for 2 days; although not specifically stated in this case report, it is presumed that a commercially available 20% acetylcysteine preparation was used and diluted to a 5% solution as recommended by the manufacturer for other indications [128]. If there is ulceration associated with the bezoar, some investigators have suggested that mucolytic and cellulolytic agents may be safer than the proteolytic regimens provided.

Mechanical therapy

Many bezoars contain insoluble agents that are not amenable to enzyme therapy, and some patients are so symptomatic that more urgent therapy is warranted. Small bezoars may be retrieved like other foreign bodies with endoscopic baskets, snares, or forceps. An esophageal overtube is frequently used to prevent inadvertent aspiration of the bezoar [129]. Similarly, many bezoars can be mechanically disrupted into small pieces with forceps such that the pieces are retrieved by suction or allowed to pass through the pylorus. For soft and permeable bezoars, a large-bore orogastric lavage tube can be placed for aggressive water lavage with subsequent

aspiration of the fragmented bezoar. Frequently, a combination of endoscopic fragmentation and subsequent orogastric lavage is used, with immediate benefits to the patient.

Other modes of mechanical disruption have been proposed. Plastic tubing has been placed through an endoscope channel and attached externally to a Teledyne Water Pik system. Water or an enzymatic solution can be pulsated against the bezoar to allow fragmentation and subsequent gastric lavage [118,130]. Neodymium:yttrium–aluminum–garnet (Nd:YAG) laser may be useful for refractory bezoars, although multiple sessions may be necessary [131]. Extracorporeal shock wave lithotripsy and mechanical lithotripsy – with an endoscopic retrograde cholangiopancreatography (ERCP) lithotriptor for hard bezoars – have also been successful [132,133]. In patients who have undergone gastroplasty and in whom the surgical stoma may be too small (predisposing to bezoar formation and not allowing passage of bezoar fragments), the stoma may require balloon dilation or even an endoscopic incision with a papillotome [134,135].

Endoscopic management is warranted for symptomatic patients only. If a bezoar is incidentally found or if symptoms are minimal, enzymatic and prokinetic therapies are likely adequate. Endoscopy is clearly indicated for more symptomatic bezoars, especially if complications such as obstruction develop.

Medical therapy

Prokinetic agents such as metoclopramide may be used on a long-term basis to aid in the prevention and recurrence of bezoars. Metoclopramide has been used alone and with concomitant endoscopic therapy in the acute setting (40 mg intravenously over 24 hours) with some success for the management of symptomatic bezoars, but patients should also be placed on a clear liquid diet under such circumstances [136]. Although liquid diets may have some benefit in bezoar dissolution, this is a slow process that is not practical as sole therapy. The prokinetic benefit of long-term oral metoclopramide use must be weighed against the severity of the patient's symptoms and the significant side-effect profile. Domperidone, not available within the United States, may be another option, with fewer side effects but similar gastric effects compared with metoclopramide. Erythromycin and tegaserod are other agents that can be used to promote gastric motility and to decrease the risk for bezoar formation, although tegaserod has been removed from the open market in the United States and is available for this indication only with a compassionate use approval from the Food and Drug Administration [137].

For patients with or at risk for the development of bezoars, prokinetic agents should be considered, based on the patient's symptom severity. Conversely, all such patients should follow basic dietary guidelines to limit bezoar formation. Specifically, smaller but more frequent meals are advisable to promote gastric emptying. Patients should chew their food adequately into small pieces. Foods that easily coalesce into a bezoar, such as persimmons, raw fruits, and stringy vegetables, should be avoided [108].

Surgical therapy

Surgery is rarely required for bezoars but may be necessary in the setting of bezoar complications such as perforation, gastric or small bowel obstruction, and uncontrollable hemorrhage. Symptomatic trichobezoars often require surgery more than other bezoar types because they are resistant to standard management techniques. Of course, other bezoars may also require surgery if they cannot be treated by the methods outlined earlier. Because surgery is unlikely to correct the underlying cause of bezoar formation and may worsen gastric motility and emptying, such a course should not be undertaken lightly.

Heterotopic pancreas

Heterotopic pancreatic tissue, also termed a "pancreatic rest," has been identified in 0.5%–14% of persons at autopsy [138]. These rests are found in the stomach, duodenum, or jejunum in 75% of cases but may also be seen in the lung, gallbladder, common bile duct, ileum, Meckel diverticula, and numerous other locations. Typically, these rests are asymptomatic, but abdominal pain, nausea, vomiting, and rarely bleeding have been attributed to rests located in the stomach. In one series of 17 patients, pancreatic rests were the presumed cause of pain in 77% of patients, of abdominal fullness in 30%, and of melena in 24% [139]. After surgical resection of the rests, significant symptom improvement was reported, but it is still somewhat controversial if rests truly do cause symptoms to warrant surgical excision. These lesions typically appear as 2–4-cm submucosal masses in the prepyloric region, and central umbilication is not unusual (Fig. 45.8). The nodules are firm and may be yellow. Because this typical appearance is not always appreciated, rests have been mistaken for malignant tumors in 67% of upper endoscopies and in 71% of barium studies [139]. If the endoscopic appearance is not diagnostic, endoscopic ultrasound may be helpful in the evaluation, especially when deep biopsies or surgical resection are being considered [140]. Surgery is indicated only in cases of symptomatic pancreatic rests.

Squamous cardiac epithelium

Squamous epithelial extension into the proximal stomach has been reported. In the earliest report, 16 patients, all male and nearly all Caucasian, were described [141]. Most of the patients had pyrosis (75%) and hiatal hernias (100%), and many had Barrett esophagus (38%). No patient had a history of caustic ingestion or prior gastric surgery. Most had solitary

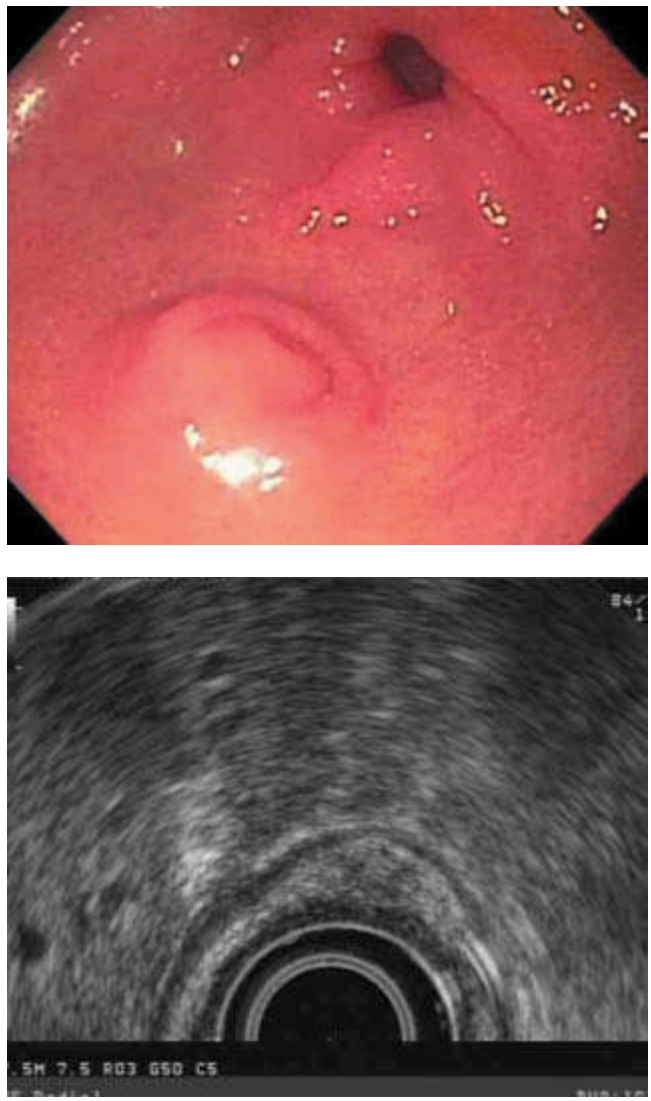

Figure 45.8 **(a)** Pancreatic rest identified in the antrum during upper endoscopy. **(b)** Endoscopic ultrasound appearance of pancreatic rest.

tongues of this squamous epithelium in the proximal stomach, but multiple tongues and islands were also identified. Squamous metaplasia of the stomach has also been described on the lesser curvature of the stomach, near the cardia [142]. Prior gastric injury, such as that from gastric ulcers or electrocautery, has been proposed as an explanation [141–143]. For example, 12 patients with previous ablation of Barrett esophagus with multipolar electrocautery have been reported to develop squamous epithelium in the gastric cardia (mean length 1.7 cm). Although some investigators have proposed that squamous epithelium in the stomach represents metaplasia from prior injury, others state that this phenomenon is a normal variant [144]. In reality, the true incidence and clinical significance of this finding are unknown.

Structural anomalies, 1100

Gross anatomy

The small intestine begins at the pyloric sphincter of the stomach and extends to the cecum. Approximately 600 cm long, the small bowel is composed of three major segments: the duodenum, the jejunum, and the ileum. The junction between the duodenum and the jejunum is anatomically demarcated by the ligament of Treitz. No similar landmark distinguishes the jejunum from the ileum, but the jejunum is usually defined as the proximal two-fifths of the small bowel after the duodenum, and the ileum as the distal three-fifths.

After the appropriate rotation of the gut and its return to the abdominal cavity in fetal life, the normal position of the small bowel loops is attained. The jejunum is generally located in the mid upper and left upper quadrants, the proximal ileum in the middle abdominal region, and the distal ileum in the right lower quadrant [1].

The first part of the duodenum, the bulb, is invested with mesentery. The descending, transverse, and ascending parts of the duodenum are retroperitoneal and partially encircle the pancreatic head (Fig. 46.1). The jejunum begins at the ligament of Treitz as the small intestine reenters the peritoneal cavity. The jejunum and the ileum are invested with mesentery. The most distal part of the ileum may occasionally be retroperitoneally located [2].

The gross appearance of the small intestine changes from the jejunum to the ileum. The wall of the jejunum generally is thicker than that of the ileum. Also, the plicae circulares, or circular folds of mucosa and submucosa that invaginate the lumen and increase the gut surface area, are prominent in the duodenum and jejunum and disappear in the middle ileum [1]. Peyer patches usually are found on the antimesenteric border of the small intestine. They are particularly prominent in childhood and atrophy with aging [1].

Extrinsic arterial, venous, and lymphatic supply

The arteries, veins, and lymphatics that supply the small bowel travel through the mesentery (see Chapter 113). The hepatic artery gives rise to the gastroduodenal artery, which branches into the anterior and posterior superior pancreaticoduodenal arteries. These anastomose around the duodenum and communicate with the inferior pancreaticoduodenal artery, which arises from the superior mesenteric artery. The superior mesenteric artery also supplies the jejunum and the ileum through a series of branches that form numerous arcades in the mesentery and then penetrate the intestine.

The superior mesenteric vein serves as the major venous conduit and joins the splenic vein to empty into the portal vein. Small lymph channels or villus lacteals drain into mesenteric lymph nodes located near the intestine and along the superior mesenteric and celiac arteries. These drain into the cisterna chyli and the thoracic duct.

Neural supply

The intestine contains an abundant, complex intrinsic neural supply that coordinates motor activities and consists of myenteric (Auerbach) and submucosal (Meissner) plexuses (see Chapter 2). The extrinsic autonomic innervation of the small intestine consists of components from the parasympathetic and sympathetic systems [3]. Postganglionic fibers arising from the superior mesenteric ganglion supply sympathetic motor innervation. These synapse with preganglionic fibers from the spinal cord in the region of the 10th and 11th thoracic roots and travel in the lesser splanchnic nerve. Adrenergic neurons innervate both the Auerbach and the Meissner plexuses. Sensory nerves arise from the dorsal root ganglia. The parasympathetic motor innervation consists of preganglionic nerve fibers that arise from the vagus nerve.

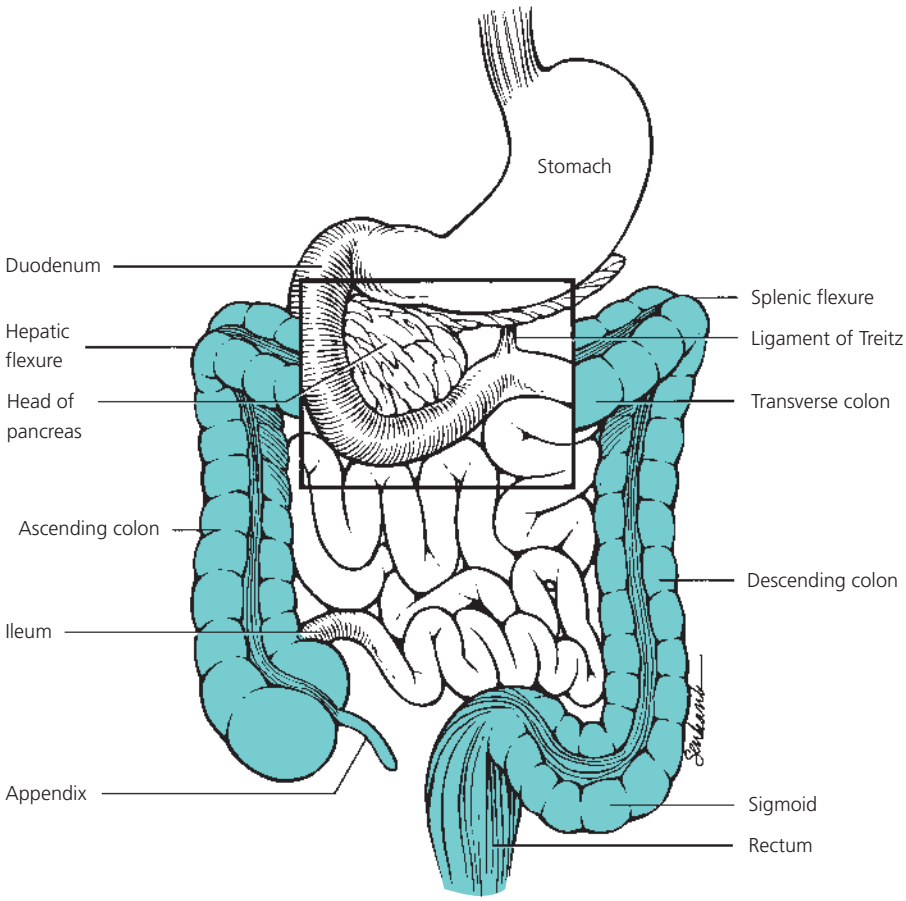

Figure 46.1 Anatomical relations of the stomach, small intestine, and large intestine. The duodenum encircles the head of the pancreas and is retroperitoneal. As the intestine reenters the peritoneal cavity at the ligament of Treitz, it becomes the jejunum. Generally, the jejunal bowel loops are located in the left and middle upper abdomen, the proximal ileum in the middle abdominal region, and the distal ileal loops in the right lower quadrant. **Inset:** Retroperitoneal duodenal loop and the ligament of Treitz, located behind the transverse colon.

Vagal fibers originate from the dorsal motor nucleus and then divide into esophageal, anterior, and posterior vagal trunks. Both the anterior and posterior trunks give rise to celiac branches that directly innervate the small bowel by communicating with the intrinsic nervous system.

The axons of a small number of intrinsic nerves project from the intestine to travel with extrinsic nerves and synapse with sympathetic postganglionic neurons at the sympathetic prevertebral ganglia.

Enhancement of small intestinal surface area: gross and microscopic features

The surface area of the small intestine is enhanced by three features that are peculiar to the gut: the plicae circulares, the villi, and the microvilli (Fig. 46.2) [2]. The plicae circulares, or circular folds, consist of visible mucosal or submucosal invaginations that are predominantly located in the duodenum and jejunum. The villi, fingerlike projections that protrude into the intestinal lumen, are approximately 0.5–1.5 mm long and cover the mucosal surface. They can be viewed by close inspection of the mucosa under low-power microscopy or as tiny mucosal protrusions at endoscopy. They consist of a layer of epithelial cells overlying the lamina propria. Their microscopic appearance varies: duodenal villi are characteristically broad and leaf-shaped, jejunal villi are tall and thin, and ileal villi are short and broad. The length and shape of the villi also vary with the geographical region; in some underdeveloped regions of the world, villi tend to be shorter than in the United States [4,5]. At the base of the villi, the epithelium enters the lamina propria and forms the crypts of Lieberkühn (Figs 46.3 and 46.4), which extend almost to the muscularis mucosae. The microvilli are sub-light microscopic tubular projections that are extensions of the apical cell membrane and compose the brush border. This complex membranous network contains the enzymes, receptors, and carriers required for terminal digestion and absorption.

Microscopic anatomy

The small intestine is composed of four concentric layers: the serosa, muscularis propria, submucosa, and mucosa.

Serosa and muscularis propria

The thin serosal lining of the small bowel consists of mesothelial cells overlying loose connective tissue. This outer layer becomes continuous with the mesentery as it joins the small bowel; many large blood vessels course through it.

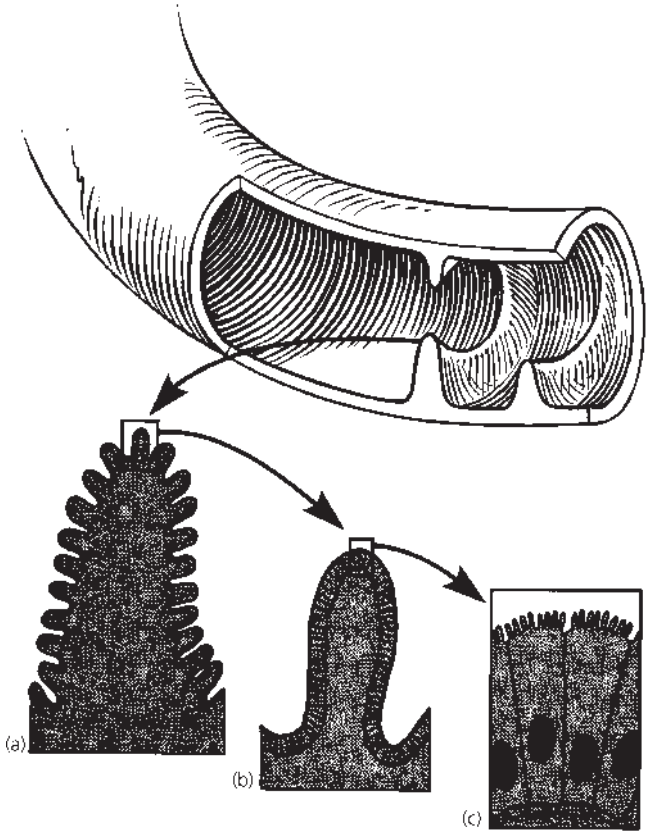

Figure 46.2 The surface area of the small intestine is enhanced by three mechanisms: the valvulae conniventes **(a)**, the villi **(b)**, and the microvilli **(c)**. Adapted from Weaver [82].

Figure 46.3 This semithin 1-μm epon section of human jejunum, stained with toluidine blue and viewed by light microscopy, depicts the mucosa. The villi are formed by a continuous sheet of columnar epithelial cells and underlying connective tissue, the lamina propria. The epithelial sheets are composed primarily of enterocytes; mucus-secreting goblet cells are also present but are much less abundant, as are rare enteroendocrine cells. At the base of the villi, the epithelial cells descend into the lamina propria to form the crypts, one of which is denoted at the left (c). The crypts are lined mainly by undifferentiated crypt cells, which can be observed in mitosis (arrows). Differentiation proceeds as these cells migrate up the villus. Paneth cells at the bases of the crypts are recognized by their dark granules. The muscularis mucosae (m), a thin layer of smooth muscle, separates the mucosa from the submucosa below. Original magnification × 150. From Rubin W. The epithelial "membrane" of the small intestine. Am J Clin Nutr 1971;24:45.

Those portions of the gut that are invested with mesentery are completely covered by serosa, whereas the retroperitoneal segments are invested only on the anterior surface. The muscularis propria consists of two muscle layers: an outer, longitudinally oriented layer and an inner, circumferential layer. Between the two layers lies the myenteric or Auerbach nerve plexus, composed of intrinsic ganglion cells and nerve fibers. The muscular layers of the gut are responsible for generating coordinated peristaltic movements.

Submucosa

The submucosa is a dense connective tissue layer containing numerous arteries as well as venous and lymphatic plexuses. Typical connective tissue cells are also present, but vascular structures predominate, consistent with the role of this portion of the gut as a conduit for absorptive and digestive products. In the duodenal bulb and descending duodenum are specialized Brunner glands that secrete mucus and bicarbonate. These glands are branched epithelial structures that fill the submucosa and are thought to be important in neutralizing stomach acid. The submucosa also contains ganglion cells and nerve fibers, termed the Meissner plexus, a collection of autonomic nerves that communicate with the Auerbach plexus. A variety of neuroendocrine substances are produced in the Meissner plexus (see Chapter 2). These plexuses interact to produce regulated, coordinated gut peristalsis.

Mucosa

The mucosal layer of the gut consists of epithelial cells overlying the lamina propria, or connective tissue core, and resting on a narrow layer of smooth muscle, the muscularis mucosae (see Fig. 46.3).

Lamina propria

The connective tissue core of the villus (lamina propria) contains a variety of cells and vascular structures (Fig. 46.5). The immune cellular component includes lymphocytes,

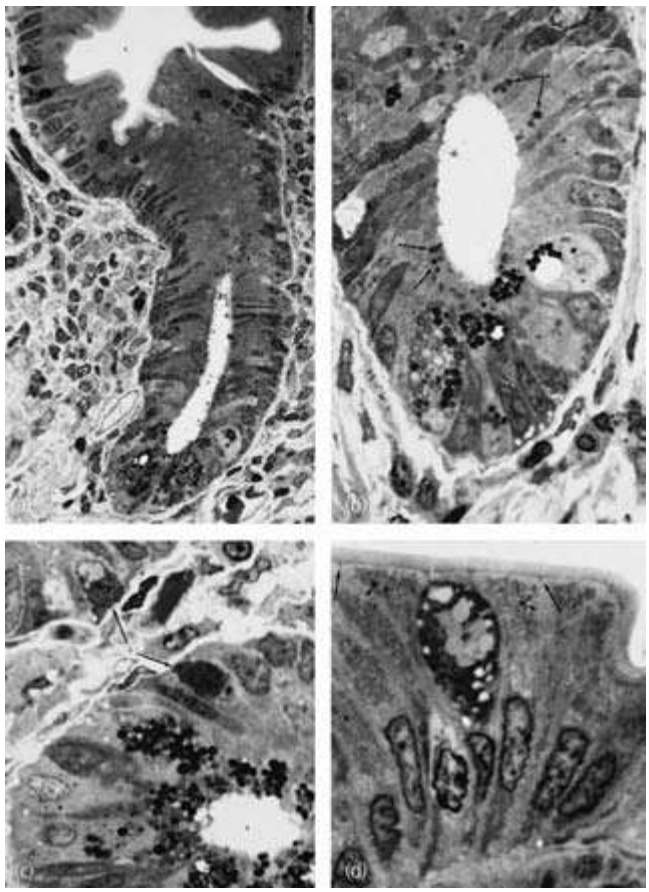

Figure 46.4 High-power views of the crypt. **(a)** A crypt is observed extending to the base of a villus. Note the prominent brush border on the differentiated cells above the villus base and the inapparent brush border on the crypt cells below. The arrow shows a short and irregular brush border on an upper crypt cell. Large, dense Paneth cell granules are evident at the crypt base; the smaller apical granules higher in the crypt are in undifferentiated crypt cells. Original magnification × 300. **(b)** The large granules in Paneth cells at the base of another crypt are located mainly in the apical cytoplasm. The scantier, lighter apical granules in cells above (arrows) are in undifferentiated crypt cells. Original magnification × 700. **(c)** The large, dense apical granules in Paneth cells at another crypt base should be contrasted with the smaller, barely resolved basal infranuclear granules observed in two endocrine cells (arrows). Original magnification × 700. **(d)** Differentiated villus epithelial cells and a goblet cell. Note the tall, prominent brush border. The narrow, light zone below the brush border represents the terminal web. The numerous light structures within the cells are mitochondria. The occasional dense apical structures are lysosome derivatives (arrowheads). The apical densities between adjoining cells at the level of the terminal web (arrows) are the terminal bars. They represent the junctional complexes of electron microscopy – the tight junctions, intermediate junctions, and desmosomes; these are specialized structures that serve to bind adjoining epithelial cells at their apices. The accumulation of mucus granules within the apical cytoplasm of the goblet cell distends it into the shape of a brandy goblet. Original magnification × 1500. From Rubin W. The epithelial "membrane" of the small intestine. Am J Clin Nutr 1971;24:45.

The small intestinal mucosa. In: Whitehead R (ed.). Gastrointestinal and oesophageal pathology. New York: Churchill Livingstone, 1989:29.

macrophages, granulocytes, plasma cells, and mast cells (see Chapter 7). The majority of lamina propria T lymphocytes are T-helper/inducer cells that are surface antigen $CD4^+$, although smaller numbers of T-cytotoxic/suppressor cells ($CD8^+$) are also present [6]. The intraepithelial lymphocytes (IELs) reside on the basolateral side of the villus epithelial cells, and can be classified as type a or type b IELs [7]. The small intestine IELs are type b, expressing T-cell receptor subtypes TCRαβ and TCRγδ. Type a cells are present but are more enriched in the colon, and are TCRαβ and surface marker CD4 or CD8αβ positive. Type a cells are more like peripheral spleen and lymph node T cells, and are present in the lamina propria. They are acquired memory T cells that migrate into the gut after an encounter with antigens outside the gut. Type b cells, in contrast, are permanent residents of the gut epithelium and are natural memory T cells [7,8]. The lamina propria plasma cells produce immunoglobulin, especially dimeric immunoglobulin A (IgA), which is taken up into the intestinal epithelium and secreted intraluminally after joining with secretory component [9]. A much smaller number of plasma cells produce IgM or IgG. The maturation of the B cell to an IgA-secreting plasma cell occurs during the

course of a migratory journey throughout the body's vascular system. Cells exit the Peyer patches through lymph vessels, enter the mesenteric lymph nodes, thoracic duct, and peripheral blood, and then finally "home" to the lamina propria of the gut (as well as to other organs, such as the lung, genitourinary tract, and breast) [9]. T lymphocytes similarly migrate from one lymphoid organ to another and eventually home to mucosal sites, which are determined by their interactions with specific proteins expressed on lymphoid cells as well as the high endothelial venules, specialized vessels of the lymph nodes, Peyer patches, and appendix [9]. These vascular structures can also proliferate in organs affected by chronic inflammation. Macrophages and eosinophils are present in the normal human intestinal lamina propria. However, neutrophils are primarily found in inflamed rather than normal gut.

Isolated lymph follicles are small collections of lymphocytes in the mucosa and submucosa, found scattered throughout the gastrointestinal tract [10–12]. Peyer patches, found in the mucosa and submucosa, are localized collections of lymphoid follicles, may be as large as 30 cm in diameter, and are most prominent in the ileum. The number of Peyer patches in the gut increases after birth [10]. The Peyer patch contains specialized epithelial cells, known as M cells, that overlie the lymphoid cells and allow luminal antigens to enter the mucosa [13,14]. The dome area of the Peyer patch lies above the lymph follicles and just below the M cells and contains lymphocytes, macrophages, and an extensive dendritic cell network [15]. The follicular or central region contains large numbers of precursor B cells that undergo active cell division. The interfollicular zone is populated predominantly by T cells. Peyer patches are involved in the induction of mucosal immune responses.

Other cellular components of the lamina propria include fibroblasts and smooth muscle cells. Arterioles, venules, and a central lacteal function to deliver nutrients into the vascular system (see Fig. 46.5).

Epithelium

The villi and crypts contain a complex, rapidly proliferating, and perpetually differentiating epithelium, a continuous sheet of simple columnar cells that rests on a filamentous basal lamina or basement membrane (see Figs 46.3 and 46.4). It constitutes the major barrier between the intestinal lumen and the lamina propria and regulates flux between these two compartments. The villus enterocytes vectorially transport the products of digestion into the lamina propria, where they enter the venous capillaries or lymphatic system and are transported to other areas of the body. Tight junctions (zonula occludens) bind adjacent epithelial cells tightly together near their apices to restrict flux between adjoining cells (the paracellular route) to small ions, small molecules, and water [16].

The crypt and villus form the basic structural and functional unit of the small bowel (Fig. 46.6; see also Figs 46.3 and 46.4). Anchored stem cells located in the crypts of Lieberkühn are the source of the four major terminally differentiated cell

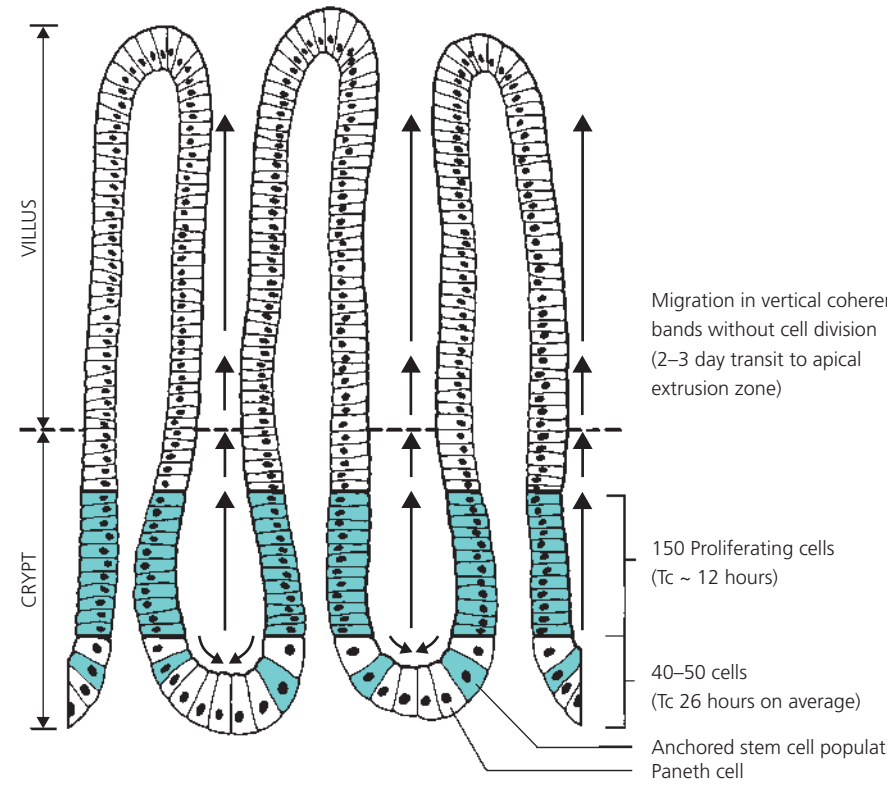

Figure 46.6 (a) Organization of the crypt–villus axis in the small intestine. The small intestinal crypt contains approximately 250 cells. The intestinal stem cell is located in the crypt base, although the precise position and identification is still controversial. The undifferentiated cells divide asymmetrically to give rise to proliferating progenitor cells that migrate up toward the villus and differentiate into enterocytes, goblet cells, and enteroendocrine cells, or migrate downward to the crypt base and differentiate into Paneth cells. Pericryptal myofibroblasts and other mesenchymal cells "condition" the crypt epithelium.

types: absorptive enterocyte, mucus-secreting goblet cell, enteroendocrine cell, and Paneth cell [17,18]. The stem cells reside in a niche composed of pericryptal fibroblasts and other mesenchymal cells [18]. Other epithelial cell types include the tuft cell (or caveolated cell), a rare constituent of the villus [19], and the M cell, a specialized epithelial cell that overlies the Peyer patch (see above). Cellular differentiation proceeds during a bidirectional migration process (see Fig. 46.6) [20]. The gut epithelial stem cells are believed to reside in the lower crypt region, approximately four to five cell positions above the crypt base [17,18,20–22]. They give rise to proliferating progenitor or transit amplifying cells, which differentiate as they migrate up the crypt onto the villus to become enterocytes, goblet cells, and enteroendocrine cells. In contrast, the Paneth cells arise as their progenitors journey to the crypt base [17,21]. Several crypts contribute cells to a single villus. The number of crypts supplying each villus varies from the duodenum to the ileum. Epithelial cell migration and differentiation occur continuously, and the process of cellular renewal and migration to the villus tip takes approximately 5 days in humans. Apoptotic cell death occurs spontaneously near the stem cell region in the crypts, presumably to regulate stem cell numbers. Effete cells are removed from the villus tip by a process known as *anoikis,* in which altered cellular adhesion results in apoptosis [22].

Cellular and topographic organization of the crypt

The present model of the organization of the crypt and its cellular kinetics is derived primarily from studies in the mouse. Crypts arise from one or perhaps a few intestinal stem cells [17]. It is postulated that between four and six stem cells are present per crypt [18,19,21–24]. The number of active stem cells in any one particular crypt is unknown [20]. In the adult gut, these cells are monoclonal [25]. The small intestinal epithelial stem cell presumably undergoes a process of asymmetric division to give rise to actively proliferating progenitor cells while the stem cell is maintained [22]. Proliferating progenitor cells or transit cells are located in the mid-crypt region, above the presumptive stem cell region. The stem cell is regulated by WNT and WNT ligands. In addition, bone morphogenetic proteins and noggin cross-talk to the WNT–β-catenin pathway through PTEN–phosphoinositide (PI) 3-kinase and regulate the production of transit-amplifying (proliferative) cells [17,26] (Fig. 46.6). The sources of these signaling molecules include crypt epithelial cells, myofibroblasts and other mesenchymal cells [17]. In mouse gut, these cells enter the cell cycle every 12 hours [27]. The progenitor cells subsequently differentiate into the four major cell types.

Undifferentiated crypt cells

Undifferentiated crypt cells have many ribosomes and polysomes but scant endoplasmic reticulum, mitochondria, and microvilli, and undeveloped terminal webs. They are basophilic because they contain large amounts of cytoplasmic RNA. Secretory granules are found near the apical surface (see Fig. 46.4b); their nature is unknown, but they stain with the periodic acid–Schiff (PAS) reaction and are not lysosomes. Undifferentiated crypt cells also synthesize secretory component (the receptor for IgA), contain chloride channels, and can secrete chloride in response to cholera toxin or other enterotoxins [28].

Absorptive enterocytes

Cellular differentiation commences during migration to the upper crypt and villus base. The production of a differentiated epithelium is regulated by Delta–Notch signaling pathways. The transcription factors Hes1 and Math1 are required for the normal production of the columnar (e.g. enterocytic) as opposed to the secretory (goblet, Paneth, and enteroendocrine) cell types [29,30]. The cells that are fated to become the absorptive enterocytes begin to express a variety of specific gene products that enable the cells to digest and absorb many different nutrients as they reach the crypt–villus junction. These include brush-border enzymes (disaccharidases, peptidases, and alkaline phosphatase); proteins involved in lipid absorption (apolipoproteins and fatty acid-binding proteins); and many receptors, carriers, and transporters [31]. Immunohistochemical and in situ hybridization analyses indicate that most major enterocyte gene products, such as disaccharidases, apolipoproteins, fatty acid-binding proteins, and the sodium-dependent glucose transporter, are expressed as cells emerge above the crypt–villus junction [32,33], but are not found in the crypts. This precise vertical differentiation continues as cells migrate up the villus. Microvilli become more prominent, and the capacity of the cell to absorb lipids, sugars, and amino acids increases.

Despite rapid cellular renewal, complex spatial differentiation in the gut is maintained from duodenum to colon. Many enterocyte genes are abundantly expressed in the proximal small bowel, but their expression decreases markedly in the distal gut [32,34–36], whereas other genes are specifically expressed in the ileum. Cloning, sequencing, and promoter analysis of these genes have provided insight into the molecular mechanisms underlying the regulation of regional differentiation in the gut [36–40]. Transgenic mouse and cell culture transfection techniques have been used to map out regulatory promoter elements [24,39–40]. In addition, transgenic mice and mice in which embryonic stem cell mutations have been created to delete specific gene products ("knockout" or null mice) have been used to determine the function of these novel regulatory genes, including the homeobox-containing Cdx family [41].

Ultrastructural features

As undifferentiated crypt cells travel up the villus, they acquire longer, more numerous microvilli, measuring 0.1 μm in width and about 1 μm in height, which produce a prominent striated (brush) border under light microscopy. The

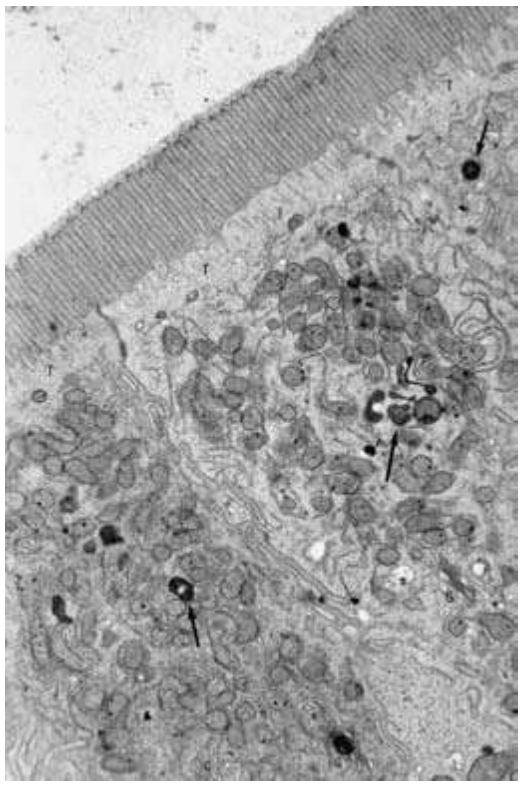

Figure 46.7 An electron microscopic picture of the apical halves of differentiated villus epithelial cells. Note the numerous tall microvilli covered with "fuzz," or glycocalyx, and an organelle-free apical zone, the terminal web (T), just below the microvilli. There are abundant mitochondria and profiles of rough endoplasmic reticulum. The irregularly shaped dense bodies (arrows) are lysosome derivatives. Supranuclear Golgi profiles are denoted by G. The intercellular space is obliterated between the apices of adjoining cells just below the level of the microvilli by the tight junction (zonula occludens), an apparent fusion of adjoining cell membranes (best seen between the two cells on the left). Transport of substances from the lumen between cells (paracellular route) is restricted to water and small molecules and ions. Most products of digestion enter the cell by crossing the microvillar membrane. Original magnification × 15 000. From Rubin W. The epithelial "membrane" of the small intestine. Am J Clin Nutr 1971;24:45.

development of these long microvilli – finger-like extensions of the apical cell membrane – markedly increases the absorptive surface of the small intestine (Fig. 46.7). The basolateral membrane is relatively smooth in comparison. These cells also develop a terminal web, an apical zone below the microvilli that contains many filaments and some vesicles. As cells migrate up the villus, they acquire more mitochondria and rough endoplasmic reticulum, lose their secretory granules, and acquire large, apical dense bodies, which represent lysosomal derivatives (Figs 46.4d and 46.7). Deep apical tubules, visualized by ruthenium red staining, are situated between microvilli and represent areas of the apical cell surface that function in endocytotic or exocytotic membrane trafficking [42]. The functional polarity of the enterocyte, with its specific apical and basolateral membrane domains, is strictly maintained, thereby ensuring the vectorial transport of a variety of nutrients and ions from the apical to the basolateral surfaces of these cells.

Filaments composed of actin extend from a dense plaque just beneath the cell membrane at the tip of the microvillus down the core of the microvillus into the terminal web [43–45]. The terminal web is a dense meshwork of filaments that contain actin, myosin, and other cytoskeletal proteins. The meshwork is oriented parallel to the surface and perpendicular to the microvillus filaments, and is attached to the lateral cell membrane at the intermediate junction (zonula adherens) [45]. The numerous filaments in the microvilli and terminal web, known as the *cytoskeleton of the brush border*, probably confer a structural rigidity to the apices of the differentiated villus cells and may provide for the movement of the microvilli [43,45,46]. This cytoskeleton probably also affects the uptake of certain nutrients and paracellular permeability [47].

Short, thin, filamentous material extends from the outer leaflet of the cell membrane covering the microvilli into the intestinal lumen, producing a surface coat, the glycocalyx (or "fuzz"). The glycocalyx represents external extensions of proteins and glycoproteins in the microvillus membrane [48]. The microvillus membrane of the differentiated villus cells contains many of the enzymes, receptors, and carriers necessary for terminal digestion and absorption, such as the disaccharidases, alkaline phosphatase, peptidases, the ileal cobalamin–intrinsic factor receptor, the bile acid receptor, and the Na^+-dependent glucose and amino acid transporters [48,49]. The hydrolytic enzymes, which are the most abundant of the microvillar membrane proteins, are localized in lipid rafts [50]. These rafts are made of glycolipids and the lectin, galectin 4, and may also represent a portal of entry for pathogens. The active portions of many of these enzymes are associated with the glycocalyx. The components of the microvillus membrane and glycocalyx turn over and are replenished by continuous synthesis, being transported from the rough endoplasmic reticulum through the Golgi apparatus to the microvillus membrane [48,51,52].

The selective vesicular transport of microvillus constituents from the Golgi apparatus to the cell apex is dependent on microtubules. Disruption of microtubules with colchicine or vinblastine results in more random routing of these components, with the incorporation of microvillus enzymes into the basolateral surface and even the formation of basolateral microvilli [51]. Some of the microvillus enzymes are finally processed in the glycocalyx by the proteolytic activity of pancreatic enzymes, especially elastase, that are adherent to the glycocalyx [48].

Paneth cells

Paneth cells are pyramid-shaped cells in the crypt base that contain large, apical eosinophilic secretory granules. They

are much longer-lived than enterocytes, with a half-life of approximately 20 days in the mouse [21]. There are approximately 5–12 Paneth cells per crypt. A role in innate immunity, host defense, and regulation of microbial density [53] is suggested by their abundant expression of lysozyme, cryptdins (see below) [54], and other antibiotic proteins, and their ability to degranulate in response to live and heat-killed bacteria [53]. Several of the defensins, a family of small peptides that are abundant in human neutrophils, are highly expressed in Paneth cells [54]. These peptides, 3–4 kDa in size, are also known as *cryptdins* (for *crypt defensins*) [54], and exhibit microbicidal activity toward many different bacterial microorganisms in vitro. Two enteric α-defensins have been identified in humans [53]. Messenger RNAs encoding tumor necrosis factor (TNF) and α_1-antitrypsin [55] have been located in human Paneth cells. In addition, Nod2 is expressed in Paneth cells, and defective Nod2 function has been implicated in the pathogenesis of Crohn's disease [56,57]. Paneth cells release defensins in response to bacteria, but not to fungi or protozoa, and the defensins have potent microbicidal activity [58]. Overexpression of human α-defensin 5 (HD-5) in the Paneth cells of transgenic mice resulted in resistance to oral *Salmonella* infection [59].

Enteroendocrine cells

The intestine contains a complex enteroendocrine cell population composed of a variety of paracrine or endocrine cell types. These cells were first characterized as argentaffin or argyrophil cells, depending on their reaction to silver staining in the presence or absence of a reducing agent. Subsequently, electron microscopy led to their classification by the appearance of granules. These cells are generally classified by immunohistochemistry, based on their primary neuroendocrine product. For example, the D cell produces somatostatin, the L cell produces glucagon-like immunoreactivity (including glicentin, glucagon-like peptide 1 [GLP-1] and GLP-2), and the enterochromaffin cell makes serotonin. A subset of enteroendocrine cells express more than one peptide or amine.

Enteroendocrine cells have two different secretory pathways, characterized by the presence of classic large, dense core vesicles, as well as a second vesicle that is smaller and synaptic-like [60]. At least 10 different enteroendocrine cell types have been identified in the small intestine. This cellular population exhibits a specific spatial distribution along the crypt-to-villus and duodenal-to-colonic axes of the gut. For example, serotonin cells are abundant throughout the gastrointestinal tract, whereas secretin and cholecystokinin cells are much more localized to the duodenum and proximal jejunum [61]. In the mouse, secretin cells are predominantly located on the villi, whereas substance P-containing cells are found primarily in the crypts. Enteroendocrine cells may also simultaneously express more than one neuroendocrine product [61,62]; this coexpression is developmentally regulated in the rodent [63].

Although early data suggested that enteroendocrine cells were derived from the neural crest, later studies indicated that they arise from the undifferentiated crypt stem cell [21,22,24]. This differentiation is hard-wired in the absence of luminal contents, including pancreaticobiliary secretions and dietary factors [62,64]. Early cell fate decisions are regulated by Notch signaling [65,66]. Inactivation of Hes1, a downstream target of Notch, results in increased enteroendocrine cell numbers. Math1 expression determines a secretory cell fate, and neurogenin 3 specifies the enteroendocrine cell lineage. The genes that regulate the appearance of each enteroendocrine cell type are still being elucidated [66]. Targeted ablation of secretin cells in transgenic mice markedly decreased the numbers of L cells as well as secretin cells, also suggesting a common developmental relationship [67].

Some of the secretory products of these cells act in a paracrine manner and function locally, whereas others are true endocrine products. The peptides and amines affect bowel motility, intestinal cellular secretion (see Chapter 4), and epithelial cell proliferation (e.g., glucagon-like peptide 2, a product of the intestinal L cell) [68]. In contrast to exocrine cells, which secrete apically into the lumen of an organ or the duct of a gland, endocrine cells are morphologically oriented toward the basement membrane. They exhibit an appreciable basal surface, and they narrow superiorly so that only narrow bands of apical cytoplasm reach the lumen. Their secretory granules are located predominantly in the basal cytoplasm below the nucleus, ready to be secreted by exocytosis through the basal membrane into the lamina propria (see Fig. 46.4c).

Goblet cells

The mucus-secreting goblet cells are present throughout the entire gastrointestinal tract but are more numerous in the ileum than the jejunum. These cells have the shape of a brandy goblet and apically located granules filled with mucin. Mucin is their primary secretory product and it presumably serves a cytoprotective and lubricant function in the gastrointestinal tract [69,70]. Biochemical differences among mucins are expressed in the stomach, small intestine, and colon, suggesting heterogeneity among goblet cell populations. The expression of specific mucins is also developmentally regulated. Intestinal trefoil factor, one of a family of small peptides that includes pS2 and human spasmolysin, is abundantly expressed in goblet cells of the small intestine and colon [71]. Intestinal trefoil factor mRNA is expressed in the crypt cells and may therefore be a marker of early goblet cell differentiation. Embryonic stem cell gene ablation experiments demonstrate a cytoprotective role for intestinal trefoil factor in the gut [72]. Goblet cells arise from the same committed stem cells as do the other principal cell types. Production of a secretory cell type (including goblet, Paneth, and enteroendocrine cells) depends on Math1 expression [30]. However, actively proliferating goblet cells have been

noted in the crypt; these cells may also contribute to the villus-associated goblet cell population.

M cells

The specialized epithelial membranous cells, or M cells, are found in the epithelium overlying Peyer patches, known as the *follicle-associated epithelium*, and may occasionally be found on the villi [14]. Unlike other absorptive cells, they lack a typical brush border, demonstrating fewer, shorter microvilli and numerous apical endocytic vesicles. Also, their cytoskeleton is less rigid and the cells can be deformed by migrating lymphocytes [11]. They serve as antigen-sampling cells and endocytose a variety of macromolecules [73], viruses, and bacteria from the lumen. These molecules are then rapidly transported across the epithelium and come into contact with immune cells, thereby initiating protective mucosal immune responses [13,74,75]. The invaginated basolateral membrane of the M cell forms an intraepithelial pocket and allows lymphocytes and macrophages to come into rapid contact with antigen [74]. The precise mechanisms involved in transepithelial transport of antigen across the M cell are still largely unknown [75]. The presumptive origin of this cell type is also the multipotent crypt stem cell [74]. M cells can be formed by culturing Peyer patch lymphocytes together with the intestinal Caco-2 cell line, or with native enterocytes [76,77]. Peyer patch development and maintenance of M cells requires B cells [78]. These and other data suggest that M-cell differentiation may be immunoregulated and that lymphoepithelial cross-talk may induce M-cell formation from follicle-associated epithelial cells. M cells have been proposed as a potential target for oral vaccines [13].

Tuft cells (caveolated cells)

Tuft, or caveolated, cells are found in the stomach, small and large bowel, pancreas, and gall bladder, as well as the respiratory tract [79]. These cells can be distinguished by unique expression patterns of villin, fimbrin, cytokeratin 18, tubulin, and ankyrin [80]. They have been postulated to act as chemoreceptors in the gut [81].

Embryology

A brief synopsis of the major events in midgut morphogenesis is presented as a basis for understanding the congenital anomalies discussed in subsequent sections of this chapter.

The primitive human gut forms when the dorsal part of the yolk sac is incorporated into the embryo at the fourth week of development, giving rise to the foregut, midgut, and hindgut [82]. The foregut is the progenitor of the esophagus, stomach, duodenum up to the biliary duct ampulla, pharynx, respiratory tract, liver, pancreas, and biliary tract. The midgut gives rise to the duodenum distal to the common bile duct, jejunum, ileum, cecum, appendix, ascending colon, and half to two-thirds of the transverse colon. The rest of the colon and the superior anal canal are derived from hindgut.

The gut endoderm is the precursor of the gastrointestinal tract epithelium. Its endothelium arises from the ectoderm of the stomodeum and proctodeum as well as the endoderm. The splanchnic mesenchyme supplies the muscular and connective tissue components of the gastrointestinal tract. The midgut first freely communicates with the yolk sac and then narrows to be connected by the omphalomesenteric or vitelline duct. The primitive gut forms a U-shaped loop; this grows so rapidly in comparison with the embryo that it herniates into the umbilical cord at the sixth week of gestation. The proximal limb of the loop elongates into multiple intestinal loops, whereas the distal limb simply develops into the cecal diverticulum. The first stage of rotation is 90° counterclockwise around the superior mesenteric artery axis. At 10 weeks, the intestines return into the abdominal cavity and rotate a further 180° counterclockwise in the second stage. Finally, the cecum and appendix descend from the right upper quadrant to the right lower quadrant, and the proximal part of the colon elongates to form the hepatic flexure and ascending colon (third stage of rotation). Fixation occurs as the ascending colonic mesentery fuses with the parietal peritoneum and becomes fixed retroperitoneally. The small bowel mesentery attains a broad-based attachment to the posterior abdominal wall, extending from the duodenal–jejunal junction to the ileocecal region. The end result of this process is a normal location of the small and large intestine (Fig. 46.1).

Congenital anomalies

Meckel diverticulum

Description and pathophysiology

During early gestation, the omphalomesenteric or vitelline duct connects the fetal yolk sac to the primitive gut. By 7–8 weeks of gestation, this duct is normally completely obliterated. A Meckel diverticulum, the most common congenital anomaly of the gastrointestinal tract, results when this structure fails to resorb completely. The duct remnant most commonly persists as a diverticular sac; alternatively, the diverticulum may be connected to the mesentery or umbilicus by a fibrous band (Fig. 46.8). Occasionally, only a thick connective tissue band remains, attaching the gut to the umbilicus. These bands may lead to volvulus or the strangulation of bowel loops. Rarely, a fistula remains patent from the ileum to the umbilicus, leading to persistent external drainage of ileal contents. Other, more unusual duct remnants include umbilical polyps and vitelline cysts.

Large autopsy series indicate a 2%–3% prevalence of Meckel diverticulum in the general population [83]. This anomaly is two to three times more common in males [84]. Meckel diverticula are true diverticula, containing all layers

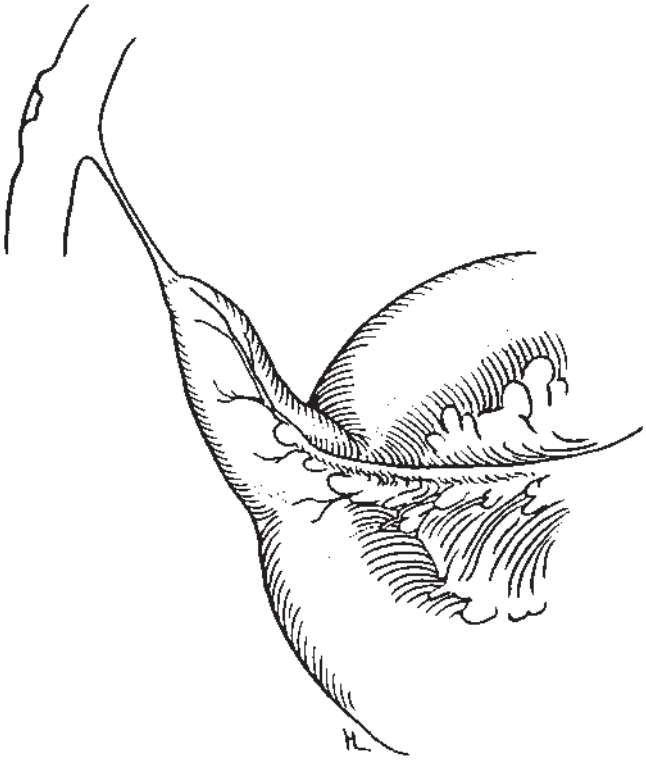

Figure 46.8 A Meckel diverticulum is attached to the umbilicus by the obliterated omphalomesenteric duct. A Meckel diverticulum may be unattached to the umbilicus or abdominal wall; alternatively, the vitelline duct may remain attached and patent, creating a fistula. Fibrous bands may predispose to volvulus and strangulation. From Johns TNP, Wheeler JR, Johns FS. Meckel's diverticulum and Meckel's diverticular disease: a study of 154 cases. Ann Surg 1959;150:241.

of the bowel from serosa to mucosa. Located on the antimesenteric border of the gut, they are most commonly found within 100 cm of the ileocecal valve but may also occur in other regions of the small bowel. Most diverticula are between 1 and 10 cm in size, although giant lesions may be as large as 100 cm in diameter. The two types of giant diverticula are: the type I lesions, which are long but of the same caliber as the ileum; and the less common type II, or ovoid, lesions [85]. Heterotopic tissue is present in approximately 50% of all diverticula [86]. Most commonly found are gastric mucosa, pancreatic tissue, or a combination of the two. Diverticula containing colonic mucosa, Brunner glands, or jejunal or hepatobiliary tissue have also been described. The presence of heterotopic mucosa correlates with an increased risk for symptomatic, complicated Meckel diverticulum. Heterotopic gastric mucosa may lead to diverticular gastrointestinal bleeding in adults and children when ileal ulceration results from acid secretion [87,88]; almost all bleeding diverticula contain gastric mucosa [89,90]. Although the data are conflicting, some studies have indicated that *Helicobacter pylori* may rarely colonize the diverticular gastric mucosa and is associated with gastritis in this site [91]. Heterotopic tissue is also associated with a modestly increased risk for other complications, including small bowel obstruction and diverticular inflammation [87].

The risk for complications dramatically decreases with age, and most adults with a Meckel diverticulum remain asymptomatic [92–94]. Patients with Meckel diverticulum have a lifetime risk of complications of ~ 6% [95]. Females are less likely than males to be symptomatic [93,94].

The complications of Meckel diverticulum include bleeding, intestinal obstruction, diverticulitis, perforation, and carcinoma. Obstruction is caused by intussusception of the diverticulum into adjacent bowel; volvulus around or herniation into a fibrous band; entrapment in inguinal, femoral, or umbilical hernia sacs (Littré hernia); or inflammation and scarring leading to blockage around the diverticular neck and adjacent ileum. The frequency of specific complications varies in adult compared with pediatric patients. The most common complications in children are gastrointestinal bleeding, most often occurring in infancy and early childhood (before 5 years of age) [89], and intestinal obstruction. In adults, intestinal obstruction is the most frequent complication. Although early studies indicated that gastrointestinal bleeding is relatively uncommon [87,88], subsequent series have indicated that bleeding from Meckel diverticulum is an important complication in adults [93]. Whereas adults most often describe melena, children usually present with painless, multiple, rapid, bright- or dark-red bowel movements. More unusual complications in adults include the development of carcinomas such as carcinoids, sarcomas, and rarely adenocarcinomas [96]. Carcinoid tumors are typically small, with biological characteristics resembling those of jejunoileal rather than appendiceal carcinoids (e.g., immunohistochemical staining and metastatic potential). Patients with carcinoid of a Meckel diverticulum are generally older (in their sixth decade) and frequently asymptomatic. Tumors larger than 5 mm in diameter have considerable metastatic potential [97]. Other complications include enteroliths, which may become lodged in the diverticulum and cause abdominal pain, vomiting, bleeding, and obstruction.

Diagnosis

The diagnosis of Meckel diverticulum remains a challenge [98,99]. Sodium pertechnetate (^{99m}Tc) radionuclide scanning is particularly useful in children. The ^{99m}Tc isotope is taken up by normal stomach tissue and by ectopic gastric mucosa in the Meckel diverticulum. Surface mucus cells from the intestine as well as the stomach accumulate and secrete this anion [100]. To enhance the sensitivity of this test, cimetidine may be administered to decrease anion secretion from the gastric mucosa [101]. Pentagastrin may also be useful, enhancing anion uptake by a poorly understood mechanism [102]. The major drawback of this detection method is that heterotopic gastric mucosa must be present in the diverticulum if a true positive result is to be obtained. In

children with lower gastrointestinal bleeding from a Meckel diverticulum, this test is sensitive and specific because almost all bleeding diverticula contain gastric mucosa, but in adults the false-positive and false-negative rates of the method are high, even in patients with bleeding [98,103]. Crohn's disease and other inflammatory disorders lead to false-positive scans. In children, a scan for Meckel diverticulum is often followed by a technetium or stannous pyrophosphate red blood cell scan to localize the site of bleeding definitively.

Small bowel follow-through is usually not useful because the diverticulum may not fill with barium and is also rapidly emptied. Enteroclysis examinations improve the sensitivity of barium studies because the contrast material under increased pressure better fills the diverticulum. Angiography can localize the source of hemorrhage and may also demonstrate the vitelline artery and its embryonic branches. This vessel arises from a distal branch of the superior mesenteric artery and ends in a characteristic blush of tortuous small vessels. Frequently, the vitelline artery involutes, and the diverticulum is directly supplied by branches from the superior mesenteric artery. Small bowel capsule endoscopy has been used successfully to detect Meckel diverticulum [104,105], and double-balloon enteroscopy may aid in the detection of obscure GI bleeding, including that resulting from Meckel diverticulum [106,107].

Management

The treatment of Meckel diverticulum complicated by bleeding, obstruction, or perforation is surgical. Diverticulectomy is performed, possibly with concurrent ileal resection if the adjacent small bowel is ulcerated, inflamed, or obstructed. These operations can be complicated, and postoperative morbidity occurs in up to 6% of all cases [87,95,108]. Laparoscopic removal has been reported [109–112]. The management of asymptomatic diverticula is controversial [99]. Because of the low risk for complications of Meckel diverticulum in adults, some authors do not recommend prophylactic removal [87,92,94,113]. However, others prefer to resect asymptomatic diverticula that are highly likely to cause complications, including: large (> 2 cm) diverticula; lesions associated with an omphalomesenteric band, which are at risk for volvulus and obstruction; lesions containing a palpable mass, which may represent tumor or ectopic mucosa; and lesions in younger male patients [90,93].

Duplications

Duplications of the gastrointestinal tract are rare congenital cystic anomalies attached to the intestinal mesenteric border (Fig. 46.9). Spherical or tubular, they are usually lined by gut mucosa, but like Meckel diverticula, they may contain heterotopic gastric mucosa or less commonly pancreatic, squamous, thyroid, or bronchial epithelium as well as lymphoid aggregates [114]. They share a blood supply with the associated native intestine and may also communicate lumen to lumen. Duplications may occur anywhere along the gastrointestinal tract from mouth to anus. Those of small bowel origin are most commonly found in the ileum [114]. The embryonic origin of gut duplications is unknown. Postulated mechanisms include aberrant recanalization of the gut lumen during morphogenesis, creating two attached yet distinct gut structures; abnormal notochord–midgut interactions; intrauterine ischemic events; and aborted (partial) twinning [115]. Intestinal atresia may be associated with duplications, supporting a possible vascular etiology. Duplications are also associated with genitourinary tract anomalies [116].

Figure 46.9 Tubular duplication of the terminal ileum in a 7-month-old boy. The duplication, lying on the mesenteric border of the bowel, was 29 cm long and communicated with the adjoining bowel near its distal end. The duplication, which is the smaller of the two cross-sections, was lined largely by gastric mucosa, and contained an ulcer near its point of communication with the bowel. Its wall contained an island of aberrant pancreas. From Arey JB, Valdes-Dapena M. Embryology and developmental disorders. In: Ming S, Goldman H (eds). Pathology of the gastrointestinal tract. Philadelphia: WB Saunders, 1992:113.

Signs, symptoms, and complications

In most patients, duplications are diagnosed in infancy or early childhood, but duplications are occasionally newly discovered in an adult. The frequency of symptoms varies inversely with age. Pediatric patients most commonly present with abdominal pain, obstructive symptoms (e.g., nausea, vomiting, pain), and hemorrhage [117]. Obstruction may result from a mass effect, from volvulus produced by a large lesion, or more rarely from inflammation of the duplication. Much less frequently, these lesions are asymptomatic and are discovered incidentally. In adults, the evaluation of relatively mild abdominal complaints by computed tomography (CT) or ultrasonography may lead to detection [118], and ultrasonography has been used for prenatal detection [119]. Intussusception may be precipitated if a duplicated gut acts as a lead point and invaginates into normal intestine. Gastrointestinal hemorrhage may result from ulceration of the duplicated or surrounding mucosa; these lesions frequently contain ectopic gastric mucosa that secretes acid and

causes ulceration. A rare complication in adults is the development of carcinoma in the duplication [120]. Carcinoid tumors, adenocarcinoma arising in ectopic gastric mucosa, and squamous cell carcinoma have all been reported.

Diagnosis

Small bowel duplications can be difficult to detect. Plain films may show a partially calcified wall of the duplication. Small bowel follow-through or enteroclysis barium examinations may reveal the duplication if it communicates with the gut lumen. Cysts that contain gastric mucosa may be detected by ^{99m}Tc abdominal scintigraphy [121], which specifically delineates gastric surface mucus cells (see "Meckel diverticulum" above). Ultrasonography (effective for prenatal diagnosis) or CT can provide clues to the diagnosis by revealing the presence of a cystic mass, and these tests are also valuable for detecting rare carcinomas, which appear as solid tissue within the cyst [120].

Management

Duplications are treated surgically. Lesions detected antenatally can be electively resected, because the majority are asymptomatic, at least for a few months after birth [122]. If small, the lesions are easily resected with the adjacent small bowel. If the duplicated bowel is extensive and resection would require the removal of too much normal bowel, the duplication is opened and the mucosa removed, with the serosa and muscular layers left intact. Alternatively, the common wall can be excised. It is important to remove all mucosa because residual ectopic gastric mucosa can lead to recurrent hemorrhage [115].

Intestinal atresia and stenosis

In intestinal atresia, the lumen of a segment of the gut is completely occluded. Stenosis is a narrowing of the gut lumen that leads to partial obstruction. Atresia is one of the most common causes of bowel obstruction in neonates [123]. Duodenal atresia and stenosis are frequently associated with Down syndrome, midgut malrotation, esophageal atresia, annular pancreas, imperforate anus, and intrauterine growth retardation (see Chapter 38) [124]. Jejunoileal atresia is much less frequently associated with other congenital anomalies. Atresias are most often single but may be multiple and are found from esophagus to rectum. The reported incidence of small bowel atresias varies but is approximately 1 in 3000 to 1 in 5000 live births [125,126]. Several types of small intestinal atresias have been described (Fig. 46.10) [127].

- Type I – a membranous septum or diaphragm of mucosa and submucosa obstructs the lumen, but the bowel wall and mesentery are intact.
- Type II – two blind bowel ends are connected by a fibrous cord, with intact mesentery in between.
- Type IIIa – two blind bowel ends are separated by a mesenteric gap.

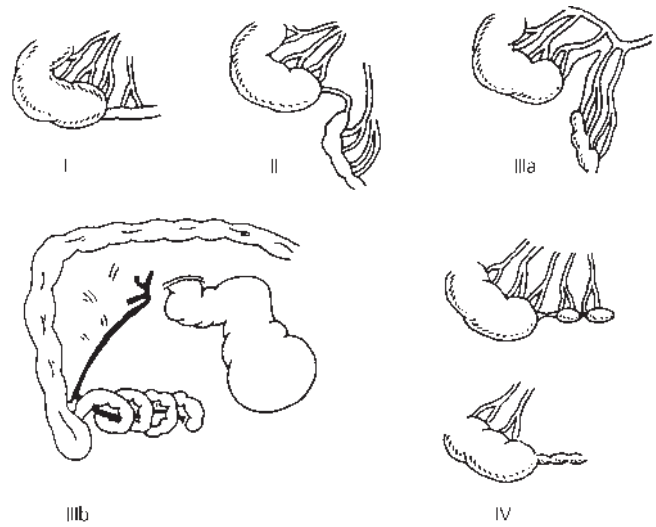

Figure 46.10 Classification of intestinal atresias. In type I, or membranous atresia, a membranous septum or diaphragm of mucosa and submucosa obstructs the lumen, but the bowel wall and mesentery are intact. In type II, two blind bowel ends are connected by a fibrous cord, with intact mesentery between them. In type IIIa, bowel lesions are separated by a mesenteric gap. Type IIIb is an "apple peel" atresia with features of proximal small bowel atresia, absence of the distal superior mesenteric artery, and coiled and foreshortened bowel. Type IV consists of multiple atresias of any type (I–IIIa). From Smith GH, Glasson M. Intestinal atresia: factors affecting survival. Aust N Z J Surg 1989;59:151.

- Type IIIb – "apple peel" atresia, characterized by proximal small bowel atresia and absence of the distal superior mesenteric artery (< 5% of all atresias) [128]. In this case, the bowel distal to the atresia is foreshortened and coiled and receives a retrograde blood supply from the ileocolic, right colic, or inferior mesenteric artery.
- Type IV – multiple atresias are present throughout the small bowel, creating the appearance of a "string of sausages;" they may be of type I, II, or IIIa.

Pathophysiology

The pathogenesis of atresia and stenosis is unknown. Duodenal atresia is thought to be caused by a failure of recanalization of the intestinal lumen after the solid cord stage, which takes place at 4–8 weeks of gestation [129]. Mutations in the α_6- and β_4-integrin genes have been reported in families affected by junctional epidermolysis bullosa and duodenal or pyloric atresia [130,131]. In mice, deletion of the fibroblast growth factor (FGF) 10 receptor, FGF2Rb, results in duodenal and colonic atresia, along with other defects such as pulmonary agenesis [132]. Ischemic intrauterine events such as midgut volvulus, arterial occlusion, intussusception, and localized volvulus secondary to meconium ileus or duplication have been implicated in the pathogenesis of small intestinal atresia, especially in single atresia and stenosis [133]. Atresia has been associated with intrauterine volvulus, gastroschisis,

cardiac and other anomalies [134], and cystic fibrosis [134,135]. A retrospective review showed a more than 200-fold increased risk for cystic fibrosis in Caucasian infants with jejunoileal atresia [136]. In a population-based study in Hawaii, small bowel atresia was associated with low birthweight, low gestational age, maternal age, and multiple births [126]. Meconium ileus is thought to predispose the bowel to ischemia or cause volvulus as a consequence of hyperperistalsis.

Pathological examination of atretic segments resected from neonates with multiple intestinal atresias suggests a role for either ischemia or a defect in recanalization of the gut lumen [137]. Rare familial cases of multiple intestinal atresias and apple peel (type IIIb) atresias have been reported [123,137–139]. An autosomal recessive inheritance pattern has been suggested [138], but variability in the types of atresia found within families and discordance in a set of monozygotic twins suggest a more complex genetic transmission [128]. Other factors implicated in the pathogenesis of atresia and stenosis are maternal ergotamine use, exposure to vasoconstrictive agents such as pseudoephedrine and amphetamine, combined with cigarette smoking [140], fetal exposure to methylene blue (which was formerly used as a marker during amniocentesis of twin pregnancies to ensure that both sacs had been sampled) [141], and toluidine blue [142]. Multiple intestinal atresias have also been reported to be associated with neonatal immunodeficiency states [143]. A new syndrome has been reported in which neonatal diabetes and hypoplastic pancreas were found in association with intestinal atresia and gallbladder hypoplasia [144].

Clinical presentation

Polyhydramnios is frequently detected in proximal gastrointestinal atresia, but the amniotic fluid may be normal in distal atresia [133]. Neonates most commonly present with signs and symptoms of obstruction within hours to 3 days after birth. Bilious vomiting early after birth is a characteristic symptom of proximal atresia, whereas abdominal distention (occasionally associated with visible bowel loops), later vomiting, and a failure to pass meconium are frequent presenting complaints of distal lesions. High atresias of the jejunum and duodenum are also associated with jaundice. The course of infants who have intestinal stenosis without atresia may be much more indolent because the obstruction is usually partial. The diagnosis may therefore be delayed.

Diagnosis

Polyhydramnios is an indication for ultrasonography, which may identify the obstructing defect [119]. Fetal echogenic bowel, enlarged stomach, and dilated loops of bowel are frequently detected [145]; the presence of fetal ascites and extralumenal calcifications may indicate aseptic perforation of the bowel, with meconium peritonitis. The intraluminal calcifications found in type IV atresias may also be seen. Ileal atresias are generally not associated with an enlarged stomach or polyhydramnios [145]. After birth, routine abdominal radiography may demonstrate multiple air–fluid levels throughout the small bowel or dilated bowel proximal to the obstruction with an absence of gas distally. A double-bubble sign on abdominal radiography or ultrasonography is classic for duodenal atresia. Barium enema shows an unused microcolon. The anatomical defect should always be definitively identified by plain films and cautious contrast radiography before surgical intervention is attempted. It is also important to identify all atretic sites, with the risk for multiple atresias kept in mind.

Important in the differential diagnosis of neonatal bowel obstruction are Hirschsprung disease, malrotation, meconium ileus associated with cystic fibrosis, duplications, Meckel diverticulum, and mesenteric bands [146]. Barium enema is recommended to rule out Hirschsprung disease and malrotation with volvulus, and to identify other atresias in the bowel distal to the primary obstruction.

Treatment and prognosis

Initial therapy consists of intravenous hydration, correction of electrolytes, and nasogastric suction to remove accumulated fluid and decompress the bowel. Surgical resection of atretic small intestine is the primary treatment, which may be challenging because bowel preservation is critical and dilation of the small bowel proximal to the obstruction makes anastomosis difficult. Several different surgical procedures have been developed, including tapering enteroplasty and the creation of an ileostomy [134]. Patients with type IIIb and type IV atresias often require extensive resective surgery, which results in short bowel syndrome and a poor prognosis. Patients with hereditary multiple intestinal atresias have particularly poor outcomes, because the extensive involvement with multiple atresias from antrum to rectum cannot be surgically corrected [139]. Small bowel transplantation in a patient with multiple intestinal atresias and immunodeficiency resulted in partial correction of immune defects, by recruitment of immune cells from the donor [147].

All patients after surgery are placed on total parenteral nutrition and monitored for a return of normal bowel function as the diet is slowly advanced. A central venous catheter should be placed early in the course of the disease. Intestinal atresia is a common prenatal cause of short bowel syndrome in children [148]. Patients with short bowel syndrome frequently require prolonged parenteral nutrition. The morbidity and mortality rates in infants have dramatically decreased since the 1950s. Postoperative survival is approximately 90%–95% [129,133]. Enhanced survival is a result of improved management of the nutritional and pulmonary status. However, overall survival has remained at approximately 84%–88% [137]. Factors adversely affecting the prognosis include the presence of other congenital anomalies

(especially cardiac), chronic pulmonary disease, or pulmonary aspiration [129,131]. Prolonged disturbance in motility is common postoperatively. The development and maturation of the enteric nervous system is impaired below the atretic segment [149].

Malrotation

Description and pathophysiology

Alterations in the normal rotation and fixation of the gut during embryogenesis result in a series of anomalies with various clinical manifestations. Malrotation or incomplete rotation is the most common disorder of rotation and fixation; it occurs when the normal 270° bowel rotation is not completed. As a result, the cecum may lie in the subpyloric region or may be in a subhepatic location. The small bowel is not attached by a broad mesentery but remains suspended from a narrow vascular pedicle. Peritoneal bands (Ladd bands) may pass from the cecum across the duodenum to the right upper quadrant or may attach to the duodenum. The two major complications of malrotation are volvulus, caused by free rotation of the midgut around the vascular pedicle, and duodenal obstruction secondary to the Ladd bands. In nonrotation, the embryonic midgut loop does not rotate and the caudal limb of the loop reenters the abdominal cavity first. Subsequently, the small intestine (jejunum and ileum) lies on the right side of the abdomen and the colon is entirely on the left. The cecum is usually located in the left iliac fossa. Frequently, the broad attachment of the small bowel mesentery does not develop, and the small bowel remains suspended by a narrow pedicle, at risk for volvulus [124,150]. In reversed rotation, clockwise instead of counterclockwise rotation of the gut leads to reentry of the colon into the abdomen first. The position of the colon is then posterior to the superior mesenteric artery and the duodenum. The placement of the duodenum is anterior to the superior mesenteric artery. The small bowel mesentery passes in front of the transverse colon, so that a mesenteric tunnel forms that causes colonic compression and obstruction. Finally, failure of the cecum to descend into its normal position in the right lower quadrant may lead to mobile cecum; the cecum remains in the right upper quadrant and is unfixed posteriorly, predisposed to cecal volvulus. The ileum may similarly be unfixed and susceptible to volvulus.

The incidence of malrotation is unknown; estimates range from 1 in 200 to 1 in 6000 live births [151].

Clinical manifestations

In approximately 50%–80% of cases of midgut malrotation, symptoms develop in infancy. Related concurrent anomalies are biliary atresia and congenital heart disease. Intestinal atresia and stenosis may result from malrotation, and omphalocele and diaphragmatic hernia may lead to malrotation secondary to abnormal placement of the bowel during rotation. In adults, malrotation is sometimes associated with absence of the superior mesenteric vein and extrahepatic biliary anomalies [152]. The most severe complications of malrotation are small bowel obstruction and volvulus, which cause recurrent bilious vomiting, passage of bloody stools or acute onset of constipation, and bowel loop distention. In patients with Ladd bands, symptoms of duodenal obstruction may develop. Patients from 1 month of age through adolescence may have symptoms that are more varied and indolent, including intermittent vomiting, failure to thrive, and recurrent abdominal pain [150]. Adults may be asymptomatic for many years [153] and then present with midgut volvulus causing abdominal pain, bloody stools, and distention [151]. Alternatively, in adult patients with a long history of recurrent abdominal pain with nausea and vomiting since childhood, the obstruction or volvulus may never have been diagnosed because it was transient and resolved before presentation [152].

Diagnosis

The diagnosis may be challenging in the older child and adult [154,155]. Plain films may reveal evidence of duodenal or small bowel obstruction. A classic double-bubble sign may be seen, indicating duodenal obstruction. However, early in the course of midgut volvulus, plain radiographs may be unrevealing, and children with bilious vomiting should undergo a contrast study to rule out volvulus [156]. Contrast radiographic studies may demonstrate anomalous small bowel, ligament of Treitz, and cecal locations. In adults with midgut volvulus, upper gastrointestinal contrast series may reveal a dilated stomach and duodenum with a typical "corkscrew" appearance of the barium in the twisted duodenum and proximal jejunum [157]. Barium enema may reveal malposition of the right colon and cecum [151,155], and CT may show reversed positions of the superior mesenteric artery and vein.

Treatment

The surgical correction of malrotation (incomplete rotation) in symptomatic patients includes relieving the obstruction caused by Ladd peritoneal bands, freeing the duodenum, reducing midgut volvulus, and broadening the mesentery to prevent recurrent rotation of the bowel around a narrow mesentery [151]. In the Ladd procedure, the bowel is placed in the position of nonrotation (small bowel on the right side of the abdomen and colon on the left). Appendectomy is performed because the cecum is incorrectly located. Variations of this operation are used to correct nonrotation and the rare reversed rotation.

In most patients, bowel function returns to normal. However, some children with recurrent and prolonged symptoms of nausea, vomiting, and pain preoperatively do not fare so well postoperatively, possibly because of persistent dysmotility syndromes associated with malrotation or damage to the small bowel resulting from long-standing, indolent obstruction [149].

Gastroschisis and omphalocele

Description and embryonic origin

Although gastroschisis and omphalocele both result from abdominal wall defects, these rare disorders are distinct entities (see Chapter 121). The incidence of gastroschisis is between 0.4 and 4 per 10 000 live births, and omphalocele is 1.5–3 per 10 000 births [158,159].

In omphalocele, the abdominal viscera herniate through the umbilical ring and persist outside the body, covered by a membranous sac but not by skin. In gastroschisis, massive evisceration of the intestines occurs through a small defect in the abdominal wall, usually to the right of the closed umbilical ring. The bowel has no membranous covering, has been exposed to amniotic fluid in utero, and is often matted, thickened, foreshortened, and covered with adhesions. It has been hypothesized that omphalocele is caused by a failure of embryonic folding at the level of the lateral folds or persistence of the body stalk [158,160]. Gastroschisis may be caused by vascular disruption in utero, leading to failure of differentiation of the somatopleural mesenchyme, or later between the time of herniation into the umbilical cord and fixation, or by disruption of the right omphalomesenteric artery. The defect is thought to occur between the fifth and tenth weeks of gestation, but perinatal insults have also been suggested in patients in whom gastroschisis was not detected sonographically [161]. Potential teratogens include tobacco, alcohol, cocaine, and other drugs [159].

Other congenital anomalies that occur in association with omphalocele are chromosomal; about one-third of cases of omphalocele with multiple anomalies have trisomy 13, trisomy 18, or the Beckwith–Wiedemann syndrome, which is characterized by macroglossia, large infant size, visceromegaly, early hypoglycemia, and increased risk of Wilms and other tumors. Gastroschisis is associated with intestinal anomalies, including atresia and malrotation, vascular disruptions, and renal and gallbladder agenesis [158]. Several mouse models of gastroschisis have been described [162–166]. In mice that are null for the bone morphogenetic protein 1 (*Bmp1*) gene, the *Alx4* gene, or the aortic carboxypeptidase-like protein gene, gastroschisis develops with early mortality. The ALX4 protein is a homeodomain transcription factor. Both BMP1 and the aortic carboxypeptidase-like protein appear to have important functions in the extracellular matrix. The relevance of these gene defects to human disease is unclear; a mutational analysis of the *BMP1* gene in human patients with gastroschisis was unrevealing [167]. Mouse models of omphalocoele have also been described [162], in mouse knockouts of insulin-like growth factor 2 (IGF-2), calreticulin, and several transcription factors. The transforming growth factor-β (TGF-β) signaling pathway has been implicated as important in ventral body wall closure [162].

Prenatal diagnosis

Elevated levels of maternal serum α-fetoprotein are associated with ventral abdominal wall defects. Gastroschisis is detected with greater sensitivity than omphalocele [160]. Improvements in the accuracy of prenatal ultrasonography have led to more frequent detection [158,159,168]. One of the major advantages of prenatal diagnosis is that the obstetrician is alerted, so that at the time of delivery the mother can be taken to a tertiary care center where appropriate surgical and neonatal intensive care support is available [160]. The role of preterm delivery to minimize intestinal damage and prevent intrauterine death is still unclear, and the factors that determine the need for this intervention are still being defined [169,170]. Intensive monitoring with ultrasonography has been utilized to determine when preterm delivery may be indicated, and this strategy appears to improve survival [170–172]. Recommendations for the appropriate mode of delivery (e.g., trial of labor vs elective cesarean section) are being debated [172–176], although it is clear that the rate of abdominal delivery is high because of peripartum complications [177].

Treatment

Surgical closure of omphalocele and gastroschisis is attempted shortly after birth. Primary closure may be possible with the use of retention sutures and stretching the abdominal wall. If this cannot be achieved, a silo or Silastic sac can be used with successive compression to reduce the herniation further. The decision to use a silo and a staged procedure may be based on intraoperative bladder or intragastric pressure measurements that reflect the intraabdominal pressure [169,178]. Careful regulation of the intraabdominal pressure is critical for successful repair; high pressures that lead to respiratory distress and intestinal and renal ischemia – the major causes of morbidity and mortality – must be avoided. The material is placed over the herniated bowel or sac and reduced manually and serially sutured to reintroduce the bowel into the abdominal cavity. A comparison of primary emergent closure vs closure following reduction with a spring-loaded silo (for gastroschisis) suggested that silos improve the overall outcome [179]. Because almost all children have bowel hypomotility, total parenteral nutrition is recommended early in the course of the illness.

Advances in surgical correction have greatly improved the prognosis of patients with gastroschisis, despite the fact that the bowel is usually damaged and slow to return to normal function. Survival rates range from 70% to more than 90% [173,180]. The presence of necrotizing enterocolitis and other anomalies (affecting other organs) or associated intestinal conditions (e.g., atresias, perforations, necrotic segments, volvulus) affects mortality rates [173,181]. In the absence of severe associated anomalies, the immediate survival and long-term outcome of patients with omphalocele have also improved in the past several years [182,183]. Survival is also related to the severity of the associated anomalies and medical conditions [158].

Structural anomalies

Volvulus

A volvulus is an abnormal twisting of the intestine around the axis of its own mesentery, resulting in obstruction of the more proximal bowel. Twisting of the mesentery may involve the mesenteric vessels and so make the involved loop particularly susceptible to strangulation and gangrene, with resulting perforation, peritonitis, and sepsis. In contrast to colonic volvulus, particularly of the cecum and sigmoid colon, small bowel volvulus is relatively rare in the United States and most of Europe [184–188]. The estimated annual incidence in the United States is 1.7–5.7 cases per 100 000 [184,185]. Small bowel volvulus occurs more frequently in parts of Africa, the Middle East, and the Indian subcontinent [184–186]. In these countries, volvulus occurs in the absence of anatomical abnormalities and is probably related to dietary factors. It has been postulated that ingesting large amounts of bulky foods after fasting may predispose to torsion of the small bowel loops. In the United States, small bowel volvulus is usually caused by a preexisting defect, such as an anomaly of rotation and fixation, postoperative adhesion, or congenital bands [189]. Other causes include jejunal diverticula and stromal tumors. Small bowel volvulus is rare in adults [186].

Clinical presentation and diagnosis

Patients present with symptoms of small bowel obstruction and an acute abdomen. Abdominal pain, nausea, and vomiting are almost always present [184–186]; the severity of the pain may be out of proportion to the physical findings. Signs include abdominal distention, rebound, guarding and rigidity, and occasionally a palpable abdominal mass.

The imaging modality of choice is CT scan [185,186]. The "whirlpool" sign, which is a whirl-like rotation of the small bowel around the axis of the superior mesenteric artery, is a sensitive indicator of volvulus [185,186]. Plain abdominal radiographs taken in supine and upright positions may demonstrate distended bowel with air–fluid levels, consistent with obstruction. Perforation may be indicated by the presence of free air. Barium studies can be useful. A typical corkscrew-like appearance of the barium in the distorted duodenum and jejunum is diagnostic. Angiography may reveal twisting of the branches of the superior mesenteric artery.

Therapy and outcome

The treatment of small bowel volvulus is surgical. Ischemic or gangrenous loops of bowel should be resected, although derotation of the bowel may be sufficient therapy in itself. Vascular compromise of the small bowel with subsequent gangrene is common and leads to increased morbidity and mortality postoperatively. Rapid recognition of volvulus and prompt surgical intervention are the keys to decreasing the fatality rate associated with this condition.

Intussusception

Description and pathophysiology

Intussusception occurs when a segment of bowel invaginates, or telescopes, into adjacent distal bowel, leading to obstruction and possible ischemic injury. The incidence, causes, clinical presentation, and therapy of intestinal intussusception are different in adult patients compared with pediatric patients [190–192]. Intestinal intussusception is one of the most common causes of small bowel obstruction in children younger than 2 years of age, but it is an unusual cause of bowel obstruction in adults. Most pediatric cases occur in children younger than 5 years of age [193]. Pediatric intussusception is most often idiopathic but may be associated with a pathological lead point in 8%–12% of cases [194,195], including: Meckel diverticulum; a variety of benign and malignant tumors, such as polyps, leiomyomas, and lymphomas; duplications; and Henoch–Schönlein purpura, in which an intramural hematoma acts as a lead point. An association between rotavirus vaccination and intussusception has been described [196,197], perhaps secondary to a lead point of vaccine-induced lymphoid hyperplasia. In idiopathic intussusception, an association with prominent Peyer patches and enlarged mesenteric lymph nodes has been observed [190]. In children, ileocolic intussusceptions are most common, followed by ileoileocolic, cecocolic, and, much less frequently, ileoileal involvement.

Among adults in the Western world, small bowel intussusception is rare, accounting for approximately 5% of all cases of intestinal obstruction [198]. A causative factor can be identified in more than 90% of adult patients [191], whereas it cannot in children [190–192]. Small intestinal intussusception may be precipitated by tumors, including leiomyomas, neurofibromas, lipomas, lymphomas, small bowel adenomatous polyps, and metastatic tumors with or without peritoneal carcinomatosis. Other causes include Meckel diverticulum or other diverticular disease and celiac disease with chronically dilated flaccid bowel. Postoperative intussusception may result from adhesions, or intussusception may follow trauma [199]. Jejunogastric intussusception may occur after Billroth II surgery, and bypassed bowel may become intussuscepted after jejunoileal bypass. Patients with AIDS and Kaposi sarcoma or diffuse enteritis are also at risk [200]. Pregnancy and the use of long intestinal or cantor tubes are other predisposing factors.

Signs and symptoms

The typical pediatric patient is a well-nourished, previously healthy child between the ages of 5 months and 5 years. The peak presenting age is 3–11 months [201]. Classic signs and symptoms include the acute onset of intermittent abdominal pain, vomiting, and hematochezia. A palpable abdominal mass, diarrhea, and somnolence are other frequent findings [194,195]. In older children, these diagnostic signs and symptoms are often not present [193]. In adults, the clinical

picture may be confusing. Abdominal pain is almost always present [202,203] but is often low-grade and chronic; patients may present after several episodes have spontaneously resolved [198,204]. A partial or complete small bowel obstruction may be present, and an abdominal mass is often palpable. Nausea and vomiting are particularly associated with small bowel compared with large bowel intussusception. Weight loss may also occur in patients with chronic, indolent symptoms.

Diagnosis and therapy

Pediatric patients

In children, an air or water-soluble contrast barium enema is performed because the ileocecal region is so frequently involved [195]. Contrast enemas demonstrate the location of the intussusception and are often successful in reducing it. Air enemas are also safe and effective in reducing intussusceptions [156,205–207]. The enema is usually administered with a surgeon in attendance in case of perforation or failure to reduce. Sonography may be used to diagnose intussusception and to monitor reduction [207]. In extremely ill patients with peritonitis, perforation, or shock, enema reduction is contraindicated. Radiological reduction is successful in 50%–90% of cases [207]. If it is not, the patient is taken to laparotomy for manual reduction. Resection is performed if ischemia or gangrene of the bowel is present. A careful search is made for a possible pathological lead point.

Plain films may reveal a crescent of gas capping the intussusceptum, outlining its leading edge, or a target sign consisting of two concentric radiolucent curvilinear lines outlining the intussusception [208]. A gasless area may also be identified, corresponding with the soft tissue mass of the intussusception. Ultrasonography may show a classical target, or doughnut, sign, characterized by multiple concentric rings of sonolucency alternating with one or two echogenic foci. The edematous outer and inner walls of the intussusception create two hypoechoic areas ringing the hyperechoic lumenal mucosa [209]. Computed tomography may similarly be useful, but it is usually avoided in children. Upper gastrointestinal contrast series may show proximal intestinal dilation and a "bird's beak" at the site of obstruction but is contraindicated if perforation or peritonitis are suspected.

Adult patients

Intussusception is diagnosed and treated differently in adult patients because its location and causes are different from those in children [190–192]. Most intussusceptions in adults are in the small bowel, although they may also occur in the colon [210]. Therefore, a combination of plain film, upper gastrointestinal series, barium enema, and CT or ultrasonography is used in adult patients. Because of the often puzzling presentation of intussusception in this age group, CT is frequently performed [191,192]. A mass of alternating high and low attenuation may be seen as a target, sausage-shaped, or bilobed lesion [204]. Mesenteric fat appears as areas of low attenuation, whereas the bowel wall itself appears as an area of high attenuation. Thickened bowel loops and an intraluminal soft tissue mass may be seen. However, this technique is not sensitive enough to determine the nature of the pathological lead point.

Because a pathological lesion is found so frequently, treatment in adults consists of surgical intervention with bowel resection. Manual reduction alone may be pursued only if it is certain that no other lesions are present [196]. With present diagnostic techniques, however, it is unlikely that a tumor or another anatomical cause can be ruled out preoperatively. Therefore, manual reduction of intussusception in adults is usually not recommended because manipulation can lead to intralumenal or intravenous tumor seeding [202]. Colonic intussusception is never treated with manual reduction because of the extremely high likelihood of malignancy [204].

Lymphangiectasia

Description and pathophysiology

Intestinal lymphangiectasia is characterized by the obstruction of lymph drainage from the small intestine and the dilation of lacteals and other intestinal lymphatics, such as those in the serosa and mesentery, depending on the level of obstruction. As a result of obstruction and increased pressure in the intestinal lymphatics, the absorption of chylomicrons and fat-soluble vitamins such as vitamin D is impaired, the reentry of intestinal lymphocytes into the peripheral circulation is impeded, and excessive amounts of intestinal lymph "leak" into the intestinal lumen. Lymphenteric fistulae may form, and intestinal lymph containing chylomicrons, protein, and lymphocytes drains directly into the intestinal lumen. Chylomicrons are sequestered in the lamina propria as well as in the distended lymphatics. Blockage of serosal and mesenteric lymphatics may lead to chylous ascites, and blockage of the thoracic duct to chylous pleural effusions.

Intestinal lymphangiectasia may occur as a primary congenital disorder or may be secondary to a disease that blocks the intestinal lymph drainage at some level. Causes of secondary lymphangiectasia include extensive abdominal or retroperitoneal carcinoma or lymphoma, retroperitoneal fibrosis, chronic pancreatitis, mesenteric tuberculosis or sarcoidosis, Crohn's disease, Whipple disease, scleroderma, celiac disease [211], constrictive pericarditis, systemic lupus erythematosus [212], chronic congestive heart failure, and following the Fontan operation (right atrium to pulmonary artery anastomosis) [213,214]. Lymphangiectasia after the Fontan procedure can occur in up to 24% of patients [214] and is thought to be caused by increased systemic venous pressure resulting in increased lymph production and decreased drainage. However, focal involvement has been reported, detectable by radionuclide studies and amenable to surgical resection [214]. Congenital intestinal lymphangiectasia

(Milroy disease) results from a malformation of the lymphatics that often affects many areas of the body.

Clinical presentation

Patients present with varying degrees of steatorrhea and malabsorption, lymphocytopenia (especially of T lymphocytes), marked hypogammaglobulinemia with impaired cell-mediated immunity, and prominent manifestations of protein-losing enteropathy. They often have edema and low serum protein levels, the reduction in serum albumin usually being the most pronounced and the only one of clinical significance. Patients with congenital disease present at any time from birth to adulthood, often with asymmetric edema of an extremity caused by peripheral lymphatic obstruction. They may also present, as do the secondary cases, with more diffuse, symmetric edema, usually the result of marked hypoproteinemia. Despite lymphocytopenia and impaired delayed hypersensitivity reactions, opportunistic infections are not common. Gastrointestinal symptoms are usually not prominent, but some patients may have diarrhea, abdominal pain, distention, nausea and vomiting, and occasionally gastrointestinal bleeding.

Diagnosis

Protein-losing enteropathy should be suspected in any patient with unexplained hypoalbuminemia, and intestinal lymphangiectasia should be considered if lymphocytopenia and steatorrhea are also present. Asymmetric lymphedema, especially dating from infancy or childhood, should suggest congenital (Milroy) disease. A diagnosis of lymphangiectasia rests on peroral jejunal biopsy demonstrating dilated lymphatic lacteals. Several specimens may be required to demonstrate the diagnostic findings because the lesions are often patchy and localized [215]. Endoscopy may reveal dilated lacteals that appear as white opaque spots or white-tipped villi, and nodular lesions and xanthomatous plaques have also been noted [216,217]. These findings aid the endoscopist in selecting appropriate regions to sample. Other pathological findings include moderate villus blunting and mild to moderate inflammatory infiltration [215]. Other tests demonstrate protein-losing enteropathy by detecting excessive enteric loss of plasma proteins. The use of radiolabeled plasma proteins, such as ^{131}I-albumin and ^{51}Cr-albumin, has been generally replaced by the measurement of gastrointestinal clearance of α_1-antitrypsin. The use of ^{99m}Tc to detect the site of protein loss appears sensitive and specific [214]. Double-contrast radiographs of the small bowel may reveal folds thickened by intestinal edema, nodular protrusions, and an absence of mucosal ulceration [218]. If secondary lymphangiectasia is suspected, appropriate tests such as CT of the abdomen should be performed to diagnose the underlying disease. The degree of malabsorption and nutritional deficiency may be assessed by quantifying stool fat and by measuring prothrombin time (which is nonspecific) and serum levels of calcium and carotene. In congenital cases, if necessary, the malformed, hypoplastic lymphatics can be demonstrated by lymphangiography. Pleural effusions and ascitic fluid may be tapped for conventional diagnostic studies and examined for chylomicrons.

Therapy

The therapy for lymphangiectasia should be directed toward treating the pathophysiological consequences, and in the case of secondary lymphangiectasia, the underlying disease (e.g., lymphoma, tuberculosis, sarcoidosis, constrictive pericarditis) should be diagnosed and treated. Substituting medium-chain triglycerides for the usual long-chain triglycerides may reduce enteric protein loss, malabsorption, and diarrhea and may improve serum albumin levels [219,220]. Medium-chain fatty acids are more water-soluble and may be more readily absorbed through portal venous channels than through the lymphatics. The concomitant reduction in dietary long-chain fatty acids presumably reduces chylomicrons in obstructed lymphatics and thereby decreases the lymphatic pressure and rate of lymph loss. Anecdotal reports have demonstrated the efficacy of octreotide [221–224]. Peripheral edema can be minimized by postural drainage and the use of elastic stockings to reduce the risk for cellulitis and lymphangitis.

Celiac artery compression

The topic of celiac artery compression is covered in Chapter 131.
