C SMALL INTESTINE

47 Dysmotility of the small intestine and colon

Michael Camilleri, Lawrence Szarka

Epidemiology, 1108
Neural control of small intestinal and colonic motility, 1109
Ontogeny of the enteric nervous system, 1109
Chronic small intestinal pseudoobstruction, 1111
Colonic dysmotility (pseudoobstruction) and megacolon, 1137

The functions of intestinal and colonic smooth muscle are controlled mainly by the intrinsic and extrinsic nerves of the gastrointestinal tract and, to a lesser degree, by gastrointestinal hormones (see Chapter 11). Therefore, any abnormality of smooth muscle, intrinsic or extrinsic nerves, or gastrointestinal hormones can theoretically cause intestinal or colonic dysmotility. Abnormal circulating levels of gastrointestinal hormones have not been definitely shown to result in dysmotility; however, diarrhea in patients with carcinoid syndrome and in some with irritable bowel syndrome is associated with elevated circulating levels of serotonin, and acceleration of small bowel and proximal colonic transit in these patients may at least partly reflect abnormal motor function.

The human small bowel and colon display widely divergent patterns of absorption, motility, and transit. Propulsive, peristaltic motility can rapidly move contents over long distances of the small intestine, with efficiency approaching that of the esophagus. The small intestine functions to facilitate emptying from the stomach, the mixing of chyme with digestive enzymes and bile, and ultimately delivery of residue to the colon. The ileum possesses a specialized type of contraction (giant migrating contraction) that sweeps unabsorbed residue to the colon and is analogous to the high-amplitude colonic contractions. Intermittent emptying ensures that enough time is available for salvage of the remaining nutrients in the small intestine. The small intestine and colon also set up feedback inhibitory reflexes (e.g., ileal brake) that retard proximal motor functions such as gastric emptying.

The fundamental motor programs of the colon, in contrast to those in other regions of the gut, are under strong inhibitory influences, slowing colonic transit for fecal contents to solidify. The well-developed muscular wall of the colon exhibits basal tone, but at the same time, it has a pronounced propensity to relax [1]. As the organ responsible for the final stages of absorption and elimination, the colon is highly relevant to diarrhea and constipation. Colonic fermentation of dietary residues, mainly the "unavailable carbohydrates," generates hydrogen, carbon dioxide, short-chain fatty acids, and methane through the anaerobic action of bacterial enzymes [2]; distention of the abdomen and flatulence can follow. Finally, for imagined, cultural, and psychosocial reasons, many populations focus on their habits of elimination. Constipation is thus a major concern of many individuals, and disturbances of colonic motility figure prominently in the minds of patients and physicians.

Dysmotility of the small intestine and colon has a wide range of clinical manifestations, regardless of the underlying cause of the disorder. Patients at one end of the spectrum may be asymptomatic, whereas those at the other end may have chronic intestinal pseudoobstruction, a syndrome characterized by recurrent or chronic symptoms that suggest obstruction in the absence of structural occlusion of the lumen. Between the two extremes, patients may have dyspeptic symptoms, including intermittent postprandial epigastric or periumbilical abdominal pain, bloating, nausea, vomiting, and diarrhea.

In patients with small intestinal dysmotility, motor function in other parts of the gastrointestinal tract may also be abnormal. In this chapter, we focus our initial discussion on the small intestine; motility disorders of the colon are manifested predominantly as constipation and megacolon. Motility disorders of other parts of the gastrointestinal tract are discussed in other chapters (see Chapters 59, 65, and 86).

Epidemiology

The prevalence of small intestinal dysmotility varies according to the underlying disease, and it seems to be less frequent than esophageal, gastric, or colonic dysmotility. The lack of sensitive techniques to evaluate small intestinal motility has made it difficult to estimate its prevalence. Since the early 1970s, several hereditary diseases with small intestinal

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

dysmotility have been reported, including two groups of diseases associated with smooth muscle degeneration, termed *familial visceral myopathies* (FVMs) [3–29] and *childhood visceral myopathies* (CVMs) [30–56], and a group of diseases associated with myenteric plexus degeneration, termed *familial visceral neuropathies* (FVNs) [57–68]. Only a small number of families have been reported, mostly Caucasian and less often African American [9] and Latino [69]. These rare familial disorders are discussed in the first part of this chapter.

Hirschsprung disease, the prototypical congenital colonic dysmotility, affects 1 in 5000 newborns. In contrast, constipation affects about 12% to 15% of the population, with epidemiological data suggesting an equal split between functional constipation and evacuation disorders [70,71]. A telephone survey of approximately 10 000 adults assessed the prevalence of constipation (defined as an inability to have spontaneous complete bowel movements). Consistent with the results of prior studies, the overall prevalence was approximately 15%; however, only 2% of the respondents were classified as having constipation-predominant irritable bowel syndrome (IBS) [72]. In contrast to the results of prior studies, which suggested that constipation increases with advancing age, these data showed an inverse trend, with a slightly lower prevalence associated with increasing age [72]. Other studies of clinic patients have indicated an overlap in the diagnoses of constipation-predominant IBS and functional constipation despite the use of strict definitions [73,74].

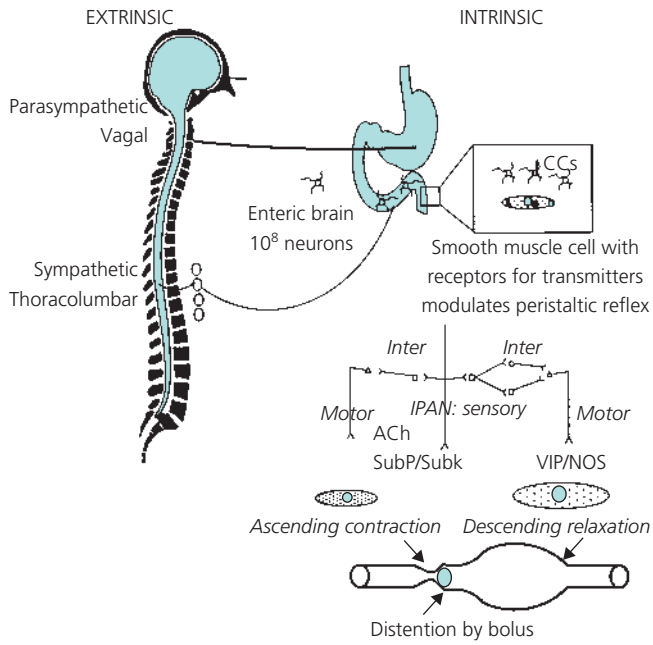

Figure 47.1 Extrinsic and enteric control of gut motility. The enteric nervous system controls stereotypical motor functions such as the migrating motor complex and the peristaltic reflex; enteric control is modulated by the extrinsic parasympathetic and sympathetic nerves, which respectively stimulate and inhibit nonsphincteric muscle. ICC, interstitial cells of Cajal; IPAN, intrinsic primary afferent neuron.

Neural control of small intestinal and colonic motility

The enteric nervous system (ENS) is a vast network of ganglionated plexuses located in the wall of the gastrointestinal tract [75,76]. Although several plexuses are identified anatomically, the most important, from a functional perspective, are the myenteric and submucosal plexuses. In association with the muscle layers, the networks of interstitial cells of Cajal are recognized as the likely pacemakers activating neuromuscular function. The ENS consists of approximately 100 million neurons in higher mammals, and this number is roughly equal to the number of neurons in the spinal cord (Fig. 47.1).

The ENS develops in utero as neural crest cells migrate to the developing alimentary canal. The migration of neural crest cells, and the sequence of innervation of different levels of the gut, are regulated by specific signaling molecules that include transcription factors (e.g., Mash-1), neurotrophic factors (e.g., the glial cell line-derived neurotrophic factor [GDNF] and its receptor subunits), and the neuregulin signaling system. These facilitate the growth, differentiation, and persistence of the migrating nerve cells once they arrive in the gut. Neuregulins are a large group of structurally related signaling proteins that are likely to have important roles in the development, maintenance, and repair of the nervous system and other selected tissues. Their receptors are the Erb-B protein tyrosine kinases, which are important in cell signaling.

Histological and electrophysiological studies [77–80] of the intestinal tract have characterized the properties of the neurons and transmitters mediating its functions, including the peristaltic reflex and the interactions between neurons and inflammatory cells [81].

Ontogeny of the enteric nervous system

Migration

The ENS cells are derived from precursor cells from three axial levels of the neural crest. These include the vagal [82], rostral–truncal [83], and lumbosacral [82,84]. levels. The enteric neurons arise mainly from the vagal neural crest of the developing hindbrain and colonize the gut by migrating in a rostrocaudal direction. Rarely, the migrating cells do not reach the entire gut; usually, the terminal portion of the bowel is affected, as in classic forms of Hirschsprung disease. Even more rarely, a zonal form of Hirschsprung disease may occur (Figs 47.2 and 47.3), which is postulated to result from the incomplete caudorostral migration of neuroblasts during embryonal development [85]. The neural crest cells that

migrate and colonize the gut become neuroblasts or neuronal support cells, glioblasts. However, *differentiation* into neurons and glial cells seems not to take place until they reach their final destinations in the gut. Movement through the gut mesenchyme, survival in the gut, and differentiation into mature cells are influenced by contacts of the precursor cells with the *microenvironment*.

The microenvironment consists of other cells in the mesenchyme, neural crest-derived cells, and the extracellular matrix. The extracellular matrix components provide direc-

tional signals to migrating neural crest cells and, together with neighboring cells, provide signals for neural crest cell differentiation. For example, the appearance of neural crest cells in the gut is preceded by the expression of extracellular matrix molecules [86], and other factors, such as GDNF, ensure the survival of committed neuroblasts [87].

Defects of the neural crest cells themselves or alterations of the microenvironment of the pathway through which the neural crest cells migrate may result in maldevelopment of the ENS. In humans, such disordered development results in congenital enteric neuromuscular diseases.

Differentiation of neurons

Migrating crest cells are multipotent [88]. The gut wall is itself a crucial site where terminal differentiation of the enteric neurons and glia occurs, and this determines what kind of nervous system arises within the bowel [89]. Combinations of enteric growth factors and their receptors influence differentiation. Combinations that enhance differentiation include the following: glial cell line-derived neurotrophic factor (GDNF)-tyrosine kinase RET (REarranged Transfection); neurotrophin 3–tyrosine kinase receptor C (NT-3–TRKC); and 5-hydroxytryptamine (5-HT, serotonin)–5-HT_{2B} receptor The RET protooncogene encodes a tyrosine kinase receptor necessary for the development of the ENS. A qualitatively different effect on nervous system development is shown by the peptide–receptor combination endothelin 3 (ET-3) and its receptor endothelin B (ET-B), which prevents the premature differentiation of enteric neurons before colonization of the gastrointestinal tract has been completed.

Several nerve growth factors are necessary, but each is insufficient individually to differentiate neurons. These include NT-3, GDNF, serotonin (5-HT), and endothelin. Enteric serotoninergic neurons appear so early that they coexist in primordial enteric ganglia with still-dividing neural precursors. Serotonin may be more than a neurotransmitter; the 5-HT_{2B} receptor in the fetal bowel is regulated and optimal at specific times, so that 5-HT strongly promotes the development of neurons at specific times and affects the development of late-arising enteric neurons [90].

These growth/differentiation factors affect virtually the entire bowel. The peptide endothelin 3 (ET3) and its receptor, ETB, play a crucial localized role in ENS development [91,92]. Examples of tyrosine kinase receptor mutations associated with specific genetic disorders, such as the multiple endocrine neoplasia (MEN) syndromes, are shown in Fig. 47.4.

Chronic small intestinal pseudoobstruction

For a review, the reader is directed to Di Lorenzo [93].

Table 47.1 Causes of small intestinal dysmotility

PRIMARY CAUSES

Familial types

Familial visceral myopathies: types I, II (MNGIE), III
Familial visceral neuropathies: types I, II
Childhood visceral myopathies: type I, type II (megacystis–microcolon–intestinal hypoperistalsis)

Nonfamilial or sporadic types

Visceral myopathies
Visceral neuropathies

SECONDARY CAUSES

Disease involving the intestinal smooth muscle

Collagen diseases (e.g., scleroderma, dermatomyositis, systemic lupus erythematosus, mixed connective tissue disease)
Muscular dystrophies (e.g., myotonic dystrophy, Duchenne muscular dystrophy)
Amyloidosis

Neurological diseases

Chagas disease, ganglioneuromatosis of the intestine, paraneoplastic neuropathy, Parkinson disease, spinal cord injury

Endocrine disorders

Diabetes mellitus, thyroid disease (i.e., hyperthyroidism, hypothyroidism), hypoparathyroidism

Pharmacological agents

Phenothiazines, tricyclic antidepressants, antiparkinsonian medications, ganglionic blockers, clonidine
Narcotics (morphine and meperidine)

Miscellaneous intestinal disorders

Celiac disease
Small intestinal diverticulosis
Radiation enteritis
Diffuse lymphoid infiltration of the small intestine
Jejunoileal bypass
After gastrointestinal viral infection

MNGIE, mitochondrial neurogastrointestinal encephalomyopathy.

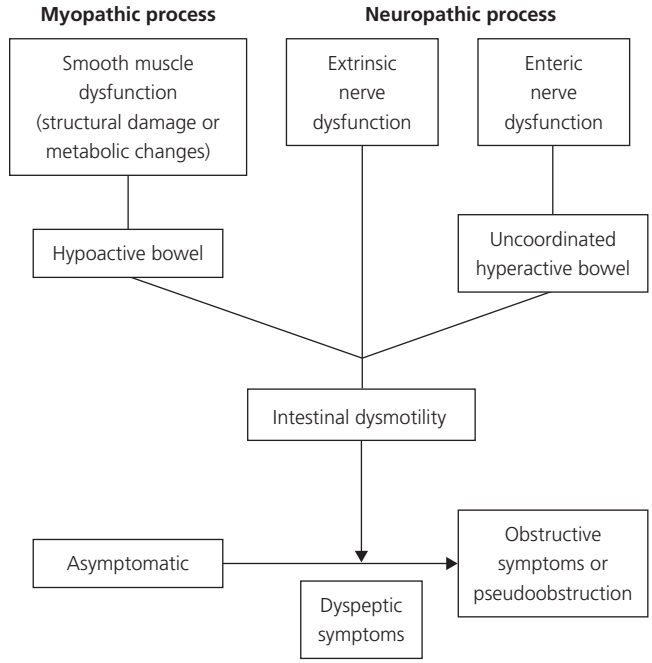

Figure 47.5 Mechanisms and manifestations of small intestinal dysmotility.

Etiology

Table 47.1 lists the causes of small intestinal dysmotility. The mechanisms and manifestations of small intestinal dysmotility are shown in Fig. 47.5. In general, small intestinal dysmotility may be secondary to neuropathy or myopathy. This is best distinguished by specialized histological and immunohistochemical study of the full thickness of the gastrointestinal wall, which is available at a few centers. Smooth muscle is best studied by sectioning across the muscle fibers and using trichrome stain [94]. The best way to evaluate the myenteric plexus is still evolving. Silver staining of sections of the gastrointestinal wall taken parallel to its long axis, described by Smith [95] and by Schuffler and Jonak [96], was state of the art but has been superseded by immunohistochemistry and confocal examination of neurons and a search for genetic markers (see below). Thus, a detailed description of phenotypes in familial cases is less pertinent than the more mechanistic or etiological descriptions that appear below.

Primary causes of small intestinal dysmotility

Primary dysmotilities are rare compared with secondary dysmotilities. They may be familial or sporadic.

Familial visceral myopathies (FVMs)

The FVMs are a group of genetic diseases characterized by the degeneration and fibrosis of smooth muscle of the gastrointestinal tract and, in one type, the urinary tract. At least three types of FVM have been reported, based on gross lesions of the gastrointestinal tract and the pattern of inheritance (Table 47.2), and, in type II FVM (also called *oculogastrointestinal neuropathy*), on documented mitochondrial DNA disorders. On routine pathology, the histological features of these three types of FVM do not differ [94]. The involved areas show a characteristic change, consisting of degenerating muscle cells and fibrosis, which may involve the full thickness of the muscularis propria but often is more prominent in or limited to the external layer (Fig. 47.6). Degenerating muscle cells appear pale, poorly defined, and fragmented. As residual thread-like remnants become surrounded by collagen, the longitudinal and circular muscles take on a vacuolated appearance that is easily recognized microscopically

Table 47.2 Classification of familial visceral myopathies

Characteristics	Type I [1–14]	Type II (MNGIE) [15–23]	Type III [24–27]
Mode of transmission	Autosomal dominant	Autosomal recessive; isolated cases	Autosomal recessive
Gross lesions	Esophageal dilation, megaduodenum, redundant colon, and megacystis	Gastric dilation, slight dilation of the entire small intestine with numerous diverticula	Marked dilation of the entire digestive tract from the esophagus to the rectum
Microscopic changes	Degeneration and fibrosis of both muscle layers	Same	Same
Clinical manifestations:			
Age at onset	After the first decade	Teens	Middle age
Percentage symptomatic	< 50%	> 75%	> 75%
Symptoms of chronic intestinal pseudoobstruction	Variable severity	Severe plus pain	Classic chronic intestinal pseudoobstruction
Extragastrointestinal manifestations	Megacystis, uterine inertia, and mydriasis	Ptosis and external ophthalmoplegia, muscle pain, peripheral neuropathy, and deafness	None observed
Treatment, prognosis	Prognosis good with or without surgery	No effective medical or surgical treatment; prognosis poor	Same as type II (MNGIE)

MNGIE, mitochondrial neurogastrointestinal encephalomyopathy.

(Fig. 47.7). Recognition of this change is greatly facilitated by the use of a trichrome stain; cytochemistry can also identify mitochondrial enzyme deficiencies in type II FVM, or mitochondrial neurogastrointestinal encephalomyopathy (MNGIE). Because several advances in our understanding of this condition have been made, a further detailed discussion of MNGIE is warranted.

Mitochondrial DNA and myopathies

Diverse myopathies are characterized by mitochondrial abnormalities in skeletal muscle or affected bowel, which show "ragged red fibers" on a Gomori trichrome stain. The metabolic abnormality also involves cells in other, non-muscle, tissues, including central and peripheral nervous system, gut, heart, kidney, liver, thyroid, pancreas, and bone marrow. The enzymes in the respiratory chain of mitochondria are encoded by nuclear and mitochondrial DNA. The disorders may be sporadic or inherited in an autosomal dominant, autosomal recessive, or X-linked pattern; maternal inheritance is more frequent.

Mitochondria are involved in the production of energy (ATP), the generation of reactive oxygen species, and the initiation of apoptosis through activation of the mitochondrial permeability transition pore [97]. Mitochondrial DNA consists of two to ten double strands of circular DNA in the mitochondrial matrix. At least 37 genes have been discovered, some of which encode the respiratory chain enzymes. The transcription of mitochondrial DNA is not closely related to the cell cycle, and mitochondrial DNA is more susceptible to mutation than is nuclear DNA.

Mitochondrial disorders manifest as organ disturbances that reflect the importance of mitochondria to normal function, as in skeletal muscle and the nervous system; similarly, metabolic disorders result from deranged cellular mitochondrial functions. The locations of selected mutations in the mitochondrial 16 569-base pair genome that result in pathological disorders and syndromes have been documented [97].

The mitochondrial disorder affecting the gut is MNGIE, also referred to as FVM type II, MEPOP (mitochondrial encephalomyopathy, polyneuropathy, ophthalmoplegia, and pseudoobstruction), and oculogastrointestinal muscular dystrophy. This is an autosomal recessive condition with gastrointestinal and hepatic manifestations that may present at any age, typically with hepatomegaly or hepatic failure in neonates, seizures or diarrhea in infants, and hepatic failure or chronic intestinal pseudoobstruction in children or adults.

MNGIE is characterized clinically by severe gastrointestinal dysmotility, external ophthalmoplegia, ptosis, peripheral neuropathy, and leukoencephalopathy. The small intestine is dilated, or multiple diverticula are present (Fig. 47.8), and the amplitude of contractions is typical of a myopathic disorder [98]. Some patients have a combination of intestinal dysmotility and the Kearns–Sayre syndrome, or transfer dysphagia secondary to abnormal coordination and propagation of the swallow through the pharynx and skeletal muscle portion of the esophagus. Clearly, this becomes even more devastating when the smooth muscle portion of the esophagus is affected by the associated MNGIE.

Apart from the obvious external ophthalmoplegia, these patients manifest skeletal muscle pain and cramps, and

systemic (lactic) acidosis. Circulating levels of muscle enzymes – creatine phosphokinase (CPK), aspartate aminotransferase (AST), alanine aminotransferases (ALT), aldolase, and others – are elevated, and muscle biopsy shows characteristic ragged red fibers on modified Gomori stain. This appearance results from the hypertrophy of mitochondria in the subsarcolemmal position in a few muscle fibers and the lack of mitochondria in other muscle fibers. Special stains for the respiratory muscle enzymes can identify the precise functional defect. For example, succinate dehydrogenase-positive fibers appear "ragged blue," and staining of the adjacent tissue section with cytochrome *c* oxidase demonstrates a deficiency of the latter enzyme and a gene defect in the control of the complex IV respiratory chain proteins (Fig. 47.9) [98]. In the intestine, hypertrophy of the circular muscle layer, atrophy of the longitudinal muscle, and megamitochondria in myenteric neurons and muscle cells are seen (Fig. 47.10) [99].

The screening tests for MNGIE are measurement of serum lactic acid, muscle enzymes, and thymidine phosphorylase

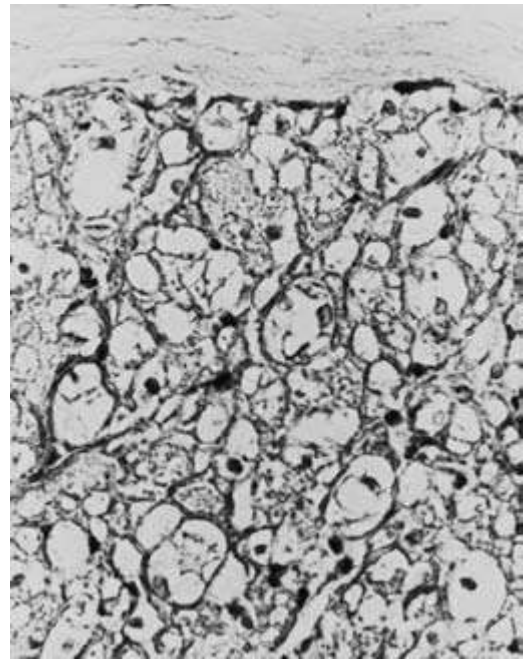

Figure 47.7 The characteristic vacuolar change, with collagen fibers encircling spaces filled by fragmented muscle cells, in a patient with familial visceral myopathy. (Trichrome stain; original magnification × 470.) From Mitros et al. [94], with permission from Elsevier.

Figure 47.8 Enteroclysis in a patient with type II familial visceral myopathy demonstrates numerous diverticula in the small intestine.

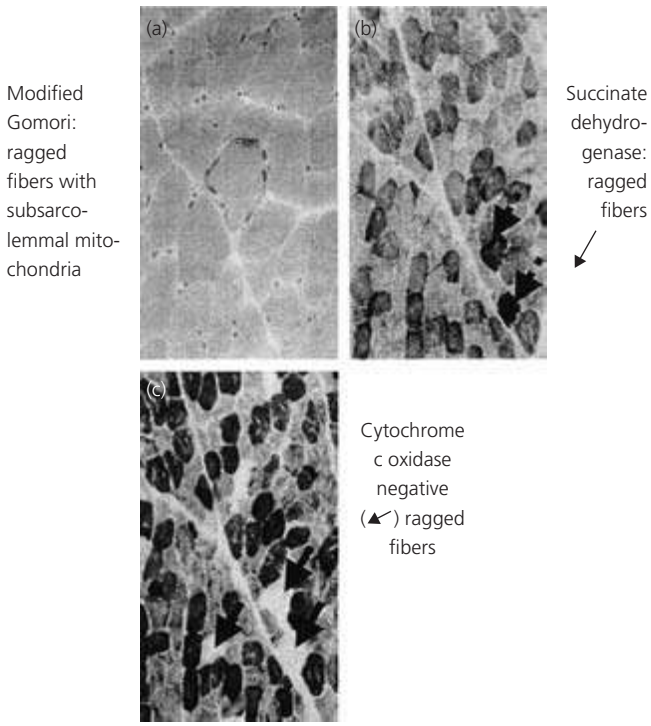

Figure 47.9 Histological and histochemical studies of a skeletal muscle biopsy specimen from a patient with mitochondrial myopathy; note the ragged red fibers, characterized by a subsarcolemmal location of giant mitochondria in a few fibers and a paucity of mitochondria in other fibers. On histochemical analysis, a few fibers are positive for succinate dehydrogenase (ragged blue appearance), but the same fibers do not express cytochrome c oxidase, suggesting a defect in the respiratory enzyme chain resulting in mitochondrial dysfunction and systemic acidosis. From Mueller et al. [98], with permission from Elsevier.

in circulating leukocytes [100]. The latter test is based on mutations identified in the gene for thymidine phosphorylase in 21 probands with MNGIE [100].

Familial visceral neuropathies (FVNs)

The FVNs are a group of genetic diseases characterized by degeneration of the myenteric plexus. At least two distinct phenotypes, I and II, have been identified, and these are summarized in Table 47.3. A number of syndromic congenital neuropathies are related to disturbances in the ontogeny of the neural crest and the ENS.

Congenital neuropathic motility disorders

These disorders can be broadly classified as follows [101]:

- *Disorders of colonization* by migrating neural crest-derived neurons, as in Hirschsprung disease, related to abnormalities in the RET gene and GDNF, or disorder of ET-3 and its receptor, ET-B.
- *Disorders of differentiation* of enteric nerves, as in intestinal ganglioneuromatosis, related to a specific germ-line point mutation in RET at codon 918 of exon 16 (M918T) or at codon 883 (A883F) in MEN type 2B syndrome.
- *Disorders of survival or maintenance of enteric nerves,* as in hypoganglionosis and possibly congenital achalasia, which can result from one of several mechanistic derangements between growth factors and their receptors: $GFR_{\alpha 2}$–neurturin, $GFR_{\alpha 3}$–artemin, TRKC–NT-3, and 5-HT_{2B}–5-HT.

Hirschsprung disease is a relatively common condition causing intestinal obstruction in neonates and megacolon in infants and adults; it is often associated with mutations in genes encoding GDNF or its receptor, RET [102,103], or in ET3 or its receptor, ETB [92,104] Mutations in RET and ETB (i.e., the receptors) are much more frequently encountered than mutations in the two ligands. At least two different mechanisms can cause the terminal colon to become aganglionic. In the first, there is a deficiency of GDNF–RET, which is not so severe as to cause the entire bowel to become aganglionic. In the second, characterized by a deficiency of ET3–ETB, crest-derived cells differentiate prematurely and precursors cease dividing and migrating before the gut has been entirely colonized, leaving the last segment uncolonized. The roles of endothelins and of gene mutation M918T in the maldevelopment of the ENS and in Hirschsprung disease are discussed later.

At least six separate genetic loci are involved in the control of four different intracellular mechanisms that result in models of congenital dysmotility and their phenotypic manifestations

Table 47.3 Classification of familial visceral neuropathies

Characteristics	Type I [55–57]	Type II [58–64]
Mode of transmission	Autosomal dominant	Autosomal recessive
Gross lesions	Dilation of lengths of small intestine, often distal small bowel; megacolon; gastroparesis in ~ 25% of patients	Hypertrophic pyloric stenosis; dilated, short small intestine; malrotation of small intestine
Microscopic changes	Degeneration of argyrophilic neurons and decreased numbers of nerve fibers	Deficiency of argyrophilic neurons and increased neuroblasts
Clinical manifestations:		
Age at onset	Any age	Infancy
Percentage symptomatic	> 75%	100%
Symptoms	Chronic intestinal pseudoobstruction in ~ 67%	Chronic intestinal pseudoobstruction in all
Extragastrointestinal manifestations	None	Malformation of central nervous system; patent ductus arteriosus sometimes present
Treatment, prognosis	No effective medical or surgical treatment; prognosis fair	No effective medical or surgical treatment; prognosis poor

Table 47.4 Genetic models of Hirschsprung disease

Genetic defect	Phenotype	Associated non-gastrointestinal disease	Dysmotility: prevalence in phenotype
RET–GDNF	Hirschsprung	None in humans	20%–50% RET, 5% GDNF
ET-3–ET-B	Hirschsprung or megacolon	Waardenburg–Shah syndrome	5%–10% Hirschsprung
SOX-10	Hirschsprung	Waardenburg–Shah syndrome	?
c-*KIT*	?Chronic intestinal pseudoobstruction/ Hirschsprung	None	?

ET, endothelin; GDNF, glial cell line-derived neurotrophic factor; RET,.

in the gut and other tissues (Table 47.4). These include abnormalities of c-*Ret*, the gene that encodes the tyrosine kinase receptor; the ETB system; the SOX-10 transcription factor; and c-KIT, which is a marker for the interstitial cells of Cajal. Disturbances in these mechanisms result in syndromic dysmotilities such as Hirschsprung disease, Waardenburg–Shah syndrome (piebaldism, neural deafness, megacolon), and idiopathic hypertrophic pyloric stenosis. Figure 47.4 shows some of the mutations in the tyrosine kinase receptor that have been reported in dysmotilities associated with familial or sporadic medullary carcinoma of the thyroid, MEN types 2A and 2B, and Hirschsprung disease. Visceral neuropathy may result in bowel dilation (Fig. 47.11), although this is generally less frequent or less severe than in visceral myopathy.

Multiple endocrine neoplasia type 2B syndrome

Multiple endocrine neoplasia type 2B is a serious congenital neuropathic condition associated with tumors of the neuroendocrine system. It presents, often in infancy, with severe constipation or megacolon (Fig. 47.12), diarrhea (when associated with enterocolitis), or obstruction [105,106]. Other external stigmata of MEN 2B are a characteristic facies, "blubbery lips" resulting from mucosal neuromas, marfanoid habitus, medullated corneal nerve fibers, and medullary thyroid carcinoma [105,107]. The latter develops eventually in almost all patients.

A feature of the intestinal pathology is transmural intestinal ganglioneuromatosis, in which massive proliferations of neural tissue (neurons, supporting cells, and nerve fibers) appear as thickened nerve trunks among mature nerve cells (Fig. 47.13).

Although MEN type 2B is a dominantly inherited disorder, at least half of all patients present with a de novo mutation because only a few survive to reproductive age and are disabled by a variety of neurological symptoms that impair reproduction. The precise molecular abnormality is in the *RET* protooncogene (see Fig. 47.4), which encodes a tyrosine kinase receptor expressed particularly in neural crest-derived cells, including the enteric ganglia. A specific germ-line point mutation in *RET* in exon 16 at codon 918 (M918T) occurs in

Figure 47.11 Small bowel radiograph from a patient with type I familial visceral neuropathy shows a normal stomach, duodenum, and proximal jejunum, but a dilated distal small bowel (arrow). From Mayer et al. [58], with permission from Elsevier.

Figure 47.12 Megacolon in a patient with multiple endocrine neoplasia type 2B; note the marked distention of the colon with a relatively small rectal diameter (arrow), and the massive dilation of the transverse colon with scoliosis and deviation of the mediastinum (arrowhead).

95% of patients; the remainder have a point mutation at codon 883 (A883F) [108,109]. The M918T mutation alters RET substrate specificity and appears to act in a ligand-independent fashion (a gain-of-function mutation) [110–112]. Receptor tyrosine kinases with these mutations also bind to and phosphorylate substrates preferred by nonreceptor tyrosine kinases. The A883F RET has not been directly tested, but given its location, it is thought that kinase specificity may also be altered in this mutant [109]. The receptor is expressed in the neural crest cell-derived ENS, adrenal medulla, parathyroid, and C cells of the thyroid. The gain-of-function mutations are susceptibility factors for endocrine tumors (medullary carcinoma of the thyroid, pheochromocytoma, and parathyroid tumors). Because surgery is the only curative procedure for medullary carcinoma of the thyroid, Smith and colleagues [113] recommend that patients who present with a clinical phenotype of Hirschsprung disease undergo adequate full-thickness biopsy of the bowel at the time of the pull-through operation, and that those with transmural intestinal ganglioneuromatosis undergo molecular diagnostic testing by RET mutation analysis. If germ-line M918T or A883F mutations are found, a prophylactic thyroidectomy is indicated; furthermore, adrenal gland surveillance with abdominal ultrasonography and urinary fractionated catecholamines and metanephrine or vanillylmandelic acid are indicated because a pheochromocytoma may develop subsequently in about 50% of cases.

Other familial visceral neuropathies

A few reported families do not fit into the two types of FVN discussed previously [20,67,68].

Schuffler and colleagues [67] reported two siblings who had generalized neurological disease and intestinal pseudoobstruction. One had ataxic gait; small, irregular, poorly reactive pupils; dysarthria; absent deep tendon reflexes; and impaired vibratory and positional senses. Radiographs revealed hyperactive, nonpropulsive contractions in a dilated esophagus and small intestine, and extensive colonic diverticulosis. The postmortem examination revealed degeneration of the myenteric plexuses of the esophagus, small intestine, and colon with reduced number of plexuses and round, eosinophilic intranuclear inclusions. The neurons and glial cells of the brain and spinal cord and the dorsal root and celiac plexus ganglia contained identical intranuclear inclusions. Intestinal smooth muscle was normal histologically.

In the family reported by Cockel and colleagues [68], affected members had megaduodenum, generalized dilation of the small intestine, malabsorption, redundant colon, mental retardation, and calcification of the basal ganglia. Histological studies showed degeneration of the argyrophobe cells, which produce acetylcholine. The patients became symptomatic for intestinal pseudoobstruction during late childhood.

Faber and colleagues [20] reported five patients with chronic intestinal pseudoobstruction in two families. Hypertrophy of

Table 47.5 Classification of childhood visceral myopathies

Characteristics	Type I	Type II (megacystis–microcolon–intestinal hypoperistalsis)
Mode of transmission	Autosomal recessive (?)	Autosomal recessive (?)
Gross lesions	Dilation of entire gastrointestinal tract	Short, malrotated small intestine and malfixation of microcolon
Microscopic changes	Degeneration and fibrosis of gastrointestinal and urinary tract smooth muscle cells	Vacuolar degeneration of gastrointestinal and urinary tract smooth muscle cells
Clinical manifestations:		
Age at onset	Infancy and young childhood	Infancy
Gender	Both	Predominantly female
Symptoms	Constipation, distention with or without chronic intestinal pseudoobstruction	Obstipation, intestinal pseudoobstruction
Extragastrointestinal manifestations	Megacystis and megaureters	Megacystis and megaureters
Treatment, prognosis	No effective treatment; prognosis poor	No effective treatment; prognosis poor

nerve fibers and an absence of ganglion cells were noted. The disease was transmitted by an autosomal recessive gene. All patients had megaduodenum; one had jejunal diverticulosis, and another dilation of the entire small intestine. Three had gastric dilation. Most patients had external ophthalmoplegia, ptosis, distal weakness of all extremities, gait disturbances, and acroparesthesia. The symptoms developed during the teen years, and the prognosis was poor.

Childhood visceral myopathies (CVMs)

The CVMs have been recognized as distinctive diseases. There are two forms of CVM (Table 47.5), the second of which is identified by the phenotype of megacystis–microcolon–intestinal hypoperistalsis. These two diseases differ from the FVMs in their clinical manifestations and modes of inheritance. Degeneration and fibrosis of gastrointestinal tract and urinary tract smooth muscle can be detected in both types of CVM [28,34,45,114] and result in bowel dilation (Fig. 47.14), ureteropelvic pyelocaliectasis (Fig. 47.15), or megacystis, which results from bladder degeneration (Fig. 47.16).

Nonfamilial visceral myopathies (sporadic hollow visceral myopathy)

Nonfamilial visceral myopathies in adults have been reported a few times [115–121]. The disease is heterogeneous, with some similarities to FVM types I and III [118]. Histologically, no difference is seen between the familial and nonfamilial types. Diffuse mixed inflammatory cell infiltration, including eosinophils, was observed in one patient [115]. In one reported case [121], acetylcholinesterase stain of the small intestine showed a considerably increased number of positive fibers, but no degeneration of neurons in the myenteric plexus. The nonfamilial type of visceral myopathy is uncommon. A careful family history must be obtained in these patients to exclude a diagnosis of FVM.

Idiopathic nonfamilial visceral neuropathies (sporadic hollow visceral neuropathy or chronic idiopathic intestinal pseudoobstruction)

Nonfamilial visceral neuropathy or chronic idiopathic intestinal pseudoobstruction typically results from damage to the

Figure 47.14 Upper gastrointestinal radiograph from a patient with type I familial visceral myopathy demonstrates severe megaduodenum.

Figure 47.15 An intravenous pyelogram of a child with type I childhood visceral myopathy shows megacystis and bilateral ureteral pyelocaliectasis. From Bonsib et al. [114].

myenteric plexus by chemicals, drugs, or viral infections. Delayed gastric emptying has been observed in patients after viral gastroenteritis [122,123], which may cause permanent damage to the myenteric plexus in some cases.

In patients with nonfamilial visceral neuropathies [124–131] the motility of the entire gastrointestinal tract is usually disturbed, but the urinary tract is generally not affected. The intestine is dilated but shows active, nonperistaltic contractions on barium examination [130]. By contrast, patients with familial visceral myopathies have an inactive, dilated intestine [130]. In sporadic visceral neuropathy, histological examination of the myenteric plexus with the Smith silver staining technique reveals a reduction in the number of neurons, and those that remain are markedly abnormal (Fig. 47.17). The neurons are enlarged, with thick, irregular, clubbed processes. The number of Schwann cells in the nerve

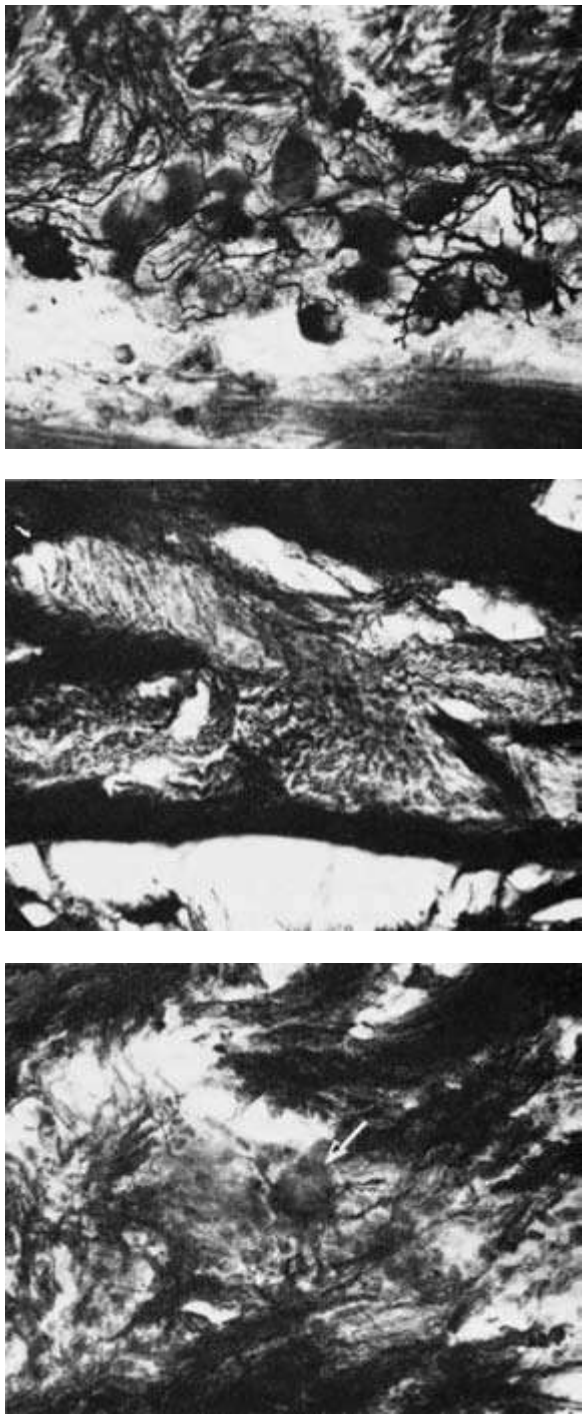

Figure 47.17 **(a)** Ganglionic area from normal control ileum demonstrates numerous argyrophilic neurons and nerve fibers. (Silver stain; original magnification × 230.) **(b)** Ganglionic area from a patient with type II familial visceral neuropathy demonstrates absence of argyrophilic neurons and few nerve fibers. There is a faint cluster of small nuclei of unknown cell type. (Silver stain; original magnification × 230.) **(c)** Another ganglionic area from the same patient shows only one poorly staining, argyrophilic neuron (arrow). (Silver stain; original magnification × 362.) From Mayer et al. [58], with permission from Elsevier.

trunks is increased, and the number of axons is reduced. Some of the remaining axons are beaded and fragmented. Hypertrophy of one or both muscle layers of the muscularis propria may also be observed. All reported cases have chronic intestinal pseudoobstruction. Infants and young children are also affected [131].

In a study of 40 patients with chronic idiopathic intestinal pseudoobstruction, the results of intestinal phasic pressure studies were abnormal, but the histological features of the gastrointestinal tract were normal in those whose tissue was available for analysis [132]. Similar findings have been reported in children with chronic idiopathic intestinal pseudoobstruction [133]. In earlier reports [134–136], histological studies of smooth muscle or myenteric plexus were not generally available for evaluation. The precise mechanism and neurotransmitter deficiencies of this disorder are unclear. Differentiation from severe IBS may be difficult if the gut is not dilated. Manometric studies may also show similar features, such as bursts or clusters of phasic pressure activity [137–139]; slow transit of chyme through the stomach or small bowel [140] provides an objective, noninvasive means by which dysmotility can be assessed.

Secondary causes of small intestinal dysmotility

The secondary causes of small intestinal dysmotility are summarized in Table 47.6 and discussed in the next sections.

Scleroderma (progressive systemic sclerosis)

The small bowel is the second most frequently involved gastrointestinal organ in scleroderma, after the esophagus. Radiographic evidence of gastric sclerosis, intestinal sclerosis, or both is found in 40% of patients with scleroderma [141–144]. Contrast studies reveal dilation of the duodenum and jejunum, delayed barium transit, and narrow valvulae conniventes, which remain tightly packed together despite the bowel dilation, producing the "hide-bound" bowel sign (Fig. 47.18) [10,144–146]. Wide-necked diverticula may be seen but are more frequent in the colon [147]. An uncommon but potentially serious finding is pneumatosis cystoides intestinalis [148].

In early scleroderma, and possibly other connective tissue diseases, antibodies that inhibit M_3 muscarinic receptors are present and may account for the defects in excitatory neurotransmission present in these conditions [149]. Later in the course of disease, degeneration of the smooth muscle and replacement with collagen is responsible for the end-stage small bowel dysmotility in scleroderma. The circular muscle layer is involved more often than the longitudinal muscle layer [10,150,151]. The submucosal and myenteric plexuses appear normal by conventional staining. Small bowel dysmotility leads to bacterial overgrowth, resulting in steatorrhea, malabsorption, and weight loss. Intestinal pseudoobstruction is a well-described gastrointestinal complication of scleroderma [10,152–155].

Table 47.6 Gastrointestinal dysmotility manifestations of some systemic diseases

Disease	Pharynx	Esophagus	Stomach	Small intestine	Colon	Anorectum
Collagenases						
Scleroderma	–	Dilation, aperistalsis of lower two-thirds, incompetent LES	Gastroparesis less frequently	Dilation with narrowed valvulae conniventes, PCI	Dilation; loss of haustra, PCI, wide-necked diverticula	Reduced internal anal sphincter tone
Dermatomyositis, polymyositis	Decreased UES tone, aspiration	Dilation, dysmotility of proximal portion	Gastroparesis rarely	Megaduodenum, distal dilation rarer	Dilation	–
SLE	–	Aperistalsis	–	–	Dilation, ischemia	–
Mixed CTD	–	Dilation lower two-thirds, aperistalsis	Not involved	Megaduodenum	Diverticula	–
Neurological						
Diabetic neuropathy	Decreased peristalsis	Decreased peristalsis, normal LES	Dilation, delayed emptying	Delayed, normal, or rapid transit	Dilation	Decreased sensation, low IAS, low EAS
Parkinsonism	Impaired peristalsis	Diffuse spasm, dilation, aperistalsis	Gastroparesis less frequently	Dilation	Dilation, sigmoid volvulus	–
Spinal cord injury	–	–	Gastroparesis infrequent	Increased gas	Delayed transit, left colon dysfunction	Pelvic floor dysfunction; sensation, IAS, EAS decreased
Neurofibromatosis	–	–	Gastroparesis infrequent	Dilation	Dilation	–
Paraneoplastic neuropathy	–	Aperistalsis/achalasia	Gastroparesis	Dilation, dysmotility	Dilation, constipation	–
Myotonic dystrophy	Decreased peristalsis, low UES tone	Decreased peristalsis, dilation	Delayed emptying, dilation	Dilation	Dilation	EAS dysfunction
Duchenne dystrophy	Decreased peristalsis	Dilation	Dilation, rare gastroparesis	Dilation	Dilation	–
Amyloidosis	–	Aperistalsis, incomplete LES relaxation	Delayed emptying	Dilation	Dilation	–
Infectious						
Chagas disease	–	Dilation, aperistalsis, incomplete LES relaxation	Dilation	Proximal dilation	Dilation	Low IAS
Endocrine						
Hypothyroidism	–	–	Delayed emptying	–	Constipation	–
Hypoparathyroidism	–	–	Delayed emptying	–	Constipation	–

CTD, connective tissue disease; EAS, external anal sphincter; IAS; internal anal sphincter; LES, lower esophageal sphincter; PCI, pneumatosis cystoides intestinalis; SLE, systemic lupus erythematosus; UES, upper esophageal sphincter.

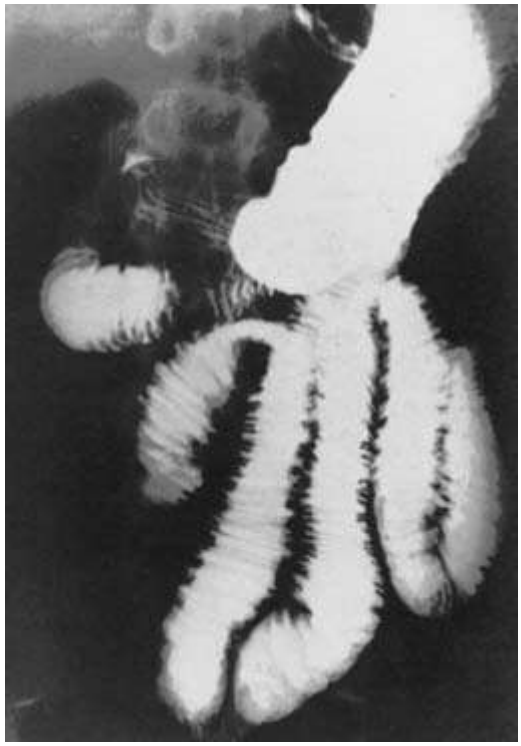

Figure 47.18 Upper gastrointestinal series in a patient with scleroderma shows dilation of the small bowel with normal appearance of the stomach. In some cases the valvulae conniventes are not thickened, as is usually seen in disorders that produce dilation, but remain narrow and crowded, producing the accordion appearance shown here. From Cohen et al. [144], with permission from Elsevier.

In patients with scleroderma and intestinal involvement, disturbances of small bowel motility [156–158] and transit [159] have been documented in several studies. Many patients have a complete absence of the interdigestive migrating motor complex (MMC); clusters of propagated and nonpropagated contractions may be the only finding in others. An abnormally prolonged MMC cycle, diminished activity of phase III activity fronts, and hypomotility of the fed pattern are other abnormal findings [156,158,160]. Antral hypomotility, when present, is characterized by low-amplitude contractions, typically below 40 mmHg; intestinal involvement usually causes the contractile amplitude to fall below 10 mmHg during fasting and postprandially [161]. In patients who have scleroderma without gastrointestinal involvement, the small bowel manometric pattern [161] and small bowel transit time are normal [162].

Oral erythromycin was effective in short-term studies that evaluated gastric emptying and symptoms in an open-label study [163]. Octreotide, a long-acting somatostatin analogue, induces phase III activity in patients with a complete absence of MMCs and may reduce bacterial overgrowth and symptoms (Fig. 47.19) [157]. More studies are required to confirm these observations and the long-term benefit of the treatments.

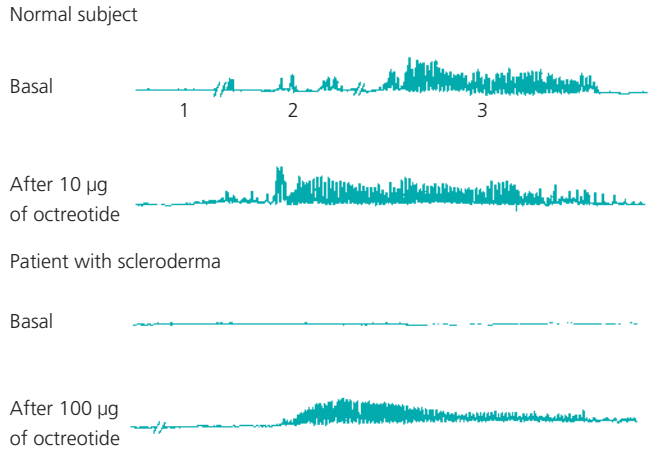

Figure 47.19 Effect of octreotide in a healthy person and in a patient with scleroderma. In the normal person, octreotide stimulates phase III activity. In the patient with scleroderma and pseudoobstruction, octreotide induces phase III activity although no migrating motor complex activity was present in the basal state. From Soudah et al. [157]. Dermatomyositis and polymyositis

The inflammatory disorders dermatomyositis and polymyositis are characterized by weakness and atrophy of the skeletal muscles; an associated skin rash distinguishes the former from the latter. The gastrointestinal tract is involved in half of cases. Esophageal involvement causes dysphagia, which often is a presenting symptom.

Studies of the small bowel in these patients are limited mainly to radiography and histology. Megaduodenum and delayed intestinal transit of barium are prominent features [164–166]. Autopsy findings have shown atrophy and fibrosis of intestinal smooth muscle, suggesting a visceral myopathy [165,166]. Acute colonic pseudoobstruction was reported in one patient with dermatomyositis, but it was limited to the colon [167].

Systemic lupus erythematosus

Abdominal pain is the most common gastrointestinal symptom in systemic lupus erythematosus, occurring in 10% to 20% of patients. Autopsy studies disclose a 60% to 70% prevalence of previous peritoneal inflammation, but documented cases of serositis as the sole cause of abdominal pain are rare [168]. The term *lupus enteritis* is used to describe the bowel changes resulting from lupus-induced vasculitis of the small blood vessels. Ischemia leads to intestinal mucosal ulceration, edema, and hemorrhage. Smooth muscle dysfunction results in dilation of the small bowel and ileus. In severe cases, necrosis of the bowel wall develops, with perforation or infarction.

Lupus enteritis is diagnosed radiographically. Small bowel changes include dilation, coarsened folds, and "thumbprinting" secondary to submucosal edema and hemorrhage [169,170]. Diarrhea occurs in 5% to 10% of lupus patients. Unusual

intestinal manifestations can pose diagnostic difficulties. Small bowel involvement in lupus may simulate Crohn's ileitis in some cases [171,172]. A severe protein-losing enteropathy was described in one patient with lupus, who demonstrated vasculitis and basement membrane thickening on full-thickness jejunal biopsy [173]. Transit or manometric studies of the small bowel have not been performed in patients with lupus.

Mixed connective tissue disease

Mixed connective tissue disease is a clinical entity characterized by overlapping features of scleroderma, polymyositis, and rheumatoid arthritis. It has a distinct serological finding of high titers of antinuclear antibody against ribonucleoprotein. The extent of gastrointestinal involvement is unknown but appears to resemble that of scleroderma, with esophageal involvement being most common. Duodenal and jejunal dilation are seen radiographically, and pneumatosis cystoides intestinalis may complicate severe disease [174].

Diabetes mellitus

Intestinal dysmotility may contribute to features of gastroparesis in diabetes [175]. Camilleri has reviewed the clinical features and treatment of the stasis syndromes associated with upper GI motor dysfunction [176].

Diabetic patients may develop diarrhea, which has a variety of causes (e.g., bacterial overgrowth, pancreatic exocrine insufficiency, bile salt malabsorption, impaired absorption or secretion). Early radiographic studies of the small bowel demonstrated variable findings, including normal, delayed, or rapid transit. Similarly discrepant results are found when the hydrogen breath test is used, and the correlation of rapid transit, based on that test, with diarrhea is poor [177–179]. In patients presenting with the gastroparesis syndrome, the small bowel may be affected and this can be detected by manometry [175] or prolonged transit [159].

Pathologically, demyelination of the proximal vagus nerve and sympathetic nerves supplying the bowel develops in diabetes. Although thickening of the small bowel muscle layers and eosinophilic hyaline bodies in smooth muscle cells have been observed [180–182], most authorities do not believe that myopathy is a cause of gastrointestinal dysmotility in diabetic patients. A marked reduction in interstitial cells of Cajal and decreased inhibitory innervation (e.g. vasoactive intestinal peptide, nitric oxide) has been described in a patient with type I diabetes and may underlie the gastroenteropathy associated with this condition [183].

The results of motility studies of the small bowel in patients with diabetes have been mixed. The MMCs are normal in many patients with documented gastroparesis [184]. Absence of intestinal phase III activity fronts has been demonstrated in some patients [177,185,186]. Other abnormalities include MMCs originating in the distal duodenum or jejunum and uncoordinated (nonpropagated or abnormally propagated) bursts of powerful contractions lasting up to 2 minutes (Fig. 47.20) [175,177]. The clinical relevance of these abnormal

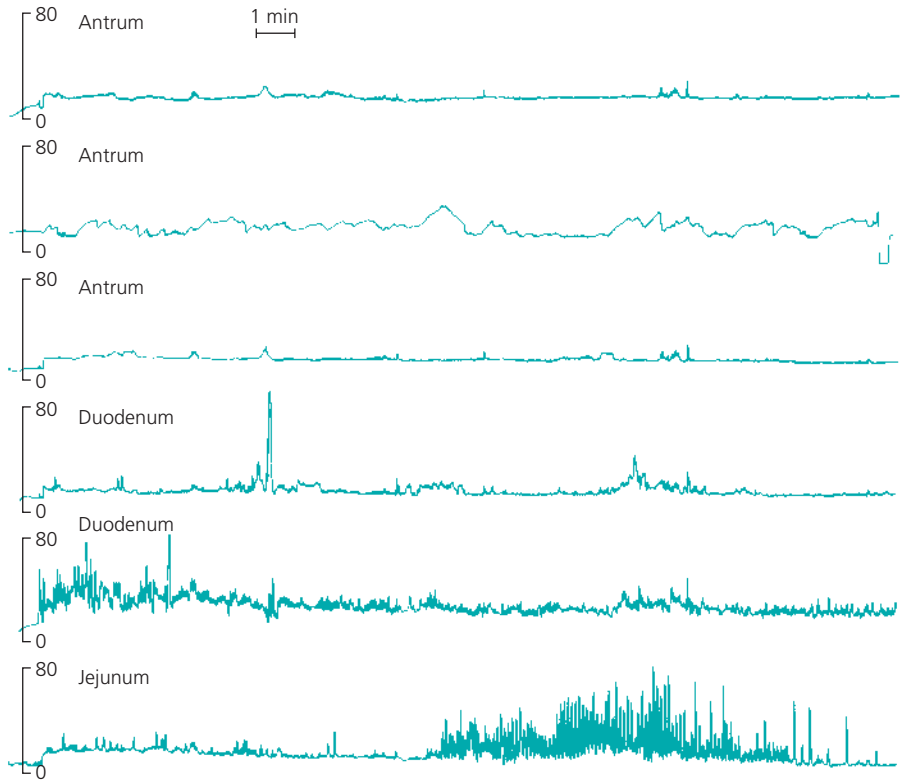

Figure 47.20 Small bowel dysmotility in diabetes. In this patient, phase III of the migrating motor complex begins in the jejunum, with no antecedent activity in the antrum or duodenum. Other patients may have a complete absence of phase III activity. From Dooley et al. [177], with permission from Taylor & Francis.

findings is uncertain. In one study, abnormal transit time and manometric abnormalities could not be correlated [177]. Hyperglycemia, which can weakly delay gastric emptying, induces intestinal phase III-like activity and alters orocecal transit time in healthy subjects [187]. However, the relevance of these findings to diabetic bowel dysmotility is unclear. Among diabetics living in the community, constipation and the use of laxatives are significantly more common than in age- and gender-matched controls [188,189]. Constipation is probably multifactorial in diabetes, as it is in nondiabetic patients [190]; acute hyperglycemia does not significantly affect colonic motor function or tone [191].

Parkinson disease

Symptoms of gastrointestinal dysmotility are common in patients with Parkinson disease. High dysphagia, nausea, bloating, constipation, and difficulty with evacuation of stool occur frequently [192]. Dilation of the small bowel may be seen radiographically [193]. Small bowel dysmotility does occur, but its frequency is unknown. Manometric studies in patients with Parkinson disease reveal infrequent MMCs (which are absent in some cases), hypomotility in the fed state, and an increased incidence of retrograde and tonic contractions in comparison with controls [194]. The contribution of these abnormalities to symptoms is not clear.

The pathogenesis of small bowel dysmotility is unknown. In patients with dysphagia and megacolon, Lewy bodies, which are neurons containing cytoplasmic hyaline inclusions, have been found in the myenteric plexus of the esophagus and colon [195,196]. Lewy bodies were originally identified in the brain and are highly characteristic of Parkinson disease. Lewy bodies have not yet been reported in the small bowel. Dopaminergic neurons are reported to be deficient in the colon of patients with parkinsonism and constipation [197].

Therapy for Parkinson disease includes drugs that adversely affect gut motility, such as dopamine agonists and anticholinergics. Symptoms are as common in untreated as in treated patients, however, suggesting that the disease itself is the primary factor producing dysmotility and resultant symptoms [192].

Spinal cord injury

Extrinsic denervation of the small bowel by spinal cord injury usually produces just mild and probably insignificant dysmotility in the small intestine. The only change revealed in manometric studies performed in a group of patients with spinal cord injury was that a greater number of phase III contractions began in the duodenum rather than the antrum in those with high spinal cord lesions [198]. Colonic dysmotility is well recognized and is responsible for the common problems of constipation and difficulty of evacuation in these patients [199]. Colonic transit is delayed at the level of the left colon and rectum, and manometric studies have shown that the baseline and postprandial colonic activity is substantially reduced in spinal cord-injured patients at the level of the descending colon, and that the postprandial response is absent at the rectosigmoid [200]. Patients with injury to the lower spinal cord demonstrated no abnormal findings, consistent with the preservation of innervation to the bowel from the vagus and third thoracic sympathetic levels. In one report, a woman with cervical spinal stenosis and paraplegia displayed normal MMCs but a two- to three-fold prolonged interval between MMCs [201].

Immediately after a spinal cord injury, a state of spinal shock develops. This is characterized by the complete loss of all sensory, motor, and reflex function below the level of injury. Paralytic ileus with abdominal distention follows and usually resolves in a few days. In the long term, postprandial abdominal distention and discomfort occur in more than 40% of patients with spinal cord injury [202]. These symptoms are likely caused by the more significant problem of constipation. In many stable patients with spinal cord injury, the amount of gas in the small and large intestine is increased on routine abdominal radiographic films (Fig. 47.21) [203].

Neurofibromatosis (von Recklinghausen disease)

Gastrointestinal neurofibromas are most commonly found in the small intestine. They are reported to occur in up to

Figure 47.21 Abdominal radiograph from a stable, healthy patient with a spinal cord injury. A nonobstructive gassy abdomen is frequently observed, even in the absence of abdominal complaints. From Gore and Mintzer [203], with permission from Elsevier.

10% of patients with neurofibromatosis; the true incidence of neurofibromas is probably underestimated, however, because they are generally asymptomatic. Small bowel neurofibromas may be single or multiple and are most frequently found in the ileum. These tumors are submucosal, and they may become large and extend to the serosa. Their presence is usually established by a small bowel series [204,205]. Ulceration through the mucosa can cause acute or chronic bleeding. Mechanical small bowel obstruction or intussusception requires exploratory surgery.

Chronic intestinal pseudoobstruction has been described in one patient with neurofibromatosis. The small bowel manometry findings were abnormal, and small bowel transit was markedly delayed [140]. Pathological studies of the nerves and muscles in the small bowel are lacking in this disease. Neurogenic changes consisting of nerve fiber proliferation in the myenteric and submucosal plexuses were found in the colon of a patient with megacolon [206].

Paraneoplastic visceral neuropathy

Chronic intestinal pseudoobstruction has been reported in association with small cell carcinoma of the lung [207–212], anaplastic lung adenocarcinoma [213], thymoma [214], epidermoid carcinoma of the lip [215], and gynecological [213] and breast cancers [216]. This phenomenon represents a paraneoplastic syndrome caused by visceral neuropathy. The small bowel, like the colon, shows widespread neuronal and axonal degeneration of the myenteric and submucosal plexuses, in addition to mononuclear cell infiltration and Schwann cell proliferation [211]. There may also be a reduction in the small intestinal network of interstitial cells of Cajal [217]. In paraneoplastic syndromes there are no metastases to the bowel.

Symptoms of pseudoobstruction are the presenting features in patients with visceral neuropathy and small cell carcinoma. The lung cancer is usually occult, missed on chest radiography, and is often found at autopsy or by chest computed tomography (CT) and mediastinoscopy. The small bowel is usually not dilated on radiographs, but barium passage through the small bowel is somewhat delayed. Small bowel manometry shows features suggestive of neuropathy, such as incoordinated bursts [210,211]. In older patients with intestinal pseudoobstruction or feeding intolerance of unknown cause and recent onset, a malignancy, especially small cell carcinoma of lung, must be suspected. A screening blood test (antineuronal enteric antibody, or anti-Hu) is highly specific [211]. If the result is positive, CT of the chest and mediastinoscopy may be necessary to confirm the diagnosis.

Myotonic dystrophy

Myotonic muscular dystrophy is a slowly progressive disease characterized by myotonia, or difficulty in muscle relaxation. Besides muscle wasting, the patient often has a nasal voice as a result of pharyngeal and palatal weakness, an early onset of cataracts, and cardiac conduction defects. Dysphagia is the most common gastrointestinal symptom resulting from esophageal involvement. Diarrhea and abdominal cramping occur in up to one-third of those affected. Malabsorption and steatorrhea have been reported in a few cases [218–220]. Constipation also is frequent and can alternate with diarrhea. Intestinal pseudoobstruction is rare [221,222]. The small bowel may demonstrate abnormal but nonspecific radiographic changes, including dilation, diminished motility, and delayed transit of barium [223].

Dysmotility of the small intestine may play a significant role in the production of intestinal symptoms. In a group of 10 patients with symptoms of intestinal dysmotility but normal findings on small bowel contrast examinations, small bowel motility was abnormal in all patients. Manometric findings included low-amplitude contractions in the fasting and fed states, retrograde propagation of phase III, interruption of phase III, and an increased incidence of tonic contractions [224]. In one patient with chronic pseudoobstruction and dilated small bowel, manometry revealed low-amplitude duodenal contractions and an increased maximal rate of contractions in the duodenum [222].

Histologically, the small intestinal smooth muscle shows changes similar to those found in dystrophic skeletal muscle; it is swollen, partially destroyed, decreased in size, and replaced by fat [225,226]. Silver stain revealed degenerative changes in the myenteric plexus of the colon in a patient with megacolon [227], indicating that intestinal dysmotility may be caused by smooth muscle as well as enteric nerve dysfunction. In most patients, the predominant cause of dysmotility appears to be smooth muscle damage.

Duchenne muscular dystrophy

Duchenne muscular dystrophy is a severe, pseudohypertrophic muscular dystrophy that follows an X-linked recessive pattern of inheritance, affecting young boys early in childhood. Skeletal and cardiac fibers are infiltrated and eventually replaced by connective and fatty tissue. Similarly, the smooth muscle of the gastrointestinal tract also is involved. Histological changes comprise degeneration and atrophy of smooth muscle fibers and separation of the fibers by connective tissue [228–230]. The myenteric plexus is not involved.

Despite typical dystrophic changes in the small bowel in most postmortem specimens, gastrointestinal symptoms are usually related to dysmotility of the esophagus and stomach, which are more severely affected than the small bowel. Dysphagia is the predominant symptom (36% in one series), followed less often by vomiting, diarrhea, and constipation [230]. The orocecal transit time is normal in asymptomatic subjects [231]; however, severe bowel dysmotility can occur. Episodes of acute intestinal pseudoobstruction, manifested by abdominal distention, persistent vomiting, and gastric or small bowel dilation, can be life-threatening [232–234].

Chronic intestinal pseudoobstruction has also been reported in Duchenne dystrophy [235].

Amyloidosis

Amyloid protein is deposited in the small bowel in all forms of amyloidosis: primary, secondary, myeloma-associated, and familial or hereditary. The degree of dysmotility is related to the amount and distribution of amyloid deposited. In all forms, the deposition of amyloid in blood vessel walls leads to ischemic ulcers, infarction, and occasionally perforation.

In primary and myeloma-associated forms of amyloidosis, the muscle layers of the small bowel are more severely affected than the mucosa, resulting in dysmotility. In the secondary and hereditary forms, the mucosa is chiefly involved, resulting in malabsorption. Amyloid deposits are infrequently found in the myenteric plexus, although in hereditary forms, familial amyloidosis neuropathy may result from deposition in major nerve trunks supplying the bowel [236,237].

Gastrointestinal symptoms include diarrhea, constipation (which is often present for years and then followed by diarrhea), malabsorption, and pseudoobstruction. Diarrhea can occur without malabsorption and is occasionally relieved by antibiotic therapy [238]. However, patients who have amyloidosis and autonomic neuropathy have been documented to have extremely rapid intestinal transit as the mechanism of their diarrhea [239]. With heavy infiltration of the small bowel muscle layers, acute intestinal pseudoobstruction is a serious and often fatal complication (Fig. 47.22) [240–242]. In patients with pseudoobstruction-related amyloidosis, radiographic features include coarsening of the small bowel mucosal pattern, dilation, and prolonged transit of barium [243].

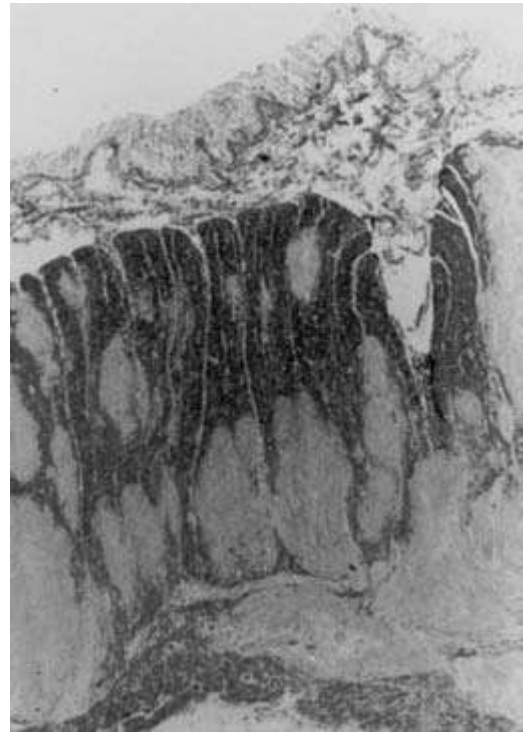

Figure 47.22 Small bowel myopathy in a patient with amyloidosis and pseudoobstruction. The large, pale areas in the muscle layer represent heavy amyloid deposition. The myenteric plexus is less frequently involved than the mucosa and muscle layers. From Mitros [242], with permission from Elsevier.

Chagas disease

Chronic infection with *Trypanosoma cruzi* leads to destruction of the submucosal and myenteric plexuses along the entire length of the gastrointestinal tract. Megacolon and megaesophagus are the most common presentations, although the small bowel may be similarly affected, with the development of megaduodenum and megajejunum. Small intestinal manometric studies in these patients demonstrate normal frequency of the MMCs, but the velocity of propagation of the activity front is significantly slowed to about half the normal value [244]. Patients with small bowel involvement may be entirely asymptomatic despite significant neuronal destruction [245]. Diarrhea, constipation, or intestinal pseudoobstruction can occur. Patients with chagasic megacolon have circulating autoantibodies that activate M_2 muscarinic acetylcholine receptors [246]. The agonist effects may result in desensitization and downregulation of the receptor, which may contribute to the development of megacolon.

Thyroid disease

Thyroid dysfunction may present primarily as gastrointestinal disease. Hyperthyroid patients may have diarrhea and mild steatorrhea, whereas hypothyroid patients frequently are constipated [247–249]. Intestinal dysmotility resulting from the altered thyroid state has been historically recognized as the cause of symptoms. This is supported by abnormalities found in the intrinsic electrical control of gut motor activity. In the duodenum, slow-wave frequencies are increased in hyperthyroid patients and decreased in hypothyroid patients [250,251]. These abnormalities return to normal after correction of the thyroid dysfunction.

Hyperthyroidism

Early radiographic studies, in which the crude barium meal test was used, reported rapid gastric emptying and rapid small bowel transit [252,253]. Later studies, in which the hydrogen breath test was used, confirmed a rapid orocecal transit time; this is a consequence of accelerated small bowel transit because the rate of gastric emptying is actually unchanged [247,254–256]. Hyperthyroid patients may present with malabsorption; more than 25% of hyperthyroid patients excrete more than 7 g of fat in their stool daily [257,258]. This is apparently caused by decreased contact time of the lumenal contents with small bowel mucosa as a result of rapid transit; the abnormality regresses after correction of the hyperthyroid state.

Hypothyroidism

In contrast to the accelerated small bowel transit in hyperthyroidism, small bowel transit is significantly slowed in hypothyroidism [247]. With adequate hormone replacement, transit may be normalized. Constipation develops in many hypothyroid patients, probably a result of colonic dysmotility. A manometric study in one patient revealed decreased amplitude of the small bowel contractions and an overall decreased motility index [259]. In severe hypothyroidism (i.e., myxedema), paralytic ileus and intestinal pseudoobstruction can occur [260–264]. Autoimmune hypothyroidism is more common in patients with celiac disease than in healthy controls, and gluten withdrawal has been reported to ameliorate the thyroid abnormality in some cases [265].

Hypoparathyroidism

The mechanism by which parathyroid hormone affects gastrointestinal motility is not known. However, calcium is essential for smooth muscle contraction, and hypocalcemia may impair gut contractile activity. Intestinal pseudoobstruction and malabsorption have been reported in association with small bowel dysmotility in hypoparathyroid subjects [266]. Barium studies reveal dilated loops of small bowel and a prolonged transit time. The symptoms are relieved by calcium administration.

Drug-induced changes in small intestinal motility

Many drugs profoundly affect gastrointestinal motility. Although the colon is usually recognized as the organ most susceptible to drug-induced dysmotility, the small bowel also is frequently affected. Phenothiazines and some antiparkinsonian drugs decrease colonic and small bowel motility and can cause constipation, colonic pseudoobstruction, and adynamic ileus [267–270]. Tricyclic antidepressants in particular are noted for causing iatrogenic ileus. The anticholinergic agents atropine and scopolamine and related belladonna alkaloids decrease intestinal tone as well as the amplitude and frequency of peristaltic contractions [271].

Opiate analgesics are well known to suppress motility throughout the gastrointestinal tract. Morphine enhances the amplitude of nonpropulsive small bowel contractions and markedly decreases propulsive contractions by its effects on μ-opioid receptors on intestinal muscle cells [272,273]. The upper small bowel is more prone to these effects than the ileum. The net effect is delayed small bowel transit. Morphine and nalbuphine significantly delay small bowel transit in comparison with placebo [274].

Loperamide, a synthetic opiate used to treat diarrhea, also reduces small bowel motility and delays transit time. This effect is antagonized by the concomitant administration of naloxone, which by itself has no effect on transit time [275,276]. Ketorolac, a nonsteroidal antiinflammatory agent used for postoperative pain, has significantly less effect on small bowel transit than morphine [277]. Whether ketorolac slows motility in comparison with controls is not known.

Calcium channel antagonists, especially verapamil, cause constipation in up to 20% of patients. The small bowel transit time in subjects taking verapamil was unchanged from pretreatment values; transit through the colon was slowed, however, and this effect likely accounts for the constipation associated with this drug [278].

Clonidine, an α_2-adrenergic agent used as an antihypertensive agent, prolongs the orocecal transit of liquids [279]; however, a comprehensive dose–response study of the transit of solids did not show any significant effects on gastric small bowel or colonic transit in healthy individuals [280]. Clonidine has been used successfully to treat diabetic diarrhea; however, its therapeutic benefit may also result from its known action of increasing fluid and electrolyte absorption from the gut [281].

Drugs that stimulate small bowel motility include erythromycin, cholinergic agonists, and tegaserod. Erythromycin binds to motilin receptors on the smooth muscle of the gastric antrum and duodenum. Motilin, in physiological doses, induces interdigestive motor complexes in the upper gut. Erythromycin has been used to treat diabetic gastroparesis; the long-term beneficial effects are not as pronounced as the short-term effects [282]. Cholinergic agonists, such as bethanechol, augment the amplitude of small bowel contractions and overall motility [283].

Octreotide is a long-acting synthetic analogue of somatostatin. In normal individuals, it increases the frequency of MMCs by significantly shortening the duration of phase II contractions [284,285]. It was shown to be useful in the short term in a small group of patients with scleroderma by inducing phase III contractions and possibly reducing small bowel bacterial overgrowth [157]. When given after a meal, intravenous somatostatin interrupts the fed pattern of motility and induces bursts of propagated activity similar to phase III activity fronts in health [286] and disease [287,288]. Octreotide retards small bowel transit in health when given before meals [289].

Tegaserod is a serotonin mimetic acting at the 5-HT_4 receptor that has demonstrated robust prokinetic effects on small intestinal and colonic transit in patients with IBS and constipation [290]. Additionally, tegaserod has been shown to accelerate the transit of intestinal gas in subjects with gas retention, and this may be one of the mechanisms by which it reduces symptoms of bloating in IBS patients [291].

Celiac disease

Intestinal pseudoobstruction occurs in association with nontropical sprue [292–294]. Dilated loops of small bowel in which the passage of barium is delayed are observed radiographically. In one patient who underwent exploratory laparotomy with full-thickness jejunal biopsy, the nerves and muscle coats appeared normal on both light and electron

microscopy [294]. Parenteral nutrition may be required during prolonged periods of pseudoobstruction.

Jejunal diverticulosis

Diverticula can occur anywhere in the small intestine, but they are most common in the jejunum. Like their counterparts in the colon, they represent herniations through the mesenteric side of the bowel and are usually acquired [242]. Jejunal diverticulosis is associated with many diseases, including scleroderma, celiac disease, Fabry disease, type II FVM, mitochondrial cytopathy, and Cronkhite–Canada syndrome [295]. Patients present with diarrhea, steatorrhea, weight loss, and megaloblastic anemia. Chronic intestinal pseudoobstruction occurs in jejunal diverticulosis and can mimic mechanical obstruction [155,296].

The concept that dysmotility causes diverticula and not vice versa is supported by a case report in which resection of the small bowel segment containing diverticula failed to relieve the patient's symptoms of pseudoobstruction [10].

In one patient, small bowel manometry showed that contractions can be antegrade, retrograde, or both simultaneously [295]. Histology of the bowel reflects the heterogeneous causes of dysmotility (e.g., visceral neuropathy, visceral myopathy) [297].

Irradiation

Ionizing radiation damages all structures of the small intestine, including the mucosa, blood vessels, connective tissue, enteric nerves, and smooth muscle. Radiation damage to the bowel can be classified as acute or chronic.

Acute injury

Above a certain threshold dose of radiation to the abdomen, symptoms of nausea, vomiting, abdominal pain, and diarrhea are common. These abate soon after exposure is discontinued. Reversible changes in small bowel absorptive function have been considered the main cause of diarrhea. Small bowel dysmotility may play a significant role in acute radiation enteropathy. In dogs, a single large dose of radiation abolishes the interdigestive MMCs. [298]. Smaller, fractionated doses, which are used for radiation treatment in humans, also result in dysmotility in the dog model. In the fasting state, manometric changes during exposure include an increased frequency of giant migrating contractions and retrograde contractions, with only a mild decrease in MMC cycle length [299]. These features revert to a normal pattern within a few days after exposure. Other studies, however, show decreased fasting and fed intestinal motility, particularly in the distal small bowel, persisting up to 1 month after the last exposure [300,301].

Motility studies have not been performed in humans in the acute phase of radiation sickness. One study demonstrated accelerated small bowel transit, compared with pretreatment values, in a group of patients undergoing abdominal and pelvic irradiation [302]. More than 75% of the patients had diarrhea during treatment.

Chronic injury

Delayed gastrointestinal complications may occur months, years, or even decades after radiation exposure. Neuronal, muscular, and vascular structures of the small bowel are affected. The resulting dysmotility leads to bacterial overgrowth, diarrhea, and malabsorption. Edema, atrophy, and fibrosis of smooth muscle fibers are characteristic histological findings [303–306]. The myenteric plexus can appear normal on routine staining; however, proliferation of the submucosal neurons with extension into the circular muscle coat has been observed [305,306]. Radiation enteropathy is also associated with microvascular endothelial dysfunction with impaired vasodilator response to acetylcholine, which may predispose to mucosal ischemia and eventual stricture formation resulting in obstruction [307].

Latent gastrointestinal symptoms resulting from previous radiation damage have been attributed to altered gut motility. Recurrent episodes of intestinal pseudoobstruction were described in two patients many years after they received abdominal radiation [306,308]. Small bowel contrast studies show dilated loops of bowel with air–fluid levels and a thickened bowel wall. Manometric evaluation in one patient revealed normal MMCs in the proximal duodenum, decreased amplitude and frequency of contractions in the distal duodenum, and an absence of peristaltic contractions in the jejunum. Subsequent histological examination of the bowel suggested smooth muscle damage as the cause of dysmotility [306].

Diffuse lymphoid infiltration

Four cases of chronic intestinal pseudoobstruction in association with diffuse lymphoid infiltration of the small bowel have been described [309]. All four patients were women who presented with diarrhea at an early age. Histology revealed lymphocytic infiltration of the lamina propria, muscularis propria, and myenteric plexus. The infiltrates were shown to be polyclonal by immunochemical stains, reflecting a pseudolymphoma rather than a true neoplasm. The myenteric plexus appeared normal with routine and silver stains. Smooth muscle cells were noted to be absent in the areas of lymphoid infiltration.

Jejunoileal bypass

Recurrent episodes of intestinal pseudoobstruction can occur in patients after jejunoileal bypass for morbid obesity [155,310]. Symptoms begin as early as 1 week postoperatively and consist of abdominal distention and pain, diarrhea, vomiting, and fever. Radiography reveals massively dilated small bowel loops and occasionally pneumatosis cystoides intestinalis. Bacterial overgrowth of the bypassed small intestine causes this enteropathy; small bowel cultures typically

grow fecal flora and anaerobes similar to those described in blind loop syndrome. Over time, either the symptoms disappear or the frequency and severity of pseudoobstruction decrease significantly. Intermittent antibiotic therapy may benefit patients with chronic symptoms.

In contrast to intestinal pseudoobstruction, mechanical obstruction secondary to ileal volvulus at the jejunoileal anastomotic site can occur and presents a difficult diagnostic challenge [311]. Contrast radiography may aid in establishing the correct diagnosis. Recurrent acute colonic pseudoobstruction also has been reported after jejunoileal bypass [312,313].

The effect on intestinal motility of bypassing a long segment of small bowel is unknown. In patients undergoing reoperation for various metabolic or hepatic complications, the bypassed segment appears normal, and normal small bowel function is restored after reversal of the bypass [314].

Anorexia nervosa and bulimia

Both anorexic and bulimic patients frequently report bloating and constipation. Delayed gastric emptying of solids is a well-established abnormality in these disorders. The orocecal transit is also modestly delayed [315,316], as is the whole-gut transit time, measured by radiopaque markers, in comparison with controls [316]. The gastric emptying abnormality and dyspeptic symptoms resolve with successful rehabilitation using nutritional therapy to achieve a target body mass index (BMI) of 18.5 kg/m^2 and cognitive-behavioral therapy [317].

Clinical manifestations

The small intestine is essential for the absorption of nutrients; therefore, individuals cannot survive without parenteral nutrition if a long segment of small intestine functions poorly. Fortunately, the small intestine is usually the last organ in the gastrointestinal tract to be affected by severe dysmotility. Severe dysmotility of the esophagus, colon, and even the stomach occur much more frequently than dysmotility of the small intestine. Isolated, severe small intestinal dysmotility is unusual; small intestinal dysmotility is generally associated with dysmotility in other parts of the digestive tract. In this chapter, the discussion is limited to the small intestine. Dysmotility in other organs of the digestive tract is discussed elsewhere in this book.

With a few exceptions, most patients with small intestinal dysmotility have similar clinical manifestations regardless of the underlying causes. The spectrum of clinical manifestations varies widely (see Fig. 47.5): at one end, a patient may be asymptomatic, whereas at the other, a patient may have recurrent symptoms and signs of small intestinal obstruction, termed *chronic small intestinal pseudoobstruction*. Between these two ends of the spectrum, a patient may have recurrent symptoms of postprandial abdominal pain – cramping, periumbilical, and epigastric – in addition to abdominal bloating, easy satiety, anorexia, weight loss, nausea, and vomiting. The symptoms are usually related to eating. Diarrhea can occur in patients with bacterial overgrowth and malabsorption. In severe cases, the patients have episodes of chronic intestinal pseudoobstruction syndrome. Plain abdominal radiographs of patients with intestinal pseudoobstruction during exacerbations show multiple air–fluid levels and dilation of the small intestine. The prevalence and severity of recurrent obstructive episodes vary from patient to patient and from episode to episode in the same patient.

The findings on physical examination vary according to the severity of the symptoms. Patients may be cachectic and malnourished because they are unable to take in adequate nutrients, or they may have malabsorption as a consequence of bacterial overgrowth in the small intestine. The abdomen may be distended and mildly tender. The bowel sounds are inactive and infrequent in patients with smooth muscle dysfunction, but they are hyperactive and high-pitched in those with myenteric plexus dysfunction. Borborygmi may be detected in some cases. In less symptomatic patients, the abdominal examination findings may be normal. In those with chronic intestinal pseudoobstruction, during an obstructive episode the abdominal examination findings may be indistinguishable from those of true mechanical obstruction.

As mentioned previously, patients with small intestinal dysmotility usually also have symptoms of dysmotility in other parts of the gastrointestinal tract. Therefore, patients with chronic intestinal pseudoobstruction may have symptoms and signs of multiple-organ dysmotility.

Extragastrointestinal manifestations may be detected in some patients, depending on the underlying disease. Megacystis and megaureter are common in type I FVM and CVM and may be associated with urinary retention and infection. Mydriasis, ptosis, and external ophthalmoplegia may be seen in certain forms of FVM, and ataxia, dysautonomia, and neurological symptoms in some forms of visceral neuropathy.

In the secondary forms of small intestinal dysmotility, patients may also have systemic manifestations of the underlying disease (e.g., scleroderma, muscular dystrophies, autonomic neuropathy). These are important clinical clues in patients whose underlying disease has not yet been diagnosed.

Complications

Malnutrition

Malnutrition develops in patients with severe dysmotility of the small intestine as the result of an inadequate intake of food and of vomiting. Postprandial abdominal pain and bloating limit oral intake. Anemia may develop secondary to iron, folate, and vitamin B-12 deficiency. Serum cholesterol, calcium, and albumin levels may be low. Supplemental formulas are useful to improve nutrition. In severe cases, small bowel transplantation or long-term parenteral nutrition may be the only methods to provide adequate nutrients, particularly to patients with familial or sporadic forms of hollow visceral myopathy.

Bacterial overgrowth in the small intestine

Bacterial overgrowth in the small intestine may complicate severe intestinal dysmotility [30,117,135,318]. The small intestine of these patients may be structurally abnormal, with dilation, diverticulosis, or strictures, or there may be only a motility abnormality. Small intestinal bacterial overgrowth causes malabsorption and steatorrhea, which result in additional weight loss. The diagnosis can be made by culturing intestinal aspirates for both aerobic and anaerobic bacteria. A number of different species are found, and the total bacterial concentration generally exceeds 10^5 aerobic organisms per milliliter or 10^3 anaerobic organisms per milliliter. Another approach to diagnosing bacterial overgrowth is the timed analysis of breath excretion of volatile metabolites produced by intralumenal bacteria. The measurement of both expired [^{14}C]carbon dioxide after the oral administration of ^{14}C-labeled substrates (e.g., D-xylose) and expired hydrogen after the administration of nonlabeled substrates has been used. This method is less accurate than culture of duodenal aspirates [319]. The patients may have macrocytic anemia secondary to vitamin B-12 deficiency. Doxycycline, metronidazole, ciprofloxacin, ampicillin, rifaximin, and other antibiotics can be used intermittently to treat intestinal bacterial overgrowth. Treatment with antibiotics results in improvement in bloating and diarrhea after 1–2 days, and the improvement persists for up to 2 weeks after a 7-day course of antibiotics [320]. In practice, different antibiotics may be rotated and given for 1 week of every month. The possibility that bacterial overgrowth occurs in the distal small bowel and may cause symptoms in IBS has been suggested [321,322], but the appropriate experiments to confirm or refute this have yet to be performed.

Pneumatosis cystoides intestinalis

Pneumatosis cystoides intestinalis is a rare condition characterized by multiple, gas-filled cysts in the wall of the small and large intestine. Pneumoperitoneum may occur. Pneumatosis cystoides intestinalis can develop in patients with small intestinal dysmotility and dilation. In most cases, the condition is found incidentally on radiographs. The pathogenesis is unknown, and no specific treatment is available. In one patient, the use of chloral hydrate was implicated as the cause of pneumatosis cystoides, based on controlled challenges of the drug [323]. Chloral hydrate is metabolized to alkyl hydrates, which potentially can inhibit bacterial consumption of hydrogen leading to overproduction of hydrogen. It has been recommended that surgery be avoided except in the cases of a complication such as an abscess or peritonitis, because surgery usually causes the patient's condition to deteriorate [154].

Diagnostic studies

The diagnostic studies for patients with small intestinal dysmotility are outlined in Table 47.7.

Table 47.7 Diagnostic studies for patients with small intestinal or colonic dysmotility

Blood tests
Complete blood cell count
Blood chemistries, including blood sugar
Antinuclear antibody
Thyroid functions: triiodothyronine, thyroxine, thyroid-stimulating hormone
Serum creatine phosphokinase and isoenzymes
Hemagglutination and complement fixation for Chagas disease
Antineuronal nuclear antibody or antititer for paraneoplastic process
Radiological studies
Plain abdominal radiography in patients with abdominal distention
Radiopaque marker transit
Upper gastrointestinal and small bowel radiography
Enteroclysis or small bowel radiography with fluoroscopy
Barium enema
Scintigraphic gastric, small bowel, and colonic transit
Intravenous pyelography
Computed tomography of chest and abdomen
Other studies
Skeletal muscle biopsy
Cultures of small bowel aspirates
Small intestinal or colonic manometry
Anorectal manometry and balloon expulsion
Histological studies of full-thickness biopsy specimens to examine the smooth muscle and myenteric plexus by special silver stain, immunohistochemistry, confocal microscopy of enteric plexuses

Blood tests

A complete blood cell count may reveal anemia and macrocytosis secondary to malnutrition and bacterial overgrowth. Blood chemistries also reflect malnutrition and malabsorption. Diabetic patients have hyperglycemia, and hypoparathyroid patients may have hypocalcemia. Patients with connective tissue disease are positive for antinuclear antibody and/or the autoantibody SCL-70. Patients with thyroid disease have altered serum levels of triiodothyronine, thyroxine, and thyroid-stimulating hormone. Patients with muscular dystrophy may have elevated levels of CPK and isoenzymes. The results of hemagglutination testing and complement fixation for Chagas disease may be positive in patients who have lived in Central or South America.

Antineuronal nuclear antibody testing is required in patients with a history of smoking to exclude paraneoplastic pseudoobstruction. Determinations of blood lactate, pyruvate (signs of acidosis), CPK, AST and ALT (muscle damage), and leukocyte thymidine phosphorylase are used to screen for mitochondrial cytopathy.

Radiological studies

Plain abdominal radiographs

These are useful in patients with abdominal distention and bloating because they may show gaseous distention of the gastrointestinal tract. Upper gastrointestinal and small bowel radiographs may show lesions typical of certain diseases. Areas affected by severe dysmotility usually are dilated.

Enteroclysis

Enteroclysis, or small bowel enema [324], is useful to detect lesions in the small intestine and rule out mechanical obstruction. Experienced radiologists can identify structural lesions in the small intestine in up to 98% of patients with mechanical obstruction. Barium enema and intravenous pyelography may be useful in detecting abnormalities of the colon and urinary tract, respectively.

Computed tomography enterography (CTE)

Unlike conventional abdominal CT, CTE utilizes thin sections and large volumes of neutral contrast such as water or low-density barium, combined with intravenous contrast to evaluate the entire thickness of the small intestinal wall, and permits better visualization of deep ileal loops that are difficult to image with conventional small intestinal radiographs [325]. In addition, CTE permits the evaluation of extralumenal disease.

Whole-gut transit with radiopaque markers

Discrete, barium-impregnated, polythene markers that move with the colonic contents have become simple but robust measures of transit. Hinton and colleagues [326] measured gastrointestinal transit times using small solids (2–5-mm polythene pellets) containing barium sulfate. These inert radiopaque nonabsorbable markers, which have a specific gravity similar to that of gut contents, were completely recoverable in the stool. Followed by either abdominal or stool radiography, the movement of such markers was taken to represent the transit of meal residues through the gut (Fig. 47.23). Of 25 normal male subjects, all but one had passed 80% of the markers by the 5th day after ingestion, but none had passed 80% by the end of the 1st day.

Segmental colonic transit

The rate of disappearance of radiopaque markers from colonic segments was monitored with daily abdominal radiographs obtained after the administration of a single dose of radiopaque markers [327,328]. Right and left colonic, sigmoid, and rectal segments were defined simply by drawing lines between bony landmarks of the vertebral column and pelvis. Methods were then developed to calculate actual segmental transit times, rather than the rate of disappearance of markers from colonic segments [329].

Metcalf and colleagues [330] simplified this method so that only one radiograph, obtained with a fast, high-kilovolt technique, was necessary; radiation exposure was therefore minimal. By this method, a fixed number of radiopaque markers were taken (24 per day) at the same time each day (0900 hours arbitrarily) for 4 days. On day 5, again at the same time, a radiograph was obtained. The method works on the assumption that a 24-hour sampling interval approximates continuous observation. In rapid transit, all the markers can be lost in the feces before radiography on day 4; conversely, in slow transit, all 96 markers may be present on the single radiograph. A film obtained on day 7 can then provide more information.

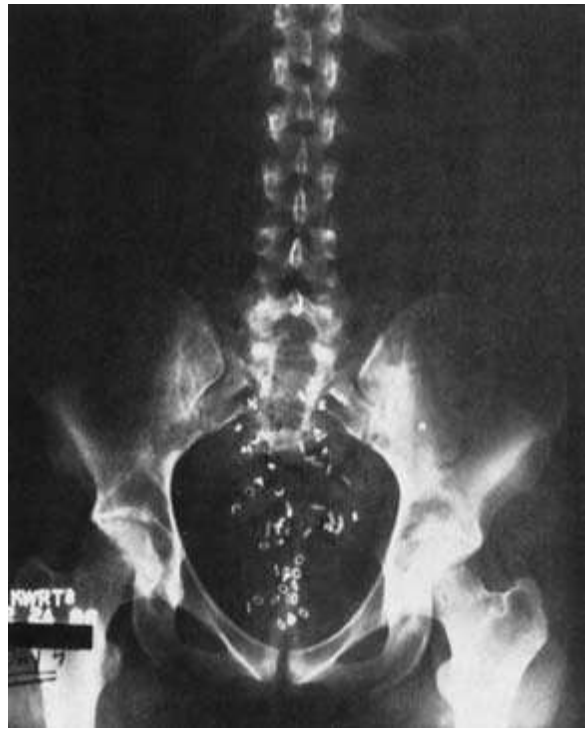

Figure 47.23 Radiograph of radiopaque markers as a measure of colon transit. Most of the markers are in the rectosigmoid colon of this patient.

Radioactive isotope transit by scintigraphy

The transit of gamma ray-emitting radioactive isotopes through the colon can be quantified with a gamma camera linked to a computerized recording and processing system [331]. The isotope can be monitored for long periods without increasing radiation exposure; this is not possible with methods using X-rays. The transit of solids and liquids can be measured simultaneously [332] if different isotopes are used to label liquid and solid bowel contents, and segmental regions of interest in the colon can be easily defined. A pH-sensitive polymer that dissolves at the pH of the ileum is used to coat capsules containing isotope-labeled beads [331]. With this approach, it has been possible to image the unprepared colon without the use of intubation; it is likely that such methods allow more "physiological" measurements of colonic transit.

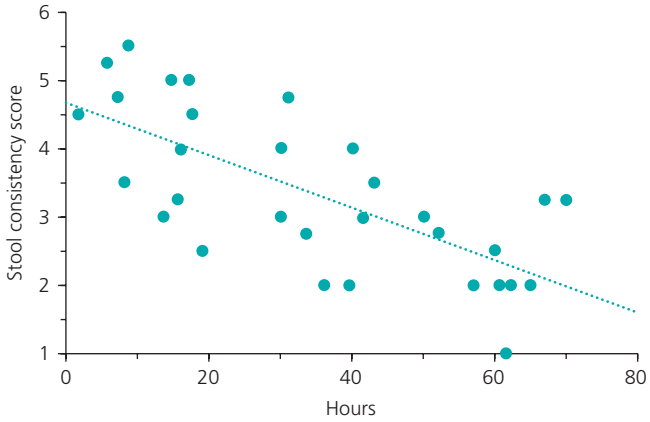

Figure 47.24 Correlation between mean colonic transit time (radiopaque markers) and physical appearance of stools (ranges from 1, small and hard, to 6, loose and semiliquid). From O'Donnell et al. [333], with permission from the BMJ Publishing Group.

The net effects of fast or slow colonic transit are most clearly seen in the consistency of the stools. O'Donnell and colleagues [333] developed a 7-point scale for describing stool form and consistency, ranging from liquids to hard solids; they were able to relate stool consistency to the overall mouth-to-anus transit time. Faster transit was associated with looser stools. Stool form was then related specifically to colonic transit [332] after colonic transit times had been altered experimentally by rapid cecal infusions of fluid. When this noninvasive approach was used [334] a good correlation was found between stool consistency and colonic transit; however, the correlation is clearly influenced by the extremes of transit and form, with little predictive value for stool that is not watery or extremely hard (Fig. 47.24).

Other studies

A biopsy of skeletal striated muscle may be required for patients suspected of having muscular dystrophy or mitochondrial cytopathy. Cultures of small bowel aspirates should be obtained from patients with clinically suspected bacterial overgrowth (e.g., steatorrhea, bloating). Small intestinal manometry is indicated if no known underlying disease is present and the nature of the dysmotility (myopathy vs neuropathy) is unclear.

If a full-thickness biopsy specimen of the dysfunctional part of the intestine is available, careful pathological examination for abnormalities in the smooth muscle or myenteric plexus with special trichrome and silver stains must be carried out. The most informative evaluation includes assessment of the neurotransmitters by immunohistochemistry and morphological assessment of the interstitial cells of Cajal with confocal microscopy.

Small intestinal manometry

A low-compliance water infusion technique is the method most often used for manometric studies of the small intestine, but ambulatory studies with miniature transducers and radiotelemetry are also used. Impedance measurements have the potential to provide pressure profiles from closely spaced sensors, although it is unclear whether these aid in the diagnosis.

The small intestine has a unique pattern of motility. During fasting, a cyclic pattern of motility, the MMC, is seen [335]. The MMC is divided into three phases. Phase I is a quiescent period that lasts for about 15 to 30 minutes. Phase II, which lasts for about 60 minutes, is a period of intermittent contractions that increase in frequency with time until phase III is initiated. During phase III, intense contractions propagate aborally from the duodenum to the ileum. Phase III lasts for 2 to 10 minutes. After phase III, the small intestine become quiescent again (i.e., enters phase I) to start a new MMC cycle. This cyclic pattern continues until the subject eats. After eating, the MMC is replaced by frequent, intermittent, irregular contractions – the fed pattern. The fed pattern usually lasts for 2 to 6 hours, depending on the size of the meal; after it is complete, the fasting pattern, or MMC, returns.

Small intestinal manometry has been used to study patients with various types of small intestinal dysmotility [132,133,139,157,160,175,177,184,224,318,336–343]. However, motility patterns are not diagnostic for any specific diseases. Many studies have been performed in patients with various clinical syndromes rather than specific diseases, which make the results difficult to interpret. Small intestinal motility studies have been performed in patients with small bowel bacterial overgrowth secondary to scleroderma [318], chronic neuropathic intestinal pseudoobstruction [132,139], autonomic disorders [344], FVM [5,17,27,338–340], nonfamilial visceral myopathy [30,340], FVN [58,59], nonfamilial visceral (paraneoplastic) neuropathy [209,211], scleroderma [157,159], myotonic dystrophy [224], and diabetes mellitus with gastroparesis [178,342,343]. Three important patterns have been recognized from these studies.

Visceral myopathic pattern

In patients with smooth muscle dysfunction or degeneration, manometry demonstrates a decrease in the frequency and amplitude of contractions in the affected segment, generally during both the fast and fed periods. During fasting, the MMC is usually present but is diminished in amplitude. Myoelectric recordings may reveal abnormalities of the slow wave, such as variability in rate or rhythm, and abnormalities of propagation, such as loss of coupling or shortening of the length or even changes in the direction of propagation. These recordings are characteristic of diseases involving the smooth muscle, such as FVM, advanced scleroderma, dermatomyositis, the muscular dystrophies, and amyloidosis [236,243,344]. Weston and associates [161] showed that in myopathic disorders, antral amplitudes are usually less than 40 mmHg and duodenal amplitudes less than 10 mmHg.

Visceral neuropathic pattern

Neurological disorders tend to produce disorganization and incoordination of motor activity. The MMC is often absent or abnormal. An abnormal rate of migration, as well as retrograde propagation of the activity front (phase III), also may be noted. Activity fronts may appear normal proximally and then become arrested or disappear in the more distal segments of the small intestine. In neurological disorders, the normal fed pattern may not replace the fasted pattern; MMC-like activity persists postprandially, and the frequency of distal antral contractions in the first hour is typically less than 1/min [161]. These abnormalities occur because the motility patterns are regulated by the ENS. The amplitude and frequency of contractions are usually normal when the inhibiting innervation and the coordinating function of the ENS are perturbed. Many of these abnormalities are seen best during sleep, when motor activity is stereotyped and normal phase II activity is suppressed [345]. The neurological disorders that have been described as producing manometric abnormalities include diabetes mellitus, Chagas disease, early scleroderma and amyloidosis, neurofibromatosis, paraneoplastic neuropathy, primary autonomic neuropathy, Parkinson disease, brain tumors, and multiple sclerosis [58,175,177, 194,244,346,347].

Mechanical obstruction pattern

Recurring episodes of intense contractions followed by periods of rest have been observed radiographically in the part of the intestine proximal to an obstruction. This phenomenon can be detected manometrically as clustered runs [139] or simultaneous prolonged contractions in conjunction with periods of intervening quiescence lasting longer than 1 minute (Fig. 47.25) [348,349]. Manometry is not the usual way to establish the diagnosis of mechanical obstruction, but these patterns should alert the physician to the possibility of mechanical obstruction and mandate careful small bowel barium radiography (e.g., enteroclysis).

Overall, small intestinal manometry lacks the specificity to diagnose the underlying disease other than suggesting the pathophysiological process. The relative merits of a laboratory-based study [350] and ambulatory manometry [351] have been discussed in the literature. From a diagnostic standpoint, the latter does not significantly enhance the results of the shorter laboratory-based studies, which have the added advantage of examining antral motor function more accurately; however, the ambulatory study is more practical and probably less costly.

Colonic manometry

Pressure waves recorded manometrically are generally equated with contractile forces. Colonic contractions are often irregular, of varying frequency and amplitude, and subject to the emotional state of the subject, the type of meal eaten, and the composition of chyme entering the colon from the ileum [352–356]. The colon is often "quiet" or exhibits isolated contractions (perhaps reflecting the dominant inhibitory control). At times, pressure waves are recorded in continuous bursts ranging in duration from 10 to 30 minutes [354], with a dominant frequency of approximately six contractions per minute in the right side of the colon and approximately three to seven per minute in the distal colon.

Phasic colonic contractions are stimulated by meals, beginning 20 to 30 minutes after a meal and lasting for up to 3 hours; sometimes, a second peak of activity occurs approximately

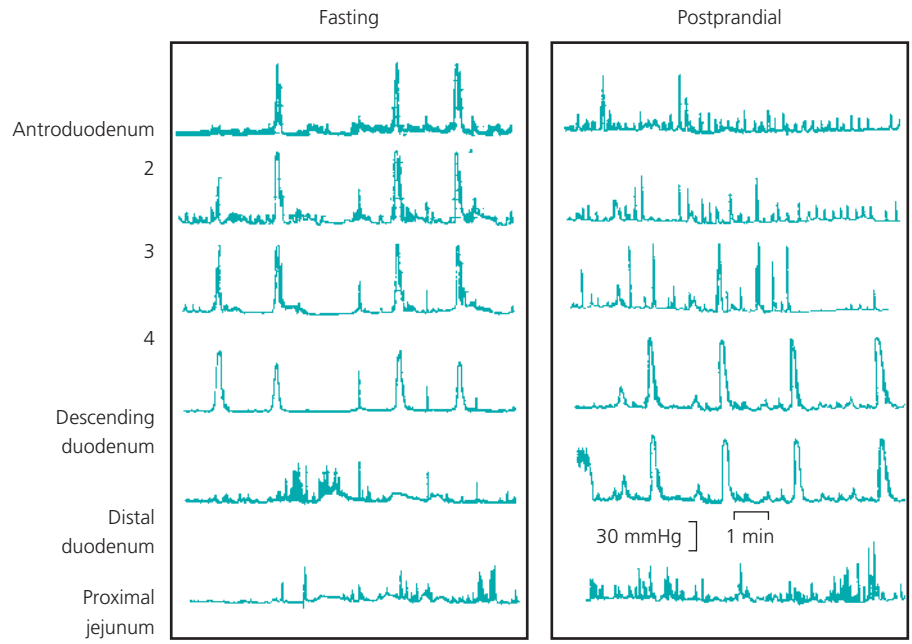

Figure 47.25 Gastroduodenal motility tracing demonstrating simultaneous prolonged contractions during fasting **(left)** and postprandial **(right)** phases. Contractions were present in the duodenum but not in the proximal jejunum (bottom tracing), a suggestion of mechanical obstruction in the distal duodenum or the proximal jejunum. From Loftus EV, Farrugia G, Donohue JH, Camilleri M. Duodenal obstruction: diagnosis by gastroduodenal manometry. Mayo Clin Proc 1997;72:130, with permission from Mayo Clinic Proceedings.

70 to 90 minutes postprandially [352–356]. This response to eating (gastrocolic reflex) remains after gastrectomy and after vagotomy [357]. If the stomach is intact, gastric distention and chemical stimulation by nutrients elicit a comparable response; ingestion of lipids or a total caloric intake of more than 500 kcal (2.1 MJ) are the most potent stimuli [1,358].

Control of the colonic response to eating involves neural and possibly hormonal mechanisms. The part of the response mediated by gastric mechanoreceptors is sensitive to blockade by atropine, but the part originating in the small intestine is only partially under muscarinic control. Cholecystokinin (CCK), which is normally secreted after meals, has been thought to play a role in the response because high blood concentrations of CCK stimulate contractile activity in both the small and large intestine. However, loxiglumide, a CCK A receptor antagonist, did not block the gastrocolic response to food [359]. Nitric oxide synthase blockade significantly increases the proximal colon propagating motor activity, suggesting that removal of nitrergic tone might be the physiological stimulus for proximal colonic emptying [360]. Low-amplitude irregular phasic activity does not propagate and probably equates with segmentation; on the other hand, high-pressure propagating waves are the equivalent of peristalsis. Isolated, high-amplitude (~ 200 mgHg) peristaltic contractions (Fig. 47.26), propagating at about 1 cm/s over long distances, are thought to be important for transit or "mass movement" in the colon. These occur infrequently (mean of six per day in healthy humans) and are most frequent after waking and meals [361]. They can be reliably induced by instilling irritants like bisacodyl [362] or fatty acids [363] into the colon. Endoluminal administration of 10 mg of bisacodyl is a potent stimulant capable of promoting high-amplitude peristaltic contractions (HAPCs) even in some patients who have manometric features of an inert colon [364].

An important variant of manometry uses the electromechanical barostat [1,365–367]. Originally developed to detect volume changes in the gastric fundus, the methodology is well suited for identifying relaxation in any hollow viscus. The 8–10-cm-long polyethylene bag used in humans is of large volume and "infinite compliance" until it reaches a volume of 500–600 mL. Air is introduced or withdrawn from the bag by a servomechanism to maintain a preset low pressure in the bag. Changes in volume are reflections of changes in wall tone. Basal tone in the proximal and distal colon exhibits rhythmic fluctuations [1], and food induces an immediate and prolonged increase in tone. The postprandial response is inhibited by 5-HT_3 blockers [368] and modified by hyperglycemia [369]. The rectum also shows a tonic response to eating [370], one that is impaired in patients with chronic slow-transit constipation [371]. The rectum also demonstrates prominent relaxation during distention [372–374].

Differential diagnosis of chronic intestinal pseudoobstruction and mechanical obstruction

In patients with severe dysmotility of the small intestine, chronic intestinal pseudoobstruction may develop. Partial small bowel obstruction from adhesions, tumors, intussusception, or stricture can mimic chronic intestinal pseudoobstruction. The features listed in Table 47.8 can be used to differentiate between these two problems. Enteroclysis, CT enterography, or careful small bowel radiography with fluoroscopy are probably the most helpful ways to differentiate

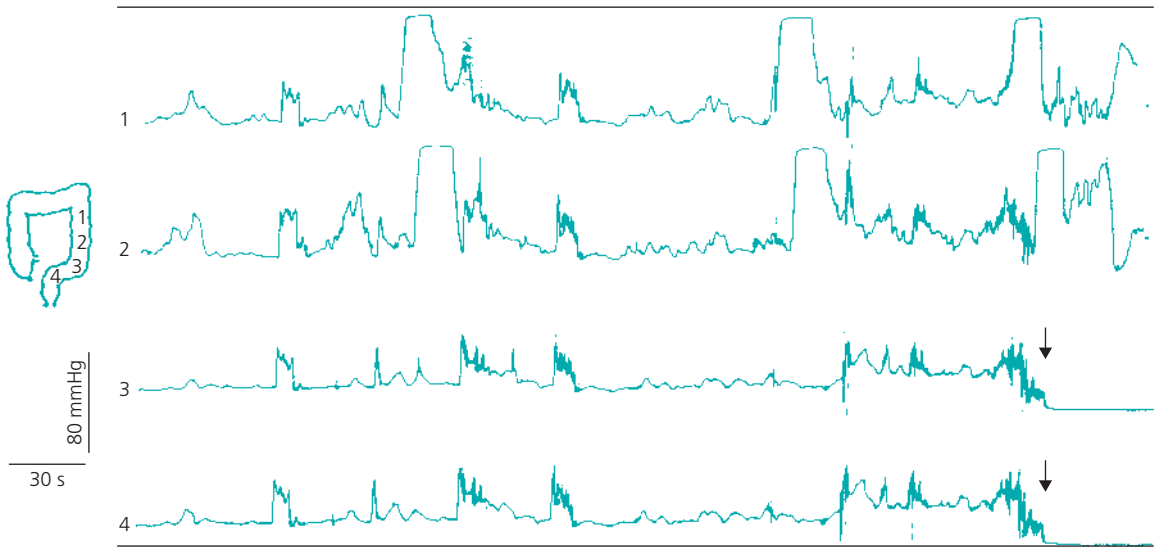

Figure 47.26 High-pressure waves recorded sequentially from four sites in the human colon. These contractions (giant migrating contractions) are thought to correspond to mass movements of colonic content. Their frequency is reduced in patients with constipation. From Narducci et al. [361], with permission from the BMJ Publishing Group.

Table 47.8 Differentiation of chronic intestinal pseudoobstruction from true mechanical obstruction

Feature	Chronic pseudoobstruction	Mechanical obstruction
Bowel symptoms	Diarrhea or constipation	Constipation and obstipation
Other gastrointestinal symptoms	± Dysphagia or symptoms of gastric atony	No esophageal or gastric problems
Between attacks	Abdominal pain, nausea, vomiting, or dysphagia	Usually symptom-free
Appearance	Cachectic	Seldom cachectic
Urinary symptoms	May have retention and infection	No urinary symptoms
Systemic disease	Symptoms and signs of systemic disease	No underlying systemic disease
Family history	Positive or negative	None
Abdominal radiography	Air throughout small bowel and colon	No air beyond point of obstruction
Esophagram	± Esophageal aperistalsis and dilation	Normal
Barium: stomach and small bowel	Gastric atony and megaduodenum	Bowel dilated above obstruction
Enteroclysis	No obstructing lesion	Obstructing lesion
Barium enema	± Redundant colon or wide-mouthed diverticula	Obstructing lesion
IVU	Megacystis or megaureter	Normal
Esophageal manometry	Diminished LES tone and low-amplitude contractions distal two-thirds (myopathy); incoordination (neuropathy)	Normal
Jejunal manometry	Fasting: absence of MMCs, and low-amplitude contractions (myopathy); fed: antral < 1/min, inactive fed pattern with MMCs (neuropathy)	Clusters, or simultaneous prolonged contractions fasting and fed periods, but MMCs during fasting
Exploratory laparotomy	No obstructing lesion found	Obstructing lesion

IVU, intravenous urography; LES, lower esophageal sphincter; MMC, migrating motor complex.

chronic intestinal pseudoobstruction from mechanical obstruction. In our experience, however, enteroclysis may not conclusively differentiate chronic intestinal pseudoobstruction from mechanical obstruction in some patients. Manometry proved useful in one series [349]; however, in most cases, exploratory laparoscopy may be necessary to rule out an obstructing lesion.

Treatment

Drug therapy to improve small intestinal motility

Theoretically, it is difficult to envision a drug that can either stimulate damaged muscle to contract effectively or normalize the coordinating functions of a damaged myenteric plexus. Many drugs that stimulate intestinal motility in normal subjects (e.g., bethanechol, neostigmine, metoclopramide, erythromycin, prucalopride) have no beneficial effects in patients with small intestinal dysmotility. No information is available on the use of domperidone for small bowel dysmotility. Tegaserod accelerates small intestinal transit, proximal colonic emptying, and overall colonic transit in constipation-predominant IBS [375].

In a small, short-term study, octreotide, a somatostatin analogue, stimulated intestinal motility, possibly reduced bacterial overgrowth, and relieved abdominal symptoms in patients with scleroderma [157]. Other open-label studies confirmed the long-term effectiveness of octreotide with erythromycin in the treatment of chronic intestinal pseudoobstruction [288].

Symptomatic and supportive treatments

Abdominal pain, bloating, nausea, and vomiting in patients with small intestinal dysmotility are often related to eating. Most of these symptoms can be minimized by manipulating the size, nature, and frequency of meals. The important point to keep in mind is to provide sufficient calories without overloading the inefficient bowel. A rule of thumb is to give approximately 25 kcal (105 kJ/kg) of the patient's ideal bodyweight per day. Adult patients should consume 1500 to 1800 kcal (6.3–7.5 MJ.day), divided into three or four equal feedings. A low-residue diet may reduce obstructive episodes. At least half of the calories should come from supplemental formulas such as Ensure because a liquid meal empties faster from the stomach and probably progresses more easily through the small bowel than a solid meal. These formulas are lactose free and contain the daily requirements of vitamins and minerals. When patients still feel full several hours after the first meal, it is important that they do not force themselves to eat subsequent meals to avoid aggravating their symptoms, and they that restrict their oral intake to fluids for the rest of the day.

In patients with chronic intestinal pseudoobstruction, recurrent symptoms and signs of intestinal pseudoobstruction may occur despite implementation of the previously described regimens. In these situations, nasogastric suction and intravenous fluids are needed when obstructive symptoms develop. When obstructive symptoms and pain persist or occur several times a week despite dietary manipulation,

long-term parenteral nutrition or small intestinal transplantation are the only treatments that will relieve symptoms and improve nutrition.

Abdominal pain unrelated to eating is uncommon in patients with small intestinal dysmotility, and if a patient has pain predominantly unrelated to meals, questions should be raised about the diagnosis. During episodes of obstruction, parenteral administration of narcotics such as morphine or meperidine may be required. Long-term narcotic use should be discouraged because addiction is possible, and narcotics can further disturb gastrointestinal motility.

Constipation is common in patients who also have colonic involvement. It is important to make certain that the patient has a good bowel movement at least once every few days because constipation tends to increase the symptoms of intestinal dysmotility. We recommend a daily osmotic laxative, such as magnesium hydroxide or polyethylene glycol, and a bisacodyl suppository if the patient has no bowel movement for 3 days. Those with severe small intestinal dysmotility should avoid bulk-forming laxatives because they increase the load on an inefficient intestine and exacerbate symptoms.

Treatment of secondary causes

A few types of secondary small intestinal dysmotility, such as those associated with myxedema, celiac sprue, and drug-induced dysmotility, can be treated with thyroid replacement, a gluten-free diet, and discontinuation of the offending drug, respectively. No specific treatments are available for most of the secondary types of small intestinal dysmotility.

Surgical treatment

Patients with dysmotility limited to short segments of the small intestine, such as those with megaduodenum, have a better prognosis than those with dysmotility throughout the length of the bowel because the dysfunctional segment can be resected or bypassed [376]. Megaduodenum, which is commonly seen in FVM type I and scleroderma, has been drained with a side-to-side duodenojejunostomy, which usually relieves symptoms. In some patients with a massively dilated duodenum, a side-to-side duodenojejunostomy may be inadequate to drain the duodenum. In these cases, resecting as much of the duodenum as possible with preservation of the papilla of Vater and anastomosing the opened jejunum to the cut edge of the duodenum to create a small conduit may be required as treatment [13,377].

For patients with long segments of small intestinal dysmotility (i.e., > 1.2 m), no effective surgical treatment is available. Any unnecessary surgery should be avoided in these cases because it can create adhesions and additional difficulties. Venting decompression by percutaneous jejunostomy or minilaparotomy or laparoscopy relieves symptoms and reduces the rate of hospitalization for recurrent exacerbations of pseudoobstruction [378,379].

Small bowel transplantation

Small bowel transplantation has become a reality, with acceptable benefit-to-risk ratio and outcomes with the introduction of isolated small bowel transplants, judicious timing of transplant, and a team approach. There is no definite consensus on indications but experienced teams recommend that those adult and pediatric patients with no jejunoileum who have guaranteed lifelong parenteral dependence, should be immediately referred to a transplant center because of the high likelihood of the development of liver disease. Similarly, patients with metastatic infectious complications from catheter sepsis, or cholestasis seen intermittently with sepsis episodes, progressive thrombocytopenia, and those with deteriorating motility disorder should be referred to an intestinal rehabilitation and transplant program. The objective of evaluation at such centers is to maximize the opportunities for rehabilitation (e.g. relief of adhesive obstruction or other "surgical complications" that compromise bowel function) while not missing the critical window of opportunity for successful transplantation when needed. Psychological preparation for transplantation and other options, while not rushing to judgment, will avoid a premature transplant [380,381]. Graft and patient survival are expected to be 80% at 3 years in a successful program. Survival has been enhanced by effective immunosuppression (chiefly tacrolimus and mycophenolate) and the less frequent need for immunosuppression by avoiding unnecessary grafts when the recipient's organ is not failing. Thus, outcomes have improved with increased experience, the avoidance of splenectomy, optimization of immunoregulatory regimens (administration of interleukin-2 receptor antagonists), and improved controls of viral infections and rejection [382]. In reaching a decision about transplantation, it is important to recall that the 3-year survival of patients on home total parenteral nutrition (TPN) is 85% [383].

Several factors limit the success of small bowel transplantation and may result in death: infection (including cytomegalovirus and Epstein–Barr virus, which together account for approximately 50% of deaths); rejection (approximately 8% of deaths); technical problems; and lymphoproliferative disease (20%–40% of deaths in different programs). The latter is particularly linked to Epstein–Barr virus infection, the use of OKT3 (muromonab-CD3) immunosuppression, and steroids [384,385].

In general, small bowel transplantation is restricted to life-threatening situations, such as necrotizing enterocolitis, intestinal failure (short bowel syndrome) in patients who cannot be maintained on TPN, and rarely chronic intestinal pseudoobstruction in young patients who have TPN-related or other liver failure and lack intravenous access for TPN.

In the future, gastroenterologists may be involved in the management of patients after small bowel transplantation. Observations that are likely to affect this practice include the following:

- zoom videoendoscopy is capable of showing the enlarged crypt areas and villus blunting or flattening that correlate with histological evidence of rejection [386]
- severe rejection (mucosal necrosis with loss of villi) is of grave prognostic significance (11% graft survival, 18% patient survival) [387] and, pending newer immunosuppressive regimens, may be an indication for removal of the graft
- living-related small bowel transplantation is technically feasible and has been reported to be followed by complete functional adaptation of the graft [388].

It is clear that survival after this formidable procedure depends on the experience of the entire transplant team and center, and aggressive treatment of infection and rejection. The rate of mortal complications, including lymphoproliferative disease, remains high [389]. The use of tacrolimus in immunosuppression is associated with a fivefold increase in lymphoproliferative disease relative to cyclosporine (ciclosporin) in children receiving liver transplants [390]. Molecular methods to screen for Epstein–Barr virus infection, improved immunosuppression, and possibly bone marrow transplantation to enhance chimerism may change the biology or prevalence of lymphoproliferative complications in the future.

Colonic dysmotility (pseudoobstruction) and megacolon

Interstitial cells of Cajal in maldevelopment and acquired diseases of the colon

The significance of the interstitial cells of Cajal (ICCs) was established during the mid-1970s and 1980s through the careful histological and electrophysiological observations of Faussone-Pellegrini and colleagues [77,78] and Thuneberg [79]; the latter established the candidacy of ICCs as the intestinal pacemaker cells. The protooncogene c-*Kit* encodes a tyrosine kinase receptor that facilitates the development of the ICCs [391]. Furthermore, mice with mutations in the dominant white spotting (*W*) locus, which have cellular defects in hematopoiesis, melanogenesis, and gametogenesis as a result of mutations in the c-*Kit* gene, also lack the network of ICCs and intestinal pacemaker activity [392]. In the 1990s, the role of ICCs became more clearly understood through studies of a mutant strain of mice (w/w^v) that lack c-KIT-positive cells and in which gastrointestinal dilation and failure of peristalsis develop [393–397].

Typically ICCs are surrounded by collagen fibers and form close contacts (Fig. 47.27) with smooth muscle cells [393]. These gap junctions with smooth muscle cells allow transmission of the pacemaking activity, which is unaffected by 10^{-6}-M verapamil, an L-type calcium channel blocker [393]. When studied in short-term primary culture, ICCs assume a triangular shape with three to four branches that are in apposition with cocultured smooth muscle cells (Fig. 47.28). Huizinga, Ward, Sanders, and their colleagues [394–396] have characterized the expression profiles of pacemaker ICCs isolated from the murine small intestine and of ICCs and smooth muscle cells involved in neurotransmission in the gastric fundus. All cell types express muscarinic receptor types M_2 and M_3, neurokinin receptors NK_1 and NK_3, and the inhibitory type 1 vasoactive intestinal peptide receptor (VIP_1) [396].

In clinical studies, a relative deficiency of c-KIT-positive cells has been reported in Hirschsprung disease, chronic intestinal pseudoobstruction [397,398], gastrointestinal stromal tumors, multiple gastrointestinal autonomic tumors [399,400], and idiopathic slow-transit constipation [401–403].

Delayed maturation or maldevelopment of ICCs is well documented (Fig. 47.29) [404]. At 1 month of age, a child with chronic colonic pseudoobstruction underwent biopsy of the affected colon, which showed no peristaltic activity and no c-KIT immunoreactivity within the circular muscle layer or the submuscular layer (see Fig. 47.29) but a normal ICC population in the myenteric plexus. At 6 months of age, the peristaltic activity was normal, and the ICCs were fully developed in all layers of a full-thickness biopsy specimen of the colon. This careful case study illustrates the following points:

- the concept of postnatal maturation of ICCs
- the importance of the conservative management of children with neonatal megacolon or pseudoobstruction
- the importance of ICCs to the overall peristaltic function of the colon.

Little is known about the transmitters expressed by ICCs in disease. However, immunoreactivity to the NK_1 receptor has been detected in ICCs and may be used as a marker of the ICCs at the deep muscular plexus; these cells may participate in the actions exerted by tachykinins on muscle cells [405].

Megacolon in an adult has also been associated with abnormal morphology and ultrastructure of ICCs. Faussone-Pellegrini and colleagues [406] demonstrated ICCs with several branches in the dilated transverse colon, but abnormal ICCs with a paucity of mitochondria, filaments, and caveolae in the nondilated descending colon.

In patients with acquired slow-transit constipation not associated with colonic dilation, the number of ICCs in the different layers of the sigmoid colon is lower (Fig. 47.30) than in controls (specimens resected for other indications). Moreover, the confocal images show irregular surface markings and a paucity of branches of the cells (Fig. 47.31) [401]. Staining of myenteric plexus for c-KIT is reduced, consistent with a reduction of ICCs or their tyrosine kinase content. In addition to the reduction of ICCs, there also appears to be a significant decrease in other neuroenteric elements, including gangliar cells, glial cells, and enteric neurons in the colons of patients with idiopathic slow-transit constipation [407].

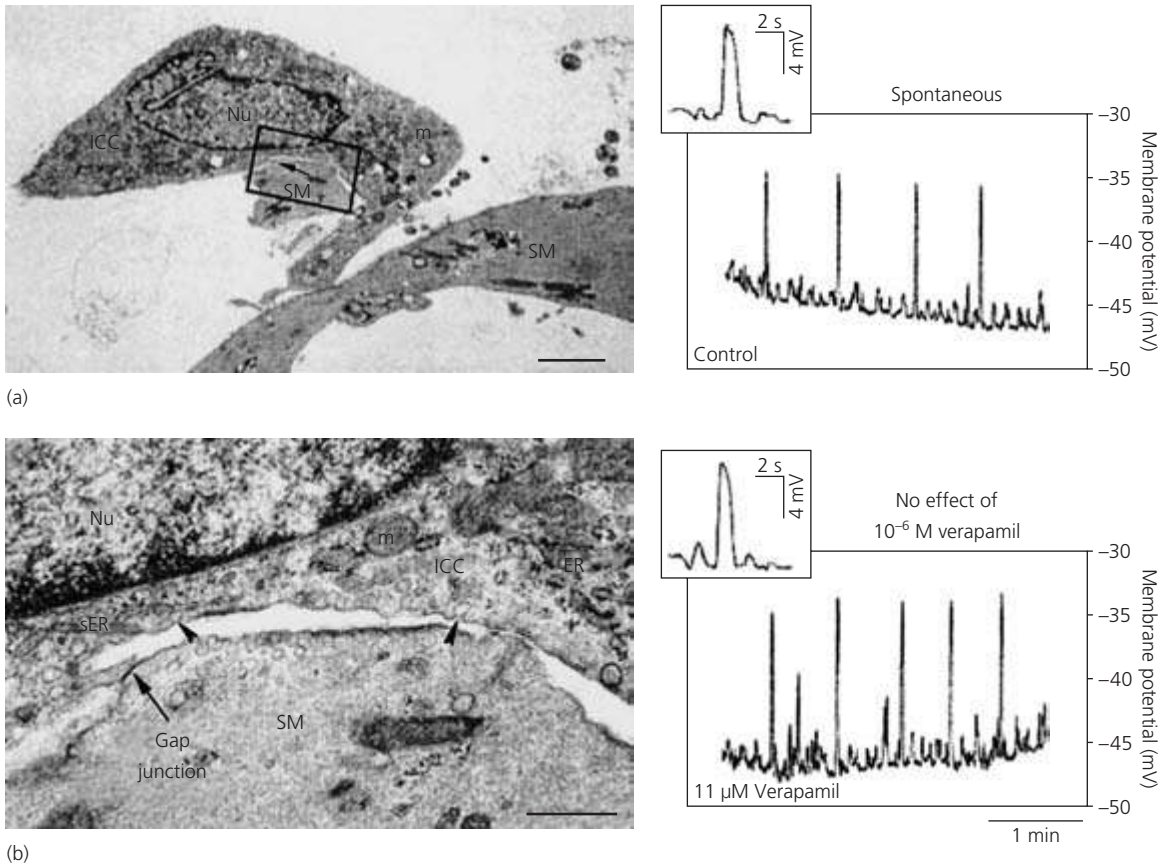

Figure 47.27 Gap junctions between interstitial cells of Cajal and smooth muscle cells; note the spontaneous electrical oscillations of the resting membrane potential of the interstitial cells of Cajal and the lack of inhibition by the L-type calcium channel blocker verapamil. From Lee et al. [393], with permission from the American Physiological Society.

Syndromes generally attributed to disorders of colonic motility

Constipation

Patients consider themselves to be constipated when they pass stools more infrequently, require more effort for passage ("straining"), or experience more pain or discomfort during passage than they think appropriate. Difficult evacuation of feces, especially when the consistency of stools is softer than normal, is more likely to be caused by disorders of the pelvic floor or anorectum than by slow colonic transit. Disorders of the pelvic floor are disturbances of evacuation (dyschezia, obstructed defecation) and are not considered here (see Chapters 43 and 92).

Slow transit through some or all segments of the colon leads to the formation of hard fecal masses that are passed infrequently and often with great difficulty. This condition, slow-transit constipation (STC), should be considered as separate from IBS and should be diagnosed only if abdominal pain is not a prominent feature. However, STC certainly merges with IBS when pain, abdominal distention, excessive rectal mucus, and intermittent episodes of frequent, looser stools also occur (see Chapter 86). STC is considered in the next section.

Slow-transit constipation (STC)

Figure 47.23 shows radiopaque markers retained predominantly in the distal colon (rectosigmoid segment) 96 hours after ingestion [326]. This technique is simple, inexpensive, and of proven value in the documentation of STC [326–330]. Gamma scintigraphy [331] offers another means of testing that can be of shorter duration (24 or 48 hours). Whatever method is used, the implications for therapy are potentially important. Most patients with STC respond to laxative programs, suppositories, or enemas. Resective surgery of the colon (usually subtotal colectomy with ileorectostomy) is occasionally necessary for severe STC. When tests of pelvic floor function identify a clinically relevant abnormality, colectomy is not indicated, even in the presence of slow transit. Retraining programs for the pelvic floor should first be used to correct the defect in expulsion, after which transit can be retested.

Manometry

In STC, the normal high-amplitude pressure (peristaltic) waves in the colon are reduced. Hirschsprung disease, or congenital megacolon (see "Hirschsprung disease: congenital

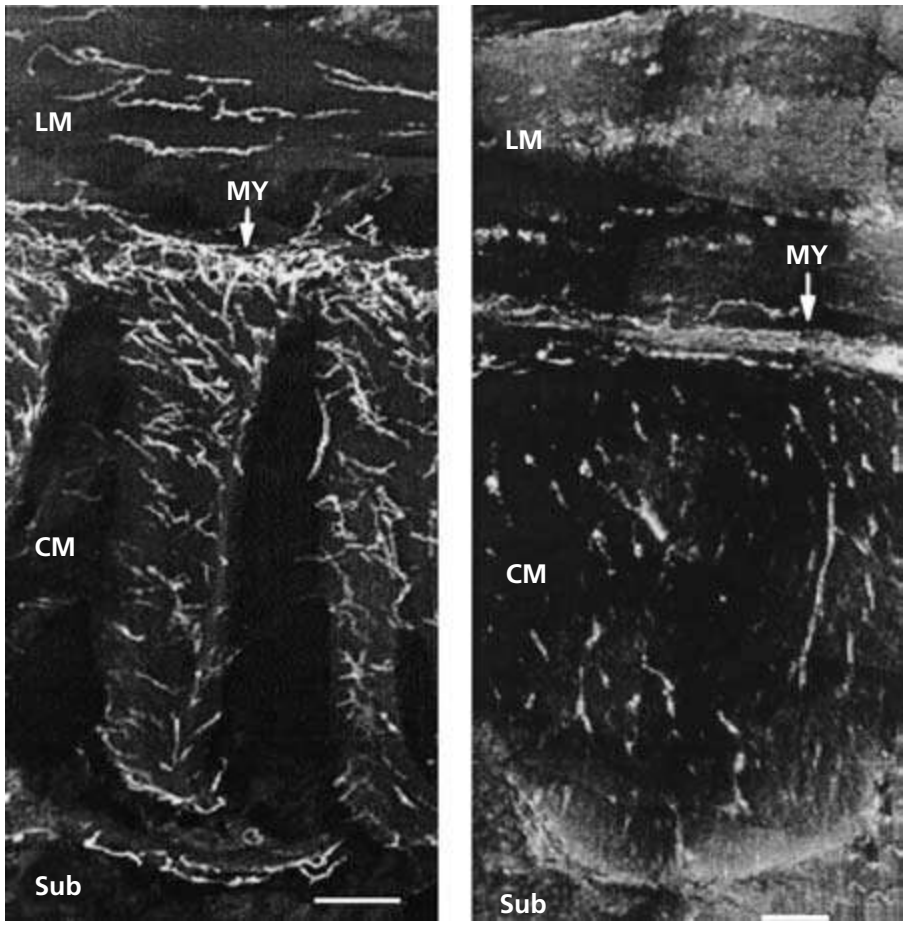
megacolon" below), is a special case in which the pathophysiological abnormality is absence of relaxation of the internal anal sphincters, manifested by absence of the rectoanal inhibitor reflex.

Myoelectric patterns

Myoelectric patterns have confirmed the concept of "paradoxical colonic motility:" patients with diarrheal disease often have a colon that demonstrates relatively little overall



(a) (b)

myoelectric activity, whereas those with constipation often have active motor patterns that favor "holding up" contents.

Histopathology

Many patients with STC severe enough to warrant subtotal colectomy display histological changes in the ENS of the resected colon on silver staining. Table 47.9 summarizes the information derived from a number of studies in the literature [401,408–418]. In general, it appears that reduced levels of substance P and increased numbers of nitrergic neurons are associated with constipation that leads to surgical resection of the colon. In Parkinson disease, evidence is found of a reduction in the dopamine content of the myenteric plexus and a significant reduction in the dopamine-positive neurons of whole mounts of the plexus [419].

Ultrastructural quantitative studies have demonstrated abnormalities of the morphology and numbers of ICCs [401]. It is assumed, therefore, that these patients have a morphological abnormality of the neural control of colonic motility. These clinical and histopathological features appear to merge with the syndromes of intestinal pseudoobstruction (see "Colonic pseudoobstruction and megacolon" below). The treatment of constipation is addressed in Chapter 000.

Colonic pseudoobstruction and megacolon

Megacolon (Table 47.10) and *megarectum* are descriptive terms without etiological or pathophysiological implications. *Megacolon* has been defined as a diameter of the rectosigmoid region or descending colon, on radiography, of more than 6.5 cm, of the ascending colon of more than 8 cm, or of the cecum of more than 12 cm [420]. Megacolon can be caused by aganglionosis (Hirschsprung disease), may be idiopathic (complicating chronic constipation of any cause), or may be a manifestation of diffuse gastrointestinal dysmotility (intestinal pseudoobstruction). *Acute megacolon* is often designated as *Ogilvie syndrome*. Rectal dilation, or megarectum, may be an isolated finding or, more often, associated with megacolon or simply prolonged chronic constipation, particularly in children with functional fecal retention. Note that megacolon does not include simple elongation of the colon (dolichocolon).

In *congenital megacolon* (Hirschsprung disease), colonic dilation results from functional obstruction (usually of the

rectum) caused by a congenital absence of the intramural neural plexuses that mediate relaxation (aganglionosis). This leads to a narrow segment of the large intestine – that is, one that fails to relax.

Acquired megacolon can complicate any of the many causes of constipation, and it can be assumed that megacolon is acquired when it can be ascertained that colonic dilation was not present at some earlier examination. A common background for acquired megacolon is colonic inertia, which occurs frequently at both extremes of life. In children, this form can be confused with the congenital condition.

Worldwide, infection with *Trypanosoma cruzi* (Chagas disease) is the most common form of acquired megacolon. In this condition, the dilated segment of colon is abnormal because of destruction of the ENS by the neurotoxin of the infecting organism. Although infection was originally confined to the South American continent, it is estimated that there are 350 000 seropositive persons in the United States; among these, one-third are thought to have chronic Chagas disease [421]. Some patients acquire megacolon as part of a generalized intestinal pseudoobstruction.

When colonic pseudoobstruction is acute and associated with another medical condition (abdominal or orthopedic surgery, spinal cord injury, serious cardiovascular or other medical problems), the term Ogilvie syndrome is often applied. Toxic megacolon is a life-threatening complication of inflammatory bowel disease and infectious colitides (see Chapters 000 and 000).

Hirschsprung disease: congenital megacolon

Pathophysiology

Aganglionosis is caused by the arrested migration of cells caudad from the neural crest; these are the cells destined to develop as the intramural plexuses of the gut. In Hirschsprung disease, the aganglionic segment always extends from the internal anal sphincter for a variable distance proximally, but in most instances it remains within the rectum and sigmoid colon. The involvement of short segments, affecting only the anal sphincters, has also been described. The aganglionic segment is permanently contracted, causing dilation proximally. Longer aganglionic segments occur in fewer than 20% of affected individuals; involvement of the entire colon is infrequent, and aganglionosis extending proximally into the small intestine is rare. Thus, the hallmark of diagnosis is the absence of ganglion cells from the myenteric and submucosal plexuses, as seen on a full-thickness or suction

Table 47.9 Colonic neuropathology in slow-transit constipation

Histological and immunohistochemical findings	References
Decreased number or abnormal appearance of silver-staining neurons or axons; increased number of variably sized nuclei within ganglia	Krishnamurthy et al., 1985 [408]

Table 47.10 Clinical classification of megacolon

Congenital megacolon (Hirschsprung disease)
"Classical" type
Short segment
Ultrashort segment
Total colonic aganglionosis, zonal loss of ganglia, and other variants

Acquired megacolon (associated with constipation)
Idiopathic
In children (associated with encopresis)
Acute form in adults (Ogilvie syndrome)

Secondary to neurological diseases
Chagas disease
Parkinson disease and central nervous system dysfunction; myotonic dystrophy
Diabetic neuropathy; others (ganglioneuromatosis, familial autonomic dysfunction)
Intestinal pseudoobstruction ("neurogenic" forms)

Secondary to diseases of intestinal smooth muscle
Scleroderma and other "collagen diseases;" amyloidosis
Intestinal pseudoobstruction ("myogenic" forms)

Secondary to metabolic diseases
Hypothyroidism, hypokalemia, porphyria, pheochromocytoma (with ganglioneuromatosis)

Drugs

Mechanical obstruction

(mucosal–submucosal) biopsy specimen of the rectum. Proximal contents fail to enter the unrelaxed aganglionic segment.

Morphologically, ganglion cells are absent from the narrowed segment and for a short distance (usually 1–5 cm) into the dilated segment. In contrast, the nerve fibers are hypertrophic, with abundant, thickened bundles. Specific stains for acetylcholinesterase highlight the abnormal morphology. Adrenergic denervation of the dilated segment is another inconsistent finding, as is a decreased supply of peptidergic nerves (containing VIP, substance P, enkephalins, and other peptides).

The most characteristic functional abnormality of aganglionosis is a failure of the internal anal sphincter to relax following rectal distention [422]. Transient distention of a balloon in the rectum causes the intralumenal pressure at the level of the internal anal sphincter to drop; the drop is often accompanied by a reflex contraction of the external sphincter. Up to 20% of normal children may have a falsely absent reflex, especially if they are premature or of low birthweight, but a positive response is strong evidence against Hirschsprung disease.

Incidence and genetics

The defect occurs once in each 5000 live births and is in some cases familial, with an overall incidence of 3.6% among siblings of all index cases [423]. Because the disease was lethal until the introduction of curative surgery in the 1950s, accurate assessment of the incidence in the offspring of

successfully treated patients is incomplete. Consanguinity of parents is exceptional, and the condition is reported to be discordant in dizygotic twins and concordant in monozygotes.

The association of congenital aganglionosis of the colon with Down syndrome is ten times more frequent than would be expected by chance [423]; approximately 2% of patients with congenital megacolon have Down syndrome. A number of other congenital anomalies have been reported: hydrocephalus, ventricular septal defect, cystic deformities and agenesis of the kidney, cryptorchidism, diverticulum of the urinary bladder, imperforate anus, Meckel diverticulum, hypoplastic uterus, polyposis of the colon, ependymoma of the fourth ventricle, the Laurence–Moon–Bardet–Biedl syndrome, and congenital central hypoventilation syndrome (Ondine curse).

The genetic disorders resulting in disordered development of the neural crest in Hirschsprung disease are discussed in detail above (see "Ontogeny of the enteric nervous system").

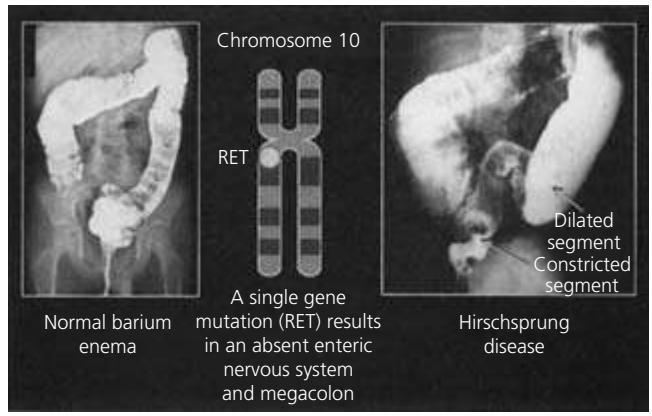

Figure 47.32 Barium enema in a normal child contrasted with a study showing megacolon and a narrow segment affected with Hirschsprung disease. The genetic defect involves a mutation of the *RET* protooncogene on chromosome 10q11.2.

Clinical features

Hirschsprung disease should be suspected shortly after birth when the infant passes little meconium and the abdomen is distended. Digital examination of the rectum, insertion of a rectal tube, or administration of a small enema causes retained fecal material to gush forth, with apparent relief of the symptoms. However, the respite is often short-lived; signs of partial intestinal obstruction return, with persistent vomiting and distention as the major features. In about 20% of patients, diarrhea persists; it is caused by pseudomembranous enterocolitis, which develops as a complication of the obstruction.

Later in life, the presentation is often less dramatic and may not mimic an acute intestinal obstruction. Severe constipation and recurrent fecal impactions are more common. Children occasionally show evidence of anemia, malnutrition, and even hypoproteinemia resulting from protein-losing enteropathy; their resistance to infection can also be impaired. Although difficulties develop in most children before the second month of life, extremely-short-segment aganglionosis may not cause severe symptoms until after infancy.

Differential diagnosis

Hirschsprung disease must be distinguished in the neonate from other developmental causes of intestinal obstruction, such as atresias and imperforate anus. Later in life, acquired (secondary) megacolon is the other major consideration. The diagnosis of congenital megacolon is usually not difficult beyond the immediate neonatal period, and the availability of improved diagnostic methods enables a positive diagnosis in most cases. Obstipation, with infrequent spontaneous passage of stool, dates from infancy, and the rectal examination reveals an empty ampulla. Overflow incontinence is not a feature of Hirschsprung disease.

A barium enema radiograph (Fig. 47.32) confirms the diagnosis if the characteristic transition from the narrowed, distal rectum or rectosigmoid to the dilated proximal colon is seen. However, when the aganglionic segment is extremely short, a narrowed segment is not seen radiologically. In patients with acquired megacolon, encopresis is common, dilation extends all the way to the anus, and a narrowed zone is not seen.

Proctosigmoidoscopy reveals a normal but empty rectum. The dilated proximal bowel, if within range of the scope, is easily traversed except for abundant feces in the lumen; occasionally, stercoral ulcers are noted. The key findings are the empty lower segment and the absence of evidence of organic obstruction.

The diagnosis is best substantiated by a full-thickness biopsy of the rectum. The presence of normal numbers of ganglion cells excludes the diagnosis. Mucosal suction biopsy, satisfactory in many instances, is the initial procedure of choice because it is performed easily and requires no anesthesia. If the depth of the examination is sufficient to show the presence of ganglia in the Meissner (submucosal) plexus, the classic form of Hirschsprung disease is excluded. However, the absence of ganglion cells does not establish the diagnosis, and a full-thickness biopsy specimen should be obtained at least 3 cm proximal to the pectinate line. A diminution or absence of ganglion cells distal to this point is difficult to interpret. Careful histology proximal to the internal sphincter reveals that myenteric ganglia may be absent from normal infants over a distance of 4 to 5 mm in this segment; ganglia may be absent from the deep and superficial submucosal layers for even longer distances. Immunohistochemical techniques can highlight the morphological abnormalities, showing an abundance of hyperplastic axons but an absence of ganglion cells. Several approaches employing antibodies to acetylcholinesterase, neuron-specific enolase, neurofilament, and neuropeptides have been described [424,425].

Physiological tests complement the diagnosis in doubtful cases, and they may be crucial when the aganglionic segment is short. Such cases are less easily detected by radiography and are also likely to be missed by biopsy. The most important pathophysiological test is the response of the anal sphincters to distention of the rectum [422]. In contrast to the internal sphincter in normal individuals and in patients with acquired megacolon, the internal sphincter in patients with congenital aganglionosis fails to relax (or contracts even further) after the rectum is distended. The most common cause of a false-positive test result is a capacious rectum in constipation or megarectum; under these circumstances, distention of the rectal balloon does not stimulate the reflex. Therefore, an enlarged rectum should be excluded before Hirschsprung disease is diagnosed.

Treatment of congenital megacolon

Definitive surgical cure is the treatment of choice. Preliminary decompression by colostomy is still sometimes necessary to relieve obstruction, or it may be necessary in some infants when it is decided to postpone definitive surgery. However, the goal should be early diagnosis and a one-stage surgical approach.

The main goals are to establish regular and spontaneous defecation, to maintain normal continence, and not to interfere with sexual potency. The surgical procedure should cause essentially no mortality and minimal morbidity. A number of different operations have been used to remove successfully or to counterbalance the obstructing effect of the aganglionic segment. Long-term results are good in the great majority of patients, but 10% to 20% have residual problems, usually with fecal soiling [426].

Variants of congenital megacolon

The spectrum of Hirschsprung disease has widened considerably. Patients with a compatible clinical picture may have an ultrashort segment of aganglionosis, involving only the internal anal sphincter [427]. Morphological confirmation of the diagnosis may be difficult, and physiological testing becomes even more important. Patchy or zonal loss of ganglia (ladder pattern) and dysplastic neurons have also been described. Cases classified as acquired aganglionosis have been reported. In these, ganglia were seen in tissues removed at an initial operation, but when clinical failure led to further surgery, an aganglionic segment was clearly demonstrable. Rather than these being cases of acquired disease, it seems more likely that a short aganglionic segment was missed on the initial evaluation. With greater awareness of the more subtle morphological and physiological abnormalities, Hirschsprung disease is being detected more often in adults [428]. The clinical, physiological, and morphological features in adulthood are usually similar to those of the milder form of the disease when recognized earlier in life. Thus, congenital megacolon (Hirschsprung disease) can be subdivided into the classic form, short-segment types, ultrashort-segment types, and other variants (see Table 47.10).

Acute megacolon

Acute toxic megacolon occurs in patients with severe, fulminant inflammatory bowel disease or infectious colitis (see Chapters 83 and 88); the colon also dilates in response to acute distal obstruction (e.g., volvulus or carcinoma). However, pseudoobstruction and acute megacolon can occur without evidence of intrinsic colonic disease or mechanical obstruction. In this latter instance, the patient has a form of acute colonic pseudoobstruction, named after Ogilvie [429]. In fact, the condition he described in two patients was longstanding and caused by malignant infiltration of mesenteric nerves. Regardless of the misnomer, the syndrome, given Ogilvie's name, should be considered as a form of pseudoobstruction localized to the colon; the characteristic time course is acute or subacute. Moreover, most cases are clearly associated with an underlying disease; the most common predisposing conditions described in a metaanalysis of 400 cases were trauma, orthopedic surgery, obstetrical procedures, pelvic and abdominal surgery, metabolic imbalance, and neurological conditions [430].

Pathophysiology

The precise cause of acute colonic pseudoobstruction is unknown. However, Ogilvie syndrome is the clearest example of the human colon dilating in response to nonmechanical factors. Ogilvie proposed that an imbalance of intrinsic and autonomic neural control is the basis for the syndrome [429]. This propensity of the human colon to relax and dilate has been studied experimentally with the barostat [1]. In these experiments, wall tone decreased markedly during sleep and in response to glucagon; a model of colonic dilation during acute distention of the ileum has been described in dogs [431]. This concept, that the wall of the colon can relax readily in response to physiological and pharmacological stimuli, may be an important basis for megacolon.

Clinical presentation

The typical patient is a middle-aged or older person who is recovering uneventfully from surgery performed a few days previously and who is already on a general diet. In one report [432], more than half the patients had undergone recent surgery or manipulation of the spine or retroperitoneum. The abdomen becomes grossly distended and breathing becomes labored, but early in the course no peritoneal signs are present and the white blood cell count is normal. An abdominal film shows massive gaseous distention of the colon with air distributed throughout, including the rectum. Usually, the small bowel is not seen. The diameter of the cecum at this point is often 9–10 cm.

Initial management

Oral feedings should be stopped, parenteral fluids started, and a nasogastric tube passed; all nonessential drugs should be discontinued. A Hypaque (water-soluble contrast) enema is administered; in this way, mechanical obstruction can be excluded and pseudoobstruction confirmed. As a side benefit, hyperosmolar Hypaque usually evacuates the colon during the diagnostic maneuvers. Once confirmed, acute colonic pseudoobstruction should be treated aggressively, with a rectal decompression tube and enemas. Any associated metabolic abnormalities or electrolyte disorders (e.g., hypokalemia) must be corrected; these are prominent in 20% to 30% of cases [432]. Efficacy has been reported for pharmacological blockade of ganglia with guanethidine followed by cholinergic stimulation with neostigmine [433], although it must be emphasized that in many cases the condition resolves with simple measures [434]. Intravenous neostigmine (up to 2 mg) was effective in acute colonic pseudoobstruction in a randomized controlled trial [435].

Subsequent management

Most of the patients who do not respond to enemas, nasogastric decompression, and drug therapy continue to have a normal white blood cell count, and fever or peritoneal signs do not develop. If the cecum measures more than 11 cm in diameter, the next step is colonoscopic decompression. The previous enema often empties the colon, facilitating endoscopy. Gas and liquid stool are aspirated while small amounts of additional air (or carbon dioxide) are insufflated. The mucosal detail is often obscured by the contents, but an obstructing lesion can usually be seen. It is not necessary to reach the cecum to accomplish adequate decompression; positioning the colonoscope at the hepatic flexure with aspiration of the distal contents usually collapses the right colon. An abdominal film should then be obtained; the collapsed cecum can be documented and the patient kept on enemas until stool and flatus pass spontaneously. Although colonoscopic decompression may have to be repeated, more than 80% of patients respond to colonoscopic decompression and require no further management. Administration of polyethylene glycol, 29.5 g daily, following successful resolution of colonic pseudoobstruction with either neostigmine or colonic decompression, was reported to be effective in preventing recurrence [436].

An operation is advisable for patients with an exceedingly large cecum (> 14 cm) and for those whose condition remains intractable to medical and endoscopic management. The most useful and efficacious approach is tube cecostomy, which is possible by laparoscopic techniques. Moreover, if at any time a patient manifests fever, leukocytosis, or peritoneal signs, abdominal exploration is mandatory. In these situations, the right side of the colon is frequently nonviable or is already perforated. For perforation, right hemicolectomy with ileostomy and a mucous fistula is the operation of choice. In patients with nonviable bowel but without perforation, a right hemicolectomy and primary anastomosis can be performed with little risk for serious complications.

For patients with megacolon, a normal-sized rectum, and a normal mechanism of defecation as determined by tests of pelvic floor function, ileorectostomy is the operation of choice; these patients usually establish a relatively normal bowel habit. Patients with megarectum, a normal-sized colon, and a defecation abnormality are candidates for proctectomy with coloanal anastomosis. The enlarged rectum is resected in its entirety; therefore, fecaliths in the rectal remnant, so common in patients after Duhamel procedures, are avoided.

Syndromes partly attributed to disorders of colonic motility

Chronic diarrhea

Diarrhea is defined as defecation that is more frequent or the passage of stools that are less well formed than thought normal by the individual. In patients with IBS and diarrhea, transit through the proximal colon is accelerated, and the rates at which the ascending and transverse portions of the colon empty are related to fecal weight [437]. Stools that are less solid (fragmented, semisolid, or liquid) result from more rapid transit through the colon; however, the most characteristic bowel pattern in IBS is one of wide fluctuations of stool frequency and consistency. Presumably, colonic transit changes dramatically in IBS, from slow to fast (or vice versa), to produce these stool patterns.

The scintigraphic method has been used to demonstrate rapid small bowel and colonic transit in the diarrhea of carcinoid syndrome [438]. A five-fold increase in the emptying rate of the ascending and transverse parts of the colon was noted; this was associated with storage of a reduced volume in the ascending colon, as measured by the scintigraphic method. The rapid transit and reduced accommodation of the proximal colon were associated with increased postprandial tone as measured by the barostat. A serotoninergic mechanism has been implicated, and in carcinoid diarrhea, octreotide and alosetron ($5\text{-}HT_3$ antagonists) reversed the abnormalities [439].

Irritable bowel syndrome: motor dysfunction

Irritable bowel syndrome (IBS) is defined usually by the criteria of an international panel that evaluated the symptomatic features of this extremely common condition. The major features are altered stool frequency or consistency and abdominal pain that is directly related to a change in the pattern of bowel movements. Thus, it is not surprising that the colon has been incriminated as the origin of these symptoms.

Colonic transit was evaluated in patients with IBS and diarrhea [437,440], and rapid transit of solids through the

proximal colon was documented. It had earlier been reported that small bowel transit also was rapid in IBS with diarrhea [440]. The variable consistency of the stools that is so characteristic of IBS presumably is the result of slow transit of some of the fecal residue and rapid transit of other portions.

The constipation experienced by some patients with IBS appears to blend imperceptibly into the syndrome of idiopathic constipation. Not surprisingly, then, the transit of radiopaque markers is prolonged in constipated patients with IBS. In a group of nearly 300 persons referred to a tertiary center with a major complaint of constipation [441], the majority had only a modest slowing of colonic transit (it was sometimes normal) and were considered to be examples of IBS.

Inflammatory disease of the colon

The diarrhea of inflammatory colitis is primarily caused by the exudation of fluid and mucus, bleeding, and impaired absorption; however, disordered motility and transit should also be considered. Connell first proposed that the colon in advanced ulcerative colitis may behave as a semirigid tube, showing fewer phasic pressure waves than is normal [442]; moreover, it is well recognized clinically that haustral contractions are absent in the late stage of colitis. These radiological phenomena (haustra) are thought to be produced by repetitive, nonpropagated, phasic contractions. Reddy and colleagues used combined manometric and scintigraphic techniques to study transit in ulcerative colitis [443]. They confirmed the paucity of phasic pressure activity in the fasting state. Postprandially, however, low-amplitude pressure waves were more frequent in colitis, and when these were propagated, they always moved contents in an antegrade direction. Thus, movement of isotope from the splenic flexure to the sigmoid colon was usually rapid, perhaps reflecting the absence of retarding pressure waves [443].

Another important disorder of motility is seen in ulcerative proctitis, in which a heightened sensitivity of the rectum to distention has been reported [444,445]. Clinically, such patients are often sensitive to small amounts of feces or mucus in the rectum. Pressure waves of high amplitude in the rectum have been recorded in proctitis and implicated in the symptom of tenesmus.

Response of the colon to drugs

Laxatives

The most complete study of laxative agents and drugs that cause diarrhea as a major side effect was that of Karaus and Sarna [446]. They studied the effects of hypertonic glucose, castor oil, neostigmine, and guanethidine in dogs with strain gauges sewn onto the colon. In all instances, when the agents induced diarrhea, powerful contractions migrated around most or all of the colon and led to an evacuation. On the other hand, a local stimulus to the rectum (distention) could provoke expulsion of the balloon without participation of the whole colon in the motor event. The motor effects of the local instillation of stimulant laxatives have been recorded from the human colon [362], and the myoelectric responses to oral administration of senna have also been reported [447]. The effects of laxative doses of castor oil on the colon should be similar to those reported for oleic acid [363]; oleic acid and the active principle of castor oil (ricinoleic acid) are both C_{18} aliphatic fatty acids. Lactulose has also been used experimentally as a stimulant of colonic transit; when it was administered in doses that induced a modest increase in stool frequency, transit through the right side of the colon was hastened [448].

Antidiarrheal agents

The most effective antidiarrheal agents are those related to opioids. Opiates are said to augment the mixing contractions that inhibit transit and to increase colonic tone, both of which might be expected to favor absorption. These actions should retard transit and help alleviate diarrhea. The effects of morphine on colonic tone have also been explored in dogs and humans using the electromechanical barostat. Under baseline conditions in the dog, the drug increased tone sharply [365] in association with an increase in phasic contractions. In the human colon [449], the effects of morphine were more complex; it relaxed a segment showing high postprandial tone and caused a late (40 minutes after injection) decrease in spontaneous tone. Thus, the effects of opiates on the colon are complex, and perhaps species dependent.

Alosetron is a 5-HT_3 receptor antagonist that has been shown to decrease colonic transit, improve stool consistency, and decrease sensation and discomfort thresholds in the rectum in patients with IBS [450–452]. Alosetron has also been shown to be clinically effective in treating females with diarrhea-predominant IBS [453,454]. However, an increased incidence of drug-related ischemic colitis has resulted in restricted availability of the drug [455].

Colonic prokinetic agents

Tegaserod is a selective 5-HT_4 receptor partial agonist. It has been shown to enhance the peristaltic reflex and increase chloride secretion and water movement into the bowel lumen and accelerate colonic transit in health [456–461]. Multiple studies have demonstrated efficacy in patients with constipation-predominant IBS and idiopathic constipation [462–464]. Longer-term studies over 13 months have also confirmed efficacy in this setting [465]. Nevertheless, the availability of tegaserod has become restricted because of a possible increase in drug-related ischemic cardiovascular events [466].

Novel approaches to treating constipation with specific secretagogues have the potential advantage of specific targeting of the secreting epithelium in the small intestine and colon, and this, coupled with low bioavailability, enhances the safety of compounds such as lubiprostone, a chloride channel agonist [467], and linaclotide, a guanylate cyclase C agonist [468].

C SMALL INTESTINE

48 Bacterial, viral, and toxic causes of diarrhea, gastroenteritis, and anorectal infections

Phillip I. Tarr, Dorsey M. Bass, Gail A. Hecht

Clinical considerations at presentation, 1157
Specific therapy, 1159
Syndromic management, including diagnosis and therapy, of community-acquired diarrhea and gastroenteritis, 1160
Specific agents, 1164
Summary, 1206

Gastrointestinal infections, frequently manifest as diarrhea or gastroenteritis, continue to plague humanity. The World Health Organization (WHO) estimates that diarrhea causes 27% of all childhood deaths beyond the neonatal period [1]. The Centers for Disease Control and Prevention (CDC) reports that there are 1.4 episodes of diarrhea per person per year in the United States [2]. Diarrhea impairs daily activities at least once annually in most citizens of the world. Because of their impact on morbidity and mortality worldwide, and especially in less advantaged countries, gastroenteritis and diarrhea, no matter how defined, are undeniably important disorders.

Diarrhea and gastroenteritis diagnosis and management pose considerable clinical and economic challenges. Decisions depend on local epidemiology, resources, microbiological expertise, and the likelihood that outcome will be affected by diagnosis or treatment. Moreover, there is the reality that diarrhea is usually self-limited, whether or not an etiological agent is identified and whether or not specific or non-specific therapies are used. Therefore, resources are often, and more appropriately, devoted to supportive care and prevention and not to determining specific etiologies in individual cases. Symptomatic relief is often used, and empiric antibiotics are often prescribed, but the value and risks of these interventions are subjects of debate.

In this chapter, we will provide an overview of diagnostic considerations for all patients with diarrhea in terms of microbiological assessments, specific and non-specific therapies, and general preventive measures. We will then discuss the history, epidemiology, pathogenesis, clinical aspects, complications, diagnosis, and treatment of a diversity of bacterial and viral gastrointestinal pathogens. Major gastrointestinal infections that are often not accompanied by diarrhea or vomiting, such as parasitic infestations of the gastrointestinal tract (Chapter 106), infectious esophagitis (Chapter 34), and *Helicobacter pylori* infections (Chapter 40), are covered in other chapters. Although many episodes of gastroenteritis go undiagnosed, and we are unable to address thoroughly all of the multidimensional aspects of the myriad agents that cause gastroenteritis and diarrhea, we believe that this orthogonal approach to gastrointestinal infections will be helpful in general and in specific situations.

Clinical considerations at presentation

Microbiological diagnosis

Comprehensive microbiological diagnosis of enteric infections, usually by examination of stool from symptomatic patients, employs diverse, pathogen-specific tests, including culture, microscopy, antigen detection, nucleic acid hybridization, and serology. This technology can be an impediment to clinical care and epidemiological surveillance. These multiple modalities are expensive and, for many, interpretation of results is "operator dependent." Results are often returned to the provider too late to be useful or are not clinically actionable. Some tests are of questionable sensitivity, and, in the case of bacterial culture, utilize technology developed in the late 1800s. Despite these limitations, good gastrointestinal practice often critically relies on the accurate identification of pathogens or on the exclusion of known infectious agents. Moreover, public health authorities depend on accurate and rapid diagnosis of enteric pathogens to halt outbreaks and to monitor incidence trends. Admittedly, the microbiologically and physically complex matrix of stool poses difficult

challenges for pathogen detection. Nonetheless, it is important to recognize that major technological advancements will be required to better diagnose gastrointestinal infections, and that new technologies which identify multiple pathogens in the same testing format, accurately, economically, and rapidly, are urgently needed.

Diagnosis is often tailored to the presentation and symptoms, with local epidemiology, custom, and laboratory practices helping to guide the tests requested and performed. The test categories can be grouped into those that identify bacterial, parasitic (eukaryotic, largely protozoal), and viral diarrheagenic agents. Within each group, a diversity of methods, reagents, and detection systems can be applied, which further complicates decisions.

Bacterial pathogen testing consists of plating stool specimens on selective agar plates and inoculating stools into various broths. The media serve several purposes. They can be variably selective (diminishing or preventing growth of nontarget organisms) or differentiating (exploiting a phenotype of a target organism to identify it among co-isolated flora), or both. Most laboratories will seek, without special requests, *Salmonella* and *Shigella* using one or more of these media (e.g., MacConkey, Hektoen, *or Salmonella/Shigella* agar, often in combination with selenite-F broth). Laboratories also usually routinely seek *Campylobacter* using selective media and incubation at 42°C under microaerophilic conditions to suppress the growth of ambient flora, which do not grow as well as *Campylobacter* at this temperature. Special requests are often needed to detect *Yersinia* (using *Yersinia* agar), *Escherichia coli* O157:H7 (using sorbitol–MacConkey agar), and other Shiga toxin-producing *E. coli* (using a broth culture and a Shiga toxin enzyme immunoassay [EIA]) [3]. Laboratories will occasionally culture for vibrios using blood or thiosulfate–citrate–bile salts–sucrose (TCBS) agar, and *Staphylococcus aureus* using blood agar plates. Laboratories sometimes screen colonies on blood agar plates by sweeping the growth onto oxidase paper and determining if oxidase producers are vibrios, *Aeromonas*, or *Plesiomonas.* In reality, most oxidase-positive colonies are *Pseudomonas aeruginosa* and not enteric pathogens. It is prudent to confirm that the laboratory to which a specimen is sent performs an appropriate array of cultures, and knowledge of local epidemiology is essential. Unfortunately, many physicians do not really know their laboratory's practices [4].

Viral studies rarely help manage individual cases of gastroenteritis. Specific therapies do not exist, and finding a viral pathogen does not alter one's approach to a patient, which is (rightly) focused on addressing hydration status. Viral enteric diagnosis, at least in North America, consists of antigen detection for rotavirus and adenovirus types 40 and 41. Tests for noroviruses (caliciviruses) and astroviruses are less often applied or are unavailable except in research settings. Viral culture of the stool does not help in the diagnosis of gastroenteritis or diarrhea.

Parasite evaluations consist of microscopy of wet mount specimens, and special additional stained slides of fresh or preserved specimens, to detect diverse definite (*Cryptosporidium parvum*, *Entamoeba histolytica*, *Giardia lamblia*, *Hymenolepsis nana*, *Isospora*, and microsporidia) and candidate (*Blastocystis hominis* and *Dientamoeba fragilis*) diarrheagenic protozoa. Antigen detection will identify *C. parvum* and *G. lamblia*, but not other parasites, and microscopy is necessary for other agents. There is considerable debate about the utility of the classically applied three ova and parasite examinations. Some authorities promote one microscopic examination [5–9], whereas others advocate the long-standing practice [10] of triplicate submissions [11–14]. Pooling of specimens from the same patient prior to examination has been proposed as a cost-saving measure and does not diminish recovery rates [15,16]. Antigen testing has been widely utilized but there are concerns about its specificity [17]. In cases in which it is important to diagnose an enteric parasite, stools should not be considered to be negative until they have been subjected to a thorough microscopic evaluation at an experienced laboratory.

Several screening tests have been employed in an attempt to improve the detection rate of bacterial pathogens in stool cultures by restricting processing to those specimens with reasonable likelihoods of containing a pathogen. These include testing for fecal occult blood, leukocytes, lactoferrin, and calprotectin [18]. Although positive tests might increase the yield of a stool culture, negative tests are not adequately predictive to be used as exclusion criteria [19]. If there is clinical suspicion of a possible bacterial enteric infection, a culture should be obtained, even if a surrogate test is negative.

We also wish to stress that clinical microbiologists are underutilized resources for many gastroenterologists. These individuals are considerably more aware of the latest diagnostic technology and protocols in enteric microbiology than are practicing gastroenterologists. We often find it helpful to confer with clinical microbiology staff on difficult cases to increase the likelihood that specimens will be handled appropriately and to ensure that the best evaluations are performed. We also encourage regular communication to ensure that specimens which are obtained by clinicians are put into the appropriate transport media and that appropriate testing is requested.

Finally, in many jurisdictions, it is the responsibility of the requesting provider to notify the local health department of reportable enteric infections. The diagnosing microbiology laboratory can usually provide contact information and a list of reportable pathogens. Even though regulations require reporting within 7 days of notification, it is important to make the report immediately, to accelerate disease control measures. A 2006 nationwide outbreak of *E. coli* O157:H7 transmitted by contaminated fresh spinach exemplifies the importance of rapid reporting and transfer of pathogens to disease control authorities as soon as possible, so that matching isolates can be further investigated [20].

Adjunct evaluations

Patients with severe gastroenteritis and diarrhea sometimes present with such profound and confusing symptoms, or with symptoms of sufficient duration, that adjunctive tests and evaluations are considered and requested. It is important to be strategic in the selection of these evaluations, because the likelihood of obtaining misleading information sometimes exceeds the likelihood of obtaining helpful results. Unfortunately, we are not aware of any rigorous analysis of the utility of such determinations. However, we wish to make several observations on commonly obtained tests, based on our experience caring for such patients.

Blood count

Although a blood count is rarely helpful in nonbloody diarrhea, several situations do arise in which this test is valuable. First, in patients presenting with acute bloody diarrhea, we find it useful to obtain a complete blood count so that we may more accurately assess trends in the platelet count if the patient is subsequently demonstrated to be infected with an enterohemorrhagic *E. coli* (EHEC) (see Enterohemorrhagic *E. coli*, Clinical aspects). Abnormally high hemoglobin concentrations could indicate dehydration, and profound left shifts without marked leukocytosis (relative bandemia) could represent *Shigella* or *Salmonella* infection.

Blood culture

We encourage blood cultures in patients with acute gastrointestinal infections that could be of bacterial origin if they are at the extremes of age, are immunocompromised, or if they might be infected with *Salmonella* Typhi. The value of blood cultures in other situations is not well established and is probably considerably less.

Urinalysis

In febrile children with diarrhea, and especially infants, it is difficult to know if a urinary tract infection is also present. However, the decision to obtain a urinalysis must be balanced by the realization that there is a high likelihood of receiving inaccurate data because the risk of fecal contamination is considerable and that the resulting administration of antibiotics might be contraindicated. We also strongly discourage obtaining catheterized specimens during acute gastroenteritis because of the risk of introducing fecal bacteria into the urinary system. There is no role for a urinary assessment if there is no fever or if the illness most closely resembles bacterial infection (sudden onset, bloody diarrhea).

Imaging studies

Abdominal ultrasonography might help clarify distal small bowel involvement during bacterial infections by demonstrating evidence of bacterial ileocecitis, especially if a patient has right lower quadrant tenderness [21]. Air- or barium-contrast enemas, or computed tomography, are occasionally warranted during acute bloody diarrhea to exclude the possibility of a surgically remediable lesion, in particular an intussusception. Contrast studies demonstrating colonic edema (e.g., "thumbprinting" of the mucosa) should raise the possibility of an EHEC infection. Computed tomography in infectious colitis generally demonstrates a diffusely inflamed colon [22]. Dilated colons can be seen on plain abdominal radiographs in a variety of infections and are non-specific. Nonetheless, imaging studies can help exclude the possibility of an obstructing intussusception.

Chemistry studies

Dehydrated patients should undergo evaluations to identify electrolyte abnormalities. We also recommend daily electrolyte, urea, and creatinine determinations in patients who are possibly or definitely infected with an EHEC (see specific recommendations below under Enterohemorrhagic *E. coli*, Treatment).

Surgical consultation

Many patients with severe gastroenteritis will have signs or symptoms suggesting an acute abdomen, most particularly acute appendicitis. Indeed, diarrhea is present in bona fide non-infectious appendicitis [23], and bacterial gastroenteritis can be associated with appendicitis [24,25] and colonic perforation [26,27]. Experienced surgical consultation should be pursued if the clinical situation warrants, even if there is a high likelihood of a patient being infected with an infectious agent.

Specific therapy

Specific therapy for enteric infections, defined as administration of a medication to eradicate the infecting agent, is best guided by microbiological results. We do not believe that it is appropriate to administer antibiotics empirically at the time of presentation because of the potential for side effects of the antibiotics, their expense, the possibility that such agents could be contraindicated, and the risk that antibiotics will select for antimicrobial resistance. We do acknowledge that the practice of treating patients empirically is not uncommon, and that several studies have demonstrated that the administration of antibiotics at the time of presentation with diarrhea to adults does shorten the duration of illness, whether or not a specific bacterial pathogen is identified [28–32]. However, the attributed benefit was only one or two fewer days of diarrhea during the illness in these studies, and not avoidance of serious complications. Additionally, in some circumstances, antibiotics are harmful, such as in *E. coli* O157:H7 infections, in which their use is associated with a higher frequency of development of the hemolytic uremic syndrome (HUS), and in uncomplicated *Salmonella* infections in otherwise healthy hosts, in which use of antimicrobials is associated with prolonged carriage [33].

Table 48.1 Composition of oral rehydration solutions

Component	Standard WHO (1975)	Reduced osmolarity WHO (2002)	Glucose plus glycine[a]
Glucose (mmol/L)	111	75	110
Sodium (mEq/L)	90	75	120
Potassium (mEq/L)	20	20	15
Chloride (mEq/L)	80	65	72
Base	10[b]	10[b]	48[c] (15[d])
Glycine (mmol/L)			110
Osmolarity (mOsm/L)	311	245	510

Rifaximin, a non-absorbable antibiotic derived from rifampin (rifampicin), has shown considerable promise in the treatment of traveler's diarrhea [34], but its appropriateness in other bacterial enteric infections is not yet established.

Symptomatic measures

The value and safety of therapies used to ameliorate the symptoms of acute gastrointestinal infections are subject to debate. Antimotility agents, such as loperamide, are controversial because studies, often small case series, have reported that these agents are associated with complications, such as toxic megacolon or ileus [35–37]. Other studies, however, attest to their safety and partial efficacy [38,39]. We are least comfortable administering antimotility agents to children, in whom safety has been less well established. In view of the fairly small benefits conferred by antimotility agents, and in consideration of their potential risks, especially in children, we urge caution in using them in cases of acute diarrhea, unless and until more substantial data emerge in support of their safety and efficacy. Oral ondansetron given in an emergency department to children with diarrhea diminished their time in the facility (though it did not affect need for hospitalization or need to return for evaluation) and is a potential adjunct to oral rehydration in situations in which vomiting might hinder this intervention [40]. However, it should be noted that ondansetron during gastroenteritis is associated with increased postadministration diarrhea [41].

Prevention

Prevention of diarrhea is an ideal goal. Vaccination has been successful only for typhoid fever, rotavirus, cholera (reviewed in [42]), and gastroenteritis necroticans [43]. Travelers should minimize risks whenever possible. Assiduous hygiene should be applied to acutely infected patients to diminish spread in the home or health-care setting. Food safety measures should be practiced by all individuals, especially those whose underlying illness or age render them more susceptible to the stress or sequelae of enteric infections. Successful prevention of morbidity and especially mortality of enteric infections is likely to follow improvements in economies and infrastructure, as demonstrated in Mexico during the 1990s [44–46].

Hydration

Maintenance of circulating volume is of paramount importance in all forms of diarrhea and gastroenteritis. Generally, oral rehydration is adequate to treat gastrointestinal fluid losses, but the ideal composition of such fluids remains subject to debate [47–49]. Parenteral fluid management is needed in children and adults who are severely dehydrated, who are unable to tolerate oral rehydration because of vomiting or abdominal pain, or who are medically fragile. Again, the ideal composition of intravenous volume expansion is also controversial, especially in children [50–52]. Reduced osmolarity solutions (Table 48.1) have been recommended by WHO in an attempt to diminish stool volumes and the need for intravenous volume replacement in patients with diarrhea. However, they carry the risk of inducing hyponatremia, especially in illnesses such as cholera in which fecal sodium loss exceeds the amount of sodium likely to be imbibed in these solutions [49].

Syndromic management, including diagnosis and therapy, of community-acquired diarrhea and gastroenteritis

Patients with diarrhea and gastroenteritis rarely present initially to consultant gastroenterologists. Therefore, experience accrued, and recommendations offered, by subspecialists is often removed from a point in these illnesses at which critical

diagnostic and therapeutic decisions are made. Nonetheless, we think it is helpful to review some considerations that we believe are pertinent to the initial presentation, in terms of syndromic profiling, because gastroenterologists are often asked to make recommendations to their colleagues in primary care about these situations.

In profiling these syndromes we recognize that purely upper or lower gastrointestinal presentations of enteric infections are rare; however, some categorizations might be instructive.

Illnesses in which vomiting predominates

Patients of all ages with illness characterized by vomiting and little or no diarrhea often are infected with a virus, in particular a norovirus, or have ingested a preformed toxin, such as staphylococcal enterotoxin. Diagnosis is often elusive, and attempts to find an etiological agent in individual clinical situations are often futile, but fortunately such illnesses resolve rapidly and spontaneously, although sometimes parenteral hydration is helpful. However, as with any form of acute vomiting illness, careful assessments should be made to confirm the absence of important noninfectious processes, such as pancreatitis. Cohorts with similar symptoms increase the likelihood that there is a point source (i.e., infectious or food-borne toxic cause) for the illness.

Nonbloody acute diarrhea

Nonbloody diarrhea often remains undiagnosed and the likelihood of recovering a pathogen from stool cultures is low in these situations, especially if there is no abdominal pain or tenderness, recent foreign travel, fever, or multiple stools in the 24 h preceding presentation [19,56]. These illnesses can usually be treated with oral rehydration and occasionally intravenous fluids, especially if the illness is accompanied by vomiting. Ensuring follow-up and that patients reseek medical care for nonimprovement or clinical deterioration are good medical practices in these situations, because assessments provide only a brief period of observation during an illness that will evolve over several more days. If microbiological diagnosis is considered, we encourage a stool culture to identify all actionable pathogens and seek, at a minimum, *Campylobacter*, *E. coli* O157:H7, *Salmonella*, and *Shigella*. Ideally, the evaluation should also include a toxin immunoassay to detect non-O157:H7 Shiga toxin-producing *E. coli* and culture for *Yersinia*. The value of testing for *Clostridium difficile* in these circumstances has not been established and is controversial [57,58], but in view of data that antibiotics have often not been recently taken by patients infected with *C. difficile*, such testing should not necessarily be limited to patients with antibiotic exposure.

Bloody acute diarrhea

Bloody acute diarrhea is a medical emergency because it is highly likely to represent an infectious colitis, is often associated with considerable patient discomfort, and is frequently amenable to intervention. Typically, in all forms of bacterial colitis, there are several days of nonbloody diarrhea before gross blood is observed, and pain is quite prominent. Fever is variable and, when it is absent on medical evaluation, suggests the possibility of an *E. coli* O157:H7 infection. Cultures should be obtained for a diverse panel of bacterial enteric pathogens (*Campylobacter*, *E. coli* O157:H7 and non-O157:H7 Shiga toxin-producing *E. coli*, *Salmonella*, and *Shigella*). Ideally, *Yersinia* should also be sought. Shiga toxin immunoassays should be requested in addition to, but not in lieu of, cultures for *E. coli* O157:H7. We also find it helpful to obtain baseline blood counts. Tests for *C. difficile* should also be requested, although, in our experience, community-acquired colitis caused by *C. difficile* usually has a period of onset that is more gradual than is seen in other causes of community-acquired bloody diarrhea. There is no role for viral testing in this setting. Similarly, in most of the developed world, parasites are very unlikely to cause acute bloody diarrhea. If parasites are sought we discourage reliance on antigen tests, because these investigations seek protozoa (*G. lamblia* and *C. parvum*) that do not cause bloody diarrhea; microscopy is preferred.

We discourage using empiric antibiotics unless and until it is known that such patients are not infected with an organism for which antibiotics are contraindicated. We strongly encourage admission to hospital and intravenous volume expansion for children and many adults with acute bloody diarrhea.

Bloody diarrhea can also be caused by non-infectious illnesses. If the age and setting are appropriate, one should consider a diagnosis of intussusception, ischemic colitis, and inflammatory bowel disease (IBD). However, sometimes these conditions can be complicated by bona fide enteric infections.

Chronic or persistent nonbloody diarrhea

Chronic or persistent diarrhea (arbitrarily defined as diarrhea of ≥ 2 weeks duration) is not very likely to be attributed to an easily diagnosed bacterial enteric pathogen and so the value of stool cultures in this setting is minimal. We encourage focusing the assessment of such patients on testing for *C. difficile* and parasites. The ideal parasite assessment combines antigen testing for *G. lamblia* and *C. parvum*, with microscopy. If testing is negative, and the patient's symptoms suggest the possibility of infection with a diarrheagenic parasite, we do think that it is appropriate to provide empiric antiparasitic therapy, usually metronidazole.

Chronic or persistent bloody diarrhea

In most of the developed world, chronic or persistent bloody diarrhea (arbitrarily defined as bloody diarrhea of ≥ 2 weeks duration) is likely to represent IBD. However, an infectious etiology should at least be considered, and workup, if it is pursued, should consist of a stool culture seeking *Campylobacter*, *E. coli* O157:H7, *Salmonella*, and *Shigella*; antigen or cytotoxicity assay for *C. difficile*; and microscopic evaluation of the stool

Table 48.2 Differentiating characteristics of acute self-limited colitis and inflammatory bowel disease (IBD)

Feature	Infectious colitis	Acute onset IBD
Distribution of lesions	Focal and segmental	Diffuse and general
Crypt architecture	Preserved	Distorted, atrophic
Mucus cell depletion	Absent or mild	Pronounced
Inflammatory cells	Mainly polymorphs in focal collections; crypt abscess formation	Chronic inflammatory cells (especially plasma cells)
Distribution of cells	Mainly mucosal	Submucosa may be involved
Epithelioid granulomas		Often present
Basal lymphoid aggregates		Present
Isolated giant cells	Absent	Basally located
Relapse	Very unusual	Present
Onset	Acute	Usually subacute, with prodromal symptoms, including extraintestinal symptoms, lasting at least several weeks
Cultures	Usually positive	Usually negative
Microcytic anemia	Usually absent	Frequently present

A panel of histological and clinical features can help differentiate acute self-limited colitis (which is presumably infectious) from acute IBD [59–63]. It is important to note that the gross appearance of the colonic mucosa cannot differentiate infections from IBD, and in a subset of cases there is a need to observe the course over time, with repeat biopsies [64].

for parasites, especially *E. histolytica*. However, these agents are usually not found, especially if patients have microcytosis, anemia, hypoalbuminemia, or elevated erythrocyte sedimentation rates or C-reactive protein [59–62], and plans should be made to make an expeditious diagnosis of IBD by colonoscopy.

Table 48.2 demonstrates criteria that help distinguish IBD from acute, self-limited, plausibly infectious colitis. In reviewing these differentiating characteristics, it is noteworthy (and troubling) that documented bacterial enteric infections can be a prelude to subsequent hospitalizations for IBD [27].

Returned traveler, or newly arrived immigrant, with acute or chronic nonbloody diarrhea

In this scenario we recommend a broad assessment, including bacterial cultures to rule out *Campylobacter*, *E. coli* O157:H7, *Salmonella*, and *Shigella*, and a thorough examination of the stool for diarrheagenic parasites. The value of empiric treatment of such cases is not known, but often performed. In view of the fact that enterotoxigenic *E. coli*, a leading and treatable cause of traveler's diarrhea, will not be detected with the available diagnostic testing, empiric antibiotic treatment is probably appropriate.

Anorectal symptoms

Patients with symptoms confined largely to the distal gastrointestinal tract (tenesmus, blood or pus in stools, pruritus ani), and who have recently had anal receptive intercourse, could have a sexually transmitted infection. Evaluation should consist of rectal swabs to seek a broad range of plausible pathogens (*Chlamydia*, *Neisseria gonorrhoeae*, and herpes simplex virus). A serological test for syphilis should also be performed. Sigmoidoscopy should be performed before starting treatment, and, ideally, treatment should be guided by culture, microscopy, or serology.

Persistent diarrhea in resource-poor settings

Many residents of resource-poor, largely tropical regions, and especially children in these populations, probably have abnormal small bowel structure and function. Changes include crypt hyperplasia, villous stunting, hypercellular lamina propria, decreased mucosal surface, and increased gut permeability. The net result of this syndrome in residents of these areas is stunting. This disorder is termed tropical enteropathy [65], tropical malabsorption [66], or tropical sprue [67]. Definite causative agents include the parasites *G. lamblia*, *C. parvum*, *Isospora belli*, *Cyclospora cayetanensis*, and the microsporidia; a strong bacterial candidate for persistent diarrhea in children in the tropics is enteroaggregative *E. coli* [68]. This condition is sometimes seen in travelers returning from the tropics. The optimal way to diagnose persistent diarrhea has not yet been found [69], although we recommend, subject to resource availability, a thorough microscopic examination of the stool, and consideration of empiric treatment with antiparasitics and antibiotics, and endoscopy. Even though it is not likely to contribute to mortality, persistent diarrhea in resource-poor countries is not a benign disorder. It is associated with, and probably a cause of, stunting, susceptibility to other diseases, and cognitive impairment [70–73]. The detection and eradication of this entity should be a priority for future research and development [74].

Diarrhea in the immunocompromised

Immunocompromised transplant recipients can be infected with a diversity of diarrheagenic agents, and so a broad approach to evaluation (including stool cultures, viral studies, and, if the patient has had environmental exposures, parasitic evaluation) is warranted. However, a limited repertoire of causative agents (*C. difficile* and cytomegalovirus) has been identified in patients who have been studied systematically and thoroughly [75,76]. It should be emphasized that it is not possible to differentiate infectious diarrhea from graft-versus-host disease in such patients, and histopathological evaluation of the intestinal mucosa is often quite helpful.

Traveler's diarrhea

Traveler's diarrhea is often brought to the attention of gastroenterologists. It has been estimated that 30%–40% of the 50 million people who travel to developing countries every year from the developed parts of the world will experience classic symptoms of traveler's diarrhea. Traveler's diarrhea has been defined as three or more loose bowel movements within a 24-h interval, accompanied by cramps, nausea, fever, blood in the stool, or vomiting, or a combination of these symptoms [77]. Interestingly, antibiotics were demonstrated to prevent traveler's diarrhea well before the recognition that bacteria were major causes of this disorder [78]. The risk of acquiring traveler's diarrhea varies from country to country (see Fig. 48.1).

A subset of patients with traveler's diarrhea will experience dysenteric symptoms, defined as diarrhea with fever, with or without visible blood in the stool, and these rates, too, vary from country to country [77]. Acute traveler's diarrhea usually occurs during the first week overseas, the average duration of untreated illnesses in travelers is approximately 4 days, and many patients have symptoms that resolve considerably sooner [79,80]. Approximately one-fifth of all patients with traveler's diarrhea experience incapacitation such that they are unable to take part in their planned activities. There is a possibility that traveler's diarrhea precipitates persisting symptoms, including chronic diarrhea and irritable bowel syndrome [81–83], although some investigators have failed to associate traveler's diarrhea with irritable bowel symptoms [84]. Also, there have been concerns that IBD could be precipitated by a recent visit to the tropics [85,86].

In view of the morbidity of traveler's diarrhea, considerable effort has been devoted to its prevention. Certainly, it is important to promote good hygiene, although data supporting

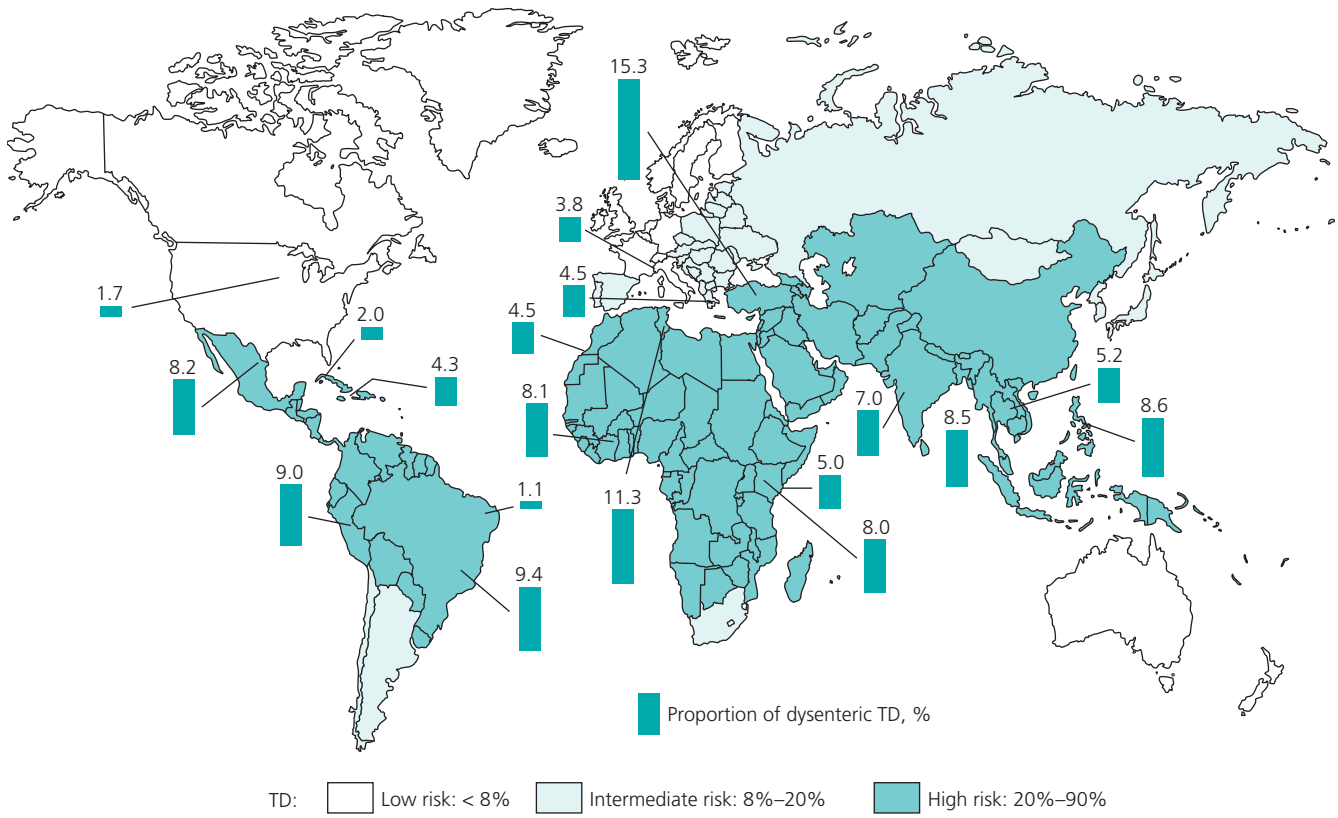

Figure 48.1 Country-specific risk of acquiring traveler's diarrhea. Percentages indicate the likelihood that travelers to specific countries will acquire diarrhea within 2 weeks of arrival. Percentages demonstrate frequency of blood in the stools and/or fever, representing "dysenteric" traveler's diarrhea. From Steffen [77], with permission from University of Chicago Press.

the efficacy of hygienic precautions are scarce [87,88]. Various pharmacological approaches have been tried including nonantimicrobial agents, most particularly bismuth subsalicylate, tannin albuminate plus ethacridine lactate, and *Lactobacillus* GG (reviewed in [89]). Agents demonstrated to be effective in treating traveler's diarrhea include antimotility/antisecretory agents such as loperamide, bismuth subsalicylate, the calmodulin inhibitor zaldaride maleate, tannin albuminate plus ethacridine lactate, and attapulgite. Racecadotril (an enkephalinase inhibitor), probiotics, tincture of opium, kaolin–pectin, and diphenoxylate ameliorate the symptoms of acute diarrhea, but have not been specifically or thoroughly evaluated in traveler's diarrhea (reviewed in [90]). A variety of antibacterial agents has been subject to placebo-controlled trials for the chemoprophylaxis of traveler's diarrhea, including doxycycline [91–93], trimethoprim–sulfamethoxazole [94,95], and the fluoroquinolones, in particular norfloxacin [96–98] and ciprofloxacin [99,100]. This topic has been extensively reviewed [90]. Interest has also been prompted by the efficacy of rifaximin, which is a poorly absorbed oral analogue of rifampin (rifampicin), in preventing traveler's diarrhea [34]. Rifaximin was comparable to ciprofloxacin in treating traveler's diarrhea caused by presumably non-invasive pathogens, but was less effective than ciprofloxacin for treating traveler's diarrhea caused by invasive pathogens [101]. Considerations regarding the use of rifaximin in the future will depend on its aftermarket side-effect profile (presumably minimal for this non-absorbed antibiotic, compared with the somewhat higher risk of fluoroquinolone-related side effects), the theoretic emergence of resistance, and cost. A National Institutes of Health (NIH) consensus conference recommended against using antibiotics to prevent traveler's diarrhea, in view of the potential side effects from these drugs, but did recommend that symptoms should be treated when they occur, quite often with antibiotics [102]. Certainly, antibiotics should be considered when traveler's diarrhea ensues, and, depending on the patient's age, medical conditions, and history of allergies, a fluoroquinolone or azithromycin [103] should be considered. An antimotility agent taken at the same time might provide additive benefit [104] but blanket use of antimotility agents is problematic, because such a recommendation would not be made for traveler's diarrhea caused by invasive bacteria, and such invasive infections often begin as nonbloody diarrhea. If a traveler develops bloody diarrhea, then antibiotics should certainly be taken.

In the returned traveler, the use of antibiotics in what appears to be persistent diarrhea is probably appropriate although not entirely risk free. Nonetheless, it is common practice. The diagnostic considerations in returned travelers also pose challenges because many of the diarrheagenic *E. coli* associated with traveler's diarrhea are not detected by routine stool cultures, and classic bacterial pathogens are found in only a small minority. Similarly, such patients could be infected with a parasite. In a returned traveler, we do think it is appropriate and advisable to obtain a thorough microbiological evaluation, including bacterial culture and microscopic evaluation of the stool and antigen studies for *Giardia* and *Cryptosporidium* before beginning therapy.

Genetic susceptibility or resistance to infections

Multiple studies have suggested that there can be a genetic predilection for acquiring certain gastrointestinal infections or for experiencing particular complications of these infections. Children with sickle cell anemia are at increased risk of extraintestinal *Salmonella* infections [105]. Patients with iron overload are prone to *Yersinia* infections [106]. Patients with HLA-B27 are at risk for postinfectious Reiter syndrome following a variety of enteric infections [107]. Patients with polymorphisms in the interleukin (IL)-8 promoter are at increased risk of acquiring clinically apparent traveler's diarrhea attributable to enteroaggregative *E. coli* [108]. Blood group O residents of a cholera-endemic area were less likely to become infected with *Vibrio cholerae*, but more likely to experience severe disease if infected [109]. Heterozygotes for the cystic fibrosis transmembrane conductance regulator (CFTR) have been postulated to be relatively resistant to cholera and enterotoxigenic *E. coli* [110,111]. Polymorphisms in the CFTR also influence susceptibility to typhoid fever [112]. Even though host genetics probably play important and underestimated roles in susceptibility to gastrointestinal infections and their sequelae, such associations are not absolute and should not, at present, be used to make diagnostic or therapeutic decisions about managing individual patients.

Specific agents

In this section, we will describe common and instructive bacterial and viral agents of gastroenteritis, listed alphabetically. We exercised some discretion regarding the breadth and depth of the discussion of each agent, because it is not possible to review every candidate etiological agent of gastroenteritis and diarrhea, and, as we note above, the etiologies of most cases encountered remain clinically undetermined. However, in deciding which pathogens to include, we believed that it would be instructive to discuss pathogens that are likely to be encountered worldwide (e.g., *Salmonella*) or that have well-defined pathogenetic mechanisms even though their epidemiology and the spectrum of illnesses that they cause are not yet well delineated (e.g., enteropathogenic *E. coli*), or agents whose role in human disease is newly emerging (e.g., *Bacteroides fragilis*). We also believed that it was noteworthy to review situations in which gastroenteritis precedes or accompanies multisystem, often overwhelming, illnesses (e.g., anthrax). Finally, we provide an overview of infections largely confined to the anorectum. We have attempted to reduce redundancy when multiple classes of

agents possess the same virulence mechanism by elaborating them only once, such as discussing Shiga toxins predominantly in the section on EHEC and providing less information in the section on *Shigella dysenteriae* serotype 1. Also, we wish to note that we do not usually provide specific dosages or durations of therapies because of the likelihood that there will be interedition changes in recommendations and because we cannot cover all dosing contingencies that pertain to patients of different ages and with different renal and hepatic function.

Bacterial pathogens

Bacteroides fragilis

History

Bacteroides fragilis has long been considered to be a member of the commensal anaerobic gastrointestinal flora. However, in the 1980s, some strains of *B. fragilis* were proposed to cause diarrhea by virtue of their ability to produce an enterotoxin in a ligated intestinal loop assay [113]. These enteroxigenic *B. fragilis* strains were isolated from infant lambs with acute diarrhea. The enterotoxin has been cloned, and several case–control studies have associated enterotoxigenic *B. fragilis* with diarrhea in children [114] and adults [115].

Pathogenesis

The only known virulence trait of diarrhea-associated *B. fragilis* is the ability to produce the *B. fragilis* enterotoxin (BFT). BFT is a 20-kDa metalloprotease, which stimulates secretion of IL-8 by epithelial cells [116]. BFT can also induce c-Myc expression and activate cellular proliferation via the mitogen-activated protein kinase p38 and β-catenin nuclear signaling [117], raising the possibility that this molecule can induce oncogenic transformation [118]. BFT also increases intestinal permeability [119].

Epidemiology and prevention

The extent of disease caused by enterotoxigenic *B. fragilis* is uncertain. Available data suggest a global distribution of enterotoxigenic *B. fragilis*, with most reports focusing on young children [120–125]. Because detection of enterotoxigenic *B. fragilis* is technically complex, extensive knowledge regarding epidemiology and prevention does not exist.

Clinical manifestations

Children and adults infected with enterotoxigenic *B. fragilis* have generally had nonbloody diarrhea; very few have fever [114,115].

Diagnosis

The ability to identify enterotoxigenic *B. fragilis* rests on the use of selective media and 48 hours of anaerobic culture [114], followed by genetic or biological assays to detect enterotoxin production. Detection of enterotoxigenic *B. fragilis* in stool is not performed outside of research studies.

Treatment

The optimal treatment for enterotoxigenic *B. fragilis* infection is not known. Patients are generally not diagnosed during their acute illness, and no therapeutic trials have been conducted.

Complications

Complications of acute enterotoxigenic *B. fragilis* gastrointestinal infections have not been described.

Campylobacter species

History

Although Theodor Escherich possibly described *Campylobacters* in the colons of infants dying of "cholera infantum" in 1886 [126], *Campylobacter* were not recognized as important human pathogens until the late 1970s [127]. What is retrospectively considered the initial *Campylobacter* outbreak occurred in Illinois in 1938, when 355 inmates of two adjacent state institutions suffered diarrhea associated with the ingestion of milk [128]. *Vibrio jejuni*, as it was then termed, was cultured from the blood of several of the patients, because methodology for recovering these organisms from stool had not yet been defined. It was not until 1968 that Dekeyser et al. [129] recovered *Campylobacter jejuni* from human feces and confirmed the intestine as the origin of the bacteremia demonstrated previously. Antibiotic susceptibility testing led to the recognition that erythromycin was effective for treatment [130]. In the 1980s, with routine microbiological culturing, *C. jejuni* came to be recognized as the leading cause of bacterial enterocolitis in humans. *Campylobacter*, and most particularly *C. jejuni*, remain the most common bacterial enteric pathogens in developed countries [131], including the United States [132].

Epidemiology and prevention

The CDC reports that *C. jejuni* caused nearly two million illnesses in the United States in 1999, comprising 14.2% of all foodborne infections [132–134]. *Campylobacter* infections are estimated to cost US$1.3–6.2 billion each year in the United States alone, in medical costs and hours lost from work [135,136]. Individuals of any age can be infected, but children under 4 years old are most susceptible, with a second peak incidence of infection occurring in those between 15 and 44 years old [128]. People with AIDS are at greater risk for infection and often exhibit more severe disease. The peak incidence of infection occurs in the summer.

Because *Campylobacter* do not multiply in contaminated foods or the open environment, large outbreaks are rare. Foods of animal origin are the most common sources of pathogenic *Campylobacters*, because *Campylobacter* spp. colonize the gastrointestinal tracts of many animals including chicken, sheep, swine, oxen [137], and cattle [138]. Various species of *Campylobacter* were found in 73% of retail meat samples in the United Kingdom [137]. The highest contamination rates (14%–98%) were in chicken [139,140]. Infections can also

be acquired from water, unpasteurized milk, or contact with infected humans or pets [131]. Undercooked poultry was responsible for 10%–50% of *Campylobacter* infections in case–control studies. Freezing diminishes *Campylobacter* viability. *Campylobacter* also accounts for 3%–50% of cases of travel-related diarrhea [128].

Of the 18 species and subspecies of *Campylobacter*, *C. jejuni*, *Campylobacter coli, Campylobacter lari, Campylobacter upsaliensis, Campylobacter hyointestinalis, Campylobacter concisus, Campylobacter mucosalis*, and *Campylobacter fetus* are confirmed or postulated pathogens of the human gastrointestinal tract. *C. jejuni*, *C. coli*, and *C. fetus* are most commonly associated with human disease, but newer diagnostic techniques have identified *C. hyointestinalis*, *C. concisus*, and *C. upsaliensis* at an increasing rate in human specimens [134,141]. In clinical laboratories, *Campylobacters* are rarely identified at the species level. The advisability and feasibility of identifying *Campylobacter* other than *C. jejuni* await further studies defining their roles in disease and their epidemiology.

The single most important source of *Campylobacter* is poultry. Proper food handling, preparation, and handwashing will reduce the incidence of these infections. The standard recommendations for avoiding traveler's diarrhea will reduce infection by this agent as well. Vaccine strategies have included the use of a killed whole-bacterial preparation combined with *E. coli* heat-labile toxin as an adjuvant [142], and a *C. jejuni* flagellar vaccine administered intranasally [143], but have not advanced to efficacy trials. Subjects have at least temporary immunity to disease (although not infection) following experimental challenge [144].

Pathogenesis

The pathogenesis of *Campylobacter* infections remains poorly defined. Four major virulence properties of *C. jejuni* and *C. coli* have been recognized: motility, adherence, invasion, and toxin production [145]. Motility enables *Campylobacter* to move to host cells so that they can adhere to and invade, and flagella are required for this property [145]. Adherence of *Campylobacter* to host intestinal epithelial cells permits colonization and enhances concentrations of secreted bacterial factors encountered by these cells. Adherence is presumed to be a prerequisite for invasion. The rates of invasiveness of *Campylobacter* spp. vary considerably [146], but might be as low as 1% of the initial inoculum [147]. Internalization into host cells requires the concerted effort of actin microfilaments and microtubules [148,149]. Once intracellular, *Campylobacters* reside in membrane-bound vacuoles where replication appears to be limited and survival is aided by the expression of catalase, which protects the organism from the oxidative stress of lysosomes [149,150].

Functional studies suggest that *C. jejuni* and *C. coli* express a cholera toxin (CT)-like enterotoxin [145], but no genes similar to CT have been identified in the *C. jejuni* genome [151]. *Campylobacter* spp. can produce several distinct cytotoxins [145], the best defined of which is the multisubunit cytolethal distending toxin (CDT). This toxin causes cell cycle arrest, leading to a characteristic elongation and swelling of susceptible cells. Although intoxicated cells remain viable for up to 72 h, they eventually die. The CdtB subunit of CDT has DNase activity [152,153]. However, the role of CDT in *Campylobacter* pathogenesis is unclear. Other organisms, including pathogenic *E. coli*, *Shigella* spp., and certain *Helicobacter* spp., also express CDT, but the contribution of CDT to fluid secretion is variable. For example, *E. coli* CDT does not stimulate intestinal secretion in rabbit ileal loops [154]. The role of the CDT family of toxins in enteric bacterial pathogenesis warrants further elucidation.

Clinical aspects

As few as 500 ingested *C. jejuni* can cause disease [155,156], suggesting that this organism possesses mechanisms of protection against gastric acid. The typical course of *Campylobacter* infection is depicted in Figure 48.2. The incubation period is from 18 h to 8 days (average 3.2 days) [157]. The onset

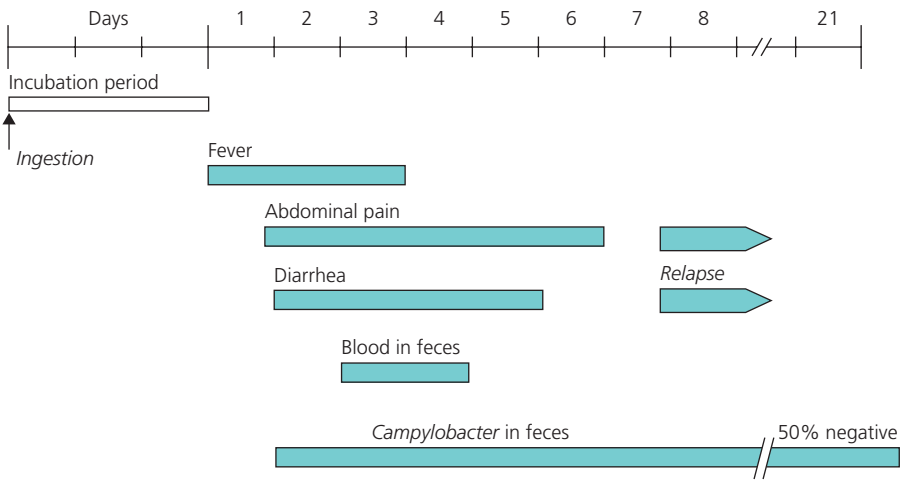

Figure 48.2 Typical course of human infection with *Campylobacter jejuni*. Redrawn by V.K. Viswanathan from Greenwood et al. [159].

of symptoms can be abrupt, with prodromal abdominal cramps, fever, headache, malaise, and myalgia, followed by diarrhea. Febrile rigors can occur. An influenza-like prodrome for 2–3 days before gastrointestinal symptoms caused by *Campylobacter* predicts more severe illness. *Campylobacter*-associated diarrhea (up to 10 stools per day) is watery initially and progresses to bloody diarrhea 1–2 days later in about 15% of patients [157]. This might indicate extension of infection to the colon. The colonoscopic appearance ranges from mild mucosal hyperemia to severe mucosal destruction with friable, edematous, and even ulcerated epithelia, but such findings are nonspecific. Histologically, there is acute inflammation, with predominant neutrophilic infiltration and crypt abscesses. The absence of distorted crypts and a normal mucus cell population can aid the differentiation of infection from IBD, but in chronic infections the distinction becomes less clear. Further blurring the boundary between *Campylobacter* infection and IBD is the potential for relapse of this infection, reported in 15%–25% of infected patients, and the possibility that IBD patients can be infected with *C. jejuni* [158].

The abdominal pain caused by *Campylobacter* can be so severe and localized that it mimics appendicitis. This is usually caused by ileocecitis and mesenteric adenitis, but *Campylobacter* has also been isolated from inflamed appendices [160]. Other symptoms include nausea and vomiting (15% of patients) and significant weight loss. Most patients begin to improve after 3–4 days, but they can excrete organisms for extended periods (mean 38 days, maximum 69 days) [161].

Circulating antibodies against *Campylobacter* antigens can be detected within 5 days of illness onset, peaking in 2–4 weeks [155]. Infection confers at least short-term protection against homologous strains, but the duration and breadth of protection are undefined. The incidence and severity of *Campylobacter* infections decrease in at-risk groups over time, suggesting some level of long-term protection in populations (or less adventurous eating habits).

Complications

Intestinal complications of *Campylobacter* infection include hemorrhage [162], ulceration of ileostomy stomas [163,164], pancolitis [165], and toxic megacolon. Extraintestinal complications include erythema nodosum [166], urticaria [167], bacteremia [168], cholecystitis [169], pancreatitis [170], abortion [171], nephritis [172], and cardiac complications [173]. More common complications include reactive arthritis, Reiter syndrome (for which HLA-B27 tissue antigen gives a strong predisposition), and Guillain–Barré syndrome (GBS) [174].

GBS is defined by flaccid paralysis, areflexia, and albuminocytological dissociation in the spinal fluid. At least four subtypes have been described [175]. It is caused by autoimmune-induced inflammation of peripheral nerves, which disrupts their function. GBS is the leading cause of acute paralysis, but has an annual incidence of only one to two cases per 100 000 population [175]. One-third of GBS patients have positive stool cultures and/or circulating antibodies to *C. jejuni* antigens [176]. Serum antibodies to *C. jejuni* lipopolysaccharide react with peripheral and central nervous system gangliosides [177]. Because antiglycoconjugate antibodies are present in GBS patients [174], molecular mimicry of neural oligosaccharides by microbial pathogens might underlie GBS pathogenesis.

Diagnosis

Campylobacters are long (0.5–5.0 μM), S-shaped, or spiraled gram-negative bacilli (rods). They have also been likened to "seagull wings." Immediate transfer into special transport medium such as Cary-Blair and inoculation onto plating medium enhances the isolation of this sometimes fastidious organism from stool. Although suboptimal, samples can be held at 4°C in transport medium for up to 24 h. The visualization of spiral organisms that rapidly dart and spin in diarrhea stools suggests *Campylobacter*, but a definitive diagnosis of *Campylobacter* infection can be made only using time-consuming bacteriology. We do not believe that a patient should be started on antibiotics in advance of positive culture results. Several rapid diagnostic tests have been developed, including latex agglutination tests to detect *Campylobacter* antigens in stool [128,178] and PCR-based tests, which provide same-day detection but which are expensive, do not allow antibiotic susceptibility testing [179], and are not widely available. Serological testing should be performed in patients with GBS, reactive arthritis, or erythema nodosum if stool cultures are negative for *C. jejuni* and such an antecedent infection is suspected [180].

Treatment

Specific therapy is not required for most patients because symptoms have usually resolved or are resolving by the time a microbiological diagnosis is made [181]. However, severely affected patients, i.e., those with dysenteric symptoms, relapsing symptoms, systemic infection, immunosuppression, or who are institutionalized, might benefit from antibiotic treatment. *C. jejuni* and *C. coli* are widely resistant to penicillins, cephalosporins, trimethoprim–sulfamethoxazole, rifampin and vancomycin [182]. Resistance rates of *Campylobacter* to fluoroquinolones are high (40%–88%) in many centers [183,184], and have been steadily increasing in the United States. Resistance is possibly caused by the administration of fluoroquinolones to animals, in particular commercial poultry [181]. Although these drugs are no longer administered to commercial flocks, resistant strains persist in the absence of selective pressure. In fact, coadministration of fluoroquinolone-resistant and -susceptible strains to the same chickens demonstrated a competitive advantage in the resistant ones, suggesting a survival advantage in the

resistant strains even in the absence of the antibiotic [185]. Erythromycin is the preferred drug for *Campylobacter* infection when antibiotics are indicated [186]. *Campylobacters* are also susceptible to the newer macrolides (azithromycin and clarithromycin), which might be better tolerated than erythromycin [181]. The resistance rates to erythromycin are up to 11% for *C. jejuni*, and up to 68% for *C. coli*. Erythromycin stearate, which is acid resistant, stable, and incompletely absorbed, offers a theoretical advantage over erythromycin ethylsuccinate (EES), but clinical evidence of superiority is lacking. EES is also the recommended treatment for children infected with *Campylobacter*. When resistance or other reasons preclude the use of erythromycin, tetracyclines and chloramphenicol are reasonable alternatives, but the prevalence of tetracycline resistance is around 60% and this drug should not be used in children in whom dental development is not yet complete. Azithromycin is an effective alternative in areas where fluoroquinolone resistance is high [187], and *C. jejuni* that are resistant to erythromycin are generally susceptible to azithromycin [188]. For systemic infections, an aminoglycoside or a carbapenem might be warranted; a simultaneous oral macrolide might aid eradication of the intestinal infection.

Clostridium infections

Clostridium difficile

History

Clostridium difficile gastrointestinal infections frequently come to the attention of consultant gastroenterologists. This organism was initially termed *Bacillus difficile* because of difficulties in culturing it; it was first described as part of the intestinal flora of newborns in 1935 [189]. Early in the antibiotic era, pseudomembranous colitis was attributed to *S. aureus*, until Bartlett et al. implicated *C. difficile* as a cause of this disorder in 1978 [190]. *C. difficile* is now the most common cause of nosocomial infectious diarrhea because of the widespread use of antibiotics and the high colonization rates in hospitalized patients. More recently, variant strains of *C. difficile* have emerged, including one that is toxin A negative/toxin B positive, at times presenting a detection challenge if cytotoxicity assays are the sole diagnosing modality [191], and one that produces the binary toxin CDT, has increased levels of toxins A and B, and is resistant to fluoroquinolones [192,193], making it potentially more virulent. Continuing studies will enable the delineation of the extent of the problems caused by this variant.

Epidemiology and prevention

Clostridium difficile is a gram-positive, anaerobic rod that is fastidious in its vegetative state but which sporulates in conditions that fail to support its growth. Sporulation allows *C. difficile* to persist for long periods in harsh environments, including dry surfaces and soil. This capacity for survival contributes to making *C. difficile* the leading infectious cause of health-care-associated diarrhea [194]. In addition, hospitals and long-term health-care facilities are often reservoirs of this pathogen, because establishment of infection usually depends on disruption of the indigenous intestinal microflora by antibiotics. Although *C. difficile* is recoverable from the stool of less than 3% of healthy individuals, it is found in approximately 20% of those hospitalized for longer than 1 week [194,195]. *C. difficile* can be cultured from the stool of up to 80% of healthy neonates and infants, but fails to produce symptoms, possibly from lack of expression of tissue receptors for toxins A and B by these children.

The incidence of *C. difficile* nosocomial infectious diarrhea in adults ranges from 20–60 cases per 100 000 patient days [195,196] and has significantly increased over the past few years [197]. There is evidence that the incidence of *C. difficile* infection in hospitalized patients has increased recently [197,198]. Interestingly, and of particular concern, the incidence of community-acquired *C. difficile*-associated diarrhea or disease (CDAD) has also increased [199]. In 1994, the number of cases of *C. difficile* infection was less than one per 100 000 persons; this had increased to 22 per 100 000 in 2004. Independent traditional risk factors for community-acquired CDAD include gastric acid suppression (proton pump inhibitors more than H_2 receptor antagonists), use of nonsteroidal antiinflammatory drugs, renal failure, IBD, malignancy, and infection with methicillin-resistant *S. aureus* [199]. In this study the role of antibiotics was questioned as only 37% of individuals had received antibiotics in the 90 days preceding the diagnosis of *C. difficile* infection. In addition, over the same interval, prescriptions for antibiotics actually decreased while those for proton pump inhibitors increased. Other studies have published similar data regarding the lack of association with antibiotic use [200], suggesting that, although certainly important, antibiotics are not a prerequisite for CDAD. The majority of studies carried out on CDAD are hospital-based, potentially exaggerating the role of antibiotics in CDAD because most patients have received such drugs. Additional investigation will be required to confirm the role of acid suppression and NSAIDs as risk factors for community-acquired CDAD.

Antibiotics predispose to CDAD by disrupting the normal colonic flora, allowing colonization after the patient is exposed to *C. difficile* or its spores, or expansion of resident *C. difficile* in response to selective pressures by antibiotics. Clindamycin is highly associated with CDAD [201] and its removal from hospital formularies has controlled outbreaks [202]. Some antibiotics, especially ampicillin and cephalosporins, often predispose to CDAD whereas others, such as parenteral aminoglycosides, vancomycin, and metronidazole, are less frequently implicated. For unclear reasons, third-generation cephalosporins are more commonly associated with *C. difficile* infection than are other broad-spectrum agents [203], and alterations in the use of these agents have decreased the occurrence of CDAD [204]. More recently, fluoroquinolones,

especially levofloxacin, have been associated with CDAD [205], which can be related to the emergence of a potentially more virulent strain [192,193].

Hospitalization is another risk factor for CDAD. There is a direct correlation between length of hospital stay and risk of becoming infected. Among patients hospitalized for greater than 4 weeks, 50% acquired *C. difficile* according to colonization analysis [206]. *C. difficile* has been isolated from numerous sites within hospital rooms, including telephones, call buttons, bed rails, toilets and bathroom floors, and from stethoscopes and the hands of health-care workers [195,207]. Patient-to-patient spread also occurs, particularly if a room is shared with an infected patient [207].

Although antibiotic administration and hospitalization set the stage for CDAD, the majority of patients exposed to these two risk factors do not manifest symptoms. Additional factors might be needed for clinical disease, such as alterations in host immunity, as suggested by the observations that patients with CDAD have lower levels of antibodies against *C. difficile* and its toxins than patients who are colonized with *C. difficile* [208]. Other possibilities include nonimmune host susceptibility and strain-specific virulence.

Outbreaks of CDAD within hospitals are often caused by a single or a related group of strains. Investigations of strains responsible for CDAD outbreaks in both the United States and Canada led to the identification of a toxin gene-variant strain of *C. difficile* [192,193]. Specifically, analysis of this strain demonstrated the presence of the gene encoding the binary toxin CDT, which is present in only 6% of *C. difficile* clinical isolates. In addition, this strain also contained a deletion in the *tcdC* gene, which is believed to negatively regulate toxin A and B expression; hence, deletion of this gene is associated with increased production of both of these toxins. Together, these genetic changes result in a more virulent strain of *C. difficile*. Hospitals worldwide have reported an increase in both the frequency and the severity of *C. difficile* infections [209–212]. Of additional concern is the resistance of this strain to fluoroquinolones; the increased use of these agents is likely responsible for the emergence of this strain.

Guidelines for preventing and controlling *C. difficile* infection have been published by the American College of Gastroenterology [213] and the Society for Healthcare Epidemiology of America [214] (Table 48.3). These guidelines have been consolidated and summarized [215]. Because the most likely method of transfer of *C. difficile* to patients is via the hands of health-care workers, good handwashing is the most important step in decreasing infection. Wearing gloves when handling *C. difficile*-infected patients or working in their environment might further reduce transmission; gowns should be worn if contamination of clothing is likely. The use of chlorine-containing disinfectants (1:100 dilutions or unbuffered hypochlorite or phosphate-buffered hypochlorite [1600 ppm]) significantly decreases environmental contamination [214]. Disinfection of thermometers and stethoscopes is also important.

Pathogenesis

The pathogenesis of *C. difficile* colitis is largely related to the production and secretion of two potent toxins, A and B [217,218]. These are high-molecular weight proteins (308 and 270 kDa respectively) that enter intestinal epithelial cells via specific, but as yet unidentified, receptors expressed on the apical surface. Once inside the host cell, these distinct but homologous (49% amino acid identity) toxins exert similar

Table 48.3 Practice guidelines for the prevention and control of *Clostridium difficile* infection

American College of Gastroenterology recommendations[a]	Society for Healthcare Epidemiology of America recommendations[b]
1. Limit the use of antimicrobial drugs	1. Antimicrobial use restriction is indicated if a specific antimicrobial, particularly clindamycin, is identified as a risk for *C. difficile*-associated diarrhea (CDAD)
2. Wash hands between contact with all patients	2. Handwashing with either an antimicrobial agent or soap is recommended after contact with patients, their body substances, or environmental surfaces
3. Use enteric (stool) isolation precautions with *C. difficile* diarrhea	3. Isolation of patients with CDAD in private rooms is recommended if private rooms are available; priority should be given to patients unable to maintain bowel continence and good hand-washing hygiene
4. Wear gloves when in contact with patients who have *C. difficile* diarrhea/colitis or with their environment	4. Glove use by personnel for the handling of body substances of all patients is recommended to reduce the rate of CDAD
5. Disinfect objects contaminated with *C. difficile* with sodium hypochlorite, alkaline glutaraldehyde, or ethylene oxide	5. Replacement of electronic thermometers with disposable thermometers is recommended if CDAD rates are high
6. Educate the medical, nursing, and other appropriate staff members about the disease and its epidemiology	

a From Fekety [213].

biochemical effects by inactivating Rho proteins (a family of small GTP-binding proteins) that regulate actin polymerization. Rho inactivation is accomplished by toxin-induced glucosylation of a specific threonine residue in the Rho proteins, for example Rho_{ABC}, Rac, and Cdc42 [219,220]. This modification depolymerizes actin filaments, which leads to collapse of the cytoskeleton and, subsequently, the characteristic cell rounding that is the basis of the diagnostic tissue culture assay for *C. difficile* toxin. The physiological effects on the intestinal epithelial cell are to increase tight junction permeability [221,222] and fluid secretion [223,224]. In addition to their direct effects on intestinal epithelial cells, toxins A and B elicit profound inflammation, contributing further to disruption of the tight junction barrier and increased lumenal fluid. Moreover, colonic damage is caused by both proteins [224]. The binary toxin CDT is similar to the iota toxin produced by *Clostridium perfringens*. The role of CDT in *C. difficile* pathogenesis is unclear because toxin A- and B-negative strains colonize hamsters but do not induce diarrhea, but instillation of purified CDT into closed intestinal loops of animals does induce fluid secretion [225].

The marked inflammation that accompanies *C. difficile* infection is a multifactorial response. One early event is activation of the inflammation-associated transcription factor NF-κB. Inhibitors of cytokine synthesis attenuate toxin A effects [226]. Toxin A also causes monocytes to release IL-1β and IL-6 [226]. These effects recruit neutrophils to the intestine [227,228]. Induction of neutropenia significantly reduced fluid secretion [229], and inhibition of neutrophil infiltration of the intestine by specific antibodies [227,230], and inhibition or depletion of mast cells, attenuated neutrophil activation, fluid secretion, and host injury in experimental models of infection [231,232]. These effects can follow initial disruption of the intestinal epithelial barrier, allowing direct interactions between toxin A and inflammatory cells residing in the lamina propia.

Enteric nerves and neuropeptides are also involved in CDAD. Substance P (SP) expression by nerve cells in spinal dorsal root ganglia is immediately up-regulated following exposure of the intestine to toxin A. SP binds to neurokinin-1 (NK-1) receptors that are expressed by macrophages, releasing tumor necrosis factor (TNF)-α, a potent cytokine [233]. NK-1-deficient mice show diminished responses to intestinal toxin A [230,234]. Neurotensin (NT) is also involved in *C. difficile* colitis [235]. Both NT and SP receptors, whose expression is NF-κB dependent, are markedly up-regulated within 15–30 min of exposure to toxin A. An NT receptor antagonist reduces the intestinal effects of toxin A, including mucosal mast cell activation [235].

Clinical features

The clinical manifestations of *C. difficile* infection are broad, encompassing a carrier state devoid of symptoms, colitis without or with pseudomembranes, and fulminant colitis with megacolon or perforation. However, it should be noted that antibiotics commonly cause diarrhea independently of *C. difficile* infection [236]. The mechanisms underlying the broad range of symptoms associated with *C. difficile* are unclear but are likely attributable to host rather than bacterial factors; they include toxin receptor density, status of the resident intestinal flora, and concentration of antibodies against bacterial/toxin antigens. Hospitalized patients receiving antibiotics but who are not colonized with *C. difficile* have no immune protection against *C. difficile* colonization [208]. Following colonization, high levels of circulating immunoglobulin (Ig)G antibody against toxin A were strongly correlated with asymptomatic carriage of *C. difficile*, whereas low serum levels of toxin A IgG antibody were correlated with a much greater risk of *C. difficile* diarrhea. There was an eightfold increase in the risk of *C. difficile* diarrhea in patients with severe underlying illnesses [237]. These data support the development of passive or active immunization to control nosocomial *C. difficile* diarrhea.

Symptoms of *C. difficile* infection typically begin 4–9 days after initiation of antibiotic therapy, but diarrhea can develop even after antibiotic treatment has been halted in up to 30% of patients. This delay complicates the diagnosis of CDAD unless the clinician is aware of this previous risk factor.

C. difficile can affect the small bowel. Additional noncolonic manifestations of *C. difficile* infection include metastatic infection and postinfectious arthritis [238].

Asymptomatic carriage of C. difficile

Although hospitalization is a risk for infection with *C. difficile*, most colonized patients are free of symptoms [195,207]. This subset of *C. difficile*-infected individuals serves as a reservoir of this organism, which can contaminate the hospital environment. Asymptomatic carriers of *C. difficile* should not, however, be treated with antibiotics in an attempt to eradicate this organism.

Nonpseudomembranous C. difficile *colitis*

About half of those with diarrhea who are confirmed as positive for the *C. difficile* organism or toxin have clinical symptoms that are similar to but less severe than those associated with pseudomembranous colitis. Typical manifestations include abdominal pain, cramps, watery diarrhea, malaise, nausea, and possibly dehydration and fever. Laboratory tests commonly demonstrate a neutrophilic leukocytosis. In fact, the sudden onset of leukocytosis in hospitalized patients who have recently received, or who are receiving, antibiotics should immediately trigger testing for *C. difficile* infection [239]. Sigmoidoscopy can show only friable and erythematous mucosa but no pseudomembranes.

Pseudomembranous colitis

Pseudomembranous colitis is the prototypic entity associated with *C. difficile* infection but occurs in less than 25% of

diagnosed cases [215]. Symptoms, including diarrhea and abdominal pain, usually begin within a week of antibiotic administration, but might not appear until even 6 weeks after antibiotics have been discontinued [228]. Fever, chills, nausea, vomiting, dehydration, and tenesmus can accompany the diarrhea and abdominal cramping. Physical findings are nonspecific and include diffuse abdominal tenderness and distention. Occult blood can be present in the stool but hematochezia is rare. Fecal leukocytes are detected in about half of patients but peripheral leukocytosis is common and can serve as a surrogate marker of this infection [239]. Three patterns of leukocytosis have been reported: a sudden increase in the white blood cell (WBC) count correlating with symptoms of *C. difficile* colitis; leukocytosis preceding *C. difficile*-associated symptoms; or exacerbation of preexisting leukocytosis plus nonspecific symptoms of *C. difficile* disease [239]. In the last two scenarios, the diagnosis of *C. difficile* colitis is generally delayed. Consideration of *C. difficile* infection as a cause of unexplained leukocytosis is therefore recommended.

Although rarely necessary, the diagnosis of pseudomembranous colitis can be confirmed rapidly by sigmoidoscopy. Characteristic yellowish-white, raised plaques, 2–10 mm in diameter, are seen. These small plaques can coalesce and cover the entire mucosa (Fig. 48.3). Microscopic analysis of biopsies from pseudomembranes shows the typical summit or "volcano" lesion in which inflammatory cells, fibrin, and mucus exude from microulcerations in the surface epithelium (Fig. 48.4).

Although sigmoidoscopy usually demonstrates such findings in up to 30% of patients, pseudomembranes can be restricted to the more proximal colon [241] or even be absent altogether. Colonoscopy is not recommended, however, unless other diagnostic measures have failed.

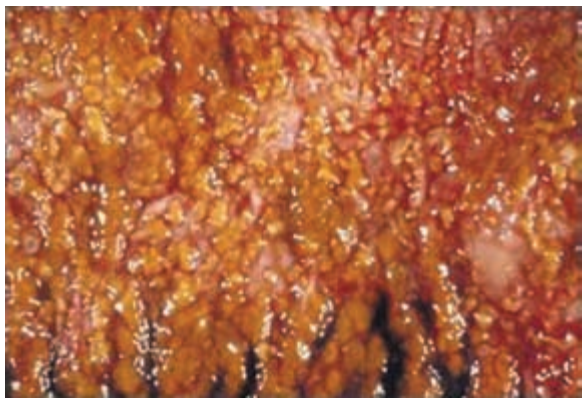

Figure 48.3 Colonoscopic appearance of mucosa with pale or yellow plaques (pseudomembranes) in patient with *Clostridium difficile* colitis. The nearly confluent light-colored pseudomembranes are typical of severe *C. difficile* pseudomembranous colitis. The pseudomembranes are composed of purulent debris. From Bartlett [240], with permission from the Massachusetts Medical Society.

Fulminant colitis

In fulminant *C. difficile* colitis, transmural inflammation can lead to the most serious complications associated with this infection. These include ileus, perforation, megacolon, and death [242]. This scenario occurs in approximately 3% of patients but might be more common in those infected with the toxin gene-variant strains that express the binary toxin and higher concentrations of toxins A and B [192]. Fulminant colitis can present acutely or evolve from a milder infection. The symptoms are typically more severe with signs of toxemia, constant, localized abdominal pain with guarding, and decreased bowel sounds. Fever, tachycardia, and ascites can also be present. Severe leukocytosis (up to 40 000 WBC/μl) can occur. Hypoalbuminemia can result from severe protein-losing enteropathy [243]. Diarrhea can actually decrease as severe colitis evolves as a result of acute colonic dilation and paralytic ileus. The diagnosis of toxic megacolon is defined as dilation of the colon to more than 7 cm in diameter and severe toxemia, manifest as fever, chills, leukocytosis, and dehydration. An abdominal flat plate can demonstrate a dilated colon and thickening of the colonic wall can be seen by computed tomography, although these findings are nonspecific. Dilation of the small bowel with air–fluid levels can accompany large bowel findings and mimic intestinal obstruction or ischemia [243]. If perforation has occurred, abdominal guarding, rebound tenderness, rigidity, and diminished bowel sounds are typical. An acute abdomen in a patient with a history of current or recent antibiotic therapy requires the urgent exclusion of *C. difficile* colitis to prevent unnecessary surgical intervention [244]. In such cases, a limited and cautious sigmoidoscopy with minimal air introduction should be considered. The finding of pseudomembranes will establish the diagnosis of *C. difficile* colitis. If, however, more severe signs, such as extreme leukocytosis (> 30 000 WBC/μl), hypotension, or metabolic acidosis are present, laparotomy and colectomy might nevertheless be indicated to treat impending or existing colonic perforation (Fig. 48.5) [244].

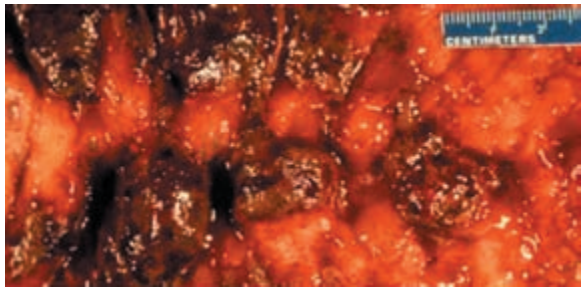

Figure 48.5 Resected colon of patient with fulminant colitis caused by *Clostridium difficile.* The photograph shows the nearly confluent light-colored pseudomembranes that are typical of severe *C. difficile* pseudomembranous colitis. The pseudomembranes are composed of purulent debris and contrast sharply with the edematous interposed darkly colored mucosa.

Diagnosis

Unlike the diagnostic strategy for other enteric pathogens, stool culture for *C. difficile* is rarely used because both toxigenic and nontoxigenic strains (i.e., nonpathogens) are detected by culture. Isolates must then be tested for toxin production, further delaying the diagnosis. Moreover, the technology needed to recover this anaerobic organism from the polymicrobial matrix of human stool is more complicated than the techniques employed in most clinical diagnostic laboratories. For these reasons, the gold standard for diagnosing *C. difficile* infection has been a tissue culture assay that seeks the presence of toxins A and B in the stool [245,246]. Diarrheal stool is filtered and applied to cultured human fibroblasts that are examined 24–48 h later for cytotoxic effects (cell rounding or detachment). Incubating the stool sample with neutralizing antitoxin antibody (antibody to *Clostridium sordellii*) and assessing for protection against cytotoxic changes confers specificity of effect. Test results are reported as positive or negative because titers do not correlate with disease activity [246]. Although this test is highly sensitive (94%–100%) and specific (99%) [227,228], it is expensive and is performed in a diminishing number of centers. Because toxins A and B each possess cytotoxic activity, this assay detects both. On a molar basis, however, toxin B is much more potent than toxin A; thus, the stool cytotoxic effect is due primarily to toxin B, which is classically (though erroneously) considered to be the sole *C. difficile* cytotoxin.

Several EIAs detect *C. difficile* products, including toxins [247] and a nontoxin *C. difficile* antigen [248]. Although these tests are somewhat less sensitive than cell culture, they are equally specific (99%), provide same-day results, and are widely utilized by laboratories. It is imperative, however, that assays capable of detecting both toxin A and toxin B be employed before calling a specimen negative, in view of the emergence of strains that are toxin A negative but toxin B positive [191]. Sigmoidoscopy or colonoscopy is rarely required to diagnose *C. difficile* colitis, but if a diagnosis is urgently required in a seriously ill patient, or if the diagnosis is in doubt, these tests can be performed. The presence of pseudomembranes (Fig. 48.3) essentially establishes the diagnosis of *C. difficile* colitis, although illness without severe colitis will not be discerned.

Treatment

Because CDAD is often a consequence of antimicrobial therapy, the first step in treatment is to discontinue such drugs [249]. However, if this is not possible, or if symptoms persist following cessation of antibiotics, then a series of therapeutic options should be pursued (Table 48.4). Antiperistaltic drugs should be avoided. This measure will resolve symptoms in 15%–23% of patients [250]. Indications for treatment of CDAD with antibiotics include severe or persistent diarrhea following discontinuation of the causative antibiotic, and clinical evidence of colitis including fever and leukocytosis. Metronidazole and vancomycin are the mainstays of therapy for *C. difficile* colitis. Oral metronidazole is the initial drug of choice because of its lower cost, excellent clinical efficacy, and rising concern regarding glycopeptide resistance in other organisms such as enterococci [249]. The efficacy of this therapy is greater than 95% [214]. The oral adult dosing regimen is 250 mg four times a day or 500 mg three times a day for 10 days. Symptomatic improvement is typically seen within 2–4 days and resolution of diarrhea by 7–10 days [251]; treatment should not be considered to have failed before 7 days of therapy. Although metronidazole is absorbed in the small bowel, it subsequently gains access to the colonic lumen by diffusing from the blood across the inflamed intestinal mucosa. Excretion into bile also contributes to the intestinal concentration [252]. Metronidazole causes a metallic aftertaste, can induce alcohol intolerance, might cause nausea, and should not be used in pregnant or lactating women.

Oral vancomycin is an alternate treatment for CDAD and its efficacy is equal to or better than metronidazole [254]. Vancomycin is not well absorbed, accounting for high fecal levels and rare side effects. Low doses (125 mg p.o. four times a day for 10 days in adults) are as effective as higher doses [255]. The expense of vancomycin and the emergence of resistant organisms have led to vancomycin being recommended for patients who fail to respond to, or who do not tolerate, metronidazole treatment [213]. For severe or fulminant pseudomembranous colitis, however, initial treatment with vancomycin is recommended. The rationale is the superb delivery of vancomycin to the colon and a slightly, but potentially important, greater efficacy in the treatment of pseudomembranous colitis [251]. In the case of ileus or toxic megacolon, however, intravenous metronidazole should be given either alone or possibly in combination with vancomycin administered by nasogastric tube or rectally.

Table 48.4 Treatment recommendations for first-occurrence *C. difficile*-associated diarrhea (CDAD) and CDAD recurrences

	Agent	Adult dose[a]	Duration	Side effects
First-line treatment, first occurrence	Metronidazole	250 mg t.i.d.	10 days	Disulfiram-like reaction, nausea, vomiting, metallic taste in mouth, peripheral neuropathy (rare during short-course therapy). Should not be used during pregnancy
	Vancomycin	125 mg p.o. q.i.d.	10 days	None
First recurrence (confirm diagnosis with antigen test for all recurrences; consider withholding treatment if symptoms are not severe)	Metronidazole	250 mg t.i.d.	14 days	Disulfiram-like reaction, nausea, vomiting, metallic taste in mouth, peripheral neuropathy (rare during short-course therapy). Should not be used during pregnancy
	Vancomycin	250 mg p.o. t.i.d.	14 days	None
7-week taper	Tapering course of vancomycin	125 mg p.o. q.i.d. 125 mg p.o. t.i.d. 150 mg q.d. 125 mg q.o.d. 125 mg q3days	1 week 1 week 1 week 2 weeks 2 weeks	
Third and subsequent recurrences	Tapering vancomycin as above, plus:			
	Saccharamyces boulardii	500 mg p.o. b.i.d.	30 days started during the last week of the taper	None
	or			
	Cholestyramine	4 g p.o. per day	Starting during the last week of the taper	Bloating, constipation, medication interactions

a Dosage recommendations are for adults and might need adjustment based on body habitus and other factors.
b.i.d, twice a day; p.o., orally; q.d., once a day; q.i.d., four times a day; q3days, every 3 days; q.o.d., every other day; t.i.d., three times a day.
Recommendations abstracted from Maroo & Lamont [253].

Relapsing C. difficile *colitis*

A minority (5%–30%) of patients develop recurrent symptoms 1–2 weeks following the discontinuation of antibiotics for *C. difficile* treatment [214], caused either by relapse from the original infecting organism or by reinfection with a different strain, especially if the patient remains in hospital. A screen of 93 hospitalized patients with recurrent *C. difficile* diarrhea demonstrated that nearly half (48%) of these cases were caused by reinfection with a different strain [256]. If only mild diarrhea is experienced, consideration should be given to symptomatic treatment without antibiotics. However, if treatment is warranted on clinical grounds, and because recurrence of CDAD is not a result of antimicrobial resistance [250], the first approach should be to administer another 10- to 14-day course of the antibiotic used initially (Table 48.4). There is no need to use higher doses of metronidazole or vancomycin to treat recurrent CDAD.

For multiple relapses, various treatment options exist and often depend on relapse severity [253]. Possibilities include a 4-week course of either metronidazole or vancomycin or a tapering schedule of vancomycin over several weeks. This regimen was curative in all patients tested with no relapses seen during follow-up ranging in duration from 2 to 12 months [257]. Rare cases in which symptoms recur following cessation of therapy and toxin assays remain positive or revert back to positive after they became negative on therapy can require tapering vancomycin over months or even years. Bacitracin is rarely used to treat CDAD today. An anion-binding resin, such as cholestyramine, which theoretically binds the toxins of *C. difficile*, can be added to this regimen. Because cholestyramine can bind to and neutralize vancomycin, patients must not take these agents simultaneously but, instead, separate the doses by 3 h. The combination of vancomycin plus rifampin has also proven effective for relapses [258], and rifaximin has been proposed to treat this infection in difficult cases [259].

Novel strategies to treat *C. difficile* infection, including the use of probiotics, are being investigated [260,261]. *Saccharomyces boulardii*, a nonpathogenic yeast, has been used to prevent antibiotic-associated diarrhea [262]. *S. boulardii* also decreased significantly the number of relapses in patients treated with high-dose vancomycin (2 g/day) but not those treated with

lower doses (500 mg/day) or metronidazole [263]. Other strategies to reestablish normal flora include the administration of *Lactobacillus* species [264] and rectal infusions of feces with or without antecedent bowel irrigation [240,265,266]. Intravenous immunoglobulin and passive oral immunotherapies, such as bovine colostrum from cows immunized with *C. difficile*, have produced increased serum antitoxin levels or resolution of symptoms [267–270].

The possibility that recurrent CDAD symptoms represent IBD should also be considered.

Clostridium perfringens

History

Clostridium perfringens was initially implicated as a cause of food poisoning in the mid-1900s [271,272]. Studies subsequently demonstrated that *C. perfringens* causes two distinct illnesses in humans: type A food poisoning [273] and gastroenteritis necroticans (also termed Darmbrand or Pig Bel) [274]. Because microbiological tests to detect this organism are rarely applied outside of epidemic settings, and because *C. perfringens* food poisoning, although common, is self-limited, gastrointestinal infections caused by *C. perfringens* are rarely diagnosed.

Epidemiology and prevention

A diarrheal syndrome resembling type A *C. perfringens* food poisoning is often identified in outbreaks and diagnosed if appropriate microbiological evaluations are applied. Meat and poultry have been the food vehicles most frequently implicated [275]. A relatively high proportion of foodborne outbreaks have been attributed to *C. perfringens* in the United States [275] and Australia [276]. Type A food poisoning from *C. perfringens* is most common in the summer [277], but infections can occur year round. The considerably rarer gastroenteritis necroticans has been limited to particular regions of the world. It was first described in post-World War II Germany, where malnourished populations suffered necrotizing enteritis following the consumption of pork. It remained endemic in the Papua New Guinea highlands until the 1980s when a vaccine was introduced that dramatically diminished its incidence and lethality [43]. Gastroenteritis necroticans is quite likely present and under-recognized in nonendemic areas [278,279].

Infections with *C. perfringens* type A are best prevented by keeping foods refrigerated [273]. Gastroenteritis necroticans is prevented by appropriate cooking of food that is likely to be contaminated, in particular pork products, and also by vaccination with a toxoid in endemic areas [280].

Pathogenesis

Clostridium perfringens is a gram-positive rod that is ubiquitous in soil and is also a normal inhabitant of human and animal gastrointestinal tracts. *C. perfringens* is characterized by its toxin-producing profiles (toxinotypes), which group these organisms into five categories (A, B, C, D, and E) (reviewed in [281]). *C. perfringens* type A, which produces alpha toxin as well as the *C. perfringens* enterotoxin (CPE), is the organism that is the chief cause of food poisoning in humans. Alpha toxin is a chromosomally encoded phospholipase C/sphingomyelinase, which disrupts membranes by hydrolyzing phospholipids. Although alpha toxin might mediate extraintestinal injury, such as myonecrosis (gas gangrene), it is not believed to play a major role in gastrointestinal illnesses.

CPE is believed to be the most important *C. perfringens* toxin in the pathogenesis of type A food poisoning. CPE is a 35-kDa protein, which, in human volunteer studies, is sufficient to produce diarrhea and cramping, symptoms that are prominent in *C. perfringens* type A food poisoning [282]. Moreover, *C. perfringens* from which *cpe*, the gene encoding CPE, has been deleted do not cause secretion in a rabbit ligated ileal loop model [283]. In type A *C. perfringens* food poisoning that is associated with human foodborne intoxications, the *cpe* gene is usually encoded on the chromosome, but sporadic cases are often associated with strains that have plasmid-encoded *cpe* [284,285]. CPE is secreted into the intestinal lumen by *C. perfringens* after sporulation is complete. It then binds to a receptor, probably a member of the claudins [286], a family of tight junction transmembrane proteins that are important for tight junction integrity and function; it is possible that the efects of CPE on the gut relate to its actions on claudins. In rabbits, CPE shortens villi and disrupts epithelial integrity [287,288]. When CPE binds to host cell plasma membranes, a so-called "small-complex" forms, which probably represents the attachment of CPE to its receptor or receptors (reviewed in [289]). In vitro, small complexes coalesce into large CPE complexes within plasma membranes, which then correlate with changes in membrane permeability in cultured eukaryotic cells. Pores permeable to water and ions are formed in the membranes. CPE can induce apoptosis via caspase 3/7 activation [290]. Additional mechanisms of cell death from CPE include calcium-mediated oncosis [291].

Toxinotype C *C. perfringens* causes gastroenteritis necroticans. Toxinotype C strains produce beta toxin, which is believed to be the critical virulence factor. An interesting hypothesis emerged in the 1970s, which proposed that dietary trypsin inhibitors (such as are found in sweet potatoes, a dietary staple in the Papua New Guinea highlands) inactivate this toxin [292]. Beta toxin is encoded on a large plasmid and forms pores within membranes [293]; its additional intracellular targets remain unknown [294]. Its role in human disease pathogenesis is established by the fact that a vaccine against a toxoid of beta toxin largely eliminated disease in an endemic area [43].

Clinical manifestations

Type A food poisoning is usually recognized as a clustered infection and consists of 1–2 days of painful, nonbloody,

afebrile diarrhea [295]. It strikes people of all ages. Preformed toxin in food can cause symptoms. Vomiting is rare [296]. Gastroenteritis necroticans generally presents with a distended, painful abdomen and might or might not be accompanied by diarrhea. Often the adult with gastroenteritis necroticans has a serious underlying disorder, including alcoholism and occasionally fecal impaction.

Treatment

Clostridium perfringens type A infections are self-limited, short-lived, and rarely warrant intervention. Gastroenteritis necroticans is considerably more serious; affected patients are treated with antibiotics and resection of the affected areas of the bowel.

Diagnosis

Clostridium perfringens type A food poisoning is best diagnosed by EIA of the stool. This test is rarely available outside of research studies or public health laboratory investigations. Gastroenteritis necroticans is best diagnosed clinically at laparotomy and confirmed by sampling enteric contents and by PCR and phenotypic analysis of recovered anaerobes.

Sequelae

There are no known sequelae to either infection, but the mortality rates from both forms of *C. perfringens* infection can be considerable in fragile hosts.

Escherichia coli

Background

Escherichia coli are typically harmless commensals that colonize the gastrointestinal tracts of humans and mammals, with the initial colonization within the first day of life. They are gram-negative bacilli and the major component of the facultative anaerobic flora. However, a subset of *E. coli* cause a variety of human intestinal illnesses, in particular diarrhea. These diarrheagenic *E. coli* often cause signature clinical manifestations and host injury patterns. Here, we will discuss the currently accepted major diarrheagenic *E. coli* groupings: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enteroinvasive *E. coli* (EIEC), EHEC, enteroaggregative *E. coli* (EAEC), and diffuse adherent *E. coli* (DAEC). It is likely that additional categories of diarrheagenic *E. coli* will be recognized in the future.

There are three major challenges pertaining to the diagnosis of diarrheagenic *E. coli*. First, diagnosis at presentation is rarely possible because, except for *E. coli* O157:H7, diarrheagenic *E. coli* have few or no phenotypes that enable them to be distinguished using standard or widely available microbiological techniques. The detection of diarrheagenic *E. coli* largely relies on cumbersome phenotypic determinations (cell invasion, adherence, toxicity assays) and DNA hybridization assays (colony hybridizations or PCR). Identifying the O (somatic) antigen can suggest categorizations of diarrheagenic *E. coli*, but such tests are rarely performed in clinical laboratories. Because most illnesses caused by diarrheagenic *E. coli* are self-limited, it is difficult to make a compelling case for diagnosis. However, the failure to detect diarrheagenic *E. coli* has hindered attempts to study their epidemiology and the diseases that they cause, and their importance is almost certainly underappreciated. Furthermore, this inability to identify the patients who are infected with diarrheagenic *E. coli* at the point of presentation thwarts our ability to determine if antibiotics can change the clinical course of such infections.

Second, diarrheagenic *E. coli* exemplify the difficulty of defining an enteric pathogen. Pathogenicity among *E. coli* is derived from multiple virulence genes, which encode molecules that overcome or subvert host defenses and enable the pathogen to adhere to, injure, and invade host cells or tissues. These molecules include adhesins, polysaccharides, toxins, invasins, and siderophores (iron acquisition proteins). However, virulence loci are often found on mobile elements (i.e., bacteriophages and plasmids) and can be horizontally transferred to and from nonpathogens and even between different bacterial species. A repertoire of virulence determinants is necessary for pathogenicity; allelic variation, synergy between virulence factors, and well-performed epidemiological studies all need to be considered before designating an organism as a pathogen merely based on the presence of one or more pathogenicity-associated loci.

Third, people without diarrhea can excrete putatively diarrheagenic *E. coli* at variable frequencies, which is frequently not the case with pathogens in other genera. To address this problem, a "pathogenicity index" was proposed, which takes into account excretion rates in people with and without diarrhea [297].

Enterohemorrhagic E. coli *(*E. coli *O157:H7 and non-O157:H7 Shiga toxin-producing* E. coli*)*

History

In 1983, two nearly simultaneous publications introduced the concept of cytotoxin-producing *E. coli* to the medical community. Karmali et al. [298] associated fecal *E. coli* that could produce a toxin lethal to cultured eukaryotic cells with childhood HUS, a disorder that often follows bloody diarrhea. Riley et al. [299] described clusters of cases of bloody diarrhea that were attributable to *E. coli* expressing O antigen 157 and H antigen 7, and which were associated with the consumption of undercooked hamburgers. Soon after it was demonstrated that *E. coli* O157:H7 produced a cytotoxin neutralizable by antibodies to the principal toxin produced by *S. dysenteriae* serotype 1 [300], and in 1987 the Shiga toxin (Stx or STEC) of *E. coli* O157:H7 was cloned and sequenced [301]. *E. coli* O157:H7, and, to lesser extents, non-O157:H7 Stx-producing *E. coli*, have subsequently been isolated worldwide. They have also been associated with HUS, epidemics, and sporadic infections. *E. coli* containing genes encoding Stx

are quite common in food and the environment; the subset that causes human disease is typically referred to as EHEC. Their virulence probably results from their ability to produce factors other than Stx, of which intimin and other molecules encoded by genes in the locus of enterocyte effacement (LEE) pathogenicity island are the best studied.

Epidemiology and prevention

Escherichia coli O157:H7 infections have most notoriously been associated with the consumption of poorly cooked ground beef and have occurred in the context of large outbreaks. However, in reality, a wide range of food and environmental vehicles have been implicated in the transmission of *E. coli* O157:H7 [302]. Furthermore, most infections occur sporadically or in conjunction with another infected member of the household and not as large epidemics [302]. EHEC have been found in resource-poor countries [303] suggesting that they are not solely a problem of industrialized countries, even though that is where they have been most frequently detected. The epidemiology and clinical aspects of non-O157:H7 EHEC infections, and the vehicles that transmit these agents, are considerably less well delineated than are *E. coli* O157:H7 infections.

Consumers and the food industry can prevent *E. coli* O157:H7 infections by thoroughly cooking food of animal origin, hygienic food preparation practices, and consuming pasteurized milk and milk products. Control of this pathogen in the environment and on fresh produce is more challenging and probably more important, because *E. coli* O157:H7 infections are at least likely to be caused by rural, environmental, and agricultural exposures, and consumption of contaminated produce, as they are to the consumption of contaminated beef. A nationwide epidemic of *E. coli* O157:H7 infections disseminated by raw spinach attests to this risk [20].

Vaccination of humans against *E. coli* O157:H7 is potentially feasible, and a purified lipopolysaccharide vaccine is immunogenic and safe in children and adults [304,305]. A plant-based vaccine strategy using Stx epitopes as the immunogen was successful in mice [306]. Challenges to the immunoprophylaxis of human infections include the need to test effectiveness for a disorder with a low incidence, duration of immunity, and lifelong risk of acquiring infection (i.e., persons of all ages are susceptible). Vaccination of, or use of probiotics in, cattle, has been proposed as a mechanism to control this pathogen in this reservoir, but efficacy will depend on a variety of ecological factors (discussed in [307]).

Pathogenesis

The cardinal virulence trait of EHEC is the ability to produce one or more variants of Stx. Stx1, and its closely related allelic forms, are nearly identical to Stx produced by *S. dysenteriae* serotype 1 [301]. Stx2 and its variants (which are more diverse than those of Stx 1) are more distantly related to Stx/Stx1. Stxs are typical A/B toxins. There are five B subunits for each A subunit in the holotoxin, resulting in an AB_5 structure.

The B subunit forms a pentamer and binds to a receptor on eukaryotic cell surfaces, namely globotriaosylceramide (Gb_3) [308]. The toxin is then internalized and the A subunit is probably the most important effector (active) subunit.

Stxs have multiple effects on eukaryotic cells [309]. The A subunit resembles ricin in structure and it functions as an N-glycosidase, cleaving the eukaryotic large ribosomal subunit at a specific adenine residue, thereby halting protein synthesis. Purified B subunit, in the absence of the A subunit, causes apoptosis [310,311]. EHEC rarely cause fatal infections as would be expected in systemic intoxications by a ricin-like molecule. Indeed, sublethal concentrations of Stx induce expression of endothelin mRNA, which could contribute to the thrombotic response to intestinal infections with EHEC [312].

Stxs typify the conundrum posed by virulence loci and their allelic variants. In animal [313] and *in vitro* [314] studies, Stx2 is more potent than Stx1. In epidemiological and cohort studies, EHEC containing Stx2 [315,316] are more often associated with extraintestinal complications and with bloody diarrhea than are organisms containing Stx1. Interestingly, and counterintuitively, *E. coli* O157:H7 that contain genes encoding Stx1 and Stx2 are less often associated with HUS than are *E. coli* O157:H7 that contain Stx2 but which lack Stx1. Additional complexities emerge when examining allelic forms of Stxs. Stx2, and to a lesser extent Stx1, belong to larger families of toxins. Some Stx2 variants (Stx2 and Stx2c) have strong associations with human disease, whereas others (Stx2d and Stx2e) are less firmly associated with pathogenicity [317].

EHEC possess a variety of putative or confirmed non-Stx virulence loci. The best studied of these is intimin. In human pathogenic EHEC, intimins usually exist as either intimin-γ (found in *E. coli* O157:H7) or intimin-β (found in many non-O157:H7 EHEC). EHEC intimins are similar to the various intimins found in EPEC and they mediate the intimate attachment of EHEC to epithelial cells. The gene encoding intimin, *eae*, is also located in the LEE pathogenicity island, which encodes many proteins that are similar to those encoded by the LEE pathogenicity island of EPEC, including proteins that are necessary for the assembly and function of the structures and molecules of the type 3 secretion system (T3SS) (described in Enteropathogenic *E. coli*). With few exceptions [318], almost all pathogenic EHEC (which have a variety of Stx alleles) contain an intimin variant. Eukaryotic nucleolin can also serve as a receptor for intimin [319], although it is likely that EHEC Tir, which is injected by the organisms into the host cell, is also a ligand for intimin; EHEC Tir, unlike its counterpart in EPEC, is not tyrosine phosphorylated [320].

Two strains of *E. coli* O157:H7 have been sequenced in their entirety [321,322]. Approximately one-fourth of the

chromosomes of these organisms are not found in *E. coli* K-12. Except for Stxs, intimin, and several other members of the LEE pathogenicity island, few loci have been examined in great depth as candidate virulence loci. Of those that have, several emerge as potentially important in virulence. StcE is a secreted protein that potentiates the effect of C1 and which might protect *E. coli* O157:H7 from the lytic effects of complement [323]. Additional interesting loci include those encoding molecules that mediate adherence of *E. coli* O157:H7 to epithelial cells, such as long polar fimbriae [324], Iha, a demonstrated virulence factor in uropathogenic *E. coli* [325], Efa1/Lif1 [326], ToxB [327], and $EspF_U$ [328], which is important for epithelial cell pedestal formation.

Clinical aspects

Escherichia coli O157:H7 infections display a spectrum of severity, including rare cases of asymptomatic carriage [329], nonbloody and bloody diarrhea [316,330,331], and HUS. HUS, a nonimmune thrombotic microangiopathy, occurs in approximately 15% of diagnosed *E. coli* O157:H7 infections in children under 10 years of age. Typically, a patient infected with *E. coli* O157:H7 will experience 1–3 days of nonbloody diarrhea, which then becomes grossly bloody diarrhea in about 80% of microbiologically diagnosed cases (Fig. 48.6). About half of all infected patients report a fever early in illness, but very few patients are febrile when they are initially evaluated, usually at the onset of bloody diarrhea. Abdominal pain, which can be quite severe, and vomiting can precede the diarrhea. The clinical manifestations of non-O157:H7 EHEC infections are less well delineated, but, as a group, they are less likely to cause HUS [3] or to be associated with bloody diarrhea [332]. The colon can be quite severely affected (Fig. 48.7).

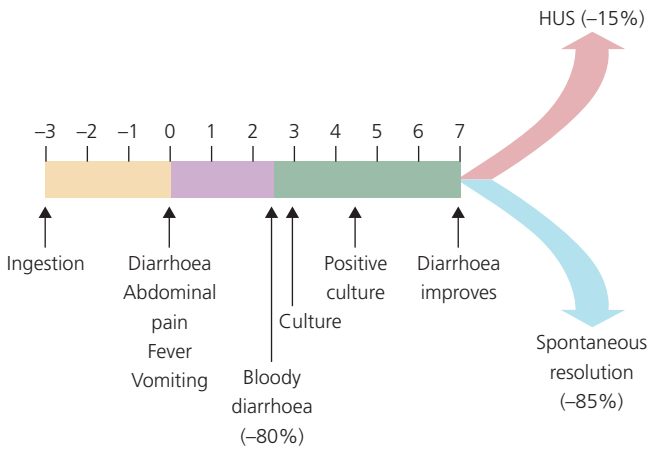

Figure 48.6 Progression of *Escherichia coli* O157:H7 infections in children. *E. coli* O157:H7 infections tend to follow a stereotypical pattern [343], and it is helpful to make clinical judgments based on stage of illness, in consideration of trends in laboratory tests, as portrayed in Figure 48.8. From Tarr et al. [302], with permission from Elsevier.

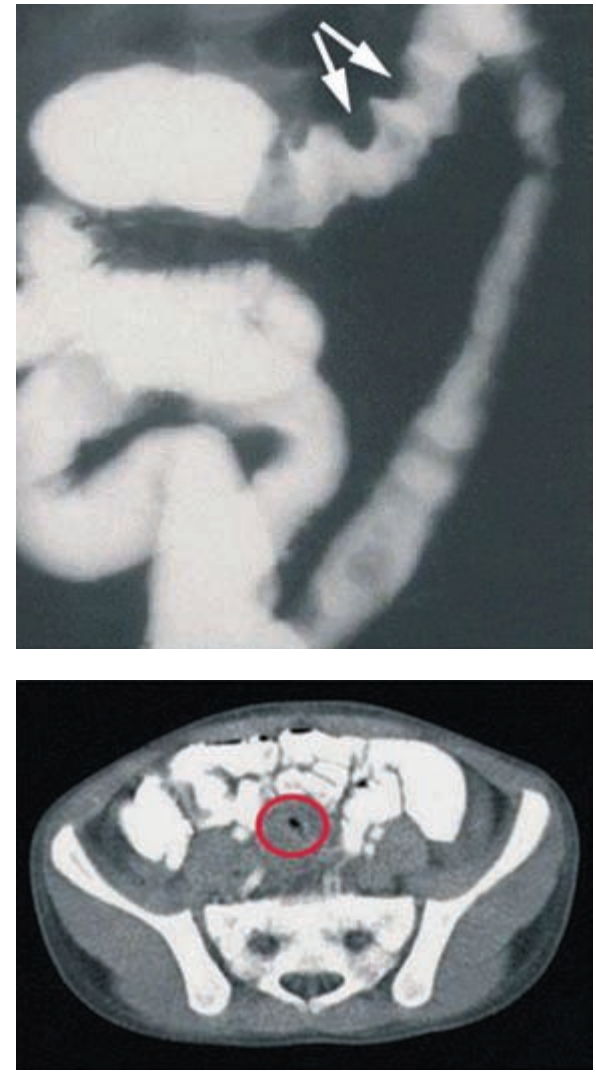

Figure 48.7 Radiographic features of *Escherichia coli* O157:H7 infection. **(a)** Radiograph after barium enema with thumbprinting appearance of mucosa (arrows), suggesting colonic edema, in a patient who subsequently developed hemolytic uremic syndrome (HUS). **(b)** Computed tomography of the pelvis of an 8-year-old boy on the eighth day of an *E coli* O157:H7 infection. Note the severely thickened colon (circled). This infection did not progress to HUS. From Tarr et al. [302], with permission from Elsevier.

E. coli O157:H7 infections follow a fairly predictable sequence of events to either resolution or development of HUS (Fig. 48.6); the course is usually apparent by the tenth day of illness (or sooner if there is no evidence of a falling platelet count). There is a variable pattern to the vascular lesions in *E. coli* O157:H7 infections (Fig. 48.8). The trend in the platelet count is the most useful indicator of deterioration into HUS or resolution of the infection without development of this complication. It should be determined daily until the trend is apparent. It need not be assessed daily if it is rising or if it is stable and the abdominal symptoms are resolving.

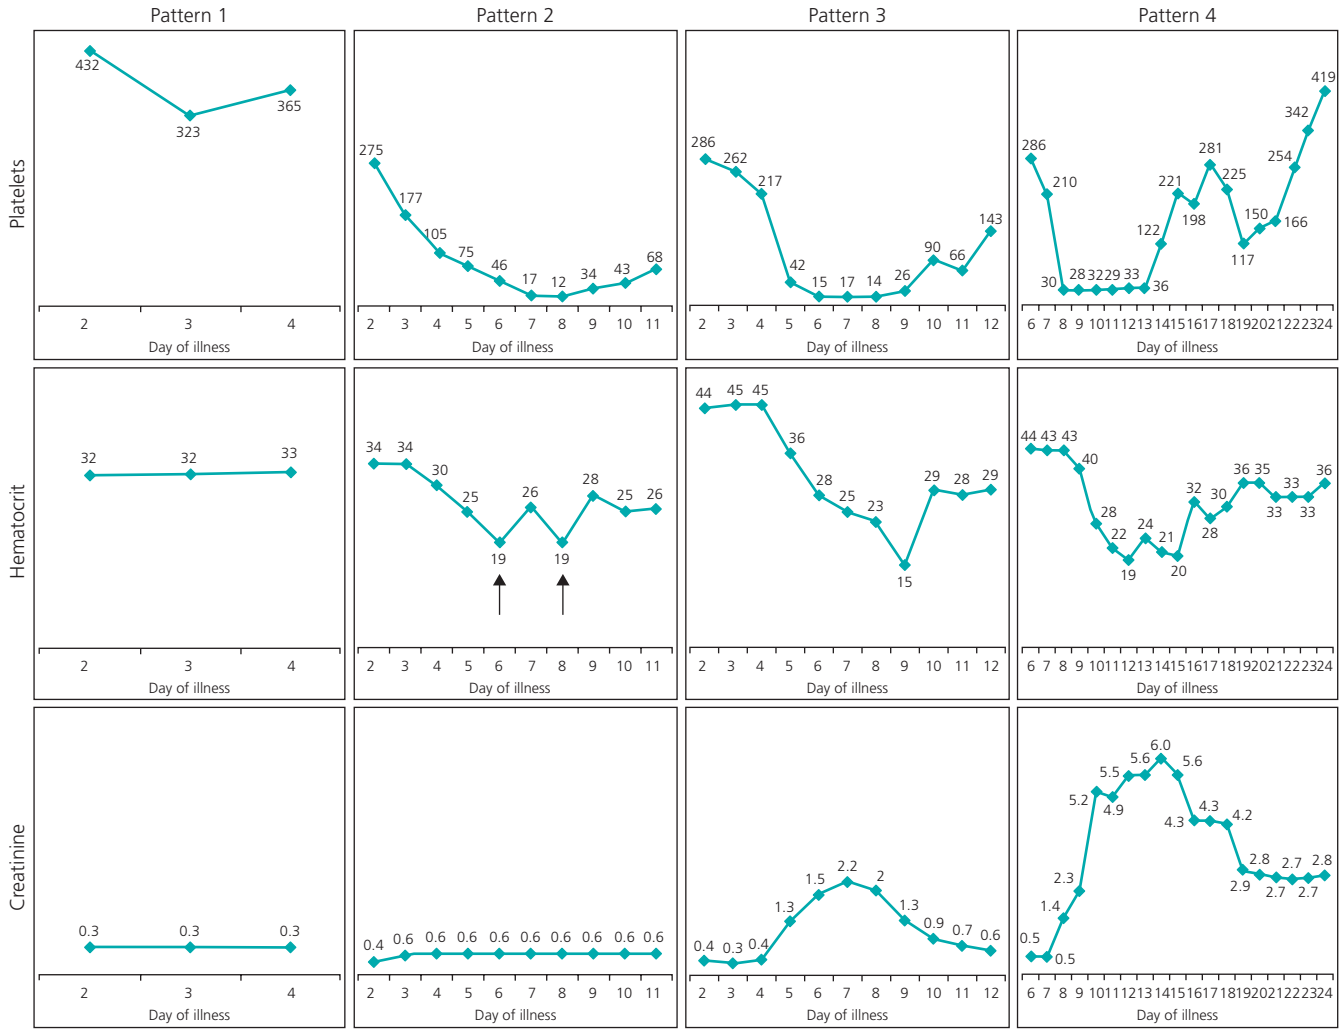

Figure 48.8 Patterns of laboratory abnormalities in human *Escherichia coli* O157:H7 infections. Pattern 1 (uncomplicated infection) occurs in approximately 70% of cases diagnosed microbiologically early in illness. In this patient the platelet count falls between the first and the subsequent determination, and then rises. In about 10% of patients the platelet count does not fall, or actually rises, between the first and subsequent assessments. On other occasions the platelet count falls quite markedly (with a nadir of less than 150 000/mm^3) but there is a minimal decrement in the hematocrit. Pattern 2 infections display substantial vascular injury in the absence of azotemia, a situation that occurs in 5%–10% of patients who we have diagnosed early in illness. This patient received vigorous intravenous volume expansion on the second day of illness because her diarrhea became bloody on the first day; her culture was presumptively positive one day later, at which time she was admitted. Hemolysis was sufficiently severe to require two erythrocyte transfusions (arrows). This pattern is sometimes termed partial hemolytic uremic syndrome (HUS), but in the absence of any evidence of renal insufficiency we do not believe that this designation is appropriate, especially because there is no risk of chronic renal sequelae if patients do not have renal failure during their acute infection [333]. Pattern 3 exemplifies nonoligoanuric HUS. This form of HUS occurs in slightly less than half of all patients who develop HUS. Patients meet the case definition of HUS (thrombocytopenia [platelet count < 150 000/mm^3], hemolytic anemia [hematocrit < 30% with evidence of intravascular erythrocyte destruction on peripheral blood smear] and renal insufficiency [creatinine > upper limit of normal for age]) between 5 and 13 days after the onset of diarrhea. These patients continue to urinate and rarely need dialysis. Pattern 4 is anuric HUS, which occurs in slightly more than half of all patients with HUS. This patient's severe course has been published previously [334]. Anuric HUS is considerably more severe than nonoligoanuric HUS, and has a worse prognosis [335,336]. Note that in patterns 3 and 4 a decrement in the platelet count precedes other laboratory abnormalities. These patterns are also seen in adults, but the proportion of patients over the age of 10 years who develop azotemia is lower, probably around 5%. Courtesy of Dr Jerrold R. Turner, University of Chicago, Chicago, IL.

Complications

HUS is the most common and serious complication of *E. coli* O157:H7 infections. Patients meet the case definition of HUS between 5 and 13 days after the onset of diarrhea, but the course is usually suggested by thrombocytopenia that occurs by day 8 or 9 of illness (Figs 48.6 and 48.8). On rare occasions, infected patients will develop HUS without antecedent diarrhea. Most infected patients will experience some degree

of diminution in their platelet counts, whether or not HUS develops. Infected patients should undergo daily assessment of their blood counts until it is clear that the platelet count is rising [302]. In some cases, enteric symptoms resolve without a rising platelet count. Nonrenal complications almost always occur only in those patients who develop HUS and include intussusception, appendicitis, intestinal perforation, pancreatitis, stroke, coma, seizures, gallstones, small bowel and colonic strictures, and sudden death [337–340], although in rare cases serious complications such as pancreatitis [341] and colonic perforation [26] can occur without HUS. *E. coli* O157:H7 infections are a risk factor for subsequent development of diarrhea-predominant irritable bowel syndrome [342].

Diagnosis

The ideal approach to diagnosing EHEC infections is to employ methods that detect O157:H7 as well as non-O157:H7 EHEC. However, it is important to not employ algorithms that delay detection of *E. coli* O157:H7, such as plating stools on MacConkey agar only if a toxin assay is positive. This goal is best achieved by initially plating all stool specimens on MacConkey agar that contains sorbitol but not lactose as its carbon source. Screening for this organism should not be limited to physician request or to stools containing only gross blood. Because *E. coli* O157:H7 fail to ferment sorbitol after overnight incubation, they can be distinguished from other enteric flora as colorless colonies on this agar. If resources permit, an additional approach would be to screen for Stx by inoculating stool into a broth and assaying an overnight culture using commercial EIAs for Stx to detect non-O157:H7 EHEC (see Non-O157:H7 pathogenic enterohemorrhagic *E. coli*). Stx assays should not replace plating of the stool on sorbitol MacConkey agar as the sole screen for the detection of pathogenic EHEC, because many of the positive results in this assay do not signify the presence of organisms that pose a substantial likelihood of leading to HUS or of causing epidemics. Moreover, a clinician needs to know that *E. coli* O157:H7 is present or absent in a stool culture when a report of a positive EIA is made. Utilization of sorbitol MacConkey agar only after an STEC EIA is positive is an undesirable and inferior practice; the two tests should be employed in parallel. Use of toxin detection methodologies leads to a delay in diagnosis or to misdiagnosis [344] if such assays are used as a screen in lieu of sorbitol MacConkey agar screening [344].

Treatment

Escherichia coli O157:H7 are usually susceptible to antibiotics. However, antibiotics should not be given to patients who are possibly or definitely infected with *E. coli* O157:H7 or other EHEC. Infected children [331,345] and adults [346,347] treated with antibiotics experience higher complication rates, in particular HUS, than patients who are not treated. A metaanalysis [348] suggesting that there was no harm accruing to patients infected with *E. coli* O157:H7 who were treated with antibiotics was erroneous, chiefly because it mischaracterized a major series from Japan in which a nontreatment group was not included [349]. There are no data on the risks or benefits of treating non-O157:H7 EHEC infections with antibiotics, but there is no reason to believe that such therapy would be useful.

We strongly recommend hospitalization and intravenous isotonic volume expansion for patients who are possibly or definitely infected with *E. coli* O157:H7 for two main reasons. First, such patients are highly infectious to others and infection control is often more difficult to practice in the community [302] than in the hospital. Second, intravenous volume expansion with isotonic crystalloid appears to confer nephroprotection [350]. Antimotility agents, nonsteroidal antiinflammatory drugs, and opioid narcotics should be avoided [302]. Monitoring of such patients must be performed assiduously, especially as the creatinine level is rising. However, if a patient is still urinating and there is no evidence of hypertension or pulmonary overload, there is no need to restrict fluids merely because the creatinine level is rising. The goal of volume expansion is to avert anuria, because anuric HUS is a categorically different and worse form of HUS than nonanuric HUS [335,336]. It is helpful in managing infected patients, especially in managing their fluids as azotemia develops, to note that if a patient does not become anuric within 10 days of the onset of diarrhea, it is very unlikely that this complication will occur.

HUS treatment is reviewed in several publications [302,351]. Transfusion might be needed in some patients manifesting a pattern B clinical course (see Fig. 48.8), or even prior to the onset of azotemia in patients who develop HUS. We use clinical indicators (especially tachycardia) to prompt red cell transfusions. Platelet transfusions should be avoided unless a surgical procedure is planned, to avoid contributing to the underlying thrombotic lesion.

Non-O157:H7 pathogenic enterohemorrhagic E. coli

This class of organisms bears mention because they are overlooked on routine culture of stool on sorbitol MacConkey agar. However, as a group, they are considerably less likely than *E. coli* O157:H7 to cause HUS or outbreaks. Even when sought appropriately, they are recovered less frequently than are *E. coli* O157:H7 [3,352]. Usually, patients whose stools produce a positive signal in assays that detect Stx but who are not infected with *E. coli* O157:H7 have considerably milder illnesses. However, some serogroups, especially EHEC expressing O antigens 26, 45, 103, 111, 113, 145 and an unusual sorbitol-fermenting clone of *E. coli* O157:H^- [353] can cause severe illnesses, outbreaks, and HUS. *E. coli* O113 produces a novel subtilase toxin [354] in addition to Stx. This toxin is a serine protease that cleaves BiP, which is a multifunctional endoplasmic reticulum chaperone protein [355]. Detection of Stx production by EIA is the best methodology to identify non-O157:H7 EHEC, but false-positive signals can occur

[344,356]. Non-O157:H7 EHEC have not emerged as large public health or clinical problems in North America, but have in Australia [357].

Enterotoxigenic E. coli

History

In Calcutta in 1956, De et al. [358] demonstrated that *E. coli* from children and adults with watery diarrhea elicited fluid secretion in ligated rabbit ileal loops, similar to the effects of cholera toxin, thereby introducing ETEC as causes of human illness. In 1968, Sack [359] demonstrated that this effect was attributed to bacterial products. In the mid-1970s, Gorbach et al. [360] and Merson et al. [361] reported that ETEC were the predominant causes of diarrhea in travelers to the developing world. Interestingly, the ability of antibiotics to prevent traveler's diarrhea, a practice that is currently recommended only in special circumstances, was demonstrated in advance of identifying the major etiological role played by ETEC in this disorder [78].

Pathogenesis

ETEC produce one or both of two distinct families of enterotoxins, which promote secretion of chloride and water into the small bowel, and inhibit reabsorbtion of fluids (reviewed in [362]). Heat-labile toxins (LTs) are similar in structure and function to cholera toxin; LT-I is the most common LT in human ETEC isolates. LTs are AB_5 toxins, with the B subunit binding GM1 and GD1bp gangliosides, and the A subunit being the enzymatically active moiety. The A subunit ADP-ribosylates, and thereby irreversibly activates, the G (stimulatory) protein. This enzyme activates adenylate cyclase and leads to increased intracellular levels of cAMP. Elevated intracellular cAMP levels activate cAMP-dependent kinases, which then stimulate chloride secretion via CFTR, leading to net secretion of chloride ions from intestinal crypt cells. These changes also inhibit sodium chloride reabsorbtion in the villus tip cells. Similar to cholera toxin, LT is an adjuvant, augmenting mucosal immune responses to coadministered antigens. LT is delivered in a polar fashion by adherent ETEC [363]; even though it is immunogenic, it might be sequestered from the immune response, accounting for discordance between circulating antibodies to LT and protection [364].

ETEC also produce heat-stable toxins (ST). STa (also termed ST-h), the predominant ST in human ETEC, is an 18- or 19-amino-acid peptide that binds reversibly to guanylate cyclase, leading to increased levels of intracellular cyclic GMP [365]. Increased cGMP levels activate cGMP- and cAMP-dependent kinases, which results in an increase in net intestinal secretion, as does LT. STa has homology to guanylin, a host molecule that binds to epithelial guanylate cyclase.

ETEC employ a wide range of adherence factors to colonize the gut. These factors were previously designated colonization factors. More recently, these largely fibrillar molecules have been termed coli surface antigens (except for CFA/I, which retains its initial designation) [366] and grouped into families that contain conserved epitopes. A subset of colonization factors is overrepresented among human ETEC, but the adherence mechanisms of many strains warrant additional characterizations [367].

Epidemiology and prevention

ETEC are probably the most common bacterial cause of acute diarrhea worldwide. In resource-poor countries, ETEC infections have their highest incidence in children under the age of 2 years. The incidence rises again in the mid-teen years. In case–control studies, non-diarrheal control subjects excrete ETEC but at lower rates than patients with diarrhea. ETEC are the leading, although by no means the exclusive, cause of diarrhea in international travelers. ETEC are spread via consumption of food or water that has not undergone reliable bactericidal processes. Person-to-person spread is also possible. Endogenous North American ETEC infections have occurred, usually from a contaminated point source or food [368,369]. Malnourished children seem to be predisposed to ETEC infection [370,371]. Moreover, repeated attacks of diarrhea, caused by ETEC as well as by other agents, could underlie malnutrition [372,373]. The infectious dose is high, estimated at greater than one million organisms [374]. Prevention is directed at avoiding food and water that has not been subjected to a reliable bactericidal process, and avoidance of street-vended food in areas of the world where ETEC infections are endemic.

Vaccination against diseases caused by ETEC has considerable appeal because of the high frequency of disease and the delineation of several potentially immunogenic virulence factors such as toxins and colonization factors. However, this approach faces challenges from antigenic variation in the colonization factors, and would be aided by a search for a common antigen [367]. Killed ETEC comprising a range of colonization factors, combined with recombinant cholera toxin B subunit, elicits, after oral challenge, a systemic response. Live vaccines have consisted of ETEC from which ST and LT genes have been deleted. Efficacy studies demonstrate immune responses, but protection of populations of children in endemic areas has been more difficult to demonstrate. Another approach is to express ETEC virulence factors in an attenuated *Shigella* vector. These strategies have been summarized [42,375].

Clinical manifestations

ETEC cause secretory, noninflammatory diarrhea. The severity of the diarrhea ranges from asymptomatic to cholera-like shock. Fever is rare. Vomiting is common among infected children [362].

Diagnosis

Identification of ETEC requires DNA hybridization studies or other analyses (EIAs or cell culture assays) that detect ST, LT,

or colonization factors. However, these technologies are not employed outside research settings. The diagnosis is usually based on syndromic recognition, taking into account the likelihood on epidemiological grounds that cholera is or is not a consideration.

Treatment

Fluid management underlies the treatment of ETEC infections. Volume replenishment and fluid maintenance can often be addressed by oral rehydration with glucose/electrolyte solutions. Antibiotics do not clearly benefit ETEC-infected children or adults in the developing world, but are used (successfully) in the empiric treatment of diarrhea in international travelers. Antibiotic therapies have tended to evolve, as has resistance to specific antimicrobials. Therapeutics have included tetracyclines, trimethoprim–sulfamethoxazole, fluoroquinolones, azithromycin, rifamycin, and, most recently, rifaximin [34,376]. Antibiotics are generally not recommended to prevent traveler's diarrhea because of their potential side effects, their effectiveness in treating traveler's diarrhea if administered soon after symptoms begin, and the desire to avoid selective pressures leading to antimicrobial resistance in the countries visited. Rifaximin, a non-absorbable derivative of rifampin, has shown promise in preventing and treating traveler's diarrhea [34,376], but sufficient experience has yet to accumulate to determine if this agent will retain its safety and efficacy profiles.

Complications

Most ETEC complications can be related to acute dehydration. However, repeated cycles of diarrhea, many of which are probably caused by ETEC, almost certainly contribute to malnutrition spirals in children in developing countries [372,373]. From an evolutionary standpoint, ETEC have been proposed to be an infectious agent that exerted selective pressure in humans in favor of heterozygous carriage of the mutated CFTR gene [111]. It is likely that ETEC precipitate at least some cases of irritable bowel syndrome that follow an episode of traveler's diarrhea [83].

Enteropathogenic E. coli

History

In 1945, Bray et al. [377] described severe epidemic infantile diarrhea in the United Kingdom associated with specific O serogroups of *E. coli*. Similar outbreaks have occurred in the United States [378]. During subsequent decades, these organisms have been demonstrated to adhere to epithelial cells in localized microcolonies and form characteristic "attaching and effacing (AE)" lesions [379], which are also visible on electron microscopy of biopsies obtained from children [380]. Profound cytoskeletal rearrangements underlie the AE lesions; the most notable phenotype is the aggregation of actin filaments under the membrane where the microcolonies are located. Furthermore, the molecular mechanisms that EPEC employ to injure host cells, especially those mediated via a T3SS, are being elucidated at an accelerating rate. However, there is discordance between the emerging knowledge of EPEC pathogenesis and the paucity of data surrounding epidemiology, clinical manifestations, and diagnosis of infections caused by EPEC.

Pathogenesis

EPEC adhere to host cells in characteristic microcolonies (Figs 48.9 and 48.10). The initial mechanism of adherence is not certain and plausibly involves proteins other than those that are more directly involved in the AE lesion.

Candidate adhesins for this initial attachment include the bundle-forming pilus [383], EspA [384], flagella [385], and LifA/Efa 1 [386]. After initial adherence, intimin is the molecule through which EPEC bind to host cell structures, by interacting with the bacterial-encoded and translocated intimin receptor (Tir) described below. Bfp is responsible for the formation of EPEC microcolonies [387].

The most characteristic trait of EPEC infections is their utilization of an intricate T3SS encoded by the LEE pathogenicity island. T3SSs are utilized by many enteric pathogens to translocate virulence factors into host cells via needle-like bacterial organelles. The prototypic EPEC LEE region is a 35-kilobase pair island, inserted into the chromosome at *selC* (the same site as the insertion of the *E. coli* O157:H7 T3SS) [388]. The transcription of open reading frames within the LEE region is promoted by intra-LEE positive regulators (LEE-encoded regulator and global regulator of LEE activator) and by a plasmid-encoded positive regulator (*per*); transcription is negatively regulated by the global regulator of LEE repressor.

When EPEC contact a host cell, a LEE-encoded syringe-like structure, largely composed of polymerized EspA filaments, translocates additional effector molecules into the eukaryotic

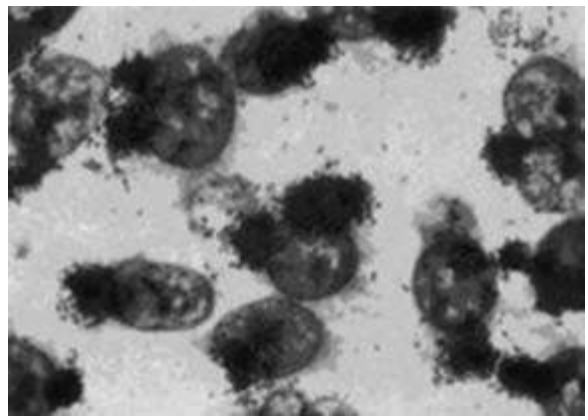

Figure 48.9 Enteropathogenic *Escherichia coli* (EPEC) adherence to cultured epithelial cells. Typical EPEC form characteristic microcolonies (arrow) at points of adherence. From Campos et al. [381], with permission from Memórias do Instituto Oswaldo Cruz.

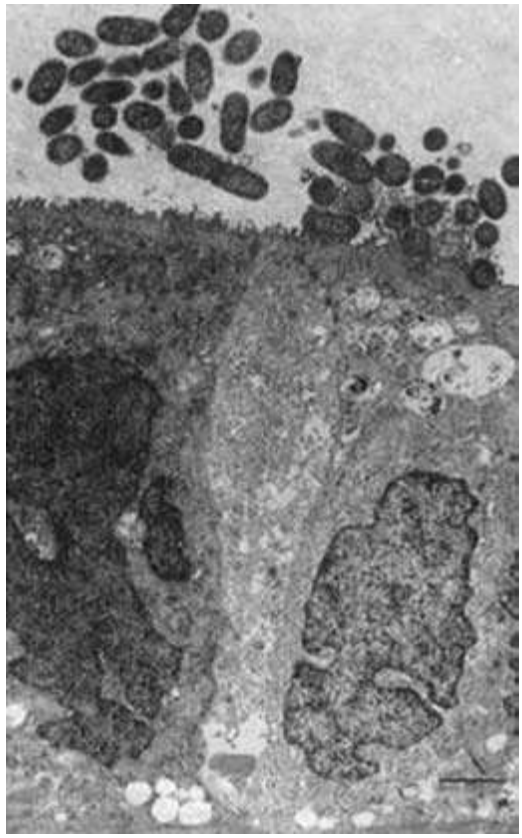

Figure 48.10 Enteropathogenic *Escherichia coli* (EPEC) attaching to epithelial cells. Transmission electron micrograph of T84 cells that have been infected with EPEC. The characteristic attaching and effacing lesions are associated with intimate bacterial attachment to the apical enterocyte membrane. Loss of microvilli is apparent adjacent to the adherent microcolony. There is also microvillus elongation, which precedes effacement. Cup-like pedestals with underlying condensation of cytoskeletal elements are also seen. The intestinal epithelial cells are intact and tight junctions are closely approximated, but electrophysiological studies demonstrate enhanced tight junction permeability. From Spitz et al. [382], with permission from the American Physiological Society.

cell, including EspB and EspD. These effectors form pores in the host cell plasma membrane. These actions allow delivery of a panel of bacterial proteins directly into the host cell cytoplasm where they participate in AE lesion formation or disrupt normal physiological functions such as intestinal epithelial barrier function (reviewed in [389]). Tir is one EPEC protein that is injected into the host cell, where it is phosphorylated by host kinases and then serves as the ligand for the attachment of intimin. Tir is required for the formation of a classic pedestal on which the EPEC sit, and for the underlying actin polymerization and aggregation at this site. Additional translocated molecules disrupt intestinal barrier function (EspF, Map) [390,391], damage mitochondria, and activate NF-κB [392]. However, it should be noted that some of the injected proteins can attenuate host cell inflammatory responses [393]. Data suggest that several EPEC effector proteins (Map, EspF, and Tir) inactivate the sodium-D-glucose cotransporter SGLT-1 [394]. The activities of other intestinal epithelial transporters (MCT-1 and NHEs) are also altered by EPEC infection [395,396].

Proteins encoded by loci outside of the LEE region also exploit the LEE-encoded T3SS to injure host cells. The best studied of these is the plasmid encoded regulator (*per*), which is encoded on the large plasmid common to "typical" EPEC [397]. EspG2, a homologue of EspG and which disrupts microtubules, is another example [398,399].

Epidemiology and prevention

Typical EPEC have been incriminated as causes of epidemic infantile diarrhea with severe illnesses in North America [378]. However, such clusters in the developed world are rare, and typical EPEC are believed to be problems of children in underprivileged settings. However, several studies have suggested that "atypical" EPEC, which consist of *E. coli* containing the LEE region but lacking the large EPEC plasmid, are also pathogenic in children [400–404]. Adults can occasionally be affected [405]. Because typical and atypical EPEC are only detected for the purposes of research studies, their epidemiology is not well delineated. Community-based preventive measures, beyond encouragement of good hygiene whenever possible, are not well formulated. If an institutional outbreak is recognized, contact precautions and cohorting should be considered. Vaccination strategies have not been well developed.

Clinical manifestations

The inability to diagnose EPEC has hampered characterizations of diseases caused by EPEC. Generally, typical and atypical EPEC are associated with nonbloody, and often protracted, diarrhea in infants and children [352,400,404].

Diagnosis

Detection of EPEC requires DNA probing or adherence assays. Serotyping of isolates has also been used but is of questionable value compared with genetic characterizations. These determinations are not performed outside research settings.

Treatment

It is reasonable to consider treatment if an EPEC is suspected on empiric grounds. Oral, nonabsorbable aminoglycosides have been used in small series with success [406], but large-scale randomized controlled studies, using rigorous definitions of EPEC, are lacking.

Complications

Infected children can present with intestinal failure accompanied by nutritional consequences and growth retardation [406]. Long-term complications in the developing world consist of the initiation or perpetuation of infection/malnutrition cycles.

Enteroaggregative E. coli

History

EAEC were first associated with human diarrhea in 1987 [407–409] in Chilean children, when *E. coli* with characteristic adherence patterns (a stacked brick appearance) were found more frequently in patients than in control subjects. Subsequent studies have identified EAEC as etiological agents of diarrhea in patients infected with HIV [410]. They are found in children and adults in developed as well as in developing countries [297,400,411].

Pathogenesis

EAEC, like other diarrheagenic *E. coli*, appear to cause disease via sequential, as well as parallel, processes. The prevailing pathogenetic paradigm suggests that initial colonization of the mucosal surface is followed by elaboration of cytotoxic, secretory, and proinflammatory factors. EAEC adhere to intestinal epithelial cells via aggregative adherence fimbriae (AAFs), for which several distinct alleles exist. EAEC are covered by a surface protein called dispersin, which is postulated to neutralize the negative surface charge conferred by lipopolysaccharides, thus freeing the positively charged AAFs of their attraction to lipopolysaccharides and enabling the fimbriae and bacteria to splay out over epithelial surfaces. EAEC also produce a mucinase (Pic), an enterotoxin termed *Shigella* enterotoxin 1 (ShET1) [412], and a homologue of ETEC ST termed EAST1 [413], which is a toxin elaborated across a broad panel of potentially diarrheagenic *E. coli* [414]. ShET1 elicits increased conductance (ion secretion) across intestinal tissue in Ussing chambers [415], as does EAST1 [416]. EAEC also frequently secrete a toxin termed Pet, which results in rounding of cultured epithelial cells, possibly by dissolving the cellular cytoskeleton [417]. EAEC infection elicits intestinal inflammation, probably by inducing release of IL-8 from epithelial cells, possibly in response to production of flagellin [418], a defined ligand of toll-like receptor 5 (TLR5), as well as of other factors [419]. EAEC pathogenesis has been thorough reviewed [420].

Epidemiology and prevention

The full spectrum of EAEC-associated diseases is beginning to emerge in North America [297,400,403], Europe [421,422], and developing regions of the world [423,424], with the most sophisticated studies having been performed in Brazil. EAEC are also associated with traveler's diarrhea [420,425]. Most studies have focused on the role of EAEC in children, but a study from Maryland and Connecticut has demonstrated its association with adult diarrhea as well [297]. Specific prevention measures cannot be proposed at this time [411].

Clinical manifestations

Volunteer challenges and cohort studies suggest that EAEC are associated with nonbloody, usually afebrile diarrhea. Prolonged illness is seen in HIV/AIDS patients [426]. A provocative study from Brazil [68] associated fecal EAEC excretion with persistent diarrhea, markers of intestinal inflammation (lactoferrin and IL-8), and growth impairment, whether or not diarrhea was present. This raises the possibility that intestinal colonization with EAEC might underlie stunting in children in resource-poor environments.

Treatment

Because EAEC are not detected in clinical laboratories, the role of antimicrobial therapy in the treatment of these infections remains poorly studied and so evidence-based recommendations cannot be made. Moreover, published studies need to be considered in the context of definitional issues: EAEC have been variably defined, using nucleic acid characterization with or without adherence studies. Ciprofloxacin has been used to treat human EAEC infections in the setting of HIV infection or in traveler's diarrhea [427,428], but many Thai isolates were resistant to a diverse panel of antibiotics [429,430]. In Bangladesh, similar high rates of resistance were noted in collections from the 1980s [431]. EAEC serogroup O44 (a serogroup of EAEC that is found worldwide) in Kenya were resistant to tetracycline, ampicillin, erythromycin, trimethoprim–sulfamethoxazole, and amoxicillin clavulanate, but susceptible to chloramphenicol, nalidixic acid, azithromycin, and cefuroxime [432]. It is concerning that EAEC from returned travelers in Spain demonstrated resistance to fluoroquinolones [433]. Rifaximin shows promise in the treatment of EAEC infections in travelers [434–436]. EAEC were moderately resistant to rifaximin but were inhibited by the high intralumenal concentrations that this agent can achieve [437].

Diagnosis

EAEC are best identified using an epithelial cell adherence assay (typically with Hep-2 cells) [438] (Fig. 48.11) or by DNA hybridization (reviewed in [420]), including several multiplex PCR assays [439,440]. Diagnosis is hampered by the specialized nature of the assays required to detect EAEC and the lack of consensus regarding sensitive and specific target loci that define these organisms. Moreover, 1%–3% [400,441] of control subjects excrete probe-positive EAEC, making it difficult to assign pathogenicity when EAEC are detected in individual cases. Phenotype (adherence assay) positive rates in control subjects can exceed 20% [400].

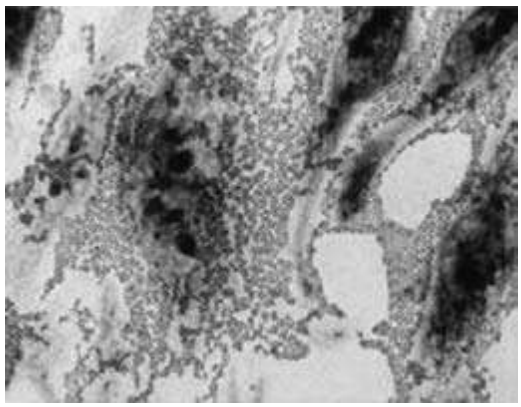
Complications

The complications of EAEC infections, beyond the acute diarrhea, appear to be related to stunting in children in developing countries [68], and irritable bowel syndrome [82]. These consequences of persistent infection warrant further investigation.

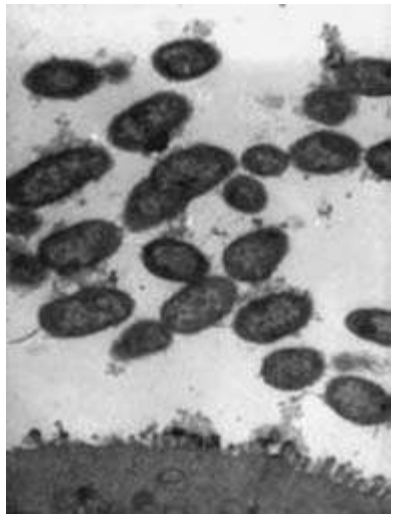
Enteroinvasive E. coli

History

Microbiologically, EIEC resemble *Shigella*, and, in fact, they



(a)



(b)

Figure 48.11 **(a)** Enteroaggregative *Escherichia coli* (EAEC) adhering to epithelial cells. Note the agglomeration of bacteria around the epithelial cells (arrow), which has also been called the "stacked brick" adherence pattern, after 6 h of incubation of bacteria and cells. Also note the accumulation of bacteria at some distance from the eukaryotic cells. From Campos et al. [381], with permission from Memórias do Instituto Oswaldo Cruz. **(b)** Human intestinal in vitro organ culture and EAEC. EAEC adherent to intestinal epithelial cells removed by biopsy from patient undergoing endoscopy. Electron micrograph courtesy of Dr Alan D. Phillips.

were initially considered to be *Shigella*. These organisms were first associated with human illnesses by Ewing and Gravatti [442] in the Mediterranean among Allied soldiers who were treated for presumptive bacillary dysentery. Some strains biochemically atypical for *Shigella* were subsequently demonstrated to be *E. coli*, but the differentiation between *Shigella* and *E. coli* is artificial [443]. Similar organisms were isolated in 1947 from British schoolchildren [444], and these isolates caused diarrhea in human volunteers [445].

Epidemiology and prevention

Most EIEC infections that have been described have been associated with outbreaks. Modes of transmission include foodborne vehicles [446], and waterborne [447] and person to person [448] transmission. In developing countries, EIEC are most frequently identified in children [449]. Specific prevention measures cannot be recommended at this time. There are no vaccines available.

Pathogenesis

The principle virulence property of EIEC is the ability to invade epithelial cells, a trait shared with *Shigella*. EIEC penetrate epithelial cells, lyse the endocytic vacuole, multiply, and extend into adjacent cells [450]. Intracytoplasmic movement is mediated by host cell actin. Most effectors of the invasion phenotype are mediated by a T3SS encoded on a 140-MDa plasmid that is found in EIEC and *Shigella* [451]. Most notably, the IpaB and IpaC proteins are injected into host cells, create pores, trigger cytoskeletal rearrangements, lead to apoptosis, and release inflammatory cytokines. Actin is polymerized via IpaC and translocated IpgD, an inositol 4-phosphatase that dephosphorylates phosphatidylinositol 4,5-bisphosphate into phosphatidylinositol 5-monophosphate, which then accumulates in the host cell. This accumulation uncouples the host cell's plasma membrane from the actin cytoskeleton, leading to extrusions (blebbing) [452]. IpaA binds to vinculin, which induces the polymerization of actin fibers. Once polymerized, the extensions induced by IpaC are transitioned into structures that permit bacterial entry into the eukaryotic cells. EIEC also possess iron acquisition systems [453].

Clinical manifestations

The full spectrum and frequency of EIEC infections are unknown. Although some cases present with a dysenteric picture [442], EIEC cause dysentery only in a small subset of patients in outbreaks [444,446,454] and in experimentally challenged subjects [445].

Treatment

Human EIEC infections are rarely diagnosed and therefore the efficacy of antibiotics is not known.

Diagnosis

The identification of an EIEC is sometimes prompted by the presence of lactose nonfermenting *E. coli* on MacConkey agar. Subsequent methods of assessment of such strains include nucleic acid hybridization, seeking loci associated with invasion, and phenotypic assays, assessing invasiveness. In reality, such testing is not performed in clinical laboratories.

Complications

Complications of EIEC infections, beyond the acute episode, are not well described.

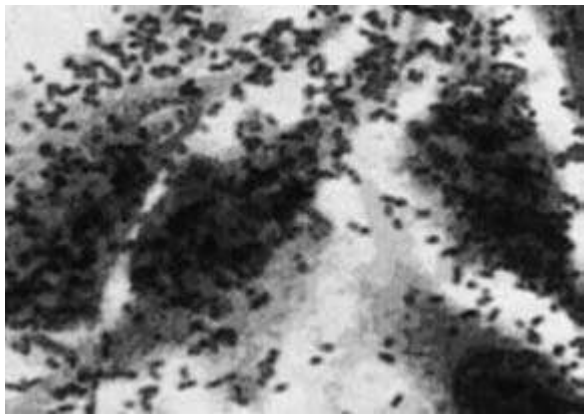


Figure 48.12 Adherence of diffuse adherent *Escherichia coli* (DAEC) to cultured epithelial cells. DAEC adhere at all regions of epithelial cells. From Campos et al. [381], with permission from Memórias do Instituto Oswaldo Cruz.

Diffusely adhering E. coli

History

DAEC characteristically adhere to epithelial cells in a diffuse pattern (Fig. 48.12). This organism was initially associated with diarrhea in case reports [455]. Subsequent work demonstrates a statistically significant association with patients with diarrhea compared with control subjects.

Epidemiology and prevention

DAEC have been implicated as causes of diarrhea in the developed [400,456] and developing world [457]. Specific preventive measures are not available.

Pathogenesis

DAEC are a genetically diverse group and the pathogenetic mechanisms that cause human disease are poorly delineated. The best characterized virulence factors are the Dr family of fimbrial adhesins expressed by many DAEC (and by some uropathogenic *E. coli* as well). These adhesins mediate binding of *E. coli* to a number of cell surface proteins including decay accelerating factor, carcinoembryonic antigen and related cell adhesion molecules, and β1 integrins [458–460]. Dr adhesin-mediated epithelial cell binding is associated with the microtubule-dependent internalization of a small proportion of adherent bacteria, but the relevance of this finding to disease has not been established [461]. Following binding, cytoskeletal alterations are mediated by activation of signal transduction cascades [462], the structures of epithelial brush borders and tight junctions are deranged [460,463], and a proinflammatory response is induced [464,465]. The epidemiology of DAEC infections is emerging. In one study in Chile, DAEC were not associated with diarrhea [457], but in studies from France [456] and Cincinnati [400], DAEC were statistically associated with diarrhea. In the most recent North American study [400] there was an appreciable carriage of DAEC in control children, but these organisms were more often excreted by ill children. The risk of DAEC diarrhea in children appears to increase with age, with stronger associations seen in children over 2 years of age [466]. The characteristics of diarrhea associated with DAEC, however, are not well established.

Clinical manifestations

DAEC tend to be isolated from children with nonbloody diarrhea. Additional details such as association with fever and duration of illness are incompletely identified.

Diagnosis

DAEC diagnosis largely relies on phenotype (adherence to epithelial cells) and DNA hybridization assays. Because these organisms can be carried by control subjects, and because detection methodologies have been exclusively formulated in research studies, useful diagnostic strategies have not emerged.

Treatment

It is not known if antibiotics diminish the duration or severity of illnesses caused by DAEC.

Complications

It is not known if DAEC infections have long-term consequences.

Listeria monocytogenes

History

Listeria monocytogenes was first described as a human pathogen in 1929 when it was recovered from a blood culture and was mistakenly thought to cause infectious mononucleosis [467]. It is typically considered to be an invasive (i.e., systemic) pathogen. When gastrointestinal symptoms occur, they usually occur during, or before, extraintestinal dissemination. During the past 15 years, multiple episodes of gastroenteritis have been attributed to infection with *L. monocytogenes* [468–473].

Pathogenesis

Listeria monocytogenes invades and replicates in epithelial cells and macrophages. It has been used extensively to study actin-mediated motility in eukaryotic systems. *L. monocytogenes* permeates the intestinal barrier via the internalin family of bacterial surface proteins [474], which bind to E-cadherin [475]. Following invasion, *L. monocytogenes* reside in vacuoles and utilize host cell actin polymerization for transport. This organism has served as a model for dissection of the mechanisms of gram-positive pathogenesis (reviewed in [476]), but the intestinal phases of infection are less well delineated. *L. monocytogenes* can survive gastric acidity, but acid suppression increases infectivity [477,478]. After exposure to acid, *L. monocytogenes* undergoes additional invasive

adaptations, a process that possibly increases virulence [479]. Osmotic forces also increase the ability of *L. monocytogenes* to achieve full virulence [480]. *L. monocytogenes* is variably resistant to the bactericidal action of bile [481]. Hsp60 has been proposed to be the epithelial cell receptor for *L. monocytogenes* [482] before the pathogen is internalized into the eukaryotic cell. However, it is not known to what extent these mechanisms contribute to the gastrointestinal symptoms observed in infected patients.

Epidemiology and prevention

Outbreaks of *L. monocytogenes* gastroenteritis have all been foodborne, and implicated vehicles include rice, chocolate milk, vegetables, smoked trout, corned beef, ham, delicatessen meat, and cheese. Risk factors for nonepidemic cases are not known because sporadic cases of gastroenteritis are rarely investigated and *L. monocytogenes* is rarely identified outside of outbreaks. *L. monocytogenes* is ubiquitous in food [483] and human infection is probably a function of inoculum size, *L. monocytogenes* serotype, and host susceptibility. In outbreaks, attack rates often exceed 50%. Inoculum density in the source is variable but usually exceeds 10 000 colony-forming units per gram of ingested vehicle. Serotypes 1/2a and 1/2b predominate in outbreaks. *L. monocytogenes* can be excreted in the stools of humans in the absence of disease [478].

Consumers can diminish the risk of listeriosis by observing food safety guidelines, which are focused on storage temperatures and ready-to-eat foods, including unpasteurized cheeses and milk, ready-to-eat delicatessen foods, and frankfurters [484]. Pregnant women should be especially vigilant. A novel mechanism of control is the addition of *L. monocytogenes*-specific bacteriophages to ready-to-eat foods that might contain this pathogen [485].

Diagnosis

Because *L. monocytogenes* can be carried by healthy people, and in consideration of the labor involved in recovering this organism from the polymicrobial milieu of stool, routine cultures for this agent in sporadic cases are not recommended [486,487]. If *L. monocytogenes* gastroenteritis is suspected, evaluation of stool for the presence of this agent should be discussed with the involved health departments and clinical microbiologists, to assure optimal specimen processing. It is important to inoculate the stool into the appropriate *Listeria* selective media, but clinical and reference or public health laboratories will often need to coordinate efforts to isolate this organism from patient stools and from suspected vehicles of transmission. Recovery of *L. monocytogenes* from sites that are otherwise sterile, such as blood or the central nervous system, would be an alternate way to make a diagnosis, but such cultures are rarely performed in cases of isolated gastroenteritis and probably would not be positive. Culture of the stool can be performed using *Listeria* selective enrichment broths, supplements containing cycloheximide, colistin, acriflavin, cefotetan, and fosfomycin, or PALCAM selective media [488]. For retrospective (i.e., postclearance) diagnosis, antibodies to listeriolysin O might identify recently infected individuals.

Clinical manifestations

The most prominent characteristic of *L. monocytogenes* gastroenteritis is fever. Most patients also have headache. Additional accompanying symptoms include musculoskeletal pain, nausea, and vomiting. In only a small subset is the diarrhea grossly bloody. Diarrhea need not be present in all cases [486]. The clinical characteristics of sporadic cases remain uncharacterized because such cases are rarely diagnosed.

Treatment

Listeria gastroenteritis is usually self-limited and lasts several days. The efficacy of antibiotics in treating infections limited to the gastrointestinal tract is not demonstrated, but some authorities recommend that antibiotics should be given to individuals in outbreaks who are at high risk of disseminated infection or complicated outcomes (such as pregnant women) [486]. By the time outbreaks come to light and the etiological role of *L. monocytogenes* is known, most cases have resolved. For uncomplicated gastroenteritis, trimethoprim–sulfamethoxazole or oral ampicillin or amoxicillin is recommended if one is compelled to prescribe an antibiotic. For invasive cases an aminoglycoside should be combined with ampicillin or amoxicillin. The efficacy of fluoroquinolones has not been established [489].

Complications

The vast majority of cases of gastrointestinal infection with *L. monocytogenes* resolve without dissemination. However, gastroenteritis is a common prelude to systemic infection with *L. monocytogenes*.

Salmonella infections

History

Salmonella were named after United States Department of Agriculture pathologist Dr Daniel E Salmon, who first isolated *Salmonella choleraesuis* from porcine intestine [490]. PCA Louis [491] differentiated typhoid fever as a separate entity based on pathological changes in the intestinal lymph nodes and spleen, and further described the association with rose spots, intestinal perforation, and bleeding [491]. Typhoid fever was further distinguished from typhus by William Jenner, who recognized that Peyer patches and mesenteric lymph nodes were enlarged in typhoid, and that previous infection protected against subsequent attacks in the former condition [492]. The organism responsible for typhoid fever was isolated in 1884 from the spleens of infected patients [493], and in 1896 a heat-killed vaccine was developed [494]. The serotyping of *Salmonella* is based on the presence of specific surface antigens detected by agglutination in response to the

presence of reactive antibodies. The classification system developed by Kaufmann and White in the mid-1900s [495] continues to be used today.

Classification

The genus *Salmonella* is a member of the Enterobacteriaceae family of gram-negative bacilli. The genus is divided into two species, *Salmonella enterica* (formerly *S. choleraesuis*) and *Salmonella bongori*. *S. enterica* is further divided into six subspecies: I – *enterica*; II – *salamae*; IIIa – *arizonae*; IIIb – *diarizonae*; IV – *houtenae*; and VI – *indica*. V is now obsolete as a subspecies of *S. enterica* and is currently designated as a separate species, *S. bongori*. *S. bongori* does not cause disease in humans. Over 2400 serovars have been reported. Serotype designation is based on the presence of specific antigens: O (somatic/cell wall) antigen and flagellar H antigens. Strains are therefore named, for example, as *Salmonella enterica* subspecies *enterica* serotype Typhimurium. The CDC recommends that the species designation be simplified to the genus and serovar only, i.e., *Salmonella* Typhimurium.

Epidemiology and prevention

Nontyphoid Salmonella

The burden of nontyphoid *Salmonella* infection is huge. According to US FoodNet data, the incidence of *Salmonella* infection was 13.4 cases per 100 000 population from 1996 to 1999 [496]; however, a population-based survey demonstrated that reporting was underestimated by a factor of 38.6, translating into an estimated 1.4 million cases of *Salmonella* illness per year. Higher incidences of infection are reported outside the United States. Of greatest concern has been the increase in the number of infections caused by *S. enterica* serovar Typhimurium definitive phage type 104 (DT104). DT104 is typically resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline and can acquire resistance to ciprofloxacin and ceftriaxone [497]. Reports from around the world indicate that the number of *Salmonella*-induced illnesses, including those caused by DT104, has significantly decreased [498,499]. For over three decades, the incidence of infection by nontyphoidal *Salmonella* has increased but there is now a reversal of that trend [499]. Unfortunately, rates of antibiotic resistance and multidrug resistance are rising. Although over 2000 serovars of *Salmonella* exist, a small minority cause most human illness, predominantly *Salmonella* Enteritidis and *Salmonella* Typhimurium. The predominant serovars isolated from infected humans vary from year to year and country to country [500].

Most *Salmonella* infections are self-limited, but hospitalization might be necessary and death can result. Between 1996 and 1999, the hospitalization rate of *Salmonella* infections was 20% and the mortality rate was 0.6% [496]. In 2000, however, the hospitalization rate decreased to 10.1% but the death rate remained at 0.8% [501]. *Salmonella* causes approximately one-third of the deaths related to foodborne illness, making it the leading cause of such mortality [501]. Salmonellosis in patients with malignancies, immunosuppression, alcoholism, sickle cell disease, cardiovascular dysfunction, and hemolytic anemias is more aggressive and if associated with bacteremia can result in mortality rates of 3% or higher [499].

Salmonella infection is usually acquired by consuming contaminated raw or undercooked food, especially meat, poultry, eggs, and milk. *Salmonella* can be commonly isolated from poultry and various types of farm animals, and is part of the normal flora of reptiles and amphibians. Most infections (85%) are associated with outbreaks, but person-to-person transmission can occur. The highest incidence of infection occurs at the extremes of life; the annual incidence in early childhood is approximately sixfold higher than the average incidence but there is a low incidence in young adulthood [499]. There is seasonal variation with the peak incidence occurring in summer and fall. Proton pump inhibitor use has been associated with an increased risk of infection with DT104 [502].

Nontyphoidal *Salmonella*, in contrast to typhoid, is rarely transmitted from person to person. The indiscriminate use of antibiotics in poultry and farm animals, as well as in humans, needs to be addressed, and mechanisms of antibiotic resistance transfer between microbes more carefully explored to control this problem.

Pathogenesis

The key feature of *Salmonella* pathogenesis is uptake by host cells. Epidemiological studies suggest that as few as 100 viable *Salmonella* can cause clinical infection [503]. The absence of gastric acid is a risk factor for illness because it reduces further the inoculum required for establishment of an active infection. Once past the stomach, *Salmonella* interact with both enterocytes and M cells and are internalized via a complex series of events triggered in the host cell. Important aspects of *Salmonella* pathogenesis are being unraveled. The virulence genes of this pathogen are localized to *Salmonella* pathogenicity islands (SPIs), of which five have been identified. The sequencing of the complete genome of *Salmonella* identified five potential additional SPIs [504]. SPI-1 encodes a T3SS that allows delivery of bacterial effector proteins into host cells. Some SPI-1 effectors include SopE and SopE2, which activate host cell Rho GTPases leading to actin rearrangement and uptake of bacteria (for a detailed review of this process, see [505]). SPI-2 also encodes a T3SS that permits *Salmonella* to survive in host epithelial cells and macrophages. Genes encoded in SPI-3 are believed to permit growth within phagosomes, where concentrations of magnesium are low [506], and SPI-4 is needed for survival within macrophages [507]. Evidence suggests that genes in SPI-5 contribute to intestinal secretion and inflammation. Other *Salmonella* virulence factors have also been reviewed [508]. Of such factors, flagellin deserves mention here. Flagellin,

which comprises bacterial flagella, is now recognized as a major proinflammatory stimulus via its interaction with TLR5 [509,510]. *Salmonella* flagellin is translocated across intestinal epithelial cells to the basolateral surface where it interacts with its receptor TLR5 and triggers the inflammatory cascade by eventually activating NF-κB. In addition, the secreted *Salmonella* effector SipA induces the expression of the eicosanoid hepoxilin A3, which is secreted apically and serves as a chemoattractant for polymorphonuclear leukocytes across the intestinal epithelial layer, resulting in the formation of crypt abscesses [511,512]. The inflammatory response is a major factor in *Salmonella*-induced enteritis; it is now clear that several factors contribute to this response.

Clinical manifestations

Salmonella infection can result in gastroenteritis, enteric fever, bacteremia, or asymptomatic carriage. The symptoms of *Salmonella* gastroenteritis are indistinguishable from those caused by other enteric pathogens and range from a few loose stools to a cholera-like illness with profuse diarrhea and significant dehydration or even dysentery. Symptoms including fever and chills, abdominal cramps, nausea, and vomiting typically develop within 48 h following ingestion of contaminated food or water. *Salmonella*-associated fever usually resolves within 2–3 days but diarrhea persists for 3–7 days. Nontyphoidal *Salmonella* typically persist in the stool for 4 or 5 weeks following resolution of gastroenteritis [513]. Bacteremia occurs in 2%–4% of patients [514] but is more frequent in children under the age of 1 year, adults over 50 years, and patients with underlying health problems including cancer, lymphoproliferative disorders, HIV/AIDS infection, valvular heart disease, hemoglobinopathies, transplant recipients, and those taking steroids.

Complications

Serious complications most commonly occur in infected patients with underlying disorders. Bacteremia and focal abscesses, which can result in septic shock, are complications seen in patients with AIDS and those with malignancies or receiving therapy for malignancies. Finally, infected aortic or iliac aneurysms in patients with preexisting atherosclerotic vascular disease can result in mortality rates of over 60%. Pleuropulmonary complications, including empyema, have also been reported and again occur most commonly in the immunocompromised [515].

Diagnosis

The diagnosis of *Salmonella* as the etiological agent of gastroenteritis is made by identifying this organism in fecal cultures or, on rare occasions, cultures of the blood or other extraintestinal sites. Frequently, local laboratories will determine that *Salmonella* is or is not *Salmonella* Typhi, but more extensive classifications of isolates are usually performed in public health reference laboratories.

Treatment

Antibiotic therapy is not recommended for otherwise healthy individuals with uncomplicated *Salmonella* gastroenteritis. Antibiotics can not only prolong the carrier state or even cause relapse but also they typically do not abbreviate the duration of diarrhea [514]. In contrast, those with predisposing factors that are associated with higher incidences of complications of *Salmonella* infection should receive antimicrobial therapy. This includes individuals under 1 and over 50 years of age and those with artificial joints or vascular grafts, degenerative joint disease, valvular heart disease, or immunocompromising conditions. Patients demonstrating signs or symptoms of sepsis or bacteremia should also receive antibiotic therapy for *Salmonella* infection as should those with local extraintestinal infections such as osteomyelitis and pleuropulmonary infection. Treatment with trimethoprim–sulfamethoxazole or fluoroquinolone, if susceptibility is demonstrated, is recommended; ceftriaxone is also effective [514]. Infants with *Salmonella* infection who are under the age of 3 months should be treated with antibiotics [516].

Drug resistance among *Salmonella* species has been increasing [517]. In particular, DT104 (see Epidemiology and prevention above) has emerged as a significant problem in North America and elsewhere. It is therefore important to determine the antibiotic susceptibility of strains isolated from infected individuals instead of resorting to empiric therapy, although antibiotics sometimes must be started before the results of susceptibility testing are known.

Salmonella *Typhi (typhoid [enteric] fever)*

Typhoid fever, a systemic disease caused by infection with *S. enterica* serotype Typhi, is more appropriately referred to as enteric fever, because this category also includes disease caused by serotype Paratyphi A, B, and C. Although *Salmonella* Typhi is responsible for 80% of cases in endemic countries, infection by *Salmonella* Paratyphi is more common among travelers [518], probably because vaccination is available and effective only for *Salmonella* Typhi. Humans are the sole reservoir for these organisms, thus the disease is transmitted from person to person or by ingestion of food that has been contaminated by an acutely infected individual or a chronic carrier. Drinking water contaminated by feces of infected individuals is also a source of infection.

Epidemiology and prevention

The worldwide prevalence of enteric fever might be as high as 30 million cases [519]. The epidemiology of this infection in developed countries, where it was once endemic, has changed dramatically over the past 50 years with a marked decrease in the incidence and a shift to cases now being associated with travel to specific geographic regions. In the 1940s the incidence of this infection was 7.5 per 100 000, but this fell to 0.2 per 100 000 in the 1990s [520]. In the late 1960s and early 1970s only 33% of cases were associated with

travel, but by the late 1990s, 80% of cases were related to foreign travel [520]. Travel to six countries accounts for 80% of enteric fever cases: India, Mexico, Philippines, Pakistan, El Salvador, and Haiti [520]; however, the risk of acquiring enteric fever is 18 times higher with travel to the Indian subcontinent than with travel to any other area [521]. Risk factors for acquisition of enteric fever by travelers include travel to rural areas, failure to adhere to food and water precautions, and the lack of education regarding such issues prior to travel. Increased age and length of stay are also associated with enhanced risk of infection [522]. Immigrants returning to their homeland are also at increased risk. They may not be aware of this and are thus less inclined to follow food and water precautions and receive vaccination for typhoid and are more likely to travel to rural areas.

In endemic areas, children and adolescents are the primary targets of disease, accounting for 90% of cases, but there is no age specificity amongst travelers. Travelers typically ingest less of an inoculum as a result of hygiene precautions; in addition, travelers are more likely to seek and have access to medical care and hence receive treatment early in illness.

Food and water precautions when traveling are crucial for preventing this infection. In addition, enteric fever caused by *Salmonella* Typhi, but not *Salmonella* Paratyphi, can be prevented by immunization. There are two types of vaccine, an injectable vaccine, which is a conjugate of *Salmonella* Typhi and recombinant *Pseudomonas* exotoxin A [523], and a live attenuated oral vaccine, which requires four doses taken every other day for 4 days [524]. The parenteral vaccines provide a circulating antibody response whereas the oral live vaccine induces a secretory IgA response and cell-mediated immunity. The efficacy of these vaccines in travelers is difficult to establish and so most trials have been performed in endemic countries, indicating approximately 55%–75% efficacy [521]. It should be noted, however, that ingesting a large inoculum of viable organisms can overcome typhoid immunity, underscoring the need to avoid contaminated food and water. A booster series of four capsules is recommended for the oral vaccine every 5 years and for the parenteral vaccine every 2 years.

Pathogenesis

Following ingestion, *Salmonella* Typhi survive gastric acid by means of a two-component system that includes induction of a pH homeostasis system and expression of acid shock proteins; together, these systems permit survival in low pH [525,526]. Once in the small intestine, *Salmonella* Typhi invade M cells, are engulfed by mononuclear cells in the underlying lymphoid tissue, and disseminate via lymphatics or the bloodstream. Intracellular multiplication proceeds in reticuloendothelial cells and macrophages in the liver, spleen, lymph nodes, and bone marrow. Infected individuals are asymptomatic during this phase. Once the concentration of *Salmonella* Typhi in these tissues is sufficient, organisms gain access to the systemic circulation resulting in the production of cytokines and symptoms in the host. It is during this phase of persistent bacteremia that extraintestinal organs are seeded and complications ensue.

Clinical manifestations

The typical incubation period of *Salmonella* Typhi is 7–14 days but it can range from 3 to 60 days. Clinical manifestations can be protean and include anorexia; abdominal pain, tenderness, and bloating; nausea and vomiting; diarrhea; and bloody diarrhea [527]. Enterocolitis, with diarrhea lasting several days, can develop but usually resolves before the onset of fever. The bacteremic phase follows this asymptomatic incubation phase and is manifest as an acute febrile illness accompanied by flu-like symptoms including frontal headache, general malaise, prostration, confusion, anorexia, and abdominal discomfort and bloating. Some individuals present with upper respiratory symptoms, such as dry cough, coryza, and sore throat, thus delaying the diagnosis. Constipation can occur early in illness but generally is followed by diarrhea in the late phase of the illness. The fever pattern is interesting in that it can increase over the initial 5–7 days with body temperatures peaking in the afternoon. Relative bradycardia for the degree of fever is considered common for typhoid fever but is certainly not specific for this infection. Blood cultures are positive in more than 90% of patients during this initial phase of fever and nonspecific symptoms. A longer period, 10–14 days, of sustained high fevers (39°C–41°C) can follow but medical attention is usually sought earlier in the course of infection, particularly by travelers, and so this phase is typically not seen in this group. The liver and spleen are frequently enlarged and abdominal tenderness is often present, particularly over the lower quadrants (at times mimicking appendicitis) and liver. Rose spots, which are 2- to 4-mm erythematous maculopapular lesions that blanch, have been reported in up to 30% of patients and occur within the first 1–2 weeks but last only 3–4 days. These typically are seen on the chest and abdomen but can be missed in individuals with darker skin. Symptoms begin to abate after the third week of untreated illness in the 90% who survive. Relapse has been reported to occur in 3%–13% of untreated patients and about 20% of treated patients, on average after 2 weeks have elapsed. The illness associated with relapse tends to be milder and shorter than the initial manifestations.

Complications

Intestinal hemorrhage and perforation related to hyperplasia of the lymphoid tissue in the ileocecum can occur. This is typically observed in untreated individuals in the third to fourth week of illness. The extraintestinal complications associated with *Salmonella* Typhi can target almost any organ system including the central nervous system (3%–35%), cardiovascular system (1%–5%), pulmonary system (1%–6%), bones

and joints (< 1%), hepatobiliary system (1%–26%), genitourinary system (< 1%), soft tissues, and hematological system (rarely). This topic has been extensively reviewed [519]. Specific complications include encephalopathy, cerebral edema, meningitis, seizures, GBS, endocarditis, myocarditis, pneumonia, empyema, osteomyelitis, septic arthritis, cholecystitis, hepatitis, hepatic abscess, splenic abscess, peritonitis, urinary tract infection, renal abscess, testicular abscess, prostatitis, and epididymitis.

The chronic carrier state is defined as excretion of the organism for 1 year or longer and occurs in 2%–5% of patients with *Salmonella* Typhi and *Salmonella* Paratyphi infections. Risk factors for becoming a chronic carrier include age less than 1 year, age older than 60 years, concomitant biliary disease, and presence of schistosomiasis. The biliary tract commonly serves as a focus of *Salmonella* organism multiplication in typhoid carriers, especially if concomitant abnormalities, such as stones or obstruction, are present.

Fatality rates can be as high as 30% in individuals from endemic countries; the fatality rate in travelers, however, is reported as less than 0.4% [520].

Diagnosis

Enteric fever is diagnosed by isolating the causative agents from blood or stool. Culture of the bone marrow is successful in recovering these pathogens from 90% of individuals who have received antibiotics [528]. *Salmonella* Typhi and *Salmonella* Paratyphi are also quite frequently isolated from rose spots.

Treatment

Ceftriaxone is currently the recommended first-line therapy for *Salmonella* Typhi and *Salmonella* Paratyphi infections [519,521]. If fluoroquinolone susceptibility is demonstrated than these agents can be used as well, but they are not approved for use in children in the United States. Alternative therapies are based on antibiotic susceptibility data of recovered strains. The frequency of multidrug-resistant *Salmonella* Typhi in the United States has increased significantly over the past two decades, with 30% being resistant to at least one antibiotic and 12% demonstrating resistance to chloramphenicol, ampicillin, and trimethoprim–sulfamethoxazole. Such strains require longer treatment with expensive agents that can be less effective, thus increasing the risk of carrier status.

High-dose dexamethasone should be given to individuals with severe typhoid fever. Perforation is one of the most serious intestinal consequences of typhoid fever and warrants surgery [529].

Shigella species

History

Shiga bacillus, now known as *Shigella dysenteriae* type 1, was originally isolated and described by Kiyoshi Shiga in 1898 [530]. As a young physician, Shiga investigated the etiology of the *sekiri* (red diarrhea) epidemic of 1897 in Japan, which affected over 90 000 individuals and had a mortality rate of greater than 20% [531]. He isolated a gram-negative bacillus from the stools of afflicted patients that, when subcultured and orally administered to dogs, caused diarrhea. Initially named *Bacillus dysenteriae*, this organism was also determined by Shiga to produce toxic factors including the now well-characterized Shiga toxin. Following the initial report of this organism, others identified related strains now known as *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* for those responsible for their description – Flexner, Boyd, and Sonne respectively [531]. The genus was renamed in 1930. It is plausible that the "emerods" that "smote" the encampment of Philistines at Ashdod [532] were rectal prolapses secondary to shigellosis, which is notorious for epidemics appearing during military campaigns through the ages. However, some scholars believe that emerods were the buboes of epidemic *Yersinia pestis* infection [533].

The genus *Shigella* belongs to the tribe *Escherichia* in the family Enterobacteriaceae and consists of four species or groups (A–D) of gram-negative, aerobic rods: *S. dysenteriae* (group A), *S. flexneri* (group B), *S. boydii* (group C), and *S. sonnei* (group D). Each species, except for *S. sonnei*, is divided into several serotypes, defined by the somatic O antigen. Only *S. flexneri* is further divided into subtypes. The distribution of *Shigella* species worldwide correlates with the level of development and hygiene, the basis of which is not well understood. *S. dysenteriae* serotype 1, a particularly virulent serotype associated with significant morbidity and mortality, occurs in less developed countries and has pandemic potential. *S. flexneri* are also most commonly isolated in developing countries, especially those with tropical climates. *S. sonnei*, which causes mild cases of watery diarrhea, accounts for most cases of *Shigella* infection in industrialized nations. *S. boydii* is rarely isolated; however, analysis of isolates from Canada and the United States in 2005 showed that they were a new *S. boydii* serotype [534].

Epidemiology and prevention

Humans are the only known reservoir of *Shigella*. Although this single reservoir should offer an advantage for their control, *Shigellae* remain one of the most common causes of bloody diarrhea worldwide. This paradox is likely explained by their exquisitely low infectious dose. Contributing to their survival is the emergence of antibiotic-resistant strains and their resistance to gastric acid. Transmission is predominantly fecal–oral, but person-to-person transmission via contaminated hands and drinking water and food can occur through fomites, food, and water [535]. The common housefly can spread *Shigella*, particularly in areas where the disposal of human waste is inadequate [536]. Approximately 165 million cases of *Shigella* infection are estimated to occur annually worldwide [537], 163 million of which occur in developing countries. In the United States, approximately 15 000 cases

are reported annually [538], but the actual number is likely to be higher. Untreated *Shigella* can be severe and fatal [539], although the mortality rate is falling [540]. Most infections occur in children under 5 years of age (69%), and most deaths (61%) also occur in this age group [537].

In industrialized countries, shigellosis is primarily a problem in populations exposed to substandard hygiene in group settings, in particular day-care centers, custodial institutions, and nursing homes. Travelers to developing countries are also at greater risk for infection. *Shigella* causes an estimated 4% of traveler's diarrhea [541,542]. Although much less common than infections by ETEC, traveler's diarrhea caused by *Shigella* is more severe.

Shigella is highly contagious, requiring a minute inoculum to establish infection. Ingestion of as few as 180 organisms caused diarrhea in 22% of healthy volunteers [543]. *Shigella* persists as a pathogen because fecal organisms in patients suffering acute shigellosis are abundant (approximately 10^9 per gram of stool).

Frequencies of infection by *Shigella* spp. vary by country and population. In a study from Calcutta, India, *S. flexneri* was the most commonly isolated species (60%), followed by *S. sonnei* (24%), *S. dysenteriae* (10%), and *S. boydii* (6%) [544]. An important observation from this study was the reemergence of *S. dysenteriae* serotype 1 after a 14-year absence; this strain exhibited multidrug resistance including to fluoroquinolones. Increased drug resistance in *S. flexneri* type 2a was also noted. In contrast, in Sweden, *S. sonnei* was the most commonly isolated species (67%), with *S. flexneri* accounting for 26%, *S. boydii* 5%, and *S. dysenteriae* 3% of infections [545]. Of greatest concern is *S. dysenteriae* serotype 1 because of the severity of the associated clinical symptoms, potential for serious complications, and the propensity of this strain to cause pandemics. In the face of emerging antibiotic resistance these traits present a major health concern [546], as highlighted by epidemics of resistant dysentery in Asia and Africa.

The major route of *Shigella* transmission is person-to-person. This is in large part because of poor handwashing and toileting practices and inadequate sanitation. Together, these can lead to the contamination of drinking water and food. Preventive interventions include the use of soap and water for handwashing, decreased contact with human excreta, disinfection of water, and overall improved sanitation. Although a *Shigella* vaccine is needed, the antigenic complexity of this species and the poor understanding of protective immunity for *Shigella* have made this a difficult task. Nonetheless, the safety and immunogenicity of serotype-specific protection with conjugate vaccines consisting of *S. flexneri* and *S. sonnei* lipopolysaccharide coupled to succinylated mutant *Pseudomonas aeruginosa* exotoxin A have been demonstrated in children and adults [547,548]. This approach has considerable promise in situations in which diseases are caused by a limited number of pathogenic serotypes. *Shigella* vaccine strategies have been reviewed [549].

Pathogenesis

The pathogenesis of *Shigella* is multifactorial and includes the production of enterotoxins (important but not essential) and its ability to invade and destroy host tissues, resulting in large part from the extensive inflammatory response associated with this infection. *Shigella* are believed to penetrate the intestinal epithelial barrier through M cells that overlie lymphoid follicles, allowing them to reach the basolateral aspect of intestinal epithelial cells where they can invade. Once internalized, the bacteria multiply rapidly and disseminate to adjacent cells. The host protein Nod1 recognizes peptidoglycan fragments of *Shigella*, leading to activation of the proinflammatory transcription factor NF-κB [550]. Approximately 30 bacterial gene products are involved in *Shigella* invasion and its intercellular spread, and these proteins are encoded on large virulence plasmids present in all *Shigella* species [551]. Some of these encoded proteins comprise a T3SS, a multiprotein complex that allows direct delivery of bacterial proteins into host cells. Recognition of host cell components by bacterial sensors can trigger the secretion of bacterial factors through this apparatus. A complex series of host cell signals ultimately leads to bacterial invasion and spread. The ability of *Shigella* to invade and colonize the intestinal epithelium is crucial to the establishment of disease and associated morbidity.

Shigella species also elaborate toxins that play a role in disease including enterotoxins, cytotoxins, and neurotoxins. The classic *Shigella* toxin, Shiga toxin (Stx), is produced by *S. dysenteriae* serotype 1. The 70-kDa Stx consists of one catalytic A subunit and five B subunits. As with EHEC Stxs, the B subunits bind the toxin to host receptors, a process that is common to many bacterial toxins. The Stx receptor, globotriaosylceramide (Gb_3), is internalized by receptor-mediated endocytosis following toxin binding [552]. Once internalized, the catalytic A subunit is released, leading to cytotoxicity via inhibition of protein synthesis. The absorptive capacity of the intestinal epithelium is impaired, contributing to diarrhea. Stx does not activate adenylate or guanylate cyclase, as other bacterial enterotoxins do, but it is biologically similar to Stxs secreted by EHEC. Similarly to these toxins it can affect renal endothelial cells, resulting in HUS, although the risk of HUS is lower than with EHEC [553].

Other *Shigella* enterotoxins have been identified. ShET1, a 55-kDa holotoxin that also has the A–B subunit structure, is unique to the *S. flexneri* 2a serotype among *Shigellae*. As with Stx, the gene encoding this protein is located on the chromosome. The presence of such a toxin was predicted by studies in monkeys showing that small intestinal secretion accounted for the watery diarrhea seen early in shigellosis [554]. ShET2, a 64-kDa holotoxin expressed by 80% of diverse *Shigella* serotypes, also contributes to the watery diarrhea associated with infection. Unlike Stx and ShET1, ShET2 is encoded by a gene on the large virulence plasmid that confers invasion [555]. Another *Shigella* secreted protein,

designated SigA, has both cytopathic and enterotoxic activity [556]. SigA, a 103-kDa product encoded within the chromosomal *she* pathogenicity island of *Shigella*, has serine protease activity, likely accounting for its toxic effects.

Invasion is more important than toxin production in the pathogenesis of shigellosis. Infection of macaques with isogenic mutants of *S. dysenteriae* that lacked either the invasion plasmid or the Stx gene demonstrated that the invasive but nontoxigenic strain induced disease which was indistinguishable from wild-type *Shigella* except that the diarrhea caused by the Stx-expressing strains was bloodier [557]. A correlation between the level of Stx production and gastrointestinal bleeding has been suggested in humans [558]. However, non-Stx producing *Shigella* can also cause notable extraintestinal complications, including seizures [559].

The cardinal feature of *Shigella* is its ability to invade the host intestinal epithelium. This is initially achieved by invasion of M cells, the specialized epithelial cells strategically positioned over lymphoid follicles. After entering M cells, the internalized organisms traverse these cells and emerge into the gut-associated lymphoid tissues (GALT) of the terminal ileum and colon where they are engulfed by macrophages. In contrast to the usual scenario whereby engulfed organisms are destroyed, *Shigella* induce macrophage apoptosis [560], releasing IL-1β [561] and thereby recruiting neutrophils to and across the intestinal epithelial layer. Intercellular tight junctions are breached and lumenally situated *Shigella* directly gain access to the subepithelial space and basolateral pole of the host intestinal epithelial cell, the only membrane domain through which these microbes can invade [562,563]. *Shigellae* multiply intracellularly and then disseminate into adjacent cells throughout the intestine and destroy the epithelium [564]. This marked inflammatory infiltrate and tissue destruction characterize shigellosis.

Clinical features

The incubation period for *Shigella* is 1–4 days and can be up as long as 8 days for *S. dysenteriae*. Most individuals infected with *Shigella* have a self-limited course lasting 5–7 days in adults and 2–3 days in children. Some adults, however, experience a subacute presentation characterized by 2–3 weeks of waxing and waning diarrhea. Such a presentation can mimic new-onset ulcerative colitis, especially because the endoscopic appearance of the mucosa (erythema with small ulcers) is quite similar [531]. In such cases it is prudent to perform stool cultures and, if *Shigella* is isolated, treatment with appropriate antibiotics should rapidly resolve the symptoms. A long-term carrier state for *Shigella* has been described, defined as fecal shedding following the resolution of symptoms from acute dysentery caused by *S. sonnei* and *S. flexneri,* but is rare [565,566].

Shigella dysentery is characterized by acute diarrhea containing blood and mucus accompanied by fever and abdominal pain. The presentation can occur in two phases, the initial phase characterized by the abrupt onset of frequent (every 20–30 min) watery diarrhea, which is followed by the second, or dysenteric, phase 12–72 h later. In this phase the passage of small amounts of blood-tinged mucus with or without blood clots occurs. Approximately half of all patients infected with *Shigella* experience grossly bloody diarrhea. Fever develops 1–3 days postinfection and is then often followed by abdominal cramps and diarrhea within 24 h. In most patients the diarrhea resolves after 7 days but symptoms can persist for up to 30 days. A much more severe clinical course can be seen in children, including fever, abdominal pain, malaise, vomiting, watery or bloody diarrhea, and tenesmus [567].

The physical examination often demonstrates only lower abdominal tenderness, and bowel sounds are normal or increased. More alarming physical findings, such as rebound tenderness or ileus, are not typical of *Shigella* infection and should suggest an alternate diagnosis. Dehydration can occur in young children, especially with prolonged (48 h) diarrhea and vomiting; in general, however, the fluid loss in shigellosis is not voluminous. Leukocytosis is unusual but is more likely to be seen in patients, both adults and children, with severe rectal histology [568]. The differential white cell count frequently demonstrates a relative "bandemia."

Complications

Shigella bacteremia is an uncommon but severe complication of *Shigella* dysentery, occurring most frequently in malnourished children, the immunocompromised, or patients over 65 years of age. *Shigella* bacteremia is probably underappreciated and usually is not associated with metastatic infections [569]. The mortality rate of shigellosis is falling, even in disease caused by *S. dysenteriae* serotype 1 [553].

Reiter syndrome, a triad of arthritis, urethritis, and conjunctivitis, occurs most often after bacillary dysentery in men aged 20–40 years who express the human leukocyte antigen (HLA)-B27 phenotype. Approximately 1%–2% of infected individuals develop Reiter syndrome [566,570,571], 80% of whom are HLA-B27 positive [571]. Of the HLA-B27-positive individuals who suffer bacillary dysentery caused by any agent, approximately 20% develop Reiter syndrome.

The clinical presentation of Reiter syndrome can be quite variable, with mild forms being common [572] and genitourinary symptoms being absent or minimal. Patients often present with asymmetric lower extremity arthritis or periarthritis 2–4 weeks following shigellosis or other bacterial dysenteries. By this point in the illness, intestinal symptoms have usually resolved and antibiotic treatment is not indicated. The arthritic symptoms tend to be chronic and relapsing, even in the absence of dysentery. Reiter syndrome is treated symptomatically with nonsteroidal antiinflammatory drugs.

HUS, most often associated with EHEC infections, is also a recognized complication of *S. dysenteriae* serotype 1 infection;

it does not follow infections with non-*dysenteriae* species because they do not make Stx. The leukemoid reaction during the diarrheal phase of *S. dysenteriae* serotype 1 infections can be a harbinger of HUS [573]. Shiga toxin and Stx1 of *E. coli* are nearly identical structurally. HUS following *S. dysenteriae* serotype 1 infection has not been as extensively studied as HUS following *E. coli* O157:H7 infection, but it is likely that there is a similar series of pathophysiological events leading to microangiopathic hemolytic anemia, thrombocytopenia, and renal failure.

Additional complications of all forms of shigellosis include hyponatremia, hypoglycemia, toxic megacolon, seizures, and rectal prolapse. *Shigella* can infect a number of extraintestinal organs, including the eyes, joints, heart, liver, skin, and nervous system [535], and can cause Ekiri syndrome, which is a *Shigella*-associated encephalopathy [574]. Unlike EHEC infections, currently available data strongly suggest the safety and efficacy of antibiotics in *Shigella* infections [553].

Diagnosis

Confirmation of *Shigella* infection requires isolation and identification of the pathogen by stool culture. Stool cultures were positive as early as 3 days following oral challenge in volunteer studies and, if untreated, remained positive for an average of 27 days [575,576]. Interestingly, not all patients with positive stool cultures suffered symptoms. Conversely, some volunteers with classic symptoms of *Shigella* dysentery had negative cultures; thus, a negative stool culture does not exclude the diagnosis. To optimize the isolation of *Shigella*, liquid stool should be collected in a sterile container and inoculated as soon as possible on media selective for *Shigella* and *Salmonella*. The presence of fecal leukocytes and gross blood greatly enhance the likelihood that a stool specimen will be positive for a bacterial pathogen. Only 20% of stool cultures from adults with acute diarrhea were positive if performed nonselectively whereas the yield increased to 75% or more if the specimen contained leukocytes [577]. A report of bloody diarrhea should also prompt a search for *E. coli* O157:H7 and other bacterial enteric pathogens.

Treatment

Antibiotics shorten shigellosis and reduce the duration of excretion of the organism. Antibiotics, therefore, are usually indicated, especially if the patient is still symptomatic when the culture results are reported back as being positive or if the patient is likely to spread infection in the convalescent phase (e.g., a child returning to day care, health-care workers, or food handlers) or is medically fragile (e.g., the elderly, malnourished, and those with comorbidities including HIV). In all cases, treatment of dehydration with either oral rehydration solutions or intravenous fluids in cases of mild to severe diarrhea is important. Antidiarrheal medications, on the other hand, can prolong symptoms and delay clearance of the organism and are not recommended [578].

Treatment recommendations for shigellosis change frequently because of the emergence of multidrug resistant strains. *Shigellae* are frequently resistant to ampicillin, nalidixic acid, sulfonamides, tetracyclines, and trimethoprim–sulfamethoxazole, hence the choices for the treatment of shigellosis are severely limited. Ideally, selection of antibiotic therapy should be dictated by culture and antibiotic susceptibility data, but such testing requires at least 2 days. Therefore, antimicrobial choices are usually made empirically but this requires an informed decision based on local antibiotic resistance patterns. A workshop organized by the WHO and a number of other international agencies recommended that ciprofloxacin be the first-line agent for the treatment of shigellosis. In one study, ciprofloxacin led to the resolution of disease or significant symptomatic improvement in 95% of patients with severe disease [579]. Of concern, however, is the report that resistance to fluoroquinolones has also emerged following the extensive use of these drugs for shigellosis. In Calcutta, for example, resistance of *S. dysenteriae* serotype 1 to fluoroquinolones increased from 15% in 2003 to 25% in 2004 [544]. Azithromycin and pivmecillinam have been reported to be effective against fluoroquinolone-resistant *S. dysenteriae* type 1 [580–582], and the third-generation cephalosporins, ceftriaxone and cefixime, are safe and effective in children [579], although concerns have been raised about treating shigellosis with cefixime [583]. If susceptibility to trimethoprim–sulfamethoxazole or ampicillin is demonstrated, these agents can also be used. For mild infections, shorter courses of therapy may be adequate, especially for non-*dysenteriae Shigellae* [584]. Recommendations for treatment of *Shigella* infections warrant frequent review given the rapidity of change in patterns of antimicrobial resistance.

Vibrio infections

Vibrio cholerae

History

Vibrio cholerae is an ancient scourge [585,586]. Initial descriptions arose in southern Asia, which is a region in which epidemics persist. Cholera is also prone to cause pandemics that extend beyond the endemic region. Cholera was the basis for the classic 1854 epidemiological study of John Snow, which demonstrated its strong association with contaminated drinking water at the Broad Street pump [587], but its causative agent, *V. cholerae*, was not identified until 1884. North America was not protected from cholera; cholera was the first reportable disease mandated by the New York Board of Health in the mid-1800s [588]. The world is in the midst of the seventh pandemic of cholera, which began in 1960. This particular pandemic strain is a biotype of *V. cholerae* serogroup 01, first isolated in 1905 in El Tor, Egypt and termed the El Tor strain [586]. A new serogroup of *V. cholerae* emerged in 1992, designated O139 Bengal, which has coexisted with the present El Tor strain in Asia.

Epidemiology and prevention

Cholera is typically a waterborne infection. Foodborne transmission can occur but such episodes are usually related to contamination of food with water that contains *V. cholerae*. Cholera occurs in one or two peaks per year in endemic areas, usually coincident with torrential rains [589–591]. Its interepidemic reservoir is unknown. One novel mechanism of pathogen control might be environmental cholera-specific bacteriophages, which reside in the lysogenized state in nonpathogenic aquatic vibrios [592]. The infectious dose needed to cause cholera is generally higher than that of other bacterial enteric pathogens. Children are disproportionately affected in endemic areas, but, when cholera is newly introduced into a population, it affects persons of all ages similarly [590]. Because *V. cholerae* is transmitted chiefly via water, reducing exposure to contaminated water and ensuring that all water undergoes a reliable bactericidal process before consumption are especially important control measures. However, infrastructures in countries where *V. cholerae* is prevalent are often insufficient to ensure that these important measures are adhered to.

Several oral cholera vaccines are available or under consideration. In the Dukoral vaccine (SBL Vaccine AB, Sweden), four different heat-inactivated *V. cholerae* strains are coadministered with a recombinant cholera toxin (CT) B subunit (which is a potent mucosal adjuvant); this vaccine requires two doses for optimal efficacy [593]. The second available vaccine is a live, attenuated strain (CVD103HgR) [594], which can be given as a single dose (Orochol, manufactured by CSL, Australia). These oral vaccines do not confer absolute protection and new formulations are being considered (reviewed in [595]).

Pathogenesis

Vibrio cholerae has two circular chromosomes and all known virulence factors are located on chromosome I, which is 3 Mb in size [596]. The principal virulence trait of *V. cholerae* is its ability to produce CT. CT is a classic AB_5 toxin, with the B subunit homopentamer mediating cellular binding. The 27.5-kDa A subunit is actually a disulfide-linked dimeric moiety. The CT A_1 fragment possesses ADP-ribosylating activity, whereas the CT A_2 fragment associates the CT A subunit with the B subunit pentamer. The 84-kDa holotoxin attaches via its B subunit pentamer to the GM_1 ganglioside (Galβ1-3GalNAcβ1-4(NeuAcα2-3)Galβ1-4Glcβ1-1ceramide) on eukaryotic cell surfaces, which is concentrated in lipid rafts [597], and endocytosis follows binding of the holotoxin. It is possible that various cell types utilize different internalization mechanisms [595,598]. After internalization, CT undergoes retrograde transport to the endoplasmic reticulum via actin-associated lipid rafts [599]. After reaching the endoplasmic reticulum, the A subunit dissociates from the pentameric B subunit. The A subunit is relatively resistant to degradation and, after it arrives in the cytoplasm, it catalyzes ADP-ribosylation of a G-stimulatory component of adenylate cyclase. Adenylate cyclase then remains bound to GTP and its activity is thereby enhanced. The resulting elevated levels of cAMP augment chloride secretion by enterocytes and diminish sodium uptake. The chloride and accompanying bicarbonate secretion also cause sodium outflow accompanied by water secretion, resulting in the profound net secretory injury that typifies cholera. The augmentation of chloride secretion is most prominent in crypt cells, and inhibition of sodium chloride reabsorption predominates in villus cells. The resulting watery diarrhea contains excessive sodium, chloride, bicarbonate, and potassium, but is not an inflammatory process.

CT is also postulated to have effects independent of its role as a secretory toxin, the most notable of which is its effect on enterochromaffin cells, releasing serotonin, which increases secretion of vasoactive intestinal polypeptide [600,601].

V. cholerae has additional virulence mechanisms. The toxin-coregulated pilus (TCP) permits colonization of the small bowel by allowing the formation of microcolonies [602]. Genes encoding TCP, and the cholera toxin operon, are located on the same bacteriophage. This bacteriophage can infect nontoxigenic *V. cholerae*, rendering the recipient organism toxigenic. However, among the large number of *V. cholerae*, only strains expressing O antigens 1 and 139 are major human pathogens. The genetic complement of the O1 and O139 strains are largely similar, suggesting commonality of virulence loci. Non-O1 or non-O139 *V. cholerae* can occasionally be pathogenic but cause neither epidemics nor pandemics.

V. cholerae produces several additional toxins that might play roles in pathogenicity. Accessory cholera enterotoxin [603] stimulates calcium-dependent chloride and bicarbonate secretion [604]. Zonula occludens toxin [605] disrupts intestinal tight junctions via protein kinase C-dependent reorganization of actin [606].

Treatment

The mainstay of cholera treatment is correcting the often profound hypovolemia and replenishing continuing fluid losses. Usually, this can be performed by oral rehydration using fluids that contain carbohydrates and electrolytes, the efficacy of which was first reported nearly four decades ago [48]. The exact composition of the rehydration fluid with respect to osmolarity [47,49] is controversial (see Table 48.1 for concentrations of oral rehydration solutions that have been used). Fluids administered intravenously or via nasogastric tubes can be utilized if oral intake is inadequate. Severely dehydrated patients can require replacement of 10% of their body weight within the first few hours of treatment; the extent of dehydration in this illness should not be underestimated. Hydration should be maintained until fluid losses abate. An oral antibiotic should be administered to patients as soon as vomiting stops. Doxycycline administered as a single dose to adults often suffices [607]. Novel

future therapeutics might include small molecular interventions that target the expression of one or more virulence traits [608].

Diagnostic microbiology

Vibrio cholerae is a gram-negative organism that is best detected by plating on TCBS agar. It can also be detected by oxidase screening of blood agar plate growth. Media that support the growth of vibrios but which suppress most other flora, such as alkaline peptone water, can be used as a preplating enrichment step. Resulting colonies are characterized as expressing the O1 or O139 antigens.

Noncholera vibrios

Vibrios other than *V. cholerae* can cause human gastroenteritis. *Vibrio vulnificus*, which usually causes extraintestinal infections such as bacteremia or skin ulcerations, can cause gastroenteritis without or before other symptoms [609]. *Vibrio parahaemolyticus* has been the most common cause of seafood-associated gastroenteritis in the United States [610]. In an outbreak of diarrhea caused by *Vibrio parahaemolyticus* in Alaska, additional signs and symptoms included abdominal cramps (82%), chills (44%), myalgias (36%), self-reported fever (34%), headache (32%), vomiting (29%), and bloody stools (7%). Patients were ill for about 5 days [611]. These organisms are isolated from stool by plating fresh specimen on TCBS agar.

Yersinia infections

History

The genus *Yersinia* consists of three species that infect humans: *Yersinia enterocolitica*, *Yersinia pseudotuberculosis* (which are predominantly gastrointestinal pathogens), and *Yersinia pestis*, the causative agent of human pulmonic and bubonic plague. *Yersinia* were overlooked as agents of abdominal illnesses until *Y. pseudotuberculosis* was isolated from mesenteric lymph nodes in patients with mesenteric adenitis, and *Y. enterocolitica* was recovered from stools of patients with diarrhea who had no other enteric pathogens [612,613].

Epidemiology and prevention

Yersinia infections are rarer than other bacterial enteric infections in North America [614]; the infection is better studied in Europe [615]. The most common source of infection is pork, but raw milk and contaminated water are additional vehicles. Most cases are sporadic and not epidemic. In the United States, African Americans are disproportionately infected by *Yersinia* [616]. *Yersinia* infections occur considerably more frequently in children than in adults [27], although adult infections with *Y. enterocolitica* [617] and *Y. pseudotuberculosis* [618] occur, and adults without diarrhea can excrete *Yersinia* [619]. *Yersinia* infections often cluster in the winter, possibly related to food preparation mishaps during the holidays [620,621]. *Y. enterocolitica* infections are considerably more common than *Y. pseudotuberculosis* infections. Iron overload syndromes, diabetes, alcoholism, and malnutrition [622,623] appear to predispose to *Yersinia* infections, and in these disorders case fatality rates are higher.

Yersinia gastrointestinal infections are best prevented by attention to adequate cooking of foods that might contain this pathogen, in particular pork products. Their tendency to cluster at end-of-year holidays provides a particular opportunity to focus on education about domestic food preparation practices.

Pathogenesis

The cardinal feature of *Yersinia* pathogenesis is cellular invasion. *Yersinia* enter M cells via the binding of bacterial YadA to β1 integrins [624,625], and then multiply in underlying Peyer patches. *Yersinia* has a well-studied plasmid-encoded T3SS, which mediates its invasiveness [626]. A unique additional feature of this system is the ability of secreted proteins of *Yersinia* to down-regulate inflammation, leading to increased intracellular survival [627]. *Yersinia* also critically depend on iron for their virulence, using their own iron uptake system [628].

Clinical manifestations

Most clinical data pertain to infections caused by *Y. enterocolitica*. Most infected individuals have abdominal pain, with fever and diarrhea being somewhat less frequent. Diarrhea is visibly bloody in up to one-fourth of all infected patients [612]. Accompanying signs and symptoms include nausea, vomiting, pharyngitis (quite common), arthralgia, erythema nodosum, and abdominal tenderness, especially in the right lower quadrant. Regional lymphatic spread occurs after invasion of Peyer patches, and this extension causes a clinical picture of pseudoappendicitis or mesenteric adenitis. Occasionally, disseminated bacteremia and extraintestinal suppuration can occur. The pseudoappendicular syndrome is more frequent in teenagers and young adults, whereas enteritis and colitis predominate in younger children [629].

Infections caused by *Y. pseudotuberculosis* are rare and can manifest as granulomatous colitis [630].

Treatment

Yersinia are generally resistant to ampicillin and variably resistant to other β-lactam antibiotics, but susceptible to fluoroquinolones, trimethoprim–sulfamethoxazole, chloramphenicol, and gentamicin [631]. However, these susceptibilities have not translated into unequivocally effective therapy. For example, in one randomized controlled trial, trimethoprim–sulfamethoxazole was no better than placebo in ameliorating disease course, although treatment was administered over a week after symptoms began [632]. In view of the potential seriousness of these infections, however, most clinicians, after establishing a diagnosis of *Yersinia* gastrointestinal infection, will prescribe an antimicrobial, usually

trimethoprim–sulfamethoxazole or a fluoroquinolone [633]. In cases of extraintestinal infection, and in particular bacteremia, antimicrobial treatment is warranted. If doubt exists whether a patient has mesenteric adenitis or pseudoappendicitis from *Yersinia* infection or true appendicitis, it is prudent to err on the side of an exploratory laparotomy.

Diagnosis

Yersinia is detected in stool using selective enrichment techniques, in particular *Yersinia* selective agar, which contains cefsulodin, irgasan, and novobiocin to suppress non-*Yersinia* flora. Cold enrichment, exploiting the preferential growth of *Yersinia* at 25°C, has been largely abandoned. Unfortunately, many clinical microbiology laboratories do not routinely seek *Yersinia* in stool cultures [634], so it is important to request that this genus be sought if there is any question of its presence. There is no need to request special techniques for *Yersinia* when submitting lymph nodes or blood for culture, because there is little likelihood of competing flora being present in these specimens.

Complications

Yersinia cause several autoimmune postinfectious sequelae, including sterile arthritis, occurring 1–2 weeks after acute enteric infection and attributed to *Yersinia* antigens in affected joints [635], Reiter syndrome, myocarditis, glomerulonephritis, and thyroiditis [612] *Y. pseudotuberculosis* has been suggested to be a precipitant of Kawasaki disease in children [636].

Miscellaneous, unusual, and controversial bacterial causes of diarrhea and gastroenteritis

Aeromonas *species*

Several studies suggest that *Aeromonas hydrophila*, and, to lesser extents, *Aeromonas caviae* and *Aeromonas sobria*, cause human diarrhea, although it is not at all clear that isolation of this genus from stool means that *Aeromonas* is the cause of diarrhea [637,638]. These organisms tend to be associated with sporadic human illnesses and not epidemics. Their reservoirs are probably contaminated food and water, including food of aquatic origin. They are detected using blood agar plates and are susceptible, if one chooses to treat them, to fluoroquinolones, aminoglycosides, third-generation cephalosporins, carbapenems, aztreonam, and, to a lesser extent, trimethoprim–sulfamethoxazole [639].

Bacillus anthracis

Infection with *Bacillus anthracis*, the cause of human anthrax, can present with prominent gastrointestinal manifestations [640] after transmission from contaminated food. It can be recovered by stool culture [640] but is more commonly isolated from extraintestinal sites, such as cultures of blood, pulmonary tissue or secretions, and skin. Anthrax can cause intestinal ulcerations, severe abdominal pain, intestinal edema, ascites, vomiting, hematemesis, diarrhea, and bloody diarrhea. There can also be prominent gastrointestinal symptoms in inhalation anthrax [641].

Bacillus cereus

Bacillus cereus is a spore-forming anaerobe that causes disease by producing toxins. *B. cereus* causes two distinct syndromes in humans. The first syndrome is an emetic disorder without diarrhea, which is attributable to cereulide, a small cyclic dodecadepsipeptide that resists heat and acid [642]. Diarrhea caused by *B. cereus* has been attributed to heat-labile enterotoxins [643], which can be divided into at least three distinct types, including a hemolysin [644], a nonhemolytic enterotoxin [645], and a cytotoxin [646]. Most cases resolve within 1–2 days but *B. cereus* emetic toxin can occasionally cause fulminant hepatic failure [647]. Treatment of all illnesses caused by *B. cereus* is supportive. Diagnosis is made by isolating the organism from food or emesis. In reality, this is performed only by public health authorities in outbreak settings. *B. cereus* infections can possibly be prevented by adequate refrigeration of prepared foods, because toxin production appears to be optimal at 12–15°C [648].

Helicobacter pylori

Helicobacter pylori have been proposed to cause diarrhea. *H. pylori* can be excreted in the absence of gastroenteritis [649] and, although their role in either acute or persistent diarrhea did not emerge in several case–control studies [650–654], other studies have demonstrated an association with these disorders [655]. Other *Helicobacter* species have been suggested as causes of acute diarrhea [656]. *Helicobacter canadensis* [657] and *Helicobacter pullorum* [658] have been reported to cause an acute gastroenteritis resembling that caused by *C. jejuni* and *Campylobacter coli*, and *Helicobacter fennelliae* and *Helicobacter cinaedi* appear to cause gastroenteritis and invasive disease in immunocompromised and immunocompetent patients [659–661]. The recognition of these organisms as pathogens has been hampered by the fact that the routine clinical microbiological techniques developed to isolate *C. jejuni* and *C. coli* are not ideal for the growth of these *Helicobacter*.

Plesiomonas shigelloides

Plesiomonas shigelloides enteric infections are diagnosed even less commonly than those associated with *Aeromonas* species. *P. shigelloides* were associated with pathogenicity in the 1970s in southern Asia [662]. Cases have been identified in North America, usually associated with travel or with the consumption of shellfish [663]. *P. shigelloides* are detected using blood agar plates. They are susceptible to a wide range of antibiotics [664], including fluoroquinolones and third-generation cephalosporins. Many isolates are resistant to trimethoprim–sulfamethoxazole. Prevention includes care in handling and preparing seafood.

Staphylococcal food poisoning

Staphylococcus aureus produces a family of superantigens, including enterotoxins A, B, C, D, E, G, H, I, K, L, and M, exfoliative toxins A and B, and toxic shock syndrome toxin. These molecules activate T lymphocytes, although not by typical antigen presentation, and cause exuberant production of cytokines. Toxemia from any of these proteins can be associated with diarrhea, usually as part of a systemic constellation of symptoms [665]. Pure staphylococcal food poisoning usually begins abruptly, and vomiting is more prominent than diarrhea. The toxin is heat stable and therefore foods that have been properly heated can still be vehicles for disease. The incubation period is short, usually within several hours of ingestion. Treatment is supportive.

Additional bacterial causes of gastroenteritis and diarrhea

Myriad extraintestinal infections can result in prominent gastrointestinal infection [666] (Table 48.5). Streptococcal enterotoxins, which are closely related to staphylococcal enterotoxins, can cause similar toxemic symptoms and be associated with vomiting and diarrhea [667]. *Legionella* infections are also often accompanied by diarrhea [668,669].

Diarrheal syndromes caused by yet to be discovered bacterial agents

Several syndromes are believed to be of bacterial origin, even though, despite thorough investigations, monomicrobial etiologies have not emerged.

*Antibiotic-associated, non-*Clostridium difficile *diarrhea*

Mild diarrhea during antibiotic therapy is common and only a minority (approximately 20%) [243] of these cases is caused by *C. difficile*. In general, antibiotics interfere with the digestion of carbohydrates by eliminating colonic bacteria that metabolize this energy source. Decreased carbohydrate metabolism can then lead to osmotic diarrhea, diminished

production of short-chain fatty acids, and disruption of water and electrolyte absorption [236]. Bile acid metabolism may also be diminished causing intestinal ion secretion. In these cases, evidence of *C. difficile* infection is absent and the colonic mucosa appears normal or mildly hyperemic. Discontinuation of antibiotics resolves symptoms. In some cases of antibiotic-associated diarrhea, *S. aureus* is recovered in high proportions in the stool and has been proposed to play an etiological role [689,690]. Other enteric bacteria that have been proposed to play roles in non-*C. difficile* antibiotic-associated diarrhea include *Klebsiella oxytoca*, enterotoxin-producing *C. perfringens*, and *Candida* [691].

Brainerd diarrhea

A cluster of nonbloody, chronic (lasting over a year in many patients) diarrhea epidemiologically associated with the consumption of raw milk was identified in Brainerd, Minnesota in 1983 [692]. Its etiology remains undetermined despite years of investigation and the appearance of similar clusters of cases [693].

Bacterial overgrowth

Data suggest that chronic abdominal pain syndromes, and especially those with diarrhea, could be related to intestinal bacterial overgrowth and be responsive to antibiotics [694,695]. In these situations, bacterial communities, and not specific pathogens, are likely to be the causative agents. Interestingly, rifaximin had a beneficial effect on irritable bowel syndrome in a randomized controlled trial [696].

Viral agents of gastroenteritis

Viral infections of the intestinal epithelium are the most common causes of acute diarrhea and gastroenteritis. Four viruses are well-established causes of acute gastroenteritis: rotavirus, calicivirus, astrovirus, and enteric adenoviruses. All four are nonenveloped icosahedral viruses, affording them great environmental stability and subsequent enhanced ability to spread in human communities. All except adenovirus are RNA viruses that lack proofreading ability in their genomic replication. This feature facilitates very high rates of mutation and enables populations of these viruses to respond quickly to selection pressures such as immune responses. Our knowledge of the assembly and structure of viruses that cause gastroenteritis in humans greatly exceeds our understanding of their pathogenesis in the infected host.

Viruses were long suspected to cause gastroenteritis but efforts to demonstrate specific agents were not successful until the 1970s when the Norwalk agent (a calicivirus) was first observed by electron microscopy in negatively stained stool suspensions [697]. Since then, agents of viral gastroenteritis have been extensively characterized and effective vaccines for rotavirus are on the threshold of widespread use.

In the vast majority of situations, viruses cause self-limited illnesses and require only supportive therapy. However, when viral gastrointestinal infections occur in children in resource-poor environments, most particularly in circumstances in which oral rehydration is not used and referral centers are not accessible, these common infections can be lethal.

Rotavirus

History

In 1973, Bishop and colleagues [698] identified round viral particles termed "rotavirus" by electron microscopy in duodenal biopsies of infants with gastroenteritis in Melbourne. Soon after, additional groups demonstrated agents with similar morphological and serological properties in other centers [699–702]. Multiple subsequent studies have demonstrated the unequivocal predominance of rotavirus as a cause of infantile and childhood diarrhea worldwide.

Rotaviruses are double-stranded RNA viruses that belong to the Reovirus family. They are encapsidated in a characteristic round triple-shelled virion [703]. There are four major groups (A–D), defined by their middle capsid layer. The vast majority of human disease is caused by group A rotaviruses, but groups B and C can cause outbreaks and sporadic human cases. Within group A rotaviruses, serotypes are determined by the outer capsid antigens VP7 (the variants of which assign G type) and VP4 (the variants of which assign P type). G types 1–4 and 9 are the most common serotypes [704], although geographic differences exist. G types 1–4 predominate in North America, Europe, and Australia, but are less common in South America, Asia, and Africa [705,706]. The G type forms the basis for serotyping and serves as the foundation for many seroepidemiological studies.

Epidemiology and prevention

Rotavirus is a major human problem. Rotavirus is one of the most important gastrointestinal causes of morbidity and mortality in all countries, and the most common cause of severe dehydrating pediatric diarrhea worldwide. It accounts for approximately 600 000 deaths each year, mainly in children in developing countries, and numerous hospitalizations throughout the world [707]. As such, rotavirus is responsible for the loss of a massive number of years of life. Although oral rehydration plays an important role in individual cases and in public health programs, there is considerable residual mortality, especially in resource-poor areas of sub-Saharan Africa and south Asia (Fig. 48.13) [707].

It has been estimated that one in 65 children born in the United States will be hospitalized for rotavirus disease in the first 5 years of life [708], and rotavirus disease is also a considerable burden on the health system in Europe [709]. Virtually all children experience rotavirus infection by the age of 5 years; the most severe illnesses occur in children under 2 years of age. Subsequent infections are milder than initial infections [710], but severe illnesses in the elderly have been reported [711,712]. Asymptomatic infection

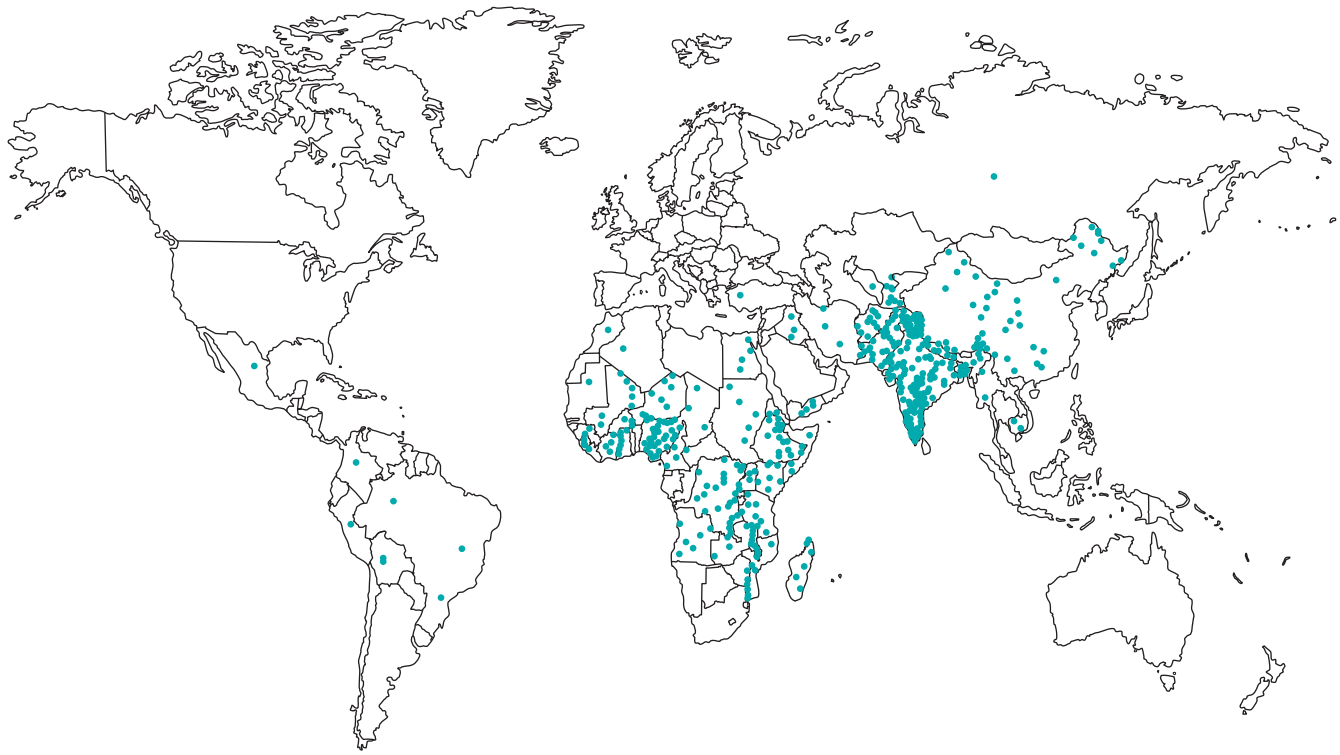

Figure 48.13 Estimated global distribution of rotavirus-related deaths. Each dot represents 1000 rotavirus-related deaths.

is quite common in neonates, older children, and adults. Rotavirus spreads by the fecal–oral route and is quite contagious. Rotaviruses can resist desiccation and persist on inanimate objects; outbreaks can have characteristics of airborne spread and can occur quite easily in hospitals [713]. In temperate climates, rotavirus infections have strong peaks in the winter [708].

An effective multivalent live attenuated rotavirus vaccine, Rotashield, was used in the United States in 1998 and 1999, but an association with intussusceptions forced its withdrawal [714]. Two new oral attenuated vaccines that appear to be free of such concerns after extensive safety trials have considerable promise as interventions to greatly reduce the morbidity and mortality caused by rotavirus. One is a monovalent attenuated human strain [715] and the other is a pentavalent bovine recombinant preparation [716]; both have received FDA approval. Because of the age group being immunized there will still be cases of intussusception temporally, but not causally, related to rotavirus vaccination, and it will be important to maintain this perspective in analyzing such associations [717]. Although there are considerable challenges to universal vaccination as a strategy to prevent rotavirus infections, for the first time we now have an opportunity to dramatically reduce the burden imposed by this worldwide gastrointestinal infection [710]. Hygienic precautions should be implemented to the extent possible to prevent nosocomial spread.

Pathogenesis

Rotaviruses replicate selectively in absorptive villous epithelial cells of the small intestine, sparing the crypts and colonic epithelium. Infected villi atrophy and shorten. There is a mononuclear cell infiltrate in the lamina propria [718–720]. *In vitro*, rotavirus inhibits eukaryotic cell RNA, DNA, and protein synthesis [721–723]. Resulting cell injury and death diminish the absorptive and hydrolytic capacities of the small bowel, leaving secretory crypt function intact. Thus, rotavirus disease has been considered to be a combination of secretory and osmotic diarrhea.

Rotaviruses possess double-stranded genomes with 11 open reading frames, with each encoding at least one protein [724] (Fig. 48.14). Antibodies to VP4 and VP7 neutralize infection [713]. This immunological protection, combined with the observation that second and subsequent infections beyond the neonatal period are milder than the initial infection, justify vaccination as a disease control strategy. The ability of rotavirus to cause disease is possibly attributable to other mechanisms in addition to direct cellular morphological injury. Rotavirus nonstructural protein 4 (NSP4) may be important in pathogenesis [725]. This 20-kDa protein undergoes glycosylation and serves several roles in viral morphogenesis [724], including facilitation of viral budding of the double-layered particles into the lumen of the endoplasmic reticulum. Most intriguingly from a pathogenesis perspective, NSP4 may function as a viral enterotoxin that promotes

chloride secretion and raises intracellular ionized calcium concentrations [726,727]. Other possible mechanisms of host injury include transcellular flux caused by damaged epithelial junctions [728], effects on the enteric nervous system [729], impaired transport of sucrase–isomaltase to the enterocyte apical surface [730], and villous ischemia [731]. These proposed mechanisms are not mutually exclusive and it is possible that no single process is responsible for human enteric illnesses caused by rotaviruses.

Clinical manifestations

In a typically severe primary infection, symptoms begin 2–7 days after exposure. In hospitalized children infected with rotavirus in Washington, DC [732], vomiting occurred in almost all, and fever in approximately half. Associated symptoms include dehydration (83%) and irritability (47%). Respiratory symptoms and signs are also common, with pharyngeal erythema, rhinitis, signs of otitis media, or palpable lymph nodes occurring in about one-fourth of all patients. Fever and vomiting, if they occur, are followed typically by profuse watery diarrhea that contains no blood or leukocytes. Vomiting abates after 1 or 2 days, while diarrhea persists for 4–7 days. Mild elevations of transaminases without cholestasis are common and of no clinical significance [733]. Infants beyond the neonatal period are the most severely affected by rotavirus diarrhea [734].

Diagnosis

Group A rotavirus infection is easily detected by EIAs of stool. Non-group A infections can be identified by electron microscopy or RNA electrophoresis of stool samples [735].

Treatment

The mainstay of treatment is managing dehydration. A reduced sodium (75 mEq/L) oral rehydration solution might be somewhat more effective in noncholera diarrhea than the standard WHO formulation (containing 90 mEq of sodium/L) [736]. Oral rehydration is adequate in most cases. Encouraging adequate nutritional intake can shorten the course of rotavirus disease and is especially important in children with baseline compromised nutrition. Clear liquid and bland carbohydrate diets do not improve outcomes despite their long tradition in both alternative and mainstream medicine. Food should not be withheld because of concern about the effect of rotavirus infection on gut function in the presence of enteral feeds. Enteric administration of immunoglobulin has been reported to reduce the duration of severe disease [737,738]. Probiotics (especially *Lactobacillus* GG) have been shown to reduce the duration of mild [739] but not severe acute disease [740]. Antimotility and antidiarrheal agents, opiates, and atropine-containing compounds are contraindicated in rotavirus and all other acute diarrheal illnesses in children [741]. In rare cases of prolonged or severe rotavirus infection, orally administered passive immune therapy has been used [742].

Human caliciviruses (noroviruses and sapoviruses)

History

These viruses were first observed in stools during a school outbreak of vomiting in Norwalk, Ohio [743] and were subsequently shown by volunteer inoculations to be pathogenic [744]. Initially, different strains were named for the sites of outbreaks, such as Norwalk, Snow Mountain, Hawaii, etc. Genomic sequencing has lead to the creation of two genera: norovirus and sapovirus. Both genera consist of small (28 nm) single-stranded RNA viruses with genomic and physical structures that are somewhat similar to picornaviruses (Fig. 48.15). The genome is approximately 7.7 kilobases in length and is a positive-sense single-stranded RNA.

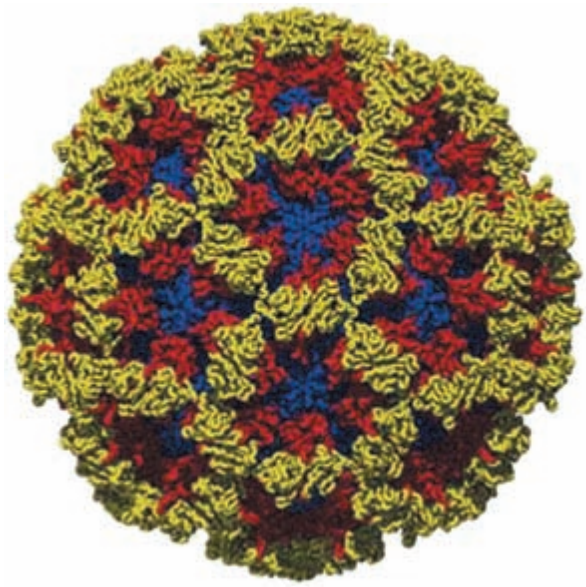

Figure 48.15 Norwalk agent particle. X-ray structure of recombinant Norwalk virus capsid showing the S (blue), P1 (red), and P2 (yellow) domains. From Estes et al. [745], with permission from Lippincott Williams & Wilkins.

Epidemiology and prevention

Noroviruses are best known for causing fulminant outbreaks of gastroenteritis in confined settings such as schools, camps, and cruise ships. All ages are affected and common-source food items or water sources can often be identified. The CDC has shown that more than 95% of such outbreaks are caused by caliciviruses [746]. Some data suggest that norovirus is an important agent of endemic pediatric gastroenteritis worldwide, accounting for up to 8% of cases [747], although other studies have shown lower rates of infection [403]. There is an increased incidence of norovirus pediatric gastroenteritis during winter. Group 2 noroviruses (a serological grouping) predominate in epidemics [748]. Norovirus outbreaks tend to affect more people than outbreaks caused by bacterial agents [749]. Syndromic recognition using the criteria of Kaplan et al. [750] is reasonable for identifying clusters, even without viral testing [751].

Because of the limited duration of natural immunity after infection, an effective vaccine would probably require frequent booster doses. A transgenic potato that expresses Norwalk capsid antigen elicits an immune response after oral administration to human volunteers [752]. In the interim, disease control measures largely consist of ensuring safe water supplies and good personal hygiene in closed populations.

Pathogenesis

Like rotavirus, norovirus appears to cause infection by replicating within small intestinal epithelium. Human volunteer studies have shown that, following challenge with norovirus, there is small bowel villous blunting, crypt hypertrophy, and mild inflammatory infiltrates [744]. Attempts to gain detailed knowledge of norovirus pathophysiology have been hampered by the lack of animal models demonstrating gastrointestinal pathogenicity and by difficulties growing norovirus in tissue culture, although success in culturing a murine norovirus has been reported [753]. Studies suggest that blood group determinants confer susceptibility to specific caliciviruses [754]. These observations explain previous enigmatic observations that adult volunteers who have no antibody response to some of these agents are not susceptible to experimental infection whereas those who do have measurable antibody often are. Several mature norovirus proteins have been identified [755]. Major capsid protein VP1 is implicated in ABO blood group susceptibility, and several nonstructural proteins are postulated to play roles in viral assembly and physiology.

Clinical manifestations

In older children and adults, symptomatic disease typically begins with the rapid onset of vomiting after 24–48 h of incubation. High fever is unusual but myalgia and headache are common. Diarrhea is often not prominent if it is even present. Symptoms typically resolve within 1–2 days. Attack rates often approach 50% of exposed populations. In young infants, diarrhea is more common and the illness resembles rotavirus infection.

Diagnosis

Because of the large number of antigenically diverse strains of human calicivirus, a simple stool EIA is not yet available in the United States. In a research setting, electron microscopy or PCR testing of stools can be performed. Most outbreaks can be identified syndromically [751].

Treatment

Specific therapy does not exist. Treatment consists of measures to ensure adequate hydration.

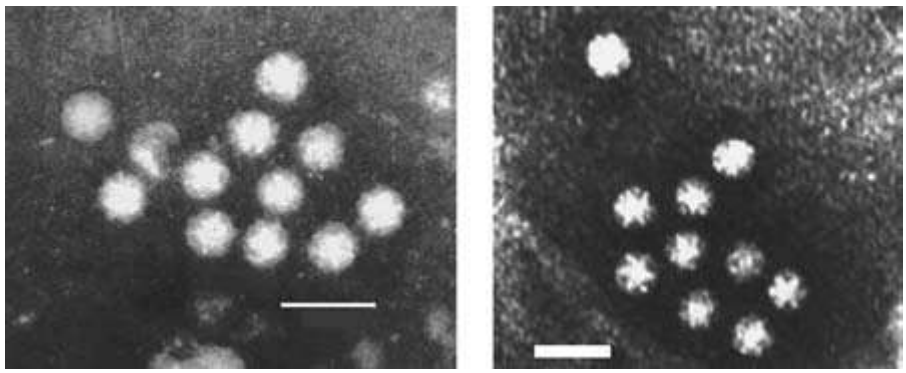
Enteric adenoviruses

History

Adenoviruses were suggested as a cause of acute diarrhea in the 1960s [756], but most fecal adenoviruses are actually respiratory pathogens. However, two serotypes (40 and 41) proposed to be causes of diarrhea in 1983, based on analyses of stools from children in the Netherlands and German [757], remain consistently associated with human gastroenteritis, although there is considerable interpopulation variability in the frequency of enteric infections caused by these serotypes [758]. Adenoviruses are 80-nm nonenveloped double-stranded DNA viruses.

Epidemiology and prevention

Enteric adenoviruses have a worldwide distribution and cause disease mainly in children under 2 years of age.



(a) (b)

The atypical "star" morphology represents intact virions. **(b)** Astrovirus particles from a fecal sample visualized by negative-stained electron microscopy (bar = 50 nm). The star morphology actually represents partial degradation of virions. Courtesy of Dr B.V. Prasad.

Adenovirus gastroenteritis occurs throughout the year without the seasonality noted in other enteric viral infections. Adenoviruses account for 3%–5% of pediatric gastroenteritis cases [19,403]. Adenoviruses are presumably acquired via the fecal–oral route. Although very large numbers of adenovirus particles are shed by infected children, large outbreaks are uncommon.

No vaccine is available. Hygienic measures probably suppress nosocomial spread.

Pathogenesis

Most adenoviruses replicate in the gastrointestinal tract, but symptomatic disease is largely restricted to serotypes 40 and 41. Disease manifestations (i.e., diarrhea) are presumably related to infection of villous epithelium; however, most research has focused on the pathogenesis of respiratory adenovirus infections and not gastrointestinal adenovirus illnesses.

Clinical manifestations

The main distinguishing feature of adenovirus gastroenteritis is its longer duration (often 2 weeks) compared with diarrhea caused by other agents [759].

Diagnosis

A commercial EIA is available for adenovirus serotypes 40 and 41.

Treatment

Adenovirus infections are treated with supportive measures. Ribavirin [760] and cidofovir [761,762] have been used in immunocompromised patients with severe adenoviral enteric illnesses, with improvement in diarrhea.

Astrovirus

History

Astroviruses were proposed as causes of human diarrhea in 1975, when they were identified by electron microscopy in the stools of children with gastroenteritis [763,764]. Astroviruses are small, 28- to 34-nm RNA viruses that infect a variety of mammalian and avian species [765]. They are named for their appearance on negatively stained electron microscopy preparations, appearing as five- or six-point stars (Fig. 48.16). They are a common cause of mild to moderate gastroenteritis in young children. There are eight human serotypes with serotype 1 being the most common cause of human gastroenteritis.

Epidemiology and prevention

Astrovirus accounts for 7%–15% of cases of infantile diarrhea [19,766–769]. Infants under 1 year of age are most likely to be symptomatic. The institutionalized elderly can be affected by astrovirus [770,771], as can other ambulatory adults [772]. Astrovirus is probably more likely to cause disease in immunocompromised hosts. Astrovirus serotype 1 infections are most common [773,774], although outbreaks involving less common serotypes have been reported in military personnel and nursing home residents [712,775,776]. The seasonal pattern resembles rotavirus (winter or rainy season predominance). Astroviruses are transmitted via the fecal–oral route [765].

No vaccine is available. Enteric precautions might contain or prevent institutional outbreaks.

Pathogenesis

Similar to rotavirus, astrovirus infects the small intestinal villous epithelium [777], but detailed studies of the gut in human infections have not been performed. Lambs challenged with an ovine astrovirus sustained viral infection of apical villous cells, and underwent short-lived villous atrophy and crypt hyperplasia. The histological changes occurred within a day in some animals, and resolved within 5 days [778]. Astroviruses enter cultured epithelial cells via endocytic pathways [779].

Clinical manifestations

Incubation ranges from 1 to 4 days. Astrovirus infections resemble rotavirus gastroenteritis but are usually considered to be milder. However, severe illness can result [780]. Astrovirus infections are frequently accompanied by vomiting and abdominal pain [765,781,782].

Diagnosis

Astroviruses are detected in the stool by electron microscopy, EIA, or PCR. These tests are not available for routine clinical use in the United States, but EIAs are available in Europe.

Treatment

Ensuring adequate hydration is the mainstay of therapy. Specific treatments do not exist, although immunoglobulin has been used to treat severely ill immunocompromised hosts infected with astroviruses [783,784].

Other viral agents

A number of systemic viral infections such as HIV, cytomegalovirus (CMV), Epstein–Barr virus (EBV), and measles can present with diarrhea [785–788]. Other viruses such as picobirnavirus [789], torovirus [790], and Aichi virus [791] are likely, but not proven, agents of human gastroenteritis. SARS coronavirus, the causative agent of severe acute respiratory syndrome, can have diarrhea as an initial manifestation [792,793].

Many other enteroviruses, reoviruses, and nonenteric adenoviruses are found frequently in stool but are not associated with any gastrointestinal disease. Available data do not support the use of viral cultures to detect diarrhea etiology in any clinical setting.

Marine intoxications with gastrointestinal effects

A variety of marine foods cause gastrointestinal symptoms [794], and affected patients might present to gastroenterologists. These illnesses are the consequences of ingesting preformed neurotoxins and not the result of consuming pathogens that then replicate in the human host. In the absence of readily available tests these disorders are likely underdiagnosed, and syndromic recognition is critical [795].

Ciguatera fish poisoning is the most common marine poisoning. Ciguatera poisoning had been largely confined to South Pacific and Caribbean fish species [796], although with globalization of the food supply this intoxication can now be acquired worldwide [794]. Finfish from the tropics and subtropics are the vehicles of transmission of ciguatoxins to humans. This toxin originates as a precursor toxin (gambiertoxins) in the aquatic dinoflagellate *Gambierdiscus toxicus*. These dinoflagellates (and their gambiertoxins) are consumed by small herbivorous fish, which then convert the gambiertoxins to ciguatoxins before they are subsequently consumed by larger finfish. When these heat-stable sodium channel poisons are consumed by humans, their net effect is to enable spontaneous firing of tetrodotoxin-sensitive channels, resulting in a variety of neurological (especially myalgias, paresthesias, and cold allodynia) and gastrointestinal (diarrhea, abdominal pain, nausea, and vomiting) effects [794]. Ciguatera poisoning is diagnosed on clinical grounds. Chronic sequelae consisting of fatigue, myalgia, headache, pruritus, depression, and hypersensitization to subsequent exposures have been reported [797,798]. Management of the acute episode is supportive, and early reports of the efficacy of mannitol have not been confirmed in randomized controlled trials [794].

Paralytic shellfish poisoning occurs worldwide after consuming shellfish, generally bivalve species such as mussels, oysters, and clams, that contain saxitoxins synthesized by dinoflagellate algae. These algae are the cause of "red tide" waters, although shellfish can assimilate this toxin in waters that are not noticeably discolored. Bivalve species consume the poison-producing algae and concentrate saxitoxins by filtration. Saxitoxins block tetrodotoxin-sensitive sodium channels and inhibit nerve conduction. Symptoms occur sequentially and consist of dizziness, paresthesias, weakness, ataxia, nausea, and vomiting. Hypersalivation and diaphoresis can also be present. Consciousness is not impaired. Symptoms begin within 3 h of ingestion. Treatment is supportive [794].

Neurotoxic shellfish poisoning resembles ciguatera poisoning. It produces a neuroexcitatory picture and not a paralytic syndrome. It occurs in selected regions (west coast of Florida, North Carolina, and New Zealand) and is the consequence of ingesting brevetoxins concentrated in filter-feeding shellfish. Brevetoxins, which originate in the dinoflagellate *Gymnodinium breve*, enhance sodium entry into cells, as do ciguatoxins [799]. The gastrointestinal effects are nausea, vomiting, and diarrhea, and the neurological effects resemble those of ciguatera poisoning. The clinical picture is usually fairly mild and treatment is supportive [794].

Amnesic (encephalopathic) shellfish poisoning is caused by the consumption of shellfish containing domoic acid. Domoic acid is produced by *Nitzschia* algae. It is an excitatory toxin that causes symptoms about 5 h after ingestion. Its most distinctive effect is its ability to induce amnesia, among other neurological (headache, weakness, confusion, aberrant eye movements, seizures, myoclonus, loss of consciousness) and nonneurological (shock, arrhythmias, increased respiratory secretions) symptoms. Gastrointestinal symptoms consist of vomiting, spasmodic abdominal pain, and diarrhea [794,800,801]. Cases can be fatal. Diagnosis is by clinical picture, with amnesia being a prominent clue, although incriminated vehicles, if available, can be tested for the presence of domoic acid. Treatment is supportive [794].

Tetrodotoxin poisoning results from the ingestion of fish, usually the Asian puffer fish, and occasionally other marine life [794]. Fillets of fish (*fugu*) containing preformed tetrodotoxin cause a gradation of intoxications, ranging from mild parethesias and perioral numbness ensuing as early as 5 min following ingestion (grade 1), to paralysis, cardiopulmonary collapse, and coma occurring between 1 and 24 h after ingestion (grade 4) [794,802,803]. The gastrointestinal symptoms of tetrodotoxin poisoning are mild and consist of nausea and vomiting [794]. Tetrodotoxin blocks sodium channels at the nodes of Ranvier and inhibits conduction. Diagnosis is by

high performance liquid chromotography (HPLC) analysis of the urine of patients or of the uneaten suspected vehicle. Treatment is supportive. Because of the serious and sudden consequences of ingesting tetrodotoxin, prevention of these illness through the education of food preparers is critically important and has been quite effective in Japan [794,804].

Diarrhetic shellfish poisoning is acquired from consuming shellfish that have sequestered dinoflagellate-synthesized okadaic acid and its dinophysitoxin analogues [805]. Mussels are the most frequently implicated vehicle, but other mollusks can transmit these toxins to consumers. This disorder occurs worldwide. Okadaic acid and its analogues are lipid soluble and survive heating; they inhibit serine and threonine protein phosphatases, especially the PP2A class of phosphatases [806]. Diarrhea begins within a day of ingestion and sometimes as soon as 30 min after ingestion [807]. There are no neurological accompaniments, unlike other toxic shellfish poisoning.

An additional rare marine toxic cause of nausea, vomiting, and diarrhea is clupeotoxism [794,803], acquired from consumption of contaminated plankton-eating fish such as herring and sardines. There is an accompanying sharp metallic taste. The mortality rate can be high. Treatment is supportive [794].

Scombroid fish poisoning (scombrotoxism, also referred to as "scombroid") is caused by systemic histamine toxicity following the consumption of dark meat of bony fish (e.g., tuna, mackerel) [808]. Bacterial decomposition of the flesh of these fish results in an increase in histidine decarboxylase activity and excessive production of histamine in the fish meat. Symptoms can begin within an hour of ingestion and resemble an allergic reaction (urticaria, flushing), but scombroid is really a histamine intoxication and not a true allergy. Diarrhea can be severe but all symptoms are short-lived. Scombroid fish poisoning is treated with antihistamines [809].

Anorectal infections

The populations at greatest risk for acquiring anorectal infections are men who have sex with men, and heterosexual women who engage in anorectal intercourse. The most commonly occurring infections in women are *Chlamydia trachomatis*, *N. gonorrhoea* and *Treponema pallidum*. Infections with *E. histolytica*, herpes simplex virus (HSV), and human papillomavirus (HPV) are endemic in men who have sex with men. Infection with multiple pathogens occurs in 22% of this population who are symptomatic [810] and is associated with high-risk behaviors.

Bacterial infections of the anorectum

Chlamydia trachomatis

Chlamydia trachomatis, a gram-negative, obligate intracellular bacterium, is the leading bacterial cause of sexually transmitted disease (STD) in the United States. *C. trachomatis* is represented by three biovars, two of which cause human disease: trachoma and lymphogranuloma venereum (LGV). The replication of trachoma is restricted to columnar epithelial cells, whereas LGV can also proliferate in macrophages, explaining the differences in symptomatology.

The results of infection by *C. trachomatis* range from asymptomatic proctitis, caused by non-LGV biovars, to severe granulomatous proctitis, usually caused by LGV biovars. Sigmoidoscopic examination of individuals infected with non-LGV biovars can demonstrate normal mucosa or erythema, friability, and erosions. Histological examination of these tissues shows neutrophilic infiltration of the lamina propria [811]. In contrast, LGV biovars induce severe proctitis or proctocolitis manifested as pruritus, purulent rectal discharge, hematochezia, and diarrhea or constipation. Physical examination might demonstrate lymphadenopathy and lower abdominal tenderness. The sigmoidoscopic findings are more impressive and demonstrate friable or bloody mucosa with multiple ulcerations [811]. The infiltrate has variable content, with eosinophils, mononuclear cells, and plasma cells in addition to neutrophils. Crypt abscesses and granulomas with giant cells can also be present and might lead to a mistaken diagnosis of Crohn's disease. Anorectal LGV biovars can also cause strictures, fistula formation, and perirectal abscesses if left untreated, further confusing the diagnosis with Crohn's disease.

Chlamydia infection is diagnosed by culturing samples obtained by rectal swab in McCoy cells. Calcium alginate swabs are less inhibitory to *Chlamydia* than wooden swabs. Sigmoidoscopic biopsies can also be sent for culture. Infected cells are identified by immunofluorescent staining, using a monoclonal antibody against *Chlamydia* antigens, which has a sensitivity and specificity of 90% and 100% respectively [812]. Uncomplicated chlamydial infection of the rectum can be treated with either a single oral dose of 1 g of azithromycin or 100 mg of doxycycline twice a day for 7 days [813]. Alternate therapies include erythromycin, ofloxacin, or levofloxacin. Surgical resection might be required to alleviate strictures.

Neisseria gonorrhoeae

Neisseria gonorrhoeae is a gram-negative intracellular diplococcus that typically infects the epithelial lining of the endocervix and urethra but which can also infect other sites including the rectum. A robust inflammatory response including submucosal abscesses occurs following attachment, internalization, and subepithelial delivery of the organism. Up to half of homosexual men assessed in STD clinics are infected with this organism, with 40% manifesting only rectal involvement. Of women with gonococcal proctitis, only 20% had rectal infection alone [814].

Most gonorrheal anorectal infections are asymptomatic; when present, symptoms include purulent, creamy, and sometimes bloody discharge with pruritus ani, tenesmus, and even constipation. Symptoms typically appear 5–7 days

after exposure. Rare complications include stricture formation, abscesses, and fistulae. The sigmoidoscopic findings are nonspecific and include friable, erythematous mucosa with superficial erosions most prominent at the anorectal junction. Culture of material obtained via rectal swab plated on selective Thayer-Martin media is the recommended diagnostic test. Gram stain of this same material is also suggested but is only positive in about half of those infected and should not replace culture. Sigmoidoscopic biopsies can also be sent for microbiology.

Anorectal gonorrhea is best treated by a single injection of intramuscular ceftriaxone, which cures more than 98% of such infections [813]. Cefixime (400 mg orally in a single dose) is reported to cure 97.4% of uncomplicated cases of anorectal infection but does not provide the same levels of bactericidal therapy as injected ceftriaxone. Fluoroquinolone-resistant *N. gonorrhoeae* have become more prevalent in Asia, the Pacific islands, and California, and fluoroquinolones are no longer universally effective for gonococcal infections in the United States [813]. The isolation of these resistant strains from men having sex with men has also increased and therefore the CDC does not recommend fluoroquinolones as the treatment of choice in this group [815]. Because of a high coinfection rate with *Chlamydia* species, it is recommended that all *N. gonorrhoeae*-infected individuals also receive 100 mg of doxycycline twice a day for 7 days [813].

Treponema pallidum

Treponema pallidum is a spirochete capable of infecting damaged skin or mucosa. Anorectal syphilis is primarily diagnosed in men who have sex with men. Primary anorectal syphilis presents as a chancre of the squamous epithelial lining of the anal canal or in the rectum. These lesions, which develop 2–6 weeks postexposure, appear as 1- to 2-cm indurated lesions with raised borders. "Mirror" or "kissing" lesions can be present [816]. Anorectal chancres are often asymptomatic unless superinfected.

The anorectal presentation of secondary anorectal syphilis is condyloma lata. This stage usually develops 6 weeks to 6 months from the time of the initial infection. Condyloma lata are smooth, wart-like lesions near or in the rectum. Colitis associated with secondary syphilis can also occur in the distal 15–20 cm of the colon. This lesion spontaneously resolves after 3–4 weeks. Intestinal lesions are rarely associated with tertiary syphilis but rectal gummas have been reported.

Anorectal syphilitic lesions show a chronic inflammatory infiltrate of lymphocytes, histiocytes, and plasma cells [817]. Dark-field microscopic examination demonstrates spirochetal organisms, but nonpathogenic spirochetes can also be present in the rectum [818].

Anorectal syphilis should be treated with a single intramuscular injection of 2.4 million units of benzathine penicillin. If the patient is allergic to penicillin, 100 mg of doxycycline twice a day or 500 mg of tetracycline four times a day can be given orally for 2–4 weeks for early and latent syphilis respectively. Proof of eradication should be sought 3 and 6 months posttreatment by serological testing and clinical response. Persistence or recurrence of symptoms or a sustained fourfold increase in nontreponemal test titer compared with the baseline or maximum titer likely indicates treatment failure or reinfection, and retreatment is indicated [813].

Viral infections of the anorectum

Herpes simplex virus

Herpes simplex virus 2 accounts for 90% of cases of anorectal herpes. The virus, for which humans are the sole reservoir, is transmitted by direct contact with an infected individual who is actively shedding viral particles. Symptoms of the primary infection begin 4–12 days after contact and spontaneously resolve after 3 weeks, although they can recur. Symptoms associated with subsequent bouts range from none to severe, painful ulcerative proctitis. Other symptoms include tenesmus, pruritus ani, constipation, inguinal adenopathy, sacral and posterior thigh paresthesias, and urinary difficulty. The symptomatic triad of constipation, urinary retention, and anorectal pain strongly suggests anorectal HSV infection.

Anoscopy typically demonstrates vesicles, pustules, or shallow ulcers depending on the stage of the lesions. Biopsies of these lesions show acute and chronic inflammation, superficial ulcerations, and microabscesses [819]. Perirectal lesions are relatively uncommon, occurring in 19% and 27% of infected women and men respectively [820]. Viral cultures should be performed to confirm the diagnosis. PCR can also be used to detect HSV DNA in clinical samples [821]. Depending on the severity of the symptoms one can choose to treat mildly symptomatic individuals with only stool softeners, sitz baths, and analgesics or with acyclovir (aciclovir; 400 mg orally three times a day for 7–10 days). This approach diminishes viral shedding and the duration of symptoms [813]. Other recommended antivirals include famciclovir or valacyclovir (valaciclovir) [813].

Human papillomavirus

Human papillomavirus enters basal germinal epithelial cells and replicates in the nucleus resulting in increased cell proliferation. This response accounts for the skin and mucosal lesions that appear as irregular, verrucous lesions called anal warts or condyloma accuminata. These lesions must be distinguished from the condyloma lata in syphilis, which are more moist and smooth. Histological examination of condyloma accuminata shows irregular, thickened epithelium containing areas of koilocytotic cells with perinuclear cavitation and nuclear atypia. Some HPV strains cause neoplasias including cervical and anal cancer [822].

The virus is transmitted through anal intercourse or autoinoculation to the perianal area and anus. Latency ranges from 1–6 months. If condyloma accuminata are present in

the perianal area, anoscopy must be performed to determine whether lesions also exist inside the anal canal.

Individuals with anal warts can be asymptomatic or complain of rectal discharge, bleeding, or pruritus ani. Diagnosis is by clinical observation, and anorectal syphilis and squamous cell carcinoma should be excluded. This is accomplished by histological examination to distinguish between benign and malignant lesions, and dark-field microscopy to exclude syphilis. Although curative treatment is still lacking, lesions can be controlled with either cryotherapy [823–825] or a 20% solution of podophyllin in tincture of benzoin [824,825]. This solution is applied for up to 12 h and this can be repeated once or twice weekly until all lesions are gone. Its caustic nature precludes intraanal use. Trichloroacetic acid or bichloroacetic acid (80%–90%) can also be used to treat anal warts. Small amounts should be applied to warts and allowed to dry, at which time a white frosting develops; weekly treatment can be used if necessary [813]. Other therapeutic options include electrocautery, electrodessication, CO_2 laser, and surgical removal. Recurrence rates vary depending upon the treatment used; in one study, 29% of warts recurred postsurgery and 65% recurred following podophyllin treatment [826].

Multiple serotypes of HPV can cause anogenital warts, and therapeutic vaccination does not add to the benefit of standard treatments [827]. It is possible that vaccination to prevent HPV infection of the cervix might, over time, diminish the prevalence of anogenital warts, even though vaccine formulations have a limited range of antigens that might not cover all serotypes that cause noncervical disease [828].

Sexual transmission of intestinal pathogens

In addition to anorectal transmission of *Chlamydia*, *N. gonorrhoeae*, *T. pallidum*, HSV, and HPV, *E. histolytica*, *G. lamblia*, *Shigellae* and *Campylobacter* species can also be transmitted sexually. The signs and symptoms associated with infection by these pathogens in men who have sex with men are the same as those experienced by individuals who acquire these organisms by ingestion (i.e., they are not confined to the anorectum).

Summary

Enteric infections are major, and unacceptable, causes of human morbidity and mortality. Children and members of less-advantaged populations disproportionately suffer from these illnesses. Multiple different agents cause diarrhea and gastroenteritis, but diagnostic approaches to these infections are Balkanized, expensive, slow, and suboptimal. There are few immunoprophylactic control measures and treatments are either nonspecific or administered too late in the course to alter outcomes. Preventing and treating gastrointestinal infections worldwide should receive high priority by the specialty of gastroenterology.

Whipple disease

Whipple disease, first described by George Hoyt Whipple in 1907 [1], is a rare, chronic, systemic infection caused by *Tropheryma whippelei*, a member of the diverse family of actinomycetes usually found in soil. Before 1985, it was estimated that 2000 patients had been afflicted since 1907 [2], and even with the advent of sensitive and specific diagnostic tests, the disease remains rare. The clinical manifestations vary widely and include malabsorption and extraintestinal symptoms, such as seronegative arthritis, fever, or neurological symptoms, which may predominate or predate the gastrointestinal symptoms by years. The disease may involve any organ system, with the predominant pathological changes occurring in the gastrointestinal tract and central nervous system. In most cases, the small intestine is involved, resulting in malabsorption. Before the availability of antibiotic treatment, Whipple disease uniformly progressed to a fatal outcome. Important advances included the identification of periodic acid–Schiff (PAS)-positive macrophages in biopsy specimens of the small bowel [3,4] and other organs [5–7], the discovery that antibiotic therapy could induce remission of the disease [8–16], and the observation by electron microscopy of the characteristic rod-shaped bacillus in mucosa and nonintestinal tissues [12,17–23]. The seminal advance in this disease occurred in 1992 when the uncultured bacillus of Whipple disease, which was named *Tropheryma whippelii* [24], was identified using polymerase chain reaction (PCR) techniques. In 2000, the bacterium was first successfully cultured in vitro, permitting antibiotic susceptibility testing [25]. These findings have provided a basis for more specific diagnostic testing [26,27].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Epidemiology

Epidemiological data for this rare disease are limited to case series and individual reports. The disease is most common between the fourth and sixth decades of life, with a mean age at onset of 50 years [15,16,28,29], but it can occur at nearly any age. The male-to-female ratio is approximately 8:1 [15,28–31]. Whipple disease occurs predominantly in Caucasians and has rarely been described in persons of African descent and other ethnic groups. No clearly defined geographical or environmental risk factors have been established, except that the disease appears to be more common in farmers and individuals involved in farm-related trades [15], consistent with the causative agent being related to soil organisms. *T. whippelii* DNA has been found in samples of waste water [32], and in the gastric juice and saliva of persons without clinical evidence of Whipple disease [33–36], suggesting that *T. whippelii* may be an environmental or commensal organism that is ubiquitous. Humans are an unlikely reservoir as *T. whippelii* rarely is found in normal intestinal mucoa [37]. Direct person-to-person transmission has not been documented, although the disease has been reported in brothers on two occasions [38,39] and in a father–daughter pair [40]. These observations are also consistent with a common environmental exposure or shared genetic susceptibility. The effectiveness of disinfection methods for endoscopes has been questioned [41], although nosocomial transmission has not been documented.

Etiology and pathogenesis

Although an infectious etiology of Whipple disease has long been suspected, early reports of successful culture of the organism were not reproducible. A major advance was the use of PCR amplification of 16S ribosomal RNA (rRNA) [42] to identify and classify unculturable bacteria, which was successfully applied to tissues from patients with Whipple disease to identify unique bacterial sequences [24,43]. Phylogenetic analysis of the sequences suggested that the Whipple disease bacillus is a gram-positive bacterium closely related to the actinobacilli, and the bacterium was given the designation

T. whippelii. Actinobacilli are actinomycetes, a diverse group of bacteria, most of which are aerobic soil organisms. Detailed analysis has more precisely placed the organism in the phylogenetic position of the actinomycetes [44]. Subsequently, *T. whippelii* was identified by PCR in patients in peripheral blood mononuclear cells, peripheral blood, pleural effusion cells [45,46], and in the vitreous aspirate of a patient with uveitis whose intestinal biopsy specimens had appeared normal by light microscopy [47]. Simplified and rapid real-time PCR techniques have been shown to have similar sensitivity and specificity compared with earlier more complex PCR methods [48,49].

In 1997, the Whipple bacillus was isolated and grown in human macrophages treated with interleukin-4 (IL-4) [50], and subsequently subcultures were established in human fibroblast cell lines [25]. Several additional strains of *T. whippelii* have been cultured from human samples, including the cerebrospinal fluid (CSF) [51–54]. In 2001, the definitive name *Tropheryma whipplei* was accepted [55]. The complete genome sequence of *T. whipplei* is available [56], and this predicts a condensed genome with a lack of key biosynthetic pathways and a reduced capacity for energy metabolism. In addition, both known and novel mechanisms for elaboration and variation of surface structures were found, suggesting that immune evasion and host interaction play an important role in the persistence of infection. Phylogenetic analysis of non-rRNA genes of *T. whipplei* confirmed its placement within the class Actinobacter [57]. With the availability of the *T. whipplei* genome, PCR targeting of repeated sequences enhances the sensitivity of organism detection [58].

Because the distribution of *T. whipplei* in the environment is unknown, it is uncertain to what extent the disease may be caused by exposure to an unusual pathogen. However, the finding of *T. whipplei* DNA in the gastric juice and saliva [33–36] of people without Whipple disease and the striking clinical features of the disease, with the persistence of intracellular bacteria in macrophages, strongly suggest that a defective host immune response may play a central role in pathogenesis. Dobbins [59] reported that the frequency of HLA-B27 was higher (28%) than would be expected in the ethnic groups affected by Whipple disease, which is of interest because HLA-B27-associated spondyloarthropathies may be caused by abnormal interactions of the host with enteric bacterial flora. However, the incidence of spondyloarthritis does not appear to be increased in patients with Whipple disease. Furthermore, one small study was unable to replicate the increased frequency of HLA-B27 [60].

Numerous studies strongly suggest that host defense defects are the basis for Whipple disease, although no single defect has definitively been shown to be the primary, rather than a secondary abnormality. Patients generally exhibit lymphopenia, diminished skin test responses, and decreased mitogen-induced lymphocyte responses in vitro, and these changes may persist after treatment [61]. The abnormality of cellular skin test responses was confirmed and extended [62]. In a study of 20 patients with Whipple disease, none had skin test responses to streptococcal antigens, whether they were untreated or in remission. Because it is known that streptococcal antigens may cross-react with bacterial antigens of actinomycetes, the authors suggested that patients with Whipple disease may have selective defects in their ability to respond to certain types of bacterial antigens. It has been shown that the expression of CD11b, a complement receptor on circulating lymphoid cells involved in bacterial phagocytosis [63], is decreased in patients with Whipple disease, suggesting that there may be a molecular basis for defective macrophage function in this disease. Subsequently, in vitro studies of stimulated monocytes from patients with Whipple disease demonstrated an impaired type 1 T-helper cell (Th1) response with decreased IL-12 production leading to reduced T-cell production of interferon-γ (IFN-γ) [64–66]. In addition, decreased concentrations of IL-12p40 and tumor necrosis factor-α (TNF-α) were found in the serum of patients with Whipple disease [67]. Furthermore, a study of the gene expression profile of macrophages from intestinal lesions in a patient with Whipple disease revealed a pattern corresponding to M2/alternatively activated macrophages suggesting that a Th2 response in the intestine may play an important in the pathophysiology of Whipple disease [68]. It has been demonstrated that IL-16 is critical for *T. whipplei* replication, with enhanced *T. whipplei* replication in patients with Whipple disease related to high levels of circulating IL-16 [69]. These studies suggest that underlying defects of monocyte/macrophage function play an important pathophysiological role, which may lead to the inability of the host response to eliminate the causal bacteria. This may have important clinical implications in patients with Whipple disease because immunomodulating therapy with IFN-γ may be beneficial [70], whereas immunosuppressive therapy for chronic inflammatory arthropathy may be associated with the appearance or exacerbation of gastrointestinal symptoms [71,72].

Histopathology

The histopathological appearance of the small bowel mucosa in Whipple disease is distinct, unique, and usually diagnostic when present, although small bowel disease may not be identified until many years after the onset of other systemic manifestations. The lamina propria is infiltrated by large foamy macrophages that grossly distort normal villous architecture, so that the villi take on a blunted, club-like appearance. The cytoplasm of these macrophages is filled with large glycoprotein granules that stain with PAS (Fig. 49.1). The lymphatic channels in the mucosa and submucosa are dilated, and fat droplets may be seen in the extracellular spaces within the lamina propria, reflecting lymphatic obstruction by enlarged mesenteric lymph nodes.

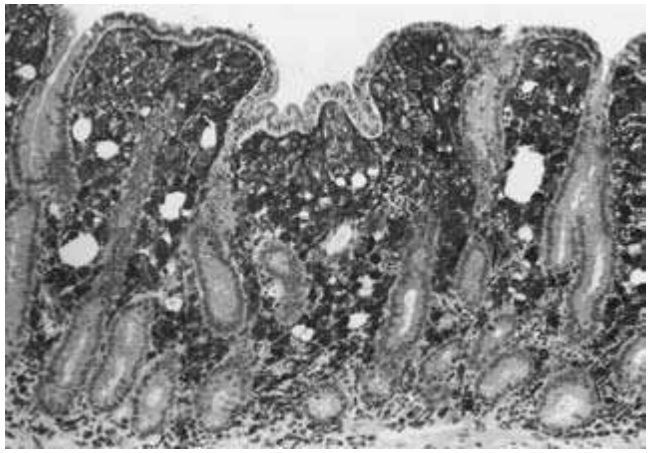

Figure 49.1 Light microscopic appearance of the intestinal mucosa in a patient with Whipple disease. The villi are clubbed, and the lamina propria is extensively infiltrated with periodic acid–Schiff (PAS)-positive macrophages. (PAS and hematoxylin stain; original magnification × 250.) From Dobbins [15].

With electron microscopy, many of the characteristic rod-shaped bacillary bodies can be seen in the lamina propria; they are most abundant just beneath the absorptive epithelium. The fine structure of the bacilli is identical in different patients. The bacilli are 0.25 μm wide and 1–2.5 μm long, with a characteristic cell wall and pale central nucleoid [10,17,18,73–75]. The bacilli are often seen within the PAS-positive macrophages (Fig. 49.2). Most of the PAS-positive glycoprotein within the macrophages likely represents remnants of the cell wall of the phagocytosed bacilli. Unlike the *Mycobacterium avium* complex, the Whipple bacillus is acid-fast-negative.

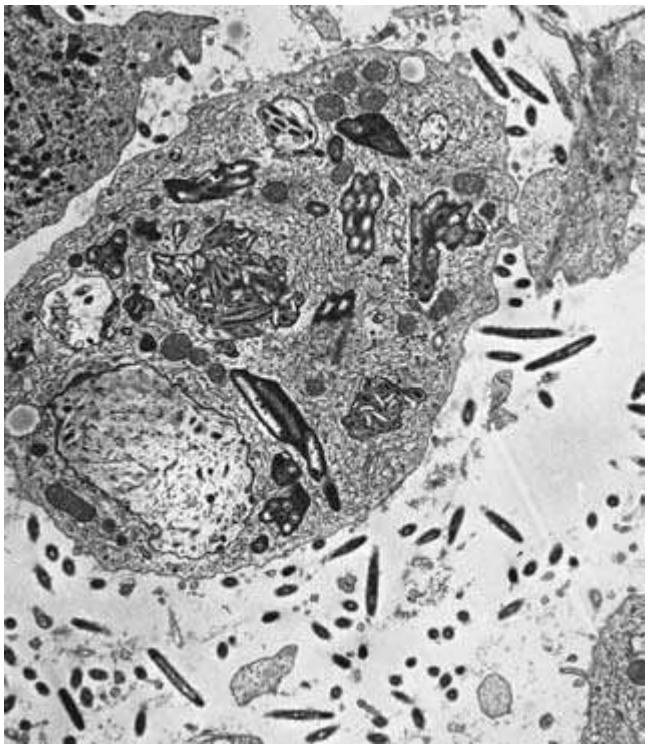

Figure 49.2 Electron micrograph showing numerous bacilli in the extracellular spaces and ingested bacilli in varying stages of breakdown within a macrophage. (Original magnification × 11 000.) From Dobbins [15].

The PAS-positive macrophages and characteristic bacilli have been identified in many nonintestinal tissues, including heart [19,76], lung [20], liver [12], and brain [21], documenting the systemic nature of the disease.

The evolution of the histology of intestinal Whipple disease after therapy has been described in a study of 48 patients [77]. Treatment is associated with a continuous decrease in PAS-positive macrophages and a change in the pattern of mucosal infiltration from diffuse to patchy. A few PAS-positive macrophages commonly persist at long-term follow-up of treated patients. Because of this finding, it is recommended that multiple biopsies be obtained to evaluate the response to treatment or a clinical suspicion of relapse and that electron microscopy be performed to detect intact bacilli, because the persistence of PAS-positive material following therapy is not diagnostic for active infection.

Clinical manifestations

The clinical features and presentation of Whipple disease are highly variable and include symptoms suggestive of malabsorption, such as steatorrhea, abdominal bloating, and weight loss (Table 49.1). Occasionally patients present only with extraintestinal symptoms, such as arthritis and fever. Extraintestinal symptoms may precede gastrointestinal symptoms by many years. Given the nonspecific nature of the symptoms, there is often a delay of months to years prior to diagnosis. Diarrhea is the most common presenting complaint. In a study of 29 patients with Whipple disease, diarrhea was the chief complaint in 39% [16], and initially present in 75% of patients, similar to observations in other reports [28–30]. Thus, although diarrhea affects most patients with Whipple disease, it is not invariably present. When present, diarrhea symptoms are usually suggestive of steatorrhea; multiple large, watery, or semiformed stools are passed daily. Other intestinal symptoms include abdominal bloating, cramps, or distention, anorexia, and occasionally melena and hematochezia [7,78,79], although bleeding, when present, is most often occult [30]. Weight loss, the second most common presenting complaint in patients with Whipple disease, is present before the initial evaluation in 89%–100% of patients [16,28–30]. Severe cachexia may result from anorexia and malabsorption. Fatigue and generalized weakness are also common. Untreated malabsorption may result in specific nutritional deficiencies and their attendant symptoms. With the loss of albumin into the intestinal lumen as a consequence of lymphatic obstruction, ascites and peripheral edema may develop.

Arthritis is the most common extraintestinal symptom and affects the majority of patients [16,28–30]. It often develops several months to years before the initial diagnosis of Whipple

Table 49.1 Symptoms and physical findings in patients with Whipple disease

Gastrointestinal	Extraintestinal	Neurological
Symptoms		
Common	**Common**	**Common**
Diarrhea	Arthritis	*Central nervous system:*
Weight loss	Arthralgias	Dementia

Hepatomegaly	Pleural friction rub	
Splenomegaly	Ocular findings	

disease and is typically an intermittent, migratory arthritis of both the large and small joints. Some patients may have only arthralgias. Permanent joint deformity is rare. Fever, usually low grade and intermittent, is the second most common extraintestinal symptom of Whipple disease [16]. Numerous other extraintestinal symptoms develop reflecting the systemic nature of the infection. Pulmonary involvement is often manifested by chronic cough or pleuritic chest pain [1,16,20,80]. Cardiac involvement [81–84] may be manifested as congestive heart failure, valvular lesions [81,82], or pericarditis [16,19,80,84]. Numerous reports of endocarditis secondary to *T. whipplei* infection in the absence of overt gastrointestinal disease have been published [85–88].

Although central nervous system (CNS) involvement is thought to be common, symptoms related to CNS Whipple disease may be present in only 10%–20% of patients (Table 49.1) [89–94]. Neurological symptoms may occur in association with gastrointestinal symptoms or as isolated symptoms [15,21,95,96]. The most common CNS symptoms are dementia, paralysis of gaze, and myoclonus [15]. Hypothalamic symptoms such as insomnia, hyperphagia, and polydipsia are also frequently present [15].

The physical findings in patients with Whipple disease are variable, depending on the organ systems involved (Table 49.1). Frequently, the findings are related to severe malabsorption and the loss of fluid and electrolytes, such as emaciation, muscle wasting, peripheral edema, purpura, glossitis, muscular irritability, and peripheral neuropathy. Hyperpigmentation and peripheral lymphadenopathy is the most common physical findings [16,29,30], seen in more than 50% of patients with Whipple disease. The palpable lymph nodes are usually firm, nontender, and mobile. Abdominal findings often include mild distention and tenderness. Abdominal fullness or mass may be caused by marked enlargement of the mesenteric lymph nodes. Ascites is uncommon but may be seen in association with severe hypoalbuminemia. Hepatomegaly and splenomegaly are uncommon [16,30]. Additional well-recognized physical findings in patients with Whipple disease

include fever, peripheral arthritis, heart murmurs, pleural or pericardial friction rubs, and ocular abnormalities, such as uveitis [47]. The neurological examination may reveal findings suggestive of CNS or cranial nerve involvement, such as dementia, ataxia, muscle weakness, sensory loss, and ophthalmoplegia.

Laboratory findings

Laboratory abnormalities, usually related to severe malabsorption, are common in patients with Whipple disease. Most have steatorrhea [16,30] in addition to low serum carotene levels [16,30] and hypoalbuminemia [16,29,97]. In patients with severe diarrhea and malabsorption, electrolyte disturbances such as hypokalemia, hypomagnesemia, and hypocalcemia may be seen. Anemia is a common finding [15,16,28–30]. The anemia is usually normochromic–normocytic, suggestive of chronic disease. Occasionally, it is hypochromic–microcytic, related to iron deficiency; however, macrocytosis secondary to folate or vitamin B-12 deficiency is unusual. Many patients have an elevated erythrocyte sedimentation rate, and the prothrombin time is often prolonged secondary to malabsorption of vitamin K [16].

Radiological and endoscopic findings

Radiological evaluation can be helpful, particularly a barium contrast study of the small intestine, the results of which are abnormal in most patients with Whipple disease [16,30,98]. The most characteristic finding is marked thickening of the mucosal folds, suggestive of an infiltrative process. This finding is usually more prominent in the duodenum and proximal jejunum, with decreased involvement distally and sparing of the ileum. In addition to the marked thickening of the proximal small bowel, abdominal computed tomography (CT) often reveals massive paraaortic and retroperitoneal adenopathy [16,99].

Gross endoscopic lesions in the duodenum have been described in Whipple disease [100,101]. The characteristic finding is pale, shaggy, yellow mucosa in the postbulbar duodenum. Yellow plaques or erosions may also be seen. Wireless capsule endoscopy revealed disease affecting the entire small intestine in a patient with refractory Whipple disease [102]. Although involvement of the esophagus and colon is unusual in Whipple disease, endoscopic lesions similar to those seen in the duodenum, consisting of pale, white, plaque-like nodules, have been described [103].

Diagnostic evaluation

The most important step in the diagnosis of Whipple disease is to consider this rare disease in the differential diagnosis of the much more common conditions that cause the many symptoms and findings associated with the disease. Thus, for example, Whipple disease should be considered in the differential diagnosis of unexplained gastrointestinal symptoms or malabsorption, weight loss, seronegative arthritis, culture-negative endocarditis, and fever of unknown origin

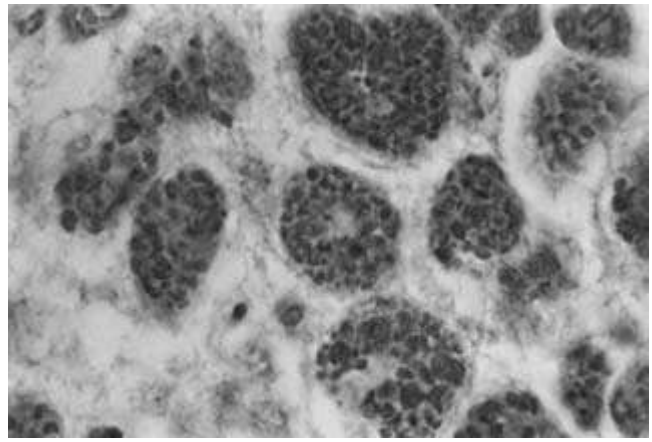

Figure 49.3 Light microscopic appearance of macrophages in the intestinal lamina propria in Whipple disease. Note that most of the periodic acid–Schiff (PAS)-stained inclusions are round or sickle-shaped. This appearance is virtually diagnostic, especially in the intestinal mucosa. (PAS and hematoxylin stain; original magnification × 1000.) From Dobbins [15].

Small intestinal mucosal biopsy is the diagnostic test of choice and is required for a definitive diagnosis. The histological finding of infiltration of the small intestinal lamina propria by PAS-positive macrophages containing gram-positive, acid-fast-negative bacilli accompanied by lymphatic dilation is specific and diagnostic of Whipple disease (Fig. 49.3). Immunohistochemical analysis has also been shown to be a sensitive and specific method for the diagnosis of Whipple disease [104,105]. Electron microscopy should also be routinely performed on the biopsy specimens to verify the presence of the characteristic bacillus. This is particularly important during the follow-up of patients treated for Whipple disease in whom PAS positivity persists [10,16,106], often for many years; electron microscopy in successfully treated patients shows the disappearance of the Whipple bacillus.

Rarely, the diagnosis of Whipple disease is established in the absence of intestinal involvement by the identification of bacilli in involved tissues, including the brain and lymph nodes. Although the colonic mucosa may occasionally be involved in Whipple disease, caution is required in the interpretation of rectal biopsy specimens, because PAS-positive macrophages may be found in normal rectal and colonic biopsies [107].

Molecular diagnosis using PCR-based diagnostic tests has become useful in confirming the diagnosis of Whipple disease and in monitoring the response during antibiotic treatment [24,43,45–47]. In two retrospective studies of intestinal biopsies, PCR was shown to be a highly sensitive and specific test to confirm the diagnosis of Whipple disease [26,27]. Additional studies have confirmed the value of PCR for diagnosis and monitoring bacterial elimination during

therapy [108–110] and in diagnosis of extraintestinal Whipple disease [111–114]. A PCR assay on stool specimens may provide a diagnostic tool that does not require endoscopy [115]. Although previous reports suggested that PCR-based tests of peripheral blood mononuclear cells or whole blood were useful [45,46], subsequent studies have not confirmed the sensitivity of this approach compared with testing of duodenal biopsy specimens [108,116].

Differential diagnosis

The differential diagnosis of Whipple disease includes other malabsorptive diseases with diffuse small intestinal involvement, such as celiac disease, and infiltrative diseases of the small intestine, such as intraabdominal lymphoma. These diseases can be easily and reliably differentiated by small intestinal mucosal biopsy.

Of particular importance, given the increasing incidence of acquired immunodeficiency syndrome (AIDS), Whipple disease must be distinguished from *Mycobacterium avium* complex (MAC) infection. The latter infection causes infiltration of the lamina propria with PAS-positive macrophages (Fig. 49.4), as in Whipple disease [117,118], but MAC bacilli are acid-fast, whereas the Whipple bacillus is not. In addition, MAC organisms can be cultured and have an electron microscopic appearance markedly different from that of Whipple bacilli. Systemic histoplasmosis and macroglobulinemia are also conditins in which PAS-positive macrophages can be seen in the intestinal lamina propria; however, in systemic histoplasmosis, large PAS-positive, rounded, encapsulated *Histoplasma* organisms are easily seen in macrophages, and the faintly staining, homogeneously PAS-positive macrophages of macroglobulinemia are distinctly different from Whipple disease.

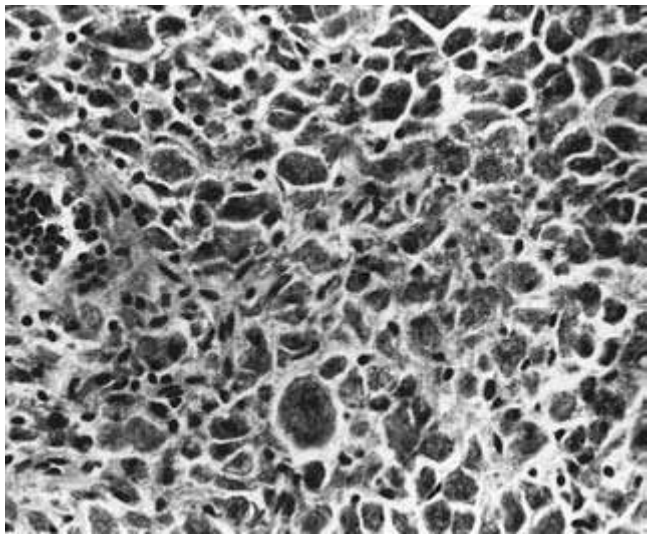

Figure 49.4 Light microscopic appearance of macrophages in the intestinal lamina propria of a patient with AIDS and *Mycobacterium avium* complex involvement of the gut. Note the easily identified bacilli within the macrophages. (Acid-fast stain; original magnification × 500.) From Dobbins [15].

Treatment and prognosis

Although controlled treatment trials have not been conducted in Whipple disease, there is substantial observational evidence to guide antibiotic thereapy, which usually results in dramatic improvement. Numerous antibiotic regimens effective against gram-positive organisms and given for variable lengths of time have been used successfully, including penicillin, penicillin and streptomycin, erythromycin, ampicillin, chloramphenicol, tetracycline, and trimethoprim–sulfamethoxazole (TMP–SMX) [8–16]. Empirical observations are supported by the development of techniques to culture *T. whipplei* [51–54], enabling antibiotic susceptibility testing [119–121]. Doxycycline, macrolides, aminoglycosides, penicillin, rifampin, chloramphenicol and TMP–SMX were found to be active in vitro against three strains of *T. whipplei*. There was heterogeneity in susceptibility to imipenem and cephalosporins. Aztreonam and fluoroquinolones were not active. Further study revealed that *T. whipplei* is naturally resistant to fluoroquinolones [119] and that the susceptibility to TMP–SMX is due to SMX alone [120]. The combination of doxycycline and hydroxychloroquine was bactericidal suggesting that this combination should be evaluated in the treatment of patients with Whipple disease [121].

Despite the initial response to antibiotic therapy, relapses are common. Relapses can occur during treatment or months to years after completion of treatment [10,14–16,92]. In a review of the long-term follow-up of 88 patients with Whipple disease who had initially responded successfully to antibiotic therapy, 31 patients eventually relapsed [14]. The mean time to relapse was 4.2 years. Of the 31 patients who relapsed, 21 had received initial therapy with tetracycline alone. Clinical relapses, consisting of a recurrence of gastrointestinal symptoms and arthritis, occurred both early and late and responded favorably to further antibiotic treatment, whereas CNS relapses tended to occur late and responded poorly to additional antibiotic therapy.

Given the concern about CNS relapses [14,64,92,95] it is reasonable to assume that all patients may have CNS involvement and to treat initially with an antibiotic that readily crosses the blood–brain barrier. One double-strength tablet of TMP–SMX (160 mg of TMP and 800 mg of SMX) given twice daily for 1 year is the best long-term option (Table 49.2) [14]. The TMP–SMX penetrates the blood–brain barrier and should effectively eradicate CNS involvement. Although shorter courses of antibiotic therapy may be effective, because of the concerns about CNS relapse and its poor response to additional therapy, it is appropriate to treat patients for 1 year [14,16,122]. Expert opinion suggests that initial therapy with parenteral penicillin G (1.2 million U/day) and streptomycin (1.0 g/day) for 10–14 days may be of additional benefit [14,16,122], resulting in the lowest

Table 49.2 Treatment of Whipple disease

	Medication	Duration
Treatment of choice	Trimethoprim–-sulfamethoxazole	1 year
	or	
	Procaine penicillin G/streptomycin (parenteral)	2 weeks
	plus	
	Trimethoprim–sulfamethoxazole	1 year
Alternatives	Penicillin or ampicillin[a]	1 year
	Chloramphenicol[b]	1 year

a May be used in patients with sulfa allergy without central nervous system symptoms.
b May be used in patients with sulfa allergy with central nervous system symptoms.

Table 49.3 Infectious diseases mimicking tuberculous enteritis

	Primary risk group(s)	Primary gastrointestinal site	Distinguishing clinical features	Diagnosis
Mycobacterium tuberculosis infection	AIDS immunosuppression	Ileum	Abdominal mass	Caseating granulomas
		Cecum		AFB in mucosa
MAC infection	AIDS	Ileum Cecum	Prominent fevers	AFB in blood
Aspergillosis	Neutropenic patients	Multiple sites	Widely disseminated symptoms	Y-shaped branching, septate hyphae in mucosa
Histoplasmosis	AIDS	Ileum Cecum	Pulmonary symptoms	Intracellular oval yeast
Mucormycosis	Malnourished patients	Multiple sites	Bleeding from multiple sites	Large, nonseptate, thick-walled hyphae in mucosa
Yersinia enterocolitis	Children	Terminal ileum	Shorter disease course	Gram-negative coccobacilli in stool
Cryptosporidiosis	AIDS	Small intestine	Diarrhea, often voluminous	Oocytes within epithelial cells or in stool
CMV infection	AIDS Transplant patients	Colon	Bloody diarrhea	Inclusion bodies in submucosal or mucosal crypts

AFB, acid-fast bacilli; CMV, cytomegalovirus; MAC, *Mycobacterium avium* complex.

relapse rate. This should be considered in all patients with Whipple disease, particularly because compliance with the prescribed regimen is often limited (Table 49.3). In patients who are allergic to or cannot tolerate TMP–SMX, parenteral penicillin and streptomycin for 10–14 days followed by oral penicillin VK or ampicillin for 1 year is reasonable. In these patients, if the development of CNS symptoms is a concern, chloramphenicol is an option. Oral chloramphenicol, like TMP–SMX, achieves relatively high CNS concentrations. In addition to antibiotic treatment, in patients with severe malabsorption and malnutrition, appropriate supplementation of specific nutrients, such as folic acid, vitamin B-12, fat-soluble vitamins, and iron, should be given to prevent deficiency.

At the conclusion of 1 year of antibiotic therapy, a small intestinal mucosal biopsy should be repeated to document the absence of residual bacilli before treatment is discontinued. Although PAS-positive macrophages may be present in the lamina propria for many years in patients treated for Whipple disease, the presence of bacilli on electron microscopy suggests inadequate treatment. At this time, PCR for *T. whipplei* in intestinal biopsy specimens is not routinely recommended; however, if available, it may provide useful

information regarding the adequacy of therapy and the likelihood of relapse. Positivity on PCR suggests inadequate treatment, whereas PCR negativity predicts a low likelihood of clinical relapse but does not guarantee an absence of future CNS relapse [26,27].

The prognosis for patients with Whipple disease who receive appropriate and effective antibiotic therapy is excellent. Extraintestinal symptoms such as fever and arthritis often disappear within a few days. Gastrointestinal symptoms frequently resolve within 1 month. Most patients are asymptomatic within a few months. After therapy has been discontinued, patients must be carefully observed for evidence of relapse, including clinical evaluation and laboratory studies. Endoscopy with intestinal biopsy should be performed at 1 year to confirm the response to treatment, but routine invasive diagnostic studies, such as annual endoscopy with intestinal biopsy, are not warranted. Relapse may be signaled by a recurrence of gastrointestinal or extraintestinal symptoms. If relapse is suspected, small intestinal biopsy should be repeated and the specimen examined for the presence of free bacilli. The treatment of a relapse of Whipple disease consists of a repetition of the initial therapy. Gastrointestinal relapse responds well to further antibiotic therapy. If the patient does not respond to TMP–SMX, then a trial of oral penicillin VK or tetracycline is reasonable. Patients with CNS relapse have a relatively poor prognosis. If the patient does not respond to a repeated course of the initial therapy, then a course of chloramphenicol is warranted. Combination therapy with antibiotics and IFN-γ may be beneficial in patients with refractory Whipple disease [70].

Tropical sprue

Tropical sprue, first reported in 1759 in Barbados, is a syndrome occurring in individuals residing in certain tropical locations [123]. The cause is presumed to be bacterial overgrowth of the small intestine. The essential clinical features of the disease are chronic diarrhea and malabsorption, with resultant weight loss. Megaloblastic anemia secondary to folate and vitamin B-12 deficiency is usually present. The diagnosis is made by small intestinal biopsy and confirmed by prompt clinical and laboratory response to treatment with folic acid and broad-spectrum antibiotics.

Epidemiology

Tropical sprue is found in many tropical locales, including India, Cuba, the Dominican Republic, Haiti, Puerto Rico, northern South America, and a number of other countries, including the Philippines. The disease is primarily found in adults, occurring only rarely in children. Tropical sprue seems to occur mostly as sporadic isolated cases, but epidemics have been described among British forces serving in Burma during World War II, American military personnel serving in the Philippines, and villagers living in southern India [124–126]. In both sporadic cases and epidemics, a peak seasonal occurrence of tropical sprue has been observed that is unrelated to the rainy season [127].

Although tropical sprue can afflict visitors within weeks or months after their arrival in a region of endemicity, it rarely occurs in short-term travelers, usually developing in persons who have lived in a region for more than 6 months to 1 year [128]. The prevalence of tropical sprue appears to be decreasing, possibly related to the frequent self-medication with antibiotics. Tropical sprue is more common where sanitary conditions are poor [129]. Rarely, tropical sprue becomes clinically apparent months or even years after individuals have moved to a temperate climate [130].

Etiology and pathogenesis

Tropical sprue is presumed to result from chronic bacterial overgrowth of the small intestine by toxigenic strains of coliform bacteria. An infectious etiology is supported by documented epidemics and seasonal variation and the response to antibiotic treatment.

Most individuals with tropical sprue exhibit bacterial overgrowth of the jejunum with strains of *Klebsiella pneumoniae* or, less often, *Enterobacter cloacae* or *Escherichia coli* [131–133]. Eradication of these bacteria with antimicrobial therapy results in cure of the intestinal abnormalities [131,133]. The organisms that overgrow the small bowel of patients with tropical sprue are facultative anaerobes, typically consisting of only one or a few species, serotypes, or biotypes in each individual patient [132]. There are no anaerobes as classically seen in diseases manifested by small bowel stasis and resultant bacterial overgrowth, such as blind loop syndrome. The organisms isolated from patients with tropical sprue have been shown to have pathogenic effects in animal models, but specific pathogenic factors have not been identified [134,135]. In most nonnative residents, tropical sprue develops after an attack of acute watery diarrhea. Acute infectious diarrhea, caused by a variety of enteric pathogens, may be associated with transient jejunal contamination by coliform bacteria [136]. Multiple factors have been suggested to contribute to the disease, including increased bacterial adherence, immune dysfunction, dietary fat, and altered motility, but no definitive primary abnormalities have been identified [137–146]. The unique role of folate deficiency in the pathogenesis of tropical sprue is not well understood. Folate deficiency leads to a decreased number of intestinal epithelial cells and atrophy of villi and is associated with a number of intestinal structural and functional alterations, including crypt hypertrophy, blunting of villi, and less efficient absorption of water, electrolytes, and carbohydrates. Treatment with pharmacological doses of folic acid results in structural and functional improvement in the small bowel of patients with tropical sprue [128].

The role of coliform bacteria has been questioned, because they have been isolated from the proximal small intestine in healthy asymptomatic controls in tropical locations such as India and South Africa [147,148], and these bacteria have not been found in all patients with tropical sprue.

Histopathology

The histopathological finding in patients with tropical sprue is partial atrophy of the villi in the small intestine. A completely flat mucosa, as is seen in untreated celiac sprue, is found in fewer than 10% of patients with tropical sprue. The histological changes consist of lengthening of the crypt area, broadening and shortening of the villi, chronic infiltration of the lamina propria by inflammatory cells, and variable degrees of abnormality of the surface epithelium (Fig. 49.5) [138,149]. The basement membrane usually appears thickened, staining as collagen on light microscopy [149]. Structural abnormalities are more prominent in the jejunum during the early phase of tropical sprue; however, eventually the entire small bowel is equally affected.

Clinical manifestations

Many individuals can identify the onset of their disease as an episode of acute diarrhea. Less commonly, the onset of tropical sprue is insidious. The chronic symptoms, including prolonged diarrhea, abdominal cramping, nausea, and anorexia with associated weight loss, are nonspecific and related to malabsorption. Fever may be present at the onset of the disease but rarely persists. Lactose intolerance often develops early in the course of tropical sprue, caused by a reduction in brush-border disaccharidase enzyme activity. Exocrine pancreatic insufficiency caused by intestinal damage may develop and contribute to the malabsorption [150]. Within a few months, malabsorption results in folate deficiency. After a variable period of time, usually about 6 months but sometimes earlier in conjunction with poor nutrition, severe depletion of folate coupled with the development of vitamin B-12 deficiency causes symptoms associated with megaloblastic anemia, such as fatigue and weakness. Later in the course of the disease, peripheral neuropathy and confusion may occur. High-output heart failure may occur as a result of severe anemia. These deficiencies and their manifestations can develop in about 10% of patients with tropical sprue who have never experienced any gastrointestinal symptoms. The physical findings include manifestations of nutritional deficiencies such as pallor, glossitis, and edema and typically appear late [151,152]. Stomatitis, hyperpigmentation, and neurological manifestations of vitamin B-12 deficiency may occur but are rare.

Laboratory findings

Megaloblastic anemia, caused by combined deficiencies of folate and vitamin B-12, is the hallmark of tropical sprue. Steatorrhea and reduced xylose absorption are frequently present. Malabsorption of fat-soluble vitamins often occurs, resulting in low serum concentrations of vitamin A (and β-carotene), 25-hydroxyvitamin D, and calcium. Marked elevation of the prothrombin time is unusual. Hypoalbuminemia and hypocholesterolemia are also seen.

Radiological and endoscopic findings

Contrast radiography of the small bowel may reveal findings suggestive of tropical sprue such as prominent, thickened mucosal folds with a coarsened or irregular contour involving the jejunum and ileum and lumenal dilation and flocculation of the barium [153]. Although these findings are nonspecific, ileal involvement is characteristic of tropical sprue and relatively uncommon in celiac sprue, Whipple disease, and other small bowel enteropathies. Endoscopic visualization of the small bowel may reveal scalloping of the valvulae conniventes and a mosaic pattern of the mucosa [154], findings frequently described in celiac sprue.

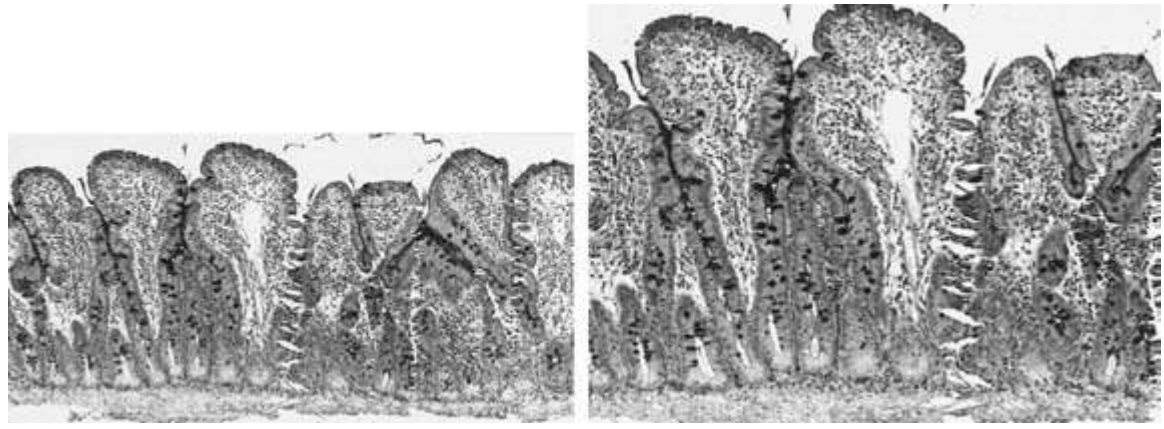

Figure 49.5 **(a)** Light microscopic appearance of the moderate villus abnormality of tropical sprue acquired by a North American during a 2-week visit to the Philippines. Note the broadened villi, infiltration of the lamina propria by plasma cells and lymphocytes, and lymphocytic infiltration of the epithelium. (Periodic acid–Schiff and hematoxylin stain; original magnification × 80.) **(b)** Enlargement of a portion of (a) reveals the epithelial changes. (Original magnification × 132.)

Diagnostic evaluation

When the diagnosis of tropical sprue is suspected, endoscopy with small bowel biopsy should be performed. The demonstration of characteristic changes in the architecture of the villi, including partial atrophy, supports the diagnosis. The diagnosis of tropical sprue is confirmed by a prompt clinical and laboratory response to the institution of appropriate treatment. Stool culture is of no diagnostic value in tropical sprue, but the stool should be examined for ova and parasites to rule out other infectious causes of chronic diarrhea, such as *Giardia*.

Differential diagnosis

The differential diagnosis includes other malabsorptive diseases and enteropathies, including celiac disease, Whipple disease, HIV enteropathy, infection of the small intestine with parasites such as *Cryptosporidium, Giardia,* and *Strongyloides*, and bacterial overgrowth caused by diseases that alter intestinal motility, such as amyloidosis, pseudoobstruction, scleroderma, and blind loop syndrome. Primary intestinal lymphoma may present with chronic diarrhea, often with significant associated abdominal pain. Intestinal tuberculosis may occur in some tropical countries but it is much less common than tropical sprue. Finally, tropical sprue occurs in areas such as Haiti, where another entity, usually referred to as *tropical enteropathy,* is prevalent [155]. Tropical enteropathy is generally associated with milder abnormalities of intestinal structure and function, and clinically significant malabsorption or nutritional deficiencies do not develop in affected persons. Unlike the abnormalities of tropical sprue, the intestinal abnormalities of tropical enteropathy resolve within a year after return to a temperate climate, even without specific therapy [156]. It is thought that the intestinal abnormalities of tropical enteropathy are a manifestation of repeated, transient episodes of intestinal infection caused by various enteric pathogens.

Treatment and prognosis

Combination therapy with tetracycline and folate is the recommended approach to the treatment of tropical sprue. This consists of 250 mg of tetracycline four times a day and 5 mg of folic acid once daily. Although 1 month of therapy has been effective in travelers with tropical sprue, treatment for up to 6 months is often required for those with chronic disease to achieve complete remission of the malabsorptive syndrome and to prevent recurrence [157–159]. Although not necessary for the acute phase of therapy, vitamin B-12 (1000 μg), administered parenterally once a week for several weeks, should also be given to replete tissue stores. Despite treatment with combination therapy for 6 months, intestinal abnormalities may persist, and clinical relapse, requiring additional courses of therapy, may occur in 10%–20% of patients who remain in tropical locations of endemicity [160].

Tuberculosis

Mycobacterium tuberculosis, the primary cause of tuberculosis (TB), infects a third of the world's population and causes more deaths than any other infectious agent except HIV [161]. It is found primarily in developing countries, where overcrowding and poor sanitation contribute to its spread. In the United States, the number of reported TB cases reached an all time low of 4.9 per 100 000 persons in 2004, and slightly more than half were among foreign-born persons [162]. Although pulmonary manifestations predominate in most cases of TB, gastrointestinal involvement can be part of a disease process affecting multiple organs; less commonly, gastrointestinal involvement in the absence of other identifiable sites of infection (so-called primary gastrointestinal TB) may be associated with symptoms and even be the primary cause of death [163–165].

Epidemiology

Before the development of effective anti-TB chemotherapy, gastrointestinal TB was seen in about 70% of persons with advanced pulmonary disease [166]. Since the advent of effective chemotherapy, gastrointestinal TB has become much rarer, and in the United States and Canada it is reported in fewer than 1% of all cases [167,168]. In developed countries, it is most commonly found in association with immunosuppression, especially in patients with AIDS [169]. In developing countries, AIDS and immunosuppression, in combination with limited access to anti-TB therapy and inadequate sanitation, appear to have increased the incidence of gastrointestinal TB. In one series from South Africa, 46% of patients with smear-positive, cavitating pulmonary TB had gastrointestinal involvement [170]. Some data suggest that the risk for gastrointestinal disease is directly related to the severity of pulmonary disease, although not all persons with gastrointestinal TB have evidence of current or past pulmonary disease [164,170,171]. Rare cases of congenital necrotizing enterocolitis have been reported in infants born to mothers with miliary TB [172].

Etiology and pathogenesis

Gastrointestinal TB is usually caused by *M. tuberculosis,* but in developing countries it may also rarely be caused by a closely related species, *M. bovis* [161]. *M tuberculosis* is an acid-fast, curved bacillus that can infect certain primates, including humans, although humans are the only known reservoir. It spreads from human to human by aerosolization. It is thought that gastrointestinal disease arises when organisms are swallowed and survive destruction by gastric acid; the source of the organisms can be either dietary, such as infected milk in the rare cases of *M. bovis* infection, or more commonly pulmonary secretions. Lesions may also occur as a result of disseminated miliary disease.

Infection of the upper gastrointestinal tract is exceptional, and lesions are more often found in areas characterized by high lymphoid density and stasis, such as the distal small bowel, cecum, appendix, and, less commonly, colon and rectosigmoid [164,166,171,173,174]. Gastrointestinal TB is thought to arise by the same pathophysiological sequence as pulmonary infection: initial infection of macrophages is followed by multiplication of the organisms in macrophages, caseation necrosis, and a secondary host immune response. The immune response is characterized by either cell-mediated immunity, with a marked influx of activated myeloid and lymphoid cells, or a delayed hypersensitivity reaction accompanied by cell death and caseation necrosis [175]. The defects of cell-mediated immunity seen in patients with AIDS and other immunocompromised hosts result in failure to contain the organism, so that these patients are predisposed to the development of clinical disease once infected.

Pathology

The pathological lesions of gastrointestinal TB are characterized by ulcers with granulomas and later extensive fibrosis [164,166,171,176]. The ulcerations presumably develop as a result of infection of gastrointestinal macrophages, with subsequent caseation necrosis and intense inflammatory changes. Multiple focal areas of involvement are typical [166,176]. Fistulae and anorectal lesions may form [164]. Histologically, in the early stages, the ulcerative lesions are characterized by granulomas, usually with caseation and larger numbers of acid-fast organisms [171]. Involvement of draining lymph nodes is common [164]. With more chronic inflammation, the bowel wall may become markedly fibrotic and stenotic, with the formation of mass lesions (tuberculomas). Strictures are typically short but may be greater than 10 cm long and involve multiple areas of the intestinal wall [164]. The number of organisms may be markedly diminished in the fibrotic stages, or organisms may be absent in patients who have received treatment.

Clinical manifestations

The symptoms of gastrointestinal TB are nonspecific, and in the absence of pulmonary TB, the diagnosis may be difficult. The most common symptom of gastrointestinal TB is abdominal pain [164,171,173,177]. Others include fever, anorexia, diarrhea, weight loss, constipation, bloating, and hemorrhage [164,166,171,173,177].

If disease is limited to the duodenum, the symptoms may be primarily those of peptic ulcer disease [178]. The physical findings may include cachexia and, in patients with an acute pulmonary process, pulmonary manifestations [179–181]. The abdominal examination may reveal a palpable mass, which in various series is the abnormality most commonly found [171,173]. Other physical examination findings include evidence of complications such as perforation, obstruction, fistulae, massive hemorrhage, and malabsorption [163,164,174,178].

Diagnostic evaluation

Barium contrast studies may demonstrate ulcerations, spasticity, strictures, fistulae, and thickening, deformity, and incompetence of the ileocecal valve; evidence of mass lesions similar to those of Crohn's disease may be seen (Fig. 49.6) [182–184]. Computed tomography and ultrasonography both show mural thickening of the bowel at sites that correlate with the pathological findings at colonoscopy [185]. Mesenteric lymphadenitis, omental thickening, and ascites are frequently associated with tuberculous enterocolitis [180]. Peritonitis is found in about 20% of patients [186]. Lesions may also be found in liver, spleen, or pancreas. Fine-needle aspiration, either CT-guided or ultrasonographically guided, has been used successfully for diagnosis [187].

The diagnostic procedure of choice is usually colonoscopy with biopsy because it does not involve surgery, and the most common site of involvement is the ileocecal region

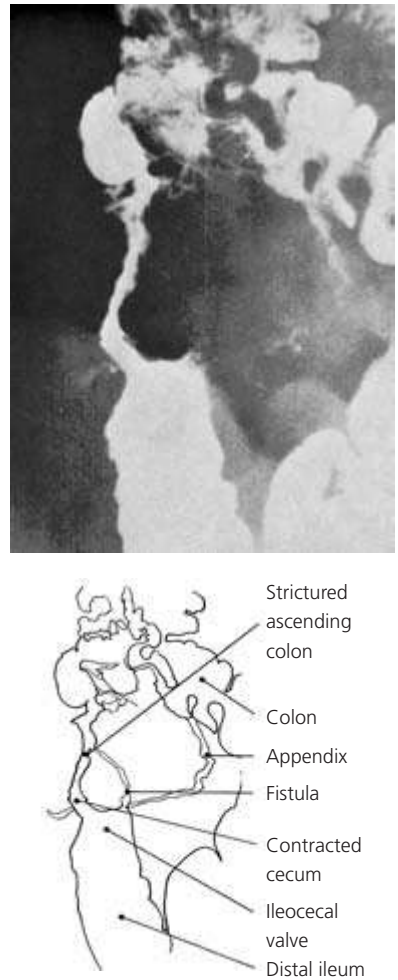

Figure 49.6 Barium study in a patient with hypertrophic tuberculosis shows a dilated distal ileum leading into a contracted cecum and strictured ascending colon. From Misiewicz JJ, Forbes A, Price A, et al. Atlas of Clinical Gastroenterology, 2nd edn. London: Wolfe, 1994:5.4, with permission from Elsevier.

[171,172,176]. Visual inspection of the involved bowel most commonly reveals multiple areas of nodular mucosa with areas of ulceration [173,176]. The ulcers are typically irregular; circumferential, in contrast to the linear ulcerations of Crohn's disease; and have a necrotic base [171,188]. Upper gastrointestinal endoscopy with jejunal or duodenal biopsy is indicated less commonly, when disease at these sites is suspected [177]. In addition, paracentesis, laparoscopy, and laparotomy can also be used to diagnose TB.

Histological studies of biopsy material showing caseating granulomas, or Ziehl–Neelsen- or Kinyoun-stained specimens showing acid-fast, beaded, slightly bent rods, may provide immediate answers, but often are nondiagnostic. Typical caseating granulomas are found less frequently in biopsy material from lymph nodes than from the intestine and may be found in only half of specimens [176]. Potentially, PCR can provide a rapid diagnosis for extrapulmonary tuberculosis, with studies showing sensitivities between 64% and 86% and specificities of 100% [189–191]. When ascitic fluid is present, a high ascitic fluid adenosine deaminase may greatly aid in the diagnosis, with multiple studies showing greater than 90% sensitivity and specificity for TB [192–195]. However, in nonendemic areas of the world, such as the United States, the sensitivity is lower, especially in patients with cirrhosis [196].

Culture of biopsy material or ascitic fluid remains the gold standard but requires at a minimum 1–2 weeks for results. The diagnostic yield is best with material obtained from peritoneal biopsies, with one case series showing positive results for 87% of patients with peritoneal biopsies compared with 54% of patients who underwent colonoscopy [177,197].

Differential diagnosis

Tuberculosis should always be considered in the differential diagnosis of patients with obscure abdominal symptoms or physical findings, especially those who are immunocompromised or living where TB is endemic. Crohn's disease often presents similarly to TB but more commonly begins earlier in life, and granulomas, when present, are poorly organized, less than 400 μm in maximum dimension, and more often located in the rectosigmoid [176]. In addition, severe active Crohn's disease is usually not found in patients with advanced HIV infection. Other entities in the differential diagnosis of TB enteritis include lymphoma, carcinoma, diverticular disease, appendicitis, and other infections of the gastrointestinal tract such as *Yersinia*, histoplasmosis, MAC enteritis, and cytomegalovirus infection (Table 49.3) [166,181,185].

Treatment and prognosis

The prognosis of a patient with gastrointestinal TB depends primarily on their immune status and the institution of the appropriate therapy in a timely manner. In untreated HIV-infected patients, the disease progresses rapidly and is almost always fatal [169]. However, the results of therapy are usually satisfactory, even in immunocompromised hosts, when therapy is started sufficiently early in the course of disease. The difficulty lies in making a timely diagnosis, and in many series significant numbers of patients die before the disease is diagnosed [165,170].

If any indication of TB is noted, such as a compatible clinical picture in a high-risk patient, a positive acid-fast stain, or histological evidence of granulomas, therapy should be started immediately pending the results of culture and susceptibility testing. The regimen of choice is 300 mg isoniazid, 600 mg rifampin, 15–30 mg/kg pyrazinamide, and 15 mg/kg ethambutol [198]. If susceptibility testing reveals that the organism is sensitive to all drugs, then ethambutol can be stopped immediately and pyrazinamide continued for only 2 months. Isoniazid and rifampin must be continued for an additional 4 months, for a total of 6 months of therapy.

If the organism is resistant to isoniazid (the most common form of resistance), then treatment should be started with or changed to rifampin, pyrazinamide, and ethambutol and continued for 6 months [198]. In cases with suspected multidrug-resistant TB, isoniazid, rifampin, and pyrazinamide plus an additional two or three agents should be started until in vitro sensitivity tests are complete. Additional agents include a fluoroquinolone (levofloxacin, moxifloxacin, or gatifloxacin), an injectable agent such as streptomycin 15 mg/kg/day (if not used previously and susceptibility to streptomycin had been established), amikacin or kanamycin 15 mg/kg/day (maximum dose 1.0 g/day), or capreomycin, with or without an additional oral drug. Adverse effects of these second-line agents include ototoxicity, neurotoxicity, and nephrotoxicity. Two to four additional second-line agents should also be used if drug malabsorption is suspected.

Surgical intervention is usually not necessary and is reserved for complications such as obstruction, perforation, fistula, or a mass that does not resolve with medical therapy [165,174,179]. In most cases, a trial of medical therapy should be undertaken before surgical intervention. Complications can be fatal, even with surgical intervention, and may occur after the initiation of anti-TB medications [163–165,199].

Mycotic infections

Mycotic infections are most often a result of dissemination from a pulmonary source and usually occur in immunocompromised hosts, although they may also occur in normal hosts. The etiological agents of aspergillosis, candidiasis, histoplasmosis, cryptococcosis, and mucormycosis have all been cultured from the small intestine. Although *Cryptococcus* has been cultured from the small intestine of patients with AIDS, it has only rarely been associated with clinical disease so it will not be discussed further here [200,201]. The differential

diagnosis for all mycotic infection of the small bowel is similar and includes other mycotic infections, Crohn's disease, TB enteritis, disseminated *Mycobacterium avium* complex (MAC), bacterial typhlitis, ischemic bowel, and carcinoma [202,203].

Histoplasmosis

Epidemiology

Histoplasmosis is a common infection in the midwestern and south central regions of the United States, where 80% of the inhabitants are infected [204]. Infection, however, rarely equates with disease. When symptoms do occur, they most commonly involve the lungs, the primary portal of entry. Gastrointestinal disease occurs usually, but not always, as a result of widespread dissemination in an immunocompromised host. Infants and children, the elderly, patients on immunosuppressive therapy, including steroids, and persons with immunosuppressive diseases (especially AIDS) are all at greater risk than the general population.

Etiology and pathology

Histoplasmosis is disease due to infection by *Histoplasma capsulatum*, a fungus that exists in the mycelial form at ambient temperature (30°C) and in the yeast form at body temperature (37°C) [204]. This dimorphic fungus produces both macroconidia and microconidia in clinical isolates. Visual inspection of the involved bowel may reveal entirely normal tissue or a variety of lesions. The most common lesions are single or multiple ulcers and tissue necrosis [202,205,206]. Other lesions include flat elevations and polypoid protrusions. Microscopic examination of pathological specimens, after staining with methenamine silver, hematoxylin and eosin (H & E), periodic acid–Schiff (PAS), or Wright–Giemsa stain, reveals tiny (2–4 μm in diameter) oval yeast forms inside macrophages [204,207]. Pathological specimens may also show granulomatous inflammation if the patient is not severely immunocompromised [204,205].

Clinical manifestations

Although involvement of the small and large bowel is common in disseminated disease, symptomatic disease is much less common. In one series, only 50% of persons with gastrointestinal ulcerations had diarrhea or abdominal pain [206]. In addition, persons with disseminated disease who have little or no gastrointestinal pathology may have diarrhea or abdominal pain. Furthermore, even when gastrointestinal symptoms are present, they are often overshadowed by systemic or pulmonary complaints [203]. Occasionally, however, gastrointestinal complaints predominate. In one series, over 40% of patients presented with gastrointestinal complaints rather than pulmonary complaints [205].

The symptoms most commonly associated with small intestinal histoplasmosis include diarrhea, weight loss, fever, abdominal pain, nausea, vomiting, lethargy, and fatigue [202,207,208]. The stools are typically liquid or semiliquid and on occasion are bloody, especially if the colon is also involved. Weight loss of up to 13.5 kg (30 lb) has been reported. The abdominal pain is usually cramping and may be diffuse or localized, depending on the underlying pathology. Other reported presentations include edema of the legs and eyelids caused by protein-losing enteropathy [202] or malabsorption with steatorrhea [203,207].

The most frequent complication and often a cause of death is perforation of the small bowel [202,209]. In one series, this was the terminal event in 11% of persons with disseminated histoplasmosis [202]. Obstruction by ileocecal masses or enlarged retroperitoneal lymph nodes can also occur, as well as intussusception in association with pseudopolypoid or polypoid lesions [202,206].

Diagnostic evaluation

Involvement of the gastrointestinal tract should be suspected in the setting of blood cultures positive for *H. capsulatum*, or a positive test result for *H. capsulatum* antigen in the blood or urine [208]. For a definitive diagnosis of gastrointestinal involvement it is necessary to perform upper gastrointestinal endoscopy with duodenal or jejunal biopsy, or colonoscopy with terminal ileum biopsy or, in rare cases, surgery. The choice of biopsy site should be guided by the symptoms and the knowledge that the ileocecal region is most commonly involved; all specimens should be cultured for diagnosis [202,206].

Treatment and prognosis

In the past, cases of disseminated disease, in which small intestinal involvement is frequent, have gone on for more than 10 years without specific therapy [202]. However, this situation is less likely today because of the increased association of the disease with immunosuppression, in particular AIDS. Immunosuppressed persons often have more severe disease that progresses relatively rapidly, and death is inevitable without treatment.

Because gastrointestinal histoplasmosis usually implies widely disseminated disease, adults with gastrointestinal disease should be with treated with amphotericin B deoxycholate 0.5 mg/kg/day intravenously until clinical improvement occurs, usually in 1–2 weeks, and then they can be switched to itraconazole for the remaining course of therapy [210]. Therapy should be continued with itraconazole for 6–18 months. Patients with AIDS require maintenance therapy for life with 200 mg of itraconazole per day [211]. If amphotericin needs to be used for the duration of therapy because of the patient's inability to tolerate oral medications, the total dose of amphotericin should be 35 mg/kg given over 2–4 months. Liposomal preparations can be used instead of amphotericin B deoxycholate if the patient is refractory or intolerant to amphotericin B deoxycholate [211].

Aspergillosis

Epidemiology

Unlike histoplasmosis, which can develop in immunocompetent hosts, aspergillosis affects only severely immunocompromised patients. Factors that have contributed to an increase in the prevalence of aspergillosis include AIDS, organ transplantation, immunosuppressive chemotherapy, and the improved survival of premature infants [212]. The small intestine is involved in about 5% of patients with disseminated aspergillosis [212,213].

Etiology and pathology

Aspergillosis is a disease caused by infection with *Aspergillus*, a mold that grows by branching and longitudinal extension of wide (2–5-μm), Y-shaped, branching, septate hyphae [214]. The most common clinical isolate is *Aspergillus fumigatus*, followed by *Aspergillus flavus*. Clinical disease is produced by vascular invasion and necrosis. Lesions seen in pathological specimens or during endoscopy include linear ulcers, hemorrhagic infarcts, and necrotic mucous plaques [212,213,215].

Clinical manifestations

The data on the clinical manifestations of aspergillosis of the gastrointestinal tract are sparse because much of the information has been derived from autopsy series. The most commonly reported symptom is gastrointestinal bleeding [212,213]. Small intestinal perforation may also occur [215,216].

Diagnostic evaluation

The diagnosis is especially difficult because *Aspergillus* is not easily cultured in the laboratory, and even when it is cultured, the culture may signify only contamination or colonization [212,214]. Biopsy with histological evidence of tissue invasion is essential to verify that *Aspergillus* is the cause of the disease process. *Candida* may also be seen on histological specimens and may contribute to the disease process [213,214].

Treatment and prognosis

Disseminated aspergillosis, regardless of whether or not small intestinal involvement is present, carries a uniformly poor prognosis unless the underlying immunosuppression can be reversed [214]. It is critical for successful treatment that antibiotic therapy be started early in the course of disease. Based on a clinical trial showing improved survival with voriconazole compared with amphotericin B for the treatment of invasive aspergillosis, the recommended treatment for small intestinal aspergillosis is voriconazole 4–6 mg/kg every 12 hours i.v. followed by 200 mg twice a day by mouth once oral medication is tolerated [217]. Therapy should be continued until a clinical response occurs and, if the patient is temporarily neutropenic, until neutropenia has resolved [214]. Amphotericin B deoxycholate and lipid formulations of amphotericin are alternative therapies. In addition, caspofungin, a new echinocandin antifungal agent for salvage therapy, is also licensed in the United States for treatment of aspergillosis in patients refractory to or intolerant to the above-mentioned therapies [210].

Candidiasis

Epidemiology

Candida species are the fourth most common organisms isolated from the blood of hospitalized patients [218] and are normal colonizers of the gastrointestinal tract [219]. The organisms are commonly associated with esophageal disease in immunocompromised patients but rarely cause disease of the small intestine. Persons at highest risk include those with AIDS, chronic mucocutaneous candidiasis, or malignancies, and those taking immunosuppressive agents.

Etiology and pathology

Candida is a yeast-like fungus that reproduces by budding small (4–6-μm), thin-walled, ovoid cells. Yeast forms, pseudohyphae, and hyphae can all be found in tissue specimens. *C. albicans* is the species most often associated with disease of the small intestine. The most common lesions associated with *Candida* are single or multiple ulcerations [215,219]. Superficial erosions, bloody masses, and pseudomembranes also occur, but with less frequency. White plaques and thickened mucosal folds may also be seen on endoscopy [215].

Clinical manifestations

Candidiasis of the small bowel is rarely diagnosed antemortem, so which symptoms are attributable to fungal invasion is often unclear. The most common symptom associated with intestinal candidiasis is diarrhea [215]. Other reported symptoms include nausea, vomiting, flatulence, abdominal pain, abdominal distention, melena, and hematochezia [215,219]. Complications include perforation and penetration of intestinal ulcers [215].

Diagnostic evaluation

Because *Candida* is a normal colonizer of the entire gastrointestinal tract and even more abundant in persons at risk for disease because of decreased immune function and antibiotic treatment, a diagnosis of small intestinal candidiasis is not easily made. The mere presence of the organism on stain or culture of specimens from the small intestine does not establish the diagnosis. A biopsy specimen of the small intestine with histological evidence of invasion is necessary. *Aspergillus* may also be found on histological sections and may be part of the disease process [213,215].

Treatment and prognosis

Therapy for *Candida* infection continues to evolve, with Food and Drug Adminstration (FDA) approval of two echinocandin antifungal agents. Because of its comparable efficacy and far fewer adverse events when compared with amphotericin

in the treatment of invasive candidiasis, we recommend caspofungin 70 mg i.v. loading dose followed by 50 mg i.v. daily [220]. Therapy should continue for at least 2 weeks and until a clinical response occurs. In patients with temporary neutropenia caused by chemotherapy, treatment should not be stopped until the neutrophil count rises above 500/mm^3. Alternative therapies include: 400 mg/day of fluconazole for stable patients who are not suspected of having azole resitance; 0.6–0.7 mg/kg/day of amphotericin B; or lipid formulations of amphotericin B for patients who do not respond or have adverse reactions to amphotericin B deoxycholate. Resection of the diseased bowel or maintenance therapy may be required, especially in patients who are permanently immunosuppressed.

Mucormycosis

Epidemiology

Like gastrointestinal aspergillosis and candidiasis, small intestinal mucormycosis is most commonly found in persons with impaired immune defenses. These include patients treated with deferoxamine mesylate and immunosuppressive medications, and patients with diabetes mellitus, malnutrition, chronic renal insufficiency, burns, aplastic anemia, solid and bone marrow transplantation, malignancy, and AIDS [221–223]. Injecting drug users and premature infants may also have significant gastrointestinal mucormycosis [223,224]. Small intestinal infection is usually acquired through dissemination from a pulmonary source, although some authors have suggested that fungi can enter the body with food [221].

Etiology and pathogenesis

The usual pathogens, *Rhizopus*, *Absidia*, and *Mucor*, are ubiquitous in nature and are inhaled as spores that produce infectious particles called sporangiospores. Organisms produce disease by invading blood vessel walls, causing infarction and necrosis [222]. They can be identified by their large, nonseptate, thick-walled hyphae with right-angled branching in tissue sections [222]. In culture, they grow as fluffy molds. Mucormycosis has a predilection for certain anatomical sites, including the sinuses, orbits, brain, and lungs. Isolated gastrointestinal lesions are uncommon. Involvement of the gastrointestinal tract may occur as a part of disseminated disease. Mucormycosis may cause mass lesions resembling carcinoma, cause infarction and perforation, or involve the ileocecal region in a pattern resembling perforated appendicitis. In neonates, small bowel infarction resembling necrotizing enterocolitis has also been reported. Mucormycosis can lead to superinfection of preexisting lesions of the gastrointestinal tract, including peptic ulcers, penetrating wounds, and TB [225].

Clinical manifestations

Fever, abdominal pain, and distention are the most common symptoms [221,222]. Nausea, vomiting, hematemesis, hematochezia, diarrhea, and melena are seen less commonly. Because multiple sites of the gastrointestinal tract are often involved, it is difficult to determine which symptoms are attributable to small intestinal involvement. In one reported case with only small intestinal involvement, the only symptom was abdominal distention [221]. The physical findings may include abdominal mass lesions or signs of bowel necrosis or perforation. Intestinal perforation is the most common complication [221,222].

Diagnostic evaluation

As in other small intestinal mycoses, disease is more commonly diagnosed postmortem than antemortem [222]. A definitive diagnosis requires biopsy for culture and histological examination for evidence of tissue invasion [226]. Endoscopy may reveal ulcerations, especially in the ileum [221,227]. Culture is frequently unsuccessful, and even when it is successful, it may signify only colonization because the agents of mucormycosis are saprophytic and ubiquitous in nature.

Treatment and prognosis

In one series, 85% of patients with gastrointestinal mucormycosis died during the course of mycosis and the majority of deaths were due to bowel perforation [223]. The treatment of choice is 1.0–1.5 mg/kg/day of amphotericin B deoxycholate combined with surgical resection [228]. Lipid formulations of amphotericin B can be used in higher doses to treat patients with renal insufficiency or those not responding to initial therapy. If a clinical response to amphotericin B occurs, dosing frequency can be decreased to every other day for an unknown duration and, in fact, may be lifelong. A newly approved azole, posaconazole, is active against many of the agents of mucor and may provide another therapeutic option [228].

Definition

Celiac disease is a gluten-sensitive enteropathy. Characteristic, although not specific, abnormalities found in the small intestine are reversed by withdrawal of gluten from the diet. The disease is defined in those in whom both clinical and pathological abnormalities are reversed by gluten elimination [1]. Gluten is the term for the storage proteins of wheat. The alcohol-soluble fraction of gluten, gliadin, is toxic in celiac disease, along with similar proteins in barley (hordeins) and rye (secalins). Although the primary disease event occurs in the small intestine, the disease clinically resembles a multisystem disease [2].

Dermatitis herpetiformis (DH), an intensely pruritic, vesicular rash, is the dermatological manifestation of celiac disease. The rash is usually symmetrical, occurring on the elbows, knees, buttocks or scalp, although it can occur anywhere on the body.

Historical aspects

The word "celiac" comes from the Greek word for abdomen. Celiac disease has been known for about two thousand years, with accounts found in the writing of Aretaeus the Cappadocian in the first century AD [3].

The first modern description of celiac disease was by Gee [4] from London. In 1888 he described the disease as occurring in all age groups, although mainly in young children. He also recognized that treatment was dietary in nature. Subsequently, medical literature reflected the restriction of certain carbohydrates and use of bananas in the diet [5]. Andersen [6], in New York, determined that some children with the celiac syndrome in fact had cystic fibrosis. However, it was the Dutch physician, Dicke, who in the 1930s recognized wheat as the cause of celiac disease [7], publishing the work in Dutch in 1941 [8]. He subsequently determined that it was the protein or gluten component of wheat which was injurious [9–11].

The gluten-free diet was first used in adults in 1952 [12], although it was not uniformly accepted in the United States as a necessary therapy [13]. Greater understanding of the nature of the disease came with the recognition of the pathological finding of villous atrophy in the small intestine [14,15]. Subsequently, the development of peroral biopsy instruments in the 1950s [16] allowed widespread use of this technique to determine that the disease was the same in children and adults [17] and that the villous atrophy improved on the gluten-free diet [18]. Booth and colleagues [19] in London, in a follow-up study of children as adults, showed persistence of the intestinal lesion into adulthood, indicating that therapy of the disease should be lifelong.

It was also noted that patients may present in subtle ways, without diarrhea or the malabsorption syndrome, increasing the clinical spectrum of the disease [20]. Marsh [21] subsequently emphasized the histological spectrum of the disease.

In the last two decades the development of very specific and sensitive antibody tests (to endomysial tissue and the enzyme tissue transglutaminase) allowed the epidemiological studies that have demonstrated the worldwide occurrence and the high prevalence (approaching 1%) of the disease [22,23]. In addition these tests have allowed the diagnosis to be considered by any physician.

The immunological mechanism of the disease has also been elucidated [24], providing the potential for the development of drugs that may be used in addition to the gluten-free diet [25].

Epidemiology

Serological screening studies have revealed that celiac disease is very common, with an incidence of nearly 1% [26–30]. It is recognized in every continent including Asia [31,32], the Middle East [28,33,34], North Africa [35–37], and South America [38] and Cuba [39]. The majority of those with celiac disease are undiagnosed [26], although the rate of diagnosis is increasing [40].

Genetic factors

Celiac disease is a polygenic disease. Concordance in monozygotic twins (70%) is much higher than in major histocompatibility complex (MHC)-identical siblings (30%). Overall about 10% of first-degree relatives of affected individuals have celiac disease. This increases to 20% if there are affected sib pairs with celiac disease in the family, and even extends to second-degree relatives [41].

Human leukocyte antigen (HLA) genes confer up to 40% of the genetic risk, the rest being attributable to non-HLA genes [42]. The human major histocompatibility molecules DQ2 and DQ8 are essential genetic factors for the development of celiac disease, with the majority of patients carrying DQ2 (DQA1*05–DQB1*02). In the remaining patients, an association with DQ8 (DQA1*0301–DQB1*0302) is found [42]. A very few patients may lack DQ2 or DQ8 (DQ2 or DQ8 negative), but carry half of the DQ2 alleles, either DQA1*05 or DQB1*02.

Among Caucasians, 30%–40% carry DQ2 or DQ8 but less than 3% will develop celiac disease, suggesting that, although necessary, DQ2 and DQ8 molecules are not sufficient to mediate the disease. Non-HLA genes have been sought and candidate genes identified. There is evidence for strong linkage at 5p31-33 [43] and also, albeit to a lesser degree, at 19p13.1 [44] and 11q [45]. A small and controversial effect of the non-HLA gene *CTLA4* located on chromosome 2q33, which encodes a molecule involved in the inhibition of T-cell activation, has been reported [46,47]. Because of the linkage disequilibrium effect it is difficult to identify associations with non-MHC class II genes that are encoded within the HLA locus. However, there are indications that the *MICB*10* gene coding for MIC B molecules is associated with celiac disease [48]. There is also evidence of an association with tumor necrosis factor (TNF)2, also encoded within the HLA locus in the MHC class III region [49]. In addition, an association with a common variant located in intron 28 of the gene myosin IXB (*MYO9B*), which encodes an unconventional myosin molecule that has a role in actin remodeling of epithelial enterocytes, has been identified [50].

Environmental factors

Considerable knowledge concerning environmental factors important in the development of celiac disease was obtained from studies of an epidemic of infantile celiac disease in Sweden in the early 1980s [51]. Lack of breast-feeding, a large amount of gluten in infant formula, and ≥ 3 infections markedly increased the risk of celiac disease [52,53]. The greatest protection from celiac disease occurred when a small amount of gluten was ingested while breast-feeding was undertaken. The timing of gluten ingestion was also important in the development of celiac disease in a cohort of at-risk children studied in the United States [54]. These data form the basis of recommendations regarding breast-feeding and the timing of gluten ingestion [55]. For at-risk children, for example children with celiac disease in other family members, breast-feeding for at least 6 months is recommended, with the introduction of gluten between the fourth and sixth months. As well as protecting against the development of celiac disease, breast-feeding delays the onset and alters the clinical presentation of celiac disease in children [56,57].

Pathogenesis

Gluten is not fully digested by humans. A 33-amino-acid peptide (33-mer) and probably other immunogenic peptides remain after the action of gastric, duodenal, and pancreatic enzymes [58]. This 33-mer is considered to be immunogenic in celiac disease.

Gliadin enters the mucosa, probably during gastrointestinal infections or because of alterations in tight junction permeability by up-regulation of zonulin, a protein that induces tight junction disassembly and a subsequent increase in intestinal permeability [59]. The gliadin-induced T-cell response comprises an adaptive and an innate component [24]. The former is a DQ2/DQ8-restricted CD4 T-cell response in the lamina propria. Gliadin is a good substrate for the enzyme tissue transglutaminase [60], which can transform glutamine residues into negatively charged glutamate residues by deamidation. In this process gliadin becomes conformationally altered, facilitating binding to the groove on the surface of DQ2 and DQ8 molecules on antigen-presenting cells. Deamidation markedly enhances the CD4 antigluten T-cell response [61,62]. Interferon-γ is the main cytokine responsible for villous atrophy (Fig. 50.1). However, the role of other cytokines in the intestinal inflammatory response is not fully defined [63].

As the antigliadin response develops in the gut, antitransglutaminase antibodies appear. Their role in the pathogenesis of the disease is not clear; however, serum IgA antibodies do inhibit crypt epithelial cell differentiation [64].

The second component of the antigluten T-cell response is the intraepithelial CD8 T-cell response involving the innate immune system [25]. The model proposed for the CD8 T-cell response in the epithelium is one directed against stressed epithelial cells [25]. There are several lines of evidence sup-

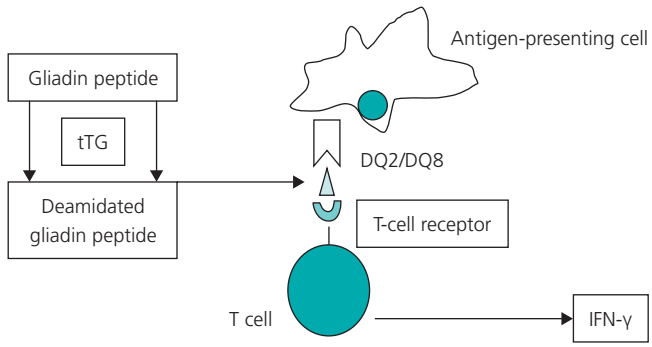

Figure 50.1 Immunological mechanism occurring in the lamina propria. Gliadin enters the lamina propria where it is deaminated by tissue transglutaminase (tTG), allowing the gliadin molecule to bind to the DQ2 or DQ8 molecule on antigen-presenting cells. Gliadin is then presented to gliadin-restricted CD4 T cells, which release interferon (IFN) and other cytokines that cause villous atrophy.

porting this model. First, intraepithelial CD8 T cells, which express the natural killer receptor NKG2D, can kill epithelial cells expressing the stress-induced MIC molecules [65,66]. Second, studies suggest that peptides not recognized by CD4 T cells can induce early epithelial changes [66,67] and induce IL-15 and MIC molecules on epithelial cells which arm the cytolytic NKG2D pathway to kill stressed epithelial cells [65,66].

It is unclear how gluten triggers the expression of stress molecules and IL-15 on epithelial cells and how the CD4 T-cell response in the lamina propria relates to the CD8 T-cell process in the epithelium.

Clinical presentation

The clinical classification of celiac disease is based on the presence of gastrointestinal symptoms. *Symptomatic* or *classical* celiac disease refers to presentations with diarrhea, with or without a malabsorption syndrome, whereas in *asymptomatic*, *atypical* or *silent* celiac disease gastrointestinal symptoms are lacking or not prominent. Females predominate over males, with a ratio of 2:1 or 3:1 [68]; however, men may have a more severe form of the disease at presentation [69]. Although the peak age of diagnosis is in the fourth and fifth decades [68], population-based screening studies from the United Kingdom revealing that 1% of both 7 year olds and adults have celiac disease suggest that celiac disease occurs in children and may remain undetected until adulthood [26,30].

The majority of those diagnosed with celiac disease have Caucasian genetic traits, although the disease has been diagnosed in Chinese people living in Canada [70], in African Americans [71], in a North American native [72], and in West Indian children living in England [73].

Younger children present with diarrhea and failure to thrive, whereas older children are more likely to present with anemia, short stature, neurological problems, and other atypical symptoms such as constipation [57].

Patients have a long duration of symptoms before diagnosis [68]. The delay in diagnosis has been attributed to physician delay rather than delay in patients seeking health care [74]. Diarrhea is the most frequent presenting symptom in adults, although the numbers of patients presenting with diarrhea has been decreasing [40,75]. Some patients present with the classical malabsorption syndrome with steatorrhea, weight loss, edema secondary to hypoalbuminemia, and hypocalcemia.

Other modes of presentation include iron deficiency [76], osteoporosis [77], and the recognition of mucosal changes in patients undergoing endoscopy for either esophageal reflux or dyspeptic symptoms [78,79], as well as screening high-risk groups including relatives of patients with celiac disease [29], type I diabetics [80], and those with Down syndrome [81]. There is increasing recognition of celiac disease as a cause of various neurological syndromes including small fiber peripheral neuropathy [82,83], epilepsy with occipital calcifications in childhood [84], and ataxia [85]. A previous diagnosis of irritable bowel syndrome is common [68], and in one study 5% of those fulfilling strict criteria for irritable bowel syndrome had celiac disease [86]. In addition, atypical presentations include rheumatological symptoms, abdominal pain, macroamylasemia, hypoalbunimemia, abnormal liver tests, and evidence of hyposplenism [2].

Abdominal pain may be severe and mimic an acute surgical condition [87]. In fact, patients diagnosed with celiac disease have a greater prevalence of surgery compared with controls. This includes a greater frequency of appendectomy, tonsillectomy, hernia repair, and cosmetic surgery. These increased surgical rates have been attributed to misdiagnosis or poor health status as well as to an impaired psychological profile [88].

Diagnosis

Traditionally, the diagnosis of celiac disease is made in an individual in whom a biopsy of the upper small intestine demonstrates the characteristic findings of villous atrophy, crypt hyperplasia, and intraepithelial lymphocytosis, and in whom there is an unequivocal clinical response to gluten withdrawal [1]. A gluten-free diet is therefore initiated when a provisional diagnosis of celiac disease is made. Patients come to biopsy because of a clinical suspicion of the disease, the presence of positive serological tests, or the recognition of abnormalities in the duodenum at endoscopy [89] (Fig. 50.2).

Serological testing for celiac disease should occur under various clinical settings (Table 50.1).

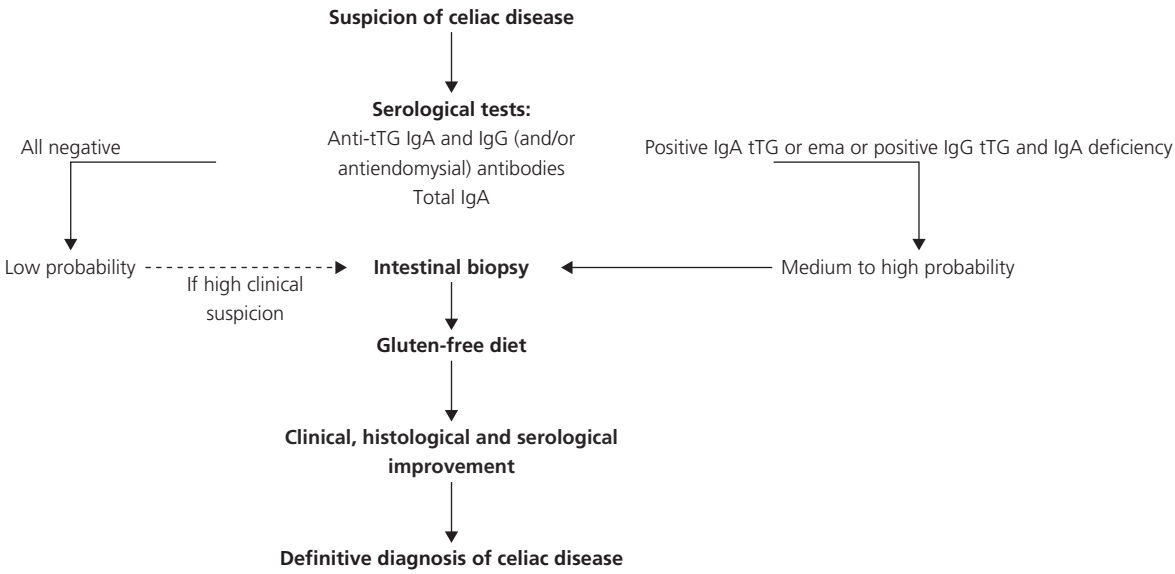

Figure 50.2 An algorithm for the evaluation of a patient for celiac disease. ema, endomysial antibody; tTG, tissue transglutaminase.

Table 50.1 Clinical indications for serological testing

Chronic diarrhea with and without malabsorption
Irritable bowel syndrome
Unexplained weight loss
Iron-deficiency anemia
Folate deficiency
Vitamin E or K deficiency
Osteoporosis
Hypocalcemia or vitamin D deficiency, secondary hyperparathyroidism, persistently low urinary calcium excretion
Unexplained elevation of transaminases
First-degree relatives of patients with celiac disease
Associated autoimmune diseases: type I diabetes, Sjögren syndrome, primary biliary cirrhosis
Down and Turner syndromes
Neurological disorders: unexplained peripheral neuropathy, epilepsy, and ataxia

Serological testing

The most sensitive tests are based on the use of IgA isotypes. The available tests include antigliadin antibodies as well as connective tissue antibodies: endomysial and tissue transglutaminase antibodies. The antigliadin antibodies have been available for many years; however, their lower sensitivity and specificity compared with the tissue transglutaminase and endomysial antibodies has resulted in their use being called into question for the diagnosis of celiac disease [90]. The role of newer generation antigliadin antibodies, specific for immunodominant epitopes of gliadin, is yet to be determined [91].

The standard test uses the IgA endomysial antibody (EMA). This is based on its very high specificity, which approaches 100%. Overall, the sensitivity of the EMA is excellent, with the majority of reports indicating greater than 90% sensitivity [90]. The EMA is detected using immunoflouresence techniques requiring either monkey esophagus or human umbilical cord as the substrate.

The recognition of the enzyme tissue transglutaminase 2 (tTG) as the autoantigen for the EMA [60] allowed the development of enzyme-linked immunoassays that are less expensive and less observer dependent than the EMA test [23]. Different commercial kits for assaying tTG have different characteristics and resultant sensitivities and specificities [92]. Overall, the sensitivity of IgA anti-tTG is greater than 90% [90]. Although the specificity of the EMA is virtually 100%, the tTG test does not achieve the same degree of specificity. There are many reports of positive tTG results in the absense of celiac disease [93–95].

Selective IgA deficiency occurs more commonly in patients with celiac disease than in the general population [96]. To detect celiac disease in those with selective IgA deficiency, a total IgA level should be incorporated into the testing for celiac disease, as well as an IgG antibody-based test, preferably IgG-tTG [97].

Several studies have revealed a lack of sensitivity of the serological tests in the clinical practice setting [86,98,99]. This is more than likely due to the inclusion of patients with lesser degrees of atrophy, a situation in which patients may not express EMA or tTG [100,101].

Antigliadin antibodies and EMA and tTG antibodies may be recovered in duodenal secretions, stool, and saliva of patients with celiac disease as well as in normal individuals and

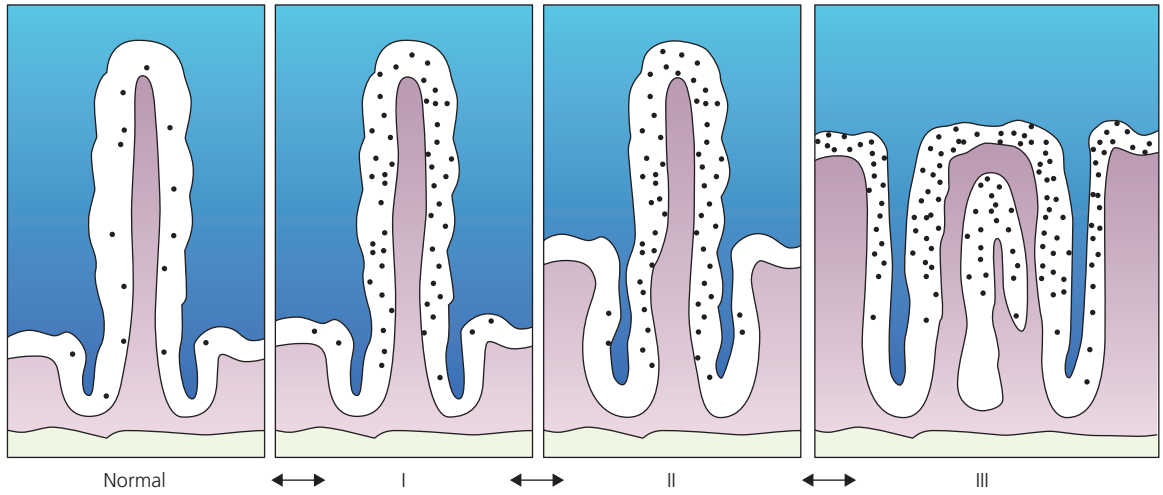

Figure 50.3 The spectrum of histological findings in celiac disease is shown diagramatically. Marsh 0 is normal with a crypt–villous ratio of 1:4. Marsh I consists of normal crypt/villous architecture together with an intraepithelial lymphocytosis (> 20 lymphocytes per 100 epithelial cells). Marsh II has, in addition to an intraepithelial lymphocytosis, crypt hyperplasia. Marsh III lesions include villous atrophy together with crypt hyperplasia and an intraepithelial lymphocytosis. Marsh III a, b and c correspond to partial, subtotal and total villous atrophy.

those with small intestinal bacterial overgrowth [102–105]; however, their value in the diagnosis of celiac disease is limited [104,106].

Biopsy and histology

Biopsy of the small intestine remains the gold standard in the diagnosis of celiac disease [107]. Biopsies of the descending duodenum rather than the more distal intestine are sufficient for the diagnosis of celiac disease [108]. The recognition of the spectrum of histological changes in celiac disease, as classified by Marsh [21], has provided a major advance in the diagnosis of celiac disease (Fig. 50.3).

The earliest lesion, Marsh I, is characterized by normal villous architecture with an intraepithelial lymphocytosis. A duodenal intraepithelial lymphocytosis is, however, not specific for celiac disease. It may be identified in giardiasis, tropical sprue, autoimmune diseases, *Helicobacter pylori* gastritis, Crohn's disease, and bacterial overgrowth [109–112]. A Marsh II lesion is identified when the intraepithelial lymphocytosis is accompanied by crypt hypertrophy. The majority of patients diagnosed with celiac disease (90%) fall into the category of Marsh III, which includes partial, subtotal, and total villous atrophy. Villous atrophy is not specific for celiac disease and may be seen in a variety of other conditions (Table 50.2).

Pitfalls in the diagnosis of celiac disease include both over- and underinterpretation of villous atrophy because of poorly oriented biopsies. Reasons for histological findings that are milder than expected include a reduced amount of gluten in the diet, as often happens in a family in which there are members with celiac disease, or the use of immunosuppressant medications.

Table 50.2 Causes of villous atrophy

Giardiasis
Tropical sprue
Collagenous sprue
Eosinophilic gastroenteritis
Combined variable immunodeficiency
HIV enteropathy
Autoimmune enteropathy
Tuberculosis
Radiation enteritis
Zollinger–Ellison syndrome
Whipple disease
Intestinal lymphoma
Crohn's disease
Other food intolerances (milk, soy, chicken, tuna as isolated case reports)

Role of HLA DQ2/DQ8 assessment

HLA DQ2 is found in up to 90%–95% of patients with celiac disease, with HLA DQ8 found in most of the remaining patients [113]. Because these HLA alleles occur in up to 30%–40% of the general population, the role of determining whether an individual carries HLA DQ2 or DQ8 rests in their high negative predictive value [114]. It is therefore of value in determining which family members should be screened, in excluding the disease when patients are already on a gluten-free diet, and when the diagnosis of celiac disease is unclear.

Associated diseases

There are many conditions associated with celiac disease (Table 50.3). These include autoimmune diseases, which occur three to ten times as frequently in those with celiac disease as in the general population [69,115,116].

Autoimmune diseases

The increased frequency of autoimmune diseases in patients with celiac disease may occur because of a common genetic and immunological mechanism as well as because of the presence of celiac disease itself. Gluten withdrawal does not protect from the development of autoimmune diseases [115], although diabetes and thyroid-specific autoantibodies may disappear in children and adolescents after starting a gluten-free diet, suggesting a relationship between the autoimmune process and gluten exposure [117]. Improvement of cardiomyopathy [118], hypothyroidism [119], or peripheral neuropathy [83] may occur on a gluten-free diet; however, generally, the associated autoimmune disorders do not improve after the diagnosis of celiac disease and treatment with a gluten-free diet. Associated autoimmune diseases include Sjogren syndrome [120] and alopecia areata [121].

Malignancy and celiac disease

Various malignancies are associated with celiac disease. These include esophageal and head and neck squamous carcinoma, small intestinal adenocarcinoma, and non-Hodgkin lymphoma [122–124]. DH also carries an increased rate of non-Hodgkin lymphoma [125]. The non-Hodgkin lymphomas are of both T- and B-cell type, occurring at both intestinal and extraintestinal sites [124–126]. A large population-based study from Sweden showed elevated risks for malignant lymphomas and small intestinal, oropharyngeal, esophageal, large intestinal, hepatobiliary, and pancreatic carcinomas [127]. A smaller study has demonstrated an increased risk for melanoma and papillary thyroid cancer [124].

The gluten-free diet is considered to be protective against the development of malignancy. Several studies have demonstrated that the increased risk for the development of lymphoma is less than previously thought [128–130], only two- to fourfold [131]. There is a reduced risk of breast cancer in celiac disease [127,132].

Hematological associations

Oxentenko et al. [76] found a high incidence (15%) of celiac disease among patients undergoing endoscopy for evaluation of iron-deficiency anemia. The same authors detected celiac disease among 8.7% of 103 patients subjected to routine duodenal biopsy at endoscopy for iron-deficiency anemia [133]. Karnam et al. [134] found a lower incidence (2.8%) of celiac disease in their prospective study of iron-deficient patients who underwent both endoscopy and colonoscopy. They concluded that all patients with iron deficiency should have duodenal biopsies routinely as celiac disease is a common etiology which is treatable [134]. In total, 5% of another series of iron-deficient anemic patients had celiac disease; all those with celiac disease had been refractory to oral iron therapy [135].

Anemia was present in 90% of children with celiac disease in an Indian series [136]. Hematological manifestations among 22 children with celiac disease included anemia alone in 19 patients (86.3%), leukopenia in two patients (9%), and thrombocytopenia in one patient (4.5%). In total, 12 patients had an iron-deficiency anemia that coexisted with zinc and vitamin B-12 deficiency [137]. Despite iron supplementation and a gluten-free diet, abnormal hematological parameters may persist [138].

Vitamin B-12 deficiency was considered rare in celiac disease. However, studies have revealed that it is common, occurring in 12% and 40% of two case series respectively [139,140].

Osteoporosis

Reduced bone density is common in patients with celiac disease [77]. A few studies have shown that screening osteoporotic patients with celiac antibodies is beneficial in diagnosing patients with silent celiac disease [141]. The prevalence of celiac disease in patients with osteoporosis has been found to be 2%–7%. Worsening T scores have also been found to correlate with more severe celiac disease [77,142]. Among 431 patients presenting for bone density determination, the prevalence of celiac disease was 1.2% in patients with osteopenia and 2.1% in those with osteoporosis [143]. The yield from screening postmenopausal patients with osteoporosis for celiac disease is low and not considered worthwhile [144].

Rheumatological manifestations

Among the extraintestinal manifestations of celiac disease, arthritis is common. There have been many case reports of arthritis being the presenting symptom in both adults and children [145–149]. In one study, systematic examination of patients with celiac disease revealed arthritis to be common; arthritis was present in 26% of 200 celiac patients compared with 7.5% of control subjects. There was also a higher incidence of arthritis among untreated celiac patients. The arthritis was seronegative and oligoarticular, similar to the other enteroarthritides [150]. Bone scintigraphy was carried out to detect early acute inflammatory lesions in 22 adult celiac patients and was positive for sacroiliitis in 14 cases (63.6%) [151]. An increased prevalence of celiac disease in juvenile chronic arthritis is controversial [152,153].

Luft et al. [154] tested the sera of patients with various rheumatological disorders including Sjögren syndrome, rheumatoid arthritis, systemic lupus erythematosus (SLE), and systemic sclerosis for the presence of tissue transglutamin-

ase antibodies and found an increased incidence (10%) of celiac disease only among patients with Sjögren syndrome. Similarly, Rensch et al. [155] screened patients with SLE for antigliadin and antiendomysial antibodies and found no patients with endomysial antibodies. They did find that 23% of patients were positive for antigliadin antibodies but that they had no evidence of celiac disease [155].

Neurological disorders

Neurological symptoms as a presenting feature of celiac disease have become increasingly recognized. The associations discussed in this chapter are not the result of vitamin or mineral deficiency states. When neurological symptoms occur in those with celiac disease, vitamins E and B-12 deficiency need to be excluded as well as copper deficiency.

The most well-documented neurological associations are with peripheral neuropathies, ataxia, and epilepsy. The celiac neuropathy is typically a sensory, small fiber neuropathy. One study reported that 23% of patients with celiac disease who were well controlled by diet had peripheral neuropathy compared with a 4% occurrence rate in the control group [156]. At a tertiary care referral center, celiac neuropathy was found in 2.5% of the patients evaluated for neuropathy [82]. Furthermore, celiac disease was found in 5% of patients with symptoms of neuropathy *and* normal electrodiagnostic studies, making celiac disease an important diagnostic consideration in the evaluation of small fiber or idiopathic sensory neuropathies [82,83].

Ataxia is one of the neurological syndromes more frequently associated with celiac disease [157,158] – it is often not suspected because of a lack of gastrointestinal symptoms or signs of malabsorption. The frequency of biopsy-confirmed celiac disease in patients with ataxia of unknown origin is about 12% [159]. One series, however, found no celiac disease-associated antibodies in 32 patients with idiopathic cerebellar ataxia [160]. Celiac disease-associated ataxia often lacks particular clinical features that would distinguish it from other forms of cerebellar ataxia [161]. Severe ataxia in association with celiac disease may respond to intravenous gamma globulin [85].

Epilepsy is recognized more in association with childhood celiac disease than with adult celiac disease [162–164]. Two large studies of adults with celiac disease failed to detect an increased association with epilepsy [165,166]. The syndrome of occipital calcification, epilepsy, and celiac disease may be reversed with a gluten-free diet [84,167,168].

Blood test abnormalities

Various blood test abnormalities have been associated with celiac disease. The more common ones include hyperamylasemia, abnormal liver function tests, and hypocholesterolemia.

Elevated serum amylase, due to macroamylasemia, has been found more commonly among untreated celiac patients than among those on a gluten-free diet [169]. In cases of recurrent pancreatitis, abnormalities of cholecystokinin, impaired secretin release, and papillary stenosis have been proposed [170].

Abnormal liver tests have been frequently associated with celiac disease. In particular, hypertransaminasemia (aspartate aminotransferase, alanine aminotransferase) may be present in up to 40% of patients, both adults and children, and is usually reversible with a gluten-free diet [171–174]. Celiac disease is detected as the cause of about 10% of cases of cryptogenic hypertransaminasemia [175,176]. The exact etiology of the liver abnormalities is unknown. Biopsies have shown nonspecific hepatitis as well as steatosis.

It is not a surprising finding that patients with celiac disease often have low cholesterol levels. Ciacci et al. [177] reviewed 100 patients with hypochromic anemia who did not have diarrhea and found an inverse correlation between cholesterol level and prevalence of celiac disease. All patients with celiac disease were found to have cholesterol levels below 156 mg/100 mL. They suggested that, among patients with hypochromic anemia, high or high–normal cholesterol could possibly be used to exclude celiac disease [177]. Lower low-density lipoprotein (LDL) levels have been found in patients with celiac disease and these levels did not necessarily rise on a gluten-free diet [178].

Oral and facial manifestations

Celiac disease may be manifested in the mouth by Sjögren syndrome [120], recurrent aphthous stomatitis [179–182], and dental enamel defects [183,184].

A large forehead has been proposed to be a sign of celiac disease [185]. This is due to failure of growth of the visceral cranium after weaning, resulting in the middle third of the face being proportionally smaller than the forehead.

Inflammatory bowel disease

Celiac disease is associated with both ulcerative colitis and Crohn's disease [186–188]. Inflammatory bowel disease was a major cause of death in a population-based study of causes of death of patients with celiac disease in Sweden [189].

It may be difficult to distinguish celiac disease from duodenal involvement by Crohn's disease because of similar endoscopic and biopsy appearances [190,191]. In addition, serological tests considered specific for Crohn's disease may be seen in celiac disease and vice versa. Anti-*Saccharomyces* antibodies can be seen in celiac disease and antitissue transglutaminase antibodies in Crohn's disease [94,192,193].

Liver disease

As well as causing an elevation of serum transaminases in adults and children [171,174,194], celiac disease is associated with primary biliary cirrhosis [195], autoimmune hepatitis [196], and autoimmune cholangitis [197]. Celiac disease identification and treatment in liver transplantation candidates reverses liver failure [198]. Hepatitis C is also associated

with celiac disease and may become evident after treatment with interferon [199,200].

Endocrine disorders

There is a well-established association of celiac disease with type I diabetes mellitus, such that many centers regularly screen for celiac disease [80]. Autoimmune thyroid disorders [119] and Addison disease are also associated with celiac disease [201].

Therapy of celiac disease

The medical treatment for celiac disease is lifelong adherence to a gluten-free diet. Patients are advised to avoid all gluten; however, there is some controversy over what this entails. Wheat is now ubiquitous in the Western diet. The amount of gluten in a slice of bread is considered to be 2.25 g [21] and the mean daily gluten intake in the general population in Western Europe is 13 g [202]. Washed wheat starch, which contains trace amounts of gluten, is allowable in the gluten-free diet in some European countries [203], but not in the United States [204] or in Australia where the standard is "no detectable gluten" [205]. In Finland studies have demonstrated that even naturally occurring gluten-free foods may have traces of detectable gluten [206].

There may be differing degrees of sensitivity or tolerance levels among different patients with celiac disease. However, inflammatory changes occur rapidly, within hours, of gluten instillation into the duodenum [207]. Infusion of gliadin into the small intestine of those with celiac disease indicates that that there is a dose response, with 10 mg of gliadin not eliciting an inflammatory reaction but 100 mg resulting in damage [208]. In Finland, where the gluten-free diet is considered to contain the equivalent of 30 mg of gluten daily, most patients do exceptionally well. Biopsies normalize [203] and, overall, patients who follow a gluten-free diet do not have an increased mortality rate [209]. The basics of the diet are shown in Table 50.3.

There is considerable confusion among some patients and their dietary advisors about the safety of some foods. Vinegars and distilled alcohol are safe. Grains such as corn, rice, quinoa, buckwheat, and millet are not related to wheat, rye, or barley and therefore are considered safe. These grains are an important cornerstone of the gluten-free diet. They provide texture, fiber, iron, and B vitamins. Flour from wheat, rye, and barley is usually fortified with iron, thiamin, riboflavin, and niacin; however, the gluten-free substitutes are frequently rice based and are not usually fortified. As a result the gluten-free diet is low in B-complex vitamins and iron [210] and after 10 years on a gluten-free diet patients frequently have evidence of poor B-vitamin status [211]. A gluten-free diet may also be low in fiber [210]. Inclusion of gluten-free alternative grains provides both variety to the diet as well as texture, fiber, and nutrients.

Table 50.3 Fundamentals of the gluten-free diet

Safe grains	Toxic grains
Amaranth	Wheat (includes spelt, kamut, semolina, triticale)
Buckwheat	Rye
Corn	Barley (including malt)
Millet	
Quinoa	
Sorghum	
Teff	
Oats	

Gluten-free starch (flour) alternatives

Cereal grains (seeds of cultivated grasses): amaranth, buckwheat, corn (polenta), millet, quinoa, sorghum, teff; rice (white, brown, wild, basmati, jasmine); Montina (Indian ricegrass)
Tubers (swollen underground plant stem): arrowroot, jicama, taro; potato (white, sweet); tapioca (cassava, manioc, yucca)
Legumes (edible seeds from a pod): beans including chickpea, lentil, kidney, navy, peas, peanuts, soybean
Nuts (edible kernel of a hard shell): almonds, walnuts, chestnuts, hazelnuts, cashews
Seeds: sunflower, flax, pumpkin

Problem area: food additives (label reading)

Additives to avoid	Safe additives
Wheat starch	Citric acid
Modified food starch (from wheat)	Maltodextrin
Malt, malt flavoring	Dextrin
Malt vinegar	Vinegar
Hydrolyzed vegetable or plant protein	Mono- and diglycerides
Soy sauce	Artificial colors and flavors
	Natural colors and flavors
	Monosodium glutamate
	Carmel color

Oats remain a dilemma for patients. Multiple studies have demonstrated that most patients with celiac disease or DH tolerate oats [212–214]. However, a few patients (only three in total) with celiac disease have been shown to mount an immune response to oats [215,216]. One problem is that oats may be contaminated with other gluten-containing grains, even brands considered to be gluten free [217].

Nutrition counseling of an individual with celiac disease must be an all-inclusive event and is probably the most important aspect of the diagnosis. Also important are a review of eating and shopping behaviors, a social/emotional assessment, and an in-depth educational component. Knowledge of the diet is gradually acquired and, as a result, follow-up nutritional counseling is important, as is follow-up medical care [218].

Patients are faced with many problems including inadequate food labeling for wheat or gluten, lack of information while eating out of the home in restaurants, use of gluten-containing products in medications, and conflicting information available from physicians, nutritionists, support groups, and the internet [219,220].

Vitamin supplementation with gluten-free forms is reasonable, especially because the major gluten-free flours are not fortified with vitamins. The routine use of pneumococcal vaccination is not established, although the high rate of hyposplenism argues for its use [221]. Bone mineral density assessment is standard as is the use of calcium supplements. If osteoporosis or hypocalcemia is present, measurement of fat-soluble vitamins, serum ferritin, vitamin B-12, and serum parathyroid hormone are necessary.

Follow-up management includes monitoring of serum antibodies, which usually normalize between 6 and 12 months after commencement of the gluten-free diet. Follow-up biopsy, although not necessary for diagnosis, is reasonable to assess the response to the diet. This is often performed too early. If the serum antibodies remain elevated, further dietary counseling is necessary. Repeat biopsy should be performed after 1–2 years. Follow-up dietary/nutritional counseling should be an annual event.

Refractory celiac disease/sprue

Before considering refractory sprue, a systematic approach to the evaluation of the poorly responsive patient needs to be undertaken [222]. Table 50.4 provides a list of the causes of a poor response to the diet. The most important part of the evaluation of the poorly responsive patient is a thorough dietary evaluation for both intentional and unintentional gluten ingestion. The presence of positive antibodies argues for persistent gluten ingestion.

Table 50.4 Causes of poorly responsive celiac disease

Incorrect diagnosis
Gluten ingestion (intentional or unintentional)
Microscopic colitis
Lactose intolerance
Pancreatic insufficiency
Bacterial overgrowth
Other food intolerances (fructose, milk, soy)
Inflammatory bowel disease
Irritable bowel syndrome
Anal incontinence
Collagenous sprue
Autoimmune enteropathy
Refractory sprue (+/– clonal T cells)
Enteropathy-associated T-cell lymphoma

Bacterial overgrowth [223], pancreatic insufficiency [224], and microscopic colitis are important causes of treatment failure in celiac disease [225]. Thorough assessment with breath tests for bacterial overgrowth and lactose intolerance, colonoscopy to rule out inflammatory bowel disease and microscopic colitis, and computed tomography (CT) scanning of the abdomen are part of the evaluation. The last will exclude the presence of significant lymphadenopathy or the rare lymph node cavitation syndrome [226].

Refractory celiac disease or sprue is considered to occur if patients have persistent diarrhea and villous atrophy despite a gluten-free diet for at least 6 months [227]. The term refractory sprue was coined because it was unclear whether all patients had celiac disease; some lack the crucial component of the diagnosis of celiac disease, that is a response to the gluten-free diet. Studies have demonstrated that some patients who are refractory to the diet have an aberrant intraepithelial T-cell population which lacks normal lymphocyte surface markers and exhibits restricted T-cell receptor (TCR) gamma gene rearrangements [228]. These patients are considered to have a type 11 refractory sprue with clonal intraepithelial T cells, whereas type 1 patients have polyclonal (normal) T cells [229]. The type 11 patients are considered to harbour a cryptic T-cell lymphoma and have a high mortality rate and a high rate of progression to enteropathy-type T-cell lymphoma [229,230]. Therapy of patients with refractory celiac disease may include steroids, either alone or in combination with azathioprine [231,232], cyclosporin (ciclosporin) [233], and infliximab [234]. Innovative therapies have been tried in refractory celiac disease, including an elemental diet [235] and recombinant IL-10 [236]. Because of the poor response of patients with refractory sprue to the above therapies, the use of stem cell transplantation is under trial [229]. The approach that we use is that of steroids and azathioprine as the initial therapy. Cyclosporin and infliximab are used as second-line therapies.

Quality of life issues

Because of the restraints encountered with adherence to a gluten-free diet, quality of life is an important issue. Those surveyed in the United States reported an improvement in quality of life after diagnosis of celiac disease and commencement of a gluten-free diet [68]. Even those diagnosed in Finland as asymptomatic, screened relatives reported an improvement in quality of life [237]. However, other studies report an impact on aspects of the quality of life. The disease and diet impact on the quality of life of females rather than males [238], those with gastrointestinal symptoms [239], and those who are less compliant [240]. An impact was also reported on activities such as dining out, social functions, and travel [241,242]. As a result, compliance with the diet remains an issue, especially in the social setting [68].

Conclusions

Celiac disease is common. The only therapy currently available is the gluten-free diet. This diet is burdensome and the development of medications that help with the diet is both feasible and attractive to patients [25].

C SMALL INTESTINE

51 Disorders of epithelial transport in the small intestine

Martín G. Martín, Ernest M. Wright

Disorders of carbohydrate assimilation, 1260
Disorders of amino acid and peptide assimilation, 1266
Disorders of fat assimilation, 1269
Disorders of mineral and electrolyte absorption and secretion, 1272
Disorders of vitamin absorption, 1277

Disturbances in intestinal nutrient and ion assimilation can lead to clinical symptoms that range from severe life-threatening diarrhea in a neonate to neurological deficits in adulthood. With the exception of lactose intolerance, most disorders of nutrient assimilation are both exceedingly rare and inherited in an autosomal recessive manner. Milder forms of all these disorders may be subtle and not diagnosed until well into adulthood. Given their genetic basis, disorders of nutrient assimilation should be entertained particularly when there is a history of consanguinity, even in the absence of other similarly afflicted family members.

Chronic diarrhea is the most common clinical manifestation of disorders that are secondary to abnormalities of nutrient digestion and absorption (Fig. 51.1) [1]. Categorizing the type of diarrhea into either malabsorptive or secretory is a useful first step in the evaluation of any patient with chronic diarrhea. Subclassifying the diarrhea may be done with either a trial of fasting, or by analysis of stool electrolytes while the patient is on a full diet. To calculate the stool osmotic gap, either cations such as Na^+ and K^+ or anions such as Cl^- and HCO_3^- may be measured in liquid fecal samples [2,3]. If the sum of twice the value of cations (or anions) is lower (< 50 mOsm/L) than the predicted osmolarity (290 mOsm/L), an osmotic gap is present, and the patient is malabsorbing dietary nutrients. In contrast, a low osmotic gap (< 50 mOsm/L) is seen in secretory diarrheas, which are generally large volume (1–3 L) and fail to abate with fasting.

Nutrient-specific malabsorption is an important characteristic of all inherited transport disorders but is generally not a feature of some of the more common chronic diarrheal disorders. However, defects of pancreatic and brush-border

enzyme function share many of the clinical characteristics seen in transport defects and will also lead to maldigestion and diarrhea of specific complex nutrients. In contrast, generalized malabsorption (i.e., not nutrient specific) occurs in the clinical setting where the overall intestinal absorptive capacity is insufficient adequately to handle a dietary load that is required to maintain appropriate growth and development [4]. Nonspecific abnormalities of intestinal absorption most often occur when either small bowel surface area is inadequate (i.e., short bowel syndrome) or when intestinal transit time is too short to allow for adequate nutrient assimilation. For instance, enteropathies such as hypersensitivity

to cow's milk proteins, celiac disease, and even more unusual disorders, such as autoimmune enteropathy, microvillus inclusion disease (Mendelian Inheritance in Man [MIM] #251850), and immunodysregulation-polyendocrinopathy-enteropathy (MIM #304790), generally present with features of nonspecific malabsorption [5,6]. In fact, the majority of patients with abnormal intestinal histology have a mixed form of diarrhea that has both osmotic and secretory components. Therefore, the identification of normal small bowel histology is an essential part of the evaluation of all patients with presumed defects of nutrient assimilation.

Secretory diarrhea is due to an imbalance between absorption and secretion of electrolytes, and the resulting elevated lumenal concentration of ions drives the influx of water to reach isoosmolar conditions with serum. During early infancy, chronic diarrhea that is purely secretory in nature is the result almost exclusively of a small number of transport disorders and is not secondary to a defect of enzymatic function, as is frequently seen in maldigestive diarrhea. Several hormone-secreting tumors may present with severe secretory diarrhea and need to be distinguished from two disorders of intestinal transport, namely congenital chloride diarrhea (MIM #214700) and congenital sodium diarrhea (CSD) (MIM #270420) [7,8].

Disorders of carbohydrate assimilation

Complex sugars are digested initially by salivary and pancreatic α-amylases and further by brush-border enzymes into monosaccharides, which are absorbed in the small intestine (Fig. 51.1). Enterocytes, which are renewed every 6 days, express the enzymes and transporters needed for carbohydrate digestion and absorption. The apical brush-border membrane of enterocytes contains various saccharidases including glucoamylase, sucrase-isomaltase, and lactase-phlorhizin hydrolase (LPH), the Na^+-dependent glucose–galactose cotransporter (SGLT1), and the fructose uniporter (GLUT5). The basolateral membrane contains the glucose–galactose–fructose uniporter (GLUT2) and the Na^+,K^+-ATPase, which maintains the low intracellular Na^+ concentration by extruding Na^+ into the blood in exchange for K^+ [9]. This Na^+,K^+-ATPase provides the potential energy required for the movement of sugars and amino acids up their steep concentration gradients across the apical membrane of the enterocyte. For instance, the low intracellular concentration of Na^+ provided by the pump enables the influx of Na^+ to be coupled to the movement of glucose up its own osmotic gradient by the active transporter SGLT1. By contrast, fructose is passively transported, moving down its own osmotic gradient, across the intestine by the brush-border uniporter (GLUT5) and by the basolateral GLUT2 uniporter.

Disturbances of carbohydrate assimilation may be secondary to defective enzymatic processing of complex sugars and disaccharides or failure to transport monosaccharides across the apical membrane (Fig. 51.1). Carbohydrate intolerance is characterized by diarrhea that subsides shortly after carbohydrates are reduced or eliminated from the diet. Therefore, abnormal carbohydrate assimilation results in the presence of major osmotic forces in colonic lumenal fluid derived from oligosaccharides, lactose, sucrose, or glucose. Unabsorbed carbohydrates are fermented by the resident colonic microflora to gas (hydrogen, methane, and carbon dioxide) and volatile short-chain fatty acids (SCFAs) such as acetate, butyrate, and propionate. A proportion of these SCFAs are absorbed across the colonic epithelium by poorly defined diffusion and transporter-mediated mechanisms [10]. The absorbed SCFAs are metabolized preferentially by colonic epithelia, where they are an important energy source and also facilitate the absorption of NaCl. Therefore, SCFA absorption leads to a reduction of lumenal osmolarity and thereby facilitates the colonic absorption of water. Nevertheless, diarrhea may result when the ileal effluent exceeds the salvaging capacity of the colon. Specifically, the passage of unabsorbed and unfermented carbohydrates and SCFAs into the distal colon provides an additional osmotic load that results in the retention of water in the gut and subsequent diarrhea.

Lactose intolerance

Abnormalities of carbohydrate assimilation can be categorized into four general forms:

- ontogenic forms that result from the normal immaturity of digestive functions during the early stages of life
- developmental forms that change at the time of weaning
- genetic forms that are congenital conditions
- acquired forms that are preceded by a variable period of normal function – particularly true for lactose intolerance resulting from either the synthesis of defective lactase-phlorhizin hydrolase or reduced expression, which may be secondary to a developmental stage or an inflammatory or infectious condition.

Lactase-phlorhizin hydrolase (LPH) (Enzyme Commission [EC] 3.2.1.108) is a large 1972-amino-acid protein whose short hydrophobic carboxyl terminus spans the brush border membrane once, with the majority of the protein situated lumenally (Fig. 51.2). Details of the synthesis and processing of the polypeptide as it proceeds from the endoplasmic reticulum to its final destination as an active hydrolase on the apical membrane have been thoroughly studied [11]. The precursor molecule is *N*- and *O*-glycosylated and eventually proteolytically cleaved at two locations, yielding a mature 145-kDa LPH enzyme protein with two distinct enzymatic sites for lactase and phlorizin hydrolysis [12]. The enzyme hydrolyzes the β-1,4-glycosidic linkage of lactose to yield glucose and galactose.

Lactase-phlorhizin hydrolase is produced predominantly in the small intestine, where it has a distinct pattern of expression along the proximo-distal axis of the intestine. Mature

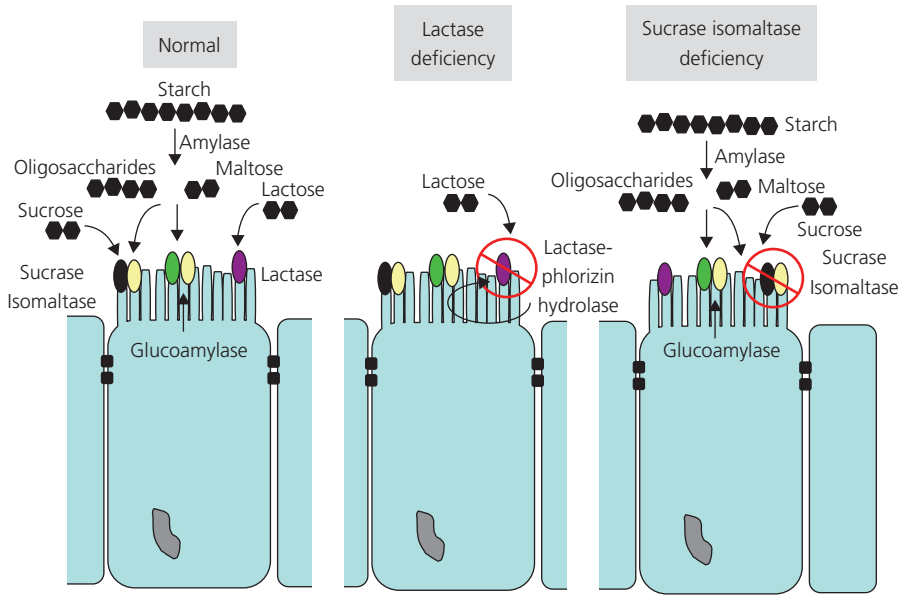

Figure 51.2 Disorders of disaccharidase deficiency.

protein is localized to enterocytes along the entire length of the villus, and is most abundant along the distal duodenum and jejunum [13]. The spatial and developmental pattern of LPH expression is regulated mainly at the level of transcription and appears to be orchestrated largely by several transcription factors that bind specific elements located in the immediate promoter region of the human and rodent lactase gene (*LCT*) promoters, including caudal-related homeodomain proteins (Cdx-2), hepatocyte nuclear factor 1 (HNF-1), and GATA-4/5/6 [14,15].

Genetics and molecular pathophysiology

Hypolactasia

In all mammals, lactase activity dramatically declines at the time of weaning, spurring the drive toward a more diversified diet depleted of lactose [16]. Several studies have indicated that the developmental regulation of lactase expression is hard-wired, and is not significantly modified by exposure to lactose-containing dietary load [17]. Hypolactasia (MIM #223100), or lactase nonpersistence, results from this hard-wired developmental decline of LPH activity that occurs in the majority of humans at a prevalence that varies based on race and ethnicity [18,19]. Lactase levels decline by as much as 90% as early as 3 years of age in children from Thailand and Bangladesh, and 10 years of age for others of Asian, African, and Latin descent [20].

By contrast, the continued presence of high levels of lactase activity throughout adulthood has been called lactase persistence, and is generally limited to descendants of people originating from northwest Europe and certain tribal regions in Africa, and is believed to result from the ability to bypass the normal developmental decline in LPH activity [16]. Several kindreds and isolated inhabitants within either lactase-persistent or lactase-nonpersistent populations have been carefully characterized and the findings suggest that lactose tolerance is determined by a homozygous inheritance of an autosomal recessive allele.

Several single-nucleotide polymorphisms along various regions of the *LCT* gene have been identified; however, no polymorphisms have been identified in either the vicinity of the *LCT* gene or its immediate promoter region that could be associated with either lactase persistence or nonpersistence. Therefore, it is generally assumed that the normal decline in LPH activity at weaning is secondary to changes in the abundance of the transcriptional factors that bind the immediate promoter region of LCT and alter its rate of transcription.

The long-sought breakthrough in understanding the molecular basis of lactase nonpersistence was made with linkage disequilibrium analysis of nine well-characterized Finnish families [19]. Sequence analysis revealed two distinct areas of sequence variability that are precisely associated with low levels of lactase activity. Specifically, C/T-13910, a DNA variant located 13 910 base pairs upstream from the *LCT* gene, and a G/A-22018 polymorphism located 8 kb further upstream, showed complete cosegregation with the nonpersistence trait. The C/T-13910 variant was also associated with hypolactasia in a large cohort of non-Finnish subjects in four different populations.

The T-13910 polymorphism is associated with lactase persistence in the European population but not in African descendants, whereas the C variant is limited to the nonpersistence population [16]. These polymorphisms are located in a potent enhancer whose transcriptional activity is augmented by the T variant, which binds Oct-1 isoform of the octamer family of transcription factors with greater avidity than the C variant [21,22]. Binding sites for other transcription

factors, including HNF-4, GATA, and Fox, were identified in the vicinity of the -13910 polymorphism. It is believed that in the presence of the T variant, this transcriptional enhancer is of sufficient potency to sustain LPH activity despite the natural age-dependent decline that is driven by elements residing in the gene's immediate promoter region.

Congenital lactase deficiency

The rarest form of lactose intolerance is the autosomal recessive congenital form (MIM #223000), which presents during the immediate postnatal period as severe watery diarrhea while the infant is on a lactose-containing diet [18,19]. This form can be distinguished clinically as a selective lactase deficiency because symptoms subside on a non-lactose-containing diet. Mucosal lactase levels are exceedingly low in the presence of normal intestinal histology. Five distinct mutations have been identified in the coding region of the *LCT* gene, including three nonsense mutations and two missense mutations that alter highly conserved residues that may be important for either the protein's catalytic activity or its three-dimensional structure [23].

Developmental or neonatal lactase deficiency

Activity of LPH is detectable as early as 26 weeks of gestation and increases dramatically in full-term neonates. Relative lactase deficiency and lactose intolerance has been described in premature infants less than 34 weeks of gestation, because lactase is the final disaccharidase to develop in premature infants. In a prospective randomized study, administration of lactase to this population was shown to result in improved weight gain and was without complications [24]. Similarly, a low-lactose diet has been shown to improve feeding tolerance, including weight gain and caloric intake, in premature infants [25].

Secondary lactase deficiency

Lactase deficiency that results from a concomitant condition is considered secondary. Common causes of secondary lactase deficiency are an assortment of infectious, allergic, and inflammatory conditions. Rotavirus is a common cause of short-term selective lactose intolerance that results from injury to lactase-containing enterocytes residing in the tips of the villi. Parasitic infections, including giardiasis, are also common causes of this form of lactose intolerance. Celiac and Crohn's disease may have lactose intolerance as one of their prominent signs and should be considered when intolerance is identified with other symptoms (e.g., weight loss, hematochezia).

Clinical manifestations

The most common symptoms associated with lactose intolerance are nausea, crampy abdominal pain, distention, excessive flatulence, and diarrhea, which begin as early as 30 min following the ingestion of lactose. The severity of symptoms depends on both the lactose load and the residual absorptive capacity of the intestine, which may vary depending on the subject's age and ethnicity.

Diagnostic criteria or laboratory investigations

The diagnosis of lactose intolerance is suggested by the resolution of clinical symptoms when subjects are placed on a strict lactose elimination diet for 2 weeks, and the recurrence of symptoms once lactose is reintroduced. However, it should be recognized that dietary history is frequently unreliable as a means of establishing the diagnosis of lactose intolerance [26]. The inconsistency of dietary history has been attributable to several factors including the patient's age, dose of lactose, and confounding clinical conditions.

A stool test that can be used to assess for carbohydrate malabsorption includes pH and the presence of reducing substances (Clinitest). Carbohydrate malabsorption and subsequent colonic bacterial fermentation result in the synthesis of high concentrations of SCFAs, which leads to the acidification of stool (pH < 5.3) [2]. Small bowel biopsies should be considered if there is a high suspicion for secondary lactose intolerance in the presence of diarrheal symptoms lasting longer than 4 weeks. Mucosal histology may assist in identifying the cause of the secondary lactose intolerance whereas disaccharidase enzyme activity can be used to assess whether there is a selective lactase deficiency or a general decline in some or all disaccharidases.

Carbohydrate breath hydrogen testing is an easily performed test that may assist in the diagnosis of several types of carbohydrate malabsorption disorders, including lactose, sucrose, glucose, and fructose malabsorption. The test relies on the colonic fermentation of unabsorbed carbohydrate by bacteria that produce methane, hydrogen, and carbon dioxide gas. This gas chromatographic analysis quantifies the level of hydrogen gas in exhaled air following the administration of either lactose at 2 g/kg bodyweight or a maximum of 25 g. An elevation of more than 20 p.p.m. above the fasting baseline is consistent with the diagnosis of lactose intolerance [27]. Genetic tests have been developed to assess for the homozygote CC (-13910) genotype that is associated with hypolactasia. Several studies have confirmed that genotyping is as reliable as breath hydrogen testing in adults and older children [25].

Treatment

As with all other disorders of carbohydrate assimilation, symptoms resulting from lactose intolerance may be minimized by the avoidance of milk and dairy products. Commercially available milk products that are either lactose-free or contain a reduced lactose content, including rice and soy-based products, may be used as substitutes. Because the malabsorptive symptoms are dose-dependent, the consumption of small quantities 100–200 g (4–8 oz) may be encouraged, either alone or with the use of oral lactase replacement. Milk

and other dairy products are rich dietary sources of calcium and vitamin D, hence alternative sources of these vital nutrients should be recommended to patients with lactose intolerance that severely limits their intake of dairy products, to reduce the long-term risk of abnormal bone density and fractures.

Sucrase-isomaltase deficiency

Sucrase-isomaltase (SI) (EC 3.2.1.48/10) is a type II integral membrane glycoprotein that forms a noncovalent homodimer complex. The human isoform is an 1827-amino acid polypeptide that undergoes posttranslational glycosylation prior to sorting to the apical membrane, where it is further processed by lumenal proteases to sucrase and isomaltase (Fig. 51.2). These functional subunits remain associated by means of hydrostatic interactions, with the isomaltase site hydrolyzing the α-1,4-glycosidic linkage of maltose and the α-1,6 glucose bonds of α-limit dextrins and isomaltose. By contrast, the sucrase site cleaves the α-1,4-glucose bonds of maltotriose and maltose and the identical linkage of sucrose into glucose and fructose. Redundant hydrolysis of the α-1,4-glucose linkage is provided by maltase-glucoamylase; however, 80% of the intestinal maltase activity is provided by sucrase-isomaltase.

Extensive studies done primarily in rodents have successfully defined the transcriptional basis of the spatial, developmental, and dietary regulation of SI [28]. The 5′-flanking region of the *SI* gene contains many functional cis-acting DNA elements that are sufficient to drive SI expression in the appropriate tissue and developmental-specific manner. The transcriptional factors that bind to the immediate promoter region of the SI gene include HNF-1, Cdx2, and GATA-4, which work in a combinatory manner to drive appropriate expression [29].

Sucrase-isomaltase expression changes during development and is modulated by diet. In humans, SI expression is measurable in the small bowel by the end of the first trimester, whereas in rodents it remains undetectable until the time of weaning, when it is dramatically induced [28]. This developmental pattern of expression is hard-wired and is controlled by cis-elements within the 5′-flanking region of the *SI* gene. Expression of SI is also induced by both corticosteroids and the introduction of either sucrose or starch to the diet [30].

Genetics and molecular pathophysiology

A deficiency of sucrase-isomaltase may result from either a selective congenital deficiency (MIM #222900) or as a global decline in disaccharidase activity that occurs with infection and inflammation. Secondary SI deficiency may result from the general decline in small bowel surface area associated with villus blunting, or because of transcriptional repression that can be induced by cytokines such as interleukin-6 (IL-6) and γ-interferon (IFN-γ) [31].

Congenital sucrase-isomaltase deficiency (CSID) is a rare autosomal recessive disorder that leads to malabsorptive diarrhea with the ingestion of sucrose and oligosaccharides [32]. Sucrase-isomaltase deficiency is particularly common among Eskimos in Greenland and Alaska, being estimated to occur in about 10% of this population. Multiple germ-line mutations have been identified in patients with CSID that result in a decline in sucrase or isomaltase activity (or both). Specifically, mutations have been characterized that result in either a selective decline in enzymatic activity, or abnormalities in the processing and sorting of the SI protein [33]. Mutations that alter protein targeting will result in a combined decline of sucrase and isomaltase activity [34].

Diagnostic criteria or laboratory investigations

The resolution of chronic diarrheal symptoms in a patient on a strict sucrose and glucose polymer-free diet is suggestive of the diagnosis of CSID. Diarrhea induced by large complex carbohydrates is usually an indication of abnormal exocrine pancreatic function, such as is seen with cystic fibrosis, but may also be attributed to a deficiency of glucoamylase synthesis or CSID [35,36]. Distinguishing between these various disorders can be accomplished by analyzing small bowel disaccharidase activity and with carbohydrate-specific breath hydrogen testing [27]. A selective deficiency of mucosal sucrase activity would be consistent with the congenital form of this disorder, whereas a general decline in multiple disaccharidases would suggest a secondary form of SI deficiency. Breath hydrogen testing can also be performed with sucrose; however, evidence of malabsorption should be followed by testing with each monosaccharide (glucose and fructose) to confirm the specific disaccharidase deficiency.

Clinical manifestations and treatment

The majority of patients will present in infancy with chronic malabsorptive diarrhea and failure to thrive. Because most neonates either breast-feed or consume a lactose-containing formula, diarrheal symptoms generally begin at about 4 months of age when the dietary repertoire is advanced to contain either sucrose or glucose polymers. An invertase (β-fructofuranosidase) preparation that hydrolyzes sucrose has been shown to be effective in reducing the severity of symptoms in patients with CSID on a sucrose-based diet [37].

Glucose-galactose malabsorption

Glucose-galactose malabsorption (GGM) is a rare disorder that causes severe life-threatening diarrhea and dehydration during the neonatal period (MIM #182380). GGM was first established when investigators demonstrated evidence of an inherited disorder of active glucose and galactose transport [38]. Confirmation was provided by in vitro studies on GGM duodenal biopsies, which demonstrated that enterocytes were unable to accumulate galactose owing to a reduction in the number of transporters in the brush-border membrane [39–41] (Fig. 51.3). Expression studies confirmed that glucose and galactose are transported by the sodium-dependent

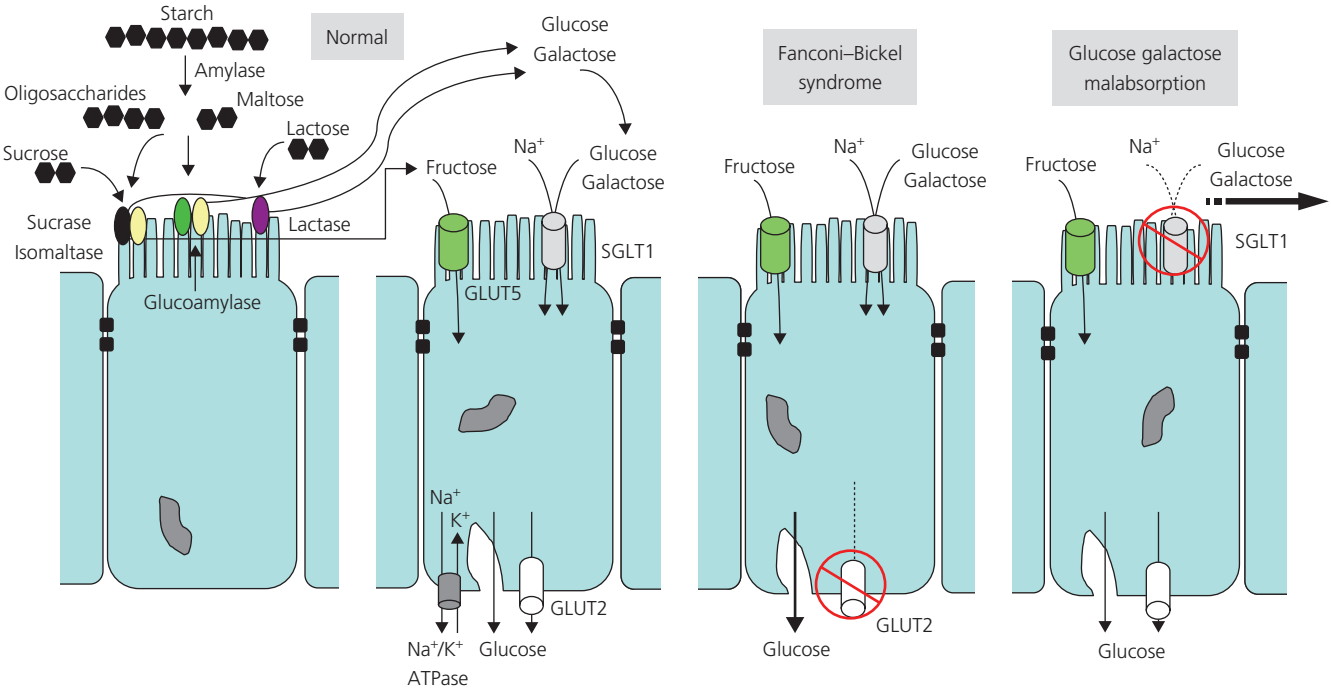

Figure 51.3 Carbohydrate absorption in normal subjects, in Fanconi–Bickel syndrome and in glucose-galactose malabsorption. ATPase, adenosine triphosphatase; GLUT2, glucose–galactose–fructose uniporter; GLUT5, fructose uniporter; SGLT1, Na^+-dependent glucose–galactose cotransporter.

transporter, SGLT1, which is defective in patients with GGM [42].

Genetics

The relative abundance of GGM in consanguineous unions and the absence of vertical transmission suggest an autosomal recessive pattern of inheritance. Genetic testing performed on 82 patients in 74 unrelated families identified 46 mutations in the *SGLT1* gene of patients with GGM [43–46]. The majority of the mutations are missense; however, six nonsense and seven frameshift mutations that produce truncated nonfunctional proteins have been identified. All missense mutations that caused a defect in sugar transport were in amino acids that were conserved within the 18 closely related genes, including eight *SGLT1* genes from different species. However, the two missense mutations that do not impair sugar transport, Phe405Ser and His615Gln, are not conserved and rarely occur in the general population. In contrast, the Asn51Ser variant occurs in the general population at a frequency of 4% in over 552 alleles analyzed.

Molecular pathophysiology

The primary carbohydrate present in breast milk is lactose, which is hydrolyzed by lactase on the external surface of the intestinal brush border. The liberated glucose and galactose are then transported across the brush-border membrane by SGLT1 and accumulated within the enterocyte (Fig. 51.3). Complex carbohydrates provide the major source of glucose in older children and adults. The facilitated carrier GLUT2 was believed to be responsible for transport of glucose and galactose across the basolateral membrane; however, studies on humans and mice with mutations of GLUT2 but no evidence of osmotic diarrhea have cast doubt on this [47,48].

The SGLT1 transporter is responsible for the tight coupling of two Na^+ ions and one sugar molecule across the membrane during one catalytic turnover. The basolateral Na^+,K^+-ATPase maintains the low intracellular sodium concentration by pumping sodium out of the cell, and this results in the net absorption of sodium (chloride and bicarbonate), sugar, and water across the epithelium [49]. Because the osmolarity of stool in both secretory and malabsorptive diarrhea is always isomolar to that of the serum, the addition of undigested solutes (glucose and galactose) and SCFA that reach the colon of patients with GGM will result in an excessive amount of water loss to maintain the obligatory fecal osmolarity.

Glucose stimulates salt and water absorption, and this is generally explained by the coupled transport of Na^+ and glucose across the brush border, and the subsequent pumping of Na^+ out of the enterocyte across the basolateral membrane by the Na^+,K^+-ATPase. It is thought that water follows solute absorption by osmosis. However, it has been postulated that there is a more direct link between sodium, sugar, and water transport across the brush-border membrane, namely water cotransport, but this is not widely accepted [50]. This link between salt, sugar, and water absorption provides the rationale for the use of oral rehydration therapy in patients

with various forms of acute diarrhea including those of infectious origin.

Clinical manifestations

The majority of patients with GGM present clinically with severe life-threatening diarrhea during the neonatal period; however, on several occasions a diagnosis has not been established until adulthood [51]. Diarrhea is most frequently detected during the first week of life, and will result in a severe metabolic acidosis and hyperosmolar dehydration. If not properly diagnosed in a timely manner and if dietary management is not implemented, GGM is frequently fatal. Isolated and profuse carbohydrate malabsorption is distinctly unusual during the first several days of life, and its presence should initiate the workup for both GGM and primary lactase deficiency.

Diagnostic criteria or laboratory investigations

Three key features are necessary to establish the diagnosis of GGM:

- elimination of glucose and galactose (and lactose) from the diet results in the complete resolution of diarrheal symptoms
- a normal intestinal biopsy
- an abnormal glucose breath hydrogen test.

When considering the diagnosis of GGM, several tests should be performed. Patients should have standard stool analysis, including pH, occult blood, and leukocyte analysis and evaluation for the presence of reducing and nonreducing sugars.

Small bowel biopsies should be performed early as they provide several important clues in establishing the diagnosis. Patients with GGM should have normal-appearing microvilli on electron microscopy, with normal villus architecture on light microscopy, including the normal distribution and number of enterocytes, Paneth cells, goblet cells, and enteroendocrine cells [52]. Mucosal biopsies can also be used to assess lactase and sucrase activity, which may be helpful in distinguishing GGM from primary lactase or sucrase deficiency.

Breath hydrogen testing is easily performed and may assist in the diagnosis of GGM. This gas chromatographic analysis quantifies the level of hydrogen gas in exhaled air following the administration of either glucose (or galactose) at 2 g/kg bodyweight or a maximum of 50 g for patients who weigh more than 25 kg. Although an elevation of more than 20 p.p.m. above the fasting baseline is consistent with the diagnosis of glucose malabsorption, most patients with GGM have levels that are frequently higher than 100 p.p.m. (MG Martin, EM Wright, unpublished observations) [53]. The specificity of an abnormal glucose breath hydrogen test may be confirmed by performing a fructose breath hydrogen test, which should be normal in GGM patients because fructose is absorbed by the unaffected uniporter, GLUT5 (Fig. 51.3). However, although slight fructose malabsorption is particularly common in younger children, breath hydrogen levels in a GGM patient will be substantially higher with glucose compared with fructose administration [54].

Treatment

With GGM, as with other disorders of carbohydrate malabsorption, symptoms resolve on an elimination diet free of glucose and galactose. Several formulas are available for managing GGM patients during early infancy, for example, Ross Carbohydrate Free Formula (Ross Products, Columbus, OH) and Galactomin 19 (Nutricia, Holland). Care should be exercised with formulas containing fructose as fructose absorptive capacity is rather limited in young children. The dietary management becomes particularly challenging as children enter late infancy and begin to exert more independence. Guidance from a well-trained dietitian is frequently invaluable. Highly motivated parents will generally benefit from dietary manuals that list the sugar content of selected foods. Although the obligatory lifelong glucose- and galactose-free diet may have significant long-term renal and cardiovascular consequences, none have been reported in several adult patients.

Fructose malabsorption

Fructose malabsorption has been implicated in both toddler's diarrhea and in a rare and poorly defined autosomal recessive disorder named isolated fructose malabsorption (IFM). Distinguishing between the more common toddler's diarrhea and IFM is particularly difficult, and it is unclear if they are distinct disorders. The clinical and genetic features of IFM are not as well defined as its counterpart carbohydrate transport disorder, GGM. Although the ability of GLUT5 to transport fructose has been demonstrated, there remains insufficient information confirming that GLUT5 represents the main fructose facilitative carrier in the intestine (Fig. 51.3) [55]. Studies have identified GLUT7 as a high-affinity glucose and fructose carrier on the brush-border membrane of enterocytes located in the distal intestine [56]. In rats studies imply that brush border GLUT2 plays a major role in the absorption of fructose [57].

Genetics and molecular pathophysiology

Eight patients with clinical evidence suggestive of IFM were evaluated for mutations in the *GLUT5* gene [58]. Analysis of both the coding region and intron and exon boundaries of the *GLUT5* gene failed to identify a deleterious mutation that could account for defective transport.

Data suggest that fructose absorption in the small intestine is accomplished by GLUT5, because the latter has a much higher Michaelis constant (K_m) (and thereby higher capacity) for fructose than GLUT7 [59,60]. Fructose absorption is independent of glucose absorption and remains intact in patients with GGM. Studies performed primarily in rodents have demonstrated that GLUT5 expression is regulated in a tissue- and development-specific manner and is induced by dietary fructose [61]. Specifically, GLUT5 messenger ribonucleic acid (mRNA) and protein levels are found at low levels prior to weaning and increase dramatically in the proximal small

intestine in weaned animals. An analysis of the age dependency of GLUT5 levels in human intestine has not been performed; however, fructose malabsorption as determined by the breath hydrogen test is certainly more common during early infancy when compared with adults [54]. Moreover, whether or not the fructose malabsorption in toddler's diarrhea is secondary to inadequate GLUT5 expression has yet to be formally established.

Clinical manifestation

Fructose is the primary monosaccharide found in fruits and fruit juices. Fruit juices that contain a high proportion of fructose relative to glucose, or an excessive amount of the nonabsorbable carbohydrate sorbitol, have been associated with infant diarrhea and abdominal pain [62,63]. Malabsorption of fruit juices is dose-dependent, and diarrheal symptoms are associated with a daily intake of juice exceeding 15 mL/kg. Whether children with toddler's diarrhea have a reduced capacity to absorb fructose compared with other similarly aged children has yet to be defined. Intolerance to dietary fructose has also been identified in infants with colic and adults with irritable bowel syndrome [64,65].

Diagnostic criteria or laboratory investigations

Fructose malabsorption can be assessed by either placing the patient on a fructose elimination diet or by performing a fructose breath hydrogen test. Fructose given at 2 g/kg bodyweight or a maximum of 50 g can be used to perform these studies [27]. Concomitant administration of glucose can attenuate the malabsorption of fructose as assessed by breath testing, presumably by improving solvent drag [66]. To determine whether the malabsorption is fructose-specific, intestinal biopsies should reveal normal intestinal histology, and malabsorption should be limited to fructose and not other monosaccharides.

Treatment

Patients experiencing significant fructose-induced diarrhea should either reduce or eliminate their dietary fructose load to resolve symptoms. It has been established in rodent models that GLUT5 levels are dependent on the chronic load of dietary fructose; therefore, it is conceivable that fructose malabsorption may resolve by initiating a feeding regimen of incrementally increasing amounts of fructose. Because fructose malabsorption is generally limited to early infancy, attempts to reintroduce fructose should be considered as patients enter into the school-age years.

Fanconi–Bickel syndrome

Fanconi–Bickel syndrome (FBS; MIM #227810) is a rare autosomal recessive disorder that is characterized by carbohydrate malabsorption, tubular nephropathy, hepatomegaly and abnormal glycogen accumulation, failure to thrive, and fasting hypoglycemia [67,68].

Genetics and molecular pathophysiology

Homozygous mutations in the facilitative glucose transporter gene, *GLUT2*, have been identified in over 60 patients with FBS (Fig. 51.3) [48]. Although most of the mutations are nonsense and result in a truncated transporter, several missense mutations were also identified. In vitro functional studies have not been performed to confirm that these mutations adversely alter the transport capabilities of the GLUT2 protein.

The mechanism by which mutation in the facilitative carrier, GLUT2, alters the fasting- and feeding-induced changes in serum glucose is not well understood; however, impaired hepatocyte transport and glucose-sensing mechanism of pancreatic β cells are possible explanations [68]. In the small intestine, GLUT2 is localized on the basolateral membrane and was previously believed to be the primary method of monosaccharide exit from the enterocyte (Fig. 51.3). However, severe osmotic diarrhea is generally not associated with FBS, and mice containing a targeted deletion of *Glut2* also retain monosaccharide transport across the basolateral membrane, suggesting that a GLUT2-independent pathway for glucose transport exists in enterocytes [69].

Clinical manifestations

The diagnosis of FBS should be considered in patients with hepatomegaly and evidence of a renal tubulopathy. Although carbohydrate malabsorption has been reported in some but not all cases of FBS, it is certainly not a dominant feature of the disorder; however, failure to thrive, rickets, and osteoporosis are clinical characteristics that are found in most patients with FBS [68].

Diagnostic criteria or laboratory investigations and treatment

Urine analysis generally shows evidence of glycosuria, a generalized aminoaciduria, and excessive urinary losses of phosphate and calcium. Histological analysis of the small bowel, liver, and kidney generally reveals excessive glycogen stores. Abdominal ultrasonography is useful to confirm the relative enlargement of the liver and kidney. Management is primarily focused on supplementing urinary electrolyte losses. Uncooked cornstarch has been used to prevent hypoglycemia and to minimize postprandial hyperglycemia [70].

Disorders of amino acid and peptide assimilation

The complex process of dietary protein assimilation begins with proteolytic hydrolysis by multiple gastric, pancreatic, and brush-border proteases to form small peptides and amino acids. Small peptides (di- and tripeptides) and amino acids are transported into enterocytes across the brush-border membrane through a series of transporters with over-

lapping specificities based on the characteristics of substrate size and charge (Fig. 51.4). Di- and tripeptides are hydrolyzed by intracellular peptidases to single amino acids, which efflux across the basolateral membrane through a second series of transporters. The 21 common amino acids add to the diversity of dietary proteins whose digestion requires a host of endopeptidases and exopeptidases with specific yet overlapping specificities. Passive and ion-mediated transepithelial absorption is mediated by a diverse group of transporters with broad amino acid specificities [71–73]. The redundant function of these enzyme and transport systems minimizes the physiological consequences of a single deficiency in almost any component of this process.

Protein digestion is initiated in the stomach by a family of pepsin proteases that are secreted in the inactive form of pepsinogen by chief cells (Fig. 51.4). Pepsinogen becomes activated by the acidic content of the stomach, where it produces nonabsorbable peptides. Under most circumstances, however, gastric hydrolysis is not essential for protein digestion. Dietary proteins that reach the intestine are further hydrolyzed into smaller peptides by a family of endopeptidases (trypsin, chymotrypsin, and elastase) and exopeptidases (carboxypeptidase A and B) that are secreted in their inactive form by the exocrine pancreas.

Enterokinase, a serine protease located on the brush-border membrane of enterocytes in the duodenum, converts the proenzyme trypsinogen to trypsin. Trypsin subsequently cleaves the precursor forms of other endo- and exopeptidases to their active equivalents. The oligopeptides undergo further hydrolysis by another large family of oligopeptidases (aminopeptidases and carboxypeptidases) located on the brush-border membrane. These proteolytic enzymes have well-defined substrate specificity and hydrolyze the dietary protein into either dipeptides or single amino acids, which are subsequently transported by a group of uniporters.

Disorders of protein digestion are rare but should be considered when evaluating a patient for a potential defect of amino acid transport. The best characterized disorder of specific protein malabsorption is a deficiency of enterokinase synthesis (MIM #226200) [74]. Individuals with enterokinase deficiency present with diarrhea, failure to thrive, and hypoproteinemic edema when on a diet of intact dietary proteins; these symptoms resolve when on an amino acid-based diet. Primary trypsinogen deficiency (MIM #276000) has also been reported and results in clinical symptoms that resemble enterokinase deficiency [75]. Nearly 90% of patients with cystic fibrosis (MIM #219700) have clinical evidence of exocrine pancreatic dysfunction that results in the impaired digestion of dietary protein, fat, and carbohydrates [35,36]. A similar type of generalized malabsorptive condition also occurs in the late stages of other disorders that result in chronic pancreatitis, including hereditary pancreatitis (MIM #167800) [76].

A large group of amino acid transporters have been isolated and characterized and these are expressed either on the apical or basolateral membrane of the enterocyte (Fig. 51.4) [71,72]. The brush-border membrane contains the B^0, B^0AT1, and $B^{0,+}$ Na^+-dependent systems that transport neutral amino acids [77]. Anionic and cationic amino acids are selectively transported by systems x_c^- and y^+, respectively. Proline and hydroxyproline are selectively transported by the IMINO system SIT1 [78]. By contrast, cationic and

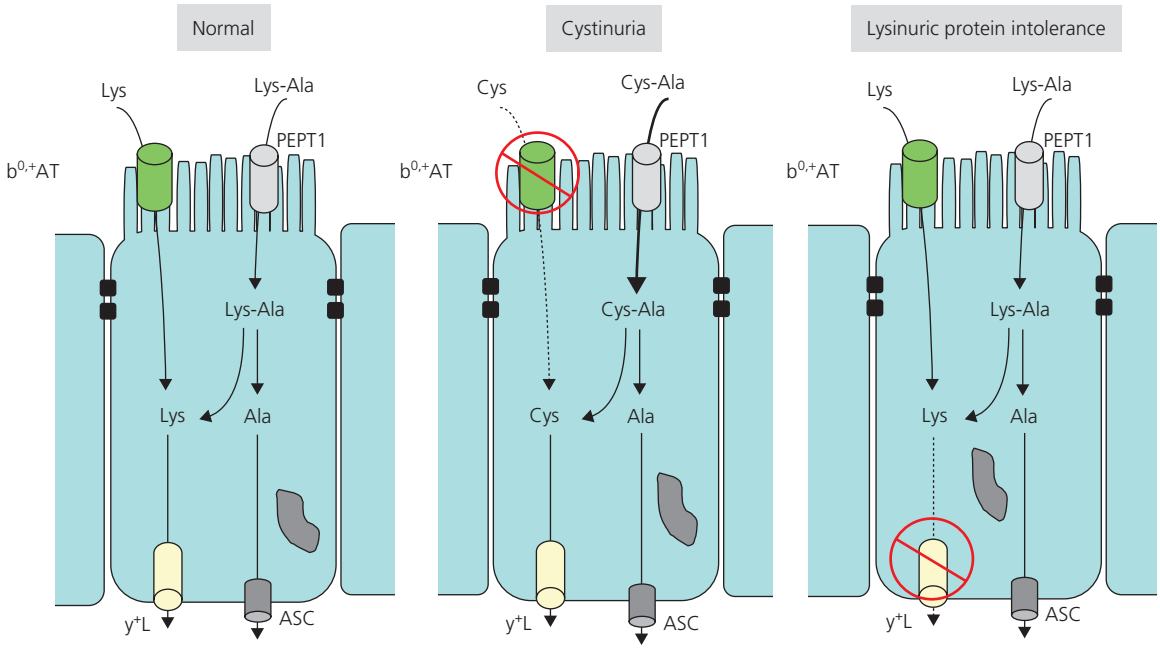

Figure 51.5 Amino acid transport in the small intestine of normal subjects, in lysinuric protein intolerance, and in cystinuria patients. Ala, alanine; ASC, small neutral amino acid carrier; $b^{0,+}AT$, ; Cys, cysteine; Lys, lysine; PEPT1, H^+–oligopeptide cotransporter; y^+L, Na^+-dependent cationic amino acid transport system.

neutral (cysteine) amino acids are transported by the Na-independent system $b^{0,+}$, which is defective in cystinuria (MIM #220100), an autosomal recessive aminoaciduria that is not associated with a significant gastrointestinal phenotype (Fig. 51.5) [79]. Although the $b^{0,+}$ system is expressed in the kidney and intestine, in patients with cystinuria dietary cysteine may still be absorbed as a component of oligopeptides by the H^+–oligopeptide cotransporter (PEPT1) [80]. Proton-coupled amino acid transporters, PAT1 and PAT2, have been identified and PAT1 is found expressed in the small intestine brush border [81,82]. The relative contributions of SIT1 and PAT1 to imino acid absorption and iminoaciduria have yet to be resolved.

Intracellular neutral amino acids efflux across the basolateral membrane in a size-dependent manner, with system L carrying the larger and system ASC the smaller amino acids (Fig. 51.5). Small neutral amino acids also cross the basolateral membrane by a Na^+-dependent ASC system, whereas the A system is selective for both neutral and imino acids. By contrast, cationic amino acids are transported by the Na^+-dependent system y^+L, which is defective in lysinuric protein intolerance (LPI). Although the redundancy in the transport specificity of these various systems essentially minimizes the gastrointestinal and nutritional consequences observed when an individual transport system is disrupted, LPI patients do experience significant gastrointestinal symptoms.

Lysinuric protein intolerance

Lysinuric protein intolerance (LPI) (MIM #222700) is an autosomal recessive disorder that results from mutations in the *SLC7A7* gene, which encodes for the cationic amino acid transporter y^+LAT-1 (Fig. 51.5) [83,84]. The y^+LAT-1 transporter is located on the basolateral membrane of the enterocyte and renal tubules, and transports cytoplasmic dibasic amino acids such as lysine, arginine, and ornithine in exchange for Na^+ and neutral amino acids [85]. Several gastrointestinal symptoms, including failure to thrive, diarrhea, vomiting, and pancreatitis, are the main clinical symptoms associated with LPI.

Genetics and molecular pathophysiology

The *LPI* gene was discovered by positional cloning, and approximately 30 mutations have been identified in more then 100 patients with LPI [83,84,86,87]. Founder mutations have been identified in Finnish, Japanese, and Italian kindreds in whom the incidence of LPI is particularly common. Ornithine and arginine are important urea cycle intermediates that fail to exit the intestinal and renal epithelium of patients with LPI. Their relative deficiency, particularly during a meal on a high-protein diet, results in urea cycle dysfunction that leads to hyperammonemia and subsequent alterations in mental status [88].

Clinical manifestations

Undiagnosed patients with LPI generally present with failure to thrive and a self-imposed restriction of dietary protein. Although diarrhea, emesis, and abdominal pain are frequent symptoms, the distinguishing feature of LPI is that high-protein diets result in hyperammonemia and dramatic changes in mental status, and chronic exposure to dietary protein is

usually associated with various degrees of mental retardation. Marked hepatosplenomegaly and frequent bone fractures are also characteristic of LPI, and life spans are generally limited by complications associated with alveolar proteinosis and osteoporosis [89,90].

Diagnostic criteria or laboratory investigations and treatment

Quantitation of plasma amino acids and urinary organic acids provides useful clues in the detection of LPI because plasma levels of diamino acids are low, whereas urinary levels of lysine and orotic acid are elevated [85]. The diagnosis can frequently be established by challenging with an enteral bolus of dietary protein. This would result in the rapid impairment of motor function and alteration of mental status resulting from hyperammonemia. Citrulline supplements (200 mg/kg/day) and dietary protein restriction (1.5 g/kg/day) are used to manage patients with LPI [88]. Mealtime supplements of citrulline are readily absorbed and reduce postprandial hyperammonemia following a protein meal. Oral carnitine supplementation has been shown to be important in a subset of patients described with LPI and hypocarnitinemia [91].

Hartnup disease

Hartnup disease (MIM #234500) and iminoglycinuria (MIM #242600) are two other autosomal recessive disorders that have been well characterized clinically [92,93]. Hartnup disease is characterized by a malabsorption and renal excretion of neutral amino acids (neutral aminoaciduria) and a heterogeneous set of symptoms ranging from a pellagra-like rash to neurological disorders [77]. Through linkage analysis a candidate gene, *B0AT1* (SLC6A19), was identified and sequencing of affected individuals found splice-site variants, deletions, and nonsense mutations that produce a truncated protein, and missense mutations. Testing of the missense mutant proteins expressed in *Xenopus laevis* oocytes eliminated amino acid transport [94,95]. B^0AT1 is a sodium-dependent and chloride-independent neutral amino acid transporter that is expressed in the intestine and kidney.

Other defects of amino acid transport

A second disturbance of amino acid transport has been characterized: system $b^{0,+}$, which is defective in cystinuria (MIM #220100) and is selective for cationic and neutral amino acid transport across the brush border membrane (Fig. 51.5) [79]. The diagnosis of this disorder can be established with analysis of urine amino acid profiles, and both disorders present with either neurological or renal symptoms and an absence of significant gastrointestinal complications. There is only one report of impaired proline absorption, which may be due to mutations in the imino transporter SIT1 [93,96]. This involved a severely retarded patient who also had familial iminoaciduria.

Disorders of fat assimilation

Assimilation of dietary fats requires hydrolysis and subsequent repackaging of lipids by a complex group of intralumenal and intracellular events [97]. The clinical consequences of disorders of fat assimilation include failure to thrive, steatorrhea, and neurological deficits that result from the malabsorption of fat-soluble vitamins. Lipolysis is initiated by gastric lipase in the stomach and concludes in the intestine through the action of pancreatic lipase. Because pancreatic exocrine function is particularly immature during early infancy, fat absorption in this age group primarily depends on the action of gastric lipase [98]. A congenital deficiency of pancreatic lipase (MIM #246600) is an exceedingly rare autosomal recessive disorder that leads to fat malabsorption [99].

Fatty acids and diglycerides are the products of triglyceride hydrolysis, and their solubilization to the aqueous phase of lumenal content requires adequate levels of conjugated bile salts; therefore, various disorders of intrahepatic and extrahepatic cholestasis will impede the delivery of lumenal bile salts and result in fat malabsorption. Bile salts are particularly important in the emulsification of long-chain fatty acids because of the lower aqueous solubility of the latter compared with their medium-chain (6–12 carbons) counterparts.

A fatty acid transport protein (FATP4) that has been localized to the brush-border membrane appears to play an essential role in the absorption of long-chain fatty acids [100,101]. Analysis of *Fatp4*-null mice demonstrates a 40% reduction in fatty acid uptake and a neonatal lethal restrictive dermopathy [102–104]. In contrast, the apical cholesterol transporter named Niemann–Pick C1-like protein (NPC1L1) was identified using a genomic-bioinformatics approach [105], and *Npc1l1*-null mice absorbed only 30% of lumenal cholesterol [106]. Ezetimibe is a potent selective inhibitor of NPC1L1, and may have an important role in curbing the absorption of dietary cholesterol in patients with hypercholesterolemia [107,108]. It has been established that cholesterol is exported across the epithelial layer by an adenosine triphosphate (ATP)-binding cassette transporter, ABCA1. The role of ABCA1 in cholesterol and phospholipid transport was confirmed when linkage analysis established it as the gene defective in Tangier disease (MIM #205400) [109,110]. Tangier disease patients have a deficiency of high-density lipoproteins, which predisposes to the development of premature coronary heart disease despite hypocholesterolemia; in addition, there is accumulation of cholesterol in tissues such as liver, spleen, lymph nodes, and small intestine. Patients with sitosterolemia (MIM #210250) have the peculiar ability to absorb an excessive amount of the main plant sterol, sitosterol. Mutations in the ABC transporter, ABCG5 and ABCG8, have been associated with sitosterolemia [111]. These proteins form a heterodimer that serves as

the primary sterol efflux mechanism in the intestine. Despite defective processing of cholesterol and sterol, patients with Tangier disease and sitosterolemia have no significant gastrointestinal phenotype except hepatosplenomegaly. By contrast, disorders that result in defective packaging of reesterified lipids into apolipoprotein-rich chylomicrons and very-low-density lipoprotein (VLDL) particles generally lead to fat malabsorption and failure to thrive.

Abetalipoproteinemia

Abetalipoproteinemia (ABL), or Bassen–Kornzweig syndrome (MIM #200100), is the classic and best-characterized disorder of fat absorption and results from failure to reassemble dietary fat in the form of β-lipoproteins. Triglyceride and cholesterol esters are primarily transported in the plasma as β-lipoproteins; therefore, ABL patients have a severe deficiency of both these neutral lipids. Patients generally present shortly after birth with failure to thrive and steatorrhea, and if, untreated, will develop irreversible neurological problems in late infancy. However, milder variants have been identified in asymptomatic adult patients who were identified by routine cholesterol screening.

Genetics and molecular pathophysiology

Wetterau and colleagues determined that the microsomal triglyceride transfer protein (MTP) was not detectable in the small bowel enterocytes of ABL patients and described homozygous mutations in the *MTP* gene [112]. The MTP protein is a 97-kDa subunit that forms a heterodimer with a 55-kDa protein named disulfide isomerase (PDI) [113]. Only a handful of missense mutations have been identified in ABL patients, and the majority involve a truncated or nonfunctional MTP; no mutations have been reported in the gene encoding the PDI protein [114]. Serum lipoproteins in patients with ABL are deficient in triglycerides and cholesterol-rich apolipoproteins B-100 and B-48, which form VLDL and chylomicrons. Apolipoprotein B-100 is synthesized by hepatocytes that produce VLDL, whereas the truncated protein (apolipoprotein B-48) is formed by enterocytes and is essential for chylomicron formation.

The role of MTP in chylomicron formation has been definitively established by investigating the consequences of ABL-causing mutations [113,115–117]. These studies demonstrate that apolipoprotein B alone is incapable of initiating lipoprotein formation and that MTP is specifically required to complete proper lipoprotein assembly. The protein component of apolipoproteins B-100 and B-48 is synthesized in the endoplasmic reticulum and must fold correctly to form a complex with lipids. Therefore, MTP has two distinct roles in lipoprotein assembly: first, to move lipids such as cholesterol and triglycerides into the lumen of the smooth endoplasmic reticulum and, second, to transfer small quantities of these lipids to the newly formed and unstable apolipoprotein B protein in a process that has been termed "lipidation" [116]. In the absence of lipoprotein assembly, lipid droplets accumulate in the endoplasmic reticulum and are not transported to the trans-Golgi apparatus in the enterocyte and hepatocytes [118].

Clinical manifestations

The typical clinical presentation is failure to thrive, emesis, and low-volume diarrhea. Poor growth despite adequate caloric intake is an early clinical feature that should hasten the evaluation of a possible defect in fat malabsorption. In the long term, patients may develop an aversion to fatty meals as a way to minimize their diarrheal symptoms. The first evidence of neuromuscular abnormalities is usually the loss of deep tendon reflexes, which results from prolonged vitamin E deficiency; other neuromuscular manifestations, including retinitis pigmentosa, ataxia, and spinocerebellar degeneration, may be mistaken for various forms of Friedreich ataxia.

Diagnostic criteria or laboratory investigations and treatment

Serum samples should be analyzed for evidence of β-lipoprotein (VLDL and chylomicron) deficiencies. Specifically, plasma triglyceride levels are generally low (< 10 mg/dL), whereas cholesterol levels range from 25 to 40 mg/dL. Acanthocytosis is usually seen in peripheral blood smears and results from abnormal lipoproteins in the plasma membrane of erythrocytes. Endoscopic evaluation of the small bowel can show yellow discoloration, and biopsies have characteristic fat-laden enterocytes located in the upper portion of the villus. Fat droplets within the cytoplasmic compartment of the enterocyte may be confirmed by electron microscopy.

To minimize diarrheal symptoms, ABL patients may be managed on a low-fat diet (~ 15 g/day), and serum levels of fat-soluble vitamins should be monitored periodically. Adequate serum levels of vitamins A and K can be achieved with supplementation of moderate oral doses; however, absorption of tocopherol is severely impaired and may require massive doses (2000 mg in infants, and 10 000 mg in older children and adults) of tocopherol to diminish the neuromuscular manifestations of vitamin E deficiency.

Hypobetalipoproteinemia

Hypobetalipoproteinemia (HBL; MIM #107730) is another well-characterized disorder of fat absorption that results from the formation of abnormally truncated forms of apolipoprotein B [119,120]. The heterozygous state has been estimated to occur in approximately 1 in every 3000 Americans [120].

Genetics and molecular pathophysiology

The primary distinction between ABL and HBL is that ABL heterozygotes have normal cholesterol and triglyceride levels, whereas HBL heterozygotes have low lipoprotein levels [121]. Therefore, HBL is inherited in an autosomal dominant

manner; however, patients with only a single defective allele generally have no gastrointestinal and only minimal, if any, neuromuscular abnormalities. In contrast, individuals with two defective alleles are indistinguishable from ABL patients based on both physical and laboratory evaluation.

Many mutations have been described in the *APOB* gene in patients with HBL [122]. The mutations all result in proteins that are truncated because of a nonsense or frameshift mutation that creates a premature downstream stop codon. Several kindreds have been described that are clinically indistinguishable from HBL and ABL, but in which mutations in either the apolipoprotein B or MTP alleles have not been identified. Various models have shown that truncation of the carboxy terminus of the apolipoprotein B protein influences the process of lipidation, as described earlier. Therefore, the inadequate addition of neutral lipids to the shortened apolipoprotein B protein leads to instability of the protein and its eventual degradation.

Clinical manifestations

The clinical manifestations of patients with homozygous mutations of the *APOB* gene are identical to those described above for abetalipoproteinemia. By contrast, defects in a single allele (heterozygotes) may cause subtle neurological findings indicative of mild vitamin E deficiency.

Diagnostic criteria or laboratory investigations and treatment

In heterozygous patients, cholesterol, triglyceride, and low-density lipoprotein (LDL) levels are lower than in other unaffected members of the same kindred. By contrast, patients with homozygous mutations of the *APOB* allele have cholesterol, triglyceride, chylomicron, and VLDL levels similar to those previously described for ABL patients. Moreover, characteristic findings such as acanthocytosis and fat-laden enterocytes are also seen. Homozygous HBL patients should be managed as described in the ABL section, including the restriction of dietary fat and the supplementation of vitamin E. By contrast, heterozygous patients should be given moderate doses of vitamin E.

Chylomicron retention disease

Chylomicron retention disease (CMRD; MIM #246700), or Andersen disease, is the least common of the classic disorders of lipid packaging in the intestine [123,124]. It is an autosomal recessive disorder in which apolipoprotein B and MTP are produced, but there is failure to secrete chylomicrons across the basolateral membrane of the enterocyte.

Genetics and molecular pathophysiology

It has been shown that CMRD is secondary to a defect in a gene named *SARA2* that encodes for the SAR1B protein, which is a member of the SAR1-adenosine diphosphate (ADP)-ribosylation factor family of small guanosine triphosphatases [125]. This family of proteins has an important role in intracellular trafficking; it is suggested that when these proteins are defective, chylomicron trafficking to the trans-Golgi apparatus may be disrupted [126]. Although some nonsense mutations have been identified, all the missense mutations alter a highly conserved residue in the guanine nucleotide-binding motif, which would presumably interfere with guanosine triphosphate (GTP) binding. This region of the SAR1B protein interacts with a series of Sec proteins (including Sec12 and Sec23) that eventually leads to membrane deformation, budding, and the eventual transport of chylomicron through the secretory pathway [127].

Clinical manifestations, diagnostic criteria or laboratory investigations, and treatment

Patients have been reported to present as neonates with severe diarrhea but may also first come to medical attention in early adolescence with neuromuscular manifestations of vitamin E deficiency. However, the retinitis pigmentosa and neuromuscular manifestations are less severe when compared with either HBL or ABL. Unlike patients with HBL and ABL, triglyceride apolipoprotein B100 levels are normal in this condition. Enterocytes are also laden with fat, as is seen in HBL and ABL. Treatment consists of restricting dietary fats and supplementing the diet with vitamin E.

Primary bile acid malabsorption

Efficient digestion and absorption of dietary lipids and lipid-soluble vitamins require their emulsification by bile salts (taurocholate) within the intestinal lumen [128]. The majority of dietary fats are absorbed in the jejunum, and residual bile salts are reabsorbed primarily by ileal enterocytes that express a Na^+-dependent bile salt transporter, ASBT (encoded by the *SLC10A2* gene), on its apical membrane. Primary bile acid malabsorption (PBAM; MIM #601295) is a rare autosomal recessive disorder that results from an impairment of bile acid reabsorption secondary to a defect in the function of the ASBT transporter [129,130]. Taurocholate malabsorption more frequently results from the loss of an adequate amount of ileum, which may occur either because of surgical resection or because of extensive inflammation secondary to disorders such as Crohn's disease [131,132]. The diarrhea that accompanies both primary and secondary forms of bile acid malabsorption may be attributed to both fat malabsorption (steatorrhea) and bile acid stimulation of colonocyte secretion of ions and fluid. Idiopathic adult-onset bile acid malabsorption has also been described in patients with presumably normal ileal function [133].

Genetics and molecular pathophysiology

Dawson and colleagues identified three missense (Ala171Ser, Leu243Pro, Thr262Met) and a splice-site mutation of the *SLC10A2* gene in patients with PBAM [129]. In vitro analysis of these missense mutations failed to alter the

proper targeting of ASBT to the cell membrane; however, the Leu243Pro and Thr262Met mutations impaired taurocholate transport [134]. The Ala171Ser mutation was found in 28% of asymptomatic individuals and appears to represent a benign polymorphism because in vitro analysis showed no impairment of bile acid absorption. A missense mutation (Pro290Ser) was identified on a single ASBT allele (in a heterozygote), a patient with Crohn's disease [135]. The Pro290Ser mutation abolishes taurocholate transport and in heterozygous carriers may influence cholesterol homeostasis and bile acid metabolism; however, the frequency and role of this and other polymorphisms in the general population await further investigations. No significant genomic mutations were identified in a large cohort of adult patients with idiopathic bile acid malabsorption [133].

The Na^+-dependent bile salt transporter ASBT is expressed on cholangiocytes and ileocytes and therefore plays an essential role in the enteric and hepatic phases of the enterohepatic circulation. Taurocholate is excreted in the biliary tree, where it is initially stored in the gallbladder and eventually enters the duodenum after cholecystokinin-induced gallbladder contraction in response to a meal. A small fraction of taurocholate is passively absorbed in the jejunum and colon. Along the horizontal axis of the intestine, ASBT expression is limited to the ileum, where it transports taurocholate by an electrogenic, Na^+-dependent mechanism. The reabsorption of taurocholate is about 95% efficient, and the 5% loss is replaced by hepatocyte conversion of cholesterol to bile salts.

Differential expression of orphan solute transporters in *SLC10A2*-null mice was used to identify the putative basolateral taurocholate transporter [136]. The heteromeric organic solute transporter, α–β, Ostα–Ostβ, is expressed in the kidney and intestine and localized by immunohistochemistry at the basolateral surface. Both proteins are required to get correct targeting of the complex to the basolateral membrane to facilitate taurocholate efflux in the ileum. Eventually, taurocholate enters the portal circulation and is transported across the hepatocyte's sinusoidal membrane by a Na^+-dependent taurocholate cotransport polypeptide, NTCP (*SLC10A1*). Transport of recycled and newly formed taurocholate out of the hepatocyte occurs across the canalicular membrane by an ATP-dependent bile salt export pump, BSEP.

Clinical manifestations

Patients with PBAM present during infancy with diarrhea, steatorrhea, failure to thrive, and low plasma levels of LDL cholesterol [129,130]. The diarrhea is generally secretory in character (persists while fasting) and is exacerbated by the addition of dietary fats.

Diagnostic criteria or laboratory investigations and treatment

The small intestine of patients with PBAM should be normal in length and architecture, and the extent of the diarrhea should improve with a trial of cholestyramine and a low-fat diet. Bile acid absorption by the ileum may be measured using the bile acid analogue ^{75}Se-homocholic acid–taurine test.

Disorders of mineral and electrolyte absorption and secretion

Congenital chloride diarrhea

The most common cause of congenital secretory diarrhea in the presence of normal intestinal mucosa is the autosomal recessive disorder congenital chloride diarrhea (CCD; MIM #214700) (Fig. 51.6) [137]. Nearly half of the reported cases have been confined to Finland, where it has been estimated to occur in 1 in 20 000 of the population; in the Persian Gulf it has been estimated to occur in 1 in 32 000 live births [138]. An earlier linkage analysis of several families identified the CCD locus to a region of chromosome 7q31 located in the vicinity of the cystic fibrosis gene, cystic fibrosis transmembrane regulator (*CFTR*) [139,140]. The defective gene in CCD is *SLC26A3*, which encodes a Na^+-independent Cl^-/HCO_3^- exchanger that is expressed primarily in the apical brush-border membrane of enterocytes (Fig. 51.6) [141].

Genetics and molecular pathophysiology

Höglund and colleagues identified several mutations in the *SLC26A3* gene in patients with CCD, including the prevalent Val317del mutation, which was found in a Finnish population and impaired chloride transport [137,141,142]. Over 30 disease-related mutations have been identified in more than 100 patients studied with CCD [137]. One-third of the mutations are either microdeletions or missense and nonsense mutations. Two other prominent founder mutations have been identified that account for the majority of cases of CCD in Poland (Ile675-676ins), and in Saudi Arabia and Kuwait (Gly187X) [138]. A small number of patients have been identified that fit the clinical characteristics of CCD but lack detectable mutations in the *SLC26A3* gene.

The main role of the SLC26A3 protein as a Cl^-/HCO_3^- exchanger is to reabsorb chloride along the length of the distal small bowel and colon (Fig. 51.6) [139]. In the distal intestine and colon, salt (NaCl) absorption is secondary to SLC26A3 transport of chloride and Na^+–H^+ exchange (NHE-3) transport of sodium. In normal physiological conditions, the expression of NHE-3 in the proximal small intestine is low, and the Cl^-/HCO_3^- exchanger secretes bicarbonate into the lumen while absorbing chloride produced by gastric acid [143,144]. Thus, the exchanger neutralizes the acidity of gastric secretion once it reaches the proximal small bowel. The CFTR protein is a chloride channel whose primary role in the small intestine is to secrete chloride, which is then absorbed in the distal intestine and colon by the Cl^-/HCO_3^- exchanger. Thus, impaired Cl^-/HCO_3^- exchanger function in CCD patients would disrupt the neutralization of gastric acid in the

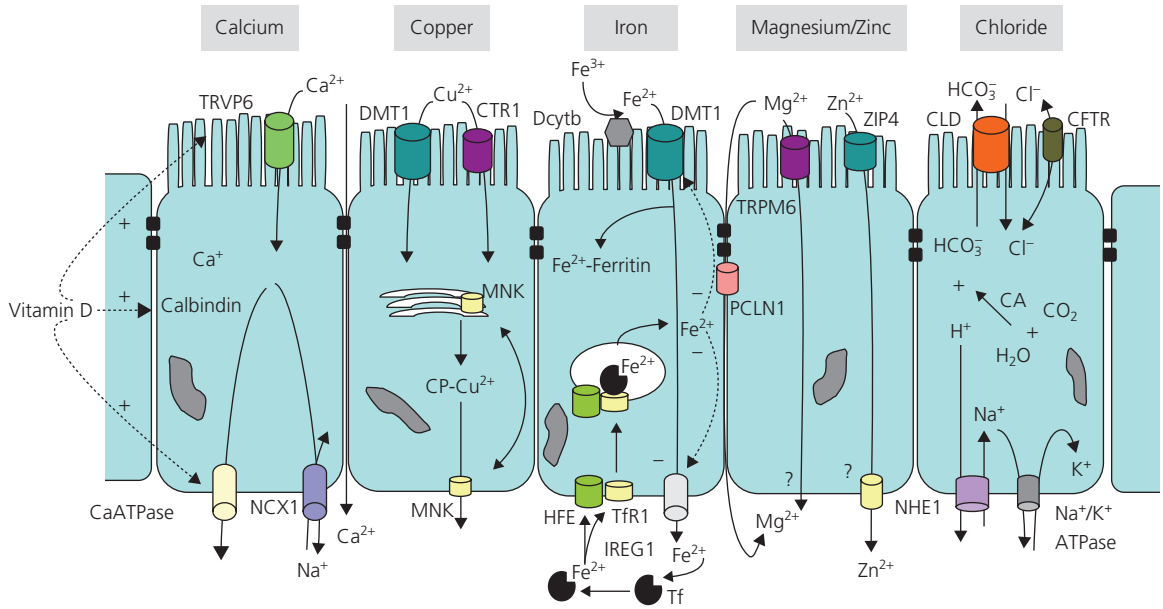

Figure 51.6 Ion and metal transport in the small intestine. proximal small bowel and impair lumenal chloride reabsorption in the distal small intestine and colon.

Clinical manifestations

The earliest clinical symptoms may occur in utero with severe polyhydramnios and dilated loops of small bowel detectable by ultrasonography and possibly resembling a distal intestinal obstruction [145]. Patients with CCD generally present during the first week of life with severe life-threatening secretory diarrhea. The profile of serum electrolytes prior to treatment is unique among the various congenital diarrheal disorders and manifests metabolic alkalosis, hypochloremia, hypokalemia, and hyponatremia.

Diagnostic criteria or laboratory investigations and treatment

The diagnosis of CCD is suggested if fecal chloride concentration exceeds the concentration of cations (Na^+ and K^+). This classic characteristic of CCD suggests that fecal HCO_3^- levels are particularly low and that another cation, presumably accounted for by H^+, contributes to the excessive electroneutral transfer of HCl. The mainstay of therapy is the oral or parenteral administration of KCl supplements. Although oral administration is the preferred route of electrolyte supplements, they are not well absorbed and may therefore contribute to the diarrhea. The administration of proton pump inhibitors slightly diminishes the severity of diarrhea, presumably by inhibiting meal-induced gastric acid secretion [146]. Orally administered butyrate has been shown to improve dramatically stool volume and electrolyte depletion in a single patient with CCD in a dose-dependent manner [147]. Lumenal butyrate can increase NaCl absorption by activation of the Cl^-–butyrate exchanger and by reducing both basal and cyclic adenosine monophosphate (cAMP)-mediated chloride secretion.

Congenital sodium diarrhea

Congenital sodium diarrhea (CSD, MIM #270420) is an exceedingly rare autosomal recessive disorder that presents with secretory diarrhea and many of the same clinical characteristics seen in patients with CCD [148,149]. Only six cases of CSD have been described in the literature, and the molecular basis of this condition has not been fully established [150]. Nevertheless, the available information suggests that the disorder results from impaired function of the intestinal Na^+–H^+ exchanger (Fig. 51.6). The gastrointestinal tract expresses primarily three Na^+–H^+ exchangers: NHE-2, -3, and -4 [151]; NHE-4 is expressed largely by gastric mucosa, whereas both NHE-2 and -3 are present in the small intestine.

Genetics and molecular pathophysiology

A study of two large Austrian kindreds with five affected members failed to identify linkage to any of the known Na^+–H^+ exchangers [150]. Vesicle transport studies performed on brush-border membrane samples confirmed that

CSD is the result of a faulty Na^+–H^+ exchanger [148]. The NHE-3 exchanger is considered to be the primary transporter responsible for Na^+ absorption because deletion of the *Nhe-3* gene in mice results in sodium secretion that resembles CSD [152,153]. These mice also had a mild proximal tubular acidosis that was secondary to the role of NHE-3 in renal Na^+ and HCO_3^- reabsorption. Although mild diarrhea was reported in these mice, the primary finding in the gut was an excess amount of lumenal fluids and an expanded surface area.

Clinical manifestations

Patients with CSD have high-volume secretory diarrhea that is exceedingly alkaline and contains high concentrations of Na^+. Therefore, patients generally have hyponatremia, low or normal excretion of urinary Na^+, and metabolic acidosis. Polyhydramnios resulting from in utero diarrhea is also associated with CSD, and a report described choanal atresia in two patients with CSD [150]. Although the intestinal biopsies of patients with selective impairment of transport function are generally considered to be normal, biopsies from three cases that fit the clinical characteristics of CSD showed partial villous atrophy and a decreased villus-to-crypt ratio, suggesting the possibility of a distinct disorder. Electron microscopy showed no evidence of microvillus atrophy or inclusion disease but demonstrated unexpected membranous whorls located in lysosomal bodies, vacuoles, and mitochondria.

Diagnostic criteria, laboratory investigations, and treatment

The diagnosis of CSD should be considered in patients who present as newborns with high-output secretory diarrhea and can be established by confirming the presence of elevated levels of fecal Na^+ and HCO_3^-. Unlike patients with CCD, who have metabolic alkalosis, metabolic acidosis is typically found in CSD and in all other forms of congenital diarrhea. The medical management of CSD patients is to maintain their fluid and electrolyte balance with the use of oral or parenteral fluids and salts.

Acrodermatitis enteropathica

Primary acrodermatitis enteropathica (AE; MIM #201100) is a rare autosomal recessive disorder of impaired intestinal absorption of zinc (Fig. 51.6) [154,155]. Although secondary deficiencies in trace elements such as zinc and selenium are a common complication of chronic diarrhea, patients with AE present in early infancy with profound depletion of total body zinc.

Genetics and molecular pathophysiology

Genome-wide screening for the AE allele was performed on two large consanguineous families, which led to the identification of a candidate gene that encodes a member of the zinc- and iron-regulated transporter family of proteins (ZIP4; Fig. 51.6) [156,157]. Sequencing of the *ZIP4* gene identified five missense mutations that altered highly conserved and critical amino acid residues in the family of zinc transporters in patients with AE [158,159]. ZIP4 is expressed on the apical membrane of epithelia in the intestine, colon, stomach, and kidney, and is a member of a family of proteins that control the transport of zinc into the cytoplasm of various cells [160]. During periods of zinc deficiency, the ZIP4 content of the brush border increases as expression is augmented and the protein is recruited to the apical membrane [161]. Although patients with AE have a markedly reduced capacity to absorb lumenal zinc, their responsiveness to high-dose oral zinc supplements raises the possibility that they retain a redundant but less efficient zinc transport mechanism in the intestine (Fig. 51.6).

Clinical manifestations

Zinc deficiency may develop either because of a primary defect in absorption or secondary to either inadequate intake or excessive losses [154]. Zinc deficiency resulting from excessive fecal losses of zinc is a common finding in patients with acute and chronic diarrhea, and short-term oral supplementation of zinc has been shown to reduce the duration and severity of diarrhea [162]. Severe zinc deficiency can present with anorexia, diarrhea, and severe failure to thrive [154]. The dermatitis located on the hands, feet, and perirectal and oral regions has a vesicobullous character, and the alopecia of the scalp and face is also a striking feature that occurs in patients with prolonged zinc deficiency. Humoral and cell-mediated immunodeficiencies have been reported in association with AE and may contribute to both poor wound healing and recurrent infections. Poorly characterized neurological features such as mental lethargy and neurosensory abnormalities may also be present.

Diagnostic criteria, laboratory investigations, and treatment

Zinc deficiency results in low levels of serum alkaline phosphatase, a zinc-dependent metalloenzyme. Alkaline phosphatase levels decline with age, and lower than expected levels should raise the possibility of zinc deficiency. Both serum and urinary zinc concentrations are significantly reduced in untreated AE patients. Radiolabeled zinc has been used to assess the absorptive capacity of the intestine using both mucosal biopsy samples and in vivo uptake studies [154]. Histology of the small intestine has shown several abnormalities that may represent the consequence of inadequate zinc concentrations in patients with AE. Paneth cells and enterocytes of the small bowel have been shown to have inclusion bodies and abnormal intracellular organelles; villus atrophy has also been reported [154]. Patients with AE can be managed with oral zinc supplementation, using ~ 1 mg elemental zinc/kg/day. Chronic supplementation with ade-

quate doses of zinc will resolve the clinical and laboratory features of this disorder.

Calcium absorption

Calcium absorption in the small intestine occurs by both active and passive transport mechanisms [163]. Passive absorption of dietary calcium occurs paracellularly along the entire length of the small bowel, and this pathway is predominant when the calcium supply is abundant. By contrast, the active calcium transport system is located primarily in the duodenum and is particularly important when the level of dietary calcium is low. The active transcellular transport system has been identified as a member of the transient receptor potential cation channel 6, or TRPV6, and is expressed primarily on the brush border membrane of enterocytes located in the proximal small bowel (Fig. 51.6) [164,165]. Once within the cytoplasm, calcium forms a complex with a calcium-binding protein called calbindin D9k, or CaBP, and calcium efflux out of the enterocyte takes place by either the CaATPase (PMCA1b) or by the Na^+–Ca^{2+} exchanger NCX1 (Fig. 51.6). Vitamin D (1,25-dihydroxyvitamin D-3) directly influences the expression of both TRPV6 and CaBP by directly activating vitamin D-responsive elements in the immediate promoter region of both genes and thereby increasing transcription [164]. Congenital disorders that impair calcium absorption include pseudovitamin D deficiency rickets (MIM #264700), which is secondary to a defective synthesis of 25-hydroxyvitamin D-3 1α-hydroxylase [166]. Specific inherited defects in the transporters that control dietary calcium absorption have yet to be described [167].

Disorders of magnesium transport

Magnesium absorption in the gut occurs primarily in the small intestine by two different pathways: a nonsaturable paracellular passive process and a saturable active transcellular transport process. Primary hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC, MIM #248250) is a rare autosomal recessive disorder that is associated with impaired absorption of dietary magnesium and a renal tubular defect of magnesium transport (Fig. 51.6) [168]. Hypocalcemia secondary to low levels of parathyroid hormone and 1,25-dihydroxyvitamin D-3 is common and may result in tetany. The molecular basis of primary hypomagnesemia was elucidated when linkage analysis led to the identification of a tight junction protein named paracellin 1 (PCLN1) [169]. Mutations in the gene encoding the PCLN protein (also called Claudin 16) were identified in ten kindreds, and the protein was located in the tight junction region of the thick ascending limb of Henle. Whether paracellin is expressed by small intestinal epithelium has not been reported, yet it accounts for the nonsaturable paracellular magnesium transport system that is particularly active at high intralumenal concentrations. Although paracellin may serve as a selective paracellular transporter of magnesium, it may also represent a sensor of magnesium concentration.

Active transcellular transport of magnesium occurs by means of a transient receptor potential (TRP) family of cation channels named TRPM6. Various missense and nonsense mutations of the *TRPM6* gene have been identified in patients with hypomagnesemia with secondary hypocalcemia (HSH, MIM #602014) [170,171]. The TRPM6 protein is located along the entire gut and in the distal tubule cells of the kidney, where immunofluorescence studies have localized it to the apical membrane [172].

Disorders of copper transport

Copper is a critical cofactor required for the synthesis and function of numerous proteins whose roles range from antioxidants to enzymes required for mitochondrial function. The diet is an important source of copper, and our understanding of the complex process of copper absorption, intracellular processing, and efflux has improved by investigating the basis of two disorders of copper transport, Menkes syndrome and Wilson disease [173,174]. Menkes syndrome (MIM #309400) is a rare (1 in 100 000) X-linked recessive disorder of copper deficiency resulting from defective synthesis of the Menkes syndrome transport protein (MNK) (Fig. 51.6) [175]. By contrast, Wilson disease (WD; MIM #277900) is a more common autosomal recessive disorder that is the consequence of copper accumulation secondary to malfunctioning of the WD transporter [176]. Both transporters have been localized to the membranes of the trans-Golgi network (TGN), where they modulate copper transport into the network. When intracellular copper levels increase, both transporters redistribute to small vesicles and the plasma membrane, where they presumably control the efflux of copper out of the cell. Expression of MNK is primarily by enterocytes and cells of the placenta and central nervous system, whereas expression of the WD transporter is limited mainly to hepatocytes. Reflecting the tissue-specific expression pattern of the respective proteins, defects in the function of MNK result in inadequate efflux of copper from the gut, whereas an alteration of WD results in failure to excrete copper to bile, which subsequently accumulates in the liver [173].

The mechanism of dietary copper absorption has not been definitively established; however, two active transporters located on the apical membrane of the enterocyte have been implicated (Fig. 51.6). The H^+-divalent metal transporter (DMT1) has a broad range of substrates, including copper, iron, manganese, and cobalt [177]. A more specific larger family of high-affinity copper transporters, CTR1 and CTR2, has been isolated and is expressed in a broad range of tissues, including the intestine [178]. Within the intracellular compartment of the enterocyte, copper may be either incorporated into copper-containing proteins or conveyed into the TGN by means of the MNK transporter [173,174]. Copper

binds ceruloplasmin within the TGN and subsequently enters the systemic circulation bound primarily to ceruloplasmin. Although copper levels do not influence the production of ceruloplasmin, the latter has a shorter half-life during copper-deficient states, resulting in low ceruloplasmin levels. Because defects of both the MNK and WD transporters lead to impaired trafficking of copper across the TGN membrane, Menkes syndrome and WD are both associated with hypoceruloplasminemia.

Genotype–phenotype relationships have been established in Menkes syndrome, and the clinical consequences of mutations in MNK are primarily the result of a copper-deficient state that leads to improper synthesis of copper-containing proteins. Patients generally present during early infancy with failure to thrive, various neurological symptoms, hyperpigmentation, and morphological changes of the hair. Most children with Menkes syndrome die during early infancy, and although copper supplementation has not been shown to be efficacious, anecdotal reports suggest that copper-histidine may delay the onset of various symptoms [179]. In contrast, WD generally presents during early adolescence with either neurological or hepatic consequences of copper overload. Chelation therapy with D-penicillamine or ammonium tetrathiomolybdate augments renal excretion of copper while improving its positive balance in the liver and brain [180]. Oral administration of zinc has been shown to inhibit dietary intake of copper, presumably by competing for transport into the enterocyte by the DMT (Fig. 51.6) [177,180].

Disorders of iron transport

Our understanding of the mechanism of iron absorption has improved dramatically over the last decade with the discovery of the molecular basis of hereditary hemochromatosis (HH; MIM #235200) [181,182]. This is an autosomal recessive disorder characterized by excessive intestinal iron absorption and secondary multiorgan failure related to excessive tissue iron content. Hemochromatosis is the most common genetic disorder among individuals of European ancestry, with an estimated carrier frequency of about 1 in 8 [181,183]. The most common form of HH is secondary to mutations in the hemochromatosis gene *HFE*, which encodes a major histocompatibility class I-like protein. Several mutations, including Cys282Tyr, His63Asn, and Ser65Cys, account for the majority of abnormal alleles of the *HFE* gene [181,182].

The role of HFE in iron absorption was elucidated when HFE was found to interact with the transferrin receptor (TfR) with an affinity comparable with that of diferric transferrin (Fig. 51.6). Immunohistochemical analysis also confirmed that HFE and TfR were localized to both the basolateral membrane and the intracellular compartment of crypt cells of the intestine. It is believed that HFE facilitates the interaction of diferric transferrin and TfR, resulting in endocytosis by clathrin-coated vesicles and the eventual release of iron into the cell cytoplasm.

The primary apical iron transporter, DMT1, was isolated by expression cloning; it also transports copper, another divalent cation (Fig. 51.6) [177]. Because the absorption of dietary iron is limited to the reduced ferric (Fe^{2+}) form, the reduction of the oxidized form (Fe^{3+}) by the brush-border enzyme duodenal cytochrome *b* (CYBRD1) prepares it for transport (Fig. 51.6). Within the enterocyte, iron can be stored in ferritin, or effluxed across the basolateral membrane by the transporter ferroportin 1 (IREG1) [184]. At the basolateral membrane, hephaestin facilitates the export of iron with its ferroxidase activity. Both apical and basolateral iron transporters are expressed primarily in duodenal enterocytes located along the upper portion of the villus, and their expression is dramatically upregulated in iron-deficient states.

The common HFE mutations appear to inhibit its interaction with its heterodimeric partner, β_2-microglobulin, and diminish the level of HFE on the basolateral membrane. Because endocytosis of the transferrin–TfR–Fe^{2+} complex requires adequate levels of HFE, mutations of the HFE protein would reduce cytoplasmic iron levels while augmenting the expression of DMT1 and FPN1 and increasing iron intake [185,186]. By contrast, in iron-abundant states associated with wild-type HFE, endocytosis of the Fe^{2+}-containing complex would increase the cellular stores of iron and thereby reduce the synthesis of DMT1 and FPN1.

Deficiencies of proteins other than HFE have been implicated in the pathogenesis of other forms of hemochromatosis. Mutations in the gene encoding ferroportin 1 have been identified in an autosomal dominant form of hemochromatosis (MIM #606069) [187]. Hepcidin, TfR2, and hemojuvelin are three proteins expressed by hepatocytes that regulate the intestinal absorption of iron [188]. Defects in TfR2 have also been identified in several kindreds (MIM #604250), whereas a juvenile form of hemochromatosis (MIM #602390) has been associated with mutations of either hepcidin (an antimicrobial peptide synthesized by hepatocytes that appears to negatively modulate intestinal absorption of iron) or hemojuvelin [189–192]. Hepcidin responds to iron body stores and inflammation and regulates iron efflux by binding to the iron exporter ferroportin [193]. Moreover, hepcidin production is increased by IL-6 and appears to explain the anemia of chronic inflammation [194].

The mechanism by which heme-containing iron is transported in the intestine has been elucidated. Heme carrier protein 1 (HCP1) is located on the apical membrane of enterocytes of the duodenum and transports the heme–iron complex intact [195]. Once within the enterocyte the complex dissociates, probably by heme oxygenase, releasing iron, which is transferred to the circulation by the basolateral transporter ferroportin. Whereas the abundance of HCP1 was not altered by the iron status of the host, its expression was dramatically upregulated by hypoxia. Interestingly, in iron-depleted states, HCP1 occupies the apical brush-border

membrane, whereas in iron-plentiful conditions it moves to internal cellular compartments and thereby interrupts lumenal absorption [195].

Disorders of vitamin absorption

Folate malabsorption

Dietary folate is found primarily in green leafy vegetables, organ meats, and grains as polyglutamylated folates. Glutamate carboxypeptidase II (GCP-II), expressed on the brush-border membrane of small bowel enterocytes, hydrolyzes folylpolyglutamates to a form (monoglutamyl folates) that can be transported by the reduced folate transporter 1 (RFC-1) (Fig. 51.7). Once within the enterocyte, folylmonoglutamate is converted to 5-methyltetrahydrofolate (5-MTHF), which exits the basolateral membrane by means of the RFC-1 transporter. The folate-binding protein mediates the transport of 5-MTHF into hepatocytes, where it is stored in the form of polyglutamylated folates; these are essential cofactors for nucleic acid and amino acid synthesis.

Folate deficiency generally results in hyperhomocysteinemia because 5-MTHF is required to synthesize methionine from homocysteine. A sufficient level of methionine is required for the synthesis of *S*-adenosylmethionine, an enzyme critical for DNA methylation. Congenital folate malabsorption (MIM #229050) is a rare autosomal recessive disorder associated with the clinical symptoms of diarrhea, glossitis, and seizures in conjunction with pancytopenia [196]. The underlying mechanism of the congenital form of folate deficiency has not been identified. Folic acid deficiency has been definitively associated with neural tube defects in neonates and an increased risk of cardiovascular disease in adults with elevated levels of homocysteine [197]. Serum folate and homocysteine levels are readily available assays that may be used to assess adequate folate stores.

Vitamin B-12 malabsorption

The absorption of vitamin B-12 (cobalamin) is a complex process that is initiated by gastric acidity, which removes cobalamin from dietary proteins and transfers it to a binding protein called haptocorrin [198]. Intrinsic factor (IF), produced by parietal cells, binds cobalamin after pancreatic proteases hydrolyze the cobalamin–haptocorrin complex in the duodenum. The enterocytes of the ileum express cubulin, which forms a heterodimer with amnionless, forming a receptor for the cobalamin–IF complex (Fig. 51.7) [198]. The role of amnionless is to direct the receptor–vitamin complex to the endosomes, where it encounters a second receptor, megalin [199]. The cobalamin–IF complex is cleaved within the endosome, resulting in the formation of a cobalamin–transcobalamin 2 complex, which traverses the enterocyte and enters the systemic circulation.

The clinical consequences of vitamin B-12 and folate deficiency overlap because cobalamin is a cofactor for methionine synthase, which uses a methyl group from 5-MTHF to convert homocysteine to methionine [200]. Hyperhomocysteinemia is thus the consequence of both vitamin B-12 and folate deficiency. Defects of cobalamin absorption are, however, uniquely associated with methylmalonicacidemia because

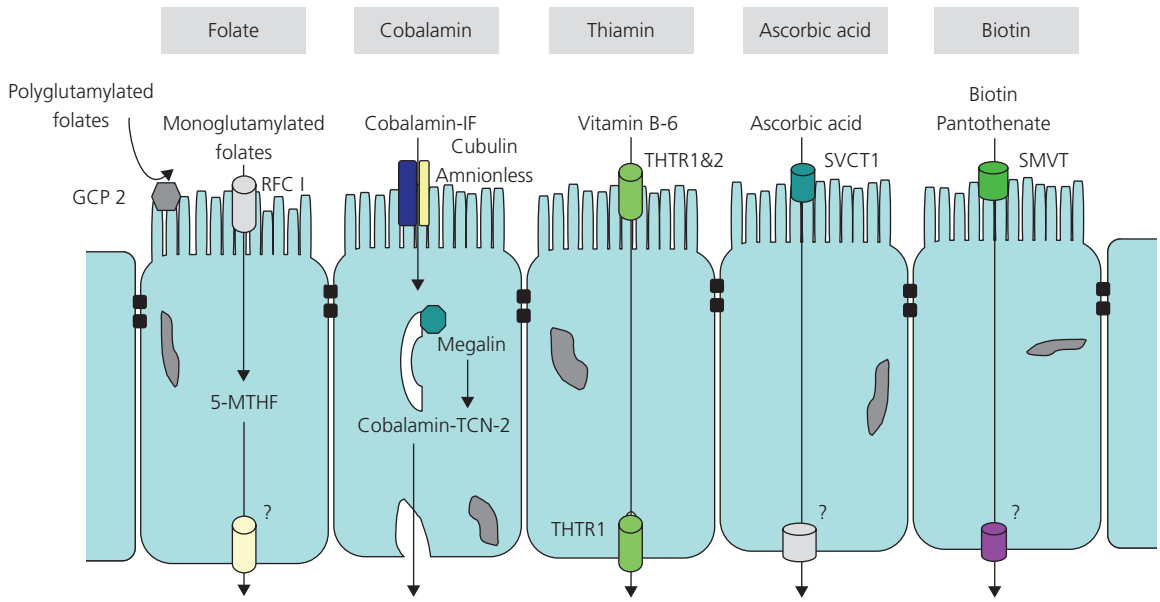

Figure 51.7 Water-soluble vitamin absorption in the small intestine. GCP, glutamate carboxypeptidase; IF, intrinsic factor; 5-MTHF, 5-methyltetrahydrofolate; RFC, reduced folate transporter; SMVT, sodium multivitamin transporter; SVCT, sodium vitamin cotransporter; TCN, transcobalamin; THTR, thiamine transporter protein.

adenosylcobalamin is required for appropriate mitochondrial fatty acid metabolism [201].

Because of the complexity of vitamin B-12 assimilation, deficiency may be secondary to numerous problems, ranging from inadequate intake to disruption of any of the various steps required for absorption [200]. Primary or secondary achlorhydria is commonly associated with cobalamin deficiency because gastric acidity is required for the formation of the cobalamin–haptocorrin complex. Bacterial overgrowth in the small intestine may also disrupt the cobalamin–IF complex and lead to a decline in cobalamin levels. Because cobalamin is absorbed exclusively in the ileum, disorders resulting in an inadequate ileal absorptive capacity will also result in vitamin B-12 deficiency.

There are three rare yet well-described autosomal recessive disorders associated with congenital forms of cobalamin deficiency. Congenital pernicious anemia (MIM #261000) is associated with an absence of IF, which facilitates the binding of cobalamin to the cubilin–amnionless receptor [202]. Imerslund–Grasbeck syndrome (MIM #261100) was originally described in both Finland and Norway. Linkage analysis of the Finnish patients identified mutations in the cubilin receptor [203], whereas the Norwegian cases were identified as secondary to mutations in the amnionless gene [198,204]. Finally, congenital defects of transcobalamin 2 (MIM #275350) have also been shown to result in inadequate levels of vitamin B-12 and in both bone marrow failure and a range of neurological deficits [205]. Measurement of serum vitamin B-12 levels and evidence of homocysteine and methylmalonic acid may be used to assess vitamin B-12 stores. The Schilling test is particularly useful in assessing the various origins of cobalamin deficiency [201].

Absorption of various water-soluble vitamins

The molecular mechanisms responsible for the absorption of several water-soluble vitamins have been elucidated. Vitamin C (L-ascorbic acid) has been found to be transported across the intestinal epithelial layer by the Na^+-dependent vitamin C transporter, SVCT1 (Fig. 51.7) [206,207]. Ascorbic acid transport by SVCT1 appears to be critical during the perinatal period because *Svct1*-null mice succumb immediately after birth [208]. Whereas dietary deficiency of ascorbic acid is common, inherited forms of a congenital deficiency have not been reported. Although the pyridoxine (vitamin B-6) transporter has not been identified, various characteristics of this pH-dependent carrier-mediated system have been determined [209].

Expression cloning techniques were used to identify the biotin transporter. The Na^+-dependent multivitamin transporter SMVT was also identified as transporting pantothenate (vitamin B-5) and lipoate with high affinities (Fig. 51.7) [210]. An abnormality of biotin transport was described in an encephalopathic child; however, the molecular mechanism has not been described [211]. Thiamin (vitamin B-1) absorption across the intestinal brush-border membrane is facilitated by two thiamin transporter proteins (THTR-1 and THTR-2). Both transporters are abundantly expressed in enterocytes, and whereas THTR-1 has been localized to both the apical and basolateral membranes, THTR-2 is restricted to the apical surface. The thiamin transporters resemble the structure of the folate transporter RFC-1, and mutations of THTR-1 have been associated with a thiamin-responsive megaloblastic anemia syndrome (MIM #249270) [212,213]. This is a rare autosomal recessive disorder that is associated with megaloblastic anemia, diabetes mellitus, and deafness.

Absorption of various fat-soluble vitamins

The most common causes of a generalized deficiency of fat-soluble vitamins include specific dietary restrictions and a wide assortment of gastrointestinal disorders that impair fat absorption. All fat-soluble vitamins are absorbed by enterocytes primarily by passive diffusion, a process that is facilitated by the emulsification of fats by bile salts. Selective deficiencies are certainly more unusual and may suggest a defect in the interaction of the vitamin with a specific transfer protein. For instance, vitamin A (retinol) is packaged in chylomicrons in the enterocyte and is eventually taken up by hepatocytes, where it is either stored or remains bound to retinol-binding protein for transfer to other cells. A rare inherited disorder of retinol-binding protein deficiency (MIM #180250) has been described and leads to an assortment of ophthalmological findings and a low serum level of vitamin A [214]. A selective vitamin E deficiency (MIM #277460) has also been identified that is secondary to mutations in the α-tocopherol transfer protein and results in a form of spinocerebellar ataxia and undetectable serum vitamin E levels [215].

Prebiotics and probiotics to alter the intestinal microflora, 1290

Bacterial overgrowth of the small bowel is a syndrome in which nutrient malabsorption is associated with excessive numbers of bacteria in the small intestine [1,2]. Other terms that have been used to describe the syndrome of bacterial overgrowth are blind loop syndrome, contaminated small bowel, small bowel stasis, and stagnant loop syndrome. Recognition dates back to 1897, when the association between pernicious anemia and strictures of the small intestine was first reported [3]. In 1939, the association of macrocytic anemia with intestinal strictures or anastomoses occurring as the result of bacterial overgrowth, or "putrefaction," was initially postulated [4].

Patients with a variety of structural or functional disorders of the intestinal tract are predisposed to the development of small bowel bacterial overgrowth [1,2]. Evidence suggests that bacterial overgrowth may develop in the absence of an anatomic lesion or a severe motility disorder, particularly in the elderly and children [5,6]. Bacterial overgrowth should be considered as a possible cause of diarrhea, malabsorption, or abdominal pain in these clinical settings. As the diagnosis of bacterial overgrowth presents many difficulties and limitations, a course of empiric treatment is often employed in clinical practice.

Conditions favoring bacterial overgrowth

The conditions favoring bacterial overgrowth can be classified according to the mechanisms involved in the normal control of the enteric microflora (Table 52.1). Furthermore, the presence of a single condition may not result in clinically significant small intestinal overgrowth until another condition favors bacterial overgrowth.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Stasis of the small intestine

Intestinal peristalsis plays a major role in preventing bacterial overgrowth. Anatomic or structural disorders that interfere with gut peristalsis frequently lead to small bowel bacterial overgrowth. These include, for example, chronic small intestinal obstruction secondary to intestinal strictures, such as those caused by Crohn's disease, lymphoma, or radiation injury [7–9]. Surgical alterations of the intestinal anatomy that create blind pouches or divert long segments of small bowel, such as end-to-side enteroenteric anastomosis, the Billroth II anastomosis, jejunoileal bypass, and the Koch distal ileal pouch (for continent ileostomies), have been associated with clinically significant bacterial overgrowth [10–12].

Table 52.1 Conditions favoring bacterial overgrowth

Intestinal stasis
Anatomic: strictures (e.g., Crohn's disease, radiation enteritis); diverticulosis of the small intestine; surgical operations
End-to-side enteroenteric anastomoses: Billroth II anastomoses; jejunoileal bypass; Koch distal ileal pouches
Small intestinal motility disorders
Scleroderma: idiopathic intestinal pseudoobstruction; diabetic autonomic neuropathy
Abnormal connection between proximal and distal bowel
Fistulae (secondary to peptic ulcer disease, carcinoma)
Gastrocolic: gastrojejunocolic
Resection of the ileocecal valve
Hypochlorhydria
Chronic atrophic gastritis
Hypochlorhydric medications
Surgical therapy for peptic ulcer disease
Immunodeficiency
Primary immunodeficiency states
Acquired immunodeficiency syndrome
Malnutrition
Age

Diverticula of the small intestine can serve as pockets of stagnation that can become clinically significant, particularly in the setting of hypochlorhydria or achlorhydria [10]. Generalized impairment of small intestinal motor function (see Chapter 47) may also lead to small bowel bacterial overgrowth. Malabsorption resulting from small intestine bacterial overgrowth has been documented in patients with intestinal hypomotility in association with scleroderma, idiopathic intestinal pseudoobstruction, and diabetic autonomic neuropathy [13–15]. Absent, or disordered, interdigestive migrating motor complex has also been associated with bacterial overgrowth [16]; in one patient, the return of the phase III complex of migrating motor complexes preceded the resolution of bacterial overgrowth [17].

Abnormal connections between proximal and distal portions of the bowel

Bacterial overgrowth of the small intestine may arise secondary to abnormal connections between the proximal bowel and the colon, which leads to seeding of the proximal bowel with colonic flora. Resection of the ileocecal valve frequently causes retrograde seeding of the small intestine with colonic flora and contributes to the development of small intestinal bacterial overgrowth [18,19]. Resection of the ileocecal valve (as well as a portion of the terminal ileum and cecum) also results in alterations of motility that may well play a contributory role in the development of bacterial overgrowth [20]. Gastrocolic or gastrojejunocolic fistulae arising in patients with gastric ulcers and ulcerating carcinomas of the stomach or colon can cause malabsorption resulting from the reflux of colonic contents, including lumenal bacteria, into the proximal bowel [21].

Gastric acid is responsible for decreasing the bacterial inoculum reaching the proximal small intestine. The proximal gastrointestinal bacterial concentration is markedly increased in patients with achlorhydria secondary to atrophic gastritis compared with healthy control subjects [22]. Gastric acid secretion is also impaired as a result of medical and surgical therapy of peptic ulcer disease. Increased bacterial counts and overgrowth have been reported in association with acid suppression therapies [23]. Gastric surgery affects bacterial proliferation by impairing gastric acid secretion and by altering gastrointestinal motility. The results of studies of both animal models and humans after surgery indicate that impaired gastric acid secretion alone is not sufficient to cause clinically significant bacterial overgrowth [11,24]. Hypochlorhydria, however, may promote intestinal overgrowth in patients who also have intestinal disorders associated with stasis (e.g., diverticula, delayed intestinal transit).

Immunodeficiency

Chronic diarrhea, malabsorption, and weight loss are observed in a number of immunodeficiency states (see Chapter 105). For example, more than half of patients with common variable immunodeficiency have chronic diarrhea. Overgrowth of bacteria is a common finding in these patients; however, the bacterial counts (particularly those of anaerobic organisms) are lower than those in cases associated with intestinal stasis [25]. Bacterial overgrowth may also be related to decreased acid secretion in some of these patients [25]. Chronic diarrhea is a prominent symptom in patients with the acquired immunodeficiency syndrome (AIDS), who may have multiple opportunistic infections (see Chapter 104); however, the cause of the diarrhea and malabsorption frequently cannot be identified. Bacterial colonization of the proximal bowel is observed in some patients with AIDS, but the role it plays in the pathogenesis of AIDS-related diarrhea remains unclear because the concentration of anaerobic organisms is lower than that usually observed in bacterial overgrowth associated with gut stasis [26].

Age

The prevalence of small bowel bacterial overgrowth increases with age, and overgrowth can occur in the elderly even in the absence of an anatomic defect of the small bowel [5,27–30]. Possible explanations are reduced gastric acidity, impaired intestinal motility, or both. As bacterial overgrowth is not associated with altered anthropomorphic measurements or bowel habits, the clinical significance of bacterial overgrowth in the elderly is unclear. However, in patients with evidence of malabsorption and bacterial overgrowth, treatment with antibiotics may prove of clinical benefit [30,31].

Pathogenesis

The pathogenesis of small bowel bacterial overgrowth can be considered in terms of the consequences of misplacing the normal colonic lumenal microbiota into the small intestine. The enteric flora, which normally is located principally within the colon, plays an important role in the metabolism of ingested substances (Table 52.2). In cases of small bowel bacterial overgrowth, microorganisms have greater access to nutrients. Mucosal injury also results in the malabsorption of fats, carbohydrates, and proteins [32,33]; however, bacterial invasion and translocation appear not to be the usual consequences of small bowel bacterial overgrowth [34].

The surgical creation of a self-filling blind loop (Fig. 52.1) in animals results in marked proliferation of both aerobic and anaerobic bacteria and reproduces the manifestations of overgrowth observed in humans [35,36]. Much of the experimental work that has defined the pathogenesis of small bowel bacterial overgrowth is based on the use of this model.

Malabsorption of fats and fat-soluble vitamins

Bacterial deconjugation of primary bile acids is a mechanism accounting for the malabsorption of dietary fats and fat-soluble vitamins [37,38]. Normal absorption of long-chain

Table 52.2 Pathogenesis of bacterial overgrowth

Bacterial metabolism of intralumenal substances
Impaired deconjugation of bile acids
Impaired vitamin B-12 metabolism
Impaired metabolism of carbohydrates
Malabsorption of fats and vitamins A, D, and E; generation of secretagogues
Malabsorption of vitamin B-12
Intestinal gas (H_2, CO_2), osmotic diarrhea
Mucosal injury
Decreased brush border enzyme activity: lactase, enterokinase, peptidase
Impaired uptake of monosaccharides
Impaired uptake of peptides
Impaired uptake of lipids
Lactose intolerance
Hypoproteinemia
Carbohydrate intolerance
Fat malabsorption

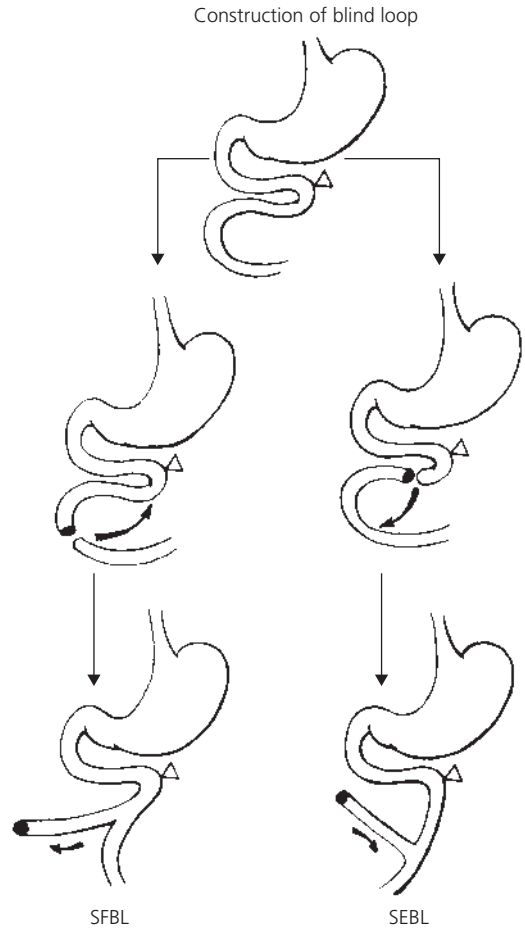

Figure 52.1 Animal model of small bowel bacterial overgrowth. Diversion of an isoperistaltic segment of jejunum results in the formation of a self-filling blind loop (SFBL). The SFBL is often used to characterize the pathophysiology of bacterial overgrowth in the small bowel because it results in the proliferation of colonic-type bacterial flora and sequelae that mimic those observed in human disease. A short, patent, antiperistaltic segment of jejunum, referred to as a self-emptying blind loop (SEBL), serves as an operated control because bacterial overgrowth and its sequelae do not develop postoperatively. From Sherman and Lichtman [45], with permission from S. Karger AG, Basel.

triglycerides requires a critical concentration of conjugated bile acids for the assembly of mixed micelles. Deconjugation of bile acids by lumenal bacteria, particularly anaerobic organisms [39], reduces the level of conjugated bile acids below the critical micellar concentration. Steatorrhea in patients [37] and experimental animals [38] with bacterial overgrowth is relieved by the administration of conjugated bile acids; however, the observation that complete biliary diversion in animals does not produce the steatorrhea seen in bacterial overgrowth indicates that other factors are also likely to play a role [19].

Deficiencies of vitamins D, A, and E have each been reported as complications of small bowel bacterial overgrowth [40,41]. The synthesis of vitamin K by lumenal bacteria, however, accounts for the absence of coagulopathy in patients with bacterial overgrowth. Bacterial metabolites, such as hydroxylated fatty acids and unconjugated bile acids, may have a direct toxic effect on the intestinal mucosa, resulting in the malabsorption of fats, carbohydrates, and proteins. These metabolites also act as secretagogues that can contribute to the development of diarrhea.

Carbohydrate intolerance

Bacterial overgrowth results in carbohydrate intolerance secondary to a reduction of brush border disaccharidases and decreased uptake of monosaccharides [42–45]. Lactase activity is the first hydrolase to be reduced and is the last disaccharidase activity to recover after antibiotic therapy is administered [43,45]. Anaerobic organisms produce proteases that either cleave or destroy hydrolases on the apical brush border of enterocytes [42,43,46]. Carbohydrate malabsorption and maldigestion result in increased delivery to the colon of osmotically active sugars, which then further contribute to the development of the diarrhea associated with bacterial overgrowth. Bacterial metabolism of unabsorbed carbohydrates to hydrogen and carbon dioxide plays a role in the development of abdominal pain and serves as the basis of the various breath tests that have been employed as indirect assays of the presence of small bowel bacterial overgrowth.

Hypoproteinemia

Hypoproteinemia is common in bacterial overgrowth, although severe protein undernutrition is rarely seen [47]. Normal protein assimilation is disrupted by multiple factors: bacteria

compete with the host for protein substrates [44]; decreased amino acid and peptide uptake is demonstrated in experimental models reflecting mucosal injury [47]; decreased levels of enterokinase are noted in patients with bacterial overgrowth, which could impair the activation of pancreatic proteases [48]; and, finally, a protein-losing enteropathy has been described both in patients and in experimental animals with small bowel bacterial overgrowth [49].

Malabsorption of water-soluble vitamins

The association of macrocytic anemia with bacterial overgrowth is the result of direct competition between the intestinal flora and the host for vitamin B-12. Anaerobic organisms are primarily responsible because only anaerobicidal therapy reverses vitamin B-12 deficiency in an experimental model of stasis [19]. Anaerobic organisms, in contrast to aerobic bacteria, use vitamin B-12 either in its free form or when it is complexed with intrinsic factor [50,51]. When bacteria take up the vitamin, not only does it become unavailable to the host but also inactive metabolites are produced that compete with normal vitamin B-12 binding and absorption [52]. In contrast, folate levels are either normal or elevated in bacterial overgrowth because bacteria synthesize folate that subsequently is absorbed by the host. Levels of thiamin [53] and nicotinamide [54] have also been reported on occasion to be low in patients with small bowel bacterial overgrowth.

Although iron-deficiency anemia is not commonly observed with small bowel bacterial overgrowth in humans, increased intestinal losses of iron and blood are documented in animal models [55]. Mineral and trace element micronutrient deficiencies have not been reported in patients with bacterial overgrowth.

Liver disease

Hepatobiliary injury is observed in experimental models of bacterial overgrowth in susceptible rat strains [56,57]. The injury can be prevented by antibiotic treatment [58]. Bacterial cell wall polymers derived from the blind loop have been identified as the underlying cause of the abnormalities identified in the liver and bile ducts [56].

A high prevalence of small bowel bacterial overgrowth is reported in patients with nonalcoholic steatohepatitis (NASH). It has been proposed that bacterial overgrowth plays a role in the pathogenesis of NASH by triggering the release of proinflammatory cytokines, including, for example, elevated levels of tumor necrosis factor-α [59,60]. Small bowel bacterial overgrowth also occurs with increased frequency in patients with cirrhosis [61,62]. The underlying mechanisms are likely to be multifactorial, including both gastric hypoacidity and delayed small bowel transit. The consequences of these changes are not fully understood, but it has been suggested that patients with cirrhosis and small bowel bacterial overgrowth are predisposed to the development of spontaneous bacterial peritonitis [61–63].

Pathology

Lumenal bacteria can clearly influence intestinal morphology. Many of the morphological characteristics of the normal intestinal epithelium are seen only in the presence of a resident microbiota (see Chapter 25). In the germ-free state, villi are thinner and longer, and the crypts are shallower. Enterocytes are cuboidal rather than columnar in shape. The lamina propria consists of a sparse stroma infiltrated with few lymphocytes and macrophages, plasma cells are absent, and the Peyer patches are smaller, with fewer germinal centers. Under light microscopy, the histological appearance of the small intestine in the setting of bacterial overgrowth usually is not markedly different from that of the normal small bowel. The main purpose of obtaining a mucosal biopsy specimen in the evaluation of these patients, therefore, is to rule out mucosal enteropathies such as celiac sprue.

Histological evidence of mucosal damage, however, has been identified in some cases of bacterial overgrowth, including subtotal villous atrophy and increased numbers of inflammatory cells within the lamina propria [33]. Focal areas of ulceration and erosion are observed in some instances and may be important in understanding the symptoms of "pouchitis" associated with bacterial overgrowth after the surgical creation of a continent ileostomy (Koch pouch) or ileoanal anastomosis [64,65]. Ultrastructural studies in experimental models of bacterial overgrowth reveal vacuolization of microvillus membranes and swelling of the mitochondria (Fig. 52.2), suggesting that bacterial overgrowth does result in damage to the enterocyte [32].

Clinical manifestations

Many of the clinical features of bacterial overgrowth can be predicted based on the pathogenesis of the disorder (Table 52.3). Diarrhea and weight loss are prominent symptoms and are largely a consequence of the malabsorption and maldigestion of fats, carbohydrates, and proteins. In addition, many patients with bacterial overgrowth curtail their dietary intake to reduce symptoms [2]. Using lactulose and confirmatory glucose breath testing, one study found that 20% of 145 consecutive patients with Crohn's disease had evidence of small bowel bacterial overgrowth [66]. Although not compared in a placebo-controlled fashion, apparent improvements in symptoms of bloating, abdominal pain, and consistency of the bowel motions were observed in the 29 subjects with bacterial overgrowth receiving oral antibiotics. Abnormal results of breath testing also returned to normal values in 27 of 29 patients treated with either metronidazole or ciprofloxacin. In one study, small bowel bacterial overgrowth was identified as the underlying cause of symptoms in 48% of 87 consecutive children evaluated for chronic diarrhea [67].

Figure 52.2 Electron micrograph of columnar cells in the midvillus area of a self-filling blind loop. In the cell at the lower left, the microvilli are regular, and the mitochondria and endoplasmic reticulum are unaltered. In the cell at the upper right, the microvilli are altered, and the mitochondria and endoplasmic reticulum are swollen. Alterations of the microvilli include blunting, swelling, budding, and ballooning. (Original magnification × 22 000). From Toskes et al. [32], with permission from Elsevier.

Table 52.3 Clinical manifestations of bacterial overgrowth

Diarrhea
Steatorrhea
Malnutrition
Macrocytic anemia
Abdominal pain
Peripheral neuropathy
Tetany
Osteomalacia
Night blindness
Dermatitis, hepatic injury, nephrotoxicity, and arthritis (observed in jejunoileal bypass)

The association of macrocytic anemia with intestinal strictures is a manifestation of vitamin B-12 deficiency. Patients also may present with the neurological changes associated with vitamin B-12 deficiency. Recurrent abdominal pain may be reported, particularly among young children [6]. Other presentations include night blindness, osteomalacia, tetany, peripheral neuropathy, and edema [68,69], reflecting malabsorption of micronutrients such as vitamins A, D, and E, as well as thiamin and nicotinamide.

It is possible that the diagnosis should also be considered in patients with symptoms of irritable bowel syndrome [70]. A high prevalence of bacterial overgrowth has been reported in patients in whom irritable bowel syndrome has been diagnosed. For instance, one report describes a prevalence of abnormal lactulose breath hydrogen tests in more than 80% of patients with irritable bowel syndrome [71]. Furthermore, treatment of the bacterial overgrowth reduced intestinal symptoms in three-fourths of the subjects. A randomized, placebo-controlled trial by other investigators is clearly warranted to confirm these provocative findings [72], as others have not been able to confirm the reported association between bacterial overgrowth and irritable bowel syndrome [73]. It is possible that the variable findings simply may be related to the method that is employed to establish the diagnosis of small bowel bacterial overgrowth [74]. In the setting of irritable bowel syndrome, lactulose breath hydrogen testing may provide false-positive test results. Alternative methods to establish the diagnosis (e.g., culture of duodenal fluid) and confirmation of the consequences of bacterial overgrowth other than carbohydrate malabsorption (including steatorrhea and vitamin B-12 malabsorption) in subjects with irritable bowel should be undertaken to clarify the current controversy in the field [75].

Extraintestinal manifestations of bacterial overgrowth have been observed, especially in patients who have undergone jejunoileal bypass. These immune complex-mediated disorders include dermatitis, hepatic injury, nephrotoxicity, and arthritis [76].

Diagnosis

The diagnosis of small bowel bacterial overgrowth should be considered in patients with chronic diarrhea who have the predisposing conditions discussed previously in this chapter. The differential diagnostic considerations include other causes of malabsorption and maldigestion: intestinal mucosal diseases (e.g., gluten-sensitive enteropathy), infections (particularly parasitic diseases such as giardiasis), and exocrine pancreatic insufficiency. In patients with underlying diseases that favor bacterial proliferation, such as Crohn's disease or scleroderma, it may be difficult to distinguish whether clinical deterioration is caused by the development of bacterial overgrowth or worsening of the primary intestinal disease.

Microbiological culture of small bowel aspirates is considered the most direct method for diagnosing bacterial overgrowth (Table 52.4). In general, the diagnosis of bacterial overgrowth is confirmed if the count exceeds 10^5 colonies per mL after duodenal intubation. A variety of techniques have been reported: the use of sterile and nonsterile tubes, the capsule method, direct needle aspiration of gut contents, and the string test [77,78]. The feasibility of collecting aspirates from the proximal small bowel under direct visualization at the time of fiberoptic endoscopy has been demonstrated and can facilitate the collection of appropriate samples [79].

Table 52.4 Diagnostic tests for bacterial overgrowth

Test	Limitations
Culture of small intestinal aspirate	Invasive, possible contamination with oral flora, difficulty in transportation of anaerobic cultures, distal intestinal overgrowth can be missed
^{14}C-xylose breath test	Radioactivity, decreased sensitivity
Hydrogen breath tests:	
Glucose–hydrogen	20% of population unable to produce hydrogen, decreased sensitivity
Lactulose–hydrogen	Distal intestinal overgrowth can be missed because of overlap between early and late peak

Small intestinal aspirates are obtained by placing a sterile suction catheter inside a sterile overtube that is passed through the suction channel of the endoscope after the desired collection site is reached. Aspirates should be transferred immediately to an anaerobic transport vial and contents plated onto agar plates for the growth of both aerobic and anaerobic organisms [79]. Small bowel bacterial overgrowth usually is associated with the detection of anaerobic organisms. However, because of the technical difficulties related to the successful culturing of fastidious anaerobic bacteria, the presence of more than 10^5 colony-forming units per mL in the duodenum is considered diagnostic for small bowel bacterial overgrowth. Analyses of unconjugated bile acids [80] and short-chain fatty acids [81] in the fluid have also been performed but remain largely investigational tools. In addition to the technical difficulties involved in collecting the specimen properly (e.g., without contamination by organisms resident as part of the normal oral microflora) and in transporting and culturing lumenal fluids, an aspirate of the proximal bowel may not accurately reflect bacterial overgrowth in the distal small intestine.

Breath tests were devised as a less invasive alternative to intubation of the proximal bowel. These tests measure the breath excretion of carbon dioxide or hydrogen produced during the intralumenal bacterial metabolism of an administered substrate. The bile acid or carbon 14-cholylglycine breath test was one of the first breath tests developed, but it does not distinguish bacterial overgrowth from ileal malabsorption [82]. Because of its relatively poor sensitivity and low specificity, this test has been largely abandoned. A radioactively labeled pentose, ^{14}C-D-Xylose, is a more suitable substrate for use in breath testing because it is minimally metabolized by the host. D-Xylose is absorbed in the proximal bowel, whereas bile acids are absorbed in the ileum, so the chance of obtaining a false-positive measurement – as a result of colonic metabolism – is reduced [19]. The sensitivity of this test ranges between 30% and 100% [31,83]. The specificity of the test appears to be high (89%–100%) [31,83]. To avoid the administration of radioactive substrates, employing stable isotopes in combination with mass spectrometry, such as the ^{13}C-xylose breath test, is likely see more widespread use in the future [84].

The hydrogen breath tests also have the advantage of not involving radioactive substrates. However, a limitation with the use of these tests is that 15%–20% of the human population harbor a resident microflora that does not produce hydrogen [85]. Lactulose and glucose are two substrates often used for the purpose of diagnosing small bowel bacterial overgrowth. Patients with bacterial overgrowth who are administered lactulose exhibit an early breath hydrogen peak from small intestinal bacterial fermentation, followed by a prolonged peak from colonic bacterial metabolism [85]. In a case of distal intestinal overgrowth, however, it may be difficult to resolve the two peaks. In a study from Burma comparing the 10-g lactulose–hydrogen breath test with the Enterotest string test, only 2 of 15 children with more than 10^5 organisms per mL had a positive breath test result [86]. In another study the glucose–hydrogen and lactulose–hydrogen tests showed sensitivities of 62% and 68%, respectively, and specificities of 83% and 44%, respectively, in comparison with jejunal culture [87]. An elevated level of fasting breath hydrogen has been observed in some patients with small bowel bacterial overgrowth, but this is a relatively insensitive indicator [88]. Analysis of the presence of unconjugated bile acids in serum may provide another noninvasive test for the diagnosis of small bowel bacterial overgrowth [89].

In summary, each of the currently available diagnostic tests has limitations. Many of the tests are still used primarily as investigational tools and are not widely available in the clinical setting. Barium studies may be useful for documenting an anatomic defect or suggesting the presence of a severe motility disorder. In certain clinical situations, such as the need to document fat malabsorption or vitamin B-12 malabsorption in the setting of an anatomic defect or severe motility disorder, it is reasonable to consider a course of empiric antibiotic therapy without further confirmation of the diagnosis. In the absence of a documented predisposing abnormality of the gastrointestinal tract, however, it is recommended that further diagnostic testing be performed. Routine upper gastrointestinal endoscopy with small bowel biopsy and culture of an aspirate obtained by means of a sterile overtube [69] may be the most efficient means of confirming the diagnosis and excluding other causes of malabsorption due to an enteropathy, such as celiac sprue, giardiasis, and previously

unrecognized infections that can mimic bacterial overgrowth syndrome [90].

Treatment

Initial management consists of fluid and nutritional support, including the correction of documented vitamin deficiencies (Table 52.5). After small bowel bacterial overgrowth has been diagnosed, an attempt should be made to identify an underlying cause. Surgical correction of an anatomic cause of intestinal stasis should be considered. Severe motility disorders are more difficult to manage. Administration of low doses of octreotide to patients with scleroderma for 3 weeks has been reported to clear bacterial overgrowth, as demonstrated by a reversal of abnormal breath hydrogen excretion [91]. At higher doses, however, octreotide can cause steatorrhea secondary to hypomotility and bacterial overgrowth [92]. The prokinetic cisapride may help to normalize intestinal motility in patients with motor disorders and has been efficacious in the treatment of bacterial overgrowth in patients with cirrhosis [63,93]. However, access to this therapeutic agent is limited in some countries, including the United States. The efficacy of motilin receptor agonists in the treatment of dysmotility-associated bacterial overgrowth remains to be tested [94].

Often, the underlying lesion predisposing to small bowel bacterial overgrowth cannot be corrected, and the primary treatment is directed at suppressing the lumenal flora by using oral antibiotics. Although numerous antibiotics have been reported to be effective, few controlled trials have formally studied the choice of antimicrobial agent. In a randomized crossover trial, both norfloxacin and amoxicillin–clavulanic acid given for 7 days were effective in treating diarrhea and in reducing the level of breath-excreted hydrogen in subjects with bacterial overgrowth [95]. However, diarrhea often recurred within a week after the antibiotics were discontinued. This observation has prompted practitioners to employ either repeated or rotating courses of antimicrobial therapy. A study of the relative efficacy of two antibiotics that were given in sequence to seven patients with bacterial overgrowth indicated that metronidazole is more effective in improving relevant clinical symptoms than the nonabsorbable antibiotic rifaximin, even though both agents reduced levels of hydrogen excretion in breath samples after the ingestion of a glucose load [96]. Another study testing three doses of rifaximin [97] showed a dose-dependent reduction in breath-excreted hydrogen following glucose ingestion in 90 subjects with small bowel bacterial overgrowth; however, this study did not compare its efficacy in symptom resolution with another antimicrobial agent.

Although the precise cause of pouchitis is not known [98], mucosal inflammation in surgically fashioned ileal neoreservoirs has been associated with the overgrowth of anaerobic bacteria. In many cases there will be a positive response to therapy with broad-spectrum antibiotics, including metronidazole. In vitro studies support the efficacy of metronidazole in reducing the proinflammatory effects of sonicated lumenal contents derived from patients with documented pouchitis [99].

Table 52.5 Treatment of bacterial overgrowth

Nutritional supplementation
Increase calorie intake
Correct micronutrient deficiencies (e.g., vitamin B-12)
Correction of intestinal stasis
Surgery (e.g., resection of strictures)
Prokinetic agents
Low-dose octreotide (in progressive systemic sclerosis)
Antibiotics

Prebiotics and probiotics to alter the intestinal microflora

Details of the normal colonic microbiota are considered in Chapter 25. Probiotics refers to live microbes that confer health benefits to the host. Prebiotics is used to refer to nondigestive carbohydrates, such as inulin and fructooligosaccharides, which in a selective manner promote the growth of probiotic agents (primarily bifidobacteria) but not strict anaerobic organisms such as *Bacteroides* and *Clostridium* species [100,101]. Synbiotics defines the mixture of prebiotics and probiotics when employed together as combination therapy. Interest has focused on the potential of probiotics as therapeutic agents in the prevention and management of a variety of disease states, including small bowel bacterial overgrowth [102,103,104].

A variety of nonpathogenic bacteria and fungi have been employed as probiotic agents. Although primarily lactic acid-producing gram-positive bacteria (lactobacilli, bifidobacteria and *Streptococcus salivarius* subspecies *thermophilus*) have been used [105], the gram-negative organism *Escherichia coli* strain Nissle 1917 and the yeast *Saccharomyces boulardii* have also been investigated in both animal and human studies. Interest has focused on the potential benefit of employing a combination of probiotic agents [106]. The need for large numbers of viable bacteria to provide greater efficacy has also been emphasized [107].

Probiotic strains exert their beneficial effects through a variety of mechanisms that appear to be unique to each strain [108]. Whether or not living microorganisms are required or even if oral administration is necessary for clinical benefit is still uncertain and might well depend on the clinical effect and the bacterial strain. For instance, several

studies in animal models have demonstrated that nonviable bacterial components could have beneficial effects. Bacterial DNA derived from a probiotic mixture attenuated colitis, an effect that was dependent on Toll-like receptor 9 (TLR-9) [109,110]. Probiotics can also impact on other Toll-like receptors (e.g., TLR-2, TLR-4), particularly in the small bowel [111]. Probiotics also modulate intestinal epithelial barrier function [112], possibly through interactions with TLR-2 [113]. Furthermore, probiotic compounds may not have to be taken orally to have benefits. One study showed, for instance, that subcutaneous delivery of *Lactobacillus salivarius* attenuated colitis and proinflammatory cytokine production in a mouse model [114]. These reports suggest that, in the future, it may be possible to use nonviable and purified probiotic components for the prevention and treatment of human diseases. By contrast, other reports [115,116], albeit using different experimental models and approaches, indicate the need for viable organisms.

Probiotics may prove useful in prolonging remission after antibiotic therapy of bacterial overgrowth. Probiotics are also reported to have efficacy as primary therapy in the treatment of small bowel bacterial overgrowth, but the data are not entirely convincing. Treatment with *S. boulardii* for 7 days showed no efficacy in one trial [95]. On the other hand, probiotic therapy with *Lactobacillus plantarum* 299V and *Lactobacillus* GG was reported as helpful in treating children with small bowel bacterial overgrowth complicating short bowel syndrome [117]. An apparent, but modest, benefit was observed using a single probiotic strain (*Lactobacillus acidophilus*) in an open uncontrolled trial to treat eight subjects with small bowel bacterial overgrowth developing as a complication of chronic renal failure [118].

Probiotics have proven to be effective in the management of ileal inflammation following colectomy and ileal pouch formation (referred to as pouchitis). Randomized controlled trials have shown that the administration of a high dose of a combination preparation of probiotics (5×10^{11} viable lyophilized bacteria per gram containing four strains of lactobacilli, three strains of bifidobacteria, and *Streptococcus salivarius* subspecies *thermophilus*) is effective in the maintenance of antibiotic-induced remission of pouchitis and in postsurgical prevention of pouchitis [119,120]. Trials using a fermented milk product containing lactobacilli and bifidobacteria have also shown some benefit [121]. A reduction in the level of proinflammatory cytokines in the neoreservoir appears to provide an explanation for the mechanism underlying the reported benefits of probiotics in the setting of both preventing and treating pouchitis [122]. By contrast, the use of *Lactobacillus* GG for the treatment of active pouchitis did not demonstrate efficacy [123].

One advantage of using probiotics as therapeutic agents is that the organisms do not permanently reside in the gut. On the other hand, the potential for adverse effects when providing large numbers of viable bacteria, even those that only transiently colonize the gastrointestinal tract, especially to undernourished and immunocompromised patients, cannot be overlooked [124,125]. Nevertheless, the mechanisms underlying the observations that probiotics may be employed as therapeutic agents in a variety of diseases are the subject of intensive research [126,127]. This knowledge could be used to define novel intervention strategies for future use in a variety of disease states, including the treatment of small bowel bacterial overgrowth syndrome and its varying clinical manifestations.

The term short bowel syndrome covers the symptoms and pathophysiological disorders associated with a malabsorptive state resulting from the removal of a large portion of the small or large intestine. The extent of intestinal resection that will produce this syndrome varies from one person to another. In children, survival without enteral supplements or total parenteral nutrition (TPN) is generally possible if there remains more than 40 cm of the small intestine (i.e., at least 20% of the normal length), measured distally from the ligament of Treitz. In adults, survival without enteral or parenteral nutrition is generally possible if the residual length of the small intestine, measured distally from the ligament of Treitz, is more than 150 cm (i.e., 25% of the normal length). In general, if the ileocecal valve is removed, longer lengths of residual bowel may not prevent short bowel syndrome.

Short bowel syndrome refers only to a well-organized clinical pattern that is sometimes seen in patients with intestinal resection and is not necessarily related to the length of intestine removed. The clinical consequences of removing a portion of the small intestine are extremely variable and depend on a number of factors, including the extent of resection, the site of resection, and subsequent adaptive processes. Thus, it is possible that the removal of identical lengths of small intestine may cause short bowel syndrome to develop in one person but not in another. Due to this confusion, consensus definitions do not include the length of residual intestine. Rather, short bowel syndrome is defined as "result[ing] from surgical resection, congenital defect or disease-associated loss of absorption and is characterized by the inability to maintain protein-energy, fluid, electrolyte or micronutrient balances when on a conventionally accepted, normal diet" [1]. A broader term, *intestinal failure*, encompasses short bowel syndrome, but also includes disease states where the intestine is not reduced in length but is functionally impaired. According to the consensus definitions, "intestinal failure results from obstruction, dysmotility, surgical resection, congenital defect, or disease-associated loss of absorption and is characterized by the inability to maintain protein-energy, fluid, electrolyte, or micronutrient balance" [1].

Significant confusion exists regarding the actual length of the small intestine. Autopsy studies report the length of the small intestine as the distance from the pylorus to the ileocecal valve. Because it is difficult to measure the length of the duodenum, however, measurements made during operations often report the length of the small intestine as the distance from the ligament of Treitz to the ileocecal valve. The mean length of the small intestine at autopsy (from pylorus to ileocecal valve) has been reported as 630 cm in men and 592 cm in women; the mean colonic length is 150 cm in both sexes. These lengths are likely to be greater than the lengths measured in vivo because tone is lost in the postmortem state. Furthermore, small intestinal lengths probably differ according to racial and genetic factors. Full-term newborns have about 250 cm of small intestine and 50 cm of colon. The small intestine develops to its adult length by about 9 years of age.

Although clear functional distinctions exist between the proximal jejunum and the distal ileum, it is difficult to determine the exact normal ratio of jejunal length to ileal length because no clear demarcation exists between the two. In general, in North American adults, the proximal two-fifths (~ 240 cm) of the small bowel are referred to as the *jejunum,* and the distal three-fifths (~ 360 cm) are called the *ileum* [2,3].

Incidence and prevalence

The overall incidence and prevalence of short bowel syndrome are extrapolated from the incidence and prevalence of home parenteral nutrition, for which short bowel syndrome is the most prevalent indication. A 1997 survey indicated

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

that the incidence of home TPN was 3 per million and the prevalence was 4 per million [4]. A retrospective review from a major pediatric referral center estimated the overall incidence of short bowel syndrome in neonates was 22 per 1000 neonatal intensive care unit admissions and 25 per 100 000 live births [5]. The small bowel syndrome case fatality rate in this cohort was 37.5%.

Etiology

Adults

Several conditions are associated with short bowel syndrome in adults (Table 53.1) [6]. The most common of these are intestinal resection following a vascular insult to the small intestine (thrombosis or embolism of the superior mesenteric artery, thrombosis of the superior mesenteric vein, volvulus, strangulation) and Crohn's disease, with or without multiple intestinal resections. Less common causes of short bowel syndrome are jejunoileal bypass for obesity, abdominal trauma with resultant intestinal resection, inadvertent gastrocolic fistulization at the time of operation, radiation enteropathy, and neoplasms involving the gastrointestinal tract.

Infants and children

Most of the underlying causes of short bowel syndrome in children develop during intrauterine life (Table 53.2) [6]. Prenatal vascular accidents presenting as intestinal atresia or volvulus that result from malrotation are a particularly common cause of short bowel syndrome in this age group. Less common postnatal causes include extensive aganglionosis, vascular insults, surgery for necrotizing enterocolitis or Crohn's disease, and trauma.

Table 53.1 Causes of short bowel syndrome in adults

Vascular insults
Thrombosis or embolism of the superior mesenteric artery
Thrombosis of the superior mesenteric vein
Volvulus
Strangulation
Postoperative
Jejunoileal bypass for obesity
Abdominal trauma necessitating bowel resection
Inadvertent gastrocolonic/ileal anastomosis
Miscellaneous
Crohn's disease, with or without surgical resection
Intestinal fistula
Radiation enteropathy
Primary or secondary neoplasms involving the gastrointestinal tract

Table 53.2 Causes of short bowel syndrome in infants and children

Prenatal
Vascular insults
Intestinal atresia
Midgut volvulus (malrotation)
Abdominal wall defects
Gastroschisis
Postnatal
Arterial thrombosis or embolism
Venous thrombosis
Necrotizing enterocolitis
Trauma
Crohn's disease
Volvulus
Hirschsprung disease
Radiation enteropathy
Complicated intussusception

Factors influencing short bowel syndrome [7–10]

Extent of intestine removed

Generally, the more extensive the resection of the small intestine, the greater the loss of absorptive surface area that transports nutrients, water, and electrolytes. It is clear, however, that the length of residual intestine and its function are more important prognostically than the extent of intestine removed. Short bowel syndrome can result from either a single massive intestinal resection or repeated lesser resections. Mesenteric vascular disease is more prevalent among patients who have undergone massive resection, whereas Crohn's disease is more prevalent in patients who have undergone repeated surgical resections leading to short bowel syndrome [11,12]. Although the 30-day mortality rate is higher in patients who have had a massive resection, those surviving longer than 30 days have similar survival rates at 5 years [12].

The amount of small intestine remaining after resection determines the surface area available for absorption, as well as the transit time and subsequently the time during which nutrients and nonnutrient fluids and electrolytes are in contact with the absorptive surface of the intestine. The retention of the ileocecal valve will have a marked effect on slowing transit time and can significantly improve absorption. By contrast, the presence of residual disease in the remaining intestine can also adversely affect absorption of nutrients and electrolytes.

About 50% (~ 300 cm) of the small intestine usually can be resected without the development of the significant nutrient or electrolyte losses that lead to short bowel syndrome. The removal of more than 75% (~ 450 cm) of the small intestine almost invariably results in fluid or electrolyte

malabsorption that requires enteral or parenteral replacement therapy.

Site of intestine removed

Jejunum

The jejunum, in its intact state, absorbs a significant fraction of the nutrients and water required by the body, but removal of the jejunum alone generally causes only a limited defect in the absorption of macronutrients, electrolytes, and free water. This limited effect is a consequence of two factors: first, the jejunum is "leaky," and thus a significant back diffusion of transported material into the lumen occurs, causing water and electrolyte absorption in this region of the bowel to be inefficient (~ 40% efficient) when compared with the ileum (~ 75% efficient); second, the ileum is the part of the intestine with the greatest capacity for adaptation, and it can compensate for almost all the absorptive functions of the jejunum [13]. Thus, jejunal resections are often reasonably well tolerated.

Removal of the jejunum reduces the secretion of cholecystokinin and secretin, which may lead to subsequent decreases in biliary and exocrine pancreatic secretions; in turn, these decreases compromise nutrient absorptive capacity. In addition, cholecystokinin, vasoactive intestinal peptide, gastric inhibitory peptide, and serotonin, all of which are distributed mainly in the jejunum, inhibit gastric secretion. Thus, gastric hypersecretion is more likely to occur after resection of the jejunum [14,15]. Increased serum gastrin levels and gastric hypersecretion also are seen more frequently after jejunal resection; these increases probably are also related to the length of bowel resected [16,17].

Ileum

The ileum, which is relatively impermeable compared with the jejunum, remains critically important in the active transport of nutrients and fluid and electrolytes. Removal of the ileum alone generally results in adequate nutrition (maintained by jejunal absorption) but results in fluid and electrolyte deficiencies. With a resected ileum the colon is often incapable of handling the large volume of chyme delivered from the jejunum, and fluid loss is exacerbated by bile acid and fatty acid-induced diarrhea. For this reason, patients usually poorly tolerate extensive ileal resections.

The ileum is the only site of active bile acid absorption from the intestine, although small amounts of bile acids are absorbed by passive diffusion in the jejunum and colon. Therefore, a loss of more than 100 cm of ileum usually precludes the active intestinal absorption of bile acids; thereafter, the passive absorptive capacity of the rest of the small intestine is rapidly overwhelmed, and bile acids are left in the lumen and spill into the colon [8]. These bile acids are deconjugated by colonic bacteria. The deconjugated bile acids directly stimulate the colon to secrete fluid and electrolytes, causing a secretory watery diarrhea and thereby aggravating the short bowel syndrome [13,14]. Bile acids stimulate active anion secretion in the colon through several mechanisms:

- increasing cytosolic calcium levels within colonocytes through a calcium ionophore effect
- increasing prostaglandin synthesis in lamina propria cells
- stimulating excitatory enteric neurons, which then stimulate active anion secretion and propulsive motor contractions
- increasing tight junction permeability to fluid and electrolytes.

During intestinal adaptation, the body compensates for bile acid loss into the colon by maintaining the size of the bile acid pool through an up to eightfold increase in hepatic bile acid synthesis. The more extensive losses of ileum, however, result in severe bile acid malabsorption wherein loss exceeds synthesis. A reduction in the circulating pool of bile salts follows, leading to impaired intestinal micelle formation and the spillage of fat (steatorrhea) into the colon. Fat within the colon is hydroxylated by bacteria into hydroxy fatty acids. Hydroxystearic acid is the hydroxy acid most often associated with steatorrhea, and it has inhibitory effects on colonic fluid and electrolyte absorption. Hydroxy fatty acids stimulate net secretion through several mechanisms: changing net absorption to net secretion, increasing mucosal permeability, and increasing propulsive motor activity. These effects are similar to those of bile acids and may be related to the detergent properties of both hydroxy fatty acids and bile acids.

The ileum is the primary site of vitamin B-12 absorption. Malabsorption of vitamin B-12 occurs after the resection of more than 60 cm of ileum. The intestine appears to be largely unable to recruit new vitamin B-12 receptors into residual ileum or jejunum.

Resection of the distal ileum also affects nutrient absorption in the jejunum. A 50% distal ileal resection in one rat model decreased transmucosal jejunal calcium absorption by unknown mechanisms that did not appear to involve the brush-border membrane [18].

Whereas the mucosal morphological and functional absorptive response to distal ileal resection has been well documented, little is known about the motor response. In dogs, initial motor responses to resections of the distal small intestine of various lengths were dominated by the development of abnormal motility patterns, with prominent cluster activity noted in the intestinal remnant [19]. The intact ileum markedly slows intestinal transit [20]; thus, ileal resection decreases the intestinal transit time significantly, impairing the ileal brake phenomenon thought to be controlled by peptide YY [21].

Colon

Patients with short bowel syndrome who retain their colon and ileocecal valve in continuity have the best prognosis. The colon becomes an important digestive organ in these patients, with its ability to absorb some fluid and electrolytes and amino acids as well as salvage energy from absorbed

short-chain fatty acids. Removal of the colon in conjunction with the jejunum or ileum (or both) often results in life-long parenteral nutrition.

Throughout the intestine, motility is slowest and absorptive capacity is highest in the colon (~ 90% efficient). The absence of the colon significantly increases the rate of transit and the liquidity of stools. The primary function of the colon is to absorb the 1–2 L of fluid it receives daily from the ileum. The liquidity of the feces and the extent of fluid and electrolyte loss in the colon depend on the total volume of fluid and its rate of arrival at the cecum, and also on the presence of unabsorbed solutes such as bile salts. The removal of both ileum and colon obviously drastically increases fluid loss, dehydration, volume depletion, hypocalcemia, and hypomagnesemia. Preservation of the colon in cases of major small intestinal resection appears to lessen the severity of short bowel syndrome because the colon not only provides an absorptive surface area but also exerts a braking effect on early gastric emptying [21]. Preservation of even 50% of the colon is associated with significantly lower morbidity and mortality rates [22].

Although retention of the colon improves fluid and electrolyte absorption, colonic conservation also can have maladaptive consequences. Colonic bacteria deconjugate and hydroxylate unabsorbed bile salts and fats, respectively, creating solutes (bile acids and fatty acids) that limit water absorption in the colon through direct stimulation of the secretion of colonic fluid and electrolytes and through osmotic effects. In addition, the combined effects of massive small bowel resection, fat malabsorption, and an intact colon lead to the formation of calcium oxalate renal stones as free fatty acids in the colonic lumen preferentially bind calcium, leaving oxalate unbound and free to be absorbed systemically through the colonic mucosa.

Presence of an ileocecal valve

The ileocecal valve functions to prolong the intestinal transit time, thereby increasing the duration of contact of the lumenal contents with the small intestinal mucosal surface and enhancing the absorption of nutrients, fluids, and electrolytes [7,8]. If the ileocecal valve is removed during an intestinal resection, the likelihood of the development of short bowel syndrome, often in a severe form, is increased [22,23]. In an outcome study of neonatal short bowel syndrome, the presence of an ileocecal valve was not significantly correlated with successful weaning from parenteral nutrition, but it did reduce the mean duration of parenteral nutritional therapy from 20 to 7 months [24]. By contrast, in a pediatric population the presence of the ileocecal valve was a strong predictor of successful weaning from parenteral nutrition; however, its presence was not a predictor of survival [25]. In addition, the ileocecal valve serves as a barrier that prevents the migration of lumenal colonic microorganisms into the distal small bowel [14,26]. Removal of the ileocecal valve may result in bacterial overgrowth within the small intestine. These bacteria deconjugate bile salts within the small intestinal lumen; impaired micelle formation follows, so that the absorption of fat and fat-soluble vitamins is reduced. Furthermore, deconjugated bile salts spill into the colon and directly stimulate the colonic secretion of fluid and electrolytes, further aggravating the short bowel syndrome. Bacterial overgrowth associated with enteritis in children with short bowel syndrome prolongs the need for parenteral nutrition [27]. Finally, the bacteria use intralumenal vitamin B-12 for their own metabolic purposes, limiting the availability of vitamin B-12 for absorption by the host and exacerbating vitamin B-12 deficiencies.

Intestinal adaptation

Following the development of a short bowel the intestine adapts to ensure more efficient absorption per unit length. Unfortunately, most of the evidence for adaptation comes from rodent and swine animal models of short bowel syndrome, and there are limited human data to support a similar extent of adaptation [28–33]. The adaptive process evolves over 1 or 2 years and is heavily dependent on enteral nutrients to maintain small intestinal structure and function [34–36]. Patients may be taught to adapt to their decreased absorption also by dramatically increasing their food intake.

Jejunum and ileum

In experimental animal models, following resection of a major portion of the small bowel, adaptive changes affect all layers of the remaining intestine. Lumenal dilation with thickening and lengthening of the gastrointestinal tract develops in association with hyperplasia of the crypt–villus axis, and the mucosal surface area increases significantly [28–33]. These effects are more noticeable in residual ileum (i.e., after jejunal resection) than in residual jejunum (i.e., after ileal resection). The number of cells in the proliferative zone of the crypts increases, and these cells rapidly migrate up the villi, causing villus hyperplasia and a parallel increase in the production of brush-border membrane enzymes. This increase in mucosal mass is confirmed by increases in mucosal wet and dry weight, protein, and RNA and DNA contents [37]. An attempt to identify the molecular mechanism behind the observation of ileal hyperplasia in the rodent model of short bowel syndrome demonstrated the expression of a variety of nutrient absorptive and heat-shock proteins in the residual intestine early in the adaptive process [38].

In addition to morphological changes, an upregulation of specific functional absorptive activity occurs in these animal models [39,40]. The absorption of glucose, sucrose, bile acids, vitamin B-12, and calcium is increased in animal models of short bowel syndrome [41]. This increase is related to an increase in the number of absorptive cells rather than to an increase in the capacity of individual cells [33,42]. In contrast to the plethora of findings in animal models of short

bowel syndrome, few data are available regarding functional absorptive adaptation following the resection of human intestine. Dowling and Booth [43] reported an increase in jejunal glucose absorption in patients with short bowel syndrome that was proportional to the amount resected; furthermore, intestinal adaptive responses in humans most often required more than 1 year to reach maximum development [14,16,17,43].

Colon

The colon also undergoes adaptive dilation, lengthening, and mucosal proliferation. These forms of adaptation result in an increased capacity to absorb fluid and electrolytes [44]. Several animal studies suggest that the colon also may be able to upregulate the absorption of glucose and dipeptides through increased expression of mucosal transporters [16,37,45].

Mechanisms of intestinal adaptation

Direct effect on epithelial cells

Enteral nutrients appear to stimulate intestinal adaptation through at least three major mechanisms: direct contact with epithelial cells, stimulation of trophic gastrointestinal hormone secretion, and stimulation of pancreatic and biliary secretions trophic to the small intestine [16]. Again, most experiments on potential stimuli and mechanisms of intestinal adaptation focus on animal, rather than human, models. Evidence that intralumenal nutrients have a direct effect on intestinal adaptation comes from animal studies in which segments of ileum were transposed into the proximal jejunum. The mass of ileal mucosa in this position increased markedly, and transposed villi became larger than those in the adjacent jejunum. In these experiments, the concentration of intralumenal nutrients, rather than simple osmolality, stimulated lengthening of the relatively short ileal villi [7,8]. Without exposure to intralumenal nutrients, intestinal adaptation did not occur; rather, hypoplasia developed [7,8]. In addition, nonnutritive agents did not stimulate mucosal growth, implying that the absorption or metabolism of lumenal nutrients is necessary for the process of adaptation to take place [8,46]. The extent to which enteral nutrients stimulate intestinal adaptation also depends on the type and complexity of the nutrient administered [46,47]. Disaccharides are more potent stimulants of adaptation than monosaccharides [47]. In addition, a nutrient need not always be metabolized for it to induce adaptation: 3-*O*-methyl-D-glucose, a nonmetabolizable glucose analogue transported by the sodium–glucose cotransport system, stimulates intestinal adaptation in a rat model of short bowel syndrome [48,49]. Fats that are highly unsaturated appear to be more effective in inducing intestinal adaptation than fats that are less unsaturated [50].

In animal models of short bowel syndrome, morphological and functional intestinal adaptation following intestinal resection generally does not occur in the absence of enteral nutrition or oral feeding; in fact, a significant degree of mucosal atrophy results if all nutrients are provided parenterally [16,37,51]. Whether it is appropriate to extrapolate findings in rodent models to human short bowel syndrome has been questioned [49,52]. Jejunal biopsy specimens taken from eight normal volunteers before and after 14 days of parenteral nutrition therapy demonstrated decreased villus height, a decreased villus cell count, and increased intestinal permeability during parenteral nutrition, but no changes in DNA, RNA, and protein content in comparison with controls, suggesting that the total enterocyte number did not change [53,54]. In a study of similar design, parenteral nutrition did not affect immunoglobulin-producing lymphocytes in the lamina propria, intestinal permeability, or bacterial translocation [55]. These results suggest that, in contrast to the findings in animal models, depriving the human intestinal lumen of enteral feeding does not lead to intestinal hypoplasia or immune dysfunction. Additional human studies of longer duration and with functional absorptive measurements must be conducted before the direct effects of enteral feeding on intestinal adaptation, identified in the rodent models of short bowel syndrome, can be confirmed [56].

Stimulation of trophic gastrointestinal hormones

The second mechanism by which enteral nutrients stimulate intestinal adaptation is stimulation of the secretion of trophic gastrointestinal hormones. Thiry–Vella fistula models have been used to demonstrate this mechanism of action. Thiry–Vella fistulae are segments of bowel in which the blood supply is intact; however, because of the creation of proximal and distal ostomies, they are excluded from the flow of enteric contents. Animals fed orally after the creation of such a fistula exhibit greater adaptation in both intact intestine and in the Thiry–Vella fistula than do animals fed intravenously [57–59]. Several different hormones are under consideration as candidate trophic hormones. Gastrin appears to have a trophic effect only in the duodenum. Secretin and cholecystokinin stimulate intestinal mucosal growth; however, their effects seem to be exerted through their actions on biliary and pancreatic secretions rather than through direct trophism. Other hormones, including corticosteroids, prostaglandins, epidermal growth factor, enteroglucagon, insulin, and growth hormone-releasing factor, appear to stimulate epithelial cell proliferation in the small intestine [33,60–64]. The role of these hormones in the intestinal adaptation that occurs following intestinal resection remains to be clarified.

Gastrin

Gastrin produces mucosal hyperplasia in the rat stomach and duodenum. When the major source of endogenous gastrin is removed by antrectomy, the resulting gastric and duodenal hypoplasia can be prevented through pentagastrin treatment. Gastrin does not promote adaptive changes in the jejunum or ileum. Furthermore, the relationship between gastrin levels and gastroduodenal adaptation is variable [65].

Cholecystokinin

Cholecystokinin exerts a consistent trophic action on the small intestine. When infused into dogs or rats maintained on TPN, cholecystokinin completely prevented villus hypoplasia in one study [66], but other investigators have been unable to substantiate this effect. Cholecystokinin probably exerts no direct trophic effect on the intestinal mucosa; instead, it likely influences the adaptive process by stimulating pancreatic or biliary secretions [66].

Insulin

Insulin stimulates intestinal mucosal proliferation in a rat model of short bowel syndrome [60]. Parenteral insulin administered twice daily increased jejunal and ileal mucosal weights as well as crypt depth. The use of insulin in humans with short bowel syndrome has not been described.

Enteroglucagon and polyamines

Enteroglucagon-producing cells are found primarily in the terminal ileum. Polyamines (putrescine, spermidine, spermine) are found in all tissues of the body and directly stimulate tissue growth. Both hormones increase RNA and DNA synthesis, which results in epithelial hyperplasia [59,67,68]. Blocking polyamine synthesis negatively affects the adaptation process, whereas blocking polyamine degradation increases intestinal adaptation [68,69]. Enteroglucagon-producing cells are stimulated by carbohydrates and long-chain triglycerides to release preformed enteroglucagon, which stimulates ornithine decarboxylase, increasing polyamine production and, thus, cellular hyperplasia and intestinal adaptation. Changes in enteroglucagon levels correspond closely to changes in the crypt cell production rate, and this peptide remains a favorite candidate as the humorally mediated trophic agent for the small bowel [65,70]. Evidence suggests that precursors of enteroglucagon, such as proglucagon-derived peptides, may be responsible for some of the activities previously attributed to enteroglucagon. Ileal proglucagon messenger RNA levels increase rapidly after intestinal resection [71]. Glucagon-like peptide 2, a product of proglucagon, is capable of inducing marked villus hyperplasia within 4 days after administration, and this change provides compelling evidence that proglucagon plays a significant role in the growth and adaptation of intestinal epithelium [72–74]. The mechanisms responsible for the upregulation of proglucagon in short bowel syndrome are not yet known; however, the fact that dietary fiber fermentation modulates intestinal proglucagon expression may explain why intestinal adaptation requires oral intake [75].

Elevated fasting and meal-stimulated plasma levels of glucagon-like peptides 1 and 2 have been detected in patients with short bowel syndrome [76,77]. The rise in glucagon-like peptide 2 correlates with the amount of intestine resected, nutrient malabsorption and crypt cell proliferation, indicating a trophic effect during the process of intestinal adaptation. Conversely, in a separate study, the meal-stimulated increase in plasma glucagon-like peptide 2 in patients with short bowel syndrome was smaller than that in control patients [78]. Although these findings may simply represent an epiphenomenon of glucagon-like peptides, the results of previous animal studies suggest that these peptides do indeed play a significant role in the intestinal adaptation of short bowel syndrome (see "Glucagon-like peptide 2 therapy" below).

Somatostatin

Somatostatin reduces the crypt cell production rate and hyperplasia in the small intestine after resection; it also inhibits the rise in enteroglucagon level that normally follows jejunal resection [79]. Therefore, somatostatin may modulate mucosal cell turnover by influencing glucagon release. Somatostatin causes a number of competing effects on the intestine. It increases intestinal transit time and inhibits gastric secretions, both of which would benefit the patient with short bowel syndrome; in contrast, somatostatin-induced reductions in pancreatic and biliary secretions can lead to frank fat malabsorption and steatorrhea.

Neurotensin

In rats with 80% of their intestine resected, the administration of exogenous neurotensin increased villus length in both jejunum and ileum. Increases in circulating enteroglucagon observed after the administration of neurotensin suggest that the trophic effect of neurotensin may be mediated, at least in part, by enteroglucagon [80].

Growth factors

Epidermal growth factor (EGF), a potent stimulant of gastrointestinal epithelial proliferation, stimulates DNA synthesis and polyamine synthesis in the small intestine of experimental animals [81,82]. In animals with 70%–80% of their intestine resected, EGF receptor activity was increased, and EGF augmented not only intestinal size but also expression of the sodium–glucose cotransport carrier [82–86]. Insulin-like growth factors (IGFs) also stimulated intestinal adaptation and increase in bodyweight when used immediately after small intestinal resection in the rat [87–89]. Insulin-like growth factor type I transgenic mouse models have been used to demonstrate that IGF regulates intestinal mass and augments colonic fluid and electrolyte absorption [74,90,91]. Nevertheless, there is no evidence for any beneficial effects of the administration of EGF at the time of resection, or to support the use of EGF in well-adapted short bowel syndrome [84], which suggests the existence of an optimal window for growth factor augmentation of adaptation.

Prostaglandins

Prostaglandins of the E_2 class stimulate mucosal hyperplasia in the proximal small bowel of rats [85,92]. Hollwarth and

colleagues [86], however, found that prostaglandins have a strong trophic effect not only in the small bowel but also in the cecum and colon.

Glutamine

Glutamine "deficiency" and subsequent supplementation have been the focus of extensive investigation during short bowel syndrome. However, solid evidence to support a major role remains elusive [93]. Glutamine is an important fuel for enterocytes and colonocytes, in the fed animal [94]. In humans who have undergone intestinal resection, however, the turnover of glutamine is markedly diminished and a relative glutamine deficiency exists [95]. Glutamine also appears to play an important role in maintaining the structural integrity of the small intestine. Indeed, in animal studies, glutamine-enriched parenteral nutrition prevented the deterioration of gut permeability and preserved mucosal structure [96,97]. By contrast, rat enteral diets supplemented with 2% glutamine had no beneficial effect on intestinal adaptation following massive small bowel resection [98]. In the setting of short bowel syndrome, intestinal use of glutamine is increased during adaptive hyperplasia following intestinal resection [99,100]. Glutamine is unstable, however, and it is not generally available in parenteral form except as alanyl-glutamine. Furthermore, to be effective, glutamine must be administered in pharmacological doses of at least 0.5 g/kg daily.

The requirements for large doses of glutamine and the variable results have raised the question of whether the role of glutamine alone, as a fuel for the enterocyte, has been exaggerated. In initial studies, the intestinal metabolism and oxidation of lumenal glutamate and glutamine were identical, with 60% of the carbon atoms of both precursors oxidized to carbon dioxide, which led to the hypothesis that perhaps both glutamate and glutamine are important amino acids in intestinal adaptation [101]. In an infant swine model in vivo, glutamate rather than glutamine appeared to be the preferred source for mucosal glutathione synthesis [102,103] and a preferred substrate for intestinal proline synthesis [104]. Taken together, these results highlight the relative importance of enteral and systemic glutamate and glutamine as key precursors for the intestinal synthesis of amino acids, which in turn may become essential during conditions of short bowel syndrome. However, no controlled human clinical trials have thus far demonstrated that glutamate or glutamine supplementation directly enhances morphological or functional improvement in the small intestine of patients with short bowel syndrome [105].

Arginine

The intestine is an important site for the synthesis of citrulline, which then enters the circulation to act as the primary precursor for renal arginine synthesis. Dietary arginine thus becomes nutritionally indispensable in rats with massive small intestinal resection [106]. The results of studies in pigs suggest that intestinal enterocytes are capable of turning on the synthesis of arginine, which in turn induces intestinal polyamine synthesis for maintenance and growth of the intestinal mucosa [107–111]. Thus, dietary and synthesized amino acids may play an important role in intestinal adaptation following intestinal resection.

Short-chain fatty acids

Acetate, propionate, and butyrate are the principal short-chain fatty acids produced by bacterial fermentation of the carbohydrates and fibrous polysaccharides that spill into the colon [112]. These short-chain fatty acids are absorbed by the colon and metabolized in the colonic epithelial cells as a source of fuel; carbon atoms are salvaged that would otherwise be lost. It has been estimated that up to 3 kJ of energy can be absorbed each day by the human colon in the form of short-chain fatty acids [113]. Supplementation of an elemental diet with pectin, a fiber completely fermented to short-chain fatty acids in the colon, improved adaptation of the ileum, jejunum, and colon after massive small bowel resection [114]. Subsequent studies on the supplementation of parenteral nutrition with short-chain fatty acids [115] and the intracecal infusion of short-chain fatty acids [116] confirmed that supplementation reduces the mucosal atrophy and intestinal immune dysfunction [117] associated with TPN following massive small bowel resection in animal models [118].

In addition to their local effects, systemic short-chain fatty acids can affect the motility of both the stomach [119] and the ileum [120] through neuroendocrine mechanisms, likely through the expression of proglucagon and peptide YY [121–123]. Furthermore, both systemic and enteral short-chain fatty acids exert a trophic effect on the jejunum [124] by increasing mucosal mass, DNA, and villus height. These morphometric effects were associated with an increase in amino acid absorption in a porcine model of small bowel resection [118]. The effects are yet to be confirmed in human short bowel syndrome. It is important to remember that excess amounts of intraluminal short-chain fatty acids, when exceeding the concentrations that can be absorbed by the colon, aggravate diarrhea by directly stimulating fluid and electrolyte secretion and by exerting an osmotic effect that limits water absorption from the colon.

Stimulation of pancreatic and biliary secretions

The third mechanism by which lumenal nutrients stimulate intestinal adaptation is the production and stimulation of pancreatic and biliary secretions. Nutrients that stimulate biliary and exocrine pancreatic secretions produce mucosal hyperplasia, especially when such nutrients are present in concentrations higher than usual in the residual ileum. Ileal mucosal growth is markedly enhanced when biliary and pancreatic ducts are transplanted to the residual ileum of

otherwise normal rats [33]. The presence of food is likely essential for these gastrointestinal secretions to exert their trophic effect [16].

Clinical manifestations

As a result of gradual intestinal adaptation, the clinical course of a patient with short bowel syndrome passes through a number of stages [125–127].

The first stage usually lasts 1–2 weeks and is characterized by a period of substantial fluid and electrolyte loss resulting from overwhelming diarrhea. During this stage, fluid, electrolytes, and nutrition are usually supplied by the parenteral route. The intensity of the watery diarrhea generally decreases during the next several months. Oral intake and subsequent gastric hypersecretion can aggravate fluid and electrolyte loss. Parietal cell hyperplasia, hypergastrinemia, and hypersecretion of gastric acid also can alter the duodenal pH and inactivate pancreatic lipase, contributing to steatorrhea.

The second stage is the period of intestinal adaptation, during which oral intake is initiated and gradually increased. Full or partial enteral or parenteral supplementation often is required to maintain optimal nutritive and fluid and electrolyte status. This stage may last from several months to longer than a year.

During the third stage, maximal intestinal adaptation is achieved, and a relatively normal oral intake is usually possible. Whereas some patients never reach the stage of full oral nutrition, life at home can continue with the patient supported by a combination of enteral or parenteral nutrients and electrolytes.

Diarrhea

Many factors make diarrhea inevitable in patients who have undergone extensive small intestinal resection, including:

- reduction of the absorptive surface area
- decrease in intestinal transit time
- humorally mediated gastric, small intestinal, and colonic hypersecretion
- increase in the osmolality of colonic contents with subsequent osmotic diarrhea secondary to malabsorption of fat and carbohydrates.

Bacterial overgrowth in the small intestine and associated structural damage to enterocytes (increased permeability, decreased brush-border membrane function) has been detected by increased breath hydrogen levels compared with healthy volunteers, and remits with antibiotic therapy [128]. It may be more common in patients with a resected ileocecal valve. Colonic hypersecretion is also a common cause of diarrhea in the short bowel syndrome patient, resulting from increased levels of dehydroxylated bile acids and hydroxylated fatty acids associated with the spillage of bile acids and fat, respectively, into the colon, where bacteria metabolize them into their secretory solutes. Because the diarrhea in short bowel syndrome is complex, it is critical to evaluate its possible causes so that management is approached correctly.

Gastric hypersecretion

Gastric hypersecretion secondary to hypergastrinemia occurs within 24 hours after intestinal resection and can result in excessive fluid and electrolyte loss, peptic ulcer disease, and compromised intestinal absorption [129–131]. Absorptive compromise occurs as a consequence of reduced lipase activity (as a result of spillage of gastric acid into the duodenum and subsequent lowering of the duodenal pH), which leads to impaired micelle formation and reduced intralumenal lipid absorption. Gastric hypersecretion responds well to histamine receptor antagonists or proton pump inhibitors; furthermore, it usually abates with time. Acid suppression during the early post-resection phase significantly decreases stool volumes and electrolyte losses [132]. A continuous infusion of proton pump inhibitor is usually administered until the patient is tolerating an oral diet [133]. This beneficial effect of acid inhibition is no longer apparent with the initiation of oral intake [132]. The cause of gastric hypersecretion remains unclear because serum gastrin levels have been found to be both elevated [129] and unchanged [134] in patients with gastric hypersecretion following intestinal resection. Normal acid secretion also has been noted in patients with hypergastrinemia, and in some patients, hypochlorhydria develops after intestinal resection.

Steatorrhea

Several mechanisms are responsible for the steatorrhea of short bowel syndrome. Following surgical resection, gastric hypersecretion can alter the pH in the duodenum and inhibit the action of pancreatic enzymes, particularly lipase (see "Gastric hypersecretion" above). In the case of ileal resection and loss of the bile salt-reabsorbing region of the intestine, depletion of the bile salt pool can lead to insufficient micelle formation and steatorrhea (see "Site of intestine removed" above).

Carbohydrate malabsorption

After extensive resection, carbohydrates pass from the small intestine into the colon, where they are metabolized by bacteria into short-chain fatty acids. These short-chain fatty acids (butyric acid, propionic acid, acetic acid) cause diarrhea through two mechanisms (see "Mechanisms of intestinal adaptation" above). First they cause an osmotic diarrhea, and then they directly stimulate the colon to secrete fluid and electrolytes. Changes in the osmotic load and malabsorption of carbohydrates are probably the most important causes of diarrhea in short bowel syndrome. Increases in intestinal permeability and further carbohydrate and fluid malabsorption have been demonstrated in patients with short bowel syndrome who have episodes of sepsis [135], and these may

help explain the intermittent and rapid deterioration that sometimes occurs in patients with short bowel syndrome with seemingly minor infections.

In children with short bowel syndrome, the development of clinically significant D-lactic acidemia and D-lactic aciduria is well described and leads to increased serum levels of lactate, acidosis, compensatory hyperventilation, and neurological symptoms including encephalopathy [136]. The D-lactic acid is derived predominantly from malabsorbed fermentable carbohydrates that are delivered to the colon, where lactobacilli abundantly metabolize them to D-lactic acid. Treatment includes reduction in dietary carbohydrates, antibiotic therapy, and possibly probiotic administration [137].

Protein malabsorption

Protein is usually well tolerated as a caloric source in short bowel syndrome and contributes relatively little to the osmotic load. However, protein is metabolized by colonic bacteria in the same way as malabsorbed carbohydrates and can produce a similar osmotic type of diarrhea, although it is consumed in much smaller quantities than carbohydrates and so usually causes much less severe diarrhea.

Fluid and electrolyte malabsorption

Fluid and electrolyte losses can be enormous and are common during the first few weeks after intestinal resection. Daily fecal effluents larger than 5 L can be seen. It is during this time that prompt replacement therapy is important to prevent severe hypovolemia, hyponatremia, and hypocalcemia.

Vitamin and micronutrient deficiencies

Vitamin B-12 deficiency is likely after ileal resection because the recruitment of vitamin B-12-intrinsic factor receptors into the jejunum is extremely limited. In addition, colonic or small intestinal bacteria can metabolize vitamin B-12, further aggravating vitamin B-12 deficiency. Vitamin B-12 deficiency (as well as folate deficiency) leads to hyperhomocysteinemia and has been associated with venous thrombosis in patients with short bowel syndrome [138]. Other water-soluble vitamins are well absorbed throughout the entire small intestinal tract and are generally well preserved except in the shortest intestines [139,140].

Mineral deficiencies, including those of calcium and magnesium, are common. They occur secondary to the malabsorption of fatty acids, which form soap complexes with these divalent cations [139]. The administration of vitamin D and calcium supplements is usually helpful in correcting calcium deficiency, but magnesium deficiency may be more difficult to manage because the enteral administration of most magnesium salts results in osmotic diarrhea. Magnesium gluconate is less likely to cause diarrhea than is magnesium oxide or magnesium sulfate. Calcium depletion can be exacerbated by malabsorption of vitamin D. Although calcium deficiency normally results in an increased secretion of parathyroid hormone, in patients with concomitant calcium and magnesium depletion, the release of this hormone is decreased because of the magnesium deficiency [139].

Steatorrhea also is associated with the decreased absorption of fat-soluble vitamins, particularly vitamin D, but also vitamins A, K, and (rarely) E.

The absorption of major trace elements (chromium, copper), like that of water-soluble vitamins, is usually sufficient after intestinal resection [139,140]. Clinical zinc (12 mg lost/L small intestinal fluid and 16 mg lost /L stool) and selenium deficiency resulting from diarrhea can develop fairly rapidly and have been described to impair intestinal epithelialization and adaptation and wound healing.

Systemic manifestations

Renal

Renal dysfunction, both permanent and intermittent, can occur as a consequence of hypovolemia. This complication often develops soon after intestinal resection, but the fluid balance of some patients with short bowel syndrome is so precarious that short episodes of viral gastroenteritis can "tip" them into renal failure.

An increased incidence of renal calculi in association with ileal resection or ileal disease is well documented [141–144]. Hyperoxaluria is frequent in these patients, and the calculi are predominantly formed from calcium oxalate [144]. The hyperoxaluria appears to be secondary to an increased absorption of dietary oxalate, particularly in the colon. The increase involves two mechanisms. First, steatorrhea contributes to the increased absorption of oxalate through an increase in lumenal fatty acids, which preferentially bind to calcium, leaving free oxalate in the lumen that can readily be absorbed. Second, bile salts that enter the colon of these patients appear to increase the colonic mucosal permeability, thereby allowing increased oxalate absorption in the colon [143,144]. In addition to hyperoxaluria, other mechanisms may be responsible for increases in renal calcium oxalate and calculi [145]. These include a decreased urinary concentration of calcium-binding anions, such as phosphate and citrate, and diminished urine flow. Conjugated bile acid replacement therapy (9 g daily) with the aim of increasing fat absorption in the proximal small bowel reduced fecal fat excretion, urinary oxalate excretion, and oxalate nephrolithiasis in patients with the colon in continuity. This may represent a treatment option for patients with a history of oxalate stone formation [146].

Hepatobiliary

Patients with short bowel syndrome are at significant risk for cholelithiasis if the length of the intestinal remnant is less than 120 cm, if TPN is required, or if the terminal ileum is resected. The incidence of gallstones increases threefold after ileal resection [147,148]. Interruption of the enterohepatic circulation of bile and the subsequent bile salt malabsorption

lead to an increase in the hepatic synthesis of cholesterol; bile becomes supersaturated with cholesterol, and gallstones develop. A significant number of patients with ileostomies have calcium-containing radiopaque gallstones rather than radiolucent cholesterol gallstones [147]. Some other mechanism, therefore, must be involved. It also appears that interruption of the intrahepatic circulation predisposes humans to an increase in pigment stones [149–151]. With this understanding of the pathophysiology of gallstone formation, prophylactic cholecystectomy should be considered in all patients who have undergone extensive intestinal resection [152].

In addition to the increased risk for cholelithiasis, the incidence of intestinal failure-associated liver disease (intrahepatic cholestasis, hepatic steatosis, and hepatic dysfunction) is up to 65% in patients with short bowel syndrome on long-term TPN; these conditions are usually associated with parenteral nutrition therapy and sepsis [153,154]. Vascular factors may also play a role in hepatic dysfunction in these patients. In a neonatal piglet model, activation of stellate cells and subsequent hepatic fibrosis is preceded by a decrease in portal blood flow [155]. Hepatic fibrosis is not seen in animals with intestinal bypass and normal portal flow, implicating altered portal blood flow as one factor in the development of liver disease in short bowel syndrome.

Liver disease in the setting of short bowel syndrome is multifactorial (Table 53.3). Hepatic steatosis has been attributed to excess lipid content in TPN, and to essential fatty acid deficiency. Cholestasis is associated with prematurity and low birthweight in infants, and the extent of bowel resected in adults. It may be caused by lack of enteral intake and reduced gastrointestinal hormone secretion or by episodes of sepsis, including bacterial translocation across a permeable intestinal epithelium. Deficiency of amino acids such as taurine in TPN may play a role, as may excess TPN lipid infusion or toxicity from manganese infusion [154].

Increasing severity of cholestatic jaundice and portal hypertension in children not only carries its own risks, but also impairs intestinal adaptation and increases the duration of parenteral nutrition 2.5-fold [156]. Hepatic dysfunction, particularly in children with short bowel syndrome, results in liver failure, cirrhosis, and the need for liver transplantation. In fact, the presence of cholestasis was the strongest predictor of mortality in a large series of pediatric short bowel syndrome patients [25].

Table 53.3 Etiology of short bowel syndrome-associated liver disease

Duration of parenteral nutrition
Length of bowel remnant
Reduced enterohepatic circulation
Lack of enteral feeding
Recurrent sepsis
Protein undernutrition
Fatty acid deficiency
Excess dextrose and lipid emulsion (> 1 g/kg/day)

Treatment of intestinal failure-associated liver disease includes the introduction of enteral nutrition, reduction or cycling of TPN, control of bacterial overgrowth (with probiotics, fiber, or glutamine supplementation), and avoidance of septic complications with fastidious central line care. Oral ursodeoxycholic acid in doses of 15–20 mg/kg has also been recommended for cholestasis related to TPN. Nonetheless, liver disease may be an indication for small bowel transplantation, with or without concomitant liver transplantation [154].

Wound healing and infection

As a result of malabsorption of macro- and micronutrients, wound healing is impaired in short bowel syndrome. In animal models, rats with extensive intestinal resections show poor anastomotic collagen synthesis and reduced anastomotic strength resulting in dehiscence or stenosis [157]. Efforts to maximize nutrition in the perioperative period may decrease postoperative complications.

An increased risk for infectious complications, mainly caused by the egress of lumenal intestinal bacteria to distant organs – a process termed *bacterial translocation* – has been described in pediatric, but not adult, patients with short bowel syndrome [49,135]. In animal models of short bowel syndrome, rates of bacterial translocation were increased to an overall incidence rate of 87% as a consequence of intestinal bacterial overgrowth in the residual bowel. Loss of epithelial barrier integrity and bacterial translocation were positively correlated with removal of the ileocecal valve [158]. *Bifidobacterium lactis*, a probiotic bacterium, decreased the rates of bacterial translocation in a rat model by 43%, raising intriguing possibilities for human trials [159].

Quality of life

Not surprisingly, patients with short bowel syndrome report a lower health-related quality of life compared with healthy controls. Patients on chronic TPN rate their quality of life lower than those who are able to maintain enteral nutrition. This is further incentive to strive for complete weaning of TPN whenever possible.

Medical management

The nutritional and medical management of short bowel syndrome has been the subject of excellent reviews [160–165].

Nutritional management

The nutritional management of short bowel syndrome is a dynamic process that follows the evolution of the clinical and adapted state of the bowel. Depending on the length of

resection and the postsurgical adaptation, the process will result in one of four nutritional outcomes:

- maintenance of a balanced nutritional status on a normal or modified oral diet
- maintenance through the use of defined enteral formula diets
- maintenance through enteral intake with parenteral electrolyte and fluid supplementation
- maintenance through total or partial parenteral nutritional intake supplemented by variable amounts of enteral intake.

Whatever the source of nutrition, the caloric and protein intake should be increased slowly and progressively until a target is reached of about 100–125 kJ/kg (25–30 kcal/kg) and 1.0–1.5 g/kg of ideal bodyweight per day, respectively. This targeted intake, in general, will compensate for the increased losses that result from inefficient and inadequate absorption.

Parenteral therapy

In the immediate postoperative period, all patients who have undergone extensive small intestinal resection require total parenteral nutrition at 100–125 kJ/kg (25–30 kcal/kg) daily. Sodium losses in early secretions are often high (80–120 mmol/L), and electrolyte losses must be monitored carefully. In general, gastric losses are replaced 1:1 with 154 mmol/L sodium chloride; pancreatic and upper small bowel losses are replaced with 4:1 with 154 mmol/L sodium chloride, sodium lactate, or sodium acetate. In addition, 20 mmol/L potassium and 10 mmol/L of magnesium sulfate are added. Dextrose is provided at a rate of 5–7 mg/kg/min. Lipids are used to provide 20%–30% of calories. Protein is delivered at 1.0–1.5 g/kg daily.

As the amount of enteral nutrition is gradually increased, the duration and intensity of parenteral nutrition infusion can be reduced. Initially, parenteral nutrition can be stopped for one or two nights each week. Eventually, administration every other night or every third night is possible. This entire process of parenteral nutrition weaning may take years. If more than 25% of the patient's intestine remains, it should be possible to stop parenteral nutrition completely. Some patients, however, require parenteral therapy, particularly fluids and electrolytes, for extended periods. In a study of 135 patients with short bowel syndrome, small intestinal length (> 35 cm with an ileojejunal anastomosis), preservation of the colon, and an ileocolonic anastomosis were the features most predictive of the ability to wean from parenteral nutrition [166]. Serum levels of citrulline, an amino acid synthesized by the intestine, also predict successful weaning from parenteral therapy, with a sensitivity of 94% and specificity of 67% [167].

Oral therapy

A balanced solution containing carbohydrates and electrolytes can be given orally once stool output is less than 2 L daily. As previously noted, early oral feeding is important to intestinal adaptation. Clear fluid diets are not useful because their nutritional value is inadequate; they are also severely hyperosmolar and likely to provoke osmotic diarrhea (Table 53.4). Because the tight junctions of the jejunum are extremely permeable, supplements high in glucose and low in sodium often promote sodium and water losses and aggravate short bowel syndrome. To optimize oral fluid and electrolyte absorption, a balanced oral replacement solution is necessary. A solution that contains an isosmotic sodium and glucose mixture takes advantage of the small intestinal sodium–glucose cotransport carrier to enhance salt and water absorption. These solutions can be purchased ready-made (Table 53.5) or mixed at home (Table 53.6). The patient should sip the solution at frequent intervals throughout the day to prevent nausea and to avoid passing a large bolus of fluid rapidly through the short intestine [168]. The oral replacement solution also can be used instead of parenteral electrolytes at a later stage to reduce parenteral requirements. Patients with short bowel syndrome, in general, require an oral intake with a higher sodium concentration. Those with less than 100 cm of residual jejunum are usually net sodium secretors [169] and can achieve an optimal sodium balance with an intake of 120–160 mmol/L/day [168], whereas oral replacement solutions with lower sodium concentrations of 90 mmol/L do not maximize sodium balance [170]. Sports drinks like Gatorade are too low in sodium

Table 53.4 Composition of some common household beverages

Liquid	Glucose (mmol/L)	Sodium (mmol/L)	Potassium (mmol/L)	HCO_3^- (mmol/L)	Osmolality (mOsm/kg)
Jello	888	20	0	0	1200
Apple juice	666	2	35	0	690
Ginger ale	333	3	3	0	540
Cola	590	2	0	0	600
Chicken broth	0	250	8	0	450
Tea	0	0	0	0	5

Note: Because of their nonphysiological osmolarity and inappropriate sodium and glucose concentrations, these beverages are inappropriate as oral replacement solutions.

to be of use as oral replacement solutions in patients with short bowel syndrome. They are designed to replace fluid losses and prevent dehydration from perspiration, not intestinal efflux.

For patients with more than 60–80 cm of small bowel, oral feeding should be reintroduced slowly until a normal or modified oral diet is reached. Because gastric emptying is slower for solids, patients have been advised to consume dry solids at meals and take only isotonic fluids 1 h later. However, this regimen has not consistently been shown to improve the absorption of nutrients [171]. Diarrhea that occurs as a consequence of oral feeding usually can be managed with an antidiarrheal agent, which should be taken on a regular basis 1 hour before meals and snacks. Waiting to take an antidiarrheal agent until after a meal has been started and diarrhea has occurred is not effective (see "Management of diarrhea" below). Fluids sweetened with disaccharides such as fruit juices will exacerbate osmotic diarrhea and should be avoided. Care must be taken to limit the amount of lactose in the diet because the initial disease, gastric hypersecretion, or surgical therapy can cause lactose intolerance. It may be useful to test the lactose tolerance of patients to provide them with specific guidelines about lactose intake. The lactose tolerance of patients with short bowel syndrome and a jejunocolonic anastomosis is greater than that of patients with a terminal jejunostomy; the lactose provided in yogurt is generally better tolerated than the lactose in milk [172]. Nonetheless, most patients with short bowel syndrome are able to tolerate at least one cup of milk per day, and should not restrict this important source of dietary calcium unless lactose intolerance has been formally diagnosed [173,174].

Patients with significant ileal resection and an intact colon in whom steatorrhea is expected to develop may require monitoring of their oxalate secretions (see "Systemic manifestations" above). A low-oxalate diet is difficult to follow, but guidance can be provided regarding which foods are high in oxalate. Oral calcium decreases oxalate absorption because of the formation of insoluble salts. A 4-g dose of cholestyramine given three times daily reduces bile salt-induced diarrhea and also binds intralumenal oxalate, further decreasing oxalate absorption.

Attention to vitamin and mineral supplementation is critical. In general, a multiple-vitamin preparation with minerals will suffice (see "Vitamin and mineral supplementation" below). For patients with ileal resection, vitamin B-12 should be administered once monthly.

Traditionally, low-fat diets (often with medium-chain triglycerides) and high-carbohydrate diets have been used to treat patients with short bowel syndrome. This practice was based on an understanding that steatorrhea has many adverse effects on fluid absorption, that dietary fat induces the secretion of gastrointestinal hormones, and that carbohydrates malabsorbed in the small bowel undergo fermentation in the colon to short-chain fatty acids. These short-chain fatty acids are easily absorbed across the colonic mucosa, so that carbohydrate energy is salvaged that would otherwise have been lost in the feces. However, this practice has been challenged. Cross-over studies have demonstrated that high-fat diets were comparable with low-fat diets with regard to total fluid, energy, nitrogen, sodium, potassium, and divalent ion absorption and ileostomy output [175–178]. Emerging

evidence from animal studies indicates that low-fat diets impede intestinal adaptation and reduce weight gain through a mechanism related to decreased cell proliferation [179]. Management thus supports the use of high-fat diets as a caloric source in patients with short bowel syndrome.

Divalent cations, including calcium, magnesium, zinc, and copper, may bind to fatty acids in the stool, and excessive fecal losses of these minerals have been documented in patients with steatorrhea [177,180]. Steatorrhea also exacerbates malabsorption of the fat-soluble vitamins A, D, E, and K. Increased fecal losses of fat also enhance dietary oxalate absorption, oxaluria, and renal stone formation. Recommendations regarding dietary fat intake therefore must be balanced between caloric requirements and fecal loss.

Medium-chain triglycerides can be used as caloric supplements for patients with short bowel syndrome. Medium-chain triglycerides are hydrolyzed in the intestinal lumen to water-soluble components, which are absorbed in the absence of bile salts [181]. These medium-chain fatty acids do not require resynthesis in the enterocyte and can be absorbed directly into the portal circulation. Thus, medium-chain triglycerides may serve as a nutritional source for patients with significant long-chain triglyceride malabsorption. However, medium-chain triglycerides have an unpleasant taste, their osmotic load in the proximal small intestine sometimes causes diarrhea (in doses of more than 35 g/day), and they do not provide essential fatty acids. Furthermore, they have a slightly lower caloric density than long-chain fatty acids – 35 kJ/g (8.3 kcal/g) compared with 37.5 kJ/g (9.0 kcal/g).

High-fiber diets remain controversial. Their use is based on observations that some types of dietary fiber, such as wheat bran, increase intestinal transit times and fecal weight [182]. It is clear, however, that dietary fiber has variable effects on the intestine [183]. Soluble fibers such as pectin do delay gastric emptying and increase intestinal transit time [184–186]. However, they also bind bile salts and have a significant water-retaining capacity. Soluble fiber is not digested or absorbed and is passed into the colon, where bacterial fermentation produces short-chain fatty acids. In high concentrations, the short-chain fatty acids cause osmotic diarrhea and colonic secretion, but in low concentrations they are absorbed as an energy source, provide fuel for colonocytes, and help to heal and prevent inflammation.

Enteral therapy

Patients who cannot tolerate a normal oral diet and those with a short bowel (< 60–80 cm) often benefit from an enteral formula. If a chemically defined formula is used, it is important to control the rate of infusion to match osmotic inflow with osmolar absorption. Rates of full-strength infusion usually begin at 25 mL/h and gradually increase to 125 mL/h. The rate is modulated according to the tolerance displayed by the small intestine. If a polymeric formula is used, it should be lactose free because most patients with a massive small intestinal resection do not have an adequate reserve of lactase.

Elemental or semielemental diets require a minimal absorptive surface [125,187]. These diets may be useful during the early adaptive stage for persons with a short gut [188]; they also decrease the secretion of digestive juices [189] and gastric hypersecretion. Nevertheless, significant evidence suggests that elemental diets are not absorbed more readily than polymeric diets and have no additional beneficial effect on nitrogen balance or intestinal permeability [175,190–192]. Elemental or semielemental formulas contain amino acids in a free form as well as dipeptides and tripeptides. Because separate carrier mechanisms exist for free amino acids and dipeptides, a mixture of amino acids and dipeptides results in increased protein absorption [193–195]. Many enteral feeding formulations have a high content of carbohydrates in the form of sucrose or glucose polymers. These high levels lead to carbohydrate malabsorption and spillage of carbohydrates into the colon, with resultant osmotic diarrhea. Elemental formulas are low in fat, often providing the minimal amounts to meet essential fatty acid requirements. The formulas are effectively absorbed within the first 100 cm of jejunum [196] and stimulate adaptation of the proximal small intestine [197]. The unpleasant taste of elemental or semielemental formulas, however, often limits oral intake, and because they are hyperosmolar, they may considerably worsen diarrhea. The formulas therefore should be provided by slow, constant infusion.

Polymeric diet supplements generally provide about 30% of calories as fat and contain intact protein sources. They are more palatable than elemental diets; they are also less hyperosmolar and considerably less expensive.

Patients with short bowel syndrome absorb less than 100% of oral calories and protein. Many of them therefore need to consume calories and protein in excess of the normal estimated requirement [171]. Nevertheless, overfeeding must be avoided because it can induce a loss of endogenous fluid and electrolytes into the gut. Excess consumption of fats, fiber, concentrated sweets and sugar, milk and milk products, caffeine, and alcohol may increase normal outputs [198–201]. High enteral loads of carbohydrate should be avoided. Alterations of the bacterial flora in the colon, particularly overgrowth of *Lactobacillus acidophilus*, may result in the excessive production of D-lactate from unabsorbed carbohydrates, and severe metabolic acidosis and encephalopathy have been described [202–204].

Vitamin and mineral supplementation

In general, vitamin and mineral supplements are included in enteral and parenteral solutions. As patients are weaned from these solutions, and once they have stopped them completely, vitamin and mineral deficiencies may slowly develop because of inadequate intake (as patients try to prevent

Table 53.7 An oral vitamin and mineral supplement for use in selected patients with short bowel syndrome

Component	Dose regimen
ADEKs multiple vitamin	Four tablets per day, chewed or crushed thoroughly; each tablet contains 4000 IU of vitamin A, 3 mg of β-carotene, 400 IU of vitamin D, 150 IU of vitamin E, 0.15 mg of vitamin K, 60 mg of vitamin C, 0.2 mg of folic acid, 1.2 mg of thiamin, 1.3 mg of riboflavin, 10 mg of niacin, 1.5 mg of vitamin B-6, 12 μg of vitamin B-12, 50 μg of biotin, 10 mg of pantothenic acid, and 7.5 mg of zinc
Calcium gluconate liquid	500 mg p.o. twice daily = 448 mg of elemental calcium twice daily
Ferrous sulfate liquid	300 mg p.o. twice daily = 60 mg of elemental iron twice daily
Vitamin D-2 capsule	50 000 IU once per week
Phosphate-Novartis (tablet dissolved)	500 mg p.o. twice daily = 500 mg of elemental phosphorus twice daily
Potassium liquid	60 mL p.o. twice daily = 40 mEq of potassium chloride twice daily
Magnesium glucoheptonate liquid	30 mL p.o. twice daily = 150 mg of magnesium twice daily[a]
Zinc gluconate	15–20 mg per liter of output, or 50–100 mg/day
Vitamin B-12	200 μg s.c. monthly
Follow-up blood work (every 4–6 months): vitamins A, B-12, D, and E; prothrombin time and international normalized ratio; zinc, magnesium, phosphorus, calcium, albumin, red blood cell folate, iron, total iron-binding capacity, ferritin; complete blood cell count; electrolytes.	

Note: Exact doses will vary depending on the requirements of individual patients.
a Patients not tolerating oral magnesium will require intravenous magnesium therapy on a regular basis.

diarrhea), excess nutrient losses (from the short bowel), or a combination of both. Table 53.7 presents an example of a liquid vitamin and mineral oral supplementation regimen that could be considered for some patients as they are weaned from parenterally supplied vitamins and minerals. Liquid supplements are preferable to solid pills because hard outside matrices often do not dissolve during rapid transit through a short bowel.

Bile supplementation

Bile acid replacement with oral conjugated bile acids (2 g per meal in the form of ox bile or synthetic cholylsarcosine supplementation) did not worsen diarrhea in a patient with an ileostomy, and caused fat absorption to increase by 40 g/day, eventually leading to a significant weight gain [205]. This carefully conducted balance study suggests that conjugated bile acid replacement therapy can be considered for some patients with short bowel syndrome. Conjugated bile acid replacement therapy (9 g daily), with the aim of increasing fat absorption in the proximal small bowel, reduced fecal fat excretion, urinary oxalate excretion, and oxalate nephrolithiasis in patients with the colon in continuity. This may represent a treatment option for patients with a history of oxalate stone formation [146].

Glutamine supplementation

Six studies (four with glutamine alone and two with glutamine and growth hormone) of patients with short bowel syndrome provided glutamine supplementation (range 0.63–0.21 g/kg/day) by mouth or intravenously for 28–56 days and found no significant changes in the parameters assessed [93]. A workshop on intestinal failure, sponsored by the National Institutes of Health (NIH), concluded that "there are no current data in humans showing that glutamine availability is rate limiting for regulation of protein metabolism in acute illness" [93]. Although glutamine supplementation is theoretically attractive its general use will need to await larger controlled clinical trials.

Medication absorption

Medication absorption is often impaired in short bowel syndrome. The oral and enteral route for medication delivery should be used whenever possible to avoid additional manipulations of the central venous catheter. Most medications are absorbed in the proximal jejunum; however, the degree to which medication malabsorption occurs depends on the intestinal site removed and the rapidity of transit. Liquid or sublingual formulations will thus provide best pharmacokinetic absorptive results.

Management of diarrhea

In general, the cause of the diarrhea must be identified before appropriate treatment can begin (e.g., bile acid-induced diarrhea, steatorrhea, osmotic diarrhea, bacterial overgrowth; see Chapters 51 and 52). Nevertheless, in the absence of sufficient intestinal adaptation, debilitating diarrhea develops simply because the intestinal surface area is inadequate for absorption to take place, and antidiarrheal therapy becomes an integral part of the management of short bowel syndrome.

Opiates are the most widely used products in the treatment of diarrhea associated with short bowel syndrome. Clinically available opiates include natural substances, such

as paregoric and opium alkaloids, and synthetic preparations, such as codeine, diphenoxylate (Lomotil), and loperamide (Imodium). These agents relieve diarrhea by reducing intestinal secretion or by promoting intestinal absorption and reducing intestinal motility. For the diarrhea of short bowel syndrome, these agents should be taken on a regular basis 1 h before meals, as the liquid formulation when available: 30–150 mg of codeine daily, 7.5–20 mg of diphenoxylate daily, or 6–20 mg of loperamide daily. As-needed dosing, rather than regular dosing, often results in unnecessary diarrhea and loss of the nutrient value of a meal before the opiate has had time to exert a therapeutic effect.

α_2-Adrenergic agonists are potent stimulators of intestinal absorption. These agents stimulate sodium and chloride absorption and inhibit bicarbonate and chloride secretion in the colon and small intestine. In addition, α_2-adrenergic agonists reduce intestinal motility. A dose of clonidine, 0.1–0.2 mg, taken with each meal, can act as an adjunct to opiates, helping to prevent the difficult-to-control diarrhea of short bowel syndrome [206–208]. Despite the fact that clonidine has profound antidiarrheal effects in experimental conditions, its centrally mediated hypotensive and sedative effects limit its use as an antidiarrheal agent.

Octreotide, a long-acting somatostatin analogue, has been used to treat diarrhea of both neuroendocrine and nonneuroendocrine origin. The response in cases of short bowel syndrome-associated diarrhea has been variable, and although the diarrhea may respond initially, tachyphylaxis has been known to occur [200]. In animal models of massive intestinal resection, physiological and pharmacological doses of octreotide reduce intestinal secretion, but paradoxically impair intestinal growth and adaptation by reducing splanchnic protein synthesis and thus mucosal protein incorporation and villus growth rate [201,209]. This important negative growth effect has not been confirmed in humans, nevertheless, octreotide should be administered cautiously in short bowel syndrome and limited to patients with a high-output jejunostomy and significant fluid and electrolyte losses [173]. The standard initial therapy is 50–100 μg given subcutaneously over an 8–12-h period; titration is based on the clinical and biochemical effects, with the dose escalated by 50 μg per week up to a maximal dose of 200 μg. The dose can be increased in 100-μg increments from 200 to 500 μg every 8 h. Once the effectiveness of octreotide has been demonstrated in an individual patient, the patient can be switched to a comparable dose of the long-acting release depot octreotide preparation, which has similar beneficial effects of decreasing fecal output [210].

The adverse effects of octreotide are usually mild and depend on the duration of therapy. Short-term side effects include pain at the injection site and transient nausea and bloating. However, octreotide predisposes to gallstone formation through inhibitory effects on gallbladder contraction, which may pose a significant risk in this group of patients who are already prone to gallstone formation [173,211]. Lanreotide, a new somatostatin analogue, significantly prolongs duodenal-to-cecal transit time in healthy male patients; however, it concomitantly decreases carbohydrate and fat absorption and thus may worsen diarrhea. It is possible therefore that somatostatin analogues have mixed effects in the management of diarrhea associated with short bowel syndrome [212].

Recombinant human growth hormone therapy

The results of six clinical trials with recombinant growth hormone therapy have been variable, with three reporting negative results and three reporting positive results [213]. The effect of low-dose growth hormone (0.024 mg/kg daily) on body composition and absorptive capacity in patients with short bowel syndrome resulting from Crohn's disease were examined in a placebo-controlled cross-over clinical trial. Whereas bodyweight and lean body mass increased there was no effect on nutrient absorption, indicating that the increased body mass may reflect water retention as a side effect of growth hormone therapy [214]. A double-blind cross-over controlled study of low-dose growth hormone (0.05 mg/kg daily) in TPN-dependent short bowel syndrome patients taking an oral diet was positive and showed increased energy and macronutrient absorption [215]. The effect of growth hormone was seen only while patients were taking the active drug, indicating a possible need for long-term drug therapy.

The combination of growth hormone and oral glutamine supplementation with a high-carbohydrate, low-fat diet was also positive and superior to either agent alone [216]. In an uncontrolled study of eight patients on this regime, protein absorption increased by 40% and stool output decreased by 30%; of the patients, 40% were weaned from TPN within 1 year and another 40% were able to decrease their parenteral nutrition requirements when they followed the diet [216]. The same investigators, a decade later, compared oral glutamine (30 g/day), high-dose growth hormone (0.1 mg/kg/day) and combined glutamine and growth hormone therapy in a randomized controlled trial of patients requiring chronic parenteral nutrition for short bowel syndrome [217]. All patients received a high-protein, high-carbohydrate diet and were closely monitored in a hospital setting for 4 weeks. Patients receiving growth hormone injections had greater reductions in volume and frequency of parenteral nutrition administration than those receiving glutamine. Furthermore, patients receiving combined growth hormone and glutamine treatment had the most marked reductions in volume and frequency of parenteral nutrition. Unfortunately, no growth hormone-treated patient was able to stop parenteral nutrition and peripheral edema occurred in 94% of growth hormone-treated patients [217].

However, these results with growth hormone therapy could not be confirmed in two other trials [218]. In a randomized,

double-blinded, controlled trial, no benefit after 3 weeks of high-dose growth hormone (0.14 mg/kg/day) and glutamine therapy on intestinal morphology, stool losses, or macronutrient absorption could be demonstrated in patients with short bowel syndrome [219]. Similarly, in a randomized, double-blinded, placebo-controlled cross-over study, a combination of high-dose growth hormone (0.12 mg/kg/day) with oral (28 g/day) and parenteral (5.2 g/day) glutamine for 28 days did not improve intestinal absorption in patients with short bowel syndrome on their usual diet [218], nor did it affect body weight or composition [220].

The importance of a multidisciplinary approach when using growth hormone is demonstrated in the review by Wilmore [221] encompassing more than 300 patients with short bowel syndrome who received glutamine, growth hormone, and a dietary regimen optimized to enhance absorption. After 2 years of long-term follow-up, 40% of the group could be weaned completely from parenteral nutrition, and 40% were able to reduce their parenteral nutrition requirements.

A meta-analysis of 13 trials involving 258 patients examined the outcome of growth hormone in combination with glutamine supplementation and a high-carbohydrate, low-fat diet; it found a significant increase in weight, lean body mass, and carbohydrate and protein absorption [222]. This combination therapy also decreased stool output and decreased reliance on parenteral nutrition. The use of growth hormone alone was not assessed in the meta-analysis.

The cost-effectiveness of growth hormone was modeled in one study, and was found to be cost-effective compared to standard TPN over 2 years of treatment. However, the model assumed that 96% of patients receiving 4 weeks of growth hormone would reduce or eliminate their need for parenteral nutrition, which is optimistic [223]. Further studies are needed to determine whether the short-term cost of growth hormone is offset by a reduction in TPN costs.

Whether growth hormone treatment will yield better outcomes in pediatric than in adult patients with short bowel remains to be determined. Indeed, case reports have been published describing particularly impressive results in children using a combination of surgical lengthening and growth hormone administration [224]. These findings may imply different intestinal responses in children and adults to trophic growth hormones. Case reports of growth hormone administration, in combination with glutamine, to children who had short bowel syndrome for 6 years or more have shown continued benefit in terms of growth and weight gain [225]. In fact, a 4-week course of bowel rehabilitation therapy consisting of enteral nutrition, oral glutamine, and growth hormone administered within 2 years of the onset of short bowel syndrome resulted in 57% of patients discontinuing parenteral nutrition after 2 years of follow-up [226].

In summary, our understanding of the role of growth hormone in treating short bowel syndrome continues to evolve. The high-dose growth hormone studies have produced conflicting results and appear to have significant adverse events (edema, arthralgia, and carpal tunnel syndrome). The low-dose trials, metaanalysis, and pediatric results appear encouraging but need replication before growth hormone can become standard therapy. Nonetheless, growth hormone has received approval from the Food and Drug Administration (FDA) for use in short bowel syndrome.

Glucagon-like peptide 2 therapy

Glucagon-like peptide 2 (GLP-2) is an enteroendocrine peptide that is released in response to lumenal nutrients, has unique trophic actions in the gastrointestinal tract, and has been postulated as a mediator of intestinal adaptation. In animal models of short bowel syndrome, basal and postprandial levels of GLP-2 correlated with the magnitude of intestinal resection and nutrient malabsorption. Furthermore, the increase in crypt cell proliferation was associated with ongoing elevation in GLP-2 release [76,77]. These findings suggest that GLP-2 is important in initiating and maintaining the small intestinal adaptive response to resection. Using a rat model of short bowel syndrome, infusion of GLP-2 in addition to TPN was shown to cause increased intestinal villus height and crypt cell proliferation as well as reduced intestinal permeability and increased transport protein expression compared with animals receiving TPN alone [227]. Markers of apoptosis were not different, indicating that GLP-2 likely exerts its trophic effect by induction of cell proliferation rather than suppression of apoptosis. The pattern of response to GLP-2 differs in the jejunum compared with the ileum, with an increase in jejunal crypt apoptotic index and absence of upregulation of the Na^+-dependent glucose–galactose cotransporter SGLT1, and the fructose uniporter, GLUT-5 [228]. The clinical importance of this difference remains to be seen.

The use of GLP-2 in humans has been reviewed [229]. In a human clinical trial, 400 μg of GLP-2 was administered subcutaneously twice a day for 35 days to eight patients with short bowel syndrome. Treatment with GLP-2 improved the intestinal absorption of energy and nitrogen, increased bodyweight, decreased stomal output, and slowed the gastric, but not the small intestinal, emptying time [230]. A subsequent open-label trial administered teduglutide, a dipeptidyl peptidase IV-resistant GLP-2 analogue, to 16 short bowel syndrome patients for 21 days. Teduglutide decreased fecal wet weight and fecal energy excretion as well as increasing villus height, crypt depth, and mitotic index in small intestinal biopsies [231]. Although the clinical effects of GLP-2 analogues in these pilot studies were modest, they are encouraging and a controlled study is underway to determine the optimal dose and duration of therapy.

Epidermal growth factor therapy

The role of epidermal growth factor in epithelial proliferation makes it an attractive candidate for augmenting intestinal

adaptation in short bowel syndrome. Animal studies have been encouraging, showing less weight loss, increased carbohydrate absorption, and reduced intestinal permeability compared with placebo [232]. A pilot trial of enterally administered epidermal growth factor in five children with short bowel syndrome showed an increase in carbohydrate absorption and increased proportion of nutrition from enteral feeds [233].

Gene therapy

Preliminary animal research has demonstrated successful plasmid transfer of a sodium–glucose transporter into colonic epithelial cells to expand the absorptive capacity of remaining colon by nearly 200% [234]. This is an exciting possible therapeutic avenue but research in this area remains in its infancy.

Surgical management

Many of the surgical approaches require technical perfection and careful patient selection, and they have yet to be well tested in clinical trials; however, along with intestinal transplantation, they will likely provide the future foundation of short bowel syndrome therapy.

Techniques designed to slow transit time

Antiperistaltic segments act like physiological valves by slowing intestinal transit and altering myoelectric activity [235,236]. These reversed segments increase the absorption of water, nitrogen, and fat [237–239]. In animal studies, antiperistaltic segments seem to induce intestinal adaptation by increasing intestinal diameter both upstream and downstream from the anastomosis, as well as increasing villus height and crypt depth [240]. The treatment of more than 50 patients with short bowel syndrome by this method has been reported thus far, with good results in about 70% of them. The ideal length for a reversal segment is 10–15 cm of distal small bowel in an adult and about 3 cm in an infant [241–247]. Reversal may provide temporary relief while intestinal adaptation is taking place [248]. Patients with an extremely short intestine may not have the 10 cm of intestine required to fashion the reversal segment. Furthermore, small bowel obstruction at the antiperistaltic site is always a risk and may necessitate additional intestinal resection.

Peristaltic activity in the colon differs from that in the small intestine; it is slower and segmental and progresses by means of infrequent peristaltic rushes [249]. In dogs and rats, isoperistaltic interposition of a segment of colon between jejunal or ileal segments prolongs the intestinal transit time without causing obstruction [249,250]. The isoperistaltic colon is placed proximally and functions by allowing the slow delivery of chyme to the distal intestine. Despite slowed transit, however, the interposed colonic segment does not show evidence of small bowel intestinalization [251] and appears to have no significant effect on the absorption of nutrients [252]. In case reports, the length of the interposed colon, which does not appear to be critical, varied from 8 to 24 cm.

The colon also can be interposed in an antiperistaltic fashion. The antiperistaltic colon is placed distally. In one study, this procedure significantly improved the absorption of fat and xylose in monkeys [253]. Other authors, however, did not identify significant benefits to intestinal absorptive function [254–256].

Various techniques are used in the construction of valves to replace lost ileocecal valves. Nipple valves can be inserted at an ileostomy site [257]. In general, excision of the outer longitudinal muscle layer allows the inner circular muscular layer to contract without opposition, so that submucosal tunneling and the development of a nipple-like valve are possible [258,259]. Distal bowel also can be everted and telescoped into the proximal bowel [260]. These techniques of constructing an artificial valve do not modify the intestinal motor response to intestinal resection but simply create a low-grade mechanical obstruction [261]. In both experimental animal models and in humans with short bowel syndrome, such valves have reduced the number of evacuations and the rate of small bowel bacterial overgrowth [262–264]. However, despite a significantly prolonged transit time, the operation has not yet been shown to result in increases in absorptive surface area, functional absorptive capacity, or bodyweight [265].

In principle, recirculating loops should prolong the transit time by promoting repeated exposure of the intestinal mucosal surface area to lumenal contents. However, this procedure has been associated with high morbidity and mortality rates in experimental animals as a consequence of extensive bacterial overgrowth [266].

Retrograde electrical pacing is designed to slow and reverse the flow of intestinal contents, so that chyme pools and absorption is increased through prolonged mucosal contact. In dog jejunum, retrograde electrical pacing increased water, sucrose, and sodium absorption [267].

In animal studies, intrinsic myenteric denervation of the ileum, in an attempt to slow the forward flow of intestinal contents, led to dilation of the residual small and large intestine in rats that had been subjected to massive intestinal resection and resulted in an increase in absorptive surface area and postoperative weight gain [268].

Techniques designed to taper and lengthen intestine

Adaptive dilation of the small intestine causes ineffective peristalsis and stasis. Under normal circumstances the dilated segment is simply excised. However, in cases of short bowel syndrome excision is not often a valid option and in this circumstance remodeling is the treatment of choice. The diameter of the dilated intestine can be reduced through

intestinal plication or tapering enteroplasty. This simple and safe technique allows the mucosal surface to be preserved [269]. Ramanujam [270], using mongrel puppies, demonstrated that plication is a remodeling technique that is superior to tapering enteroplasty.

Bianchi [271] described a technique for lengthening the bowel of pigs by using the dilated segment, and has reviewed the human trials of this technique [272]. The intestine is tapered, and the redundant small intestine is used for lengthening purposes. Since the first clinical application, this has been the surgical technique most frequently used in attempts to reverse short bowel syndrome in children [273,274]. Although the intestinal length is increased, mucosal function may be compromised. In one study, sucrose transport was found to be decreased across the segment involved in the intestine lengthening [39]. In dogs with a 75% distal ileal resection, tapering and lengthening impaired nutritional status and intestinal absorption and adaptation. The changes in absorption and transit appeared to be related to altered intestinal transit rates, and the impaired adaptation was related to decreased enteroglucagon levels and increased somatostatin levels [275]. These findings are not surprising given that intestinal lengthening does not provide new mucosa. Any benefit is likely to be attributable to the mechanical effect of slowed intestinal transit.

In a series involving five human subjects, isoperistaltic tapering and lengthening (Bianchi procedure) resulted in improvement of intestinal function. At 1 and 6 months postoperatively, stool output was decreased, D-xylose absorption was increased, and fecal fat was decreased in comparison with preoperative measurements [276]. Bianchi reported that isoperistaltic tapering and lengthening resulted in survival off parenteral nutrition in 45% of 20 pediatric patients; however, successful weaning from parenteral nutrition was related to an initial intestinal length of more than 40 cm [277]. Similar results have been reported by separate German and American pediatric surgical groups [278,279]. The length of intestine after the Bianchi procedure seems to correlate with the potential for weaning from parenteral nutrition [280].

Georgeson and associates [281] combined several different surgical techniques. If the intestine was not sufficiently dilated, a nipple valve was constructed distally to provide partial small bowel obstruction and so induce dilation. Following this, the Bianchi technique was used to lengthen the intestine. In a small series of case reports, length was increased on average by a factor of 2.5 during 1 year; enteral intake averaged 66% of the total requirement, in comparison with less than 10% before the operation.

Serial transverse enteroplasty (STEP) is a lengthening procedure performed by stapling of dilated small intestine perpendicularly to the longitudinal axis of the bowel sequentially along the intestine. This creates a longer, zigzag-shaped bowel. In animals, this procedure increases intestinal length, and improves carbohydrate and fat absorption, as well as increased body weight [282]. A case series of five children who underwent the STEP procedure showed increased intestinal length and weight, and increased enteral intake in all the children, with discontinuation of parenteral nutrition in one patient [283]. In addition, one patient who had been listed for a combined liver and small bowel transplant due to severe TPN cholestasis had normalization of bilirubin levels after STEP. This procedure may also reduce small bowel bacterial overgrowth through improved intestinal motility, and was used to treat bacterial-induced refractory D-lactic acidosis in one case report [282,284]. A web-based registry of outcomes from the STEP procedure, the International STEP Data Registry (www.stepoperation.org), was initiated by the study authors to ascertain multicenter outcomes.

Intestinal regeneration takes place in full-thickness intestinal defects patched with a variety of substances, including small intestinal submucosa and prosthetic materials [285,286]. The new intestinal tissue, which develops by lateral growth, is functionally similar to normal intestinal mucosa [287].

Intestinal transplantation

As outcomes in intestinal transplantation continue to improve the role of this therapy is being clarified; for reviews see Fryer [288] and Abu-Elmagd [289].

Natural history of short bowel syndrome treated with parenteral nutrition

The long-term rates of survival and dependence on parenteral nutrition of adult [290] and pediatric [290] patients with short bowel syndrome have been reviewed. Rates of 5-year survival and dependence on parenteral nutrition in adults are 55% and 45%, and in children 73% and 75%, respectively. Survival is negatively related to end-enterostomy, ileocecal valve removal, colonic resection, small bowel length of less than 50 cm (adult) and 15 cm (children), advanced age, early persistent cholestatic jaundice, and arterial infarction as a cause of the short bowel syndrome [25,290–292]. In one small series, patients with less than 50 cm of small intestine without a colon had 100% mortality at 1 year due to multiorgan failure, compared with 50% mortality in patients with a colon and 50–100 cm of small intestine, indicating the need for earlier consideration of transplant in patients with extensive intestinal resections [293]. Dependence on parenteral nutrition is positively related to a small bowel length of less than 100 cm and to the absence of a terminal ileum, ileocecal valve, or colon. After 2 years of parenteral nutrition, the probability of a permanent need for parenteral nutrition is 95%. Children with short bowel syndrome may have slightly better outcomes, as series show 5-year survival rates of more than 70%, with 64%–77% of children free from parenteral nutrition [25,291].

Long-term home parenteral nutrition, although it can maintain normal nutritional parameters in 80% of patients, results in frequent hospitalizations, predominantly for catheter-related problems, a 30% rate of regular opiate use, and an inability to achieve complete rehabilitation [294]. The Oley foundation registry of home parenteral nutrition described hospital admission rates of 0.70–2.23 times per patient years on TPN, mostly due to septic complications, with a mortality rate ranging from 5% to 25% per year [295]. Liver disease related to TPN develops at a rate of 15% in patients receiving TPN for over 1 year, and carries a mortality of up to 100% within 2 years of diagnosis [296]. Given the risks inherent in any transplant procedure, less invasive therapeutic modalities must be exhausted prior to transplantation. This was demonstrated by a series of 13 children with short bowel syndrome who were referred for consideration for combined intestinal and liver transplantation due to TPN-related cholestatic liver disease. These patients showed significant reduction in bilirubin levels and TPN requirements through treatment at a multidisciplinary intestinal rehabilitation program with the goal of optimizing management through diet, antibiotic therapy, and selected nontransplant bowel lengthening surgery [297]. These complex patients are best managed by a dedicated multidisciplinary team approach.

Indications

Intestinal transplantation has become a life-saving treatment that can be considered for patients with irreversible intestinal failure who cannot be maintained on parenteral nutrition. Life-threatening complications of parenteral nutrition that warrant a consideration of intestinal transplantation include: parenteral nutrition-associated liver disease; recurrent sepsis; recurrent dehydration; and loss of central venous access. The indications are similar for children and adults. The fact that intestinal failure itself can lead to the development of profound neuropathological abnormalities in the brain may be a reason to consider earlier transplantation [298]. Patients with a high likelihood of progressing to intestinal transplantation will also benefit from early referral. These patients include those with no jejunoileum, patients with short bowel syndrome who are not able to wean from TPN and show progressive thrombocytopenia, and patients with deteriorating motility disorders – all have a high likelihood of lifelong TPN dependence and ultimate indications for intestinal transplantation [299]. Their care can be optimized at a referral center and appropriate timing for small intestinal transplant considered.

Also, although waiting times for intestinal transplant are comparable with those for other organs, the mortality on the waiting list is greater for patients awaiting intestinal transplant than for any other organ [173]. The waiting list mortality is largely due to patients requiring combined intestinal and liver transplant. Other factors prolonging the wait for intestinal transplant are the need for cytomegalovirus (CMV)-negative donors to decrease the risk of CMV enteritis, and the need for smaller donors due to restricted peritoneal cavity size in the short bowel syndrome patient [173]. Therefore, it is important that patients with life-threatening complications of intestinal failure and parenteral nutrition therapy be identified and referred for transplantation early [298,300,301]. Case reports of intestinal transplants from a living-related donor are available, and this may be one way to overcome the limitation of donor availability [302]. Because the survival rate of isolated intestinal transplants is higher than that of combined intestinal–liver transplants, patients should be considered for transplantation before bridging fibrosis and cirrhosis develop. Finally, an appreciation of the unique and specific nutritional needs of the recipient and the donor is important in maximizing survival [303].

Results

Intestinal transplantation is an evolving procedure with survival rates comparable, at some larger centers, with those for parenteral nutrition [304]. The Intestinal Transplant Registry (www.intestinaltransplant.org) provides updated data for graft and patient survival from intestinal transplant centers across the world. Sixty percent of the recipients are children or adolescents. Short bowel syndrome with a failure of maintenance on parenteral nutrition is the most common indication for transplantation [305]. The types of grafts are different in the adult and pediatric population. In pediatric recipients, 50% require combined intestine and liver transplantation, 37% require intestine alone, and 13% receive a multivisceral transplant, which includes portions of stomach, duodenum, or pancreas [306]. By contrast, in adults only 21% require combined intestine and liver transplantation, 55% require intestine alone, and 24% require multivisceral transplants.

A 2003 review of an international small intestinal transplant registry showed 1-year graft/patient survival rates of 65%/77% for small intestinal transplant, 59%/60% for combined small bowel and liver transplant, and 61%/66% for multivisceral transplant [306]. These results are similar for both adult and pediatric transplantations. The registry data also demonstrated that outcomes of intestinal transplantation have improved over the past decade. Indeed, one site has shown 1- and 3-year patient survival of 94%/73% for transplants between 1999 and 2003 compared with survivals of 77%/52% between 1991 and 1998 [307].

The single most important factor in both graft and patient survival is the number of transplants a center completes each year. Rates of intestinal transplantation are increasing as outcomes improve, from 11 cases annually worldwide in 1990 to 140 cases annually in 2003 [306]. However, the majority (75.5%) of intestinal transplants were performed in the United States, and 83% were performed at 10 highly specialized centers. In a retrospective review from a single center

performing a large number of intestinal transplants, the 1-year patient/graft survival was reported as 93%/71% [308]. Evidence of a threshold effect, where a certain volume of procedures is required for optimal outcomes, is lacking but centers with greater than 10 transplants have improved survival.

Increased graft and patient survival is also seen in patients waiting for transplant at home compared with hospitalized recipients, emphasizing the need for early referral for transplant assessment. Other predictors of a positive outcome are the use of induction immunosuppressive treatment with antiinterleukin-2 (anti-IL-2) or antibodies to T-lymphocytes and B-lymphocytes, and the use of maintenance immunosuppressive treatment with rapamycin and tacrolimus [306,309]. Anti-IL-2 antibody use increased 1-year survival from 33% to 62.5% in one series [310]. Combined liver and small intestinal transplant may improve survival of the intestinal graft and decrease acute rejection episodes [310]. The mechanism behind this effect is unclear. Donor type, donor organ irradiation, recipient diagnosis, and maintenance immunosuppression do not affect survival [306]. Approximately 80% of survivors of transplantation have been able to discontinue parenteral nutrition and resume oral nutrition, 10% have a partially functioning or nonfunctioning transplant in place, and 10% have had their transplant removed. Physical and psychosocial quality of life indicators as determined by the child recipient 1 year posttransplant show no difference from those of normal schoolchildren [311,312]. By contrast, parental proxy assessments perceived decreased general health and physical functioning [311].

Rejection remains the single most important factor leading to graft failure and removal, accounting for 60% of graft failure. The donor intestine carries a large lymphoid mass, the gut-associated lymphoid tissue (GALT), which expresses MHC class I and class II antigens. The immunogenicity of the intestine may contribute to the high rates of organ rejection traditionally associated with small intestinal transplantation [288]. However, advances in immunosuppression have significantly reduced rejection rates. Part of the challenge in managing these patients is maintaining the delicate balance between immunosuppression, which is necessary to prevent graft-versus-host disease and rejection, and immunosuppression-related adverse effects. The required degree of immunosuppression is associated with a high risk for lymphoproliferative disorders and intestine-derived sepsis. Rejection may also increase the risk of sepsis and subsequent multiorgan system failure through increased intestinal permeability leading to bacterial translocation, further complicating the issue of immunosuppression after intestinal transplantation. The incidence of lymphoproliferative disease after intestinal transplantation is 15%; it appears to be linked to Epstein–Barr virus (EBV) infection, OKT3 (anti-CD3) induction therapy, and corticosteroids [313]. Epstein–Barr virus-associated lymphomas are treated with reduction of immunosuppression and anti-CD20 monoclonal antibodies. The risk of organ rejection and infection necessitates a thorough posttransplant protocol. This may include enteral decontamination with antibiotics for the first posttransplant month, with weekly quantitative stool cultures, prophylactic ganciclovir, weekly polymerase chain reaction (PCR) for EBV, and frequent biopsies of the intestinal graft [310]. Additional reasons for graft failure are thrombosis, ischemia, and bleeding (25%), multiple-organ failure (10%), sepsis (6%), and lymphoma (1%).

Sepsis is the most frequent cause of death in this transplant population (46%) [306]. Up to 92% of intestinal transplant recipients show evidence of bacterial infection postoperatively, with an average of 2.6 episodes per patient [314]. The most common sources are catheter-related infection (29.5%), intraabdominal infection (16.5%), and respiratory infection (5.7%) [314]. Reduced rates of sepsis and improved survival rates have been described following living-related transplantation [315–317]. Investigations of bacterial translocation following intestinal transplantation have suggested that cold ischemia time, not rejection or the associated transplantation of the colon, influences bacterial translocation [318]. Animal studies show a decrease in bacterial translocation after intestinal transplant when nitric oxide donors and various apoptosis inhibitors are administered, but no human trials have examined this effect [319]. Additional causes of death are multiorgan failure (2.5%), respiratory failure (6.6%), lymphoma (6.2%), graft thrombosis (3.2%), technical problems (6.2%), and graft rejection (11.2%) [306].

Intestinal transplantation has gone from being an experimental procedure to one that is mainstream, albeit at highly selected sites. Nevertheless, it has not replaced parenteral nutrition for short bowel syndrome but instead should be reserved for the patient in whom parenteral nutrition has reached its limits, with life-threatening complications, loss of vascular access, or liver disease.

C SMALL INTESTINE

54 Tumors of the small intestine

Robert S. Bresalier, Sharmila Anandasabapathy

Descriptive epidemiology, 1322
Etiology and pathogenesis, 1322
Risk factors and associated conditions, 1324
Clinical picture, 1325
Adenocarcinoma, 1325
Carcinoid tumors, 1328
Mesenchymal tumors, 1332
Lymphomas, 1334
Secondary tumors, 1337

Small intestinal tumors (tumors of the duodenum, jejunum, and ileum) are uncommon compared with those occurring elsewhere in the gastrointestinal tract, and fewer than 2% of malignant gastrointestinal tumors are derived from this organ [1–6]. Primary small intestinal tumors are derived from both epithelial and mesenchymal components of the small bowel (Table 54.1). Primary malignant tumors include adenocarcinomas, carcinoids, lymphomas, and sarcomas (i.e., gastrointestinal stromal cell tumors). Approximately 6100 new cases of primary small intestinal cancer occurred in the United States in 2008 (equally distributed between men and women), with 1100 estimated cancer deaths [1]. The diverse nature of small intestinal tumors makes it difficult to generalize about the group as a whole. Some tumors represent distinct entities, whereas others share overlapping features.

Descriptive epidemiology

The frequency of small bowel tumors varies among different populations [7]. Reviews of the incidence and natural history of small bowel tumors comprise small series of patients, and some may include both primary or secondary (e.g., lymphomas) tumors. Some series include periampullary tumors and tumors of the ampulla of Vater, whereas others do not [2]. The relative frequency of primary tumors ranges in the literature, with adenocarcinoma (24%–52%), malignant carcinoid (17%–41%), lymphoma (12%–29%), and sarcomas (11%–20%) the most frequent [2–6,8–14]. The pattern of distribution of tumors in the small intestine is dependent on histological type. In Western countries, adenocarcinomas are most commonly found in the duodenum. In the setting of Crohn's disease, adenocarcinomas may occur distally in the ileum. Carcinoids and primary lymphomas occur predominantly in the ileum and jejunum. Sarcomas are found more evenly distributed. Metastases to the small bowel from adenocarcinomas and sarcomas account for approximately 50% of all small bowel tumors.

An overall age-adjusted incidence of primary small bowel cancers of 1.4 per 100 000 was reported in a US population-based study [5]. Small but significant increases in the incidence of adenocarcinomas and carcinoids have been noted since the 1970s [15], with a slight male predominance. The incidence of small bowel cancers rises with age, beginning at 30 years, with a mean age of diagnosis of approximately 60 years [16,17]. Incidence rates for adenocarcinomas and malignant carcinoids are higher in African Americans than in whites (6.4% and 1.4% increase per year, respectively) [15].

Etiology and pathogenesis

Why are small bowel tumors rare?

Several hypotheses have been proposed to explain this phenomenon, but objective data are mostly lacking [17].

- Rapid transit time and liquid lumenal contents reduce physical damage and mucosal contact with putative carcinogens; moreover, the latter are detoxified by mucosal enzymes such as benzpyrene hydroxylase.
- Bacterial enzymes have been postulated to play a role in colonic carcinogenesis. When the bacterial flora is altered, as in bacterial overgrowth syndromes, small intestinal carcinomas develop with a higher frequency than expected. The small intestine, conversely, has low bacterial counts, with an absence of anaerobes under normal conditions.
- Stem cells located at the crypt base lie deeper in the small intestine than their counterparts in the colon, perhaps reducing contact with lumenal carcinogens. The rapid differentiation of stem cells into mature, nonproliferating enterocytes and goblet cells may also protect against factors that deregulate cell growth and promote cancer development.

Table 54.1 Classification of small intestinal tumors[a]

Benign epithelial tumors
Brunner gland lesions[b]
Benign intestinal epithelial polyps
Adenomas
Hamartomas (Peutz–Jeghers syndrome, Cronkhite–Canada syndrome, juvenile polyposis, Cowden disease, Bannayan–Riley–Ruvalcaba syndrome)
Malignant epithelial lesions
Primary adenocarcinomas
Secondary carcinomas (metastases)
Carcinoid tumors (neuroendocrine tumors)
Lymphoproliferative disorders
B-cell:
Diffuse large cell lymphoma
Small noncleaved cell lymphoma
MALT cell lymphoma
Mantle cell lymphoma (multiple lymphomatous polyposis)
Immunoproliferative small intestinal disease
T-cell:
Enteropathy-associated T-cell lymphoma
Mesenchymal tumors[c]
Gastrointestinal stromal tumors (benign and malignant)
Fatty tumors (lipoma, liposarcoma)
Neural tumors (gut autonomic tumors, schwannomas, neurofibromas, ganglioneuromas, granular cell tumors)
Paragangliomas
Smooth muscle tumors (leiomyoma, leiomyosarcoma)
Vascular tumors (hemangioma, angiosarcoma, lymphangioma, Kaposi sarcoma)

a This is a partial list of tumors found in the small intestine. Whereas the overall incidence of small intestinal tumors is low, many different benign and malignant lesions have been described in this organ.
b It is unclear whether these lesions should be classified as hyperplasias, neoplasia, hamartomas, or adenomatous proliferations.
c Some mesenchymal tumors represent clear-cut diagnostic entities, whereas many are more difficult to classify into any specific cell lineage. The latter are designated gastrointestinal stromal tumors.
MALT, mucosa-associated lymphoid tissue.

- Based on preclinical data from murine models [18], apoptosis involving damaged cells and potentially tumorigenic clones differs between the small and large intestine.
- Lymphoid tissue in the lamina propria and Peyer patches of the ileum may provide immune surveillance against neoplastic cells through IgA-rich secretions.

Diet

The limited descriptive epidemiology of small intestinal tumors has not provided strong evidence for environmental influences on tumor formation, in contrast to studies of the large intestine. Weekly or more frequent consumption of red meat or salt-cured foods has been associated with a two- to threefold increase in risk of small intestinal cancer [19]. Another study [20] reported odds ratios (OR) for cigarette smoking of 4.6 for adenocarcinomas and 4.2 for carcinoids and an OR for alcohol consumption of 4.0 for adenocarcinomas and 3.1 for carcinoids. A population-based case–control study [21] observed a significant threefold increased risk of adenocarcinoma of the small bowel in heavy drinkers (≥ 80 g/day of ethanol) relative to moderate drinkers or nondrinkers. Frequent intake of foods rich in heterocyclic amines (fried bacon, ham, barbecued or smoked meat and fish) was associated with a significant four- to fivefold increased risk of adenocarcinoma in men, but not in women. There was also a consistent and significant trend in risk with increasing sugar intake, with an OR of 3.8 in the highest intake category. In a hospital-based case–control study [22], alcohol and tobacco did not increase the risk of adenocarcinoma of the small intestine. Risk was positively related to intake of bread, pasta, or rice (OR = 3.8), sugar (OR = 2.9), and red meat (OR = 4.6), and it was inversely related to coffee (OR = 0.4), fish (OR = 0.3), vegetables (OR = 0.3), and fruit (OR = 0.6).

Molecular biology and biochemical changes

In comparison with colorectal cancer, relatively little is known about the molecular genetic events associated with the evolution of small bowel tumors.

Cellular protooncogenes are evolutionarily conserved human genes that play a role in signal transduction and normal regulation of cell growth. Human *RAS* genes encode guanine nucleotide-binding proteins that regulate intracellular signaling pathways. Point mutations in *KRAS* (K-*ras*), especially at codon 12, have been reported in 14%–53% of primary small intestinal adenocarcinomas [23,24] but not in carcinoids. Mutations of *KRAS* were common in sporadic and Crohn's disease-associated adenocarcinomas of the small intestine [25]; *KRAS* mutations were present in all four sporadic carcinomas with contiguous adenomas, in 2 of 11 (18%) without adenomas, and in 4 of 7 (43%) of Crohn's disease-associated carcinomas.

Allelic losses involving tumor suppressor genes play major roles in the genesis of intestinal tumors. The *APC* gene on the long arm of chromosome 5 (5q21) is mutated in the germ line of patients with familial adenomatous polyposis (FAP), and somatic mutations of *APC* occur in 60%–80% of sporadic colorectal carcinomas and adenomas (see Chapters 000, 000). Mutation of the mouse homologue of *APC* (*Apc*) by chemical carcinogenesis or by genetic manipulation [26] results in the development of polyps in both the large and the small intestine. Small intestinal and periampullary adenomas and carcinomas are common in patients with FAP. Mutations in *APC* have also been reported in sporadic small intestinal adenocarcinoma [24], but they appear to occur at a much lower frequency than in sporadic colorectal cancer.

Deletions of chromosome 17p involve the *p53* tumor suppressor gene, whose product normally prevents cells with damaged DNA from progressing from the G1 phase to the S phase in the cell cycle and regulates apoptosis. Mutations in *p53* were found in 27% of small bowel adenocarcinomas in one series [24], whereas alterations in the p53 gene product and allelic loss of chromosome 17p were present in 47% of sporadic small bowel adenocarcinomas, 33% of contiguous adenomas, and 71% of Crohn's disease-associated carcinomas in a second series [25].

Candidate tumor suppressor genes on chromosome 18q include the *DCC* (deleted in colon cancer) gene and *DPC4* (*SMAD4*). The *DPC4* gene belongs to the SMAD gene family, which is involved in signal transduction pathways activated through the transforming growth factor β (TGF-β) family receptors. Loss of 18q has been reported in intestinal tumors from the Apc 1638N mouse model [26], but rarely in human small intestinal adenocarcinomas [25]. However, chromosome 18 deletions appear to be common events in classical midgut carcinoids of the small intestine [27,28].

Alterations in genes that help to maintain DNA fidelity during replication (mismatch repair, or MMR, genes) are characteristic of patients with hereditary nonpolyposis colorectal cancer (HNPCC). Mismatch repair gene mutations in *hMLH1* and *hMSH2* were present in 15 of 42 (36%) of HNPCC-associated small bowel carcinomas in one series [29]. Pathogenic germ-line mutations in genes including *MLH1, MSH2,* and *MSH6* were identified in 81% of individuals with HNPCC and small bowel tumors in another large series [30]; 89% of these cases had loss of MMR protein expression. DNA replication errors characterized by microsatellite instability were also reported in 13% of sporadic small bowel carcinomas [25].

Most gastrointestinal stromal cell tumors (GISTs) contain gain-of-function mutations in the c-*KIT* oncogene resulting in activation of the KIT tyrosine kinase [31]. Some tumors contain mutations in the platelet-derived growth factor α (PDGFRA) receptor tyrosine kinase. Activation of *KIT* is a crucial oncogenic mechanism in sporadic and familial GISTs. Mutations in *KIT* or *PDGFRA* are found in over 90% of adult GISTs, and predict response to therapy with tyrosine kinase inhibitors.

Risk factors and associated conditions

Numerous risk factors and associated conditions have been described with relation to tumors of the small intestine (Table 54.2).

Table 54.2 Conditions associated with an increased risk of primary small intestinal neoplasia

Adenocarcinoma
Familial adenomatous polyposis
Hereditary nonpolyposis colorectal cancer
Peutz–Jeghers syndrome
Juvenile polyposis syndrome
Crohn's disease
Previous history of cholecystectomy
Long-standing ileostomy (especially with Crohn's disease)
Ileal loop conduits, ileal pouches, ileal cystoplasty
Duplication cysts and Meckel diverticula
Gluten-sensitive enteropathy
Non-Hodgkin B-cell lymphoma
Immunoproliferative small intestinal disease
Gluten-sensitive enteropathy
Nodular lymphoid hyperplasia
Acquired immunodeficiency syndrome
Crohn's disease

Familial adenomatous polyposis (FAP)

Periampullary duodenal carcinoma is the most common extracolonic malignant tumor in patients with FAP. There were 11 cases of duodenal and ampullary adenocarcinoma reported among 1391 patients with FAP [32], representing a relative risk (RR) of duodenal adenocarcinoma of 331, and an RR of 124 for ampullary carcinoma compared with the general population. Mean ages of diagnosis were 53 years for duodenal carcinoma and 49 years for ampullary carcinoma. Duodenal adenomas are common in patients with FAP, and they have been reported in up to 90% of such patients.

Hereditary nonpolyposis colorectal cancer (HNPCC)

Hereditary nonpolyposis colorectal cancer is an inherited disease in which colon cancers arise in discrete adenomas, but polyposis (i.e., hundreds of polyps) does not occur (see Chapter 65). Forty-two members of 40 families with HNPCC developed 42 primary and 7 metachronous small bowel tumors [29]. There were 46 adenocarcinomas and 3 carcinoid tumors. The median age at diagnosis of the index small bowel tumor was 49 years. The small bowel was the first site of carcinoma in 24 (57%) patients. The relative risks of small bowel cancer in families that fulfilled the Amsterdam II and Bethesda criteria for HNPCC (see Chapter 65) were 36.1 and 5.75, respectively, in a report from a Swedish registry [33].

Hamartomatous polyposis syndromes

Hamartomatous polyposis syndromes are a group of disorders marked by the finding of multiple hamartomatous polyps in the gastrointestinal tract (see Chapter 64). The *Peutz–Jeghers syndrome* is an autosomal dominant disease, which in most families has been mapped to chromosome 19p13.3 and the *STK11* (serine threonine kinase 11) gene. Adenomatous changes have been reported in 3%–6% of hamartomas. Extracolonic cancers are common, occurring in

50%–90% of patients (small intestine, stomach, pancreas, esophagus, ovary, lung, uterus, breast). The RR for all cancers is 15.2 compared with the general population [34]. The small intestine represents the most frequent site of cancer development, with an RR of development of adenocarcinoma of 520 compared with the general population. Patients with Peutz–Jeghers syndrome have characteristic mucocutaneous pigment spots, which are frequent in the perioral region and across the vermilion border. Polyps are distinctive, with an arborizing pattern of growth of the muscularis mucosa extending into the branching fronds of the polyp. Patients often present with obstructive symptoms and may develop intussusception of the small bowel.

Juvenile polyposis syndrome is an autosomal dominant disease in which hamartomatous polyps may be limited to the colon, or to the stomach, or occur throughout the gastrointestinal tract. Mixed juvenile and adenomatous polyps have been reported. The RR for small intestinal cancer is unclear, but cancers of the duodenum have been reported. Patients may present with bleeding, intussusception, and obstruction. A life-threatening protein-losing enteropathy has been reported in some patients. Germ-line mutations in the *SMAD4* (chromosome 18q21.1) and *PTEN* (chromosome 10q23) genes have been reported in separate kindreds with juvenile polyposis syndrome [35].

Crohn's disease

An increased incidence of both small intestinal adenocarcinoma and lymphoma has been reported to occur in Crohn's disease. The RR of small bowel carcinoma in Crohn's disease (mostly ileal) has been estimated to be 60–100 times that of the general population [36,37]. A dysplasia–carcinoma sequence occurs in the small intestine in Crohn's disease similar to that of the colon and rectum [25,38]. Crohn's disease-associated small bowel carcinomas and dysplasias are accompanied by frequent genetic alterations in *KRAS* and *p53*.

Diversion of bile (previous cholecystectomy)

Diversion of bile to the lower small intestine either surgically or by feeding cholestyramine increases the yield of intestinal carcinomas in carcinogen-treated animals. Thus, cholecystectomy, which increases delivery of bile to the proximal bowel, could theoretically lead to an increased risk of small and large bowel cancer. Indeed, patients who underwent cholecystectomy had an increased risk of proximal intestinal adenocarcinoma that declined with increasing distance from the common bile duct [39]. The risk was significantly increased for adenocarcinoma of the small bowel (RR = 1.71) and the right-sided colon.

Gluten-sensitive enteropathy (celiac disease)

An increased risk of both small intestinal adenocarcinoma and non-Hodgkin lymphoma has been reported to be associated with celiac disease (gluten-sensitive enteropathy) [40,41] (see Chapter 50). The overall incidence of malignant disease in this condition has been reported to be 11%–13%, with an incidence of small bowel lymphomas of 4%–7%. In some reported cases, it is not clear whether the primary diagnosis is actually celiac sprue or whether the histological changes are secondary to lymphoma per se. Lymphomas in the setting of celiac disease are usually of T-cell origin (enteropathy-associated T-cell lymphomas, or EATLs). Adenocarcinomas may arise in focal areas of dysplasia [42].

Other conditions may carry an increased RR for small bowel neoplasia (see Table 54.2), but they are relatively rare. Patients with urinary diversion to the small bowel (ileal loop conduits) appear to have an increased risk of carcinoma. Adenocarcinomas arise in the mucosa of ileostomies and ileal pouches in patients with inflammatory bowel diseases and FAP [40], although this event is probably rare [43,44].

Clinical picture

The clinical signs and symptoms of small bowel neoplasms may have some common features, but for the most part they depend on the individual tumor type (Table 54.3). Abdominal pain may result from partial or complete small bowel obstruction, intussusception, or ischemia. Obstruction may be the result of the physical bulk of the tumor, infiltration, or annular constriction. An intense dermoplastic reaction by carcinoids causes intestinal buckling or kinking. Intussusception may occur with benign polypoid lesions (which account for half of adult cases of intussusception) and is common in patients with GISTs. Occult gastrointestinal blood loss is another common feature of benign and malignant small bowel tumors. However, bleeding may be acute and brisk in the case of ulcerated GISTs. Weight loss is especially common and pronounced in patients with small bowel lymphoma.

Adenocarcinoma

Epidemiology and risk factors

Adenocarcinoma is the most common primary malignant disease of the small intestine. The incidence of primary small bowel adenocarcinoma ranges between 3.0 and 6.5 per million, representing approximately 40% (range 24%–42%) of primary small bowel tumors in most population-based studies [17]. Small bowel adenocarcinoma accounts for approximately 2% of gastrointestinal tumors and 1% of gastrointestinal cancer deaths. Fifty-five percent of these tumors occur in the duodenum, 18% in the jejunum, 13% in the ileum, and 14% in nonspecified sites [2]. The overall 5-year survival is 30.5%, with a median survival of 19.7 months. A slight male predominance is usual. The incidence of small bowel adenocarcinoma is slightly higher in black people compared with white people [15].

Table 54.3 Clinical features of small bowel tumors

Symptom	Benign	Malignant
Abdominal pain	Most frequent symptom	Most frequent symptom: one-third of patients develop partial or complete obstruction
Intussusception	Most common cause of intussusception in adults, lipomas the leading cause	Rare
Occult blood loss	25%–50% of cases	Up to 50% of cases
Frank bleeding	Rare	Rare; GIST most likely tumor
Weight loss	Exceedingly rare	Up to 50% of cases, most severe with lymphoma
Palpable abdominal mass	Rare	40% of cases
Perforation	Exceedingly rare	About 10% of cases, almost all of which are lymphomas or GIST
Jaundice	Rare occurrence with benign periampullary tumor	Occurs with about 80% of malignant periampullary tumors
Flushing	Metastatic spread of carcinoid tumor required for carcinoid syndrome to occur	Occurs in a few cases of metastatic carcinoid tumor
Diarrhea	Exceedingly rare	Common with lymphoma and can occur with carcinoid syndrome

GIST, gastrointestinal stromal cell tumor.

Adenocarcinomas arise from adenomas or dysplastic changes of the small intestine (see "Pathology, natural history, and staging" below). Adenomas and adenocarcinomas of the small intestine, and especially of the duodenum and ampulla of Vater, are most frequently encountered in the setting of FAP. Untreated duodenal and ampullary adenomas in patients with FAP were followed in the context of an endoscopic surveillance program [45]. Duodenal polyps progressed in size in 26% (25 of 95), in number in 32% (34 of 106), and in histology in 11% (5 of 45). Morphology and histology of ampullary adenomas progressed in 14% (15 of 110) and 11% (12 of 105) of patients, respectively. One patient developed a periampullary carcinoma.

Pathology, natural history, and staging

Adenocarcinomas of the small intestine arise in discrete adenomatous polyps, in adenomatous changes involving the ampulla of Vater, or in dysplasia associated with inflammatory bowel disease. In hamartomatous polyposis syndromes, carcinomas may arise from discrete adenomas or mixed polyps containing adenomatous components [32]. Dysplasia is associated with familial juvenile polyps, but not with solitary, sporadic juvenile polyps. Dysplastic polyps contain markers suggesting a loss of proliferative control within the epithelium and mutations in *APC* [46].

Adenomas in the small intestine display the same gross and microscopic features as those in the large intestine. They may be pedunculated or sessile. Tubular adenomas tend to be small, whereas those with villous architecture tend to be larger. The presence of multiple duodenal adenomas or adenomatous changes in the ampulla of Vater suggests the diagnosis of FAP. Tubular adenomas contain tall, columnar, pseudostratified epithelial cells. Villous adenomas contain finger-like villous or papillary processes similar to those in the colon. Small intestinal adenomas exhibit a spectrum of dysplasia ranging from mild dysplasia to intramucosal carcinoma and invasive cancer. Glandular crowding ("back to back" glands), loss of epithelial polarity, an increased nuclear-to-cytoplasmic ratio, and increased mitoses characterize high-grade dysplasia. These changes, accompanied by invasion into the lamina propria, define *intramucosal carcinoma.*

Invasive carcinoma may be found in one-fourth to half of resected villous adenomas in the setting of FAP [46], but most duodenal adenomas appear to progress slowly to carcinoma [45,47], and the actual risk of malignant degeneration is probably considerably lower. Adenomatous polyps of the small intestine do occur outside the setting of FAP, but even less is known about their natural history.

Small intestinal adenocarcinomas may appear grossly as flat, stenosing, ulcerative, infiltrating, or polypoid lesions. Most are moderately differentiated tumors with gland formation and variable degrees of mucin secretion. Poorly differentiated tumors occur in approximately 20% of cases. The presence of *signet cells*, in which a large vacuole of mucin displaces the nucleus to one side, is a feature of some of these tumors. Rare adenosquamous carcinomas of the duodenum have been reported.

Adenocarcinomas are staged depending on the extent of bowel wall invasion, the presence or absence of invasion into adjacent structures, and the presence or absence of lymph node or distant metastases (Table 54.4) [48]. The prognosis of patients with adenocarcinomas of the small bowel is poor. In one report, the overall 5-year disease-specific survival in the United States was 30.5%, with a median survival of 19.7 months [2]. Factors significantly correlated with survival included age (poorer prognosis for patients > 75 years), tumor site (duodenum worse than jejunum or ileum), disease stage, and whether cancer-directed surgery was performed.

Table 54.4 Staging of small intestinal adenocarcinoma: American Joint Committee on Cancer (TNM classification)

Stage 0
Carcinoma in situ: TIS N0 M0
Stage I
Tumor invades lamina propria or submucosa: T1 M0 N0
Tumor invades muscularis propria: T2 N0 M0
Stage II
Tumor invades muscularis propria into the subserosa or into the nonperitonealized perimuscular tissue (mesentery or retroperitoneum[a]) with extension 2 cm or less: T3 N0 M0
Tumor perforates the visceral peritoneum or directly invades other organs or structures, includes other loops of small intestine, mesentery, or retroperitoneum more than 2 cm, and the abdominal wall by way of the serosa; for the duodenum only includes invasion of the pancreas: T4 N0 M0
Stage III
Any degree of bowel wall perforation with regional lymph node metastasis; any T N1 M0
Stage IV
Any degree of bowel wall perforation with or without regional lymph node metastasis, with distant metastasis

a The nonperitonealized perimuscular tissue is, for the jejeunum and ileum, part of the mesentery, and for the duodenum, in areas where serosa is lacking, it is part of the retroperitoneum.
T, tumor; N, node; M, metastasis.
From American Joint Committee on Cancer [48].

Five-year survival rates were 65% for stage I, 48% for stage II, 35% for stage III, and 4% for stage IV tumors. Similar trends have been reported from Europe [6,49,50]. Adenocarcinomas arising in the setting of HNPCC have a better prognosis than those occurring in FAP or in the general population [29]. Patients with tumors arising at or near the ampulla of Vater may do better than those with more distal tumors, perhaps because they become symptomatic earlier. Five-year survival rates approaching 50% have been reported for patients with node-negative cancers of the ampulla after radical resection.

Clinical picture

The mean age of presentation for adenocarcinomas is approximately 65 years, although the range of age at presentation is wide [2]. Less than 1% of tumors occur before the age of 30 years, and approximately 85% occur after the age of 50 years. Symptoms relate to tumor size, location, and blood supply. Small tumors are asymptomatic or may present with anemia secondary to chronic blood loss, but for the most part they are indolent and difficult to diagnose. Abdominal pain and other obstructive symptoms such as nausea and vomiting are common late symptoms as tumors obstruct from infiltration with lumenal narrowing or mass effect. Anorexia and weight loss are also common symptoms. Ileal tumors may present uncommonly with intussusception. Tumors located in the periampullary duodenum or ampulla of Vater may cause obstruction of the common bile duct, presenting with jaundice and other signs of biliary obstruction.

Diagnosis

Endoscopy (with forward and side viewing) may be used to examine the duodenum where a lesion is suspected or in families with FAP. Screening for duodenal adenomas and lesions of the ampulla of Vater, plus surveillance following endoscopic removal of adenomas, should be performed in persons exhibiting the phenotype of FAP or in family members in whom genetic testing is positive for mutations in the *APC* gene. Individual polyps may be examined by biopsy or, if possible, removed by snare cautery and the ampulla examined by biopsy as necessary. There is a high incidence of adenomatous change in the papilla, even if the appearance is normal. It has been suggested that the slow evolution of duodenal and papillary lesions may justify an endoscopic surveillance interval of 3 years for most untreated patients with FAP [43]. Upper endoscopic surveillance should begin at age 20 years, and biopsies should be taken of any suspicious lesions and of the papilla, even if normal appearing. Push enteroscopy is of use in identifying and biopsying small bowel lesions seen on small bowel barium studies or computed tomography (CT), in evaluating occult gastrointestinal bleeding, and in surveillance of patients with Peutz–Jeghers syndrome, in whom polyps occur throughout the gastrointestinal tract [51]. Capsule endoscopy has been demonstrated to be effective in diagnosing small bowel adenocarcinomas in patients with obscure gastrointestinal bleeding [52]. Colonoscopy with intubation of the terminal ileum may be helpful in examining the terminal ileum in patients with Crohn's disease or in biopsy of suspicious lesions suggested by radiographic procedures.

Small bowel follow-through is 70%–80% accurate for detection of duodenal lesions [53]. Accuracy can be improved by the use of hypotonic duodenography. Barium studies, however, are not as accurate in detecting more distal tumors. The tumor detection rate of enteroclysis (95%) is greater than that for small bowel follow-through (61%) [54]. The radiological appearances of small bowel adenocarcinomas are similar to those of the colon, including annular narrowing or stricture formation (Fig. 54.1) and filling defects comprising polypoid or ulcerated masses. Seventy percent of tumors in the duodenum are polypoid. Large duodenal lesions are ulcerative in 20% of cases. Adenocarcinomas of the jejunum are primary annular-constricting lesions (75%)

Figure 54.1 Annular constricting adenocarcinoma of the jejunum. This upper gastrointestinal barium study demonstrates an "apple-core" lesion (arrow).

Figure 54.2 Computed tomography scan demonstrating intussusception in the terminal ileum resulting from a small intestinal cancer (asterisk). Intussusception gives the impression of a soft tissue "mass" or "bowel within bowel" surrounded by contrast. Layers of serosal fat are seen in the periphery and centrally.

and may be partially ulcerated or fungating. Differentiation of the infiltrating form of adenocarcinoma from stenosing Crohn's disease may be difficult.

Increasingly, CT is used in demonstrating small bowel tumors and their complications, and is often preferable to small bowel follow-through [55]. Intussusception and obstruction may be associated with polypoid adenocarcinomas that are detectable on CT examination (Fig. 54.2), and CT can be helpful in guiding the surgeon to the source of obstruction. Endoscopic ultrasonography can also be used for diagnosing and staging small bowel tumors.

Therapy

Pedunculated adenomas of the duodenum may be removed by endoscopic snare polypectomy. It is often difficult to remove villous adenomas of the small intestine in this manner. These lesions are often sessile and contain foci of invasive carcinoma. Local mucosal resection can be performed surgically for some lesions, but wide excision is indicated for villous adenomas containing invasive cancer. Endoscopic resection of benign tumors of the duodenal papilla with and without intraductal growth using endomucosal rection (EMR) may be performed in some cases [56].

Surgical resection is the treatment of choice for adenocarcinoma of the small intestine. Resection of the tumor with adjacent mesentery and lymph nodes with a wide margin (≥ 10 cm) of normal bowel on either side of it is practical for adenocarcinomas of the jejunum. Malignant tumors of the terminal ileum are treated as cecal tumors with terminal ileal resection and right hemicolectomy. Villous adenomas of the duodenum containing invasive carcinoma and carcinomas of the ampulla of Vater usually require pancreatoduodenectomy (Whipple procedure) with curative intent. Disease-specific survival for primary small bowel adenocarcinomas confined to the small intestine (local disease) was 47%, for regional disease it was 33%, and in distant disease it was 3.9% [2].

The role of postoperative chemotherapy, either in the adjuvant setting or for unresectable lesions, has not been defined in patients with adenocarcinoma of the small intestine. Small series have claimed some benefit for 5-fluorouracil (5-FU) [57], and combination chemotherapy with 5-FU and other agents such as platinum compounds and irinotecan has been advocated for advanced disease [58]. Objective evidence of an impact on survival is lacking. Palliative radiation may have some role in controlling chronic blood loss associated with duodenal tumors, but it is difficult in more distal small bowel tumors because of a mobile mesentery and difficulty in localizing the target field. Chemoprevention with aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) and selective cyclooxygenase-2 (COX-2) inhibitors may be useful in the care of patients with FAP. Whereas several short-term studies have demonstrated the ability of these agents to reduce the size and number of colonic polyps in FAP, data concerning small intestinal tumors are scant [59].

Carcinoid tumors

Epidemiology

Carcinoid tumors, or argentaffinomas, belong to a family of rare neuroendocrine neoplasms known also as amine

precursor uptake and decarboxylation tumors. This entire family of neoplasms has in common the ability to secrete amines and polypeptides, which produce the characteristic clinical syndromes with which they sometimes present. Seventy-four percent of carcinoid tumors occur in the gastrointestinal tract [60]. Most appear in the appendix, followed in frequency by the small bowel and rectum. Most of the clinically significant carcinoid tumors are located in the small bowel, i.e., small bowel carcinoids. Most (87%) small bowel tumors are in the ileum, especially within 60 cm of the ileocecal valve. The incidence rate of small bowel carcinoids is estimated to be 1.2–6.5 cases per million persons [5,16,17,60–64]. Autopsy studies cite a tenfold higher rate of carcinoids that were not evident clinically [65]. The median age at diagnosis is 60 years, but carcinoids have been detected in a wide range of ages (22–84 years). In the United States, the incidence of small bowel carcinoids is somewhat higher in men and in African Americans [60].

No specific risk factors for carcinoids have been proven. Whereas the role of alcohol is controversial, cigarette smoking has been associated with an increased risk of developing small bowel carcinoids [21]. The incidence rates of carcinoids in first-degree relatives of patients with carcinoid tumors was higher than the expected population incidence rates [66]. The calculated cumulative probability that a first-degree relative will develop a carcinoid tumor by age 80 years was 1.5%. Persons with carcinoid tumors, particularly tumors of the small bowel, may have an increased incidence of coexisting noncarcinoid malignant diseases [60,65,67], although a lack of association has also been reported [64,66]. The noncarcinoid neoplasms are mostly adenocarcinomas of the gastrointestinal tract (50%), followed in frequency by lung, cervix, and prostate carcinomas [65].

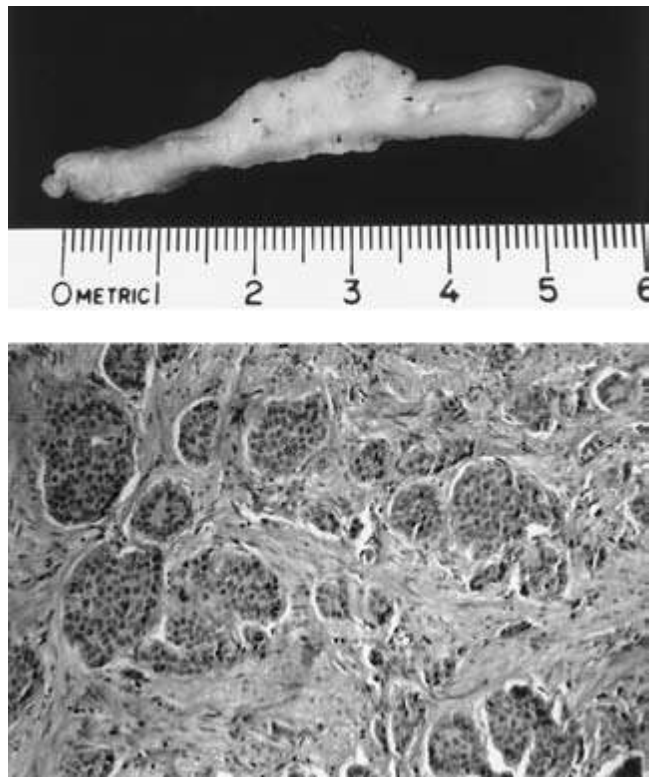

Figure 54.3 Carcinoid tumors of the small intestine. **(a)** A gross specimen of a nodular small intestinal carcinoid is demarcated by arrowheads. Carcinoid tumors develop deep in the mucosa and grow slowly, extending into the underlying submucosa and the overlying mucosa. **(b)** Histological section shows a small intestinal carcinoid tumor characterized by closely packed, round, regular, and monomorphous cell masses, buds, and islands. Lumena and rosette-like structures are also present. A desmoplastic reaction is responsible for many of the clinical findings of small intestinal carcinoid tumors.

Pathology, natural history, and staging

Carcinoid tumors are malignant, despite the indolent course associated with some tumors. Small bowel carcinoids, in particular, are associated with locoregional spread or metastases at the time of diagnosis. The tumors are usually intramucosal, and they rarely ulcerate to the lumen of the bowel. Small bowel carcinoids spread locally. When serosal breach has occurred, an intense local fibroblastic reaction is commonly seen [68,69]. The desmoplastic reaction is responsible for many of the clinical findings in patients with small bowel carcinoid. Another characteristic feature of small bowel carcinoids is multicentricity: at the time of diagnosis, 35% of patients will have more than one tumor in the small intestine [65,70]. Tumor size varies in several series, but most are 2 cm or less in diameter. Only 6% of small bowel carcinoids smaller than 1 cm have been associated with metastases, whereas 80% of patients with tumors larger than 2 cm will present with metastases [67–73]. Microscopically, sheets of uniform cells with hyperchromatic nuclei are arranged in characteristic clumps (Fig. 54.3). Light microscopy of metastases to the liver cannot differentiate a carcinoid from an islet cell tumor.

Carcinoid tumors can be classified in terms of the substances they secrete, and over 40 different secretory products have been identified [74,75]. "Typical" small bowel (midgut) carcinoids secrete serotonin (5-hydroxytryptamine, 5-HT), and they contain the enzyme dopa decarboxylase, which converts 5-hydroxytryptophan (5-HPT) to 5-HT. The 5-HT is further metabolized and is excreted in the urine as the metabolite 5-hydroxyindoleacetic acid (5-HIAA). "Atypical" carcinoids (mostly foregut and hindgut) lack dopa decarboxylase and do not secrete 5-HT [76]. 5-Hydroxytryptophan is released into the blood and can be measured in platelets and urine. Some 5-HPT is decarboxylated in the kidney before excretion, and 5-HT can thus be detected in the urine, but not 5-HIAA [77].

Carcinoid tumors do not have a specific staging system. Most authors describe small bowel carcinoids in terms of size, degree of bowel wall invasion, presence or absence of

lymph node involvement, and presence or absence of distant metastases.

The natural history of small bowel carcinoids is more favorable than that of adenocarcinomas of comparable stage, with overall 5-year survival rates of 60% [78]. However, the 25-year survival of patients with regional spread is reported to be less than 20% [65]. Patients with liver metastases and the carcinoid syndrome have a prognosis similar to that of patients with metastases who do not have the syndrome, but survival is lower for patients with carcinoid heart disease who develop valvular dysfunction [65,77].

Clinical picture

Patients with small bowel carcinoids can present with nonspecific gastrointestinal symptoms, small bowel obstruction, intestinal ischemia, intussusception, gastrointestinal hemorrhage, hepatomegaly, or symptoms of the carcinoid syndrome [79]. Many of the signs and symptoms of small bowel carcinoids result from the intense desmoplastic reaction of the mesentery in proximity to the tumor, leading to partial small bowel obstructions, weight loss, and intermittent crampy abdominal pain [80]. Approximately 50% of patients with metastatic carcinoid initially present with intestinal obstruction requiring surgery [81]. Nodal involvement causes compression of the main mesenteric arteries, leading to small bowel infarction [82]. Regional vascular thickening of medium-sized arteries has been described with carcinoid, and this may act synergistically in the development of bowel ischemia [83,84]. Gastrointestinal hemorrhage and intussusception are uncommon presentations of small bowel carcinoids [85]. Asymptomatic hepatomegaly from metastases is more common with carcinoids and islet cell tumors than with neoplasms of epithelial origin, so transaminases may not be abnormally elevated despite hepatomegaly and a large tumor burden [86].

The most common clinical situation is a prolonged history of nonspecific abdominal pain that did not much alter the patient's lifestyle. The median time from onset of symptoms to diagnosis is reported to be 2 years, and it may be as long as 20 years [65,87]. Investigation is not always sought by the patient, or has a low yield, thus prolonging the interval to diagnosis and treatment.

Patients with liver metastases from carcinoids may exhibit symptoms and signs of the *carcinoid syndrome*, caused by a variety of mediators. Overall, 10%–18% of patients with small bowel carcinoid tumors will present initially with the carcinoid syndrome [88–90]. Flushing of the face and neck occurs in most patients, and it may be episodic or permanent. Flushing is most commonly transient and simulates a mild sunburn involving the face, neck, and upper trunk (the *midgut flush* associated with ileal carcinoids). The so-called *foregut flush* is more intense, frequently associated with conjunctival injection and edema, and has a greater tendency to involve the body more diffusely [65]. Diarrhea is seen in 75% of patients and manifests as intermittent episodes of explosive, watery diarrhea resulting from intestinal hypermotility. Steatorrhea is rare. Abdominal cramping may accompany the diarrhea episodes about 50% of the time. Dyspnea can result from advanced carcinoid heart disease or, less frequently, from pulmonary fibrosis, bronchoconstriction, and asthma [91]. Two-thirds of patients with carcinoid syndrome will present with a large liver or an abdominal mass; 40% will have heart valve abnormalities that can be auscultated at presentation. Other less common signs include cyanosis (25%), peripheral edema, arthritis, and pellagra (2%–7%) [88,90].

Diagnosis

Carcinoid tumors of the small intestine frequently do not manifest clinically until regional spread has occurred or metastatic disease is present. Small, localized tumors are most often diagnosed incidentally during endoscopic or radiological examinations performed for unrelated reasons, or at the time of surgery for other abdominal disorders.

Biochemical markers

Urinary 5-HIAA is the most common test used to screen for carcinoid tumors. Most small bowel carcinoids secrete 5-HT, and urinary 5-HIAA is consequently high [92]. Unfortunately, it is not highly specific or sensitive for localized tumors because other neuroendocrine tumors can secrete 5-HT, and small carcinoids may secrete minute amounts of 5-HT. In contrast to localized tumors, urinary 5-HIAA is highly sensitive and specific for the carcinoid syndrome because of the large tumor burden necessary to produce the features of the syndrome [93]. Elevated levels of more than 30 mg of 5-HIAA in 24 h with provocative testing are diagnostic of the syndrome. False-positive 5-HIAA measurements can occur in diseases such as celiac disease, Whipple disease, and tropical sprue, and when 5-HT-rich foods such as walnuts, bananas, and avocado are ingested [94], but these levels are lower than those associated with carcinoid tumors. False-negative 5-HIAA determinations have been reported with the use of aspirin, levodopa, and phenothiazines. Overproduction of 5-HT can also be assessed by measuring platelet and urinary 5-HT levels, which are not affected by food or medications [26]. Urinary 5-HIAA, platelet 5-HT, and urinary 5-HT levels are elevated in all patients with small bowel carcinoids [76].

Chromogranin A is another useful biochemical marker of carcinoid tumors found in the serum. Chromogranin A is produced by most neuroendocrine tumors, and it has a high sensitivity for all types of neuroendocrine tumors. The sensitivity of this substance for carcinoid tumors approaches 80% [95]. It can be used to monitor treatment response and recurrence or for diagnostic purposes in patients who do not have elevated 5-HIAA urine measurements. Other biochemical markers such as bradykinin, substance P, neurotensin,

neuropeptide PP, neuropeptide K, and human chorionic gonadotropin (HCG), have been described; however, none is as specific or predictive as chromogranin A or 5-HIAA [96].

Radiological imaging

Conventional barium studies of the small intestine may identify the primary lesion as a smooth, semilunar filling defect in the lumen or, more often, as wall thickening, lumen angulation, and nonspecific mass effect. Enteroclysis is generally more successful than conventional small bowel barium studies. [55,97]. Computed tomography and magnetic resonance imaging (MRI) can provide initial localization of carcinoid tumors or their metastasis; however, their detection rates and sensitivities are lower than hormone-based imaging with indium and octreotide. Radiographic findings include mass lesions as well as calcification and fibrosis. Radiating strands of fibrosis and spiculation are characteristic. Mesenteric lymph node metastases are seen on CT in 91% [98,99]; CT scans are also useful to detect hepatic metastases but are somewhat less sensitive than MRI examinations [100]. Positron emission tomography (PET) may be useful in assessing the response of metastatic carcinoid to treatment, but it has not been shown to be greatly superior to CT or MRI in detecting tumors [99]. Scintigraphy has long been used for detecting neuroendocrine tumors. Radioiodine – ^{131}I- or ^{123}I-labeled metaiodobenzylguanidine (I-MIBG) – has a sensitivity of 55%–70% and a specificity of 95% [101,102]. Somatostatin receptors are expressed by 87% of carcinoid tumors and are therefore ideal for detection using radiolabeled somatostatin analogs. Indium-labeled (^{111}In) pentetreotide has a sensitivity of 80%–90% for detection of primary carcinoid and metastatic lesions [103–105]. [^{111}In]pentetreotide is more sensitive than [^{123}I]MIBG and conventional CT scanning [106]. Octreotide-labeled scintigraphy is useful for diagnosis, to predict who will respond to octreotide therapy and to locate tumors before surgical debulking [105,106]. Positron emission tomography with octreotide labeled with copper tetraazacyclotetradecane is as sensitive as indium-labeled pentetreotide scintigraphy for detecting metastatic carcinoids [107].

Endoscopy

Small bowel carcinoids have been detected endoscopically in the duodenum, proximal jejunum, and terminal ileum. The tumors generally appear as nodular, submucosal protuberances that are yellowish and shiny. Ulcerated lesions and pedunculated lesions have been reported as well [108]. Endoscopic biopsies of lesions are often unrevealing, because the tumors are frequently subepithelial. Snare polypectomy or endoscopic mucosal resection of the lesion is much more successful for obtaining a histological diagnosis [109]. Duodenal carcinoids as small as 2–3 mm [110] can also be diagnosed by endoscopic ultrasound. Small noninvasive lesions usually arise from the deep mucosa or submucosa, and at endosonography appear as moderately hypoechoic masses in the second or third echo layers [111–114]. Determination of invasion with endoscopic ultrasound can be useful for staging purposes [111], and to gauge the appropriateness of endoscopic resection as a therapeutic measure [113,114,115]. Capsule endoscopy has been shown to have utility in surveying the small intestine for carcinoid tumors and has superseded enteroscopy in this role [116].

Treatment

Localized tumors

Localized small bowel tumors should be resected completely [71,74,117]. Duodenal carcinoids are less likely to metastasize, and they can often be removed endoscopically, preferably after endosonographic verification that there is no deep tumor invasion. Pedunculated carcinoids can be removed by snare polypectomy, but subepithelial sessile growths will require endoscopic mucosal resection after submucosal injection of saline [109,115,118–120]. Duodenal carcinoids that show spread beyond the submucosa and carcinoids of the jejunum or ileum should undergo surgical resection. Surgery is effective for both local tumor manifestations (e.g., obstruction, bleeding) and symptoms caused by secretory agents. The 5-year survival of patients with local disease who undergo wide excision and removal of regional lymph nodes approaches 75% [121].

Tumors with regional spread

Small bowel carcinoids with regional spread should also undergo wide surgical resection [71,75,86,117]. In some case series, the 5-year survival of patients for whom careful excision of all peritoneal and nodal metastases was possible was 65%–71% [122,123], compared with a 5-year survival of 38% for patients in whom regional tumor spread could not be completely excised [123]. If residual tumor is present after surgery, long-acting somatostatin analogues have proven effective in symptom management [124].

Distant metastases

The approach to patients with metastatic small bowel carcinoids is multimodal [125]. The goals of therapy are to suppress the symptoms of carcinoid syndrome, to improve quality of life, and, if possible, to prolong survival.

Patients with symptomatic bowel obstruction can undergo segmental bowel resection or enteroenteric bypass and, if possible, surgical debulking of tumor deposits to decrease symptoms related to tumor burden [65,77]. Targeted scintigraphic therapies may be more successful when the tumor burden is small [126–128]. Wedge resection or lobectomy of liver metastases can reduce symptoms and possibly improve survival [129].

Hepatic artery occlusion (e.g., ligation, embolization) has been shown to decrease symptoms of carcinoid syndrome and produce tumor regression in 65% of patients [130]. Embolization combined with sequential chemotherapy has

been even more successful, with a reduction in tumor size noted in 78% of subjects [131]. The mortality from hepatic artery embolization or chemoembolization is 0%–2%. Common complications include fever, abdominal pain, nausea and vomiting, and transient transaminase elevations. Less commonly, myelosuppression, arterial thrombosis, liver abscess, and cardiac dysrhythmias may occur [132,133]. Cryosurgical debulking and radiofrequency ablation of hepatic metastases have been described, but have not been well studied [134].

Receptor-targeted therapy with [^{131}I]MIBG and [^{111}In]pentetreotide is variably successful for controlling the symptoms of metastatic carcinoid syndrome [75,135–137]. These therapies require patient isolation during treatment but have few adverse effects, produce some disease stabilization, and decrease octreotide requirements [138,139].

Symptom control is best achieved with octreotide, a somatostatin analogue that inhibits 5-HT release. Administered subcutaneously every 6–12 h, octreotide is effective in resolving symptoms of flushing and diarrhea in 70%–80% of patients. It decreases urinary 5-HIAA levels in about 70% of patients, and it may prevent further tumor growth in patients who respond symptomatically to octreotide [140]. The long-acting somatostatin analogue, lanreotide, can be injected once every 2–4 weeks, with comparable efficacy to that of daily administered octreotide [141,142]. Complications of prolonged high-dose octreotide therapy include steatorrhea, gallstone formation, and development of resistance to the medication.

The role of systemic cytotoxic chemotherapy (5-FU, doxorubicin, actinomycin D, streptozocin, dacarbazine) in the management of metastatic carcinoid is debated. Toxicity is significant and response rates have ranged between 10% and 40% [143–150]. At present, chemotherapy is reserved for patients who do not respond to the other treatment modalities described earlier.

A combination of chemotherapy and immunotherapy with interferon has been studied but has not been shown to be beneficial [151,152]. The addition of interferon to octreotide monotherapy may improve symptom control [153], or it may lead to stabilization of tumor progression [153]. Combination interferon therapy and hepatic chemoembolization has been shown to improve the median survival of patients treated with interferon alone [154].

Mesenchymal tumors

Of the mesenchymal small intestinal tumors, the most common variant is the *mesenchymal spindle cell tumor* (Table 54.1). Some mesenchymal tumors represent clear-cut diagnostic entities (e.g., lipoma, ganglioneuroma), whereas most are more difficult to classify into any specific cell lineage. Tumors may share overlapping features of several diagnostic entities, or they may be histologically heterogeneous. Thus, the general term *gastrointestinal stromal cell tumors* (GISTs) was coined to describe the group. Most GISTs have a spindle cell appearance, but electron microscopy and immunostains indicate that most GISTs are not true smooth muscle tumors [155,156]. It has been suggested that up to 94% of "smooth muscle" tumors in the older literature are actually not of muscle origin and would be classified today as GISTs [155,157].

Epidemiology

Approximately 60% of GISTs are found in the stomach, 20%–30% occur in the small bowel, and the remainder are scattered in the esophagus, colon, and mesentery [156]. Benign GISTs are three to four times more common than malignant GISTs [155,158,159]. Malignant GISTs are gut-specific sarcomas and represent 11%–12.7% of all small bowel malignant tumors, with an incidence of 1.2–1.5 cases per million persons [5,16,160]. Malignant GISTs are somewhat more common in male than in female patients, and they can be found in all ages, but the most common age range at the time of diagnosis is 50–59 years [17,161].

Kaposi sarcoma is thought to result from a herpes-type virus [162,163]. Small bowel schwannomas can be seen in patients with neurofibromatosis [164]. Small bowel ganglioneuromas have been reported in association with the multiple endocrine neoplasia type 2 syndrome [165].

Pathology

In the small bowel, GISTs occur most frequently in the jejunum, followed by the ileum, and then the duodenum. Benign GISTs are generally less than 5 cm in diameter, but tumors larger than 20 cm have been reported. Malignant GISTs are greater than 5 cm at time of diagnosis in 80% of patients [161,166,167]. In most cases, GISTs arise from the muscularis propria and generally grow extramurally, but benign GISTs of the duodenum are more likely to grow intralumenally or intramurally [161]. The histological appearance of GISTs differs from that of true leiomyomas, leiomyosarcomas, and schwannomas, with more cellularity and less cytoplasmic eosinophilia. Small bowel GISTs generally have a spindle cell-like appearance, but infrequently they can appear epithelioid [155]. Ultrastructural characteristics can be used to classify GISTs as myoid, neural, or ganglionic phenotypes, but the frequent presence of several different ultrastructural phenotypes suggests a common origin to all subtypes [157].

Ninety-four percent of GISTs express CD117, the product of the *KIT* protooncogene and a transmembrane receptor for the stem cell growth factor [168]; and 70%–80% of GISTs express CD34, the human progenitor cell antigen [169,170]. Less frequently, GISTs stain positive for actin and desmin (implying myogenic differentiation), but seldom are they S100 positive (a protein found in neuron-differentiated cells) [155]. True leiomyomas and leiomyosarcomas are positive

for actin and desmin, but do not express CD117 or CD34; and schwannomas express S100, but not CD117 or CD34. When spindle-cell tumors are excised, immunohistochemical markers should be used to determine whether the neoplasm is a GIST or not [156].

Observations that normal intestinal Cajal cells also express CD117 and CD34 suggest that GISTs are of the same embryonic origin as Cajal cells. This would explain the similar morphology and intramural location of GISTs and true smooth muscle tumors [155]. The *KIT* gene on chromosome 4 is most commonly mutated at exon 11, especially in malignant tumors [171,172]. Some malignant GISTs also display loss of 14q and chromosome 22 on comparative genomic hybridization [173]. These genetic changes are not found on true smooth muscle tumors.

Natural history and prognosis

Small bowel GISTs tend to invade locally, and they frequently present with peritoneal seeding or direct invasion to adjacent organs [161,167]. Lymph node metastases are uncommon, but 31%–41% of patients with small bowel GISTs will present with liver metastases.

Overall, 5-year survival rates are variable, ranging between 7% and 56% [161,167,174–176]. In general, survival chances are most favorable in patients without extralumenal tumor invasion or metastases and for tumors smaller than 2–5 cm.

Many factors have been suggested as prognostic indicators for GISTs (Table 54.5) [167,176–178]. Unfortunately, except for tumor size and the number of mitotic figures, most of these factors are not found consistently. The most useful indicators of survival and the risk of metastases are the size of the tumor at presentation, the mitotic index (the number of mitotic figures per 50 high-power fields), and histological evidence of tumor invasion into the lamina propria [156]. None of the other factors in Table 54.5 has consistently been shown to predict prognosis accurately. Classification of GISTs should not be in terms of "benign" or "malignant," but rather by the risk for malignant behavior.

Table 54.5 Gastrointestinal stromal cell tumors: prognostic factors[a]

	Risk of malignancy	
Factor	**Low risk**	**High risk**
Size	< 2 cm	> 5 cm
Mitosis	0–1 per 30–50/ high-power field	> 5 per 10–50/ high-power field
Cellularity	Low	High
Necrosis	Absent	Present
KIT exon 11 deletion	Absent	Present
Anatomic site	Rectum	Jejunum
Infiltration into lamina propria[b]	Absent	Present
Cystic spaces[b]	Absent	Present
Irregular borders[b]	Absent	Present

a Size and mitosis are the only factors consistently reported.
b Endoscopic ultrasound criteria.

Clinical picture and diagnosis

Most GISTs less than 5 cm in diameter are discovered incidentally at endoscopy, by barium radiography, or in gastrointestinal specimens resected for other reasons. The small tumors are generally asymptomatic. By contrast, at least 80% of patients with larger tumors will have symptoms related to the GIST [161,167,174,175,178]. More than 50% of patients with tumors greater than 5 cm will have either a palpable abdominal mass or gastrointestinal hemorrhage. Bleeding from ulcerated small bowel GISTs is usually acute, and it may be brisk [179]. Thirty to forty percent of patients with small bowel GISTs will present with abdominal pain, nausea and vomiting, or weight loss, and 40% of patients with ileal tumors may present with intussusception [161].

Small bowel barium studies can detect GISTs 53%–72% of the time [180]. Computed tomography has been reported to detect 89%–98% of large GISTs [181]. Angiography may also be useful because of the characteristic "tumor blush" noted in more than 85% of tumors.

Endoscopic diagnosis of small bowel GISTs is difficult because most tumors are submucosal. If ulceration is present, biopsies can identify the tumor as a GIST. On endoscopic ultrasound GISTs appear as hypoechoic masses arising from the fourth echo layer (muscularis propria). Putative endosonographic criteria to differentiate benign from malignant GISTs include tumor size greater than 4 cm, irregular extralumenal margins, and cystic spaces [182–184]. The positive predictive value for malignancy approaches 100% when any two of these findings are present.

Immunohistochemical staining should be performed on resected spindle-cell tumors and biopsies of tumors suspected to be GISTs. Positivity for CD117 confirms that the tumor is a GIST.

Response to targeted therapies (see "Treatment" below) may be monitored with CT or [^{18}F]deoxyglucose positron emission tomography (FDG-PET) [185].

Treatment

Segmental bowel resection, and not simple enucleation, is the treatment of choice for GISTs [157–161]. Aggressive resection of organ segments that have been invaded with tumor and of hepatic metastases appears to confer some improvement in survival [176,178,186–189]. Despite complete resection with negative margins, 44%–80% of patients will suffer local or peritoneal recurrence. Most recurrences will occur within 2 years, but lag times of 10 years have been reported [190,191].

Chemotherapy and radiation therapy have not been beneficial for patients with unresectable metastases or for patients with tumor recurrence [192,193]. Imatinib mesylate is an inhibitor of the KIT, ABL, BCR–ABL, and PDGFR tyrosine kinases. A growing body of evidence indicates that imatinib and several newer tyrosine kinase inhibitors that target KIT and PDGFR are effective in the control of metastatic GISTs [194,195]. The 1-year progression-free survival has increased from 10% with chemotherapy to 70% with imatinib. Specific mutations in the *KIT* gene may affect prognosis and response to targeted therapy [196,197]. Although the accepted treatment of small bowel GISTs larger than 4–5 cm is surgical resection, it is unclear what to do with smaller tumors. This gap in our knowledge is important because as the use of endosonography becomes more prevalent, more small GISTs will likely be diagnosed.

Lymphomas

Primary small bowel lymphoma (PSBL) is characterized by the following:

- absence of palpable peripheral lymphadenopathy
- normal peripheral leukocyte count and differential
- no mediastinal lymphadenopathy on a chest radiograph
- involvement of only the organs of the gastrointestinal tract and proximal regional lymph nodes
- no involvement of the liver or spleen, unless by direct extension from the primary gastrointestinal tumor [198–200].

Extranodal lymphomas of the intestine can be classified according to the cell lineage (Table 54.1) or according to their clinical characteristics. The latter method categorizes small bowel lymphomas into either PSBLs, which tend to be focal, or immunoproliferative small intestinal disease (IPSID), which is diffuse.

Epidemiology

Small bowel lymphomas represent 1%–10% of all extranodal lymphomas [198] and 7%–25% of all small bowel tumors [5,16]. Incidence rates of small bowel lymphomas range from 0.9 to 3.6 cases per million [5,16,63,198,201,202]. In the United States, small bowel lymphomas are more common in whites than African-Americans. Population registries from the Middle East suggest a higher incidence than in Europe or the United States [198] due to the predominance of IPSID. Studies from the United Kingdom [201], Germany [63], Denmark [202], Ireland [203], and the United States [17] show an increase in incidence of 30%–50% since the early 1970s. Primary small bowel lymphoma is typically diagnosed in the sixth aand seventh decades of life and is more common in men than in women, at a ratio of 1.5:1; IPSID, however, is generally diagnosed in the second or third decades of life and affects men and women equally [204].

Risk factors

Several diseases and immunodeficiency states are associated with an increased risk of developing PSBL. Patients with long-standing celiac disease have a 7% incidence of enteropathy-associated T-cell lymphoma (EATL) [205,206]. Nodular lymphoid hyperplasia is usually an incidental finding in the terminal ileum. Diffuse nodular lymphoid hyperplasia is seen in primary immunodeficiencies, and it is associated with intestinal lymphomas [207]. Rarely, diffuse nodular hyperplasia and intestinal lymphoma can occur in the absence of immunodeficiency [208]. Some authors report an increased incidence in patients with inflammatory bowel disease using immunosuppressive medications [209]; some report an increased risk only in male patients with Crohn's disease [210]; and others report no increased risk at all [211,212]. Small bowel lymphoma has been associated with congenital and acquired immunodeficiency states [213]. Patients with AIDS have a 30% risk of developing lymphomas, of which 10%–25% will be PSBLs [214]. Immunosuppression after solid organ transplantation has been associated with an increased risk of lymphoma. Most extranodal lymphomas are PSBLs. Risk seems to be correlated with the nature and dose of immunosuppression. For example, 30% of small bowel, heart, or lung recipients will develop lymphoma, whereas only 5% of kidney recipients will acquire the disease [215].

Immunoproliferative small intestinal disease is considered an infectious-pathogen-related lymphoma. Although the causative agent remains a subject of debate, molecular and immunohistochemical studies have suggested an association with *Campylobacter jejuni* [216]. The disease is most prevalent in the Middle East, Africa, Southeast Asia, and South America, regions in which poor hygiene and malnutrition are endemic. Malnutrition can impair the normally vigorous defenses of the bowel in a variety of ways [217]. In response to the abnormal antigenic presentation, specific clonal lines of IgA-secreting B cells proliferate in the lamina propria [158]. The α-heavy chains can be detected in the blood of up to 69% of patients with early-stage IPSID [218].

Pathology

The ileum is the site most frequently affected by PSBLs, followed by the jejunum and then the duodenum [5,16,63]. They are generally localized to one segment of the bowel, except in the case of *mantle cell lymphoma* (*multiple lymphoid polyposis*; MLP). The tumors have many different appearances. They may be large exophytic masses (Fig. 54.4a), polyp-like (Fig. 54.4b), ulcer-like, or nodular [219]. Tumor growth and extension are frequently intramural for a prolonged period. Involvement of regional lymph nodes is present in approximately 50% of patients with most types of PSBL, except low-grade *mucosa-associated lymphoid tissue (MALT) lymphomas,* in which lymph nodes are involved in only 30% of patients [219–222]. Immunoproliferative small

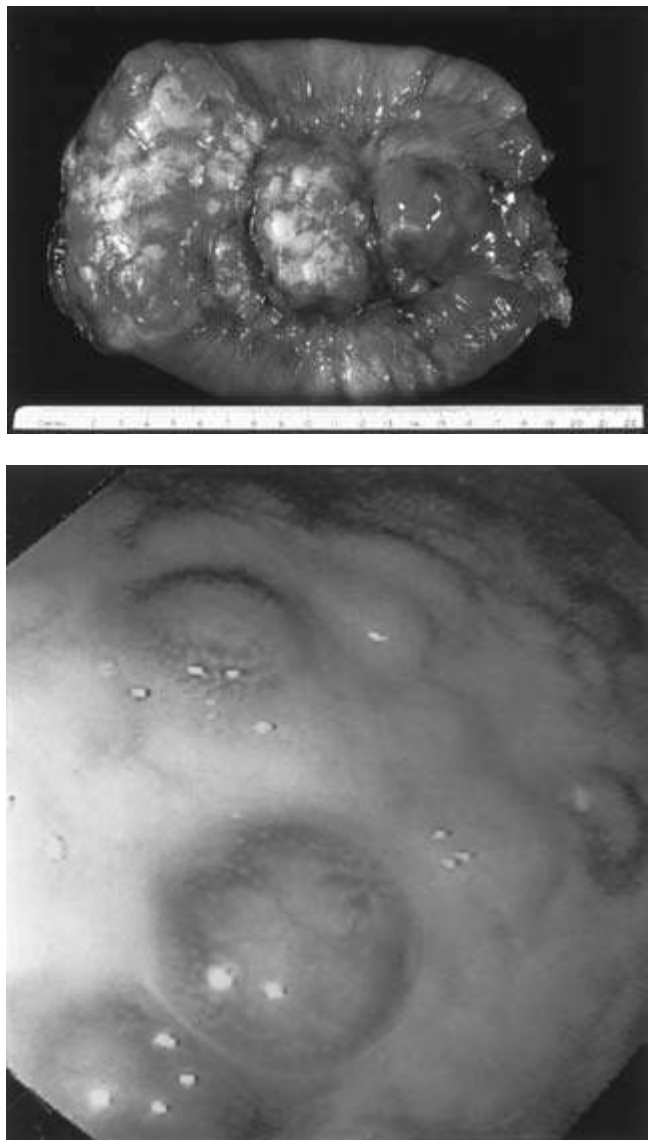

Figure 54.4 Primary small intestinal lymphomas. **(a)** A gross specimen of a primary lymphoma extensively involving the small intestine. **(b)** Mantle cell lymphomatous polyposis of the intestine seen endoscopically. The mucosa is studded with elevated polypoid nodules.

intestinal disease tends to be a diffuse jejunal disease. Gross findings can range from thickened folds to discrete masses [223,224] affecting a significant portion of the intestine in a contiguous fashion [225]. This feature probably explains the different clinical presentation of IPSID from PSBL, which usually has normal mural architecture in bowel segments not affected.

With the exception of EATL, most small bowel lymphomas are B-cell derived. The different histological patterns of small bowel lymphomas are summarized in Table 54.6. The diffuse large-cell type – the most common intestinal lymphoma – and the small noncleaved cell type are similar histologically to their nongut counterparts [205]. Mucosa-associated lymphoid tissue lymphomas occur in nongut sites, but they are most common in the gastrointestinal tract. The characteristic cells are centrocyte-like cells that resemble the small cleaved centrocyte cells of nodal follicular cell lymphomas [226]. Mantle cell lymphomas (MLP) show monotonous small cells with irregular nuclei arranged in a pattern similar to the mantle zone of lymph node follicles. The mucosa and submucosa are most often involved. Despite the lack of deep invasion, MLP is an aggressive lymphoma that presents frequently with distant lymph node and bone marrow involvement [222,227]. Enteropathy-associated T-cell lymphoma is a high-grade lymphoma composed of large cells resembling histiocytes. The adjacent mucosa displays the characteristic findings of celiac disease: villous atrophy, crypt hyperplasia, and abundant intraepithelial lymphocytes. Epithelial invasion is common, and the subsequent mucosal ulceration displays an intense inflammatory infiltrate [228]. The distinctive histological appearance of IPSID is characterized by a dense mucosal and submucosal cellular infiltrate throughout the length of the affected intestine. In the early phase, plasma cells and small lymphoid cells predominate. In the late phase, dysplastic changes in the small cells are noted, with an increase in the proportion of large cells evolving into a diffuse large cell lymphoma [223,224].

Staging and prognosis

Traditionally, a modified version of the Ann Arbor system was used for staging primary gastrointestinal (GI) lymphomas [229]. This system did not account for tumor histology, bulk, and other prognostic factors, and was replaced by a version of the Blackledge system (Table 54.7) [230].

Of the intestinal lymphomas, MLP, EATL, and IPSID (immunoblastic stage) tend to have the worst prognosis [231–235]. Patients presenting with stage I PSBLs or low-grade MALT PSBLs have median 5-year survivals of 50%–60%, and 44%–76%, respectively, and they have the best chance of cure [236]. The median survival of patients with stage II disease is only 20% [231–235].

In addition to the stage at presentation and the cell type, many criteria have been reported as being adverse prognostic factors for PSBL. These include a tumor larger than 7 cm, poor performance status, age greater than 70 years, the presence of B symptoms (fever, night sweats, and weight loss), mural invasion beyond the muscularis propria, distant lymph node involvement, unresectability of the tumor, elevated serum lactate dehydrogenase, elevated serum β_2-microglobulin, and the presence of *BCL-2* genomic alterations [231–235,237–242].

The clinical course of IPSID is different from that of other intestinal lymphomas and rarely involves extraabdominal sites. Hence, two different staging systems have been proposed for IPSID. One stages IPSID by the histological findings of prelymphomatous and lymphomatous stages [224], and the other stages the disease by the bulk of tumor and extent

Table 54.6 Features of the major gastrointestinal lymphomas

Type	Histology	Immunohistochemistry	Genotype
Diffuse large B-cell lymphoma	Diffuse growth of large lymphoma cells, often with necrosis	B markers (B1), $^{+}$sIG	Ig gene rearranged
Small noncleaved-cell lymphoma (includes Burkitt)	Medium-sized cells with many mitoses, "starry sky" appearance from histiocytes	B markers, $^{+}$sIG, CD10^{+}	Chromosomal translocation involving *MYC*
Low-grade B-cell MALT lymphoma	Centrocyte-like cells with formation of lymphoepithelial lesions	B markers, CD22^{+}, LN-1^{+}, CD5^{-}, CD10^{-}, CD23^{-}	Ig genes rearranged, trisomy 3 common
Multiple lymphoid polyposis (mantle cell lymphoma)	Monotonous small cells with irregular nuclei; epithelial invasion uncommon	B markers, CD5^{+}, CD23^{-}, cyclinD1^{+}, often IgM^{+}, IgD^{+}	t(11:114) translocation with implication of *bcl-1* oncogene
Enteropathy-associated T-cell lymphoma	Large cells with intense surrounding inflammation; adjacent atrophic mucosa	T-cell markers, CD103^{+}, HML-1, CD4^{-}, CD8^{-}	T-cell receptor genes rearranged
IPSID	Early: plasma cells, superficial Late: atypical large lymphoma cells with bowel wall invasion	B markers, KB61^{+}, α-heavy chain paraprotein	

CD, cluster of differentiation; HML-1, ; Ig, immunoglobulin; IPSID, immunoproliferative small intestinal disease; KB61, ; LN-1, ; MALT, mucosa-associated lymphoid tissue; sIG, secretory immunoglobulin.

Table 54.7 Staging system of primary gastrointestinal lymphoma

Stage I
Tumor confined to the gastrointestinal tract
Single primary lesion or multiple noncontiguous lesions

Stage II
Tumor extending in the abdomen from a primary gastrointestinal site
Nodal involvement
II1: local (paragastric or paraintestinal)
II2: distant (mesenteric, paraaortic, paracaval, pelvic, inguinal)

Stage IIIE
Penetration of serosa to involve adjacent organs or tissues

Stage IV
Disseminated extranodal involvement or a gastrointestinal tract lesion with supradiaphragmatic nodal involvement

of distant nodal and organ involvement [225]. Neither system has been validated in large survival cohorts.

Clinical picture and diagnosis

The symptoms of PSBL are usually nonspecific and may continue for 4–18 months before a diagnosis is rendered [231,233]. Abdominal pain, often described as crampy, is reported in 65%–87% of patients with PSBL, and weight loss is seen in approximately 50%. The remaining symptoms are present in fewer than 30% of patients and include gastrointestinal hemorrhage, malaise, night sweats and fatigue, or acute abdomen resulting from bleeding or perforation [225,231,232,234,235,239]. Small bowel obstruction is the presenting symptom in 5%–12% of patients. Diarrhea and malabsorption are common in EATL. In fact, patients with celiac disease who become unresponsive to a gluten-free diet should be investigated aggressively for small bowel lymphoma [228]. The most common physical finding is a palpable abdominal mass, present in 30%–50% of patients.

The symptoms of IPSID differ from those of PSBL. Nearly all patients with IPSID have diarrhea, weight loss, anorexia, and abdominal pain. Emesis and fever occur in 50% of patients. The physical examination in IPSID reveals clubbing of the fingers and ankle edema in 50%–75% of patients. Later in the disease, ascites, hepatomegaly, and a palpable mass may be present [223–225]. Up to 70% of patients will have the α-heavy chain paraprotein in the serum.

Small intestine barium studies, especially enteroclysis, are fairly accurate for detecting small bowel neoplasms [180]; CT is less sensitive for small lesions, but it detects most lesions larger than 5 cm. Small bowel lymphomas are categorized by CT as follows:

- primary, divided into circumferential and cavitary
- diffuse, usually EATL
- mesenteric [181].

Capsule endoscopy has been evaluated in patients with known small bowel lymphomas; however, diagnostic accuracy rates have not been determined [243]. Because of their location, most small bowel lymphomas require laparotomy for tissue diagnosis. Those located within the proximal 60 cm of the jejunum can usually be identified and sampled for biopsy at enteroscopy [108]. The accuracy of endoscopic

biopsy for diagnosing lymphomas is 82% on the first attempt, with an additional 10% on the second attempt [164]. Tissue should be sent both in formalin for standard studies and in saline for flow cytometry analysis. Characteristic findings at endosonography of an irregular hypoechoic mass disrupting the normal echo architecture may suggest the presence of a PSBL despite normal mucosal biopsies [112]. Unlike primary gastric lymphomas (especially MALT lymphoma), the role of endoscopic ultrasound in staging of duodenal lymphomas is not clear. Laparotomy for a diagnosis of lymphoma should be performed if the suspicion for IPSID is high despite normal endoscopic biopsies.

Patients with a confirmed diagnosis of small bowel lymphoma should undergo several studies for staging purposes, including a physical examination, indirect laryngoscopy to exclude involvement of Waldeyer ring, CT scan of the abdomen and chest to assess distant lymph node sites, bone marrow aspiration and biopsy, and lactate dehydrogenase and β_2-microglobulin determinations [215].

Treatment

The mainstay of treatment for PSBL is surgical resection. Complete resection with lymph node sampling is recommended to avoid a further operation [215]. Complete resection is associated with an improved survival compared with retained tumor after the surgical procedure [244,245], and may improve response to chemotherapy and radiotherapy [245–247].

Primary small bowel lymphoma that cannot be completely resected is usually treated by chemotherapy and sometimes with the addition of radiotherapy. The chemotherapeutic regimen usually includes anthracycline, but there is no consensus on the best combination of drugs [248–251]. Aggressive chemotherapy causes perforation of the small bowel in 5%–15% of patients. For some patients with diffuse MLP and EATL, chemotherapy is the only option, but response to chemotherapy is usually poor. The 5-year survival for patients with stage I and II MLP and EATL is approximately 20%–25% [219,233,234,252].

Immunoproliferative small intestinal disease is less amenable to surgical resection than PSBL because of the diffuse nature of the tumor and the low performance status of patients at the time of presentation. Nutritional support with total parenteral nutrition is essential, because malnutrition is severe and likely will not improve unless significant tumor regression is possible. Patients with IPSID in the prelymphomatous stage can be offered a trial of tetracycline or metronidazole for 6–24 months. Complete remission rates of 33%–70% have been reported [204]. Patients who do not respond to antibiotics or patients already in the lymphomatous stage may benefit from anthracycline-based chemotherapy [253]. A few patients with resectable stage I and II disease have a 5-year survival of 40%–47%, whereas most other patients whose tumors are unresectable have a 5-year survival of only 0%–25% [254]. A complete response rate of 62%–69% and a 3.5-year survival rate of 58%–70% have been reported in small groups of patients receiving anthracycline-based combination chemotherapy with or without tetracycline [255–257].

Secondary tumors

Metastatic tumors represent the most common tumors involving the small intestine in many series. Grossly, secondary tumors often present as submucosal nodules or plaques, and they may grow to form intramural masses that cause obstruction, intussusception, or perforation. Often, tumors present as stenotic lesions or infiltrative lesions simulating Crohn's disease. Metastases to the small intestine from melanoma and from carcinomas of the lung, testes, adrenal, ovary, stomach, large intestine, uterus, cervix, liver, and kidney have all been reported. Metastatic melanoma accounts for one-third of small bowel metastases [258]. Lesions are typically multiple and present as polypoid lesions that may cause obstruction or intussusception. Tumors of the pancreas, stomach, colon, or mesentery may also involve the small bowel by contiguous spread.

C SMALL INTESTINE

55 Miscellaneous diseases of the small intestine

Marc S. Levin, C. Prakash Gyawali

Ulcers of the small intestine, 1343
Drug-induced small bowel disease, 1352
Necrotizing enterocolitis, 1356
Protein-losing gastroenteropathy, 1357

The diseases discussed in this chapter should be considered in patients presenting with gastrointestinal hemorrhage, abdominal pain, diarrhea, intestinal obstruction, or perforation that eludes diagnosis by routine gastroduodenal endoscopy and radiographic studies. Topics include ulceration of the small intestine, small intestinal complications of drug therapy, necrotizing enterocolitis (NEC), and protein-losing gastroenteropathy (PLGE). Although most of these entities are infrequently encountered in clinical practice, differentiating them from diseases that are more common can yield important therapeutic benefits.

Advances in diagnostic techniques over the past few years have allowed improved visualization of the small bowel mucosa, leading to more frequent identification of small bowel pathology. Push enteroscopy is a useful adjunct for the diagnosis of small intestine lesions because of improvements in equipment and technique [1–6]. With the advent of wireless capsule endoscopy, visual images can be captured from the entire small bowel, although localization of abnormal findings is not always accurate [7–13]. Wireless capsule endoscopy is superior to push enteroscopy and enteroclysis for the detection of small intestinal ulcers in that it allows evaluation of almost the entire small bowel mucosa [12–16]. When findings on wireless capsule endoscopy need further evaluation, double-balloon enteroscopy is a novel endoscopic procedure that may allow endoscopic inspection or intervention within the small bowel [17–21]. Preliminary results indicate a new diagnosis can be made with double-balloon enteroscopy in as many as two-thirds of patients with undiagnosed small bowel disorders including obscure gastrointestinal (GI) bleeding [21–23]. Intraoperative enteroscopy with laparotomy or laparoscopy also can be a valuable adjunct in difficult cases, or when findings on other tests suggest the need for resection of a diseased small bowel segment [24–26].

Advances in radiological imaging techniques have also provided greater detail in evaluating the small bowel. Enteroclysis, involving instillation of contrast agent into the duodenum through a nasoduodenal tube, has a better sensitivity and specificity for lumenal small bowel abnormalities compared with oral small bowel follow-through imaging [27]. Multidetector row computed tomography (CT) enteroclysis demonstrates an even higher degree of diagnostic accuracy in characterizing lumenal, mucosal, intramural, and extramural abnormalities in small bowel inflammatory diseases [28–30]. Magnetic resonance enteroclysis is another emerging imaging technique, and has been mostly studied in the evaluation of small bowel Crohn's disease. Using this imaging modality, deep ulcers and wall thickening can be easily identified in the small bowel in patients with active Crohn's disease, suggesting that other small bowel mucosal inflammatory or neoplastic lesions can be similarly identified [31–33].

Ulcers of the small intestine

Many causes of small intestine ulcerations distal to the duodenum have been identified (Table 55.1). Most of these produce solitary ulcers with sharp borders and normal surrounding mucosa. With surgical resection or removal of offending agents, these ulcers seldom recur and are associated with a benign clinical course. The mortality from multiple ulcers occurring in an abnormal mucosa, as is occasionally seen with gluten-sensitive enteropathy (GSE) or unclassified sprue, chronic ulcerative (nongranulomatous) jejunoileitis (CUJ), or lymphoma, can be as high as 75% [34]. Attempts to define the underlying cause of small intestine ulcers are therefore crucial for their management.

Table 55.1 Causes of small intestine ulceration

Category	Causes
Infectious	Tuberculosis, typhoid, cytomegalovirus, syphilis, parasites, strongyloidosis hyperinfection, *Campylobacter*, yersiniosis
Toxic	Acute jejunitis (β-toxin-producing *Clostridium perfringens*), arsenic
Inflammatory	Crohn's disease, systemic lupus erythematosus with high serum antiphospholipid levels, diverticulitis
Mucosal	Gluten-sensitive enteropathy (jejunoileitis)
Neoplastic	Malignant histiocytosis, lymphoma (primary), adenocarcinoma, melanoma, Kaposi sarcoma (secondary)
Vascular	Mesenteric insufficiency, giant cell arteritis, vasculitis, vascular abnormality, amyloidosis (ischemic lesion)
Hyperacidic	Zollinger–Ellison syndrome, Meckel diverticulum, stomal ulceration
Metabolic	Uremia
Drug-related	Potassium chloride, nonsteroidal antiinflammatory drugs, antimetabolites
Radiation-induced	Therapeutic, accidental
Idiopathic	Primary ulcer, Behçet syndrome

Primary (idiopathic) small bowel ulcers

Epidemiology and etiology

The diagnosis of primary small bowel ulcers is made after identifiable causes of small bowel ulcers have been eliminated and thus is unlikely to represent a distinct etiological entity. With increasing recognition of secondary causes of small intestine ulceration, fewer patients fall into this diagnostic category. The incidence of idiopathic small bowel ulceration is unknown. A review based on 59 patients (6 were taking enteric potassium preparations) found an incidence of four small bowel ulcers per 100 000 new patients [35]. Men and women were affected equally, and all age groups were affected (Table 55.2) [35–40]. These data suggest that primary small bowel ulceration is an uncommon disorder. However, because asymptomatic and uncomplicated intestinal ulcers are rarely detected, the true incidence of this entity may be higher than estimates.

Clinical features

Symptomatic complications of small bowel ulcers include bleeding, perforation, and obstruction. The incidence of these complications is not known. Intestinal obstruction appears to occur more frequently than with duodenal ulcers. Intermittent crampy abdominal pain resulting from partial small bowel obstruction is the most frequent presenting complaint (63%–100% of patients; see Table 55.2). Symptoms related to intermittent partial small bowel obstruction have been reported for periods ranging from 3 days to 20 years preceding

Table 55.2 Profile and presenting symptoms of primary small bowel ulcers

Study and year	Number of patients	Gender (male to female) ratio	Age	Small bowel obstruction (%)	Bleeding (%)	Acute abdomen (%)	Duration of symptoms
Davies and Brightmore, 1970 [36]	8[a]	5:3	16–62 years	63	38	25	No data

b Included six subjects taking potassium chloride.
c Included one subject taking nonsteroidal antiinflammatory drugs.

presentation [35]. Patients with small intestine obstruction or perforation also can present with an acute abdomen. Although ulcers are more commonly seen in the ileum, perforated ulcers are more common in the jejunum (78% vs 11%) [35]. Because ileal ulcers, which are less likely to perforate, are more prevalent, the overall incidence of perforation is only 22%. Gastrointestinal bleeding is also common, especially in younger patients, who present with intestinal hemorrhage or with occult blood loss. In a series of nine patients with idiopathic small bowel ulcers undergoing surgical resection for gastrointestinal bleeding, multicentric stenoses were seen, with multiple, sharply demarcated ulcers without much inflammatory infiltrate [41]. In addition, patients presenting with gastrointestinal bleeding often have symptoms of intermittent intestinal obstruction. Significant weight loss leading to emaciation may also be seen [41]. The diagnosis of small intestine ulceration should be considered if intestinal bleeding and evidence of small intestine obstruction coexist.

Pathology

Most primary small intestine ulcers (75%) are located in the middle to distal ileum [34]. In one report, a solitary ulcer was found in 70%, two or three ulcers in 20%, and more than three in 10% of patients [35]. Ulcers typically have sharply demarcated borders and vary in diameter from 0.3 cm to 5 cm [35,41]. The pathological features are nonspecific and are identical to those of peptic ulcerations [42]. A marked eosinophilic or lymphoplasmacytoid infiltrate is sometimes present [43,44], but a nonspecific pattern of inflammatory cells may be also seen [41]. The surrounding mucosa is usually normal. Granulomas, sinus tracts, and pathological vascular changes are not seen. Granulation tissue and fibrosis that extend deep into the bowel wall may produce intestinal stenosis. Normal surrounding mucosa and absence of granulomas are features that help to distinguish idiopathic ulcers from those seen in Crohn's disease or CUJ.

Diagnosis

Both evidence of intestinal ulceration and exclusion of known etiological agents are required to support a diagnosis of primary small bowel ulcers. A careful history is necessary to identify exposure to potentially ulcerogenic substances such as nonsteroidal antiinflammatory drugs (NSAIDs) and enteric-coated potassium preparations. Prior abdominal surgery and other risk factors that predispose to intestinal ischemia should be identified. Assessment of immune status also may be useful. It is important to exclude cytomegalovirus infection in immunocompromised patients because of the propensity for cytomegalovirus ulcers to bleed or perforate. Other infectious causes, including *Salmonella typhi*, need to be excluded [45,46].

There are no pathognomonic biochemical abnormalities, and the only laboratory tests that are useful for diagnostic purposes are those that help to establish an alternative diagnosis. Small intestine ulcers can be detected radiographically, endoscopically, or at laparotomy.

Although small intestine ulcers cannot be detected by plain abdominal radiographs, small bowel dilation suggestive of obstruction and pneumoperitoneum indicative of perforation may be detected. Conventional contrast radiography of the small intestine rarely identifies primary ulcers of the small intestine [35]. Enteroclysis is a superior technique for demonstrating small intestine mucosal lesions (see Chapter 128), and this can be performed using CT or magnetic resonance (MR) imaging with improved sensitivity. Ileal ulcers can, on rare occasions, be detected if contrast material is refluxed into the terminal ileum; however, the yield from barium enemas does not justify their use for this purpose. Wireless capsule endoscopy complements contrast radiography in the evaluation of mucosal lesions and ulceration in the small bowel. The small risk of capsule obstruction at the site of a stricture makes the use of contrast studies a prerequisite in patients with obstructive symptoms [8,47]. Other radiographic techniques, such as technetium 99m (^{99m}Tc)-labeled red cell scanning and mesenteric angiography used for the evaluation of gastrointestinal bleeding, or ^{99m}Tc pertechnetate for the diagnosis of a Meckel diverticulum, may lead indirectly to the detection of small intestine ulcerations.

Despite the refinement of enteroclysis and enteroscopy, many symptomatic idiopathic small intestine ulcers are not detected without surgical intervention. In the patient with persistent gastrointestinal blood loss and iron deficiency anemia or abdominal pain with evidence of small bowel obstruction, advanced imaging or endoscopic techniques should be given serious consideration prior to proceeding to surgical exploration with or without intraoperative enteroscopy (see Chapter 119) [48,49].

Therapy

The therapy for primary small intestine ulcers is dictated by the severity of complications. Emergency surgical intervention is required if an acute abdomen or pneumoperitoneum indicative of intestinal perforation is evident. Life-threatening intestinal bleeding is an indication for diagnostic and therapeutic mesenteric angiography or surgical exploration (see Chapter 135). The best therapy for ulcers that present with less serious complications is also surgical resection. Detection of small bowel ulcers is usually readily accomplished at laparotomy, which can be facilitated by advanced imaging and endoscopic studies preoperatively. Intraoperative enteroscopy may be a useful adjunct. Most ulcers can be managed by surgical resection with end-to-end anastomosis, providing adequate material for pathological analysis with a low incidence of complications or ulcer recurrences. Simple oversewing of primary small bowel ulcers is not recommended. With such an approach, the amount of material available for pathological analysis is limited, and the risk of ulcer recurrence is high. Medical management with antiinflammatory

or immunosuppressive agents is not effective therapy for intestinal ulcers or strictures. Furthermore, unsuspected perforation is often found at surgery [35].

Drug-induced small bowel ulcers

The entrapment of a pill or capsule before dissolution or the release of large concentrations of a drug in a segment of intestine can result in localized ulceration because of physical pressure or specific cytotoxic effects. The most common cause of drug-induced small intestine ulcers are NSAIDs. In the 1960s, enteric-coated potassium chloride (KCl) was introduced and was soon recognized to be an intestinal ulcerogen. Ferrous salts, digoxin, corticosteroids, zirconium, and clofazimine have all been implicated as ulcerogens as well [50].

Nonsteroidal antiinflammatory drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are a heterogeneous group of organic acids that inhibit prostaglandin synthesis and have analgesic, antiinflammatory, and antipyretic properties [51]. They have been used for decades in the treatment of inflammatory arthropathies, and lately also for many nonrheumatological problems [51]. Many generic NSAIDs are available without prescription. As a result, NSAIDs are among the most commonly used drugs worldwide. Numerous publications have addressed the magnitude and cost of NSAID-associated gastrointestinal complications, which have been described as an emerging epidemic [52–62].

Because of the increased use of NSAIDs, the introduction of more potent NSAIDs, and improvements in small intestine diagnostic methods, small bowel enteropathy is a more frequently diagnosed complication of NSAID use. Multiple ulcerations, mucosal diaphragms, ileal strictures, and perforations have all been associated with NSAID use [56,63–67]. Small bowel ulcers related to NSAID use can occur even in the absence of similar lesions elsewhere in the gut [68]. An ulcerating ileitis resembling Crohn's ileitis has also been described [69]. Cyclooxygenase-2 (COX-2)-selective inhibitors reduce the incidence of gastroduodenal ulcers. A prospective randomized comparison by wireless capsule endoscopy of healthy adults treated for 2 weeks with celecoxib, naproxen with omeprazole, or placebo, suggests that the protection extends to the small intestine [70]. In this study the percentage of patients with mucosal breaks and the number of breaks per patient were significantly reduced in the celecoxib group compared with the naproxen with omeprazole group. However, both of these parameters were significantly increased compared with the placebo group.

The epidemiology of NSAID-induced enteropathy is not well characterized. Up to 70% of patients who take NSAIDs have evidence of increased intestinal permeability or inflammation [56,71–75], but most are asymptomatic. In a small study of 41 patients, wireless capsule endoscopy detected visual evidence of mucosal injury to the small bowel in as many as 71% of NSAID users, compared with only 10% of controls [76]. An autopsy study showed the presence of nonspecific small intestine ulcers in 8.4% of 249 patients who had NSAIDs prescribed during the 6 months before death, compared with an incidence of 0.6% in 464 patients who had not used NSAIDs [77]. Three of the long-term users of NSAIDs were found to have died of perforated nonspecific small intestine ulcers. Small intestine erosions or ulcerations were detected by small bowel enteroscopy in 7 of 15 iron-deficient patients receiving long-term NSAID therapy for rheumatoid arthritis [78]. All the patients had negative results of upper and lower endoscopy. These studies indicate a high prevalence of unsuspected gastrointestinal lesions in patients taking NSAIDs. A metaanalysis of studies examining the association between NSAIDs and serious adverse gastrointestinal events indicated that NSAID users are at three times greater risk than nonusers [77,79]. Independent risk factors seem to be age over 60 years, previous NSAID complications, and concomitant steroid use. This study did not analyze small bowel effects independently, so it is not certain whether this risk profile is applicable to NSAID-induced small intestine enteropathy.

Pathophysiology

Increased intestinal permeability, which enhances susceptibility to lumenal macromolecules and toxins, has been implicated in the pathogenesis of NSAID-induced enteropathy [80]. This defect in permeability is evident within hours after NSAID administration [56,81], and in rats it may be ameliorated by pretreatment or simultaneous treatment with glucocorticoids, sulfasalazine, or tetracycline [82]. The mechanisms by which NSAIDs injure the small intestine mucosa are unknown but are thought to include roles for enteric bacteria, the enterohepatic circulation, neutrophil infiltration, and suppression of prostaglandin synthesis [83,84]. Because COX-1-mediated synthesis of prostaglandins appears to be less important as a cytoprotective mechanism in the small intestine, NSAID-mediated COX inhibition is not thought to be the major pathogenic mechanism in NSAID-induced enteropathy [85,86]. Furthermore, COX-1 knockout mice had no apparent intestinal disorders [87]. Although nitric oxide derivatives of NSAIDs are equally potent as their parent compounds as suppressors of prostaglandin synthesis, the magnitude of small intestinal injury is markedly attenuated with these agents [88–91].

In rats, diclofenac, but not nitrofenac (a nitric oxide derivative that does not undergo extensive enterohepatic circulation), caused increases in epithelial permeability, gram-negative bacterial colonization, and intestinal ulceration [92]. In these rats, the increased bacterial load, which occurred after the changes in intestinal permeability, may have exacerbated the NSAID injury [83]. These studies suggest that NSAIDs primarily alter intestinal permeability through local rather than systemic effects, and suggest a pathogenic role for enteric bacteria. Additional studies indicate that NSAID-induced

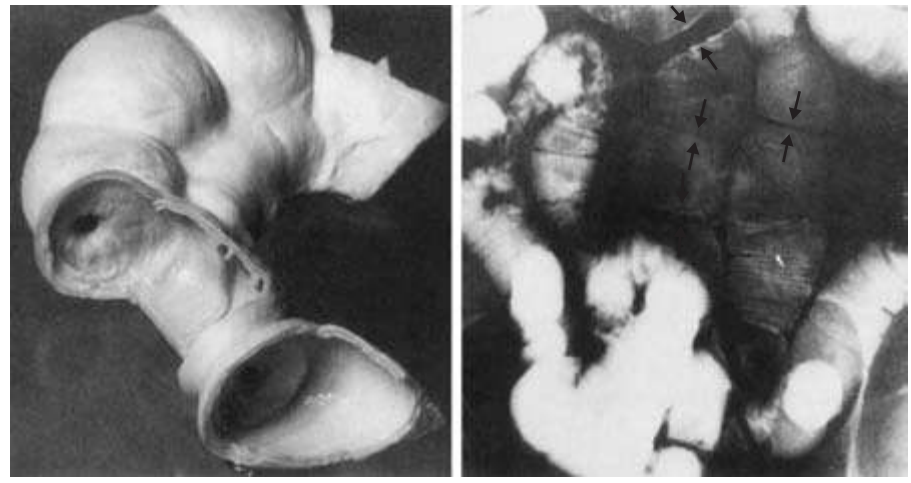
microvascular leakage also contributes to NSAID-induced enteropathy [93]. In rats, NSAID-induced plasma leakage requires induction of calcium-independent nitric oxide synthase and occurs only in the presence of gut bacteria [94]. The relative importance of local and systemic effects in the pathogenesis of NSAID-induced enteropathy was also addressed in human volunteers who received either indomethacin (indometacin) or the prodrug nabumetone. Because only indomethacin increased intestinal permeability, local effects of NSAIDs appeared to be more important [95]. Another prodrug, sulindac, was compared with indomethacin, with similar results [96]. To date, clinical trials comparing COX-2-selective inhibitors with nonselective COX inhibitors have not had the power to address the comparative magnitudes of small intestinal enteropathy. A proposed COX-independent direct mechanism for NSAID damage is inhibition of glycolysis and the tricarboxylic acid cycle, leading to reduced cellular adenosine triphosphate (ATP) production and uncoupling of oxidative phosphorylation [85,97,98]. Coadministration of glucose and citrate with indomethacin to humans was shown to prevent the increased permeability seen with indomethacin alone [97], a finding compatible with this hypothesized mechanism.

Intestinal injury due to NSAIDs primarily affects the distal small intestine. Intestinal ulcers induced by NSAIDs are pathologically identical to primary ulcers and to other drug-induced ulcers. Strictures are seen in up to 5% of patients receiving long-term NSAID therapy for arthritis [56]. In addition to strictures that are indistinguishable from those seen in Crohn's disease and other disorders, apparently unique, diaphragm-like strictures have been described (Fig. 55.1) [63,65,99–101]. These strictures encroach on and narrow the lumen to an opening as small as 1 mm in diameter [99]. They usually occur as multiple strictures separated by only a few centimeters of normal bowel [99]. Submucosal fibrosis replacing or merging with the muscularis mucosae is characteristic [63,99]. Mild inflammation of the overlying mucosa is invariably present, with or without shallow ulceration [63]. The adjacent mucosa is usually completely normal. Despite the strong association with NSAID use, a single case report without apparent NSAID use suggests that diaphragm disease may be a nonspecific response to intestinal injury [102]. Patients with this "diaphragm disease" present with weight loss, hypoalbuminemia, anemia, and intermittent vague abdominal pain [99]. The diaphragm-like strictures are difficult to detect radiologically and can be missed at laparotomy unless an enterotomy is performed [99–101]. Small bowel enteroscopy, which is useful for detecting intestinal ulcers [78], may also be useful for detecting NSAID-related intestinal abnormalities [103].

Morphologically, the presentation of NSAID-related enteropathy is often similar to that of Crohn's disease, with transmural injury that can cause stricture formation [85,98]. Some patients receiving long-term NSAID therapy do present with clinical features of Crohn's disease, although most patients with NSAID-associated small intestine enteropathy are asymptomatic [51]. In a prospective study, 10% of patients with colitis not due to Crohn's disease were thought to have NSAID-induced colitis [104]. There is also evidence that NSAIDs may exacerbate Crohn's disease and ulcerative colitis [54,105–111]. These studies emphasize the importance of obtaining an accurate drug history for all patients presenting with an illness resembling Crohn's disease. Reports have also associated NSAIDs with a variety of other intestinal disorders, including collagenous colitis [112], nonceliac flattening of small intestinal mucosa [113–115], celiac sprue, intestinal malignant diseases [115], and perhaps diverticulitis [85]. However, the available data are not sufficient to establish a true cause and effect relationship between NSAID use and any of these conditions [98].

Therapeutic considerations

Wireless capsule endoscopy and double-balloon endoscopy are newer investigative techniques that may have diagnostic



(a) (b)

Figure 55.1 Nonsteroidal antiinflammatory drug-induced small intestine strictures. **(a)** Diaphragm strictures of the small intestine are apparent in resected intestine. **(b)** Enteroclysis study in a patient taking nonsteroidal antiinflammatory drugs. Diaphragm strictures (arrows), which were found at surgery, are difficult to appreciate and resemble exaggerated plicae circulares. From Bjarnason et al. [85], with permission from Elsevier.

utility in assessing the effects of NSAIDs on the small intestine, as an alternative to endoscopy or surgery [13,67,68,76]. Most patients who take NSAIDs appear to have intestinal inflammation as assessed by indium 111 leukocyte scans and fecal excretion [72], and increased intestinal permeability as assessed by chromium 51 (^{51}Cr)-ethylenediaminetetraacetate (EDTA) absorption. These abnormalities usually resolve after the medications are discontinued, but inflammation may persist for up to 16 months [56]. Discontinuation of NSAIDs should be sufficient for treatment of uncomplicated ulcers. Surgical intervention is required for therapy of intestinal perforation or symptomatic strictures.

The optimal regimen for patients for whom there is no good alternative to continued NSAID use has not been established. Based on the observation that nabumetone and sulindac did not increase intestinal permeation to [^{51}Cr]EDTA, switching to these or other prodrugs may be beneficial. Observations in rats indicate that switching to NSAIDs that are less potent inhibitors of COX also may be helpful [116,117]. The hypothesis that COX-2-selective NSAIDs, by preserving the cytoprotective effects of prostaglandins synthesized by COX-1, may be less enteropathic than nonselective NSAIDs has not been directly addressed by the clinical trials completed to date. A double-blind cross-over study demonstrated that unlike indomethacin, COX-2 inhibition with rofecoxib did not increase intestinal permeability in healthy subjects [118]. In another double-blind cross-over study, nimesulide, another COX inhibitor, did not increase intestinal permeability or excretion of calprotectin, a marker of intestinal inflammation [119].

Delivery of NSAIDs encapsulated in liposomes was protective in a rat study [120]. The degree of ulceration in rats was related to the amount of active drug excreted in bile [116,117,121]. Human studies have not established that the incidence of small intestine enteropathy or upper gastrointestinal bleeding can be reduced by measures such as using prodrugs, NSAIDs with decreased biliary excretion of active drug, enteric coatings, or slow-release formulations [67].

Germ-free rats are resistant to indomethacin-induced intestinal lesions [122], and antibiotics can reduce the incidence of indomethacin-induced small intestine ulcers in rats [123]. In humans, metronidazole [98] and sulfasalazine [124] reduce intestinal inflammation, a response not yet proven to correspond to prevention of or recovery from NSAID-induced complications.

In studies using rats, pretreatment or concurrent treatment with glucocorticoids, sulfasalazine, tetracycline, sucralfate [125], pentagastrin [126], naloxone (tested because morphine potentiates the ulcerogenic effect of indomethacin) [127], clonidine [128], or thromboxane synthetase inhibitors [82] reduced indomethacin-induced permeability and inflammatory changes in rats. Drugs that exacerbated the intestinal toxicity of indomethacin in rats include cyclosporine [129] and morphine. Although prostaglandin E analogues such as misoprostol and enprostil prevent NSAID-associated injury of the stomach and duodenum [130–134], their effects in the remaining small intestine are not known. Protection was demonstrated in animal models [135–137]. In humans, high-dose misoprostol prevented NSAID-induced permeability changes in one study [138], but therapeutic doses did not [95].

Potassium chloride

The introduction of enteric-coated potassium chloride (KCl) tablets in the 1960s was associated with an unacceptably high incidence of small intestine ulceration, attributed to high lumenal concentrations of KCl from rapid dissolution of the tablets in the small intestine. Slow-release formulations using a wax-polymer matrix (dissolution in approximately 4 h) or microencapsulation (dissolution in 8–10 h) were developed to eliminate this adverse effect; gastrointestinal ulceration was reduced in incidence but not eliminated. Two cases of small intestinal ulceration occurred from 1970 through 1983 (3 in 100 000 patient-years of slow-release wax-matrix tablet use), compared with 56 cases from 1960 through 1965 (65 in 100 000 patient-years of enteric preparations) [139]. Regardless of the preparation used, the risk of ulceration is increased if intestinal transit is delayed by small bowel disease, concurrent medications, general debility, or advanced age [140].

The clinical presentation, diagnosis, and treatment of patients with KCl-induced small intestine ulcers or strictures are the same as those for patients with primary or NSAID-induced ulcers. Although the ulcers can occur anywhere along the gastrointestinal tract, they are most common in the distal ileum [141].

Other drugs

Parenteral gold therapy also has been associated with enterocolitis, in which edema and ulceration are limited to the ileum [142–144]. This rare complication, most common in middle-aged women, can occur shortly after the initiation of therapy and has a high mortality rate; thus, prompt cessation of gold therapy is essential. Therapy includes bowel decompression and antibiotics. Steroids are frequently used, although efficacy has not been proven. Octreotide was used successfully in one case [145].

Other drugs reported to cause small intestine ulcers or perforation include corticosteroids [146], cytarabine [147] and other chemotherapeutic agents, digoxin [148], ferrous sulfate preparations [50], and kayexalate [149].

Small bowel ulcers associated with systemic disorders (see Chapter 109)

Behçet syndrome

Behçet syndrome is a systemic disease that affects the skin, joints, vascular system, central nervous system, and intestinal tract. Chromosomal trisomy 8 has been reported in asso-

ciation with intestinal Behçet disease, suggesting that this chromosomal anomaly may play a role in some forms of Behçet disease [150]. Oral and genital ulcers are a common feature; intestinal ulceration has been described in fewer than 1% of all patients with Behçet syndrome [151]. The ileocecal region is most frequently involved [152]. Multiple deep ulcers in a background of minimally inflamed mucosa are characteristic; fold thickening, granular mucosa, and pseudopolyp formation have also been described [153]. The lesions predominate at sites coinciding with intramucosal lymphoid tissue [154]. The ulcers bleed easily and are often penetrating [155,156]. The abnormalities are readily differentiated from those of Crohn's disease or ulcerative colitis [152,153,157].

The optimal treatment of Behçet syndrome has yet to be established. No medical treatment significantly alters the natural course of this syndrome. Immunomodulation with corticosteroids, methotrexate, colchicine, thalidomide [158,159], cytotoxic agents, cyclosporine (ciclosporin), and tacrolimus (FK506) have been used for treatment of multisystem Behçet syndrome [160]. Recombinant α-interferon may benefit patients with systemic involvement including intestinal ulcers [161–164]. Surgery with wide resection margins should not be delayed in patients with complicated intestinal cases, although ulcer recurrence is common postoperatively [152,165,166]. Most recurrences occur within 2 years of surgery and consist of one or two deep ulcers at or near the anastomotic site [158].

Collagen vascular diseases

Patients with *systemic lupus erythematosus* (SLE) can develop intestinal ulceration as an uncommon complication, thought to be secondary to microthrombosis and vasculitis [167]. Mesenteric vasculitis can result in enteritis, which may present with nausea, vomiting, fever, diarrhea, and hematochezia [168,169]. This can progress to bowel infarction, which is associated with high mortality. Mesenteric vasculitis presenting with small bowel ischemia and stricture has also been reported in patients with other inflammatory disorders [168], including rheumatoid arthritis, scleroderma, polyarteritis nodosa, Henoch–Schönlein purpura, Wegener granulomatosis, giant-cell arteritis, Churg–Strauss syndrome, and Sézary syndrome [170]. Spondylarthropathies have also been associated with an increased incidence of ileal ulceration, although this is most often caused by concurrent inflammatory bowel disease [171]. Patients with acquired antiphospholipid antibodies and SLE or related autoimmune diseases are at increased risk of developing intestinal ischemia and hemorrhage related to mesenteric arterial thrombosis [172,173].

Cryptogenic multifocal ulcerous stenosing enteritis is an idiopathic syndrome consisting of intermittent bouts of intestinal obstruction and ulcerative stenosis, and characterized by steroid responsiveness [174–176]. Patients present with multiple jejunal and proximal ileal stenoses associated with superficial ulcers. They often have a chronic and relapsing course but share no other characteristics of Crohn's disease. Iron deficiency anemia has also been reported [176]. The presence of systemic symptoms (weight loss, fever, malaise) in most patients, responsiveness to steroids, and demonstration of C2 deficiency in one reported case suggest that this syndrome is a variant of polyarteritis nodosa or an unclassified independent vasculitis [174,175], although overt signs of vasculitis are not always present [175].

Diffuse small bowel ulceration and concurrent malabsorption

A rare clinical syndrome consisting of malabsorption, abdominal pain, and multiple nonmalignant ulcers of the small intestine has been described [177]. Typically, these patients are in the sixth or seventh decade of life and have long-standing GSE. In such patients, the disorder is characterized by extensive villus atrophy and small bowel ulcerations that fail to improve on gluten withdrawal. There is also a distinct subgroup of patients who do not have GSE. The term *chronic ulcerative (nongranulomatous) jejunitis* (CUJ) – and synonyms such as idiopathic mucosal enteropathy, idiopathic chronic ulcerative enteritis, unclassified sprue, malignant histiocytosis, and enteropathy-associated T-cell lymphoma (EATL) – have been applied to this latter group of patients. The nomenclature reflects the poor understanding of the etiology and pathophysiology of CUJ [177,178]. For the purposes of this chapter, CUJ is used to describe this disease in patients with and without evidence of GSE.

The typical histological features of CUJ are partial or total villus atrophy, mucosal ulceration, crypt hyperplasia, and an inflammatory cell infiltrate [179,180]. The loss of intestinal villi results in a marked decrease in the absorptive area of the intestine, and the aborted maturation of the enterocytes results in reduced levels of digestive enzymes on the intestinal brush border. The effects of these disturbances are malabsorption of all dietary components and a variable degree of PLGE. Although the mechanism is poorly understood, villus atrophy appears to be related to infiltration by activated T cells [181].

Etiology

Chronic ulcerative jejunitis without a prior history of GSE is usually more extensive in distribution and fails to respond to gluten withdrawal. Both CUJ and GSE are associated with splenic atrophy of unknown origin, and most cases of CUJ are preceded by a variable period of suspected or proven GSE [34,182,183]. Nevertheless, it seems clear that CUJ can develop without GSE [184,185].

Although small bowel lymphoma can resemble GSE clinically [186], there is strong evidence that lymphomas arise in chronic GSE [187–191]. The incidence of malignant degeneration may be decreased by a strict gluten-free diet [192].

In contrast to primary small intestine lymphomas, the typical lymphoma associated with GSE is derived from T cells [193–195]. These lymphomas, which are referred to as *enteropathy-associated T-cell lymphomas* (EATLs), are difficult to differentiate from those of CUJ. Histologically, both EATLs and CUJ exhibit villus atrophy, ulceration, and mucosal infiltration by activated T cells. Both disorders usually present with splenic atrophy. The major diagnostic difficulty results from the observations that EATL may be indolent in its early stages and patients with CUJ can develop lymphoma several years after diagnosis. In some cases, retrospective examination of biopsy samples obtained at the time of diagnosis of CUJ has revealed typical malignant cells [179,182,196]. Using the polymerase chain reaction, clonal rearrangements of the T-cell receptor were found in tumor specimens and, from the same patients, in enteropathic bowel without evidence of tumor involvement [197,198]. Analysis of intestinal biopsies from patients with CUJ and refractory GSE revealed that the monoclonal cytologically normal, noninvasive intraepithelial T lymphocytes share an aberrant immunophenotype with EATL [199]. In one series, all patients with CUJ had metastatic disease at the time of diagnosis [179], but in another retrospective study, no evidence of preexisting lymphoma was detected [200]. Chromosomal analysis in patients with EATL has demonstrated loss of heterozygosity at chromosome 9p21 (a frequent site of deletions in patients who develop lymphomas), suggesting that genetic abnormalities may participate in the development of EATL [201]. These data indicate that CUJ is a significant risk factor for the development of lymphoma and suggest that this development may be invariable.

Non-T-cell lymphomas, such as immunoproliferative small intestinal disease and Mediterranean (B-cell) lymphoma, can also be accompanied by mucosal atrophy and ulceration and may have all the features of CUJ (see Chapter 54). This group may have a dramatic response to antibiotics or cytotoxic agents [202–205]. These lymphomas cannot be differentiated solely based on morphology; thus, it is important to determine cell surface markers for proper diagnosis.

Clinical features

The age at diagnosis of CUJ tends to be older than it is for typical GSE. Childhood cases have not been reported. The onset of CUJ is indolent. Patients with CUJ with and without known GSE were symptomatic for a mean of 13 and 4.5 years, respectively. Most patients present with chronic symptoms that are typical of malabsorption syndromes. Midepigastric pain and weight loss associated with steatorrhea and diarrhea are common [200]. Shortly after presentation, 20%–30% of patients have ulcer complications such as small bowel obstruction (30%), melena (25%), and perforation (22%). Along with symptoms caused by these complications, patients with CUJ may have low-grade fever and signs of malnutrition.

Pathology

Multiple superficial or deep ulcers are invariably present in the stomach, small bowel, and colon [200,206]. Splenic atrophy is often present. Lymphomatous infiltration of lymph nodes, liver, spleen, and bone marrow is common with concurrent lymphoma [179].

According to Isaacson [180], there are "variable degrees (usually severe) of villus atrophy, crypt hyperplasia, intraepithelial lymphocytic infiltration, irregularity of surface enterocytes, and a dense lamina propria infiltrate consisting almost solely of plasma cells with a variable number of eosinophils and occasional neutrophils." Invasion of the epithelial layer may cause ulceration (Fig. 55.2). Subepithelial collagen deposition, which is also seen in GSE, and marked fibrosis of the ulcer base also may be present. Crypt hyperplasia and villus atrophy are seen in the adjacent mucosa, and the remaining mucosa is usually normal. It is imperative that multiple sections be exhaustively examined for malignant cells to avoid missing the diagnosis of lymphoma. Neoplastic cells are derived from T cells [193–195,207]. They resemble histiocytes, with minimal or no atypia, and the presence of intracellular erythrocytes, platelets, and cell debris is a common feature (Fig. 55.3) [179]. Confusion with Hodgkin disease may occur because of similarities with Reed–Sternberg cells [186,187,208].

Diagnosis

The diagnosis of CUJ should be considered in patients with established or apparent GSE who present with worsening malabsorption despite continued compliance with gluten-free diets. Essentially CUJ is a diagnosis of exclusion, whether or not a history of celiac disease is present, unless lymphoma is detected. Disorders presenting with malabsorption and intestinal ulceration that must be excluded include Crohn's disease, ischemic enteritis, radiation enteritis, lymphoma,

drug-induced ulceration, vasculitis, Zollinger–Ellison syndrome, and Whipple disease.

The patient with suspected CUJ should be assessed for malnutrition, and a careful evaluation of the extent of disease should be undertaken. Malabsorption and PLGE account for hypoalbuminemia, and hypoglobulinemia and deficiencies of divalent cations, iron, and folate are common. Hyposplenism is often present [183]. Intestinal perforation should be ruled out if leukocytosis, with or without fever and peritoneal signs, is present.

The diagnosis of CUJ is rarely made radiographically. Evidence of bowel thickening and of complications such as small bowel perforation or obstruction may be present on plain films. Demonstration of small bowel strictures by contrast studies (Fig. 55.4) or by CT helps to distinguish CUJ from uncomplicated GSE: small bowel dilation is typical of the latter [209–211]. Bowel thickening, mesenteric lymphadenopathy, and splenic atrophy are consistent with CUJ. However, lymphadenopathy in patients with GSE is not diagnostic of lymphoma.

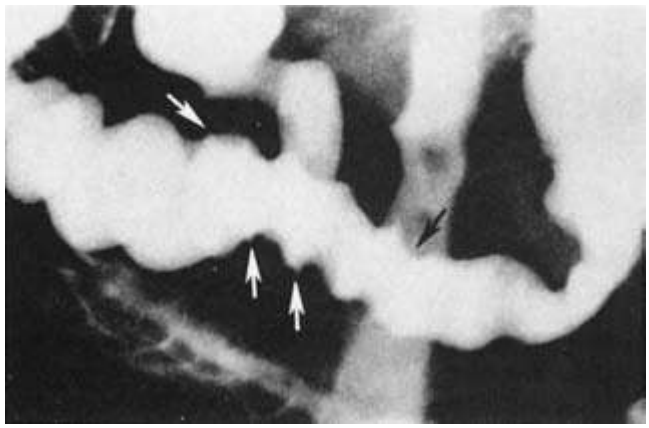

Figure 55.4 Chronic ulcerative nongranulomatous jejunoileitis (CUJ). Thirty-minute small bowel follow-through shows prominent intestinal folds, thickening of the bowel wall, diffuse lumenal narrowing, and mucosal ulceration (arrows). Dilation, which is typical of gluten-sensitive enteropathy, is not a feature of CUJ. From Freeman & Cho [211], with permission from Blackwell Publishing.

Small bowel biopsies are essential for establishing the presence of CUJ. Although the yield from blind biopsies is poor, improvements in the ability to obtain endoscopic biopsy samples should markedly reduce the need for surgery to establish the diagnosis [211]. Biopsy samples obtained from ulcerated regions are the most desirable. It is essential that adequate tissue is obtained, sectioned extensively, and examined by an experienced pathologist before excluding the diagnosis of EATL; immunohistology and T-cell flow cytometry may be useful adjuncts [180,212]. A careful search for disseminated lymphoma at the time of presentation is essential, using imaging techniques such as CT, MR, and positron emission tomography (PET) scanning [179,212]. It is also important to assess for the presence of B-cell surface markers because B-cell lymphomas and immunoproliferative small intestinal disease may be associated with villus atrophy. Polymerase chain reaction has been used to detect T-cell receptor gene rearrangements in biopsies [202].

Therapy

No specific therapy has been shown to modulate the course of CUJ. Most patients have unresponsive malabsorption, and life expectancy at diagnosis is less than 2 years. Surgical resection of severely affected bowel has been of benefit in some cases [196,200]. Although patients with CUJ are at increased risk of intestinal perforation, prednisone therapy should be considered in all symptomatic patients with no evidence of lymphoma. The dose should be reduced to the minimum necessary to maintain a symptomatic response with tolerable side effects. Azathioprine has been studied in small series, one study reporting clinical improvement in five of seven patients at doses of 2 mg/kg/day, used in conjunction with oral prednisone (1 mg/kg/day) for a mean of 11 months [213].

Although CUJ does not respond to removal of dietary gluten, it is possible that this measure may impede the development of lymphoma [192,214]. If a localized lymphomatous infiltrate is found, local excision is mandatory. Although some patients have been cured by resection alone [215], most remain symptomatic after the surgical procedure. Mortality in these patients is high, presumably because of progression of the lymphoma. The impact of chemotherapy with or without adjuvant radiation has not been evaluated in clinical trials. Disseminated T-cell lymphoma should be treated with aggressive chemotherapy using combinations, such as cyclophosphamide, hydroxydoxorubicin, vincristine, and prednisone, that are used in the treatment of other lymphomas. In a retrospective study of 33 patients treated with

high-dose chemotherapy regimens, the 5-year survival rate was 19.7% and the disease-free rate was 3.2% [216].

Autoimmune enteropathy

Autoimmune enteropathy is another rare malabsorptive disorder that can present with chronic diarrhea and weight loss, and has been described in both children and adults [217–220]. Diagnosis is based on the presence of small intestinal villous atrophy, and circulating antienterocyte antibodies, which are pathognomonic for this disorder [219–221]. Associations include immunoglobulin deficiencies and thymomas; autoantibodies to other gut organs may coexist, with gastritis, hepatitis, colitis, pancreatitis, and pernicious anemia in some instances. Autoimmunity against multiple sites in the gut has led to suggestions that this may represent a generalized autoimmune gut disorder resulting from inappropriate T-cell activation and increased tumor necrosis factor α (TNF-α) production [222]. The mainstay of therapy is immunosuppression, using corticosteroids as first-line therapy; alternate agents that have been successfully used for maintenance of immunosuppression include azathioprine, cyclosporine, and tacrolimus [222–225]. Two case reports outline the use of infliximab infusions to induce and maintain remissions with success [219,226].

Drug-induced small bowel disease

Many contemporary drugs mediate various mechanisms of injury, including the following:

- erosive damage by NSAIDs and KCl
- ischemic damage by cardiac drugs, cocaine, ergotamine alkaloids, and oral contraceptives
- hematomas from anticoagulants
- motility disorders from opiates
- malabsorption
- inhibition of epithelial cell turnover by chemotherapeutic agents.

These adverse reactions may be reversible if the drug is discontinued, but some medications produce permanent effects. This section focuses on drugs that have a profound or permanent effect on the small intestine, except for those causing erosive damage, as discussed earlier. The pathological and radiological features of drug-related lesions of the intestinal tract have been reviewed [227–230].

Drugs causing ischemia

Mechanisms by which drugs and toxins can produce occlusive or nonocclusive intestinal ischemia include induction of arterial vasoconstriction, systemic or splanchnic hypotension, and thrombosis of mesenteric vessels (see Chapter 113). Regardless of cause, the mortality rate from small bowel ischemia progressing to bowel infarction ranges from 70% to 90% [231,232]. Delays in presentation and diagnosis and coexistent health problems account for this high mortality. Patients with drug-induced mesenteric ischemia usually present with severe, poorly localized abdominal pain, low-grade fever, and hematochezia. Signs of peritonitis or abdominal distention secondary to ileus may be present. Evidence of intestinal perforation, obstruction, or ileus can be obtained by radiographic studies. The demonstration of bowel wall edema and thumbprinting, pneumatosis intestinalis, or portal venous gas are consistent with mesenteric infarction (Fig. 55.5) [231]. Computed tomography is a reliable diagnostic method [233,234]. Radiographic studies may be normal in patients with nonocclusive ischemia, such as occurs with digitalis-induced mesenteric spasm and antihypertensive medications [235,236]. Mesenteric angiography may be needed to document digitalis-induced ischemia [237].

Besides measures specific to the offending agent, general supportive measures include administration of fluids and oxygen, correction of electrolyte and acid–base disorders, and antibiotic therapy [231]. Surgical resection of infarcted small bowel is necessary, although most patients are high-risk surgical candidates.

Cardiac drugs

Intestinal ischemia or infarction may result from drugs that produce or potentiate arterial vasoconstriction or hypotension [238]. The incidence of these side effects is greatest when the splanchnic circulation is already compromised, such as in congestive heart failure. Antihypertensive agents and diuretics can induce intestinal ischemia secondary to hypotension and hypovolemia. Drugs with direct vasoconstrictive effects, such as norepinephrine (noradrenaline), dopamine, and intraarterial or intravenous vasopressin, reduce intestinal blood flow and can cause mesenteric infarction [239,240]. Digitalis glycosides can further reduce splanchnic flow in patients with congestive heart failure. Intestinal ischemia resulting from digoxin use may be reversed with nitroprusside and calcium channel blockers [237,241].

Cocaine

Cocaine is a lipophilic drug that is readily absorbed by mucosal surfaces, including the intestinal mucosa. It has potent stimulatory effects on the central nervous system because of inhibition of presynaptic reuptake of norepinephrine, dopamine, and serotonin (5-hydroxytryptamine, 5-HT), in addition to causing increased synthesis of norepinephrine and dopamine [242,243]. Excessive sympathetic stimulation produces peripheral vasoconstriction and tachycardia, which can cause hypertension and nonocclusive intestinal ischemia [244]. Rebound vasodilation after intense vasoconstriction can further compromise intestinal perfusion.

Gastrointestinal manifestations of cocaine use include appetite suppression, nausea, vomiting and hyperperistalsis,

perforated gastroduodenal ulcers (most common in crack users), enterocolitis, and hepatotoxicity [245,246]. Intestinal ischemia is a serious but rare complication of cocaine and crack abuse, and carries a 50% mortality if peritonitis ensues [246–252]. Life-threatening gastrointestinal problems are more likely to be encountered by "body packers." Such persons transport illicit drugs by ingesting drug-containing packets or condoms or by inserting them in the rectum [244,253,254]. Complications include mechanical intestinal obstruction and rupture of a packet, which can release a lethal quantity of cocaine [254,255]. Signs of drug toxicity, mechanical intestinal obstruction, or marked leukocytosis, which may indicate the presence of gangrenous bowel, are indications for laparotomy [239]. Asymptomatic patients should be treated with activated charcoal to bind any leached drug and with mild cathartics to stimulate gastrointestinal transit [239,253]. Abdominal radiographs may reveal evidence of intestinal obstruction or ileus as well the pathognomonic "double-condom sign" [256].

Ergotamines

Ergot alkaloids such as ergotamine, dihydroergotamine, methylergonovine, and methysergide are used in the symptomatic treatment or prevention of migraine headaches. However, due to side effects, numerous contraindications, and the introduction of more efficacious drugs, their clinical use has been sharply reduced [257]. Common intestinal complications of ergots include abdominal pain, nausea, and vomiting. There are several reports of bowel infarction after administration of large doses of ergots [200,201].

Oral contraceptives

Oral contraceptives have been reported to cause small intestine infarction and, more commonly, segmental colitis [258]. The mechanisms are not known, although mesenteric arterial occlusion [259–262] or mesenteric venous thrombosis [263–267] is often present. Progestins cause arterial occlusion, whereas estrogens can produce both arterial and venous occlusion [268,269]. Mechanisms that have been implicated include hypercoagulability, reduced mesenteric venous blood flow, and endothelial proliferation [261,270]. The risk is increased by ancillary factors such as collagen-vascular disease, hypercoagulable states, smoking, and hypertension [271]. The duration of contraceptive use is not an independent risk factor and does not correlate with the severity of symptoms [261].

The diagnosis should be considered in contraceptive users presenting with poorly localized colicky abdominal pain, bloody diarrhea, or hematochezia. Fever is often present, and presenting symptoms may also include nausea and vomiting [262]. Although abdominal pain may be present for several weeks or months, pain serious enough to warrant hospitalization is usually of recent onset. Results of laboratory studies, including platelet count, prothrombin time, and partial thromboplastin time, are usually normal [262]. The diagnosis depends on the demonstration of intestinal ulceration or ischemia in contraceptive users. Abdominal radiographs may demonstrate bowel wall thickening or ileus. Ulceration, which may be detected with contrast studies, is usually continuous in involved segments [262]. The diagnosis of small intestinal infarction may rarely be made at exploratory laparotomy for an acute abdomen [267].

Oral contraceptives should be discontinued and supportive therapy initiated. Although mesenteric ischemia may be reversible, the mortality rate in severe cases is almost 50% [262]. The risk of thromboembolic complications decreases to normal levels within 1 month of discontinuation of oral contraceptives [270].

Anticoagulants

Gastrointestinal hemorrhage is a common complication of anticoagulant therapy with heparin or warfarin. Antiplatelet

therapy with ticlopidine has been associated with chronic severe diarrhea that is related to altered motility but not to hemorrhagic complications [272,273]. The incidence of bleeding depends on the intensity of therapy, the adequacy of monitoring and dosage adjustment, the route of administration, concurrent drug therapy, and the gender, age, and underlying condition of the patient. In the Boston Collaborative Drug Surveillance Program the incidence of gastrointestinal bleeding requiring transfusion for medical inpatients without predisposing illness was 1.2% and 0.2% for heparin and warfarin, respectively [274]. Minor gastrointestinal bleeding occurred in 8.3% and 3.3%, respectively. Gastrointestinal bleeding should be thoroughly investigated, even if it is a minor symptom, and regardless of the prothrombin time [275–279]. Most episodes of gastrointestinal bleeding in patients who are taking anticoagulants are attributable to a demonstrable gastric or intestinal lesion [278,279].

The most common hemorrhagic small intestine complication is spontaneous or trauma-induced intramural hematoma [280], usually in the jejunum, presenting as intestinal obstruction [281–283]. This has been reported with both oral and parenteral anticoagulants in the setting of supratherapeutic coagulation parameters. The relative fixation of the descending duodenum is responsible for a higher susceptibility to intramural hematoma in response to blunt abdominal trauma [280]. Hematomas may cause colicky abdominal pain and symptoms secondary to intestinal obstruction. Biliary symptoms or pancreatitis may result from obstruction of the biliary or pancreatic ducts. Minor intestinal bleeding is detected in 25%, and major bleeding occurs in 3.5% [284]. Patients may present with an acute abdomen that can be differentiated from other causes by the more gradual onset of symptoms and the acute fall in hematocrit [285].

Abdominal tenderness, low-grade fever, and a palpable abdominal mass are common physical findings. Evidence of proximal small bowel obstruction may be present on plain abdominal radiographs. An upper gastrointestinal series may show the classic coiled-spring, picket-fence, or stack-of-coins sign (Fig. 55.6), caused by extravasation of blood into the valvulae conniventes, narrowing the lumen with spike-like projections of barium outlining the normal caliber of the lumen [275,280]. Accurate diagnosis is provided by CT scans, and findings may include circumferential wall thickening, intramural hematomas, and lumenal narrowing [282]. Serial ultrasound examinations can be useful for monitoring the behavior of the hematoma [286].

Conservative medical management is usually sufficient because most hematomas undergo spontaneous reabsorption, with resolution of symptoms within 3 weeks. Reversal of anticoagulation with fresh-frozen plasma and vitamin K, intravenous hydration, and continuous nasogastric suction are sufficient for management of most patients. Surgical intervention may be required if there is complete intestinal

obstruction or if conservative medical management fails to resolve intestinal bleeding, obstructive symptoms, or fever [277,284].

Drugs causing motility disorders

Drug-induced intestinal pseudoobstruction can occur as follows: with use of anticholinergic drugs; with use of drugs, such as phenothiazines and tricyclic antidepressants, opioids, verapamil, and clonidine, with anticholinergic effects; and, occasionally, with initiation of cyclosporine therapy. Neurotoxicity induced by such drugs as vincristine can also produce intestinal pseudoobstruction [287], which frequently appears within 3 days of the initiation of therapy and resolves within 2 weeks of cessation of therapy. Direct toxicity to the enteric nervous system is probable because evidence of peripheral nerve dysfunction is not always present in patients with this complication.

Persistent use of narcotic analgesics can produce the *narcotic bowel syndrome*, characterized by abdominal pain, intermittent vomiting, weight loss, and other symptoms suggestive of intermittent pseudoobstruction [288]. Poorly localized chronic abdominal pain that is colicky, with acute exacerbations, is typically the major symptom. The pain is initially responsive to narcotic analgesics, but, with continued narcotic use, progressively larger doses are required for pain relief. Although the differential diagnosis includes biliary colic, pancreatitis, peptic ulcer disease, and renal calculi, the history, physical examination, and laboratory tests are usually not consistent with these entities. Abdominal radiographs typically are consistent with ileus and, on rare occasions, with mechanical small bowel obstruction [288]. The diagnosis of narcotic bowel syndrome is readily made with an intake history of more than 2 weeks of moderate to heavy doses of narcotics and a workup that excludes more serious disorders [288].

Narcotic withdrawal is essential for treatment of narcotic bowel syndrome. On withdrawal of these drugs, the patient may experience vomiting, diarrhea, and cramping resulting from increased intestinal motility [288]. These symptoms can be markedly reduced or abolished by the α_2-adrenergic receptor agonist, clonidine [289,290]. Opiates are discontinued, and clonidine is gradually increased from 0.1 mg twice daily to 0.1 mg four times daily [289]. After 1 week of therapy, the dose is tapered over 3 days. Narcotic bowel syndrome and withdrawal symptoms can be successfully treated in 90%–95% of patients with this regimen. Metoclopramide, narcotic antagonists, and rotating opioid use have been used with variable benefit in patients with cancer [291,292].

Drugs causing malabsorption

Drug-induced malabsorption of nutrients, electrolytes, and concurrently used medications occurs by several different mechanisms [235,262,293,294]. These include the following:

- intralumenal interactions that interfere with the solubilization, digestion, or transport of nutrients
- increased rate of intestinal transit
- mucosal injury
- direct inhibition of absorptive processes
- inhibition of gastric, biliary, or pancreatic secretions.

Drugs that impede nutrient assimilation by direct interaction include the following: tetracycline, which chelates calcium ions; cholestyramine, which binds to iron and vitamin B-12; mineral oil, which reduces the solubilization of β-carotene and fat-soluble vitamins; and aluminum and magnesium hydroxide, which precipitate calcium and phosphate ions. Prokinetic agents and cathartics can impair fat absorption by increasing intestinal transit [295]. Mucosal injury resulting in diminished nutrient absorption has been reported with drugs such as colchicine, neomycin, and methotrexate. Colchicine inhibits mitosis and brush-border disaccharidases and impairs absorption of fat, vitamin B-12, β-carotene, D-xylose, lactose, bile salts, and steroids [296]. Neomycin is thought to cause brush-border damage by inhibiting enterocyte protein synthesis [297,298], and to impair micellar solubilization of bile salts, cholesterol, fatty acids, and fat-soluble vitamins by directly binding to bile salts. Azotorrhea and decreased D-xylose absorption can also occur with neomycin. The malabsorption varies in degree according to the dose of neomycin, and can be seen with as little as 3 g/day [297]. Discontinuation of the drug typically reverses the malabsorption and diarrhea.

Methotrexate decreases the height of intestinal microvilli and brush-border membrane protein and lipid content. Other drugs that produce histological changes in the jejunal mucosa associated with fat malabsorption include methyldopa [299], allopurinol [300], and mefenamic acid [301]. The histological features of mefenamic acid enteropathy closely resemble those associated with celiac disease. Sodium aminosalicylate [302] and thiazide diuretics, which impair ileal vitamin B-12 and sodium transport, respectively, are examples of drugs that directly inhibit nutrient transport. A reported case study convincingly showed that azathioprine therapy induced small bowel villus atrophy and associated severe diarrhea; the malabsorption was reversed with drug discontinuation [303].

Clofazimine, when used in high doses for the treatment of leprosy, can cause a distinctive enteropathy characterized by red-brown birefringent crystals in the small bowel mucosa and submucosa as well as in the mesenteric lymph nodes [304]. Clofazimine enteropathy is associated with nonspecific clinical and radiological signs including diarrhea, abdominal pain, anorexia, vomiting, diarrhea, and weight loss but not clinically significant malabsorption [305].

The clinical significance of drug-induced malabsorption is influenced by such variables as baseline nutritional status and dietary intake, underlying disorders that interfere with intestinal function, and pharmacological considerations

such as drug dosage and schedule and duration of therapy. Awareness of the nutritional consequences of drug therapy facilitates the prevention and early detection of these disorders. For some drugs, prophylactic nutritional supplementation is reasonable. For example, patients treated on a long-term basis with sulfasalazine, phenytoin, or colestipol should receive folic acid, and patients receiving the latter two drugs should also receive vitamin D supplementation.

Chemotherapeutic agents

Most chemotherapeutic agents produce cytotoxic effects in normal cells because they have low therapeutic indices. Cells that have a high turnover rate, such as those of the small intestine crypt epithelium, are particularly vulnerable to drugs that inhibit cell proliferation. The magnitude of gastrointestinal toxicity is highly variable among patients and is affected by dose, duration of treatment, specific agents used, concurrent radiotherapy, and nutritional status of the patient. Nausea and vomiting are common acute side effects of antineoplastic drugs and are mediated in part by the chemoreceptor trigger zone in the brain. These symptoms predominate in the early stages of therapy. After a single course of therapy, intestinal mucosal damage is usually evident within the first 3 days. Regeneration and repair occur rapidly after cessation of therapy, with grossly normal mucosa present by 14 days, although inflammatory changes may be present for several weeks [306].

Erosive enteritis, with or without stomatitis, presents with abdominal pain, bleeding, vomiting, ileus, or diarrhea. It is most common with methotrexate therapy but is also seen with 5-fluorouracil, irinotecan, actinomycin D, doxorubicin, cytarabine (cytosine arabinoside; Ara-C), bleomycin, and vincristine. Other complications result from these chemotherapeutic agents. Methotrexate is also associated with malabsorption (see above). Irinotecan also causes cholinergically mediated diarrhea within hours of infusion in ~ 50% of patients [307], in addition to late-onset diarrhea resulting from secretory and exudative mechanisms [308]. The erosive enteritis associated with cytarabine when used in combination regimens occurs within 8–11 days of the start of therapy and is associated with hypokalemia, hypocalcemia, PLGE, and a syndrome characterized by telangiectasis and intramural hematomas [309]. Recombinant interleukin-2 (IL-2), which is used for treatment of advanced renal cell carcinoma, has been associated with intestinal ischemia, necrosis, perforation, and diffuse bowel ulceration requiring surgery [310]. These complications have occurred with IL-2 alone or in combination with γ-interferon (IFN-γ) or lymphokine-activated killer cells. Cyclosporine-induced vasoconstriction can contribute to the development of nonocclusive mesenteric ischemia in renal transplant recipients [311]. Vincristine can induce acute intestinal pseudoobstruction (as already discussed). Preconditioning for bone marrow transplantation with cyclophosphamide and total-body irradiation produces diffuse intestinal injury. Symptoms, including crampy abdominal pain, watery diarrhea, and anorexia, are common within the first 3 weeks after transplantation. Symptoms that persist beyond 3 weeks should be investigated to rule out enteric infection or other intestinal disorders. Neutropenic enterocolitis or typhlitis is most frequently encountered after chemotherapy for leukemia or lymphoma. Diffuse patchy mucosal necrosis involving the ileocecal region is associated with nonspecific symptoms and fever, nausea, vomiting, right lower quadrant pain, and hematochezia. Colon complications resulting from these drugs are discussed in Chapter 59.

Necrotizing enterocolitis

There are several synonyms for nectrotizing enterocolitis (NEC), including pigbel, enteritis necroticans, darmbrand, nonspecific jejunitis, epidemic regional jejunitis, Pasini regional jejunitis, and necrotizing jejunitis. Although there were numerous European outbreaks during and after World War II [312], acute jejunitis is largely a problem in nonindustrialized nations [313–315]. Outbreaks are most frequent in communities where protein deprivation and poor food hygiene are prevalent [316]. The disease was a major cause of illness and death among children in the highlands of Papua New Guinea until immunization against the β-toxin of the causative organism, *Clostridium perfringens,* was begun in 1980 [317]. Isolated cases continue to be reported from industrialized nations, although detection of the causative organism is not always reported [318–321]. Well-documented North American cases include four previously healthy adult males [321] and a 12-year-old boy with poorly controlled diabetes who had eaten pig intestines (chitterlings) [322].

C. perfringens type C (initially identified as *C. welchii* type F) is a heat-resistant bacterium that can often be isolated from the tissues, stool, and food of affected patients [323–326]. One-sixth of healthy persons have been shown to harbor a less pathogenic strain. A similar illness attributed to pathogenic strains of this organism has been described in certain nonhuman animal species [327,328]. Immunization against the β-toxin resulted in a reduction in hospital admissions for acute jejunitis to less than one-fifth of previous figures [317]. These observations have firmly established that this organism is a causative agent of acute jejunitis. The agent has also been isolated from children in Bangladesh with nonnecrotizing diarrheal illnesses [329]. Nevertheless, there are patients who have an identical syndrome without evidence of *C. perfringens* type C infection or the β-toxin [330]. *C. perfringens* type A, which does not produce the β-toxin, was implicated as the causative agent in adult patients with an NEC-like

illness involving the small bowel and colon [322]. Another cytotoxin, isolated from *Bacillus cereus*, has been identified as a putative cause of acute jejunitis [331]. Additional factors associated with development of acute jejunitis include ingestion of foods containing trypsin inhibitors (e.g., sweet potatoes), reduced gastric acidity, and reduced gastrointestinal motility [321].

Acute jejunitis, with or without colonic involvement, occurs sporadically and in epidemics. Illness is characterized by bloody diarrhea, fever, and abdominal pain, with a high mortality rate (58%) [316]. Nonocclusive small intestinal ischemia resulting in necrosis of varying severity, with areas of full-thickness necrosis, is usually found. Early recognition, treatment with antibiotics, and surgical resection are essential for successful treatment.

Neonatal NEC is a disease of focal or diffuse small intestine ulceration and necrosis that is seen almost exclusively in premature infants and low-birthweight neonates who have been fed enterally. Similar pathophysiological mechanisms may operate in adult necrotizing enteropathies. The putative causes, clinical presentation, differential diagnosis, pathology, and management of NEC are discussed in several excellent reviews [332–341].

The cause of NEC is unknown, but several factors appear to be implicated, including prematurity, intestinal ischemia, infectious agents and bacterial colonization, and the initiation of enteral nutrition [342,343]. However, a randomized trial and subsequent reviews [344,345] are at odds with earlier case–control studies suggesting that stressed infants are at greater risk of developing NEC if enteral feedings are advanced rapidly or if excessive volumes are used [346–349]. The pathogenesis of NEC is clearly multifactorial, and susceptibility of individual patients to NEC is probably also dependent on unidentified host factors [342,343]. For example, prospective studies that reported a reduced incidence and severity of NEC in neonates randomized to receive probiotics support a role for alterations of the gut flora in the pathogenesis and treatment of this disorder [350,351]. Successful delineation of these factors and other pathogenic mechanisms should improve the ability to prevent and treat NEC and should provide insight into the mechanisms of similar disorders seen in adults.

Protein-losing gastroenteropathy

Definition

Protein-losing gastroenteropathy (PLGE) is a syndrome characterized by enteric loss of plasma proteins in abnormal amounts. Many intestinal and extraintestinal diseases may be associated with PLGE, and treatment is aimed almost exclusively at the underlying disorder. The recognition of PLGE mandates a careful search for an associated illness.

The defining characteristic of PLGE is hypoproteinemia resulting from gastric or intestinal losses. Studies of iodine 131-labeled albumin secretion identified the stomach as the site of excessive protein loss in patients with hypertrophic gastritis and atrophic gastritis, and the intestine as a site of loss in patients with inflammatory bowel disease.

Under physiological conditions, sloughed enterocytes and pancreatic and biliary secretions account for almost all the endogenous protein that is found in the intestine. Most of these proteins are digested, and the constituent amino acids are reabsorbed [352,353]. Gastrointestinal loss of serum proteins, as indicated by measuring serum albumin kinetics, accounts for less than 10% of daily protein catabolism [354–358]. This may increase four- to fivefold in patients with PLGE. Hypoproteinemia results if the capacity to increase protein synthesis is not sufficient to compensate for increased intestinal protein losses. For example, albumin synthesis is increased no greater than two-fold in patients with PLGE [359].

Etiology

Most gastrointestinal disorders associated with PLGE cause exudative protein losses secondary to ulcerative or nonulcerative enteropathies or secondary to lymphatic obstruction or increased lymphatic hydrostatic pressure (Table 55.3). Enteropathies resulting in PLGE include ulcerating gastrointestinal carcinomas and inflammatory disorders such as Crohn's disease and ulcerative colitis. Increased enteric protein loss and increased catabolism are the primary contributors to the hypoalbuminemia and reduced protein pools that are seen in these disorders. In the case of inflammatory bowel disease, the magnitude of enteric protein loss is most significant, and it is directly related to the extent and activity of mucosal inflammation [360,361].

Nonulcerative diseases such as Ménétrier disease [362], atrophic gastritis, tropical sprue, celiac disease, allergic gastroenteritis, eosinophilic gastroenteritis, collagenous colitis, and polyposis syndromes (including Cronkhite–Canada syndrome, juvenile polyposis, and Peutz–Jeghers syndrome) have also been associated with PLGE [362–371]. In addition to neurological symptoms, defects in glycoprotein biosynthesis (the carbohydrate-deficient glycoprotein syndromes) can also present with severe PLGE [372].

Acute and chronic intestinal infections can result in PLGE, including acute staphylococcal, *Salmonella* [352], and *Shigella* [373] infections. The incidence of PLGE is species and strain dependent; for example, *Shigella dysenteriae* type 1 infections cause greater loss of enteric protein than do other strains [373]. Both pseudomembranous colitis and asymptomatic colonization by *C. difficile* can result in enteric loss of protein [374,375]. In a study of elderly nursing home patients, PLGE was documented in all 12 patients with pseudomembranous colitis, in 6 of 14 with *C. difficile* diarrhea, and in 6 of 12

Table 55.3 Causes of protein-losing gastroenteropathy

Increased interstitial pressure
Congenital intestinal lymphangiectasia, mesenteric lymphatic obstruction, tuberculosis, sarcoidosis, lymphoma, retroperitoneal fibrosis, increased central venous pressure, constrictive pericarditis, congestive heart failure, Fontan procedure
Ulcerative diseases
Erosive gastritis or enteritis, *Helicobacter pylori*-associated gastritis, neoplasia (carcinoma or lymphoma), Crohn's disease, pseudomembranous enterocolitis, acute graft-versus-host disease
Nonulcerative diseases
Giant hypertrophic gastropathy (Ménétrier disease), viral enteritides, bacterial overgrowth, parasitic diseases (malaria, giardiasis, schistosomiasis, helminth infections), cystic fibrosis, Whipple disease, allergic enteritis, eosinophilic gastroenteritis, gluten-sensitive enteropathy, tropical sprue, systemic lupus erythematosus

colonized with *C. difficile* without toxin or diarrhea [375]. Parasitic diseases with documented PLGE include *Strongyloides stercoralis* infection [376], schistosomiasis [377,378]. and giardiasis [379–381]. Acute viral illnesses including cytomegalovirus, measles, and varicella also have been linked to PLGE [382–386]. Small bowel bacterial overgrowth can also be associated with PLGE [387].

It has been well documented that PLGE occurs in patients with SLE [388–395], most commonly in young women; moreover, it may be the initial clinical manifestation of SLE. Fifty percent of these patients present with steroid-responsive diarrhea without steatorrhea [396]. Mixed connective tissue disease [397,398], Henoch–Schönlein purpura [399], and other collagen-vascular diseases also can be complicated by PLGE [400]. Another cause of PLGE is secondary amyloidosis complicated by small intestinal tract ulcers, resulting from arteriole and lymphatic infiltration with amyloid deposits [401,402]. Thee is also an association of PLGE with mesenteric vascular changes resulting from neurofibromatosis [403] and idiopathic mesenteric thrombophlebitis [404].

Diseases that produce disruption of intestinal lymphatic vessels or obstruction of lymph flow are an additional cause of PLGE. Tortuous, dilated mucosal and submucosal lymphatic vessels are the hallmark of primary intestinal lymphangiectasia (see Chapter 46). Most patients with this disease present by 30 years of age with edema, diarrhea, hypoproteinemia, and lymphocytopenia resulting from epithelial leakage and lymphatic rupture [405]. A similar lesion has been implicated as the mechanism of enteric protein loss in some patients with systemic sclerosis and SLE [406,407].

Inflammatory granulomatous diseases such as sarcoidosis and mesenteric tuberculosis cause PLGE [408,409]. By producing retroperitoneal lymph node enlargement or fibrosis, Whipple disease [410,411], lymphoma [412], endometriosis of the small intestine [413], and Crohn's disease [360,414] impair lymphatic egress by causing mechanical obstruction or increased hydrodynamic pressure. Additional retroperitoneal processes, including pancreatitis, pancreatic cancer, and other retroperitoneal tumors, also can present with PLGE. Right-sided congestive heart failure, constrictive pericarditis, superior vena caval obstruction, and other causes of elevated central venous pressure [415,416] commonly produce PLGE.

Clinical features

The major clinical manifestation of PLGE is dependent edema resulting from decreased plasma oncotic pressure. Although all plasma proteins are usually lost, selective loss of low-molecular-weight proteins may occur without lymphatic obstruction. Proteins such as albumin, immunoglobulins (IgM, IgG, and IgA but not IgE), fibrinogen, ceruloplasmin, and α_1-antitrypsin that have long circulating half-lives and a limited capacity for increased synthesis are most likely to exhibit depressed levels. Decreased levels of proteins other than albumin are rarely symptomatic, although in the setting of lymphatic obstruction, symptomatic lymphopenia and steatorrhea may be present.

Diagnosis

Edema and hypoproteinemia resulting from enteric protein loss are presenting manifestations of disease, but they are often minor aspects of the underlying disease. The diagnosis should always be considered in hypoalbuminemic patients if other causes such as malnutrition or protein loss from other sites are not apparent. If it is necessary to document intestinal protein losses, the preferred method is to quantitate fecal α_1-antitrypsin concentration or clearance. Alternative methods employing radiolabeled substrates for quantitating enteric protein loss remain useful research tools, but they are seldom used for clinical purposes. Clinical studies indicate that PLGE can be diagnosed and the sites of albumin loss can occasionally be determined scintigraphically using ^{99m}Tc-labeled albumin or dextran [417–422].

α_1-Antitrypsin is particularly valuable because it constitutes approximately 4% of serum proteins, has a molecular weight similar to that of albumin, is resistant to proteolysis, is not actively absorbed or secreted, is normally present in low quantities in stool, and is easy to assay. For detecting protein-losing gastropathy, particularly in patients with Zollinger–Ellison syndrome, acid secretion must be suppressed because α_1-antitrypsin is degraded at a pH below 3 [423–425]. The α_1-antitrypsin concentration in stool and the plasma clearance of α_1-antitrypsin were compared in healthy persons and

in consecutive patients with chronic diarrhea, malabsorption, or unexplained hypoalbuminemia [426]. The plasma clearance is the product of daily stool volume and stool α_1-antitrypsin concentration divided by the serum α_1-antitrypsin concentration [427]. In contrast to earlier studies [428–430] there is ample evidence that analysis of fecal α_1-antitrypsin concentration is not a reliable substitute for measurement of α_1-antitrypsin clearance [426]. There is a highly significant correlation between α_1-antitrypsin clearance and serum albumin concentration and fecal loss of radiolabeled albumin. When the α_1-antitrypsin clearance was elevated more than three-fold, serum albumin levels were less than 3.0 g/dL. α_1-Antitrypsin clearance levels may be increased in otherwise healthy persons with diarrhea secondary to ingestion of lactulose, sorbitol, sodium sulfate, or phenolphthalein [426]. Clearance levels also may be overestimated if hematochezia or meconium is present.

Therapy

There is no specific therapy for PLGE. Optimal therapy of the primary illness is the only effective remedy. For example, PLGE associated with autoimmune diseases (e.g., CREST syndrome [calcinosis, Reynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia] and SLE) has been successfully treated by aggressive immunosuppressive regimens including steroids, cyclosporine, azathioprine or cyclophosphamide [388,431,432]. Octreotide and medium-chain triglycerides were beneficial when added to immunosuppressive therapy in a patient with SLE [389]. Severe PLGE with intractable diarrhea due to systemic AA amyloidosis has also been successfully treated with corticosteroids and octreotide [433]. In the case of Ménétrier disease, octreotide and eradication of *Helicobacter pylori* may reduce enteral protein losses [434,435]. Prophylactic measures to avoid complications resulting from peripheral edema should be instituted. In the setting of lymphangiectasia, reduction of lymphatic transport may reduce enteric protein loss. Low-fat diets supplemented with medium-chain triglycerides may be beneficial in this setting [436,437]. Surgical drainage of dilated lymphatic channels (lymphovenous anastomosis) is occasionally helpful [414,438].

Surgically altered anatomy, 1380

Anatomy of the colon

The colon is a tubular organ that extends from the ileocecal valve to the proximal rectum. It is approximately 90–150 cm (3–5 feet) in length. Its principal functions are absorption of water and electrolytes as well as storage of intralumenal contents to permit controlled elimination of the feces. The terminal ileum enters the cecum on its posteromedial border at the ileocecal valve. The cecum is a large, blind pouch, approximately 7.5–8.5 cm in diameter, which projects from the antimesenteric side of the ascending colon. The colon progressively diminishes in size toward the sigmoid colon, which is approximately 2.5 cm in diameter and is the narrowest portion of the colon. This size discrepancy accounts for the fact that cecal tumors often grow to be large and bulky before the onset of symptoms but sigmoid tumors are symptomatic at smaller sizes. In addition, tension on the bowel wall is directly proportional to the diameter of the bowel. This is explained by the law of LaPlace: $T = PR$, where T is tension in the wall of the bowel, P is internal pressure, and R is the radius of the bowel. Because the cecum has the largest diameter, it is usually the first part of the bowel to rupture as a result of distal obstruction.

The omentum is attached to the transverse colon on its anterior superior edge. The ascending colon, descending colon, rectum, and posterior surface of the hepatic and splenic flexures are fixed retroperitoneal structures. The cecum, transverse colon, and sigmoid colon are intraperitoneal and are prone to volvulus because of their location and relative lack of fixation.

The longitudinal muscle is an incomplete layer and is seen as three bands of muscle, called taeniae coli, located 120° apart around the circumference of the colon. The taeniae converge proximally at the appendix as distinct bands and disappear at the level of the sacral promontory. Haustra coli are sacculations between the taeniae and are separated by crescent-shaped folds called plicae semilunares. Appendices epiploicae are fatty appendages covered by peritoneum and have no anatomical or pathological significance.

The rectal wall consists of mucosal, submucosal, inner circular, and outer longitudinal muscular layers (Fig. 56.1). There is no serosal layer in the rectum. The rectum is approximately 12–15 cm in length and extends from the sigmoid colon to the anal canal, following the curve of the sacrum. The proximal rectum begins at the sacral promontory (third sacral vertebra), at which point the taeniae fan out to form a complete layer of longitudinal muscle.

The anal canal is approximately 4 cm long and appears as a collapsed anteroposterior slit in the normal patient (see Fig. 56.1). The anal verge is the junction between anal and perianal skin. Anal epithelium (anoderm) lacks hair follicles, sebaceous glands, and sweat glands. The dentate line is a true mucocutaneous junction located 1–1.5 cm above the anal verge. A 6–12-mm transitional zone exists above the dentate line, in which the squamous epithelium of the anoderm becomes cuboidal and then columnar epithelium. The columns of Morgagni are 8–14 mucosal folds located just above the dentate line that are surrounded by anal crypts. Small rudimentary glands open into some of the crypts. These glands go through the internal sphincter into the intersphincteric groove but do not penetrate the external sphincter. The anorectal ring is 1–1.5 cm above the dentate line and is the palpable upper border of the anal sphincter complex. The anatomical anal canal extends from the anal verge to the dentate line. The surgical anal canal extends from the anal verge to the anorectal ring.

Arterial supply

The superior mesenteric artery arises from the ventral surface of the aorta below the celiac axis, passes behind the pancreas, and crosses in front of the third portion of the duodenum

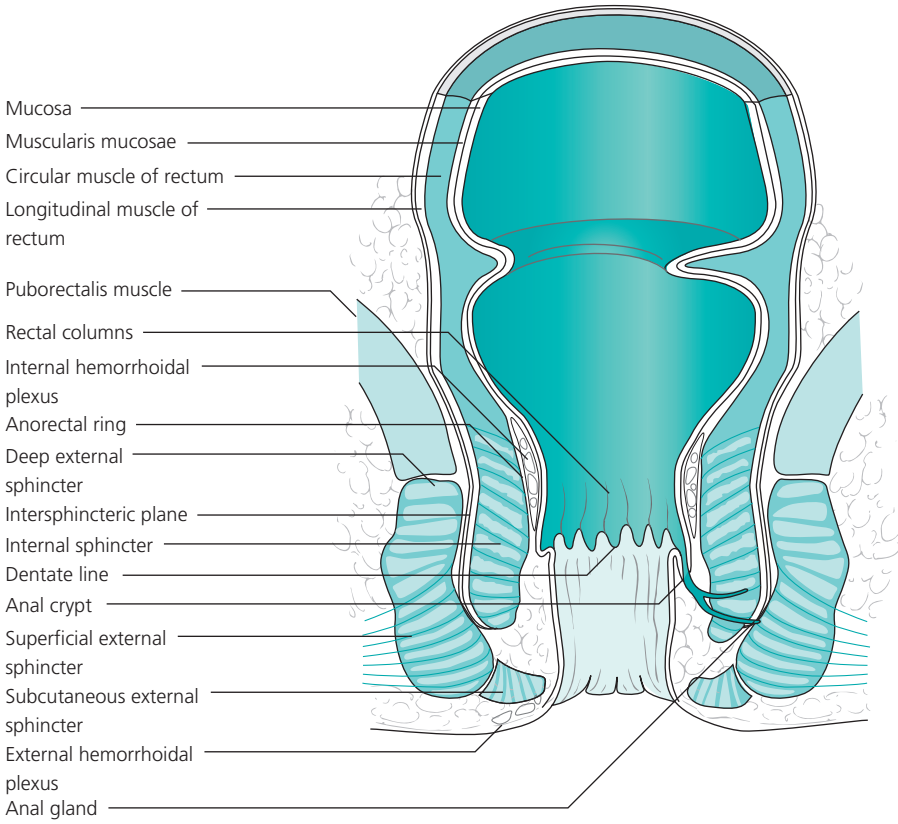

Figure 56.1 Anorectal anatomy. Illustrated by John A. Craig. From Clinical Symposia 1985;37/6.

(Fig. 56.2). The cecum, ascending colon, and transverse colon are supplied through its ileocolic and middle colic branches. Cadaver studies have shown that the right colic artery arises from the ileocolic artery in the majority of patients and from the superior mesenteric artery in less than 15% of patients [1]. The inferior mesenteric artery arises from the infrarenal aorta and supplies the descending colon, sigmoid colon, and upper rectum through its left colic, sigmoidal, and superior rectal branches.

Collaterals exist between the superior and inferior mesenteric arteries in the region of the splenic flexure [2]. The arcades of the ileocolic, right, middle, and left colic arteries are peripherally connected by the marginal artery of Drummond, which runs along the mesenteric border of the colon and provides the vasa recta to the colon. The arc of Riolan is a tortuous, inconstant vessel that exists between the left colic branch of the inferior mesenteric artery and the middle colic branch of the superior mesenteric artery. It is frequently referred to as the meandering mesenteric artery and is best seen if there is an occlusion of either the inferior or superior mesenteric artery.

The terminal branch of the inferior mesenteric artery becomes the superior rectal artery, which descends in the sigmoid mesocolon and bifurcates at the level of the third sacral vertebra (Fig. 56.3a). Branches of the superior rectal artery supply the upper and middle rectum. The middle rectal arteries arise from the internal iliac arteries, and the inferior rectal arteries are branches of the internal pudendal arteries. These arteries supply the lower two-thirds of the rectum [3]. The middle sacral artery arises just before the aortic bifurcation and provides little blood supply to the rectum. Anastomosis exists between the middle and superior rectal arteries; there are no anastomoses with the inferior rectal arteries. Preservation of the middle rectal arteries is necessary to maintain viability of the rectal stump after high ligation of the inferior mesenteric artery [3].

Venous drainage

The veins draining the colon follow the same course as the corresponding arteries except for the inferior mesenteric vein. The inferior mesenteric vein drains the descending colon, sigmoid colon, and proximal rectum and runs in a retroperitoneal location to the left of the ligament of Treitz, at which point it enters the splenic vein. The superior mesenteric vein drains the cecum, ascending colon, and transverse colon and joins the splenic vein to form the portal vein.

The venous drainage of the rectum enters the portal or systemic (caval) system. The upper and middle rectum are drained by the superior rectal vein, which enters the portal system through the inferior mesenteric vein (Fig. 56.3b). The

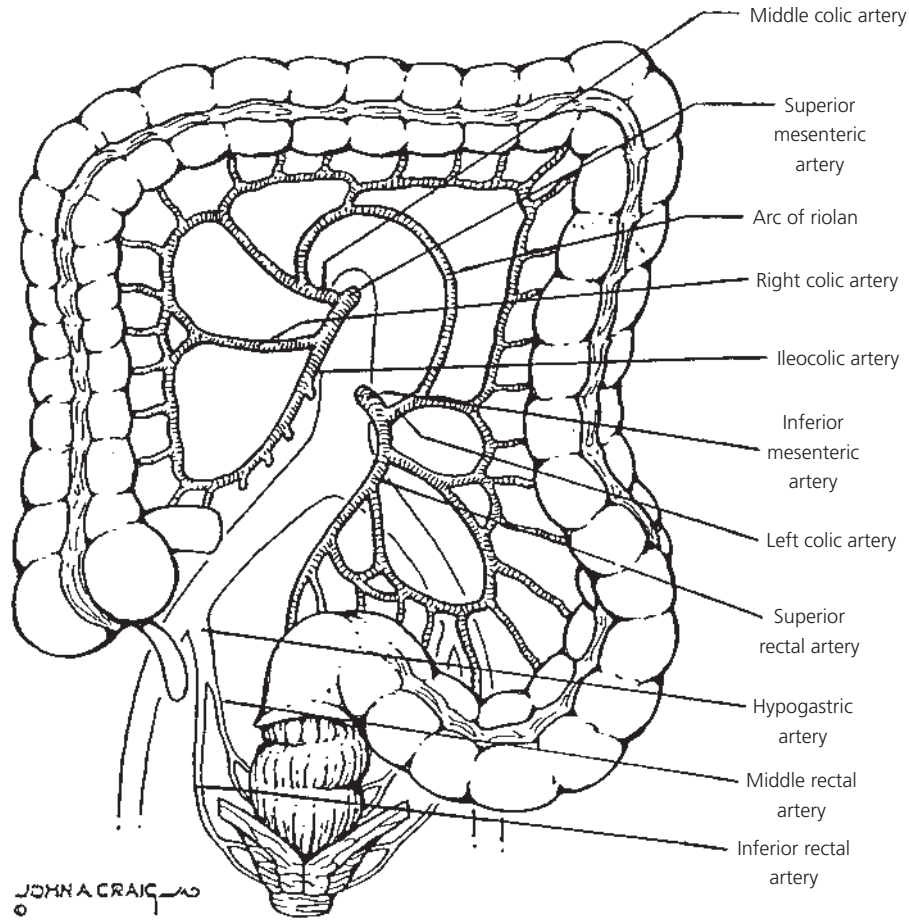

Figure 56.2 Arterial blood supply of colon and rectum. From Kodner IJ, Fry RD, Fleshman JW, Birnbaum EH. Colon, rectum and anus. In: Schwartz SI (ed.). Principles of Surgery, 6th edn. New York: McGraw-Hill, 1993, with permission from the McGraw-Hill Companies.

lower rectum and upper anal canal are drained by the middle rectal vein, which empties into the internal iliac veins and then into the caval system. The inferior rectal veins drain the lower anal canal and empty into the pudendal veins, which empty into the caval system through the internal iliac veins. Rectal tumors can metastasize through venous channels into either the portal or systemic venous systems.

Three submucosal internal hemorrhoidal complexes (normal hemorrhoidal tissue) are located above the dentate line. Hemorrhoidal tissue receives its blood supply from the superior, middle, and inferior rectal arteries. The left lateral, right posterolateral, and right anterolateral internal hemorrhoids drain into the superior rectal vein (Fig. 56.3b). The external hemorrhoids are located below the dentate line and drain into the pudendal veins. There is communication between the internal and external plexi, and mixed internal–external hemorrhoids result if these communications become engorged (see Chapter 66).

Lymphatic drainage

The colonic mucosa has rich vascular plexi but no lymphatics. Lymphatic capillaries encircle the colon in the submucosal and muscularis mucosae layers. This segmental architecture limits longitudinal intramural extension of tumors, and circumferential extension results in annular lesions. Lymphatic vessels follow the blood supply of the colon.

Lymph nodes are located on the bowel wall (epicolic), along the inner margin of the bowel (paracolic), around the named mesenteric arteries (intermediate), and along the origin of the superior and inferior arteries (main) (Fig. 56.4). Lymph from the upper and middle rectum drains into the inferior mesenteric nodes. The lower rectal lymphatics follow the superior rectal artery and enter the inferior mesenteric nodes. Lymph from the lower rectum can also flow laterally along the middle and inferior rectal arteries, posteriorly along the middle sacral artery, or anteriorly through channels in the rectovesical or rectovaginal septum [4]. These channels drain to the iliac nodes and subsequently to periaortic lymph nodes.

Lymphatics from the anal canal above the dentate line drain through the superior rectal lymphatics to the inferior mesenteric lymph nodes or laterally to the internal iliac lymph nodes. Below the dentate line, the lymphatics drain primarily to the inguinal nodes but they can drain to the inferior or superior rectal lymph nodes as well [4].

Nerve supply

The sympathetic and parasympathetic nerves to the colon follow the course of the blood vessels. Sympathetic nerves inhibit and parasympathetic nerves stimulate peristalsis. Sympathetic fibers to the right colon originate in the lower six thoracic segments and travel in the thoracic splanchnic nerves to the celiac plexus and then to the superior mesenteric plexus. The sympathetic supply to the left colon and rectum originates in the first three lumbar segments. These nerves join the preaortic plexus and become the inferior mesenteric plexus below the bifurcation of the aorta. The parasympathetic supply to the right colon is presumed to come from the right vagus. The parasympathetic nerves to the left colon ascend from the pelvis, pass through the sigmoid mesocolon, and spread out toward the sigmoid and the descending colon.

The rectum is innervated by both sympathetic and parasympathetic nerves [5]. Sympathetic nerves from thoracolumbar segments unite below the inferior mesenteric artery, forming the inferior mesenteric plexus, and descend to the superior hypogastric plexus below the aortic bifurcation. The nerves bifurcate and descend in the pelvis as the hypogastric nerves, supplying sympathetic innervation to the lower rectum, bladder, and sexual organs, in both males and females. Injury to the inferior mesenteric plexus can result during ligation of the inferior mesenteric artery at its origin.

Parasympathetic fibers from the second, third, and fourth sacral roots (the nervi erigentes) unite with the hypogastric nerves anterior and lateral to the rectum, forming the pelvic plexus [5]. The periprostatic plexus arises from the pelvic plexus. Mixed fibers from these plexi innervate the rectum, internal anal sphincter, prostate, bladder, and penis. The pudendal nerve (originating from the second, third, and fourth sacral nerves) mediates sensory stimuli from the penis or clitoris through the dorsal nerve. Damage to the periprostatic plexus may occur during dissection of the rectum. Injury to the pelvic autonomic nerves may result in bladder dysfunction, impotence, or both.

Below the dentate line, afferent fibers of the inferior rectal and perineal branches of the pudendal nerve convey cutaneous sensations of temperature, pain, and touch. Numerous free nerve endings make this area sensitive to sensations [6]. Above the dentate line, a poorly defined dull sensation, experienced if the mucosa is pinched or if internal hemorrhoids are ligated, is probably mediated by parasympathetic fibers.

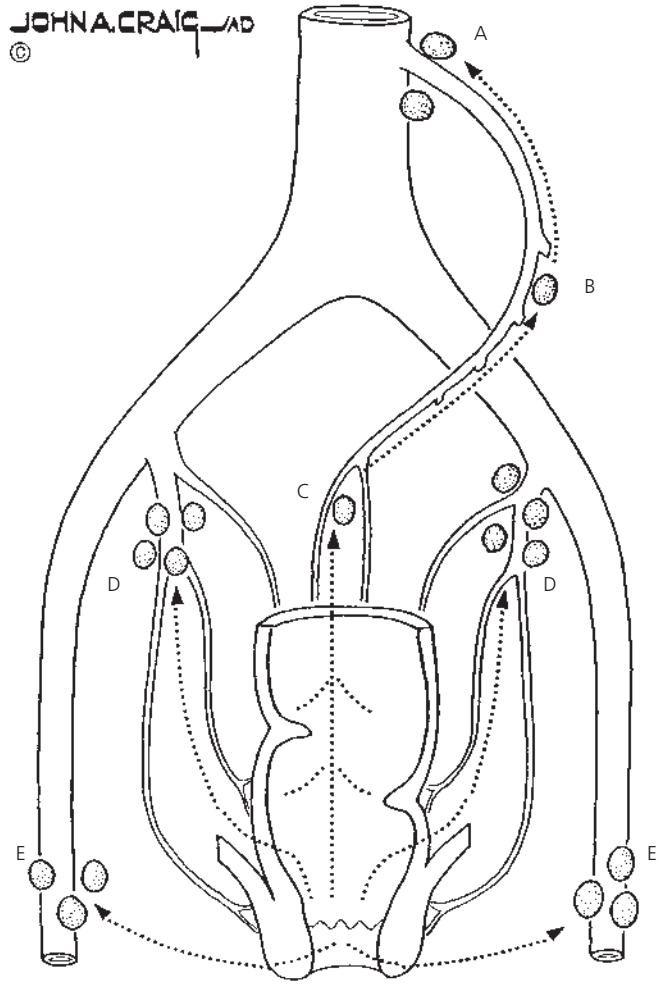

Figure 56.4 Lymphatic drainage of the rectum and anus. **(A)** Nodes at origin of inferior mesenteric artery; **(B)** nodes at origin of sigmoid branches; **(C)** sacral nodes; **(D)** internal iliac nodes; **(E)** inguinal nodes. Norwalk, CT: Appleton & Lange, 1989, with permission from the McGraw-Hill Companies.

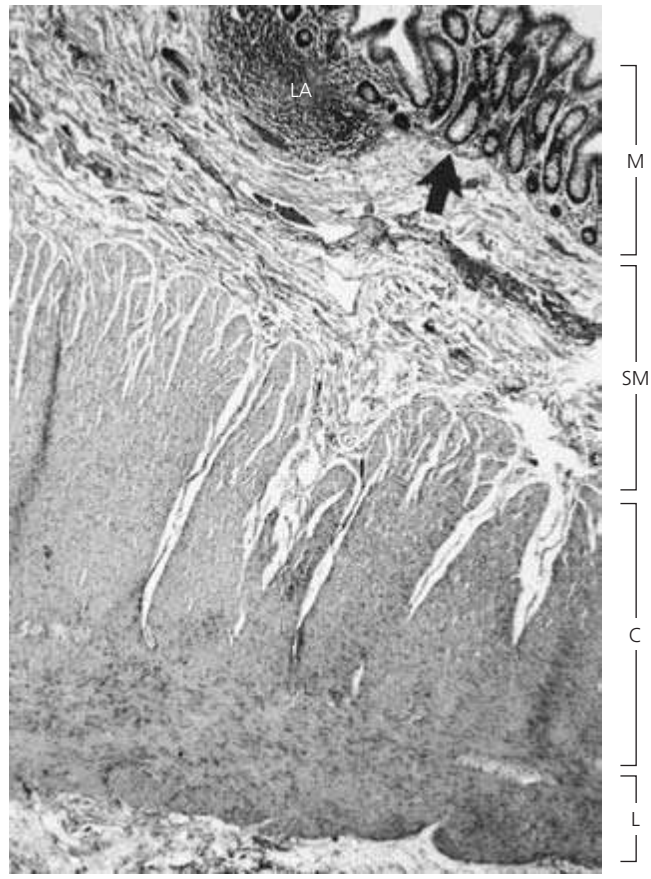

Figure 56.5 Anatomy of the colonic wall. The muscularis mucosae is indicated (arrow). C, circular smooth muscle layer; L, longitudinal smooth muscle layer; LA, lymphoid aggregate; M, mucosa; SM, submucosa. (Paraffin-embedded 4-μm H & E stained section, original magnification × 40.)

Histology

The colonic wall consists of mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa (Fig. 56.5). The colonic mucosa is similar in organization to the small intestine mucosa except that it lacks villi. The mucosa is lined by a simple columnar epithelium that forms straight tubular crypts that are about 0.5 mm in length (Fig. 56.6). The lamina propria extends from the simple columnar epithelium to the muscularis mucosae and contains many cells involved in immunological functions of the gut (see Chapter 7). Numerous immunoglobulin-secreting plasma cells, macrophages, and lymphocytes are present, in addition to abundant lymphoid nodules that often extend through the muscularis mucosae

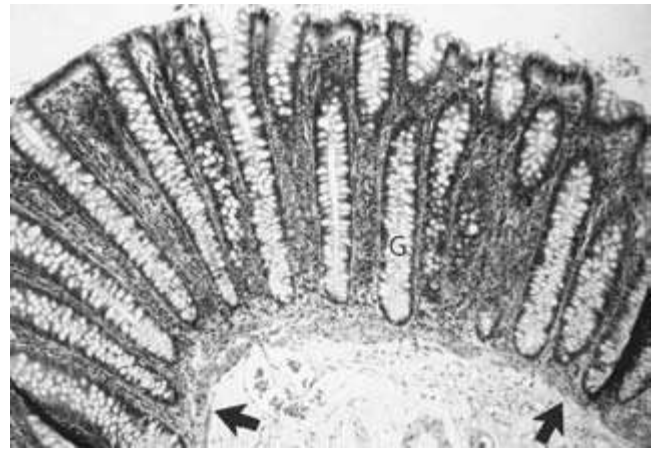

Figure 56.6 Histology of the colonic mucosa. Straight, simple colonic glands (G) extend from the muscularis mucosae (arrows) to the lumenal surface of the colon. Note the numerous small arteries, veins, and lymphatics coursing through the loose connective tissue stroma in the submucosa. (Paraffin-embedded 4-μm H & E stained section, original magnification × 100.)

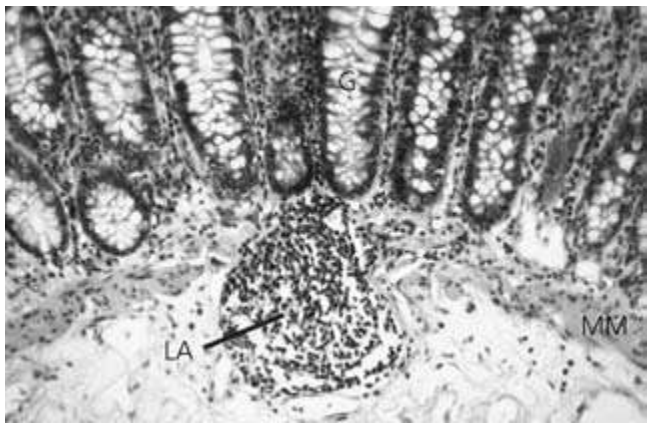

Figure 56.7 A lymphoid aggregate (LA) arises in the lamina propria and extends through the muscularis mucosae (MM) into the submucosa. (Paraffin-embedded 4-μm H & E stained section, original magnification × 200.)

into the underlying submucosa (Fig. 56.7). Subepithelial fibroblasts surround each crypt and produce the collagen table as well as many of the extracellular matrix components that underlie the basal lamina of the epithelium (Fig. 56.8). These fibroblasts and the extracellular matrix they secrete appear to have an important role in regulating cellular proliferation and differentiation within the overlying epithelium [7–11]. The submucosa contains numerous small veins, arteries, and lymphatic channels surrounded by loose connective tissue. The inner circular muscle fibers form a continuous layer around the colon. The outer longitudinal smooth muscle fibers are condensed into three bands (taeniae coli) equidistant around the circumference of the colon. Haustra are the bulging sacculations that form between adjacent taeniae coli. The serosa is a mesothelial-derived cell layer that covers the peritoneal surface of the colonic wall. Therefore, regions of the ascending colon, the descending colon, and the rectum that lie outside the peritoneal cavity have no outer serosal layer (see "Anatomy of the colon" above).

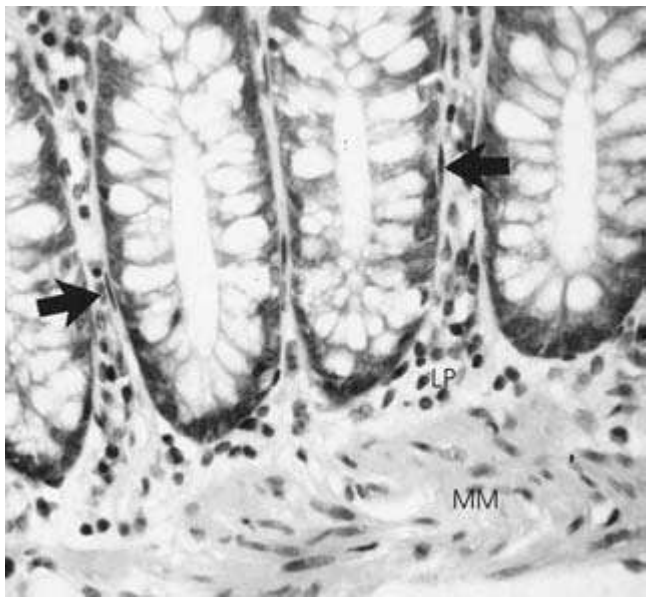

Figure 56.8 Colonic crypts. Note the subepithelial fibroblasts (arrows). Numerous plasma cells, macrophages, and lymphocytes are seen in the lamina propria (LP). MM, muscularis mucosae. (Paraffin-embedded 4-μm H & E stained section, original magnification × 400.)

The colonic epithelium undergoes continuous and rapid renewal; epithelial cells are sloughed from the flat lumenal surface of the colon and are replaced by replication of the descendants of epithelial stem cells located in the bottom one-third of each crypt. There are three principal differentiated epithelial cell types present in the adult colonic epithelium: absorptive colonocytes, goblet cells, and enteroendocrine cells. All these cell lineages appear to be derived from a common epithelial cell stem cell precursor. Undifferentiated cells, replicating cells, and enteroendocrine cells predominate near the base of each colonic gland (crypt) [12]. Cells belonging to each of the principal cell lineages differentiate during a highly ordered migration away from the zone of proliferation. The average life span of goblet cells and absorptive cells, from their birth deep in the crypt to the point where they are sloughed into the lumen, is approximately 6 days [13]. Some enteroendocrine cell subtypes appear to have a much longer life span, suggesting that their migration up the crypt to the surface epithelium must be uncoupled from that of adjacent epithelial cells [13]. The epithelial cell population of each small intestine or colonic crypt is derived from a single stem cell or, at most, a small number of stem cells [14–18]. Although the mechanisms that regulate epithelial cell renewal have yet to be fully elucidated, a number of peptide growth factors are emerging as important potential regulators of the dynamic balance between cell proliferation and cell loss in the intestinal and colonic epithelium (see Chapter 23) [19].

The principal function of absorptive columnar cells is the regulation of water and electrolyte content of the feces. The mature adult absorptive columnar cell in the colon absorbs sodium, chloride, and water; potassium and bicarbonate are secreted (see Chapter 14) [20]. In contrast to the enterocytes of the small intestine, however, colonocytes cannot absorb significant amounts of glucose or amino acids. Under normal conditions, lipid absorption is complete in the small intestine, but under pathological conditions in which lipid absorption in the small intestine is incomplete, the surface columnar cells of the colon have a limited capacity for uptake of fatty acids and subsequent packaging of them into chylomicrons [21]. As these cells differentiate during their migration up the crypt, they develop microvilli and clear, apically oriented vesicles containing a fibrillar, glycoprotein-rich secretory product that may contribute to the glycocalyx [21].

Goblet cells are flask-shaped cells with large apical vesicles that store and secrete mucus [22]. Mucus secreted by the goblet cell forms a viscous gel that functions as a lubricant

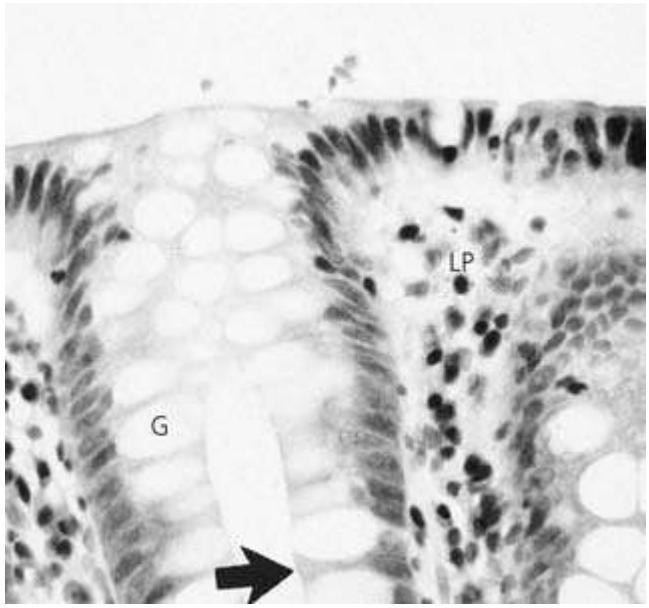

Figure 56.9 Surface epithelium of the colon. The mature absorptive columnar epithelial cells (arrow) lose their apical vesicles as they migrate into the upper regions of the colonic glands and emerge onto the lumenal surface. Goblet cells (G) elongate as they emerge onto the surface epithelium because of accelerated secretion of their mucus granules. LP, lamina propria. (Paraffin-embedded 4-μm H & E stained section, original magnification × 400.)

and also protects the surface epithelium against adherence of invading pathogens. Mucins are a family of large, sulfated glycoproteins that are synthesized in the rough endoplasmic reticulum (Fig. 56.9). Glycosylation and sulfation of these proteins occur posttranslationally in the Golgi apparatus. The composition of mucus shows regional variability along the cephalocaudal axis of the gut [22]. Mucus granules accumulate during the migration of goblet cells toward the lumenal surface of the colon, distending the apical aspect of the cell and giving it its broad, flask-like appearance. As goblet cells emerge onto the surface epithelium, the secretion of mucus occurs more rapidly, depleting the apically stored granules and causing the goblet cells to elongate (Fig. 56.9). Increased cholinergic stimulation can cause accelerated secretion of mucus from crypt-associated goblet cells, leading to deep invaginations of the apical surface. Certain components of mucus may become depleted in pathological conditions, such as ulcerative colitis (see Chapter 57).

Originally thought to be of neuroectodermal origin, the enteroendocrine cells found in the intestinal and colonic epithelium in fact arise from the same common stem cell precursor as the other principal cell lineages found in the gut epithelium. A number of different enteroendocrine cell types are found within the colonic epithelium [23,24], including:

- L cells, which contain both enteroglucagon and peptide YY (PYY)
- cells that secrete only PYY
- EC1 cells, which secrete serotonin, substance P, and [Leu]enkephalin
- pancreatic polypeptide-secreting cells
- rare somatostatin-secreting cells.

These enteroendocrine cells are characterized by their polygonal shape, their broad base, and the numerous membrane-bound secretory granules present in their basilar portions. Enteroendocrine cells are identified in pathological specimens using argentaffin or agyrophilic silver staining techniques or through immunohistochemical methods using antibodies to the particular neuroendocrine products stored in each enteroendocrine cell subtype. The narrow apical process of the enteroendocrine cell communicates with the lumen of the crypt and may serve to sense changes in the lumenal environment. Each enteroendocrine cell is joined to other adjacent cells in the epithelium through junctional complexes located near the apical pole [13]. The regulatory peptides or bioamine products stored in the basally located secretory granules are secreted through the basolateral membrane and act through paracrine or endocrine mechanisms as mediators of gastrointestinal secretion, absorptive function, and motility in response to lumenally or basolaterally derived signals (see Chapter 8). Enteroendocrine cells are more numerous in the appendix and the rectum than in the rest of the colon. This may explain, in part, the more frequent occurrence of certain subtypes of neuroendocrine tumors at these sites.

The appendix is similar in histological organization to the rest of the colon. The mucosa of the appendix consists of deep folds lined by a columnar epithelium forming simple tubular or forked glands [21]. This epithelium contains abundant goblet cells and enteroendocrine cells. Numerous lymphoid nodules are found in the lamina propria. The normal histological architecture of the adult appendix is often replaced by fibrous scar tissue as a result of subclinical bouts of appendicitis.

Colonic development

The primitive foregut, midgut, and hindgut develop during the fourth week in utero. The midgut lengthens, herniates out of the abdominal cavity, and rotates 90° counterclockwise around the superior mesenteric artery during the sixth week in utero. By the tenth week, the midgut rotates an additional 180° as it returns to the abdominal cavity. The cecum descends to the right iliac fossa, where it becomes fixed. The base of the small bowel mesentery then runs from the ligament of Treitz in the left upper quadrant to the ileocecal valve in the right lower quadrant [25,26].

The small intestine (distal to the entrance of the common bile duct), cecum, appendix, ascending colon, and proximal transverse colon all arise from the midgut and are supplied by the superior mesenteric artery. The distal transverse colon, descending colon, sigmoid colon, rectum, upper portion of

the anal canal, and part of the lower urogenital tract are derivatives of the hindgut and are supplied by the inferior mesenteric artery. The lower third of the anal canal is ectodermal in origin and is supplied by branches of the internal pudendal artery.

The cloaca is located at the distal end of the hindgut; by the end of the sixth week it is separated by the anorectal septum into a ventral urogenital sinus and a dorsal rectum [27]. The anal membrane covering the cloaca ruptures at the end of the eighth week, forming the anal canal. The dentate line is the approximate location of the transition from endoderm to ectoderm, at the junction of the upper two-thirds of the anal canal with the lower one-third.

The enteric nervous system forms during early fetal life. Neural crest cells, precursors of ganglion cells, migrate from cephalad to caudad during the first 12 weeks in utero [28]. The migration from the midtransverse colon to the anus takes 4 weeks to complete. Smooth muscle cells begin to appear within the mesenchymal layer around the tenth week of gestation. The developing circular muscle layer spreads cranially. The outer longitudinal bands of smooth muscle (taeniae coli) and haustra begin to appear between the 10th and 11th weeks of gestation [29]. By the 12th week of gestation, Auerbach and Meissner plexuses and the circular and longitudinal muscle layers of the colon are well formed, and colonic motility may be observed in isolated fetal colon as early as this developmental stage [29,30].

Failure of the neural crest cells to complete their cephalocaudal migration results in a congenital absence of the myenteric plexus in a distal segment of bowel and is thought to be the cause of Hirschsprung disease (see "Structural and congenital abnormalities" below). Qualitative differences in laminin and type IV collagen have been found in some patients with Hirschsprung disease, suggesting a potential role for abnormalities in fetal extracellular matrix components in the pathogenesis of this disease [31]. Studies using the (ls) mouse, a model for Hirschsprung disease, confirm the importance of mesenchymally derived nonneural crest cells in directing appropriate migration of ganglion cell precursors during normal embryogenesis [32,33]. A number of genes involved in the susceptibility and development of Hirschsprung disease have been identified. A recessive susceptibility locus for Hirschsprung disease that encodes the endothelin-B receptor has been mapped to human chromosome 13q22.3, and mutations of the mouse endothelin-B receptor or endothelin-3 ligand genes also result in aganglionosis and a megacolon phenotype [34–36]. Over 30 distinct missense and deletion mutations in the *RET* receptor tyrosine kinase gene located on human chromosome 10q11.2, distributed along the entire length of the receptor, have been identified in autosomal dominant forms of Hirschsprung disease [37–42]. Mutations of RET are found in approximately 10%–20% of sporadic cases and 50% of patients with a familial history of Hirschsprung disease [39–41]. Most RET mutations associated with Hirschsprung disease result in loss of receptor function [39]. Segregation analysis in a Mennonite family has indicated the existence of other major loci for susceptibility to Hirschsprung disease [34]. These findings confirm the multigenic nature of this disease.

The development of the colonic epithelium parallels that of the small intestine epithelium (see Chapter 46). At 8–9 weeks of gestation, the developing colon consists of a pseudostratified columnar epithelium several cell layers deep, with a slit-like lumen surrounded by mesenchymal tissue forming a simple tubular structure [43–45]. Epithelial ridges form between 10 and 11 weeks of gestation, giving the colonic lumen a stellate appearance. Small secondary lumens form at the base of the pseudostratified epithelium and subsequently extend to the primary lumen, resulting in the formation of broad primary villi. Between the 13th and 15th weeks of gestation, the formation of cyst-like spaces within these primary villi and the accompanying upward growth of mesenchymal tissue result in the division of primary villi into numerous secondary villi. During this developmental stage, epithelial cells near the bases of the primary villi undergo rapid proliferation and bud into the surrounding mesenchyme to form the developing colonic crypts. Numerous goblet cells, columnar epithelial cells with well-developed microvilli, and enteroendocrine cells can be observed in the epithelium by this time [23,46]. The fetal enteroendocrine cell population has been found to secrete a variety of neuroendocrine mediators, some of which may have important trophic effects on the developing epithelium. The mesenchymal tissue underlying the developing colonic epithelium appears to play a crucial role in the induction of appropriate regional differentiation in the gut epithelium [47,48–50].

Colonic villi are present through at least week 29 of gestation but are not found in the colon of full-term infants [46,52]. Prominent supranuclear inclusion bodies, originally termed meconium corpuscles, can be observed in the principal epithelial cells lining the fetal colon. These membrane-bound inclusion bodies are the result of apoptosis, emphasizing the role of programmed cell death in the morphological restructuring of the epithelium that occurs during fetal life [51]. During fetal life, the colonic epithelium is similar to the developing small intestine in its biochemical characteristics, including the expression of many brush-border hydrolases also found in the developing small intestine [43,52–55]. By full term, however, the activities of these brush-border hydrolases have declined to levels similar to those found in the adult colon.

Structural and congenital abnormalities

Congenital abnormalities of the intestine are common; most arise from errors in rotation or fusion of the mesenteries or from failure of neural crest cells to complete their migration

during fetal colonic development. Imperforate anus, duplication, and malrotation are usually identified in the neonatal period. Hirschsprung disease may present in the neonatal period, in childhood, or, more rarely, in the young adult.

Omphaloceles and gastroschisis

Abdominal wall defects are present at birth. Omphaloceles are identified by a mass of bowel and viscera in the central abdomen covered by a translucent membrane. The size of the defect varies, and it can be associated with other congenital anomalies. Gastroschisis is usually a small defect that occurs at the junction of the umbilicus and normal skin. Although no membrane covers the bowel, there are usually no associated anomalies. Both omphaloceles and gastroschisis require immediate surgery. Only in gastroschisis are reduction of the bowel and primary closure of the defect usually possible. If the bowel is edematous and thickened or the defect is too large to close primarily, a Silastic silo can be constructed to achieve gradual reduction of the bowel (see Chapter 46 for a more complete discussion).

Hirschsprung disease and congenital megacolon

Hirschsprung disease is a result of the failure of neural crest cells (precursors of ganglion cells) to complete their caudal migration during normal colonic development (see section "Colonic development" above). The aganglionic segment does not relax and causes a functional obstruction. The normal proximal bowel hypertrophies and eventually dilates. The rectosigmoid is involved in approximately 75%–80% of cases [56]. The entire colon and various lengths of small bowel are aganglionic in 5%–10% of cases [57]. A short aganglionic segment is the typical finding in adult Hirschsprung disease.

Delayed passage of meconium and abdominal distention are often the presenting symptoms in the newborn [58]. Chronic constipation, abdominal distention, volvulus, or perforation may be symptoms of the disease in a child. Hirschsprung disease in the adult is rare but must be considered in the evaluation of patients with chronic constipation dating back to childhood [59–62]. Patients with total colonic aganglionosis may present with less dramatic intermittent symptoms of constipation [57].

Digital rectal examination aids in the diagnosis. The rectal vault is empty in patients with Hirschsprung disease and is full of stool in patients with idiopathic megacolon. Abdominal radiographs usually show colonic dilation and a paucity of gas in the rectum. Barium enema may suggest the presence of a short, narrow segment or transition zone (Fig. 56.10). Patients with total aganglionosis or short segment Hirschsprung disease may have a normal-appearing barium enema. Newborns may have a normal-appearing barium enema because the proximal bowel has not had time to dilate.

Anorectal manometry may be useful in the evaluation of patients with suspected Hirschsprung disease but is difficult to perform in the newborn and is reserved for older infants and children. Typically a normal sphincter profile (resting pressure of 40–80 mmHg and squeeze pressure of 80–160 mmHg) and an abnormal rectoanal inhibitory reflex are seen in patients with Hirschsprung disease. The rectoanal inhibitory reflex is the normal relaxation of the internal sphincter in response to rectal distention. The internal sphincter does not relax in response to rectal distention in patients with Hirschsprung disease, and an abnormal reflex during manometry aids in the diagnosis [63,64]. This reflex is easily identified using anal manometry with a manometric catheter and a balloon to distend the rectum. When the rectal balloon is distended, the manometry tracing will reveal a normal external sphincteric contraction but no compensatory relaxation of the internal anal sphincter. The rectoanal inhibitory reflex may be normal in patients with short-segment Hirschsprung disease. These patients may have a short segment as their primary disease or the short segment may be residual disease after surgery. High anal resting pressures and impaired rectal emptying may be seen.

Histological evaluation is necessary to make the diagnosis of Hirschsprung disease. Hyperplasia or hypertrophy of nerve fibers can be seen, but ganglion cells are absent in the submucosa and myenteric plexus of these patients. Mucosal

Figure 56.10 Radiological study from a patient with Hirschsprung disease. The short, collapsed, aganglionic segment (arrows) is evident on this radiograph of a barium enema performed on a 28-month-old infant with constipation. The colon proximal to the aganglionic segment is often dilated and filled with stool.

pinch biopsy specimens are not adequate for diagnosis because sufficient submucosa must be present in the biopsy specimen to conclude that ganglion cells are absent. Suction biopsies are simple to perform, but the mucosa and submucosa must be identifiable to have an adequate specimen. Full-thickness rectal biopsy samples may be necessary for confirmation. Routine hematoxylin–eosin staining misses ganglion cells in almost 40% of normal patients [65]. Acetylcholinesterase staining has been found to be more accurate in identifying patients with Hirschsprung disease. Acetylcholinesterase-positive nerve fibers are increased in number in the lamina propria and muscularis propria in these patients. A positive diagnosis may be obtained even by evaluation of superficial suction biopsy samples.

Colostomies are usually performed after the diagnosis is made in newborns. This allows a period of stabilization and growth before definitive repair. A colostomy may be used in the older child or adult to allow hypertrophied bowel to resume a more normal caliber. Pull-through operations (Swenson technique, Duhamel procedure, or Soave procedure) have been devised to anastomose normally innervated bowel to the anus with or without resection of the abnormal bowel [58–61]. Intraoperative biopsy results must demonstrate the presence of ganglion cells at the level of the colostomy and the proximal margin of the colonic resection. Rectal myectomy may be curative in patients with short-segment Hirschsprung disease.

Intestinal duplications

Intestinal duplications are rare congenital anomalies that can occur anywhere along the gastrointestinal tract. There are many theories regarding the cause of intestinal duplication, including failure of the bowel to recanalize in utero, caudal twinning, and incomplete separation of the notochord from the entoderm. The resultant structures may either be tubular, communicating with the intestinal lumen, or, more commonly, closed cystic duplications. These cysts are lined with gastrointestinal mucosa and contain a layer of smooth muscle within their walls. Duplications are usually found on the mesenteric side of the intestine. They frequently share a common wall and blood supply with the involved bowel. All regions of the gastrointestinal tract may be involved; the esophagus and ileum are the most commonly involved sites. The colon and rectum account for 5%–10% of all gastrointestinal duplications [66].

Duplications are usually symptomatic during childhood. They can produce symptoms of obstruction, volvulus, or hemorrhage. Duplications in adults are often asymptomatic and may be discovered incidentally. They can be complicated by infection, bleeding, or malignant degeneration. Plain abdominal radiographs, barium enemas, and computed tomography (CT) scans may reveal soft tissue masses or the point of communication with normal bowel. Evaluation of the genitourinary tract should be performed to rule out associated anomalies.

Resection is indicated for rectal duplications because of the risk of neoplasia, even for asymptomatic duplications. Cystic duplications can often be excised. Dividing the common wall is the treatment for tubular duplications. Mucosal excision may be necessary if heterotopic gastric mucosa is present [66].

Malrotation

Malrotation occurs if the midgut fails to complete the 270° counterclockwise rotation as it returns from herniation (10–12 weeks of gestation) [26,67]. The base of the small bowel mesentery normally stretches from the ligament of Treitz in the left upper quadrant to the ileocecal valve in the right lower quadrant. In malrotation, the entire midgut and its vascular pedicle have a narrow-based mesenteric attachment in the right upper quadrant. The duodenojejunal junction (ligament of Treitz) comes to lie to the right of the spine. The cecum and right colon overlie the duodenum in the right upper quadrant, and Ladd bands form over the duodenum in an attempt to peritonealize the cecum. Associated anomalies, such as small bowel atresias, intussusception, Hirschsprung disease, and abdominal wall defects, have been reported in 30%–60% of patients [67,68].

Most infants present with evidence of malrotation within 1 month of birth [67,68]. The clinical picture is one of a high small bowel obstruction, volvulus, or ischemia. One should suspect the diagnosis in an infant with bilious vomiting and a flat abdomen. Bloody stools indicate vascular compromise. Less severe forms of malrotation can present in childhood or into adulthood.

Plain abdominal radiographs may show evidence of a complete gastric or duodenal obstruction with a paucity of gas in the distal small bowel. A barium upper gastrointestinal series shows the ligament of Treitz to the right of midline. A barium enema is rarely needed, but it may demonstrate the cecum in the right upper quadrant.

The treatment of malrotation is operative. Most neonates with an obstruction from malrotation have a midgut volvulus [68]. The volvulus is reduced by untwisting it in a counterclockwise rotation [69]. Ladd bands overlying the right colon and duodenum are lysed. The duodenum is placed in the right upper quadrant and the cecum in the left upper quadrant. An appendectomy is performed because the alteration in anatomy would make future diagnosis of appendicitis difficult [68].

Imperforate anus

Imperforate anus occurs in 1 in 20 000 live births and is associated with other congenital anomalies in 50% of cases. Genitourinary anomalies and sacral abnormalities are frequently seen. Cardiac and gastrointestinal anomalies (primarily esophageal atresia) are also associated with imperforate anus.

Imperforate anus is classified according to the relationship of the rectum to the levator ani muscles [70]. High lesions are those in which bowel of normal or greater caliber terminates above the levator muscle complex. The rectum often ends in the prostatic urethra in males. In low lesions, the rectum terminates distal to the levators, often ending in a fistula. Low lesions are more common in females. Fistula tracts may connect the distal rectum with the perineum, vagina, or other hollow organs. Intermediate lesions are found within the levator complex and may be associated with a partial anal canal or perineal fistula.

The diagnosis is usually made by physical examination at birth. Most infants with imperforate anus fail to pass meconium at birth unless a fistula is present. Radiography can be used to determine the type of defect. Air invertograms can be used to identify the location of the rectum in relation to the perineum but are difficult to interpret. Fistulography may be performed, and CT and magnetic resonance imaging (MRI) are useful in evaluating high lesions. The urinary tract should be evaluated with an intravenous pyelogram and voiding cystourethrogram because of the associated urogenital anomalies.

Treatment depends on the type of lesion [70]. Low lesions can be treated by dilation of fistula tracts with or without anoplasty. Most healthy infants with low lesions do not require colostomies. Intermediate and high lesions are treated with an initial diverting colostomy to allow a period of stabilization and growth. A number of pull-through operations have been advocated. The posterior sagittal approach developed by Peña and deVries [71] identifies and divides the levator muscle complex. The rectal segment is then identified and brought through the center of the divided muscles. A coloanal anastomosis is performed in the location of the anal dimple. Most series have claimed a 70%–82% success rate with intermediate and high lesions [72]. A greater success rate can be expected with low lesions.

Volvulus

Volvulus occurs whenever an air-filled segment of bowel twists about its mesentery; it almost never occurs if the colon is filled with solid stool. A dilated, redundant colon with a narrow-based mesocolon is a prerequisite for colonic volvulus. In the United States, fewer than 10% of colonic obstructions are caused by colonic volvulus. In countries with high-fiber diets, volvulus has been reported as the most common cause of intestinal obstruction [73]. Volvulus is classified and treated according to its location in the colon.

Sigmoid volvulus accounts for approximately 60% of all volvulus seen in the United States [74]. It usually occurs in older adult or institutionalized patients or in patients with various neuropsychiatric disorders. Chronic constipation, laxative abuse, and colonic atony have been implicated as the causes of the dilated, redundant sigmoid colon.

Patients usually present with abdominal pain, distention, and obstipation. Evidence of peritoneal irritation on physical examination, fever, or an elevated leukocyte count indicates gangrenous bowel. Plain abdominal radiographs showing an inverted, U-shaped, sausage-like loop with a dense line running toward the point of torsion are diagnostic for sigmoid volvulus. In questionable cases, radiological enema examination with barium or with water-soluble contrast may be diagnostic. The "bird's beak" deformity forms where the contrast tapers to a point at the site of obstruction (Fig. 56.11). Reduction of the volvulus can occur during these examinations. If the patient has signs of peritoneal irritation or gangrene is suspected, barium or Gastrografin enema (Bracco Diagnostics, Inc., Princeton, NJ) should not be attempted, and the patient should undergo emergency exploration.

If peritonitis is not present, sigmoidoscopy should be performed. Inserting a soft rectal tube past the point of obstruction can often reduce the volvulus. This results in dramatic decompression, and the rectal tube is left in place to assist with further decompression. Volvulus beyond the limits of the rigid sigmoidoscope may be reduced by flexible sigmoidoscopy or colonoscopy [75]. A 43% recurrence rate after nonoperative reduction can be expected [76]. Therefore, after reduction, medically stable patients should undergo mechanical bowel preparation and an elective resection. Evidence of mucosal ischemia, bloody discharge, or unsuccessful detorsion indicates strangulation and possibly gangrene. If this occurs, sigmoidoscopy should be terminated,

Figure 56.11 Sigmoid volvulus. Hypaque enema shows tapering of the column of contrast at the site of torsion ("bird's beak" sign) of the sigmoid colon.

and the patient should undergo an emergency exploration. Mortality is related to the presence of gangrenous bowel [76].

Cecal volvulus accounts for less than 20% of all cases of colonic volvulus and is generally seen in younger patients [75]. It is thought to be caused by anomalous fixation of the right colon, leading to a freely mobile cecum [77]. Other precipitating factors include adhesions from previous surgery, pregnancy, and obstructing lesions of the left colon. Ninety percent of patients with cecal volvulus have a full axial volvulus twisting the associated mesentery and blood vessels [73]. In the remaining patients, the cecum folds in an anterior cephalad direction (cecal bascule). The cecal bascule is not a true volvulus around a mesentery, but gangrene can result from tension on the bowel wall.

Abdominal pain, nausea, vomiting, and obstipation are common symptoms of cecal volvulus. Patients with cecal volvulus appear clinically to have a small bowel obstruction. Many patients give a history of similar, chronic, intermittent symptoms [73]. A plain abdominal radiograph may show the cecum as a kidney-shaped, air-filled structure in the left upper quadrant. Multiple air-filled levels may be seen and indicate a distal small bowel obstruction. Radiological examination with barium or with a water-soluble contrast enema may show obstruction of the column of contrast at the level of the volvulus. The tapered edge of the contrast points toward the site of torsion. Barium studies should not be routinely performed if the diagnosis is clear. Colonoscopy has been used to treat cecal volvulus, but with limited success, and should rarely be attempted [75,78].

Operative detorsion alone, cecopexy, and cecostomy are associated with variable rates of recurrence [73,79]. Right hemicolectomy with primary anastomosis or cecopexy and cecostomy is recommended if there is no evidence of gangrenous bowel. Resection, ileostomy, and mucous fistula are indicated if there is evidence of gangrene. Mortality is increased in the presence of gangrenous bowel.

Volvulus of the transverse colon is rare because the mesentery is short and broad-based. Failure of the mesentery to fuse normally or narrowing of the mesenteric attachments may predispose the transverse colon to volvulus. Patients present with a clinical picture of large bowel obstruction. Barium enema is diagnostic and reveals the point of obstruction. Although successful attempts at colonoscopic detorsion have been reported, most patients require operative detorsion and resection of the redundant transverse colon [80,81].

Surgically altered anatomy

Many diseases of the colon and rectum will require surgery. In general, surgery of the colon and rectum involves a segmental resection of the colon and the restoration of intestinal continuity. However, when the restoration of intestinal continuity is either not possible or desirable, a surgical ostomy may be created. These procedures will alter normal anatomy. An understanding of surgically altered anatomy is important as physicians treat patients who have had previous colon and rectal surgery.

Right colectomy

A *right colectomy* involves the resection of the proximal one-third to one-half of the intraabdominal colon. The resected specimen will include the ileocecal valve, a variable length of ileum, and the appendix. Ligation of the ileocolic and right colic arteries is nearly always performed. A surgical anastomosis is then created between the ileum and the transverse colon.

Colonic neoplasia is the most common indication for a right colectomy. Tumors involving the cecum or ascending colon are treated with a standard right colectomy. To ensure the complete removal of the associated lymphatics, the ileocolic and right colic vessels are ligated at the origin of the superior mesenteric artery. However, tumors located at the hepatic flexure will also have lymphatic drainage associated with the middle colic artery. Under these circumstances an *extended right colectomy* is performed, which includes ligation of the ileocolic, right colic, and middle colic arteries at their origins, requiring additional resection of the transverse colon. The blood supply of the remaining colon is provided solely by the inferior mesenteric artery.

Crohn's disease is the most common benign indication for removal of a portion of the right colon. Because the terminal ileum is usually involved, a variable length of terminal ileum is resected in addition to a portion of the right colon, usually the cecum. Because more ileum is resected than with a standard right colectomy, this resection is termed an *ileocolic resection.* Ligation of the colonic vessels can be done closer to the colon, because removal of the associated lymphatics is not necessary with benign disease.

Left and sigmoid resection

A true *left colectomy* involves the complete resection of the descending and sigmoid colon as well as the distal one-third to one-half of the transverse colon. The left colic and superior rectal arteries are ligated and the transverse colon is then anastomosed to the top of the rectum. The most common indication for a left colectomy is colonic neoplasia. To ensure adequate lymphatic removal, the inferior mesenteric artery may be ligated at the aorta.

A *sigmoid resection* involves just the sigmoid colon. The superior rectal artery is ligated and the distal descending colon is anastomosed to the top of the rectum. For cancer, ligation of the superior rectal artery is done just distal to the takeoff of the left colic artery, whereas for diverticulitis the vasculature can be ligated closer to the colon.

Low anterior and abdominal perineal resection

A *low anterior resection* is generally performed for a neoplasia involving the upper and middle thirds of the rectum. The

inferior mesenteric artery is ligated just distal to the takeoff of the left colic artery, and the descending colon is anastomosed to the rectum. For tumors of the upper third, about one-half of the rectum is resected. However, for tumors of the middle and lower thirds the entire rectum and the associated mesorectum is removed, leaving intact, when possible, the anal sphincter mechanism. A hand-sewn or stapled anastomosis is then performed. When the tumor invades the anal sphincter than an *abdominal perineal resection* (APR) is performed. Under these circumstances, the rectum is resected as described above and then the anus is also completely removed using a wide elliptical excision. A permanent end colostomy is then created using the descending colon.

Total proctocolectomy

A *total proctocolectomy* involves the simultaneous removal of the entire colon and rectum. The most common indication is chronic ulcerative colitis. Other indications include familial adenomatous polyposis (FAP) and Crohn's colitis. Often, the anus is also resected and a permanent end ileostomy is created.

In selected patients who do not want a permanent ileostomy, an *ileal pouch anal anastomosis* (IPAA) can be performed. This is most commonly performed using a stapling technique. The distal rectum is transected, using a transverse stapling device, about 1–2 cm above the anal sphincter. A 20-cm J-pouch is created from the terminal ileum and then a stapled end-to-end anastomosis is performed. When performed in this way it is important to understand that about 1–2 cm of rectal mucosa is left in situ. This mucosa is susceptible to the development of rectal cancer [82]. Therefore, continued surveillance is necessary. A *mucusectomy* can be performed to remove the last 1–2 cm of rectal mucosa. When this is done then a hand-sewn anastomosis must be performed. A mucusectomy is technically more difficult and the functional results of the pouch may be inferior [83,84]. Therefore, a stapled technique is far more common and, although controversial, is even performed for FAP [84,85]. More importantly, a mucusectomy does not completely remove the risk of developing subsequent rectal cancer, so continued surveillance may still be necessary [86,87].

Anastomoses

Once a portion of intestine has been removed, intestinal continuity is restored by reconnecting the two ends of the intestine, thus creating a surgical *anastomosis*. Although the purpose of all intestinal anastomoses is the same, there are several different techniques used for their construction. A general understanding of these techniques can be helpful when trying to interpret the endosocopic or fluoroscopic appearance of an anastomosis.

Originally all intestinal anastomoses were hand sewn, using a variety of suture materials. Over the past several decades surgical stapling devices have been introduced, and many anastomoses are created with a combination of linear and circular staplers. Although stapling is generally quicker than hand sewing an anastomosis, there is no evidence to suggest staplers create a more secure anastomosis [88,89]. Anastomotic leaks, although uncommon, still occur in about 3%–15% of patients having a colectomy and seem to be independent of surgical technique. Therefore, the choice of sewing or stapling is a surgeon's preference. Regardless of the technique, it is not uncommon to visualize endoscopically either suture material or staples at an anastomotic site. Staples are nonreactive and therefore cause little surrounding inflammation of the mucosa. However, permanent suture material, especially silk, can be reactive and cause mucosal inflammation around the anastomosis, which can be easily misinterpreted as recurrent disease [90].

When the two ends of the intestine are directly connected, either by staples or suture, the anastomosis is referred to as an *end-to-end anastomosis*. Similarly, when the two pieces of intestine are laid side by side and then connected in this manner the anastomosis is referred to as a *side-to-side* or *functional end-to-end anastomosis*. End-to-end anastomoses are more common on the left-hand side (e.g., left colectomy, sigmoid colectomy, low anterior resection) whereas side-to-side anastomoses are more common on the right-hand side (ileocolectomy, right colectomy). Endoscopically, an end-to-end anastomosis can be subtle and difficult to detect. However, a side-to-side anastomosis is generally recognizable because the lumen of the intestine will take a sharp turn. In fact, it can often be difficult to intubate the anastomosis when they are constructed in a side-to-side fashion. This can easily be misinterpreted as a stenotic anastomosis. When there is doubt about the patency of a side-to-side anastomosis, a barium enema can be extremely helpful.

Although schematic drawings of anastomoses are precise it is important to remember that an actual anastomosis may not have an ideal appearance. Not uncommonly, a real anastomosis has numerous "nooks and crannies" because overlapping of staple lines can cause distortions. Therefore, endoscopy of an anastomosis must be done carefully to ensure that all of the mucosa in the various "nooks and crannies" has been adequately visualized.

Colostomy, ileostomy, and mucus fistula

Although the restoration of intestinal continuity is desirable it is not always possible. Under these circumstances, a surgical ostomy is created to divert the fecal stream. An *ileostomy* refers to stomas created using the ileum, whereas a *colostomy* is constructed using the colon. Ostomies are frequently performed during emergency colon surgery, such as perforated diverticulitis, when the creation of a primary anastomosis is considered dangerous. Generally, the diseased portion of the colon is resected, the end of the proximal colon is pulled through the rectus sheath, and a surgical colostomy is

created at the skin level. The distal segment is closed and left in situ as a *Hartmann pouch.* Because the Hartmann pouch is in continuity with the anus, any residual stool or mucus can readily pass. However, under circumstances when the distal colon or rectum is completely obstructed, decompression of the Hartmann pouch through the anus is not possible and residual stool or mucus can leak through the proximal end of the pouch, leading to life-threatening sepsis. Therefore, in the presence of complete distal obstruction, the surgeon may chose not to close the Hartmann pouch but instead to pull also the proximal portion of the pouch through the abdominal wall and open the colon at the skin level. This will allow the obstructed Hartmann pouch to decompress. This is referred to as a *mucus fistula*, because mucus will continue to drain from this opening.

Most colostomies and ileostomies are *end ostomies*, because the end of the ileum or colon is used to create the surgical opening. On examination of an end ostomy only one lumen should be present. However, *loop ostomies* are also commonly constructed. Loop ileostomies and colostomies are most commonly created when fecal diversion is desired but the distal intestine remains in continuity with the anus. Common clinical examples include perineal sepsis from Crohn's disease or a distal obstructing rectal cancer, when fecal diversion is necessary but a primary resection is not desirable. Under these circumstances, a loop of proximal intestine is pulled through the rectus sheath. The intestine is then opened and secured to the skin, creating the stoma. Examination of a loop colostomy or ileostomy should demonstrate two lumens; the proximal one allowing for the egress of stool and the distal opening allowing for the decompression of the distal intestine, similar to a mucus fistula.

An understanding of surgically altered anatomy is critical in treating patients with previous colon and rectal surgery. A basic understanding of common surgical procedures should help the treating physician, especially during endoscopic evaluation. If a second colonic surgical procedure is necessary a precise understanding of the existing anatomy is imperative to ensure adequate blood supply for the remaining colon and a successful outcome. Although most surgical procedures are performed in a similar fashion the details of any procedure can only be ascertained by the actual operative notes. Obtaining these records can be extremely helpful in delineating the altered anatomy of any given patient.

Functional results

Because the primary purpose of the colon is water absorption, partial resection of the colon can alter daily function. Fortunately, in most patients, a segmental colonic resection does not significantly alter clinical function. Up to 75% of the abdominal colon can be resected with little impact. However, complete removal of the abdominal colon with an ileorectal anastomosis will alter daily function. Patients having this operation can expect approximately five loose bowel movements per day [91]. Because the rectum has been preserved there is little urgency or incontinence [91]. Furthermore, other complications associated with rectal dissection, such as impotence and infertility, are generally avoided.

Nutritionally, segmental colon resection has little long-term impact on patients. However, with both right colectomy and ileocolectomy, a variable length of ileum is also resected. When done for cancer only about 5–10 cm of terminal ileum is removed, which is generally not enough to cause nutritional deficiencies. However, for Crohn's disease the length of the terminal ileum resection is highly variable, depending on the extent of disease. This can have an impact on vitamin B-12 absorption and may result in the sequelae of vitamin B-12 deficiency [92,93]. In addition to vitamin B-12, bile salt absorption can also be impaired and may contribute to the postoperative diarrhea often seen in patients with Crohn's disease who have had an ileocolic resection [94].

In contrast to segmental colon resection, removing the rectum does have a functional impact on the patient. The rectum is an effective storage device. Stool can be stored in the rectal vault and most people can defer the call for evacuation until an appropiate time. However, after the rectum has been resected, as is done with a low anterior resection, a neorectum is created using intraabdominal colon. Unfortunately, the neorectum has less storage capacity, which often results in urgency, increased stool frequency, and occasional incontinence. Collectively this has been referred to as the anterior resection syndrome [95]. There can be functional improvement for up to 1 year after the operation, but rarely does function return to preoperative levels. Because of these functional difficulties some surgeons create a small colonic J-pouch or perform a coloplasty to increase neorectal capacitance [95,96]. Although short-term results seem better with these techniques, long-term results appear to be similar to the straight low anterior resection [97,98]. Even with suboptimal results, most patients still prefer to have their intestinal continuity restored if the only other option is a permanent colostomy. However, in frail elderly patients or in patients who have preoperative incontinence, the low anterior syndrome may be debilitating and, therefore, a colostomy may be more appropriate.

In addition to affecting gastrointestinal function, rectal resection can be associated with a number of other functional issues. The pelvis contains numerous sympathetic and parasympathetic nerves, damage to which can cause both sexual and urinary dysfunction. Men are at risk for impotence or retrograde ejaculation whereas woman may have dyspareunia [99,100]. The rates of these problems increase considerably with age and are more common in patients with cancer, who often receive pelvic irradiation as well [101]. Fortunately, sexual dysfunction in young men with benign disease remains uncommon [99]. In addition to dyspareunia, women who have had rectal surgery have a higher rate of infertility [102,103]. This seems to be secondary to pelvic

adhesions, because assisted reproduction is still possible. In light of these potential devastating side effects, rectal resection should be avoided until it is clearly medically indicated.

Total proctocolectomy with an IPAA is an effective treatment for patients with severe chronic ulcerative colitis. Following this procedure patients can expect about 6–7 loose bowel movements per day. Not infrequently nighttime evacuation may be necessary. Although continence is generally good, some patients will experience leakage and incontinence. This is more common at night when patients are sleeping [104]. Ironically, because most patients who have this surgery have severe ulcerative colitis, this level of function is a considerable improvement and enhances their quality of life [105,106]. Patients who have normal preoperative function, such as those with FAP, are less pleased with the functional results [107], but still prefer this procedure to the alternative, which is a permanent ileostomy. Because a total proctocolectomy does include the rectum, patients are at risk for the associated complications of rectal dissection, such as sexual dysfunction and infertility (see above). Interestingly, because of the severity of the patient's disease, there may actually be an overall improvement in sexual activity, although a small number of patients do experience true sexual dysfunction [99,100,108].

Ulcerative colitis and Crohn's disease, chronic inflammatory diseases of the gastrointestinal tract, are identified and diagnosed by the appearance of a set of clinical endoscopic, and histological characteristics [1–3]. The inflammatory response in ulcerative colitis is largely confined to the mucosa and submucosa, but in Crohn's disease inflammation extends through the intestinal wall from mucosa to serosa. Ulcerative colitis is confined to the colon, and colectomy is a curative procedure. Crohn's disease, in contrast, has the potential to involve the patient's entire gastrointestinal tract, even through only a small segment is involved initially. Resection of the inflamed segment is not curative in Crohn's disease, and inflammation is likely to recur in the gastrointestinal tract sometime after resection. Despite these differences in distribution, no single finding is absolutely diagnostic of one disease or the other. Moreover, a group of patients, accounting for 5%–15% of those with inflammatory bowel disease (IBD), have characteristics of both diseases and cannot be cleanly classified; these patients are considered to have indeterminate colitis.

The genetic basis of these diseases is being elucidated. Both appear to be multigenic diseases. Patterns of familial aggregation suggest that the genetic influences at least partially overlap. Relatives of patients with each disease have an increased risk of that particular disease as well as of the other form of IBD [4]. Consequently, not only is there an increased incidence of Crohn's disease in relatives of those with Crohn's disease but their relatives also have an increased incidence of ulcerative colitis. This pattern holds for patients with ulcerative colitis as well.

In view of the similarities in clinical and histological presentation and the shared genetic background, these two diseases are presented in a single chapter. In the absence of established etiological agents or definitive markers, it is possible that what is designated as ulcerative colitis or Crohn's disease may in fact be a mixture of diseases with diverse causes but a common clinical presentation. Actually, more than two diseases may exist under the name of inflammatory bowel disease. Presentation in a single chapter emphasizes the common characteristics of these diseases and minimizes splitting them into groups that may not be valid. This combined presentation allows the areas of similarity to be detailed without repetition and allows comparisons in areas of dissimilarity.

Epidemiology

The incidence and prevalence of Crohn's disease (1–6 and 10–100/100 000, respectively) and of ulcerative colitis (2–10 and 35–100/100 000, respectively) vary greatly with geographic location. These rates are for Caucasian populations in northern Europe and North America. The countries of greatest incidence and prevalence encompass the industrialized world. Rates in central and southern Europe are somewhat lower. In South America, Asia, and Africa these diseases remain uncommon but appear to be increasing. Within geographic areas, ethnic and racial variations exist in the incidence of IBD [5]. Crohn's disease is three to eight times more common in Jewish than in non-Jewish persons. Similarly, the incidence of ulcerative colitis is two to four times higher among Jews. The incidence among Israeli Jews, however, is much lower than among American and European Jews. Furthermore, in Israel the incidence is lower among Sephardic or Oriental Jews of Asian or African origin than among Ashkenazi Jews of European or American origin [5]. In the United States, the incidence of both ulcerative colitis and Crohn's disease in the African-American population has

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

been one-fifth to one-half that in the Caucasian population, but in recent years that gap appears to be narrowing [6].

Some of the apparent increases in incidence of IBD over time may reflect greater awareness of these diseases, better diagnostic studies, and improved reporting. Moreover, some patients diagnosed as having Crohn's colitis may have been diagnosed as having ulcerative colitis in the past. Despite these ambiguities, certain trends are apparent [7,8]. In geographic areas where the incidence of these diseases has been slight, it is increasing. In northern Europe and North America, where the incidence of both diseases has been substantial, the incidence of ulcerative colitis has leveled, but that of Crohn's disease is still increasing.

The peak age of onset for both diseases is between 15 and 25 years. In some but not all series, a second, lesser peak of incidence occurs between 55 and 65 years [6]. Both diseases occur in childhood, although the incidence is much lower before the age of 15 years than after. Ulcerative colitis is more common than Crohn's disease in children younger than 10 years. Most series show an approximately equal incidence of both diseases in males and females, but other studies show an incidence of Crohn's disease that is greater in females by up to 30% and an incidence of ulcerative colitis that may be greater among males [6]. These gender differences of disease distribution may represent confounding environmental factors such as use of tobacco. The similarities between ulcerative colitis and Crohn's disease in geographic distribution, racial and ethnic distribution, distribution by sex, and age of onset support the contention that the two diseases are related.

One fascinating but unexplained difference between patients with these two diseases is the incidence of smoking. Among patients with ulcerative colitis, the incidence of smoking is less than that in the general population. In several studies, the risk of developing ulcerative colitis was increased among nonsmokers compared with current smokers and increased even further among former smokers compared with lifetime nonsmokers [9–12]. Quitting smoking can provoke the emergence of ulcerative colitis, although this is still much less of a risk than smoking on overall health [13,14]. In contrast, the incidence of smoking among patients with Crohn's disease is higher than in the general population [10]. Smokers have a more severe course of Crohn's disease, require more immunosuppressive medications, and demonstrate a faster recurrence after surgery [15,16]. Cessation of smoking may moderate the clinical course although the greatest benefit of cessation is seen with the heaviest smokers [17]. The active ingredients in cigarette smoke that increase the risk of Crohn's disease or decrease the risk ulcerative colitis have not been defined, nor have mechanisms of action. On the assumption that nicotine is the active ingredient in cigarette smoke, trials of transdermal nicotine and nicotine gum for the treatment of ulcerative colitis have been performed; in two trials transdermal nicotine was somewhat effective [18,19].

Appendectomy strongly protects against the development of ulcerative colitis, while not having any influence on Crohn's disease [20]. This effect in ulcerative colitis is noted particularly when appendectomy is performed for an inflammatory problem, such as lymphadenitis or appendicitis and if done before the age of 21 years [21]. Poor sanitation in childhood is a protective factor against the development of Crohn's disease, although not against ulcerative colitis [22,23].

Etiology and pathogenesis

Genetics

Any theory of the pathogenesis of IBD must deal with the evidence for a genetic basis of the disease. The most firmly established and quantitatively greatest risk factor for developing IBD is a positive family history [24]. Approximately 15% of patients with IBD have first-degree relatives who also have IBD [25]. The lifetime risk of developing IBD among first-degree relatives of affected individuals is 8.9% for offspring, 8.8% for siblings, and 3.5% for parents [26]. The incidence of disease among first-degree relatives is higher in Crohn's disease than in ulcerative colitis. The incidence of IBD among first-degree relatives of patients with IBD is 30–100 times that of the general population. Moreover, although the relatives of patients with Crohn's disease are more likely to have Crohn's disease than ulcerative colitis, the incidence of ulcerative colitis in this group is also higher than in the general population [4]. Similarly, relatives of patients with ulcerative colitis have a higher incidence of both ulcerative colitis and Crohn's disease than the general population. These data support the contention that ulcerative colitis and Crohn's disease are related diseases. The incidence of IBD is not increased in spouses of patients.

Studies of twins also support the presence of a genetic basis for these diseases. A study of unselected twins from a Swedish twin registry demonstrated that dizygotic twins have the same rate of concordance as would be expected for siblings. There was concordance for Crohn's disease in eight of 18 monozygotic twin pairs; whereas there was concordance for ulcerative colitis in only one of 16 monozygotic twin pairs [27]. No case has been reported of monozygotic twins in which one twin had Crohn's disease and the other ulcerative colitis, suggesting that these diseases have a similar but not identical genetic background.

No clear-cut mendelian pattern of inheritance in IBD has been established; however, specific mutations have been associated with IBD. Work by two different groups has led to the identification of NOD2 mutations associated with Crohn's disease [28,29]. NOD2, a cytosolic protein expressed in monocytes, functions as an intracellular receptor for a bacterial product, muramyl dipeptide [30,31]. NOD2 is a component of the innate immune system. Crohn's disease is

associated with frameshift mutations in NOD2 resulting in a truncated and nonfunctioning protein. Although NOD2 mutations are seen much more commonly in Crohn's disease than in the general population, only a small portion (~ 15%) of all patients with Crohn's disease have a mutation in NOD2. This demonstrates that Crohn's disease is genetically heterogeneous and suggests that other mutations in other genes may contribute to Crohn's disease in other populations. Genome-wide association studies have identified other novel genetic associations with Crohn's disease including a subunit of the receptor for the proinflammatory cytokine interleukin-23 (IL-23R) and the ATG16 autophagy-related 16-like 1 (ATG16L1) [32,33]. The association of Crohn's disease with mutations in NOD2 and IL-23R suggests that both the innate and adaptive immune systems participate in its pathogenesis.

It has become increasingly clear over the last few years that Crohn's disease is clinically heterogeneous and that there is a genetic basis for the clinical heterogeneity. Not only are patients with Crohn's disease more likely to have relatives with Crohn's disease, but those relatives are likely to have Crohn's disease that is similar to that of the proband in terms of anatomical location, age of onset, and disease behavior (inflammatory vs. fistulizing vs. stenotic) [34–37]. In affected parent–child pairs, the age of onset for the parents was significantly higher. In contrast, affected siblings were highly concordant for age of onset [35]. It is not clear whether these genetically based clinical patterns reflect differences in the genes associated with Crohn's disease or the presence of another set of genes that affect the timing and location of the appearance of Crohn's disease in patients who are genetically disposed. Genetic markers have been implicated as predictive of disease severity in ulcerative colitis [38]. Human leukocyte antigen (HLA) *DRB1*0103* and allele 2 of the IL-1 receptor antagonist are associated with extensive disease.

Another approach to understanding the genetic basis of IBD is the search for subclinical markers, i.e., parameters used to detect the abnormal genotype in the absence of the full clinical phenotype. The two subclinical markers that have received the most attention are increased intestinal epithelial permeability in Crohn's disease and antineutrophil cytoplasmic antibodies (ANCA) in ulcerative colitis. There is a report of increased intestinal permeability to PEG-400 in patients with Crohn's disease and their first-degree relatives [39]. A genetic defect of intestinal epithelial cells allowing permeation of lumenal antigens across the epithelial monolayer could result in nonspecific activation of the intestinal immune system; however, subsequent studies have yielded inconclusive data [40,41]. The other subclinical marker that has received considerable attention is the presence of ANCA in the sera of patients with ulcerative colitis and Crohn's disease [42]. Two groups of ANCA-positive patients have been defined based on this intracellular staining pattern: pANCA positivity reflects a perinuclear pattern, whereas cANCA reflects a diffuse cytoplasmic pattern. About 70% of patients with ulcerative colitis are pANCA positive, with no correlation with disease extent or activity. Fewer than half of patients with Crohn's disease are ANCA positive and these patients are almost evenly divided between cANCA-positive and pANCA-positive. Many patients with Crohn's disease who are pANCA-positive have left-sided colitis and a clinical picture similar to ulcerative colitis [43]. The role, if any, of ANCA in the pathogenesis of IBD is unknown; however, clinically healthy relatives of patients with ulcerative colitis have an increased incidence of ANCA positivity compared with the general population, suggesting that ANCA is more than just a marker for colonic inflammation [44].

Potential etiological agents and antigenic triggers

Clear evidence exists for the activation of the immune response in IBD. The lamina propria is infiltrated with lymphocytes, macrophages, and other cells of the immune system. A gene chip analysis of gene expression in ulcerative colitis mucosa demonstrated up-regulation of many genes associated with immune activation [45]. In any immune response, a specific antigen serves as a trigger for the response and as a target for the effector arm of the response. Over the past 30 years, an intensive search has been conducted for the antigens that trigger the immune response in IBD. Immune activation in IBD is largely confined to the gastrointestinal tract; therefore, the search for the antigenic trigger has focused on the intestinal lumen, where most of the antigens are of microbial or dietary origin. Three major hypotheses as to the antigenic triggers in IBD have been postulated.

One hypothesis is that the antigenic triggers are microbial pathogens that have not yet been identified because of fastidious culture requirements. According to this hypothesis, the immune response in IBD is an appropriate but ineffective response to these pathogens. Various viruses and bacteria have been proposed as candidate organisms, but little evidence has been found to support any of these organisms as having a causative role in IBD. One organism that created some interest is a species of mycobacteria similar to or identical with *Mycobacterium paratuberculosis*; however, there are few data to support this organism as a causal agent in Crohn's disease [46–48].

The second (and best supported) hypothesis as to the antigenic trigger in IBD is that it is some common dietary antigen or usually nonpathogenic microbial agent against which the patient mounts an abnormal immune response. In healthy persons, a finely tuned, low-grade chronic inflammation is present in the intestinal lamina propria. Presumably, this chronic inflammation is a product of chronic exposure of the lamina propria to lumenal antigens. Failure to suppress this inflammatory response could result in the uncontrolled immune activation seen in IBD. As a result of failure of normal suppressor mechanisms, immune activation in IBD may be an inappropriately vigorous and prolonged response to

some normal lumenal antigen. The genetic basis of IBD may relate to a genetically determined ability to mount an immune response to a specific lumenal antigen. It may be that patients with IBD are genetically programmed to mount an intense immune response to some common lumenal antigen – either dietary or microbial – to which most people do not respond. In genetically based mouse models of colitis, defects in T-cell function or cytokine production result in uncontrolled immune responses to normal colonic bacteria [49]. In IL-$10^{-/-}$, IL-$2^{-/-}$, and T-cell receptor double-negative ($TCR^{-/-}$) mice inflammation only develops in the presence of normal colonic flora. If these mice are grown under germ-free conditions they do not develop inflammation. These studies demonstrate that normal colonic flora can stimulate a pathological inflammatory response in the presence of a defect in immune regulation. Moreover, a number of different defects in immune regulation result in a mucosal inflammatory response to normal colonic flora. This has two potential implications for IBD. The first is that IBD may result from the initiation of an immune response to normal flora as a result of a defect in immune regulation. The second is that ulcerative colitis and Crohn's disease may be a group of diseases resulting from a number of defects in immune regulation but all manifesting as a mucosal inflammatory response to normal flora. The demonstration that a fraction of patients with Crohn's disease have mutations in *NOD2*, a gene that codes for a protein involved in the response to bacterial products, supports both the suggestion that Crohn's disease involves a dysregulated immune response to bacteria and the suggestion that Crohn's disease is genetically heterogeneous [32,33].

The third hypothesis (autoimmunity) as to the antigenic trigger in IBD is that it is one expressed on the patient's own cells, particularly intestinal epithelial cells. In this theory, the patient mounts an appropriate immune response against some lumenal antigen, either dietary or microbial; however, because of similarities between proteins on the epithelial cells and the lumenal antigen, the patient's immune system also attacks the epithelial cells. Under the autoimmune theory, the immune response is directed specifically toward the epithelial cell, and the epithelial cell is destroyed by one of two immune effector mechanisms, either antibody-dependent cellular cytotoxicity, which requires an antibody directed against an epithelial cell surface antigen, or direct cell-mediated cytotoxicity. Although little evidence exists to support a role for autoimmunity in Crohn's disease, several investigators have reported the presence of anticolon antibodies in the sera of patients with ulcerative colitis [50,51]; however, similar antibodies have been found in the sera of healthy persons and in patients with systemic lupus erythematosus in whom there was no intestinal inflammation [52]. Das and colleagues [53,54] demonstrated the presence of a tissue-bound antibody that could be eluted from surgical resections performed for ulcerative colitis; this antibody is directed against tropomyosin. Whether this antibody participates in the pathogenesis of ulcerative colitis or is just a marker for immune activation is not clear. The presence of an anticolon antibody does not necessarily mean that the antibody plays a pathogenetic role. A more convincing case for a pathogenetic role could be made by the demonstration that this antibody participates in antibody-dependent cellular cytotoxicity.

Immune response

The first step in the immune response to an antigen is the uptake and processing of the antigen by macrophages or other antigen-presenting cells (Fig. 57.1). CD4 (helper/inducer) T cells recognize soluble antigens in conjunction with HLA class II molecules (HLA-DP, -DQ, and -DR) present on dendritic cells and macrophages. Class II antigens on intestinal epithelial cells also may play a role in antigen processing within the intestinal immune compartment. Class II molecules are present on epithelial cells of the normal human small intestine but not on those of the colon. Class II antigen expression on small intestine epithelial cells is retained in patients with Crohn's disease. HLA-DR-like molecules on human intestinal epithelial cells may be involved in antigen-induced triggering of intraepithelial lymphocytes. Marked enhancement of colon epithelial cell HLA-DR staining occurs in active ulcerative colitis and Crohn's colitis, and intestinal epithelial cells from patients with IBD are capable of processing and presenting antigens in vitro [55].

The activated macrophage, in addition to presenting antigen to the T cell, releases IL-1, which activates the T cell. The activated T cell releases IL-2, which promotes the clonal expansion of cytotoxic T cells and increases the function of helper T cells and B cells. Cell-mediated immune responses may be involved in the pathogenesis of IBD. There is a finely balanced chronic low-grade immune response in the normal intestine and colon. The immune response is a product of $CD4^+$ T-cell activation by bacteria in the lumen, as the response is largely absent in germ-free animals. This activation is promoted by interferon-γ (IFN-γ) and is down-regulated by IL-10 and transforming growth factor-β (TGF-β) produced by regulatory T cells (see Fig. 57.1). The current data suggest that IBD is a product of genetically determined immune dysregulation to lumenal antigens. Whether the immune dysregulation produces an overly active up-regulation of the immune response or an inadequate down-regulation is not clear. It is also not clear whether this dysregulation is specific to certain antigens.

There are three T-cell effector phenotypes: T helper type 1 (Th1), Th2, and Th17 subsets. Th1 and Th17 effector cells mediate Crohn's disease whereas Th2 effector cells are thought to play a role in ulcerative colitis. The Th17 effector cells, the most recently described effector phenotype, are associated with chronic inflammation [56]. Th17 cells express IL-23R and produce IL-17 in response to IL-23. The association of Crohn's disease with a mutation in IL-23R suggests a role for Th17 cells in the pathogenesis of Crohn's disease.

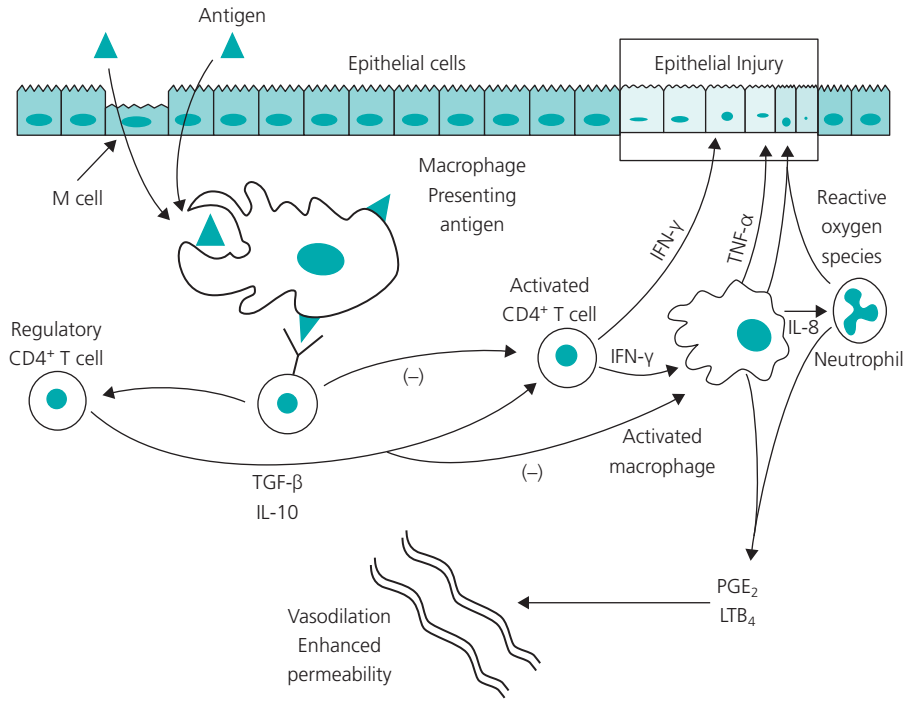

Figure 57.1 An immunological sequence postulated to account for the inflammatory response observed in inflammatory bowel disease starts with an exogenous sensitization to lumenal antigens, presumably bacterial, facilitated by genetic influences. The first cell population involved is the dendritic cell, which phagocytoses and processes antigen and presents it to a $CD4^+$ T cell. Two populations of $CD4^+$ T cells are produced: one an activated effector population and the second a population of regulatory T cells. The activated T cells produce interferon-γ (IFN-γ), which activates macrophages and participates in epithelial injury. The regulatory T cells produce transforming growth factor-β (TGF-β) and interleukin-10 (IL-10), which down-regulate both the activated $CD4^+$ T cells and the activated macrophages. Activated macrophages make IL-12, which further promotes the differentiation of $CD4^+$ T cells towards a T helper type 1 phenotype. Activated macrophages participate in epithelial injury by producing tumor necrosis factor-α (TNF-α) and reactive oxygen species and by recruiting neutrophils, which also produce reactive oxygen species. Macrophages and neutrophils also produce prostaglandin E_2 (PGE_2) and leukotriene (LTB_4), which contribute to the vasodilation and enhanced vascular permeability that is characteristic of inflammatory bowel disease.

Not only T-cell effector phenotypes but also regulatory cells (Tregs) are important in regulating the intestinal immune response [57,58]. The Tregs play important roles in self-tolerance and in the response to lumenal antigens. They come in two varieties, natural Tregs (nTregs), which are generated in the thymus and have high-affinity TCR to self antigens, and adaptive Tregs, which are generated outside the thymus in response to antigens encountered in organs or secondary lymphoid tissue. The role of Tregs in regulating mucosal inflammation is best demonstrated by the decrease in colonic inflammation associated with the adoptive transfer of Tregs in mouse models of colitis.

Antibody secretion

In view of the increased access of lumenal antigens to the immune cells of the lamina propria, it is not surprising that there is increased antibody secretion by intestinal mononuclear cells in IBD. Not only is the number of antibody-secreting cells increased, but also the distribution of immunoglobulin classes is changed. In healthy persons, the vast majority of the immunoglobulin secreted by intestinal mononuclear cells is immunoglobulin A (IgA). In IBD, there is markedly increased production of IgM and IgG. IgA does not fix complement, whereas IgM and some IgG subclasses do. There are subclasses of IgG that are defined by the structure of their constant regions. There is some subclass specificity in the increase in IgG production seen in IBD. Ulcerative colitis is associated with increased production of IgG1 and IgG3, whereas Crohn's disease is associated with increased production of IgG2. IgG1 and IgG3 antibodies account for the predominant IgG response to proteins and T-cell-dependent antigens. IgG2 provides the predominant IgG response to carbohydrates and many bacterial antigens. Delineation of the stimuli and antigens that induce the increased secretion of IgG subclasses may provide insight into the etiology and pathogenesis of IBD.

Cytokines

Cytokines are glycosylated proteins that mediate potent biological function at low concentrations in a hormone-like fashion (see section on cytokines, Chapter 7). Like hormones, they act through receptors, but unlike hormones, which act

on cells at a distance from their cell of origin, cytokines act on neighboring cells. Originally, cytokines were described as being produced by immune cells and acting on immune cells, but it is clear that they are both produced by and act on non-immune cells. Cytokines almost certainly play important regulatory roles in IBD, as they do in other chronic inflammatory states [59]. The best-developed data are those demonstrating increased production of most of the major proinflammatory cytokines (IL-1, IL-6, IL-8) and tumor necrosis factor-α (TNF-α). The proinflammatory cytokines contribute to many of the characteristic attributes of IBD: neutrophil infiltration (IL-8), T-cell activation (IL-1), expression of adhesion molecules (IL-1 and TNF-α), and enhanced epithelial permeability (IFN-γ). TNF-α and IFN-γ may contribute directly to epithelial injury (see Fig. 57.1). The natural inhibitor of IL-1, IL-1 receptor antagonist, is a protein produced by macrophages in parallel with IL-1. The ratio of IL-1 receptor antagonist to IL-1 is lower in IBD mucosa than in normal mucosa. Other cytokines, including IL-10 and TGF-β serve to down-regulate the immune response (Fig. 57.1). Genetic mouse models in which IL-10 or TGF-β is disrupted have colitis as their phenotype. These models demonstrate that failure of the regulatory processes that down-regulate the immune response can lead to chronic inflammation.

$CD4^+$ T cells have been divided into subsets based on the profile of the cytokines produced. IL-12, which is produced by macrophages, causes naive lymphocytes to differentiate to Th1 lymphocytes. The cytokines produced by Th1 lymphocytes, IL-2 and IFN-γ, are associated with cellular immune responses and increased IgG2 production. IL-4, which is produced by macrophages, causes naive lymphocytes to differentiate to Th2 lymphocytes. The cytokines produced by Th2 lymphocytes, IL-4, IL-5, IL-6, and IL-10, are associated with hypersensitivity reactions and increased IgG1 production. Crohn's disease appears to be associated with activation of Th1 lymphocytes as demonstrated by increased levels of IL-2, IL-18, IFN-γ, and IgG2 [60–63]. Th17 effector T cells make IL-17 (or IL-17A), IL-17F and IL-6 [56]. Crohn's disease is associated with a mutation in IL-23R and increased levels of IL-17, suggesting an association with Th17 cells [32,64]. Ulcerative colitis is associated with activation of Th2 lymphocytes as demonstrated by increased IL-5, IL-10, and IgG1 [60]. These findings indicate that Crohn's disease is characterized by dysregulated Th1 and Th17 responses and ulcerative colitis is characterized by a dysregulated Th2 response but they do not reveal the mechanisms involved in the induction of these dysregulated responses. Genetically based animal models of colitis are also characterized by dysregulated Th1, Th2, and Th17 responses. In these animal models it is clear that an abnormal immune response is mounted against normal bacterial flora, raising the possibility that the antigenic trigger for the dysregulated immune response in IBD is the normal flora. The evidence for dysregulation of the Th1, Th2, and Th17 systems in IBD is strong. A number of therapeutic strategies that target these pathways are sure to be tested [65].

The major cell source of the proinflammatory cytokines is almost certainly activated macrophages in the lamina propria, although other cell types may make important contributions. Cytokines, particularly IL-1, TNF-α, and IFN-γ, stimulate epithelial, endothelial, and mesenchymal cells and activate immune cells. They also are involved in the regulation of wound healing and fibrosis [66]. Cytokines may be useful as markers of disease activity, especially tissue IL-1 levels in ulcerative colitis and serum IL-2 receptor levels in Crohn's disease [67,68].

The demonstrated efficacy of infliximab, a chimeric antibody to TNF-α, in Crohn's disease supports the key role of cytokines in IBD pathogenesis [69]. TNF-α is produced in Th1-mediated immune responses and the effectiveness of infliximab in Crohn's disease supports the suggestion that Th1 lymphocytes are important in mediating immune activation in Crohn's disease. The success of infliximab will certainly lead to other attempts to treat Crohn's disease by modulating Th1 cytokines.

Genetically based animal models of colitis

A number of genetically based animal models of IBD have been developed [49]. In most cases, these models were developed to study the effects of specific genetic perturbations of the immune system rather than as models of colitis. A surprising product of these manipulations of the immune system was the discovery that many genetic abnormalities in the systemic immune system have as their only phenotype the development of colitis. Furthermore, the development of colitis in these genetic models requires the presence of intestinal bacteria. The genetic defects that have colitis as their phenotype in animals with conventional bacterial flora have no phenotype in germ-free animals.

These genetically based models of colitis fall into three groups. One group of models includes three cytokine knockouts. Mice with disruption of the genes for IL-2, IL-10, and TGF-β all develop colitis [70–72]. The second group of models includes mice or rats with T-cell defects. Among these are mice with defects in the T-cell receptor and transgenic rats into which the human *HLA-B27* gene has been introduced [73,74]. In the *HLA-B27* transgenic rats, colitis is not the only phenotype; these animals also have gastritis and arthritis. An especially interesting model is the severe combined immunodeficiency disease (SCID) mouse repleted with CD45RBhi $CD4^+$ T cells [49]. SCID mice lack all $CD4^+$ cells yet they develop no colitis; however, when these mice are repleted with a subset of $CD4^+$ cells, they develop colitis. The third group of models includes mice lacking $G\alpha_{12}$, a subunit of a G-protein [75]. Whether T cells are the important targets in this genetic model is not clear.

It is possible that all of these models relate to T cells and their regulation by cytokines. One could imagine a model in

which immune activation in the intestinal lamina propria in response to lumenal bacteria is kept in check by a population of regulatory T cells through the secretion of down-regulatory cytokines, such as IL-10 or TGF-β (see Fig. 57.1). Defects in that T-cell population or in its ability to produce down-regulatory cytokines would remove the brake on immune activation induced by bacterial stimulation of other T-cell populations. The interaction of T cells and cytokines was demonstrated further in studies with the CD45RBhi $CD4^+$ T-cell repleted SCID mice. Administration of a monoclonal antibody against IFN-γ to these animals completely eliminated the colonic inflammation, and administration of a monoclonal antibody against TNF-α reduced it significantly. These studies raise the possibility that the intestinal damage caused by unrestrained T-cell activation is mediated by IFN-γ and TNF-α.

In general the animal models that most resemble Crohn's disease are those associated with abnormalities in Th1 cytokines. Colitis induced by rectal administration of trinitrobenzene sulfonic acid has a histological picture consistent with Crohn's disease. There are high levels of IFN-γ in the colons of mice receiving trinitrobenzene sulfonic acid and the colitis can be abrogated with antibodies to IL-12 [76]. Both these findings are consistent with inflammation mediated by Th1 lymphocytes. There is an especially intriguing spontaneous mouse model, called the SAMP1/Yit mouse, that closely resembles Crohn's disease [77]. Adoptive transfer studies demonstrate that $CD4^+$ T cells that produce a Th1-like profile of cytokines mediate intestinal inflammation in this model. In contrast animal models that most resemble ulcerative colitis are those associated with elevated levels of Th2 cytokines. A histological picture similar to ulcerative colitis develops in mice with a mutant T-cell receptor alpha gene [73]. Analysis of spontaneous cytokine expression by mesenteric lymph node cells showed a decrease in IL-2 and an increase in IL-4 in the $TCR\alpha^{-/-}$ mice with colitis. The decrease in IL-2 and increase in IL-4 is consistent with a Th2-mediated response.

Two of the major themes in the pathogenesis of IBD have been the importance of the lumenal bacteria driving the immune response and the importance of Th1 and Th2 T cells in mediating the immune response. These two themes were combined in a study of a spontaneously occurring model of colitis in the C3H-HeJBir mice [78]. Adoptive transfer of bacterial antigen-activated $CD4^+$ T cells from colitic C3H/HeJBir mice to SCID mice induced colitis. This study demonstrated that T cells reactive with conventional antigens of the enteric flora can mediate IBD.

Although most animal models of colitis involve defects in lymphocyte regulation, enhanced Th1 activity and chronic colitis occur in mice with a cell type-specific disruption of the *Stat-3* gene in neutrophils and macrophages [79]. *Stat-3* codes for a protein involved in the signal transduction of the receptor binding of a number of cytokines and growth factors including IL-6, IL-10, and granulocyte colony-stimulating factor. There are other genetic models of intestinal inflammation based on defects in epithelial cells. N-cadherin is a protein involved in the attachment of adjacent epithelial cells. Mice expressing a dominant-negative N-cadherin along their crypt-villus axis develop IBD [80]. Keratin 8 is a cytoskeletal molecule in epithelial cells. Mice in which the keratin 8 gene is disrupted develop crypt abnormalities and inflammation of the lamina propria and submucosal [81].

The finding that a wide variety of defects in the systemic immune system and epithelial cells results in colitis is informative in defining the regulation of the mucosal immune system. It is less informative in defining the defects in immune regulation or epithelial cells that may be involved in the mediation of human IBD. The pathogenesis of IBD may involve one or more of these regulatory systems or, more likely, may involve other regulatory systems.

Inflammation

IBD is considered a disorder of chronic inflammation, a view reinforced by the large numbers of lymphocytes and histiocytes in the diseased mucosa and submucosa. Ulcerative colitis and Crohn's disease also have histological characteristics of acute inflammation, including an intense infiltration of the mucosa and submucosa with neutrophils. Large numbers of neutrophils leave the bloodstream and enter the inflamed mucosa and submucosa of the bowel [82]. Some neutrophils migrate across the epithelium into the lumen and are passed in the stool, and others are destroyed in the inflamed tissue before they have a chance to migrate into the lumen. This constant flux of neutrophils is mediated by the expression of adhesion molecules on circulating neutrophils and vascular endothelial cells, which allow the neutrophils to bind to the endothelium before migrating into the tissue. Both the expression of adhesion molecules and the migration of neutrophils are regulated by inflammatory cytokines (IL-8 and TNF) and lipid mediators of inflammation, including platelet activating factor and leukotriene B_4 (LTB_4). Neutrophil activation in the inflamed gut results in the release of granule-bound proteases and the production of superoxide and other reactive oxygen species (see Fig. 57.1) [83]. These products of activated neutrophils probably play a role in the destruction of epithelial cells in IBD.

Some of the functional and macroscopic changes seen in IBD, including mucosal hyperemia and edema, are typical of changes seen in any inflammatory state, no matter which organ system is involved. These changes are the products of soluble mediators released in the process of inflammation. Mediators cause tissue edema by increasing vascular (postcapillary venule) permeability to albumin and other macromolecules; hyperemia results from mediators that induce vasodilation. Progress has been made in characterizing the soluble mediators of inflammation and their role in the amplification of the immune response in IBD. There are two reasons for defining their pathogenic role. First, the soluble

mediators appear to be largely responsible for the clinical and histological changes seen in the disease. Second, the drugs that have proved to be beneficial for ulcerative colitis and Crohn's disease appear to exert their therapeutic effects by blocking the synthesis of those mediators. Corticosteroids down-regulate the expression of proinflammatory cytokines and block the migration of neutrophils out of the bloodstream. 5-Aminosalicylate (5-ASA) appears to act farther downstream; it is an antioxidant and may act to block the tissue damage induced by reactive oxygen species. Corticosteroids and sulfasalazine block the synthesis of prostaglandins and leukotrienes in vivo and in vitro [84,85]. Until the etiological agents of ulcerative colitis and Crohn's disease are identified, it is likely that advances in medical therapy will be in the area of regulation of the synthesis of soluble mediators of inflammation.

Almost all mammalian cells, including intestinal epithelium and cells associated with inflammatory events (e.g., mast cells, macrophages, platelets), produce prostaglandins. Prostaglandins, particularly those of the E series, have biological properties that are proinflammatory, including enhanced vascular permeability, vasodilation, and production of pain. Prostaglandin levels are elevated in mucosa and serum in IBD and correlate with disease activity [86]. There are two cyclooxygenases that synthesize prostaglandins. Cyclooxygenase-1 (COX-1) is a constitutive enzyme, whereas COX-2 is induced by proinflammatory cytokines. COX-2 is not expressed in colonic epithelial cells in the absence of inflammation but is expressed in epithelial cells from areas of inflammation in ulcerative colitis [87]. Nonsteroidal antiinflammatory drugs (NSAIDs), which are potent inhibitors of prostaglandin production through both pathways, reduce inflammation in chronic inflammatory diseases, such as rheumatoid arthritis, but are not effective in IBD. Small trials of indomethacin administered orally and rectally revealed no improvement in ulcerative colitis; there was even some suggestion that indomethacin causes clinical deterioration despite decreasing prostaglandin production [88,89]. Prostaglandin E_2 produced through COX-2 appears to be important in gastrointestinal wound healing [90]. The negative effects of NSAIDs in IBD may be related to impaired wound healing.

The mucosa in IBD contains large amounts of LTB_4 [91], a neutrophil chemotactic factor [92]. The concentrations of LTB_4 are markedly higher in rectal dialysates from patients with ulcerative colitis than from controls and in vitro studies have identified LTB_4 [93] as a major neutrophil chemotactic agent in IBD mucosa. Despite the strong evidence that LTB_4 [92] is the major neutrophil chemotactic factor in IBD, clinical trials of inhibitors of LTB_4 synthesis in ulcerative colitis have failed to demonstrate clinical efficacy [94]. Dietary supplementation with fish oil containing eicosapentaenoic acid, which reduces LTB_4 production by acting as a competitive substrate for 5-lipoxygenase, results in significant but modest improvements in ulcerative colitis symptoms [95].

Nitric oxide is found in large amounts in the mucosa in IBD, and inducible nitric oxide synthase is expressed in epithelial cells in patients with IBD but not in epithelial cells from healthy persons [96]. Nitric oxide may contribute to vasodilation and mucosal edema. Whether the net effect of nitric oxide in IBD is to promote tissue injury or tissue repair is not clear.

The inflammatory response can be viewed as a component of the larger process of wound healing. The inflamed mucosa in IBD is characterized by the activation not only of typical inflammation-associated genes, such as COX-2 and IL-8, but also by the activation of genes associated with wound healing including growth factors and metalloproteinases [97,98].

Ulcerative colitis

Clinical findings and natural history

Ulcerative colitis is characterized by diffuse, superficial inflammation of the colonic mucosa that begins in the rectum and extends proximally to involve any contiguous length of colon. The small bowel is not involved, although the distal ileum may exhibit similar superficial inflammation, usually in the setting of extensive colitis, termed backwash ileitis [99]. The extent of colitis usually remains constant from the onset with the length of colonic involvement defining the classification of ulcerative colitis: proctitis (limited to the rectum), proctosigmoiditis or left-sided colitis (extending up to the splenic flexure), or pancolitis/extensive colitis (extending into the transverse colon) (Fig. 57.2) Proximal extension

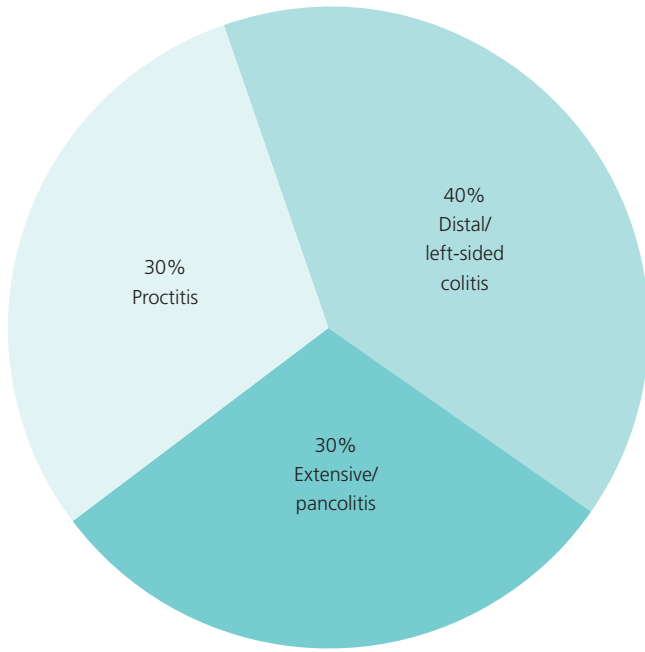

Figure 57.2 Extent of ulcerative colitis at time of initial disease presentation.

occurs in approximately one-third of patients with distal disease, and regression from pancolitis is also possible [100–102]. The extent of involvement does not necessarily imply severity but does impact both prognosis (e.g., the risk of cancer) and treatment selection [103]. The symptoms and course of ulcerative colitis relate to both the extent and the severity of inflammation within the involved segment of colon.

Clinical manifestations

The presenting symptoms of ulcerative colitis are, typically, insidious rather than abrupt; although the disease occasionally presents acutely after infectious colitis or traveler's diarrhea [104]. The presence of rectal inflammation makes bleeding the most consistent presenting feature and this may be gross, or associated with evacuation of mucopus. Symptoms of rectal urgency and tenesmus are related to diminished compliance of the rectum [105]. Increased stool frequency is, likewise, related to decreased rectal compliance and proximal fecal stasis in patients with distal colitis [106] and "bowel movements", per se, should distinguish passage of mucopus without stool. The greater the length of inflamed colon, the more likely patients will present with diarrhea and, conversely patients with proctitis often present with constipated bowel movements with interim passage of blood or mucus [106]. Colicky abdominal pain or cramps preceding bowel movements are common, whereas localized abdominal pain or tenderness (related to transmural inflammation) signifies progressive, severe disease. In the setting of severe or fulminant colitis, systemic symptoms including night sweats, fever, nausea and vomiting, and weight loss accompanied by diarrhea. Most often, nausea and vomiting occur while patients are on the toilet associated with tenesmus. Extraintestinal manifestations (see below) can include inflammation of the eyes, skin, joints, and liver.

Ulcerative proctitis is defined by inflammation limited to the distal 15–20 cm of rectum and is the most common, and usually the mildest presenting extent of ulcerative colitis; accounting for approximately 25%–30% of cases [101,107]. Patients with ulcerative proctitis typically present with hematochezia, a sense of rectal urgency, and constipated bowel movements because of delayed transit of fecal material in the right colon [106]. Systemic manifestations are uncommon with proctitis, but skin or joint symptoms can occur [107]. The disease usually remains confined to the rectum but may advance proximally in as many as 30%–40% of patients [101,102,107].

Proctosigmoiditis or left-sided colitis, accounting for about 40% of ulcerative colitis cases, is an intermediate syndrome in which patients may present with either constipation or diarrhea accompanied by tenesmus, urgency, and rectal bleeding. Colicky left lower quadrant pain is more common than with proctitis, as are extraintestinal symptoms. The proximal disease margin usually remains fixed throughout the course but can spread more proximal or even retract distally [101,102,107].

Extensive colitis (pancolitis) is diagnosed when inflammation extends into the transverse or right colon. In this setting patients are more likely to present with diarrhea as a result of the diminished absorptive capacity of the colon [106], accompanied by rectal bleeding, urgency and tenesmus. Cramping abdominal pain may be diffuse or localized, and patients are more likely to have weight loss, systemic or extraintestinal symptoms, and anemia [107].

Toxic megacolon is the most severe manifestation of ulcerative colitis, diagnosed when the inflammation extends from the superficial mucosa into the submucosal and muscular layers of the colon [108]. Toxic megacolon occurs more commonly in the setting of extensive colitis but can also occur with severe distal colitis. The manifestations of toxic megacolon include: fever, prostration, severe cramps, abdominal distention, and abdominal tenderness that may be localized, diffuse, or associated rebound tenderness. These *toxic* manifestations result from transmural extension of inflammation producing circular muscle paralysis and precipitating dilation along with a "tissue-paper" thin colonic wall.

The clinical severity of ulcerative colitis depends on both the length of colon involved and the severity of colonic inflammation. The symptomatic criteria most commonly used to define the severity of disease were established by Truelove and Witts [109] to assess improvement in the first clinical trial of cortisone for ulcerative colitis and remain useful to classify severity in clinical practice [110–112]. The criteria define *mild* and *severe* disease activity with *moderate* activity being present when there are intermediate symptoms. These criteria may also be modified to include *fulminant* colitis (Table 57.1). Most patients present with *moderately* severe symptoms of ulcerative colitis [113] and the course is, typically, intermittent with the majority of patients maintained in clinical remission or having mild symptoms despite a 90% likelihood of relapse if medical therapy is not maintained.

Table 57.1

Criteria	Mild	Severe	Fulminant
Stools (no. per day)	< 4	> 6	> 10
Blood in stool	Intermittent	Frequent	Continuous
Temperature (°C)	Normal	> 37.5°C	> 37.5°C
Pulse (beats/minute)	Normal	> 90	> 90
Hematocrit (%)	Normal	< 75%	Transfusion
ESR* (mm/h)	< 30	> 30	> 30

ESR, erythrocyte sedimentation rate.
Modified Truelove and Witts' Clinical Classification of Ulcerative Colitis Severity. Adapted from Truelove SS, Witts LI. BMJ 1955;2:1041.

Mild symptoms are defined as patients with fewer than four bowel movements daily and minimal cramping and urgency. Typically, most of the bowel movements occur early in the day, and after the morning evacuations patients are able to proceed with the activities of daily life.

Moderate ulcerative colitis severity is defined by symptoms of four to eight bowel movements daily, typically in the early morning and after meals, associated with rectal urgency. Blood or mucopus are present with most evacuations and nocturnal awakening for bowel movements is common. The disease can interfere with daily work or school activities and social life [113].

Severe ulcerative colitis is manifest by more than eight bowel movements daily, nocturnal bowel movements, severe urgency with or without incontinence, and systemic signs including low-grade fever, night sweats, weakness, and weight loss. Abdominal tenderness, tachycardia, anemia, leukocytosis, and hypoalbuminemia are common [107].

Although not included in Truelove and Witts original classification, patients with *fulminant* colitis have more than 10 bowel movements a day, nocturnal bowel movements, severe abdominal pain or relentless tenesmus, rebound tenderness or distention with tympanic bowel sounds. They also have prostration, high fever, and hypotension. Radiographic studies show evidence of mucosal edema, intramural air (pneumatosis coli), colonic dilation (toxic megacolon), or free abdominal air (perforation) (see below).

Disease course

The natural history of ulcerative colitis is modified by medical therapy. In a population series, the average duration of symptoms before diagnosis was 4.5 months [114] and less than 10% of patients required surgery (colectomy) in the first year (Table 57.2). Untreated, more than 90% of patients will have intermittent or relapsing disease activity [113] and about 50% will have a relapse in any year although only a small minority of patients have chronic, continuous disease activity. More than 90% of patients are able to maintain the ability to work or attend school [113]. Ultimately, up to a third of patients with extensive colitis will require a colectomy at some time through the disease course and up to 30% of patients with disease severe enough to require corticosteroids will undergo colectomy within the subsequent year [115]. Mortality rates, however, for ulcerative colitis are not significantly different from those of the general population [116,117].

Table 57.2 Clinical course in ulcerative colitis

Clinical course	Number of patients	Percentage
Acute fulminating	20	8.0
Chronic intermittent	161	64.4
Chronic continuous	18	7.2
One attack only	45	18.0
Total colectomy in first attack	2	0.8
Died in first attack of other causes	1	0.4
Unknown	2	0.8
Total	249	100.0

Diagnosis

In the absence of pathognomonic features, the diagnosis of ulcerative colitis is made on the basis of clinical, endoscopic, and histological findings. There may also be overlapping pathophysiology between ulcerative colitis and postinfectious irritable bowel syndrome [118]. Thus, the first order of diagnostics is to determine whether there is an inflammatory process or whether symptoms (diarrhea and abdominal cramps) are related to irritable bowel syndrome. Subsequently, the differentiation between ulcerative colitis and other forms of inflammatory bowel disease is the priority for patients presenting with diarrhea and, despite all efforts, we continue to be confronted with patients whose inflammatory pattern remains "indeterminate" between ulcerative colitis and Crohn's disease. At presentation, stool examination for fecal leukocytes confirms the presence of an "inflammatory bowel disease" and cultures should be performed to rule out infectious diseases that may mimic or complicate ulcerative colitis, such as infection with *Salmonella*, *Shigella*, *Campylobacter*, hemorrhagic *Escherichia coli*, and, in particular, *Clostridium difficile* [99].

In contrast to patients presenting with diarrhea, alone, the presence of rectal bleeding should raise the suspicion of ulcerative colitis in individuals below the age of 40. Most often the presentation is subacute or chronic, but it may also be intermittent or progressive [99].

Ulcerative colitis always involves the rectum so inflammatory changes should be visible with a limited examination. The easiest way to exclude ulcerative colitis is by direct examination of the rectosigmoid colon with a proctoscope or flexible sigmoidoscope. Radiographic examinations (e.g., barium enemas), aside from plain abdominal radiographs in patients with severe presentations, have been almost completely supplanted by more sensitive endoscopic examinations.

History and physical examination

A full history should include recent travel; recent infections; use of medications (in particular antibiotics and NSAIDs); past and current smoking history, and family history of inflammatory bowel disease, other immune-mediated inflammatory diseases (psoriasis, eczema, arthritis, liver disease, multiple sclerosis), and colon polyps or cancer. While not of immediate necessity, these can give clues to potential long-term complications and risk factors (e.g., colon cancer). In addition to symptoms of bleeding and diarrhea the history should

determine the assessment of severity related to nocturnal bowel movements, incontinence, weight loss, fevers, and other extraintestinal symptoms such as arthritis, back pain, skin lesions, eye inflammation, and oral ulcerations. In women a menstrual history is relevant related to disease activity and potential therapies.

In most patients with ulcerative colitis, the physical examination is normal, including the abdominal examination. There may be mild abdominal tenderness to deep palpation, particularly in the left colon, but significant abdominal findings are limited to patients with moderate to severe disease, in whom tenderness is more prominent. Abdominal distention, tympany, diminished bowel sounds, or rebound tenderness are ominous signs of fulminant colitis or toxic megacolon. Despite frequent diarrhea, perianal manifestations are absent in ulcerative colitis. Any significant perianal findings (e.g., large hemorrhoids, skin tags, fissures, abscesses, or fistulae) suggest Crohn's disease rather than ulcerative colitis.

Conjunctival or nail bed pallor are common signs of anemia. Patients may present with ocular inflammation, erythema nodosum, pyoderma gangrenosum, or arthritis of larger joints [119]. Low back pain with diminished range of motion, or sacroiliac tenderness, is uncommon. Hepatomegaly, splenomegaly, or evidence of chronic liver disease is rare and limited to patients with end-stage primary sclerosing cholangitis.

Laboratory investigations

Investigations for patients with suspected ulcerative colitis should include a complete blood count and differential. Assessment of liver enzymes is relevant regarding potential hepatic complications and baseline kidney function is necessary for any patient for whom an aminosalicylate test is planned. Microbiological testing should test for potential causes of infectious diarrhea including ova and parasites, enteric pathogens, and, in particular, *C. difficile* [99].

Fecal markers

A hallmark of ulcerative colitis is the presence of neutrophilic infiltration into the epithelial crypts and lamina propria in conjunction with exudation of fecal leukocytes into the colonic lumen. The absence of fecal leukocytes rules out the presence of an inflammatory diarrhea and focuses subsequent diagnostic strategies toward irritable bowel or structural abnormalities of the colon. In addition to direct examination of stool for fecal leukocytes with methylene blue, several fecal tests have become available to assist with the diagnosis of inflammatory bowel disease and have the potential of contributing to quantification of disease activity [120]. Calprotectin is a granulocyte-derived, calcium-binding protein that has been evaluated as a diagnostic assay to identify inflammatory diarrhea [121–123] and to quantify "inflammatory activity" [124–126]. Similarly, lactoferrin, a neutrophil granulocytic protein quantified by a latex agglutination assay [127] or by a polyclonal antibody-based enzyme linked immunoassay has been evaluated to discriminate between active IBD and irritable bowel syndrome [128].

Serological markers

There has been considerable interest in identifying serological markers for diagnostic and prognostic utility in IBD [129,130]. Advances in techniques have improved the sensitivity and specificity of ANCA and pANCA determinations pertaining to the diagnosis of ulcerative colitis [131]. Progress has been made regarding the targeted antigen(s) for pANCA. Both the nuclear heterochromatin DNA-bound protein H1 [132] and protein epitopes expressed by colonic bacteria [133], as well as cathepsin G, elastase, lysozyme, lactoferrin, catalase, enolase, and high-mobility group nonhistone chromosomal proteins [130] have been recorded as cross-reacting with pANCA.

The prevalence of pANCA in patients with ulcerative colitis ranges from 50% to 80% and levels usually remain stable throughout the course of the disease. Differences between various populations may be related to ethnic differences, referral bias, or methodological differences between assays [131,134]. Unfortunately, pANCA can also be identified in up to 31% of patients with an "ulcerative colitis-like" pattern of Crohn's disease [130,135,136].

In contrast to the predominance of pANCA in ulcerative colitis, antibodies to the baker's yeast *Saccharomyces cerevisiae*, (ASCA) are more specific for patients with small bowel Crohn's disease [130] and are present in 40%–60% of patients [137]. The specificity of ASCA appears to relate to small bowel pathology as between 40% and 60% of patients with celiac disease also have ASCA present [137].

Additional serological markers identified in patients with IBD react with the outer membrane of *E. coli* cell wall (OmpC) or an RNA-derived immunologically associated bacterial sequence of *Pseudomonas fluorescens* (I2 peptide) and have been associated more with Crohn's disease than ulcerative colitis and have not been useful in discriminating between the IBD subtypes [131]. The identification of serological markers to microbial antigens provides additional evidence for the loss of tolerance to normal commensal bacteria that has been postulated to occur as an initiating event in the failure to down-regulate the inflammatory cascades in IBD [138–140].

Potential roles for assessing serological assays in IBD include: as markers of disease specificity or prognosis, as a screening tool to discriminate IBD from other digestive disorders, and to assist in the understanding of disease mechanisms or immune interactions. At present, the primary utility of these markers has been to identify disease subgroups with similar immune interactions [131]. In addition, there is evidence that high titers of pANCA correlate with the risk of chronic pouchitis after colectomy and ileoanal anastomosis [141] whereas high titers of ASCA have been associated with intestinal complications and the need for surgery in Crohn's

disease [136,137,142]; the presence of anti-OmpC has been associated with internal penetrating Crohn's disease, and anti-I2 with stricturing Crohn's disease [137].

In contrast, the utility of screening for IBD has been limited to the pediatric population where invasive testing (i.e., colonoscopy) is less acceptable and more costly [143,144]. In adult populations the ability to diagnose ulcerative colitis by flexible sigmoidoscopy or colonoscopy is less of an issue and offers immediate confirmation and access to histology such that serological markers are not necessary to screen for or exclude ulcerative colitis compared to conventional (endoscopic) investigations.

Finally, the potential for serological studies to discriminate between ulcerative colitis and Crohn's disease, particularly for patients with "indeterminate colitis", has been evaluated. The presence of pANCA is not helpful to discriminate between ulcerative colitis and Crohn's disease in patients with indeterminate colitis. In contrast, the presence of ASCA is more helpful, but the sensitivity in indeterminate colitis is so low that a positive or negative predictive value will be low [145]. The serological pattern of $pANCA^+$ $ASCA^-$ is more common in ulcerative colitis compared to $pANCA^-$ $ASCA^+$ in (classic, i.e., small bowel involvement) Crohn's disease with sensitivity for the former of 44%–58% and specificity of 81%–98%. In contrast, the pattern of $pANCA^-$ $ASCA^+$ has a sensitivity of 30%–64% and specificity of 92%–97% for (classic) Crohn's disease [137]. In the future, the addition of OmpC or I2 peptide may help to further discriminate between ulcerative colitis and Crohn's disease in the setting of indeterminate colitis [131].

Table 57.3 Frequency of clinical features in Crohn's disease

	Disease location (%)		
Clinical feature	**Ileitis (%)**	**Ileocolitis (%)**	**Colitis (%)**
Diarrhea	~ 100	~ 100	~ 100
Abdominal pain	65	62	55
Bleeding	22	10	46
Weight loss	12	19	22
Perianal disease	14	38	36
Internal fistulae	17	34	16
Intestinal obstruction	35	44	17
Megacolon	0	2	11
Arthritis	4	4	16
Spondylitis	1	2	5

Endoscopy

Ulcerative colitis can almost always be diagnosed by endoscopic examination of the rectum and sigmoid colon [99,146]. The disease presents as diffuse, continuous inflammation beginning in the rectum, with proximal extension that varies among individual patients. In most cases it is advisable to determine the proximal margin of disease, from the standpoints of prognosis and therapy [110,111,146]. To avoid confusion with trauma or inflammation from administration of an enema or oral laxatives the initial examination can be performed without enema preparation as patients with active mucosal inflammation rarely have any fecal material in the involved lumen. Complete colonoscopy into the cecum and terminal ileum is most helpful in distinguishing ulcerative colitis from Crohn's disease [147] (Table 57.3).

Healthy colonic mucosa is smooth and glistening, reflects light back from the endoscope, and demonstrates a branching mucosal vascular pattern. With inflammation, the mucosa becomes edematous, erythematosus, and more granular, breaking apart the light reflection (Fig. 57.3). Mucosal granularity

may be fine or coarse; the latter represents microscopic or pinpoint ulcerations and is associated with friability (either spontaneous or scope-induced hemorrhage from the mucosa). Exudates of mucopus are a common associated finding whereas gross ulcerations represent more severe disease and, although usually shallow, can progress to a total denudation of the mucosa with exposure of the underlying circular musculature. Before treatment, these changes are continuous up to a distinct margin of normal appearing mucosa (Fig. 57.4), or they may extend diffusely to the cecum and, occasionally, into the distal ileum (backwash ileitis). Examination and biopsies of the ileum in the setting of backwash ileitis can differentiate ulcerative colitis from Crohn's disease [146,147]. In the setting of pancolitis, the ileocecal valve is usually patulous, allowing easy entry into the terminal ileum. Limited inflammatory changes in the cecum, around the appendix (peri-appendiceal or cecal red-patch), may be present in patients with distal disease, in which case the focality is not assumed to be related to Crohn's disease [148].

As ulcerative colitis heals, the mucosal changes may become more focal [149,150]. The colonic mucosa regenerates with granularity replacing ulceration, and eventual restitution of the mucosal vascular pattern, which is chronically "distorted" with less distinct branching or irregular, vessels that appear "pruned". In areas that had been more severely inflamed, granulation tissue may protrude and become reepithelialized as postinflammatory, "pseudopolyps" (Figs 57.5, 57.6). These postinflammatory changes can arise in a variety of sizes and shapes and often become fingerlike projections, or even mucosal bridges, in areas that had severe, undermining ulcerations. Pseudopolyps have no neoplastic potential but can be difficult to differentiate from adenomatous polyps. When extensive, pseudopolyps can totally carpet the mucosa, making it impossible to discern distinct, potentially neoplastic polyps.

In the setting of severe colitis, colonoscopy can be performed safely, *in experienced hands*, to assess the severity of mucosal changes as the presence of deep ulcerations bode a poor prognosis for medical treatment [151–153]. Colonoscopy and with biopsies can also assist in the exclusion of complicating infections, including *C. difficile* [146] and cytomegalovirus [154]. However, in the setting of severe colitis it may be difficult to differentiate infectious from idiopathic colitis [155].

Histology

The histological features of ulcerative colitis parallel the endoscopic appearance of a diffuse, continuous pattern of superficial inflammation within the involved mucosal segments and normal proximal mucosa. The principle components are disruption of glandular architecture and an inflammatory infiltrate [156,157]. While there are no pathognomonic histological criteria for the diagnosis of ulcerative colitis [103] a

primary distinction between chronic inflammatory bowel disease such as ulcerative colitis and acute self-limited (infectious) colitis is architectural distortion (Table 57.4). In ulcerative colitis, the normal vertical ("test-tube") alignment of glands is distorted and, often branched or irregularly shaped (Fig. 57.7). The glands are separated by expanded lamina propria lymphocytes, plasma cells, and eosinophils, as well as by neutrophils, which are normally sparse. The neutrophilic infiltrate is localized to the base of the glandular crypts and invades the crypts, producing crypt abscesses (Figs 57.8, 57.9) In more severe disease, the epithelial lining is destroyed, with denuding ulcerations over the lamina propria. The

inflammatory changes are usually superficial, limited by the muscularis mucosae (Figs 57.10, 57.11). In fulminant colitis, the muscular layers are breached by expanding inflammatory ulceration that can leave the bowel wall tissue-paper thin and protected only by the serosa.

As the mucosa heals, the glandular crypts may become atrophied or shortened and irregularly shaped, with a thinned-out lamina propria. Inflammatory polyps comprise vascular granulation tissue with a thin colonic epithelium. In quiescent colitis, the architectural distortion is present but acute inflammation (neutrophils and crypt abscesses) is absent. Both acute inflammation and regeneration of the colonic epithelium produces cellular atypia that must be distinguished from epithelial dysplasia [158,159]. In regenerating mucosa, the glandular epithelium becomes irregularly shaped and hyperchromatic, with depletion of normal apical mucus. Stratification of nuclei or loss-of-polarity are manifestations of neoplastic transformation, i.e., dysplasia (see below).

Imaging studies

Conventional barium radiography has largely been supplanted by endoscopic examinations for the diagnosis and assessment of ulcerative colitis, but radiological examinations may be a valuable adjunct to endoscopy in specific clinical situations [160]. Plain abdominal radiographs are useful in the setting of severe colitis where outlines of the air-filled colon can demonstrate the presence or absence of haustrations or dilation of the colon (to rule out toxic megacolon) (Fig. 57.11). Extralumenal gas under the diaphragm (free air), pneumatosis coli, and evidence of an ileus pattern are additional features of severe colitis. Plain abdominal radiographs also provide a view of the sacroiliac joints and lumbosacral spine as a gross assessment of sacroiliitis or ankylosing spondylitis for patients presenting with low back pain.

Contrast barium studies, once the primary diagnostic modality, are less sensitive and specific than endoscopic examinations that also permit histological sampling [110,111]. Air contrast barium enemas demonstrate the fine or coarse mucosal granularity of microscopic ulcerations or the diffuse, continuous, and symmetric pattern of ulceration involving the rectum to the proximal extent of disease (Fig. 57.12). Other features of ulcerative colitis that may be visible on barium enemas are the loss of haustration in inflamed segments, foreshortening of the colon, and an increase in the space between the sacrum and rectum (Fig. 57.13). Barium enema examinations are contraindicated in severely ill patients because of the potential for perforation or the induction of a toxic megacolon.

Scintigraphic scanning with indium-labeled or technetium-labeled leukocytes has, occasionally, been used to assess severely ill adults or children for relatively rapid determination of the extent, severity, and continuity of inflammation

Figure 57.12 Mild to moderate, left-sided, ulcerative colitis shows granularity of mucosa without ulceration. Courtesy of Dr Dennis Balfe, St Louis, MO.

Figure 57.13 Full-column barium enema in a patient with ulcerative colitis shows shortening of the colon and loss of haustral markings. Courtesy of Dr Dennis Balfe, St Louis, MO.

when the extent of colitis is uncertain or when small bowel disease has not been excluded [161]. Scintigraphy is noninvasive and occasionally helpful in discriminating ulcerative colitis from Crohn's disease.

Computed tomography (CT) enterography has also been evolving as a diagnostic technique for patients with IBD. The technique uses a negatively charged or neutral contrast agent (e.g., water, isoosmotic mannitol, or methyl cellulose) to enhance mucosal viewing and allow improved ability to diagnose small bowel disease [137]. Routine CT scanning can be useful in patients with severe disease or potentially complicating abdominal complications such as an abscess or perforation.

Magnetic resonance imaging of the colon is also an evolving, potentially helpful modality to detect histological inflammation in patients with suspected IBD [162,163] but the sensitivity and specificity are lower than with colonoscopy [164].

Wireless capsule endoscopy is a potential tool to exclude the presence of Crohn's disease in patients with indeterminate colitis [137]. The superiority of wireless capsule endoscopy has been demonstrated compared with enteroscopy [165] and small bowel radiography [166,167] at identifying small intestinal "lesions". However, the differentiation between "normal" small ulcerations or aphthae, and true Crohn's disease lesions, has not been well defined [168–170]. In addition, the utility of wireless capsule endoscopy to identify the etiology of chronic abdominal pain has not been established [171]. The development of an endoscopic classification of small bowel lesions is necessary and minimal prospective "endoscopic" criteria for the diagnosis of Crohn's disease will be required before this novel procedure gains utility in patients with ulcerative colitis [131].

Crohn's disease

Crohn's disease is manifest by focal, asymmetric, and transmural inflammation of the digestive tract that may, or may not, be accompanied by granuloma formation. In contrast to the diffuse, continuous, superficial (mucosal) inflammation limited to the colon in ulcerative colitis, the inflammation of Crohn's disease is patchier (focal), may be transmural, and can involve any segment of the gastrointestinal tract from mouth to anus. The transmural nature of Crohn's disease can lead to intestinal complications of stenoses (strictures) and fistulae. The histological finding of noncaseating granulomas is a hallmark of Crohn's disease, but these lesions are identified in only about 30% of patients; and are not necessary to make the diagnosis.

Crohn's disease has the potential to involve any segment of the gastrointestinal tract so the presentations are more heterogeneous than those of ulcerative colitis: yet they are still are determined by the location, extent, and severity of inflammation as well as the inflammatory pattern. Despite the concept of "skip areas," the location and pattern of intestinal inflammation tends to remain constant for each individual [100]. The spectrum of inflammatory patterns in Crohn's disease ranges from superficial inflammation similar

to ulcerative colitis, to formation of fibrostenosing strictures, to penetration of the bowel wall and fistula formation accompanied by a mesenteric inflammatory mass or perienteric abscess. An attempt to classify Crohn's disease on the basis of inflammatory patterns [172] has been compromised by the tendency towards the development of stenoses over time [173]. In contrast to the potential of curing ulcerative colitis with a colectomy, Crohn's disease is usually not cured by surgery; intestinal resection and anastomosis is almost inevitably followed by recurrence of the disease involving the anastomotic site and proximal intestine [174].

The instrument most commonly used to quantify disease activity has been the Crohn's Disease Activity Index (CDAI) [175], however, because of its complex derivation and lack of discrimination between symptoms and inflammation, the CDAI is not used in clinical practice. Numerous alternative indices have been used in clinical trials, however, to date, none have superseded the CDAI as an investigative tool or for regulatory approval [176]. Instead, physicians perform individualized assessments of the severity of disease according to inflammatory symptoms, obstruction, fistulization, abscess formation, systemic complications, and effect on the patient's quality of life [177].

Diagnosis

Similar to ulcerative colitis, there is no pathognomonic clinical, endoscopic, or pathological marker, or a biomarker for the diagnosis of Crohn's disease which, instead, is diagnosed on the basis of composite clinical, radiographic, endoscopic (Table 57.3), and histological criteria (Table 57.4). Both macroscopic (endoscopic or radiographic) and microscopic (biopsy or surgical specimen) evidence of discontinuous intestinal inflammation with or without granulomas is a hallmark of Crohn's disease. It is not uncommon, particularly in children [178,179], to have inflammation confined to the colon with features that cannot be categorized as ulcerative colitis or Crohn's disease (indeterminate colitis) [180]. Serological studies are becoming more specific for Crohn's disease but, as yet, they do not have sufficient positive or negative predictive values to suffice as confirmatory studies [137], in particular for patients with low, or high, pretest probabilities [181]. At present, the clinical presentation and key features of the history, physical examination, in combination with laboratory studies (including serologies) confirm the presence of IBD and determine a diagnostic workup, to differentiate Crohn's disease from ulcerative colitis and other enterocolonopathies [99].

Clinical manifestations and natural history

Crohn's disease most commonly involves the terminal ileum and cecum. However, the pattern of Crohn's disease can be varied. The presentation is determined by the site, extent, severity, and complications of intestinal and extraintestinal disease [99,182] (Table 57.5). Patients usually present with chronic disease with more than 6 weeks of symptoms, but Crohn's disease can be acute, presenting with severe abdominal pain, intestinal blockage, or hemorrhage. Chronic diarrhea is the most common presenting complaint and abdominal pain and weight loss are present in over 60% of patients at diagnosis. Abdominal pain is a more common feature of Crohn's disease than ulcerative colitis because of the transmural extension of inflammation that results in stimulation of pain receptors in the serosa and peritoneum. Abdominal cramping and postprandial pain are common symptoms that often are accompanied by diarrhea, rectal bleeding, nocturnal bowel movements, fevers, night sweats, and weight

Table 57.5 Histological features that allow the physician to distinguish among acute self-limited colitis (ASLC), ulcerative colitis (UC), and Crohn's disease (CD)

loss [182]. Nausea and vomiting occur in the presence of intestinal strictures that produce partial or complete bowel obstructions. Transmural disease commonly manifests in the perianal region as skin tags or perirectal abscesses or fistulae that occur in approximately 10% of patients at the time of diagnosis [183], but also can present as an inflammatory mass in the right lower quadrant. Extraintestinal manifestations including musculoskeletal symptoms with peripheral or axial arthritis, or skin lesions, primarily erythema nodosum, may precede, or accompany, intestinal symptoms and are most common when the colon is involved [119]. In children and adolescents, the presentation often is more insidious, with weight loss, failure to grow or to develop secondary sex characteristics, arthritis, or fevers of undetermined origin [184,185].

Crohn's disease of the esophagus, stomach, and duodenum

Crohn's disease involving the upper gastrointestinal tract is most commonly accompanied by small or large bowel involvement [186,187]. Infrequently, Crohn's disease involving the esophagus, stomach, or duodenum presents with symptoms that mimic gastroesophageal reflux or peptic ulcer disease. Heartburn, dysphagia, nausea, dyspepsia, epigastric pain, and early satiety or postprandial vomiting typically accompanies other systemic inflammatory symptoms such as fever, night sweats, or rectal bleeding. Often, esophageal symptoms and findings resolve with treatment for intestinal disease activity [188]. Duodenal Crohn's disease may present with obstruction, fistula formation, or biliary obstruction [189,190] (Fig. 57.14).

Figure 57.14 Crohn's disease involving the antrum and duodenum. Courtesy of Dr Dennis Balfe, St Louis, MO.

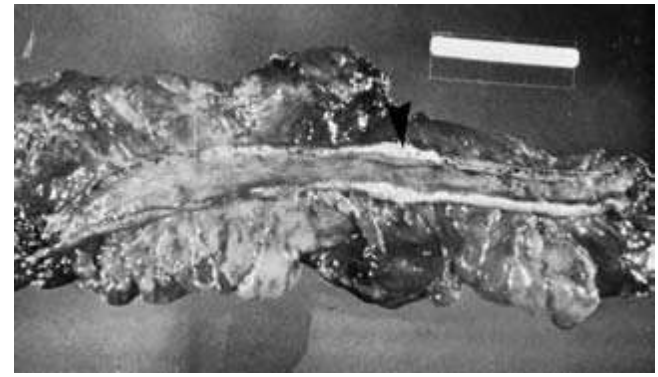

Figure 57.15 Crohn's disease of the small intestine showing lumenal narrowing and thickening of the intestinal wall (arrowhead). There is also a large amount of fat on the serosa. Courtesy of Dr Ira Kodner, St Louis, MO.

Jejunoileitis

Crohn's disease involving, primarily, the proximal small bowel most often presents with vomiting and diarrhea, cramping abdominal pain, and weight loss [189, 191]. The presentation typically includes borborygmi related to focal, segmental strictures compromising the passage of enteric contents. Diarrhea is multifactorial and can be secondary to malabsorption as a consequence of inflammation, protein-losing enteropathy, or stasis and small bowel bacterial overgrowth proximal to strictures.

Ileitis and ileocecal Crohn's disease

Crohn's disease most commonly presents as right lower quadrant abdominal pain and tenderness (often accompanied by an inflammatory mass), diarrhea with or without rectal bleeding, weight loss, fevers, chills, and night sweats. The pain is often described as cramping and usually occurs after meals related to partial or intermittent obstruction of the narrowed intestinal lumen, in which case abdominal distention, nausea, and vomiting may accompany the pain (Fig. 57.15). An acute presentation may mimic appendicitis; occasionally, Crohn's ileitis will be diagnosed at exploratory laparotomy for presumed appendicitis.

Crohn's colitis

Approximately 15% of Crohn's disease cases are limited to the colon [191]. Distinguishing these cases from ulcerative colitis can be difficult, because the clinical manifestations – diarrhea, rectal bleeding, and urgency – overlap with those of ulcerative colitis [103,192]. However, Crohn's disease of the colon is more likely than ulcerative colitis to be accompanied by perianal manifestations (skin tags, perirectal abscess or fistulae) [100] and the rectum is often spared, whereas ulcerative colitis always involves the rectum. In approximately 10%–20% of patients presenting with colitis, the classification may be indeterminate in the setting of diffuse or severe inflammation, or questionable focal inflammation [192] (Fig. 57.16).

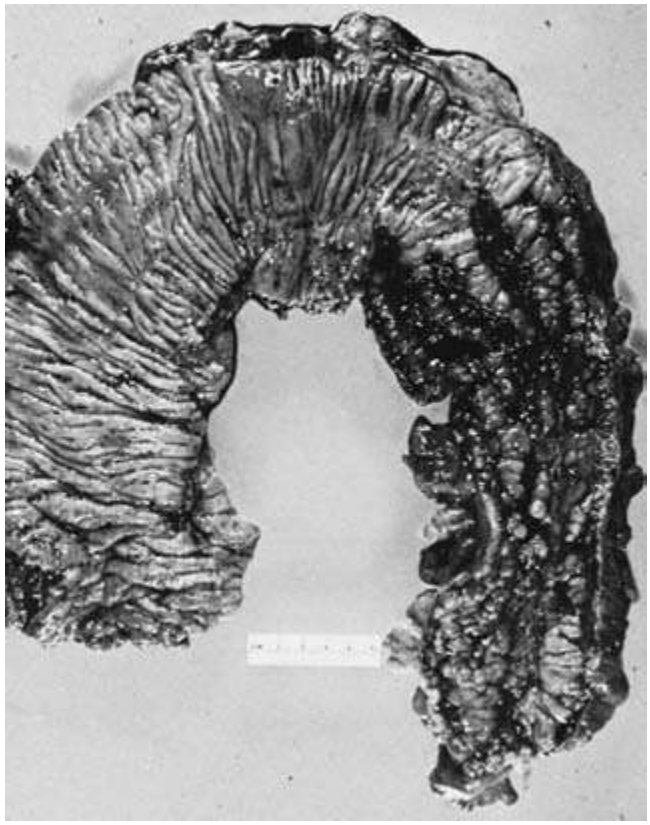

Figure 57.16 Crohn's colitis colectomy specimen shows deep, clawed linear ulcers in the transverse and descending colon. Courtesy of Dr Ira Kodner, St Louis, MO.

Perianal Crohn's disease

Perianal involvement in Crohn's disease develops at some point in the course of Crohn's disease in approximately 25% of patients and most often accompanies colonic disease [193]. Perianal inflammation arises from the anal crypts at the anorectal junction and progresses through or around the anal sphincter, presenting as perirectal abscesses or fistulae. Often, perianal tissue becomes hypertrophied, producing skin tags that may be misdiagnosed, or attributed to hemorrhoids. At times, perianal manifestations are the primary presentation and in extreme situations, the anal sphincter and perineum can become grossly deformed [183,193].

Disease course

Crohn's disease, like ulcerative colitis, has been described as a relapsing and remitting disease. However, such a description takes into account, primarily, symptomatic activity rather than disease progression and does not take into account differing genetic patterns [194], disease location [195], or the nature of medical or surgical therapy [196]. Furthermore, there are environmental factors [197], such as cigarette smoking [198], NSAIDs [199], intercurrent infections [200] and stress [201–203], that may impact on symptoms or inflammatory features.

At any time the majority of patients are either in a symptomatic remission or having mild disease activity [204,205]. The long-term "prognosis" of Crohn's disease depends on the definition of the end point. Mortality is not substantially greater than for the general population [206]. Most deaths are related to either severe disease [207] that may be complicated by infectious complications related to therapy [208]. The association between Crohn's disease and smoking may also contribute to long-term mortality risks, particularly in women [209]. The disease "course" does not "burn out" as similar proportions of patients from cohort studies have evidence of clinical activity or the need for surgery over several decades [210].

The course, as defined as the need for surgery, is impacted by genotypic/phenotypic correlations. Patients with *NOD2/CARD15* mutations are more likely to develop fibrostenosing ileal disease [211,212] that has a high risk of evolving to a need for surgery [195]. Similarly, ileal disease and ileocolonic disease are risk factors for surgical resections [195]. Early onset Crohn's disease is also a risk factor for the need for surgery [136,213,214]. The presence of perianal disease is a risk factor for a more complicated (stricturing, penetrating) course of Crohn's disease [213,214] as is the presence of multiple, or high-titer antimicrobial antibodies [137], particularly in pediatric patients [136,142]. Cigarette smoking is a modifiable risk [215] related to the need for surgery [198] and of post-operative recurrence [216]. Additional factors that have been associated with disease flares are similar to those in ulcerative colitis including: intercurrent infections, in particular *C. difficile* [200,217]; concurrent use of NSAIDs [199,218], and, possibly, stress in selected individuals [201]. The latter concept of stress-induced flare-ups is obfuscated by the possibility of stress-induced symptoms or coexistent irritable bowel syndrome [118] rather than increased inflammatory activity.

Medical therapy also impacts on the disease course and interpretation of effects requires comprehension of specific therapeutic end-points [112,176]. There is a hierarchy of end points according to requisite changes in the CDAI (e.g. 70- to 100-point decrease vs remission defined as a CDAI < 150) and, most recently, both maintenance of clinical remissions and the achievement of "mucosal healing" with the use of biological agents have been correlated with reductions in the need for hospitalizations and surgery [219,220]. Conversely, patients who are treated with acute courses of corticosteroids have a poor, long-term prognosis [115,221] and a likelihood of developing more refractory disease or steroid-dependence. Early introduction of immune-modulators (see section on medical therapy) with corticosteroids improves 1-year remission rates in adults [222] and children [223]. However, the increasing use of thiopurines has not altered the composite risk for surgery [224], possibly because of the delay in introduction of therapy.

Despite the low mortality, Crohn's disease can have a substantial impact on quality of life [225]. Of greatest concern to

patients is the possible need for an stoma, the uncertain nature of disease, and the lack of energy [226]. Patients have problems with employment, social activities, and interpersonal relationships. The quality of life in Crohn's disease is, on average, less good than in ulcerative colitis [227]. The majority of patients are employable but disease activity has a substantial impact on employment that improves with clinical remissions [228,229]. There is also a higher incidence of depression as a comorbid condition with Crohn's disease that diminishes the quality of life [227].

Physical examination

The key findings on physical examination of patients with Crohn's disease include both abdominal and general systematic abnormalities. The abdominal examination may be significant for distention and tympany with high-pitched, abnormal bowel sounds in the presence of intestinal strictures producing partial intestinal obstruction. Tenderness in the area of involvement and the presence of an inflammatory mass are common. It is important to examine the perianal region for evidence of abscess, fistula, skin tags, or anal stricture.

Patients with Crohn's disease often are chronically ill and can present with weight loss and pallor. The eye examination may demonstrate episcleritis or uveitis. Aphthous ulcerations in the mouth are common and in extreme cases patients may exhibit evidence of profound weight loss (temporal and interosseous wasting) and nutritional deficiencies (e.g., cheilosis, tongue atrophy).

Examination of the musculoskeletal system may demonstrate swelling or redness of large joints (e.g., knees, ankles, wrists) or clubbing of the fingers. Skin examination can reveal erythema nodosum or, rarely, pyoderma gangrenosum [119].

Laboratory studies

Laboratory studies in Crohn's disease are largely nonspecific [110]. Anemia is common and can result from deficiencies of iron, vitamin B-12, or folic acid or from chronic disease. Serum ferritin levels correlate better than iron and iron-binding protein levels with bone marrow iron stores in IBD [230]. Leukocytosis is common, depending on the severity of inflammation and the presence of suppurative complications. Thrombocytosis also is common and is related to inflammation or iron deficiency [231]. Elevated erythrocyte sedimentation rates and C-reactive protein levels reflect nonspecific acute-phase reactions [232,233]. Electrolyte disturbances depend on the severity of diarrhea and dehydration. Serum albumin often is reduced as a result of malnutrition and enteric protein losses [234]. Patients with severe weight loss may have prolonged clotting times because of vitamin K deficiency [235]. Urinalysis commonly demonstrates calcium oxalate crystals or red blood cells related to nephrolithiasis.

Quantitative stool examinations are useful in the setting of diarrhea to assess fecal leukocytes (confirming inflammatory diarrhea), stool volume, and fecal fat. Quantification of either fecal calprotectin [236] or lactoferrin [128] are surrogates for the presence of fecal leukocytes [137,237]. As discussed above, the presence of the serological markers anti-*Saccharomyces cerevisiae* antibody and an antibody to the outer core membrane of *E. coli* (OmpC) have high specificity for Crohn's disease and the addition of an RNA-derived immunologically associated bacterial sequence of *Pseudomonas fluorescens* (I2 peptide) improves the sensitivity and specificity of the serological studies for Crohn's disease [137,237]. Nevertheless, these markers have primarily been evaluated and correlated with known diagnostic patterns of Crohn's disease and are less sensitive for the diagnosis in the case of a low pretest probability and their specificity has not been sufficiently evaluated compared to other enteropathies such as celiac disease or NSAID-induced enterocolitis [137].

Imaging studies

There is an evolution of imaging studies to evaluate patients with Crohn's disease [137]. The decision as to which imaging modality to use is made on the basis of the question being addressed because they are complementary techniques with their own strengths and weaknesses. Air-contrast radiography is better for assessing mucosal detail, colonic distensibility, and the presence of strictures. However, in an acutely ill patient with Crohn's disease, a CT scan is often the preferred initial diagnostic test to answer urgent clinical questions concerning the presence of extralumenal complications such as an abscess, or possible obstruction.

For the most part, air-contrast or double-contrast studies are preferred to single-contrast studies because they give much better definition of fine mucosal detail and can even assess the depth of ulcerations. Although contrast studies are usually well tolerated, some precautions should be observed. Barium enema is contraindicated in patients with severe colitis because injection of air and barium into the inflamed colon may precipitate toxic megacolon. In addition, nonsoluble barium contrast agents should be used with caution when obstruction is suspected.

Radiographic findings do not correlate well with symptomatic disease activity [232]. In particular, asymptomatic patients may have markedly abnormal radiographic studies because of fibrosis of the bowel wall with resultant loss of distensibility. A peroral pneumocolon, a regular air-contrast, small bowel follow-through in which air is insufflated in the colon, can assist in determining distensibility of the terminal ileum and can improve the visualization of the ileum. However, air-contrast studies are frequently unhelpful in distinguishing whether a narrowed segment is the result of fibrosis or inflammation.

The earliest form of Crohn's disease detectable by air-contrast barium studies is the presence of aphthous ulcers, which appear as small discrete collections of barium surrounded by radiolucent halos of inflammatory infiltrate

Figure 57.17 Crohn's colitis with numerous aphthous ulcers (arrowhead). Courtesy of Dr Dennis Balfe, St Louis, MO.

(Fig. 57.17). These small ulcers are usually multiple, and the intervening mucosa is normal. Aphthous ulcers are not, pathognomonic to Crohn's disease; they are seen in amebiasis, Behçet syndrome, shigellosis, and other conditions. As Crohn's disease becomes more severe, the aphthous ulcers enlarge, deepen, and connect with one another to form stellate and linear ulcers; the intervening mucosa develops a nodular appearance on radiograph, a process termed cobblestoning.

Progressive deepening of ulcers leads to formation of abscesses or fistulae and transmural inflammation and fibrosis induce limited distensibility, with decreased lumenal diameter and stricture formation and a potential "string sign" or "chain of lakes" appearance in the setting of multiple strictures with intervening prestenotic dilation. Thickened bowel wall and adjacent mesentery induce a separation of bowel loops or the appearance of a mass (Fig. 57.18). Formation of fistuliae can also be identified.

Small bowel Crohn's disease can be evaluated by small bowel follow-through or by enteroclysis with the evolving potential to utilize either CT (Fig. 57.19) or magnetic resonance imaging (MRI) enteroclysis (Fig. 57.20) [160,238]. These techniques combine CT scanning with the ability to

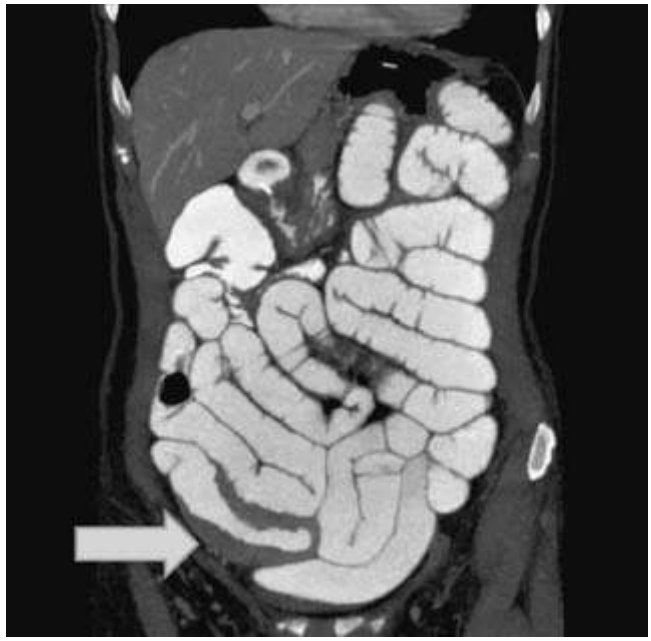

Figure 57.19 Computed tomographic enterography showing thickened terminal ileum (arrow) in a patient with Crohn's disease.

assess a wall-thickening, inflammatory reaction in adjacent fat ("creeping fat"), and extralumenal complications such as abscesses or a mesenteric inflammatory mass allowing a rapid assessment and helping to guide therapy such as percutaneous drainage of an abscess.

CT is particularly critical in evaluating a patient for intestinal complications of Crohn's disease, most notably fistulae, abscesses, and obstruction (Fig. 57.21). The iodinated contrast used in CT scans is safer in the presence of an intestinal obstruction than barium. In addition, extraintestinal manifestations of Crohn's disease (including hydronephrosis, sacroiliitis, gallstones, and renal calculi) can be identified by CT.

Other imaging modalities occasionally may have a role in IBD, including ultrasonography and MRI. Ultrasonography can be used to complement CT scans for localization and percutaneous drainage of abdominal abscesses whereas MRI examinations are sensitive tools to measure inflammatory activity [165] and to identify perianal disease [193]. Perianal complications can also be identified by transrectal ultrasound [193]. Occasionally, scintigraphy using leukocytes labeled with indium or technetium can be helpful to define locations of intestinal inflammation when barium studies are not possible or their results are indeterminate [161,239].

Endoscopy

Endoscopy and radiology serve complementary roles in the diagnosis and management of patients with Crohn's disease. Endoscopy serves to diagnose Crohn's disease involving the terminal ileum or colon, to distinguish between ulcerative colitis and Crohn's disease, to determine the extent and severity of disease, to assess response to treatment, and to screen for dysplasia. With its ability to visualize the mucosa directly and obtain biopsies, endoscopy has become established as the primary diagnostic tool. In contrast to the characteristic findings of rectal involvement with a pattern of diffuse, continuous inflammation, absent mucosal vasculature with friability, granularity and superficial ulcerations in ulcerative colitis; the distinguishing features of Crohn's disease include rectal sparing, areas of active disease interspersed with normal mucosa; sharp, punched-out ulcerations surrounded by normal mucosa; and "cobblestoning," or nodular mucosa often intersected by crossing linear ulcerations [161,240] (Table 57.4).

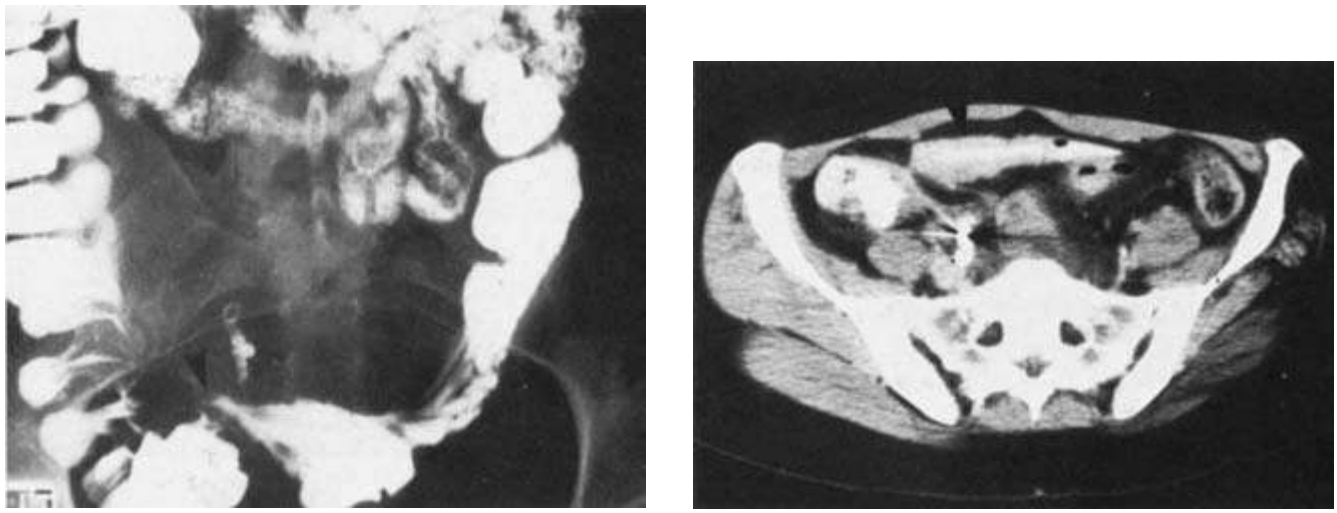

Figure 57.21 Crohn's disease of the terminal ileum (arrows) on small bowel follow-through **(left)** and computed tomography (CT) scan **(right)** in the same patient. Thickening of the intestinal wall is easily appreciated on the CT scan. On small bowel follow-through, wall thickening is indicated by the separation of the columns of barium. Figure 57.23 Crohn's ileocolitis with rounded, punched-out ulcers around the ileocecal valve. Courtesy of the Crohn's and Colitis Foundation of America, New York, NY.

The earliest endoscopic manifestations of Crohn's disease are aphthous ulcers (Fig. 57.22), small discrete ulcers a few millimeters in diameter surrounded by a thin red halo of edematous tissue. Aphthous ulcers are usually multiple, and the intervening mucosa is normal. They can grow to form rounded, punched out ulcers (Fig. 57.23), or long serpiginous or large stellate ulcers (Fig. 57.24). Longitudinal and transverse ulcers may intersect to form a grid with intervening cobblestone-like areas of nonulcerated mucosa. The diffuse mucosal irregularities of erythema, edema, and granularity, which are prominent in ulcerative colitis, occur less commonly in Crohn's disease. Areas of involvement can be interspersed with normal "skip areas". In a prospective endoscopic study of patients with Crohn's disease who were about to start a course of prednisone, the incidence of endoscopic findings was as follows: superficial erosions, 93%; deep erosions, 74%; mucosal edema, 48%; erythema, 44%; pseudopolyps, 41%; aphthous ulcers, 10%; ulcerated stenosis, 8%; and nonulcerated stenosis, 2% [241]. An endoscopic scoring system has been developed and validated [242] to assess the severity of ileal and colonic disease, but as a result of the complexity of assessing multiple aspects of lesions it has been simplified and based on ulcer size, ulcerated surface, affected surface, and lumenal narrowing [243]. In recent clinical trials with biological agents, an even more simplified assessment of mucosal healing was defined as the absence of mucosal ulceration in all examined segments of the colon and ileum [220].

Colonoscopy has also been used to assess postoperative recurrence of Crohn's disease at ileocolonic anastomoses. Given the high likelihood of recurrent endoscopic and clinical disease [244] the severity of lesions at the anastomosis predicts the likelihood of clinical relapse [245].

Similar endoscopic features may be present in the esophagus, stomach, or duodenum [246] that usually accompany small or large bowel involvement [247]. In addition, the finding of granulomas or focal "enhanced" or "active" gastritis, in the absence of ulceration or *Helicobacter pylori*, at gastric biopsy can help to establish a diagnosis of Crohn's disease [247].

Wireless capsule endoscopy is being used to diagnose Crohn's disease allowing access to parts of the small bowel that cannot be reached by standard endoscopy (Fig. 57.25) [247]. Capsule endoscopy may be more sensitive than conventional imaging studies, including CT enterography or small bowel enteroclysis, for identifying subtle lesions [248]; however, the specificity of small lesions such as "mucosal breaks" identified by capsule endoscopy to diagnose or attribute findings to Crohn's disease activity is compromised by the presence of these lesions in 14% of normal controls [137,249]. Furthermore, there is a significant risk of capsule "retention" in patients with known or asymptomatic strictures [137]. Therefore, patients need to be informed of the risk of capsule retention and the potential need for surgical removal; although some clinicians claim therapeutic benefit from surgical treatment of strictures identified at capsule

endoscopy the appropriate algorithm for diagnosis of Crohn's disease supports the use of conventional imaging studies before capsule endoscopy [137] because of the risks and the lack of specificity [249].

Histology

The pathological findings in Crohn's disease reflect the gross pattern of focal and asymmetric intestinal involvement [156] (Fig. 57.26). The primary lesion is an aphthous ulcer; minute erosions overlying lymphoid aggregates [250,251]. As the microscopic ulceration extends in either a linear or a transmural pattern, the histological changes that develop include a mixed acute and chronic inflammatory cell infiltrate comprising lymphocytes, plasma cells, and neutrophils (Table 57.5). Crypt abscesses are common, and the inflammatory infiltrates are often located adjacent to normal epithelium. Noncaseating granulomas, which may be identified in mucosal biopsies or in resected specimens, are characteristic of Crohn's disease (Fig. 57.27); however, the presence of granulomas is not necessary to confirm the diagnosis [179] because they only occur in biopsy specimens from approximately one-third of patients [252]. However, the finding of granulomas in a mucosa that appears grossly normal, such as the "spared" rectum, can help to support the diagnosis of Crohn's disease [253,254]. Granulomas also can be found in lymph nodes, mesentery, peritoneum, and liver [255]. Inflammatory "pseudopolyps" can also be observed in areas of acute or previously inflamed intestine in Crohn's disease [256]. Also, similar to ulcerative colitis, medical therapy can affect the

histological appearance of the mucosa with focal, or near complete resolution of acute inflammatory changes [150].

Gross examination of the intestine from resected specimens in Crohn's disease shows the transmural nature of inflammation producing thickening of the bowel wall [255]. The adjacent mesentery is thickened, edematous, and contracted, which fixes the intestine in one position. Adipose tissue extends from the mesentery and "creeps" over the serosal surface of the intestine. Transmural inflammation may cause loops of intestine to be matted together. All layers of the intestine are thickened, and the lumen is narrowed (Fig. 57.15). There may be paradoxical involvement of the deeper layers of the bowel wall with lymphoid aggregates overlying normal-appearing epithelium. Submucosal fibrosis, deep fissuring ulcerations, and fistulizing ulcerations communicate between loops of bowel or into the adjacent mesentery (Fig. 57.28). Deep linear ulcers typically are present along the mesenteric surface of the mucosa and contract the lumen in an asymmetrical pattern [257]. Linear ulcerations surrounding "islands" of normal mucosa produce a "cobblestone" appearance whereas parallel deep linear ulcerations can produce a "bear-clawed" appearance (Fig. 57.16).

Extraintestinal manifestations

Although ulcerative colitis and Crohn's disease primarily involve the bowel, both are associated with manifestations in other organ systems. For some patients, especially those with sclerosing cholangitis or ankylosing spondylitis, the extraintestinal manifestations may be more troublesome than the bowel disease. The extraintestinal manifestations can be divided into two major groups: those in which the clinical activity follows the activity of the bowel disease and those in which the clinical activity is unrelated to the clinical activity of the bowel disease. Most extraintestinal manifestations occur more commonly with ulcerative colitis or Crohn's colitis than with Crohn's disease confined to the small intestine.

Peripheral arthritis

The most common extraintestinal manifestation of IBD is arthritis [258–260]. The arthritic complications of IBD are colitic or peripheral arthritis and ankylosing spondylitis or axial arthritis. Peripheral arthritis can be either panciarthitis (four or fewer joints) or polyarthritis (five or more joints) [261].

Panciarthritis is typically asymmetric and predominately affects larger joints (elbow, knees, and wrist) whereas polyarthritis, which is less common, is symmetric and predominately affects smaller joints. The activity of panciarticula arthritis is more likely to follow the activity of the bowel disease whereas in polyarticular arthritis the joint pain can be independent of the activity of the bowel disease. Peripherial arthritis is more common with Crohn's colitis than ulcerative colitis and is uncommon with Crohn's disease confined to the small intestine. Most arthritic flares last only a few weeks, although recurrences are common with renewed disease flares. Deformity with radiological changes occurs in fewer than 25% of cases. Serology for rheumatoid factor is negative in these patients. Peripheral arthritis, uveitis, and erythema nodosum often are seen together. Acetaminophen can be used for joint discomfort. NSAIDs are generally avoided because they may induce a flare or worsening of the colitis. Infliximab is useful in peripheral arthritis [262].

Axial arthritis

Ankylosing spondylitis is seen in patients with IBD, but its activity does not follow that of the bowel disease, and treatment of the bowel disease does not affect the spondylitis [259,260]. Ankylosing spondylitis presents with morning stiffness, low back pain, and stooped posture. Radiography of the spine in ankylosing spondylitis shows squaring of the vertebrae and straightening of the spine. Syndesmophytes appear along the lateral and anterior portions of the intervertebral discs, giving the picture of "bamboo spine" (Fig. 57.29).

Patients with ulcerative colitis have a 30-fold increase in the incidence of ankylosing spondylitis compared with the general population. Even though there is no increased incidence of HLA-B27 in ulcerative colitis, 80% of those with both ulcerative colitis and ankylosing spondylitis are B27-positive [261]. IBD-associated ankylosing spondylitis occurs frequently in females (perhaps up to 40%), whereas, ankylosing spondylitis unassociated with intestinal disease occurs at a male-to-female ratio of nearly 9 : 1. In contrast to peripheral arthritis, which is episodic and usually nondeforming, ankylosing spondylitis can be relentlessly progressive and crippling. The results of medical management of ankylosing spondylitis in IBD are poor. Physical therapy plays a major role in maintaining function. Pain management is a problem, and narcotic addiction is common. NSAIDs, although they reduce inflammation and pain in spondylitis and in colitic arthritis, do not halt the progression of the disease and may exacerbate intestinal inflammation. Medical treatment of IBD and colectomy are not helpful in managing the ankylosing spondylitis. A report of successful treatment with infliximab suggests a hopeful, possibly effective option [263].

Sacroiliitis, inflammation of the joint between the sacrum and the ileum, can be seen in conjunction with ankylosing spondylitis but more often is seen alone. Over 20% of patients with IBD, most of whom have no back pain, have radiographs consistent with sacroiliitis [264,265]. Some will present with low back pain which can be slowly progressive, not related to intestinal inflammation. Radiographs of the pelvis reveal blurring of the margins of the sacroiliac joints, with patchy sclerosis.

Figure 57.29 Sacroiliitis and ankylosing spondylitis demonstrating obliteration of the sacroiliac joints (large arrow) and bamboo spine with syndesmophytes (small arrow). Courtesy of Dr Dennis Balfe, St Louis, MO.

Osteoporosis

Osteoporosis or osteopenia occurs in as many as half of patients with IBD [266]. The incidence of fractures in an IBD population was 40% higher than in a cohort population [267]. In Crohn's disease osteopenia may be present at diagnosis. Numerous factors may contribute including malnutrition, malabsorption, and smoking. Persistent inflammation and steroid use may be the most important factors; TNF enhances bone resorption. Although osteopenia may occur independent of steroid use, steroids can still worsen the problem. In ulcerative colitis, the loss of bone density occurs more directly as a result of steroid use. Patients with primary sclerosing cholangitis, particularly with longer standing disease, can have more severe osteoporosis. The therapeutic options include estrogen replacement therapy, raloxifene, calcitonin; bisphosphonates; alendronate (Fosamax), and risedronate (Actonel) [268]. Screening patients using dual photon absorptiometry is recommended. Guidelines for the management of osteoporosis in IBD have been developed by the British Society of Gastroenterology and the American Gastroenterological Association [269,270].

Renal complications

The incidence of kidney stones in patients with IBD, with estimates ranging between 1% and 25%, is several times that in the general population [271]. Calcium oxalate stones are seen in patients with small intestine Crohn's disease. Ileal resections or ileal disease can lead to fat malabsorption, and unabsorbed fatty acids bind calcium in the lumen. In healthy persons, oxalate in the lumen is bound to calcium. Calcium oxalate is poorly soluble and poorly absorbed. If calcium is bound to malabsorbed fatty acids, however, oxalate combines with sodium to form sodium oxalate, which is soluble and is absorbed in the colon [272]. The development of calcium oxalate stones in Crohn's disease requires an intact colon to absorb oxalate; patients with ileostomies do not develop calcium oxalate stones. However, the presence of an ileostomy predisposes to other kinds of kidney stones, particularly urate stones, because of the diminished urine volumes in patients with significant ileostomy volume losses [273]. Measurement of 24-h urinary oxalate, uric acid, and citrate may be useful to guide therapy. Dietary restriction of oxalate and citrate supplementation can help prevent recurrence of oxalate stones.

Other urinary tract complications are associated specifically with Crohn's disease. Inflammation from the bowel extending into the retroperitoneal space can occlude the ureters, leading to obstruction and hydronephrosis [274]. This process most commonly extends from the area of the cecum and terminal ileum and involves the right ureter. Also in Crohn's disease, fistulae can form between an inflamed bowel and the urinary bladder, leading to urinary tract infections [275]. Amyloidosis is seen in patients with Crohn's disease and has caused death from renal insufficiency [276]. Renal amyloidosis does not respond to conventional medical therapy for Crohn's disease and, for the most part, does not improve after the inflamed section of intestine is resected.

Dermatological manifestations (see Chapter 110)

The two common dermal complications of IBD are pyoderma gangrenosum and erythema nodosum. Pyoderma gangrenosum is seen with colitis and ileocolitis and is associated with extensive long-standing disease. The incidence of pyoderma in ulcerative colitis is low (1%–5%), and it is even lower in Crohn's disease; however, 36%–50% of all patients with pyoderma gangrenosum have IBD [277,278]. The typical lesion is a discrete ulcer with a necrotic base, usually found on the lower extremities (Fig. 57.30) but may occur elsewhere, particularly the face. Lesions often occur at the site of previous injury (pathergy) and are seen around stomas. The ulcers may drain purulent material, but the drainage is sterile on culture. These ulcers can become large and deep, with destruction of surrounding soft tissues. Activity of pyoderma gangrenosum may or may not follow the activity of the bowel disease, but these lesions almost always develop during a bout of acute colitis. Usually, the lesions resolve with control of the colitis by use of oral corticosteroids. Alternatively, corticosteroids can be injected directly into the skin lesions. Therapies with Periactin, dapsone, and azathioprine have been reported, with cyclosporine (ciclosporin [rINN]) increasingly recommended [279–281]. Infliximab has also been reported to be dramatically effective in some cases [282]. Topical tacrolimus has also been effective [283].

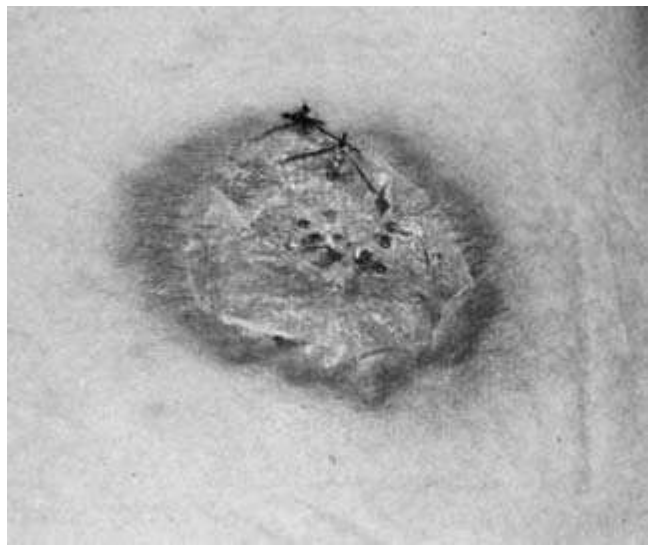

Figure 57.30 Pyoderma gangrenosum (with stitches after biopsy). Courtesy of Dr Ira Kodner, St Louis, MO.

Erythema nodosum is seen particularly in association with Crohn's disease in children [284]. The lesions are raised, tender nodules, usually found over the anterior surface of the tibia. Activity of erythema nodosum follows the activity of the bowel disease and responds to treatment of the bowel disease. Most patients have only a single episode of erythema nodosum. Sweet syndrome (acute febrile neutrophilic dermatosis), which has some similarity to erythema nodosum, is another dermatological condition associated with IBD [285].

Eye complications

The ocular complications of IBD are uveitis and episcleritis [286]. Uveitis (iritis) is an inflammatory lesion of the anterior chamber, presenting with blurred vision, headache, eye pain, photophobia, and conjunctival injection. Diagnosis is made by slit-lamp examination, which demonstrates perilimbic edema and cells in the anterior chamber. Scarring and blindness can be prevented with local therapy of corticosteroids and atropine or other agents that dilate the pupil. Episcleritis is a less serious problem, presenting with burning eyes and scleral injection. Treatment with topical steroids is effective. Infliximab can be useful for refractory uveitis [287].

Thromboembolic complications

Thromboembolic complications, with arterial as well as venous events, occur in 1%–2% of patients with ulcerative colitis

and Crohn's disease [288]. Nonetheless, in half of patients with IBD with thrombotic events no clotting defect can be identified [289]. Deep vein thrombosis and pulmonary emboli affect patients with active disease. In a population study there was a three- to four-fold increase in the incidence of deep venous thrombosis in pulmonary embolism in patients with IBD compared with a control group [290]. Thromboembolic events in the eye and in intracranial vessels also have been described [288,291]. These thrombotic events should be treated with anticoagulants just as they would be in patients without IBD. Activation of clotting factors and thrombocytosis are common. In patients with active disease, procoagulant factors tend to be increased and fibrolytic factors are decreased, potentially generating a hypercoaguable state. In both Crohn's disease and ulcerative colitis increased levels of factor V, factor VIII, and fibrinogen and decreased levels of antithrombin III have been demonstrated [292,293].

Hepatobiliary complications

The hepatic complications of IBD include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. The biliary tract complications are sclerosing cholangitis and gallstones. Cholesterol gallstones occur in patients with ileal disease or ileal resections owing to malabsorption of bile salts and the resultant decrease in the size of the bile salt pool. Pericholangitis is the most common hepatic complication of IBD, with prevalences as high as 50%–80% reported [294,295]. Patients with pericholangitis are usually asymptomatic. Elevations of alkaline phosphatase are seen frequently; elevations of bilirubin are less common. Histologically, there is inflammation of the portal tracts, with lymphocyte and eosinophil infiltrates and degenerative changes of the bile ductules [296]. In more advanced cases, progressive fibrosis can develop. The relationship between pericholangitis and primary sclerosing cholangitis is uncertain. Some studies have suggested that pericholangitis may be a part of the spectrum of sclerosing cholangitis, and the histological manifestations of sclerosing cholangitis and pericholangitis on liver biopsy may be indistinguishable [297]. Patients diagnosed on liver biopsy as having pericholangitis may need to undergo endoscopic retrograde cholangiopancreatography (ERCP) to rule out sclerosing cholangitis. There is no effective therapy for pericholangitis.

Sclerosing cholangitis is a chronic cholestatic liver disease marked by fibrosing inflammation of the intrahepatic and extrahepatic bile ducts; it occurs in 1%–4% of patients with ulcerative colitis and with lower frequency in Crohn's disease [298,299]. Most patients with sclerosing cholangitis have IBD. The prevalence of IBD is so high in patients with sclerosing cholangitis that colonoscopy should be performed even on patients who are without intestinal symptoms. Endoscopic and histological evidence of IBD are commonly found in patients with sclerosing cholangitis without intestinal symptoms. Patients with ulcerative colitis and sclerosing cholangitis have a higher risk of colon cancer than those with ulcerative colitis alone and should undergo more intensive screening [300]. Sclerosing cholangitis can affect intrahepatic bile ducts, extrahepatic bile ducts, or both. In patients with IBD and sclerosing cholangitis, usually both intrahepatic and extrahepatic ducts are affected. Early in the disease, liver biopsy shows enlargement of the portal tracts, with edema and bile duct proliferation. Later, biopsies show extension of fibrosis out of the portal space, eventually leading to cirrhosis.

Bile duct strictures are the major clinical problem in sclerosing cholangitis; strictures can occur in both intrahepatic and extrahepatic bile ducts (Fig. 57.31). Patients may be asymptomatic until the disease is far advanced and then present with fever, right upper quadrant pain, and jaundice. More often, sclerosing cholangitis is first recognized in the evaluation of abnormal laboratory studies: elevated alkaline phosphatase, bilirubin, and aminotransferases. The differential diagnosis of sclerosing cholangitis includes biliary tumors and common duct gallstones; diagnosis is made by ERCP or

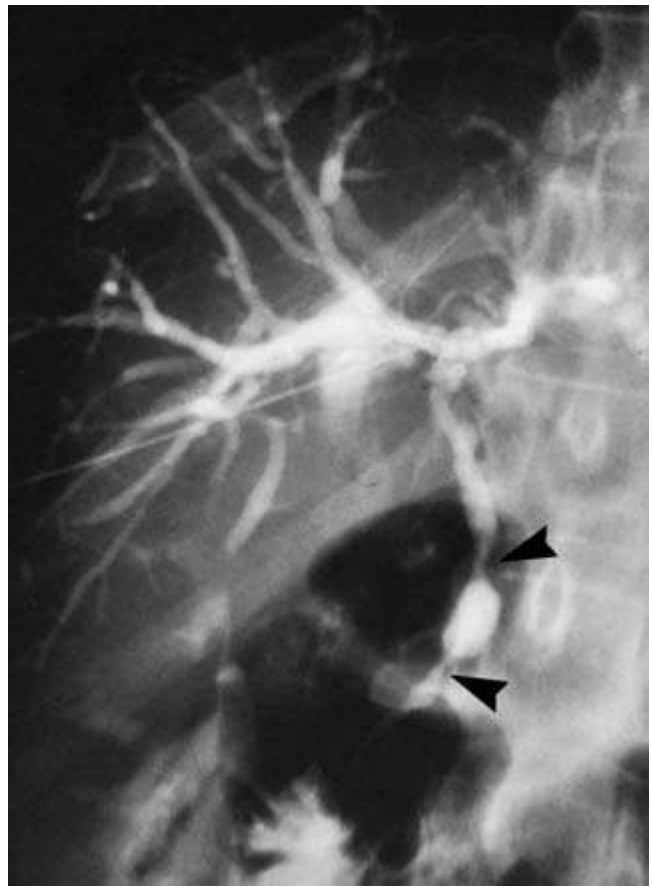

Figure 57.31 Sclerosing cholangitis with segmental strictures (*arrows*) in common bile duct. There are also strictures in the intrahepatic bile ducts. Courtesy of Dr Dennis Balfe, St Louis, MO.

transhepatic cholangiography. Sclerosing cholangitis progresses to cirrhosis, hepatic failure, and death in 5–10 years [301]. Clinical features at presentation associated with a poorer prognosis include hepatomegaly, splenomegaly, elevated serum alkaline phosphatase, advanced histological stage, and age [302]. Endoscopic balloon dilation or stenting of extrahepatic and intrahepatic strictures may be palliative. Cholestyramine, a bile-salt-binding resin, may help to relieve pruritus. Colectomy and medical therapy of the bowel disease are without benefit in the management of sclerosing cholangitis. Ursodeoxycholic acid can decrease alkaline phosphatase and aminotransferases but does not alter histological progression or influence the occurrence of clinically important events such as time to transplant or death [303]. Liver transplantation has been used with success, and sclerosing cholangitis is one of the most common indications for liver transplantation in adults. Cholangiocarcinoma develops in 10%–15% of patients with IBD with long-standing sclerosing cholangitis. Differentiating cholangiocarcinoma from the benign strictures of sclerosing cholangitis is difficult. ERCP with brushing or cholangioscopy with biopsy may help to make this distinction.

Differential diagnosis

IBD should be considered in any patient who presents with rectal bleeding or chronic diarrhea. Identification of fecal leukocytes is the simplest means of discerning an inflammatory process of the intestine. Other causes of rectal bleeding are either traumatic or neoplastic. Diarrhea is nonspecific and has a large differential schema. The primary chronic diarrheal illness that requires differentiation from ulcerative colitis or Crohn's disease is irritable bowel syndrome (IBS). However, IBS is never a cause of rectal bleeding and nocturnal symptoms or associated weight loss is rarely seen in IBS, alone. The presence of occult blood or fecal leukocytes excludes IBS. Although there is no evidence that IBS predisposes to IBD [304,305], the two conditions not, infrequently, coexist and may be associated with depressive symptoms [306]. In addition to IBS, diarrhea and rectal bleeding secondary to NSAIDs is a common mimic of IBD and the recent advent of wireless capsule endoscopy has made differentiation difficult between NSAID enteritis (or colitis) and Crohn's disease [307–309].

The most common problem in the differential diagnosis of an acute presentation of IBD (including flare-ups of quiescent disease) is ruling out infectious colitis (see Chapter 48) [99,104,217,310,311]. An important distinction between acute bacterial infections and IBD is that the diarrhea in the infectious diseases tends to be limited to a period of days to a few weeks, whereas the diarrhea of IBD is typically of longer duration. In patients who present with prolonged diarrhea, the diagnosis of other protozoal diseases, such as giardiasis, must be considered. Stool cultures for enteric pathogens, ova, and parasites and serological tests for amebiasis help to distinguish infectious diarrhea from IBD. Infections with *Shigella*, ameba, *Giardia*, *E. coli* O157:H7, and *Campylobacter* organisms all cause symptoms similar to those of ulcerative colitis and the endoscopic findings of infections with *Shigella* or *Campylobacter* organisms can be identical to those seen in ulcerative or Crohn's colitis. In contrast to bacterial infections of the colon, protozoal infections can produce more chronic symptoms. Amebiasis can cause bloody diarrhea with an endoscopic appearance resembling ulcerative or Crohn's colitis, but in amebiasis the ulcerations are usually scattered, 5–15 mm in diameter, and covered with a yellow exudate that contains organisms. These ulcers may occur anywhere in the colon but are most common in the cecum and ascending colon. Diarrhea secondary to *Giardia* infection is not associated with rectal bleeding but, like Crohn's disease, can present with cramping abdominal pain, weight loss, and lactose intolerance.

Sexual transmission of enteric pathogens by anal intercourse can lead to proctitis resembling idiopathic IBD [312]. *Neisseria gonorrhoeae*, chlamydial organisms, herpes simplex virus, *Treponema pallidum*, and lymphogranuloma venereum can all cause proctitis. The increased prevalence of the human immunodeficiency virus (HIV) has broadened the number of potential enteric pathogens to include *Cryptosporidium* and *Isospora* species, *Mycobacterium avium* complex, and cytomegalovirus (see Chapter 104) In patients without risk factors for HIV infection, the primary diagnostic studies needed to rule out infectious colitis are stool cultures for enteric pathogens, examination of stool for ova and parasites, and stool examination for *C. difficile* toxin (on three separate days). Patients at risk for HIV infection require a more elaborate evaluation with viral culture and histological examination of biopsy specimens to identify potential cytomegalovirus and herpesvirus. In addition, patients who are immunosuppressed as the result of therapy for IBD may have cytomegalovirus complicating their IBD.

Intestinal tuberculosis resembles Crohn's disease both clinically and pathologically (see Chapter 49). *Mycobacterium tuberculosis* most commonly involves the ileum and cecum and is not difficult to diagnose in the presence of pulmonary tuberculosis [313], but can occur more insidiously without pulmonary involvement, including the development of intestinal strictures [314], perianal abscesses, and fistulae [313,315]. Although colonoscopic features overlap, significantly, with Crohn's disease including ulcerations, nodularity, and an inflammatory mass, histological findings that help to distinguish tuberculosis from Crohn's disease include: confluent granulomas, more than 10 granulomas per biopsy site, and caseous necrosis in tuberculosis as well as ulcers lined by conglomerate epithelioid histiocytes and disproportionate submucosal inflammation [316]. Although Crohn's disease may be increasing in the developing world, intestinal tuberculosis remains a higher diagnostic probability among recent emigrants from developing countries and should be

ruled out among this population before a presumptive diagnosis of Crohn's disease is made.

Much has been written about the necessity for differentiating the initial episode of ileocolonic Crohn's disease from acute appendicitis; however, in practice, this distinction is seldom a major problem [317]. In contrast to patients with Crohn's disease, who usually provide a history of more chronic diarrhea before the episode of severe pain, a more acute presentation of severe pain, guarding, and a more rapid course is indicative of appendicitis. A CT scan is likely to help sort out this dilemma preoperatively. Another consideration in this differential diagnosis of right lower quadrant abdominal pain accompanied by diarrhea and fever is acute ileitis caused by *Yersinia* infection. *Yersinia* infection may present with a clinical picture resembling appendicitis or the initial onset of appendicitis and there have been reports of *Yersinia* infections evolving into Crohn's disease [318]. At laparotomy, the acute *Yersinia* ileitis may be indistinguishable from Crohn's ileitis. The diagnosis of this infection is made by stool culture, and antibiotic therapy is curative.

Whipple's disease can also mimic Crohn's disease with the common presenting symptoms of diarrhea, occult bleeding, weight loss, and arthritis associated with anemia, leukocytosis, thrombocytosis, elevated acute-phase reactants, and laboratory evidence of malabsorption. The diagnosis is made by endoscopy of the duodenum and jejunum, which demonstrates focal changes of the small bowel mucosa with erythema, friability, and erosions with associated histopathological findings of magenta-stained inclusions in macrophages of the lamina propria with periodic acid–Schiff staining [319].

Intestinal lymphoma can produce symptoms similar to those of Crohn's disease – fever, weight loss, diarrhea, rectal bleeding, and abdominal pain [320,321]. Small bowel radiographs in lymphoma may show diffuse involvement with masses in the bowel wall, but in Crohn's disease there is usually more localized involvement of the ileum, with ulceration and narrowing of the lumen.

Collagenous or lymphocytic colitis are chronic inflammatory diseases marked pathologically by the presence of a thick collagen deposition in the subepithelial layer of the colonic mucosa, lymphocyte infiltration, or both [179,322–324]. The clinical presentation is chronic watery (secretory) diarrhea that most commonly occurs in middle-aged women. These conditions are often associated with the use of NSAIDs and may be seen in conjunction with other "autoimmune" conditions such as celiac disease, rheumatoid arthritis, and thyroiditis. The endoscopic appearance of the colon is usually normal or mildly edematous and the histological findings provide the diagnosis. Collagenous colitis is discussed more fully in Chapter 59.

Intestinal ischemia may also mimic Crohn's disease and should be considered in older adults or others at particular risk for ischemic disease [325] (Chapter 113). Bloody diarrhea and abdominal pain are common with ischemic colitis. Colonoscopy reveals mucosal edema and erythema, and there may be discrete ulcers similar to those seen in Crohn's colitis. Usually, ischemic colitis spares the rectum because of its extensive collateral circulation. Differentiation of ischemic colitis from IBD, especially Crohn's colitis, may be impossible on clinical, histological, or endoscopic grounds [326]. In contrast to IBD, ischemic colitis usually resolves spontaneously over a few weeks. However, as many as 10% of patients with acute ischemic disease can continue into a chronic picture resembling Crohn's disease, distinguished only in its failure to respond to treatment. If the mesenteric vasculature is involved, systemic vasculitis can have small intestinal manifestations similar to Crohn's disease [247]. Small intestinal ulcerations, perforation, and hemorrhage are seen in systemic lupus erythematosus, polyarteritis nodosa, rheumatoid arthritis, and dermatomyositis but almost exclusively in the setting of active vasculitis outside the gut. Similarly Henoch–Schönlein purpura presents with rectal bleeding and abdominal pain before the development of the characteristic rash on the legs and buttocks (see Chapter 110).

Behçet syndrome is marked by oral and genital ulcers with uveitis. There is an associated inflammation of the ileocecal area with aphthous ulcers and a lymphocytic infiltrate; these lesions can resemble Crohn's disease [99]. Moreover, Behçet syndrome and Crohn's disease share a number of extraintestinal manifestations, including arthritis, erythema nodosum, and iridocyclitis (see Chapter 109).

Inflammatory diverticular disease (diverticulitis or diverticular colitis) (see Chapter 61) may be difficult to separate from both ulcerative colitis and Crohn's disease [99,179] especially in older adult patients. There may also be shared pathogenesis as some cases of diverticular colitis evolve into a more chronic pattern of IBD that can mimic either ulcerative colitis or Crohn's disease, including the development of fistulae tracking along the sigmoid colon [328–330]. Often diverticular colitis presents with hematochezia or gross rectal bleeding, with or without abdominal pain, fever, and diarrhea. The presence of inflammation away from diverticula or the presence of perianal disease suggests Crohn's disease whereas extension of sigmoid colitis into the rectum determines an evolution to ulcerative colitis.

Diversion colitis occurs in the presence of colon excluded from the fecal stream and is the result of a lack of nutrients provided by bacterial production of short chain fatty acids to feed colonocytes is a nonspecific inflammation of segments of colon excluded from the fecal stream [331] and can occurs in patients who have had surgery for Crohn's colitis with creation of a Hartmann pouch or in patients undergoing staged colectomy for ileoanal anastomoses [332]. In these cases, diversion colitis may be difficult to differentiate from either ulcerative colitis or Crohn's disease in the excluded segment [179]. Many patients with diversion colitis have severe endoscopic findings with minimal symptoms. A clinical response

to antibiotics or to enemas of short-chain fatty acids should differentiate diversion colitis from active Crohn's disease [333].

It is not uncommon for symptoms of mild ulcerative colitis or proctitis in which rectal bleeding is the primary manifestation to be attributed to hemorrhoids or anal fissures. The presence of urgency or diarrhea is more consistent with ulcerative colitis or proctitis. Sigmoidoscopy should easily differentiate ulcerative colitis from these perianal problems. Solitary rectal ulcer is another mimic of idiopathic proctitis that typically presents in young individuals with rectal urgency, bleeding, and passage of mucus. Most often the patient presents with a history of constipation or straining on the toilet and, at sigmoidoscopy there is a semicircumferential or circumferential ulceration, often with heaped-up margins along the first rectal fold [334]. Histological features are those of mucosal prolapse [335].

Nutritional management

Malnutrition is an important clinical problem in IBD, particularly in Crohn's disease. At diagnosis, most patients with Crohn's disease have lost weight. Hypoalbuminemia, anemia, and vitamin D deficiency can all result from malnutrition in Crohn's disease.

Five factors lead to malnutrition in Crohn's disease. The first, diminished oral intake primarily as a result of loss of appetite, is the most important cause of malnutrition in patients with Crohn's disease [336]. Anorexia may result from inflammation, depression, or the side effects of medication. Even in the absence of anorexia, many patients diminish their food intake because eating causes pain, cramps, and diarrhea; this problem is seen particularly in patients with small bowel obstruction. The second factor is the increase in caloric requirements because of the catabolism associated with fever and inflammation; however, this factor makes a relatively minor contribution to malnutrition in Crohn's disease [327]. The third factor is malabsorption of nutrients as a result of a reduction in the absorptive area by extensive surgical resections or involvement of large areas of small bowel with inflammation. Rarely, fistulae can result in malabsorption as a result of nutrients bypassing absorptive epithelium. The nutrients most likely to be affected are calcium, magnesium, fats and fat-soluble vitamins, and vitamin B-12. Bile salts and vitamin B-12 are selectively absorbed in the distal ileum, the area of the small intestine most commonly involved in Crohn's disease and the area most commonly resected. Malabsorption of bile salts leads to a decrease in the total bile salt pool and so to fat malabsorption. Bacterial overgrowth in the small intestine proximal to strictures leads to deconjugation of bile salts by bacteria. The deconjugated bile salts are absorbed passively and so are not retained in the lumen to participate in the absorption of fat and fat-soluble vitamins. The fourth factor is the loss of proteins and electrolytes in the intestinal lumen in areas of inflammation. Bleeding into the intestinal lumen results in iron deficiency. Magnesium and zinc can be depleted by losses into the intestine. The fifth and last factor is drug therapy. Sulfasalazine impairs folate absorption but uncommonly leads to anemia. Corticosteroids induce negative nitrogen balance and decrease intestinal calcium absorption.

For most patients with IBD, the only nutritional therapy required is the instruction to eat adequate amounts of a well-balanced diet. Patients look for a nutritional basis to their disease and for nutritionally based therapy. These expectations lead many to decide that exacerbations of pain or diarrhea were caused by the foods they ate before the exacerbation. They exclude from their diets a lengthy list of foods that were associated temporally with an exacerbation of disease. As a result, these patients place themselves on a diet that has limited variety and is likely to be nutritionally unbalanced. Foods should be eliminated from the diet only if they consistently and reproducibly result in symptoms. Some patients have lactose intolerance and should avoid dairy products or use lactase-containing products, such as Lactaid. Patients with strictures should avoid fibrous, high-residue foods such as nuts, popcorn, bean sprouts, and celery.

More involved nutritional therapy in Crohn's disease can be directed toward one of two goals: treating nutritional deficiencies or reducing inflammation. Deficiencies of specific nutrients usually can be managed by supplementation. Oral or parenteral iron supplementation may be necessary in patients with significant intestinal bleeding. Specific supplementation with calcium, magnesium, zinc, vitamin B-12, vitamin D, and vitamin K may be required if clinical or biochemical manifestations of deficiency occur (see Chapter 101). These nutrients may be malabsorbed if there is extensive involvement of the small bowel mucosa. Bone densitometry will reveal evidence of calcium loss from bone caused by calcium malabsorption or steroid therapy. Even in the absence of clinical or biochemical evidence of micronutrient deficiency, it is reasonable to give multivitamin supplements to patients with small bowel Crohn's disease. Extensive (> 100 cm) resections of the terminal ileum or lesser resections combined with active disease or scarring in the remaining ileum lead to vitamin B-12 malabsorption. Some clinicians evaluate patients with serum vitamin B-12 levels, but others empirically treat all patients with significant ileal resections with parenteral vitamin B-12 (1000 μg once a month). Ileal resection and ileal disease also lead to malabsorption of bile salt and fat. Diarrhea induced by bile salts can be managed with cholestyramine, a resin that binds bile salts and prevents them from inducing water and electrolyte secretion from the colonic mucosa. Cholestyramine therapy, however, further depletes the bile salt pool and can worsen fat malabsorption. Unabsorbed fatty acids entering the colon are hydroxylated by bacteria. Hydroxylated fatty acids induce colonic water and electrolyte secretion. Fatty acid-induced

diarrhea is managed by reducing the fat content of the diet. Caloric deficiencies are made up by increasing the intake of complex carbohydrates. Alternatively, medium-chain triglycerides, which do not require bile salts for absorption, can be substituted for part of the conventional long-chain triglycerides in the diet. The dose of medium-chain triglycerides is limited to about 3 tablespoons per day (300 kcal) because larger amounts cause diarrhea.

Anorexia leads to inadequate nutritional intake and malnutrition in many patients with IBD, even if absorptive function is normal. Supplementation of the patient's oral intake with defined formula diets can prevent or reverse malnutrition. Defined formula diets can be taken orally or administered by nasogastric tube, gastrostomy tube, or jejunostomy tube (see Chapter 21). Most patients with IBD who require nutritional supplementation can be managed with enteral therapy. In some cases, however, parenteral nutrition is required: in the presence of chronic small intestine obstruction that is not amenable to surgical resection; after massive small bowel resection, especially if the amount of remaining small intestine is insufficient for absorption of daily caloric needs; or if enteral nutrition results in severe, uncontrollable diarrhea.

The use of total enteral administration of an elemental diet as specific therapy in IBD is controversial (see Chapter 101). Elemental diets consist of amino acids, monosaccharides, vitamins, minerals, and essential fatty acids. The results of controlled trials comparing elemental diets with drug therapy have been inconsistent [338–341]. In Crohn's disease, elemental diets have been used more extensively in children than adults. Providing adequate nutrients can reverse growth failure in Crohn's disease. Elemental diets taken orally or by nasogastric tube enhance linear growth in children with Crohn's disease [342]. In these studies, enteral nutrition was superior to steroids in promoting growth. In several studies of active Crohn's disease in adults enteral nutrition was found to reduce clinical activity. This has been the subject of a Cochrane review [343]. There is less experience of enteral nutrition as a maintenance therapy in Crohn's disease; however, long-term maintenance therapy with enteral nutrition plus mesalamine was found to be superior to mesalamine alone [344]. In this study the patients took 50% of their calories as oral nutrition and 50% as enteral nutrition. Therefore, the beneficial effects of the enteral nutrition probably do not relate to the diminished dietary antigen exposure.

Malnutrition is less common in ulcerative colitis than in Crohn's disease. Malabsorption of nutrients is not a problem in ulcerative colitis; however, diminished food intake is common. Patients with ulcerative colitis may decrease their food intake because of diminished appetite or because eating worsens their diarrhea. Nutritional requirements are increased in severe ulcerative colitis because of the catabolism associated with fever and inflammation. Total parenteral nutrition (TPN) has been used to improve the nutritional status and reduce the symptoms of patients with severe ulcerative colitis [345]. This approach has been especially successful in improving the nutritional status of patients before colectomy is undertaken. Improved nutritional status decreases the likelihood of complications for surgical procedures in general and, presumably, for IBD surgery in particular. No evidence has been found that TPN reduces the necessity for colectomy or that it is an effective primary therapy for the disease. Two studies compared the rates of colectomy in patients with ulcerative colitis receiving TPN with those on regular hospital food. In both studies, the rates for colectomy were the same in the two groups [346,347]. Dietary supplementation with fish oil may have antiinflammatory activity because the *n*-3 fatty acids in fish oil compete in the substrate pool for the enzymes that synthesize prostaglandins and leukotrienes. Supplementation with high-dose fish oil over a period of months reduced steroid requirements in ulcerative colitis [348]. Fish oil supplementation was tested in placebo-controlled trials as maintenance therapy in Crohn's disease. In one trial it was effective [349], but in the other it was not [350].

Drugs used in inflammatory bowel disease

Aminosalicylates

Formulations of 5-aminosalicylic acid (5-ASA, mesalamine, mesalazine) have been the primary therapies to treat mild to moderately active ulcerative colitis and to maintain remission [110,111] (Table 57.6). Their efficacy in the treatment of Crohn's disease has become somewhat more controversial [110,351–354]. These agents have a long history of clinical use and have been extensively studied in clinical trials for both ulcerative colitis [355,356] and Crohn's disease [357,358]. Sulfasalazine, the prototype aminosalicylate formulation, was developed with the concept of providing both an antibacterial (sulfapyridine) and antiinflammatory (5-aminosalicylic acid, mesalamine, mesalazine) agent into the connective tissues [359]. Sulfasalazine had been the benchmark agent for the initial comparison trials with alternative 5-ASA agents, but it is recognized that the 5-aminosalicylic acid moiety accounts for the primary therapeutic benefits whereas sulfapyridine causes the majority of side effects [354,360]. This recognition has allowed the development of a series of sulfa-free aminosalicylates that can be targeted to specific sites along the gastrointestinal tract [361,362] (Fig. 57.32).

Sulfasalazine

Sulfasalazine (salazopyrine) is a compound linking sulfapyridine with 5-ASA via an azo-bond. With oral administration the compound remains, mostly, intact with minimal enteric absorption until reaching the colon where the azo-bond is cleaved by colonic bacteria. The sulfapyridine is almost completely absorbed from the colon and undergoes a genetically

Table 57.6 Currently available mesalamine (5-ASA) preparations in the United States

Product	Formulation	How supplied	Typical dosing	Site of action
Canasa	5-ASA suppository	1000 mg	q.d.–b.i.d.	Rectum
Rowasa	5-ASA enema	4 g (60 mL)	q.h.s.	Rectum; distal colon
Azulfidine (sulfasalazine)	5-ASA linked to sulfapyridine	500 mg tablet	3–4 g; b.i.d.–q.i.d.	Colon
Asacol	5-ASA coated with acrylic resin; release at pH ≥ 7	400 mg tablet	2.4–4.8 g; q.d.–b.i.d.	Distal ileum; colon
Lialda	5-ASA coated with acrylic resin and multi-matrix; release at pH ≥ 7	1.2 g capsules	2.4–4.8 g; b.i.d.–t.i.d.	Distal ileum; colon
Pentasa	5-ASA in ethylcellulose	500 mg capsules microgranules	3–4 g; b.i.d.–q.i.d.	Small bowel; colon
Dipentum	5-ASA dimer	250 mg capsules	1–2 g; b.i.d.	Colon
Colazal	5-ASA linked to inert carrier	750 mg capsules	6.75 g; b.i.d.–t.i.d.	Colon

5-ASA, 5-acetylsalicylate; b.i.d., twice a day; t.i.d., three times a day; q.d., every day; q.i.d., four times a day; q.h.s., every bedtime.

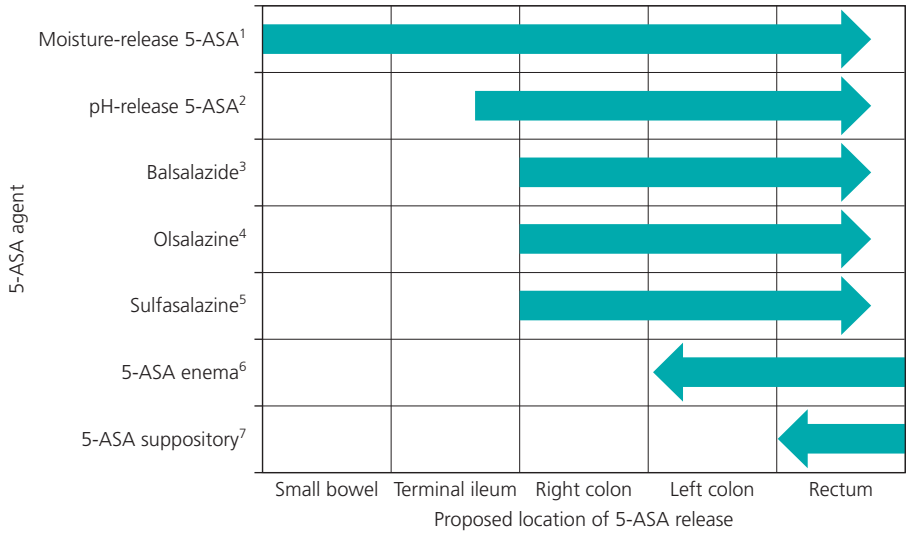

Figure 57.32 Proposed location of release of 5-aminosalicylate (5-ASA; mesalamine) preparations available in the United States. 1, Pentasa; 2, Asacol or Lialda; 3, Colazal; 4, Dipentum; 5, Azulfidine; 6, Rowasa; 7, Canasa.

determined hepatic acetylation and subsequent renal excretion [360]. Slow acetylators achieve higher plasma concentrations of sulfapyridine than rapid acetylators, which translate into a greater or lesser likelihood of intolerance to the compound. In contrast, once delivered to the colon 5-ASA is acetylated by colonic bacteria or within the colonic epithelium and is poorly absorbed. The majority of 5-ASA is eliminated as acetylated 5-ASA in the feces [363]. The small amount (~ 15%) of 5-ASA absorbed from the colon is acetylated within the colonic mucosa or liver and is excreted from the kidneys, again primarily as acetylated 5-ASA. Thus, sulfasalazine functions, primarily, as a carrier of 5-ASA to distal sites in the intestinal tract.

A specific mechanism of action for sulfasalazine and 5-ASA has yet to be established [360,364] and novel antiinflammatory [354] and antineoplastic [365] effects continue to be elucidated. There are multiple antiinflammatory effects including inhibition of the arachidonic acid cascade involving the cyclooxygenase, lipoxygenase, and platelet-activating factor pathways [360]. In addition, the aminosalicylates are inhibitors of oxygen radical production and scavengers of free radicals [340]. They also inhibit lymphocyte and monocyte function as well as plasma cell production of immunoglobulin. Sulfasalazine also has been shown to inhibit IL-1 production and nuclear factor-κB [366] and mesalamine has been shown to activate the γ form of peroxisome proliferator-activated receptors involved in the control of inflammation, cell proliferation, apoptosis, and metabolic function [365]. A basic premise regarding the aminosalicylates is that the effects of 5-ASA are topical (mucosal), not systemic, and that the active moiety needs to be delivered to the site of intestinal inflammation [354].

Side effects of sulfasalazine are relatively common and the majority of adverse reactions are related to plasma sulfapy-

ridine concentrations [367]. In general, the side effects can be divided into intolerance or allergy, although there are also direct toxic effects on spermatozoa. Intolerance side effects from sulfasalazine (e.g., nausea, vomiting, malaise, anorexia, dyspepsia, and headaches) are dose-related and worse in patients who are genetically slow acetylators. Administration with meals or gradually increasing the dose can minimize these symptoms, as can administration of an enteric-coated formulation. Most of these side effects occur within the first few days or weeks of therapy and resolve with discontinuation.

In contrast to the dose-related intolerance side effects, allergic or hypersensitivity reactions including rash, fever, hemolytic anemia, agranulocytosis, hepatitis, hypersensitivity pneumonitis, pancreatitis, or worsening of colitis, are not related to sulfapyridine concentrations and are far less frequent [368–370]. Idiosyncratic pancreatitis, pneumonitis, and worsening of colitis are related to the 5-ASA moiety while reversible sperm abnormalities and folate malabsorption are complications related to sulfasalazine. Sulfasalazine interferes with folate absorption and may contribute to anemia, leading to the recommendation of folate supplementation during therapy [371]. Additional drug interactions identified with sulfasalazine include the potential for warfarin resistance [372] and inhibition of thiopurine methyl transferase that clinically has been shown to increase 6-thioguanine nucleotide levels with coadministration of sulfasalazine, mesalamine, or balsalazide leading to a risk of leucopenia [373] as well as lowering of 6-thioguanine nucleotide levels when a sulfasalazine or alternative aminosalicylates is withdrawn [374].

Non-sulfa containing aminosalicylates

In contrast to sulfasalazine, 5-ASA (mesalamine) is rapidly absorbed from the proximal gastrointestinal tract depending on local concentrations and lumenal pH [363]. A variety of approaches have been followed to deliver 5-ASA to distal sites along the intestine with the intent of "protecting" 5-ASA from proximal absorption without exposure to the toxicities associated with sulfapyridine (Table 57.6). Since initial studies demonstrated that mesalamine is the active ingredient of sulfasalazine and that it works when topically applied to the rectum [375] an initial approach was to formulate 5-ASA into suppositories [376,377] or enemas [378] for treatment of colitis confined to the rectum or the left colon. Subsequently, oral formulations of 5-ASA have been developed to deliver sufficient lumenal concentrations at distal sites in the small and large intestine (Fig. 57.32). The latter include mesalamine formulations that are "protected" against proximal absorption or mesalamine compounds with 5-ASA linked by the same azo-bond present in sulfasalazine, but instead, to an alternative carrier.

The oral formulations of mesalamine vary in their coating mechanisms to prevent proximal absorption and, hence, inactivation as 5-ASA is considered a topically active anti-inflammatory [379]. Although all of these formulations deliver "pure" mesalamine, there are pharmacological differences in the release and intestinal delivery [380] although no distinct clinical differences between the pure mesalamine agents have been identified when they are administered for ulcerative colitis on a gram for gram basis [354,363,381]. The Pentasa formulation of 5-ASA uses ethylcellulose-coated granules that behave as a semipermeable membrane to release 5-ASA at pH 6 and above, thus delivering approximately 50% of 5-ASA into the small bowel and the remainder into the colon. Because 5-ASA is a zwitter ion and its absorption depends on both local concentrations and pH, "release" does not equate with "absorption" and only about 35% of mesalamine is absorbed from this formulation, independent of intestinal transit time [363]. Another formulation of mesalamine (Lialda) uses a "matrix" combination of pH-resistant coatings and semipermeable ethylcellulose to deliver 5-ASA primarily into the colon [382,383]. Other pure mesalamine formulations use Eudragit resins to provide more of a bolus-release of 5-ASA targeted according to intestinal pH. Asacol uses Eudragit-S, dissolves at pH 7 or above, and releases 5-ASA primarily in the colon and terminal ileum whereas Salofalk (Mesasal) is formulated with Eudragit-L, which releases at pH 6. The latter, because of the proximal bolus release, leads to slightly more absorption and renal elimination [363].

The azo-compounds of 5-ASA include olsalazine and balsalazide. Olsalazine (Dipentum) is a dimer of two 5-ASA molecules linked covalently through an azo-bond similar to that in sulfasalazine. Each mole of olsalazine provides two moles of 5-ASA [384]. The second azo-compound is balsalazide (Colazal), in which 5-ASA is linked via an azo-bond to 4-aminobenzoyl-β-alanine, an inert carrier [385]. Similar to sulfasalazine and olsalazine, balsalazide releases 5-ASA entirely into the colon. In contrast to the pure mesalamine compounds, the azo-compounds have the potential to induce chloride secretion in the small intestine, resulting in watery diarrhea in 5%–10% of patients treated with olsalazine at dosages of 1–2 g/day. Sulfasalazine and balsalazide are less likely to induce diarrhea at the prescribed dosage, which provide smaller amounts of 5-ASA (e.g., 4 g sulfasalazine provides 1.6 g 5-ASA whereas 6.75 g balsalazide provides approximately 2.4 g 5-ASA) [386].

In contrast to sulfasalazine, the pure mesalamine and azo-compounds have relatively few side effects and in trials using up to 4.8 g/day of delayed-release formulations there have not been any dose-related toxicities [367,370]. Indeed, the primary advantage of the non-sulfa-containing aminosalicylates is the improved side effect profile compared with sulfasalazine [355,356]. Eighty percent of patients who are unable to tolerate sulfasalazine can tolerate a non-sulfa-containing 5-ASA [387,388]. Rare, idiosyncratic reactions including pericarditis, myocarditis, pancreatitis, pneumonitis,

hepatitis, nephritis, and worsening of colitis have been reported. In contrast to the idiosyncratic hypersensitivity reactions related to mesalamine, diarrhea related to olsalazine is dose-dependent, improved by administration with food, and is less prevalent in patients with inactive colitis.

Two potential side effects of all 5-ASA products should be mentioned. Worsening of colitis has been described with all formulations and is a rare, presumably hypersensitivity reaction [388]. Increasing symptoms of colitis (bleeding, diarrhea, rectal urgency) can be seen with administration of oral or rectal aminosalicylates. On occasion, 5-ASA-induced colitis may be masked by corticosteroid therapy and can become symptomatic as corticosteroids are tapered. Therefore, for patients with steroid-refractory ulcerative colitis who have never been in remission with 5-ASA agents, a trial off of 5-ASA, with an alternative maintenance agent should be considered.

The other recognized, but rare, consequence of 5-ASA is an idiosyncratic, presumed hypersensitivity, form of interstitial nephritis [389]. Nephrotoxicity is not dose-related, has been described with all 5-ASA agents (overall estimated risk ~ 0.26% per patient year), and often presents gradually over months or years. The labeling of all 5-ASA agents warns against the potential for nephrotoxicity and recommends monitoring of kidney function. However, the optimal means of monitoring has not been established. As a result of the frequency of abnormal urinary sediment findings in patients with IBD, measurement of baseline or follow-up urinary sediments is not adequate and monitoring of the blood urea nitrogen and serum creatinine is warranted at baseline, after 3–6 months of therapy, and yearly, thereafter [368,389,390]. Clinicians should be aware of mild elevations of serum creatinine in young individuals that can reflect significant reductions in renal function. 5-ASA agents should be discontinued in the presence of rising serum creatinine and referral to a nephrologist is warranted to determine the etiology of abnormal kidney function [389].

Aminosalicylates in ulcerative colitis

Mild or moderate ulcerative colitis

Sulfasalazine and all of the oral aminosalicylates have been efficacious in the treatment of mild to moderate ulcerative colitis as long as the active component (5-ASA) is delivered to the site of disease activity [110,111,356,391]. Oral aminosalicylates are effective for both proximal and distal colitis and the topical agents are efficacious for distal colitis as long as the formulation reaches the proximal extent of disease [392]. The dose–response for sulfasalazine is often compromised by dose-related toxicity [356,369,370]; the dose–response for mesalamine formulations is not associated with dose-related toxicities up to the tested dosage of 4.8 g/day [393,394]. Whereas a dose–response for the oral aminosalicylates is well defined for the treatment of active disease [356] there do not appear to be increasing benefits from topical formulations (suppositories, foams, or enemas) above 1 g daily [392,395,396]. In comparison trials between sulfasalazine and the alternative agents there is no advantage of one compound over another from a therapeutic standpoint as long as equal amounts of 5-ASA are delivered [356]. Similarly, there does not appear to be a significant difference between the oral aminosalicylates regarding their efficacy in extensive or distal ulcerative colitis [362,380] or in the pharmacokinetic profiles [363].

The clinical response to sulfasalazine or an alternative aminosalicylate for active (mild-to-moderate) ulcerative colitis averages between 40% and 80%, but varies considerably between clinical trials because of differing patient populations and end-point definitions of response [380,391]. There is a dose–response for sulfasalazine between 1 and 4 g daily and in reports dosages up to 6 g/day have been tested. Mesalamine is equally effective with a dose–response between 1.5 g/day and 4.8 g/day, the latter being the highest dose evaluated in clinical trials [356,393,394]. The azo-bond compounds olsalazine and balsalazide have been tested in dosages up to 3 g/day and 6.75 g/day (comparable to 3 g and 2.4 g of mesalamine, respectively) [356]. Whereas increasing doses of sulfasalazine (intolerance) and olsalazine (diarrhea) are associated with incremental dose-related side effects, an advantage for mesalamine compounds and balsalazide is that, within the tested therapeutic range, the dose–response is not compromised by dose-related side effects [356,369,370].

Rectal formulations of mesalamine have been highly efficacious for the treatment of distal colitis [392]. Mesalamine suppositories reach the upper rectum (approximately 15–20 cm), and enemas or foams up to the splenic flexure or distal transverse colon according to volume and disease activity [397]. In the setting of distal colitis topical (rectal) mesalamine has been more effective than corticosteroid enemas or equivalent doses of oral mesalamine [392] and combination treatment with oral and topical mesalamine is superior to either single approach [397]. Mesalamine enemas can also be used as adjunctive therapy for patients with extensive colitis to accelerate healing [398].

Severe ulcerative colitis

The aminosalicylates are not regarded as effective when ised as single agents for severe colitis and because of the frequency of gastrointestinal intolerance, the small risk of worsening colitis, and their inferior antiinflammatory properties compared to corticosteroids, they are not recommended until patients have stabilized. These agents can be added or resumed when the patient has responded to treatment for severe disease with resumption of normal bowel habits and consumption of a full oral diet [399]. Unlike corticosteroid enemas, rectal mesalamine formulations have not been evaluated in severe disease and clinical experience has shown that in this setting they may be less well tolerated than rectal corticosteroids.

Maintenance of ulcerative colitis remission

Prevention of relapse and the prolongation of remission have been primary indications for all of the aminosalicylates [110,111,355]. In contrast to the evidence base for mild to moderate active ulcerative colitis there are fewer data regarding a dose–response for the aminosalicylates for maintaining remissions [355,400,401]. Nevertheless, in the setting of quiescent colitis there is likely to be a similar dose–response although there is no consensus on an "optimal" maintenance dose [401]. Similar to the setting in active disease, with maintenance therapy all of the non-sulfa-containing formulations provide comparable efficacy to sulfasalazine when equimolar doses of 5-ASA are administered [355,363,401]. Historically, the dose-related side effects of sulfasalazine led to the compromise in maintenance dosing based on the efficacy and side effects and recognition that many patients are not compliant with prescribed doses, the suggested maintenance dose for sulfasalazine has been 50% of the dose for active disease [402]. However, this historical "dogma" does not apply to the non-sulfa-containing aminosalicylates that are devoid of dose-related side effects and clinical experience has dictated that a substantial proportion of patients who require higher doses of an aminosalicylate to achieve remission will, similarly, benefit more from maintaining the same induction dose to maintain remissions [362,380].

Topical mesalamine formulations are also effective at preventing relapse in the setting of ulcerative proctitis and distal colitis and are more effective than oral treatment [403,404]. Many patients with distal colitis who require topical therapy to achieve remission will require maintenance therapy with a rectal formulation [380,392,405].

Aminosalicylates in Crohn's disease

Mild to moderate active Crohn's disease

The role of aminosalicylates in the setting of Crohn's disease has become more controversial [352,353,357,362,380,406]. Numerous factors contribute to the debate regarding the role of aminosalicylates in Crohn's disease including: the heterogeneous presentations (disease location, severity, complications), transmural nature of Crohn's disease (vs the mucosal activity of aminosalicylates), definition of disease activity and response, dose and delivery systems of varied formulations, clinical trial design and evolution of clinical trials over the past two decades. Compared to the evidence base for ulcerative colitis, the efficacy of sulfasalazine in Crohn's disease is less definitive and more dependent on location of disease activity [357,362,380,406]. The necessity for colonic bacterial azo-reductase activity to liberate 5-ASA implies that sulfasalazine is unlikely to benefit proximal (small intestinal) Crohn's disease and, in two early clinical trials evaluating more than 500 patients with active Crohn's disease sulfasalazine at dosages of 3–5 g/day were superior to placebo only for patients with ileocolonic or colonic disease but not for patients with disease confined to the small intestine [407,408]. Although sulfasalazine has been commonly used to prevent relapse for patients with quiescent Crohn's disease, neither the National Cooperative Crohn's Disease Study nor the European Cooperative Crohn's Disease Study demonstrated maintenance benefits at (low) dosages of 1–3 g/day. While one trial utilizing a 3 g/day dosage of sulfasalazine demonstrated efficacy at reducing the likelihood of postoperative clinical recurrence [409] there remains little evidence of a maintenance benefit after medically-induced clinical remissions [358].

The non-sulfa aminosalicylates have also been evaluated in clinical trials for the treatment of mild to moderately active Crohn's disease. Overall, clinical remission rates range between 40% and 50% [357,406] but the heterogeneity of clinical trials and high placebo response [410] in this population makes it difficult to confirm a reasonable number needed to treat in specific scenarios of active disease. Clinical trials evaluating non-sulfa-containing aminosalicylates as maintenance agents for Crohn's disease have also produced conflicting results [353,358,406]. Again, the heterogeneity of maintenance scenario has also hampered an interpretation of their potential. Mesalamine agents may have maintenance benefits when initiated immediately on induction of remission [411] but have not been effective after corticosteroid-induced remissions in Crohn's disease [412].

Maintenance of Crohn's disease in remission

Clinical trials have yet to evaluate mesalamine as a maintenance agent for individuals who have responded to mesalamine as an inductive agent. Mesalamine agents have also been evaluated in a series of trials to delay postoperative recurrence after resection in CD. Although initial metaanalysis suggested benefits at reducing both endoscopic and clinical evidence of disease [413] the inclusion of a subsequent (negative) large trial [414] would have invalidated the overall positive results. Nevertheless, there does appear to be a modest, overall (~ 10%) benefit for mesalamine at reducing the likelihood of recurrent Crohn's disease after an ileocolonic resection [227,415].

Antibiotics

The unknown etiology of the inflammatory bowel diseases, along with the expanded understanding of the gut immune system's interactions with the intestinal flora [416], have led not only to investigations into the role of infectious agents as initiators or instigators of disease flares, but also into antimicrobials as potential therapies. Most of the attention has been directed towards antibiotics targeting bacterial species.

Antibiotics in ulcerative colitis

There are no well-designed clinical trials or even large case series that suggest a convincing therapeutic role for antibiotics in the treatment of ulcerative colitis, although some practitioners advocate them in the setting of severe

colitis to potentially decrease sepsis and other complications [417–419]. Combined therapy with intravenous tobramycin and metronidazole showed no benefit over placebo in clinical response, incidence of complications, or need for emergent colectomy in patients with severe colitis [420]. Oral vancomycin [421], oral ciprofloxacin [422], and intravenous metronidazole [422] were found to be not effective in these patients.

There may be a role of antibiotics for patients with less-severe colitis. A recent metaanalysis of 10 randomized, placebo-controlled trials (530 patients), however, suggested that antibiotics used as an adjunct to corticosteroids or mesalamine yielded a pooled odds ratio of 2.14 (confidence interval [CI] 1.48–3.09) favoring antibiotics [423]. Clinical remission was higher in a pooled analysis of short-term therapy with antibiotics (5–14 days), odds ratio 2.02 (CI 1.26–3). Short-term symptomatic remission rates were better with the addition of oral tobramycin (vs placebo) to corticosteroids in 84 patients with acute relapsing ulcerative colitis (74% vs. 43%, respectively) [421], the durability of these responses is unknown. The addition of ciprofloxacin (vs placebo) to a regimen of corticosteroids and mesalamine resulted in lower 6-month failure rates in the patients receiving the antibiotic (21% vs. 44%) [424]. Rifaximin has also shown promise in some patients with corticosteroid-refractory disease [425].

Antibiotics are first-line therapy in the treatment of *pouchitis* for patients with ulcerative colitis who have undergone an ileopouch anal anastomosis. Ciprofloxacin and metronidazole are the two antibiotics with the most use and success; often one is started and the other is added in refractory cases [426,427]. For refractory cases, adding antibiotics such as rifaximin [428–430] or combination therapy with ciprofloxacin and tinidazole [431] has proven efficacy. Prophylaxis against pouchitis onset [432] or prevention of relapse of chronic pouchitis [433,434] has been shown in placebo-controlled trials using a probiotic cocktail containing viable lyophilized bacteria of four strains of lactobacilli, three strains of bifidobacteria, and one strain of *Streptococcus salivarius* subsp. *thermophilus*.

Antibiotics in Crohn's disease

There is also a surprising absence of controlled data supporting the use of antibiotics in patients with Crohn's disease [435]. Multiple studies of metronidazole, either as sole-therapy or as a combination with other antibiotics, have failed to show convincing remission data, although in a randomized, placebo-controlled trial, patients receiving high-dose metronidazole (20 mg/kg) had improved disease activity, with the greatest benefit seen in colonic or ileocolonic disease [436]. That same dose was also shown to be initially effective as postoperative prophylaxis in a placebo-controlled trial of 60 patients undergoing curative ileocolonic resections for Crohn's ileitis. Twelve weeks of therapy decreased severe endoscopic recurrence rates at the time of therapy discontinuation (13% vs. 43% for placebo); the benefit over clinical recurrence rates was maintained at 12 months 4% vs. 25%), but not afterwards [437]. Limited by a high incidence of neuropathy, a subsequent similar study randomized 80 patients with Crohn's disease undergoing curative ileocolonic resection to either ornidazole (1 g/day) or placebo for 1 year [438]. Clinical recurrence rates at 1 year were lower with ornidazole (8% vs. 38%), as were endoscopic recurrence rates (54% vs. 79%). Side effects, however, limit long-term use.

Ciprofloxacin is often used in patients with Crohn's disease, despite the absence of benefit from large controlled trials. Smaller trials or case series have suggested that ciprofloxacin may be superior to placebo [439] and comparable to mesalamine [440]. Combination therapy with metronidazole has been effective in open-label experience [441], showed efficacy similar to corticosteroids in one trial [442], but adding the same combination to budesonide proved no better than adding a placebo in another trial [443].

Many other antibiotics have been studied, either alone or in combination, with varying results [444–446]. A recent metaanalysis [447] of the use of broad-spectrum antibiotics in Crohn's disease calculated a pooled odds ratio of 2.257 (CI 1.68–3.04) favoring the antibiotics over placebo.

Antibiotics are typically used in perianal or enterocutaneous fistulous Crohn's disease, although there is little published literature regarding the topic. One study showed a benefit of combined therapy with metronidazole and ciprofloxacin in patients, some of whom were already receiving or initiating therapy with azathioprine [448]. The presence of draining pus in many of these patients makes it advisable to use antibiotics, especially if also initiating immunosuppressive therapy.

Corticosteroids

Corticosteroids have been a mainstay of acute therapy for moderate to severe, and fulminant ulcerative colitis and as a first-line agent for moderate to severe Crohn's disease. In addition, nonsystemic corticosteroids (e.g., ileal-release budesonide) have become a therapeutic option for patients with mild to moderate Crohn's disease involving the ileum or right colon.

The mechanisms of action of corticosteroids continue to be elucidated [449–453]. Glucocorticoid receptors are present on most human cells and their concentration is autoregulated. The ubiquitous distribution accounts for the systemic effects and side effects on most organ systems. By binding to intracytoplasmic glucocorticoid receptors found in most cell types, glucocorticosteroids activate glucocorticoid-responsive elements that influence multiple signal transduction pathways. An important action is the switching off of multiple activated inflammatory genes through the inhibition of histone acetylase activity and recruitment of histone deacetylases

to the inflammatory gene transcriptional complex resulting in transrepression of proinflammatory transcription factors (e.g., nuclear factor-κB) and apoptosis of inflammatory cells and activated lymphocytes [450]. Glucocorticoids also activate several antiinflammatory genes and increase the degradation of messenger RNA encoding inflammatory proteins, resulting in a broad spectrum of effects on the immune system including inhibition of the recruitment and proliferation of lymphocytes, monocytes and macrophages, migration of neutrophils to sites of inflammation, and decreased production of soluble inflammatory mediators including cytokines, leukotrienes, and prostaglandins [451,452].

There is a large variation in plasma concentrations of glucocorticoids after oral administration in both normal subjects and patients with inflammatory bowel disease and the biological half-life of glucocorticoids is 18–36 h compared with a 2- to 4-h plasma half-life [451]. The most commonly used oral glucocorticoids are prednisone (or prednisolone) and methyl-prednisolone. The potencies of prednisone/prednisolone and methyl-prednisolone compared to hydrocortisone are 4 : 1 and 5 : 1, respectively [451,452]. In Europe, prednisolone metasulfobenzoate has been used to minimize systemic absorption with oral delivery and enema formulations [370]. The bioavailability after rectal administration of hydrocortisone is dependent on disease activity and retention time, but can be up to 80% of an administered dose [451]. Nonsystemic corticosteroids have been developed for both topical and rectal administration [370,452]. The most commonly used oral and rectal formulation of a nonsystemic steroid is budesonide, which has been targeted in an oral formulation for ileal and right colonic delivery [454].

There have been conflicting reports describing glucocorticoid receptors in patients with inflammatory bowel disease but it appears that mucosal glucocorticoid receptors are decreased in patients compared with healthy controls [452]. Glucocorticoid-resistance has also been described [455] related to ligand-induced down-regulation of the receptor, the dominant-negative inhibition by the β-isoform of the receptor, or repression by the transcription factor nuclear factor-κB [453]. Other potential mechanisms of steroid-resistance include: decreased cytoplasmic glucocorticoid concentration secondary to increased P-glycoprotein-mediated efflux from target cells secondary to overexpression of the multidrug resistance gene (*MDR1*) [456]; impaired glucocorticoid signaling because of dysfunction at the level of the glucocorticoid receptor; and constitutive epithelial activation of proinflammatory mediators, including nuclear factor-κB, resulting in significant inhibition of glucocorticoid signaling, and decreased efficacy of glucocorticoids [457].

The ubiquitous side effects of corticosteroids are the major factor limiting their use in IBD [370,449,451]. Although the majority of corticosteroid side effects are dose dependent, there is a wide range of patient susceptibility such that some patients tolerate prolonged courses of high-dose corticosteroid therapy without ill effects, but others develop devastating side effects with short courses of low-dose therapy. Patients taking more than 10 mg prednisone daily for longer than 3 weeks should be viewed as having a suppressed hypothalamic–pituitary–adrenal axis for 1 year after cessation of therapy and should receive supplemental glucocorticoids for surgery or severe illness. Patients should be instructed about adrenal suppression and the need for glucocorticoid supplementation for surgery and severe illness even after cessation of therapy.

Patients also need to be educated about the benefits and toxicities of glucocorticoids. Common predictable side effects include increased appetite, central obesity, moon facies, acne, insomnia, increased risk of infection, and, in children, growth retardation. Less common problems requiring patient monitoring include hypertension and glucose intolerance. Steroid-induced glucose intolerance may require reatment with insulin or oral hypoglycemic agents and in patients with diabetes; steroids may make blood-sugar control more difficult. Sleep disorders are common along with mood swings. More profound psychiatric problems, including depression and psychosis, may become unmasked or exacerbated by steroid therapy. Osteonecrosis, particularly of the femoral heads, can be related to corticosteroid therapy or the underlying disease [458,459].

Osteoporosis is a common and potentially devastating side effect of corticosteroid therapy when fractures occur. Virtually every patient treated with glucocorticoids develops negative calcium balance although there is a variation in risk of bone loss that typically occurs within the first months of therapy [449,460]. The effects of corticosteroids on bone include both enhanced bone resorption and diminished bone formation. Bone loss characteristically involves trabecular bone in ribs, vertebrae, and distal radius. Rib fractures and vertebral compression fractures are common. Patients with small intestinal Crohn's disease are at greater risk for steroid-induced bone loss because of malabsorption of calcium and vitamin D. The incidence of symptomatic bone loss also is higher in children and postmenopausal women. To minimize bone loss, the management of patients on corticosteroids should include the following [460]:

- use of the lowest possible dose of corticosteroids
- smoking cessation, limitation of alcohol consumption, and 30–60 min of weight-bearing exercise per day
- history, physical examination, and laboratory evaluation, including bone mineral densitometry
- dietary or supplemental calcium (1500 mg/day)
- vitamin D (50 000 IU 1–3 times/week) or calcitriol (0.5 μg/day)
- consideration of hormone (estrogen) replacement therapy where appropriate
- consideration of a bisphosphonate antiresorptive agent.

Posterior subcapsular cataracts occur frequently with corticosteroid therapy; also related to dose and duration of

therapy and increased intraocular pressure can occur in up to 40% of patients and can rarely lead to irreversible glaucoma and blindness. Periodic ophthalmological examinations with measurements of intraocular pressure and slit-lamp examination should be performed for patients on long-term corticosteroid management.

While budesonide is generally associated with fewer adverse events than prednisone, and in short-term trials has a similar side effect profile to placebo [461], monitoring for steroid-related side effects is warranted, particularly in long-term use. With long-term use budesonide at doses up to 9 mg daily is unlikely to induce osteoporosis [462], however, because patients with ileal Crohn's disease are already at increased risk, bone density monitoring and calcium and vitamin D supplementation are warranted.

Corticosteroids in ulcerative colitis

Oral corticosteroids

Oral corticosteroids are indicated for the treatment of outpatients with moderately severe ulcerative colitis [110,111,449,463]. Although the original trials of corticosteroids in ulcerative colitis evaluated 100 mg oral cortisone daily [109], there has since been a general consensus that prednisone or prednisolone are favored preparations related to their pharmacokinetic profiles and ease of administration on a regimen from once a day to four times a day. There is a dose–response for prednisone from 20 mg to 60 mg daily, although the modest benefits of the higher dose are offset by increasing steroid side effects [464]. Similarly, there is scant evidence regarding dosing schedules with only a single small trial that compared once daily dose of 40 mg prednisone with 10 mg administered four times a day [465]. In the 45-patient trial there was no difference in the clinical outcomes over 2 weeks, leading to the trend to use single daily dosing. Recognizing that there have been considerable differences in outcome measures in clinical trials of ulcerative colitis [466], overall oral corticosteroids have been effective at inducing remission in approximately 70% of patients with a number needed to treat of 2 [391]. Similarly, in population series approximately 50% of patients achieve a remission with 4 weeks of treatment and an additional 30% attain a partial response [115]. Unfortunately, once initiating steroid therapy 16% of patients failed to respond and, after 1 year, less than one-half were in remission and over 20% of patients required a colectomy (Fig. 57.33).

Oral corticosteroids have neither been effective nor indicated for maintaining remissions of ulcerative colitis. In distinction, steroid-dependence is common [115]. Neither cortisone 50 mg daily [467] nor prednisone up to 15 mg daily [468] was effective at preventing relapse. While high-dose (40 mg) alternate-day prednisone in addition to sulfasalazine did reduce relapse rates in a small, 24-patient trial, side effects of oral corticosteroids rarely justify their long-term use [110,111,391,463,469].

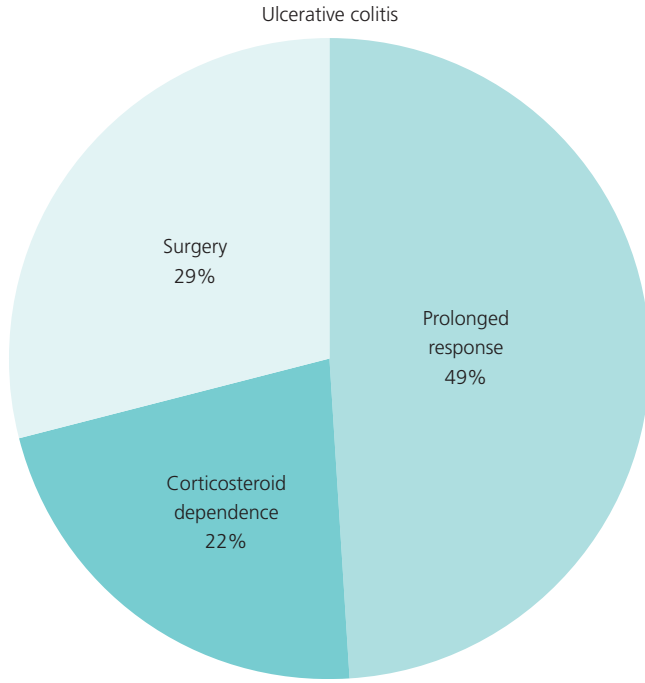

Figure 57.33 One-year outcomes after the first course of corticosteroids in 63 patients with ulcerative colitis. Data from Faubion et al. [115].

Topical corticosteroids

Topical corticosteroids (i.e. formulations applied per rectum) have long been recognized as an important therapeutic approach in patients with ulcerative colitis, as either first-line therapy in patients with disease limited to the distal colon or rectum, or as combination therapy in patients with more extensive colitis [470,471]. A recent metaanalysis described pooled odds ratios for symptomatic and endoscopic improvement at 0.21 (95% CI 0.07–0.71) and 0.27 (95% CI, 0.10–0.77), respectively [472]. For disease located solely in the rectum, corticosteroid-containing suppositories or foam are preferable. Patients with proctosigmoiditis may find improvement with a foam or liquid enema preparation, while those with inflammation extending past the sigmoid colon are best treated with the liquid enema formulation. Corticosteroid enemas are also useful in as adjunctive therapy in patients with severe colitis [418]. Estimates of systemic absorption of the corticosteroid from a corticosteroid enema preparation range from 40% [473] to 75% or 80% [451,474]. As a result, long-term use of topical corticosteroids is discouraged; patients should preferentially be treated with mesalamine-based products when possible, which comparative analysis has shown to be more efficacious than the corticosteroid-containing agents [392,472]. Novel topical corticosteroid preparations, such as budesonide [475], beclomethasone dipropionate [476], and others, allow for targeted mucosal release and effect with minimal systemic side effects, but have yet to achieve Food and Drug Administration approval in the United States.

Parenteral corticosteroids

Parenteral corticosteroids have been a mainstay of therapy for hospitalized patients with severe-fulminant ulcerative colitis despite an absence of controlled trial data in this complicated group of patients [449]. While placebo-controlled trials would be unethical in this setting, several studies have compared parenteral hydrocortisone with adrenocorticotropic hormone (ACTH; corticotropin) but variations in response between formulations failed to define an "optimal" approach between hydrocortisone and ACTH. Although the latter may have a small advantage for steroid-naïve patients [477], the majority of hospitalized patients will have been hospitalized as the result of the failure of outpatient corticosteroid treatment. In addition, ACTH has been associated with adrenal hemorrhage and is no longer marketed as a therapy in the United States. Most clinicians have therefore moved to equivalent doses of prednisolone, methylprednisolone or hydrocortisone, although the last of these is less preferred because of higher mineralocorticoid effects and greater potassium losses. A dose–response for parenteral steroids has not been clarified in clinical trials although there is no evidence to favor significantly higher doses than 48 mg/day of methylprednisolone [478]. Furthermore, it does not appear to matter whether intravenous steroids are administered as a bolus infusion or as a 24-h continuous infusion [479].

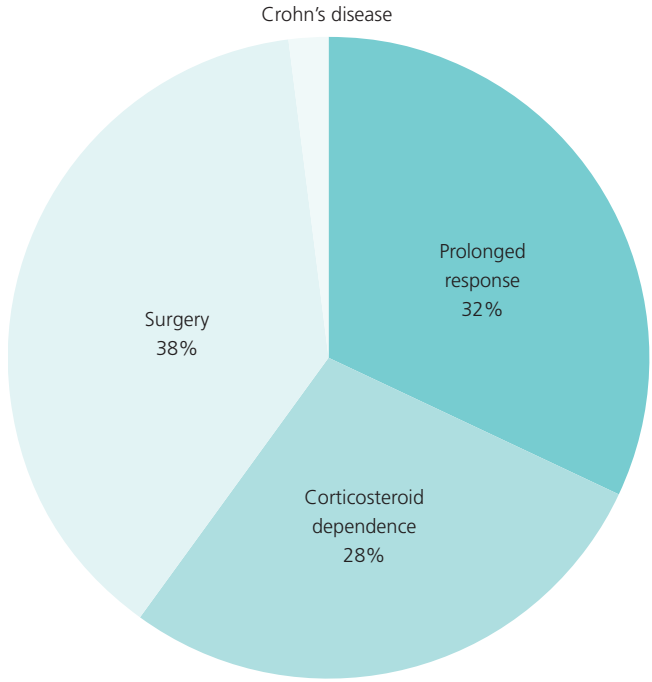

Figure 57.34 One-year outcomes after the first course of corticosteroids in 74 patients with Crohn's disease. One patient was lost to follow-up. Data from Faubion et al. [115].

Corticosteroids in Crohn's disease

Oral corticosteroids

Oral corticosteroids are indicated for the induction of a clinical response and remission in patients with moderately or severely active Crohn's disease (Fig. 57.34). Dosed within a range of 0.25–0.75 mg/kg with subsequent taper after remission induction, prednisone or prednisolone were shown to be superior to placebo in both the National Cooperative Crohn's Disease Study [480] and the European Cooperative Crohn's Disease Study [408]. Studies of higher doses (1 mg/kg of prednisolone) showed superior remission rates, from roughly 60% to over 90% [241]. However, because of prohibitive side effects at the higher doses, many clinicians treat at an initial dose of 40 mg/day, in either single or divided doses. Once remission is attained, doses are tapered, although no discrete tapering regimens have been established. In one study, 6-month outcomes were similar with a 4-week vs. 12-week taper of methylprednisolone from an initial dose of 40 mg daily [481].

Clinical trial outcomes in Crohn's disease are superior to sulfasalazine [407,408] and to elemental diets (with and without antibiotics) [482,483]. Remission rates with oral corticosteroids were better than for combination therapy with metronidazole and ciprofloxacin [442]. Coadministration of prednisone (30 mg/day) or 6-methylprednisolone (48 mg/day) with sulfasalazine therapy (3–6 g/day) showed improved efficacy [484] the reverse, however, was not seen [485], suggesting that the corticosteroid is the more effective agent in remission induction [408].

Oral budesonide has proven an effective alternative to traditional corticosteroids for patients with Crohn's disease affecting the small intestine and right colon (the location of release from the drug's pH-dependent coating) [454]. Controlled ileal release (CIR) budesonide was superior to placebo in the treatment of active Crohn's disease, with an optimal dose of 9 mg daily (8-week remission rates 51% vs. 20%, $P < 0.001$) [486]. Budesonide 9 mg/day was more effective than mesalamine 4 g/day at both 8 weeks (69% vs. 45%, $P = 0.001$) and 16 weeks (62% vs. 36%, $P < 0.001$) of therapy, with minimal impact on the adrenal–pituitary axis [487].

Comparisons of efficacy between budesonide and "traditional" oral corticosteroids have had mixed results; most have had similar outcomes between regimens, with a tendency for the budesonide to have slightly lower remission rates, but with far fewer corticosteroid-related side effects and less measured impact on the adrenal–pituitary axis [488–490]. Metaanalysis has shown budesonide to be more likely to induce remission in Crohn's disease than placebo (relative risk [RR] = 1.82, 95% CI 1.15–2.88) or than mesalamine (RR = 1.73, 95% CI 1.26–2.39), but less frequently than conventional corticosteroids (RR = 0.87, 95% CI 0.76–0.995). It was also less likely to cause corticosteroid-associated adverse events than conventional corticosteroids (RR=0.65, 95% CI 0.53–0.80) [461]. Optimal dosing of

budesonide is 9 mg once daily [490]; higher doses have not shown greater efficacy, but are associated with higher rates of adrenal suppression [486].

Topical corticosteroids

Topical corticosteroids have not been well studied in Crohn's disease; many practitioners use the same enemas, foams, and suppositories that are successful in ulcerative colitis for patients with Crohn's disease with distal disease, or for Crohn's disease of an ileoanal pouch [491].

Parenteral corticosteroids

Parenteral corticosteroids have been reserved for patients with Crohn's disease who are refractory to oral corticosteroids. Intravenous prednisolone is more effective than oral delivery; continuous infusion of intravenous prednisolone provides higher mean serum concentrations than bolus administration [492]. No large controlled trials of intravenous corticosteroids in Crohn's disease have been conducted, and open-label studies are few in number. One group reported a 76% response rate in 49 patients, with the lowest rates in patients with ileocolonic disease [493]. A double-blinded randomized trial comparing intravenous administration of either 120 units/day of ACTH or 300 mg/day of hydrocortisone revealed similar 10-day response rates (82% vs. 93%, respectively). As a result of the risk of adverse events from ACTH, methylprednisolone is preferentially used, typically at doses initially ranging from 40 mg/day to 60 mg/day, with subsequent transition to oral corticosteroids in patients who respond adequately to the intravenous therapy.

Immunomodulators

The term "immunomodulators", often used interchangeably with "immunosuppressants", refers to nonbiological therapy that directly targets the immune systems' cellular processes. These agents are often loosely grouped into families based on their primary proposed mechanisms of action. The common families include the antimetabolites (azathioprine, 6-mercaptopurine, and methotrexate), and the calcineurin inhibitors (cyclosporine, tacrolimus). The immunomodulators have traditionally been used in patients who are corticosteroid-dependent, or refractory, although there has been a recent emphasis on starting these therapies earlier in patients with IBD, particularly those with an initial moderately severe or severe presentation. These agents require frequent safety monitoring, and so are only suitable for use in patients who are compliant with the necessary medical testing, and should not be prescribed by practitioners unfamiliar with their use and risks.

Azathioprine and 6-mercaptopurine

Often used interchangeably in the management of IBD, azathioprine is a prodrug which undergoes initial conversion to 6-mercaptopurine. Further hepatic metabolism results in the formation of a variety of metabolites; the 6-thioguanine nucleotides are believed to be the primary nucleotides that account for the drugs' efficacy. Increased intracellular concentration of these nucleotides and other metabolites inhibits purine metabolism, and in turn DNA synthesis and repair, inhibiting cellular proliferation [494]. There are multiple cell-types whose activities are either directly or indirectly inhibited by these compounds, including lymphocytes [495] plasma cells [496], and natural killer cells [497].

Neither azathioprine nor 6-mercaptopurine is a therapeutically active agent; rather, it is the various 6-thioguanine nucleotide metabolites of these drugs that subsequently impact the body's biological systems. One of the critical enzymes necessary for the metabolism of the parent drugs is thiopurine methyltransferase (TPMT) [494,498] (Fig. 57.35). It is important that the genetic variations in the presence and activity of this enzyme are understood when dosing these drugs. Approximately 88% of the population is a wild-type for both TPMT alleles; another 11% is heterozygous, and 0.3% is homozygous-deficient for either allele [499,500].

Furthermore, mutant alleles can account for variation in the enzyme activity. Absence or low activity of the TPMT enzyme shunts much more of the parent drug towards the production of 6-thioguanine (6-TG) nucleotides, leading to toxicity at seemingly very low doses of the parent compounds. Conversely, there is little or no production of the 6-methylmercaptopurine (6-MMP) nucleotide, which at high levels has been associated with elevation of liver function tests.

Erythrocyte TPMT has been shown to be an accurate reflection of the enzymatic activity in other tissue, allowing for commercially available measurement of TPMT genotype and enzymatic activity from a simple blood sample [500]. This may be an important tool in determining the appropriate initial dosage, and subsequent evaluation of changes in hematological or hepatic parameters after therapy has been initiated. For example, patients who are wild type for the TPMT enzyme, or who have high levels of TPMT activity, may be eventually dosed with azathioprine at 2.0–3.0 mg/kg/day, or 6-mercaptopurine at 1.0–1.5 mg/kg/day. However, those who are heterozygous for the TPMT genotype, or have

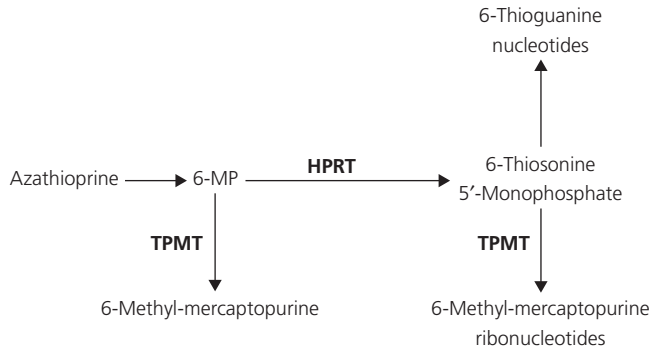

Figure 57.35 Metabolism of azathioprine and 6-mercaptopurine.

only intermediate levels of enzyme activity, are typically targeted at 50% of the full dose. Patients who are homozygous deficient for both alleles, or in whom enzyme activity is very low, should not be treated with either agent [501,502].

It is recommended to check TPMT enzyme genotype or phenotype before or shortly after initiating therapy, and to adjust the initial and subsequent dosing appropriately [503]. However, it is important to realize that nearly two-thirds of leukopenic events on these medications result from events that are *independent* of the TPMT enzymes. As a result, it is prudent to start patients at low doses of these drugs (1.0 mg/kg of azathioprine; 0.5–0.75 mg/kg of 6-mercaptopurine) and monitor complete blood counts, platelet count, and differential, and liver function tests every 2–3 weeks when initiating therapy and following a dose increase [502,504]. Once the doses are stable, it is advisable to follow the hematological studies every 3–4 months, and the liver function tests at least twice yearly.

The utility of monitoring levels of the 6-TG and 6-MMP is less clear. Retrospective studies have suggested that patients with IBD with 6-TG levels of 235–250 or greater are more likely to be in remission than those with levels below that limit, although there were clearly patients in remission with "subtherapeutic" levels and others who still had evidence of active disease with levels exceeding that limit [502–505]. The 6-MMP nucleotide, while in some instances shown to also correlate with drug efficacy, has been more directly linked to a higher risk of toxicity [506] and developing increased liver function test abnormalities, particularly at levels greater than 5600. However, hepatotoxicity can occur at lower levels, and many patients have 6-MMP levels far higher than this limit without evidence of hepatic compromise. Until well-designed prospective trials reveal the true clinical relevance of monitoring these metabolite levels, which would justify measurement in all patients receiving these agents, there are a few scenarios where one could gain valuable information from these tests [503]. The first is ensuring patient compliance (or absorption) of these oral agents; low levels of both metabolites suggest that an adequate dose is either not being taken or not being absorbed. The second scenario is the patient in whom there is no apparent response to therapy; in this instance, patients who preferentially shunt towards the production of 6-MMP at the expense of a low 6-TG have been shown to be ill-served by dose increase, which simply drives up the 6-MMP with little effect on the 6-TG. Experimental investigations into the controversial administration of low-dose allopurinol (100 mg) while drastically decreasing the dose of the purine analogue to 25–50 mg/day has shown some exciting results, with increases of the 6-TG nucleotide, low levels of 6-MMP, and patient responses. However, strict monitoring of cell counts must maintained, as there is a risk of profound pancytopenia in some individuals.

A third scenario whereby one should consider the 6-TG and 6-MMP levels is when a patient's aminotransferases increase while on therapy. Finding a 6-MMP level > 5600 suggests that simple dose reduction might be sufficient, although repeating the hepatic enzyme levels to ensure normalization is important. In this particular patient scenario, if the patient has a "low" 6-TG level, and active disease, one should consider switching to a different class of immunomodulator [504].

A few novel approaches to patients who are either intolerant to the purine analogues, or preferentially shunt metabolism away from the active 6-TG nucleotide towards the 6-MMP nucleotide have been tried. The first is to substitute therapy with another agent in the purine metabolic chain, 6-TG. Therapeutic studies of 6-TG have shown the agent to be effective in Crohn's disease and ulcerative colitis [507–509]. However, overriding safety concerns, especially the development of nodular regenerative hyperplasia in 76% of patients with liver function test abnormalities, and 33% of those with normal liver chemistries [510], has relegated this agent to experimental trials, or dosing under strict safety parameters, if at all [511,512]. A different approach in patients who preferentially are shunting metabolism towards the 6-MMP nucleotide has been experimental combination therapy with very low doses of azathioprine and a low dose of allopurinol [513]. Previously considered to be a contraindicated therapeutic approach, very low doses seem to shift the metabolism of the purine analogue towards the 6-TG nucleotide, as well as achieving clinical efficacy. Very careful safety monitoring is required; this is not an approach advocated for general use at this time.

The safety of the purine analogues when used appropriately in patients with inflammatory bowel disease has generally been at a level acceptable to support their use, particularly as therapies sparing patients from the toxicities of long-term corticosteroids [514–519]. Side effects noted on initial introduction of therapy are often a reflection of allergic sensitivities, or idiosyncratic reactions, such as fevers, rash, back pain, headaches, diarrhea, pancytopenia, and pancreatitis [516,520,521]. Some of these reactions may be seen with azathioprine but not 6-mercaptopurine, and vice versa. Some patients may be successfully switched to the other agent without redevelopment of side effects [522–524], although pancreatitis and pancytopenia almost always recur in this setting, and should not lead to rechallenge with the other agent.

Adverse events that may develop after the initial dosing period are expanded to include cytopenias, hepatitis, infections, and neoplasms (particularly lymphomas) [501,516,520,525]. As the mechanism of action of these agents interfered with the purine synthesis pathway, any of the major blood cell lines may be adversely impacted by these drugs, most commonly the white cell lineage [525]. Bone marrow toxicity has been thought to be primarily due to the activity of the TPMT enzyme; however, the implication that a normal TPMT level allows for unfettered higher dosing in patients without concern for cytopenias is incorrect, and potentially dangerous.

One investigation into myelosuppression in patients with IBD treated with the purine analogues determined that 73% of the patients who experienced myelosuppression had no known TPMT mutation, with cases reported as late as 87 months after initiation of therapy [501]. Hepatic toxicity is most commonly thought to be related to elevated levels of the 6-MMP nucleotide (> 5700 pmol/8 × 10^8 erythrocytes) [502], although drug-induced cholestatic hepatitis [527] nodular regenerative hyperplasia [528,529] and venoocclusive disease [527] have been reported.

Concerns about infections with the use of the purine analogues are greatest for opportunistic infections; serious infections are rare [504,516,520] and may not be any greater than those seen in sick patients with IBD treated with corticosteroids or other agents [208]. However, patients must be monitored while on therapy, especially if on concomitant immunosuppressive agents. Concerns over the development of Epstein–Barr virus-related non-Hodgkin lymphomas [530,531] has raised concern over the need for better dosing guidelines with these agents, and discouraged the use of concomitant immunosuppressants. It is still not clear whether overall cancer and lymphoma rates are higher in patients with IBD on the purine analogues [532,533], especially those neoplasms that are not virally mediated. A larger retrospective series suggested an overall neoplasm rate of 3.1% [520]. Another review compared cancer rates between 626 patients with IBD treated for a mean duration of 27 months with azathioprine to 1578 patients with IBD who did not receive the drug [534]. Rates of all cancers (4.5% vs. 4.5%, respectively), colon cancers/high-grade dysplasias (2.2% vs. 2.8%), and lymphomas were similar between the two groups. Sustained leukopenia has been identified as a risk factor for the development of neoplasms in patients with IBD treated with these agents [535]. Most recently, rare instances of hepatosplenic T-cell lymphomas have been reported in young, almost exclusively male, patients with Crohn's disease receiving concomitant therapy with a purine analogue and infliximab [536]. This rare, typically fatal lymphoma has been reported previously in patients solely receiving the purine analogues [537], and raises further concerns over the use of multiple immunosuppressants in these patients [538].

Azathioprine and 6-mercaptopurine in ulcerative colitis

Although these agents are mainstays of therapy in the treatment of patients with corticosteroid-dependent or refractory IBD, the literature is surprisingly sparse in well-designed studies supporting their efficacy [539]. This may be partly the result of their delayed time-to-efficacy, shown by metaanalysis to be at least 17 weeks [540], and initial overlap in many studies with a tapering course of corticosteroids to induce the initial remission. As a result, the drugs' efficacy is typically not reflected in the outcomes at 1-month, but rather as a maintenance drug of a corticosteroid-induced remission, with a nearly 50% benefit over placebo [541]. Double-blinded withdrawal trials have shown azathioprine to be beneficial compared to placebo in preventing relapse (relapse rates 36% for azathioprine vs. 59% for placebo), with subgroup analysis showing the benefit extended to those previously in remission for more than 6 months (relapse rates 31% vs. 61%, respectively) [542]. When given in a placebo-controlled trial as combination therapy with sulfasalazine and an induction course of corticosteroids in patients with severe ulcerative colitis, remission induction rates were similar, but relapse rates were much lower with azathioprine than placebo (23.5% vs. 55.6%) [543,544]. The impact of the aminosalicylates on azathioprine's success in maintaining remission has been subsequently shown to be minimal, with relapse rates of 0.21/year for combination therapy vs. 0.19/year for those on azathioprine alone [545].

Open-label long-term retrospective analyses also yield information that supports the role of the purine analogues in inflammatory bowel disease. A 30-year survey of 662 patients treated with azathioprine in the Oxford IBD clinic reported remission rates of 45% for Crohn's disease, and 58% for ulcerative colitis; those rates improved to 64% and 87%, respectively, in patients receiving at least 6 months of therapy [518]. The proportions of patients remaining in remission wre 95% at 1 year, 69% at 3 years, and 55% at 5 years. These rates were notably lower in patients who stopped their azathioprine (63%, 44%, and 35%, respectively). Similar success with 6-mercaptopurine was reported in a 20-year retrospective survey from the Mount Sinai Hospital in New York, with a complete clinical remission rate of 65% and an additional 24% of patients achieving partial remission [515]. While 35% of patients subsequently had a relapse, remission was successfully restored in 88%, while relapse rates in those who stopped therapy were reported at 87%. These high success rates, and subsequently high relapse rates when the medications are discontinued, have strongly supported the use of these purine analogues as long-term therapy in ulcerative colitis [514].

Frustrated by the long delay until these therapies become efficacious, attempts at hastening onset of action by intravenous loading have been unsuccessful, and potentially toxic [546]. As a result, most of the studies mentioned above have relied on corticosteroids to induce an initial remission. For patients who are refractory or intolerant of high-dose corticosteroids, the purine analogues have proved successful in maintaining a remission induced by cyclosporine [547–549] or tacrolimus therapy [550,551].

Azathioprine and 6-mercaptopurine in Crohn's disease

There have been multiple placebo-controlled trials of the purine analogues in patients with Crohn's disease [221,480,552–556] most of which support the use of these agents in the induction or maintenance of remission, and in the closure of Crohn's fistulae. A metaanalysis calculated an odds ratio for response (vs. placebo) of 3.09 for patients with

active disease, 2.27 for quiescent disease, and 4.44 for fistulous disease [540]. A subsequent Cochrane analysis of the efficacy with azathioprine in the maintenance of remission reported odds ratios of 2.16 (CI 1.35–3.47) for maintenance of remission with azathioprine, 5.22 (CI 1.06–25.68) for corticosteroid-sparing, and 4.36 (CI 1.63–11.67) for withdrawal because of adverse events [557].

The success of these agents has led to subsequent studies of early intervention in patients with newly diagnosed moderate to severe Crohn's disease. One group randomized 55 children within 8 weeks of initial diagnosis to receive 6-mercaptopurine (1.5 mg/kg/day) or placebo, along with a tapering dose of prednisone (initially 40 mg/day). The children who received the purine analogue had a shorter duration of corticosteroid use, lower cumulative corticosteroid dose, and far lower relapse rates (9% vs. 47%) [223]. Unfortunately, intravenous loading of azathioprine was not shown to be successful in hastening time to response or remission in Crohn's patients [558].

The purine analogues have also been evaluated in fistulous Crohn's disease [559]. In a study of Crohn's fistulae with an 8-week treatment regimen of ciprofloxacin and metronidazole, patients who were already receiving azathioprine (2.0–2.5 mg/kg) at study initiation were more likely to achieve a response than those who were not on the purine analogue (48% vs. 15%) [448]. Outcomes were also notable in pediatric Crohn's patients, with 67% of patients improving and 40% closing their fistula with either azathioprine or 6-mercaptopurine. The purine analogues also are effective in maintaining fistula closure in patients whose fistulae were initially closed with cyclosporine [560] or tacrolimus [561].

There is also a growing body of literature supporting the use of the purine analogues as a postoperative preventative therapy in patients with Crohn's disease [562,563]. A multicenter, double-blind, double-dummy trial comparing daily doses of 6-mercaptopurine (50 mg) or mesalamine (3 g) to placebo reported lower 24-month rates of clinical (50% vs. 77%) and endoscopic (43% vs. 64%) recurrence with 6-mercaptopurine compared to placebo [562]. In another study, azathioprine (2 mg/kg) was also shown to be superior to mesalamine (3 g) in nearly halving surgical recurrence rates, with the greatest benefit seen in patients who had more than one previous surgery [563].

Methotrexate

Methotrexate is a competitive inhibitor of dihydrofolate reductase, preventing DNA synthesis and purine production [564]. Methotrexate therapy decreases levels of many of the proinflammatory cytokines found to be elevated in patients with inflammatory bowel disease, such as IL-1 [565], TNF, IFN-γ [566], and others. Methotrexate dosing in IBD was "borrowed" from that used in psoriasis and rheumatoid arthritis [567]; unlike those diseases, however, only parenteral methotrexate has been shown to be effective in clinical trials in IBD. This may be the result of variable bioavailability when dosed orally, as compared with over 90% bioavailability when dosed subcutaneously or intramuscularly [568]. Methotrexate is delivered weekly, to minimize side effects and hepatotoxicity [569], with folic acid supplementation (1 mg daily).

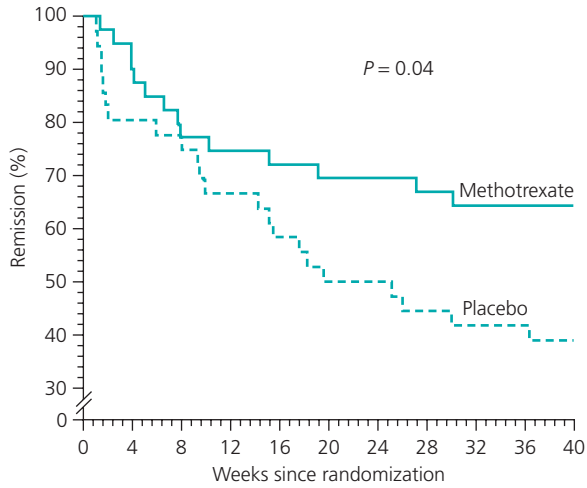
Toxicity is not uncommon with methotrexate, although the lower doses used in autoimmune diseases make the agent safer than when used for hematological malignancies. Side effects have been reported in nearly one-half of the patients with Crohn's disease treated in some series [570], leading to withdrawal of therapy in nearly 18% [570,571]. While most adverse events are the result of allergic reactions or intolerance, some are the result of the antimetabolic effects, similar to those seen in patients receiving chemotherapeutic agents [572]. Hepatic fibrosis and cirrhosis are rarely seen, leading to a withdrawal of the recommendation for a surveillance liver biopsy at 1.5 g cumulative dose [573], unless repeatedly elevated aminotransferases or decreased serum albumin are detected [574].

Methotrexate in ulcerative colitis

Although advocated by some clinicians, there have yet to be convincing clinical trials proving methotrexate's efficacy in ulcerative colitis. Although five of the seven patients in the initial experiment reported by Kozarek had a clinical response, none had mucosal healing, although the histological scores did improve [567]. While there are individual centers and case reports of success with methotrexate [575,576] a recent Cochrane analysis did not find convincing support for use of the drug, in part because of a lack of suitable randomized controlled trials in ulcerative colitis [577]. The only placebo-controlled trial found nearly identical remission rates with oral methotrexate 12.5 mg daily (46.7%) and placebo (48.6%). Larger trials with parenteral therapy are needed.

Methotrexate in Crohn's disease

Methotrexate has been shown to be efficacious in the induction and maintenance of remission in Crohn's disease, when given either intramuscularly [571] or subcutaneously [570,575]. Data on oral dosing have been disappointing [578]; a Cochrane Database review concluded that there was insufficient evidence supporting oral delivery in Crohn's disease [579]. The pivotal induction trial for methotrexate dosed 141 patients with corticosteroid-refractory Crohn's disease with either methotrexate 25 mg intramuscularly weekly or placebo in a 2 : 1 ratio, along with prednisone 20 mg which was tapered over 10 weeks [571]. Remission rates were higher with the methotrexate (39% vs. 19%), while total prednisone received was less in that same group. A subsequent "continuation" remission maintenance study in this group randomized 76 of the patients who had achieved remission to either intramuscular methotrexate (15 mg/week)



No. at risk

or placebo [580]. Week 40 remission maintenance rates were higher with methotrexate (65% vs. 39%), with comparable safety rates (Fig. 57.36). The University of Chicago group subsequently published open-label data showing a remission rate of 37% at a mean dose of 20 mg/week, with maintenance of remission in 46% with parenteral (but not oral) methotrexate [570].

Cyclosporine and tacrolimus

Cyclosporine (a polypeptide produced by the fungus *Tolypocladium inflatum*) and tacrolimus (a macrolide antibiotic) both bind specific proteins which, in turn, inhibit calcineurin, an enzyme required for activation of T lymphocytes [581–583]. Both are metabolized by the cytochrome P450 system, and care must be taken when dosing these agents with other medications or foods that interact on the same pathway.

Cyclosporine is typically administered intravenously to achieve a rapid response, and then patients are converted to oral dosing. There are two oral formulations that differ greatly in intestinal absorption and bioavailability: the cremaphor-based Sandimmune and a microemulsion Neoral [584,585]. It is important to identify which agent the patients are receiving, as accurate dosing by blood levels is critical to allow for efficacy and to avoid toxicity [586]. One of the main advantages of cyclosporine is the rapid onset of response (typically within a few days), even in the most severely ill patients. Used mostly for corticosteroid-refractory ulcerative colitis, cyclosporine is typically added on to the corticosteroids as a continuous intravenous infusion at 2–4 mg/kg/day, with dose titration to achieve whole blood adjusted radioimmunoassay or high-performance liquid chromatography levels of 250–400 ng/mL [111,463,547,587,588]. Dose adjustments are often necessary because of side effects. Patients who are successful in achieving a complete clinical response are transitioned to an oral formulation of cyclosporine (twice the daily dose as was given intravenously, dosed twice a day), oral prednisone, and initiated on long-term therapy with either 6-mercaptopurine or azathioprine. Over the subsequent 2–3 months, the purine analogue dose is optimized, and the other agents tapered off.

Tacrolimus is more potent than cyclosporine, and has been used intravenously in the pediatric population in the same setting of severe refractory colitis [550], but more commonly is dosed orally [550, 551,589]. Initial doses are 0.10–0.15 mg/kg twice daily, titrated to trough levels of 10–20 ng/mL. Transitioning patients to the longer-acting, safer purine analogues is also typically the goal of therapy.

Cyclosporine and tacrolimus have formidable toxicities that limit their use to selected patients, and for limited periods of time. Most concerning is the nephrotoxic impact of these agents, with decreases in creatinine clearance of approximately 20% with chronic use of cyclosporine [590]. The most common side effects reported in center series of patients with IBD treated with cyclosporine were paresthesias, hypertension, hypertrichosis, renal insufficiency, infections, gingival hyperplasia, and seizures [547,591]. Rare opportunistic infections, including *Pneumocystis carinii*, have been reported, as well as patient deaths. Large-scale experiences with tacrolimus in IBD have not been reported, but the literature links the drug to higher rates of neurotoxicity, diarrhea, diabetes mellitus, pruritis, and alopecia [592]. For both agents, prophylaxis against *Pneumocystis carinii* is advocated.

Cyclosporine and tacrolimus in ulcerative colitis

Cyclosporine's major role in IBD has been its use as an intravenous infusion in patients with severe ulcerative colitis that is refractory to intravenous corticosteroids. In a small placebo-controlled trial conducted by the University of Chicago and New York's Mount Sinai Hospital, 82% of the patients who received cyclosporine (4 mg/kg/day delivered as a continuous infusion) responded to therapy at a mean of 7 days, as compared to 0% of the placebo-treated patients [593]. Of note, all of the patients were still receiving intravenous corticosteroids and corticosteroid enemas; it was clearly the cyclosporine that made the difference. Retrospective open-label reports found similar initial response rates of 76%–86% [547,594,595]. It may be possible to use lower dose intravenous cyclosporine; in one study, patients who were randomized to receive 2 mg/kg had nearly identical response rates to those who received 4 mg/kg (85% vs. 84%, respectively), although only 55%–60% of the study participants were true failures of high-dose corticosteroids

[596]. Lower response rates have been reported with cyclosporine monotherapy (64%) [597], suggesting that this might be suitable in patients for whom corticosteroids are contraindicated, or poorly tolerated [598].

It quickly became apparent that while intravenous cyclosporine was effective in "putting out the fire" for patients with severe refractory ulcerative colitis, maintenance therapy with oral cyclosporine was ineffective [597,599,600]. Relapse rates resulting in surgery were high, except in patients who were transitioned to one of the purine analogues. Treatment paradigms with cyclosporine quickly adapted to use the agent solely as a "bridging therapy" to the slower acting but effective azathioprine or 6-mercaptopurine [463,547,587] (Fig. 57.37). The use of oral cyclosporine to induce a response or remission has not been formally investigated in clinical trials, although open-label experiences suggest that it is an effective short-term strategy [584,601,602].

Tacrolimus has not been studied in large controlled trials. Open-label experience in severe pediatric ulcerative or Crohn's colitis showed an initial response rate of 69%, although only 38% of patients avoided colectomy at 12 months, despite the institution of concomitant therapy with azathioprine or 6-mercaptopurine [551]. Small studies in ulcerative or indeterminate colitis have shown initial response rates of 47%–66%, with colectomies in approximately one-third of patients [550,589].

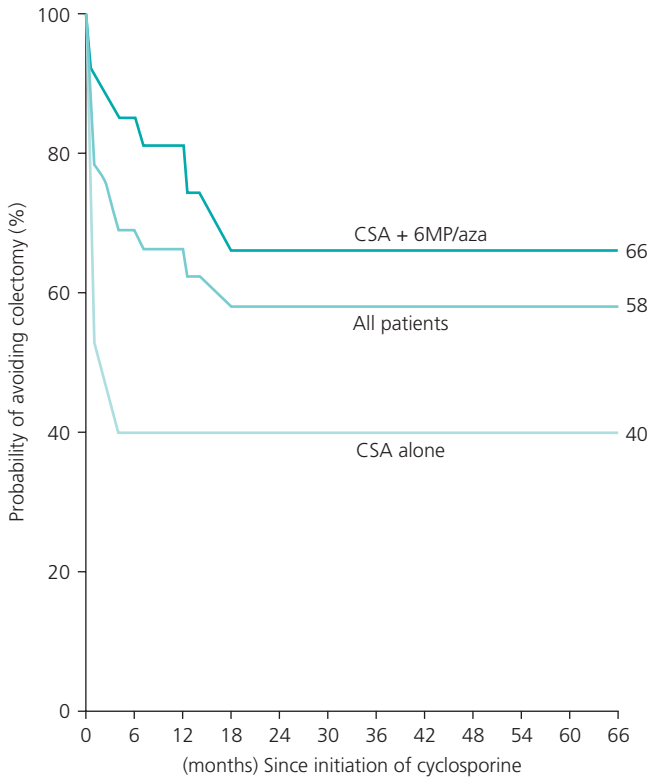

Figure 57.37 Predicted avoidance of colectomy over time in 42 patients with severe intravenous corticosteroid refractory ulcerative colitis treated with intravenous cyclosporine, followed by short-term oral cyclosporine and either long-term therapy with 6-mercaptopurine or azathioprine (6MP/aza) vs. no long-term purine analogue. ($P = 0.04$ Mantel–Haenszel χ^2; $P = 0.045$ log rank χ^2) From Cohen RD et al. [547].

Cyclosporine and tacrolimus in Crohn's disease

Cyclosporine use for Crohn's disease has been mostly abandoned, partly because of the lack of successful controlled trials, the toxicity of the drug, and the introduction of infliximab as a therapeutic agent for Crohn's disease in the late 1990s. Studies in lumenal Crohn's disease have been disappointing, with only high-dose (7.6 mg/kg/day), and potentially toxic, cyclosporine proven effective in clinical trials [603–605]. While still used in some instances of refractory fistulous disease, there are no published controlled clinical trials, or even large case series that utilize cyclosporine in these patients. Although initial fistula closure rates range from 88% to 90% in small case series [606,607] relapse rates were high (82%), in the absence of continued therapy with azathioprine [560].

Oral tacrolimus (0.2 mg/kg/day) has been shown in one randomized placebo-controlled trial to improve draining perianal or enterocutaneous Crohn's fistulae (43% vs. 8% for placebo), although complete fistula closure rates were similar between the groups [608]. Other open-label experiences have had mixed results [561,609].

Anti-tumor necrosis factor agents

The introduction of therapies that have activity against TNF has opened up an exciting new pathway in the treatment of inflammatory bowel disease. While most of these agents are still under investigation, the anti-TNF antibodies infliximab and adalimumab are commercially available, and certolizumab is anticipated to follow. Thalidomide is also an agent believed to work through similar pathways [610,611] but its use is extremely limited because of toxicity. Clinical trials with etanercept were not successful [612], and some of the other investigational agents (onercept [613], CDP571 [614]) also failed in clinical trials and are unlikely to come to market yet.

One of the overriding issues when using the biological anti-TNF agents is the awareness that certain rare opportunistic infections have been directly linked to their use [615–619] the most concerning of which is reactivation of *Mycobacterium tuberculosis* [620]. Screening of all patients using the most appropriate tests for their population (purified-protein derivative, chest radiograph, or QuantiFERON test) is important before starting therapy. Patients who test positive, or in whom history or physical examination suggests possible tuberculosis infection should not receive therapies directed against TNF until they have completed therapy. Anti-TNF therapies should not be used in patients with known or suspected infections, neoplasms, demyelinating disease, or moderate to severe heart failure. Lupus-like events and other rare disorders have also been reported with the anti-TNF agents [621].

Infliximab

Infliximab is a monoclonal mouse/human chimeric IgG_1 antibody that targets TNF-α. It binds both free and membrane-bound TNF, and causes apoptosis of TNF-producing cells [622]. Immune processes initiated by complement fixation and antibody-mediated cellular cytotoxicity are also possibly mediated by interaction with infliximab and TNF [623]. Infliximab is delivered intravenously; IBD patients typically receive an initial loading dose regimen of three infusions at weeks 0, 2, and 6, and subsequently receive maintenance infusions every 8 weeks (Fig. 57.38). The standard dose is 5 mg/kg; higher doses up to 10 mg/kg have proved effective in patients who have lost response to the 5 mg/kg dose. Lower doses have not been shown to be effective.

Loss of efficacy, and some adverse events, have been linked to the development of antibodies against infliximab [624], referred to as "HACAs" (human anti-chimeric antibodies), or more appropriately, "ATI" (antibodies to infliximab), as they do not cross-react with other chimeric antibodies, or other anti-TNF antibodies. The likelihood of HACA formation is lower in patients receiving maintenance infusions of infliximab [624,625] or those with either pretreatment with hydrocortisone [626], or concomitant treatment with azathioprine, 6-mercaptopurine, or methotrexate [627]. Coadministration with another immunosuppressant had been strongly advocated; recent safety concerns have led some experts to advocate switching to monotherapy after maintenance therapy has been established [538] (see below). Long hiatuses of therapy are discouraged [628], because of the development of a "serum-sickness-like" delayed hypersensitivity reaction in 25% of patients, characterized by severe arthralgias and loss of drug efficacy, along with very

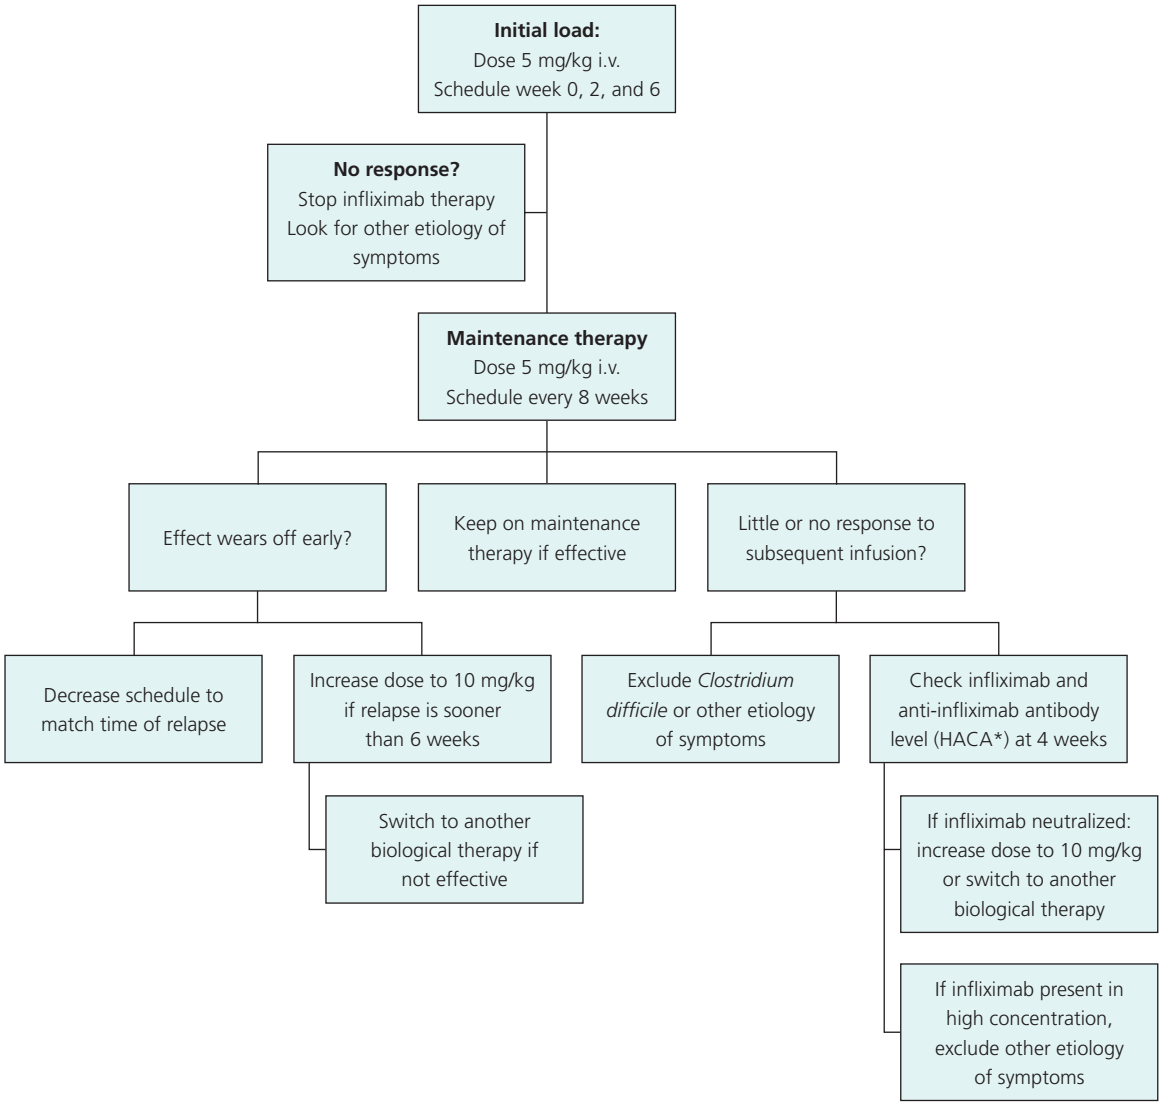

Figure 57.38 Dosing regimen for infliximab in patients with Crohn's disease or ulcerative colitis. *HACA = human antichimeric antibodies; more accurately described as antibodies to infliximab (ATI).

high titers of the "HACA" [629]. Maintenance infusions are typically given every 8 weeks; patients may be infused sooner if needed, but extending beyond 8 weeks has been associated with worse outcomes, and is discouraged.

Adverse events to infliximab can be categorized as those related to the infusion itself, and those thought to be independent of the infusion process. Infusion-related reactions were reported in 20% of all patients (all indications) in clinical trials (the rate was 10% in patients receiving placebo infusions) [621]. Among all infliximab infusions, 3% were accompanied by nonspecific fevers or chills, 1% by cardiopulmonary reactions (chest pain, blood pressure changes, dyspnea), and less than 1% by pruritus, urticaria, or a combination of symptoms [621]. Serious reactions, such as anaphylaxis, convulsions, and hypotension occur in less than 1%. The most common side effects in all clinical trials, similar in occurrence between patients receiving infliximab and those who received placebo, were upper respiratory infections, nausea, headache, and other gastrointestinal and respiratory complaints [621].

Infections requiring antibiotic treatment were reported in 32% of patients by the end of the 52-week ACCENT I Crohn's disease trial; serious infections were seen in 4% [625]. In the ACT I ulcerative colitis trial, serious infections were seen in 4.1% of the patients receiving placebo, 2.5% of the patients receiving infliximab at 5 mg/kg, and 6.6% of the patients receiving infliximab at 10 mg/kg. Regression analysis of the date from the TREAT registry (an industry-sponsored safety registry enrolling over 6000 Crohn's patients, half of whom have received infliximab) linked serious infections with the use of prednisone and of narcotics, but not with infliximab usage [630]. Mortality rates were also higher with prednisone use, but not with infliximab.

The rates of neoplasms in patients treated with infliximab are similar to those in the general population [621]. Lymphoma rates are higher with the immunosuppressants than in the healthy population; it is unclear whether the rates are elevated over patient cohorts matched for severity and duration of disease [621]. Rare instances of hepatosplenic T-cell lymphomas have been reported in young patients with Crohn's disease receiving concomitant therapy with a purine analogue and infliximab [536], although not in patients treated with infliximab alone. As a result, there has been a change in practice patterns to avoid long-term use of multiple immunosuppressants in patients receiving infliximab [538].

Infliximab in ulcerative colitis

Although a small clinical trial of infliximab in severe ulcerative colitis was promising [631], subsequent open-label experiences had mixed results [632–634] and infliximab was not widely used in ulcerative colitis until pivotal clinical trials were conducted. The ACT-1 and ACT-2 (Active Ulcerative Colitis Trials 1 and 2) trials each randomized 364 patients to receive intravenous infusions of either placebo or infliximab (dosed at 5 or 10 mg/kg) at weeks 0, 2, and 6, and then every 8 weeks [635]. The ACT-1 study continued for a total of 52 weeks, and boasted clinical response rates at week 8 of 37%, 69%, and 61% for placebo, 5 mg/kg infliximab, and 10 mg/kg infliximab, respectively, while week 54 rates were 20%, 55%, and 45%, respectively (Fig. 57.39). The ACT-2 study continued for 30 weeks, with week 8 response rates of 29%, 64%, and 69%, respectively, and week 30 rates of 26%, 47%, 60% (Fig. 57.39). The infliximab-treated patients also had superior mucosal healing rates, greater decreases in median corticosteroid dosage, and comparable safety results to patients given placebo. These studies ultimately led to the approval of infliximab for the induction and maintenance of remission in patients with moderate to severely active ulcerative colitis who were refractory to other therapies. The role of infliximab in patients whose severe ulcerative colitis is refractory to corticosteroids has been less clear. In a randomized blinded placebo-controlled trial, infliximab 5 mg/kg was shown to be an effective salvage therapy, with lower 3-month colectomy rates (29% vs. 67% for placebo) [636]. The utility of infliximab as a successful long-term option in the severe colitis patient refractory to intravenous corticosteroids has still yet to be determined.

Infliximab in Crohn's disease

There are multiple randomized placebo-controlled clinical trials that have established infliximab as an effective therapy in the treatment of moderate to severe lumenal Crohn's disease. The initial large trial was a 12-week study where patients received a single dose of infliximab at 5, 10, or 20 mg/kg or placebo. Clinical response rates at 4 weeks were 81%, 50%, 64%, and 17%, respectively. Overall, 12-week response rates were 41% for infliximab and 12% for placebo [637]. Retreatment of the responders with four infusions of infliximab 10 mg/kg at 8-week intervals maintained patient response and remission rates, while those patients randomized to placebo tended towards relapse [638].

The ACCENT-I trial treated 573 patients with moderate to severe Crohn's disease with a single infusion of infliximab at 5 mg/kg; responders at week 2 where then randomized to receive subsequent infusions of placebo, of infliximab 5 mg/kg at weeks 2 and 6 and then every 8 weeks, or of infliximab 5 mg/kg at weeks 2 and 6 and then infliximab at 10 mg/kg every 8 weeks [625]. Fifty-eight percent of patients responded at week 2; week 30 remission rates were 21% (placebo), 39% (5 mg/kg), and 50% (5 mg then 10 mg/kg group) (Fig. 57.40). There were also benefits seen in median time to loss of response, and in sparing of corticosteroids. Patients who lost response to their therapy were allowed a one-time change to increase the dose of the subsequent infusions by 5 mg/kg.

There were separate trials for patients with fistulous Crohn's disease. In the first trial, 94 patients with draining

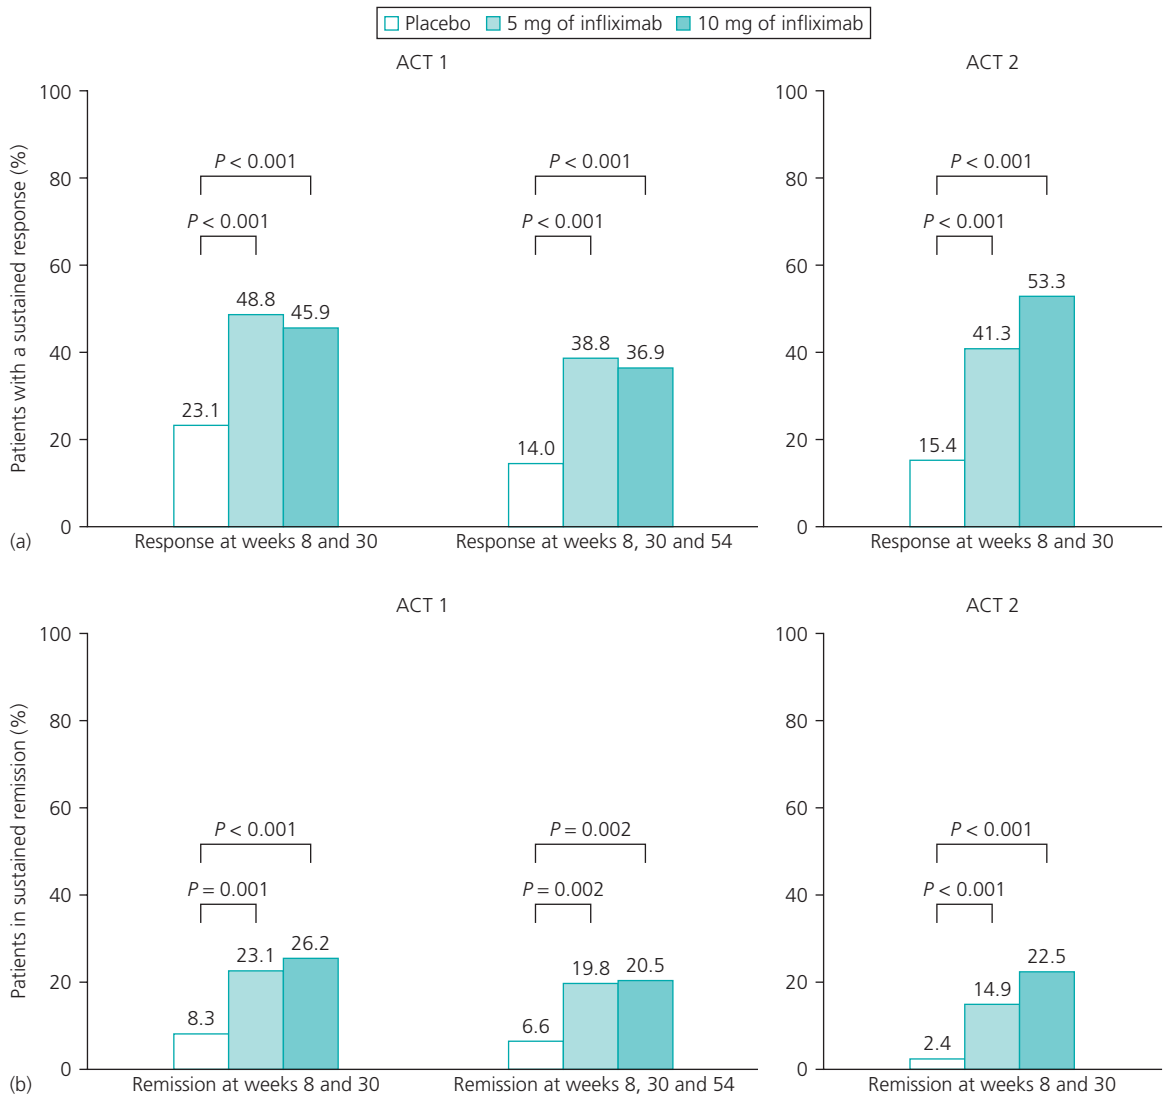

Figure 57.39 **(a)** Percentage of patients with moderate to severe ulcerative colitis who achieved a sustained response or **(b)** sustained remission after receiving randomized therapy with placebo, infliximab 5 mg/kg, or infliximab 10 mg/kg at weeks 0, 2, 6, and then every 8 weeks. From Rutgeerts et al. [635], with permission from the Massachusetts Medical Society.

abdominal or perianal fistulae were randomized to receive three infusions of placebo, infliximab 5 mg/kg, or infliximab 10 mg/kg at weeks 0, 2, and 6 [639]. The success rates of decreasing the number of draining fistulae by 50% or more were 26%, 68%, and 56%, respectively. Complete closure of all fistulae was seen in 13%, 55%, and 38%, respectively. The median time of fistula closure was 3 months. Subsequently, the ACCENT-II trial infused 306 adult patients with Crohn's disease and draining abdominal or perianal fistulae with infliximab 5 mg/kg at weeks 0, 2, and 6 [640] (Fig. 57.41). Responding patients were then randomized to receive either infliximab 5 mg/kg or placebo every 8 weeks. Time to loss of response was longer with infliximab (greater than 40 weeks) than placebo (14 weeks). At week 54, fistula closure rates were 36% and 19%, respectively.

Adalimumab

Adalimumab is a monoclonal human IgG_1 antibody that targets TNF-α. It binds both free and membrane-bound TNF, and causes apoptosis of TNF-producing cells [641]. Adalimumab is delivered subcutaneously in either a prefilled syringe or a self-injectable pen. Either device contains 40 mg adalimumab, which is delivered as a single dose. Adalimumab has many of the same safety concerns as infliximab, with the exception of infusion-related complications. Injection site reactions were reported in 20% of patients in the clinical trials (14% in placebo patients); other common adverse events in the clinical trials (similar in occurrence between patients receiving adalimumab and those who received placebo) were upper respiratory infection, injection site pain, headache, and sinusitis [642]. Whether antidrug antibody

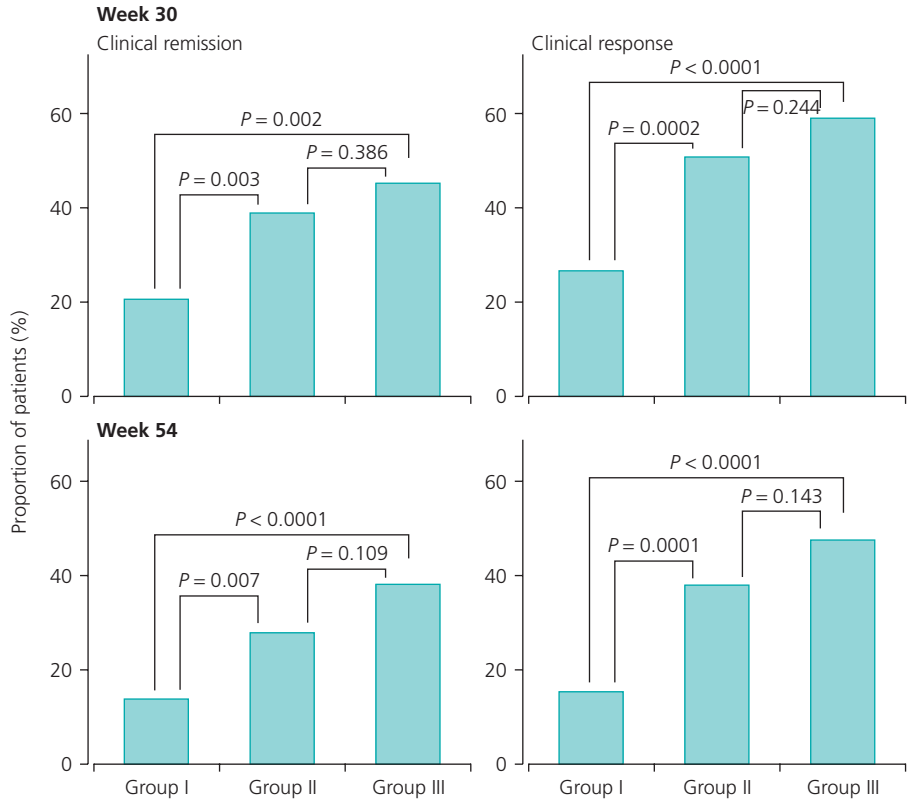

Figure 57.40 Clinical remission and response rates in patients with moderate to severe Crohn's disease who responded to an initial open-label infusion of infliximab 5 mg/kg at week 0, and then were randomized to receive week 2, week 6, and then 8-weekly doses of placebo (Group 1), infliximab 5 mg/kg (Group 2), or infliximab 5 mg/kg for week 2 and week 6 followed by infliximab 10 mg/kg every 8 weeks (Group 3). From Hanauer et al. [625].

levels are clinically relevant has yet to be fully determined. To date, there have been no published clinical trials of adalimumab in patients with ulcerative colitis; one clinical report showed short-term efficacy in four of 10 patients who had lost response or become intolerant to infliximab [643].

Adalimumab in Crohn's disease

There have been multiple clinical trials of adalimumab in Crohn's disease. While patients treated with adalimumab for other disorders are not started on an initial higher load, adalimumab must be given with a loading dose of 160 mg (four injections) at week 0, followed by 80 mg (two injections) at week 2, and then 40 mg every other week starting at week 4. Patients who lose response are switched to weekly dosing (Fig. 57.42).

The induction regimen of 160 mg at week 0 and then 80 mg at week 2 was established in two clinical trials. In the CLASSIC I trial, 299 patients with moderate to severely active lumenal Crohn's disease were randomized to receive two injections (week 0 and 2) of either placebo, adalimumab 40 mg/20 mg, adalimumab 80 mg/40 mg, or adalimumab 160 mg/80 mg [644]. The 4-week remission rates were statistically higher for only the highest dose (36%) than for placebo (12%). The same 160 mg/80 mg loading dose was used in the GAIN trial, with a 4-week remission rate of 21% compared with 7% for placebo [645].

The maintenance regimen of 40 mg given every 1–2 weeks was established in two other clinical trials. In the CLASSIC II trial, 55 patients (20% of induction population) who had achieved remission after receiving two open-label injections of 40 mg adalimumab at weeks 0 and 2 were randomized at week 4 to receive subsequent injections of either adalimumab 40 mg every other week, adalimumab 40 mg weekly, or placebo for the remainder of the year [646]. Remission maintenance rates were 68%, 83%, and 39%, respectively. In the CHARM study, 778 patients who had achieved a clinical response after receiving open-label adalimumab 80 mg at week 0 and 40 mg at week 2 were randomized to the same three maintenance groups as in CLASSIC II [647]. Their 1-year remission maintenance rates were 36%, 41%, and 12%, respectively (Fig. 57.43).

Adalimumab is effective in some patients with Crohn's disease who previously responded to infliximab, but then either lost response, or had an allergic reaction to either the infliximab or the infusion and could not continue therapy. In the GAIN trial (Gauging Adalimumab Efficacy in Infliximab Nonresponders), 325 such patients with moderate to severely active Crohn's disease were randomized to receive two injections of either placebo or adalimumab 160 mg at week 0, followed by 80 mg at week 2. Week 4 remission rates were 7% and 21% for placebo and treatment, respectively. Remission rates were similar in patients who had lost response to infliximab (8% vs. 20%) and those who had a previous intolerance to infliximab (5% vs. 22%).

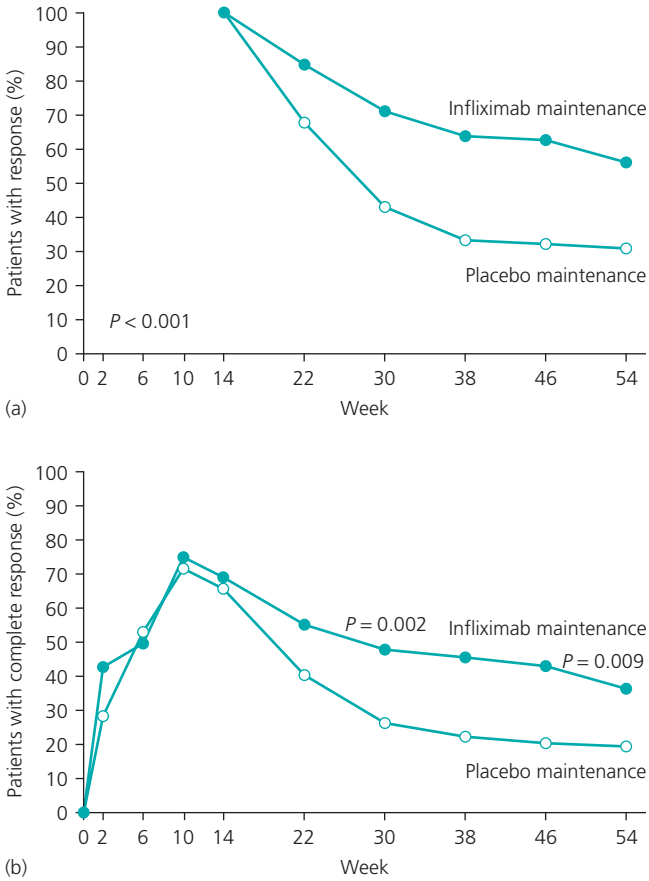

Figure 57.41 **(a)** Time to loss of response in patients with fistulous Crohn's disease who responded to an initial open-label induction therapy with infliximab 5 mg/kg at weeks 0, 2, and 6 and were then randomized at week 14 to receive maintenance infliximab 5 mg/kg or placebo every 8 weeks. **(b)** Percentage of patients with a complete response (absence of draining fistulas). Other investigational agents

The "biological revolution" that has descended on the field of medicine has resulted in an ever-expanding list of agents that target, duplicate, or otherwise influence the immune cascade. This list is constantly changing; many products that seem promising never see the light of day, and are quickly replaced by others. There are two agents that have completed multiple large-scale Phase III clinical trials in IBD that will be briefly mentioned here.

Certolizumab

Certolizumab pegol is a pegylated humanized Fab' fragment that binds TNF-α [648]. Early studies have been promising in Crohn's disease [649]. A recent randomized, double-blind, placebo-controlled trial of 662 adults with moderate to severe Crohn's disease stratified patients to receive either 400 mg of certolizumab pegol or placebo subcutaneously at weeks 0, 2, and 4 and then every 4 weeks [650]. There were superior response rates with certolizumab than placebo, but remission rates were similar between the two groups. In a separate maintenance trial, 668 adults with moderate to severe Crohn's disease all received open-label certolizumab pegol 400 mg at weeks 0, 2, and 4 [651]. The responders (64%) were then randomized to receive either certolizumab pegol 400 mg or placebo as a monthly injection for 6 months. Of the initial responders, 26-week response rates were 63% for treatment compared with 36% for placebo, while remission rates were 48% and 29%, respectively. Subsequent studies have been completed and are awaiting publication.

Natalizumab

Natalizumab is a humanized antibody directed against the integrin α_4, an important mediator of cellular trafficking in various tissues. There has been early data suggesting natalizumab may be an effective therapy for ulcerative colitis [652], as well as multiple large Phase III studies in Crohn's disease, with convincing evidence of a role for natalizumab in the induction and maintenance of remission in Crohn's disease [653–655]. Natalizumab is also effective in patients who are intolerant to infliximab, or who have lost response to that agent.

An unfortunate safety issue arose after natalizumab was released for the treatment of multiple sclerosis, with three confirmed cases of progressive multifocal leukoencephalopathy as the result of the JC human polyomavirus out of the roughly 3000 patients in the original clinical trials [656–658]. Extensive safety evaluations have failed to uncover other cases, and the drug is back on the market for multiple sclerosis under a strict registry program. It is anticipated that its initial use in Crohn's disease will be limited to patients who have failed anti-TNF therapies, and concomitant immunosuppressants will be disallowed [659].

Medical management of ulcerative colitis

Medical therapeutic decisions in treating patients with ulcerative colitis should be based on a few important issues. The first thing to determine is the extent of the colitis. It is helpful to determine from your colonoscopy whether the patient has inflammation limited to the rectum only (proctitis), to the rectum and sigmoid (proctosigmoiditis), extending up to 60 cm from the anal verge (left-sided colitis), or colitis extending beyond that boundary (extensive or pancolitis). It is also helpful to know if the normal-appearing colonic mucosa that is proximal to the area of colitis is indeed histologically normal, or if there is evidence of mild or quiescent colitis. One might choose to use more than just a topical therapy in patients whose colitis reaches beyond the proximal extent of a rectally applied therapy, to help maintain quiescence in that area (although this is a theoretical and not yet proven strategy).

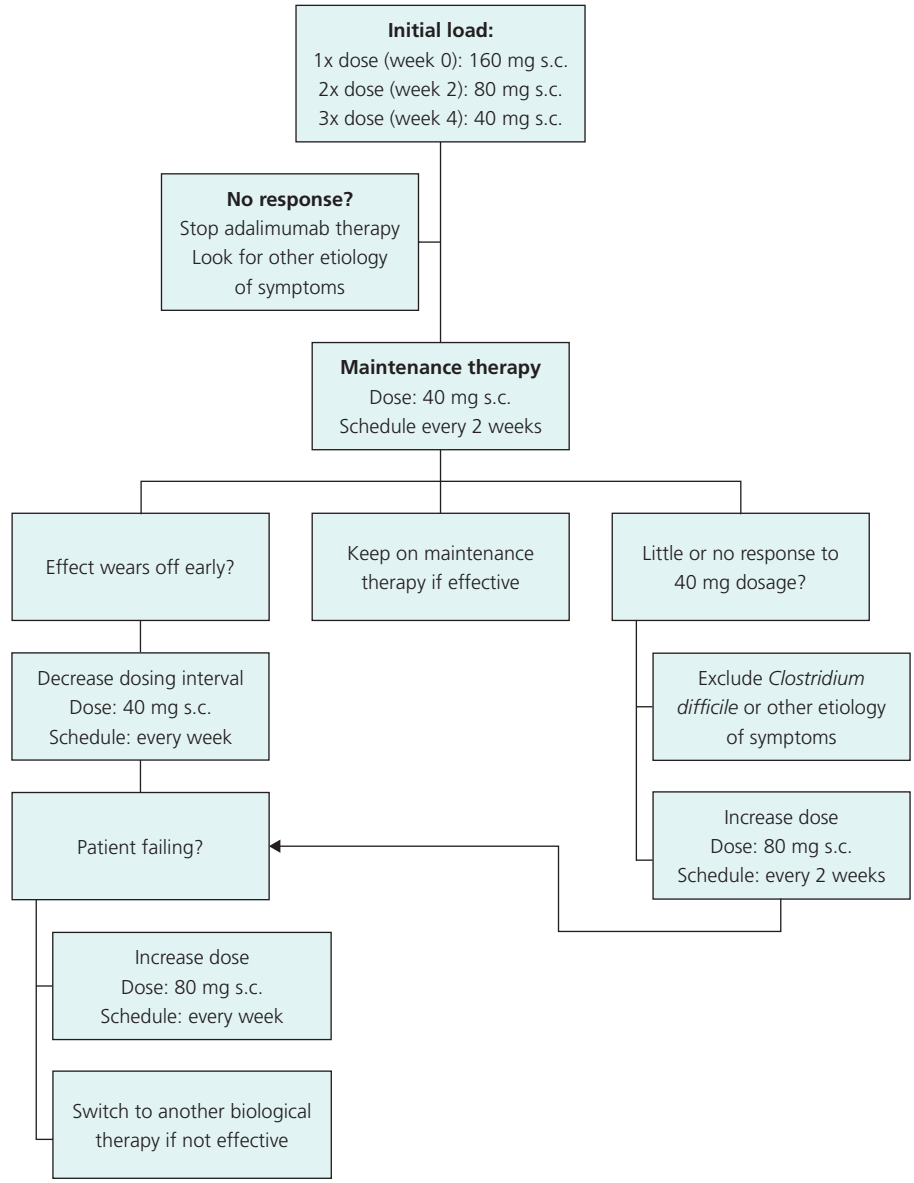

Figure 57.42 Dosing regimen for adalimumab in patients with Crohn's disease.

The second point to consider is the severity of the colitis, both clinically and endoscopically. The mesalamine-based therapies have their greatest success in patients with mildly active colitis, as well as some patients with moderately active disease (Table 57.1; Fig. 57.3). Corticosteroids are often held back in patients with mild disease, but play an important role in the sicker patient. Although the purine analogue immunomodulators do not work quickly, it may be reasonable to start these in patients who are likely to be beyond the first-line agents, to avoid longer than necessary illness or corticosteroid exposure. Earlier use of infliximab may also be appropriate, particularly if the patient is ill and is either refractory to, or has a contraindication to, corticosteroid therapy. In the case of patients with fulminant colitis, immediate surgical consultation is required and cyclosporine should be considered.

A patient's prior clinical course, previous response (good or bad) to therapies, and concomitant medical conditions are also factors that should be weighed when designing the safest, most efficacious therapeutic approach. Unfortunately, some of the medical and surgical decisions may be swayed by a patient's willingness or ability to commit to a medical or surgical treatment plan, and by the financial constraints that may exist in certain circumstances.

Whether one should treat the patient's symptoms alone, or include the endoscopic findings in determining long-term therapeutic decisions has been a hotly debated topic. The relevance of mucosal healing is implied, but not proven. Recent studies linking mucosal healing to better patient outcomes, fewer hospitalizations and surgeries, and possibly lower colorectal cancer rates may change these attitudes and guide therapy [220,660–663].

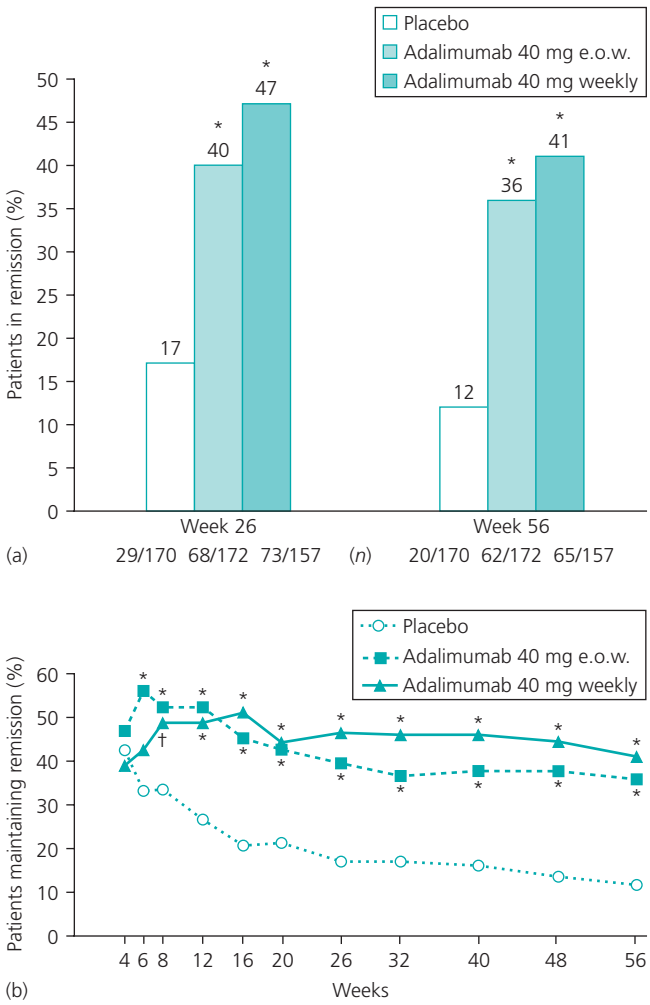

Figure 57.43 **(a)** Clinical remission rates in patients with moderate to severe Crohn's disease who responded to an initial open-label induction therapy with adalimumab 80 mg (week 0) and 40 mg (week 2) who were then randomized to either placebo, adalimumab 40 mg every other week (eow) or weekly. *$P < 0.001$ for pairwise comparison between each adalimumab treatment group and placebo e.o.w., every other week. **(b)** Clinical remission rates over time in each group. *$P = 0.001$ vs. placebo. †$P = 0.005$ vs. placebo. From Colombel et al. [647].

Patients with colitis who are not responding to therapy, or who develop new diarrhea (sometimes with blood) that differs from their usual disease presentation should be ruled out for *C. difficile* infection. Coinfection with this organism is endemic in colitis patients [664], and repeated checks may be necessary with any relapse in the treatment course. Other microorganisms should also be excluded, as well as other mitigating factors that might cause a colitis flare, or similar symptoms, such as NSAIDs, new diets, sorbitol, or new prescription medications or "alternative" therapies. Sicker patients should have full blood panels (complete blood and platelet counts, differential, C-reactive protein, comprehensive metabolic panel, coagulation factors, thyroid-stimulating hormone, cholesterol) and multiview abdominal radiographs to rule out megacolon or obstruction. It may be helpful to do a limited endoscopic examination into the rectum and sigmoid to document the severity of disease and exclude cytomegalovirus and other infections. Care should be taken to ensure a gentle examination, with limited insufflations, decompression of the bowel on withdrawal, and minimal (if any) narcotics.

The inflammation in patients with ulcerative colitis is limited to the mucosal, and sometimes submucosal, layers. While patients with long-standing colitis may develop a tubular, featureless colon, or one filled with inflammatory pseudopolyps, these patients should not be forming true stenotic strictures of the colon. The finding of strictures signals either that the patient likely has Crohn's colitis, or that they have developed a possible colonic neoplasm. In the absence of evidence of Crohn's disease, a strictured colon in ulcerative colitis should be considered a likely colon cancer until proven otherwise by surgical removal (colectomy, proctocolectomy) [665,666].

The use of narcotic pain relievers is controversial in patients with ulcerative colitis. Studies in toxic megacolon have implicated narcotic use as an inciting event [667], as well as other anticholinergics [668] and colonoscopy [108]. Therapy should be directed to decreasing inflammation, not covering up warnings of a more severe colitic process. Patients with active colitis who are having severe pain should undergo a CT scan to exclude fulminant colitis, abscess, vascular event, or Crohn's disease, as well as evaluation by a surgeon. Patients with pain severe enough to require narcotics require hospitalization and intensification of therapy, or surgery. There is no role for narcotics in the outpatient management of ulcerative colitis.

Patients with mild to moderate disease may benefit from the use of antispasmotics, antidiarrheals, and simethicone. While a low-residue diet is advised for patients with diarrhea and colitis, some patients find that fiber or cholestyramine provides more form to their stool. Patients with distal disease with constipation may benefit from fiber in their diets, non-fermentable fiber-based therapy, or polyethyleneglycol-based laxatives. A multivitamin with iron (if needed and tolerated), calcium supplementation, and avoidance of NSAIDs is recommended for all patients. A helpful website for all patients with IBD is the Crohn's and Colitis Foundation of America (www.ccfa.org), which provides useful information and links covering a wide range of topics of interest to health-care professionals, patients, their families, and caregivers.

Ulcerative proctitis

Patients with ulcerative proctitis have inflammation limited to the rectum; as a result, it makes good clinical sense to utilize topical therapies in the induction and maintenance of response and remission in these individuals, even if they are

also being treated with other agents. Mesalamine suppositories have been the mainstay of treatment in these patients [669], with efficacy and safety data superior to corticosteroid preparations [392]. Suppository dosing is typically nightly (twice or three times a day in more refractory patients) (Table 57.6). Once in remission, many patients can taper to alternate-day or twice-a-week dosing, although many stop therapy altogether. Subsequent relapse in symptoms often identifies those patients whom might benefit from maintenance dosing. Mesalamine foams, gels, and liquid enemas are also efficacious in patients with ulcerative proctitis. The choice of an agent may be based on patient tolerance or preference.

Topical corticosteroids are also effective in ulcerative proctitis, and sometimes less irritating than the mesalamine products. Systemic absorption (with subsequent corticosteroid side effects) is most pronounced for the liquid enema formulations. Adequate studies detailing the absorption of the various corticosteroid gels, foams, or suppositories have not been performed. Nevertheless, one might favor one of the newer corticosteroid formulations with fewer systemic side effects, such as budesonide, beclomethasone, or prednisone-metasulfobenzoate, although they are not available in many countries.

Although many patients, and perhaps physicians, prefer to use oral mesalamine agents as a first-line attempt for treating active ulcerative proctitis, they are not as effective as the topical agents [392]. Many clinical trials of ulcerative colitis therapies exclude patients who have only proctitis, and adequate comparative studies of oral agents in treating proctitis have not been published. The role of oral mesalamine agents in maintaining a remission that was achieved with a topical agent also has not been thoroughly investigated. Although on achieving remission with topical therapy (either alone or as a combination with oral therapy) many physicians switch patients to an oral mesalamine agent alone in an attempt to maintain remission, placebo-controlled trials have not been published that prove this to be an effective therapeutic approach.

Patients who have more severe or refractory proctitis are treated with a therapeutic approach that is similar to the one outlined below for patients with more extensive colitis, although one should keep patients on topical therapies (if effective) while pursuing other agents, as they help to decrease the tenesmus, urgency, mucus discharge, and blood loss that plague many of these patients.

Ulcerative proctosigmoiditis

There are not many trials that separate out patients with proctosigmoiditis for treatment, or separate out the results for this patient subpopulation. Many of the same principles that were discussed for proctitis can be applied to patients with proctosigmoiditis, with the topical therapies being the mainstay of the medical approach, either alone or in combination with oral agents. Since suppositories are not believed to adequately reach above the rectum, mesalamine enemas, foams, and gels are the preferred first-line agents. The enemas are typically given at bedtime (Table 57.6); patients should be encouraged to empty their bladder before instilling the liquid formulation, and lie with their left-side down for at least 20–30 min to let the enema have a chance to coat the sigmoid and left colon. The mesalamine enemas are retention enemas; that is, the intent is to retain them as long as possible (numerous hours, if not all night) before expelling. Some patients find it helpful to take an antidiarrheal (such as loperamide) or even a sleeping aid to assist in this endeavor. Foams and gels may be used multiple times a day; it is difficult for many patients to hold the liquid enema unless they are lying down. Combination therapy with a nighttime enema, and morning mesalamine suppository is helpful in some patients.

The corticosteroid-based enemas, foams, and gels are also useful in these patients, but because of systemic absorption, they are typically used in patients who are allergic to or intolerant of the mesalamine-based products. These steroid formulations may be easier for the sick colitis patient to hold; one approach is to induce a remission with the steroid-based products, and then transition to the mesalamine compounds. Further treatment approaches to patients with proctosigmoiditis are similar to those discussed below in the section on left-sided ulcerative colitis.

Left-sided ulcerative colitis

Seventy percent of patients with ulcerative colitis have their inflammation limited to the distal colon or rectum; as a result, most of the patients a physician will treat will benefit from the therapies discussed here and in the previous two sections [101,102,107]. Once again, topical mesalamine agents are the most efficacious, quickest, and, unfortunately, most often over-looked therapies for these patients (Table 57.6). Mesalamine enemas are superior to oral mesalamine, as well as to corticosteroid enemas [392]. Combination therapy with oral mesalamine is superior to oral mesalamine alone in the induction and maintenance of treatment response or remission [397,403]. Often the patients are weaned off the topical therapy once they are are well, but some patients will require maintenance enema therapy. Dosing mesalamine enemas every second or third night is also an effective maintenance strategy.

Corticosteroid enemas are also highly effective in patients with left-sided ulcerative colitis, but because of systemic absorption, estimated at 40%–80%, they are suitable only for short-term use [451]. They are particularly useful in patients with active colitis who cannot hold the mesalamine enemas, although transition back to the mesalamine compound should be attempted once the patient is well. Corticosteroid enemas should be tapered off when used; abrupt cessation is not recommended in patients who have been on long-standing therapy because Addisonian crisis may result.

Oral mesalamine agents are typically used in patients with left-sided ulcerative colitis, either as sole-therapy or in combination with a topical agent. Sulfasalazine and all of the mesalamine-based therapies (mesalamine, balsalazide, olsalazine) are effective in the treatment of left-sided ulcerative colitis. Further differentiation between the agents, and treatment of refractory colitis, will be discussed in the next section on the treatment of pancolitis.

Pancolitis

Roughly 30% of patients with ulcerative colitis have inflammation extending proximal to the splenic flexure [101,102,107]. Although all of them might not have truly "pan-" ulcerative colitis, patients with extensive colitis and pancolitis have the same treatment protocols. These are the patients most likely to undergo surgery, and who are at a higher risk for colorectal cancer; new data suggest that this risk may be decreased with medical therapies that decrease inflammation, particularly mesalamine.

Mild disease

First-line therapy for patients with pancolitis are oral mesalamine agents; combined therapy with topical agents is often helpful. Although inexpensive, many practitioners have shied away from using sulfasalazine because of high rates of patient allergy or intolerance. All of the mesalamine-based therapies are effective in the treatment of acute colitis, and are used for maintenance therapy. There are high-relapse rates in patients that stop therapy so long-term maintenance therapy should be the rule when treating these patients.

The mesalamine agents are typically categorized by their release mechanism (Table 57.6, Fig. 57.32), as detailed earlier in this chapter. Head-to-head blinded randomized studies with equimolar doses of azo-bond release balsalazide and pH-release mesalamine have shown superior remission rates, earlier time to complete absence of symptoms, as well as other outcomes favoring balsalazide in some, but not all, studies [670–672]. Whether this benefit extends to other azo-bond release agents has not been firmly established [381,673]. Patients with an inadequate response to a "standard" daily dose of mesalamine-equivalents (2–3 g) are often subjected to a dose escalation to 4.0–4.8 g. Adequate clinical trials subjecting such patients to a higher dose have not been published; in fact, there are few data supporting a role of oral mesalamine in daily doses higher than 2.4 g; some trials have shown that sicker patients (i.e., those with moderately severe colitis) may have better improvement rates (but not remission rates) and endoscopic outcomes at a dose of 4.8 g [393,394,674]. Some patients who are not responding (or possibly worsening) with one mesalamine-based therapy may have success with another agent. Others are either intolerant, or their disease is too advanced, for these agents to work.

Moderate disease

Some patients will have success with high-dose oral mesalamine, or combination therapy with oral and topical mesalamine agents. Corticosteroid enemas are also helpful in patients who cannot hold, or who are intolerant to, mesalamine enemas. Those for whom this therapy fails are acutely treated with corticosteroids. Prednisone 40 mg daily (or equivalent) is a typical starting dose; some patients who do not respond may require 60 mg, although the side effects are much higher at this level. The goal of corticosteroid therapy is to induce remission, and then slowly taper therapy while maintaining patients on their oral or topical mesalamine, or the purine analogues (6-mercaptopurine or azathioprine). Patients who repeatedly relapse on corticosteroid taper will need initiation or optimization of their purine analogue therapy, or infliximab should be started (Figs 57.37, 57.38). Patients who are not adequately responding to high-dose oral corticosteroids should be considered for treatment with infliximab or hospitalization for intravenous corticosteroids (see below). Oral tacrolimus or cyclosporine is another option, but can only be used with strict monitoring, and with the intent of maintaining the patients on safer therapies.

Severe disease

Patients with severe ulcerative colitis need immediate evaluation and treatment to avoid progression to a fulminant or toxic state. Full assessment of laboratory parameters, serial abdominal films to exlude megacolon, and CT scan if pain is a dominant factor should be performed. Hospitalization, aggressive repletion of fluid and electrolyte losses, and stool cultures to exclude pathogens and *C. difficile* should be performed (and repeated if symptoms or laboratory parameters worsen). While many of these patients may have normal white blood cell counts, worsening left-shift towards band forms is an indication for reevaluation (examination, abdominal radiograph, stool examination for *C. difficile*). Intravenous corticosteroids in divided doses or continuous infusion (methylprednisolone 40–60 mg; hydrocortisone 200–300 mg) should be started after an initial bolus dose. Oral mesalamine agents are typically held; topical therapy with hydrocortisone enemas is encouraged if helpful. Surgical consultation is recommended, as well as nutritional assessment.

Patients who have initial signs of colonic dilation, but are otherwise not toxic (i.e., febrile, hypotensive) need to have serial abdominal films, correction of fluid and electrolytes, and may benefit from "rolling" from decubitus positions to the prone position, to decompress the colon [675]. Surgical consultation is necessary; any worsening should lead to urgent colectomy. Cyclosporine has been used successfully in some cases.

Although initially patients are kept nil-by-mouth, those who are improving and able to eat without a worsening of symptoms are encouraged to take a low-residue diet, often

after an initial trial of clear liquids. Parenteral nutrition is recommended for patients who are nutritionally depleted, but line-related thromboses are common and precautions must be taken. All hospitalized IBD patients should receive higher-dose prophylaxis with heparin 5000 IU delivered three-times daily, or enoxaprin 40 mg subcutaneously daily.

Patients who do show any response to corticosteroids within 3 days have a poorer prognosis for avoiding surgery [676]. Reassessment of clinical status with radiographs, stool studies excluding *C. difficile*, and gentle unprepped sigmoidoscope without insufflation into the rectum and rectosigmoid to exclude infections such as cytomegalovirus (biopsies taken of ulcers) is recommended.

Reconsultation with surgery, and consideration of the addition of infliximab (Fig. 57.38) or intravenous cyclosporine (Fig. 57.37) should be given. Before infliximab, exposure to tubercuolosis should be excluded by careful patient history, purified protein derivative placement, QuantiFERON test (in patients who have already had bacillus Calmette–Guérin), or chest radiograph. Before cyclosporine use, serum cholesterol must be checked, with a dosage decrease to 1 mg/kg for levels around 100 mg/dL, and avoidance of the drug for levels below 100 mg/dL. Long-term results with cyclosporine have been disappointing in patients already established on adequate doses of the purine analogues [677]; the drug should not be used in patients with renal disease, neurological disorders, hypertension, or who are noncompliant with therapy [587]. Patients with severe colitis should have near complete, if not complete, resolution of signs and symptoms of severe disease before discontinuation of intravenous therapy. Careful monitoring as outpatients is mandatory because relapse is not uncommon. Surgical intervention should not be withheld in the hope of an unlikely "miraculous" cure.

Fulminant colitis and toxic megacolon

Dilation of the colon on radiograph (Fig. 57.44) with signs of systemic compromise (fever, tachycardia, hypotension) is a surgical emergency; patients should be rescuscitated and taken for an emergency total abdominal colectomy with ileostomy and Hartman's pouch. Often intravenous broad-spectrum antibiotics are given, as well as blood products and other supportive therapies. Subsequent surgeries for completion proctectomy and creation of an ileoanal pouch anastomosis (if desired) can be performed months later after full rehabilitation of the patients. Narcotics, anticholinergics, and colonoscopies are contraindicated. Rolling the patient from side-to-side and onto their stomach has been described as a technique to decompress the dilated colon [675].

Maintenance of remission

The agent used to induce remission is often the one to initially try to maintain remission, with the exception of corticosteroid-containing therapies. In those instances, the appropriate maintenance therapy is started, while the patient is weaned off corticosteroids. The rate of weaning is dependent on the duration and dose of therapy, experience with previous attempts at weaning, extraintestinal manifestations (especially joint pains) patient's age, and speed at which the maintenance therapy is expected to work. For example, if the intent is to maintain a corticosteroid-induced remission with a slow-acting agent such as azathioprine or 6-mercaptopurine, a more gradual taper will be used compared with the patient who is started on infliximab and may experience benefit within days. Some extraintestinal conditions such as erythema nodosum may suddenly appear with a quick corticosteroid taper. Caution should also be exercised in patients with asthma, who were deriving pulmonary benefit from

the steroid therapies. Corticosteroid enemas should also be tapered, rather than stopped abruptly, if the patient has been using them for more than a few weeks.

Maintenance with oral mesalamine-based therapies should initially be at the same dose used to induce remission. Some patients may be able to subsequently decrease the dose to roughly one-half to two-thirds of the induction dose; relapse may occur, and patients who initially failed those lower doses, or who were difficult to induce into remission should be advised to stay at or near their induction doses. Rectum-based mesalamine therapies should be continued if needed, although many patients fare well with dosing every second or third night. Abrupt cessation is not recommended because of "rebound" relapse, which has been noted by physicians experienced in the use of these products. Combination therapy with oral and topical mesalamine is superior to maintenance therapy with oral agents alone, at least in patients with distal colitis [403].

The recommended maintenance dosing with the purine analogues is the same as the final induction dose, adjusted for any safety-related matters. Routine dose reduction is not recommended in patients with normal blood counts and liver chemistries, in the absence of other side effects. Prescribers need to be aware that purine-analogue-related cytopenias and blood dyscrasias have been reported years after initiation of therapy; as a result, patients need blood tests and office examinations every few months, even on stable-dose therapy.

Infliximab should be given as a maintenance infusion every 8 weeks (earlier if necessary) at the same dosage necessary for induction of remission [625] (Fig. 57.38). Some patients require dose escalation to 10 mg/kg; if this was performed because of a loss of response and the formation of antibodies then it is recommended that subsequent maintenance doses stay at this higher level. There are anecdotal experiences of successful dose reduction back to the 5-mg level in some patients who had experienced a flare-up of symptoms during standard therapy and regained remission in the absence of neutralizing antibodies.

Complications of ulcerative colitis

General

Patients who are acutely ill with colitis must be adequately monitored for dehydration, electrolyte abnormalities, anemia, and the related physiological processes that can result from these conditions, such as renal insufficiency, kidney stones, cardiac arythmias, ischemic events, and others. Rapid identification and replacement of fluids, electrolytes, and blood products is essential. Chronically ill patients may suffer from similar consequences, as well as nutritional deficiencies, acquired coagulopathy defects, bone mineralization deficiencies, and hair and skin changes. Additional complications are discussed in the section on Crohn's disease.

Toxic megacolon

One of the most feared complications of severe colitis is the development of a toxic megacolon. In this situation, the colonic lumen dilates to a diameter of 6 cm or more, there is evidence of toxicity (dehydration, hypotension, mental status change, or electrolyte abnormalities) and the patient has at least three of the following:

- fever above 38.6°C
- tachycardia above 120 beats per minute
- leukocytosis above 10 500 cells/mm^3, or
- anemia [108,678,679].

Physical examination often reveals a distended, tympanitic, diffusely tender abdomen, with minimal or absent bowel sounds. Radiographic evidence of the dilation may be pancolonic or limited to segments (Fig. 57.44). The transverse colon is traditionally involved, perhaps because of the distribution of the bowel gas when in the supine position. In fact, rolling the patient into the right-lateral decubitus and subsequently prone position has been shown to temporarily "deflate" the distended colon [675].

Conditions that may initiate or exacerbate a toxic megacolon include the use of narcotic or anticholinergic drugs, electrolyte abnormalities, discontinuation of corticosteroids, barium enema, or colonoscopy [108]. These patients needs aggressive repletion of fluids and electrolytes, blood products, discontinuation of any inciting medications, and complete bowel rest. Gastrointestinal pathogens, especially *C. difficile*, should be excluded. Decompression is recommended by both nasogastric and rectal tube, as well as by repositioning the patient as detailed above. Intravenous corticosteroids and broad-spectrum antibiotics should be initiated and there should be a surgical consultation for urgent colectomy. Serial abdominal radiographs (every 6–12 h) should be performed; signs of progressive dilation or toxicity require surgery. Patients should not undergo colonoscopic examination, or have barium (or air) instilled rectally. Patients who are not initially taken to surgery should undergo colectomy if they do not improve within 24–48 h [680]. Mortality rates as a result of perforation fall from 44% to only 2% with appropriately timed surgery [681].

Patients with colonic dilation but without signs of true toxicity can be managed as above; worsening of their intestinal or physiological parameters are indications for surgery. Cyclosporin has been used successfully in select cases.

Perforation

Colonic perforation in severe colitis can occur in the absence of a megacolon [682]. Free perforations are often of abrupt onset, with evidence of peritoneal signs, fever, and subsequent decompensation. Perforations may be seen in patients with new onset colitis that follows a fulminant course, as well as in patients with chronic colitis, where suspicion for a colonic neoplasm is heightened [683].

Subacute perforations, often sealed off at the serosal surface by a forming phlegmon or abscess, are more commonly seen in Crohn's disease or in associated with diverticular disease, but may also occur in patients with ulcerative colitis. Prompt rescucitation of the patient, plain film radiographs (and often CT scan), and surgical evaluation are required. Broad-spectrum intravenous antibiotics are advised, as are repletion of other fluids, electrolytes, and blood products. In the instance of a sealed off abscess cavity, radiographic drainage of the abscess cavity may allow for improved surgical outcomes. Colonoscopy is contraindicated in patients with a presumed perforation or diverticulitis; single-column gastrograffin enema evaluation may be helpful in selected cases, after consultation with the radiologist. The vast majority of these patients will require surgery so additional testing should only be conducted if it were to reasonably change treatment course of action.

Stress-dose corticosteroids should be given to patients who are already on these agents, or at risk for adrenal insufficiency because of recent corticosteroid use. Patients who are not on corticosteroids should not start them, unless there is a need for decreasing inflammation in a patient with a sealed off perforation who is not a surgical candidate at the time.

Colonic stricture

Often considered a finding more consistent with Crohn's colitis, colonic narrowing or strictures have been reported in up to 12% of surgical specimens [684]. Since ulcerative colitis by definition is a disease only affecting the mucosal or submucosal linings, true strictures should raise suspicion for colonic neoplasm, Crohn's disease, or, in selected patients, diverticular or ischemic disease. Patients often have longstanding colitis that has been characterized by either continuous or repeated episodes of active colonic inflammation. Symptoms suggestive of a possible stricture may include focal pain, unpredictable diarrhea, and, in the case of rectal strictures, fecal incontinence. Ironically, some patients may enjoy an initial period of improvement in previously difficult to control diarrhea.

Medical management of Crohn's disease

Most of the recommendations in the preceding section on Medical management of ulcerative colitis are carried over to patients with Crohn's disease, especially Crohn's colitis. It is recommended that the reader refer first to the previous section, and then refer back here for special circumstances that are more unique for patients with Crohn's disease.

The location of disease in the patient with Crohn's disease, and the severity of disease in each area, helps to guide therapeutic management. Distribution of Crohn's disease is typically broken down into lumenal and fistulous disease. Lumenal disease categories are upper gastrointestinal (esophageal, stomach, duodenum), small bowel, ileocolonic, colonic, and perianal. The perianal designation implies penetrating (fistulous, abscess) disease, but fistulae can occur in other locations as well. There are rare patients with oral Crohn's disease, as well as very rare "metastatic" Crohn's disease, with an autoimmune inflammatory disease lesion appearing in a location discontiguous with the bowel (usually the skin). Many of these less common entities have not been adequately studied; the literature, if any, consists of single or a few case reports that detail the particular clinical course and response to therapy.

Lumenal disease is often classified as "inflammatory", "stricturing", or "penetrating" [172,173]. Epidemiological studies suggest that there may be a gradual transition from an inflammatory to stricturing to a penetrating state, with surgery required eventually. Crohn's disease recurs postoperatively in most settings so the patients may start the cycle again. Defining the phenotype of disease may guide therapeutic choices; those patients with more advanced disease are the ones in whom systemically acting immunomodulators may be started earlier, even as first-line treatment. Patients with penetrating disease may benefit from cotherapy with an antibiotic, at least for antiinfective if not antiinflammatory benefits. Surgical therapy is turned to sooner in patients who already have obstructive strictures or penetrating disease that is unlikely to respond to medical therapies.

Patients with stricturing Crohn's disease often need to avoid dietary intake of materials that are poorly digested by humans, which might create an obstruction at the stricture point, depending on the lumenal diameter. Foods that should be discouraged include raw fruits, vegetables, salads, and whole grains. It is wise to entirely avoid nuts, seeds, corn, popcorn, and similar products. Attempts at endoscopic dilation or stenting of strictures pose a substantial risk for bowel perforation [685–687]. Endoscopically directed injection of corticosteroids into the strictures rarely provides long-term relief [688,689]; infliximab injections have also been reported to have short-term success [690].

Mechanisms of diarrhea in patients with Crohn's disease can be multifold and complex. Small bowel disease (and resection) can lead to reduced absorptive surface, as well as secretion or weeping of fluid. Roughly 2.54 m (100 inches) of healthy small bowel is needed to avoid "short-bowel syndrome" and the potential need for parenteral nutrition, hydration, or electrolyte repletion. A diseased or removed terminal ileum results in disruption of the enterohepatic recirculation of bile salts and can result in a coloretic diarrhea, fat malabsorption, and vitamin deficiencies. The diarrhea that results is often alleviated by bile-acid-binding resins, such as cholestyramine, colestipol, or colesevelam. The latter two are available in pill form, given as one or more

pills before meals, and are better tolerated by patients. These agents should not be used in patients with a short bowel because they can exacerbate fat-soluble vitamin deficiency. Patients may develop oxalate kidney stones, and need oral calcium therapy to bind the oxalate in the lumen. Another mechanism of diarrhea is "dumping" from the loss of the "ileal brake" following ileocolecomy. Patients with Crohn's colitis can suffer from diarrhea as the result of a diseased large bowel, and the condition can be exacerbated by perianal disease that limits fecal continence. Antidiarrheals (loperamide, diphenoxylate, and even tincture of opium) are often required in patients with Crohn's disease who have diarrhea. Infection with *C. difficile* should be excluded in patients with diarrhea that is unexplained, relapsing, or refractory to treatment.

Mild to moderate Crohn's disease

First-line therapies in patients with mild Crohn's disease consist of the mesalamine agents and antibiotics. There is a running debate on the overall efficacy of mesalamine in Crohn's disease [413,691,692]; however, removed from the limitation of clinical trials, there are some patients who benefit from therapy. The guidelines are the same as laid out in the previous section on Medical management of ulcerative colitis, although many practitioners use a higher dosage in the patients with Crohn's disease (3–4 g daily) (Table 57.6, Fig. 57.32). For patients with small bowel Crohn's disease, moisture-released mesalamine (Pentasa) is the preferred choice [693,694], because it is not dependent on a pH-based system, and the azo-bond agents are thought to be released almost exclusively in the colon. Maintenance therapy with the same agent (and dose) that induced remission is advised. Patients with distal disease may benefit from mesalamine enemas and suppositories.

The data supporting the use of antibiotics in lumenal Crohn's disease is sparse; clinical trials that have found an effect have been more convincing in patients who have solely colitis, or ileocolitis. Recommended doses are ciprofloxacin 1000 mg or metronidazole 10 mg/kg to 20 mg/kg daily. Long-term use of metronidazole is discouraged because of the risk of neuropathy, sometimes permanent, which mandates cessation of the drug therapy. High-dose rifaximin (1600 mg daily) is effective in some patients as well, without evident toxicity [445]. Maintenance therapy has not been studied; nevertheless, in the absence of other effective therapies, it is reasonable to continue patients on the antibiotics long-term (other than metronidazole); an appreciable rate of emergence of resistant organisms has not been widely reported.

Patients with Crohn's disease affecting the small bowel or right colon in whom the first-line therapies are ineffective, or who have more moderately active disease, can be successfully treated with budesonide-CIR 9 mg once daily for 8–12 weeks [486,695], with a taper by 3 mg every few weeks at the latter part of the treatment course. Maintenance therapy with 6 mg (but not 3 mg) has been proven for 3–6 months, but not longer [696,697]. For those patients who fail on 9 mg budesonide, or who require more than 9 mg equivalent doses of budesonide, treatment with conventional steroids can be used. Although budesonide has far fewer corticosteroid-related side effects than traditional steroids, long-term use can lead to suppression of the pituitary–adrenal axis, and steroid-related effects can be seen. As a result, maintenance therapy should be attempted with one of the other first-line therapies discussed above, or with long-term immunomodulators.

Azathioprine and 6-mercaptopurine can be used to induce remission in Crohn's disease, although the clinical studies typically used a corticosteroid induction regimen, and then a maintenance dosing strategy with the purine analogues [540,557]. Another option in Crohn's disease is injectable methotrexate for the induction or maintenance of remission. Methotrexate is administered at 25 mg intramuscularly or subcutaneously once weekly, with oral folic acid (1 mg daily) supplementation [571]. Dose reduction is necessary if side effects occur. Maintenance doing in the clinical trials was 15 mg [580] but other clinical results maintained the patients at their highest tolerated dose [570]. Oral dosing has not been shown to be effective in Crohn's disease.

Moderate to severe disease

Patients with moderately severe, or severe, Crohn's disease can be given budesonide 9 mg (if they have small bowel or right colon disease), prednisone (or its equivalent) 40–60 mg orally four times a day, infliximab (Fig. 57.38) or adalimumab (Fig. 57.42). The last two agents mentioned are typically used only in patients who are relapsing while still on corticosteroids, who have had repeated corticosteroid courses or relapses despite the appropriate use of azathioprine, 6-mercaptopurirne, or methotrexate, or who have a contraindication to receiving corticosteroids. Patients not responding to oral prednisone are hospitalized for intravenous corticosteroids (40–60 mg intravenous methylprednisolone or equivalent) or initiated on anti-TNF therapy. Short-term use of the calcineurin inhibitors tacrolimus or cyclosporine may be appropriate in individual cases, but not as long-term maintenance. The other drugs are used as maintenance therapies, with the exception of corticosteroids.

Hospitalized patients with severe Crohn's disease

Many of the same warnings and recommendations for this patient population appear in the previous sections on severe and fulminant ulcerative colitis, as detailed above. Intravenous cyclosporine is rarely given for Crohn's disease; use of infliximab or adalimumab has supplanted that drug's role. Complete bowel rest with TPN supplementation is necessary in patients with refractory pain, diarrhea, or abscesses; extended therapy may be necessary in some patients. Ruling out infection with *C. difficile*, cytomegalovirus, or other

opportunistic organisms is necessary. Many patients are hospitalized for obstructive Crohn's disease; failure to respond to conservative medical management results in surgery. CT scans are helpful in excluding inflammatory phlegmonous masses, abscesses, and fistulae; abscess cavities may be drained under radiographic guidance, but many of the patients will subsequently require surgical resection. Patients who have suspected abscesses or other infectious processes should not be treated with anti-TNF therapies, or other potent immumosuppressants. Small bowel series, CT enterography (Fig. 57.19), or MRI enterography (Fig. 57.20) may be helpful in locating the level of a bowel obstruction, and determining whether it is related to disease, infiltrative processes, or simply adhesions from a previous surgery. Capsule endoscopy is discouraged in patients with Crohn's disease who have not had a small bowel radiographic test to exclude strictures; however, there are patients whose strictures are missed on the examinations, so precapsule testing with the "patency capsule" is advised.

Fistulous Crohn's disease

Crohn's fistulae affect an estimated 30% of patients; most commonly they are in or near the perianal area (including the perineum, vagina, and scrotum), although fistulae to the abdominal wall (often following an abdominal surgery, or tracking along a previous scar or drain site), and internal fistulae to surrounding organs can be seen. The fistulae that affect the perianal area often originate from the dentate line, and repeated abscesses and surgeries can lead to compromise of the anal sphincters and fecal incontinence.

Management of perianal disease (fistulae, abscesses, inflammatory skin tags) often involves a combined medical and surgical approach. Suspicion of an abscess should lead to prompt initiation of antibiotics (typically ciprofloxacin 1 g and metronidazole 10–15 mg/kg, or equivalent) surgical evaluation, and in some cases, pelvic CT scan (for abscesses) or MRI (for fistulae). It is important to instruct the radiology staff to extend the scanning to the mid-thighs, to ensure that the perineum is fully visualized. Soaking the area multiple times a day (sitz baths) in very warm water may promote drainage. The finding of an abscess cavity on digital rectal examination, fever, or other signs of systemic illness should prompt a surgical examination and drainage. Marsupialization of the abscess cavity may occur; in other instances, the drainage tracts from the abscess cavity are intentionally kept open with a seton or purse-string to allow drainage while the tract closes. Unfortunately, many fistulous tracts close only intermittently or recur, so effective medical therapy is also necessary.

If antibiotic therapies alone are not sufficient, then initiation of azathioprine, 6-mercaptopurine, or perhaps methotrexate should follow, although the literature supporting these therapies is sparse. For patients already on these agents, or in whom it is not desirable to wait for the slow (if any) response, infliximab has emerged as a highly effective therapy (Fig. 57.41). After the initial loading dose of 5 mg/kg at weeks 0, 2, and 6, maintenance therapy with infusions every 8 weeks is recommended. Failure to continue infliximab often leads to reopening of the fistulae. Continuing antibiotic therapy until the fistula is closed and not tender is advisable to potentially decrease the risk of abscess. Adalimumab has also been shown to be effective in some patients with Crohn's fistulae, although formalized fistula trials have not yet been published. Tacrolimus and cyclosporine are also effective in closing fistulae, but neither is safe, nor effective, as maintenance therapy.

Postoperative recurrence prophylaxis

Crohn's disease recurs after most bowel resections with reanastomosis at rates approaching 50%–75% in 10 years [247,698–700]. Numerous therapies have been studied in an attempt to decrease the incidence of disease relapse. The data with mesalamine have been mixed [701–704]; a metaanalysis suggested that 2.4–3 g mesalamine decreases the risk of relapse by 13% [413] – the evidence was strongest in patients with ileal disease. Controlled trials with either metronidazole (20 mg/kg/day) [437] or ornidazole (1 g/day) [438] showed efficacy in decreasing endoscopic and clinical relapses, although the benefit faded on discontinuation of the antibiotic therapy. Neither budesonide (6 mg/day) [704] nor Lactobacillis GG proved effective in preventing relapse. Low-dose 6-mercaptopurine (50 mg daily) was superior to placebo in preventing clinical and endoscopic relapse [562], and azathioprine (2.5 mg/kg) almost halved the surgical relapse rate compared with 3 g mesalamine [705]. Infliximab is anticipated to effectively decrease relapse rates, although data on the drug's efficacy has yet to be published.

At the current time, it is reasonable to assess the risk relapse, the impact of relapse, and the options feasible for each individual when deciding on a postoperative strategy. Patients deemed at lower risk for early relapse (nonsmokers and those with nonpenetrating disease, first surgery, or long-duration of disease before surgery) might be offered no therapy, mesalamine (2.4 g or higher daily), or antibiotics. One treatment approach is to perform a colonoscopy at 6–12 months following surgery [245]; signs of more aggressive disease, such as more than five aphthous lesions or an already ulcerated anastomosis (Rutgeerts' Grade II) [244], would suggest that a more aggressive approach was necessary.

Those at higher risk, who have already had previous surgeries, have failed the first-line therapies, have lost substantial amounts of bowel, and who might not be able to weather another recurrence, let alone a resection, should be treated with azathioprine or 6-mercaptopurine. If they were already on these agents immediately after their previous surgery, at an adequate dose, and nevertheless developed new disease, then escalation to an anti-TNF therapy is reasonable. Patients who "failed" on anti-TNF (but had an initial

prolonged response) should be checked for neutralizing antibodies; if present, an alternative anti-TNF agent should be used.

Complications of Crohn's disease

General

Patients with Crohn's disease who suffer from diarrhea or vomiting require repletion of fluids and electrolytes. Those with anemia, either from blood loss or from iron-deficiency, may require transfusion of blood products. Patients with small bowel Crohn's disease with malabsorption often need correction of deficiencies of iron, folate, vitamin B-12, zinc, the fat-soluble vitamins (A, D, E, and K), as well as other trace minerals and vitamins (by supplementation with a multivitamin formulation).

Patients with small bowel malabsorption of fat are at higher risk of developing kidney stones comprised partially of oxalate; dehydration can also lead to other kidney stone compositions. Gallstones are more common in patients with Crohn's disease, and certain medications may cause pancreatitis or hepatitis.

There are numerous systemic events that are seen more commonly in patients with acutely or chronically active Crohn's disease or ulcerative colitis. They may develop a hypercoagulable state, which may lead to venous thromboses and related complications. Pericardial and pleural effusions have been linked to the disease state or medications, and patients with severe metabolic disorders may develop cardiac arrhythmias or tetany. Bone diseases such as osteoporosis, osteomalacia, osteonecrosis, and avascular necrosis must be monitored. Psychiatric disorders are also prevalent in this population, although often as a result of, rather than as a cause of, the physical disease states. A myriad of extraintestinal complications are covered elsewhere in this chapter.

Abscesses and fistulae

Crohn's disease that penetrates through the bowel lining can result in the formation of a sealed off cavity containing succus, stool, or pus (an abscess) or extension of the inflammatory process to the surrounding viscera or through the skin's surface (a fistula). Roughly one-third of patients with Crohn's disease are estimated to suffer from these penetrative complications. Abscesses and fistulae that result from anorectal Crohn's disease are diagnoses, are treated differently, and will be discussed separately.

Abscesses

Abscesses have been reported in up to 20% of patients with Crohn's disease [706]. Intraabdominal abscesses are located adjacent to the inflamed bowel, most typically the terminal ileum. Suspicion for an abscess to the ileopsoas area can be detected on physical examination by flexion of the right hip (psoas sign), or localized severe abdominal pain [707]. While patients with abscesses classically have pain, fever, chills, or rigors, these findings may be absent or masked in patients on immunosuppressants or narcotics. While one would expect that a perforation through the intestinal wall would result in obvious peritonitis, the chronic nature of Crohn's may result in an inflammatory phlegmon or a sealed off abscess, with minimal symptoms other than an abdominal mass.

Laboratory findings in patients with abscesses may include leukocytosis, acidosis, mild elevations of aminotransferases, and often greatly elevated erythrocyte sedimentation rates or C-reactive protein levels. Diagnosis is confirmed by an abdominal–pelvic CT scan with oral and intravenous contrast; in some cases, abdominal or transvaginal ultrasound, MRI, or radionucleotide scanning may suggest an abscess [708–710].

Drainage of an abscess cavity under CT or ultrasound guidance is often the first step in reducing the immediate pain and infection; surgical resection of the defective bowel area is ultimately required (and advised) in most cases to avoid recurrence and further complications. The infectious agents are often polymicrobial; broad-spectrum intravenous antibiotics (including coverage for anaerobes) should be started immediately and continued until definitive surgery is performed. Blood cultures should be checked, and antibiotic treatment should be tailored to the results of the culture from the blood or abscess cavity. Corticosteroid use is initially discouraged in the setting of acute abscess and infection until after drainage and once sepsis has been excluded, although stress doses may be needed for those on chronic corticosteroid therapy. Patients with an inflammatory phelgmon, evidence of surrounding bowel inflammation, and with a drained abscess often benefit from the addition of corticosteroids to their regimen. Allowing time for the abscess cavity to be drained, and for the intravenous antibiotics (and in some cases corticosteroids) to decrease the associated infection and inflammation may help the surgeon limit the resection to only the diseased portion of bowel, and enable a primary anastomosis with a primary closure of the abdominal incision, without the need for a temporary diverting ostomy. Keeping the patient absolutely nil by mouth with TPN support may be beneficial. Anti-TNF therapies or other potent immunosuppressants should not be used (or continued) until the abscess area is resected.

Fistulae

Fistulae have been reported in 20%–40% of patients with Crohn's disease [706]. Often associated with a strictured area of diseased bowel, fistulae can originate in any portion of the bowel affected by Crohn's disease. Their destination can be a nearby organ, the skin, or a convoluted course to seemingly nowhere, ending in an inflammatory collection. Depending on their location, they may be asymptomatic (as is the case with many enteroenteric fistulae), or result in physical findings specific for the location. For example, patients with gastrocolic or enterosigmoid fistulae often have profound diarrhea.

Enterovesicular or colovesicular fistulae may be characterized by pneumaturia or fecaluria. Those existing cutaneously present initially with painful swelling at the skin site, followed by breakthrough and subsequent drainage.

Diagnostic studies for internal fistulae are also specific for their location. Enteroenteric fistulae may be shown on small bowel series or enterography, colic fistulae with barium enema, and vesicular fistulae by cystography. Fistula entrance or exit sites may be seen endoscopically or with cystoscopy. The course of cutaneous fistulae may be determined by cannulation of the fistula exit point at the skin and instillation of contrast material to locate the source in the bowel. Patients with multiple fistulae often have just a single originating defect in the affected bowel that drains to a sealed of inflammatory "pool" from which multiple fistulae may branch out.

Therapies that are effective in the treatment of fistulous Crohn's disease are discussed in the preceding section on medical therapy. Enterocutaneous fistulae are often responsive to these therapies. There are no controlled trials of medical therapies for the treatment of internal fistulae. Asymptomatic enteroenteric fistulae do not necessarily require a change in medical management, although their associated bowel inflammation may require more effective therapies. Fistulae that threaten other body organs or systems, such as enterovesicular fistulae that lead to repeated infections or pyelonephritis, should be managed surgically. In many cases, the fistulae arise just proximal to or within an area of severely diseased or strictured bowel that will ultimately require resection. Complete bowel rest with TPN repletion may be required in patients with complicated fistulous disease that is not amenable to medical or surgical therapy.

Postoperative fistulae are often a confusing issue in patients with Crohn's disease. Often assumed to be the result of active Crohn's disease, fistulae that arise from a recent surgical anastomosis are more likely to be the result of a leak at the sight, rather than de novo Crohn's disease. Anastomotic leaks may be more common in patients on corticosteroids, in those with poor nutritional status, or in patients whose connected bowel loops contain active disease. Surgical exploration and revision of the defective anastomosis is often required. Crohn's disease typically recurs in the area of previous resection so patients who had an uncomplicated postoperative course yet subsequently present with anastomotic fistulae after 6 or more months should be evaluated for recurrent disease as the etiology.

Anorectal abscesses and fistulae

The diagnosis and treatment of Crohn's disease of the anorectal area often involves a multidisciplinary approach between the gastroenterologist, surgeon, and radiologist. The fistulae typically originate in the anorectal glands at the dentate line, and can drain into a blind cavity (forming an abscess), or the nearby skin, genitals, or urinary system (Fig. 57.45). Multiple fistula tracts are not uncommon; they often originate from one or two initial sources. Dedicated CT, MRI, endoscopic ultrasound, and dynamic proctography may each be helpful investigations. The course of cutaneous fistulae may be shown by injection of contrast material directly into the exiting orifice. Fistulae to the vagina may be heralded by vaginal pain, bacterial vaginosis, passage of air, mucus, or feces from the vaginal vestibule. Sometimes difficult to find, and initially misdiagnosed as Bartholin gland cysts, these fistulae are often inferoposterior, and the fistula tract can be discerned by digital examination of the anterior anorectal canal and vaginal vestibule.

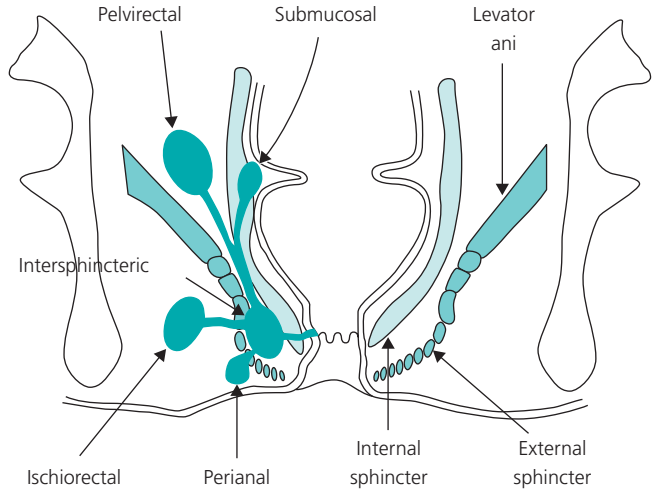

Figure 57.45 In Crohn's disease perirectal abscesses develop from fistulous tracts that begin in rectal ulcers of anorectal glands. These fistulae extend into the intersphincteric space and then follow tissue planes to a variety of pelvic locations where abscesses may form.

Surgical examination under anesthesia with incision and drainage of abscess cavities, fistulectomy, or seton placement is recommended in patients with acute abscesses and refractory fistulae. Antibiotics (typically ciprofloxacin and metronidazole) should be promptly initiated and continued until the abscess is draining and the area is free of inflammation, and while the fistula is draining. Chronic antibiotic administration (usually with ciprofloxacin or a derivative) is common in patients with persistent or recurrent disease, and should also be used in patients with fistulae who are undergoing treatment with anti-TNF therapy. Corticosteroids have not been shown to be efficacious in closing the fistulae per se, but in the case of patients with active Crohn's disease in the area of fistula origination, may be helpful in decreasing the inflammation in the bowel that is feeding the process. Topical use of mesalamine or corticosteroids is helpful in some patients.

Medical therapies directed at fistula closure are discussed in the preceding section. Cessation of therapy often leads to fistula recurrence; maintenance therapy is required. Patients with complicated or recurrent fistulae may benefit from the initiation of infliximab therapy (Fig. 57.41), following initial

surgical therapy. The surgical management of complicated fistulae, especially rectovaginal fistulae, is best covered in a dedicated text. Although fecal diversion with colostomy or ileostomy often leads to improvement of the downstream bowel and perianal area, relapse on reversal of the ostomy is common; whether use of the anti-TNF drugs can change the course of disease remains to be seen.

Obstruction

The nature of Crohn's disease with stricture leads to obstruction of the bowel in many cases of long-standing disease [191,711]. As is the case with other types of bowel obstructions, signs and symptoms depend on the location of the blockage. Pyloric or duodenal obstructions are characterized by early satiety, gastric distention, belching, and vomiting during or immediately after eating. Patients with jejunal obstruction often have pain and vomiting shortly after meals; ileal obstructions will present with pain, while vomiting may occur long after meals are completed and may be feculant. Patients with small bowel obstructions will often first notice a cessation of flatus and then bowel movements; an impending obstruction may be heralded by increasing pain, early satiety, and a change in bowel patterns. Colonic obstructions are more insidious and may present with increased diarrhea or constipation with pain. Anorectal obstructions are seen in patients with distal disease, are often associated with local fistulous disease, and may be characterized by fecal incontinence and worsening of fistula symptoms.

Patients who present with acute obstructions need intravenous hydration, and often nasogastric suctioning, while being kept nil by mouth. Intravenous corticosteroids are used to quickly control the inflammatory components of the disease process, although they may ultimately be of little or no use in patients with fibrostenotic disease. Anti-TNF agents are discouraged in the setting of obstructive strictures because there have been reports of worsening symptoms; retrospective analyses have not shown such an association, although some patients may have been excluded from receiving these therapies and not included in the analyses [712]. Adhesive disease as the result of previous abdominal or pelvic surgeries (or inflammation) can be a particularly troublesome cause of repeated bowel obstructions, and will often require surgical intervention.

Abdominal radiographs (multiple view), CT scan, or MRI may be helpful in assessing the location and etiology of the obstruction. Small bowel series, enteroclysis, or enterography may be performed to further localize the obstructive point, after the bowel is decompressed and vomiting has ceased. Patients with high-grade obstructions that do not quickly decompress require surgical intervention; otherwise, the conservative management described above is usually successful. Patients who have repeated obstructions, strictures that are not responsive to medical therapy, or who do not completely resolve their obstructions will likely require surgery.

The role of endoscopy in patients with Crohn's disease with stenoses is primarily to exclude obvious neoplasms, although many of the neoplasms are deeper than can be determined by mucosal biopsies, and adequate prospective trials have not been conducted (nor are they likely to be). Patients in whom the strictures cannot be adequately traversed and biopsied require surgical resection. The inability to adequately survey the colon proximal to an obstruction to rule out dysplasia and neoplasm is another controversial issue that may prompt surgical intervention. Attempts at endoscopic dilation, in some instances with direct injection of corticosteroids into the strictures, have been reported [685–689]. High perforation rates, and early restenoses argue against this approach in the majority of patients.

Dietary indiscretion is a frequent cause of obstructions in patients with small bowel stricturing disease. Strict adherence to a low-residue diet is advised in all such patients, avoiding poorly digested foods such as seeds, nuts, corn, popcorn, raw or slightly cooked fruits and vegetables, and whole grain products. Patients with gastric or duodenal Crohn's disease should be encouraged to also avoid food that interferes with gastric emptying, or is poorly absorbed.

Surgical management (see also Chapter 58)

Ulcerative colitis

About 20%–25% of patients with extensive ulcerative colitis eventually undergo colectomy, usually because their disease has not responded adequately to medical therapy [713,714]. For some, the indications for colectomy are urgent and compelling, but more commonly the decision for or against colectomy is made at a time when the disease is active but stable. The decision between surgery and continued medical therapy is often not clear, and in many cases arguments can be made for either course. It is important in these cases to attempt to balance the risks and benefits of the two approaches. Excessive enthusiasm for and avoidance of operative therapy are both inconsistent with the patient's best interests. At the time of first diagnosis, the patient may reject even the consideration of eventual colectomy. However, a single prolonged episode of severe colitis or multiple recurrent episodes of more moderate severity increase the patient's desire to eliminate this debilitating disease with its restrictions on activity, and the prospect of colectomy becomes less intolerable.

In ulcerative colitis, colectomy is a curative procedure, in contrast to Crohn's disease, in which there is a significant likelihood of recurrence sometime after colectomy [715]. The assurance of a permanent cure increases the appeal of colectomy in ulcerative colitis. The development of the ileoanal anastomosis, eliminating the need for a permanent ostomy, has made the idea of colectomy more tolerable for many patients. The patient's age, social circumstances, and

duration of disease all influence the decision for or against colectomy. The morbidity of severe ulcerative colitis in childhood and the morbidity of corticosteroids in childhood combine to lead to early consideration of colectomy as the definitive therapy. For young adults with moderately severe disease, colectomy may be more acceptable for those in stable marriages than for those who are single. The risk of developing malignancy enters into the equation when considering colectomy in those with long-standing ulcerative colitis; if the other indications are equivocal, the risk of malignancy may tilt the balance in favor of colectomy.

Emergency colectomy may be required in toxic megacolon or in a severe fulminating attack without toxic megacolon [716]. Although colectomy for acute attacks of ulcerative colitis is more commonly associated with toxic megacolon, it is clear that acute fulminating ulcerative colitis in the absence of colonic dilation can also proceed to perforation. The goal is to recognize the necessity for surgical intervention before perforation occurs. If perforation does occur, it is an absolute indication for surgery. Perforation in this circumstance is a medical disaster, with a 40% mortality rate [717]. For fulminant colitis, in the absence of toxic megacolon, the general indications for operation are similar. Before the patient undergoes colectomy for intractable ulcerative colitis, it is important to rule out complicating conditions that can be treated. The possibilities of infection with *Giardia* spp., amoebae, *C. difficile*, and cytomegalovirus should be considered and, if indicated, testing for these organisms should be performed. The presence of worsening colitis and especially worsening systemic signs (e.g., fever, prostration, tachycardia, hypotension) in the face of aggressive medical therapy is a sign that surgical intervention may be indicated. Severe hemorrhage is another indication for emergency colectomy.

The failure of medical therapy to control the activity of ulcerative colitis, resulting in an unacceptable lifestyle, is the most common indication for colectomy in ulcerative colitis. There are several varieties of intractability. In one variety, the disease enters a chronic continuous phase in which the patient no longer achieves remission even with maximal medical therapy, and chronic diarrhea is severe enough that the quality of life is severely compromised. Frequent bowel movements prevent the patient from moving far from a bathroom and do not allow normal travel or employment. In some cases, the patient's or the physician's aversion to colectomy results in months or years of functional disability far worse than would have existed if a colectomy had been performed. Another type of intractability occurs when adequate control of the patient's symptoms requires high doses of corticosteroids over a long period. It is appropriate to attempt to reduce steroid requirements by administering azathioprine or 6-mercaptopurine. The side effects of corticosteroids are dose and time dependent and vary considerably from patient to patient. Unacceptable side effects (e.g., psychosis, accelerated hypertension) occur in some patients even with modest doses given over a short period. In these cases, the decision for surgery is clear.

A more difficult and more common problem is the patient who requires moderate to high doses of corticosteroids to control disease activity but who has had no specific problem with the corticosteroid treatment. Although this is a decision in which factors specific to the individual patient play a large role, some general guidelines may be useful. In patients who have taken large doses of prednisone (> 15 mg/day) for more than 6 months, even if no specific corticosteroid side effects are present, the morbidity of continued steroid therapy must be weighed against the morbidity of surgery. Ophthalmological examination for cataract and bone densitometry may help to identify patients with clinically silent corticosteroid side effects. The identification of asymptomatic but clinically important corticosteroid side effects may make the decision for colectomy easier. Growth failure in children is another form of intractability. Adequate nutritional support helps in most young patients, but some require colectomy. Surgical intervention should be strongly considered if growth retardation persists despite maximal nutritional and medical therapy [718]. In such cases, it is important to initiate therapy before puberty and the closing of epiphyses.

Surgery plays a relatively small role in the management of extraintestinal manifestation in ulcerative colitis. Uveitis, pyoderma gangrenosum, and arthritis usually resolve with colectomy. Some other extraintestinal manifestations, including ankylosing spondylitis and sclerosing cholangitis, do not. The extraintestinal manifestations that respond to colectomy usually respond to medical management as well. Extraintestinal manifestations are an infrequent indication for colectomy.

In the past the standard operation for ulcerative colitis was a proctocolectomy and Brooke ileostomy. This procedure is definitive and curative and additional surgery is seldom required. The patients' functional status can be predicted with confidence. Most patients make a remarkably good adjustment to the ileostomy and lead full, useful lives. The difficulty with this procedure is the perminate ileostomy with the requirement for an appliance. Although the proctocolectomy and ileostomy is still a reasonable choice for some patients, the more commonly performed procedure is the proctocolectomy with an ileoanal anastomosis, a procedure that does not require a permanent appliance [719–721]. In this procedure, the colon is removed completely, but the mucosa and submucosa of the rectum are dissected from the muscularis; the mucosa and submucosa are removed and the muscularis, including the internal and external sphincters, is left in place. A pouch is constructed from the terminal 30 cm of ileum. The distal end of the pouch is pulled through the anal canal and the ileal mucosa is sewed to the dentate line. The advantage of the ileoanal anastomosis is that the patient has no ostomy and no appliance; however, a proximal temporary diverting loop ileostomy commonly is used to protect the ileoanal anastomosis until it heals. For several months

after the creation of an ileoanal anastomosis, the patient has numerous bowel movements [722]. The number gradually declines so that, at 12 months, most patients are having five or six bowel movements per day. Twelve months after operation, 75% of patients have complete daytime continence, 23% have daytime seepage (minor staining of underclothes), and 2% have daytime incontinence [723]. Twelve months after the operation, 48% of patients are completely continent at night, 47% have nighttime seepage, and 5% have nighttime incontinence. Results are better for patients younger than 50 years than for older patients. An in-depth discussion of these surgical alternatives is presented in Chapter 58.

Crohn's disease

Within 10 years of diagnosis, about 60% of patients with Crohn's disease undergo surgery for their disease [724]. The surgical approach to Crohn's disease differs markedly from the approach to ulcerative colitis. Surgical resection is not curative in Crohn's disease as colectomy is in ulcerative colitis. As a consequence, there has been a more conservative approach to the amount of tissue removed, in the knowledge that recurrences are likely and that additional surgical resections may be necessary. A controlled trial comparing limited resection (narrow margins) and extended resection (wide margins) found no difference in the incidence of recurrence [725]. Intractability, or failure of medical management, is a common cause for resection in Crohn's disease, as it is in ulcerative colitis, but complications (e.g., obstruction, fistula, abscess) are often indications for resection in Crohn's disease. The line between failure of medical management and a more defined complication, such as obstruction, is often indistinct. If a patient with a radiographically identifiable stricture has symptoms consistent with intermittent partial obstruction (i.e., diarrhea and pain brought on by eating) and does not respond to medical management, it is difficult to say whether the indication for surgery is obstruction or failure of medical management. Indications for surgery have been used for defining two subsets of patients with Crohn's disease, those with perforating indications (perforation or fistula) and those with nonperforating indications (obstruction or stricture) [726]. If a patient's initial surgery was for a perforating indication, it is likely that subsequent surgeries also will be for perforating indications; similar results are seen with surgery for nonperforating indications.

Defining the point at which medical management has failed in Crohn's disease is somewhat more involved than in ulcerative colitis, because in Crohn's disease symptoms are not always caused by disease activity. Diarrhea and weight loss may be the result of fatty-acid malabsorption, bile-salt-induced colonic secretion, or small bowel bacterial overgrowth. Pain may not be the result of obstruction. Optimal medical management requires recognition and treatment of these disorders. If these problems are not identified, patients may be subjected to unnecessary surgery.

As in ulcerative colitis, surgery for failure of medical management in Crohn's disease falls into two groups. In the first group, surgery is required because the progression of the disease has led the patient to a condition of unacceptable disability and invalidism despite optimal medical management. Whereas in ulcerative colitis the major source of disability is diarrhea, in Crohn's disease there is more commonly a combination of diarrhea, pain, weight loss, and malnutrition. In evaluating the possibility of surgical intervention in ulcerative colitis, the patient's current morbidity from disease activity is balanced against the relatively predictable morbidity of a colectomy. In Crohn's disease, however, the current morbidity must be balanced against the less well-defined morbidity of more limited surgery and also against the projected long-term morbidity as the disease progresses. Another distinction between surgical therapy in ulcerative colitis and Crohn's disease is that surgery for ulcerative colitis is almost always performed to remove actively inflamed tissue, but surgery for Crohn's disease may be required to remove actively inflamed tissue or to remove the sequelae of inflammation. For example, strictures requiring surgical intervention may occur in Crohn's disease at the site of a surgical anastomosis where there is considerable scarring with only a modest amount of active inflammation. This distinction is important because there is no point in treating a stricture with a therapeutic trial of steroids if scarring and fibrosis have caused the stricture. In addition, if the problem is known to be largely scar tissue and fibrosis, a stricturoplasty can be performed or the extent of the surgical resection can be limited to the area of narrowing without worry about maintaining adequate uninflamed margins.

The second group of patients who undergo surgery for failure of medical management in Crohn's disease includes those suffering side effects from drugs, usually corticosteroids. The guidelines for surgical intervention in patients with Crohn's disease with complications of medical therapy are exactly the same as for patients with ulcerative colitis. A problem frequently faced by physicians treating Crohn's disease is the patient whose disease is controlled with corticosteroids but flares if the dose of corticosteroids is reduced below a certain level. The level varies from patient to patient, but one study put the average at 0.15 mg prednisone per kilogram per day [727]. Several options are available in this situation. One approach is to maintain the patient at a steroid dose above the critical level and to monitor the patient carefully for manifestations of steroid toxicity. This follow-up includes bone densitometry and ophthalmological examinations. A second approach, not exclusive of the first, is the use of immunomodulators to achieve a steroid-sparing effect. This approach trades potential complications of corticosteroids for those of immunomodulators. A third approach is to resect the involved segment, knowing that the chance of eventual recurrence is high. Each of these approaches

has advantages and disadvantages, all of which should be explained to the patient before a decision is made.

The incidence of recurrence after ileal resection for ileitis or ileocolic resection for ileocolic disease is about 50% after 10 years and 75% after 15 years, as assessed by rates of reoperation [728]. If the presence of recurrence is assessed endoscopically, it is clear that recurrence after resection occurs more rapidly than was previously appreciated [729]. Routine colonoscopic surveillance 1 year after ileocolic resections revealed a 72% incidence of recurrence, as manifested by the presence of aphthous ulcers on the ileal side of the ileocolic anastomosis [728]. Many patients who undergo ileocoloic resection for Crohn's disease will later require another resection. Predicting which patients will require a second surgery and how long after the first resection that will be is an area of active investigation [730]. Reliable predictors of time to reoperation have not been established. Whether the time to initial operation or reoperation can be prolonged with maintenance medical therapy is under investigation. Studies of azathroprine and 6-mercaptopurine in preventing relapse after operation and in prolonging time to initial operation have given inconsistent results [730–733].

A surgical alternative to resection for strictures in the small intestine, termed stricturoplasty, involves longitudinal incision of the strictured segment, followed by transverse closure [734,735]. This method preserves bowel and has a low rate of complications [736,737].

Surgical approaches to Crohn's colitis include segmental resection, subtotal colectomy with ileoproctostomy, and total colectomy with ileostomy. Segmental resection of Crohn's colitis is appropriate if a relatively short segment of colon is involved. Recurrence rates are high, approximating those described for ileal and ileocolic disease. Subtotal colectomy with ileoproctostomy should be considered only in a patient with an absolutely normal rectum [738]. Even in selected patients, the recurrence rate after this procedure is high, about 75% at 10 years [739]. For patients with extensive disease including the rectum, the procedure of choice is total proctocolectomy with a Brooke ileostomy. Total colectomy with ileoanal anastomosis is not appropriate in Crohn's colitis because recurrence of Crohn's disease in the ileal segment forming the new pouch would require a repeat operation and loss of a long segment of ileum.

Colon cancer, dysplasia, and colonoscopic surveillance

Patients with extensive ulcerative colitis have an increased risk for colon cancer compared with the general population. The molecular pathway to the development of colon cancer in ulcerative colitis is different from that seen in sporadic colon cancers [740]. In the development of most sporadic colon cancers the loss of function of the suppressor gene adenomatosis polyposi coli (APC) is an early event and is associated with the formation of adenomatous polyps. However, in ulcerative colitis the loss of APC is a late event in carcinogenesis and polyps do not typically develop. In contrast p53 mutations typically occur late in the adenoma–carcinoma sequence in sporadic colon cancers but occur early in the development of colon cancer in ulcerative colitis. These differences in the molecular events leading to colon cancer are associated with differences in presentation. Ulcerative colitis cancers are more likely to be submucosal, more likely to occur in flat mucosa, and less likely to be associated with polyps. In sporadic colon cancers multicentric cancers are seen in 2%–3% of individuals but more than 20% of ulcerative colitis cancers are multicentric [741].

The magnitude of the risk of colon cancer in ulcerative colitis is uncertain. Early reports of extremely high incidences of colon cancer among patients with ulcerative colitis (50% cumulative risk at 30 years) were biased by the use of referral-based populations that were not representative of the general population [742]. Data from a metaanalysis suggest that the risk of colon cancer in ulcerative colitis is 2% after 10 years of disease, 8% after 20 years of disease, and 18% at 30 years [745]. Some populations of patients with chronic ulcerative colitis do not have an increased risk of colorectal cancer compared with the general population. In a population-based cohort from Olmsted County, Minnesota the cumulative probability of colorectal cancer was 0% at 5 years, 0.4% at 15 years, and 2% at 25 years after the diagnosis of ulcerative colitis [744]. It is possible that the lower rate of colorectal cancer seen in certain ulcerative colitis populations may relate to improved medical management, increased use of chronic 5-ASA therapy, higher rates of surveillance colonoscopy with proctocolectomy for dysplasia, and higher rates of proctocolectomy for medical treatment failures. Each of these interventions might decrease the risk of colorectal cancer in a population of patients with chronic ulcerative colitis.

The identified risk factors for colorectal cancer in patients with ulcerative colitis include duration and extent of disease and the presence of primary sclerosing cholangitis. A family history of colorectal cancer is an independent risk factor as well. The risk of developing colon cancer becomes appreciable 8–10 years after diagnosis of ulcerative colitis and increases with time. Age of onset of ulcerative colitis seems to have little impact on the incidence of colon cancer. The risk of malignancy, however, is a larger issue for those who develop ulcerative colitis earlier in life because they have a longer period at which they are at risk and thus a higher cumulative incidence of cancer. Colon cancer in the general population is a disease of late middle and older age, but in ulcerative colitis colon cancer develops earlier and is commonly seen in the fourth decade of life. The risk of malignancy is also a function of the anatomic extent of disease; the risk is much greater with pancolitis than with left-sided colitis or proctosigmoiditis.

Patients with long standing ulcerative colitis are at risk for developing cancer even if their symptoms have been relatively mild [742,745]. Patients are seen with colon cancer whose ulcerative colitis has been quiescent for 10–15 years. The risk of colon cancer is much higher in individuals with ulcerative colitis and primary sclerosing cholangitis than in those with ulcerative colitis alone [746]. Although the risk of colon cancer is increased in ulcerative colitis it is not high enough to recommend proctocolectomy for all patients at a certain time after diagnosis. However, the risk is high enough to consider screening patients with ulcerative colitis to identify those at particular risk for colon cancer. In the general population colon cancer commonly develops in polyps and screening colonoscopy looking for cancer and polyps is recommended for people over 50 years of age. This approach is less effective in ulcerative colitis where colon cancer usually develops in flat mucosa rather than in polyps.

In ulcerative colitis the tumor may be indistinguishable from the surrounding mucosa; it may appear as a flat, plaque-like lesion, or it may present as a stricture. The large exophytic masses with sharp margins seen in colon cancer in the general population are less common in ulcerative colitis.

An effective approach to colonoscopic surveillance in ulcerative colitis came from the observation that colon cancer in ulcerative colitis is associated with dysplasia elsewhere in the colon. Dysplasia is an unequivocal neoplastic transformation in the epithelium without penetration to the lamina propria. It is marked by nuclear stratification, loss of nuclear polarity, and nuclear and cellular pleomorphism. In 1967, Morson and Pang [747] reported on a group of nine patients with ulcerative colitis who were found to have dysplasia on rectal biopsy and underwent colectomy. Of these nine patients, five were found to have malignancies elsewhere in the colon. Other groups have confirmed these observations and it is clear that the vast majority of colons resected for malignancy in ulcerative colitis have dysplasia somewhere in the specimen. These findings suggest that dysplasia may precede the development of carcinoma and that dysplasia may be a marker to identify patients with ulcerative colitis who have developed or are at risk of developing carcinoma [748]. Dysplasia should therefore be viewed as not a marker for future cancer but an indicator of a high risk of concurrent cancer in the colon at that point in time. These findings have led to the suggestion that patients with long-standing ulcerative colitis undergo periodic colonoscopy with biopsies and, if the biopsies show dysplasia, then patients should undergo prophylactic colectomy.

This plan of action has several problems. The first is that dysplasia is not easy to read on colonic biopsy, and interobserver variation is considerable. A group of pathologists have developed a classification of dysplasia that should help to resolve this problem [749]. This classification divides biopsies into negative, indefinite, and positive groups; the positive group is further divided into those of high-grade and low-grade dysplasia. Even in major academic centers, considerable interobserver variation occurs in diagnosing low-grade dysplasia. A second problem is that the presence of inflammation often makes it effectively impossible to determine if dysplasia is present. For this reason surveillance colonoscopy should be performed when the patient's disease is quiescent. A third problem is that, although dysplasia may be extensive, it is more often patchy and can be missed entirely by standard screening protocols. Although the vast majority of carcinomas in ulcerative colitis are associated with dysplasia elsewhere in the specimen, this does not mean that colonoscopy with biopsies will always find the dysplastic area.

Despite these limitations a consensus guideline for colonoscopic screening in ulcerative colitis has been developed [750]. The recommendation is that screening should begin 8–10 years after the onset of symptoms in patients with pancolitis or left-sided colitis. Surveillance should be repeated at 1- to 2-year intervals. For patients with only proctosigmoiditis the risk of colon cancer is considerably lower than that for patients with left-sided disease or pancolitis and in this population the recommendation for colon cancer screening is the same as for the general population. For patients who have ulcerative colitis and primary sclerosing cholangitis there is a markedly increased risk of colon cancer compared with patients who have ulcerative colitis alone and yearly colonoscopic examinations are recommended beginning as soon as the diagnosis of primary sclerosing cholangitis is made. The consensus recommendations for surveillance colonoscopy include four-quadrant biopsies taken every 10 cm, beginning at the proximal extent of disease. The data supporting these recommendations are thin. There are no large-scale studies comparing different schedules for colonoscopies or different protocols for the number or distribution of biopsies. There are some data suggesting that in patients with dysplasia the larger the total number of biopsies the more likely dysplasia will be found.

Guidelines have been developed for decision-making based on the results of the surveillance biopsies [751]. A patient with low-grade or high-grade dysplasia found in a discrete adenoma-like polyp, but nowhere else, can be safely managed with polypectomy and accelerated surveillance. When a polyp is removed, separate biopsies should be taken from the flat areas around the base of the polyp. If dysplasia is found in the area around the polyp then colectomy is recommended because of the high association with synchronous cancer. Dysplasia of any grade found in an endoscopically unresectable polyp or high-grade dysplasia found in flat mucosa are both strong indications for proctocolectomy. High-grade dysplasia in a flat area is associated with a high risk of synchronous colorectal cancer elsewhere in the colon and a colectomy is recommended. The management of low-

grade dysplasia found in flat mucosa is controversial. Some investigators recommend colectomy whereas others recommend repeat colonoscopy within 6 months. The controversy about the management of low-grade dysplasia relates to the widely varying reports of the predictive value of low-grade dysplasia. In a review of 10 surveillance studies low-grade dysplasia was associated with synchronous cancer in 19% of patients [752]. In patients who were followed after a diagnosis of low-grade dysplasia a significant number (16%–29%) progressed to high-grade dysplasia, dysplasia-associated lesion or mass, or cancer. However, in other studies only 3%–10% of patients with low-grade dysplasia progressed to more severe disease [751,753]. In any case in which the diagnosis of dysplasia will influence management, it is reasonable to have the slides reviewed by a second expert pathologist.

Assessing the value of surveillance colonoscopy is a difficult issue. No randomized prospective control trials have been carried out, nor are they likely to be performed. In one retrospective study variables associated with colorectal cancer were assessed in 188 patients with ulcerative colitis-related cancer and a similar number of matched patients with ulcerative colitis but without colorectal cancer [755]. Fifty-five of the patients with colon cancer had undergone surveillance colonoscopy whereas 97 of the controls had undergone surveillance colonoscopy. These data suggest that the surveillance colonoscopy reduces but does not eliminate the risk of colon cancer. The largest prospective study of the efficacy of colonoscopic biopsies followed 600 patients with ulcerative colitis who underwent 2627 colonoscopies during 5932 patient years of follow up [756]. Seventy-four patients (12.3%) developed neoplasia, including 30 colorectal cancers. Sixteen of the 30 cancers were interval cancers, i.e., they either presented after an initial negative colonoscopy or presented as advanced cancers at surveillance. The cumulative incidence of colorectal cancer by colitis duration in this group of individuals undergoing surveillance was 2.5% at 20 years, 7.6% at 30 years, and 10.8% at 40 years. Although this is the largest prospective study of the utility of colonoscopic surveillance in ulcerative colitis the results are not easy to interpret. There was no control group and it is difficult to use historical controls because of the wide range of reported rates of colorectal cancer in populations where surveillance was not carried out. This study does demonstrate that even in a program where colonoscopic surveillance is well organized and where expert pathological services are available the incidence of colorectal cancer in patients with ulcerative colitis undergoing surveillance is still substantial.

Chronic use of 5-ASA compounds as maintenance therapy for ulcerative colitis is associated with a decreased risk of developing both dysplasia and colorectal cancer [757,758]. The relative risk reduction for colorectal cancer seen with 5-ASA use is 46%–81% in a series of retrospective studies. The chemopreventive effects of 5-ASA are dose-related, with at least 2 g/day being required for any effect. The reported benefits of 5-ASA are for individuals who have not already progressed to dysplasia. There is no evidence that initiating 5-ASA affects the progression of low-grade dysplasia.

Much less information is available on cancer in Crohn's disease than in ulcerative colitis [759]. For those with Crohn's colitis, the incidence of colon cancer is higher than in the general population; the risk of colorectal cancer in extensive Crohn's colitis appears to be similar to that of ulcerative colitis [760–762]. As with ulcerative colitis, the incidence of colon cancer in Crohn's colitis increases with the duration of the disease and is associated with dysplasia. Also, as in ulcerative colitis, colon cancers occur in patients with Crohn's disease at a younger age than in the general population. A similar surveillance strategy has been suggested with extensive Crohn's colitis as with ulcerative colitis [762].

An association between small intestine Crohn's disease and adenocarcinoma of the small intestine has been found [763]. Most adenocarcinomas occur in areas of the small intestine actively involved with Crohn's disease. Adenocarcinoma of the small intestine occurs at an earlier age in patients with Crohn's disease than in the general population. There is also an association of small intestine adenocarcinoma with surgically bypassed loops of small bowel. It is not clear whether the high incidence of cancer in bypassed bowel is a product of the bypass procedure or merely reflects the long duration of the disease.

Pregnancy and inflammatory bowel disease

Because IBD affects many women in early adulthood, the effect of IBD on pregnancy is an important clinical issue [764,765]. Fertility in women with IBD is normal or only minimally impaired [766,767]. Fertility in men taking sulfasalazine is diminished but returns to normal a few months after cessation of the drug [768,769].

Most pregnancies in women with IBD produce healthy babies. The incidences of stillbirth and developmental defects are similar to those of the general population [770]. The children of women with Crohn's disease have a slight increase in the incidence of prematurity and a slight decrease in birth weight [771]. The incidence of spontaneous abortion is higher in women with IBD (12.2%) than in the general population (9.9%). There is some suggestion that the incidence of fetal complications is somewhat higher in cases in which the mother's disease is clinically active, irrespective of drug therapy [770]. The incidences of prematurity and spontaneous abortion are both higher in patients with more active disease. Proctocolectomy with the creation of a J-pouch and an ileoanal anastomosis is associated with markedly decreased fertility [772,773].

Many women with IBD take medication on a chronic basis, and the possibility of the fetus suffering undesirable effects from the drugs is a matter of concern [774,775]. Many women have taken sulfasalazine throughout the course of pregnancy, and there is no evidence of harm to the fetus or newborn. In one series of 174 patients, sulfasalazine had no effect on spontaneous abortion, prematurity, or fetal weight [776].

Pregnant women have an increased requirement for folic acid, and sulfasalazine interferes with folate absorption. Women taking sulfasalazine who are pregnant or considering pregnancy should receive folate supplements (1 mg twice daily) to ensure that the fetus receives amounts that are adequate for normal development. Up to 1 mg daily of folate supplementation is recommended for all pregnant women to prevent congenital neural tube malformations. It seems reasonable, therefore, that all women taking sulfasalazine who are pregnant or contemplating pregnancy should take 2 mg folate daily to ensure absorption of adequate amounts, as the period surrounding conception is the most critical for neural tube development. The use of corticosteroids by pregnant women with IBD is not associated with an increased rate of fetal complications [776]. In general, it appears that the risks to the pregnancy of treatment with sulfasalazine or corticosteroids are less than the risks of allowing disease activity to go untreated.

Most data on azathioprine and 6-mercaptopurine in pregnancy come from the transplant literature and involve higher doses than are commonly used in IBD. Reported fetal effects in the transplant population include congenital malformations, immunosuppression, prematurity, and growth retardation. However, surveys of women with IBD taking azathioprine or 6-mercaptopurine during pregnancy have demonstrated no increase in the number of birth defects [777]. It is reasonable for a patient to continue maintenance therapy with azathioprine as 6-mercaptopurine during pregnancy. Breast-feeding is not recommended for women taking these drugs. Methotrexate induces abortions and should not be used in women at risk for pregnancy. Metronidazole, in the short courses used to treat trichomoniasis, appears to be safe in pregnancy; however, there are no data for the longer courses commonly used in IBD. The available data suggests that infliximab is safe in pregnancy but the number of patients is small [778].

A number of studies have assessed the effects of pregnancy on disease activity in IBD. If the patient's disease is inactive at the time of conception, it is likely that it will remain inactive during the course of the pregnancy [779]. If the disease is active at the time of conception, the course is harder to predict. Ulcerative colitis that is active at the time of conception tends to worsen. In two-thirds of patients with Crohn's disease that is active at conception, the degree of activity remains the same; among the other third, some improve clinically and others deteriorate.

Inflammatory bowel disease in childhood and adolescence

Although the peak incidence of IBD is in young adulthood, 15% of patients with ulcerative colitis and 25%–33% of patients with Crohn's disease present before 20 years of age. For the most part, IBD presenting in childhood is similar to the disease in adults [780,781]. The clinical presentation of ulcerative colitis in childhood, as in adulthood, is marked by diarrhea and rectal bleeding. The clinical presentation of Crohn's disease, however, is somewhat different in childhood [782]. Abdominal pain, weight loss, and diarrhea are common in both adults and children, but extraintestinal manifestations (e.g., arthritis, iridocyclitis, clubbing, erythema nodosum) are more likely to be major components of the initial clinical presentation in children than in adults. Abdominal pain in Crohn's disease tends to be periumbilical and colicky and is confused with the pain of functional disease. Psychosocial issues are an important part of the morbidity of pediatric IBD. Anxiety, depression, and antisocial behavior are common. Delayed growth and maturation and the cosmetic effects of steroid therapy contribute to the psychosocial burden of IBD in childhood and adolescence.

Whether cytokines and other factors produced during inflammation contribute to the growth retardation is unknown. Corticosteriod therapy also may contribute to the growth failure. Growth retardation is less common in children with ulcerative colitis than in those with Crohn's disease. Bone demineralization is also a bigger problem in the pediatric IBD population than in adult patients. Decreased activity, corticosteroid therapy, and decreased intake and absorption of calcium and vitamin D all contribute to bone demineralization.

Medical management of IBD in childhood is largely the same as in adulthood. All the major controlled studies of therapy in IBD purposefully excluded children. Treatment in children is extrapolated from those studies. The indications for sulfasalazine therapy in children are the same as in adults. In children, sulfasalazine is begun at 25–40 mg/kg daily and increased to 70 mg/kg daily. The indications for corticosteroid therapy are also the same as for adults with IBD. Typical starting doses for moderate to severe disease would be 1–2 mg prednisone per kilogram per day. Continuous therapy with prednisone in doses as low as 10 mg/day can inhibit normal growth. After acute symptoms are under control, an attempt should be made to convert the patient from prednisone to an immunomodulator.

Immunomodulators, specifically 6-mercaptopurine and azathioprine, have been used in childhood Crohn's disease much as they have been used in the adult disease [783–785]. Over the last few years there has been a trend to introduce azathioprine and 6-mercaptopurine earlier in themanagement of IBD in children with some practitioners using them as primary therapy [786,787].

Indications for colectomy in ulcerative colitis in childhood are the same as for adults, with the addition of growth failure as an indication. Growth failure may be the result of either disease activity or corticosteroid administration. Surgical resection of localized areas of disease activity may be useful in children with Crohn's disease; however, the success of surgical resections in reversing growth retardation has been disappointing [788].

Growth retardation is a common element in pediatric Crohn's disease; corticosteroid therapy may contribute to growth retardation but the major cause is uncontrolled disease activity. In two randomized controlled trials of enteral feedings with elemental diets compared to corticosteroids the enteral feeding groups had improved weight gain [789].
