The diagnosis of juvenile hemochromatosis is usually made in the right clinical context: presentation below the age of 30 years (at least in one affected member of the family) with iron overload in the absence of both causal HFE mutations and causes of secondary iron overload [78].

Screening

Several large-scale screening studies have suggested that a large proportion of C282Y homozygotes have elevated TS and serum ferritin, particularly among males [55,116–118]. Among white subjects, various studies have reported a population prevalence of 0.4%–0.5% for C282Y homozygozity, with 75%–86% of males and 40%–100% of females having elevated TS, and 71%–88% of males and 33%–57% of females having elevated serum ferritin [57,116,119]. Despite the high prevalence and the high penetrance as manifested by the proportion of individuals with elevated TS and serum ferritin, morbidity associated with C282Y homozygozity has been argued to be relatively low [54,120]. However, hepatic fibrosis and cirrhosis have been documented in 6%–25% of C282Y homozygotes indicating that a substantial number of individuals with the mutation are at risk of developing long-term complications [116,117,120]. Population surveillance for hemochromatosis using *HFE* gene testing is not recommended because of these conflicting data about the potential benefits of identifying asymptomatic individuals and concerns about possible negative social, legal, and insurance consequences for the identified individual with homozygous *HFE* mutations [111]. The systematic review by the US Preventive Services Task Force evaluated these risks and benefits and concluded that data are inadequate to allow a decision on the benefit of genotypic screening of general population for hemochromatosis [119]. Genotypic screening with mutational analysis is also expensive when applied to the general population and is recommended only in first-degree relatives of confirmed cases of hemochromatosis and in individuals with elevated serum iron markers (in addition

to those with unexplained liver function abnormalities or symptoms as mentioned under the heading "Diagnosis") [106,121,122].

A recent systematic review by the American College of Physicians observed that the association between phenotypic markers of iron overload such as serum ferritin and TS and the development of iron-related complications is inconsistent [123]. However, phenotypic screening with TS has been found to be a cost-effective strategy for screening, even if as few as 20% of the identified patients develop symptomatic disease [121,122]. Therefore, phenotypic screening with TS may be appropriate for use in individuals as part of routine health maintenance [106]. Furthermore, the availability of an inexpensive, safe and effective treatment in the form of phlebotomy and the fact that at least some of the patients with elevated TS would develop the complications of iron overload support population screening with TS [124,125]. Age between 18 and 30 years has been suggested as the ideal time for such phenotypic screening because it has to be done after TS is elevated, but before significant organ damage has occurred [126].

Treatment and prognosis

Phlebotomy

Phlebotomy is the safest, most effective, and most economical therapeutic modality for iron depletion, and should be initiated in all individuals with significantly increased body iron stores based on serum ferritin or hepatic iron content [11].

One unit of blood (containing approximately 250 mg iron) should be removed once or twice a week until the serum ferritin level is below 50 ng/mL. This might take up to 2 or 3 years. Once the serum ferritin reaches the target level, the goal of phlebotomy treatment is to maintain the serum ferritin below 50 ng/mL. The required frequency of maintenance phlebotomy is highly variable, usually ranging from once in 3–4 months to once every month, reflecting the individual variability in iron absorption [106].

Certain clinical features, such as malaise, fatigue, skin pigmentation, insulin requirements (in patients with diabetes), and abdominal pain, improve with phlebotomy, whereas arthropathy, hypogonadism, and cirrhosis generally do not respond [106]. Life expectancy in patients with hemochromatosis is normal if phlebotomy is initiated in the precirrhotic stage; however, once cirrhosis has developed, life expectancy is shortened and there remains an increased risk of hepatocellular carcinoma, even with iron depletion. Vitamin C should be avoided by patients undergoing phlebotomy [106].

Liver transplantation

Liver transplantation should be considered in patients with hepatic decompensation or hepatocellular carcinoma [106]; however, survival after liver transplantation is decreased in hemochromatosis compared with other chronic liver diseases [64,127–130]. Decreased survival in hemochromatosis has been attributed to increased serious infections, especially fungal infections, which are more common in patients with hepatic iron overload, and are considered to be secondary to the immunological effects of iron overload [131,132]. However, a recent study of a large cohort of patients in the National Hemochromatosis Transplant Registry found that patients with *HFE*-associated hemochromatosis have even worse posttransplant outcomes than those with hepatic iron overload because of other causes, suggesting that factors other than iron overload might also have a role in the adverse outcome [127].

Metabolic diseases of the neonate and of childhood, 2235
Mitochondrial hepatopathies, 2240

Inborn errors of metabolism commonly involve the liver. In these disorders, mutations in genes that regulate a single enzyme within an important metabolic pathway or that code for essential transport proteins result in significant blocks in the metabolism or transport of the substrate. Either a deficiency of an important product of the enzyme or the accumulation of toxic precursors leads to the disease phenotype. In many hepatic metabolic diseases, environmental exposure to a specific substrate (galactose, fructose, copper, protein load) is an essential cofactor that modifies the time of onset and severity of the disease phenotype. As new genetic causes of many diseases are identified, many prior cryptogenic acute and chronic liver diseases have been attributed to specific metabolic defects, and there are certainly many more to be discovered. It has become apparent that modifier genes most certainly play a major role in determining the clinical phenotype, severity of disease, and onset of illness for many metabolic and genetic liver diseases that were previously thought to be caused by single gene mutations.

Metabolic liver disease may present in a variety of clinical phenotypes, including the appearance of acute hepatitis, bacterial sepsis, metabolic coma, mimicking ingestion of a toxin or drug overdose, or as end-stage liver disease with portal hypertension. A high index of suspicion is necessary in order to perform the correct metabolic testing and establish the diagnosis of a metabolic disorder. Clinical features that suggest a metabolic liver disease include hepatic steatosis, acute fulminant liver failure, presence of neuromuscular or cardiac findings, hypoglycemia, hyperammonemia, organic acidemia, hepatic synthetic functional failure, mildly elevated aminotransferases, episodes of recurrent vomiting or severe gastroesophageal reflux, developmental delays, failure to thrive, chronic diarrhea, cataracts, abnormalities of skin or hair, and a family history of similarly affected infants or children, or of consanguinity. Most metabolic liver diseases are inherited in an autosomal recessive manner; however, several segregate into autosomal dominant and X-linked inheritance patterns. Diseases with maternal inheritance (mitochondrial DNA diseases) also commonly involve the liver.

Childhood metabolic liver diseases present clinically in three patterns. The neonatal cholestasis syndrome (Table 87.1) is a common presentation that requires rapid diagnostic evaluation so that effective therapy can be instituted to avert permanent injury to the liver or other organs. A second presentation is that of chronic liver disease with progressive hepatic fibrosis, frequently with accompanying steatosis, culminating in cirrhosis and portal hypertension. Finally, a *metabolic syndrome* may include hypoglycemia, metabolic acidosis, encephalopathy, variable ketonemia or lactic acidosis, or hyperammonemia. A complete categorization of all metabolic liver diseases affecting children and adults is beyond the scope of this chapter. The reader is referred to recent textbooks on liver disease in children for extensive review of this topic [1]. This chapter focuses on six major areas of metabolic disease: Wilson disease, α_1-antitrypsin deficiency, Reye syndrome, porphyria, a group of important metabolic liver diseases presenting in early childhood, and mitochondrial hepatopathies.

Wilson disease

Clinical features

Mutations in the *ATP7B* gene cause Wilson disease, a progressive accumulation of copper in the liver accompanied by copper deposition in other organs that generate its clinical features. Clinical symptoms are rarely apparent prior to 4–5 years of age [2]. Asymptomatic elevation of aminotransferases occurs in the first decade of life in most patients: the youngest reported patient presenting with hepatic clinical symptoms was 4 years old [3]. After the storage capacity of the liver is exceeded, circulating non-ceruloplasmin-bound copper levels increase, distributing the excess copper to other target organs that produce the clinical manifestations of

Table 87.1 Metabolic and genetic causes of neonatal cholestasis

Disease	Inborn error	Hepatic pathology	Diagnostic studies
Galactosemia	Galactose 1-phosphate uridyltransferase	Cholestasis, steatosis, necrosis, pseudoacini, fibrosis	Galactose 1-phosphate uridyltransferase assay of red blood cells
Fructose intolerance	Fructose 1-phosphate aldolase	Steatosis, necrosis, pseudoacini, fibrosis	Liver fructose 1-phosphate aldolase assay or leukocyte DNA analysis
Tyrosinemia	Fumarylacetoacetase	Necrosis, steatosis, pseudoacini, portal fibrosis	Urinary succinylacetone, funarylacetoacetase assay of red blood cells
Cystic fibrosis	Cystic fibrosis transmembrane regulator gene mutations	Cholestasis, neoductular proliferation, excess bile duct mucus, portal fibrosis	Sweat test and leukocyte molecular analysis
Hypopituitarism	Deficient production of pituitary hormones	Cholestasis, giant cells	Thyroxine, TSH, cortisol levels
α_1-Antitrypsin deficiency	Abnormal α_1-antitrypsin molecule (PiZZ or SZ phenotype)	Giant cells, cholestasis, steatosis, neoductular proliferation, fibrosis, PAS- and diastase-resistant cytoplasmic granules	Serum α_1-antitrypsin phenotype or genotype
Gaucher disease	β-Glucosidase	Cholestasis, cytoplasmic inclusions in Kupffer cells (foam cells)	β-Glucosidase assay in leukocytes
Niemann–Pick disease	Lysosomal sphingomyelinase	Cholestasis, cytoplasmic inclusions in Kupffer cells	Sphingomyelinase assay of leukocytes or liver, molecular analysis
Glycogen storage disease type IV	Branching enzyme	Fibrosis, cirrhosis, PAS- and diastase-resistant cytoplasmic inclusions	Brancher enzyme analysis of leukocytes or liver, molecular analysis
Neonatal hemochromatosis	Unknown	Giant cells, portal fibrosis, hemosiderosis, cirrhosis	Histology, iron stains
Peroxisomal disorders (e.g., Zellweger syndrome)	Deficient peroxisomal enzymes or assembly	Cholestasis, necrosis, fibrosis, cirrhosis, hemosiderosis	Plasma very long-chain fatty acids, qualitative bile acids, plasmalogen, pipecolic acid, liver electron microscopy
Abnormalities in bile acid metabolism	Several enzyme deficiencies defined	Cholestasis, necrosis, giant cells	Urine, serum, duodenal fluid analyzed for bile acids by fast atom bombardment–mass spectroscopy, molecular analysis
Progressive familial intrahepatic cholestasis (PFIC)	*FIC-1*, *BSEP*, and *MDR3* gene mutations for PFIC 1, 2 and 3, respectively	Cholestasis, necrosis, giant cells, fibrosis	Histology, family history, normal cholesterol, low or normal γ-glutamyltransferase (types 1 and 2), molecular analysis
Alagille syndrome (syndromic paucity of interlobular bile ducts)	*Jagged 1* gene mutations	Cholestasis, paucity of interlobular bile ducts, increased copper levels	Three or more clinical features, liver histology, molecular analysis

BSEP, bile salt export pump; FIC1, familial intrahepatic cholestasis 1; MDR3, multiple drug resistance 3; PAS, periodic acid–Schiff; TSH, thyroid-stimulating hormone.

Wilson disease. This redistribution of copper deposition is best illustrated by the organ involvement at presentation. Of those diagnosed before 10 years of age, the majority (80%) present with hepatic symptomatology with only 17% showing neuropsychiatric manifestations. In contrast, between 10 and 18 years of age approximately 50% present with either hepatic or neuropsychiatric symptoms, and after 18 years of age 25% present with hepatic and 75% neuropsychiatric symptoms [4]. After hepatic saturation with copper, copper may also accumulate in the ocular cornea, leading to the characteristic Kayser–Fleischer (KF) ring, a greenish-brown pigment at the periphery of the cornea on its posterior surface in the membrane of Descemet [5]. Less commonly, a *sunflower cataract* is caused by deposits of copper in the anterior and posterior lens capsule. Other features include a variety of renal disturbances including proteinuria, glucosuria,

phosphaturia, generalized aminoaciduria, microscopic hematuria, and nephrolithiasis [6]. Acute renal failure is a common feature of the fulminant presentation of Wilson disease. Intravascular hemolysis is present in approximately 15% of patients. Cardiac involvement includes echocardiographic abnormalities in up to one-third of adults [7], as well as arrhythmias, orthostatic hypotension, and histological changes in the heart [7]. Skeletal manifestations include bone demineralization, rickets, spontaneous fractures, osteochondritis desiccans, chondromalacia patellae, and degenerative arthritis [8]. Skin pigmentation may be increased, particularly on the anterior aspect of the lower legs [9]. Endocrine abnormalities have also been reported [10,11].

The liver is both the site of the Wilson disease biochemical defect in copper metabolism and the initial target of copper toxicity. Clinical presentations include acute hepatitis, fulminant hepatic failure, chronic active hepatitis, and cirrhosis. Occasionally, elevated aminotransferase levels are detected in asymptomatic patients for whom a chemistry panel is drawn, or in siblings of a patient with Wilson disease. Any patient under 50–60 years of age with chronically elevated aminotransferase levels and no clear etiology should have Wilson disease excluded by appropriate studies.

Acute hepatitis is the presentation in approximately 25% of patients with Wilson disease, with typical findings that mimic the features of infectious hepatitis. Laboratory tests show typically elevated aminotransferases, normal serum albumin and prothrombin time, with conjugated hyperbilirubinemia. If serological testing for viral hepatitis is negative, Wilson disease needs to be considered. A mild hemolytic anemia or a depressed serum uric acid level (due to renal tubular losses) may be key features to alert the clinician to this diagnosis. If not identified, patients generally recover from this presentation and the diagnosis may be missed.

Fulminant hepatic failure is a dramatic presentation of Wilson disease. It typically occurs in the adolescent or young adult who develops an acute icteric hepatitis that rapidly evolves to liver failure within days, with extreme jaundice, fatigue, hepatic coma, severe coagulopathy, ascites, renal failure, and invariably death, if liver transplantation is not performed. A Coombs-negative hemolytic anemia is caused by the rapid release of massive amounts of copper from the necrosing liver, and is the single most important diagnostic feature suggesting Wilson disease in this clinical setting. Acute renal failure rapidly ensues usually requiring dialysis. Interestingly, serum aminotransferase levels are not as high as in other patients with acute liver failure, alkaline phosphatase is generally very low, and serum aspartate aminotransferase (AST) is significantly more elevated than alanine aminotransferase (ALT) [12]. Serum copper levels are paradoxically elevated above normal in this presentation of Wilson disease, because of the massive release of copper from the liver. Because KF rings are present in no more than half of patients with this presentation [4], their absence does not exclude the presence of Wilson disease. This presentation is not amenable to medical therapy, so prompt referral of patients with this presentation to a liver transplantation center is essential in order to save the patient's life. A similar presentation of acute fulminant liver failure and death has been described in Wilson disease patients who had been successfully treated with copper chelation therapy, but who unadvisedly discontinued therapy or became noncompliant for as little as 8 months.

Approximately 30% of patients have a presentation of chronic hepatitis, generally occurring during adolescence or young adulthood. Cirrhosis is common at the time of diagnosis. Typical findings of malaise, anorexia, fatigue, abdominal pain, nausea, and weight loss may precede the onset of jaundice. Amenorrhea, delayed onset of puberty, edema, polyarthralgia, ascites, and clubbing may also indicate the chronic nature of this hepatitis. Physical examination invariably reveals hepatomegaly and usually splenomegaly. Liver histology mimics autoimmune or chronic viral hepatitis, and thus a high suspicion for Wilson disease is essential. It is important to note that histochemical stains for copper-associated proteins in the liver may be negative, and should never be used as the diagnostic criteria for copper overload. KF rings are present only 50% of the time. Thus, it is imperative that biochemical screening for Wilson disease be undertaken in all patients younger than 50–60 years who present with chronic hepatitis and no identifiable cause. The presence of steatosis is common in Wilson disease and can lead to confusion with alcoholic hepatitis and nonalcoholic fatty liver disease.

Cirrhosis and its complications are relatively common features of advanced Wilson disease. Virtually all adults with the neuropsychiatric presentation of Wilson disease have underlying compensated cirrhosis. Other than the findings of a mild hemolytic anemia, a KF ring, positive family history, or neuropsychiatric symptoms, there is little to clinically distinguish this cause of cirrhosis from others.

Cholelithiasis is relatively common in adolescents and young adults with Wilson disease because of ongoing hemolysis and the presence of cirrhosis. Interestingly, hepatocellular carcinoma has been quite unusual in patients with Wilson disease, even those with advanced cirrhosis.

Neuropsychiatric presentation

Neurological or psychiatric symptoms are the first indication of illness in approximately 40–50% of patients with Wilson disease, having been recorded in children as young as 6 years and in adults as old as 72 years of age [13]. Primary involvement is the motor system with extrapyramidal or cerebellar dysfunction [14,15]. Symptoms segregate into pseudoparkinsonism, pseudosclerosis, and dyskinesia [4], each of which correlates with specific magnetic resonance imaging (MRI) lesions in the brain [16]. Extrapyramidal symptoms include facial grimaces, drooling, a fixed grin, dysphasia, and

contractures of the jaw and extremities. Features of pseudoparkinsonism include bradykinesia, cognitive impairment, cogwheel rigidity, and an organic mood syndrome. The pseudosclerosis presentation is characterized by ataxia, tremor, and reduced functional capacity. Because cognitive function is preserved, frustration and depression are common. The neurological basis for these abnormalities is dysfunction of the basal ganglia and cerebellum, although corticospinal and corticobulbar pathways are also affected.

It is well appreciated that a primary psychiatric presentation may include organic dementia, neurotic behavior, bipolar disorder, schizophrenic psychosis, or antisocial behavior. In children and adolescents, a major change in affect or personality may impair socialization skills and school performance. Psychiatrists must measure plasma ceruloplasmin and search for a KF ring in all young patients with psychiatric disorders. KF rings are present in over 90% of patients with the neuropsychiatric presentation of Wilson disease.

Histology of the liver

Early histological findings in the liver of asymptomatic children with Wilson disease include periportal, glycogen-filled, swollen nuclei [17] and microvesicular and macrovesicular steatosis [18]. Macrovesicular steatosis may be confused with alcoholic liver disease or nonalcoholic fatty liver disease. A chronic hepatitis appearance may predominate, characterized by portal tract mononuclear cell infiltrates, interface hepatitis, Mallory bodies, and varying amounts of periportal fibrosis. Eventually, mixed micronodular and macronodular cirrhosis develops. In the fulminant hepatitis presentation, liver histology is characterized by microvesicular fat, coagulative cell necrosis, pigment-laden Kupffer cells, collapse of stroma, and dropout of hepatocytes, with underlying well-established cirrhosis. Histochemical stains for copper or copper-associated proteins may be negative in Wilson disease despite massive accumulation of copper in the liver, and may be positive in other causes of cholestasis and chronic hepatitis. There is no correlation between histochemical staining of copper and quantitative copper measurements of liver biopsy samples in Wilson disease. Therefore, these histochemical stains should *not* be used to establish or exclude this diagnosis.

Electron microscopy may be helpful in Wilson disease because of characteristic ultrastructural lesions. In the early stage of Wilson disease, hepatocellular mitochondria are pleomorphic and large, and show widened intracristal spaces, increased matrix density, large granules, and sometimes crystalline, vacuolated or dense inclusions in the mitochondrial matrix. There is usually microvesicular steatosis present at the same time. These mitochondrial changes diminish with progression of the lesion toward cirrhosis.

Genetics

The *ATP7B* gene, located on the long arm of chromosome 13, was identified in 1993 as the gene mutated in Wilson disease [19–22]. By 2007, over 260 mutations in this gene had been identified from patients with Wilson disease, most being small deletions or missense mutations [23,24]. In addition, over 40 non-disease-causing allelic variations have been identified. There are no predominant mutations, although specific mutations appear to be more common among certain ethnic groups [23]. Thus, the most common mutation (His1069Glu) may be present in as many as 40% of cases in specific ethnic populations. Genotyping of suspected patients is now offered in a number of clinical and research laboratories and may be helpful in questionable cases (see http://www.genetests.org). Haplotype analysis (microsatellite markers or single nucleotide polymorphisms) may be particularly helpful in evaluating relatives of a known case in which markers are informative [25].

Pathogenesis and biochemistry

The *ATP7B* gene is highly expressed in the liver and kidney, with lower expression in the lung, placenta and other tissues. The encoded protein is a P-type cation-transporting ATPase, and includes domains for copper-binding sites and ATP binding. ATP7B is located in the trans-Golgi compartment of the hepatocyte and is essential for the transport of copper into vesicles bound for lysosomes and targeted to the bile canaliculus. ATP7B also makes copper available for synthesis of ceruloplasmin. In Wilson disease, *ATP7B* mutations cause impairment of both copper secretion into bile and copper incorporation into ceruloplasmin, resulting in toxic levels of copper within the hepatocyte. Ceruloplasmin is the primary carrier by which copper is secreted from the liver into the systemic circulation. Ceruloplasmin functions to mobilize iron from tissues by oxidizing ferrous iron for transfer into transferrin. Although ceruloplasmin levels in plasma are very low in Wilson disease, the ceruloplasmin gene is normal.

More than 80% of copper absorbed from the diet is normally excreted in bile. Therefore, copper accumulates in the liver in any condition that causes cholestasis; however it is primarily lysosomal-bound in these conditions and may not necessarily be hepatotoxic. In Wilson disease, the copper appears to be free to enter other compartments, such as the mitochondria and nucleus. Although the precise intracellular target for the toxic action of copper is not known, results have suggested that mitochondrial oxidative injury initiated by copper may be one of the primary pathogenetic events in Wilson disease [26–28]. Several studies have also demonstrated that hepatocyte apoptosis may be the primary mode of cell death in copper toxicity [29,30].

Diagnosis

The diagnostic criteria for Wilson disease vary with the clinical presentation [31]. In patients presenting with neurological or psychiatric symptoms, the absence of a KF ring in combination with a normal ceruloplasmin level virtually exclude the diagnosis of Wilson disease. However, in a series

Table 87.2 Diagnostic tests for Wilson disease

Diagnostic test	Diagnostic values	Causes of false positive	Causes of false negative
Serum ceruloplasmin	< 20 mg/dL	Kwashiorkor, nutritional copper deficiency, protein-losing state, fulminant hepatitis, hepatic failure, hereditary hypoceruloplasminemia or aceruloplasminemia, Wilson disease heterozygote, Menkes syndrome, normal neonate	Acute inflammation (hepatitis), malignancy, pregnancy or estrogen therapy in Wilson disease (5% of patients), immunoassays of apo-ceruloplasmin
Hepatic copper concentration	> 250 μg/g dry weight	Primary biliary cirrhosis, Indian childhood cirrhosis, chronic cholestatic liver disease, primary sclerosing cholangitis, Alagille syndrome, liver tumors, newborn liver	Copper chelation therapy in Wilson disease
24-Hour urine copper excretion	> 100 μg/24 h	Copper chelation therapy, chronic active hepatitis, chronic cholestatic liver diseases, primary sclerosing cholangitis, hepatic failure, nephrotic syndrome	Copper chelation therapy in Wilson disease
Presence of Kayser–Fleischer rings	Present	Chronic cholestatic liver diseases, primary biliary cirrhosis, neonatal cholestasis	Early Wilson disease
Incorporation of ^{64}Cu into ceruloplasmin	Low	Ceruloplasmin < 20 mg/dL, Wilson disease heterozygote	Pregnancy, estrogens, inflammation or malignancy in Wilson disease

Adapted from Scheinberg & Sternlieb [2], with permission.

of 20 patients with neurological symptoms, two did not have KF rings [32]. In the presence of "normal" neurological or psychiatric function, the absence of a KF ring does not exclude Wilson disease, as it is present in only 50% of these patients. The common biochemical tests used for diagnosis of Wilson disease are plasma ceruloplasmin, hepatic copper concentration, and 24-h urine copper excretion (basal and after penicillamine challenge) (Table 87.2). For patients presenting with liver dysfunction, ceruloplasmin is generally less than 20 mg/dL, 24-h urine copper is above 100 μg, and hepatic copper concentration is greater than 250 μg/g dry weight. Other conditions that can give rise to increased hepatic copper concentration (Table 87.2) must be excluded with appropriate testing. Two studies [33,34] demonstrated improved discrimination between Wilson disease and other liver disorders when 24-h urine copper was measured after a penicillamine challenge (500 mg given orally immediately before and repeated 12 h into the urine collection). Values above 1575 μg of copper in this 24-h urine collection indicated Wilson disease. Quantitative hepatic copper determination is essential, with normal copper content below 50 μg/g dry weight [35] but virtually always above 250 μg/g dry weight in Wilson disease [2], if not considerably higher. It should be stressed that liver biopsy samples must be obtained in copper-free stainless steel needles to prevent contamination.

Unfortunately, the assays used to analyze serum for ceruloplasmin have changed over recent years from chemical to immunological techniques. Apo-ceruloplasmin is recognized by these assays, resulting in higher values than those previously measured by oxidase techniques [31]. Therefore, a ceruloplasmin level between 20 and 30 mg/dL cannot be used on its own to definitively exclude Wilson disease. If there is a high suspicion of Wilson disease, the 24-h urine copper excretion, slit-lamp examination, and perhaps liver biopsy or genetic testing should be performed despite a low normal level of ceruloplasmin. If a sibling has Wilson disease, genetic diagnosis or microsatellite (haplotype) analysis is helpful for diagnosing Wilson disease. Incorporation of copper 64 (^{64}Cu) into ceruloplasmin is no longer an available test. Finally, genotyping of *ATP7B* (see http://www.genetests.org for available laboratories) may be useful if diagnosis cannot be definitely established using biochemical and clinical criteria [36].

In patients with fulminant hepatic failure, specimens to establish the diagnosis of Wilson disease may be difficult to obtain. Standard liver biopsy may be contraindicated because of coagulopathy, and the patient may be in acute renal failure so collection of a 24-h urine specimen for copper analysis may not be possible. However, the diagnostic features of a severe hemolytic anemia, extremely high serum bilirubin, acute oliguric renal failure, low serum alkaline phosphatase, elevated serum copper values, and inappropriately mild elevations of aminotransferase levels are very suggestive of this diagnosis. If transjugular liver biopsy is performed, quantitative copper should be obtained. Because these patients will either succumb to their illness or undergo a liver transplant, the explanted or autopsied liver should be evaluated for histology and for copper content to confirm this diagnosis.

Treatment

Wilson disease is uniformly fatal without effective therapy. Therefore the hallmark of medical management is early

diagnosis followed by reduction (or chelation) of the accumulated burden of copper and prevention of further retention of copper [31]. For symptomatic patients, most authorities recommend copper chelating agents and a low-copper diet. For maintenance therapy, copper chelators or oral zinc therapy may be effective.

When the diagnosis of Wilson disease is established in a symptomatic patient, treatment should begin with either triethylenetetramine dihydrochloride (trientine) or penicillamine [31]. In recent years it has become evident that trientine is better tolerated in most patients than penicillamine. The dose of trientine in adults and adolescents is approximately 1–2 g daily in three divided doses 1 h prior to meals. The dose of penicillamine is also 1–2 g per day in three divided doses, given at least 30 min before or 2 h after meals [2]. In young children, the dose for each of these drugs is approximately 20 mg/kg daily rounded to the nearest multiple of 250 mg given in divided doses over 24 h. After stabilization, the dose of trientine or penicillamine can be divided into two daily doses, and reduced to approximately 1 g/day in adults. Penicillamine may have an antipyridoxine effect [2], and thus all patients receiving this medication should also receive pyridoxine 25 mg daily. It is recommended that penicillamine or trientine be started at one-fourth to half the desired dose and increased gradually over 1–2 weeks to assure tolerance of the medication. Within the initial month of therapy the patient should be monitored for signs of acute allergic reactions or other toxicities. Thus, a complete blood count, urinalysis, and renal and liver tests should be obtained weekly for the first month. If the patient responds appropriately, monitoring is then performed each 1–3 months for the first year, and then every 6–12 months thereafter. Some experts recommend following 24-h urine excretion of copper to monitor chelation therapy, obtained several times in the first 12 months and then yearly thereafter. Several hundred milligrams to several grams of copper should initially be excreted over 24 h, but after several years of chelation as little as 0–300 μg of copper should be excreted daily [2,51]. If urinary copper excretion is very low or very high, it suggests poor compliance with therapy. If KF rings had initially been present, then serial ophthalmological examinations annually should be performed to be certain that these lesions disappear with time. The failure of disappearance again suggests poor compliance. Many authorities recommend lifelong chelation therapy with trientine or penicillamine in patients who respond well to therapy and show no sign of toxicity rather than converting to zinc monotherapy (see below). Sudden discontinuation of chelation therapy can precipitate fulminant liver failure within months, which is usually fatal or requires liver transplantation [37]. Recent reports suggest that the combination of trientine and zinc therapy may offer benefit in patients with decompensated liver disease [38].

It has been demonstrated that up to 30% of patients [39] will have some worsening of neurological symptoms when treated with penicillamine. It has been proposed that the cause of this neurological worsening is a transient increase in blood copper and then brain copper exposure as the penicillamine mobilizes hepatic copper stores [40,41] or that penicillamine may form a complex of intracellular copper that is more toxic [41]. Neurological exacerbation has also been reported following initiation of treatment with trientine [42], thiomolybdates [43], and zinc [44]; however the frequency seems to be lower than with penicillamine. For these reasons, Brewer and colleagues [45] have proposed the use of ammonium tetrathiomolybdate for initial therapy in neurologically affected patients, although it remains an investigational compound. Ammonium tetrathiomolybdate complexes with dietary copper, thus preventing its absorption, and when absorbed forms complexes with copper and albumin in blood that prevent cellular uptake and decrease intracellular copper stores. Concerns have been raised regarding bone marrow suppression and other toxicities of ammonium tetrathiomolybdate, and this drug is under continuing investigation. A study has suggested improved preservation of neurological function in newly diagnosed patients treated with ammonium tetrathiomolybdate compared with trientine [46].

Penicillamine may produce both allergic and toxic effects in up to 20% of patients [31] Trientine is associated with a lower frequency of side effects, and is therefore recommended by many authorities as a safer initial chelator for Wilson disease. Side effects of penicillamine include fever, skin rash, lymphadenopathy, pancytopenia, proteinuria, nephrotic syndrome, drug-associated systemic lupus erythematosus, Goodpasture syndrome, optic neuritis, and bone marrow suppression. Long-term therapy with penicillamine may cause a dermatopathy [47,48].

Patients who present with fulminant hepatic failure caused by Wilson disease rarely, if ever, survive unless orthotopic liver transplantation is performed. These patients require critical care therapy in a liver transplantation center fully equipped to use hemodialysis, plasmapheresis, and other means of sustaining the patient until liver transplantation can be performed.

The use of oral zinc therapy has been proposed as maintenance or adjunctive [49] therapy for Wilson disease. Zinc inhibits intestinal absorption of copper by increasing metallothionein binding of copper in intestinal epithelia, which are sloughed in the gut. Some authorities recommend starting zinc acetate at 50 mg elemental zinc three times daily [50] or zinc sulfate 150–220 mg three times daily [50]. The zinc must be given between meals, and compliance may limit the effectiveness of this therapy. Zinc therapy is generally not used as initial therapy of symptomatic patients because of its slower onset of action; however, it has been substituted for copper chelators as chronic maintenance therapy with excellent results [31,51]. It may also play a role in presymp-

tomatic patients or siblings (especially young children) who are diagnosed with Wilson disease. Iron status needs to be monitored on patients undergoing chronic zinc therapy as it may interfere with iron absorption.

Finally, the use of antioxidants as adjunctive therapy in Wilson disease has not been fully explored. Because copper induces oxidative damage to the hepatocyte [27,52] and because α-tocopherol levels may be low during copper overload [27,52], it has been proposed that α-tocopherol might be an adjunctive therapy in symptomatic patients with Wilson disease [36].

The role of orthotopic liver transplantation is well established in patients with fulminant liver failure caused by Wilson disease [31]. In addition, patients with end-stage liver disease caused by Wilsonian cirrhosis should be considered for liver transplantation, as would other patients with cirrhosis. Long-term survival is excellent following liver transplantation and the liver lesion does not recur following transplant because of the presence of ATP7B in the donor liver. Neurological features generally improve following liver transplantation, although transplantation is not recommended for treating the isolated neurological presentation of Wilson disease.

Reye syndrome

In the 1960s and 1970s, reports of children developing an apparently new disease called encephalopathy with fatty liver appeared in Australia, the USA, and Europe. Mortality was 40–70%, and the disease tended to occur in epidemics, linked to influenza B, varicella infection, and other viral infections. The incidence of Reye syndrome peaked in the early 1980s, rapidly falling during the late 1980s and 1990s following the restriction of aspirin use in children [53]. The decline in incidence was also associated with the discovery and identification of numerous inherited metabolic defects of fatty acid transport and mitochondrial fatty acid oxidation, which harbor similar clinical features to Reye syndrome. Therefore, it is not completely clear whether the near disappearance of Reye syndrome was the result of reduction of aspirin use or the reclassification of many patients into newly discovered inborn errors of metabolism, or both. Many of these fatty acid oxidation defects are now detected by expanded newborn metabolic screening, so clinical presentation at older ages will become rarer in the next decade.

Clinical features

Reye syndrome is characterized by a prodromal febrile illness, usually a viral respiratory illness, followed by the abrupt onset of protracted vomiting after it appears that the child is in a recovery phase from the viral illness. Although cases have most often been linked to epidemics of influenza A and B and varicella infections, Reye syndrome has been reported in associated with almost every viral illness. The vomiting occurs within 3–7 days of the onset of the viral illness, and leads to dehydration and hyperpnea. Patients then rapidly pass through graded stages of encephalopathy, progressing to seizures, cerebral edema, coma, and possibly death. In over 90% of cases in the USA, a history of aspirin use for the treatment of the initial viral illness is obtained. Physical examination reveals an anicteric state with mild to moderate hepatomegaly, neurological dysfunction, overly brisk deep tendon reflexes, and varying degrees of dehydration. Biochemical testing reveals elevated AST and ALT (several hundred to several thousand units per liter), a normal serum bilirubin and albumin, elevated prothrombin time and international normalized ratio (INR), hyperammonemia, and hypoglycemia, particularly in young children. The Centers for Disease Control case definition of Reye syndrome includes the presence of acute noninflammatory encephalopathy with a normal cerebrospinal fluid cell count and protein; liver involvement characterized by microvesicular steatosis, AST/ALT elevation of threefold or greater, or hyperammonemia; and no other known explanation for the patient's illness. In recent years various metabolic disorders that induce fatty liver have been identified in patients presenting in this manner. During epidemics, patients with Reye syndrome were generally school age to teenage children who were previously healthy; however, a subgroup of children presented within the first few years of life, frequently with underlying failure to thrive and hypoglycemia in the presentation. Interestingly, respiratory alkalosis was present, lactic acidosis was rare, but dicarboxylic organic aciduria was common.

Hepatic histology

Reye syndrome causes extensive hepatic panlobular microvesicular steatosis, characterized by foaminess of hepatocytes with centrally placed nuclei. The fat deposition may be subtle and require special fat stains to identify microvesicular steatosis. Cholestasis is absent, and inflammation is unusual. Electron microscopic examination of the liver shows striking mitochondrial morphological abnormalities. Variable degrees of mitochondrial swelling, pleomorphism, loss of dense bodies, and matrix edema are present, correlating with severity of the disease. Striking microvesicular steatosis is present early in the course, progressing to macrovesicular steatosis during the recovery phase. Similar findings have been reported in fatty acid oxidation disorders and mitochondrial respiratory chain deficiencies. Hepatocytes do not undergo necrosis, but rather suffer from temporary metabolic (mitochondrial) failure. The central nervous system shows marked cerebral edema, particularly in fatal cases, with changes in neuronal mitochondria resembling those in the liver. Kidney lesions also show lipidosis and mitochondrial abnormalities. Thus, Reye syndrome is believed to be caused by generalized mitochondrial dysfunction and was one of the first well-described mitochondrial hepatopathies.

Genetics

Reye syndrome occurs in children generally aged between 4 and 12 years, with only very rare cases being reported in adults. Occasional cases of recurrent Reye syndrome were reported in very young children, now believed to have been caused by fatty acid oxidation defects and other metabolic disorders that were not identified at the time. Familial cases of Reye syndrome have also been reported, most likely caused by autosomal recessively inherited inborn errors of metabolism.

Pathogenesis and biochemistry

Generalized acute mitochondrial dysfunction underlies the biochemical and clinical abnormalities observed in patients with Reye syndrome [54]. The etiology of the mitochondrial lesions is most likely a combination of viral-induced cytokine-mediated cellular injury and the effect of aspirin on mitochondrial oxidative phosphorylation in perhaps genetically predisposed individuals. Because Reye syndrome has been reported in patients with collagen vascular disorders receiving large doses of aspirin who did not have apparent viral infections, isolated cases may have been caused purely by the effects of aspirin. The similar clinical presentation of fatty acid oxidation defects suggests that many cases of Reye syndrome in the past were undiagnosed defects in this important pathway for cellular energy metabolism, perhaps exacerbated by aspirin ingestion or the effects of viral infection.

The epidemiological association between aspirin intake and Reye syndrome was established in the USA in the late 1970s [55,56]. Subsequently, in 1982, the United States Surgeon General advised against the use of salicylates in children with febrile illnesses, and warning labels were placed on all aspirin products. A dramatic reduction in the use of aspirin in children followed over the next several years, with a coincident decline in the number of reported cases of Reye syndrome. However, in other parts in the world, such as Australia and Asian countries, aspirin use was not associated with Reye syndrome, yet there was dramatic reduction in the number of cases. Thus it has been proposed [57,58] that the discovery of new metabolic diseases (e.g., fatty acid oxidation defects) and closer examination of cases resulted in a clinical reclassification of cases that previously would have been labeled as Reye syndrome. Others claim that the effects of salicylates on mitochondrial oxidative phosphorylation may have brought to clinical recognition cases of subclinical metabolic liver disease [59].

Diagnosis

The diagnosis of Reye syndrome is made clinically, based on a prodromal viral illness, intake of aspirin products, and acute onset of vomiting with progressive encephalopathy and cerebral edema [60]. Hyperammonemia, elevated AST and ALT, prolongation of prothrombin time, and normal or only slightly elevated bilirubin are characteristic. A normal cerebrospinal fluid excludes infectious or other causes of similar illnesses. Toxin ingestion needs to be excluded, as do fatty acid oxidation defects, respiratory chain deficiencies, organic acidopathies, adrenal insufficiency, urea cycle enzymopathies, intracranial lesions such as brain tumors, and nonaccidental trauma. The finding of microvesicular steatosis in a non-inflamed liver with characteristic mitochondrial changes on electron microscopy is consistent with the diagnosis, but may be seen in other inborn errors of metabolism as well [61].

Treatment

Management of Reye syndrome requires early diagnosis and a high index of suspicion for the disease. Initial treatment includes controlled rehydration for the vomiting, and administration of 6–8 mg/kg per min of concentrated solutions of dextrose plus electrolytes to maintain blood glucose above 100 mg/dL. Excessive sedation is avoided and the treatment of hyperammonemia varies among institutions. Intracranial pressure monitoring is necessary for patients who reach the encephalopathy stage of delirium and combativeness, with treatment (intravenous mannitol, pentobarbital coma, hypothermia) aimed at carefully reducing intracranial pressure to maintain cerebral perfusion pressure above 45–50 mmHg [62]. Complications such as pancreatitis, acute renal failure, sepsis, pulmonary hemorrhage or cerebral hemorrhage increase the risk of mortality. Unfortunately, most contemporary cases of Reye syndrome present in stage 3–4 coma, and do not have acceptable central nervous system outcome, despite survival. It should be pointed out that the metabolic liver failure in Reye syndrome undergoes spontaneous reversal (consistent with the effects of a toxin or metabolic disorder) during the first 2–3 weeks of illness, except for continued hepatic steatosis.

α_1-Antitrypsin deficiency

α_1-Antitrypsin deficiency affects 1 in 600 to 1 in 2000 live births. The PiZZ homozygous phenotype (and the rarer PiSZ phenotype) causes an autosomal recessive disorder in which there is defective folding and secretion of α_1-antitrypsin from the liver, resulting in serum levels of only 10–20% of normal. The mutant α_1-antitrypsin Z protein is trapped in the endoplasmic reticulum of the hepatocyte, causing overt liver injury in 10–20% of affected individuals [63]. The protein belongs to the family of circulating serine protease inhibitors called *serpins*, and is an approximately 55-kDa secreted glycoprotein that inhibits neutrophil proteases and elastases. In recent years, other functions of α_1-antitrypsin have been identified that may be of clinical importance [64]. For reasons that are not clear, only 10–15% of PiZZ-affected individuals develop liver abnormalities during the first 20 years of life. In adults, emphysema is common in affected homozygotes, particularly in association with chronic exposure to cigarette smoke and other pollutants. α_1-Antitrypsin deficiency is the most common genetic cause of liver disease in children

that leads to cirrhosis, and hence is the leading genetic indication for orthotopic liver transplantation.

Clinical features

Persistent neonatal cholestatic jaundice is the most common childhood presentation of α_1-antitrypsin deficiency. Occasional infants present with acholic stools, direct hyperbilirubinemia, and high serum levels of γ-glutamyltransferase, mimicking the clinical appearance of biliary atresia. Affected infants tend to have been small for gestational age at birth. Serum aminotransferase levels, alkaline phosphatase, and γ-glutamyltransferase may all be elevated. Hepatomegaly with a firm liver and splenomegaly are variable on physical examination. Occasionally patients present with a secondary vitamin K deficiency coagulopathy causing bleeding in the first few months of life. Other affected infants and young children will present abruptly with symptoms of portal hypertension, such as esophageal variceal bleeding or hypersplenism. A very small number of patients present in acute fulminant liver failure during infancy. In adults, α_1-antitrypsin deficiency may cause chronic hepatitis, cirrhosis, portal hypertension, or present as hepatocellular carcinoma [65]. There is also a slight increase in the risk of cryptogenic cirrhosis in adults who are PiMZ heterozygotes.

Sveger [66] has conducted a long-term prospective study examining α_1-antitrypsin phenotype in 200 000 newborn infants in Sweden. Of these 200 000 infants, 127 PiZZ infants were detected, 14 of whom had cholestatic jaundice in infancy, nine of whom had severe liver disease. Approximately 50% of the PiZZ individuals had abnormal aminotransferase levels without any other indication of liver involvement. Through childhood, more than 85% of the 127 patients had normalization and persistently normal aminotransferase levels with no evidence of liver disease or liver dysfunction. This prospective study in Swedish children suggests that only 5–10% of all PiZZ children will develop significant liver disease. However, it is well appreciated that subclinical hepatic fibrosis and even cirrhosis can occur in this disease without elevated liver blood tests.

Several other alleles of α_1-antitrypsin have been associated with liver disease. Children with the less common phenotype PiSZ appear to develop liver disease in a similar manner to PiZZ-affected children. PiSS-affected children do not develop liver disease. Other rare forms of α_1-antitrypsin deficiency have occasionally been associated with liver disease [67,68].

It is rare for emphysema or any significant pulmonary involvement to affect children with α_1-antitrypsin deficiency. In one study there were no significant differences between pulmonary function of PiZZ children and that of an age-matched control group between 13 and 17 years of age [69]. In adults over the age of 25 years, approximately 60–70% with α_1-antitrypsin deficiency may develop variable degrees of emphysema, generally in the fourth or fifth decade. Thus it is recommended that α_1-antitrypsin phenotype or genotype be evaluated in all adults with chronic obstructive pulmonary disease.

Hepatic histology

Liver histology in PiZZ homozygotes ranges from a benign-appearing, almost normal liver to one of extensive cirrhosis. The classic hallmarks of this deficiency are the periodic acid–Schiff (PAS)-positive, diastase-resistant globules that appear in periportal hepatocytes. These globules represent retained α_1-antitrypsin material in the endoplasmic reticulum of hepatocytes. Globules may not be easily recognized in PiZZ infants until up to 6 months of age [70], and thus initial liver biopsy in an affected infant may not reveal these globules. In the neonate, a giant-cell hepatitis with multinucleated giant cells, lobular disarray, cellular and canalicular cholestasis, and bile duct proliferation is commonly observed. Occasionally, the extent of bile duct proliferation and bile duct plugging suggests the diagnosis of biliary atresia. As the child becomes older, a more benign appearance of bridging hepatic fibrosis with minimal or no giant-cell transformation is observed. The liver can also manifest the appearance of a chronic hepatitis, and show increased iron deposition. Approximately 10–30% of affected infants with cholestatic jaundice develop a mixed macronodular and micronodular cirrhosis. Bile ducts are generally normal; however, in 5–10% of children who present with neonatal cholestasis, paucity of interlobular bile ducts will develop, causing chronic cholestatic disease.

Genetics

α_1-Antitrypsin is encoded by a 12.2-kb gene located on human chromosome 14q31–32.2 [71,72]. Structural variants of the α_1-antitrypsin protein are classified by the protease inhibitor phenotype system defined by agarose electrophoresis or isoelectric focusing of plasma [72]. A letter is assigned to variants according to the position of migration of α_1-antitrypsin in these gel systems. The more common normal variant migrates in an intermediate isoelectric point, and has been designated M. The most severe deficiency form migrates to a high isoelectric point, and has been designated Z. More than 100 allelic variants of α_1-antitrypsin have been reported, all inherited in an autosomal recessive fashion. With some variants there is no α_1-antitrypsin detectable in serum, the so-called null variants. Not all variants are associated with clinical disease. Emphysema and liver disease have been associated with the PiSZ, PiZZ, M_{malton} and M_{duarte} variants. The heterozygote state does not confer disease susceptibility, except for the small increased risk that the PiMZ heterozygote state poses for cryptogenic cirrhosis in adults. Studies have also suggested that the PiMZ state may predispose to more severe liver disease in a variety of hepatic disorders [73].

Pathogenesis and biochemistry

The pathogenesis of liver injury in α_1-antitrypsin deficiency has not been completely defined. It is clear that the

accumulation of mutant α_1-antitrypsin protein in the endoplasmic reticulum of liver cells is involved in its pathogenesis. In fact, transgenic mice carrying the mutant Z allele of the human α_1-antitrypsin gene develop PAS-positive, diastase-resistant globules in the liver as well as liver injury [74,75], despite possessing the normal mouse α_1-antitrypsin gene. It is difficult therefore to understand why only 10–15% of patients develop significant disease, since all PiZZ-affected individuals have globules present in their liver. Perlmutter and colleagues have demonstrated delay of degradation of mutant α_1-antitrypsin Z protein in fibroblasts from PiZZ individuals with liver disease compared to those without liver disease [76], providing evidence that other factors affecting the fate of mutant α_1-antitrypsin molecules may play a role in determining genetic susceptibility to liver disease. It has also been suggested that another normal cellular mechanism for disposing of endoplasmic reticulum-accumulated proteins, autophagy, may be genetically defective in those patients who develop liver disease [77]. This important role for a modifier gene may help explain the 10–15% incidence of significant liver disease in this and other single-gene mutation metabolic disorders [78].

Diagnosis

Diagnosis is established by isoelectric focusing or agarose electrophoresis of a patient's serum α_1-antitrypsin, or by genotyping for the Z allele. Generally, with the PiZZ phenotype, total serum levels of α_1-antitrypsin are found to be 10–20% of normal values. Establishing the exact phenotype or genotype assists in determining the risk to the patient for liver disease. For example, the PiSS phenotype elicits no risk for liver disease, whereas PiSZ and PiZZ do pose this risk. All infants with neonatal cholestatic jaundice require α_1-antitrypsin testing, inasmuch as it may be very difficult to clinically or histologically identify the disease at this time. Infants with α_1-antitrypsin deficiency may mimic the presentation of biliary atresia, including acholic stools, failure of biliary excretion on nuclear scintigraphy, and liver biopsy findings that are similar. It is said that α_1-antitrypsin concentrations may increase during the acute-phase response; however, serum concentrations virtually never exceed 50–60 mg/dL in patients with the PiZZ phenotype, allowing the use of serum concentrations as a screen for deficiency. The finding of PAS-positive, diastase-resistant globules on liver biopsy should never in itself be used to either confirm or exclude the diagnosis of α_1-antitrypsin deficiency, as some patients with the MZ phenotype have been reported to harbor these inclusions on liver biopsy.

Treatment

There is no specific therapy for α_1-antitrypsin deficiency-associated liver disease; however, several measures are taken in infants with the cholestatic presentation. Fat-soluble (vitamins A, D, E and K) supplementation and an infant formula containing medium-chain triglyceride oil are administered until the cholestasis resolves. In addition, ursodeoxycholic acid is frequently prescribed to increase bile flow and reduce liver injury from cholestasis, as in other neonatal cholestatic diseases. Although early studies suggested that breast-feeding might be beneficial [79], subsequent data from the Swedish Nationwide Screening Study did not support this contention [80]. Approximately 10–30% of infants diagnosed with α_1-antitrypsin deficiency who have neonatal cholestasis progress within the first 5 years to cirrhosis and end-stage liver disease, requiring liver transplantation sometime during childhood. The remaining 70–90% of patient either show complete recovery from liver injury or have variable degrees of chronic elevated aminotransferases and progressive hepatic fibrosis.

Complications of portal hypertension are treated as they are in other childhood liver diseases. Orthotopic liver transplantation is required for children with end-stage liver disease, in whom hepatic synthetic functional failure or severe complications do not respond to standard therapy.

Patients with emphysema caused by α_1-antitrypsin deficiency are now treated with replacement therapy with purified or recombinant plasma α_1-antitrypsin, either by intratracheal aerosol administration or by intravenous administration [81]. Improvement in serum concentrations of α_1-antitrypsin without significant side effects results from these therapies. One nonrandomized trial suggested that there was slower decline in forced expiratory volume in 1 s (FEV1) in patients on replacement therapy [82]. Lung transplantation has been performed in a number of patients with severe emphysema. Actuarial survival is approximately 50% at 5 years [83]. Clinical trials with 4-phenylbutyrate, a chemical chaperone used to potentially increase α_1-antitrypsin secretion from the hepatocyte, failed to show any clinical benefit yet with considerable side effects [84]. α_1-Antitrypsin deficiency is certainly a disease that could benefit from successful gene replacement therapy and investigation in this arena will continue.

Finally, siblings of all affected patients with the PiZZ phenotype should be screened by isoelectric focusing, agarose gel electrophoresis, or genotyping. If identified as a homozygote, strict avoidance of cigarette smoke and other air pollutants may help prevent the onset of emphysema later in life.

Porphyria

Eight metabolic disorders called the porphyrias are caused by inherited deficiencies or inhibition of the enzymes involved in the heme biosynthesis pathway. Each of these disorders is characterized by the accumulation of distinct substrates or precursors of heme that provide characteristic biochemical footprints in blood, urine, and feces, allowing differentiation of the specific type of porphyria. The accumulated compounds, rather than impaired synthesis of heme, are responsible for

Table 87.3 Clinical features of human porphyrias

Disease	Affected enzyme	Mode of inheritance	Site of expression	Urine porphyrins	Fecal porphyrins	Clinical manifestations
Acute porphyrias						
ALA dehydratase deficiency	ALA dehydratase	Recessive	Liver	ALA		Neuropsychiatric
Acute intermittent porphyria	PBG deaminase	Dominant	Liver	ALA, PBG		Neuropsychiatric
Hereditary coproporphyria	Coproporphyrinogen oxidase	Dominant	Liver	ALA, PBG, coproporphyrin	Coproporphyrin	Neuropsychiatric, cutaneous
Variegate porphyria	Protoporphyrinogen oxidase	Dominant	Liver	ALA, PBG coproporphyrin	Protoporphyrin, coproporphyrin	Neuropsychiatric, cutaneous
Cutaneous porphyrias						
Porphyria cutanea tarda	Uroporphyrinogen decarboxylase	Dominant or acquired	Liver ± RBCs	Uroporphyrin, 7-carboxylporphyrin	Isocoproporphyrin	Cutaneous
Hepatoerythropoietic porphyria	Uroporphyrinogen decarboxylase	Recessive	Liver, RBCs	Uroporphyrin, 7-carboxylporphyrin	Isocoproporphyrin	Cutaneous
Congenital erythropoietic porphyria	Uroporphyrinogen III synthase	Recessive	RBCs	Uroporphyrin I, coproporphyrin I	Coproporphyrin I	Cutaneous, hemolytic anemia
Protoporphyria	Ferrochelatase	Dominant or recessive	RBCs and liver		Protoporphyrin, coproporphyrin	Cutaneous, liver disease

ALA, aminolevulinic acid; PBG, porphobilinogen; RBC, red blood cell.

the cutaneous, hepatic, neuropsychiatric, and hematological manifestations of the porphyrias. Three of the porphyrias are inherited in autosomal recessive fashion, and five by autosomal dominant inheritance. Most patients present during or after puberty; however, onset in infancy or early childhood has been reported on occasion [85–91]. Five of the porphyrias are expressed exclusively in the liver, two in both liver and erythroid cells, and one type has only erythroid expression [85–88]. Porphyrias are generally classified into the acute and cutaneous porphyrias based on their clinical presentation. In the acute porphyrias, one or both of the porphyrin precursors, aminolevulinic acid (ALA) and porphobilinogen (PBG), is increased. In the cutaneous porphyrias, porphyrins rather than ALA accumulate. Diagnostic studies and clinical features of the major porphyrias are outlined in Table 87.3.

Acute porphyrias

Four hepatic porphyrias present with acute attacks of potentially life-threatening neurological dysfunction. These attacks generally begin around puberty, and may diminish after the fifth decade of life. The most common symptoms include abdominal pain, constipation, and vomiting, presumably caused by autonomic nervous system dysfunction of the gastrointestinal tract. A peripheral neuropathy may develop into flaccid quadriplegia with respiratory compromise in severe cases. Psychiatric symptoms may include depression, psychosis, and hysterical behavior [85–87,92–98]. The development of neurological symptoms is related to blood levels of ALA, although the exact mechanism by which ALA functions as a neurotoxin has not been determined. Drugs and toxins that increase cytochrome P450 activity may precipitate acute attacks; relative iron deficiency and cyclical progesterone excretion in menstruating females may be responsible for the higher frequency of acute attacks in women compared to men.

Hepatic abnormalities in the acute porphyrias are characterized by mild AST and ALT elevations during acute attacks. Histology of the liver typically shows steatosis and increased iron deposition. Intramitochondrial crystalline inclusions have also been described [92,93,99–103]. A disturbing high incidence of hepatocellular carcinoma has been described in patients with inducible porphyrias [104].

Acute intermittent porphyria

The most common form of acute porphyria is acute intermittent porphyria (AIP). Porphobilinogen deaminase (also known as hydroxymethylbilane synthase) is the defective enzyme in this autosomal dominant disease. The prevalence is approximately 1 in 1000 to 1 in 2000 [92,105]. Diagnosis is established by the determination of large amounts of ALA and PBG in 24-h urine collections during acute attacks, with

PBG excretion exceeding ALA. A characteristic of AIP is a black or red color of a patient's urine after exposure to light or air. In asymptomatic patients, urinary PBG and ALA excretion may be normal. A diagnosis is then established by enzyme analysis in liver tissue or red blood cell lysates, or identification of disease-causing mutations in leukocyte DNA [93,106]. There have been more than 240 mutations identified in porphobilinogen deaminase.

Mild attacks of AIP are treated by careful management of fluids and electrolytes and intravenous carbohydrate loading, avoidance of drugs that may precipitate symptoms, and observation. Pain is controlled by narcotic analgesics. Restlessness and insomnia may be treated with benzodiazepines. Severe neurological symptoms are treated with intravenous hematin, which inhibits hepatic ALA synthetase activity, yielding lower circulating levels of ALA [107,108]. The standard dose is 3–4 mg of heme in the form of lyophilized hematin (Ovation Pharmaceuticals). Neuropathy may require months or years to show complete recovery. Liver transplantation has been used in very unusual circumstances for severe unremitting symptoms [109]. The risk of hepatocellular carcinoma is increased, frequently unassociated with elevated serum α-fetoprotein. Annual hepatic imaging has been recommended to screen for hepatocellular carcinoma.

Other acute porphyrias

Hereditary coproporphyria (HCP), variegate porphyria (VP), and ALA dehydratase deficiency comprise the other acute porphyrias. HCP and VP are inherited in an autosomal dominant fashion. Urinary and fecal coproporphyrin III excretion is elevated in these two disorders, with fecal protoporphyrin being present in VP. Cutaneous manifestations predominate over neurological symptoms in these two dominant conditions. The accumulation of porphyrins in the skin is responsible for the cutaneous lesions. Neurological symptoms can resemble those of AIP. ALA dehydratase deficiency is a very rare autosomal recessive disorder, yielding exclusive excretion of ALA without PBG in the urine. The disease is characterized by severe acute neuropsychiatric porphyria episodes that are poorly responsive to medical treatment [110]. Treatment of neurological attacks in all these conditions follows the protocol for the treatment of AIP attacks.

Cutaneous porphyrias

Four of the porphyrias are characterized by cutaneous lesions without neurological or psychiatric involvement, although significant hepatic involvement may be observed. These diseases include porphyria cutanea tarda (PCT), hepatoerythropoietic porphyria (HEP), congenital erythropoietic porphyria (CEP), and protoporphyria. Two types of skin photosensitivity develop in the cutaneous porphyrias. Skin lesions appear to be the result of photoexcitation of porphyrins located in the upper levels of the epidermis or walls of dermal blood vessels, with resulting reactive oxygen species generation leading to tissue injury by a variety of proposed mechanisms [111–116]. Patients with PCT, HEP, and CEP have increased skin fragility in light-exposed areas, manifested by the formation of bullous lesions, secondary scarring, and hypertrichosis. Patients with protoporphyria show immediate photosensitivity with itching, burning, and erythema soon after light exposure. Although they do not develop bullae, chronic skin changes evolve into leathery hyperkeratotic skin in light-exposed areas.

Porphyria cutanea tarda

PCT is the most common form of porphyria in North America and Europe, inherited as an autosomal dominant disorder or acquired during chronic hepatitis C and other infectious diseases. PCT may also be associated with toxins, particularly halogenated hydrocarbons. The genetic form of PCT is caused by deficiency of uroporphyrinogen decarboxylase. Urinary and fecal uroporphyrins are elevated (Table 87.3) but PBG levels are normal. Most patients with PCT present in adulthood, with photosensitivity skin reactions, scarring, infection, and lichenification of the skin. Because many individuals with the identical enzyme deficiency remain asymptomatic, others have sought coexisting abnormalities that must be present in order to develop overt disease. These include iron overload, a mutated allele in the hereditary hemochromatosis (*HFE*) gene, the presence of hepatitis C viral infection, ethanol ingestion, or Alagille syndrome. Ingestion of ethanol, toxins, and estrogens may also be involved in the development of sporadic cases of PCT.

Liver involvement is a frequent finding in PCT, even in those without chronic hepatitis C or ethanol abuse, manifested by hepatomegaly, focal inflammation, granuloma formation, and hepatic hemosiderosis. Progression to cirrhosis is not uncommon [117–119]. It remains controversial whether there is an increased risk for hepatocellular carcinoma in patients with PCT [120,121].

Therapy for PCT includes phlebotomy or chelation therapy to reduce the iron burden. Chloroquine has been used to form complexes with uroporphyrin to enhance removal of these deposits from skin, especially if there is a contraindication to phlebotomy. These treatments may be combined in patients with significant liver disease, although their efficacy is still unclear [87,90,117,122]. It has been recommended that treatment of concurrent hepatitis C infection should be delayed until the PCT has been treated and is in remission.

Erythropoietic protoporphyria

Erythropoietic protoporphyria is one of the most common forms of porphyria in North America, caused by a defect in ferrochelatase. The enzyme can be measured in liver and red blood cells, being less than 50% of normal in almost all cases. Affected patients have elevated levels of erythrocyte, plasma, and fecal protoporphyrin [123–125]. The primary clinical

manifestation of protoporphyria is photosensitivity, which generally appears in childhood as burning, pruritus, erythema, and edema in light-exposed areas. Scarring and lichenification of the skin develop with time. Avoidance of light, use of sunscreens, and oral administration of carotenoids appear to be the most efficacious treatments for the skin lesions. Approximately 20% of patients may have minor abnormalities of liver function; however, 5–10% of affected patients develop significant hepatic involvement, with reports in children as young as 10 years of age. Jaundice is generally the first indication of hepatic dysfunction, although rapid progression of decompensated cirrhosis may lead to liver failure within several years of clinical presentation [126–130]. The liver is black in color, enlarged, and exhibits fibrosis and macronodular cirrhosis. Dark brown pigment representing protoporphyrin deposits are found in hepatocytes, Kupffer cells, and small biliary ducts. Insoluble protoporphyrin appears to plug small bile ducts, interrupting bile flow, and may initiate oxidative injury to hepatocytes. It is unclear why only 5–10% of patients develop progressive liver disease, but other gene modifiers or environmental factors must be involved. Other manifestations of protoporphyria include hemolysis, neurological dysfunction, and gallstones.

Treatment of individuals with liver disease is aimed at reduction of protoporphyrin levels in the liver. Iron supplementation and blood transfusions have been used in the past to diminish erythropoiesis, thereby reducing protoporphyrin production [131]. Plasmapheresis or hematin therapy has similarly been shown to decrease plasma protoporphyrin in several patients [132]. Interestingly, administration of chenodeoxycholic acid has been demonstrated to increase protoporphyrin excretion into bile [87–90,122]. Cholestyramine and activated charcoal both bind protoporphyrin, interrupting the enterohepatic circulation and increasing fecal excretion [93,133]. These modalities do decrease circulating levels of protoporphyrin, but have not been shown to conclusively affect the course of liver disease. Although orthotopic liver transplantation has been performed in several patients with end-stage liver disease, protoporphyrin production continues in the bone marrow, depositing protoporphyrins in the newly transplanted allograft [134,135]. In addition, skin lesions and neurological symptoms may continue, complicating the postoperative course. Thus, bone marrow transplant, either alone or following liver transplant, has been suggested in patients with severe disease [136,137].

Congenital erythropoietic porphyria

CEP is an autosomal recessive disorder caused by deficiency of uroporphyrinogen III cosynthase. It is quite rare, with fewer than 100 patients reported. The major manifestations are photosensitivity, hypertrichosis, and hemolysis. Liver disease is present and may progress to cirrhosis, with iron overload playing a significant role [87,90,122,138]. Treatment includes limiting light exposure, sunscreens, and β-carotene. Hematin or blood transfusions to decrease erythropoiesis have also been attempted in patients with liver disease [139,140]. Bone marrow and cord blood transplantation have been effective in several severely affected children [141,142].

Metabolic diseases of the neonate and of childhood

Hepatic involvement may be the presenting symptom of a variety of metabolic disorders that occur primarily or exclusively in infancy and childhood. Because effective treatments have been developed for many of these diseases, patients are now surviving into adulthood. Disorders of amino acid, carbohydrate, lipid, ammonia and mitochondrial metabolism may all have hepatic involvement as the primary clinical manifestation. It is beyond the scope of this chapter to describe in detail all childhood metabolic liver diseases; the reader is referred to recent textbooks for further details [1]. This chapter describes several of the most common genetic metabolic liver diseases of infancy and early childhood.

Hereditary tyrosinemia

Hereditary tyrosinemia is caused by deficiency of the enzyme fumarylacetoacetate hydrolase (FAH), the terminal enzyme in the pathway of phenylalanine and tyrosine degradation. Many mutations of the *FAH* gene have been identified, with unique mutations being common in specific ethnic groups, although there are no definite genotype–phenotype correlations in severity of the disease. Thus undefined environmental or other genetic factors play a role in determining the clinical severity of tyrosinemia. A number of metabolites of tyrosine accumulate proximal to the FAH block, including tyrosine and succinylacetone. Succinylacetone and succinylacetoacetate inhibit enzymes such as porphobilinogen synthase, which causes the build-up of ALA and symptoms similar to that of AIP [143,144]. It is unclear how accumulated toxic compounds initiate liver injury in tyrosinemia.

Tyrosinemia may present in infancy as acute hepatic failure, neonatal cholestasis, rickets, failure to thrive, or as compensated or decompensated cirrhosis later in childhood [145]. There is also a very high incidence of hepatocellular carcinoma in untreated affected children. Episodes of acute peripheral neuropathy may lead to pain, respiratory depression, and even death [146]. Children who present during infancy have decreased survival compared to those with a later presentation in childhood [147]. Cardiomyopathy has been described in 30% of newly diagnosed patients, with inteventricular septal hypertrophy being the commonest finding, although this lesion resolved during treatment in almost all patients [148].

Liver histology is characterized by macrovesicular steatosis, pseudoacinar formation of hepatocyte rosettes, hemosiderosis,

and varying degrees of hepatocyte necrosis and apoptosis. A fine diffuse fibrosis develops, eventually progressing to micronodular cirrhosis. Regenerative nodules are frequently present, and frank hepatocellular carcinoma may occur in patients as early as 2 years of age. The incidence of tyrosinemia is approximately 1 in 100 000; however, there are pockets of high frequency secondary to a founder effect, such as in the Saguenay-Lac Saint Jean region of Quebec, Canada, where the incidence is 1 in 1800 live births [149].

The diagnosis of hereditary tyrosinemia is suggested by features of metabolic liver disease in infants or older children, including diminished hepatic synthetic function (hypoglycemia, coagulopathy, hypoalbuminemia) in the face of only mildly elevated aminotransferases and cirrhosis. Bilirubin may be elevated or normal, and hypophosphatemic rickets may be present. Renal tubular dysfunction causes glycosuria, proteinuria, aminoaciduria, and hyperphosphaturia. Serum α-fetoprotein levels are usually extremely high for age. The diagnosis of tyrosinemia is established by the finding of succinylacetone in the urine. In some research laboratories, FAH activity can be measured in red blood cells. Genetic diagnosis is generally not necessary; however, in Quebec, 100% of patients have a single mutation of the *FAH* gene [150]. Hypertyrosinemia is a nonspecific finding and is not used to establish this diagnosis. Neonatal screening on newborn blood spots dried on filter paper is being carried out in high incidence regions, such as Quebec.

Treatment of hereditary tyrosinemia involves a diet restricted in phenylalanine and tyrosine, although this does not prevent the liver disease but may have beneficial effects on kidneys. Orthotopic liver transplantation reverses the hepatic metabolic abnormalities and reduces the risk for hepatocellular carcinoma, prevents neurological disease, and is usually associated with stabilization of kidney disease. Liver transplant has been considered the preferred option for children with tyrosinemia over the age of 1–2 years. However, the metabolic inhibitor 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC, also called nitisinone) has been shown to be effective in tyrosinemia diagnosed early in infancy [151]. This compound inhibits 4-hydroxyphenylpyruvate dioxygenase, the second enzyme involved in tyrosine degradation which, when inhibited, prevents the production of succinylacetone. Therefore, toxic precursors do not accumulate, liver disease improves dramatically, patients exhibit reduction of α-fetoprotein levels, liver synthetic function improves, and renal tubular damage may resolve. Hundreds of patients have been treated with NTBC. Neurological crises and liver failure are prevented if treatment is initiated within the first month of life. In Quebec, no hepatic nodules have developed in infants treated in this manner, although initiation of therapy at 2–8 months of age has permitted the development of nodules in several patients [151]. The major concern has been that mice homozygous for the *FAH* gene mutation and which develop tyrosinemia respond to NTBC but still develop hepatocellular carcinoma [152]. Whether treatment with NTBC will reduce the high risk for development of hepatocellular carcinoma in children with tyrosinemia over the long term is unknown. In addition the long-term safety of this compound has not been demonstrated. The current recommendation is for continued surveillance for hepatic masses and ocular lesions in children under long-term NTBC therapy. Neurological crises are treated with intravenous dextrose, pain control, NTBC, or hematin.

Galactosemia

Classic galactosemia, an autosomal recessive disorder, results from mutations in the gene for galactose 1-phosphate uridyltransferase (GALT), leading to deficiency of the enzyme [153]. Patients develop chronic cholestatic liver disease, failure to thrive, mental retardation, and cataracts in classic galactosemia. Two other conditions result in elevated plasma galactose concentrations, although without observable liver disease. These include uridine diphosphate 4-epimerase deficiency and galactokinase deficiency, the latter causing only juvenile cataracts. Classic galactosemia is a disease in which toxicity of the liver results from ingested dietary galactose and its failure to be converted to glucose. Most cases are now detected by newborn screening programs, such that it is an unusual patient who presents with neonatal liver disease because treating infants detected by newborn screening prevents liver injury.

The classic presentation of galactosemia is that of vomiting, diarrhea, and failure to thrive following the institution of lactose-containing infant feedings, either breast milk or lactose-containing infant formula [154]. Within weeks to months of birth, hepatomegaly, cholestatic jaundice, and cataracts develop in the affected infant. If left completely untreated, mental retardation develops as well as cirrhosis of the liver. Another classic presentation is that of *Escherichia coli* urinary tract infections and bacteremia, sometimes with a fatal course. Affected females may show ovarian failure due to in utero injury from the galactose toxic products. Laboratory findings include elevated serum aminotransferase levels, prolonged prothrombin time, conjugated hyperbilirubinemia, and hypoalbuminemia. Hemolytic anemia occurs frequently. Renal tubular dysfunction is characterized by generalized aminoaciduria in combination with proteinuria and galactosuria [154].

Pathogenesis

Galactose 1-phosphate accumulates in classic galactosemia, causing injury to the affected organs [153]. Galactose may also be reduced to galactitol, which causes cataracts when it accumulates in the lens of the eye. It appears that galactose 1-phosphate or galactosamine accumulation are responsible for the renal, ovarian, hepatic, and brain abnormalities. Galactose 1-phosphate may also interfere with phosphoglucomutase, an enzyme which allows the release of glucose from glycogen.

Liver biopsy reveals macrovesicular steatosis in the first months of life, with pseudoacinar transformation of hepatocytes, although giant-cell transformation is generally absent. Bile duct proliferation is accompanied by portal fibrosis and the development of cirrhosis over the first several months of life if untreated. The diagnosis of galactosemia is suggested by the detection of reducing substances in the urine with a negative glucose oxidase paper test on the urine. Since vomiting or poor intake of lactose-containing formula or breast milk may limit galactose excretion in the urine, false-negative results of urine reducing substance tests may occur in galactosemia. More specific diagnosis is based on measurements of erythrocyte GALT. If an infant with galactosemia has received a red blood cell transfusion, the red cell enzyme level may be raised into the normal range and the diagnosis missed. Newborn screening programs have been established across the USA and in many areas of the world [154]. Measurement of GALT activity or galactose compounds is the analysis performed on newborn blood spots. There are other causes of elevated galactose in newborn blood spots (e.g., congenital portosystemic shunts), so further evaluation is needed.

Treatment

Treatment of galactosemia is based on the complete elimination of dietary galactose. Infant lactose- and galactose-free formulas have been marketed around the world and are instituted as soon as a diagnosis is made. As the child becomes older, a complete lactose- and galactose-free diet must be maintained [155,156]. It has been suggested that endogenous production of some galactose may be the mechanism that underlies some of the delayed toxicity present in children maintained on a lactose- and galactose-free diet [157]. Follow-up studies have revealed that some patients treated from infancy still suffer poor growth, learning disabilities, and primary ovarian failure in females [157,158].

Hereditary fructose intolerance

Hereditary fructose intolerance is an autosomal recessive disorder caused by deficiency of fructose 1-phosphate aldolase B enzyme activity in the liver. Symptoms occur when fructose is added to the infant's diet, usually in the form of fruit juices or infant formulas that contain sucrose [159,160]. Infants develop vomiting, irritability, hypoglycemia, and even convulsions following the ingestion of fructose. If fructose is not removed from the diet, hepatomegaly, failure to thrive, chronic diarrhea, conjugated hyperbilirubinemia, and metabolic dysfunction ensue, including proximal renal tubular abnormalities [161]. Older children may have a self-aversion to sweets, knowing that these tend to make the child feel ill. Growth delay, the consequences of repeated episodes of hypoglycemia on brain development, and metabolic acidosis eventually complicate the clinical picture.

Liver histology is characterized by diffuse macrovesicular steatosis, scattered hepatocellular necrosis, bile duct proliferation, and periportal fibrosis. Cirrhosis has also been described with complications of portal hypertension. The toxic moiety leading to liver injury is accumulated fructose 1-phosphate. Both hypoglycemia and ATP depletion in hepatocytes is caused by the accumulation of this compound [161].

Diagnosis of hereditary fructose intolerance is suggested by the onset of hypoglycemia, a profound hypophosphatemia, and hyperuricemia following fructose ingestion with detection of fructose in the urine by chromatography. Several common mutations in the gene for this enzyme allow genetic diagnosis in most cases [162]. The incidence of the disease is approximately 1 in 20 000 newborns [163,164]. Because the enzyme is also present in jejunum, it has been suggested that jejunal biopsies can be used for enzyme analysis to establish the diagnosis. Genetic testing is available in clinical and research laboratories [165].

Treatment of hereditary fructose intolerance is based on the complete and lifelong elimination of fructose, sucrose, and sorbitol-containing foods, juices, medications or other compounds from the diet [159,166–168]. Low levels of chronic fructose ingestion may lead to growth failure [166] and persistent hepatic steatohepatitis.

Glycogen storage diseases

Excessive accumulation of glycogen or abnormal synthesis of glycogen in the liver or muscle tissue is the underlying basis for a group of diseases called the glycogen storage diseases (GSD). Seven of the glycogen storage diseases primarily involve the liver, causing a variety of hepatic manifestations. Types Ia, Ib, Ic, and III lead to hypoglycemia and characteristic metabolic derangements; types III, IV, and IX are associated with hepatomegaly and periportal fibrosis; and types VI and IX are associated with benign hepatomegaly. Understanding the underlying genetic enzymatic defects in each of these disorders has produced a better understanding of the pathophysiology and the development of treatment strategies (Table 87.4).

GSD type I

There are three forms of GSD type I, involving the glucose 6-phosphatase enzyme system. Glucose 6-phosphatase catalyzes the last step in the enzymatic degradation of glycogen with release of glucose into the blood. Failure of the proper function of glucose 6-phosphatase leads to profound hypoglycemia during the fasting state. GSD type Ia is caused by deficiency of the glucose 6-phosphatase enzyme. GSD type Ib involves abnormalities in the translocase responsible for movement of glucose 6-phosphate across microsomal membranes to the site of action of glucose 6-phosphatase. GSD type Ic is caused by deficiency of the phosphate–pyrophosphate translocase [169].

GSD type Ia

GSD type Ia (von Gierke disease) is characterized by recurrent episodes of profound and severe hypoglycemia, lactic

Table 87.4 Hepatic glycogen storage diseases (GSD)

GSD type	Enzyme defect	Hepatic symptoms	Liver lesions	Laboratory tests
Ia	Glucose 6-phosphatase	Hypoglycemia, hepatomegaly, lactic acidosis, growth failure	Glycogen accumulation, macrovesicular steatosis	AST/ALT elevations, hyperlipidemia, lactic acidosis, hyperuricemia,
Ib	T1 translocase	Hypoglycemia, hepatomegaly, lactic acidosis, neutropenia and infections, growth failure	Glycogen accumulation, macrovesicular steatosis	AST/ALT elevations, hyperlipidemia, lactic acidosis, hyperuricemia, neutropenia
III	Amylo-1,6-glucosidase (debrancher enzyme)	Hypoglycemia, lactic acidosis, growth failure, variable fibrosis and portal hypertension, hypotonia, cardiomyopathy	Glycogen accumulation, portal fibrosis	AST/ALT elevations, variable hyperlipidemia, lactic acidosis, hyperuricemia
IV	Amylo-1,4→1,6-transglucosidase (brancher enzyme)	Jaundice, hepatosplenomegaly, liver failure, portal hypertension, hypotonia	Glycogen accumulation, cirrhosis, PAS-positive storage material	AST/ALT elevations, coagulopathy, conjugated hyperbilirubinemia, hypoglycemia, hyopalbuminemia
VI	Liver phosphorylase	Hepatomegaly	Glycogen accumulation	AST/ALT elevations
IX	Liver phosphorylase b kinase	Hepatomegaly, rarely portal hypertension	Glycogen accumulation, variable fibrosis	AST/ALT elevations

ALT, alanine aminotransferase; AST, aspartate aminotransferase; PAS, periodic acid–Schiff.

acidemia, hyperuricemia, hypertriglyceridemia, and hypercholesterolemia with accompanying massive hepatomegaly, short stature, and immaturity. The hypoglycemic events frequently start during infancy, when the interval between feedings becomes prolonged beyond 2–3 h, or when the child starts sleeping for longer at night. The untreated child suffers from growth failure and short stature, extreme hepatomegaly without splenomegaly, bleeding episodes caused by platelet dysfunction, renomegaly, and a cherubic appearance secondary to the deposition of "baby fat" in the face and trunk. The abdomen is protuberant, and arms and legs are frequently thin. Impaired glucose production through glycogenolysis leads to overproduction of glucose 6-phosphate, which is shunted into pathways for synthesis of lactate, triglycerides, cholesterol, and uric acid [170]. As a result, glucagon levels are high and insulin levels low. Patients suffer from growth failure if untreated or poorly treated, and eventually develop multiple hepatic adenomas that may evolve into hepatocellular carcinoma. As glucose 6-phosphatase is also expressed in the kidney, enlarged kidneys are common, and nephrocalcinosis or glomerulosclerosis may also develop over time [171]. Hyperuricemia may contribute to chronic renal disease as well as to gouty arthritis [172]. Progressive hepatic fibrosis and portal hypertension virtually never occur in this disorder, although hepatomegaly is extremely prominent. The diagnosis is established by demonstrating elevated hepatic glycogen content and low activity of glucose 6-phosphatase on frozen liver tissue.

Liver histology shows markedly enlarged hepatocytes with pale cytoplasm, causing a mosaic histological appearance. Macrovesicular steatosis is frequent and there is an accumulation of glycogen in both cytoplasm and nucleus under electron microscopy. There is no hepatic fibrosis, cirrhosis, or chronic inflammation.

Treatment of GSD type Ia is directed at providing a continuous source of exogenous glucose to prevent hypoglycemia and the resultant hormonal and metabolic changes [173]. Frequent daytime high-starch meals along with uncooked cornstarch supplements are provided. Cornstarch is given in doses of 1.5–3 g/kg every 3–6 h as needed. In order to maintain blood sugar at night, constant drip feedings of a high glucose-containing elemental formula or glucose solutions are provided through either a nasogastric tube or a gastrostomy tube. The goal is to maintain blood sugar of at least 70 mg/dL. As children become older, many opt to discontinue constant drip feedings at night and ingest uncooked cornstarch at bedtime, and awaken every 4 h at night to drink a dose of cornstarch. Either of these techniques can effectively maintain blood sugar, reverse metabolic abnormalities, and provide adequate growth [174–180]. However, blood sugars need to be monitored periodically and care taken to prevent malfunction of nocturnal enteral pumps. It should be pointed out that hypoglycemia is better tolerated when the children are hyperlipidemic and acidotic than when they are adequately treated with cornstarch or constant drip feedings. However, once the children are well controlled with these modalities, they may react severely to episodes of hypoglycemia, with neurological depression, convulsions, and even death. For patients who cannot be controlled with these therapeutic modalities and for patients with multiple hepatic

adenomas, liver transplantation has been advocated [181]. However, the vast majority of patients can maintain a high quality of life with their native liver.

GSD type Ib

GSD type Ib presents in the same manner as GSD type Ia, although patients also have neutrophil dysfunction and frequently are neutropenic. Therefore they have a propensity toward recurrent bacterial infections, inflammatory bowel disease-like lesions, and oral ulcerations [182–186]. The diagnosis of GSD type Ib is suggested by the finding of neutropenia in a patient who appears to have all the other classic features of GSD type Ia (hypoglycemia on fasting, lactic acidosis, elevated AST and ALT, hypertriglyceridemia, hyperuric acidemia, hepatomegaly, growth failure). This disorder is confirmed by measurements of liver glucose 6-phosphatase activity. In GSD type Ib, which involves the glucose 6-phosphate T1 translocase enzyme, fresh liver homogenate will yield defective activity, whereas frozen liver homogenate will have normal glucose 6-phosphate activity. The reason for this is that freezing disrupts the microsomal enzyme barrier, allowing access of the substrate to glucose 6-phosphatase, thereby bypassing the need for the translocase enzyme. In fresh homogenate tissue, the microsomes are intact, thus necessitating the requirement for the translocase enzyme. This disease is treated similarly to GSD type Ia, plus injections of granulocyte colony-stimulating factor (G-CSF) to elevate neutrophil counts. Inflammatory bowel lesions generally respond to G-CSF therapy but may require other traditional medications for inflammatory bowel disease.

GSD type III

GSD type III is due to deficiency of debrancher enzyme [170], also known as amylo-1,6-glucosidase. This enzyme degrades the α-D-1,6 branch-points of the glycogen molecule after hepatic phosphorylase has hydrolyzed the outer branches. Patients with GSD type III have either liver and muscle involvement (type IIIa) or liver involvement alone (type IIIb), the latter being the minority of patients. Patients may present in identical manner to GSD type Ia, with hepatomegaly, hypoglycemia, hyperlipidemia, hyperuricemia, growth retardation, and similar biochemical features. However, blood lactate and uric acid levels may be normal in GSD type III, with moderate elevations of serum AST and ALT. Patients have the potential to develop progressive portal fibrosis, leading to cirrhosis and complications of portal hypertension [187] as well as hepatocellular carcinoma [188]. Myopathic weakness may worsen as the patient ages into adulthood. Cardiomyopathy with ventricular hypertrophy may also occur in GSD type III patients.

GSD type III is inherited in an autosomal recessive manner, the human gene being an 85-kb gene composed of 35 exons located on chromosome 1p21. Mutations in this gene have been described in both types IIIa and IIIb GSD. Molecular and tissue enzymology diagnoses are possible [189]. Liver histology in GSD type III resembles that found in type Ia, although there is less steatosis and periportal fibrosis progressing to cirrhosis may be present [190]. Treatment of GSD type III depends on the symptomatology. In patients with hypoglycemia, acidosis, and hypertriglyceridemia, treatment is similar to that in GSD type Ia. However, many patients with GSD type III can be managed on a high-starch diet, without the need for cornstarch therapy. There is one report of a high-protein diet and continuous nocturnal infusion of a high-protein formula improving muscle strength in a patient with myopathy. There is no other effective treatment for the progressive myopathy or cardiomyopathy.

GSD type IV

GSD type IV (Andersen disease, amylopectinosis) is caused by an autosomal recessive deficiency of the glycogen brancher enzyme, amylo-1,4→1,6-transglucosidase, present in leukocytes and in liver. The disease is extremely heterogeneous in terms of tissue involvement, age of onset, and clinical manifestations. An abnormal amylopectin-like glycogen is formed in the liver that contains few branch-points, which appears to be toxic to hepatocytes [191]. The human gene coding for this enzyme is on chromosome 3p12 and consists of 16 exons [192]. There appears to be a phenotype–genotype correlation that may explain clinical variability [193]. Patients may present with three clinical scenarios:

- progressive liver injury and cirrhosis, leading to liver failure and death during the first 5 years of life
- chronic liver disease without progressive fibrosis
- abnormal neuromuscular development with hypotonia, muscle atrophy, absent deep tendon reflexes.

Cardiomyopathy may also develop because of deposition of amylopectin in myocardial cells. Adults with milder symptoms, but with similar muscle histology have been described [193]. Children with early-onset liver failure present with failure to thrive, hepatosplenomegaly, cholestatic jaundice, and occasionally hypotonia. Complications of cirrhosis such as ascites and coagulopathy prevail and death usually occurs by 2–4 years of age [194]. Diagnosis is established by finding the characteristic abnormal structure of glycogen on electron microscopy in muscle culture fibroblasts or liver, or through molecular testing [192]. Verification of deficient branching enzyme activity may also be determined in muscle, leukocytes, cultured fibroblasts, or liver. Liver histology is characterized by micronodular cirrhosis and hepatocytes that appear to contain excessive glycogen, which is PAS-positive and diastase-resistant [195]. Electron microscopy shows large irregular areas of glycogen fibrils, and finely granular material [195]. Liver transplantation appears to be the only effective therapy for children with progressive liver failure and cirrhosis [196–198]. Although many patients have done well following liver transplantation without cardiac or

muscle involvement, a single report suggests that cardiac disease may be a posttransplantation complication [199].

GSD types VI and IX

GSD types VI and IX are caused by genetic deficiencies of the phosphorylase system of enzymes that stimulate degradation of hepatic glycogen. Deficiency of hepatic phosphorylase causes GSD type VI, of which there are many subtypes. Patients generally present with asymptomatic hepatomegaly, elevated aminotransferases, variably with hypoglycemia or hyperlipidemia. Growth retardation occasionally occurs, but many children are found to be normal in stature. Lactic acidosis is rare and the prognosis is generally very good. Hepatomegaly improves as the patient reaches adulthood, and growth also is generally normal by adulthood. Liver biopsy findings include glycogen-filled hepatocytes, but generally the absence of inflammation, cell injury, and fibrosis.

GSD type IX is caused by phosphorylase b kinase deficiency. This disorder is characterized by asymptomatic hepatomegaly, mild elevation of aminotransferases, glycogen-filled hepatocytes on liver biopsy, and variable degrees of hepatic fibrosis. Slow progression to cirrhosis has been reported in several cases with the development of portal hypertension. Diagnosis is established through enzyme analysis of liver and erythrocytes [200,201] or by molecular analysis [202]. Phosphorylase b kinase deficiency (GSD type IX) is more frequent than true phosphorylase deficiency. Rarely, patients with GSD type IX develop biochemical features of GSD type I or type III. Treatment is generally not necessary for GSD type IX.

Mitochondrial hepatopathies

Hepatic involvement is a common feature of disorders affecting mitochondrial oxidative phosphorylation. Many of the disorders of the mitochondrial respiratory chain may present as neonatal acute liver failure, hepatic steatohepatitis, cholestasis or cirrhosis with chronic liver failure of insidious onset. Mitochondrial hepatopathies occur primarily in early childhood, although secondary disorders present at any age. Diagnosis is based on biochemical testing, enzymology, and genetic testing. Treatments for mitochondrial support are inadequate at present.

Classification of mitochondrial hepatopathies

Sokol and Treem [203] have developed a classification scheme for mitochondrial hepatopathies (Table 87.5) that divides these disorders into primary disorders, in which the mitochondrial defect is the primary cause of the liver disorder, and secondary disorders, in which a secondary mitochondrial insult is caused by a genetic defect affecting nonmitochondrial proteins (e.g., Wilson disease) or by an acquired injury to mitochondria (e.g., exogenous toxin or drug). Leonard and Schapira [204] further divided primary mitochondrial diseases into those caused by mutations in mitochondrial DNA (mtDNA) genes, called class 1a, and those caused by mutations in nuclear genes that encode proteins or cofactors which affect mitochondrial biogenesis, repair or structural proteins (e.g., respiratory chain complex subunit), called class 1b. This section focuses on four of the primary mitochondrial hepatopathies.

Table 87.5 Classification of primary mitochondrial hepatopathies

Electron transport (respiratory chain) defects
Neonatal liver failure
Complex I deficiency
Complex IV deficiency (*SCO1* mutations)
Complex III deficiency (*BCS1L* mutations)
Multiple complex deficiencies
Mitochondrial DNA depletion syndrome (*DGUOK*, *MPV17*, *POLG* mutations)
Delayed-onset liver failure: Alpers–Huttenlocher syndrome (*POLG* mutations)
Pearson marrow–pancreas syndrome (mtDNA deletion)
Mitochondrial neuro-gastrointestinal encephalomyopathy (*TP* mutations)
Chronic diarrhea (villous atrophy) with hepatic involvement (complex III deficiency)
Navajo neurohepatopathy (mtDNA depletion; *MPV17* mutations)
Fatty acid oxidation and transport defects
Long-chain hydroxyacyl-CoA dehydrogenase deficiency
Acute fatty liver of pregnancy (LCHAD enzyme mutations)
Carnitine palmitoyltransferase I and II deficiencies
Carnitine-acylcarnitine translocase deficiency
Fatty acid transport defects
Electron-transfer flavoprotein (ETF) and ETF-dehydrogenase deficiencies
Disorders of mitochondrial translation process
Urea cycle enzyme deficiencies
Phosphoenolpyruvate carboxykinase (PEPCK) deficiency (mitochondrial)

CoA, coenzyme A; LCHAD, long chain hydroxyacyl-CoA dehydrogenase; mt, mitochondrial.

Clincal features

Neonatal liver failure

Mitochondrial hepatopathies involving the respiratory chain frequently present as acute liver failure with onset within the first weeks to months of life. Symptoms include lethargy, hypotonia, vomiting, poor suck, and seizures [205,206]. It is difficult to differentiate the symptoms of liver failure from those of neuromuscular involvement in some infants. In other infants, a viral infection or some other undefined inciting

event triggers hepatic deterioration in an otherwise normal-appearing infant. Key biochemical features are a markedly elevated plasma lactate concentration (2.5–10 mmol/L), an elevated molar ratio of plasma lactate to pyruvate (> 20 and frequently > 30), and a raised β-hydroxybutyrate and arterial ketone body ratio of β-hydroxybutyrate to acetoacetate (> 2.0). Respiratory chain complex analysis of liver or muscle generally shows low activity of complex I, III, or IV. Molecular analysis may indicate mutations in the nuclear *SCO1* gene (associated with complex IV deficiency) [207] and *BCS1* gene (associated with complex III deficiency) [208]. Liver failure generally progresses to death within weeks to months, although occasional infants have recovered or have undergone successful liver transplantation if involvement was limited to the liver.

mtDNA depletion syndrome

The mtDNA pool is maintained either by import of cytosolic deoxyribonucleoside triphosphates (dNTPs) through dedicated transporters or by salvaging deoxynucleosides within the mitochondria. The mitochondrial deoxynucleoside salvage pathway is regulated by nuclear-encoded enzymes, including deoxyguanosine kinase (DGUOK) and thymidine kinase-2 (TK2). Imbalance of this mitochondrial dNTP pool has been proposed as responsible for a group of diseases in which there is inadequate synthesis of mtDNA relative to nuclear DNA, called the mitochondrial DNA depletion syndromes (MDS) [209]. In these disorders, there is insufficient synthesis of respiratory chain complexes I, III, IV, and V. There are two forms: the hepatocerebral and myopathic forms of MDS. Patients with the hepatocerebral form present within the first weeks to months of life with hepatomegaly, progressive liver failure, and generally death a few months later [210]. Presenting symptoms include vomiting, severe gastroesophageal reflux, failure to thrive, or developmental delay. Lactic acidosis, hypoglycemia, moderately raised serum ALT and AST, coagulopathy, and elevated total and conjugated bilirubin are common. Liver biopsy shows macrovesicular and microvesicular steatosis, cellular and canalicular cholestasis, variable degrees of periportal fibrosis depending on the age of the patient, and iron deposition in hepatocytes and sinusoidal cells [211]. There is considerable overlap between the clinical and laboratory features of patients with MDS and those with the neonatal liver failure form of respiratory chain disease. Mutations in several genes have been identified in patients with MDS: *DGUOK*, *POLG*, and *MPV17* in the hepatocerebral form and *TK2* in the myopathic form [209].

Alpers–Huttenlocher syndrome (delayed-onset liver disease)

Typically, the onset of symptoms occurs between 2 months and 8 years of life and is characterized by hepatomegaly, jaundice, progressive coagulopathy, and hypoglycemia. In most of these children liver failure is preceded by the development of hypotonia, feeding difficulties, intractable vomiting or symptoms of gastroesophageal reflux or failure to thrive, and ataxia followed by the onset of refractory partial motor epilepsy or multifocal myoclonus [212]. Multiple anticonvulsants are generally used to control the seizures; the addition of valproic acid may further impair respiratory chain enzyme activity and precipitate liver failure. Diagnostic criteria include refractory mixed-type seizures that include a focal component, psychomotor regression that is often episodic and triggered by intercurrent infections, and hepatopathy with or without acute liver failure [213]. Mutations in the *POLG* gene have been shown to be common in patients with Alpers–Huttenlocher syndrome [214].

Navajo neurohepatopathy

Navajo neurohepatopathy (NNH) is a unique sensorimotor neuropathy with progressive liver disease confined soley to full-blooded children or young adults of the Native American Navajo tribe. This disorder presents with muscular weakness, hypotonia, areflexia, virtual complete loss of sensation in the extremities leading to mutilation of fingers and toes, trigeminal neuropathy leading to corneal ulceration, poor growth, short stature, and serious systemic infections [215]. Liver involvement is characterized by Reye syndrome-like episodes, cholestasis, and cirrhosis or liver failure in infancy or childhood. Cerebral MRI of the brain demonstrates progressive white matter lesions, and peripheral nerve biopsies show severe loss of myelinated fibers [216]. Three clinical presentations have been described: an infantile form, with jaundice and poor growth progressing to liver failure and death within the first 2 years of life, with or without neurological findings; a childhood form presenting between 1 and 5 years of age with rapid development of liver failure; and the classical form in which progressive neurological findings dominate although liver dysfunction is present in all patients. Liver biopsy demonstrates macrovesicular and microvesicular steatosis, pseudoacinar formation of hepatocytes, multinucleated giant cells, cholestasis, periportal inflammation, and portal fibrosis or micronodular cirrhosis [215]. The liver involvement is progressive, with liver failure developing within months to years in most patients. There is no effective treatment for affected children. In 2006, sequencing of the *MPV17* nuclear gene, which has been shown to cause MDS, in six NNH patients from five families demonstrated a single homozygous disease-causing R50Q mutation in exon 2 of all patients [217].

Diagnosis

Diagnosis of a respiratory chain disorder is typically established by enzymatic analysis for respiratory chain activity of an affected tissue. These studies can be performed on frozen samples of small biopsies of liver, muscle, kidney, myocardium, or other tissue since they do not require the isolation

of mitochondrial fractions and can be carried out on tissue homogenates, lymphocytes, or cultured skin fibroblasts. Molecular diagnosis is becoming more useful as more nuclear genes are identified that cause specific respiratory chain and MDS disorders. For nuclear genes, whole blood for isolation of genomic DNA will usually suffice for genotyping. For mtDNA mutations or deletions, which are less common causes of mitochondrial hepatopathies (with the one exception of Pearson marrow–pancreas syndrome) affected tissues must be analyzed. Molecular analyses are now available at a number of clinical and research laboratories (see http://www.genetests.org).

Treatment

There is no effective therapy for most patients with respiratory chain disorders, including those with liver failure and more slowly progressive liver disease. A variety of mitochondrial substrates, cofactors, antioxidants, and other compounds have been suggested, although it is not clear that any currently available medical therapy significantly alters the course of severe disease [209]; some patients have experienced improvement of neuromuscular symptoms. Liver transplantation can be successfully performed in patients with no clinical, biochemical or imaging evidence of extrahepatic involvement, although progressive systemic symptoms may develop following liver transplantation [209,218]. Liver transplantation does not halt the progression of neurological, muscular, cardiac or other involvement, and is thus contraindicated in patients with significant signs of other organ involvement.

Epidemiology

In the United States, about 15–20 million people suffer from alcoholism. According to a 1990 survey by the US Department of Health and Human Services, alcohol is the third leading cause of preventable mortality, behind cigarette smoking and obesity, with about 100 000 deaths annually and an annual economic burden of more than $100 billion in the United States [1,2]. Surveys have demonstrated that alcohol-induced liver injury accounted for around 40% of all deaths from chronic liver disease in the United States between 1990 and 1998 [3].

Alcohol abuse can be found in all age groups. However, the age group at highest risk for hospitalization as the result of alcohol-related liver diseases (ALD) is that between 45 and 64 years, with a prevalence of 94.8 per 10 000 [4–6]. In elderly hospitalized patients, the prevalence of alcohol-related diagnoses ranges from 48.2 to 65.1 per 10 000 [4–6]. Of note, the overall prevalence decreases with increasing age, but the prevalence always remains higher for men than for women. There were notable ethnic differences in the prevalence of ALD and mortality [7]. The highest and lowest alcohol-related cirrhosis mortality rates between 1991 and 1997 were white Hispanic and black Hispanic, respectively. However, black nonHispanic women had the highest alcohol cirrhosis mortality rate among all women [7]. Alcohol intake is best quantified in terms of grams of ethanol per day. Each common unit of drinking contains about 10–15 g of ethanol: 1-ounce or shot of distilled spirits (30 mL), a 12-oz bottle of beer (355 mL), or a 4-ounce glass of wine (118 mL). There is no difference in the risk of ALD associated with the use of any of these forms of alcohol. Drinking alcohol at times other than at meals, which includes binge drinking, was associated with increased risk of liver injury [8]. There is general agreement that the risk of ALD increases with increasing alcohol consumption. The amount of ethanol that can be safely drunk is estimated to be up to 20 g (two drinks) per day for men and up to 10 g (one drink) for women, and in fact this amount of alcohol consumption is associated with reduced risk of myocardial infarction [9]. These levels of drinking are referred to as "moderate drinking." Women have a higher risk of developing cirrhosis than men do even at the lower daily alcohol intake and lower cumulative exposure to alcohol [10–12]. In men, the risk of alcoholic cirrhosis increases with daily alcohol consumption greater than 60–80 g/day; women have a lower threshold and are considered to be at risk with daily alcohol intake greater than 20 g/day. Additionally, there is a more rapid development of liver disease in women who abuse alcohol compared with men. The peak incidence of ALD is in the 40- to 55-year age range in men, but occurs a decade earlier in women. Of note, a larger percentage of women progress to more advanced liver disease [13,14]. The male to female ratio of alcoholism is about 10 to 1, but that for ALD is about 3 to 1. This strongly supports the clinical impression of an increased susceptibility of women to ALD, and emphasizes the need to help women control abusive drinking at a younger age. In the past, ALD was attributed to malnutrition (hence the term "Laennec nutritional cirrhosis"). However, alcoholic cirrhosis can occur in well-nourished persons. To date, it remains an unsolved question why only a subset of alcoholics develops serious liver injury (no more than 35% of heavy drinkers develop alcoholic hepatitis and only 20% develop cirrhosis).

Metabolism of ethanol and genetic predisposition to alcoholism and ALD

In humans, more than 90% of ingested alcohol is eliminated through metabolic degradation in the liver, and 2%–10% is

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

eliminated in urine and breath. Ethanol is first metabolized into acetaldehyde through several enzymatic and nonenzymatic mechanisms [15–17]; which include the alcohol dehydrogenase (ADH) pathway in the cytosol; the cytochrome P4502E1 (CYP2E1) pathway in the smooth endoplasmic reticulum, and the catalase pathway in peroxisomes (Fig. 88.1). Acetaldehyde is converted by aldehyde dehydrogenases (ALDH) to acetate, which is released from the liver and metabolized by the heart and muscle [17]. The rate of ethanol metabolism by ADH and ALDH may be critical in determining its toxicity because the intermediates of this pathway are themselves potentially toxic. The maximal activities of ADH and ALDH in the liver are similar, so that each enzyme contributes to the overall control of the rate of alcohol oxidation.

Alcohol dehydrogenase (ADH)

ADH is a cytosolic, zinc-dependent dimeric enzyme using the oxidized form of nicotinamide adenine dinucleotide (NAD^+) as a cofactor [18]. It is responsible for the bulk of hepatic alcohol oxidation [19]. Human ADHs are categorized into five classes on the basis of their structural and kinetic characteristics [17]. However, under physiological conditions, the main isoenzymes involved in human ethanol metabolism are ADHs from classes I, II, and IV. Class I contains α, β, and γ isoenzymes. These enzymes have a low Michaelis constant (K_m < 5 mM) for ethanol and they are abundant in the liver, and therefore play a major role in ethanol metabolism. Class I ADH comprises three genes, *ADH1*, *ADH2*, and *ADH3*, making up gene clusters located on chromosome 4q21–23, spanning about 80 kilobases [20]. These loci have been renamed *ADH1A*,

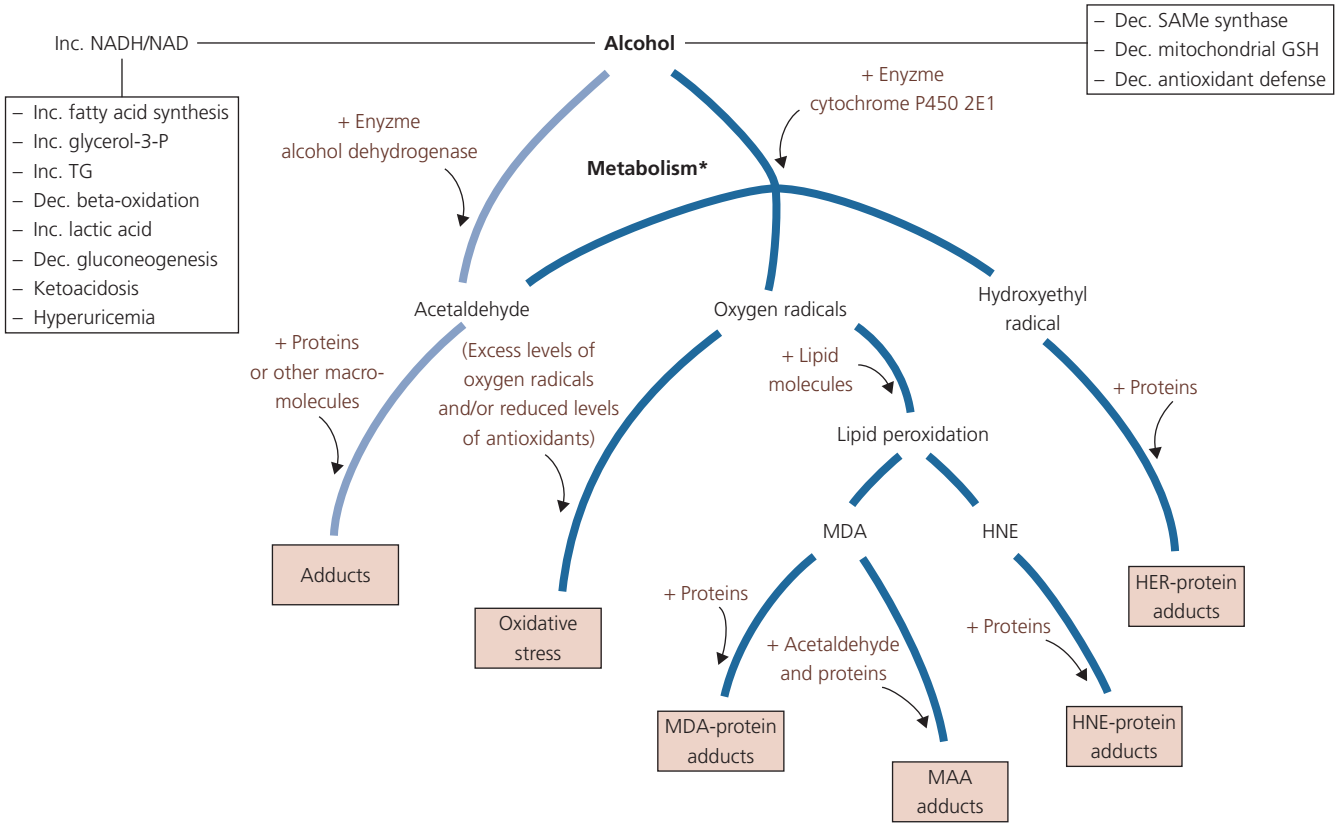

Figure 88.1 Pathway of alcohol metabolism and its effect on metabolism of hepatocytes. The major alcohol-metabolizing enzymes are alcohol dehydrogenase (ADH) and cytochrome P450 2E1 (CYP2E1). Acetaldehyde is then oxidized by aldehyde dehydrogenase (ALDH). The ADH and ALDH reactions generate free reduced nicotinamide adenine dinucleotide (NADH). The increase in the ratio of NADH to NAD^+ (the oxidized form of NAD) modifies many metabolic pathways, which leads to increased fatty acid synthesis and decreased fatty acid oxidation. Acetaldehyde can react with other proteins in the cell to generate hybrid molecules known as adducts. CYP2E1 also generates acetaldehyde, as well as highly reactive oxygen-containing molecules called oxygen radicals, including the hydroxyethyl radical (HER) molecule. Elevated levels of oxygen radicals can generate oxidative stress, which through various mechanisms leads to cell damage. Oxygen radicals can also interact with fat molecules (lipids) in the cell in a process known as lipid peroxidation, resulting in reactive molecules such as malondialdehyde (MDA) and 4-hydroxy-2-nonenal (HNE). Both of these can react with proteins to form MDA–protein and HNE–protein adducts. MDA can also combine with acetaldehyde and protein to form mixed MDA–acetaldehyde-protein adducts (MAA). Other effects of alcohol include depletion of antioxidants such as *S*-adenosylmethionine (SAMe) and glutathione (GSH). Other abbreviations: Dec, decrease; Inc, increase; TG, triglyceride. ADH1B, and *ADH1C*; however, this chapter will use the older nomenclature. Among these genes, polymorphisms with physiological significance exist in the *ADH2* and *ADH3* loci. These polymorphic variants differ in their efficiency for ethanol oxidation. People of different racial backgrounds inherit different sets of ADH isoenzymes. African Americans who carry a copy of the *ADH2*3* gene, encoding an enzyme with high maximum velocity, have a somewhat faster rate of alcohol metabolism [21]. The kinetic properties and population distributions of these allelic enzymes are shown in Table 88.1.

Class II ADH (π-ADH) was first found in human liver; it has a higher K_m for ethanol and is less sensitive to pyrazole inhibition than class I enzymes [22]. Class II ADH plays a less important role in liver ethanol metabolism than class I. The class IV enzyme (μ-ADH, for the *m*ucosal isozyme or σ-ADH, for the *s*tomach isoenzyme) has been purified from the stomach and esophagus. This ADH form is involved in the first-pass metabolism of ethanol in the stomach [23]. The ADH reaction rate is controlled by the amount of ADH, the acetaldehyde level, and the ratio in the cytosol of free reduced NAD to oxidized NAD ($NADH/NAD^+$) [24]. The amount of ADH in the liver is not induced by chronic drinking; however, with fasting, protein malnutrition, and liver disease, ADH activity and the ethanol elimination rate are decreased [25]. The properties of the enzymes in each of the ADH classes are summarized in Table 88.2.

Microsomal ethanol oxidizing system

Aside from the ADH pathway, ethanol can be metabolized by a microsomal ethanol oxidizing system (MEOS) involving mostly the cytochrome P450 2E1 (CYP2E1) [26]. Two other cytochromes, CYP1A2 and CYP3A4, also contribute to the MEOS, although to a lesser extent [16,27–29]. CYP2E1 is associated with NADPH-cytochrome P450 reductase in the microsomal membrane, and reduces molecular oxygen to water as ethanol is oxidized to acetaldehyde [26]. It has a low ethanol catalytic efficiency relative to ADH and is therefore responsible for only a small part of total ethanol metabolism [16]. CYP2E1 is inducible by chronic drinking [28,29], especially in the perivenular zone [30], and it may contribute to the increased rates of alcohol elimination in heavy drinkers. CYP2E1 can also be induced in fasting and diabetes and by a diet high in fat [31]. It has a high K_m for ethanol and may assume a greater role in ethanol metabolism at high blood alcohol levels. CYP2E1 is unusually "leaky" and generates reactive oxygen species, including hydroxyl radicals ($OH\cdot^-$), superoxide anions ($O_2\cdot^-$), hydrogen peroxide (H_2O_2), and hydroxyethyl radicals [31]. Thus, CYP2E1 is a major source of oxidative stress in the hepatocytes. Of importance, this P450 enzyme also has capacity to activate many xenobiotics to toxic metabolites, most notably acetaminophen [32].

Table 88.2 Properties of alcohol dehydrogenases (ADH) in man

Gene locus	New nomenclature	Subunit type	K_m (ethanol)	Tissue distribution
Class I				
ADH1	*ADH1A*	α	4	Liver
ADH2	*ADH1B*	β	0.05–34.0	Liver, lung
ADH3	*ADH1C*	γ	0.6–1.0	Liver, stomach
Class II				
ADH4	*ADH2*	π	34	Liver, cornea
Class III				
ADH5	*ADH3*	χ	1000	Most tissues
Class IV				
ADH7	*ADH4*	σ, μ	20	Stomach, esophagus
Class V				
ADH6	*ADH5*		30	Liver, stomach

Catalase

The enzyme catalase has also been shown to oxidize ethanol to acetaldehyde within the peroxisomes. This process is hydrogen peroxide-dependent. However, under normal physiological conditions, it plays only a minor role in ethanol metabolism [16,29,33].

Aldehyde dehydrogenase (ALDH)

The second step of ethanol metabolism is mediated by ALDH. It converts acetaldehyde to acetate, which is released from the liver and metabolized by heart and muscle [34]. Like ADH, ALDH enzymes use NAD^+ as a cofactor, but are expressed in a wider range of tissues than the ADH isoenzymes. In humans, there are multiple forms of ALDH that are divided into nine major families [35]. However, only some of these isoforms are significantly involved in acetaldehyde metabolism, whereas the others metabolize a variety of substrates. To date, a significant role in acetaldehyde oxidation has been identified only for cytosolic ALDH1 and mitochondrial ALDH2 [17,36]. Mitochondrial ALDH2 plays the central role in human acetaldehyde metabolism because of its submicromolar K_m for acetaldehyde [17]. ALDH2 is inhibited by disulfiram (Antabuse). Consumption of alcohol while taking disulfiram or a number of other drugs (metronidazole, and some sulfonylureas and cephalosporins) results in the accumulation of acetaldehyde, producing vasodilation, facial flushing, tachycardia, nausea, and vomiting [37]. Similar to the class I *ADH* gene, the *ALDH2* gene is polymorphic and the variants demonstrate the vital role of ALDH2 in ethanol oxidation. The normal allele is termed *ALDH2*1*. The allele *ALDH2*2* has been thoroughly studied because it causes inactivation of the enzyme leading to acetaldehyde accumulation [38]. The *ALDH2*2* allele contains a G→A substitution resulting in the replacement of glutamate with lysine at position 487 in ALDH2 [38,39]. *ALDH2*2* homozygotes have essentially no ALDH2 activity, whereas heterozygotes have markedly reduced but still detectable activity [40]. *ALDH2*2* is found almost exclusively in populations of Asian origin [41] and approximately 45% of Japanese have the ALDH2-deficient phenotype [42]. Therefore, flushing as the result of acetaldehyde accumulation after alcohol ingestion is commonly seen in the Asian population. The properties and tissue distribution of human ALDHs are summarized in Table 88.3.

Nonoxidative ethanol metabolism

In addition to the main oxidative pathways described above, ethanol is also metabolized, although to a minor extent, by a nonoxidative pathway to form fatty acid ethyl esters [43–45]. This reaction is catalyzed by fatty acid ethyl ester synthase and may be of importance in organs lacking ethanol oxidative metabolism, such as the heart and pancreas. Fatty acid ethyl esters disturb membrane function, and may thus contribute to alcohol-induced organ dysfunction [46].

Table 88.3 Properties and tissue distribution of human aldehyde dehydrogenase (ALDH)

Gene locus	K_m (acetaldehyde)	Tissue distribution
Class I		
ALDH1	30 μM	Many tissues, liver
Class II		
ALDH2	≤ 1 μM	Low levels in most tissues Liver > kidney > muscle > heart
Class III		
ALDH3	11 mM	Stomach, liver, cornea

Genetic predisposition to alcoholism and ALD

The strongest genetic associations identified to date are those between risks of alcoholism and genes encoding alcohol-metabolizing enzymes. The *ADH2*2* (*ADH1B*2*) allele has been shown to reduce the occurrence of alcohol abuse and alcoholism in Asians and Jewish populations in which this allele has a relatively high prevalence [17]. Several studies have reported a higher frequency of *ADH2*2* in nonalcoholics and in moderate drinkers relative to heavy drinkers [47–49]. Since *ADH2*2* codes for a high activity enzyme (β2-ADH), it is postulated that this allele protects against alcoholism because of the unpleasant symptoms associated with acetaldehyde accumulation after alcohol drinking [50]. However, individuals with this genotype do not have increased steady state venous blood acetaldehyde concentration after alcohol drinking, despite a somewhat higher rate of ethanol elimination [51,52]. It is possible that these individuals have increases in arterial, and therefore brain, acetaldehyde after drinking.

The *ALDH2*2* allele also provides strong protection against alcoholism, especially in *ALDH2*2* homozygotes, presumably because of the severity of their flushing [49,53]. Several studies demonstrated a reduced frequency of the *ALDH2*2* allele in alcoholics compared with nonalcoholics [54–56]. Individuals with the *ALDH2*2* allele have a 10-fold reduction in the risk of alcohol dependence [54]; they also drink less alcohol and have a lower prevalence of binge drinking [57,58].

The evidence for a genetic risk for ALD is less strong than that for the risk for alcoholism. The largest study, the US Veterans Administration Twin Panel Study, showed a higher concordance for cirrhosis in monozygotic twins than in dizygotic twins, indicating a genetic component to the risk [17,59]. Reanalysis of the database supported this conclusion, but found that most, but not all, of the genetic liability for cirrhosis was the result of shared risk for alcoholism [60]. This study is limited by lack of information on the prevalence of hepatitis C in the cohort. The effect of ADH and ALDH

variants on the risk of ALD could be complex [61]. High activity of ADH variants and low activity of *ALDH2*2* decrease alcoholism risk, but if individuals with these isoenzymes persist in drinking, hepatic injury might result from high intrahepatic concentrations of acetaldehyde. Indeed, one study has demonstrated an increased risk of ALD among *ADH2*2* heterozygotes or homozygotes [62]. Another study suggested that *ALDH2*2* heterozygotes who drink heavily develop alcoholic hepatitis at a lower cumulative alcohol intake than those with active ALDH2 [63]. To date, none of the ADH and ALDH polymorphisms has been clearly identified in replicate studies as predisposing to the development of ALD [17].

Pathogenesis of alcoholic liver disease

Although the ultimate control of ALD will require the prevention of alcohol abuse, better understanding of the mechanisms of alcohol-induced liver injury may lead to treatments of fatty liver, alcoholic hepatitis, and prevention or delay of occurrence of cirrhosis.

Role of redox state

Fatty liver, the accumulation of triglyceride droplets in the liver, is the most common and earliest response of the liver to alcohol in heavy alcohol use [64]. Synthesis of fatty acids and triglyceride in excess of the capacity to oxidize it or export it in very-low-density lipoprotein particles results in hepatic steatosis [65]. The effect of ethanol was initially attributed to increased levels of cytosolic and mitochondrial NADH, generated from the ADH and ALDH reactions [66]. Increasing intracellular NADH levels inhibit the oxidation of fatty acids (Fig. 88.1). Increased levels of L-glycerol-3-phosphate and fatty acids, as well as induction of a number of enzymes involved in de novo fatty acid synthesis, result in accelerated synthesis of triglycerides. Existence of this redox mechanism was supported by in vitro studies. Cell lines engineered to express ADH metabolized alcohol and generated a reduced cytosolic redox potential, reflected by an increase in the lactate: pyruvate ratio in the medium. Coincident with this, the cells accumulated large amounts of triglyceride and free fatty acids [67].

The redox hypothesis of alcoholic fatty liver has been challenged by studies in which antioxidants prevented the development of fatty liver in animals receiving large single doses or chronic feeding of alcohol [68]. In addition, with chronic alcohol feeding of baboons, the redox shift in the liver becomes less severe, but the fat accumulation persists. This suggests that over time, the redox state is no longer the primary cause of alcoholic-induced liver injury [69]. Several additional mechanisms for alcohol-induced steatosis have been investigated over the past two decades, discussed in detail below.

Role of oxidative stress

There are two principal ways by which chronic alcohol use can induce oxidative stress, the CYP2E1 pathway and the mitochondrial electron transfer system [29] (Fig. 88.1). In both cases, increased rates of single electron transfers (at the sites of flavin coenzymes in the cytochrome catalytic cycle or the electron transfer system) facilitate the transfer of electrons to oxygen. CYP2E1 is induced by chronic alcohol use and is "leaky", in that electrons transferred to it from CYP450 reductase can be transferred to molecular oxygen in the absence of substrate, forming superoxide [70]. The preferential expression of CYP2E1 in the central zone of the liver corresponds with the prominence of alcohol-induced injury to this zone [29]. An end result of oxidative stress is lipid peroxidation, a chain reaction of lipid radical formation that follows the removal of an electron from polyunsaturated fatty acid (PUFA). The lipid free radical undergoes addition of oxygen to form a lipid hydroperoxide, and ultimately decomposition to form reactive aldehydes such as malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE) [71].

The most convincing data indicating that oxidative stress contributes to ALD come from studies using the intragastric infusion model. In these studies, ALD was associated with enhanced lipid peroxidation, protein modification, formation of 1-hydroxyethyl radical, and lipid radicals, and decreases in hepatic antioxidants, particularly glutathione [72–74]. Moreover, changes in the animals' diets that helped promote or reduce oxidative stress led to corresponding changes in the extent of liver injury. For example, when PUFA were replaced with saturated fats or medium-chain triglycerides, lipid peroxidation as well as alcohol-induced liver injury was reduced [75]. Studies in the *in vitro* system also demonstrated the important role of oxidative stress in the pathogenesis of ALD. Exposure of CYP2E1-expressing HepG2 cells to high concentrations of ethanol produced morphological changes and DNA fragmentation, activation of caspases 1 and 3, and apoptosis [76]. These changes were not observed in control HepG2 cells, and could be prevented by an inhibitor of CYP2E1, by antioxidant compounds, or by the inhibition of the caspases [77,78], and were exacerbated by the presence of PUFA. Taken together, these findings indicate that alcohol-induced oxidative stress is a pivotal factor in the development of ALD.

Role of diet and nutrition

It is important to emphasize that ethanol itself, rather than a nutritional deficiency, can cause ALD. Baboons chronically given large amounts of ethanol, despite a nutritionally complete diet, developed fatty liver and significant fibrosis [79]. Rats fed by constant intragastric infusion of a nutritionally adequate liquid diet containing ethanol comprising 50% of total calories developed fatty liver, necrosis, and fibrosis. Of importance, there are interactions between diet and alcohol in the development of liver injury. The most obvious is that

severe liver injury in the rat model required a high content of PUFA in the diet [80] and hepatic steatosis is in fact prevented by substituting saturated fat or medium-chain triglycerides for the PUFA [81]. This has been suggested to be the result of increased susceptibility of PUFA to lipid peroxidation. It is interesting that there appears to be an inverse relationship between dietary saturated fat and risk of ALD [82] and such a protective effect is postulated to result from increased secretion of adiponectin by adipocytes [83]. Administration of ethanol in a liquid diet that is very low in carbohydrate also causes liver inflammation and severe fatty liver in rats [84]. Lastly, obesity has been found to be a risk factor for the development of cirrhosis in humans [85]. Obesity doubles the risk of steatosis among heavy drinkers [86]. Dietary folate deficiency may also promote steatosis (see below).

Role of ethanol effects on transcription factors and metabolic regulators

Recent studies have shown that alcohol-induced fatty liver is associated with alterations in two transcription factors, peroxisome proliferator-activated receptor-α (PPAR-α) and sterol regulatory element binding protein 1 (SREBP-1), and the regulatory enzyme adenosine monophosphate-dependent protein kinase (AMPK) [87–89]. PPAR-α is a member of the nuclear hormone receptor superfamily, which, when dimerized with retinoid X receptors, controls transcription of a set of genes containing peroxisome proliferator response elements involved in transport and oxidation of free fatty acids [90]. SREBP-1 belongs to a family of basic helix–loop–helix leucine zipper transcription factors and regulates the enzymes responsible for cholesterol, fatty acid, and triglyceride synthesis in liver and other tissues. In liver, SREBP-1c is involved in fatty acid synthesis, whereas SREBP-2 plays a major role in the regulation of cholesterol synthesis [91,92].

Ethanol inhibits PPAR-α function in cultured cells and in ethanol-fed mice [88]. Ethanol feeding decreased PPAR-α–retinoid X receptor α binding to its consensus sequence, and the levels of messenger RNAs for PPAR-regulated genes such as long-chain and medium-chain acyl coenzyme A (acyl-CoA) dehydrogenases. Treatment of the mice with the PPAR-α agonist WY14643 increased the levels of PPAR-α and reversed fatty liver despite continued feeding of ethanol.

The role of SREBPs in alcoholic fatty liver was suggested by the battery of lipogenic enzymes induced by ethanol feeding. Ethanol treatment significantly increased SREBP activity in hepatoma cells. In vivo, a substantial increase in the amount of mature SREBP-1 protein was found in the livers of ethanol-fed mice, and the levels of messenger RNA for several SREBP-1 target hepatic lipogenic genes including fatty acid synthase, steroyl-CoA desaturase, malic enzyme, adenosine triphosphate citrate lyase, and acetyl-CoA carboxylase (ACC) [89].

AMPK is emerging as a "metabolic master switch" regulating pathways of hepatic triglyceride and cholesterol synthesis [93]. It phosphorylates and inhibits the enzymes involved in lipid metabolism, such as 3-hydroxy-3-methyl glutaryl-CoA reductase and ACC. ACC is generally regarded as the rate-limiting enzyme in fatty acid synthesis [93]. It has been firmly established that SREBP-1 can be both transcriptionally and posttranscriptionally regulated by AMPK [89,94,95]. Chronic ethanol feeding inhibited hepatic AMPK activity and enhanced the activity of its target protein ACC [96]. Activators of AMPK, e.g., metformin or aminoimidazole-4-carboxamide ribonucleotide, partially blocked the ethanol-mediated induction of SREBP-dependent promoter activity in hepatoma cells [87]. These findings suggest that AMPK may play a role in regulating the effects of ethanol on hepatic SREBP-1 activation and fatty acid metabolism. Potential mechanisms underlying the effect of alcohol on these transcription factors are summarized in Fig. 88.2.

Role of protein adduct formation

Protein adducts are covalent linkages formed between the amino acid side chains (typically lysine) of liver proteins and a low-molecular-weight reactive chemical such as acetaldehyde, hydroxyethyl radical, and lipid peroxide-derived aldehydes, such as 4-HNE and MDA (Fig. 88.1) [97]. There is much evidence that adducts are generated in vivo during ethanol metabolism, and that these adducts elicit an immune response [98]. Antibodies directed against acetaldehyde, MDA, HNE, mixed MDA–acetaldehyde protein adducts, and hydroxyethyl-radical-derived adducts are found in animals and humans that chronically consume alcohol [98–100]. In fact, hepatitis can be induced in guinea pigs by feeding alcohol to animals previously immunized with acetaldehyde adducts [101].

Acetaldehyde adducts form early in ALD and primarily in the perivenous region of the liver, which is also the primary region affected by alcohol-induced liver injury [100]. Moreover, in advanced liver disease they are found in the same areas that show evidence of inflammation and fibrosis [98,102]. Several mechanisms by which adducts could contribute to liver damage besides the formation of neoantigens are known. Aldehydes can interfere with the functions of proteins with critical lysine residues [103], such as lysine-dependent enzymes, calmodulin, and the cytoskeletal protein tubulin. Acetaldehyde–tubulin adducts appear to be especially relevant to alcohol-induced liver injury [104]. Impaired microtubule function could account for defects in protein secretion and other protein transport pathways that result from chronic alcohol consumption [104], and might contribute to endoplasmic reticulum stress (see below).

Role of cytokines, lipopolysaccharide, and the Kupffer cell

The Kupffer cell serves as the primary effector cell of the innate immune response within the liver [105], and plays a key role in the early pathogenesis of alcohol-induced liver

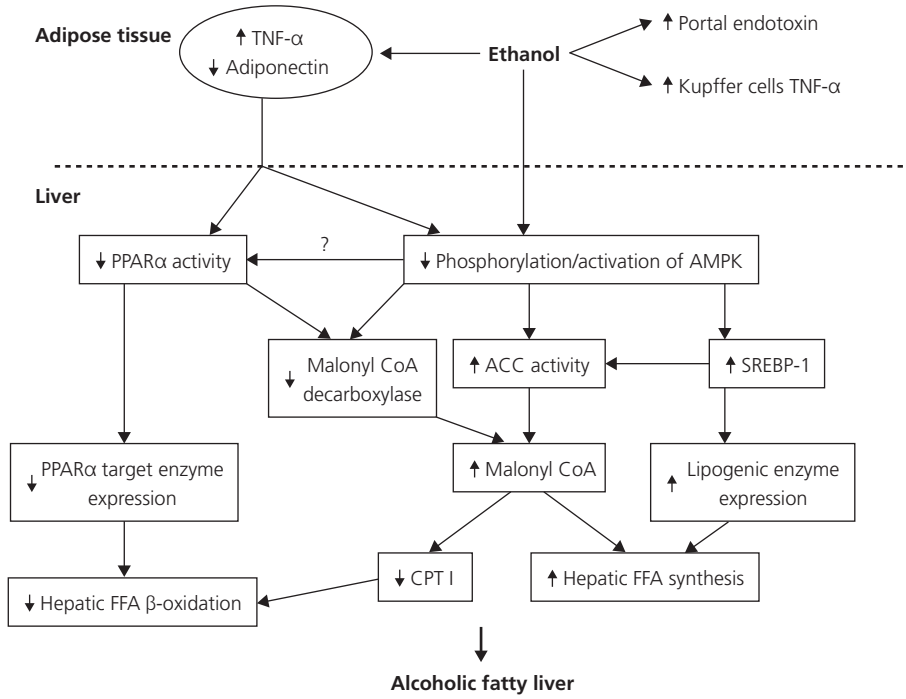

Figure 88.2 Potential mechanisms underlying the effect of alcohol on transcription factors, tumor necrosis factor-α (TNF-α), and adiponectin. Ethanol may influence the activity of peroxisome proliferator-activated receptor-α (PPAR-α), sterol regulatory element binding protein 1 (SREBP-1), and adenosine monophosphate-dependent protein kinase (AMPK) directly or by way of effects on adiponectin and TNF-α. These effects in turn activate lipogenic pathways, inhibit fatty acid oxidation pathways, and increase the concentration of malonyl-coenzyme A (CoA). Malonyl-CoA inhibits the entry of free fatty acid (FFA) into the mitochondria and blocks fatty acid oxidation in the mitochondrion. ACC, acetyl-CoA carboxylase; CPT I, carnitine palmitoyl transferase. From You & Crabb [323], with permission from the American Physiological Society.

injury [106–108]. Inactivation of Kupffer cells by gadolinium chloride ameliorates the ALD seen with chronic ethanol administration using the Tsukamoto–French model [109]. Endotoxin, or lipopolysaccharide (LPS), is derived from the cell wall of gram-negative bacteria (Fig. 88.3). There are three possible mechanisms involved in alcohol-induced endotoxemia:

- dysfunctional Kupffer cells with reduced ability to clear endotoxin
- bacterial overgrowth in the gut leading to excessive generation of endotoxin
- disruption of intestinal barrier function and increased permeability to endotoxin and bacteria [110].

Alcohol feeding increases endotoxin levels in the portal vein and induces the expression of the LPS binding protein and its receptor present on the Kupffer cell. CD14 (the Kupffer cell endotoxin receptor) plays an important role in ALD. Endotoxin binds CD14 in association with Toll-like receptor 4 (TLR4) to initiate intracellular signaling [107]. It has been shown that mice deficient in CD14 or TLR4 are resistant to ethanol-induced liver injury [108].

Kupffer cells that are stimulated by LPS produce inflammatory mediators, among them tumor necrosis factor-α (TNF-α), which is a cause of hepatocyte apoptosis; transforming growth factor-β1 (TGF-β1), the most important stimulus for collagen synthesis by stellate cells; interleukin-8 (IL-8), which attracts neutrophils to the liver (plasma IL-8 levels are markedly increased in patients with alcoholic hepatitis on admission, decreasing with recovery); IL-1 and IL-6, which elicit an acute-phase response; eicosanoids, which are implicated in the increased rate of hepatocyte oxygen consumption during ethanol metabolism; other chemokines that stimulate the migration of leukocytes into the liver; and platelet-derived growth factor, a major stimulator of hepatic stellate cell proliferation [111]. Kupffer cells are also capable of producing large amounts of potentially damaging free radicals, including superoxide, through the NADPH oxidase system. TNF-α appears to play a particularly important role in ALD [112]. TNF-α signals through two distinct cell surface receptors (TNFR1 and TNFR2). Multiple experimental approaches have revealed that TNFR1 initiates the majority of the biological activities of TNF-α in the liver [113]. Knockout mice lacking TNFR1 [114] and rats given antibody against TNF-α [115] are protected against liver injury in the Tsukamoto–French model.

Role of methionine cycle and folate metabolism

Chronic ethanol feeding of rodents impairs their ability to synthesize methionine, elevates homocysteine levels, reduces the synthesis of *S*-adenosylmethionine (SAM), and increases the levels of *S*-adenosylhomocysteine (SAH). This effect is explained by ethanol inhibiting methionine synthase (which converts homocysteine to methionine in conjunction with N5-methyl-tetrahydrofolate and vitamin B-12 [116,117]). McClain and colleagues demonstrated that a decrease in the SAM to SAH ratio was associated with significant increases in hepatic TNF-α levels, caspase-8 activity, and apoptotic rates [117]. SAH also sensitized hepatocytes to caspase-mediated apoptosis [118]. Folate deficiency commonly occurs in alcoholics and compounds the hyperhomocysteinemia [119].

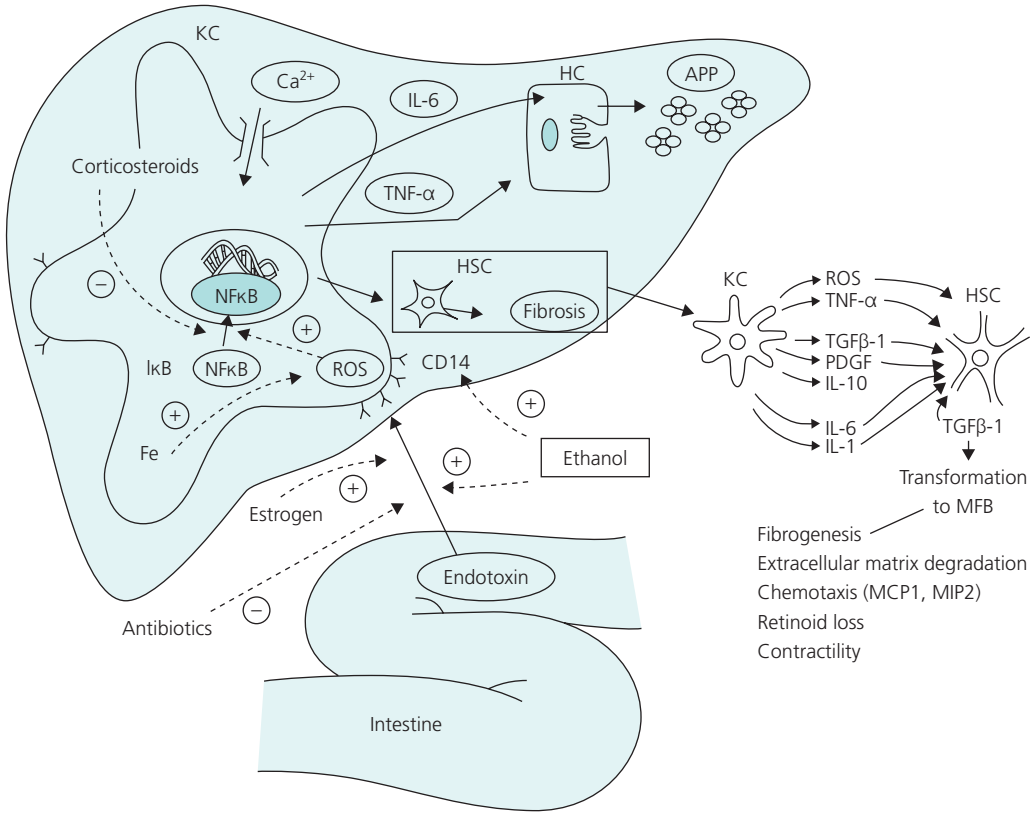

Figure 88.3 Ethanol consumption increases the absorption of lipopolysaccharide (LPS, endotoxin) from the gut. LPS in turn stimulates the endotoxin receptors (CD14) on Kupffer cells (KC). This action is more pronounced in females because of the effect of estrogen. Binding of endotoxin to the CD14 leads to activation of nuclear factor-κB (NF-κB); which then activates numerous inflammation-related genes, notably tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), and transforming growth factor-β1 (TGF-β1). These cytokines have effects on the hepatocyte (HC), such as synthesis of acute-phase reactant protein (APP) and generation of reactive oxygen species (ROS). Their effects on hepatic stellate cells (HSC) lead to retinoid loss, and changes in extracellular matrix and collagen synthesis. Other abbreviations: IκB, inhibitor of NF-κB; Fe, iron; MFB, myofibroblast; MCP, monocyte chemotactic protein; MIP, macrophage inflammatory protein.

Micropigs fed ethanol on the background of a folate-deficient diet developed steatosis much earlier than those fed ethanol with a folate-supplemented diet [120], and also induced CYP2E1 and increased the levels of SREBP-1c [121]. Taken together, these data suggest that both folate deficiency and abnormal hepatic methionine metabolism may play an important role in the pathogenesis of ALD.

Role of endoplasmic reticulum stress

Recent work has implicated hyperhomocysteinemia in the pathogenesis of ALD through a mechanism involving endoplasmic reticulum stress [122,123]. The current hypothesis is that homocysteinylation of proteins causes their accumulation or malfolding in the endoplasmic reticulum, leading to a set of responses referred to as the endoplasmic reticulum stress response [124]. These include alterations of glucose-regulated proteins 78 and 94, SREBP, and caspase 12 [124] resulting in steatosis and apoptosis. Indeed, several recent studies have shown that alcohol may modulate both apoptotic and fat synthetic gene expression through homocysteine-induced endoplasmic reticulum stress [121,125] and correction of hyperhomocysteinemia by betaine reduced hepatic steatosis and the endoplasmic reticulum stress response [123,125].

Roles of adipokines

Adiponectin is a hormone secreted by adipocytes. Full-length adiponectin undergoes proteolytic processing, and a small amount of globular adiponectin circulates in plasma. Two adiponectin receptors, AdipoR1 and AdipoR2, have been identified [126]. AdipoR1 is a high-affinity receptor for globular adiponectin and a low-affinity receptor for the full-length ligand, whereas AdipoR2 is an intermediate-affinity receptor for both forms of adiponectin. AdipoR1 is abundantly expressed in skeletal muscle, whereas AdipoR2 is predominantly expressed in the liver [126]. Decreased levels of circulating adiponectin are associated with obesity, insulin resistance, type 2 diabetes, and atherosclerosis, and administration of adiponectin diminished the abnormalities

associated with the metabolic syndrome [127]. The effect of adiponectin is largely mediated by an increase in fatty acid oxidation associated with activation of AMPK and PPAR-α pathways downstream of the adiponectin receptors, both in vitro and in vivo [94]. Chronic consumption of a high-fat, ethanol-containing diet significantly decreased circulating concentrations of adiponectin by 30%–40% after 3–4 weeks [128]. Delivery of recombinant adiponectin into these mice dramatically alleviated hepatomegaly and hepatic steatosis. Whereas chronic ethanol feeding significantly decreased the rate of hepatic fatty acid oxidation, adiponectin treatment restored it [128]. It is possible that reduction of hepatic fatty acid oxidation during ethanol consumption results from the suppression of adiponectin (Fig. 88.2). The inhibitory effect of alcohol on adiponectin is mediated through alcohol's ability to activate TNF-α [128], suggesting the importance of interactions between cytokines and adipokines in the pathogenesis of ALD.

Role of microsomal triglyceride transfer protein, c-Met, and hepatocyte growth factor

Export of triglyceride from the hepatocyte requires the synthesis of apolipoprotein B and microsomal triglyceride transfer protein (MTP) [129,130]. Ethanol feeding has been shown to down-regulate the transcription of the MTP gene [131] and decrease its activity [132]. Hepatocyte growth factor can reverse alcohol-induced steatosis by inducing expression of the genes for both MTP and apolipoprotein B [133]. Hepatocyte growth factor acts by way of a receptor encoded by the protooncogene c-Met [134]. Of note, a recent study showed that pioglitazone, a PPAR-γ agonist, can also activate c-Met, increase hepatic apolipoprotein B expression, and thereby attenuate ethanol-induced hepatic steatosis [135].

Role of apoptosis

Numerous factors related to alcohol metabolism can induce apoptosis of hepatocytes. It may result from oxidative stress induced by ethanol, reducing glutathione levels [136], and increased levels of TNF-α [137] and TGF-β [111]. Hepatocyte apoptosis is regulated by a system consisting of Fas and Fas ligand [138,139]. Fas (CD95) is a receptor found on hepatocytes, and it can interact with the Fas ligand present on the surface of certain T cells. These receptor/ligand proteins are evolutionarily related to the TNF/TNFR proteins. The interaction between the Fas ligand and soluble Fas triggers activation of apoptosis-inducing caspases and release of cytochrome c from the mitochrondria [139]. Apoptosis is a rapid process so routine hematoxylin & eosin staining for apoptotic bodies underestimates the extent of apoptosis; so, the TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling) assay and immunohistological methods are needed to evaluate apoptosis. Apoptosis is widespread in alcoholic hepatitis, and the apoptotic index is correlated with Maddrey discriminant function (see below) [140] and histological severity [141] in patients with alcoholic hepatitis.

Role of cytokines in activation of hepatic stellate cells

The final elements in alcoholic liver injury are activation of the hepatic stellate cells (HSC) and production of collagen and other matrix proteins [142]. This fibrogenic process requires the interaction of Kupffer cell-derived cytokines with the HSC (Fig. 88.3). One of the earliest events is the activation of nuclear factor-κB (NF-κB) in the HSC [143]. Products of ethanol metabolism and lipid peroxidation such as acetaldehyde, MDA, MDA–acetaldehyde adducts, and 4-HNE can also induce HSC to express collagen genes [142]. The γ-isoform of PPAR may participate in the control of HSC differentiation. Expression of this receptor falls during HSC activation, and treatment of the cells with PPAR-γ ligands retards the activation of the cells [144,145].

Once NF-κB is activated, the HSC express receptors for and can be stimulated by platelet-derived growth factor [146]. They also can be stimulated to secrete collagen by TGF-β1 and IL-1 [142]. This activation may become irreversible, leading to progressive fibrosis and cirrhosis. The irreversible activation may be driven by the changes the cells make in the extracellular matrix, such as deposition of type I collagen, production of TGF-β1 by the HSC themselves, and depletion of retinyl ester stores in the HSC [142]. HSC themselves can be activated directly by endotoxin through the CD14/TLR4 pathway [147]. Of note, these factors may lead to progressive collagen deposition even if the patient stops drinking.

Gender differences in the response to alcohol

There are important gender differences in the pathogenesis of ALD. At any given level of alcohol consumption, women have a higher likelihood of developing ALD than men [14]. This phenomenon is not fully understood; however, one study showed that the levels of gastric ADH were lower in women than in men, which led to higher blood alcohol concentrations in women who consumed the same amount of alcohol [148,149].

Female rats are more susceptible to ALD than male rats. Kupffer cells from female rats fed ethanol had a significantly greater response to LPS than Kupffer cells from male rats [150]. Moreover, female rats produced more TNF-α in response to chronic ethanol than males, suggesting that Kupffer cells in females are more active following ethanol exposure [150]. CD14 expression and NF-κB activation are also higher in Kupffer cells isolated from female mice. Estrogen might play role in ALD in females by modulating the oxidative stress of ethanol metabolism [151]. In summary, many mechanisms may conspire to make female alcoholics more prone to the development of alcoholic hepatitis and cirrhosis.

Clinical manifestations

ALD represents a spectrum of clinical illness and pathological change in individuals with acute and chronic alcohol consumption. Patients may have minimal abnormalities from steatosis or may develop more severe signs and symptoms of liver disease associated with the inflammation seen in alcoholic hepatitis or cirrhosis. Since alcohol abuse or dependence may be present in all stages of ALD, physicians should take a thorough history concerning alcohol use and standard screening questionnaires should be performed on all patients [152]. Denial is a major component of alcohol abuse, and alcoholics typically underestimate their consumption or deny that they have a problem with alcohol [153]. Several questionnaires have been developed and validated to screen for or establish the diagnosis of alcoholism. The CAGE questionnaire is the most commonly used for screening because it is fast and easy to remember [154]. The CAGE questionnaire consists of a battery of four questions:

- Have you ever felt the need to **C**ut down on drinking?
- Have you ever felt **A**nnoyed by criticism of your drinking?
- Have you ever felt **G**uilty about drinking?
- Have you ever had an **E**ye opener (early morning drinking)?

As a screening tool, the CAGE questionnaire does not discern between current and past drinking patterns. Another tool, the Alcohol Use Disorder Identification Test (AUDIT), was developed to improve the sensitivity of identifying heavy drinking and active alcohol use [155]. When using the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) criteria for an alcohol-use disorder as the gold standard, the AUDIT performed best at a cutoff score of 9 (sensitivity, 0.76; specificity, 0.79), and CAGE at a cutoff score of 1 (sensitivity, 0.69; specificity, 0.63). The AUDIT performed better overall than the CAGE test [156].

Clinical diagnosis of the three major stages of ALD is difficult because these stages may occur in any combination in the same patient, emphasizing the importance of liver biopsy. A study from Italy showed that there was no clear-cut association between typical histological features of ALD and the amount of alcohol consumption [64]. However, for purposes of instruction, it is useful to divide ALD into its three major types, alcoholic fatty liver, alcoholic hepatitis, and cirrhosis, and to discuss the clinical, laboratory, and pathological features of each. The role of physical examination to diagnose ALD is limited and the findings may vary from normal to evidence of hepatic decompensation or cirrhosis. A number of less common variants are listed in Table 88.4 and are discussed within the following sections.

Table 88.4 Less common pathological features of alcoholic liver disease

Alcoholic fatty liver with perivenular fibrosis
Alcoholic foamy degeneration (alcoholic microvesicular steatosis)
Sclerosing hyaline necrosis
Alcoholic cirrhosis with chronic hepatitis[a]
Cholestasis
Hepatic iron overload
Lipogranuloma
Massive hepatic necrosis (due to acetaminophen ingestion)
Focal fatty liver or focal fat sparing

a A significant proportion of these patients likely have concomitant hepatitis B or C virus infection.

Alcoholic fatty liver

Consumption of ethanol in sufficient quantities (in the range of 120–150 g/day for 2–3 weeks) will result in fatty liver and a classic study showed that abstinence for 4 weeks leads to resolution [157]. Stigmata of alcoholism (e.g., Dupuytren contractures, testicular atrophy, palmar erythema, spider angiomata, and gynecomastia) may also be present. Evidence of hypogonadism and feminization are evident in alcoholic males before the onset of liver disease, resulting from the toxic effects of ethanol on Leydig cells, leading to decreased testosterone production; impairment of hypothalamic–pituitary function resulting in low levels of luteinizing hormone; and induction of aromatase in adipose tissue and increased conversion of androgens to estrogens [158].

Alcoholic fatty liver is rarely diagnosed clinically because most patients are asymptomatic and do not seek medical attention. However, some cases of biopsy-proven alcoholic fatty liver are associated with constitutional symptoms of weakness, cachexia, fever, anorexia, nausea, vomiting, jaundice, hepatic tenderness, splenomegaly, or ascites. Most likely, such cases represent a combination of fatty liver and alcoholic hepatitis, because the classic lesions of alcoholic hepatitis are difficult to find in livers with panlobular steatosis, or may be missed because of sampling error. Laboratory abnormalities in alcoholic fatty liver are generally mild. Bilirubin is elevated in 25% of cases, but is usually less than 5 mg/dL. As in all stages of ALD, serum aspartate aminotransferase (AST) and alanine aminotransferases (ALT) are usually less than 300 IU/l (with the exception of foamy degeneration, see below). The AST is usually higher than serum ALT (with the AST : ALT ratio being at least 2 in 80% of cases). Hepatic deficiency of pyridoxal-6-phosphate, a cofactor necessary for ALT enzymatic activity, is thought to cause the smaller ALT elevation in these patients [159]. Alkaline phosphatase is usually no more than 300 IU/dL. The ratio of γ-glutamyltransferase to alkaline phosphatase activity can be more than 5, as a result of the disproportionate induction of γ-glutamyltransferase by alcohol abuse. This ratio is more specific than sensitive provided that the patient is not on drugs that also induce γ-glutamyltransferase (e.g., anticonvulsants). In alcoholic fatty liver, serum albumin and globulin levels are expected to be normal in the absence of coincidental medical

conditions, including malnutrition. Microscopically, there is great variation in the number of cells affected, with a tendency for fat accumulation in the perivenous and midzones of the liver lobule. Occasionally, hepatocytes rupture to form a fatty cyst, and then a lipogranuloma. Generally, there is sparse cell necrosis or inflammation. Intrahepatic cholestasis and mild cholangiolitis may be seen in the absence of extrahepatic biliary obstruction [160].

Another clinical variant of ALD is alcoholic foamy degeneration [161]. It is characterized by a marked, transient elevation of serum aminotransferases, alkaline phosphatase, serum lipids, and bilirubin levels. Liver biopsies demonstrate an intact lobular architecture, and perivenular hepatocytes show the presence of megamitochondria, extensive microvesicular fat accumulation without nuclear displacement, and cytoplasmic bile pigment deposition. Foci of hepatocyte dropout without a significant parenchymal infiltration with neutrophils are seen in these patients, more consistent with a degenerative than an inflammatory process [161]. All patients recover rapidly after abstaining from alcohol. Alcoholic foamy degeneration has been noted in about 2% of a series of over 300 patients in Spain [162]. There are yet other variants of fatty liver diagnosed radiographically as focal fatty liver and focal fat sparing. As these names imply, the former is the result of focal accumulation of fat while the rest of the liver is not steatotic. The latter indicates the reverse. These lesions may be confused with mass lesions on ultrasound or abdominal computed tomography (CT) scan. In the past, these conditions could be diagnosed by liver spleen scan [163,164]. With today's technology, magnetic resonance imaging will provide definitive diagnosis of these conditions and will distinguish them from mass lesions.

Alcoholic hepatitis

Alcoholic hepatitis is the most florid manifestation of ALD and is associated with a high mortality [165]. Classically, alcoholic hepatitis presents with fever, jaundice, hepatomegaly, and signs of decompensated liver disease, such as ascites and hepatic encephalopathy. Fever is common and it is important to exclude other potential sources of infection, including spontaneous bacterial peritonitis, pneumonia, and urinary tract infection. Once set in motion, alcoholic hepatitis seems to progress despite stopping drinking. Physical examination usually reveals obvious signs of protein-calorie malnutrition [166]. Stigmata of chronic liver disease should increase the suspicion of underlying cirrhosis. On laboratory examination, pancytopenia is not uncommon and it is secondary to the toxic effects of ethanol on the bone marrow, impaired pyridoxine metabolism, folic acid deficiency, iron deficiency from blood loss, or hypersplenism. Patients might present with leukocytosis, and it is probably driven by increased levels of IL-8 generated in the liver or concurrent infections [167,168]. Serum AST and ALT are elevated in all cases and the AST : ALT ratio is usually greater than 2. Alkaline phosphatase is elevated in 80% of cases. High values of serum AST and ALT (> 300 IU/L) should raise the suspicion of alternative diagnoses, such as coincidental viral hepatitis, hypoxic liver injury (in which the AST : ALT ratio is also increased), acetaminophen overdose, or sclerosing hyaline necrosis (see below). Bilirubin is usually increased, whereas albumin is usually decreased and the prothrombin time is often prolonged. Electrolyte abnormalities are frequent in alcoholic hepatitis, and include hyponatremia, hyperchloremia as the result of renal tubular acidosis, hypokalemia, and hypophosphatemia from poor dietary intake, vomiting, or diarrhea, hypomagnesemia from increased urinary loss, and respiratory alkalosis from hepatic encephalopathy.

The common histological findings in alcoholic hepatitis are ballooning degeneration, focal hepatocyte necrosis, and neutrophilic infiltration [160]. The latter two are considered absolute criteria for the diagnosis of alcoholic hepatitis. More than 30% of patients develop Mallory bodies, an aggregation of perinuclear, eosinophilic, amorphous material. Although highly suggestive of ALD, Mallory bodies are also seen in many other liver diseases (Table 88.5). Other pathological findings in alcoholic hepatitis include steatosis and fibrosis or cirrhosis [160]. These pathological findings may be indistinguishable from features seen in nonalcoholic steatohepatitis. Clinically, patients with alcoholic hepatitis are much sicker than those with nonalcoholic steatohepatitis. In a few cases of alcoholic hepatitis, there is *sclerosing hyaline necrosis*, which is characterized by severe, irregular, confluent, centrilobular necrosis with obliteration of the central vein by collagen [169]. Venoocclusive lesions have also been described and these pathological findings are associated with recalcitrant ascites, variceal bleeding, and a high mortality rate [170].

Alcoholic cirrhosis

Patients with alcoholic cirrhosis have similar clinical features to those with other types of cirrhosis. Cirrhosis may be suspected in patients with stigmata of chronic liver disease on physical examination or laboratory abnormalities suggestive of synthetic dysfunction. Of note, alcoholic cirrhosis may be asymptomatic in 10%–20% of patients. The liver test abnormalities in alcoholic cirrhosis are less pronounced than those in alcoholic hepatitis. In fact, in compensated cirrhosis, many of the liver tests are close to normal. Laboratory abnormalities may include mild increases in aminotransferases and alkaline phosphatase, low serum albumin, polyclonal elevation of serum globulins (greater than 4 g/dL), thrombocytopenia, and anemia. Interestingly, thrombocytopenia is an excellent predictor for the presence of large varices and therefore cirrhosis [171].

The pathological end-stage of ALD is characterized by fibrous bands connecting portal triads with central veins, and by regenerative nodules. The nodules are typically small (1–3 mm) and uniform in size [160]. Ethanol suppresses hepatic regeneration [172]; so with prolonged abstinence,

Table 88.5 Differential diagnosis of liver diseases exhibiting Mallory hyaline

Alcoholic cirrhosis (especially with continued drinking)[a]
Steatohepatitis
Alcoholic steatohepatitis[a]
Nonalcoholic steatohepatitis[a]
Chronic hepatitis C
Parenteral nutrition-induced liver disease
Drug-induced liver disease (e.g., griseofulvin, nifedipine, nicardipine, didanosine, diethylstilbestrol, tamoxifen, tetracycline, valproic acid, vitamin A, diltiazem, glucocorticoids, methotrexate, or amiodarone)
Chronic cholestatic disorders
Primary biliary cirrhosis[a]
Primary sclerosing cholangitis
Chronic biliary obstruction
Extrahepatic biliary atresia
Copper overload conditions
Wilson disease[a]
Indian childhood cirrhosis[a]
Congenital hepatic fibrosis
Copper-associated liver disease of childhood
Hepatocellular neoplasms/masses
Hepatocellular carcinoma
Hepatic adenoma
Dysplastic hepatocellular nodule
Focal nodular hyperplasia
Adenomatous hyperplasia
Weber–Christian disease
Inherited diseases of metabolism
Abetalipoproteinemia
α_1-Antitrypsin deficiency
Glycogen storage disease, type Ia[a]
Postinfantile giant cell hepatitis
Juvenile Parkinson disease

a Indicates that Mallory bodies are found occasionally to commonly; in the other conditions, they are rare.

nodular regeneration becomes more vigorous and may result in mixed micro/macronodular or macronodular cirrhosis. Superimposed fatty change and alcoholic hepatitis are often seen with cirrhosis. There may also be increased stainable iron in biopsy samples. Iron overload in alcoholic cirrhosis can be differentiated from hereditary hemochromatosis by genetic analysis for *HFE* mutations or by quantitative iron analysis. In hereditary hemochromatosis, the hepatic iron index (hepatic iron content expressed as μmol/g dry weight divided by the patient's age) in the cirrhotic liver is more than 1.9 whereas that in the cirrhotic liver of alcoholics is less than 1.9 [173]. In some patients with alcoholic cirrhosis, there is portal inflammation with piecemeal necrosis. This feature may reflect an autoimmune component of ALD, unsuspected Wilson disease (particularly in young patients), or, most commonly, coexistent chronic viral hepatitis – particularly hepatitis C virus (HCV) infection [174].

Role of liver biopsy

Liver biopsy provides valuable information by evaluating for alternative etiologies of liver disease, providing prognostic information by the severity of liver pathology, and confirming the diagnosis of alcoholic hepatitis; however, it is controversial whether a liver biopsy should be performed in patients with suspected ALD. A liver biopsy may be needed if the diagnosis is in doubt or other alternative diagnoses are suspected. However, a percutaneous liver biopsy in such patients is often contraindicated because of the underlying coagulopathy, thrombocytopenia, and ascites. In such cases, transjugular liver biopsies may be necessary [175].

Differential diagnosis

There are numerous pitfalls in the diagnosis of ALD, among them failing to consider ALD in patients not conforming to the alcoholic stereotype, and assuming that abnormal liver tests in an alcoholic patient are the result of ALD. It should be noted that in some populations, more than 50% of patients with alcohol abuse who develop chronic liver disease have concurrent viral hepatitis, especially HCV [176]. As previously mentioned, alcoholism should be considered in any patient with liver disease, and a careful drinking history should be obtained from the patient and a reliable third party, such as a family member.

Alcoholic fatty liver

As outlined in Table 88.6, fatty liver can result from many processes. The differential diagnosis of massive hepatomegaly includes fatty liver, right heart failure, constrictive pericarditis, Budd–Chiari syndrome, infiltrative processes (e.g., amyloidosis, myeloproliferative disorders, reticuloendotheliosis, and lipid storage diseases), and neoplasms. A helical CT scan with dual (arterial/venous) phases is the diagnostic modality of choice to evaluate the cause of hepatomegaly because it is more sensitive in detecting focal hepatic masses than a CT scan performed only in the venous phase, an ultrasonogram, or a sulfur colloid scan [177].

Alcoholic hepatitis

The clinical presentation of patients with alcoholic hepatitis may mimic the presentation of patients with nonalcoholic steatohepatitis or cholangitis from choledocholithiasis. Generally, patients with alcoholic steatohepatitis are much sicker than those with nonalcoholic steatohepatitis and they tend to have higher AST : ALT ratios [165]. Imaging of the liver and biliary tree may be necessary to exclude choledocholithiasis. Depending on the experience of the ultrasonographer, the sensitivity of abdominal ultrasound to detect

Table 88.6 Potential causes of fatty liver

Macrovesicular fat
Alcoholic steatohepatitis
Nonalcoholic steatohepatitis
Hepatitis C
Toxins and drugs: methotrexate, halogenated hydrocarbons, niacin, HIV protease inhibitors, glucocorticoids, heavy alcohol use
Nutritional disorders: obesity, diabetes, choline deficiency, systemic carnitine deficiency, celiac disease, kwashiorkor, parenteral nutrition
Lipodystrophy
Wilson disease
Abetalipoproteinemia
Inflammatory bowel disease
Weber–Christian disease
Q fever
Microvesicular fat[a]
Reye syndrome
Parenteral alimentation
Yellow fever
Heat stroke
Toxins and drugs: valproic acid, intravenous tetracycline, toxic shock syndromes, salicylate overdosage in children, Jamaican vomiting disease, FIAU, nucleoside reverse transcriptase inhibitors, mycotoxins
Metabolic diseases: cholesterol ester storage disease, galactosemia, Wolman disease, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency, medium-chain acyl-CoA deficiency
Complications of pregnancy: acute fatty liver of pregnancy, eclampsia, HELLP syndrome

a Microvesicular fatty liver is usually the result of mitochondrial damage and defects in lipid oxidation pathways; however, there is significant overlap with many disorders occasionally producing microvesicular fatty liver.

CoA, coenzyme A; FIAU, fialuridine; HELLP, hemolysis, elevated liver enzymes, and low platelet syndrome; HIV, human immunodeficiency virus.

choledocholithiasis is around 50%–90%. A CT scan of the abdomen has similar sensitivity to ultrasound to detect common bile duct stones [178–180]. Magnetic resonance cholangiopancreatography and endoscopic ultrasound are much better diagnostic tests to detect common duct stones with sensitivities of 90% and 95%, respectively [180]. However, these tests might not be readily available in most centers. The gold standard test to detect choledocholithiasis is endoscopic retrograde cholangiopancreatography, which (compared to other tests) has the advantage of permitting intervention if a common bile duct stone is present. However, endoscopic retrograde cholangiopancreatography is invasive and may cause complications such as pancreatitis.

Alcoholic cirrhosis

Alcoholic cirrhosis is usually micronodular but may sometimes be macronodular. The differential diagnosis of alcoholic cirrhosis includes posthepatitic cirrhosis (whether as the result of chronic viral infection, drugs, metabolic disorders, or autoimmune hepatitis), the cirrhotic stage of primary or secondary biliary cirrhosis, Wilson disease, hemochromatosis, and cirrhosis caused by nonalcoholic steatohepatitis. The degree of fatty infiltration of the liver may decrease as cirrhosis develops [181]. Alcoholic cirrhosis with features of chronic hepatitis may reflect superimposed hepatitis B or C or an autoimmune process incited by alcoholic injury [176]. Disease processes that mimic cirrhosis (e.g., constrictive pericarditis, Budd–Chiari syndrome, venoocclusive disease, idiopathic portal hypertension, portal vein thrombosis, and myeloid metaplasia) should be considered.

Special considerations

HCV and ALD

Alcohol abuse and HCV infection coexist with chronic liver disease in many patients. The prevalence of HCV markers in alcoholic patients without liver disease ranges from 0% to 14%; in all alcoholic patients the prevalence ranges from 11% to 35%; and in alcoholic patients with chronic liver disease the prevalence ranges from 18% to as much as 51% [182]. There is no clear-cut explanation for the increased prevalence of hepatitis C infection in alcoholics. Some reports suggested that the increased prevalence of anti-HCV in alcoholics is primarily the result of a past history of intravenous drug use [183,184]. Several studies have shown that alcohol accelerates the progression of liver injury in patients with HCV, leading to cirrhosis and hepatocellular carcinoma [185]. Histological activity and fibrosis increase with the amount of alcohol use. One study from France showed that in patients with HCV who drank more than 50 g of alcohol per day, there was a 30% increased rate of fibrosis compared with those who drank less [186]. The effect of alcohol consumption on the progression of HCV is also seen in patients who drank even moderate amounts of alcohol, as low as 30–50 g/day in men and 20–50 g/day in women [187]. Another possibility for the progression of fibrosis in patients with HCV and ALD is the concurrent use of illicit drugs, especially marijuana, in alcoholics. The cannabinoids present in marijuana exert biological effects through cannabinoid receptors CB1 and CB2, which regulate progression of experimental liver fibrosis. In a recent population-based study, daily cannabis use was found to be an independent predictor of fibrosis progression rate when compared to nonusers or occasional users (odds ratio 3.6; 1.5–7.5). Furthermore, severe fibrosis was also predicted by daily cannabis use (odds ratio 2.5; 1.1–5.6; $P = 0.034$), independently of Metavir activity grade, excessive alcohol intake, age at liver biopsy, and underlying steatosis [188]. The results of these studies highlight that there is no known safe drinking level for patients with HCV infection, and that patients with HCV

infection should be advised to refrain from drinking alcohol and from illicit drug use.

The mechanisms of advanced liver injury caused by coexisting ALD and HCV remain poorly understood. Hepatitis C core protein can inhibit MTP, leading to hepatic steatosis [189]. Alterations in the immune system secondary to alcohol use have also been reported. One study in mice showed that ethanol-fed mice have inhibition of T helper and cytotoxic T-lymphocyte responses to HCV core protein, and so have reduced production of the cytokines needed to eradicate the virus. Additionally, in the presence of HCV, alcohol consumption causes an enhanced inflammatory response in the liver. So the immunosuppressive effect of alcohol might contribute to both the lack of clearance of HCV and the viral persistence, which results in an increased nonspecific inflammatory response [185,190,191]. Oxidative stress might also play a role in the progression of fibrosis. Both ethanol consumption [29] and HCV core protein [192] cause oxidative damage by triggering the release of mitochondrial reactive oxygen species, leading to increased rates of lipid peroxidation. A recent study showed a synergistic effect of alcohol and HCV on the production of several cytokines such as TGF-β and TNF-α [193].

Alcohol also exerts effects on HCV quasispecies generation. HCV quasispecies complexity was increased, leading to viral escape from the immune response in alcoholic patients [194]. There are conflicting reports about the effects of alcohol on serum HCV RNA. A recent metaanalysis of 14 studies failed to show an association between alcohol use and HCV viral load [195].

Alcohol consumption has been shown to decrease the response to interferon in patients with HCV. Tabone and colleagues studied the effect of interferon treatment in patients with hepatitis C whose ALT levels remained twice the upper limit of normal despite 6 months of complete alcohol abstinence [196]. The sustained virological response was 33% in non-drinkers, 20% in mild drinkers, and only 9% in those who drank heavily. Alcohol use also has an impact on treatment response and it is associated with treatment failure in patients with hepatitis C undergoing treatment with pegylated interferon and ribavirin [197]. These findings suggest that patients should be abstinent from alcohol before the initiation of hepatitis C therapy.

Hepatic iron stores and ALD

Iron is a vital element in cellular electron transport and is involved in heme-containing enzyme function. However, excess iron facilitates the generation of reactive oxygen species and catalyzes the formation of hydroxyl radicals from hydrogen peroxide [198]. Increased hepatic iron stores and serum markers of iron overload have been observed in alcoholics [199,200]. The mechanism of the increase in iron accumulation is not known, although increased hepatocyte iron uptake secondary to upregulation of the transferrin receptor has been found in animal models and in humans [201].

The degree of iron accumulation in ALD is usually mild. However, approximately 4% of patients may have hepatic iron stores twice the upper limit of normal [198,202]. The confusion as to whether hepatic iron overload is a form of ALD or hereditary hemochromatosis has been resolved by the use of the hepatic iron index and by the availability of *HFE* gene analysis [173,198]. The former is valuable in the distinction of ALD with iron overload from hereditary hemochromatosis by emphasizing that the index is greater than 1.9 μmol/g dry weight of liver per year of life in individuals with hereditary hemochromatosis [203], but not ALD. Moreover, with the availability of *HFE* gene analysis, the distinction of hereditary hemochromatosis from other liver diseases with iron overload has become further defined [198]. Patients with ALD and a high hepatic iron index are usually homozygotes for the C282Y *HFE* mutation [204]. Patients with hereditary hemochromatosis who are heavy alcohol drinkers (> 60 g/day) have a higher prevalence of cirrhosis at lower levels of hepatic iron and a reduced long-term survival, despite adequate phlebotomy therapy, which is indicative of the synergy between the hepatotoxic effect of alcohol and iron [205].

Clinical course and prognosis of alcoholic liver disease

Alcoholic fatty liver

Historically, patients with evidence of only hepatic steatosis on biopsy were thought to have a benign prognosis. However, in 1995 Teli and colleagues demonstrated that 18% of patients with simple hepatic steatosis progressed to fibrosis or cirrhosis in 10 years [206,207]. Severity of steatosis, female sex, and the presence of giant mitochondria were independent predictors of disease progression [206]. In animals, fatty livers are highly susceptible to toxicity from endotoxin [208], and it is well known that steatotic donor livers increase the risk of graft nonfunction after liver transplantation [209,210], therefore, fatty liver is not a benign condition as previously thought.

Alcoholic steatohepatitis

Alcoholic steatohepatitis occurs less frequently than alcoholic steatosis but carries a worse prognosis. It has been estimated that 10%–30% of heavy drinkers will develop alcoholic steatohepatitis in their lifetime [152,211]. Factors influencing the progression of disease in patients with steatohepatitis include continued alcohol consumption, female gender, age, and high body mass index [211,212]. As many as 56% of patients with steatohepatitis who continue to drink heavily will progress to cirrhosis and improvement in histology is found in 27% of patients who achieved abstinence [212].

Alcoholic hepatitis is perhaps the most severe manifestation of ALD and is associated with a high mortality. Identification of those patients at greatest risk of death is vital not only for decisions relating to individual management but also for the design of clinical studies assessing possible treatments for this condition. Several clinical scoring systems have been derived to predict the clinical outcome of patients with alcoholic hepatitis. These scores include the Child–Turcotte–Pugh score (CTP) [213], which is used commonly to stage the severity of cirrhosis, the combined clinical and laboratory index of the University of Toronto (CCLI) [214], the Maddrey discriminant function [215], the MELD (model for end stage liver disease) scores [216], and most recently the Glasgow alcoholic hepatitis score (GAHS) [165]. The admission CTP score is independently associated with mortality; however, this scoring system is not sensitive to predict the mortality during the hospital stay [217] The CCLI permits a linear estimate of acute mortality in persons with alcoholic hepatitis. Its major disadvantages are the large number of variables that must be scored and the complexity of the calculation itself [214]. The discriminant function (DF) score was derived in clinical trials of patients with alcoholic hepatitis and has been widely applied clinically. The score is based on prothrombin time and bilirubin, and it is calculated as follows: (4.6 × prothrombin time prolongation) + total serum bilirubin in mg/dL. In combination with the presence of encephalopathy, a DF score greater than 32 is highly correlated with a more than 50% short-term (30-day) mortality rate. Although DF is a continuous scoring system, its interpretation (using the cutoff of 32) has converted it into a categorical method of classification [207]. Therefore, this scoring system suffers from the problem that once patients' scores have exceeded the cutoff value, they cannot be further characterized [207]. The model for end-stage liver disease (MELD) is a recently developed scoring system that has been validated as an independent predictor of short-term survival in patients who are on the liver transplantation list. In a study of 34 patients, there was a 45% 30-day survival in patients with a MELD score greater than 11, whereas those with a score of 11 or less had a survival of 96% [216]. Two recent studies showed that the MELD score is useful for predicting 3-month mortality of patients with severe alcoholic hepatitis who are not treated with corticosteroids [217,218]. Its accuracy was comparable to that of DF in predicting 3-month mortality of patients with severe alcoholic hepatitis [218,219]. Using the optimal cutoff point (21 for MELD and 37 for DF), MELD had a sensitivity of 75% and a specificity of 75% and DF had a sensitivity of 88% and a specificity of 65%. Another study confirmed that DF and MELD had similar accuracy in predicting survival of patients with alcoholic hepatitis [217,219].

The GAHS was developed and validated in 2005 [165]. The GAHS was derived from five variables independently associated with outcome: age, and (based on day 1 results) serum bilirubin, blood urea nitrogen, and (based on day 6–9 results), serum bilirubin, prothrombin time, and peripheral white blood cell count (Table 88.7). Values obtained ranged from 5 to 12 and there was a marked rise in mortality when a score greater than 9 was attained. Although this cutoff value had less sensitivity to predict mortality when compared with the DF score, a GAHS of at least 9 on day 1 had an overall accuracy of 81% when predicting 28-day outcome. In contrast, the DF had an overall accuracy of 49%. Similar results were found using information at 6–9 days to predict 84-day mortality [165].

Table 88.7 The Glasgow Alcoholic Hepatitis Score

	Score		
	1	**2**	**3**
Age (years)	< 50	≥ 50	
White blood cell count (× 10^9/mL)	< 15	≥ 15	
Blood urea nitrogen (mmol/L)	< 5	≥ 5	
Prothrombin time ratio (INR)	< 1.5	1.5–2.0	> 2.0
Bilirubin (μmol/L)	< 125	125–250	> 250

Alcoholic cirrhosis

As previously mentioned, the amount of ethanol that can be safely drunk (moderate drinking) is estimated to be up to 20 g (two drinks) per day for men and up to 10 g (one drink) for women. Approximately 15%–20% of patients who chronically drink alcohol will progress to cirrhosis in their lifetime [211]. Abstinence from alcohol is essential in treatment because it has been shown to abrogate the progression of disease and need for liver transplantation [220]. The prognosis is poor in patients who continue to drink. One study reported 80% mortality within 7 months in those with decompensated alcoholic cirrhosis who continued to drink [211,221]. Overall 5-year survival rates range from 20% to 50% [222,223].

Complications of alcoholism and alcoholic liver disease

Metabolic disorders

One of the metabolic complications in alcoholic patients is alcoholic ketoacidosis [224]. Alcoholics who are fasting while drinking heavily exhibit similar metabolic alterations to an insulin-deficient state; i.e., high serum free fatty acids, low insulin, and high glucagon and catecholamine levels. Patients with alcoholic ketoacidosis typically present with an otherwise unexplained high anion gap metabolic acidosis, ketonemia (specifically, elevated β-hydroxybutyrate, as the result of the redox shift that accompanies alcohol metabolism), and a variable plasma glucose concentration that may be low, normal, or modestly elevated. Of note, lactic acidosis can also

occur in these patients [225]. Other electrolyte disorders, including hyponatremia, hypokalemia, hypophosphatemia, hypocalcemia, and hypomagnesemia, are common [226].

Another unique metabolic complication in alcoholic patients is hypoglycemia. The high NADH concentration occurring during alcohol metabolism promotes the formation of reduced metabolites, which in turn inhibit gluconeogenesis, resulting in fasting hypoglycemia. Treatment for these patients includes adequate hydration and administration of glucose. Generally, this syndrome is rapidly reversible and has a low mortality [226].

Lastly, the interaction between induced activity of CYP2E1 in alcoholics and acetaminophen is clinically important [227]. Although therapeutic doses of acetaminophen are harmless when consumed by alcohol-naive individuals, in alcoholics such doses can produce serious liver disease with extremely high aminotransferase levels, massive perivenular hepatic necrosis, pancreatitis, and renal failure. Heavy drinkers should be warned to avoid acetaminophen, and in particular to read medication labels of over-the-counter medications to be sure that they do not inadvertently consume more than 2 g/day. On the other hand, small doses of acetaminophen are safer in patients with cirrhosis than nonsteroidal antiinflammatory drugs, which have adverse effects on platelet and renal function.

Infections

Alcoholics are more prone to infections than other patients with liver disease as a result of malnutrition, impaired phagocyte function, and other immune defects [228]. Bacteremia and spontaneous bacterial peritonitis are common in patients with cirrhosis. Other infections include pneumonia and lung abscess, bacterial meningitis, and urinary tract infections [229]. Patients with cirrhosis are also at increased risk of sepsis from opportunistic fungal infections, *Listeria monocytogenes*, or *Vibrio* spp., especially *V. vulnificus*, when they consume raw seafood such as oysters [230] or have skin wounds that are exposed to brackish water. Patients with possible infections should have a chest X-ray, urinalysis, surveillance blood cultures, and perhaps lumbar puncture. A sample of ascites, if present, should be analyzed for the serum–ascites albumin gradient, the cell count, and the differential, and cultured in blood culture bottles. An absolute neutrophil count over 250/μL indicates infection [231]. Direct inoculation of ascitic fluid into blood culture bottles substantially improves the chances of culturing an organism because the concentration of bacteria in the fluid is low [232].

Another important issue is the concomitant infections occurring during or after variceal bleeding in patients with alcoholic cirrhosis. Bacterial infections occur in up to 20% of patients who are hospitalized with gastrointestinal bleeding [233]. Multiple studies and a recent metaanalysis demonstrated that prophylactic antibiotics reduced the overall infectious complications and mortality rate in patients with cirrhosis hospitalized for bleeding [233–236]. Antibiotics may also reduce the risk of recurrent variceal bleeding in hospitalized patients [237].

Altered neurological status

It is difficult to evaluate neurological status in sick and intoxicated alcoholic patients. Some neurological disorders are predominantly the result of inadequate nutrition (e.g., thiamine deficiency), but others appear to involve the neurotoxicity of ethanol. It is essential to exclude intracranial pathology, such as chronic or acute subdural hematoma from head trauma, stroke, or meningitis. Other metabolic or toxic causes should be fully sought as the potential causes for altered mental status. These include hypoglycemia, hyponatremia, and hepatic encephalopathy [238]. In most patients with impaired consciousness, a noncontrasted head CT should be performed and it is highly desirable before performing lumbar puncture, unless the clinical suspicion of meningitis is high, in which case lumbar puncture should be performed promptly [238]. The requirement for thiamine is increased by carbohydrate so alcoholic patients should be given thiamine promptly on admission. Supplementation of other water-soluble vitamins, especially pyridoxine and folate, is advisable.

Hepatic encephalopathy may be difficult to diagnose [239]. Patients with hepatic encephalopathy usually have advanced chronic liver disease and have many of the physical and laboratory stigmata associated with severe hepatic dysfunction. Generally, hepatic encephalopathy is reversible and a precipitating cause (e.g., gastrointestinal bleeding; electrolyte and acid-base imbalance; high protein intake; severe constipation; noncompliance with medications; drug use, including sedatives; and infection), rather than worsening of hepatocellular function, can be identified in the majority of patients.

Renal dysfunction

Renal insufficiency commonly complicates the clinical course of patients with alcoholic cirrhosis. There are several causes of renal failure in such patients, such as volume depletion from diuretics or poor oral intake, shock from sepsis or bleeding, exposure to nephrotoxic drugs, or other intrinsic renal disease. However, renal failure in these patients normally occurs in the absence of these precipitating factors. This type of renal dysfunction is known as the hepatorenal syndrome [240]. There are no specific clinical findings in hepatorenal syndrome, although most patients have features of advanced liver disease. Renal failure in hepatorenal syndrome is associated with oliguria, benign urinary sediment, sodium retention (urinary Na^+ more than 10 mEq/L), dilutional hyponatremia, and low fractional excretion of sodium [240]. As a result of the lack of specific diagnostic tests to differentiate between hepatorenal syndrome and other causes of renal insufficiency, the diagnosis is based on the guidelines proposed by the International Ascites Club [241]. The therapy for hepatorenal syndrome is beyond the scope of this review.

Treatment

Treatment for alcoholism

Abstinence is important to prevent further liver injury and it appears to benefit patients at every stage of the disease [242]; therefore, establishing long-lasting sobriety should be the highest priority for these patients. The success of therapies for alcohol abuse varies from 30% to 90% and the results are improved when the abuse is detected at an early stage and the patient has social support from family, peers, and employers [243,244]. Medications to facilitate abstinence, such as naltrexone and acamprosate, both singly and together, have been shown to be effective in some patients [245]. A 6-month, randomized, double-blind, placebo-controlled trial attempted to determine the efficacy and tolerability of a long-acting intramuscular formulation of naltrexone for the treatment of alcoholism. Compared with placebo, 380 mg long-acting naltrexone resulted in a 25% decrease in the event rate of heavy drinking days and 190 mg resulted in a 17% decrease [246]. Generally, treatment of alcohol disorders through the use of combinations of pharmacological and behavioral modalities may be more effective than single-modality approaches. A large multicenter clinical trial sponsored by the National Institute on Alcohol Abuse and Alcoholism, Combining Medications and Behavioral Interventions (COMBINE), showed that patients receiving medical management with naltrexone, combined behavioral intervention, or both, fared better on drinking outcomes. Acamprosate was not efficacious in this trial. Medical management of alcohol dependence with naltrexone, if implemented with behavioural intervention, could greatly expand patient access to effective treatment [247].

Current methods for monitoring alcohol consumption in patients who are under treatment are not satisfactory. Serum carbohydrate-deficient transferrin has been approved as a tool to identify possible chronic heavy alcohol consumption. This form of transferrin lacks the normal number of sialic acid moieties as a result of the effects of ethanol on its post-translational modification in the Golgi apparatus, and on its rate of removal from the plasma. The sensitivity and specificity of this test for significant alcohol intake are 60%–70%, and 80%–90%, respectively [248,249], and a rise in its concentration is suggestive of relapse [250]. Lower sensitivity (< 50%) has been reported [251], therefore, the usefulness of this test to detect heavy alcohol use is unclear.

Other modifiable factors that might interfere with the progression of liver disease are cigarette smoking, obesity, and caffeine consumption. Several epidemiological studies showed that fibrosis worsens more rapidly in patients with ALD who smoke, presumably secondary to the effect of oxidative stress from smoking [252,253]. Obesity is associated with the development of steatosis and high body mass index has been shown to be an independent risk factor of ALD [212]. Several epidemiological studies have found an inverse association of coffee consumption and the levels of liver enzymes [254–257]. Interestingly, coffee drinking was found to be a protective factor against alcoholic and nonalcoholic liver cirrhosis in case–control studies [252,258] and against alcoholic cirrhosis in several prospective studies [253,259]. Such a protective effect is believed to be from the antioxidant property of caffeine [254]. Therefore, lifestyle modification is important in the treatment of ALD.

Treatment for alcoholic hepatitis

Achieving sobriety is paramount in the treatment of alcoholic hepatitis. Many therapeutic agents have been used for the treatment of alcoholic hepatitis. Specific medical therapies are discussed below.

Corticosteroids

Corticosteroids suppress the immune system activated by enhanced generation of neoantigens, such as MDA and acetaldehyde protein adducts, cytochrome P4502E1 and 3A4, and liver membrane antigen [242]. It also inhibits the production of TNF-α, activation of HSC, and possibly fibrogenesis. At least 12 randomized, controlled clinical trials have assessed the effectiveness of corticosteroids in patients with alcoholic hepatitis. Several studies found no benefit [260–266], whereas others reported improved survival [215,267–270]. Subsequent metaanalyses also produced conflicting results [271]. Two suggested a beneficial role of corticosteroids [272,273], whereas one questioned their efficacy [274]. The American College of Gastroenterology recommended glucocorticoid treatment (prednisolone, 40 mg daily for 4 weeks followed by a taper) in patients with severe alcoholic hepatitis (DF > 32) with hepatic encephalopathy [152]. The therapy should not be initiated in patients with gastrointestinal bleeding, active infection, renal failure, or acute pancreatitis. A major disadvantage to corticosteroids is therefore the fact that they cannot be used by many patients with alcoholic hepatitis. It has been estimated that seven patients need to be treated with corticosteroids to prevent one death [271].

Patients with alcoholic hepatitis are invariably malnourished and the severity of protein-calorie malnutrition has been shown to closely correlate with mortality rate [166]. The underlying mechanisms responsible are unknown, although it has been speculated that protein-calorie malnutrition worsens mortality in patients with alcoholic hepatitis by effects on the immune system, by impairing protein synthesis, which is essential for hepatic regeneration [271,275], and by aggravating depletion of glutathione. A recent randomized controlled trial compared the therapeutic efficacies of corticosteroid therapy (40 mg/day) vs enteral nutrition (2000 kcal/day) with outcomes assessed at 28 days (the end of therapy) and 1 year later or at death. Both therapies showed similar initial outcomes, however, fewer long-term infections were found in those treated with enteral nutrition [276]. This important study suggests that aggressive nutritional

support is as effective as treatment with prednisone. Another small pilot study suggests that enteral nutrition in combination with a short course of steroids might be a good therapeutic strategy for severe alcoholic hepatitis; however, this treatment strategy deserves investigation in a randomized controlled trial [277].

Anabolic steroids

There are several reasons to use anabolic steroids in patients with alcoholic hepatitis. These medications were shown to improve nutritional status in patients with wasting syndrome [278] and they accelerated the disappearance of steatosis and promoted the synthesis of coagulation factors [207]. In animal models, these medications can prevent chemically induced liver injury and promote liver regeneration [207,279]. Several randomized trials have tested the benefit of using anabolic steroids, oxandrolone or testosterone, in patients with alcoholic hepatitis. In a multicenter, randomized, placebo-controlled study, 263 patients with moderate and severe alcoholic hepatitis were randomized to one of three treatments: prednisolone, oxandrolone, or placebo. During the first 30 days, mortality in the groups receiving steroid therapy was not significantly different from mortality in the placebo group. Although neither steroid improved short-term survival, oxandrolone therapy was associated with a beneficial effect on long-term survival, especially in patients with moderate alcoholic hepatitis (as estimated by bilirubin and prothrombin time). As most patients with alcoholic hepatitis were malnourished, a combination therapy with nutritional treatment and oxandrolone was conducted in a veteran population. Oxandrolone appeared to be most beneficial in patients with moderate malnutrition, particularly in those who received sufficient calories during the study [280]. This study supports the notion that nutritional support in patients with alcoholic hepatitis is essential and combined medical and nutritional therapies may be more efficacious than agents used singly. A metaanalysis on the efficacy of anabolic–androgenic steroids for alcoholic liver disease was performed in a Cochrane review. This systematic review could not demonstrate any significant beneficial effects of anabolic–androgenic steroids on any clinically important outcomes of patients with alcoholic liver disease [281].

Propylthiouracil

Propylthiouracil (PTU) has been used to treat alcoholic hepatitis, based on the prediction that it would decrease the hypermetabolic state induced by alcohol and protect perivenous cells from hypoxic injury [282,283]. It also inhibits neutrophil myeloperoxidase and may thereby reduce oxidative stress from hypochlorous acid released by neutrophils [284]. There have been several trials of PTU in patients with alcoholic hepatitis. In one study, PTU improved symptoms and laboratory tests [285]; however, in another series of more severely ill patients, PTU was not effective [286]. A Cochrane database systematic review published a metaanalysis by combining the results of six randomized clinical trials to determine the effectiveness of PTU in alcoholic hepatitis [287]. The analysis of 710 patients demonstrated that there were no significant effects of PTU vs placebo on all-cause mortality (relative risk [RR] 0.93, 95% confidence interval [CI] 0.66–1.30), liver-related mortality (RR 0.80, 95% CI 0.50–1.29), complications of the liver disease, or liver histology. There is therefore no evidence for using PTU for ALD outside randomized clinical trials [287].

Anti-TNF therapy

As previously mentioned, TNF-α appears to play a particularly important role in ALD. Several recent studies have focused on the use of medications that exert their function on the activities of TNF-α. Pentoxifylline, a phosphodiesterase inhibitor, has been shown to decrease the transcription of the TNF-α promoter and the production of TNF-α, and to inhibit the activation of NF-κB [288,289]. A prospective, randomized, double-blind study using pentoxifylline was performed in 101 patients with severe alcoholic hepatitis (DF > 32) [290]. The study showed that the patients who received 400 mg pentoxifylline three times daily for 4 weeks had a 40% reduction in mortality compared to the placebo group (receiving vitamin B-12). Based on the difference in mortality between the pentoxifylline and placebo groups, the number needed to treat to prevent one death was about 5. The reduction in 4-week mortality was mainly attributed to the concomitant decrease in the incidence of hepatorenal syndrome by 65%–70%. The mechanism whereby pentoxifylline decreased the development of the hepatorenal syndrome is unclear [290].

Based on the result of this study and animal data, infliximab, a chimeric mouse–human anti-TNF monoclonal antibody, has been tested in patients with severe alcoholic hepatitis. The first trial evaluated tolerance and effectiveness of infliximab combined with steroids in reducing the 2-month mortality rate among patients with severe alcoholic hepatitis, defined by a DF greater than 32 [291]. Patients were randomly assigned to group A, receiving intravenous infusions of infliximab (10 mg/kg) at weeks 0, 2, and 4; or group B, receiving placebo. All patients received prednisolone (40 mg/day) for 28 days. Patients received standard nutritional support as well as prophylactic antibiotic therapy. After randomization of 36 patients, the study was terminated by the data safety committee because of a substantially higher death rate in the infliximab group (39% compared with 18%) [291]. However, a problem with this study was that the dose of infliximab was high, particularly in combination with prednisone, which may further impair both humoral and cell-mediated immune responses and increase the risk of infection. Another trial was an open label study that included 12 patients with biopsy-proven alcoholic hepatitis [292]. All patients received a single infusion of infliximab,

5 mg/kg body weight, in the first 5 days along with supportive care. Two patients died during hospitalization from sepsis whereas 10 remained alive for a median of 15 months (range 12–20 months). Another study has focused on the use of etanercept, a dimeric fusion protein comprising the extracellular ligand-binding portion of the human TNF receptor linked to the Fc portion of human immunoglobulin G. Etanercept (32 mg/m^2 body surface area, up to 50 mg intravenously on day 1, and followed by 25 mg administered subcutaneously on day 4, day 8, and day 12) was given to 13 patients with moderate or severe alcoholic hepatitis as assessed by a DF value greater than 15 or the presence of spontaneous hepatic encephalopathy [293]. The 30-day survival rate of patients receiving etanercept was 92%. Adverse events that were encountered included infection, hepatorenal syndrome, and gastrointestinal bleeding; these required premature discontinuation of etanercept in 23% of patients [293]. Based on the results of these studies, a larger randomized control trial is warranted to determine the efficacy and safety of anti-TNF therapy in the treatment of alcoholic hepatitis.

S-Adenosyl-L-methionine

Abnormal methionine metabolism occurs in animals fed ethanol and in patients with end-stage cirrhosis as a result of abnormalities in the enzymes of methionine and glutathione metabolism. Patients with alcoholic hepatitis have decreased hepatic methionine, *S*-adenosyl-L-methionine (SAMe), and glutathione levels [294]; however, randomized controlled trials using SAMe in patients with alcoholic hepatitis are limited because most studies were performed in patients with alcoholic cirrhosis. A Cochrane systematic review failed to demonstrate any significant effect of SAMe on mortality, liver-related mortality, mortality or liver transplantation, and liver complications of patients with ALD (see below).

Colchicine

Colchicine is an antiinflammatory and antifibrotic medication [295]. A few studies have been conducted to determine the therapeutic efficacy of colchicines in alcoholic hepatitis; however, none showed a therapeutic benefit [296,297]. A recent metaanalysis by the Cochrane group showed no significant effects of colchicine on mortality (RR 1.00, 95% CI 0.87–1.16) and liver-related mortality (RR 1.08, 95% CI 0.88–1.33) in patients with ALD [298].

Vitamin E

A small study was performed to determine the effect of vitamin E administration on clinical and laboratory parameters of liver function and on markers of fibrogenesis in patients with mild to moderate alcoholic hepatitis [299]. Twenty-five patients received 1000 IU vitamin E per day, while 26 patients received placebo for 3 months. Vitamin E did not result in significantly greater decreases in serum aminotransferases and bilirubin or in greater increases in serum albumin compared with placebo. Four patients in the treatment group and five in the placebo group died during the 1-year study. This small study showed that vitamin E treatment has no beneficial effects on tests of liver function in patients with mild to moderate alcoholic hepatitis [299].

Liver transplantation

Liver transplantation for patients with alcoholic hepatitis is not recommended according to the current guidelines [300]. In an era of organ shortage, use of liver transplants in patients with severe alcoholic hepatitis, who by definition have been actively drinking recently (less than 6-month sobriety), may negatively affect the public attitude on transplantation and organ donation [219].

Treatment for alcoholic cirrhosis

Several medical interventions have been studied in the setting of alcoholic cirrhosis.

Colchicine

Colchicine (1 mg/day) was studied in a randomized, placebo-controlled trial of 100 patients with cirrhosis over a 14-year period [301]. Of these, 45 patients had alcoholic cirrhosis. Seventy-three patients were in class A, 26 were in class B, and one was in class C. A survival benefit was seen in the treated patients at both 5 years (75% vs 34%) and 10 years (56% vs 20%) years. The VA Cooperative study group reported another randomized, placebo-controlled trial of colchicine in the treatment of alcoholic cirrhosis [302]. The aim of this study was to compare the efficacy and safety of long-term colchicine, compared with placebo. Five hundred forty-nine patients with advanced (Pugh B or C) alcoholic cirrhosis were randomized to receive either colchicine 0.6 mg twice per day (274 patients) or placebo (275 patients) and the treatment lasted for from 2 to 6 years. In an intention-to-treat analysis, all-cause mortality was similar in the colchicine-treated (49%) and placebo-treated (45%) patients. Mortality attributed to liver disease was 32% in patients given colchicine and 28% in patients given placebo. There were several differences between this study and the previous one [301] that reported improved survival with colchicine treatment. This recent study was larger (549 patients compared with 100 patients), excluded patients with early (Class A) cirrhosis, enrolled only patients with alcoholic cirrhosis, and treated for a shorter duration (maximum 6 years compared with maximum 14 years, respectively). A Cochrane systematic review failed to demonstrate any significant benefit in survival outcome in patients with alcoholic cirrhosis treated with colchicine [298].

Propylthiouracil

The rationale of using PTU in the treatment of ALD was previously mentioned. Orrego and colleagues observed, in a larger cohort, that the administration of PTU reduced the

mortality due to ALD [303]. In this randomized clinical trial of 310 patients, a significant improvement in survival was seen in patients treated for a maximum of 2 years with PTU (300 mg/day) compared to those who received placebo: 13% vs 25% overall and 25% vs 55% in severely ill patients. This randomized placebo-controlled clinical trial was remarkable for the care taken to monitor alcohol consumption by the study participants, thereby controlling for the greatest confounding factor complicating the interpretation of investigations of treatment for ALD [303,304]. As mentioned previously, a Cochrane metaanalysis review failed to find evidence to support the use of PTU in ALD [287].

Phosphatidylcholine

Phosphatidylcholine, purified from polyunsaturated lecithin, was reported to oppose alcohol-induced fibrosis in baboons by decreasing the activation of stellate cells to transitional cells, and possibly also by stimulating collagenase activity [305]. A large study of phosphatidylcholine supplementation in 789 veterans with ALD was conducted. Treatment was maintained for 2 years; however, no histological benefit was observed in the treatment group when compared to placebo [306].

S-adenosylmethionine

Abnormal methionine metabolism occurs in animals fed ethanol and in patients with end-stage cirrhosis, which is the result of abnormalities in the enzymes of methionine and glutathione metabolism. Patients with alcoholic liver disease have decreased hepatic methionine, SAMe, and glutathione levels [116]. Mato and colleagues published a randomized, placebo-controlled clinical trial, using SAMe in 62 patients with alcoholic cirrhosis [307]. During the 2-year follow-up period, there was no difference in overall mortality in treated patients when compared to controls. However, when patients in Child class C were excluded from the analysis, the overall mortality/liver transplantation rate was significantly greater in the group given placebo than in the group given SAMe (29% compared with 12%) [307]. SAMe was also shown to improve 2-year survival. However, a recent Cochrane systematic review that included eight placebo-controlled trials found no significant benefit of using SAMe in patients with ALD [308].

Silymarin (milk thistle)

Several studies have shown the antioxidant property of silymarin, the active ingredient in milk thistle [309]. The results of clinical trials using silymarin in ALD are inconclusive. In a double-blind, prospective, randomized clinical trial involving 170 patients with cirrhosis (91 with alcoholic cirrhosis), 87 patients were treated with 140 mg silymarin three times daily and 83 patients received placebo. The mean follow-up period was 41 months. Fifty eighty percent of silymarin-treated patients, compared with 39% of placebo-treated patients, survived for 4 years or longer. In another study, 200 patients with histologically proven alcoholic cirrhosis were randomized to receive either silymarin (150 mg three times per day) or placebo [310]. There was no survival benefit noted during the 2-year study period. A recent Cochrane systematic review concluded that when compared to placebo, silymarin had no significant effect on overall mortality (RR 0.78, 95% CI 0.53–1.15), complications of liver disease (RR 0.95, 95% CI 0.83–1.09), or liver histology [311].

Liver transplantation

Guidelines for liver transplant evaluation have been established by the American Association for the Study of Liver Diseases [300]. Indications for orthotopic liver transplantation in patients with end-stage liver disease from alcohol are no different than those for other causes of end-stage liver disease. Abstinence is the only effective treatment for most patients and many patients with apparently far-advanced ALD who completely abstain can recover to the degree that transplantation is not required [300]; therefore, a period of abstinence before providing transplantation for patients with ALD seems to be prudent. More than 85% of transplantation programs in the United States require 6 months of abstinence and careful evaluation by professional counselors to directly address the addiction to alcohol before transplantation [300,312]. Of note, it has been shown that pre-orthotopic liver transplantation abstinence of less than 6 months is an important predictor of post-orthotopic liver transplantation recidivism [313]. If a patient has a drinking relapse while on the transplant waiting list, 97% of transplant centers in the United States would remove the patient from the list for at least 3–6 months and 15% would remove them permanently [312].

The outcome after liver transplantation for alcoholic liver disease is comparable to that of patients transplanted for other conditions. One-year and 5-year patient survival was 80%–85% and 70%–82%, respectively [314]. Five-year graft survival was 60%–70% [314,315]. Patients with alcoholism and hepatitis C have been shown to have slightly lower graft and patient survival [316]. The alcohol relapse rates vary considerably from center to center. Most studies have shown a recidivism rate between 20% and 30% by 2 years after orthotopic liver transplantation [317]. However, graft loss as a consequence of abusive drinking after transplantation is uncommon [300,318,319].

One important issue in patients who underwent liver transplantation for ALD is the higher rate of late deaths as a result of lung and oropharyngeal cancer [320,321]. This is likely because alcohol and tobacco use commonly cooccur, with at least 90% of those with an alcohol problem also using tobacco [322]. A study from Pittsburgh found that transplant recipients who had ALD resume smoking early posttransplantation and quickly become tobacco-dependent [322]. There are no recommendations for the posttransplant sur-

veillance for such malignancies. However, health-care providers should be aware of these conditions, especially in those who continue to smoke after transplantation.

Diagnostic approach, 2292
Treatment, 2293

Nonalcoholic fatty liver disease (NAFLD) represents a spectrum of changes in liver histology characterized by predominantly macrovesicular steatosis [1]. By definition, these changes are not caused by the consumption of alcohol. In North America the most common cause of persistent abnormalities in liver enzyme tests is NAFLD [2]; its prevalence appears to be increasing and is related to the widespread problem of obesity. It is also increasingly recognized as a cause of end-stage liver disease and a potential risk factor for hepatocellular cancer [3,4]. The histological features, pathogenesis, clinical evaluation, and management of NAFLD are discussed below.

Histological definition

There are two broad histological patterns of NAFLD:
- hepatic steatosis or fatty liver
- steatohepatitis.

Contrary to its literal meaning, steatohepatitis does not simply represent the presence of steatosis and inflammation. Steatohepatitis is defined by the presence of hepatic steatosis along with evidence of cell injury, that is, cytological ballooning or Mallory hyaline along with varying degrees of inflammation and pericellular fibrosis (Fig. 89.1) [5]. These changes are typically most marked in the centrilobular regions. The inflammation associated with steatohepatitis is usually modest and mainly lobular in distribution. Although some reports have suggested that the inflammation is mainly neutrophilic in nature [6], others have described a mixed inflammatory infiltrate [7]. A dense lymphocytic infiltrate in the portal areas is not typical of NAFLD, and an alternate cause of such an infiltrate should be sought when it is present. Portal fibrosis may be associated with NAFLD, particularly in pediatric subjects and in those who are morbidly obese [8,9].

Grading and staging

The grade of steatohepatitis reflects the amount of cell injury and necroinflammatory activity that is present. The stage of the disease reflects the amount of fibrosis or how far an individual has progressed towards cirrhosis. The ideal system for grading and staging of NAFLD remains to be defined. An optimal system should be easy to use, highly reproducible, relate to long-term outcomes, show sensitivity to change, and be free of ceiling and floor effects. Thus, the distribution of grade and stage should be such that a large proportion of subjects should not be at the lowest (floor effect) or highest grade or stage (ceiling effect). Unfortunately such a system remains to be designed.

A fundamental requirement of any scoring system is a high degree of reproducibility. Younossi et al. examined 19 individual parameters grouped under steatosis, hepatocyte injury, inflammation, and fibrosis in a blinded manner by four pathologists and twice by two pathologists [10]. Substantial concordance was observed with respect to assessment of extent of steatosis, sinusoidal location of steatosis, perivenular fibrosis, stage of fibrosis, ballooning degeneration and glycogen nuclei. There was, however, considerable interobserver variation in the assessment of inflammation. All of the abovementioned observations have been corroborated by the National Institutes of Health (NIH) NASH clinical research network [11].

Several systems of grading and staging of NAFLD have been proposed. However, only two systems have been validated to any degree. A landmark study by Brunt et al. examined 12 separate histological parameters [12]; these included hepatic macrovesicular steatosis, hepatocellular ballooning, intraacinar inflammation, portal tract inflammation, Mallory hyaline, acidophil bodies, glycogen nuclei, lipogranulomas,

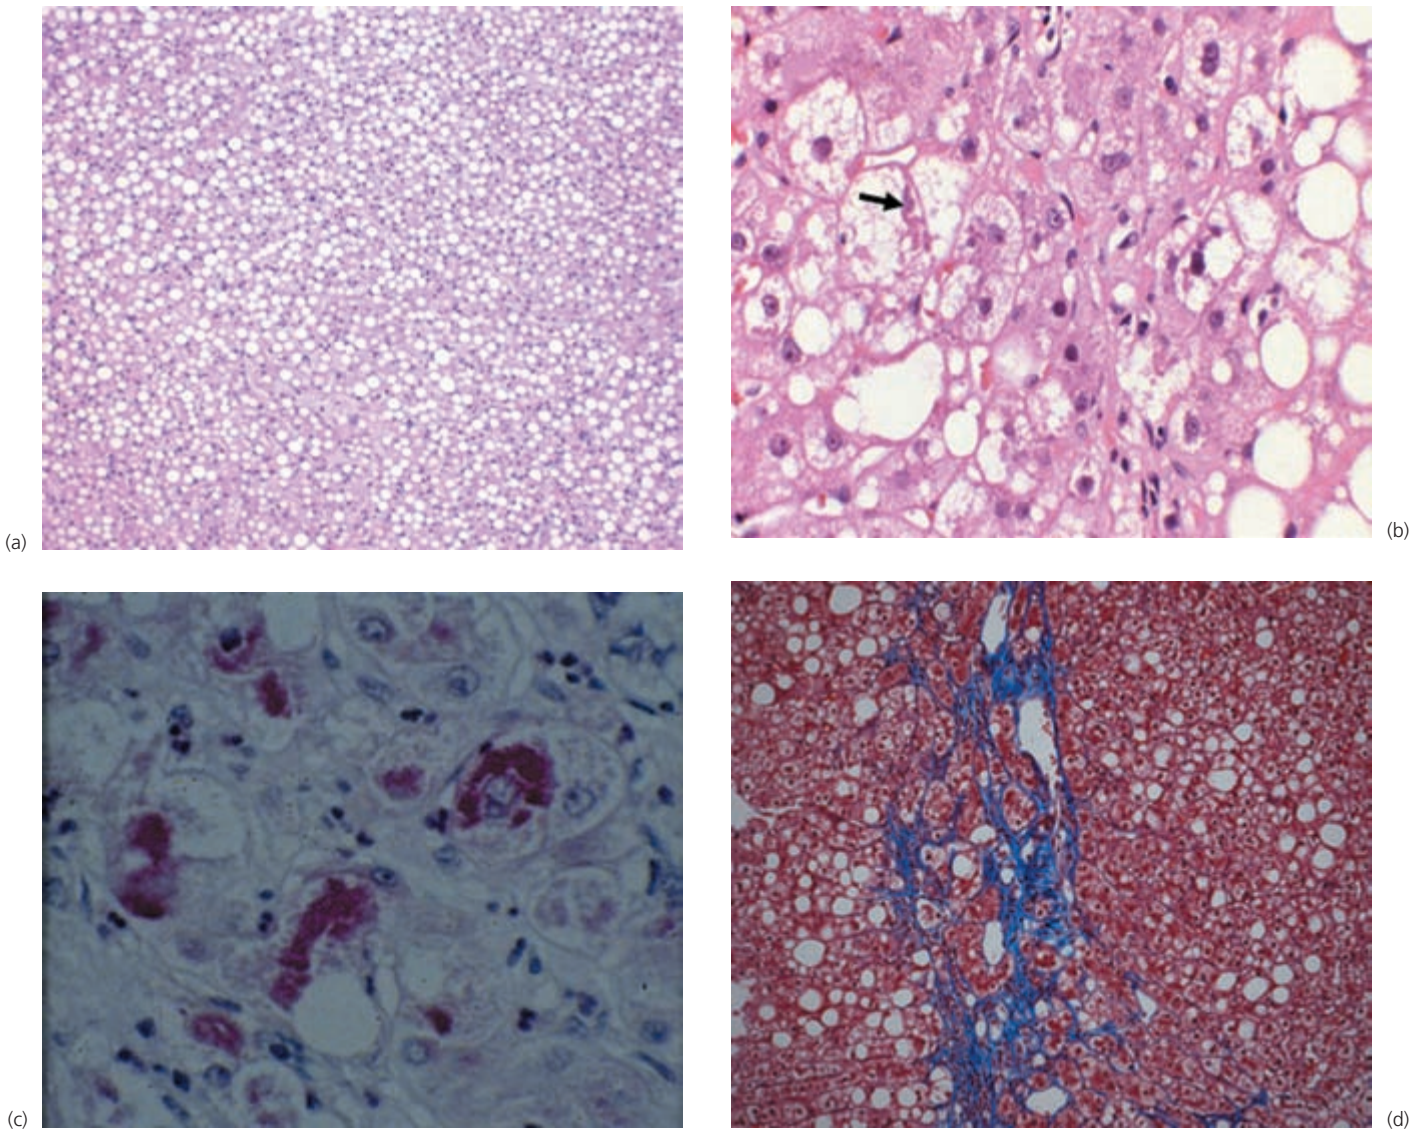

Figure 89.1 The hepatic histology of nonalcoholic steatohepatitis. **(a)** Macrovesicular hepatic steatosis (hematoxylin–eosin stain). **(b)** Cytological ballooning, with Mallory hyaline within a ballooned cell (see arrow). **(c)** Mallory body stained with antibodies to ubiquitin. **(d)** A Masson trichrome stain demonstrates pericellular fibrosis, which is mainly centrilobular in location.

hepatocellular iron, perisinusoidal fibrosis, portal fibrosis, and bridging fibrosis. Based on these parameters, a three-grade and four-stage system of classifying NAFLD was developed. The necroinflammatory grade correlated with the alanine aminotransferase (ALT) activity.

Subsequently, using the Brunt classification as a starting point, the NIH NASH clinical research network has developed a histological scoring system for NAFLD that has been validated [11]. Although 14 separate parameters were evaluated, four were scored semiquantitatively. These include steatosis (0–3), cytological ballooning (0–2), inflammation (0–2), and fibrosis (0–4). A NASH activity score was then developed that included the unweighted scores for steatosis, inflammation, and fibrosis (Table 89.1). The NASH activity score correlated well with the presence of steatohepatitis during a blinded validation process and was typically associated with a score greater than or equal to 5. Those with a score of 3 or less were usually not found to have steatohepatitis, whereas a score of 4 was associated with some divergence of opinion (Fig. 89.2). Importantly, this system divides stage 1 into several subsets (Table 89.1) thereby improving the sensitivity to change in the earlier stages of the disease. This system is expected to be extremely valuable as a research tool for the design and analysis of clinical trials in this area. However, its role in routine clinical practice remains to be established.

A major limitation of any histological scoring system is sampling variability. In one study, two biopsies were obtained

Table 89.1 Grading and staging of nonalcoholic fatty liver disease

Parameter	Description	Score
1. Macrovesicular steatosis	< 5%	0
	5–33%	1
	34–66%	2
	> 66%	3
2. Cytological ballooning	None	0
	Few cells	1
	Many cells	2
3. Inflammation	None	0
	< 2 foci per 200 ×	1
	2–4 foci per 200 ×	2
	> 4 foci per 200 ×	3
4. Fibrosis	None	0
	Perisinusoidal centrilobular mild	1a
	Perisinusoidal centrilobular moderate	1b
	Periportal	1c
	Pericentral and periportal	2
	Bridging	3
5. Mallory hyaline	None to rare	0
	Many	1

Based on Kleiner et al. [11].
The NASH (nonalcoholic steatohepatitis) activity score is based on scores for steatosis, cytological ballooning, and inflammation.

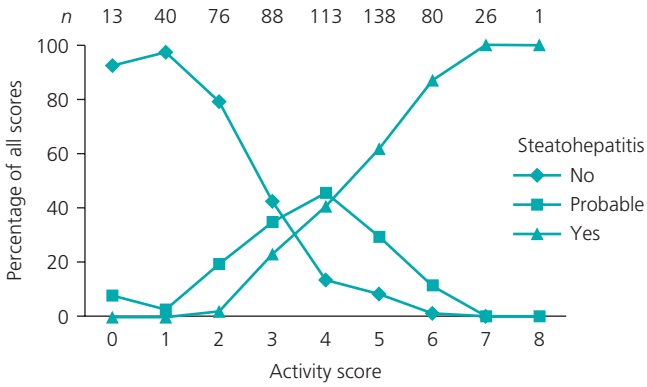

Figure 89.2 The relationship between the NASH activity score and the probability of having steatohepatitis. Steatohepatitis was diagnosed to be present, absent, or probable based on an overall gestalt by a group of experienced pathologists. The same biopsies were also independently scored to determine the NASH activity score by the same pathologists, who remained blinded to their evaluation of steatohepatitis. A score greater than 4 was considered to indicate a high probability of steatohepatitis. From Kleiner et al. [11], with permission from John Wiley & Sons, Inc.

from the same site at the same time [13]. Approximately 20% of subjects had at least a one-stage variability between biopsies, whereas 12% had a two-stage variation. Similar data have been obtained from studies where biopsies from the left and right lobes have been compared [14]. Although a 4-cm core is ideal [15], it is imperative to obtain at least a 2-cm-long core with a 15 or 16 gauge needle to evaluate a biopsy for grading or staging of any liver disease.

Epidemiology and associated conditions

(Table 89.2)

It is established that NAFLD represents the hepatic manifestation of the metabolic syndrome [16]. The metabolic syndrome is characterized by obesity, hypertension, diabetes,

Table 89.2 Conditions associated with nonalcoholic fatty liver disease (NAFLD)

Metabolic syndrome
Drugs, e.g., amiodarone, tamoxifen, HAART
Abetalipoproteinemia
Lipodystrophy
Weber–Christian syndrome
Jejunoileal bypass surgery
Total parenteral nutrition

HAART, highly active antiretroviral therapy.

Table 89.3 Diagnostic criteria for the metabolic syndrome

Abdominal obesity (waist circumference > 102 cm for men and > 88 cm for women)
Triglycerides > 150 mg/dL
HDL < 40 mg/dL for men or < 50 mg/dL for women
BP ≥ 130/85 mmHg
Fasting blood glucose ≥ 110 mg/dL

Based on Adult Treatment Panel (ATP) III criteria [18].
BP, blood pressure; HDL, high-density lipoprotein.

hypertriglyceridemia, and low levels of high-density lipoprotein (HDL) cholesterol (Table 89.3) [17]. It is estimated that about 47 million individuals in the United States are afflicted with the metabolic syndrome, and over 80% of such subjects have NAFLD [18,19]. The corollary is that over 90% of subjects with NAFLD have some features of the metabolic syndrome [20].

The common thread that connects the disorders that define the metabolic syndrome is the presence of underlying insulin resistance [21]. Although several systems for defining the metabolic syndrome have been proposed [17,22,23], these fail to capture with optimal sensitivity the presence of the underlying insulin resistance [24]. Indeed, many individuals in the general population have biochemical evidence of insulin resistance even in the absence of features of the metabolic syndrome [25,26]. It may be argued that the development of the metabolic syndrome is analogous to the development of end-organ disease. Thus, although it is important to identify those with end-organ disease for treatment, it may be even more important to identify those at risk, that is, those with insulin resistance, before the metabolic syndrome develops. This would appear to be a rational approach given the impact of insulin resistance-related disorders to overall morbidity and mortality in the general population [27].

Several approaches have been taken to define the prevalence of NAFLD in the general population. On the one hand, hospital-based studies are flawed because of ascertainment bias. On the other hand, population-based studies have mainly relied on noninvasive imaging studies, such as sonography, to define the presence of NAFLD [28–30]. Unfortunately, sonography has poor specificity for the diagnosis of NAFLD [31]. Magnetic resonance imaging (MRI) has been used to define and quantify the amount of hepatic steatosis [32–34]. This technique has been validated and used to define the prevalence of hepatic steatosis in the general population. Based on this technique, it is estimated that about 33% of the US population has hepatic steatosis [35]. In Hispanic subjects, the prevalence reaches 45%, whereas African Americans have a lower prevalence of NAFLD (24%). Approximately 70%–80% of affected subjects have a normal ALT level [36]. These data are in keeping with the observation that 7.9% of the US population have persistently elevated ALT values and that most individuals with such elevations have underlying NAFLD [37].

In an autopsy series where liver histology was used to define the presence of a fatty liver [38], hepatic steatosis was found in approximately 2.7% of lean individuals and 18.5% of obese individuals. Similar data have been reported from autopsies of air-crash victims [39]. A relationship between the body mass index and the presence of a fatty liver has also been established in otherwise apparently healthy individuals being considered as donors for live-donor liver transplantation [40].

Regardless of the methodology used, several aspects of the epidemiology of NAFLD are consistently observed. Fatty liver and NASH occur in all age groups, including children [41,42]. Whereas studies published prior to 1990 [1,6,43] emphasized that NASH occurred mostly in women (53%–85% of all patients), later studies [7,44] have shown that NASH occurs with equal frequency in males (~ 50%). The prevalence of NAFLD is directly related to the body mass index (BMI), with over 80% of subjects with a BMI greater than 35 having steatosis [16,45,46]. The waist circumference may even be a better predictor of underlying insulin resistance and NAFLD than the BMI [47].

An important confounder is the impact of social consumption of alcohol on the development and categorization of subjects with NAFLD. The precise levels of alcohol consumption that separate those with alcoholic liver disease from NAFLD have not been clearly defined. It is certainly feasible that subjects with risk factors for NAFLD may be at higher risk of hepatic steatosis if they consume alcohol in any quantity. Indeed, it has been found that obese individuals who regularly consume alcohol have the highest prevalence of hepatic steatosis [48].

The complexity of NAFLD means that the phenotype of this condition is highly likely to reflect complex interactions between environmental and lifestyle-related factors with the underlying genetic composition. Obesity and diabetes are often clustered within families [49,50]. The causes of such familial clustering include both genetic and environmental factors [51]. In one study [52], eight families with a total of 18 members with NAFLD including NASH with cirrhosis were described, but no clear-cut pattern of inheritance of risk for NAFLD was identified.

Numerous other conditions have also been associated with NAFLD (Table 89.2). These include abetalipoproteinemia and some rare syndromes characterized by severe insulin resistance, such as lipoatrophic diabetes and Mauriac syndrome [53–55]. The liver disease in both abetalipoproteinemia and lipodystrophy can progress to advanced fibrosis and cirrhosis [53,56]. There is also an association between NAFLD and the use of several drugs, including amiodarone, tamoxifen, and diltiazem [57–59]. The mechanisms involved

in the development of steatosis are somewhat variable across these conditions and they should ideally be considered separately from fatty liver disease, which is associated with the metabolic syndrome.

Hepatic steatosis is also related to the presence of underlying hepatitis C infection or human immunodeficiency virus (HIV) infection [60–63]. Hepatic steatosis is a risk factor for increased hepatic fibrosis in subjects with hepatitis C [64] and is associated with the presence of underlying metabolic syndrome for most subjects with genotype 1 infection [65]. It is also associated with a higher risk of failure to respond to antiviral therapy [66]. The development of steatosis in those with HIV infection has been linked to the use of highly active antiretroviral therapy (HAART), the presence of lipodystrophy, dyslipidemia, and insulin resistance [67,68]. A detailed description of these conditions is beyond the scope of this chapter and the reader is referred to reviews for more information on the subject [63,69].

Pathogenesis

There are two fundamental lesions in NAFLD: hepatic steatosis and steatohepatitis. It has traditionally been considered that if the liver was able to adapt to the development of steatosis it manifested the phenotype of fatty liver alone whereas if these adaptive responses were inadequate it would lead to steatohepatitis. This was the basis for the two-hit hypothesis, in which the development of a fatty liver was the first hit and an additional pathophysiological abnormality was required to cause steatohepatitis [70]. Over time, the concepts have evolved somewhat from these original ideas and focus on NAFLD as an expression of disordered energy homeostasis. To appreciate how disordered energy homeostasis leads to steatosis and steatohepatitis, one must first understand the normal physiology of energy homeostasis.

Normal energy homeostasis

Adipose tissue plays a critical role in energy homeostasis. It serves as an "energy bank" where excess energy is stored and then released to meet the energy needs of the body. Oxidation of free fatty acids (FFA) yields more energy than proteins or carbohydrates, and triglycerides are therefore the most efficient "currency" for energy homeostasis. During periods of caloric excess, the extra "energy" is stored as triglyceride. This normally causes increased expression of leptin, which acts centrally to decrease food intake. When diet-derived calories are not available or are inadequate to meet the "energy" requirements of the body, adipose tissue triglycerides undergo lipolysis releasing FFA and glycerol into the circulation, from where they can be taken up by the liver. This is regulated by the adipocytokine profile at a given adipose tissue location (Table 89.4) and by several hormones. Insulin is a key systemic regulator of adipocyte function and promotes lipogenesis while inhibiting lipolysis. Its actions are balanced by counterregulatory hormones such as growth hormone and glucagon. In addition to endocrine, paracrine, and autocrine regulation of adipose tissue, β_3-adrenergic neurons innervating adipose tissue add another layer of regulatory influence on the balance between lipogenesis and lipolysis [71].

Regulatory mechanisms of metabolic pathways in adipose tissue and liver

Adipocytokines

Adipocytes produce numerous cytokines that have metabolic functions. These include tumor necrosis factor-α (TNF-α), adiponectin, interleukin-6 (IL-6), resistin, and plasminogen activator inhibitor-1 (PAI-1) [72,73]. Of these TNF-α, IL-6, and PAI-1 have been implicated in promoting inflammation and the atherothrombotic predilection in obesity and the metabolic syndrome [74]. By contrast, a low adiponectin level has been associated with insulin resistance and NAFLD [75].

Tumor necrosis factor-α is a proinflammatory cytokine that is secreted by adipose tissue and macrophages [76]. It interferes with insulin signaling through the activation of intracellular signaling pathways such as those involving the Jun N-terminal kinase and inhibitor κ-B kinase-β [77]. In addition, it inhibits adiponectin, which, as described above, has many important actions with respect to insulin sensitivity and lipid metabolism [78]. Thus, high levels of TNF-α seen in the setting of low adiponectin contribute to the development of disordered lipid metabolism and severe insulin resistance [79]. An association has also been reported between NAFLD and promoter polymorphisms in the TNF receptor as well as increased expression of TNF in both adipose tissue and in the liver [80,81].

Adiponectin is another adipocytokine that bears similarity to complement [82]. It increases fatty acid β-oxidation in muscle and liver [72]. It also improves hepatic insulin sensitivity resulting in improved insulin-mediated suppression of hepatic glucose output [83] It acts upstream of AMP kinase, an allosteric inhibitor of acyl CoA carboxylase, which catalyzes the rate-limiting step for lipogenesis [84,85]. AMP kinase also promotes fatty acid oxidation in the mitochondria. By decreasing lipogenesis and increasing FFA oxidation, adiponectin decreases hepatic steatosis. Low levels of adiponectin have been associated with NAFLD [86,87]. In murine models of NAFLD, adiponectin improves insulin sensitivity and hepatic steatosis [88].

Hormones

The ability of the body to respond to different substrate concentrations and varying energy requirements depends on a closely integrated regulation of carbohydrate and lipid metabolism (Fig. 89.3). Insulin promotes glucose uptake and utilization by glycogen synthesis and glycolysis, respectively. It also promotes lipogenesis, and under conditions of long-term

Table 89.4 Adipocytokines and their known effects on inflammation and insulin actions

Adipocytokine	Effect on inflammation	Effect on insulin actions

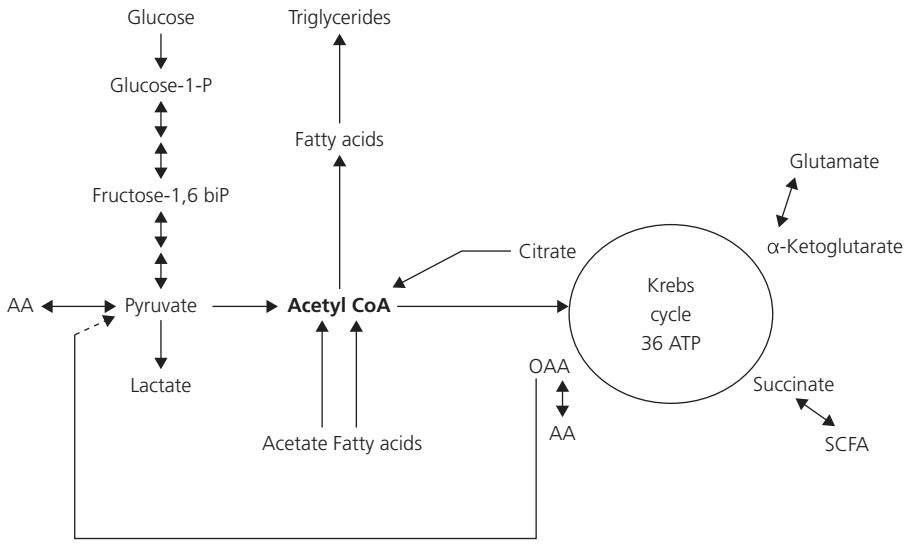

Figure 89.3 An integrated view of intermediary metabolism. Glycolysis leads to pyruvate formation. Under anaerobic conditions, lactate formation is used for ATP generation (Embden–Meyerhof pathway). Under aerobic conditions, pyruvate enters the Krebs cycle, which yields 36 ATP. During periods of caloric excess, extra calories are shunted into acetyl CoA, which is used to form triglycerides and cholesterol. During periods of starvation, oxaloacetate (OAA) can lead to phospho*enol*pyruvate and reverse synthesis of glucose (gluconeogenesis). Under conditions of severe starvation, amino acids (AA) can be transaminated to yield metabolic intermediates that can be used in the Krebs cycle. Short-chain fatty acids (SCFA) can also be converted to succinate, an intermediate in the Krebs cycle.

energy excess, glucose is converted to triglycerides for storage. These are important mechanisms for the postprandial control of metabolism and the utilization of the calories that are consumed. In the interdigestive phase, the glucose supply for tissues that are critically dependent on it is provided by glycogenolysis and gluconeogenesis. Similarly, during periods of food deprivation or during periods of increased energy requirements, for example, growth, wound healing, or inflammation, there is an increase in the mobilization of FFAs from adipose stores and their utilization as a source of fuel for energy-requiring processes. This is accomplished by increased levels of counterregulatory hormones that antagonize the effects of insulin, notably glucagon.

The immediate effects of insulin and its counterregulatory hormones are mediated by alterations in signal transduction cascades following binding of the hormones to their receptors. These signaling pathways alter the activity of regulatory kinases (e.g., protein kinase A), which in turn affect the activity of specific enzymes in various metabolic pathways. In the long term, these hormones regulate the metabolic pathways by transcriptional up- or down-regulation of key enzymes.

Transcription factors that mediate the effects of cytokines and hormones

Several transcription factors play an important role in metabolic homeostasis and mediate the effects of insulin and its counterregulatory hormones (Table 89.5). The sterol regulatory element binding protein (SREBP) group of basic helix-loop-helix/leucine zipper transcription factors are important transcriptional regulators of lipogenesis. They are synthesized as inactive precursors bound to the endoplasmic reticulum [89]. Their activation requires their cleavage and transport to the Golgi apparatus, where they undergo further cleavage thereby releasing the N-terminal region of the protein, which translocates to the nucleus and binds to sterol response elements in the promoters of target genes. Three isoforms of SREBP are known: SREBP-1a, SREBP-1c, and SREBP-2. Of these, SREBP-1c plays a major role in mediating insulin-directed lipogenic activity. It increases de novo lipogenesis (DNL) by transcriptionally increasing the expression of several key lipogenic enzymes (Fig. 89.4). It also increases expression of acetyl CoA synthetase, which increases production of acetyl CoA, the starting point for lipogenesis [90]. The SREBP-1c isoform further contributes to a positive triglyceride balance by inhibiting expression of the microsomal transfer protein resulting in decreased formation of very-low-density lipoproteins (VLDL) [91].

The cellular abundance of SREBP is affected by dietary nutrients, metabolites, hormones, and cytokines. Whereas glucose, saturated fats, and sterols increase SREBP abundance, polyunsaturated fats decrease SREBP and thus decrease lipogenesis [92,93]. Insulin mediates its signature "lipogenic activation" profile through liver X receptor (LXR)-mediated activation of SREBP-1c [94,95]. Several hormones and cytokines, such as leptin, also affect SREBP transactivation

Table 89.5 Transcription factors involved in fatty acid and cholesterol synthesis

Transcription factor	Target genes	Location	Function
SREBP-1c	ACC, FAS, ACS, ATP citrate lyase	1. Liver 2. Adipose tissue	↑ Lipogenesis
SREBP-2	HMG CoA reductase, LDL receptor	1. Liver 2. Constitutive	↑ Cholesterol synthesis
ChREBP	Pyruvate kinase, FAS, ACC	1. Liver 2. Adipose tissue	↑ Lipogenesis (in carbohydrate excess states)
PPAR-α	ACS, FATP1, CPT1, ABCA 1	1. Liver 2. Muscles	1. ↑ Catabolism 2. ↑ Cholesterol efflux
PPAR-γ	LPL, FATP, ACS	1. Adipose tissue 2. Intestines	1. ↑ TG synthesis/storage 2. ↑ Adipocyte differentiation
LXR	CYP7A1, ABCG1, ABCA1, SREBP1c, LPL, CETP, apoE	1. Liver 2. Intestines 3. Adipose tissue	1. FA synthesis, BA synthesis 2. XOL/PL absorption and synthesis 3. Lipoprotein metabolism

ABCA, ATP-binding cassette genes; ACC, acyl CoA carboxylase; ACS, acyl CoA synthetase; apoE, apolipoprotein E; BA, bile acids; CETP, cholesterol ester transporter protein; ChREBP, carbohydrate responsive element-binding protein; CPT1, carnitine palmitoyl transferase-1; CYP, cytochrome P450; FA, fatty acid; FAS, fatty acid synthetase; FATP-1, fatty acid transporter protein-1; HMG CoA, hydroxymethylglutaryl CoA; LDL, low-density lipoprotein; LPL, lipoprotein lipase; LXR, liver X receptor; PPAR, peroxisome proliferation-activated receptor; SREBP, sterol regulatory element binding protein; TG, triglyceride; XOL/PL, cholesterol and phospholipids.

Insulin promotes SREBP-1c activity by means of LXR. Whereas saturated fats enhance SREBP-1c activity, polyunsaturated fatty acids inhibit SREBP-1c activity. ACC, acyl CoA carboxylase; FAS, fatty acid synthase; LCFA, long-chain fatty acids; MUFA, monounsaturated fatty acids; PDH, pyruvate dehydrogenase; PUFA, polyunsaturated fatty acids; SCD, stearoyl-CoA desaturase.

through phosphorylation by various mitogen-activated protein kinases (MAPKs) [96].

Liver X receptor is another important transcriptional regulator of metabolism. It binds to its response elements (LXRE) in DNA promoters of its target genes along with its heteromeric partner retinoid X receptor (RXR) [97]. On ligand binding, corepressor proteins are inactivated and coactivation proteins are recruited resulting in gene transcription [98]. Liver X receptor-α is present in liver and adipose tissue and is activated by oxysterols and insulin. Liver X receptor increases lipogenesis by increasing SREBP-1c transcription (Fig. 89.4) [94,99]. It also promotes cholesterol utilization by increasing primary bile acid synthesis [100]. Liver X receptor activates ABCA1 (ATP-binding cassette A1) transporters and promotes cholesterol efflux [101,102].

The carbohydrate response element binding protein (CHREBP) is another important transcriptional regulator of metabolism. Under periods of carbohydrate overload, it promotes the conversion of carbohydrates to lipids by the transcriptional increase in expression of the enzymes involved in lipogenesis [103,104]. It is activated by glucose and along with its heteromeric partner, MAX-like protein X (MLX), binds to carbohydrate response elements of the pyruvate kinase, acetyl CoA carboxylase, and fatty acid synthetase genes, thereby increasing their transcription [105,106]. Carbohydrate feeding affects energy balance and lipid homeostasis by increasing carbohydrate oxidation and lipogenesis as a result of increased SREBP and CHREBP activity.

The peroxisome proliferation-activated receptors (PPARs) also play a major role as metabolic regulators. Three isoforms have been identified: PPAR-α, -β/δ, and -γ. The PPAR-α isoform is expressed in organs where fatty acid oxidation is an important means of energy utilization, such as liver, heart, kidney, whereas PPAR-γ is preferentially expressed in adipose tissue and the intestine [107]. Long-chain fatty acids and oxidized phospholipids activate PPAR-α, which then increases FFA uptake, activation to acyl CoA esters, and mitochondrial FFA β-oxidation [108,109]. Agonists of PPAR-α increase FA utilization and limit the availability of FFA for lipogenesis [109,110]. In the small intestine, PPAR-β/δ increases expression of fatty acid binding protein (FABP) and may play a role in the intestinal adaptation to changes in dietary lipid content [111]. The PPAR-γ isoform promotes adipocyte differentiation and lipoprotein lipase activity thereby making triglyceride-derived FA available for uptake. It also induces fatty acid transport protein and acyl CoA synthetase, thus increasing adipose tissue lipogenesis, and induces expression of adiponectin, which is an important insulin-sensitizing cytokine [112]. The synergy between PPARs and LXRs means that they increase each other's expression [113]. The PPAR-γ isoform also antagonizes NF-κB, and thus has antiinflammatory effects [114,115].

Integration of systemic and local regulatory mechanisms of intermediary metabolism

From a physiological perspective, the formation of acetyl CoA (Fig. 89.3) is a key step that connects the glycolytic pathway to the Krebs cycle as well as to the lipogenic pathway. Although these pathways exist in all cells, there is organ-specific differentiation of the various limbs of these pathways. The rapid uptake of glucose by striated muscle and liver allows clearance of the postprandial glucose load. This is stored mainly as glycogen in the short term and as triglyceride within adipocytes, muscle, and liver in the long term.

During periods of caloric abundance, excess carbohydrate-derived energy can be diverted through acetyl CoA to lipid synthesis by the lipogenesis pathway under the control of insulin and several transcription factors, as noted above (e.g., LXR and CHREBP). Similarly, excess dietary fat can be stored as triglycerides. Acetyl CoA may also be derived from FFA oxidation and serve as a substrate for FFA synthesis again if required.

Yet another source of acetyl CoA is citrate, through the action of citrate lyase, another insulin-sensitive enzyme. This pathway assumes importance when the Krebs cycle slows down because of an altered NADPH:NAD ratio and citrate accumulates in the cell [116,117]. Also, when energy is required, proteins may be deaminated to ketoacids or to intermediates in the Krebs cycle, thereby providing a source of acetyl CoA and energy. This pathway is particularly important for the response to starvation or severe caloric deficiency. Free fatty acids derived from lipolysis may be oxidized to release acetyl coA, which can be used for the Krebs cycle. But FFAs interfere with hepatic insulin signaling and are associated with an increase in local and systemic lipolytic cytokines, such as TNF-α [118–121].

There is increasing evidence that FFAs themselves may play an important role as integrators of lipid and carbohydrate metabolism. As the major metabolic product of adipocytes, they have both direct effects on intermediary metabolism and also specifically affect insulin signal transduction pathways [122,123]. In particular, FFAs derived from visceral adipose tissue impair insulin signaling and promote gluconeogenesis [124,125]. Thus, insulin regulates lipolysis and thus the availability of FFAs, whereas FFAs regulate the function of insulin.

Insulin resistance and its effects on energy homeostasis

Several lines of evidence have implicated insulin resistance in the pathogenesis of NAFLD. The original clinical descriptions of NAFLD noted an association between obesity and diabetes, the two conditions best known to be associated with insulin resistance (IR) [1]. Since then, several large epidemiological studies have found a direct correlation between body mass index (BMI) and the probability of having a fatty liver as defined by hepatic sonography [126,127]. Two studies have examined the relationship between NASH and the presence of the metabolic syndrome. In the first study [128], patients with NASH were found to have lower insulin sensitivity and higher insulin secretion rates compared with age and gender-matched normal controls. In the second study [20], IR, as measured by the homeostatic model (IR_{HOMA}), was present in 65/66 subjects whereas the metabolic syndrome was only present in 55/66 subjects. Insulin resistance was present in lean as well as obese individuals. Importantly, the metabolic syndrome was present in 75% of patients with NASH compared with only 8.3% of those age- and gender-matched subjects with hepatitis C, indicating that the association between NASH and IR is highly specific for the condition. Finally, the presence of IR has been confirmed using a euglycemic, hyperinsulinemic clamp in nondiabetic, precirrhotic individuals with fatty liver as well as NASH [21].

The development of IR is multifactorial and involves both genetic and environmental factors. Inherited disorders of IR are extremely rare and include leprechaunism, Rabson–Mendenhal syndrome, and type A insulin resistance syndrome [129,130]. The genetics of IR and the phenotypic variations that may be observed as a consequence of isolated gene defects have been studied in detail using single-gene-knockout mouse models. Although these models are excellent tools for understanding the specific mechanisms of IR, they do not reflect the genomic alterations associated with the actual disease process in the body. This difficulty arises from the polygenic nature of IR and the polymorphism of different genes involved in the process of pancreatic insulin secretion and their action on specific target organs.

Studies have shed light on the early events in the genesis of insulin resistance [131,132]. With increasing adipose mass, especially visceral adipose mass, the adipose tissue is infiltrated by macrophages (Fig. 89.5). Relative hypoxia with release of

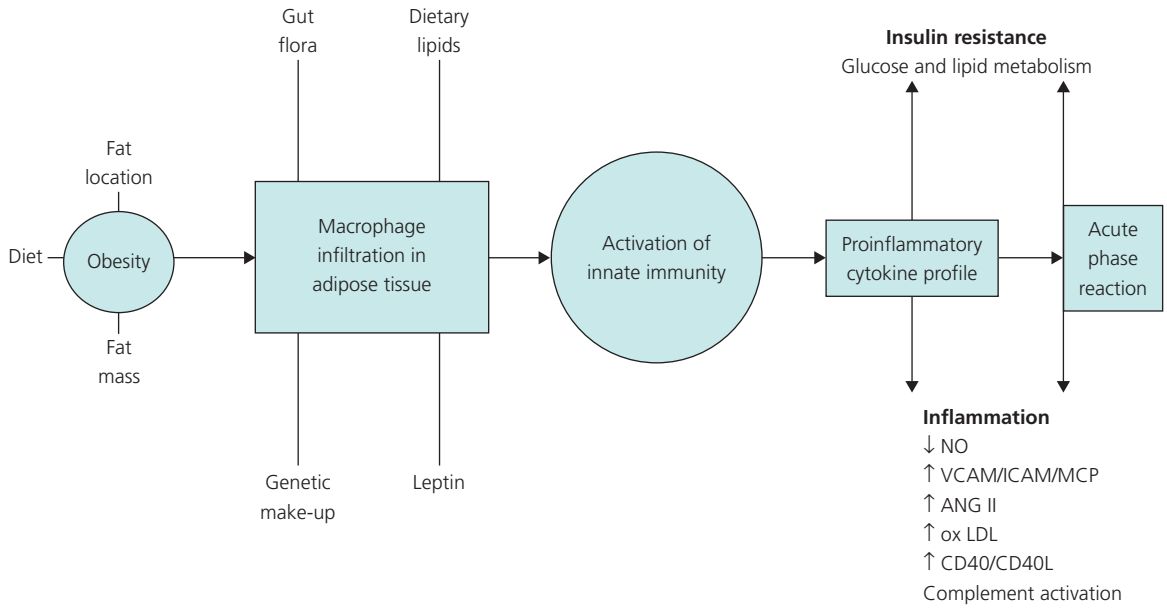

Figure 89.5 Early pathophysiological events in the development of insulin resistance. As fat mass increases, a variety of factors including relative ischemia, dietary components, cytokines (e.g., leptin), and gut flora lead to chemotactic-induced migration of macrophages into the adipose tissue. This is most prominent in visceral adipose tissue. The cell–cell interactions between macrophages and adipocytes lead to activation of the macrophages (part of the innate immune system) and production of proinflammatory cytokines. These have metabolic effects that promote insulin resistance, and they also promote inflammation. These cytokines further stimulate the liver to produce additional cytokines, which are part of the acute-phase reaction, which often accompanies the insulin-resistant state. ANG II, angiotensin II; ICAM, intercellular adhesion molecule; MCP, monocyte chemotactic protein-1; NO, nitric oxide; ox LDL, oxidized low-density lipoprotein; VCAM, vascular cell adhesion molecule.

hypoxia-inducible factor, specific dietary constituents, hormones (e.g., leptin), and gut flora-derived products have all been implicated in this process [133,134]. The interactions between these activated macrophages and adipocytes cause release of adipokines with a net proinflammatory profile, which produce a chronic inflammatory state within this tissue [135]. They also have metabolic effects that cause insulin resistance. These cytokines further affect the liver and lead to an acute-phase reaction. The net effect is a systemic proinflammatory and fibrogenic state along with metabolic insulin resistance [136].

Metabolic consequences of insulin resistance

Insulin resistance is defined by the ability of insulin to clear glucose from blood [25]. This is also how insulin sensitivity is defined, and the two terms essentially reflect two sides of the same phenomenon. It is also important to remember that the sensitivity to insulin is measured on a continuous rather than a categorical scale. Thus, insulin sensitivity and resistance each vary along a continuous scale and there is no threshold cut-off value that marks the onset of insulin resistance in a given individual.

The fundamental physiological abnormality in the insulin-resistant state is an impairment in the insulin-mediated suppression of lipolysis [21,25]. Visceral adipose tissue is less sensitive to insulin-mediated suppression of lipolysis than subcutaneous adipose tissue [137]. It is believed that this is the result of increased expression of 11β-hydroxysteroid dehydrogenase, the rate-limiting enzyme for steroid synthesis. Thus, increased FFA release from visceral adipose tissue affects hepatocytes, where the FFAs interfere with insulin signaling and cause increased gluconeogenesis and impaired glucose utilization. In striated muscle, FFAs impair glucose uptake by impairment of insulin signaling and decreased translocation of the GLUT-4 transporter to the cell surface [138,139]. Increased FFA levels and glucose load consequent to impaired clearance results in pancreatic compensation and hyperinsulinemia. Thus, the insulin level for any given plasma glucose concentration is elevated; this is the biochemical hallmark of the insulin resistant state. The role of FFAs as a potential integrator of carbohydrate and lipid metabolism has also been referred to as the single gateway hypothesis of metabolic regulation [140].

It is possible that different organs and metabolic pathways may have differential sensitivity to insulin. Thus, although IR exists almost universally in subjects with NAFLD, it is important to delineate the specific metabolic pathways that are affected. Thus, whereas there is considerable resistance to the effects of insulin on lipolysis, its effects on lipogenesis are maintained and the rates of lipogenesis are increased [141,142]. This may be due to the effects of hyperinsulinemia on SREBP and lipogenic enzyme expression and activity.

Insulin resistance and the pathogenesis of hepatic steatosis

A characteristic feature of NAFLD is the accumulation of triglycerides in the liver [16]. Triglycerides accumulate in the liver because of an imbalance between production and turnover. They are formed by the esterification of a glycerol moiety with three fatty acid molecules.

Triglyceride synthesis in the liver and the genesis of hepatic steatosis

The net pool of free fatty acids (FFAs) available for triglyceride synthesis depends on the balance between formation and utilization of fatty acids. There are two major sources of FFAs in the liver:

- FFAs that are taken up from circulation
- FFAs that are formed in the hepatocyte itself.

The availability of FFAs for triglyceride synthesis also depends on their utilization for phospholipid synthesis and for oxidation.

There are two main sources of FFAs in the circulation, diet and peripheral lipolysis. There are only limited data on the dietary intake of subjects with NAFLD and its contribution to circulating FFA levels. A high level of saturated fat, high concentration of refined sugars, and a low fiber content in the diet have all been associated with the development of insulin resistance [143–145]. There are, however, no data in subjects with NAFLD comparing them with those with obesity but without NAFLD to see if there are any specific excesses or deficiencies in their diet. In one study [146], increased fat intake correlated with increased steatosis whereas increased carbohydrate intake correlated with the presence of inflammation in the liver.

Insulin resistance is associated with increased peripheral lipolysis and higher levels of fasting FFA concentrations [147]. Compared with age, gender, and race-matched controls, NAFLD is associated with higher fasting concentrations of FFAs [21]. Moreover, fatty liver and steatohepatitis are associated with progressive resistance to insulin-mediated suppression of lipolysis as determined by the rates of appearance of glycerol during a euglycemic hyperinsulinemic clamp [21]. Studies are ongoing to define the nature and relative quantities of FFAs in circulation in subjects with NAFLD.

The hepatic pool of FFAs is also derived from FFAs that are synthesized de novo in the liver. This pathway, also known as the de novo lipogenesis (DNL) pathway, involves the synthesis of FFA from acetyl CoA [148]. Under physiological circumstances, DNL contributes to only 5%–8% of triglycerides synthesized in the liver [149]. However, the physiological relevance of DNL is not well understood. The substrates for DNL include acetate, carbohydrate-derived acetyl CoA, and acetyl CoA derived from lipid oxidation. The relative contributions of these sources to DNL under varying conditions are not known. Nonalcoholic fatty liver disease is associated

with increased DNL [150]. As noted above, the enzymes of DNL are under the control of SREBP-1c, which is an insulin-sensitive transcription factor [151]. Hyperinsulinemia is also associated with NAFLD [21]. It appears that despite the resistance of lipolysis in peripheral adipose tissue to the effects of insulin, its effects on DNL in the liver are maintained in NAFLD. It is likely that this is facilitated by low adiponectin levels, which would decrease AMP kinase activity and thus disinhibit acyl CoA carboxylase, the rate-limiting enzyme in DNL [84]. Low levels of polyunsaturated fatty acids (PUFAs) in the liver may also promote maturation of SREBP-1c from the endoplasmic reticulum–Golgi system [152,153]. This forms the rationale for the use of PUFAs in NAFLD. De novo lipogenesis is also increased by the intake of fructose, especially high levels of corn syrup fructose, a common additive to many foods and beverages [154]. It bypasses the regulated steps in carbohydrate metabolism and forms glycerol-3-phosphate and acetyl CoA, both of which can serve as precursors for DNL. The national consumption of total fructose has been increasing and correlates well with the increasing prevalence of obesity in the United States [154].

It is well known that acetyl CoA can be used either for the formation of malonyl CoA or for mevalonate. The former leads to FFA synthesis and is under the control of SREBP-1c, whereas the latter leads to cholesterol synthesis and is regulated by SREBP-2 [155,156]. The two pathways are known to be coordinately regulated. If so, up-regulation of DNL should be accompanied by increased cholesterol synthesis. However, the principal features of the dyslipidemia associated with the metabolic syndrome and NAFLD are hypertriglyceridemia and a low concentration of HDL cholesterol. Liver X receptor senses the intracellular levels of oxysterols and modulates lipid synthesis in the liver [157–159]. The potential role of LXR in the dyslipidemia associated with NAFLD and the increase in DNL remains to be defined. Also, the potential role of farnisoid X receptor (FXR), which determines bile acid transport into bile, and its interactions with LXR in defining the dyslipidemia associated with the metabolic syndrome and NAFLD, are under active investigation. Liver X receptor affects the ATP-binding cassette lipid transporter (ABCA1) and modulates the export of cholesterol to HDL [160]. Also, steroyl CoA desaturase, a SREBP-1c-sensitive enzyme that catalyzes the formation of monounsaturated fatty acids, destabilizes the ABCA1 function [161]. These are likely mechanisms that cause the low HDL-cholesterol levels in NAFLD.

The availability of FFAs for triglyceride synthesis is also affected by their utilization for oxidation and for phospholipid synthesis. Subjects with NAFLD do not have systemic defects in the incorporation of FFA into phospholipids [21]. Phosphatidylcholine serves as a reservoir for PUFAs in the cell and, theoretically, lowering phospholipase A_2 ($iPLA_2$) should reduce levels of PUFAs and increase SREBP-1c activity. The potential role of such a mechanism in NAFLD remains to be explored.

Finally, the availability of FFAs for triglyceride synthesis is also affected by their utilization for oxidation. Free fatty acids can undergo β-oxidation in the mitochondria or peroxisomes [162]. They may also be oxidized by the microsomal enzyme or cytochrome P450 system [163]. Compared with matched controls, NAFLD is associated with increased β-hydroxybutyrate levels and higher lipid oxidation rates [21]. Also, during a euglycemic clamp, normal individuals suppress β-hydroxybutyrate levels, indicating that mitochondrial fatty acid oxidation is normally suppressed by insulin. However, fatty liver and NASH are associated with an impairment in insulin-mediated suppression of serum concentrations of β-hydroxybutyrate, confirming that these conditions are associated with resistance to insulin effects on fatty acid oxidation. These data are compatible with the known effects of increased FFA delivery on mitochondrial fatty acid oxidation. At a molecular level, FFAs may directly interfere with insulin signaling and inhibit insulin-mediated suppression of ketogenesis [164,165]. Also, increased activity of the suppressor of cytokine signaling-1 (SOCS-1) has been associated with impairment of insulin signaling pathways [166,167]. Although there are no human data on peroxisomal fatty acid oxidation in those with NASH, peroxisomal proliferation has been reported in those with NAFLD [168].

Triglyceride export from the liver and the genesis of hepatic steatosis

There are no accurate estimates of quantitative flux rates for the amounts of triglyceride synthesized from DNL vs reesterification of circulating FFA vs transport from the liver in subjects with NAFLD. Triglycerides are packaged in VLDL in the liver by a process requiring the microsomal transfer protein (MTP) and apolipoprotein B100. Several rare syndromes of NAFLD are associated with defects in the MTP or in VLDL assembly [169,170]. The incorporation of labeled leucine into apoB-100 is decreased in subjects with NAFLD [171]. It is, however, unclear if this is a disease-specific effect or if it is a cause or effect of the NAFLD. In summary, hepatic steatosis results from either or both increased synthesis and decreased export from the liver. Insulin resistance contributes to hepatic steatosis in multiple ways, by increasing levels of FFA for reesterification, increasing the rate of DNL, and providing the substrates for DNL.

In summary, the overall integration of metabolic pathways are closely regulated to maintain homeostasis (Fig. 89.8). An imbalance in hepatic lipid metabolism (synthesis and import vs metabolic utilization and export) causes fat accumulation in hepatocytes. Imbalances in these processes, which are controlled by transcription factors such as SREBP, result from dysregulated transcriptional control, which is, in turn, influenced by the abnormal endocrine and paracrine milieu associated with insulin resistance. All of these layers of complexity are further modulated by many factors such as genetic makeup, diet, and lifestyle. Metabolism is a complex biological

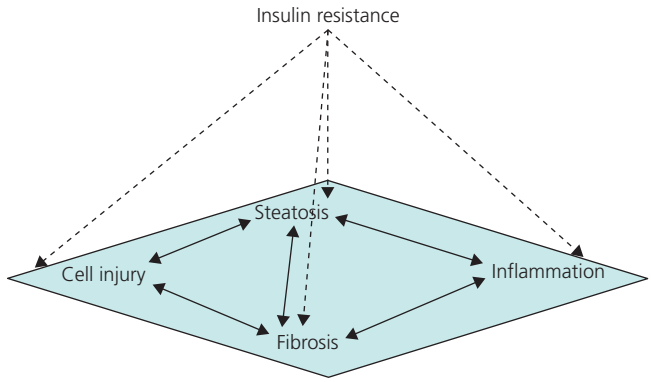

Figure 89.6 Schematic illustrating the pathogenesis of nonalcoholic steatohepatitis (NASH). Insulin resistance promotes steatosis, cell injury, inflammation, and fibrosis. Each of these factors further promotes each other, eventually causing cell injury, inflammation, and fibrosis – the hallmarks that distinguish steatohepatitis from steatosis alone.

state, and this explains why simple paradigms focused on a single mechanism fail in one or more clinical scenarios.

Pathogenesis of steatohepatitis

It was originally proposed that the development of NASH required two hits: insulin resistance that produced hepatic steatosis, and an additional hit that led to development of steatohepatitis. Since the 1990s, it has become apparent that the situation is more complicated (Fig. 89.6). Insulin resistance has been shown to promote directly or indirectly hepatic steatosis, hepatocyte injury, inflammation, and fibrosis. Moreover, the pathways involved in each of these processes affect the pathogenesis of all of the other endpoints that produce the phenotype of steatohepatitis.

Role of oxidative stress

It is generally believed that oxidative stress plays an important role in the pathogenesis of steatohepatitis. Animal models of NAFLD have demostrated the presence of oxidative stress [172]. In human studies, NAFLD has been associated with increased lipid peroxides, a marker of oxidative stress [21]. Evidence of increased lipid peroxides is seen in both those with hepatic steatosis alone as well as those with steatohepatitis. However, subjects with NAFL have lower levels of lipid peroxides compared with those with NASH [21].

Oxidative stress results from increased production of prooxidants – reactive oxygen species (ROS) or reactive nitrogen species (RNS) – or from decreased antioxidant defenses. There are several potential sources of ROS in the liver (Table 89.6). These include mitochondria, peroxisomes, the microsomal oxidative system, and iron overload. The mitochondria of hepatocytes in liver afflicted by NASH are markedly abnormal; they become ballooned and lose cristae (Fig. 89.7) [21,173]. This is accompanied by formation of paracrystalline intramitochondrial inclusions. These changes are relatively specific for NASH and are not commonly seen in NAFL. Within each hepatocyte some 10%–40% of mitochondria demonstrate these abnormalities.

The precise composition of the paracrystalline inclusions is not known. Similarly, nothing is known about the mechanisms by which mitochondrial morphology become abnormal. However, such inclusions are commonly seen in other cell types in diseases associated with mitochondrial DNA mutations [174]. Mitochondrial DNA encodes several components of the electron transport chain in the mitochondria. It has been shown that there is a generalized decrease in the activity of the hepatic electron transport chain enzymes in subjects with NASH [175]. Decreased electron transport chain activity in the face of continued fatty acid β-oxidation due to increased fatty acid delivery to the liver and intrahepatic mitochondrial insulin resistance should cause an uncoupling of oxidation and phosphorylation [176,177]. Uncoupled oxidation–phosphorylation causes ROS formation and enhances oxidative stress. This concept is further supported by evidence of decreased ATP formation in the liver of subjects with NASH [178]. It is possible that minor degrees of ROS formation from increased fatty acid oxidation cause oxidative damage to mitochondrial DNA, which becomes depleted over time causing the electron transport chain activity to decline, thereby further worsening oxidative stress. This remains to be verified experimentally. It is also not known whether mitochondria regenerate if insulin resistance is corrected.

Another source of oxidative stress is the cytochrome P450 system. This system, particularly CYP2E1, is overexpressed in subjects with NAFLD [179,180]. Using chlorzoxazone as a substrate for this enzyme, it has been shown that the activity of this enzyme is also increased in subjects with NASH [181]. This member of the cytochrome P450 system can be induced by the insulin-resistant state as well as by FFAs [182,183]. Impairment of insulin signaling-induced CYP2E1 overexpression in NASH is most likely secondary to posttranslational enzyme stabilization, although more direct transcriptional control also may have a role in this process [184]. It is believed that overexpression of this enzyme is associated with futile cycling of the enzyme, which generates ROS. Induction of CYP2E1 may be expected to be associated with expansion of the endoplasmic reticulum [183]. There are no studies evaluating the presence or absence of an expansion of

NASH Fatty liver

Figure 89.7 Mitochondrial morphology in nonalcoholic steatohepatitis (NASH). Whereas hepatocyte mitochondria in fatty liver are generally normal **(right panel)**, the mitochondria in NASH are often ballooned with loss of cristae and development of paracrystalline inclusions **(left panel)**. From Sanyal et al. [21], with permission from Elsevier.

the endoplasmic reticulum in subjects with NASH. Also, CYP2E1 induction has been described in subjects with the metabolic syndrome even in the absence of a fatty liver [185]. Finally, there is induction of CYP2E1 even in subjects with NAFL, and additional mechanisms must be required to produce steatohepatitis.

Peroxisomes also oxidize long-chain fatty acids but do not generate ATP. As a consequence, peroxisomal fatty acid oxidation causes ROS formation. It has been shown that peroxisomes are more numerous in subjects with alcoholic as well as nonalcoholic fatty livers [168]. There are almost no data on the function of peroxisomes in subjects with NASH. Iron overload has been associated with increased oxidative stress [186]. Although some studies have shown an association between NASH and iron overload [187], others have failed to find such an association [188,189].

The impact of oxidative stress in the liver depends on the balance between prooxidant and antioxidant activity. Little is known of the status of antioxidant pathways in the liver of subjects with NASH. A single study showed decreased paraoxonase-1 activity in the metabolic syndrome [190]. It has also been suggested that promoter polymorphisms in several Mn-superoxide dismutase may affect the progression of NASH [191].

Oxidative stress produces its biological effects through several mechanisms. These include direct lipid peroxidation of membranes of organelles, oxidative changes in DNA, mitochondrial DNA depletion, and changes in the expression of redox-sensitive genes [192]. These changes in gene expression have far-reaching effects on a multitude of cellular functions and can lead to adaptive changes or cell death. Readers are referred to several excellent reviews for in-depth discussion of this subject [192–195].

Mechanisms of cell injury and death

The phenotype of steatohepatitis is characterized by the presence of cytological ballooning, Mallory hyaline, apoptosis, inflammation, and pericellular fibrosis [196]. The pathogenesis of cytological ballooning is not known. A priori, one would expect a defect in the maintenance of normal cell volume regulation because an increase in cell volume is the hallmark of cytological ballooning. Cell volume is regulated by a number of complex processes including osmotic receptors and the intracellular actin network, which tethers the cell membranes [197]. In a fibroblast cell line, insulin has been shown to produce reorganization of the actin network [198]. The potential role of hyperinsulinemia and dysregulation of insulin signaling in the liver in the genesis of cytological ballooning remains to be defined. It is also unclear why occasional cells undergo cytological ballooning whereas other adjacent cells do not.

It has been shown that Mallory bodies are composed of heat-shock proteins that are ubiquitylated but fail to undergo proteosomal degradation [199]. Heat-shock proteins are a family of proteins that are produced in response to a variety of cellular stresses, including oxidative stress – a direct function of insulin resistance and uncoupling of oxidation and phosphorylation in mitochondria. It is likely that these proteins are induced in response to the oxidative stress found in subjects with either NAFL or NASH. However, in subjects with NASH, there may be defects in protein trafficking to the proteosomes or in proteosomal function itself that lead

to accumulation of heat-shock proteins within intermediate filaments. The nature and mechanisms involved in defective protein trafficking and proteosomal function in NASH remain unknown. Of note, Mallory bodies are almost always seen within ballooned hepatocytes. The mechanistic relationship between altered cytological ballooning and the development of Mallory hyaline also remains unknown.

Another characteristic feature of NASH is extensive apoptotic activity [200]. Several mechanisms have been invoked to explain the proapoptotic state in NASH. Triglyceride accumulation itself increases apoptosis by the interaction of unoxidized palmitoyl CoA with serine to form dihydrosphingosine, a precursor of ceramide [201]. Ceramide is a potent inducer of apoptosis through an inducible nitric oxide synthetase (iNOS)-mediated pathway that requires the transcription factor NF-κB [120]. It has also been shown that increased FFA delivery to hepatocytes, secondary to increased peripheral lipolysis in the insulin-resistant state, may also induce apoptosis [121]. Free fatty acids produce a translocation of BCL2-associated X protein (BAX) to lysosomes, where it causes releases of cathepsin. Cathepsin, acting by means of NF-κB, induces expression of TNF-α and activation of TNF-receptor-associated death pathways.

Interest has surrounded the potential role of endoplasmic reticulum stress (ER stress) in the development of cell injury in NASH. The ER is the principal site for synthetic activity within cells. Such activity requires not only appropriate synthesis but also local mechanisms to ensure that the proteins are correctly folded because this is essential for their recognition by the appropriate receptors and trafficking to their final destination. Under conditions where there is increased protein or lipid synthetic activity in the ER, depletion of ATP, depletion of calcium, or altered glucose homeostasis, the regulatory function of the ER in maintaining normal synthetic function is disrupted. This leads to activation of an intracellular program called the unfolded protein response (UPR) [202].

Activation of the UPR initially leads to an adaptive response in which protein synthesis decreases and allows restoration of normal ER function. Simultaneously, proteosomal degradation of unfolded proteins is increased – ER-associated degradation (ERAD). However, if the initiating factors are not corrected, alarm pathways are activated; these include activation of a number of stress kinases, which eventually result in activation of C/EBP homologous protein (CHOP), a potent apoptosis-inducing factor. Although animal studies suggest that ER stress is induced in fatty liver, there are no human data to confirm that ER stress plays a role in the genesis of cell injury in NASH.

Mechanisms of inflammation

Nonalcoholic steatohepatitis is characterized by a scattered, predominantly lobular, mixed inflammatory infiltrate. The precise mechanisms of inflammation in NASH have not been defined. It is generally presumed that the products of cell death and the release of inflammatory cytokines within the liver cause changes in blood flow and endothelial function that promote inflammation.

At a cellular level, activation of proinflammatory pathways is associated with activation of the stress kinase JNK (c-JUN N-terminal kinase) (Fig. 89.8). This enzyme can be activated by ER stress, oxidative stress, and inflammatory cytokines, for example, TNF-α [203–205]. It may also be activated by TNF-independent pathways [206]. Activation of JNK has numerous effects: it activates other kinases, which results in activation of the transcription factors NF-κB and activator protein-1 (AP-1) [207], which leads to transcriptional induction of inflammatory cytokines (e.g. TNF-α) [208,209]. These transcription factors also directly affect cellular metabolic activity [210]. Activated JNK can also produce serine phosphorylation of the insulin receptor substrate and further worsen insulin resistance and the propensity to develop steatosis [211]. Activation of JNK can also be modulated by the suppressor of cytokine signaling (SOCS) [212]. It must be noted that these data have been obtained almost entirely in animal models and their activation in NASH remains to be demonstrated.

Another important factor is the role of the innate immune system in the promotion and progression of inflammation in the liver in subjects with NASH (Fig. 89.5). An early event in the development of insulin resistance is the infiltration

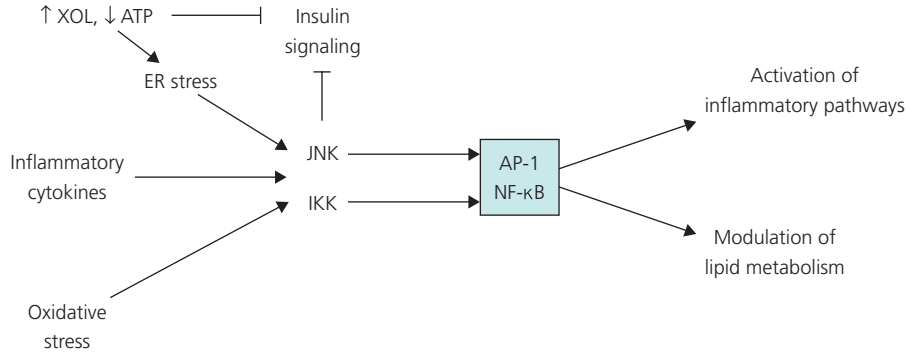

Figure 89.8 Cellular pathways involved in steatohepatitis. Endoplasmic reticulum stress (ER stress), inflammatory cytokines, and oxidative stress all lead to activation of c-JUN terminal kinase (JNK) and IκB kinase (IKK) resulting in activation of the transcription factors AP-1 and NF-κB. These increase expression of genes regulating proinflammatory cytokines and also further impair metabolic homeostasis and cause both glucose intolerance and hepatic steatosis. XOL, cholesterol.

of adipose tissue, especially visceral adipose tissue, by macrophages [132]. Relative tissue hypoxemia and induction of hypoxia-inducible factor-1 along with several dietary constituents have been implicated in this process [213,214]. These macrophages produce a number of proinflammatory cytokines, which further induce production of additional cytokines from adjacent adipocytes [74,215]. These cytokines antagonize insulin-mediated suppression of lipolysis and also produce a proinflammatory milieu within the adipose tissue [73]. They also enter the circulation and induce an acute-phase reaction by the liver. Interleukin-6 plays a key role in this process [114,216]. These cytokines and the secondary cytokines produced in the liver alter endothelial function and promote vascular dysfunction, and leukocyte adherence and migration. The role of the innate immune system in the initiation and maintenance of inflammation within the liver is under active investigation.

Mechanisms of fibrosis

Pericellular fibrosis in the hepatic sinusoids is a histological hallmark of NASH [217]. This results from activation of quiescent hepatic stellate cells, which then produce a collagenous matrix. Over time, the fibrosis extends to form central-to-central and central-to-portal bridges, which then evolve to cirrhosis. Several factors have been implicated in the activation of the stellate cells. These include a variety of cytokines, of which transforming growth factor-β (TGF-β) is the best known [218]. Both hyperinsulinemia and increased leptin levels increase collagen synthesis by activated stellate cells [219,220]. It is also conceivable that if stellate cell apoptosis is inhibited, the total fibrotic process may be enhanced. Some studies have focused on the role of N-cadherin, tissue inhibitor of metalloproteinase (TIMP), and endocannabinoids in this process [221,222]. The mechanisms involved in activation and perpetuation of the fibrotic processes is an area of active investigation. Importantly, following improvement of insulin resistance, hepatic fibrosis can regress [223,224].

Progression of NASH to cirrhosis

The progression of NASH to cirrhosis reflects a balance between cell injury vs repair and regeneration (Fig. 89.9). On the one hand, cell injury results from both the metabolic disturbances associated with insulin resistance and the inflammatory state of the liver. The latter is associated with the presence of proinflammatory cytokines (e.g., TNF-α) and products of inflammation (e.g., leukotrienes). On the other hand, tissue repair involves both repair of cells that have sublethal injury as well as the removal and replacement of dead hepatocytes with either new hepatocytes derived from stem cells or by scar tissue. Our understanding of the mechanisms of hepatic tissue repair and pathological wound healing in disease states is limited. Specifically, the mechanisms by which hepatic architecture is disrupted with progression to cirrhosis remain poorly understood.

Clinical features

Symptoms and signs

Most subjects with NAFLD are asymptomatic (Table 89.7). In such cases, the diagnosis is often made when the person is discovered to have either abnormal liver enzymes or features of a fatty liver on an imaging study performed for unrelated reasons. Others are diagnosed because the liver looked unusual during abdominal surgery, and yet others are diagnosed because of persistent hepatomegaly. It is, however, important to remember that only a small minority of subjects with NAFLD have been diagnosed and the great majority of afflicted individuals remain undiagnosed.

When symptoms do occur, the most common ones to bring NAFLD patients to clinical attention include malaise, fatigue, and right upper quadrant discomfort. The discomfort is often described as a nondescript vague discomfort rather than pain. Such symptoms antedate the diagnosis of NAFLD in one-third of patients [225].

Fatigue is often present in patients with NAFLD and is frequently the most debilitating aspect of the condition for the individual subject. In our experience, fatigue is the most common symptom in this patient population. Several clinical variations of the fatigue syndrome can be recognized. Most commonly, subjects complain of chronic malaise and a sensation of severe lethargy and sleepiness during the day. This is associated with disturbed sleep patterns, and patients often wake up feeling tired. Many subjects have associated sleep disorders and, on direct questioning, will acknowledge that they snore. The spouses of affected individuals often report that the patient is restless at night. It has been recognized that the insulin resistance syndrome is not simply a function of diet and lifestyle but is also markedly affected by abnormal sleep patterns [226,227]. Thus, abnormal sleep leads to insulin resistance whereas the insulin resistance syndrome is associated with abnormal sleep patterns [228,229]. It has been our experience that some of these subjects have underlying sleep-apnea syndrome, and correction of this condition produces a dramatic improvement in energy levels. This type of fatigue does not correlate with the grade or stage of steatohepatitis. The relationship of other sleep disorder-related abnormalities and insulin resistance remains poorly defined.

Other subjects wake up relatively rested but tire easily. This pattern is more often associated with more advanced disease. Some patients have mixed patterns of fatigue that are often difficult to evaluate and manage. Approximately 25% of subjects with NAFLD also carry a diagnosis of chronic fatigue syndrome [230]. Some patients complain of aching soreness in their muscles along with fatigue, and about 20% of all subjects suffer from a chronic pain disorder [231]. At our institution, 27% of subjects diagnosed with NAFLD were taking analgesics, including narcotics (7%), at the time of diagnosis [230].

Table 89.7 Common symptoms and signs of 400 subjects with nonalcoholic fatty liver disease (NAFLD)

Feature	NAFL (*N* = 75)	NASH (*N* = 325)
Symptoms and signs (%)		
Asymptomatic	60	55
Fatigue	30	45
Pruritus	2	4
RUQ discomfort	30	32
Edema	4	5
Hepatomegaly	22	28
Stigmata of chronic liver disease	8	10
Obesity	65	60
Diabetes	45	50
Hypertension	60	65
Dyslipidemia	65	69
Lab abnormalities (ULN) (mean ± SD)		
AST (< 75 IU/L)	65 ± 55	76 ± 66
ALT (< 75 IU/L)	135 ± 70	148 ± 78
Alkaline phosphatase (< 110 IU/L)	132 ± 21	128 ± 34
Total bilirubin (< 2 mg/dL)	0.8 ± 0.3	0.7 ± 0.7
Albumin (3.5–4.5 g/dL)	3.8 ± 0.4	3.7 ± 1
Prothrombin time (< 11 s)	10.9 ± 0.6	11.1 ± 0.6
Proportion of cirrhotics	0	16

ALT, alanine aminotransferase; AST, aspartate aminotransferase; NAFL, nonalcoholic fatty liver; NASH, nonalcoholic steatohepatitis; RUQ, right upper quadrant; ULN, upper limit of normal.
From Ramesh & Sanyal [231], with permission from Elsevier. Data from the NAFLD clinic at Virginia Commonwealth University.

Obesity is the most common physical finding, and is present from in 50%–90% of subjects [16]. About two-thirds of subjects with NAFLD also have other features of the metabolic syndrome. Hepatomegaly is the most common liver-related physical finding in subjects with NAFLD [7]. A minority of subjects have stigmata of chronic liver disease, such as spider angiomas or palmar erythema. Jaundice and features of portal hypertension, such as ascites and variceal hemorrhage, are seen in a small minority of subjects who present with advanced liver disease [232].

Other common associated conditions

The association of NAFLD with obesity, diabetes, hypertension, and hypertriglyceridemia is well known. I have performed a detailed inventory of associated symptoms and conditions in a cohort of 61 subjects with NAFLD [230]. In addition to confirming the classic associations with NAFLD, it was found that 26% of subjects had various allergies and 25% suffered from chronic depression, whereas 10% carried a diagnosis of an anxiety disorder and over 50% of subjects were taking a psychotropic drug at the time of diagnosis. On detailed questioning, the onset of weight gain often corresponded with a life event that is also associated with depression or anxiety, for example, divorce, accident, or child birth. In some of these cases, the onset of weight gain was temporally related to the development of the behavioral disorder and the use of an antidepressant drug. Given the propensity of several antidepressant drugs to cause weight gain, the potential role of such drugs in the weight gain and subsequent development of insulin resistance is an important and as yet unexplored question.

Whether depression and anxiety disorders are unrelated or related to NAFLD remains to be evaluated. Also, the prevalence of NAFLD in the general population of subjects with chronic pain or fatigue is unknown. One should, however, be aware that NAFLD may also be present in subjects with chronic fatigue, fibromyalgia, and depression.

Studies have highlighted the importance of a fatty liver as an independent risk factor for a variety of endpoints related to the metabolic syndrome. In a 5-year follow-up study of 633 subjects, subjects with abnormal liver enzymes had a 2.2–2.8-fold increased risk of developing the full-blown metabolic syndrome and outperformed the C-reactive protein [233]. Similarly, other studies have shown that those with abnormal liver enzymes have a higher risk of developing hypertension and diabetes [234,235]. The presence of NAFLD (either NAFL or NASH) is also independently associated with endothelial dysfunction, abnormal vascular reactivity, increased carotid intimal thickness, and the number of plaques in the carotids [236,237]. These data indicate that although having a fatty liver may not have many clinical consequences for the liver, it can have multiple deleterious effects on health in general.

Insulin resistance and the metabolic syndrome, which are present, respectively, in over 75% and 90% of subjects with NAFLD [20], are associated with numerous abnormalities of the coagulation cascade. The metabolic syndrome is associated with increased concentrations of circulating tissue factor (TF) and factor VII thereby creating a prothrombotic state [238]. The severity of insulin resistance, that is, hyperinsulinemia and adipose tissue mass, both determine the levels of TF and factor VII [239–241]. Factor VII and TF form a complex that activates factor X, which, together with factor V, converts prothrombin to thrombin. This step is further amplified by activation of factor IX by the TF–factor VII complex, as well as by thrombin itself along with recruitment of cofactors V and VIII. Thrombin converts fibrinogen to fibrin thereby forming a clot. The metabolic syndrome has also been associated with high levels of factor VIII and fibrinogen, further promoting the procoagulant state in this condition [242].

The tendency to form clots is counteracted by inhibitors of the clotting pathways, and by fibrinolysis, which is initiated by plasminogen activators. The impact of insulin resistance on inhibitors of coagulation, such as protein c, protein s,

and TF pathway inhibitor, has not been fully defined. Plasminogen activator inhibitor-1 (PAI-1) is the principal physiological inhibitor of fibrinolysis. Insulin resistance is associated with increased PAI-1 levels resulting from increased production and release by adipose tissue and adipose-tissue-associated stromal cells [243]. Expression of PAI-1 is increased by TNF-α, TGF-β, insulin, hyperglycemia, increased FFAs, and triglycerides [243–245].

In summary, the presence in a patient of risk factors for NAFLD, right upper quadrant discomfort, hepatomegaly, or elevated liver enzymes should trigger an evaluation for NAFLD. Other subjects with persistently elevated liver enzymes (e.g., ALT) who do not have viral hepatitis, hemochromatosis, or other common liver diseases, such as Wilson disease, should also be evaluated for NAFLD. It is also important to remember that there are no symptoms or signs to distinguish between those with NAFL and those with NASH.

Laboratory abnormalities

Approximately 7.9% of the US population have persistently abnormal liver enzymes with negative tests for viral hepatitis and other common causes of liver diseases [37]. The presence of abnormal liver enzymes is related to the BMI and other risk factors associated with NAFLD. Thus, the majority of these subjects have NAFLD. It is also important to note that a large number of subjects with NAFLD have persistently normal liver enzymes, and the entire histological spectrum of NAFLD can be seen in such individuals.

The most common liver enzyme abnormality is an elevated serum concentration of ALT. The degree of elevation is usually modest and when the values exceed 300 IU/L, alternate causes of liver disease should be carefully sought. The aspartate aminotransferase (AST) level is elevated to a lesser degree, and the AST:ALT ratio is usually less than 1. In some individuals, an elevated serum level of alkaline phosphatase is the only abnormality. When elevated, it rarely exceeds twice the upper limit of normal.

The hepatic synthetic functions are not altered until the disease is far advanced. The serum albumin and prothrombin time become abnormal before the bilirubin level becomes elevated. In diabetic subjects, isolated hypoalbuminemia can result from diabetic nephropathy. Hematological parameters are usually normal unless cirrhosis and portal hypertension lead to hypersplenism. About 30%–50% of subjects with NAFLD have elevated blood glucose levels, and about 60% of patients with NAFLD also have associated hypertriglyceridemia or a low HDL cholesterol level [20,231]. An elevated ferritin level is also often seen in subjects with NAFLD [7,187]. It is, however, not associated with iron overload in most cases and usually reflects an acute-phase response [7].

From a practical point of view, the laboratory evaluation of a subject with suspected NAFLD involves:

- exclusion of alternate causes of liver enzyme abnormalities
- documentation of hepatic steatosis
- making the distinction between hepatic steatosis and steatohepatitis
- evaluating the stage of the disease
- evaluating the presence and severity of insulin resistance and other complications of the metabolic syndrome (Table 89.8).

In a given subject, each of these must be carefully considered and a decision made about how aggressively the answer to each is to be sought. A liver biopsy remains the gold standard for diagnosing steatohepatitis and for the staging of the liver disease unless clinically evident cirrhosis is present.

Natural history (Fig. 89.9)

There are only limited data concerning the natural history of NAFLD. Most studies are cross-sectional in nature and have focused on highly selected patient populations. In such studies, the majority of subjects have NAFL. It is generally believed that NAFL rarely progresses to more advanced liver disease [44]. However, there are several reported cases of development of steatohepatitis in subjects with NAFL, particularly after rapid weight loss following bariatric surgery [45]. This occurs more frequently after jejunoileal bypass and only rarely after proximal gastric bypass or vertical banded gastroplasty [246,247].

The long-term natural history of subjects with NAFLD is affected by the presence of underlying metabolic syndrome, and these patients are at risk from morbidity related to diabetes and cardiovascular disease. One study has found increased cardiovascular mortality in subjects with cirrhosis due to NASH compared with those with hepatitis C [248]. Subjects with the metabolic syndrome are also at risk for

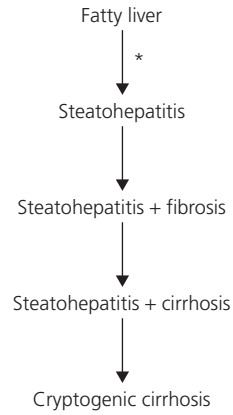

Figure 89.9 The natural history of nonalcoholic fatty liver disease (NAFLD). *It is debated whether steatosis progresses to steatohepatitis. The frequency with which this occurs, especially in the absence of severe weight loss such as that seen after bariatric surgery, remains debated. About 20% of subjects with nonalcoholic steatohepatitis (NASH) develop increasing fibrosis and eventually cirrhosis. Following development of cirrhosis, the hepatic steatosis and the other features of NASH may disappear leading to the presentation of cryptogenic cirrhosis.

Table 89.8 Evaluation of a subject with nonalcoholic fatty liver disease (NAFLD)

1. Exclusion of alternate causes of abnormal liver enzymes
2. Evaluation of presence of hepatic steatosis:
   a: sonography[a]
   b: CT scan
   c: MRI
3. Assessment of presence of steatohepatitis:
   a: liver biopsy only definitive method of making assessment
4. Assessment of stage of disease:
   a: This is sometimes clinically evident (cirrhosis) but usually requires a biopsy. Subjects may be selected on basis of markers of advanced fibrosis: increasing age, persistently abnormal ALT, elevation of AST greater than ALT, presence of other end organ diseases associated with the metabolic syndrome, e.g., diabetes and increasing body mass index and waist-to-hip ratio
5. Assessment of presence of other features of metabolic syndrome:
   a: diabetes – fasting blood sugar
   b: hypertension
   c: dyslipidemia – fasting lipid profile
   d: body mass index and waist circumference
6. Evaluation of other diseases commonly associated with NAFLD:
   a: obesity
   b: sleep apnea
   c: coronary artery disease: monitor Framingham risk score
7. Measurement of degree of insulin resistance:
   IR_{HOMA} (homeostatic model): fasting insulin and glucose[b]

a Sonography is the most commonly used method.
b A fasting insulin level serves just as well.
ALT, alanine aminotransferase; AST, aspartate aminotransferase; CT, computed tomography; IR_{HOMA}, homeostasis model assessment of insulin resistance; MRI, magnetic resonance imaging.

development of gallstones. Although gallstones are well known to occur in subjects with obesity, the specific prevalence of gallstones in subjects with NAFLD is unknown.

The natural history of NAFLD was evaluated by chart review of subjects diagnosed in the last 20 years in Olmstead county [249]. The overall survival of subjects with NAFLD was lower than that of a matched population in Minnesota. Higher mortality was associated with age (hazard per decade 2.2; 95% confidence interval [CI] 1.7–2.7), impaired blood glucose (hazard ratio 2.6; 95% CI 1.3–5.2), and cirrhosis (hazard ratio 3.1, 95% CI 1.2–7.8). Liver disease was the third leading cause of death in this population, whereas it was the 13th cause of death in Minnesota. These data confirm previous studies in which the presence of cirrhosis and steatohepatitis were associated with increased mortality [250].

There are only limited data about the progression of NASH to cirrhosis. Most studies are retrospective and methodologically flawed. However, based on the limited data available, the risk of progression to cirrhosis is estimated to be about 20% [251]. In a study of 103 subjects who had multiple liver biopsies over a median duration of 3.2 years, 37% of subjects showed progression of fibrosis whereas 29% showed regression [252]. It is, however, unclear whether these findings reflect sampling variability. It has been reported that a biopsy length of about 4 cm is required to obviate such variability [15]; this length is rarely obtained in routine clinical practice. In cross-sectional studies, increasing age, diabetes, and BMI have been associated with advanced fibrosis [188]. In other studies, a combination of hypertension, abnormal ALT levels, and insulin resistance as measured by the homeostatic model have been associated with a higher probability of having advanced fibrosis in severely obese individuals [46]. Evaluation of the existing literature suggests that older subjects with additional features of the metabolic syndrome, such as diabetes and hypertension, are more likely to have advanced disease.

Once cirrhosis develops, the natural history of NASH is characterized by an approximately 4% annual rate of decompensation [248]. In a 10-year follow-up of 150 subjects with cirrhosis due to NASH, the rate of decompensation was found to be slightly but significantly lower compared with a matched population of subjects with hepatitis C and cirrhosis. These difference were mainly due to lower rates of development of ascites and synthetic failure (Fig. 89.10). Although some studies have suggested that hepatocellular cancer occurs frequently in NASH, they have not evaluated the population at risk, that is, the denominator [253,254]. One study found that 10/149 subjects with cirrhosis due to NASH developed hepatocellular cancer over a 10-year period compared with 25/147 subjects with hepatitis C (Fig. 89.11) [248].

Another aspect of NASH is that hepatic steatosis and other features of steatohepatitis decrease after cirrhosis develops [232]. In some cases, these features disappear completely

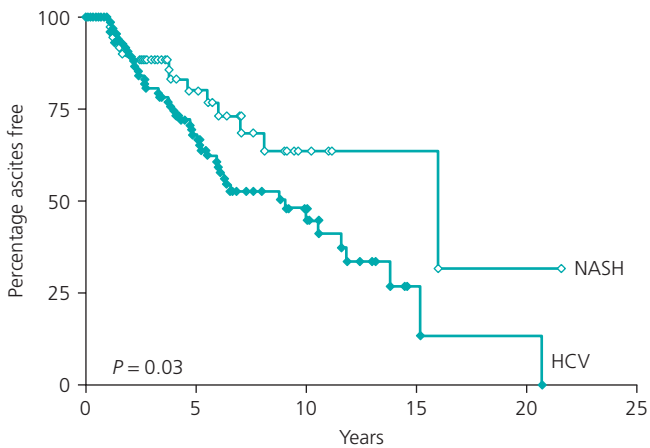

Figure 89.10 The natural history of cirrhosis due to nonalcoholic steatohepatitis (NASH): ascites. The probability of developing ascites and decompensation in those with cirrhosis caused by NASH is less than that seen in subjects with cirrhosis due to hepatitis C. From Sanyal et al. [248], with permission from John Wiley & Sons, Inc.

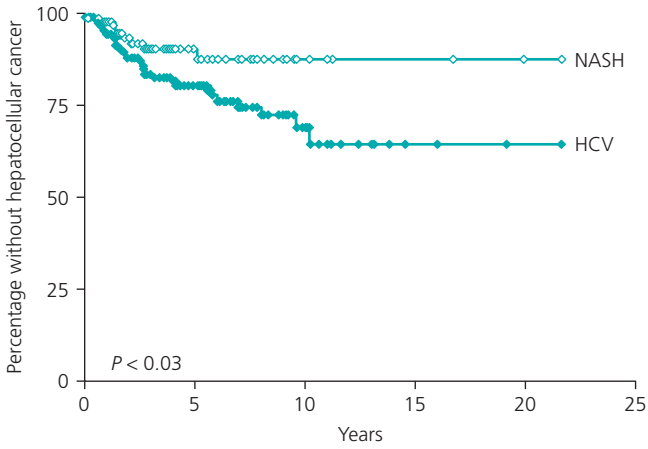

Figure 89.11 The natural history of cirrhosis due to nonalcoholic steatohepatitis (NASH): hepatocellular cancer. Subjects with cirrhosis due to NASH can develop hepatocellular cancer but the cancer risk appears to be somewhat lower than that seen in those with hepatitis C (HCV). From Sanyal et al. [248], with permission from John Wiley & Sons, Inc.

and such cases present as cryptogenic cirrhosis. In fact, most subjects with cryptogenic cirrhosis have underlying fatty liver disease. About 7%–14% of subjects referred for liver transplantation have cryptogenic cirrhosis [3,255]. Hepatic steatosis develops universally in subjects with cryptogenic cirrhosis after liver transplantation compared with 20% of those with hepatitis B, primary biliary cirrhosis, and alcoholic liver disease [256]. Steatohepatitis develops at a later time and most such subjects have recurrence of disease between 2 and 5 years after transplant. However, graft function is maintained over the first 5–10 years posttransplant and there is no evidence of an increased rate of graft loss compared with subjects undergoing transplant for other indications.

Diagnostic approach

A complete evaluation of a patient with NAFLD includes confirmation of the diagnosis, assessment of the etiology, and delineation of the grade and stage of the disease. The diagnosis of NAFLD requires two steps:

- to establish the presence of fatty liver disease
- to establish the "nonalcoholic" nature of the condition.

Also, several other forms of chronic liver disease are extremely prevalent in the general population, such as hepatitis C, and these can often coexist with NAFLD [65]. It is therefore imperative that the initial evaluation includes appropriate laboratory studies to exclude other common causes of liver disease.

The gold standard for the diagnosis of fatty liver disease is a liver biopsy. However, given the invasive nature, costs, and risks of a liver biopsy, there is considerable interest in trying to make the diagnosis using noninvasive methods.

Figure 89.12 An ultrasound picture of hepatic steatosis. The parenchyma is hyperechogenic and brighter than the adjacent kidney. Also, the edges of the blood vessels are blurred. From Ramesh & Sanyal [231], with permission from Elsevier.

Noninvasive diagnostic methods

Two-dimensional sonography, computerized tomography (CT), and magnetic resonance imaging (MRI) are the most-studied methods that are also available at most medical centers. The sonographic features of NAFLD include increased hepatic parenchymal echotexture and vascular blurring [257,258]) (Fig. 89.12). However, these features are also seen in any form of chronic liver disease and, although sensitive (85%–95%) they are nonspecific (positive predictive value 62%) [6]. Also, the ability to detect fatty liver by sonography drops off markedly once the degree of hepatic steatosis decreases to 30% or less [31].

Imaging of the liver by CT provides a more specific method for the noninvasive diagnosis of NAFLD (Fig. 89.13). Hepatic steatosis decreases the CT attenuation of the liver. When the hepatic parenchymal attenuation is 10 or more Hounsfield units lower than the spleen on a non-contrast-enhanced scan, a diagnosis of hepatic steatosis can be made. When intravenous contrast is administered, the hepatic enhancement lags behind the spleen and the liver-to-spleen attenuation differential exceeds 20 Hounsfield units [259]. Although these features allow hepatic steatosis to be defined with a 76% positive predictive value [31], they do not permit distinction between fatty liver and steatohepatitis. Also, the diagnostic sensitivity of the test depends on the severity of the steatosis, and falls off when the steatosis is mild. Computed tomography imaging also does not provide any information about the stage of fibrosis in the liver unless features of portal hypertension are present. This only occurs in the presence of cirrhosis of the liver. Finally, it is worth remembering that CT scans are substantially more expensive than sonography.

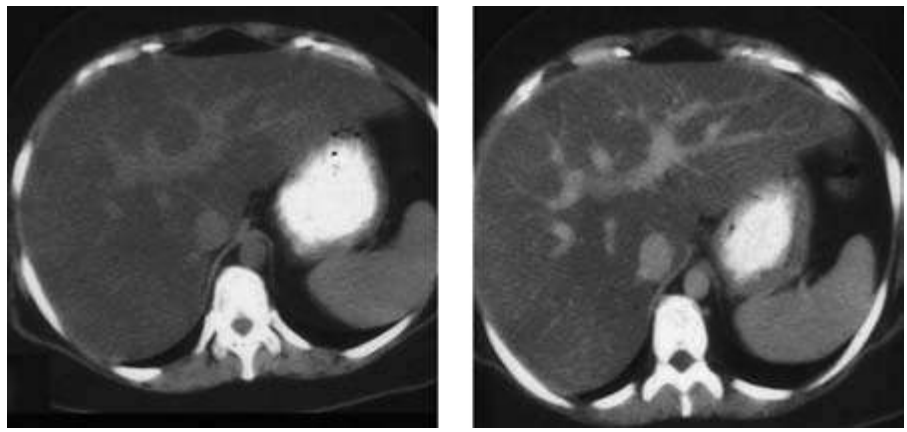

Figure 89.13 Computed tomography (CT) images of hepatic steatosis. In non-contrast-enhanced scans **(left panel)**, the liver attenuation is decreased resulting in the blood vessels standing out. Also, the liver is darker compared with the spleen. When intravenous contrast is given **(right panel)**, the liver attenuation increases but to a lesser degree than the spleen. When the difference exceeds 20 Hounsfield units, hepatic steatosis can be diagnosed with relative specificity. From Ramesh & Sanyal [231], with permission from Elsevier.

Magnetic resonance imaging is even more sensitive than a CT scan for the assessment of hepatic steatosis. Techniques of MRI have been refined to provide a highly reproducible and validated measure of hepatic triglyceride content [34]. Unfortunately, MRI also has many of the same limitations as CT imaging noted above. It is even more expensive than a CT scan and is not universally available. In clinical practice, a hepatic sonogram is the most commonly used modality to evaluate the presence of steatosis. However, it is important to note that none of these methods can diagnose steatohepatitis or accurately assess the stage of the disease.

Role of a liver biopsy

A liver biopsy is the gold standard for the diagnosis of NAFLD, separating those with a fatty liver alone from those with steatohepatitis and evaluation of the stage of hepatic fibrosis. Unfortunately, it is invasive, uncomfortable, expensive, and occasionally causes severe morbidity and mortality. There is also no established, specific pharmacological treatment for NASH at this time. Establishing a diagnosis of NASH vs NAFL does not therefore lead to specific treatment interventions in routine clinical practice. The invasive nature of a liver biopsy coupled with the lack of management options have led to a reluctance on the part of many physicians to perform a liver biopsy in cases of suspected NAFLD.

In order for the practicing clinician to make intelligent decisions regarding who to biopsy and when to biopsy, he or she must consider the information to be obtained and how this will affect the individual undergoing the biopsy. It is important to remember that, in subjects with persistently abnormal ALT values and negative viral serologies, approximately 20%–30% of subjects have an alternate diagnosis [260,261]. The probability of having NAFLD is likely to be higher if other features of the metabolic syndrome are also present in such individuals. The clinical corollary is that individuals without risk factors for NAFLD are more likely to have an alternate cause for their abnormal liver enzymes. A treating physician who is interested in identifying such cases may consider selecting such individuals for liver biopsy to establish the diagnosis. In other cases, the need for a biopsy simply to make a diagnosis of NAFLD should be individualized. For example, demonstration of isolated hepatic steatosis may allow an individual to obtain life insurance.

The second unique piece of information obtained from a liver biopsy is the distinction between hepatic steatosis and steatohepatitis. It is generally believed that steatohepatitis can progress to cirrhosis in 15%–20% of individuals [262]. There are numerous clinical centers engaged in phase II and phase III clinical trials with a variety of agents at this time. I therefore recommend that the physician discusses with the patient the possibility that they have NASH, with its attendant risks of progression, and ask the patient if they would like to be referred to a center to participate in a clinical trial. In those who are interested in pursuing this approach, a liver biopsy may be considered. Also, vertical banded gastroplasty has been shown to improve NASH [263,264]. In cases where NASH is found on a liver biopsy, this option may be considered if the BMI exceeds 35.

A liver biopsy is also the best way to assess the degree of fibrosis in the liver. Therefore, if the physician is concerned about the possibility of having advanced fibrosis, a liver biopsy is the only way to answer the question. In some circumstances, the presence of bridging fibrosis may direct management. For example, in a morbidly obese subject who is likely to be turned down for liver transplant listing because of their obesity, the presence of bridging fibrosis may lead the treating physician to consider aggressive weight loss measures such as pharmacological or surgical interventions. The risk of having advanced fibrosis (i.e., bridging fibrosis or cirrhosis) increases with advancing age, elevated BMI, and the presence of diabetes [188]. These criteria may be used to identify those who are most likely to benefit from a biopsy.

Treatment

There is no clearly established treatment of NAFLD. The focus of management remains the treatment of the risk factors for

NASH, namely obesity and insulin resistance. Dietary modification and lifestyle changes are the principal methods used for weight management. Although several drugs have been used for either weight control or treatment of insulin resistance, they remain experimental.

Weight management

The goal of weight management is to bring the patient's weight as close as possible to the ideal bodyweight. However, it is not essential for the weight to be normalized to improve the metabolic status of overweight or obese individuals. Even modest weight loss can be accompanied by substantial improvement in insulin resistance [265]. There have been a large number of studies of various dietary and lifestyle interventions to improve bodyweight in subjects with obesity. The results are somewhat heterogeneous but still allow certain conclusions to be made.

First, most diets work in the short term. However, long-term weight loss with diet alone is difficult to accomplish. Similarly, lifestyle interventions often appear to be effective in the short term but are difficult to sustain. Combined approaches using intense diet and exercise interventions have also had limited effect because of the high recidivism rate after discontinuation of the studies. The data underscore the need for diet and lifestyle changes that are palatable to the patient, and easy to accomplish and maintain in the context of the socioeconomic, family, and cultural milieu in which a given patient lives. This further indicates that it is unlikely that a single magic solution will work for all subjects. Using a transtheoretical model to analyze the behavioral status of patients with NASH, a preliminary report indicates that most subjects are in the precontemplation phase [230]. This indicates that most subjects with NASH do not perceive that they have a weight-related problem; these data provide a clue about why most patients with NASH do not achieve long-term benefits from lifestyle interventions.

It is my practice to educate the patient as much as possible before they embark on a diet and exercise program. Also, in those with long-standing diabetes or cardiovascular risk factors, it is prudent to perform a basic cardiac, vascular, ophthalmic, and neurological evaluation before starting an exercise program. In subjects who are overweight or obese, the National Heart, Lung and Blood Institute (NHLBI) guidelines for weight management are the best evidence-based treatment guidelines [266]. It is generally recommended that the diet should be planned to achieve a daily caloric deficit of 2–4 MJ (500–1000 cal). Also, an increase in everyday activities should be encouraged. For diabetic individuals, the American Diabetes Association guidelines for diet should be followed [267]. For subjects with a BMI greater than 30, or with a BMI greater than 27 plus other comorbidities (e.g., sleep apnea), pharmacological weight management with orlistat or sibutramine may be considered [266]. The latter is a serotonin reuptake antagonist and is contraindicated in subjects with heart disease. Orlistat causes fat malabsorption; a nonrandomized trial suggested that this agent could produce a beneficial effect on NASH [268].

Table 89.9 Drugs used for the treatment of nonalcoholic steatohepatitis (NASH)

Insulin sensitizers
Metformin
Pioglitazone
Rosiglitazone
Antioxidants
Vitamin E
Silymarin
Vitamin C
Hepatoprotective agents
Betaine
S-Adenosylmethionine
Ursodeoxycholic acid
Hypolipidemic drugs
Fibrates (e.g., gemfibrozil)
Statins
Anti-TNF regimens
Pentoxifylline
Adiponectin
Angiotensin receptor blockers
Losartan

TNF, tumor necrosis factor.

Both proximal gastric bypass and vertical banded gastroplasty have been shown to be safe in subjects with NASH. In the first few months following these procedures, the steatosis decreases whereas the inflammation may worsen [45]. However, in the long term, the hepatic steatosis, cell injury, and fibrosis all regress once the weight stabilizes following these operations [45,269]. In subjects with a BMI greater than 35, these operations are viable treatment options provided the operative risks are within the acceptable range.

Pharmacological treatment (Table 89.9)

There are two classes of drugs that have been shown to correct insulin resistance:

- biguanides (e.g., metformin)
- thiazolidinediones (e.g., rosiglitazone and pioglitazone).

The former work by mechanisms that are undefined. The roles of all of the pharmacological agents discussed below are experimental.

Metformin

In an animal model of steatohepatitis, metformin treatment improved hepatic steatosis and inflammation. However, in

human studies, although the ALT improves and liver size decreases, metformin has not been consistently found to improve liver histology [270]. In an open-label randomized trial, metformin (2 g/day given orally) improved ALT more often than vitamin E (800 IU/day) (odds ratio 3.1, $P < 0.001$) [271]. However, only limited histological data are available from this study. The role of metformin remains experimental and a large-scale clinical trial is underway to define the utility of metformin for NASH.

Thiazolidinediones

This class of drugs act through the peroxisome proliferator-activated receptor-γ and improve insulin sensitivity [223,224,272–274]. A small nonrandomized trial of troglitazone demonstrated an improvement in ALT in 9/10 subjects and improvement in inflammatory scores in five subjects. Troglitazone has also been shown to be beneficial in those with NAFLD associated with lipodystrophy. Three pilot trials supported the use of thiazolidinediones for NASH [223,224,274], and are the basis for a large ongoing NIH-sponsored clinical trial. Caution should be exercised when interpreting these data because of the small number of subjects. The potential risk for hepatotoxicity with these drugs warrants caution when interpreting the data, and their use should be limited to clinical trials.

Lipid-lowering agents

In one controlled trial, clofibrate had no beneficial effects on liver functions or hepatic histology, whereas in another small controlled trial, gemfibrozil improved liver chemistry [275]. However, no histological data are available from the latter study. Thus, in general, such agents are not used for the treatment of NASH.

Vitamin E

In one published series of 11 pediatric patients with NASH who received vitamin E (DL-α-tocopherol) 400–1200 IU, the ALT improved [276]. However, no follow-up liver histology was available from this study, thus preventing us from knowing whether this was a cosmetic effect or whether the hepatic histology was indeed improved. In a study undertaken by I and my colleagues, we found that 400 IU of DL-α-tocopherol improved hepatic steatosis significantly but only produced a trend toward improvement in other histological parameters [223]. In a single pilot study [277], a combination of vitamins E + C (1000 IU/day vitamin E + 1000 mg/day of vitamin C) improved hepatic fibrosis but did not affect inflammation.

Ursodeoxycholate (UDCA)

Ursodeoxycholate is a hydrophilic bile acid with hepatoprotective properties. In one study, UDCA produced improvement in liver enzymes and a decrease in hepatic steatosis [278]. The long-term benefits of UDCA and its optimal dose remain to be established. A randomized clinical trial was unable to establish the benefits of UDCA for NASH [279].

Taurine

Taurine is believed to function as a lipotropic factor and improve mobilization of hepatic fat. In a single uncontrolled series, 10 children treated with taurine supplements orally had radiological resolution of their fatty liver [280]. Radiological improvement was accompanied by a decrease in glycine/taurine-conjugated bile acids.

Betaine

Betaine is a precursor of *S*-adenosylmethionine, a hepatoprotective factor. In one study, 10 subjects received betaine anhydrous for 12 months in two daily divided doses. Seven of the ten subjects completed 1 year of treatment. In this group, an improvement in aminotransferase activity as well as liver histology was noted [281]. Similar data were reported in another study, in which betaine was administered along with diethanolamine glucoronate and nicotinamide ascorbate [282]. These findings require confirmation in large prospective trials.

Pentoxifylline

This agent antagonizes TNF-α and is available for long-term oral use. In two small pilot studies [283,284], the ALT improved following several months of treatment at a dose of 400 mg three times a day. However, histological data are not available. Also, although the drug was well tolerated in one study, 9/20 subjects in the other study dropped out due to side effects, especially nausea. Several trials are underway to confirm these initial findings.

Losartan

Angiotensin II has been implicated in hepatic stellate cell activation and matrix production [285]. A small pilot study of an angiotensin receptor blocker, losartan, found an improvement in ALT [286]. These data also require validation in large-scale studies before any recommendations can be made.

90 Ascites and its complications

Guadalupe Garcia-Tsao

Suspected ascites, 2303
New-onset ascites, 2303
Cirrhosis and ascites, 2308
Cirrhosis and hepatic hydrothorax, 2315
Spontaneous bacterial peritonitis, 2315
Cirrhosis and acute renal failure, 2317
Hepatorenal syndrome, 2319

Ascites is the accumulation of fluid in the peritoneal cavity. In the Western world, cirrhosis is the main cause of ascites, accounting for more than 75% of the cases (Table 90.1). Other less common causes of ascites are peritoneal malignancy, which accounts for ~ 12%, cardiac failure in 5%, and peritoneal tuberculosis in only 2% of the cases [1], although the latter is still an important cause of ascites in many developing countries. Approximately 5% of patients will have more than one cause of ascites, such as cirrhosis and heart failure, cirrhosis and tuberculous peritonitis, or cirrhosis and malignancy [2].

In patients with cirrhosis, ascites is one of the complications that mark the transition from a compensated to a decompensated stage [3]. Initially, ascites is "uncomplicated," that is, it responds well to diuretics and is not infected. As cirrhosis progresses and the mechanisms that lead to ascites formation worsen, ascites ceases to respond to diuretics (refractory ascites). Bacteria may infect ascites, an entity known as spontaneous bacterial peritonitis (SBP), which occurs mainly in hospitalized patients with severe liver disease. With further progression of cirrhosis, the patient with ascites may develop hyponatremia and functional renal failure (hepatorenal syndrome). The hemodynamic alterations that lead to ascites and refractory ascites are the same as those that lead to hyponatremia and hepatorenal syndrome, differing only in the degree of abnormality, with the latter complications denoting a more deranged circulatory status.

The approach to a patient with ascites depends on the setting surrounding its presentation. In a patient with new-onset ascites, the priority is to determine the etiology of ascites, because this will determine its management. In a patient with ascites caused by cirrhosis, management depends on the phase that the patient has reached, ranging from uncomplicated ascites to hepatorenal syndrome.

Table 90.1 Etiology of ascites and classification by serum–ascites albumin gradient (SAAG) and ascites protein level

	SAAG	Ascites protein
Main etiological factors of ascites		
Cirrhosis or alcoholic hepatitis	High	Low
Congestive heart failure	High	High
Peritoneal malignancy	Low	High
Peritoneal tuberculosis	Low	High
Other etiologies of cirrhosis (account for < 2% of all cases)		
Massive hepatic metastases	High	Low
Nodular regenerative hyperplasia	High	Low
Fulminant liver failure	High	Low?
Budd–Chiari syndrome (late)	High	Low
Budd–Chiari syndrome (early)	High	High
Constrictive pericarditis	High	High
Venoocclusive disease	High	High
Myxedema	High	High
Nephrogenous (dialysis) ascites	High	High
Mixed ascites (cirrhosis + peritoneal malignancy)	High	Variable
Pancreatic ascites	Low	High
Serositis (connective tissue disease)	Low	High
Chlamydial/gonococcal	Low	High
Biliary	Low	High?
Ovarian hyperstimulation syndrome	Low?	High
Nephrotic syndrome	Low	Low

Those assessments followed by a question mark are theoretical and have not been confirmed by data in the literature.

Suspected ascites

History and physical examination are important in determining the presence and etiology of ascites, but they are not definitive.

The most frequent symptoms associated with the development of ascites are increased abdominal girth, described as tightness of the belt or garments around the waist, associated with weight gain. However, sometimes weight gain is masked by concomitant loss of muscle mass as a result of cirrhosis or malignancy. The rapid onset of symptoms in a matter of weeks helps to distinguish ascites from obesity, which develops over a period of months to years.

Physical examination is relatively insensitive for detecting ascitic fluid, particularly when the amount is small or the patient is obese. When present in small to moderate amounts (> 1500 mL), ascites can be identified on examination by bulging flanks, flank dullness, and shifting dullness. Shifting dullness is the most sensitive finding in the clinical diagnosis of ascites (compared with abdominal distention, bulging flanks and fluid wave) and its absence can rule out ascites with over 90% accuracy [4]. The presence of an umbilical hernia or diastasis recti suggests that the patient has had tense ascites.

Imaging investigations

The initial, least invasive, and most cost-effective method to confirm the presence of ascites is *abdominal ultrasonography*. It can detect amounts as small as 100 mL and is considered the gold standard for the diagnosis of ascites [5]. Abdominal ultrasound is also useful in locating the optimal site to perform a paracentesis, particularly in patients with a small amount of ascites or in those with loculated ascites. Additionally, ultrasound can be accompanied by Doppler examination of the hepatic venous system – an important initial test to rule out the presence of hepatic vein obstruction, a frequently overlooked cause of ascites [6].

Abdominal *computed tomography (CT) scan* is also highly sensitive and specific in diagnosing the presence of intra-abdominal fluid; however, its cost precludes it as a first-line diagnostic method to confirm the presence of ascites. Abdominal CT scan is more sensitive than ultrasonography in determining the presence of cirrhosis or malignancy. Finding a small nodular liver, splenomegaly, and collaterals on CT scan establishes the diagnosis of cirrhosis.

New-onset ascites

In a patient with new ascites, the priority is to establish the cause of ascites because this will determine its management.

Initial evaluation

The history and physical examination are important in guiding the evaluation of ascites. Several aspects of the physical examination should receive special attention. The presence of spider angiomas, palmar erythema, and muscle wasting in addition to jaundice or signs of portal hypertension, such as splenomegaly and abdominal wall collaterals, suggests cirrhosis. Finding a palpable (or ballotable) left lobe of the liver (in the epigastric area) is almost pathognomonic of cirrhosis. Distended neck veins, gallop rhythm (S3), and uniform hepatomegaly with hepatojugular reflux or peripheral edema suggests congestive heart failure. The presence of a small nodule at the umbilicus (Sister Joseph Mary nodule) or an enlarged supraclavicular lymph node (Virchow node) suggests malignant ascites. Large veins with an upward flow localized in the back suggest obstruction of the inferior vena cava.

Diagnostic paracentesis

The simplest and most inexpensive way to orient the diagnostic workup of a patient with new-onset ascites is through the analysis of ascitic fluid. A diagnostic paracentesis should be the first test performed in a patient with new-onset ascites (see Fig. 90.1). It is a safe procedure with a low incidence of serious complications, the most serious being the development of large hematomas, which occurs in 0.2%–0.9% of cases [7,8]. Coagulopathy is not a contraindication to performing a diagnostic paracentesis particularly if it is performed with a small-gauge needle [7,8]. Care should always be taken to avoid surgical scars, abdominal wall collaterals, and the area of the inferior hypogastric artery, which lies midway between anterior superior iliac spine and pubic tubercle. If there are doubts about the presence of ascites or if no fluid is obtained in the first attempt, paracentesis should be performed under sonographic guidance.

In a diagnostic paracentesis, 20–50 mL of ascitic fluid is obtained. Tests that should be performed on the fluid are shown in Table 90.2, and their use in the differential diagnosis of ascites is detailed below.

Appearance of ascitic fluid

Uncomplicated "normal" ascitic fluid is transparent, straw colored to slightly yellow. In patients with marked jaundice, the fluid may have a deeper yellow color. Fluids with a leukocyte count greater than 5000/mm^3 appear cloudy, and those with a leukocyte count exceeding 50 000/mm^3 appear frankly purulent and indicate the presence of a gross intra-abdominal infection (secondary peritonitis) or an abscess [1].

Purulent ascites may be confused with the milky fluid associated with a high fat content (chylous ascites). Lack of odor and a triglyceride level greater than 200 mg/dL establishes the diagnosis of chylous ascites. An easier way to confirm the presence of chylous ascites is to refrigerate a tube with ascites – in case of chylous ascites, a creamy layer will separate at the top.

Fluids with a red blood cell count exceeding 10 000/mm^3 will appear pink, whereas frank bloody fluid is usually associated with a red blood cell count greater than 20 000/mm^3. In

Table 90.2 Tests performed in diagnostic paracentesis

Routine analysis of ascitic fluid
Gross appearance
Total protein
Albumin (with simultaneous estimation of serum albumin) so that the ascites–serum albumin gradient can be calculated by subtracting the ascitic fluid value from the serum value
White blood cell count and differential
Bacteriological cultures
Focused analysis of ascitic fluid
Cytology (to exclude malignant ascites)
Amylase (if pancreatic ascites is suspected)
Acid-fast bacilli smear and culture and adenosine deaminase determination (if peritoneal tuberculosis is suspected)
Glucose and lactic dehydrogenase (if secondary peritonitis is suspected in a patient with ascites PMN > 250/mm^3)
Triglycerides (if the fluid has a milky appearance, i.e., chylous ascites)
Red blood cell count (if the fluid is bloody)

PMN, polymorphonuclear leukocytes.

the presence of bloody fluid, the question will be whether it is the result of a traumatic tap or whether it is due to hemoperitoneum. Blood in the fluid resulting from a traumatic tap will clot, whereas fluid from a hemoperitoneum will not clot because blood has already clotted (intraperitoneally) and the clot has lysed. A tap performed immediately in the opposite flank will also clarify the situation. Hemoperitoneum suggests malignant ascites.

A tea-colored fluid can be seen in pancreatic ascites and the result of breakdown of ascitic fluid red cells. This phenomenon is more pronounced in hemorrhagic pancreatitis, resulting in a black fluid. Bile-stained fluid is green and can be seen with gallbladder or intestinal perforation.

Serum–ascites albumin gradient and ascites total protein levels

These two inexpensive tests taken *together* are the most useful in determining the etiology of ascites and thereby in further directing the workup of patients with ascites (see Table 90.1).

The *serum–ascites albumin gradient (SAAG)* is obtained by subtracting the concentration of ascites albumin from that of serum albumin (ideally determined from specimens obtained on the same day) and is a reflection of hepatic sinusoidal pressure [9,10]. The SAAG concept is based on Starling forces. When sinusoidal hypertension (hydrostatic pressure) is the cause of ascites, the colloidosmotic gradient (exerted mainly by serum and ascites albumin) has to increase to counterbalance the high hydrostatic pressure that is driving fluid into the peritoneal cavity. SAAG correlates well with the hepatic venous pressure gradient ($r = 0.72$), a measure of hepatic sinusoidal pressure [9]. The cutoff value that best distinguishes patients in whom ascites is caused by sinusoidal hypertension vs ascites caused by peritoneal malignancy is a SAAG of 1.1 g/dL, with a SAAG greater than 1.1 g/dL indicating ascites resulting from sinusoidal hypertension (e.g.,

cirrhosis, heart failure) [11]. Interestingly, the SAAG value of 1.1 g/dL roughly corresponds to a hepatic venous pressure gradient (HVPG, a measure of sinusoidal pressure) of 11–12 mmHg [9], which is the threshold pressure necessary for the development of ascites in cirrhosis (see below). The accuracy of SAAG is reduced if samples are not obtained simultaneously, if serum albumin levels are low or if ascites is chylous (falsely high SAAG). Serum hyperglobulinemia (> 5 g/dL) leads to a high ascitic fluid globulin concentration and can narrow the albumin gradient by contributing to the oncotic forces. To correct the SAAG in the setting of a high serum globulin level, the uncorrected SAAG should be multiplied by (0.16) × (serum globulin [in g/dL] + 2.5) [12].

The *ascites total protein content* at different cutoff values (2.5–3.0 g/dL) has been traditionally used to divide ascitic fluid into "exudates" secondary to peritoneal processes (malignancy, tuberculosis) or "transudates" in case of ascites secondary to sinusoidal portal hypertension. It is increased in peritoneal processes because of leakage of high-protein mesenteric lymph from obstructed lymphatics or from an inflamed peritoneal surface [13]. However, exudative ascites is also present in ascites secondary to heart failure [2], in which the mechanism is an increased hepatic sinusoidal pressure. In this situation, the process that leads to sinusoidal hypertension is posthepatic and therefore the hepatic sinusoids are normal. Normal hepatic sinusoids are uniquely permeable ("leaky") and hepatic congestion secondary to hepatic vein or inferior vena cava obstruction or cardiac failure has been shown to lead to profuse outpouring of protein-rich lymph into the peritoneal cavity [14]. In cirrhosis, there is deposition of fibrous tissue in the sinusoids ("capillarization of the sinusoid") that renders the sinusoid less leaky to macromolecules, and this leads to an abnormally low protein content of liver lymph [15,16]. Therefore, in addition to identifying peritoneal causes of ascites (high protein), the ascites total protein enables differentiation of intrahepatic (e.g., cirrhosis) causes of ascites (low protein) from posthepatic causes (e.g., heart failure, Budd–Chiari) of ascites (high protein), in both of which the SAAG is elevated [2]. This differential is extremely important because constrictive pericarditis is one of the few curable causes of ascites. Also, the distinction between cardiac or hepatic origin of ascites is especially important in alcoholic patients, who can have ascites secondary to alcoholic cardiomyopathy or from cirrhosis, with significant management implications.

In addition to being useful in determining the etiology of ascites, total protein levels in ascites are useful to determine susceptibility of developing bacterial infection [17]; cirrhotic patients with an ascites protein concentration below 1.0 g/dL have a higher risk of developing infection (spontaneous bacterial peritonitis). Contrary to what occurs with pleural fluid, ascites does not become an "exudate" with infection [18]; however, protein levels greater than 1.0 g/dL have been described as being suggestive of secondary (surgical) peritonitis.

All causes of ascites and their known/expected SAAG and total protein levels are shown in Table 90.1. The diagnostic workup for the three main causes of ascites is outlined in Fig. 90.1. In cases in which the etiology of ascites is still undetermined because of contradictory or borderline results of SAAG or ascites total protein, the ultimate test will be the determination of the HVPG.

Hepatic venous pressure gradient measurement

The hepatic venous pressure gradient (HVPG) is an indirect measure of portal pressure and a direct measure of hepatic sinusoidal pressure. The concept is the same as the measurement of the pulmonary wedged pressure. The HVPG is obtained by introducing a catheter in the right femoral vein or the internal jugular vein and advancing a balloon catheter into the right main hepatic vein. Pressures are recorded with the balloon inflated (wedged hepatic venous pressure, or WHVP) and deflated (free hepatic venous pressure, or FHVP). The WHVP is the direct measurement of sinusoidal pressure but it is usually corrected by subtracting the FHVP (a measure of systemic pressure that acts as an internal zero) thereby yielding the HVPG. Normal WHVP is 5–7 mmHg, normal FHVP is 1–2 mmHg, and normal HVPG is 3–6 mmHg. Portal hypertension is defined as an HVPG greater than 6 mmHg; however, the development of ascites requires that a threshold portal pressure gradient of 12 mmHg is exceeded [19,20]. Importantly, patients in whom the HVPG is reduced below 12 mmHg, or at least 20% from baseline values, show a decrease in the development of ascites [21].

Therefore, and as shown in Table 90.3, in cirrhotic ascites the HVPG will be elevated at the expense of an elevated WHVP and a normal FHVP, and the levels are usually greater than or equal to 12 mmHg. In cases of cardiac ascites, both the WHVP and the FHVP will be elevated (reflecting elevated systemic pressures) and therefore the HVPG will be normal [22]. In cases of peritoneal ascites (i.e., malignancy or tuberculosis), all hepatic venous pressure measurements (WHVP, FHVP, and HVPG) will be normal, unless the patient has coexisting cirrhosis or heart failure. When performed properly, HVPG measurements are reproducible and safe [23]; in

Table 90.3 Differential of ascites based on hepatic venous pressure gradient (HVPG) measurements

Cause of ascites	WHVP	FHVP	HVPG
Cirrhosis	Increased	Normal	Increased
Cardiac ascites	Increased	Increased	Normal
Peritoneal malignancy or TB	Normal	Normal	Normal

FHVP, free hepatic venous pressure; TB, tuberculosis; WHVP, wedged hepatic venous pressure.

fact, hepatic vein catheterization for measurement of hepatic vein pressures enables the performance, in the same procedure, of a transjugular liver biopsy, which will further define the etiology of ascites [24].

Evaluation of infection

Tests to investigate infection should be performed if the ascites is purulent or in any patient with cirrhotic ascites with symptoms or signs suggestive of spontaneous bacterial peritonitis (SBP) or who is admitted to the hospital [25]. A low ascites protein content (< 1.0 or 1.5 g/dL), present in most patients with cirrhosis, is the most important predictor of ascites infection [17]. SBP is the infection of ascitic fluid in the absence of an obvious local source, and it is the most common bacterial infection in hospitalized patients with cirrhosis. Importantly, the development of SBP is not associated with a significant change in ascites protein levels [18].

Total and differential cell counts

A predominance of neutrophils or polymorphonuclear leukocytes (PMN) in the ascitic fluid indicates the presence of an acute intraabdominal inflammatory process. Processes such as cholecystitis, appendicitis or diverticulitis can lead to ascites with a high neutrophil count, but in the absence of cirrhosis, the amount of fluid is generally minimal.

The diagnosis of SBP, that is, the infection of cirrhotic ascites, is established with an ascites PMN count greater than 250/mm^3 [25]. In patients with bloody ascites (i.e., ascites RBC count > 10 000/mm^3), 1 PMN per 250 RBC should be subtracted to adjust for the presence of blood in ascites.

Ascites PMN cell counts are performed manually and this may take several hours and not be available outside regular work hours. Although the use of reactive strips for leukocyte esterase has been proposed as an alternative to manual counting [26], several studies (mostly including small numbers of patients with SBP) show sensitivities that range widely between 50% and 100% [27]; therefore these strips cannot be recommended until larger studies are performed and the method is standardized.

A predominance of mononuclear cells indicates a chronic process and would suggest the presence of tuberculous peritonitis.

Smears and bacteriological culture

Sample collection at the bedside inoculating blood culture bottles (both aerobic and anaerobic) with 10 mL of ascitic fluid is more likely to yield an infecting organism compared with samples that are centrifuged and plated [28]. Although ascites culture is negative in approximately 40% of patients with clinical manifestations suggestive of SBP and increased ascites PMN [25], it is important to isolate an infecting microorganism, as this will further guide management [29]. Gram stain is positive in less than one-third of cases of SBP.

Ascites glucose and lactate dehydrogenase levels

In contrast to pleural fluid, ascites glucose and lactate dehydrogenase (LDH) levels are of little value in determining the cause of ascites or in determining the presence of infection. The ascites/serum LDH ratio is approximately 0.4–0.5 in uncomplicated cirrhotic ascites and increases in SBP, presumably because of the release of LDH from PMNs [18]; however, its diagnostic accuracy is low. It has been proposed that a ratio greater than 1.0 (i.e., if the ascites LDH is higher than serum LDH) and an ascites glucose below 50 mg/dL would suggest the presence of secondary bacterial peritonitis, although the specificity of these criteria is low [30] and they have not been validated prospectively.

Ascites lactate and pH

These tests were thought to be useful in the rapid diagnosis of SBP. However, several studies have demonstrated that they are no more useful than the ascites PMN determination [31].

Evaluation of malignancy

This should be undertaken in patients with a compatible clinical presentation. It is important to distinguish malignant ascites secondary to an infiltrated peritoneum (peritoneal carcinomatosis) from ascites secondary to massive liver metastases or "pseudocirrhosis" secondary to profound desmoplastic response to infiltrating breast cancer [32] or secondary to nodular regenerative hyperplasia related to chemotherapy [33]. In patients with cancer and ascites, peritoneal carcinomatosis is the cause of ascites in two-thirds of the patients [34].

Cytology

Cytological examination of ascites should be performed in all patients with suspected malignancy, particularly in those with low SAAG and high ascites protein, findings that suggest the presence of peritoneal carcinomatosis (as opposed to hepatic malignancy or pseudocirrhosis). In peritoneal carcinomatosis, SAAG is low, total protein high, and the diagnostic yield of cytology is as high as 97% (but could be as low as 42% [35]), whereas in patients with massive liver metastases, SAAG is high, ascites protein is low, and cytology is often negative [34].

It has been suggested that flow cytometry may be a useful adjunct to cytology in the diagnosis of peritoneal carcinomatosis, particularly when related to lymphoma or pancreatic cancer [35,36]; however, in a patient with suspected malignancy, low SAAG, high ascites protein, and negative results on cytological examination, the test of choice is probably a peritoneoscopy with peritoneal biopsies.

Tumor markers in ascites

Although CA-125 levels may be considered a sensitive tumor marker in patients with ovarian cancer, high serum CA-125 levels are elevated in *any* patient with ascites regardless of etio-

logy. In fact, serum and ascites CA-125 levels were comparable among patients with cirrhotic ascites, patients with malignant ascites, and those with "benign" ascites [37]. Awareness of this association can prevent unnecessary workup and cost.

Other ascites markers such as carcinoembryonic antigen, fibronectin, and cholesterol have been found to be nonspecific and unhelpful in the diagnosis of malignant ascites, mostly because in the studies analyzing such markers patients were not stratified by the type of malignant ascites [38].

Evaluation of peritoneal tuberculosis

Although the incidence of peritoneal tuberculosis (PTB) appears to be rising in the United States, it remains an uncommon cause of ascites although it commonly occurs in patients with cirrhosis [39]. This makes its identification more problematic. In a noncirrhotic patient, ascites secondary to peritoneal tuberculosis is associated with a low SAAG and a high ascites protein. In a cirrhotic patient, findings associated with cirrhosis will predominate, that is, high SAAG and low protein. A diagnostic algorithm of patients with suspected PTB has been proposed [40].

Acid-fast bacilli culture and smear

Although isolating acid-fast bacilli (AFB) in ascites is the gold standard in the diagnosis of PTB, less than 40% of patients with PTB have positive ascitic fluid cultures, and Ziehl–Neelsen staining of the ascitic fluid for mycobacterial detection is positive in only about 3% of cases with proven PTB [40]. Additionally, conventional culture media require 4–8 weeks to detect AFB, which can lead to a delay in the initiation of specific therapy. Newer methods of identifying mycobacterial isolates include liquid chromatography and DNA probes, which reduce the turnaround time, and rapid amplification-based tests like polymerase chain reaction (PCR), which can yield results in days. However, their diagnostic value requires further analysis.

Ultimately, laparoscopy is the best test to diagnose PTB, either by visualization alone (typical findings) or in combination with biopsy, culture, and histological examination. This test should be considered at an early stage whenever PTB is suspected.

Adenosine deaminase ascitic fluid activity

With difficulties in the bacteriological diagnosis of PTB, there has been an ongoing search for alternative rapid and noninvasive tests, with adenosine deaminase (ADA) activity in the ascitic fluid being the most promising.

Adenosine deaminase is an enzyme related to proliferation and differentiation of lymphocytes, and establishing its activity appears to be a fast and discriminating test for diagnosing PTB, as shown by a metaanalysis of 12 studies (some performed in countries with a higher prevalence of PTB) including 264 patients, of which 50 (18.9%) had peritoneal tuberculosis. ADA levels showed high sensitivity (100%) and specificity (97%) using cutoff values from 36 to 40 IU/L, with an optimal cutoff point of 39 IU/L [41]. Although a retrospective study suggested that ADA activity is much less sensitive in detecting PTB in the setting of cirrhosis [39], other systematic reviews have not confirmed this contention [42]. Given its diagnostic accuracy and easy availability, performance of this test is recommended in suspected PTB.

Evaluation of pancreatic ascites

Pancreatic ascites is caused by extravasation of pancreatic fluid from the pancreatic ductal system, either from a leaking pseudocyst or from a ruptured pancreatic duct. Therefore, this fluid has high amylase levels (much higher than serum amylase) and a protein content greater than 2.5 g/dL. Because pancreatic ascites is not secondary to sinusoidal hypertension, the SAAG will be lower than 1.1 g/dL. In a relatively large series, only about two-thirds of the patients experienced abdominal pain [43], and it has been suggested that pancreatic ascites occurs more often than reported and a workup for it should be done even in the face of unconvincing radiographic evidence [44]. Of note, nonpancreatic tumors (e.g., ovarian) may cause an increase in the serum and ascitic fluid amylase, which may be incorrectly diagnosed as pancreatic ascites. However, isoenzyme analysis of this amylase will show that it is salivary isoamylase [45].

Evaluation of chylous ascites

Chylous ascites is an uncommon form of ascites resulting from an accumulation of peritoneal fluid rich in triglycerides, due to the presence of lymph in the abdominal cavity. A triglyceride level greater than 200 mg/dL is diagnostic of chylous ascites.

It occurs because of disruption of the lymphatic system resulting from obstruction (malignant infiltration or inflammatory process) or traumatic injury (surgery, trauma) with leakage of chylomicron-rich fluid into the peritoneum. Altered hemodynamics leading to increased caval (constrictive pericarditis) and hepatic venous pressures (cirrhosis) can also lead to an increased formation of hepatic duct lymph.

The most common cause of nontraumatic chylous ascites in adults is abdominal malignancy, with non-Hodgkin lymphomas accounting for at least one-third to half of these malignancies [46,47]. In addition to lymphomas other tumors that cause chyloperitoneum may arise from the ovary, colon, kidney, prostate, pancreas, and stomach. The most common inflammatory causes of chylous ascites are abdominal or pelvic radiation, pancreatitis, and tuberculosis. Surgical procedures that involve extensive retroperitoneal dissection are most commonly associated with postoperative chylous ascites, including the distal splenorenal shunt. Blunt trauma, stab wounds, and gunshot wounds can also lead to traumatic chylous ascites.

Cirrhotic ascites has chylous characteristics in only 0.5–1.3% of cases. Spontaneous transformation of previously clear ascites appears to be associated with a poor prognosis.

In contrast, the appearance of chylous ascites de novo in a cirrhotic patient appears to indicate a more favorable outcome [48].

Given the multiple etiologies of chylous ascites, workup of the patient is directed by clinical and ascitic fluid findings as described for nonchylous ascites. The only caveat is that the SAAG may be falsely elevated in chylous ascites. Additional tests to determine the presence of lymphatic disruption include lymphangiography and lymphoscintigraphy.

Cirrhosis and ascites

To understand the natural history of the patient with cirrhosis and ascites and its management at each stage it is important to understand the pathophysiology of ascites.

Pathogenesis and natural history of cirrhotic ascites

In cirrhosis, ascites results from two main pathogenic mechanisms: sinusoidal hypertension and sodium retention (Fig. 90.2). Ascitic fluid leaks into the peritoneal space as a result of sinusoidal hypertension, which in turn results from hepatic venous outflow block secondary to regenerative nodules, fibrosis, and active vasoconstriction. As mentioned previously, there is a minimal sinusoidal pressure necessary for ascites formation [19,20]. This would be a self-limited process but for the continuous replenishment of the intravascular volume through sodium and water retention. Sodium retention results from splanchnic and peripheral vasodilation resulting in a decrease in effective arterial blood volume, and activation of neurohumoral systems (angiotensin, renin, aldosterone) that leads to renal sodium retention [49]. As liver disease worsens, vasodilation also worsens leading to the nonosmotic release of antidiuretic hormone, which then leads to water retention and hyponatremia [50]. In the final stage of cirrhosis, vasodilation is extreme and in addition to marked sodium and water retention (refractory ascites with or without hyponatremia) there is renal vasoconstriction, which leads to a decrease in glomerular filtration rate and renal failure (hepatorenal syndrome, HRS).

Therefore, a patient with cirrhosis goes through a sequence of diuretic-responsive ascites, followed by refractory ascites, and then hyponatremia and HRS [51], with each stage reflecting a more deranged circulatory state. Overall, most cirrhotic patients with ascites have "uncomplicated" ascites, that is, ascites that is not infected, is not associated with renal dysfunction, and responds to diuretic therapy [52]. However, the prevalence of uncomplicated ascites is lower in certain settings (e.g., transplant centers, in hospital).

Therapies for ascites

Different therapies for ascites and their site of action are depicted in Fig. 90.3. Except for transplant, none of the different treatments of ascites has resulted in significant improvements in survival. However, treating ascites is important, not only because it improves the quality of life of the cirrhotic patient but also because SBP, a lethal complication of cirrhosis, does not occur in the absence of ascites.

Liver transplant

The development of ascites in a patient with cirrhosis denotes a poor prognosis, with a median survival of about 1.5 years, compared with a median survival of more than 12 years in patients who remain compensated [3]. In the presence of

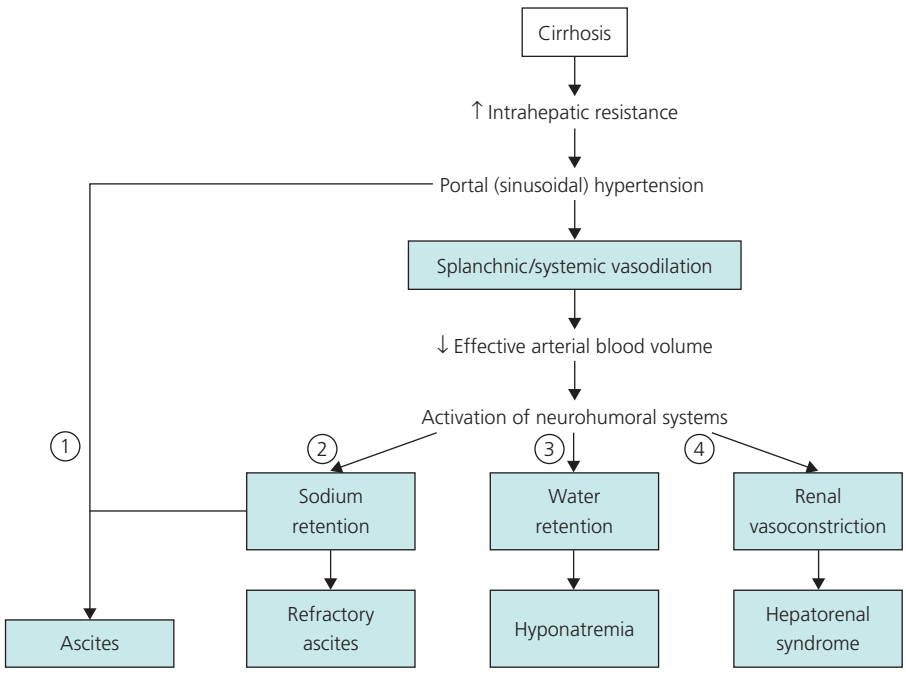

Figure 90.2 Common pathogenesis of ascites, hyponatremia and hepatorenal syndrome. Ascites (1) results from increased sinusoidal pressure and sodium retention. Sinusoidal pressure increases as a result of increased intrahepatic resistance. Sodium retention results from splanchnic and systemic vasodilation that leads to decreased effective arterial blood volume and subsequent upregulation of sodium-retaining hormones. With progression of cirrhosis and portal hypertension, vasodilation is more pronounced, leading to further activation of the renin–angiotensin–aldosterone and sympathetic nervous systems. The resulting increase in sodium and water retention can lead to refractory ascites (2) and hyponatremia (3), respectively, while the resulting increase in vasoconstrictors can lead to renal vasoconstriction and hepatorenal syndrome (4).

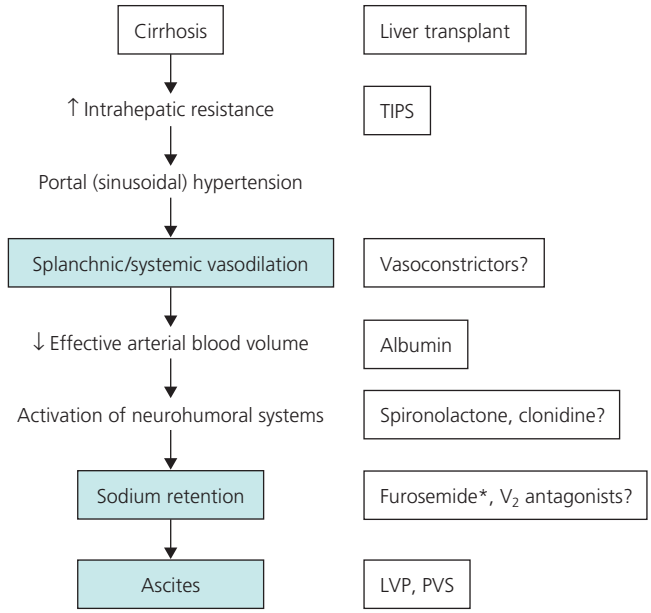

Figure 90.3 Site of action of different therapies for ascites. *Furosemide should only be used in conjunction with spironolactone. LVP, large-volume paracentesis; PVS, peritoneovenous shunt; TIPS, transjugular intrahepatic portosystemic shunt; V_2, arginine vasopressin type 2 receptor.

ascites, mortality in cirrhosis is about 20% per year [53]. Patients with cirrhosis who develop ascites should therefore be evaluated for liver transplantation because this constitutes the ultimate treatment for ascites and its complications.

Sodium restriction and diuretics

Sodium restriction is recommended in all cirrhotic patients with ascites. Restriction to approximately 90 mEq/day (i.e., 2 g sodium/day = 5.2 g of dietary salt/day) is the recommended goal [52]. Further restriction of sodium is unrealistic and difficult to achieve. Nonpalatability of a salt-restricted diet may lead to inadequate food intake. In these cases, liberalizing sodium restriction and adding or increasing diuretics is preferable to compromising the already compromised nutrition of the cirrhotic patient with ascites.

Although loop diuretics such as furosemide are the most potent natriuretics, randomized controlled trials have demonstrated that spironolactone is significantly more effective than furosemide alone in the treatment of cirrhotic ascites [54,55]. When furosemide is used alone, sodium not reabsorbed in the loop of Henle is taken up at the distal and collecting tubules as a result of the hyperaldosteronism present in most cirrhotic patients with ascites. Therefore, spironolactone, which acts by blocking aldosterone, is the diuretic of choice in the treatment of ascites. Furosemide can be used together with spironolactone but should not be used alone.

There is no evidence that other diuretics such as metolazone, thiazides, or torasemide offer an advantage over spironolactone and furosemide.

In contrast to the treatment of acute heart failure, where the response to therapy needs to be fast and an intravenous (i.v.) route is preferable, elimination of cirrhotic ascites should be slow (only about 500 mL/day can be eliminated) and an oral route is preferred. Nonsteroidal antiinflammatory drugs or aspirin blunt the natriuretic effect of diuretics and should be avoided in cirrhotic patients with ascites [56,57]. Although selective cyclooxygenase-2 (COX-2) inhibitors have not been shown to impair natriuresis or to induce renal dysfunction in cirrhotic rats [58], preliminary data in patients indicate that celecoxib may be related to a decrease in renal function [59] and therefore COX-2 inhibitor use should also be avoided until more clinical data become available.

Complications of diuretic therapy

Common complications are renal impairment caused by intravascular volume depletion (25%), hyponatremia (28%), and hepatic encephalopathy (26%) [60–62]. Spironolactone is often associated with adverse events, mainly painful gynecomastia, related to its antiandrogenic activity. Potassium canrenoate, one of the major metabolites of spironolactone, has a comparable diuretic effect and a lower antiandrogenic activity and could be used in cases in which gynecomastia and mastalgia are side effects of spironolactone therapy. However, this drug is not available in the United States. Amiloride, another potassium-sparing diuretic, does not produce gynecomastia and is recommended in patients with intolerable painful gynecomastia, but it has significantly less natriuretic effect than spironolactone [63]. Amiloride is used at an initial dose of 20 mg/day and can be increased to 60 mg/day. In patients in whom the natriuretic response with amiloride is suboptimal it may be worthwhile to attempt retreatment with spironolactone.

Large-volume paracentesis

Several randomized studies have demonstrated that large-volume paracentesis (LVP) associated with i.v. albumin is as effective as standard therapy with diuretics in patients with uncomplicated ascites but with a significantly faster resolution and the same or a lower rate of complications [60,61]. However, LVP is a local therapy that does not act on the mechanisms of ascites formation (Fig. 90.3) and ascites recurrence is the rule. Additionally, the procedure is more costly and requires more resources than the administration of diuretics.

The standard therapy for refractory ascites is LVP + albumin. Although initially the recommendation was to perform daily 5-L paracenteses until the disappearance of ascites, it was subsequently determined that total paracentesis (i.e., removal of all ascites in a single procedure accompanied by the concomitant infusion of 6–8 g albumin per liter of ascites removed) was as safe as repeated partial paracenteses [64].

The frequency of LVP is determined by the rate of ascites reaccumulation and, ultimately, on the need to relieve the

patient's discomfort. The rate of ascites reaccumulation depends largely on the patient's compliance with salt restriction and diuretics and the degree of sodium retention. A randomized controlled study showed that the administration of diuretics after LVP is associated with longer time to recurrence of ascites without any differences in complications [65]. Notably, in this study the urinary sodium of patients in the diuretic group in whom ascites recurred by day 30 was significantly lower at 3 days and 2 weeks (8 and 15 mEq/L, respectively) compared with that of patients in whom ascites had not recurred by day 30 (109 and 67 mEq/L, respectively). This suggests that although sodium restriction and diuretics should be used after LVP, in patients with a urinary sodium less than 30 mEq/L diuretics are not useful and should be discontinued, particularly if associated with complications [52].

Complications of large-volume paracentesis

Procedure-related complications consist mainly of bleeding and ascites leakage. Major *bleeding* occurs rarely but may be lethal [66] and has been related to rupture of mesenteric varices rather than as a result of coagulopathy. In fact, in a series of over 1000 LVPs there was no significant bleeding, not even in patients with marked thrombocytopenia or prolongation in the prothrombin time [67]. Renal dysfunction, more than coagulopathy, appears to be associated with a higher risk of post-LVP hemorrhage [8]. LVP should probably be avoided in patients with renal failure and clinically evident severe coagulopathy. Care should be taken to avoid abdominal wall collaterals and to avoid the area of the inferior hypogastric artery, which lies midway between anterior superior iliac spine and pubic tubercle. Technically, the midline below the umbilicus is often recommended as a site for paracentesis because of its presumed avascularity. However, a laparoscopic study in 20 patients with cirrhosis demonstrated that, in patients with portal hypertension, this area is commonly vascular [68].

Leakage of ascitic fluid is rare and occurs when extraction of ascites is incomplete. Therefore, this complication can be resolved by completing the LVP preferably in a site remote from the leaking puncture site. Another complication of paracentesis that is rare but should be recognized is the development of sudden *scrotal edema* that results from subcutaneous tracking of peritoneal fluid into the scrotum. This can be resolved by elevation of the scrotum [69].

One of the main complications of LVP is the development of *postparacentesis circulatory dysfunction* (PCD), defined as a significant increase in plasma renin activity (PRA) 6 days after LVP. Development of PCD is associated with a faster recurrence of ascites, development of renal dysfunction, and a higher mortality [70,71]. Two factors are independent predictors of the development of PCD: the amount of ascites removed and the type of volume expander used in association with LVP [70]; the lowest rates are observed when less than 5 L is removed or when albumin is used as a plasma volume expander (rate around 16%) [70,72–74]. The presence (or absence) of peripheral edema is not a predictor of the development of PCD. Albumin should be administered at a dose of 6–8 g of albumin i.v. per liter of ascites removed. For LVP less than 5 L, a synthetic plasma expander (Haemaccel, Dextran-70) or even saline solution can be used instead of albumin, and it has been suggested that no plasma expansion may be necessary in this setting [52,70,74]. The pathogenesis of PCD appears to be a worsening of the vasodilatory state of the cirrhotic patient with a consequent further decrease in effective arterial blood volume and marked activation of neurohumoral systems that lead to further sodium retention, renal vasoconstriction, renal dysfunction, and death [71]. Therefore LVP should not be performed in the setting of conditions that have been associated with a worsening in the vasodilatory state of cirrhosis, such as SBP.

Regarding the possibility of infection in outpatients undergoing serial LVP, three studies have shown that SBP is not a significant complication in this setting [75–77].

Transjugular intrahepatic portosystemic shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is a nonsurgical, percutaneous procedure performed by an interventional radiologist by which a portosystemic shunt is established inside the liver parenchyma by connecting, through a metal stent, a main portal branch with a large hepatic vein. By acting as a side-to-side portocaval shunt, it relieves sinusoidal pressure, the main driving force in the formation of ascites. Although TIPS placement is associated early on with a worsening in systemic hemodynamics (increase in cardiac output, further decrease in systemic vascular resistance) and a worsening of liver synthetic function, these changes are no longer present 3 months after TIPS insertion [78]. Additionally, despite deterioration of the hyperdynamic circulatory state and of liver synthetic function, urinary sodium excretion increases significantly as soon as 7 days after TIPS placement and correlates closely with a decrease in plasma renin activity (PRA) and aldosterone levels [78–84]. In addition to sinusoidal decompression, TIPS placement has the advantage of, at least transiently, increasing the effective arterial blood volume by transferring blood volume from the splanchnic to the systemic circulation.

Five prospective randomized trials have compared TIPS (using uncovered stents) with LVP in the treatment of refractory ascites [81,85–88]. Metaanalysis of these trials demonstrates that an uncovered TIPS stent is more effective at preventing ascites from recurring; however, it is associated with an increased occurrence of hepatic encephalopathy without differences in survival [89]. However, when the trial that included Child C patients [81] is excluded, metaanalysis showed a tendency for an improved survival with TIPS [89]. In these trials, the rate of post-TIPS shunt morbidity was an important issue that increased its cost [86]. However, new polytetra-fluoroethylene (PTFE)-covered stents are associated

with improved TIPS patency, and a decrease in the number of clinical relapses and reinterventions, without increasing the risk of encephalopathy [90]. In fact, a case–control study suggested that patients undergoing TIPS with covered stents have higher 2-year survival rates when compared with patients with uncovered TIPS [91]. This benefit needs to be prospectively evaluated in patients with refractory ascites. Until then, the consensus recommendation is to consider TIPS placement when the frequency of LVP is greater than two to three times per month [52].

Complications of transjugular intrahepatic portosystemic shunt

The procedure-related complication rate is around 9%, with the most common being intraperitoneal hemorrhage [92]. Other important complications are heart failure and hemolysis, which may develop in 10%–15% of patients. As mentioned above, long-term complications of TIPS are new onset or worsening of hepatic encephalopathy and shunt dysfunction. Each occurs in about one-third of the patients, with a mean follow-up of about 1 year [78]; the incidence for both complications appears to be lower with covered TIPS stents. Resolution of ascites post-TIPS has been associated with the development of abdominal wall hernia incarceration [93].

Contraindications to transjugular intrahepatic portosystemic shunt

TIPS can precipitate death secondary to liver failure. The strongest predictor of survival post-TIPS placement for patients with refractory ascites is the serum bilirubin concentration [78,89], and a cutoff level of 3 mg/dL has been proposed [94]. Consensus recommendations also suggest that an age greater than 70 years, preexisting cardiac dysfunction, and a Child–Turcotte–Pugh (CTP) score greater than 11 should be considered contraindications to TIPS placement in the setting of refractory ascites [52]. Serum bilirubin may be the decisive factor in reaching the CTP cutoff score of 11 because patients with refractory ascites have, by definition, the highest score for ascites (i.e., tense ascites) and most have the highest score for albumin [78]. TIPS is not recommended in patients with heart failure (ejection fraction < 55%), firstly because with high right-sided pressures there may not be an adequate pressure gradient between the portal and the systemic venous systems for TIPS to function, and secondly because TIPS placement in this setting may precipitate exacerbation of heart failure. Patients with alcoholic cirrhosis who are drinking alcohol may improve with alcohol abstinence and therefore TIPS should be delayed in these patients.

Peritoneovenous shunt

The peritoneovenous (PVS) shunt is a therapy that combines removal of intraperitoneal fluid and replenishment of the intravascular volume. It consists of a silicone tube system and a one-way valve that transfers ascites from the peritoneal cavity to the internal jugular vein (i.e., the systemic circulation). The increase in fluid return to the cardiopulmonary circulation can lead sequentially to decreased activity of sodium-retaining and vasoconstrictive mechanisms (such as the renin–angiotensin–aldosterone system), a marked rise in urinary sodium excretion, and a modest elevation in glomerular filtration rate.

In randomized controlled trials of refractory ascites PVS has been shown to be more effective than diuretics [95] (a predictable result) and as effective as LVP + albumin [96,97]. In these studies, no differences in survival have been observed among therapies. However, as a result of its high obstruction rate, PVS requires frequent admissions for shunt revision or for the management of other more serious complications. The use of PVS has been progressively abandoned over the years because LVP + albumin is a simpler procedure that can be performed in the outpatient setting and because of the advent of TIPS. In a small randomized trial comparing PVS with uncovered TIPS, control of ascites was achieved sooner after PVS, but longer-term (3-year) efficacy favored TIPS, with numerous interventions required to assist patency with both shunts. This study suggests that PVS is a reasonable option for a short (< 1-year) period, particularly because the mean patency of the shunt is around 6 months [95,96]. In fact, a case series of 36 patients listed for liver transplantation who had PVS placed for refractory ascites and who were followed for a mean of 9 months, reported adequate palliation (i.e., no need for further LVP until transplant) in 83% with a lower occurrence of renal failure (compared with historical controls) [98]. Although PVS might complicate liver transplant surgery given its ability to produce peritoneal adhesions, none of the 16 patients who were transplanted in this series had intraoperative complications secondary to PVS [98].

Traditionally, placement of PVS has been performed by surgeons under general anaesthesia and employing venous cutdown. But there is increasing experience of these shunts being placed by radiologists in the interventional suite, with successful revision in case of dysfunction in the majority of patients [99].

Therefore, placement of PVS should clearly be considered in patients who are not TIPS candidates, and it can also be considered (based on local surgeon preference) for patients on the transplant list.

Complications of peritoneovenous shunt

The major problem with PVS is the relatively high rate of complications, although in randomized controlled trials PVS has a similar rate of complications as LVP + albumin [96,97]. The complications related to PVS include disseminated intravascular coagulation (due to introduction of endotoxins and other procoagulants from ascites into the systemic circulation), infection of the shunt (which can can lead to bacteremia and requires shunt removal), variceal bleeding or heart

failure resulting from volume expansion and a concurrent rise in systemic and portal venous pressure, and small bowel obstruction from peritoneal adherences [100]. The transoperative drainage of ascites can minimize the complications related to massive ascites infusion, such as disseminated intravascular coagulation and increased systemic and portal pressures [101].

Therapies under investigation for the treatment of ascites

Sympathetic system antagonists

Clonidine is a centrally acting α_2-agonist with antiadrenergic activity in cirrhosis. In a small randomized pilot study, the administration of clonidine, at a dose of 0.075 mg orally (p.o.) twice a day, plus spironolactone to patients with refractory ascites increased natriuresis and significantly decreased plasma norepinephrine (noradrenaline) and aldosterone levels and plasma renin activity. In a mean follow-up of 10.5 months and compared with patients who were treated with LVP + albumin ($n = 10$), patients who received clonidine plus spironolactone ($n = 10$) had fewer readmissions for ascites, a longer time to ascites reaccumulation, and decreased spironolactone requirements [102].

A single-center randomized double-blind placebo-controlled trial from the same group of investigators evaluated the efficacy of clonidine in patients with uncomplicated ascites and an activated sympathetic nervous system (as defined by serum norepinephrine levels > 300 pg/mL). Patients randomized to clonidine ($n = 32$) had a significantly lower number of readmissions for ascites and a longer time to readmission, and lower requirements for LVP, spironolactone, and furosemide compared with patients randomized to placebo ($n = 32$), with a lower rate of hyperkalemia and renal impairment [103]. These promising results require further investigation before clonidine can be widely recommended.

V_2 receptor antagonists

Selective inhibition of arginine vasopressin type 2 receptors (V_2) was considered important only in the treatment of dilutional hyponatremia in cirrhosis. However, data from experimental animals show that V_2 receptor antagonists also have a natriuretic effect [104–106]. In fact, a phase II study of satavaptan, a V_2 receptor antagonist, in 148 patients with cirrhosis and ascites without hyponatremia demonstrated a dose-related increase in urine volume and a dose-related decrease in body weight without changes in serum creatinine [107]. Furthermore, in a randomized double-blind placebo-controlled study in 151 patients treated with LVP plus spironolactone, satavaptan was associated with a longer time to recurrence of ascites requiring LVP and a significantly lower number of paracenteses [108].

Therefore, V_2 receptor antagonists could be useful adjuvants to diuretics in the treatment of ascites (refractory or nonrefractory ascites) by preventing diuretic-induced hyponatremia and by a synergistic natriuresis. However, further analysis is required.

Vasoconstrictors

Because vasodilation is one of the main mechanisms in the formation of cirrhotic ascites, a rational therapeutic approach is the use of vasoconstrictors. There is limited experience with these agents. A pilot study shows that a 7-day course of midodrine (at a dose of 10 mg p.o. three times a day) was associated with significant increases in urinary sodium, mean arterial pressure, and creatinine clearance and with significant decreases in plasma renin activity and plasma aldosterone levels [109]. Its effect as an adjuvant to diuretics in the treatment of ascites remains to be determined.

Two small randomized studies have compared terlipressin with albumin in the prevention of postparacentesis circulatory dysfunction [110,111]. Both studies showed that the postparacentesis circulatory dysfunction (i.e., plasma renin activity before and 4–6 days after LVP) did not differ between the study groups; however, given the small numbers of patients included in these studies, results are not conclusive.

Cirrhosis and uncomplicated ascites

The approach to the patient with cirrhosis and uncomplicated ascites is depicted in Fig. 90.4.

In contrast to the treatment of heart failure, where achieving a negative sodium and water balance demands a certain urgency given the risk/presence of pulmonary edema, therapy of cirrhotic ascites is not an emergency because the risk of death is not implicit unless the fluid is infected. Therefore, most patients with uncomplicated ascites should treated in a stepwise, unhurried fashion, and treatment should only be initiated in a "stable" cirrhotic patient, that is, one in whom complications such as gastrointestinal hemorrhage, bacterial infection, or renal dysfunction are absent or have resolved. One exception is the patient with tense ascites who experiences not only abdominal discomfort but also respiratory distress. In these patients, a single large-volume paracentesis should be performed prior to or concomitant with starting diuretic therapy.

Because renal dysfunction secondary to diuretics results from a reduction in effective arterial blood volume, diuretics should not be initiated in patients with concomitant complications of cirrhosis known to be associated with a decreased effective arterial blood volume, such as variceal hemorrhage and SBP.

Treatment aimed at achieving a negative sodium balance (i.e., sodium restriction and diuretics) still constitutes the mainstay of therapy in patients with uncomplicated ascites, given its general applicability, low cost, and ease of administration. However, in hospitalized patients with moderate/tense ascites in whom other complications have been resolved,

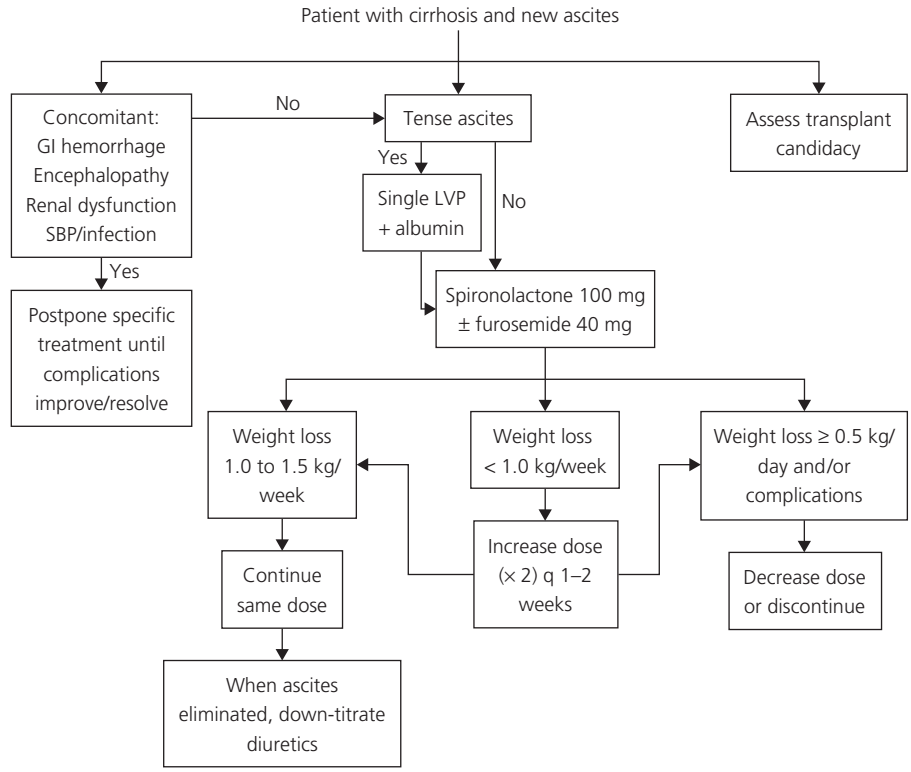

Figure 90.4 Approach to the patient with cirrhosis and uncomplicated ascites. GI, gastrointestinal; LVP, large-volume paracentesis; SBP, spontaneous peritonitis.

it is reasonable to initiate therapy with total paracentesis as this will accelerate discharge from the hospital.

Diuretic therapy can be initiated with spironolactone alone (initial dose of 100 mg p.o. daily) or with spironolactone (100 mg p.o. daily) plus furosemide (40 mg p.o. daily). Both schedules are equally effective; however, dose adjustments are needed more frequently in patients in whom treatment is initiated with combination therapy because of a more rapid mobilization of fluid with consequent increases in blood urea nitrogen or decreases in serum sodium [54,112]. In an inpatient setting, where renal function can be monitored more frequently, combination therapy can be used. However, in the outpatient setting it is preferable to initiate therapy with spironolactone alone at a daily dose of 100 mg p.o. Because spironolactone takes several days to act it should be administered in a single daily dose. If weight loss is not optimal (weight loss < 1 kg in the first week and < 2 kg/week in subsequent weeks) the dose should be increased in a stepwise manner with increases of 100 mg every 1–2 weeks to a maximum of 400 mg p.o., q.i.d [52]). If hyperkalemia develops before the maximal dose is reached, furosemide should be added at an initial single daily dose of 40 mg, increased in a stepwise fashion in increments of 40 mg to a maximum of 160 mg/day.

Before considering that ascites is refractory to diuretics, it is necessary to ascertain whether the patient has adhered to the prescribed sodium-restricted diet and has restrained from using nonsteroidal antiinflammatory drugs. Nonadherence to dietary sodium restriction or diuretics should be suspected if patients fail to lose weight despite an adequate 24-h urine sodium excretion (> 50 mEq/L or greater than daily sodium intake). In a patient in whom ascites disappears, one can attempt to downtitrate the dose of diuretics and maintain it at the minimal effective dose so that complications can be minimized.

In patients who develop renal dysfunction (elevation in creatinine > 50% to a creatinine > 1.5 mg/dL) or encephalopathy, diuretics should be temporarily discontinued and restarted at a lower dose when creatinine returns to baseline. Patients who develop hyponatremia (serum sodium < 130 mEq/L) while on diuretics should be managed with fluid restriction and a decrease in the dose of diuretics. The role of V_2 receptor antagonists in this setting is promising [106,113]. To minimize the rate of complications, patients without edema should not lose more than 0.5 kg/day, whereas in patients with edema a weight loss of 1 kg/day is allowable.

There are insufficient data to support the use of long-term antibiotic prophylaxis to prevent SBP and other bacterial infections in patients with uncomplicated ascites who are not hospitalized with gastrointestinal hemorrhage or who have not had a previous episode of SBP, even in those with an ascites protein concentration < 1 g/dL [27]. Limiting the use of prophylactic antibiotics is important given the increased rate of infections with quinolone-resistant and trimethoprim–sulfamethoxazole (cotrimoxazole)-resistant

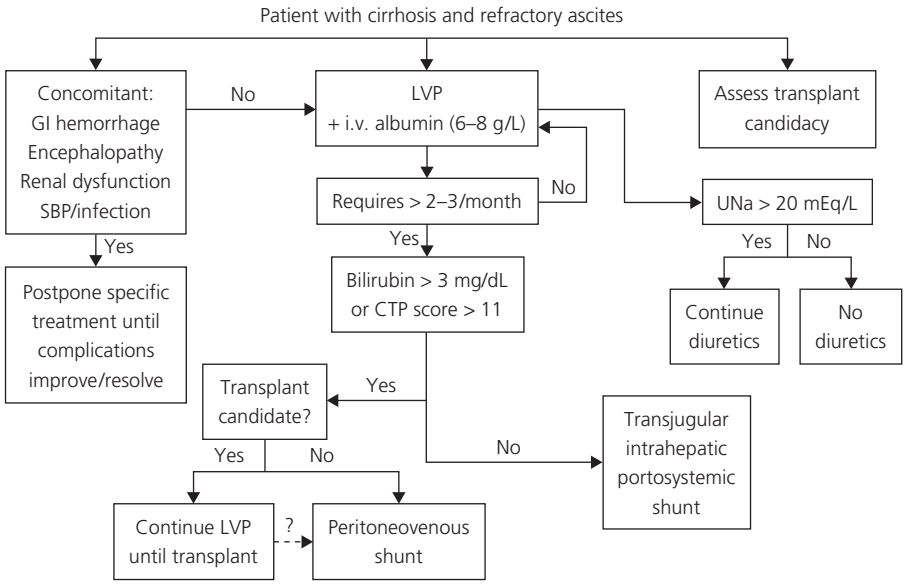

Figure 90.5 Approach to the patient with cirrhosis and refractory ascites. CTP, Child–Turcotte–Pugh; GI, gastrointestinal; i.v., intravenous; LVP, large-volume paracentesis; SBP, spontaneous bacterial peritonitis; UNa, urine sodium concentration.

organisms observed in patients on long-term norfloxacin prophylaxis [114,115].

Cirrhosis and refractory ascites

The approach to the patient with cirrhosis and refractory ascites is depicted in Fig. 90.5.

Refractory ascites assumes either diuretic-resistant ascites (ascites that is not eliminated even with maximal diuretic therapy) or diuretic-intractable ascites (ascites that is not eliminated because maximal doses of diuretics cannot be reached given the development of complications) [116]. The majority of patients with refractory ascites have the diuretic-intractable type [51]. Vasodilation is more pronounced in patients with refractory ascites (Fig. 90.2), thereby leading to a further decrease in effective arterial blood volume and further activation of the renin–angiotensin–aldosterone and sympathetic nervous systems. Further alteration in hemodynamics results in a greater susceptibility to develop hyponatremia or renal dysfunction in these patients. In fact, hepatorenal syndrome (HRS) type 2, in which renal dysfunction is characterized by a moderate and steady or slowly progressive renal failure (serum creatinine < 2.5 mg/dL), is almost exclusively seen in patients with refractory ascites [116]. Patients with type 2 HRS are predisposed to develop type 1 HRS following infections or other precipitating events.

The median survival of patients with type 2 HRS (4–6 months) is worse than that of patients with nonazotemic cirrhosis with ascites [117]. Therefore, a patient with refractory ascites who has not yet been evaluated for liver transplant candidacy should be evaluated without delay.

First-line therapy for patients with refractory ascites is serial LVP, adding albumin if more than 5 L is removed at once. In patients in whom 5 L or less is being removed, a plasma volume expander can be used. To increase the time between paracenteses, patients should continue on maximally tolerated diuretic dose provided that the urinary sodium is greater than 30 mEq/L. Otherwise, diuretics can be discontinued [52].

Routine cell count and culture analysis are not warranted in asymptomatic cirrhotic patients undergoing outpatient paracenteses for refractory ascites because studies have shown a low prevalence (0%–3.5%) of SBP in this setting [75–77]. Data from a randomized double-blind placebo-controlled trial suggest, however, that in patients with a low concentration of ascites protein (< 1 g/dL) who also have evidence of deranged circulatory status (creatinine > 1.2 mg/dL or blood urea nitrogen (BUN) > 25 mg/dL or a serum sodium ≤ 130 mEq/L) or severe liver disease (CTP score ≥ 9 and a serum bilirubin concentration ≥ 3 mg/dL) primary prophylaxis with norfloxacin at a daily dose of 400 mg p.o. is associated with a significantly lower incidence of first SBP and a reduced 3-month mortality [118]. These criteria will probably be met by most patients with refractory ascites.

In patients who require LVP more than two to three times per month or in whom ascites is loculated and cannot be entirely removed with a single LVP, evaluation for TIPS placement should be undertaken. In general, TIPS should not be performed in patients with serum bilirubin greater than 3 mg/dL, a CTP score greater than 11, age over 70 years, or evidence of heart failure [52,78] because these factors are associated with a poorer survival and a poorer shunt function. Although studies of TIPS for refractory ascites were performed using uncovered stents, covered stents should be used because of the lower rate of shunt dysfunction and potential benefits regarding development of encephalopathy and survival [90].

Although the goal of TIPS is to reduce the portosystemic pressure gradient to less than 12 mmHg (the threshold for the formation of ascites), too low a reduction (e.g., to levels

< 5 mmHg) carries a higher risk of post-TIPS portosystemic encephalopathy [119] and should therefore be avoided.

Most cases of post-TIPS encephalopathy respond to standard therapy, and only about 3%–10% develop recurrent, severe encephalopathy that can be treated with stent reduction [120], with preliminary evidence suggesting that covered reduction stents are better than uncovered reduction stents [121]. In a randomized controlled trial, prophylactic therapy with lactitol or rifaximin for 1 month after TIPS placement was ineffective in preventing portosystemic encephalopathy [119], and prophylaxis is therefore not recommended.

Because TIPS placement improves but does not normalize sodium excretion [82], peripheral edema may continue to be a problem and the use of diuretics after the procedure is advisable. Diuretic therapy immediately after the procedure also has the theoretical advantage of improving the pressure gradient across the shunt by reducing central pressure more than portal pressure.

Serial assessment of shunt patency is not necessary after TIPS unless there is recurrence of ascites, a clinically obvious event indicative of stent dysfunction.

In patients requiring frequent LVP and who are not TIPS candidates, a peritoneovenous shunt (PVS) should be considered. Placement of a PVS may hinder future placement of TIPS. The intraabdominal limb of the PVS is associated with the formation of peritoneal adhesions and may complicate transplant surgery; therefore it has also been considered a contraindication in patients who are candidates for transplant. However, a case series of pretransplant patients showed that PVS is not associated with surgical complications [98].

Cirrhosis and hepatic hydrothorax

Pleural effusion (hepatic hydrothorax) develops in approximately 5%–10% of patients with cirrhosis, most probably as the result of the transdiaphragmatic movement of fluid from the peritoneum to the pleural space through diaphragmatic defects [122,123]. The negative intrathoracic pressure favors the movement of fluid across these defects, and patients usually have minimal or mild ascites. In fact, hepatic hydrothorax may be present in patients without detectable ascites [124]. Pleural effusion is right-sided in 85%, left-sided in 13%, and bilateral in 2% of the cases [125].

Although large amounts of ascites can accumulate in the peritoneal cavity before resulting in significant patient discomfort, the accumulation of smaller amounts of fluid (1–2 L) in the pleural space results in severe shortness of breath and hypoxemia. A diagnostic radionuclide ascites scan is useful in the diagnosis of hepatic hydrothorax, particularly in cases where ascites is absent [126]. It consists of the injection of technetium-99m-labeled sulfur colloid [127] or macroaggregated serum albumin [126] into the peritoneal cavity followed by chest imaging every 15–30 min. Transdiaphragmatic movement of ascites into the pleural space is demonstrated generally within 2 h of intraperitoneal injection of the radiotracer.

Hepatic hydrothorax should be treated in the same manner as cirrhotic ascites, that is, the mainstay of therapy is sodium restriction and diuretics. Before determining that hydrothorax is refractory, a trial of in-hospital diuretic therapy should be attempted. In patients with refractory hepatic hydrothorax other therapeutic options such as repeated thoracenteses, TIPS, or pleurodesis should be considered. Regarding thoracentesis, and given that no more than 2 L is removed at a time because of the risk of reexpansion pulmonary edema, the procedure may need to be repeated frequently. When thoracentesis is required every 2–3 weeks, alternative strategies such as TIPS should be considered. Uncontrolled studies of TIPS have shown resolution of the pleural effusion or a decrease in the need for thoracentesis in 67% of patients; however, mortality is high, particularly in nonresponders to TIPS [128]. In patients who have not responded to TIPS, an option is video-assisted thoracoscopy to repair diaphragmatic defects and to perform pleurodesis. However, information is available on only a small number of patients, and the procedure is associated with significant morbidity and mortality [123]. Placement of a chest tube should be avoided in patients with hepatic hydrothorax because it has been associated with multiple complications, mainly volume and electrolyte disturbances.

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) is the most common type of bacterial infection in hospitalized cirrhotic patients, occurring in about 9% of the patients and accounting for about 25% of all infections [115].

SBP is an infection of ascitic fluid that occurs in the absence of perforation of a hollow viscus or of an intraabdominal inflammatory focus, such as an abscess, acute pancreatitis, or cholecystitis.

Bacterial translocation – the migration of bacteria from the intestinal lumen to mesenteric lymph nodes and other extraintestinal sites – is the main mechanism implicated in the pathogenesis of SBP. Impaired local and systemic immune defenses and intestinal bacterial overgrowth promote bacterial translocation and, together with shunting of blood away from the hepatic Kupffer cells through portosystemic collaterals, allow a transient bacteremia to become more prolonged, subsequently colonizing ascitic fluid. Bacterial translocation and the development of SBP in cirrhosis worsen the hyperdynamic circulatory state by a cytokine-mediated aggravation of vasodilation [129–131]. By worsening vasodilation,

SBP can lead to renal dysfunction and the hepatorenal syndrome [132].

SBP occurs in patients with reduced ascites defense mechanisms, such as low ascites complement levels. Because ascites complement levels correlate with ascites protein levels, it follows that the most important predictor in the development of SBP is a low concentration of ascites protein (< 1 g/dL) [17,133].

When first described, the mortality of SBP exceeded 90%; however, with early recognition of the disease and prompt and appropriate antibiotic therapy, mortality has been reduced to around 20%–30% [134], a much lower but still significant mortality.

The approach to the patient with cirrhosis and SBP is depicted in Fig. 90.6. Early recognition of SBP involves the performance of a diagnostic paracentesis (for total and differential cell counts and bacteriological culture) in any patient in whom SBP is suspected. Suspicion of SBP should be raised in patients with symptoms or signs directly due to SBP, such as fever, abdominal pain or tenderness, and leukocytosis, but should also be raised in the presence of unexplained encephalopathy, jaundice, or worsening renal failure – complications of sepsis. Simultaneous blood and urine cultures and a chest radiograph should also be obtained because any bacterial infection in cirrhosis can lead to similar manifestations. In patients with hepatic hydrothorax in whom an infection is suspected and SBP has been ruled out, a diagnostic thoracentesis should be performed to rule out spontaneous bacterial empyema, an entity akin to SBP that may occur in the absence of ascites or SBP and that should be managed as described below for SBP [135].

Isolation of an infecting organism is definitive in establishing the diagnosis of SBP. The most common organisms isolated in SBP are gram-negative bacteria, and the infections are mostly monomicrobial [31,115]. However, despite the use of sensitive culture methods that include inoculation of ascites into blood culture bottles, ascites cultures are negative in up to 60% of patients with clinical manifestations compatible with SBP and increased ascites PMN counts [115].

Therefore, the diagnosis of SBP is established with an ascites PMN count greater than 250/mm^3, and treatment should be initiated before obtaining bacteriological culture results [25]. If the PMN count is below 250/mm^3, culture results must be awaited. If ascites culture is positive (bacterascites), the ascites cell count should be repeated and, if the repeat PMN count is greater than 250/mm^3, SBP has developed and should be treated. However, if the PMN count remains below 250/mm^3, the results of a second bacteriological culture should be awaited. In most cases, the repeat culture will be negative but if it continues to be positive for the same organism it is assumed that bacteria are being seeded into ascites from an extraabdominal source and, although it is not causing peritonitis, bacterascites should then be treated [25].

The most effective (~ 90% resolution rate) and safe antibiotics are intravenous cefotaxime (2 g i.v. every 12 h) or other third-generation cephalosporins, such as ceftriaxone (1–2 g i.v. every 24 h) or ceftazidime (1 g i.v. every 12–24 h) [136–139]. The combination of amoxicillin/clavulanic acid (1 g/0.2 g i.v. every 8 h) has been shown to be as effective and safe as cefotaxime in the treatment of SBP [140]. Patients who develop SBP on prophylactic quinolones have been shown to

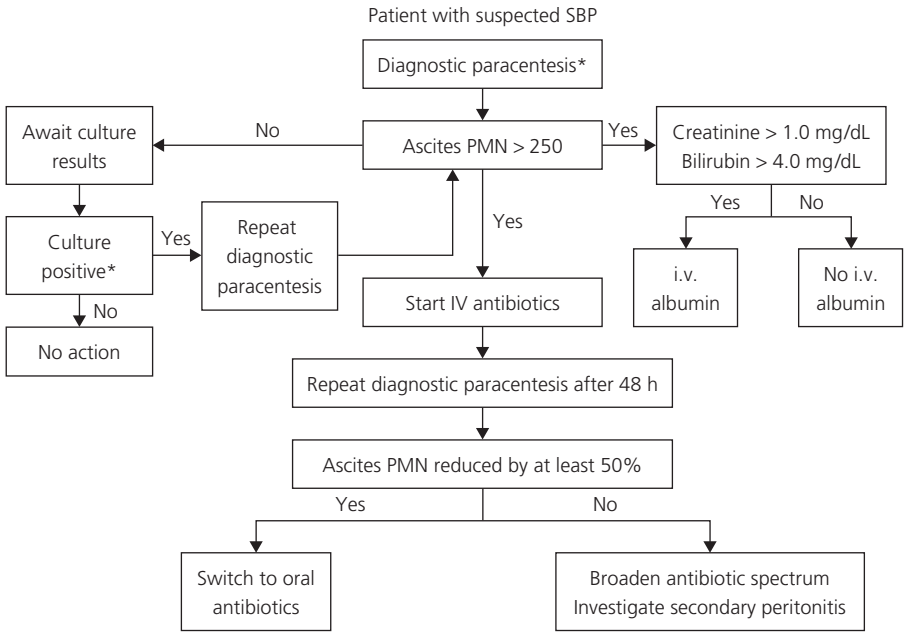

Figure 90.6 Approach to the patient with suspected spontaneous bacterial peritonitis (SBP). *A diagnostic paracentesis should be performed in any patient with symptoms or signs suggestive of SBP, any patient with unexplained renal dysfunction or encephalopathy, and in any hospitalized patient with cirrhosis and ascites. i.v., intravenous; PMN, polymorphonuclear leukocytes.

respond as well to cefotaxime as patients not on prophylaxis [141]. The antibiotics recommended above have been associated with few side effects and no renal toxicity. By contrast, aminoglycosides should be avoided in patients with cirrhosis because of their increased propensity to develop aminoglycoside-induced nephrotoxicity [142,143].

Renal dysfunction is the main cause of death in SBP and both can be prevented by the use of intravenous albumin [144]. Because renal dysfunction and death in SBP occur almost exclusively in patients with a baseline concentration of serum bilirubin greater than 4 mg/dL and a serum creatinine level exceeding 1 mg/dL [144,145], the prophylactic use of albumin in SBP can probably be restricted to this subgroup of high-risk patients [146]. The dose of albumin used is arbitrary: 1.5 g/kg of body weight during the first 6 h, followed by 1 g/kg on day 3, with a maximum of 100 g/day. There is a subgroup of patients with SBP – those with community-acquired infection, no encephalopathy, and normal renal function – that have a 100% cure rate and 100% survival with antibiotic therapy alone [147]. Albumin would not be indicated in these patients [146].

A control paracentesis performed 48 h after starting therapy is recommended to assess the response to therapy and the need to modify antibiotic therapy (depending on the isolation of a causative organism) or to initiate investigations to rule out secondary peritonitis [25]. If clinical improvement is obvious, this control paracentesis may not be necessary. Failure of initial therapy, defined as a decrease in PMN of less than 25% from baseline, occurs in up to 23% of the cases and is associated with a poor prognosis. In the presence of either clinical or cytological improvement, intravenous antibiotics can be switched to oral antibiotics after 2 days of therapy. This strategy has been shown to be as effective as continuous intravenous antibiotic therapy in two trials that used ciprofloxacin (first intravenous and then oral) [148,149]. Although a growing number of infections involving quinolone-resistant organisms may limit the use of quinolones as first-line antibiotic therapy in SBP [115], switching from intravenous cephalosporins to oral quinolones is a common practice recommended in complicated urinary tract infection in adults [150].

Total duration of antibiotic therapy should be for a minimum of 5 days. However, in prospective trials in which ascites PMN counts were carefully monitored, the median time to SBP resolution (i.e., a decrease in PMN count below 250/mm^3) was 8 days and therefore this duration of therapy is probably more recommendable [151].

In patients who survive an episode of SBP, the one-year cumulative SBP recurrence rate is high, at about 70%. Recurrence, particularly secondary to gram-negative organisms, is significantly and markedly lower with the use of norfloxacin at a dose of 400 mg p.o. per day [152,153]. It is therefore essential that patients surviving an episode of SBP are started on antibiotic prophylaxis to prevent recurrence. The use of weekly quinolones is not recommended because it has been shown to be less effective in preventing SBP recurrence and is associated with a higher rate of development of quinolone-resistant organisms [153]. Prophylaxis should be continuous until disappearance of ascites (i.e., patients with alcoholic hepatitis), death, or transplant.

Cirrhosis and acute renal failure

Acute renal failure occurs in 14%–25% of hospitalized patients with cirrhosis [143,154,155]. There are three types of acute renal failure: prerenal failure, which results from renal hypoperfusion without a glomerular or tubular lesion; intrinsic renal failure, which results from tubular necrosis (ischemic or toxic), glomerulonephritis, or interstitial nephritis; and post-renal failure, which results from urinary tract obstruction.

In hospitalized patients with cirrhosis, the most common cause of acute renal failure is prerenal (accounting for 60%–80% of the cases) [154,156,157], followed by acute tubular necrosis (20%–40%) [154,156,157], with postrenal causes accounting for less than 1% of the cases [156,157].

Prerenal failure results from any factor that will further decrease the already decreased effective arterial blood volume of the patient with cirrhosis. Therefore prerenal failure can result from factors that cause hypovolemia, such as gastrointestinal hemorrhage, overdiuresis, or diarrhea; factors that worsen vasodilation, such as sepsis, use of vasodilators, and the postparacentesis circulatory dysfunction; and factors that cause renal vasoconstriction, such as nonsteroidal anti-inflammatory drugs or intravenous contrast agents. These factors account for up to 80% of the causes of prerenal failure [154]. The persistence of acute renal failure despite exclusion or reversal of the above-mentioned precipitant factors indicates the presence of type 1 hepatorenal syndrome (HRS), which accounts for only about 20% of cases of acute renal failure in cirrhosis [156]. HRS type 1 is a type of prerenal failure because it results from hemodynamic abnormalities (extreme vasodilation) leading to renal vasoconstriction [49] (Fig. 90.2). The other type of HRS, type 2, although also resulting from vasodilation, is a chronic form of renal failure associated with refractory ascites and is not considered in the differential diagnosis of acute renal failure in cirrhosis.

In patients with cirrhosis, acute tubular necrosis (ATN) is mainly caused by an ischemic insult to the renal tubules, mostly as a result of a hypotensive event, although the use of aminoglycosides (which cause renal failure by direct toxicity to renal tubules) was found to be the most important predictor of renal failure in cirrhosis in a study performed in US veterans [143]. Studies are needed on the natural course, diagnosis, and treatment (e.g., hemodialysis) of acute tubular necrosis in patients with cirrhosis.

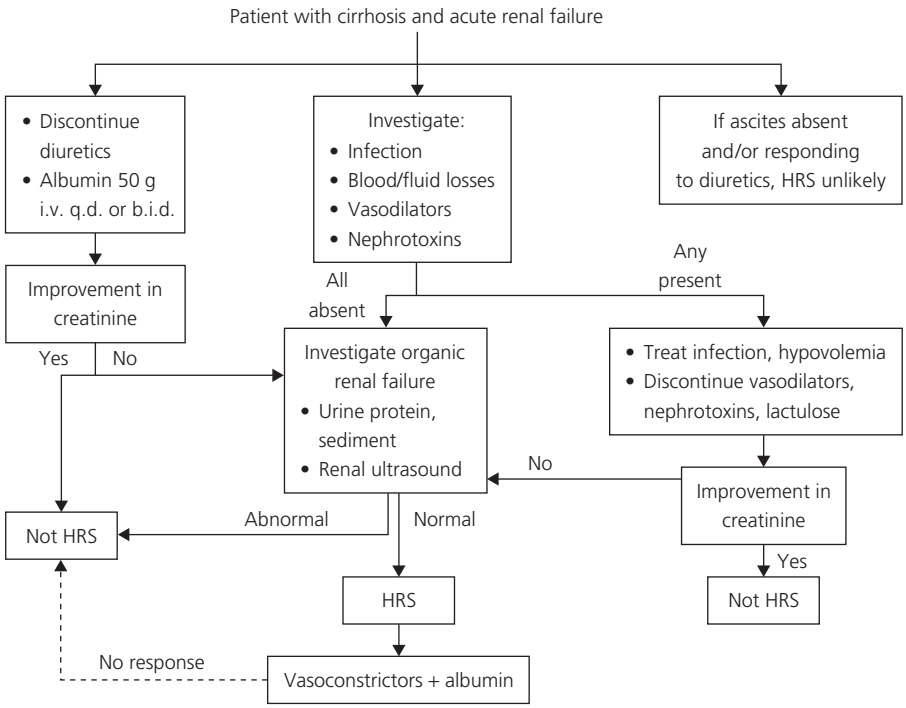

Figure 90.7 Approach to the patient with cirrhosis and acute renal failure. b.i.d., twice a day; HRS, hepatorenal syndrome; i.v., intravenous; q.d., once a day.

The approach to a patient with cirrhosis and acute renal failure is depicted in Fig. 90.7 [132,158].

In a patient with cirrhosis who presents with an acute deterioration in renal function as evidenced by a doubling of serum creatinine to more than 2.5 mg/dL within a 2-week period [116], the main issue is to rule out HRS as this entity involves a totally separate therapeutic approach (see below). Indirect estimates of glomerular filtration rate such as the Modification of Diet in Renal Disease (MDRD) equation have not yet been evaluated in the assessment of renal failure in patients with cirrhosis.

Urine indices (urine osmolality, urinary sodium concentration, and fractional excretion of sodium) may help to distinguish prerenal failure (including HRS) from acute tubular necrosis. The tubular ability to reabsorb sodium and to concentrate urine is preserved in prerenal azotemia and is impaired in acute tubular necrosis. Therefore, patients with prerenal failure have low urinary sodium concentrations (< 20 mEq/L) and elevated urine osmolality (> 500 mOsm/kg) whereas patients with tubular necrosis have high urinary sodium concentrations (> 40 mEq/L) and a urine osmolality below 350 mOsm/kg. However, the urinary sodium concentration may be low early in the course of certain processes that lead to tubular necrosis, such as sepsis, and some cases of HRS with elevated urinary sodium concentrations have been reported [158].

If the patient with acute renal failure does not have ascites, the diagnosis of HRS is highly unlikely, because HRS is the result of maximal derangement in the hemodynamics that lead to ascites formation (Fig. 90.2) [49].

A first step in the diagnostic workup is to discontinue diuretics and to expand the intravascular volume with albumin at a dose of 50 g i.v. This dose can be repeated in 12 h if the creatinine has not normalized. A reduction in creatinine will rule out HRS.

At the same time, investigations to rule out the precipitants of renal dysfunction should be undertaken, specifically diagnostic paracentesis (to rule out SBP), blood and urine bacteriological cultures and chest radiograph to rule out a bacterial infections other than SBP, and stool investigations to rule out gastrointestinal hemorrhage. If any of these precipitants is identified, the patients should be treated accordingly.

Once precipitants of renal dysfunction are excluded or treated and if creatinine does not improve or continues to worsen despite diuretic discontinuation and continued volume expansion the differential diagnosis is between intrinsic renal failure, postrenal failure, or HRS. To rule out intrinsic renal failure, urinary sediment and urine protein should be analyzed. To rule out postrenal failure, a renal ultrasound should be obtained. To ensure that volume has been adequately expanded, it is reasonable to perform central venous pressure measurements at this point.

If ATN or other organic or postobstructive causes of renal failure are ruled out, the patient has HRS type 1. The differentiation between acute tubular necrosis and HRS is the most difficult, and it has been suggested that the response to vasoconstrictors plus albumin (see below) may be used to establish this differential [158].

Hepatorenal syndrome

HRS is a potentially reversible functional renal failure that occurs in patients with cirrhosis, ascites, and liver failure and in patients with acute liver failure and alcoholic hepatitis [132]. HRS is secondary to renal vasoconstriction that results from markedly decreased effective arterial blood volume and the resultant activation of renal vasoconstrictive systems. Decreased effective blood volume is in turn the result of intense vasodilation (Fig. 90.2) and, as postulated, of a relatively low cardiac output [132]. Because HRS represents the extreme of the spectrum of abnormalities that lead to sodium and water retention, ascites unresponsive to diuretics is universal, and dilutional hyponatremia is almost always present (Fig. 90.2).

HRS is divided into two types based on clinical characteristics and prognosis. Type 1 HRS is characterized by rapidly progressive renal failure defined by doubling of the serum creatinine concentrations to a level greater than 2.5 mg/dL in less than 2 weeks. It may appear spontaneously, but often develops after a precipitating event, particularly SBP. Its prognosis is poor, with a median survival of 2–4 weeks [159,160]. Type 2 HRS is a moderate renal failure (serum creatinine 1.5–2.5 mg/dL), with a steady or slowly progressive course, and is associated with refractory ascites. Survival of patients with type 2 HRS is shorter than that of nonazotemic cirrhotic patients with ascites but better than that of patients with type 1 HRS (median survival about 6 months) [132,160]. Type 2 HRS will not be considered in this section.

Patients with ascites have 1- and 5-year probabilities of developing HRS of around 20% and 40% respectively [159]. The likelihood of developing HRS is highest in patients with more marked sodium and water retention and more marked activation of vasoconstrictive systems (renin–angiotensin and sympathetic nervous system) [159], indicative of marked vasodilation (Fig. 90.2). A low cardiac output and high plasma renin activity were found to be independent predictors of HRS in patients with cirrhosis and uncomplicated ascites [161].

As mentioned previously, HRS is diagnosed by exclusion of other known causes of acute renal failure (Fig. 90.8).

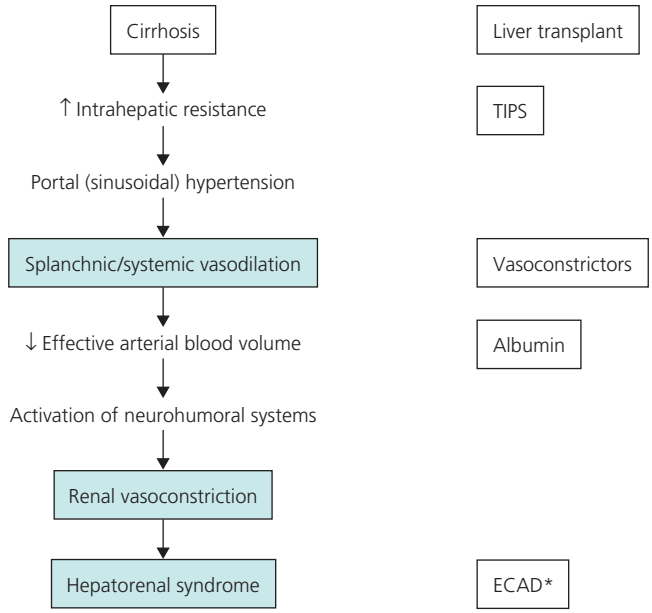

Figure 90.8 Site of action of different therapies for hepatorenal syndrome. *ECAD (extracorporeal albumin dialysis) is an experimental therapy that seems to improve hepatorenal syndrome; it probably acts by decreasing the amount of circulating vasodilators. TIPS, transjugular intrahepatic portosystemic shunt.

Therapies for hepatorenal syndrome

Different therapies for HRS and their site of action are depicted in Fig. 90.8. Except for transplant, none of the different treatments of HRS has resulted in significant improvements in survival. However, treating HRS is important because patients who respond to therapy have a better survival and because the presence of renal disease has an impact on post-liver transplant outcomes [162].

Liver transplant

The first and only definitive therapy for HRS is liver transplantation because it is the only therapy that will provide long-term survival. With the implementation of the Model for End-stage Liver Disease (MELD) score in the allocation of organs in the United States, priority for transplant is given to patients with a high creatinine [163]. In a study aimed at assessing prognostic factors in HRS, MELD score and the type of HRS (type 1 or 2) were independent predictors of death. Whereas all patients with type 1 HRS had a high MELD score (> 20) and had a poor outcome (median survival 1 month), survival of patients with type 2 HRS was longer and depended on their MELD score [160]. This suggests that the development of HRS type 1 per se should indicate a high priority for transplant, independent of MELD.

Patients with HRS who are transplanted have more complications and a higher in-hospital mortality rate than those without HRS [164–167]. Therefore, HRS should be treated before transplantation in an attempt to improve renal function. In fact, the outcome of liver transplantation in patients with HRS treated with vasopressin analogues prior to transplant is similar to that of patients transplanted without HRS [168]. HRS alone should not be a reason for combined kidney and liver transplant; however, this is being considered in patients with HRS who become dialysis-dependent and show no recovery after 8 weeks of dialysis (the usual recovery time for acute renal failure) [162]. The need for dialysis should theoretically be prevented by the early treatment of HRS with the "bridging" therapies outlined below.

Vasoconstrictors plus albumin

The rationale behind this approach is to improve the deranged circulatory function by ameliorating vasodilation thereby improving effective arterial blood volume and decreasing renal vasoconstriction. Albumin, an intravascular volume expander, has been used to increase effective blood volume. However, albumin dialysis (see below) is associated with an increase in blood pressure attributable to the ability of albumin to bind vasodilators. It is therefore conceivable that an improvement of renal function in patients with HRS treated with vasoconstrictors and albumin is the result of the additive effects of both agents in producing peripheral vasoconstriction.

Data about the use of vasoconstrictors in HRS have been mostly derived from uncontrolled studies. The vasopressin analogue ornipressin was the first vasoconstrictor to be used, and although it was found to be effective, its use was abandoned because of a high rate of ischemic side effects [169,170]. Terlipressin, another vasopressin analogue, has been the most widely used vasoconstrictor agent in type 1 HRS and is associated with a low incidence of side effects [156,171–175]. The combination of midodrine plus octreotide has been effective in two small uncontrolled studies [176,177]. It is uncertain whether the effectiveness of this therapy is the result of midodrine alone (an α-adrenergic agonist) or the combination, because octreotide alone has been shown to have no effect in HRS when compared with placebo [178] or with a vasopressin infusion [179]. The combination of intravenous noradrenaline (another α-adrenergic agonist) plus albumin was effective and safe in a small uncontrolled study [180]; however, the need for medication infusion in an intensive care setting limits its applicability.

In most of these studies, albumin was associated with the vasoconstrictor, and one of them showed that treatment with terlipressin and albumin was associated with a significant decrease in the serum creatinine level and an increase in arterial pressure, changes that were not observed in a nonconcurrent group of patients treated with terlipressin alone [181].

In total, 11 uncontrolled studies have been published using vasoconstrictors and including 215 patients with HRS type 1. Reversal of HRS (decrease in creatinine below 1.5 mg/dL) was observed in 64% of the cases and, interestingly, HRS recurred in only a minority (23%) of these patients once therapy was discontinued. One-month survival was 39%, with a better survival in patients who responded to vasoconstrictors [156,179]. Terlipressin may induce ischemic side effects and arrhythmias requiring drug discontinuation.

A small, nonblinded, placebo-controlled study suggested that terlipressin (compared with placebo) was associated with an improvement in HRS (5/12 vs 0/12) and in survival (5/12 vs 0/12) [182]. However, a large multicenter, randomized, placebo-controlled double-blind trial of terlipressin vs placebo in the treatment of type 1 HRS showed that, although reversal of HRS was significantly better in patients in the terlipressin group (19/56, or 34%, in the terlipressin group vs 7/56, or 13%, in the placebo group), survival was identical in both treatment groups (27/56, or 48%, survival at 60 days for both groups) and, notably, HRS reversal rate (34%) was much lower than that demonstrated in uncontrolled studies [183]. The study also confirms that survival is significantly better in patients who responded to terlipressin.

Transjugular intrahepatic portosystemic shunt

Only three small prospective but uncontrolled studies have assessed the role of TIPS in HRS type 1, using 6, 14, and 5 patients (who had responded to octreotide/midodrine), respectively [177,184,185]. All studies showed a decrease in serum creatinine in most patients and a decrease in plasma renin activity. The rate of decrease in creatinine in most patients was slower than that obtained using terlipressin plus albumin. Recurrence of HRS was rare as long as the shunt remained patent but portosystemic encephalopathy was a frequent complication. Post-TIPS resolution of HRS type 1 appeared to improve survival. Long-term success was demonstrated in the study that explored sequential treatment with vasoconstrictors and albumin followed by TIPS [177]. Notably, a great majority of patients included in these three studies had alcoholic cirrhosis, many with active alcoholism, and therefore the improvement observed could have resulted from improvement in an acute-on-chronic process. Also, all three studies excluded patients with a CTP score equal to or greater than 12.

Given the paucity of data, TIPS could be used as a treatment of type 1 HRS only in the setting of prospective randomized trials.

Extracorporeal albumin dialysis

In a small, randomized study, the molecular adsorbent recirculating system, a modified dialysis method using an albumin-containing dialysate (eventually combined with intermittent venovenous hemofiltration), was shown to improve 30-day survival in eight patients with HRS type 1 compared with five patients treated with intermittent venovenous hemofiltration alone [186]. Because extracorporeal albumin dialysis (ECAD) incorporates a standard dialysis machine or a continuous venovenous hemofiltration monitor and glomerular filtration rate was not measured, the decrease in serum creatinine observed in most patients could be related to the dialysis process. However, clear beneficial effects on systemic hemodynamics and on hepatic encephalopathy were observed. ECAD is still considered an experimental therapy and its use in patients with type 1 HRS cannot be recommended outside prospective pathophysiological or therapeutic investigations.

Suspected hepatorenal syndrome

Patients with suspected type 1 HRS should be managed as inpatients for diagnostic investigation and treatment. Vital

signs, urine output, and blood chemistry should be closely monitored. Diuretics should continue to be withheld in these patients to prevent further decreases in effective arterial blood volume. Saline solution should not be administered as it will lead to significant increases in ascites and edema because sodium retention is severe in these patients. Because most patients have dilutional hyponatraemia, fluids (both oral and intravenous) should be restricted to approximately 1000 mL/day. Early identification of bacterial infections and treatment with broad-spectrum antibiotics is fundamental, because severe infections are common and contribute to death in these patients. The patient should be evaluated for liver transplantation and, if already on a transplant list, his or her status should be updated.

Specific treatment with vasoconstrictors plus albumin should be initiated as soon as the diagnosis is suspected. The best evidence supports the use of terlipressin, which should be started at a dose 0.5–1 mg i.v. every 4–6 h. If there is no early response (> 25% decrease in creatinine levels after 2 days), the dose can be doubled every 2 days up to a maximum of 12 mg/day (i.e., 2 mg i.v. every 4 h). Treatment can be stopped if serum creatinine does not decrease by at least 50% after 7 days at the highest dose, or if there is no reduction in creatinine after the first 3 days. In patients with early response, treatment should be extended until reversal of HRS (decrease in creatinine below 1.5 mg/dL) or for a maximum of 14 days [132].

A more rational method for adjusting the dose of vasoconstrictors is by monitoring mean arterial blood pressure (an indirect indicator of vasodilation). This method has been used for adjusting the dose of midodrine plus octreotide [176], an alternative to terlipressin in places such as the United States where terlipressin is not available. In this study, the doses of octreotide and midodrine were titrated to obtain an increase in mean arterial pressure of at least 15 mmHg; midodrine was administered orally at an initial dose of 7.5 mg t.i.d and, if necessary, increased to 12.5 mg t.i.d; octreotide was administered subcutaneously at an initial dose of 100 μg t.i.d and, if necessary, increased to 200 μg t.i.d [176]. In another study, different doses of midodrine (2.5 mg p.o., t.i.d) and octreotide (i.v. infusion of 25 μg/h after an initial bolus of 25 μg) were used [177].

Other alternatives to terlipressin are vasopressin or noradrenaline. Noradrenaline is used as a continuous intravenous infusion at an initial dose of 0.5 mg/h, adjusted to achieve an increase in mean arterial pressure of at least 10 mmHg or an increase in 4-h urine output to more than 200 mL. If these goals are not reached, the dose is increased every 4 h in steps of 0.5 mg/h, up to the maximum dose of 3 mg/h [180]. Vasopressin is also used as a continuous intravenous infusion, starting at a low dose of 0.01 U/min and titrating up to a dose of 0.5 U/min, depending on changes in mean arterial pressure and urine output and the presence of ischemic side effects. In the study that assessed vasopressin for HRS, the mean vasopressin dose in the group of responders was 0.23 ± 0.19 U/min [179].

Albumin should be administered with the vasoconstrictor. The maintenance dose, once the diagnosis of HRS is established and vasoconstrictors are initiated, is 20–40 g/day. Albumin may be discontinued if the serum albumin concentration exceeds 45 g/L and should be withdrawn in case of pulmonary edema. Because this complication is uncommon, catheterization to monitor central venous pressure is not mandatory, but careful physical and radiological monitoring of cardiopulmonary function is recommended [132].

In early responders, treatment with vasoconstrictors and albumin should be maintained until normalization of serum creatinine (< 1.5 mg/dL). Once reversal of HRS is obtained (creatinine < 1.5 mg/dL), the dose of vasoconstrictors can be titrated down until discontinuation.

Renal replacement therapy should be considered in patients who develop pulmonary edema, severe hyperkalemia, or metabolic acidosis not responding to medical therapy.

Prophylaxis of hepatorenal syndrome

Three randomized controlled studies suggest that HRS can be prevented in three specific clinical settings: SBP, ascites with low protein associated with severe liver and/or renal dysfunction, and alcoholic hepatitis.

In a non-placebo-controlled study in patients with SBP, the intravenous administration of albumin (1.5 g/kg at the diagnosis of the infection and 1 g/kg 48 h later) together with antibiotics decreased the risk of HRS by 66% compared with treatment using antibiotics alone (10% vs 33%) and improved hospital survival [144]. The beneficial effect of albumin is probably related to its capacity to improve effective arterial blood volume, as shown by a decrease in plasma renin activity, and is mainly observed in high-risk patients (i.e., those with a serum creatinine > 1.0 mg/dL or a serum bilirubin > 4 mg/dL) [145].

In a placebo-controlled study, the daily administration of norfloxacin (400 mg p.o.) in patients with low ascites protein (< 1.5 g/dL) and either renal or severe liver dysfunction was associated with a lower probability of developing HRS than placebo-treated patients [118].

In a double-blind, placebo-controlled study in patients with alcoholic hepatitis, the administration of pentoxifylline (400 mg t.i.d) was associated with significantly lower rates of HRS (8% vs 35%) and mortality (24% vs 46%) compared with patients randomized to placebo [187]. The beneficial effect of pentoxifylline could be related to its capacity to inhibit production of tumor necrosis factor and the resultant vasodilation; however, the study failed to show significant changes in plasma levels of tumor necrosis factor and did not report on hemodynamics.

In these three studies, the relation between prevention of HRS and improved survival is further proof that renal failure is an important determinant of death in patients with decompensated cirrhosis [3].

G LIVER

91 Central nervous system and pulmonary complications of end-stage liver disease

Javier Vaquero, Andres T. Blei, Roger F. Butterworth

Hepatic encephalopathy, 2327
Hepatopulmonary syndrome, 2335
Portopulmonary hypertension, 2342

End-stage liver disease and advanced portal hypertension result in blood from the splanchnic circulation accessing the systemic circulation without being adequately detoxified by the liver. In addition, the injured liver may be a source of abnormal mediators or fail to produce essential metabolites. The consequence of these alterations is the exposure of peripheral organs to an altered composition of blood. Hepatic encephalopathy, hepatopulmonary syndrome, and portopulmonary hypertension are the result of the exposure of brain and lungs to this altered milieu. Together with variceal bleeding, ascites, and hepatorenal syndrome they are the major manifestations of advanced liver disease and can cause significant deterioration of quality of life, morbidity, and mortality. Medical therapies often attenuate the symptoms or delay the progression of these complications, but liver transplantation is considered the only definitive cure.

Hepatic encephalopathy

Definition and classification

Hepatic encephalopathy (HE) is a serious neuropsychiatric complication of both acute and chronic liver failure, with a significant impact on quality of life. Results of a working group were published in 2002 and they include a definition of HE and a new system of classification (Table 91.1). HE is defined as a spectrum of neuropsychiatric abnormalities seen in patients with liver dysfunction after exclusion of other known brain diseases [1]. This multiaxial definition of HE defines both the type of hepatic dysfunction and the characteristics of the neurological manifestations. Three types of hepatic abnormalities are defined, namely:

Table 91.1 Classification of hepatic encephalopathy (HE)

Type **A**	Encephalopathy associated with **a**cute liver failure
Type **B**	Encephalopathy associated with portosystemic **b**ypass and no intrinsic hepatocellular disease
Type **C**	Encephalopathy associated with **c**irrhosis and portal hypertension or portosystemic shunts
	1 Episodic HE
	a Precipitated
	b Spontaneous
	c Recurrent
	2 Persistent HE
	a Mild
	b Severe
	c Treatment-dependent
	3 Minimal HE

- Type A: HE associated with **a**cute liver failure
- Type B: HE associated with portosystemic **b**ypass with no intrinsic hepatocellular disease
- Type C: HE associated with **c**irrhosis and portal hypertension or portosystemic shunts.

In the case of chronic liver disease, the terms *episodic HE* and *persistent HE* were coined and the term *minimal HE* was invoked to replace *subclinical encephalopathy*. It is anticipated that this new system of classification of HE will help to dispel the confusion frequently present in classical textbook definitions and to facilitate recruitment of patients into multicenter clinical trials.

Diagnosis

Neuropsychiatric symptoms characteristic of HE include shortened attention span, sleep abnormalities, and motor incoordination progressing through lethargy to stupor and

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

coma. Psychiatric symptoms, particularly anxiety and depression, are not uncommon. Type B HE is, in practice, uncommon. In type C HE, symptoms take an undulating course progressing relatively slowly. In type A HE associated with acute liver failure, the neurological disorder may progress from altered mental status to coma within days, seizures may occur, and mortality rates are high. In these patients, death is frequently the result of brain herniation caused by brain edema and intracranial hypertension.

In patients with an episode or worsening of HE, it is essential to identify potential precipitating factors and to initiate corresponding treatment immediately. Common precipitating factors are gastrointestinal bleeding, hypovolemia, hyponatremia, hypokalemia, hypoxia, hypoglycaemia, infection, and the use of sedative drugs [2].

Diagnosis of HE in chronic liver failure is generally based on clinical and laboratory criteria following exclusion of other causes of neuropsychiatric dysfunction (Table 91.2). Differential diagnosis may require the use of computed tomography (CT) scans to eliminate other causes of encephalopathy such as traumatic brain injury, tumors, or edema.

Grading of HE in clinical practice is generally performed using the West Haven criteria (Table 91.3), which assess mental status on a scale of I to IV based on levels of consciousness, intellectual function, and personality changes [3]. Asterixis or flapping tremor (common in patients in stage II and III) refers to the presence of rapid involuntary flexion and extension movements of the wrist when the patient is told to maintain them actively in dorsiflexion with the fingers extended. Flapping tremor may also be observed during tongue protrusion or pedal dorsiflexion. Patients in stage IV of the West Haven classification may be better assessed using the Glasgow coma scale (Table 91.4).

Psychometric testing is commonly used to quantify the degree of impairment of neurological function, particularly in mild or minimal HE. Tests most commonly used include the Number Connection Test (NCT) and measurement of reaction times to visual or auditory stimuli. The Psychometric Hepatic Encephalopathy Score (PHES) consists of a series of psychometric tests including NCT-A, NCT-B, line tracing test, digit symbol test, and the serial dotting test. This battery of tests examines such entities as visual perception, construction, and visuospatial orientation in addition to motor speed, accuracy, attention, and memory function [4].

Electroencephalographic (EEG) changes in HE start with a bilateral synchronous decrease in wave frequency, increase in amplitude, and loss of normal α rhythm. Computer-assisted spectral EEG analysis facilitates measurement of mean dominant EEG frequency and decreases interoperator variability. Other more sophisticated tests used for grading of HE in chronic liver failure include the use of event-related evoked responses (typically the P300 peak following auditory stimuli) [5] and measurement of critical flicker frequency [6].

Table 91.3 West Haven criteria for clinical grading of hepatic encephalopathy

Stage 0	No abnormality detected
Stage I	Trivial lack of awareness, euphoria, or anxiety Shortened attention span Impairment of addition or subtraction
Stage II	Lethargy Disorientation for time Obvious personality change Inappropriate behavior
Stage III	Somnolence to semistupor, but responsive to stimuli Confusion Gross disorientation Bizarre behavior
Stage IV	Coma Tests of mental state not possible

Neuropathology and neuroimaging

Neuropathology

The principal neuropathological finding in type C HE is altered astrocyte morphology. The term *Alzheimer type II astrocyte* is

Table 91.4 Glasgow coma scale

Criteria	Points awarded
Eyes open	
Spontaneous (eyes open does not imply awareness)	4
To speech (any speech, not necessarily a command)	3
To pain (should not use supraorbital pressure for pain stimulus)	2
Never	1
Best verbal response	
Oriented (to time, person, place)	5
Confused speech (disoriented)	4
Inappropriate (swearing, yelling)	3
Incomprehensible sounds (moaning, groaning)	2
None	1
Best motor response	
Obeys commands	6
Localizes pain (deliberate or purposeful movement)	5
Withdrawal (moves away from stimulus)	4
Abnormal flexion (decortication)	3
Extension (decerebration)	2
None (flaccidity)	1

used to describe the characteristic morphological features manifested by astrocytes in type C HE, which consist of large, pale (watery-looking) nuclei, margination of the chromatin, and prominent nucleoli. The nuclei take on a variety of shapes from round (in cerebral cortex) to irregular or lobulated forms (in basal ganglia), and in many cases occur in pairs or triplets suggestive of hyperplasia [7]. Intranuclear glycogen inclusions are also evident in these cells. The number of cells that manifest the Alzheimer type II phenotype is significantly correlated with the severity of encephalopathy [8,9].

Mixed glial-neuronal cultures exposed to sera from HE patients develop morphological changes characteristic of Alzheimer type II astrocytes [10]. Although rare, neuronal cell death and severe neuronal dysfunction have been documented in several clinical entities in chronic liver failure, which include acquired (non-Wilsonian) hepatocerebral degeneration, postshunt myelopathy, cerebellar degeneration, and extrapyramidal disorders (parkinsonism) [11].

Neuroimaging

Bilateral signal hyperintensities have been described in globus pallidus on T1-weighted magnetic resonance imaging (MRI) (see Fig. 91.2a; see also "Manganese" below), and T2-weighed Fast-FLAIR MRI reveals white matter lucencies along the corticospinal tract in cirrhotic patients with overt HE [12]. Both of these MRI alterations resolve following liver transplantation.

Studies using positron emission tomography (PET) and $^{13}NH_3$ have been used to investigate brain ammonia metabolism in cirrhotic patients. In one study, patients with mild HE presented a significant increase in the cerebral metabolic rate for ammonia, accompanied by an increase of the blood–brain barrier permeability to ammonia, which suggested an increased ease of ammonia for entering the brain in patients with HE [13]. This could explain the hypersensitivity of cirrhotic patients to ammoniagenic conditions such as protein loading, gastrointestinal bleeding, and constipation, and the occurrence of HE in patients with near normal arterial ammonia levels. Results of a subsequent $^{13}NH_3$ PET study, however, suggested that increased cerebral trapping of ammonia in cirrhotic patients with HE was primarily the result of increased circulating ammonia rather than altered blood–brain ammonia kinetics [14].

Pathophysiology

Bloodborne toxins

Ammonia

There is evidence for a pathogenetic link between hyperammonemia and the phenomenon of Alzheimer type II astrocytosis, because the latter phenotype has been described in hyperammonemic syndromes associated with congenital urea cycle enzyme defects, in experimental animals with urease-induced hyperammonemia, and in primary cultures of rat cortical astrocytes exposed to ammonia [9].

A network of organs is involved in ammonia homeostasis (Fig. 91.1) and there is a convincing body of evidence to suggest that hyperammonemia in liver failure results from altered interorgan trafficking of ammonia [15]. In chronic liver failure, hyperammonemia results primarily from reduced hepatic

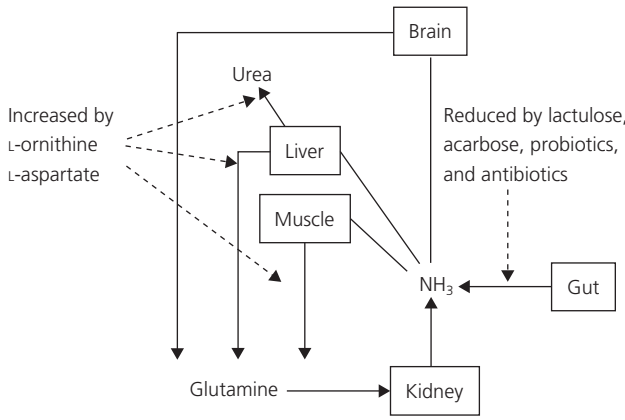

Figure 91.1 Interorgan trafficking of ammonia. Ammonia (NH_3) produced by the gut and kidney is, under normal physiological conditions, removed primarily by the liver (as urea and glutamine) and to a lesser extent by muscle and brain (as glutamine). In liver failure, liver urea and glutamine production is severely impaired, and muscle (not brain) becomes the organ principally responsible for removal of circulating ammonia. Ammonia production in the gut is lowered by treatment with lactulose, acarbose, probiotics, and antibiotics. Hepatic ammonia removal as urea and glutamine together with muscle ammonia removal (as glutamine) are stimulated with L-ornithine L-aspartate.

urea synthesis rather than increased intestinal ammonia production [16]. Urea is synthesized in the liver from ammonia by the urea cycle in periportal hepatocytes, whereas perivenous hepatocytes also transform ammonia into glutamine by glutamine synthetase. Cirrhotic patients have intra- and extrahepatic portosystemic shunts that account for a large portion of portal blood flow. This, in addition to the loss of hepatocytes and impaired residual hepatocyte function, results in decreased ammonia removal by the liver. Increased renal ammonia synthesis reported in liver failure is offset by increased ammonia excretion into the urine [16].

In contrast to the liver, skeletal muscle and brain are devoid of an effective urea cycle and rely only on glutamine synthesis for ammonia removal. In liver failure, muscle becomes the major route for ammonia detoxification [17], because chronic hyperammonemia results in increased glutamine synthetase (GS) activity because of a posttranslational increase of GS [18]. In contrast to skeletal muscle, brain does not adapt its ammonia removal capacity by induction of GS. On the contrary, GS activities are consistently decreased in brains of animals with experimental chronic liver failure [18] and in autopsied brain tissue from cirrhotic patients who died in hepatic coma [19]. This decreased GS activity in brain may be explained by increased GS protein tyrosine nitration, as demonstrated in both in vitro and in vivo models of hyperammonemia and liver failure [20]. Moreover, NMR spectroscopic studies in liver-impaired animals [21] have been unable to demonstrate significant increases of de novo glutamine synthesis in the brain, suggesting that the increased brain glutamine reported in liver failure results primarily from decreased glutamine release from astrocytes or decreased glutamine degradation by glutaminase.

Manganese

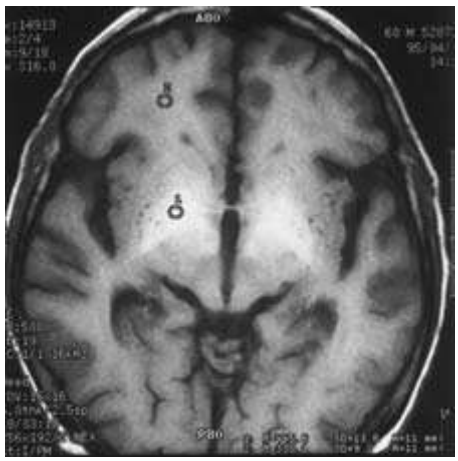
Evidence suggests that manganese deposition is the cause of the bilateral T1-weighed hyperintensities of basal ganglia observed in the MRI of cirrhotic patients (Fig. 91.2). Manganese, which is normally eliminated by the hepatobiliary route, is increased in the blood of cirrhotic patients, who manifest pallidal signal hyperintensities on MRI. Similar MRI pallidal signals probably caused by manganese deposition have been reported in other cholestatic conditions such as Alagille syndrome [22], intrahepatic bile duct paucity, and in patients during total parenteral nutrition [23]. Direct measurements using neutron activation analysis reveal up to sevenfold increases in manganese content of dissected globus pallidus obtained postmortem from cirrhotic patients who died in hepatic coma (Fig. 91.2b) [24]. Experimental animals with surgical portacaval shunts also manifest selective accumulation of manganese in pallidus globus and in other basal ganglia structures [25].

Cerebral blood flow and energy metabolism

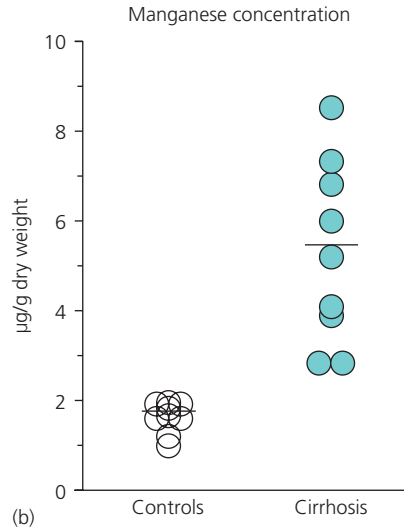
Alterations of brain glucose utilization, of cerebral blood flow, and of brain glucose metabolic pathways have consistently been reported in HE resulting from chronic liver failure. PET studies using ^{18}F-deoxyglucose revealed significant decreases in glucose utilization localized to the anterior cingulate cortex in cirrhotic patients with mild HE [26], and the extent of such decreases correlated with the reduced performance in attention-demanding tasks such as NCT and digit symbol psychometric tests. Anterior cingulate cortex is known to be implicated in the control of the anterior attention system responsible for monitoring the selection of responses to visual stimuli.

Measurement of cerebral blood flow using ^{15}[O]H_2O-PET reveals a redistribution of flow from cortical regions such as the anterior cingulate to subcortical structures such as the thalamus [27].

Precipitation of severe encephalopathy and coma in experimental animals with chronic liver failure following the administration of ammonium salts results in severe alterations of



(a)



(b)

Figure 91.2 **(a)** Typical bilateral signal hyperintensities in globus pallidus on T1-weighted magnetic resonance imaging of a 47-year-old cirrhotic patient with minimal hepatic encephalopathy. Signal hyperintensities resolved following liver transplantation. **(b)** Increased pallidal manganese concentrations in autopsied brain tissue from cirrhotic patients who died in hepatic coma. Data from Pomier-Layrargues et al. [24].

brain glucose metabolism leading to accumulation of lactate [28]. Increased brain lactate concentrations are consistent with impaired oxidation of pyruvate in brain in liver failure. Increased brain and cerebrospinal fluid lactate concentrations have consistently been reported in HE patients [29,30].

Neurotransmitters

Neurotransmission defects in HE have been ascribed to direct neurotoxic effects of the ammonium ion (NH_4^+) on inhibitory (GABA[γ-aminobutyric acid]ergic) and excitatory (glutamatergic) neurotransmission, to the accumulation of neuroactive metabolites of tryptophan, to altered glutamatergic synaptic regulation, and to activation of "peripheral-type" benzodiazepine receptors resulting in the synthesis of neuroactive steroids with potent GABA agonist properties.

Glutamate

In a report by Schmidt et al. [31], the exposure to blood obtained from cirrhotic patients with varying degrees of HE resulted in a dose-dependent inhibition of the uptake of D-aspartate (a nonmetabolizable glutamate analogue) in rat hippocampal slices, and the relative potency of the inhibition correlated with blood ammonia concentrations. Other studies demonstrate ammonia-induced inhibition of high-affinity glutamate uptake into rat synaptosomal preparations [32] and cultured rat astrocytes [33]. Alterations of several subclasses of glutamate binding sites expressed by both neurons and astrocytes have been reported in experimental models of chronic liver failure [34,35].

Serotonin (5-hydroxytryptamine, 5-HT)

Tryptophan is increased in the cerebrospinal fluid (CSF) of patients with hepatic coma [36], and its blood–brain barrier transport is enhanced in dogs with portacaval anastomosis [37]. Because tryptophan hydroxylation (the rate-limiting step in brain 5-HT synthesis) is not saturated at normal blood and brain tryptophan concentrations, increased availability of tryptophan has the potential to result in increased 5-HT synthesis in brain. Supporting an increased synthesis and turnover of 5-HT in the brain in HE, the concentration of 5-hydroxyindoleacetic acid (a metabolite of 5-HT) is increased in the CSF of cirrhotic patients in hepatic coma [36], and in autopsied brain tissue from both HE patients [38] and portacaval-shunted rats [39]. Measurement using an in vivo decarboxylase inhibition assay also revealed increased 5-HT turnover [40] in the brains of portacaval-shunted animals. Increased brain 5-HT turnover correlates with the degrees of portosystemic shunting and hyperammonemia in rats with variable portal vein stenosis [41], an animal model of minimal HE. Other evidence for altered 5-HT metabolism and function in human HE include the report of increased activity and mRNA of monoamine oxidase A (MAO-A; the enzyme responsible for 5-HT breakdown in human brain) [42] and of increased concentration of 5-hydroxyindoleacetic acid in brain tissue from patients who died in hepatic coma [38]. Increased densities of postsynaptic 5-HT_2 receptors were also described in this material [43]. Together, these findings suggest a serotonin synaptic deficit in HE. 5-HT_2 plays a key role in the regulation of sleep, and altered serotoninergic neurotransmission is present in a range of psychiatric disorders in humans. Changes in cerebral 5-HT_2 turnover in HE, therefore, could underlie some early signs and symptoms, such as altered sleep patterns and depression.

γ-Aminobutyric acid

Throughout the 1980s a great deal of attention was focused on the theory that HE was the result of alterations of the GABA neurotransmitter system in brain. Abnormalities of the brain GABA system were initially reported in animal models of acute liver failure [44]. In animal models of chronic liver failure, however, no alterations of this system have been reported, whether reflected by GABA content, its related enzymes, or receptor sites [45–48]. Autopsied brain tissue from cirrhotic patients who died in hepatic coma also contains normal activities of GABA-related enzymes and unchanged densities and affinities of GABA binding sites [19,49,50].

In the central nervous system, benzodiazepine binding sites form part of the GABA-A receptor complex. Stimulation of the benzodiazepine binding site "facilitates" the action of GABA on the functionally linked GABA-A site of the complex, and results in increased chloride channel opening leading to hyperpolarization and inhibition. Administration of the benzodiazepine antagonist flumazenil has been noted to ameliorate the neurological status in cirrhotic patients with HE [51,52]. It was suggested that the beneficial action of flumazenil in HE was the result either of inhibition of increased densities of benzodiazepine binding sites or of inhibition of the action of an "endogenous" ligand at these sites. Subsequent investigations revealed no alterations of densities or affinities of binding sites in either experimental or human HE [50], leaving open the possibility that the beneficial effects of flumazenil were the result of the blockage of "endogenous" benzodiazepines [53]. Initial reports demonstrated that CSF and sera from patients with advanced HE contained significant amounts of "benzodiazepine-like" substances, among which were isolated two known benzodiazepines that are positive allosteric modulators of GABA neurotransmission (diazepam and its *NN*-desmethyl metabolite) [54]. Unfortunately, the interest generated by these reports was tempered by the fact that these benzodiazepines were in most cases pharmaceutical in origin. Moreover, the concentrations of benzodiazepines reported in blood, CSF, and brain extracts of HE patients were well below levels associated with their sedative actions.

An alternative theory to explain increased GABAergic neurotransmission in HE has emerged. Two distinct types of benzodiazepine receptors are expressed in brain. The first type, mentioned in the previous paragraph, forms part of the GABA–benzodiazepine receptor complex and is situated on

the postsynaptic neuronal membrane. The second type is the "peripheral-type" benzodiazepine receptor (PTBR), so-called because of its initial discovery in peripheral tissues but subsequently identified on the outer mitochondrial membrane of astrocytes. Increased densities of PTBRs have been reported in autopsied brain tissue from cirrhotic patients who died in hepatic coma [55], and increased PTBR binding sites and mRNA have been reported in the brain of portacaval-shunted rats [56,57]. Endogenous ligands for the PTBR include the neuropeptide diazepam binding inhibitor and its processing peptide octadecaneuropeptide (ODN) [58]. Portacaval anastomosis in the rat results in increased ODN-immunolabeling of astrocytes and other nonneuronal elements in several brain regions [59]. Exposure to PTBR ligands results in proliferation and swelling of mitochondria in cultured glioma cells [60] and, because mitochondrial proliferation and swelling are observed in astrocytes in liver failure, PTBR activation could play a role in the pathogenesis of this astrocytic response.

Activation of PTBRs in brain in liver failure results in increased synthesis of a novel class of compounds known as neurosteroids, many of which (e.g., allopregnanolone) are potent GABA-A receptor agonists and consequently potent inhibitory agents. Allopregnanolone concentrations are increased up to sevenfold in autopsied brain tissue from cirrhotic patients who died in hepatic coma [61].

Histamine

Histamine is involved in a wide range of physiological functions including sleep, arousal, and circadian rhythmicity. In rats, portosystemic shunting results in increased hypothalamic concentrations of both histamine and its principal metabolite, tele-methylhistamine, and in increased hypothalamic release of histamine [62], suggesting increased histaminergic activity. Increased brain histamine could result from increased brain availability of the precursor amino acid L-histidine. Postsynaptic histamine H_1 receptors are implicated in the entrainment of circadian rhythms to the light–dark cycle in mammals [63], and their activation suppresses deep slow-wave sleep [64]. Upregulation of histamine H_1 receptors has been reported in cerebral cortex of patients with HE and of portacaval-shunted rats. Therefore, it is plausible that increased histaminergic activity through H_1 receptors contributes to the disorganization of the normal sleep cycle and decreased total duration of slow-wave sleep that are characteristically observed in cirrhotic patients with HE [65]. Similar changes in sleep patterns and diurnal rhythms have been reported in portacaval-shunted rats [66]. Histamine H_1 receptor blockade, known to affect sleep quality in humans, significantly improved circadian rhythmicity in these animals [66].

Dopamine

Studies in autopsied brain tissue from cirrhotic patients who died in hepatic coma reveal several-fold increases in the dopamine metabolite homovanillic acid [38]. Similar findings, consistent with increased dopamine metabolism or turnover, were reported in the brains of rats following portacaval anastomosis [67]. A possible explanation for these findings could relate to the increased activities of the monoamine metabolizing enzyme MAO-A [42]. Densities of postsynaptic dopamine (D_2) receptors are significantly reduced in brain tissue obtained at autopsy of cirrhotic patients who died in hepatic coma [68], and in living patients with mild HE studied by PET using [^{11}C]methylspiperone [69].

Opioids

Cirrhotic patients are particularly sensitive to morphine, and portacaval shunting is known to increase pain sensitivity, which involves the endogenous opioid neurotransmitter system. Increased circulating levels of endogenous opioid [Met]enkephalin have been reported in patients with primary biliary cirrhosis [70], and brain levels of β-endorphin are increased in experimental chronic liver failure [71]. Portacaval anastomosis in the rat results in region-selective increases of μ and δ opioid receptor sites in brain [72], a finding that has been linked to increased ethanol consumption in these animals [73].

Oxidative/nitrosative stress

Portacaval anastomosis in the rat results in increased expression of neuronal nitric oxide synthase (nNOS) in brain [74]. NOS activities are also increased by ammonia-induced stimulation of L-arginine uptake into neuronal preparations both in vitro and in vivo. Exposure of cultured astrocytes to millimolar concentrations of ammonia results in oxidative stress and protein tyrosine nitration [20], a process dependent on increases in the inducible isoform of NOS (iNOS). Astrocytic protein tyrosine nitration was also described in the brains of rats following portacaval anastomosis [20], confirming the presence of nitrosative stress under these conditions.

Inflammation

It is becoming increasingly evident that ammonia and manganese neurotoxicity are not the only pathophysiological processes with the potential to affect adversely cerebral function in liver failure. In particular, there is evidence that infection and inflammation also play a significant role.

The severity of HE in acute liver failure is significantly influenced by the so-called systemic inflammatory response syndrome (SIRS) [75], which is a response to the action of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) or the interleukins IL-1β and IL-6. Infection and inflammation are also common in cirrhotic patients, in whom increased circulating levels of TNF-α and IL-6 have been described [76]. Shawcross et al. studied 10 patients with cirrhosis who had evidence of infection and SIRS but no clinically evident HE [77]. In these patients, exogenously induced hyperammonemia was associated with significant

deterioration in neuropsychological testing during the inflammatory state but not after its resolution, indicating that SIRS may modulate the effects of ammonia on brain function.

Therapy

Therapy for HE continues to be a challenge. The reasons for this include a lack of standardization of assessment of mental status, the hesitation by some ethics boards to sanction placebo controlled trials, confounding issues such as the presence of precipitating factors (infection, hyponatremia, unidentified neuroactive drugs, and others), and difficulties related to the effective blinding of patients and clinical investigators to the treatment regimen. A schematic approach to the management of HE is shown in Fig. 91.3.

Nutritional support

Severe restriction of dietary protein is no longer recommended as a means of preventing HE in cirrhotic patients [78]. Long-term nitrogen restriction is potentially harmful, and a positive nitrogen balance is essential to promote liver

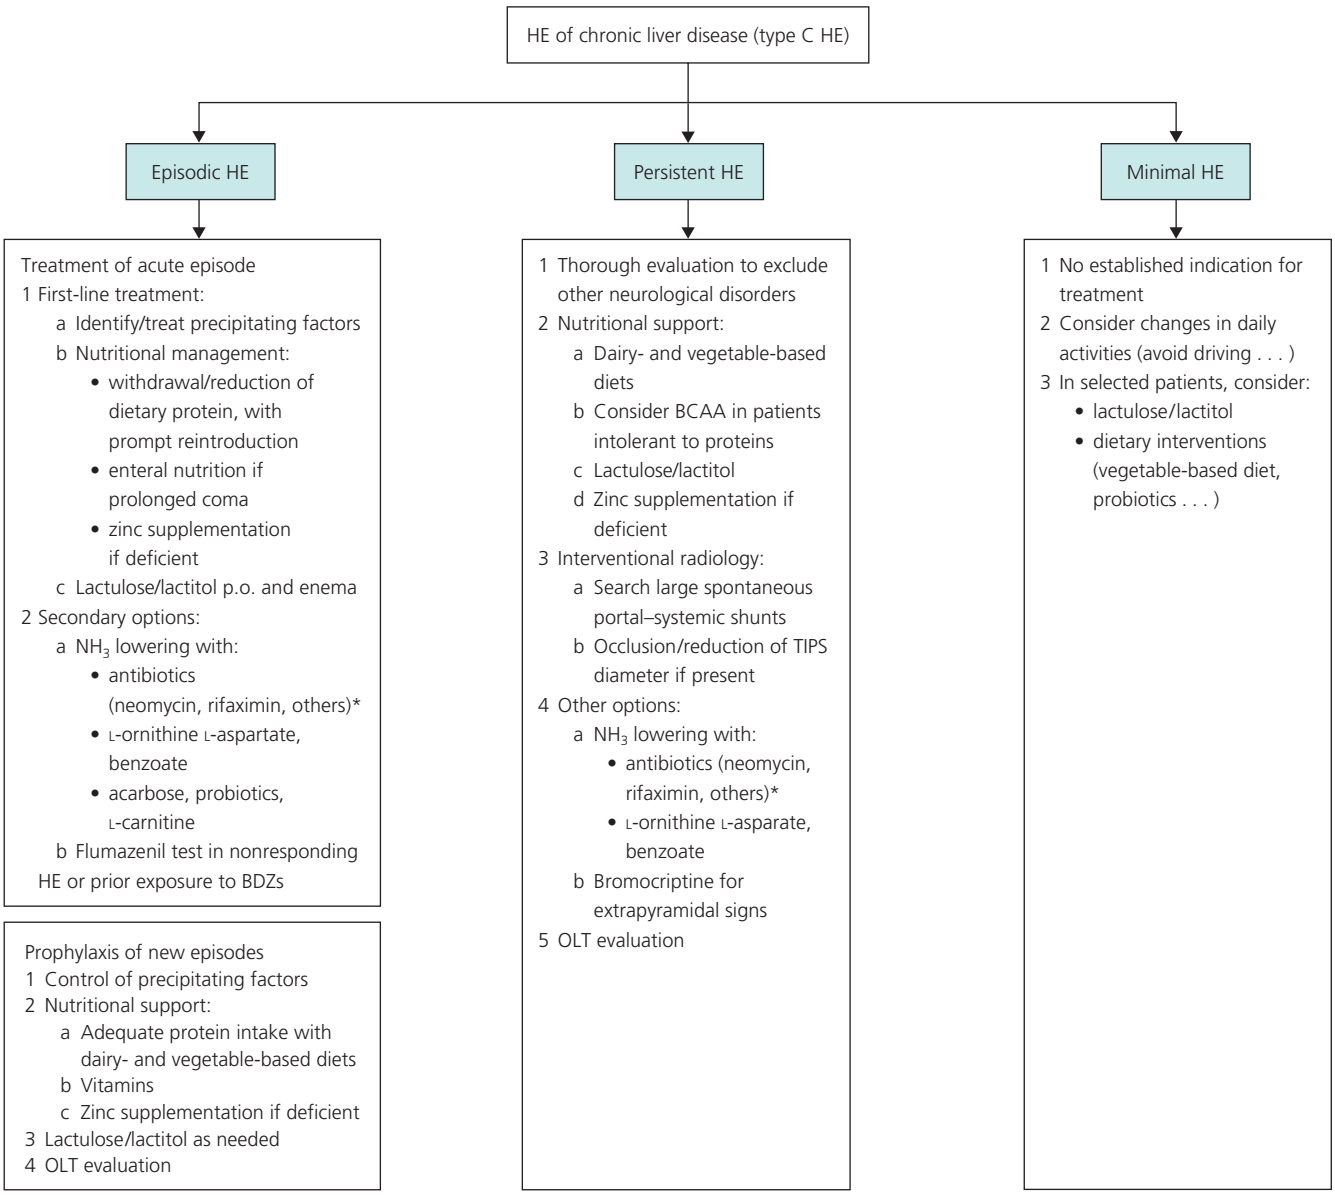


Figure 91.3 General management of hepatic encephalopathy (HE) of chronic liver disease (type C HE). No therapy has conclusively been shown to improve HE compared with placebo in randomized clinical trials. A majority of patients with HE, however, are effectively managed by following the present orientative scheme, based on published guidelines [2,238]. The management of the recurrent type of episodic HE would be similar to that of persistent HE. *Neomycin for chronic use requires periodic monitoring to avoid toxicity (renal, otological). BCAA, branched-chain amino acids; BDZ, benzodiazepine; OLT, orthotopic liver transplant; p.o., orally; TIPS, transjugular intraheptic portosystemic shunt.

regeneration and to increase the capacity for ammonia removal by skeletal muscle. Protein intake in the 1–2 g/kg/day range is generally recommended to maintain an adequate nitrogen balance [2]. Oral supplements of branched-chain amino acids have been suggested to offer significant improvement in severely protein-intolerant patients with chronic HE [79].

Ammonia-lowering strategies (Fig. 91.1)

Nonabsorbable disaccharides, such as lactulose and lactitol, are routinely used to decrease ammonia production in the gut despite a paucity of adequate controlled clinical trials. In the case of lactulose, the ammonia-lowering effect involves increased fecal nitrogen excretion by facilitation of the incorporation of ammonia into bacteria as well as a cathartic effect. In the colon, lactulose and lactitol are catabolized, respectively, to lactic and acetic acids, leading to a lowering of colonic pH to around 5.0. This reduction in pH favors the formation of the less absorbable NH_4^+ from NH_3 thus effectively trapping ammonia in the colon. The dose of lactulose (45–90 g/day) is titrated to achieve 2–3 soft stools per day. Major side effects include abdominal cramps, flatulence, and diarrhea. Antibiotics such as neomycin are also traditionally used to lower blood ammonia by inhibiting bacterial ammonia production. However, neomycin therapy is associated with significant side effects and is increasingly being replaced by alternative antibiotics such as rifaximin.

Significant lowering of blood ammonia and concomitant improvement in neuropsychiatric status in cirrhotic patients with grade I–II HE has been demonstrated following administration of the novel hypoglycemic agent acarbose [80]. One suggested mechanism of action of acarbose involves inhibition of proteolytic flora responsible for gut ammonia production. Along these same lines, there is renewed interest (after a 40-year hiatus) in the area of lowering gut ammonia production by oral supplementation of probiotics [81]. The objective of probiotics is to increase the intestinal proportion of urease-negative bacteria thereby decreasing gut ammonia production. Lactic acid-producing probiotics have the advantage of reducing gut ammonia absorption. Synbiotic preparations consist of both lactic acid-producing probiotics and fermentable fiber. Controlled clinical trials with these agents reveal significant improvement of neurological status and lowering of venous ammonia [81].

An alternative means of lowering blood ammonia in chronic liver failure involves the stimulation of ammonia fixation. Ammonia is normally removed by urea formation (periportal hepatocytes) and by glutamine formation (perivenous hepatocytes, muscle and brain) (Fig. 91.1). Several strategies are aimed at stimulating residual urea or glutamine synthesis. One of the most successful, L-ornithine L-aspartate, has been shown to lower blood ammonia and concomitantly improve neuropsychiatric status in cirrhotic patients in controlled clinical trials in Europe and Asia [82]. Studies in experimental chronic liver failure reveal that this beneficial effect is primarily due to the stimulation of urea and glutamine formation in the liver and in the stimulation of glutamine formation by skeletal muscle [83]. In experimental acute liver failure, the ammonia-lowering effect of L-ornithine L-aspartate appears to be due predominantly to the stimulation of muscle glutamine synthetase. Successful lowering of blood ammonia concentrations in cirrhotic patients has also been accomplished using sodium benzoate, an agent that combines with glycine to form hippurate. A controlled clinical trial with 5 g sodium benzoate twice daily in patients with acute HE found it to be as effective as lactulose but 25 times less expensive [84].

Studies in both experimental animal models of HE [85] and in cirrhotic patients [86] demonstrate that L-carnitine is effective in lowering blood ammonia and improving neurological status. The mechanism of action probably involves improvements in mitochondrial metabolism.

Neuropharmacology

As the precise pathophysiological mechanisms and alterations in neurotransmitter systems responsible for the pathogenesis of HE become more clearly defined, novel pharmacological approaches are starting to emerge.

Agents acting on the GABA-receptor complex

A number of controlled clinical trials have evaluated the efficacy of the benzodiazepine receptor antagonist flumazenil in HE patients [2]. In a subset of HE patients, improvements following flumazenil are spectacular [51]. However, enthusiasm for this approach has been tempered by the possible confounding effects of prior exposure to pharmaceutical benzodiazepines (used as sedatives or as part of an endoscopic workup) and by the poor correlation between the clinical response and blood levels of benzodiazepines in these patients. Adding to these difficulties is the short half-life and lack of an oral formulation for flumazenil.

Benzodiazepine partial inverse agonists display weak negative intrinsic activity and act as mild GABA-A receptor antagonists [87]. One such agent, Ro15-4513, ameliorates the symptoms of HE in rats with thioacetamide-induced [88] and ischemic [89] acute liver failure (ALF), and similar results were obtained with a second benzodiazepine partial inverse agonist, sarmazenil. A major mechanism responsible for the beneficial effect of these agents appears to involve the attenuation of the effects of neurosteroids such as allopregnanolone at the GABA-A receptor complex [90]. Surprisingly, no studies have so far been undertaken to test the efficacy of benzodiazepine partial inverse agonists in patients with acute or chronic liver failure.

Dopamine receptor agonists

Both L-DOPA (the amino acid precursor of dopamine) and the dopamine receptor agonist bromocriptine have been

used in clinical trials in patients with portosystemic encephalopathy [2]. Although results were not encouraging in terms of overall cognitive improvement, it is possible that these agents have a beneficial effect on motor performance.

Histamine H_1 receptor antagonists

Following up on the demonstration of a beneficial effect of histamine H_1 antagonists on neurological function in an experimental animal model of HE [66], results of a controlled clinical trial revealed improvements in sleep quality in cirrhotic patients with minimal HE following administration of the H_1 blocker hydroxyzine [91].

Liver assist devices

In chronic liver disease, the role of liver assist devices to treat HE is likely to be relevant only to a small proportion of patients, because of the complexity, associated adverse effects, and discontinuous use of these devices, in addition to the frequent resolution of HE episodes with standard medical therapy. These devices have been used mainly in patients who had advanced chronic liver disease with superimposed acute injury (so-called acute-on-chronic liver failure) [92]. Dialysis against albumin, which allows the removal of water-soluble and non-water-soluble toxins bound to albumin in the blood, has received most attention. In one study of patients with acute-on-chronic liver failure, treatment with albumin dialysis was associated with an improvement of HE, which was not observed in those treated only with standard medical therapy [93]. In a preliminary report of 70 patients with advanced cirrhosis and severe HE, those randomized to albumin dialysis presented significant improvements of HE compared with those receiving standard medical therapy alone [94]. The use of liver assist devices for treating HE, however, is still experimental.

Liver transplantation

The appearance of HE in a patient with cirrhosis is a poor prognostic factor and should prompt evaluation of the patient for liver transplantation [95]. Elective liver transplantation should not be performed during an acute episode of HE; it is preferable to wait until the episode and its precipitating factors are corrected.

Liver transplantation corrects the majority of alterations related to HE, including neuropsychiatric symptoms and altered neuropsychometric tests [96,97], alterations of electroencephalogram [96], alterations of regional cerebral blood flow [98] and regional brain glucose metabolism [99], cerebral osmolyte disturbances [100], basal ganglia hyperintensities [100], and the decrease of the magnetization transfer ratio in the brain [100]. The posttransplant normalization of the cerebral osmolyte disturbances correlates well with the correction of the neuropsychological alterations [100].

Despite the reversibility of HE, neurological complications are common (~ 30%) following liver transplantation, especially within the first weeks [101,102]. In one study, the presence of HE pretransplant was an independent risk factor for developing these complications [101], which include central pontine myelinolysis, cerebrovascular disease, anoxia, seizures, and infections [101,102]. Neurotoxicity from immunosuppressive medications is also common in the early postoperative period [103], but it usually responds to the reduction or discontinuation of the drug. Liver transplantation candidates may also have neurological impairment related to the etiology of liver disease, such as frontal lobe and cerebellar atrophy in alcohol consumption [104], or cognitive and ^{1}H-NMR spectroscopic alterations associated with hepatitis C virus infection [105]. The posttransplant evolution of these preexisting conditions has not been completely characterized.

Hepatopulmonary syndrome

The association between liver disease and pulmonary dysfunction has been known for more than 100 years, since Fluckiger described in 1884 the case of a woman with chronic liver disease presenting cyanosis and digital clubbing [106]. Subsequently, similar cases were reported, and a wide range of structural alterations in the pulmonary vascular tree of patients with liver disease were described [107]. The term *hepatopulmonary syndrome* (HPS) was coined in 1977 by Kennedy and Knudson as an analogy to the *hepatorenal syndrome*, recognizing the vascular nature of the altered gas exchange in these patients [108].

Today, HPS distinguishes a subgroup of patients with liver disease or portal hypertension who present alterations of arterial oxygenation caused by the development of intrapulmonary vascular dilations (IPVDs). The term IPVD reflects the variety of pulmonary vascular alterations leading to altered gas exchange in HPS, from diffuse peripheral dilations of pulmonary capillaries to true anatomical arteriovenous shunts.

Definition

HPS is defined by the three following criteria, all of which must be present to establish the diagnosis [109,110]:

- presence of chronic liver disease or portal hypertension
- alteration of arterial oxygenation, usually defined as a widened age-corrected alveolar–arterial oxygen gradient on room air with or without arterial hypoxemia
- evidence of IPVDs.

In early definitions, the presence of other cardiopulmonary causes of hypoxemia was incompatible with the diagnosis of HPS. However, it is generally accepted that HPS can be diagnosed in patients with coexisting intrinsic cardiopulmonary disease [110]. Increased experience and the ability to detect specifically the presence and degree of IPVDs has made it possible to distinguish HPS in such a setting.

Epidemiology

Most patients with HPS have underlying liver cirrhosis with variable degrees of portal hypertension. A prevalence of HPS of approximately 10%–20% has been reported in cirrhotic patients evaluated for liver transplantation [111–115] and in less selective populations [116–120]. HPS is not associated with any specific etiology of liver disease, and there is no clear relation between HPS and the degree of hepatic dysfunction [110]. Therefore, HPS should be suspected independently of the stage of liver disease.

HPS has also been diagnosed in noncirrhotic portal hypertension (extrahepatic portal vein thrombosis, Budd–Chiari syndrome, and others) and in liver diseases where portal hypertension is not a significant feature, such as in acute and chronic viral hepatitis without cirrhosis [110]. In a series of critically ill patients with diverse cardiopulmonary diseases, criteria of HPS were fulfilled by almost 50% of those who developed hypoxic hepatitis compared with 0% of patients without liver disease [121]. Structural pulmonary vascular changes characteristic of HPS have also been described in patients with fulminant hepatic failure [122]. These reports underscore that both portal hypertension and liver dysfunction (acute or chronic) are important factors in the pathogenesis of HPS.

Natural history

The natural history of HPS has not been completely elucidated. Approximately 10%–20% of cirrhotic patients present evidence of IPVDs without alterations of arterial oxygenation [112,116–118], not fulfilling the diagnostic criteria of HPS. This situation may represent an initial phase of HPS, but its evolution is unknown.

Once established, the diagnosis of HPS has important implications for the patient with liver disease. Although spontaneous improvement of HPS has been reported [123], progressive deterioration of arterial oxygenation occurs in most cases even in the setting of stable liver disease [124,125]. In patients with HPS awaiting liver transplantation, a mean P_aO_2 decline of 5.2 mmHg per year has been estimated [125]. Diagnosis of HPS is also associated with increased mortality [115,125]. In a prospective study of 111 patients with cirrhosis, the median survival time was 10.6 months in those with HPS compared with 40.8 months in those without HPS ($P < 0.05$), with the survival disadvantage for HPS being independent of the severity of liver disease [115]. In patients who do not undergo liver transplantation, the 5-year survival is significantly diminished in those who have HPS (20% vs 32%–63% in those without HPS) [115,125]. The severity of HPS also influences prognosis, with a $P_aO_2 < 60$ mmHg being correlated with worse survival [115,125]. The causes of mortality, including respiratory failure, are similar in patients with and without HPS and are mainly liver- or portal hypertension-related events [115,125].

Pathophysiology

Pathology

Alterations in the pulmonary vascular tree, generally within a normal lung parenchyma, are the distinctive pathological feature of HPS. In 1956, Hoffbauer and Rydell first described numerous abnormal vascular channels connecting the pulmonary arteries and veins in a patient with cirrhosis and cyanosis [126]. In subsequent years, a range of pulmonary vascular abnormalities were described in necropsy studies of patients with hypoxemia and liver disease. A diffuse dilation of pulmonary vessels mainly at the precapillary and capillary levels was the most conspicuous finding [127–129]. Other common alterations included pleural and subpleural spider nevi [127,129], thickening of walls of pulmonary capillaries and venules by collagen [128], discrete or multiple anatomical pulmonary arteriovenous communications [127,130], and communications between pulmonary veins with portal [131] or systemic veins [132]. All these alterations allow venous or mixed venous blood to pass directly to the pulmonary veins without being fully oxygenated.

Mechanisms of altered arterial oxygenation

Early studies suggested that the cause of hypoxemia in patients with cirrhosis was a decreased affinity of hemoglobin for oxygen, but subsequent research has shown that it was not a sufficient explanation and pointed instead to pulmonary causes of hypoxemia [133]. Among these, hypoventilation can be dismissed because hyperventilation is commonly found in HPS. The other theoretical pulmonary causes of hypoxemia, namely ventilation/perfusion mismatch, diffusion impairment, and vascular shunt, may all play a role in HPS (Fig. 91.4) [133]. Determination of which mechanism is more relevant in individual patients may have therapeutic implications.

Ventilation/perfusion mismatch is the most common cause of hypoxemia in clinical medicine. In normal conditions, the relation between ventilation and perfusion is maintained constant in each lung unit by the modulation of tone in pulmonary arterioles. Thus, arterioles that perfuse poorly ventilated alveoli undergo vasoconstriction and divert blood to better ventilated areas where it can be adequately oxygenated. The presence of abnormally elevated perfusion due to IPVDs results in areas with a low ventilation/perfusion ratio, or "physiological" shunts, which is considered the predominant mechanism of hypoxemia in mild-to-moderate HPS [134]. Characteristically, hypoxemia due to alterations of ventilation/perfusion mismatch has an excellent response ($P_aO_2 > 500$ mmHg) to breathing 100% oxygen (Fig. 91.4). In addition, an impaired pulmonary vasoconstrictive response to hypoxia is present in many patients with cirrhosis [135,136], and it has been associated with more advanced hypoxemia, pulmonary and systemic vasodilation, and ventilation/perfusion mismatch [135]. The extent to which a blunted hypoxic pulmonary vasoconstriction contributes to

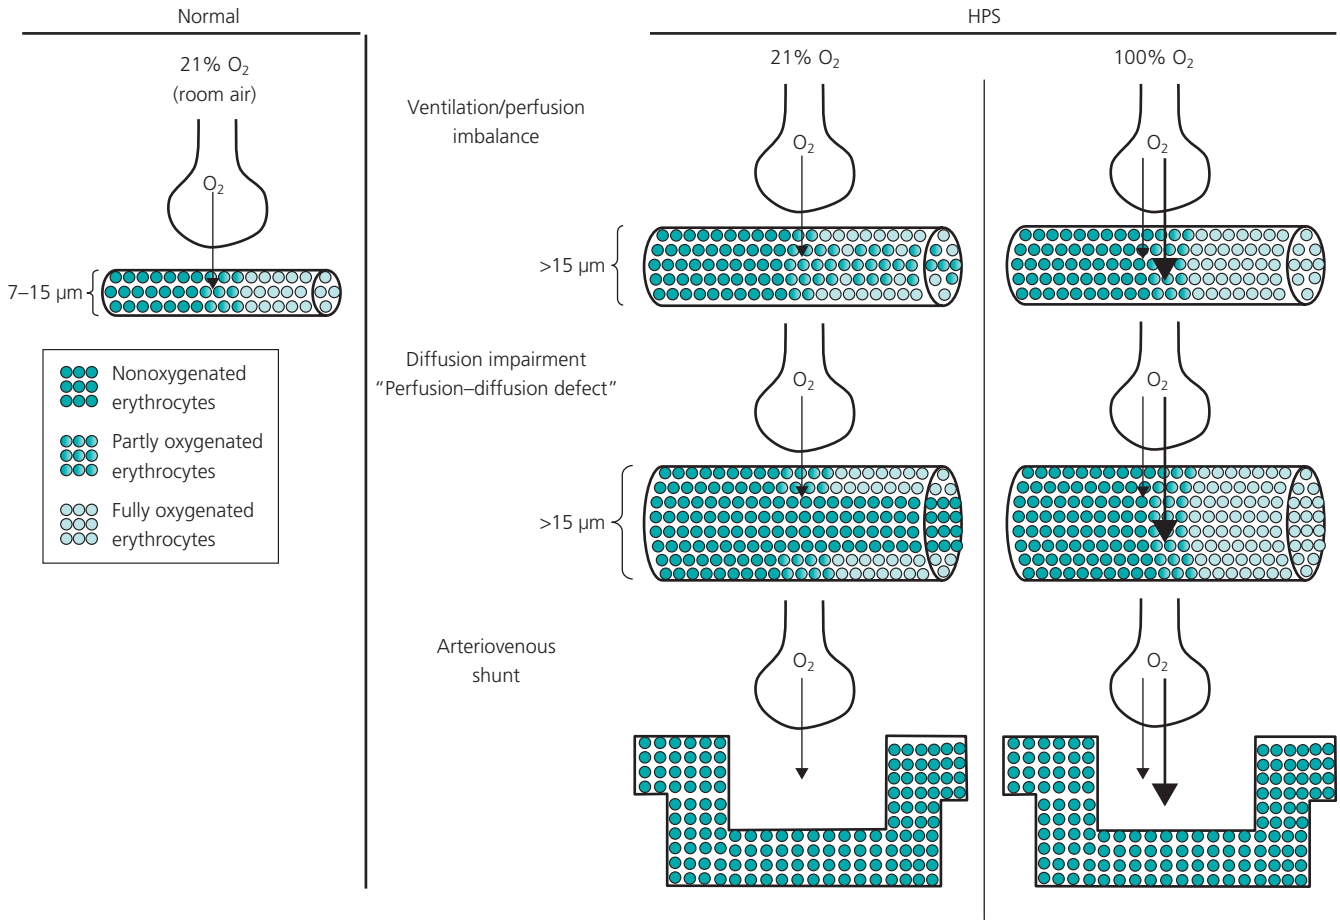

Figure 91.4 Schematic representation of the major mechanisms of hypoxemia in hepatopulmonary syndrome (HPS) and response to breathing 100% oxygen.

ventilation/perfusion mismatch in patients with HPS is, however, controversial [136].

Diffusion impairment is common in patients with liver disease, with up to 55% of candidates for liver transplantation [111,118,137–139] and almost 100% of patients with HPS [111,124,140] presenting an abnormal diffusing capacity for carbon monoxide. A so-called diffusion-perfusion defect has been suggested in HPS [141], where the oxygen pressure within the alveoli would not be sufficient to oxygenate the erythrocytes that travel in the central portion of pulmonary precapillaries and capillaries, because of their abnormal dilation (Fig. 91.4). Based on this hypothesis, the excellent response to 100% oxygen in HPS could be explained by the increased oxygen pressure enhancing the oxygenation of those central erythrocytes. Interestingly, impaired diffusion persists after liver transplantation in many patients despite the reversibility of the hypoxemia and the IPVDs [142], suggesting that the impairment of diffusion is multifactorial.

True anatomical arteriovenous shunts may be present in patients with HPS. Large arteriovenous fistulae between the pulmonary artery and veins are occasionally detected in pulmonary angiography [143]. These arteriovenous communications separate blood from the respiratory interface and, therefore, breathing 100% oxygen does not improve arterial oxygenation (Fig. 91.4). Vascular plexuses between bronchial arteries and veins are common in the pleural surface of patients with cirrhosis, and may be recognized on visual inspection at autopsy as spider nevi [127]. The contribution of portopulmonary anastomoses to the hypoxemia in HPS is likely to be small, because portal venous blood is relatively rich in oxygen (~ 50 mmHg) and the flow through these vessels is small [133].

Importantly, *extrapulmonary factors* also influence gas exchange in these patients. In particular, increased cardiac output may impair arterial oxygenation by decreasing the transit time of erythrocytes through the dilated alveolar capillaries [144].

Mechanisms of pulmonary vasodilation

Pulmonary vascular alterations similar to those of HPS occur in rare cases of congenital heart malformations with anomalous drainage of hepatic veins [145]. Such alterations are

reversible after surgical correction, indicating that factors produced or cleared by the liver strongly influence the pulmonary vascular structure. Mechanisms involved in the development of HPS include altered regulation of pulmonary vascular tone and processes of vascular remodeling and angiogenesis [146]. The cellular and molecular factors implicated have been investigated in humans and in an animal model of HPS, the rat with common bile duct ligation (CBDL) [147,148]. CBDL rats develop severe cholestatic liver disease, hyperdynamic circulation, and, starting 2 weeks after CBDL, progressive arterial oxygenation abnormalities and IPVDs [147,148]. HPS does not develop in other animal models of portal hypertension or liver disease [149].

Nitric oxide (NO), a vasodilator molecule that stimulates guanylyl cyclase in vascular smooth muscle, may be a major mediator of the pulmonary vascular abnormalities of HPS [110,150,151]. The development of HPS, however, is not a mere consequence of the increased NO in the systemic circulation that occurs in portal hypertension. The levels of exhaled NO, which represent local production in the lungs, are increased in patients with HPS compared with cirrhotic patients without HPS or healthy controls, and correlate with the alterations of arterial oxygenation [117]. Transient improvements of arterial oxygenation have been reported in patients with HPS after the inhibition of guanylyl cyclase (using methylene blue) [152,153] or nitric oxide synthases (NOS) (using $N_{(G)}$-nitro-L-arginine methyl ester [L-NAME]), a nonselective inhibitor [154]. L-NAME also improves arterial oxygenation [155] and prevents the development of IPVDs and HPS in CBDL rats [156]. In this animal model, the expression of the endothelial isoform of NOS (eNOS) increases progressively in the pulmonary vascular endothelium from the second week after CBDL in parallel with the IPVDs and the altered gas exchange [157–159], suggesting that it is a major source of increased NO production. An important but transient increase of the inducible isoform of NOS (iNOS) can also be detected later in time, localized in accumulated pulmonary intravascular monocyte/macrophages [158–160]. Alterations of the endothelin-1 system, a major regulator of vascular tone, may determine the altered pulmonary expression of NOS and NO production in CBDL rats [110,150]. In particular, the combination of increased circulating levels of endothelin-1 [149,159] and increased expression of endothelin type B (ETB) receptors in pulmonary vascular endothelium [159] appears to be unique to CBDL rats. Signaling of endothelin-1 through ETB receptors mediates vasodilation by stimulating endothelial NOS activity and NO production. Inhibition of ETB receptors in CBDL rats reduces the expression of both endothelial NOS and ETB receptors, and ameliorates HPS [159]. Rats with prehepatic portal hypertension, which have increased pulmonary expression of the ETB receptor but normal circulating endothelin-1, also develop increased pulmonary expression of endothelial NOS, altered oxygenation and IPVDs when they are infused with low doses of endothelin-1 [149]. Whether these mechanisms are relevant to human HPS, however, is unknown.

Carbon monoxide is another molecule that can induce vasodilation by stimulating guanylyl cyclase. Patients with cirrhosis and HPS present higher arterial levels of carboxyhemoglobin than those without HPS, and the levels moderately correlate with gas exchange abnormalities [114]. In CBDL rats, the expression of heme oxygenase 1, an enzyme that produces carbon monoxide from heme, is induced in liver tissue and pulmonary macrophages, and inhibition of heme oxygenase activity normalizes carboxyhemoglobin levels, attenuates gasexchange abnormalities and IPVDs, and restores hypoxic pulmonary vasoconstriction [158,161]. These findings, therefore, suggest that carbon monoxide production by heme oxygenase contributes to the pulmonary vascular alterations of HPS.

Other factors may influence the development of HPS. In CBDL rats, the presence of bacterial translocation is associated with higher levels of circulating TNF-α and more severe HPS [162]. Treatment with the antibiotic norfloxacin selectively decreases gram-negative bacterial translocation and attenuates gas-exchange abnormalities and IPVDs in these rats [160]. Pentoxifylline, a nonspecific inhibitor of TNF-α, also prevents the development of HPS in CBDL rats [163]. In rats with prehepatic portal hypertension that receive an intravenous (i.v.) infusion of endothelin-1, the development of HPS is associated with an increase of circulating TNF-α [149]. Overall, these studies suggest that inflammation and bacterial translocation, which are frequent in patients with portal hypertension, may play a role in the development of HPS.

Diagnosis

Clinical manifestations

The diagnosis of HPS requires a high index of suspicion. Symptoms related to HPS may be erroneously attributed to progression of the underlying liver disease, which in most cases had been diagnosed years before, or to other conditions common in these patients, such as anemia, malnutrition, ascites, or intrinsic lung disease. This may delay the diagnosis of HPS, and thus it is common to find significant hypoxemia when the diagnosis is finally established.

There are no symptoms or physical signs pathognomonic of HPS. Many patients with HPS may be asymptomatic. The most common complaint (57%–78% of patients) is the insidious onset of dyspnea on exertion and subsequently at rest, but dyspnea is also frequent in cirrhotic patients without HPS (25%–46%) [111,112,164]. Platypnea (worsening of dyspnea in the standing position) is more specific for HPS, but it is present in only a few patients [111]. Spider angiomas, cyanosis, and finger clubbing are signs associated with HPS. Spider nevi are found in the majority of patients with HPS (> 80%) [111,112,165], and have been associated with more

severe liver disease, prominent hyperdynamic circulation, and worse arterial oxygenation [112,135]. However, spider nevi can also be found in 40%–70% of cirrhotic patients without HPS [111,112]. Cyanosis and finger clubbing, by contrast, are highly specific for advanced HPS, reflecting the impact of chronic hypoxemia. Their sensitivity for HPS, however, is low as they are absent in many patients [111,164].

Arterial blood gases

Demonstration of altered arterial oxygenation is required for establishing the diagnosis of HPS. Several thresholds and parameters of arterial oxygenation have been used for defining HPS, partly explaining the variable prevalence reported [112]. In general, HPS can be diagnosed if the age-corrected alveolar–arterial oxygen pressure gradient is higher than normal (age-corrected upper limit of normal = 10 + [0.26 × age – 0.43]) with or without hypoxemia (P_aO_2 < 70 mmHg) [110]. The use of the alveolar–arterial oxygen gradient increases the sensitivity, as it includes in its calculation a correction for the value of P_aCO_2. This gradient is known to increase with age and, therefore, an age correction is necessary to avoid HPS overdiagnosis. The ERS Task Force on Pulmonary-Hepatic Vascular Disorders has staged the severity of HPS based on the P_aO_2 value on room air into mild (≥ 80 mmHg), moderate (≥ 60 and < 80 mmHg), severe (≥ 50 and < 60 mmHg), and very severe (< 50 mmHg; < 300 mmHg if on 100% oxygen), a classification that has prognostic significance [109].

Orthodeoxia (worsening of arterial oxygenation in the standing position) is relatively common in patients with HPS [124], but it can also be encountered in other medical conditions. In patients with HPS, orthodeoxia has been defined as a fall in P_aO_2 ≥ 5% or ≥ 4 mmHg from supine, and it is caused by a gravity-induced heterogeneous redistribution of blood flow to lung bases that increases intrapulmonary shunt and ventilation/perfusion imbalance [165]. To maximize the chance of revealing HPS, the determination of arterial blood gases should be done in the sitting or standing position.

Analysis of arterial blood gases while breathing 100% oxygen may add valuable information, and also allows the quantification of the "physiological shunt." Many patients with HPS present an excellent response to 100% oxygen (P_aO_2 > 500 mmHg), indicating that ventilation/perfusion imbalance or diffusion impairment are the principal mechanisms of hypoxemia. A poor response to 100% oxygen (P_aO_2 < 300 mmHg) indicates the presence of perfusion without ventilation, and suggests (especially if P_aO_2 < 150 mmHg) the presence of anatomical arteriovenous shunts.

Chest radiography and lung function tests

Chest radiography and lung function tests must be done to detect other cardiopulmonary conditions that may cause hypoxemia (see Table 91.5). These conditions may be related to liver disease, such as a hepatic hydrothorax, or may be secondary to intrinsic cardiopulmonary diseases. Importantly, one-third of patients with HPS have coexisting chronic pulmonary conditions, such as chronic obstructive pulmonary disease or bronchial asthma [166,167]. If liver transplantation is being considered it is crucial to evaluate the extent to which these conditions are responsible for the hypoxemia.

The chest radiograph of patients with HPS may reveal bilateral interstitial and pulmonary vascular markings in lower lobes that correspond to the presence of IPVDs [124], but this finding is not specific.

In lung function tests, the majority of patients with HPS present mild to moderate alterations of the diffusing capacity of carbon monoxide [111,124,140], but this is also frequent in patients without HPS [111,118,137–139]. A restrictive pattern can be found in patients who have ascites, pleural effusions, or muscular wasting. In patients with coexisting intrinsic pulmonary diseases, lung function tests will present the corresponding patterns.

Assessment of intrapulmonary vascular dilations

The diagnosis of HPS requires the documenting of the presence of intrapulmonary vascular dilations (IPVDs).

Transthoracic contrast-enhanced echocardiography

Transthoracic contrast-enhanced echocardiography (TT-CEE) is the preferred screening method, because it is noninvasive, highly sensitive for IPVDs, and allows the simultaneous detection of cardiac anomalies and the estimation of right ventricular systolic pressure. Approximately 20% of patients with cirrhosis and a positive TT-CEE for IPVDs, however, do not present alterations of arterial oxygenation [112,116–118]. TT-CEE is usually performed by injecting 10 mL of agitated saline i.v., which produces echogenic microbubbles 24–180 μm in diameter [119]. The microbubbles can be detected in right heart chambers within seconds, they are then trapped in lung capillaries (7–15 μm in diameter) and, in normal conditions, no contrast is observed in left heart chambers. If they are detected in left heart chambers after three heartbeats of their detection in the right chambers, it indicates intrapulmonary shunting. If detected before three heartbeats, it is indicative of intracardiac communication, such as a patent foramen ovale. Different contrast agents, such as indocyanine green solution, may have slightly different sensitivity for IPVDs [119]. TT-CEE cannot quantify the degree of shunt or determine the type of intrapulmonary shunt present (microdilation of fine vessels vs arteriovenous fistula). Transesophageal CEE (TE-CEE) may provide more anatomical information by visualizing specific pulmonary veins, and it is also more sensitive for detecting IPVDs, especially when image quality is bad with the transthoracic approach [118]. However, TE-CEE is more invasive and expensive than TT-CEE, and therefore its main use is in patients with a high suspicion of HPS and negative TT-CEE [118].

Radionuclide lung perfusion scanning

Evidence of right-to-left shunting can be obtained by the intravenous injection of technetium-labeled macroaggregated albumin particles (^{99m}Tc-MAA, 20–90 μm in diameter) combined with whole-body scintigraphy. In normal subjects, ^{99m}Tc-MAA particles are trapped in lung capillaries, and less than 6% of the isotopic activity can be detected in brain, kidneys, spleen, or liver. When the ^{99m}Tc-MAA activity in extrapulmonary tissues (usually calculated from the activity in the brain) is higher than 6% of the total, it indicates the presence of a right-to-left shunt. The ^{99m}Tc-MAA technique permits quantification of the shunt fraction, allowing a better evaluation of the contribution of HPS to the hypoxemia in patients with coexisting cardiopulmonary diseases [140,167]. The calculated ^{99m}Tc-MAA shunt fraction is strongly correlated with arterial oxygenation parameters in patients with HPS [140]. Compared with TT-CEE, the main disadvantages of ^{99m}Tc-MAA are that it may be negative in patients with less severe disease (P_aO_2 > 60 mmHg) [140], and that it cannot distinguish between intracardiac or intrapulmonary shunt, evaluate cardiac disease, or estimate the pulmonary arterial pressure.

Pulmonary angiography

Pulmonary angiography is an invasive, nonsensitive test for the detection of IPVDs. Low pulmonary arterial pressure and low pulmonary vascular resistance are common findings in HPS. Two different angiographic patterns of IPVDs have been described. Type I (diffuse) is characterized by a diffuse dilation of small peripheral branches of the pulmonary artery, mainly in lower lobes. The less common type II (focal) refers to the presence of discrete pulmonary arteriovenous communications [124]. The main indication for pulmonary angiography is patients with a poor response to 100% oxygen (P_aO_2 < 150 mmHg), who may have pulmonary arteriovenous communications amenable to embolization [168]. In patients with a good response to 100% oxygen, the likelihood of finding discrete arteriovenous communications is minimal [167].

High-resolution chest computed tomography (CT)

High-resolution chest CT is useful to diagnose coexisting intrinsic cardiopulmonary disease. When evaluated with this technique, patients with HPS present greater peripheral pulmonary artery diameters and pulmonary artery/bronchus ratios compared with healthy controls and normoxemic patients with cirrhosis [169,170]. The degree of dilation is correlated to some extent with the severity of gas exchange abnormalities [169]. The reliability of this technique for diagnosing IPVDs in HPS, however, requires further study.

Screening

All candidates for liver transplantation should be screened for HPS. Detection of HPS allows a better evaluation of the prognosis and the risk of perioperative complications in individual patients. Guidelines also support the expedited transplantation of patients with severe HPS (P_aO_2 < 60 mmHg on room air) by providing additional points for the Model for End-stage Liver Disease (MELD) [171], because of the unacceptable posttransplant mortality if P_aO_2 falls below 50 mmHg [172]. Under these conditions, screening for HPS in liver transplant candidates is cost-effective, especially with pulse oximetry, and may improve survival [173]. In patients who are not candidates for liver transplantation, general screening for HPS is not recommended, but the diagnostic evaluation of those presenting dyspnea, finger clubbing, or cyanosis should include consideration of HPS.

A general diagnostic approach is shown in Fig. 91.5. If pulse oximetry is used, arterial blood gases should be obtained if oxygen saturation is ≤ 97%. Lower thresholds could miss the diagnosis in many patients because pulse oximetry overestimates arterial oxygenation [113]. Most diagnostic strategies recommend the use of TT-CEE for the detection of IPVDs, reserving the use of ^{99m}Tc-MAA lung perfusion scanning to evaluate those patients with positive TT-CEE and coexisting cardiopulmonary disease [109,110].

Therapy

Oxygen therapy

Mortality in HPS increases with the severity of hypoxemia and is mainly due to liver-related complications [115,125], suggesting that hypoxemia may accelerate the progression of liver disease. Experimental studies suggest that hepatocellular hypoxia enhances fibrogenesis [174]. For these reasons, oxygen therapy is used in patients with significant hypoxemia. Improvement of liver function after long-term oxygen therapy has been reported in two patients with HPS [175]. Despite the rationality behind its use, no study has assessed the effects of oxygen supplementation on the evolution of HPS or liver disease.

Pharmacological therapy

There are no effective pharmacological agents for treating HPS. Somatostatin analogues, indometacin (indomethacin), almitrine bismesylate (a pulmonary vasoconstrictor), inhaled NO, and norfloxacin, have all been tested in small numbers of patients showing minimal (or no) beneficial effects [110,164]. Inhibitors of the NO–guanylyl cyclase pathway (L-NAME, methylene blue) transiently improved hypoxemia, intrapulmonary shunt fraction, and systemic hemodynamics in some studies [152–154], but no effects or even worsening of hypoxemia have also been reported [176,177]. Of note, improvement of arterial oxygenation has been noted in a total of 16 of 33 patients (49%) with HPS treated with garlic powder [178–182]. Despite some promising observations, no clear conclusions can be made regarding the efficacy or safety of any of these agents, because they were all tested in noncontrolled, small series of patients.

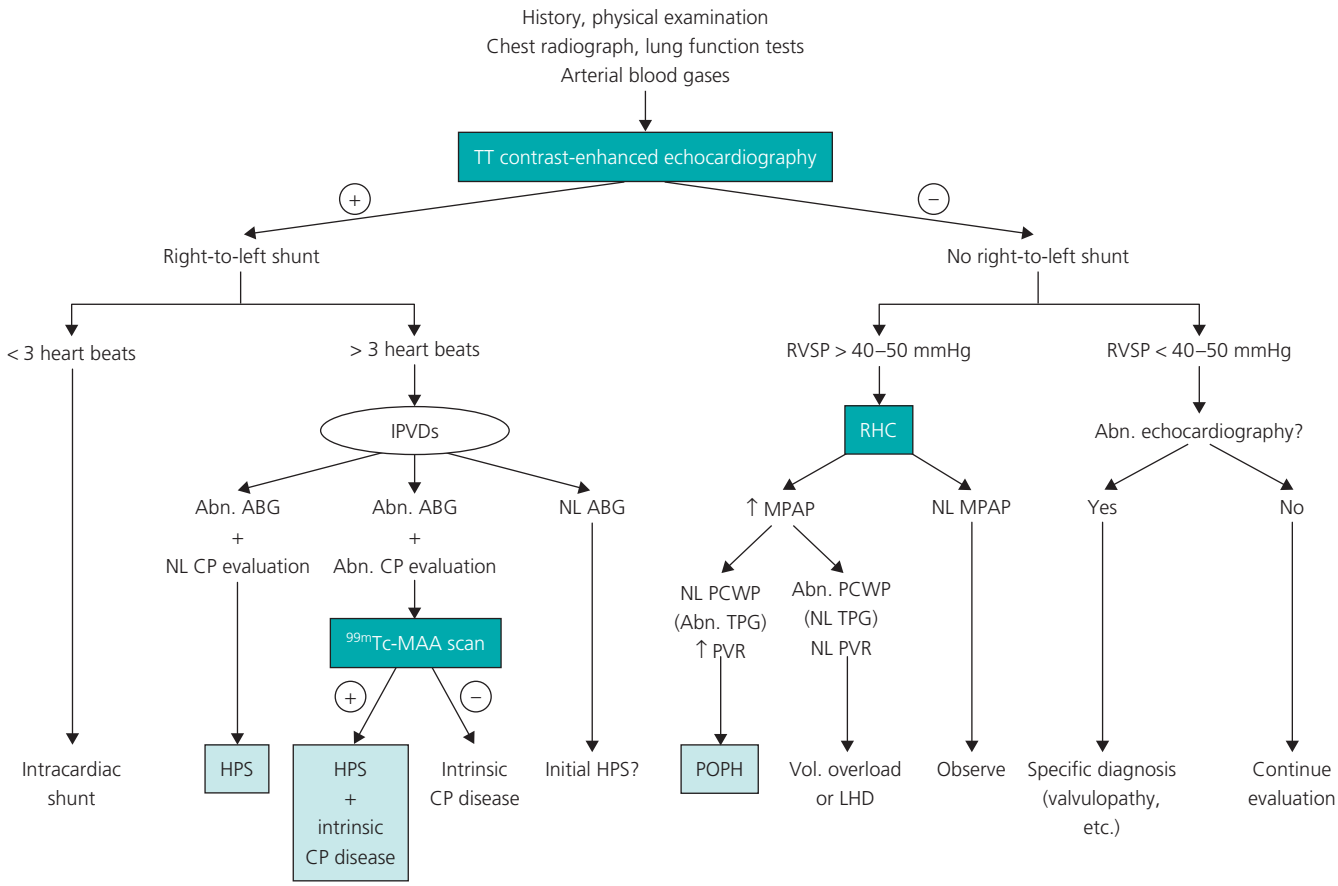

Figure 91.5 General diagnostic approach for hepatopulmonary syndrome (HPS) and portopulmonary hypertension (POPH). Patients with liver disease or portal hypertension presenting with respiratory symptoms or specific signs should be evaluated. All patients being evaluated for major surgical procedures (including liver transplantation) should undergo screening for HPS and POPH, even if asymptomatic. ABG, arterial blood gases; Abn., abnormal; CP, cardiopulmonary; IPVD, intrapulmonary vascular dilation; LHD, left heart dysfunction; MPAP, mean pulmonary arterial pressure; NL, normal; PCWP, pulmonary capillary wedge pressure; PVR, pulmonary vascular resistance; RHC, right heart catheterization; RVSP, right ventricular systolic pressure; ^{99m}Tc-MAA, technetium-labeled macroaggregated albumin; TPG, transpulmonary gradient; TT, transthoracic; Vol., volume.

Interventional radiology

Pulmonary angiography with coil embolotherapy may improve oxygenation in selected patients with HPS and discrete pulmonary arteriovenous fistulae [168].

Transjugular intrahepatic portosystemic shunts (TIPS) could theoretically improve HPS by relieving portal hypertension, but reports of both improvement and no improvement of HPS have appeared [110]. Short follow-up times and coexistence of hepatic hydrothorax limit the interpretation of the case reports. In general, significant IPVDs persist in most patients after TIPS, suggesting that oxygenation is improved because of blood flow redistribution to regions with normal ventilation/perfusion ratios rather than a true reversal of HPS [164]. Consequently, TIPS should not be considered a therapy for HPS until more evidence of its efficacy and safety is provided [109].

Liver transplantation

Liver transplantation is the only effective therapy for HPS, based on the resolution of hypoxemia and intrapulmonary shunt noted in the majority of reported cases [125,133,183]. In some patients with stable liver disease, severe HPS may constitute the indication per se for liver transplantation. The reversibility of HPS after liver transplantation may be slow (> 1 year), probably reflecting the presence of important structural alterations in the pulmonary vasculature [146]. In general, patients with HPS who undergo liver transplantation have better survival than those who do not, but the effect of comorbid conditions in the latter cannot be dismissed [125]. In patients undergoing liver transplantation, mortality tends to be higher in those with HPS compared with those without HPS [125,172], and it increases with the severity of HPS. A $P_aO_2 \leq 50$ mmHg and a ^{99m}Tc-MAA shunt

fraction ≥ 20% are strong predictors of postoperative mortality [172]. The most common posttransplant complications in patients with HPS include infections and respiratory failure with persistent or worsening hypoxemia [172], but more specific complications of HPS may occur, such as cerebral embolic hemorrhages [184] or the development of portopulmonary hypertension [185]. Despite the beneficial influence of liver transplantation, the criteria used for selecting or prioritizing patients with HPS in the waiting list still require refinement to optimize outcomes and organ allocation [171].

Portopulmonary hypertension

In the early 1950s, Mantz and Craige first described cor pulmonale in a patient with portal vein thrombosis, portal hypertension, and portosystemic shunt [186]. Today, portopulmonary hypertension (POPH) refers to a pathological obstructive process in the pulmonary vasculature of patients who have portal hypertension, resulting in increased resistance to blood flow and pulmonary arterial hypertension. In common with HPS, POPH is also a complication of portal hypertension. In contrast to HPS, however, POPH is characterized by pulmonary vasoconstriction rather than vasodilation.

Definition

POPH is defined as pulmonary arterial hypertension (PAH) associated with portal hypertension, with or without underlying liver disease [109,187]. POPH is not considered a "secondary" form of PAH, but is classified in the same group as idiopathic PAH, familial PAH, and PAH associated with diverse conditions (collagen vascular disease and others) [187].

The following traditional criteria must be fulfilled to diagnose POPH:

- presence of portal hypertension with or without cirrhosis
- mean pulmonary arterial pressure (MPAP) > 25 mmHg (3.33 kPa) at rest
- pulmonary capillary wedge pressure (PCW) < 15 mmHg (2.0 kPa)
- pulmonary vascular resistance (PVR) > 240 dyn·s·cm^5 (3.0 mmHg/L/min).

Performance of right heart catheterization with complete hemodynamic study is, therefore, required to diagnose POPH correctly.

Epidemiology

By definition, the diagnosis of POPH is made in patients with portal hypertension. Most patients have underlying cirrhosis, but POPH can also develop in patients with noncirrhotic portal hypertension, such as nodular regenerative hyperplasia or portal vein obstruction [188]. The diagnosis of portal hypertension usually precedes by more than 4 years that of POPH [189]. POHP may occur at any age, including childhood, but the diagnosis is most common in the fifth decade, compared with the fourth decade in idiopathic PAH [188].

POPH is a rare complication of portal hypertension, but it appears to be more common than reported in early studies. In 1983, a series of 17 901 unselected autopsies noted changes characteristic of idiopathic PAH more commonly in patients with cirrhosis than in the whole series (0.73% vs 0.13%) [190]. In a cohort of 507 patients with portal hypertension (of cirrhotic origin in 85%) undergoing hemodynamic studies, the prevalence of POPH was 2% [189]. In two studies in candidates for liver transplantation, the prevalence of POPH was more than double these rates (5%–6%) [191,192], maybe reflecting a longer duration of portal hypertension. No clear correlations exist, however, between the severity of POPH and the etiology or severity of liver disease, degree of portal hypertension, or hyperdynamic circulation [188,189,192]. In patients with refractory ascites evaluated for TIPS placement, an unusually high prevalence of POPH of 16% has been reported [193].

Natural history

The diagnosis of POPH carries a dreadful prognosis [194]. No cases of spontaneous resolution of POPH have been reported. A median survival as low as 6 months was noted in the preliver transplantation era [195]. In subsequent series, the overall 3- to 5-year probability of survival (irrespective of the medical management, including liver transplantation) was approximately 30%–50% [196–198]. The natural history of POPH is not well defined, however, and predicting survival in individual patients is a difficult task [189].

Complications of liver disease and those directly related to POPH (right-sided heart failure, sudden death) account for a similar proportion of deaths in patients with POPH. A low cardiac index is a strong predictor of mortality in these patients, particularly for death resulting from cardiopulmonary complications [189,197]. Increased plasma levels of brain natriuretic peptide reflect right ventricular stress and have been associated with poor prognosis in idiopathic PAH [199]. Limited data suggest that vasodilator therapy and liver transplantation influence the course of POPH, but the extent to which these interventions may reverse the condition or improve survival is unknown.

Pathophysiology

Pathology

The pathology of POPH is indistinguishable from that observed in idiopathic PAH, and is characterized by vasoconstriction and structural changes in the pulmonary arterial tree that result in the obstruction of pulmonary blood flow [190,200]. The main changes affect small pulmonary arteries and arterioles, and consist of hypertrophy of medial smooth muscle, with proliferation or fibrosis of endothelium and adventitia. Thrombosis with recanalization may develop in situ in these vessels. The plexiform lesion, characteristic of idiopathic PAH,

can also be observed in POPH. It consists of small branches of pulmonary arteries dilated close to their origin that present thinning of medial smooth muscle, and an intralumenal plexus of endothelial cells and narrow slit-like channels.

Pathogenesis

Knowledge of the pathogenesis of POPH is limited, due to the rarity of the condition and the lack of adequate animal models. The mechanistic connection between portal and pulmonary hypertension is not completely understood, but some pathogenetic factors postulated for idiopathic PAH may be enhanced in patients with portal hypertension [201]. Two major features of portal hypertension may affect the pulmonary circulation [187,188]. First, the hyperdynamic circulation with increased cardiac output increases shear stress in the pulmonary vasculature and may lead to altered endothelial expression of genes involved in regulation of vascular tone and angiogenesis. Second, portosystemic shunting and defective liver metabolism expose the pulmonary vasculature to blood that has not been processed by the liver, which presumably causes an imbalance between vasodilator/vasoconstrictor and antiproliferative/growth-promoting mediators in the pulmonary circulation. This may include the elevation of levels of potent vasoconstrictors involved in the pathogenesis of idiopathic PAH, such as endothelin-1 (through ETA receptors) and 5-HT_2, and others such as prostaglandin $F_{2\alpha}$, thromboxane B_2 or angiotensin I. By contrast, the expression of prostacyclin synthase, the enzyme that produces the vasodilator prostacyclin, is decreased in small pulmonary arteries of patients with POPH [202]. Portosystemic shunting of bacterial products translocated from the intestines may lead to macrophage sequestration and secretion of cytokines in the pulmonary vasculature, which may contribute to the pathological process. The coagulopathy of patients with cirrhosis may also influence the development of in situ thrombosis in the affected vessels, causing further resistance to blood flow.

Many patients with portal hypertension are likely to present the above factors, but it is unclear why only a small subset of them develops POPH. An autoimmune origin of POHP has been postulated in some patients based on a high prevalence of autoimmune antibodies [197], but this finding is not conclusive. A genetic predisposition may also be a factor, but genetic variations linked to idiopathic PAH affecting bone morphogenetic protein receptor II, activin-like kinase type-1 or the 5-HT transporter have not been confirmed in patients with POPH [109,187].

Diagnosis

Clinical manifestations

Patients with POPH usually have a previous diagnosis of portal hypertension. Many patients may be asymptomatic [189], underscoring the need for screening patients with liver disease who will undergo surgical procedures, particularly liver transplantation. The diagnosis of POPH may be delayed more than 1 year after the onset of symptoms [189], with dyspnea on exertion being the most common complaint [195]. Patients can also present with progressive fatigue and orthopnea. The presence of chest discomfort and syncope indicates advanced disease. In addition to signs of liver disease and portal hypertension, patients with POPH will present signs derived from progressive right-sided heart dysfunction, which include jugular venous ingurgitation, cardiac auscultation with increase of the P_2 pulmonic valve component and tricuspid regurgitation murmur, right ventricular heave, and edema of lower extremities.

The differential diagnosis of dyspnea in liver disease is broad (Table 91.5), and reaching a diagnosis of POPH may require an extensive diagnostic workup [187,188]. Arterial blood gases in patients with POPH usually reveal an increase of the alveolar–arterial oxygen gradient, hypocapnia, and, less frequently, a mild degree of hypoxemia, even in the

Table 91.5 Differential diagnosis of cardiopulmonary dysfunction in liver disease

Intrinsic cardiopulmonary conditions
Obstructive lung diseases
Chronic obstructive pulmonary disease
Asthma
Others, including emphysema
Diseases of lung parenchyma
Pneumonia
Interstitial lung disease
Others, including atelectasis
Pulmonary vascular diseases
Pulmonary embolism
Secondary pulmonary hypertension (due to heart/lung disease or others)
Disorders of the heart and circulatory system
Congestive heart failure
Valvular heart disease
Cardiomyopathy
Others (including arrhythmias, coronary artery disease)
Conditions related to liver disease and portal hypertension
Associated with specific liver diseases
α_1-Antitrypsin deficiency: emphysema
Primary biliary cirrhosis: fibrosing alveolitis, pulmonary granulomas
Sarcoidosis: lung restrictive disease, nonnecrotizing granulomas, cardiomyopathy
Hemochromatosis: cardiomyopathy, arrhythmias
Cystic fibrosis: bronchiectasis, pneumonia
General complications of liver disease and portal hypertension
Ascites
Hepatic hydrothorax
Muscular wasting
Pulmonary vascular abnormalities
Hepatopulmonary syndrome
Portopulmonary hypertension

setting of moderate-to-severe POPH [203]. In moderate-advanced POPH, a chest radiograph may show a prominent main pulmonary artery and cardiomegaly without any parenchymal alterations. An electrocardiogram indicating right atrial enlargement, right ventricular hypertrophy, or right bundle branch block should increase the suspicion of POPH. Lung function tests are important to exclude significant air flow obstruction and other lung diseases, and frequently reveal a reduced diffusing capacity for carbon monoxide in patients with POPH. Ventilation/perfusion lung scanning may show a "mosaic" pattern in patients with POPH; segmental defects would instead suggest pulmonary embolism. Compared with the pulmonary angiographic pattern of idiopathic PAH, POPH presents a lesser degree of sparse arborization and tapering of peripheral arteries, and a dilation instead of narrowing of proximal pulmonary arteries [204].

Transthoracic echocardiography

Transthoracic Doppler echocardiography is the most important noninvasive test for screening POPH (Fig. 91.5). It may exclude valvulopathies and other cardiac causes of elevated MPAP, and also screens for HPS. Most patients with POPH (~ 80%–90%) present a tricuspid regurgitant jet, which allows estimation of the right ventricular systolic pressure (RVSP). The echocardiographic findings reflect the cardiac consequences of progressive resistance to pulmonary blood flow, including pulmonic valve insufficiency, right atrial dilation, right ventricular hypertrophy and dilation, interventricular septal wall thickening, and paradoxical septal motion.

The estimated RVSP is a useful screening parameter for POPH, but there is no consensus regarding which value should be used [205]. Most studies use estimated RVSP cutoff values of 40–50 mmHg, which have a sensitivity of almost 100% for detecting POPH [206]. The correlation between the RVSP values estimated by echocardiography and those directly measured during right heart catheterization is weak [192,207]. Furthermore, echocardiography cannot evaluate PVR. For these reasons, approximately 30%–40% of patients satisfying the previous estimated RVSP thresholds will have normal PVR measured during right heart catheterization and they will not be diagnosed with POPH [191,192]. Another echocardiographic parameter proposed for screening POPH is a pulmonary acceleration time > 100 ms [208], which may have better diagnostic accuracy and can be used in patients in whom RVSP cannot be estimated [192]. In addition to screening, transthoracic echocardiography is useful for following up patients with a diagnosis of POPH.

Hemodynamic assessment

Diagnosing POPH requires the performance of right heart catheterization (Fig. 91.5). This test allows the direct measurement of MPAP, PCWP, and cardiac output, and the calculation of PVR and systemic vascular resistance (SVR). An increase of MPAP alone is not diagnostic of POPH in patients with portal hypertension. Hemodynamic parameters distinguish three origins of increased MPAP in these patients [109,206]:

1 *Hyperdynamic circulatory state*. This hemodynamic pattern is the most common in patients with liver disease. It is characterized by a significant increase of cardiac output and decreased SVR, with a normal PCWP and normal or low PVR. MPAP may be mildly elevated as a result of increased cardiac output.

2 *Increased pulmonary venous volume*. In this case, MPAP is mildly or moderately elevated in the setting of an increased PCWP, reflecting the presence of volume overload or left ventricular dysfunction. PVP is normal or mildly elevated.

3 *Pulmonary vascular obstruction*. This pattern must be present to diagnose POPH. It is distinguished by the significant increase of PVR, leading to elevations of MPAP that may be severe. PCWP is normal or mildly decreased. In contrast to idiopathic PAH, cardiac output is usually increased in patients with POPH. A decrease of cardiac output in POPH indicates advanced right-sided heart failure, and is a sign of poor prognosis [189,197].

Hyperdynamic circulation and volume overload are common in patients with liver disease. According to traditional criteria, the diagnosis of POPH would be missed in these patients if PCWP is greater than 15 mmHg. To avoid this situation, use of the transpulmonary pressure gradient (TPG = MPAP – PCWP) has been proposed [109]. A TGP > 12 mmHg indicates obstruction to flow, independent of the value of PCWP [192].

The value of MPAP obtained during right heart catheterization is used to stage the severity of POPH into mild (> 25 and < 35 mmHg), moderate (≥ 35 and < 45 mmHg) and severe (≥ 45 mmHg) grades, which provides important prognostic information [109].

If POPH is diagnosed, an acute vasodilator testing should be performed during right heart catheterization, generally using epoprostenol i.v. or inhaled NO. A vasodilatory response is significant when MPAP and PVR decrease by more than 20% from baseline values without a decrease of cardiac output [109]. This test reflects to what extent the hypertensive state is caused by reversible vasoconstriction, helping to characterize the severity of the disease and the therapeutic expectations. In a small study of 14 patients with moderate-to-severe POPH, 6 (43%) presented a significant vasodilatory response to i.v. epoprostenol [209]. In these patients, epoprostenol i.v. induces greater increases of cardiac output than inhaled NO [210], and has been suggested to detect a higher proportion of responders [109].

Treatment

General medical treatment

The general management of patients with POPH consists in avoiding circumstances that may worsen portal hypertension, pulmonary vasoconstriction, or stress to the heart. Surgery

should be indicated with caution in patients with POPH, even in those with mild disease, and it would require special anesthetic care [211]. TIPS is not recommended in patients with POPH, because the increase in cardiac output may worsen pulmonary hypertension and precipitate right-sided heart failure. Patients with POPH and hypoxemia may benefit from oxygen therapy to avoid hypoxic pulmonary vasoconstriction. Diuretics (furosemide, spirolonolactone) may be used in patients with volume overload. Withdrawal of β-blocker treatment in patients with POPH has been associated with improvements in exercise capacity and pulmonary hemodynamics [212]. Alternative methods for preventing variceal bleeding, therefore, may be desirable. Oral anticoagulation and calcium channel blockers, medications used for idiopathic PAH, are not recommended in patients with portal hypertension because they may increase the risk or severity of bleeding and the hepatic venous pressure gradient, respectively [213].

Specific vasodilator therapy

Specific vasodilator therapy improves symptoms, pulmonary hemodynamics, and survival in large clinical studies of idiopathic PAH [201]. In patients with POPH, however, the experience is limited to case reports and small, uncontrolled studies, impeding the establishment of conclusive guidelines. In general, this therapy is not offered to asymptomatic patients with mild POPH (MPAP < 35 mmHg), who should undergo only periodic follow-up with transthoracic echocardiography. Patients with moderate-to-severe POPH (MPAP > 35 mmHg) and a significant vasodilatory response may benefit from this therapy, especially if combined with liver transplantation. The duration of the effect of vasodilator therapy and its impact on POPH survival, however, are unknown.

Prostacyclin analogues

Epoprostenol, a potent pulmonary vasodilator with antiproliferative and anti-platelet aggregating properties, is the best-studied agent. Because of the short half-life (3–5 min) of epoprostenol, treatment requires long-term catheterization of a central vein for continuous i.v. administration. In series totalling more than 45 cases, both the acute and long-term administration of epoprostenol significantly decreased MPAP and PVR and increased cardiac output in patients with POPH [209,214–217]. Common side effects include headache, flushing, diarrhea, nausea, muscle pain, and hypotension [201]. Development of splenomegaly with leukothrombocytopenia was reported in four patients [218]. The potential complications arising from long-term venous access, such as infection or thrombosis, are the major limitations for this therapy. Moreover, accidental interruption of the perfusion may cause life-threatening sudden pulmonary vasoconstriction. More stable prostacyclin analogues, such as iloprost and treprostinil (approved for idiopathic PAH by the US Food and Drug Administration [201]), and a variety of routes of administration (inhalation, oral, subcutaneous, i.v.) have been investigated. The experience with these agents in POPH, however, is still limited to anecdotal reports [219,220].

Endothelin receptor antagonists

Bosentan is a dual ETA and ETB receptor antagonist that can be administered orally. A dose-dependent increase of liver enzymes, however, occurred in approximately 11% of patients treated with this agent in clinical trials of idiopathic PAH [201]. In preliminary reports comprising a total of 13 patients with POPH and well-compensated cirrhosis, treatment with low-to-medium doses of bosentan for more than 1 year resulted in improvement of exercise capacity and pulmonary hemodynamics without notable adverse effects, except systemic arterial hypotension in one patient [221–223].

Phosphodiesterase inhibitors

Sildenafil is an oral medication also approved for idiopathic PAH. Sildenafil inhibits the degradation of NO by phosphodiesterase-5, promoting vasodilation. Preliminary reports have communicated variable improvements of exercise capacity or pulmonary hemodynamics in a total of 17 patients with advanced cirrhosis and severe POPH treated with sildenafil alone or in combination [224–227]. The administration of sildenafil, however, may exacerbate portal hypertension and hyperdynamic circulation [228], and variceal bleeding during treatment with sildenafil has been reported [229].

Other agents

It has been reported that MPAP and PVR were decreased by isosorbide-5-mononitrate [230] in one patient, and by inhaled NO in five out of six patients with POPH [231].

Liver transplantation

It is unclear how liver transplantation influences the natural history of POPH. Normalization, improvement, no change, and worsening of POPH have all been reported in patients undergoing liver transplantation [109,205]. In favorable cases, POPH may take months to years to resolve. De novo development of POPH, transition from HPS to POPH, and recurrence of POPH in cases of graft failure have also been noted after liver transplantation [187]. For these reasons, in contrast to HPS, POPH is not an indication for liver transplantation.

Impact of POPH on liver transplantation outcomes

The presence of POPH is associated with increased morbidity and mortality in patients undergoing liver transplantation. A transplant hospitalization mortality of 36% has been reported in these patients, with 40% of the deaths occurring intraoperatively [232]. Screening of POPH in liver transplant candidates and adequate staging by right heart catheterization are critical for assessing the risk of complications [233]. Despite adequate screening, a few patients may be diagnosed in the operating room [191,232]. The rate of mortality in

patients with POPH undergoing liver transplantation increases from 0% if MPAP < 35 mmHg or TPG < 15 mmHg, to 50% if MPAP is between 35 and 50 mmHg and PVR ≥ 250 dyn·s·cm^5 (3.125 mmHg/L/min), to 100% if MPAP ≥ 50 mmHg [233]. Based on this and other studies, a MPAP ≥ 50 mmHg is usually considered an absolute contraindication for liver transplantation [109]. Successful liver transplantation of these patients, however, has been occasionally reported [234]. Eligible candidates with mild POPH (MPAP < 35 mmHg) could benefit from expedited liver transplantation before POPH progresses, but the provision of additional MELD points is controversial [205].

The risk of complications in patients with POPH undergoing liver transplantation is maximal during the induction of anesthesia, before and after graft reperfusion, and in the immediate postoperative period [235]. Increases of MPAP during reperfusion of the graft may cause right-sided heart failure [109], the main cause of intraoperative and perioperative mortality in these patients [232]. Dobutamine stress echocardiography with volume challenge may improve the prediction of this complication [236]. Circumstances that impair heart function, such as hypoxia, hypothermia, hyperkalemia, metabolic acidosis, or hypercarbia, should be prevented. Anesthesia with isofluorane and intraoperative use of vasodilators may help to control increases of MPAP in these patients [109,235]. Combined liver, heart, and lung transplantation has been reported in highly selected patients but remains experimental [237].

Specific vasodilator therapy for rescuing candidates for liver transplantation

Patients with moderate-to-severe POPH (MPAP > 35 mmHg) who do not have contraindications for liver transplantation are the most likely to benefit from vasodilator therapy. Using this approach, up to 75% of them may achieve reductions of MPAP below 35 mmHg and PVR below 400 dyn·s·cm^5 (5.0 mmHg/L/min) and can be successfully bridged to liver transplantation [187]. Preliminary data suggest that this combination provides a survival advantage to these patients [205,217]. Vasodilator therapy should continue during and after liver transplantation, but withdrawal has been safely achieved within 1 year in many patients [209,216,217]. Despite the evidence supporting the use of vasodilator therapy, a prospective collection of data from 1996 to 2001 in 10 liver transplant centers of the United States showed that vasodilator therapy is not commonly offered to these patients [232].

Evaluation for liver transplantation, 2367
Posttransplant management, 2369

Introduction

In the fourth decade since the inception of human orthotopic liver transplantation [1], this procedure has become a highly successful treatment for patients with life-threatening, advanced liver disease, and is performed in 137 centers across the United States [2]. According to data from the Organ Procurement and Transplantation Network for all adult liver transplants performed in the United States from 1996 to 2005, patient survival following deceased donor liver transplantation was 93% at 3 months, 87% at 1 year, and 73% at 5 years (Fig. 92.1) [2]. The applicability of liver transplantation as a therapy is, however, limited by a critical donor organ shortage [3]. The total number of transplants performed yearly has increased steadily over the last 10 years, reaching 6441 procedures in 2005. This rise is mainly attributable to deceased donor liver transplantation, the number of which increased by 30% since 2001 after rising more slowly over the previous decade (Fig. 92.2). The size of the waiting list for a liver transplant has increased continuously, with a peak in 2001 at 14 897 patients (Fig. 92.3) [3]. The interruption of this rise in 2002 coincided with the implementation of the allocation system based on the Model for End-stage Liver Disease and Pediatric End-stage Liver Disease (MELD/PELD). A total of 12 822 candidates were actively listed for liver transplantation in 2005, compared to 12 650 in 2003. Although the death rate among patients on the waiting list has declined steadily over the past decade (174.3 deaths per 1000 patient-years at risk in 1996 compared with 125.5 deaths per 1000 patient-years at risk in 2005), since 1999, there have been approximately 2000 deaths per year among recipients on the waiting list [3]. The continued disparity between cadaveric donor organ supply and recipient demand has undoubtedly contributed to these deaths, and remains a major challenge in this field and continues to motivate the need for improving strategies for optimizing donor organ availability and organ allocation, and developing expertise in the management of patients with severe acute and end-stage liver disease.

This chapter reviews the aspects of surgical technique and donor organ sources and organ preservation, the indications and process of evaluation for liver transplantation, disease-specific issues, outcomes, and the management of posttransplant complications and immunosuppression.

Surgical technique, sources of donor organs, and organ preservation

General considerations

Matching an appropriate donor organ with a liver transplant recipient requires compatibility of the ABO blood type but not the human leukocyte antigen (HLA) tissue type. The conventional recipient operation involves orthotopic transplantation of the donor organ (i.e., in the normal anatomical location). The procedure is conventionally divided into three phases: the hepatectomy phase (removal of the recipient native liver), the anhepatic phase, and the reperfusion phase (circulation of blood through the newly transplanted liver). The order of anastomoses usually commences with the venous revascularization of the donor organ (systemic and portal venous anastomoses) followed by arterial reconstruction, followed finally by biliary reconstruction. Numerous variations exist in the technique of implanting the donor organ, based on surgical preference, anatomical variations, and considerations imposed by recipient disease etiology [4]. Strategies for systemic venous reconstruction involve either caval replacement, which is applicable only in the setting of deceased donor liver transplantation, or the "piggyback" technique applicable for either deceased or living donor transplantation. When the cava is replaced, the suprahepatic and infrahepatic vena cava is clamped and the retrohepatic caval segment of the recipient is replaced with that of the

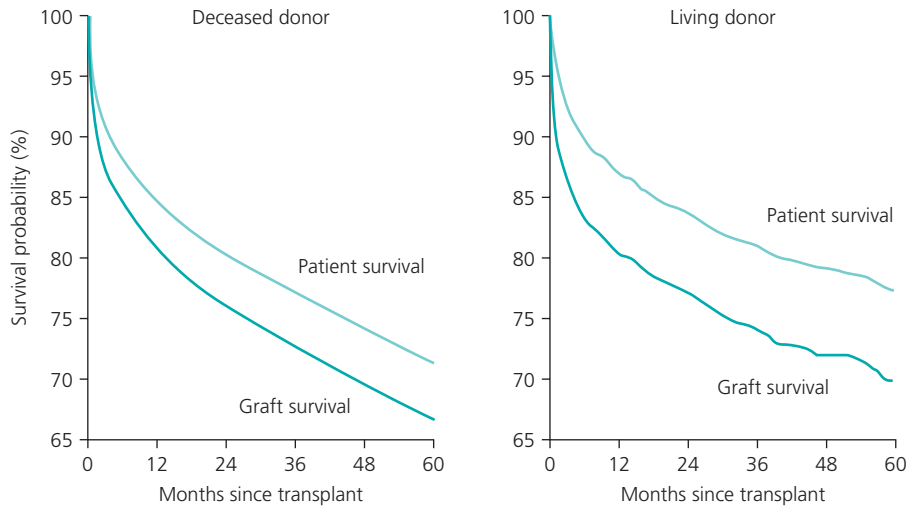

Figure 92.1 Unadjusted patient and graft survival for all deceased donor liver transplantation (DDLT) and living donor liver transplantation (LDLT) recipients In the United States between 1996 and 2005. Patient survival following DDLT was 93% at 3 months, 87% at 1 year, 79% at 3 years, and 73% at 5 years. The corresponding patient survival was slightly better for recipients of LDLT (96%, 92%, 83%, and 77%, respectively). A similar pattern is evident when analyzing graft survival. From the Scientific Registry of Transplant Recipients [352].

donor. Two systemic venous anastomoses are then performed to reestablish caval continuity. When the piggyback technique is used, additional dissection is performed to divide the small hepatic veins that enter the cava directly up to the main right, middle, and left hepatic veins to preserve the recipient's vena cava in situ. Then, the hepatic veins can be clamped with or without partial caval clamping and the anastomosis to the donor liver's suprahepatic cava or right hepatic vein (in the case of a right lobe living donor liver transplantation) is performed. Avoidance of full clamping of the inferior vena cava may decrease the risk of cardiovascular stress, hemodynamic instability, and venous hypertension of the kidneys during the anhepatic phase. Hepatic arterial reconstruction is commonly achieved with an end-to-end anastomosis of the donor celiac axis (with or without a Carrel patch of aorta) for deceased donor livers or the right hepatic artery for living donor livers to the recipient common, proper, or right hepatic artery. Vascular grafts extending from the recipient aorta are occasionally necessary if inflow at the level of the hepatic artery or the celiac axis is inadequate, most frequently as a result of vascular dissection. Typically, deceased donor iliac artery or recipient saphenous, gonadal, or jugular vein is used as the conduit. The usual approach to biliary reconstruction employs a duct-to-duct anastomosis (choledochocholedochostomy for deceased donor transplants or hepaticocholedochostomy for living donor transplants). Common exceptions include pediatric transplants, multiple donor ducts (as is frequent in living donor transplants), disease involving the recipient duct (primary sclerosing cholangitis, biliary atresia), and a large discrepancy in size between the recipient and donor ducts. In these cases, biliary reconstruction is performed with a Roux-en-Y limb of jejunum. To reduce the risk of hemodynamic instability and minimize congestion of the kidneys or bowel during the anhepatic phase, some centers employ venovenous bypass of the systemic circulation with or without the portal circulation [4].

The biggest challenge facing liver transplantation today is the insufficient supply of organs to meet the increasing demand. In response, liver transplant surgeons have aggressively expanded the frontiers of utilization for deceased donor organs and even traversed into the realm of living donors, both of which are discussed in greater detail below.

Deceased donor liver transplantation

The first incremental advance towards maximal use of deceased donor livers emerged in the early 1990s as an outgrowth of technical innovations spurred by the high mortality rate of pediatric liver transplant candidates. The relative shortage of size-matched organs for infants and toddlers considered together with the segmental anatomy of the liver inspired the development of reduced-size liver transplantation, the transplantation of portions of a liver appropriate for the age and size of the intended recipient [5,6]. The maturation of this technique led to the next innovation, split-liver transplantation whereby a single deceased donor liver was divided into two smaller, transplantable grafts [7–9]. Today, this technique is frequently applied to the transplantation of one adult and one pediatric recipient and occasionally applied to the transplantation of two adults [10,11].

In addition to incremental technical innovations, which have increased the number of available donor organs, there has been gradual expansion of the criteria for donor organs to be considered acceptable for transplantation. It has long been known that young, healthy people dying of trauma provide the ideal organs. Such ideal organs have already become the exception rather than the rule. Whole livers from donors between 18 and 40 years of age who have suffered brain death from trauma account for approximately one-third of transplants performed today [12]. Characteristics that exert the greatest negative impact on graft function and survival are increased donor age, split or partial liver transplantation, and donation after cardiac death. Compared to livers from donors younger than 40 years, livers from donors

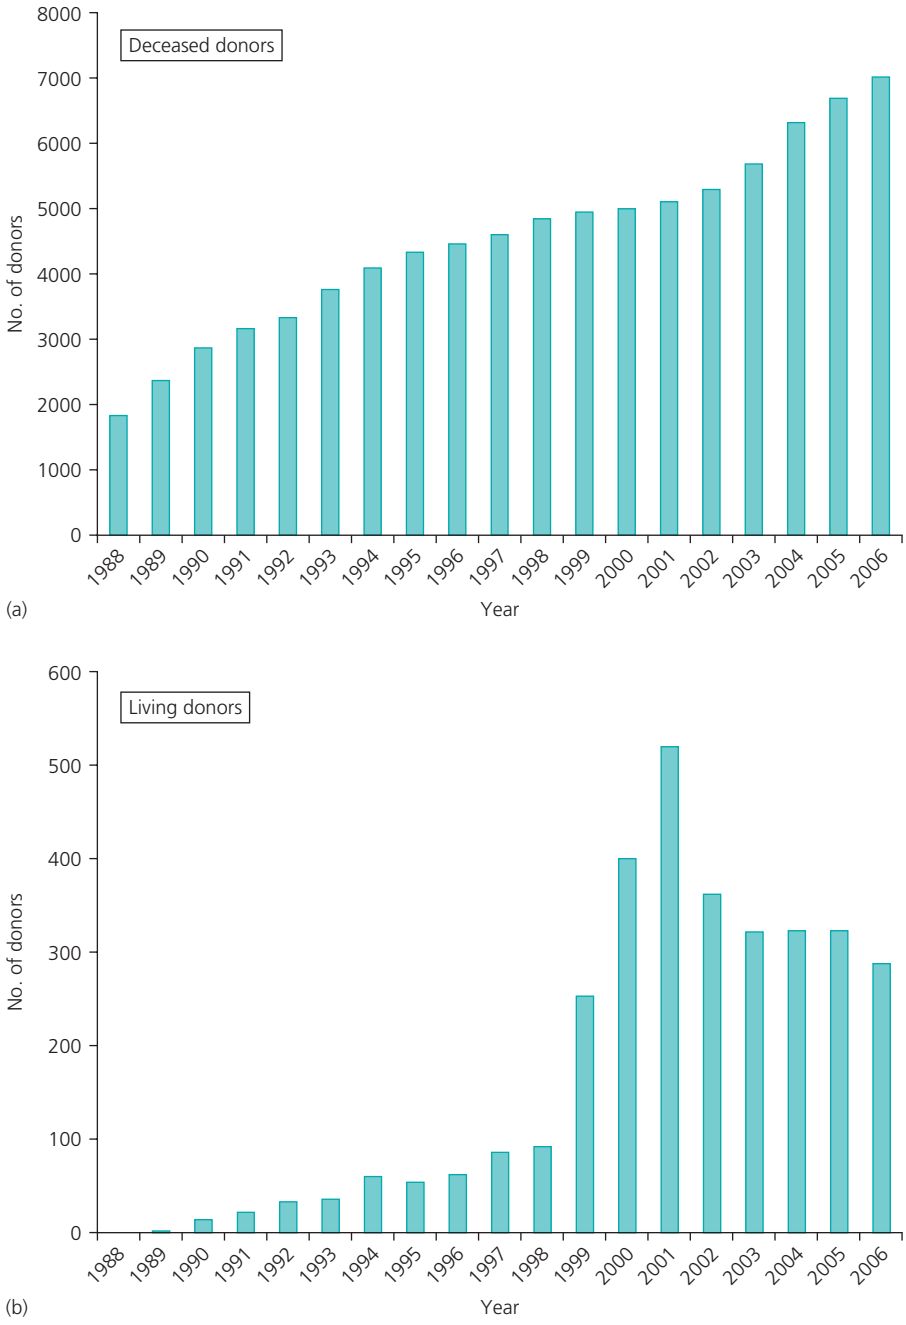

Figure 92.2 Donors recovered in the United States by year between 1988 and 2006. **(a)** Deceased donors; **(b)** living donors. Data from the Organ Procurement and Transplantation Network (OPTN).

aged between 60 and 69 years have a 49% increased risk of graft failure (95% confidence interval: 32%–68% increased risk) whereas livers from donors older than 70 years have an 88% increased risk of graft failure (95% confidence interval: 60%–121% increased risk) [12]. Interestingly, the deleterious effect of increased donor age on transplant outcomes is not uniformly exerted but is differentially exerted on recipients based on disease etiology, affecting those with hepatitis C the most and those with hepatitis B the least [13]. Split/partial livers and livers donated after cardiac death are both associated with approximately a 50% increased risk for graft loss compared to whole livers and livers donated after brain death, respectively [12]. The number of split liver transplants increased over 10-fold during the late 1990s (from 8 in 1995 to 95 in 2000) but this rate of increase has since leveled out. The requirements for relatively ideal donors, a high level of technical expertise, and both a pediatric and an adult recipient suggest that the volume will remain relatively stable. In contrast, the steeply increasing trend of liver utilization from donation after cardiac death is anticipated to continue [8]. The Institute of Medicine has concluded that donation after cardiac death is an ethically proper approach to recovering

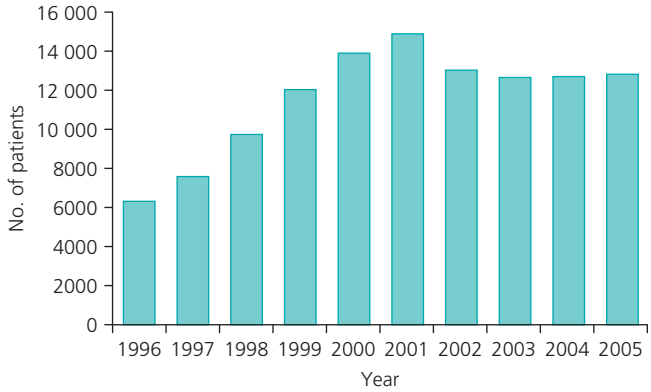

Figure 92.3 Number of patients on the active liver waiting list, 1996–2005. From the Scientific Registry of Transplant Recipients [352].

organs from a deceased patient for the purpose of transplantation [14]. Donation after cardiac death can occur when family member(s) or surrogate decides to withdraw life support (typically by extubation) from someone who has suffered devastating neurological injury but does not meet the criteria for brain death. After determination of death according to circulatory criteria, organ donation proceeds as determined by the wishes of the family member(s) or surrogate [14,15]. The time period between withdrawal of life support and circulatory death engenders a variable amount of warm ischemic injury, which is compounded by additional warm ischemic injury during the time period between circulatory death and initiation of organ preservation. This injury, which does not occur with donation after brain death, is largely responsible for the increased risk of short- and long-term graft failure associated with liver transplantation using organs donated after cardiac death [12,14,15].

Organ preservation

A major advance in the preservation of donor organ viability and extension of the geographic distance over which organs can be procured and transported was the development of the University of Wisconsin (UW) cold-storage solution with which the donor organ is flushed and cooled prior to removal and transportation [16]. The UW solution has extended the cold ischemia time for liver preservation for up to 24 h, although it is uncommon for organs that have been preserved for longer than 16 h to be used on a routine basis. Key principles of the UW solution are a high K^+ and Mg^{2+} and low Na^+ and Ca^{2+}. This solution maintains intracellular ion concentrations, using adenosine as a substrate for adenosine triphosphate synthesis, hydroxyethyl starch as an oncotic solute to reduce interstitial edema, and allopurinol and glutathione as antioxidants.

An alternative preservation solution has been developed called Histidine-Thym-K (HTK) solution. This is a crystalloid solution with much lower viscosity than UW solution that, in theory, may result in improved perfusion through the hepatic microcirculation and thereby improve biliary tract preservation. Several centers have reported their experience using this new preservation solution and shown no significant functional advantage in patient or graft survival or biliary tract complications over traditional solutions [17,18].

Living donor liver transplantation

Living donor liver transplantation represents incremental technical innovations that have expanded the organ pool. Like the split or partial deceased donor transplantation discussed above, living donor transplantation was an outgrowth of reduced liver transplantation. The strategy was first developed in the early 1990s for pediatric candidates whereby typically, the left lateral segment (Couinaud segments 2 and 3) or the left lobe was procured from a blood-type-compatible parent. The strategy was then adapted to adult candidates in the late 1990s using the right lobe, which typically represents approximately 60% of the entire liver mass [7,8,19] (Fig. 92.4).

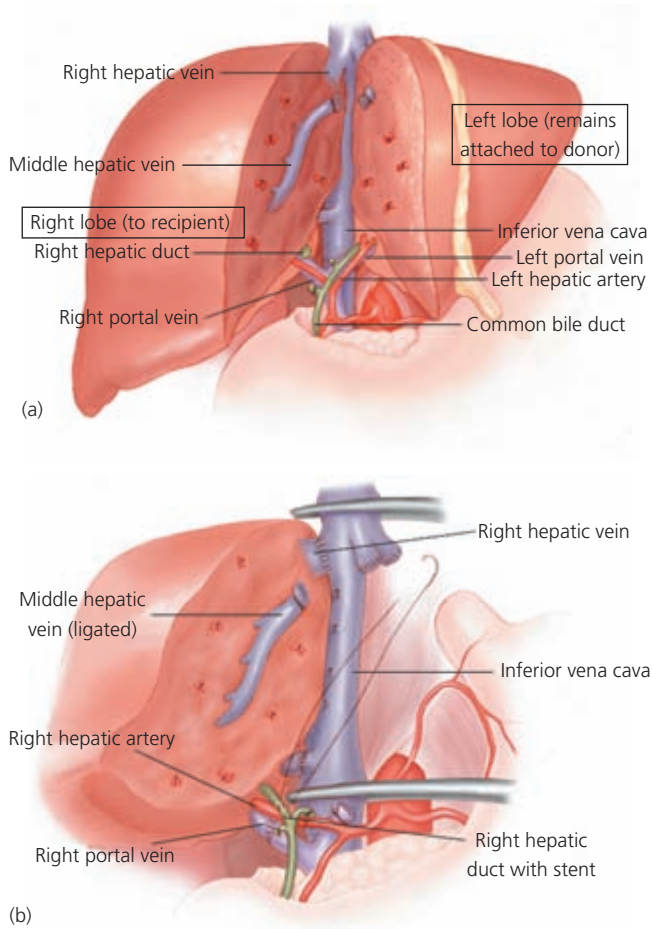

Figure 92.4 Illustration of technique of living donor liver transplantation. **(a)** Right donor hepatic lobectomy; **(b)** right lobe implantation into recipient. Courtesy of John P. Roberts, MD, Department of Surgery, University of California, San Francisco, CA.

In both the donor and the recipient, there is rapid regeneration of the liver. While the recipient appears to achieve the anticipated liver mass within 6–8 weeks, the donor may not regenerate fully even after a full year [19–21].

From the candidate's perspective, the primary advantage of living-related liver transplantation is the assurance of a transplant opportunity at an elective time point in the course of progressive liver disease. The primary disadvantage of living-related liver transplantation is the increased rate of vascular and biliary complications. Hepatic artery thrombosis, portal vein thrombosis, and especially biliary leaks and strictures occur at significantly increased frequency compared to deceased donor liver transplantation [22–27]. From the donor's perspective, there is the risk of not only morbidity but also mortality with donor hepatectomy [28–31]. It is generally acknowledged that the risk of left lateral segmentectomy is less than that of right hepatectomy, although the full and accurate extent of risk is undetermined because both the numerator and the denominator are not precisely known [20,32,33]. To date, the surgical mortality risk is estimated at 0.1% for left lateral segment donation and may approach 0.5% for right lobe donation [32]. There have been several position papers presenting the ethics and surgical techniques of adult-to-adult, living donor liver transplantation and practice guidelines have been established at both national and international consensus conferences [8,32,33].

Indications for liver transplantation

Prognostic models for liver failure and non-disease-specific complications

Liver transplantation should be considered for patients with cirrhosis when one or more signs of hepatic decompensation develop. In a study from Barcelona [34], the probability of decompensation was 58% at 10 years after the diagnosis of cirrhosis. Ascites was the most common manifestation of hepatic decompensation, followed by jaundice, hepatic encephalopathy, and variceal bleeding. The median survival with compensated cirrhosis was 8.9 years, compared to only 1.6 years for decompensated cirrhosis [34].

The Child–Turcotte–Pugh (CTP) scoring system [35] has been used for several decades to determine prognosis for patients with advanced chronic liver failure from a wide spectrum of liver diseases [36]. This scoring system is based on five variables:

- stage of encephalopathy
- severity of ascites
- serum bilirubin level
- serum albumin level
- international normalized ratio (INR) for prothrombin time.

A CTP score of 7 was determined to be the minimum criterion for listing for cadaveric liver transplantation in the past [37], but this requirement is no longer necessary. This system was also previously employed by the United Network for Organ Sharing (UNOS) to determine priority for organ allocation [38], but it lacks objectivity in assessing the severity of encephalopathy and ascites. In 2002, this system was replaced by the MELD system for determining the priority for receiving a cadaveric organ among liver transplant candidates.

Model for End-stage Liver Disease (MELD)

The MELD prognostic score was developed using a formula based on serum creatinine, serum bilirubin, and INR for prothrombin time to predict short-term mortality for patients with end-stage chronic liver disease (Table 92.1). This model was based on multivariate analysis of readily and objectively measurable variables that was originally developed to assess the short-term prognosis of patients with cirrhosis undergoing the transjugular intrahepatic portosystemic shunt (TIPS) procedure [39]. The MELD scoring system was subsequently shown to be also useful in grading the risk of death at 1 week, 3 months, and 1 year for patients with end-stage chronic liver disease (Table 92.1) [40]. The MELD score was implemented by UNOS in 2002 as a disease severity index to determine priority for organ allocation [41], replacing the previous system based on the CTP score and other specific clinical criteria [38].

Using the MELD, the patient with the highest score (range 6–40) – reflecting the greatest risk for short-term mortality – will receive a liver transplant first, and the length of waiting time will be a minimal factor in determining organ allocation [41]. It has been shown in one study that the survival advantage of liver transplantation increases with increasing MELD score, and is only evident when the recipient MELD score exceeds 15 at the time of liver transplantation [42]. In this

Table 92.1 The Model for End-stage Liver Disease (MELD) scoring system determining disease severity and priority for organ allocation: 3-month mortality acccording to the MELD score[a]

	MELD score				
	≤ 9	10–19	20–29	30–39	≥ 40
Hospitalized patients with cirrhosis	4% (6/148)	27% (28/103)	76% (16/21)	83% (5/6)	100% (4/4)
Outpatients with cirrhosis	2% (5/213)	6% (14/248)	50% (15/30)	–	–

a Data from Wiesner et al. [41]
MELD risk score[b] = 10 × (0.957 × log e [creatinine mg/dL] + 0.378 × log e [bilirubin mg/dL] + 1.120 × log e [INR]) + 6.43.
Current calculation of a MELD score uses a minimum value for the creatinine of 1.0 mg/dL, bilirubin of 1.0 mg/dL, and INR of 1.0.
A maximum value of 4.0 mg/dL applies to creatinine. The scores are rounded to the nearest whole number with a score range of 6 (minimum) to 40 (maximum).
The MELD calculator is available from the Internet: http://www.thedrugmonitor.com/meld.html

study, patients with a lower MELD score, below 15, have a greater likelihood of being alive on the waiting list without liver transplantation than surviving the first year after liver transplantation [42]. Since 2005, UNOS policy also requires that donor livers be allocated to local candidates with MELD scores less than 15 only if there are no regional candidates with MELD scores of 15 or more. Patients with fulminant liver failure, who are at greatest risk for short-term mortality, are classified in a separate category and listed at the highest priority (status 1).

Ascites and related complications

Approximately 50% of patients with cirrhotic ascites succumb in 2 years [43]. Up to 10% of patients with cirrhotic ascites are refractory to standard diuretic therapy. Treatment options for refractory ascites include serial therapeutic paracentesis, peritoneal venous shunt, and TIPS [44]. Survival for patients with refractory ascites is only about 25%–50% at 1 year regardless of the type of treatment they have received [44–48]. Ascites may be associated with spontaneous bacterial peritonitis and hepatorenal syndrome, both of which further shorten survival. The 1-year probability of survival was reported in one study to be 66% for patients with cirrhosis and ascites without spontaneous bacterial peritonitis, compared to only 38% for patients with this complication [49]. In one-third of patients with spontaneous bacterial peritonitis, renal impairment develops despite treatment of the infection [50,51]. The use of intravenous albumin has been shown to be of benefit in improving renal impairment in patients with spontaneous bacterial peritonitis [51]. The use of midodrine and subcutaneous octreotide may lead to improvement of hepatorenal syndrome in patients with end-stage liver disease [44,52].

Portal hypertensive bleeding

Bleeding from esophageal or gastric varices carries a high 30-day mortality ranging from 30% to 50%, and the risk of recurrent variceal bleeding is about 60%–70% within 2 years of the index hemorrhage [53]. Better understanding of the basic pathophysiology of portal hypertension and bleeding has led, in addition to endoscopic therapy, to important advances in pharmacological therapy including beta-blockade for primary and secondary prophylaxis of variceal bleeding, and somatostatin for the initial control of hemorrhage [53].

A major advance in the treatment of variceal bleeding is the use of TIPS, which has a more than 90% technical success rate in experienced hands [54,55]. Compared to endoscopic treatments, TIPS confers a lower rate of rebleeding but no survival advantage [53,56,57]. The current accepted indications for TIPS include emergency (rescue or salvage) therapy for uncontrolled, acute portal hypertensive bleeding and prevention of recurrent portal hypertensive bleeding for which endoscopic or pharmacological therapy has either failed or cannot be applied [57]. Severe hyperbilirubinemia occurring after the creation of TIPS is a sign of rapid hepatic decompensation, associated with a particularly ominous short-term prognosis [58]. Encephalopathy develops in about 30% of patients after TIPS and is usually reversible with medical therapy [53].

A major problem with TIPS is the high incidence of shunt stenosis or occlusion, estimated to be 30% over the first year and 50% at 2 years [59]. TIPS has not been shown in a study from the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Liver Transplant Database to have any significant impact on liver transplantation in terms of total operative time, blood product requirements, survival or length of hospital stay [60]. Consequently, preoperative portal decompression solely for facilitating liver transplantation is not an acceptable indication for TIPS. Occasionally, TIPS also creates technical difficulties for liver transplantation secondary to stent migration or extension into the extrahepatic portal or hepatic vein [57].

Portosystemic shunt surgery provides more definitive control of bleeding compared to sclerotherapy [53,61,62] or TIPS [63] in patients with adequate hepatic function to tolerate surgery, but does not improve survival and is also associated with an increased incidence of encephalopathy. Mesocaval or splenorenal shunts are the preferred surgical approaches in consideration for future liver transplantation because the hepatic hilum is avoided.

Hepatic encephalopathy

Hepatic encephalopathy is a complex neuropsychiatric syndrome that may be present in 50%–70% of all patients with cirrhosis, including those with subtle abnormalities only demonstrable by psychometric testing [64]. Hepatic encephalopathy is aggravated by portosystemic shunting by way of collaterals secondary to portal hypertension, and is also associated with surgical portosystemic venous shunting and the creation of TIPS [53]. Nonabsorbable disaccharides such as lactulose, and antibiotics including neomycin and rifaximin with activities against urease-producing bacteria are effective in reversing hepatic encephalopathy. The efficacy of lactulose and neomycin in the treatment of hepatic encephalopathy appears to be equal. Rifaximin, a nonabsorbed oral antibiotic used in the treatment of traveler's diarrhea, provides an effective, safe alternative for the treatment of hepatic encephalopathy [65]. Symptomatic hepatic encephalopathy is an indication for consideration of liver transplantation. Uncommonly, some patients with hepatic encephalopathy have progressive, debilitating neurological or neuropsychiatric syndromes such as dementia, spastic paraparesis, cerebellar degeneration, and extrapyramidal movement disorders, associated with structural abnormalities of the central nervous system [64]. If very advanced, neurological injury may not be reversible with liver transplantation, although one report has suggested that there may be gradual improvement after liver transplantation [66].

Quality-of-life issues

Encephalopathy, ascites, and debilitating fatigue are some of the common manifestations of end-stage liver disease that markedly impair a patient's quality of life. Even subclinical hepatic encephalopathy, determined only by psychometric analysis, can cause significant impairment of daily functioning [67,68]. Liver transplantation improves quality of life, and facilitates a return to gainful employment in over half of patients [69–71]. However, improving the quality of life of a patient should not be the sole indication for liver transplantation in the absence of advanced liver disease evidenced in a MELD score of 15 and CTP score of 7.

Disease-specific issues and outcome after liver transplantation

More than 60 distinct diseases have been treated with liver transplantation [72]. Hepatitis-C-related cirrhosis is the most common indication for liver transplantation in the United States, accounting for close to 50% of all liver transplants. The guidelines for liver transplantation, special considerations, the controversial aspects of certain disease indications, and posttransplant outcome for specific types of liver disease are selectively reviewed (Table 92.2). Many of the less common types of liver disease will not be discussed in detail in this Chapter.

Table 92.2 Summary of disease-specific guidelines for liver transplantation

Liver disease	Guidelines for liver transplantation and pretransplant issues	Special considerations
Alcoholic liver disease	• Abstinence ≥ 6 months • Favorable assessment by substance-abuse professional • Acceptance by center evaluation committee • Appropriate medical indications for liver transplantation	• Lack of reliable predictors for recidivism • Reduced long-term graft survival if return to abusive alcohol consumption
Hepatitis B virus	Suppression of HBV DNA before liver transplantation with nucleoside/nucleotide analogues reduces risk for posttransplant recurrence and may improve liver function	• HBIG prophylaxis effective but expensive • Combination of HBIG and lamivudine or other antivirals now standard prophylaxis • Potential role of low-dose HBIG or short-term HBIG + antiviral in low-risk patients
Hepatitis C virus	Suppression of HCV RNA with antiviral therapy before liver transplantation in selected patients (LADR)	• High rates of recurrence despite favorable medium-term survival • Suboptimal response and poor tolerance to interferon and ribaviron after transplant • Adverse impact of recurrent HCV on graft survival ≥ 5 years
Hepatocellular carcinoma	Milan criteria for liver transplantation: • single lesion ≤ 5 cm • fewer than three lesions each ≤ 3 cm	• Improved recurrence-free survival using the Milan criteria • Impact of MELD organ allocation on waiting time and dropout • Potential role for expansion of Milan criteria and down-staging
Hemochromatosis	Cardiac dysfunction due to iron overload should preclude liver transplantation	• Reduced survival after liver transplantation due to cardiac and infectious complications • Early diagnosis and phlebotomy
Wilson disease	List status 1 for acute Wilson disease with fulminant liver failure	Neuropsychiatric manifestations may not reverse after liver transplantation
PBC/PSC		• The groups with the best survival after liver transplantation • Increased risk of cholangiocarcinoma in PSC • Recurrent PBC and PSC in about 20%, generally mild disease
Fulminant hepatic failure	• List for liver transplantation (status 1) when stage 2 encephalopathy • King's College and other prognostic criteria to help predict need for liver transplantation	• Cerebral edema and sepsis as major causes of death • ICP monitoring for advanced stage encephalopathy • Sustained cerebral perfusion pressure (MAP – ICP) < 40 mmHg precludes liver transplantation

HBIG, hepatitis B immunoglobulin; HBV, hepatitis B virus; HCV, hepatitis C virus; ICP, intracranial pressure; MAP, mean arterial pressure; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

Alcoholic liver disease

Once considered a highly controversial indication for liver transplantation on both medical [73] and ethical [74] grounds, alcoholic liver disease is second only to hepatitis C as the leading indication for liver transplantation, accounting for up to 20% of all cases [75]. Early reports have suggested that survival at 5 years following liver transplantation for alcoholic liver disease is at least as good as for most other indications [75,76]. The obvious concern, however, is the possibility of returning to alcohol consumption after liver transplantation. Long-term follow-up data have emerged showing a significant adverse impact of alcohol recidivism on long-term patient survival at 10 years after liver transplantation [77,78], especially among patients who returned to abusive drinking [77]. There are insufficient data to fully understand the impact of modest alcohol consumption after liver transplantation, and the extent and pattern of graft injury. Nevertheless, the patient transplanted for alcoholic liver disease who drinks again creates a highly emotional and demoralizing issue and is often perceived as a treatment failure, even though the absolute alcohol intake may be low and graft function normal. The reported incidence of recidivism following liver transplantation has typically been about 20%, but the definition of recidivism varies widely in these studies [75,79]. In a recent prospective observational study using structured interviews and a standardized Alcohol Abuse and Alcoholism quantity–frequency questionnaire [80], 42% of patients transplanted for alcoholic liver disease admitted to using alcohol at least once following liver transplantation, and over 20% had returned to abusive drinking. Better insight into patient selection, closer monitoring, and ongoing counseling for these patients after liver transplantation are therefore needed.

There is a strong consensus based on a survey of liver transplant centers and a National Institutes of Health workshop to require an established period of abstinence, typically 6 months, before approval for listing for liver transplantation [81,82]. The required period of abstinence is useful because abstinence alone can often lead to sustained clinical improvement, thereby obviating the need for liver transplantation. Although some studies have reported a significant correlation between a short duration of alcohol abstinence of less than 6 months and the risk of recidivism [77,83], the 6-month rule for alcohol abstinence as a predictor of long-term sobriety remains controversial [84], and should be used in conjunction with other psychosocial and psychiatric parameters in the patient selection process [85]. In most transplant centers, the current criteria for liver transplantation in patients with alcoholic liver disease include:

- alcohol abstinence of at least 6 months
- favorable assessment by a substance abuse professional
- approval by the transplant center evaluation committee
- fulfillment of the medical criteria to be listed for liver transplantation.

Hepatitis B

In the late 1980s and early 1990s, liver transplantation for patients with cirrhosis as a result of chronic hepatitis B infection was considered a relative contraindication because of the high rates of hepatitis B recurrence and graft failure. The most aggressive form of hepatitis B recurrence, known as fibrosing cholestatic hepatitis, often leads to death within weeks of onset of graft reinfection [86]. Subsequently, the use of high-dose intravenous hepatitis B immunoglobulin (HBIG) after liver transplantation to maintain hepatitis B surface antibody titer above 100 IU/L has significantly reduced the incidence of hepatitis B recurrence and improved survival [87–90]. Patient and graft survival in patients undergoing liver transplantation for hepatitis B are comparable to that in patients transplanted for other nonmalignant liver disease [91,92]. The benefit of HBIG appears to be greatest among patients with negative hepatitis B DNA and hepatitis B e-antigen before liver transplantation [87]. Despite excellent graft and patient survival, hepatitis B recurrence still occurs in 6%–52% of patients who receive intravenous HBIG prophylaxis after liver transplantation [93]. Graft reinfection despite HBIG prophylaxis may be caused by inadequate neutralization because of overwhelming amounts of hepatitis B virus replication or breakthrough infection by hepatitis B surface antigen protein escape mutants [94,95]. Another concern of intravenous HBIG is its high cost, estimated to be $30 000–$50 000 in the United States during the first year of therapy after liver transplantation.

Another major advance in the treatment of hepatitis B infection in the past decade is the development of oral nucleoside and nucleotide analogues. Four of these antiviral agents, lamivudine, adefovir, entecavir, and telbivudine, have been approved by the Food and Drug Administration for the treatment of hepatitis B virus infection in the United States. In contrast to interferon-α, these antiviral agents appear to be safe and well tolerated in patients with advanced decompensated cirrhosis caused by chronic hepatitis B [96–99]. The primary goal of treatment is to suppress virus replication to achieve undetectable hepatitis B DNA before liver transplantation, thereby lowering the risk for posttransplant hepatitis B recurrence [91]. In some patients with decompensated cirrhosis due to hepatitis B virus infection, treatment with lamivudine has been shown to improve or stabilize liver function to the extent of delaying or even preventing liver transplantation [73–76]. An important concern of long-term use of lamivudine beyond 6–9 months, regardless of the clinical setting, is the high rate of emergence of lamivudine-resistant mutant virus (YMDD mutant). Newer agents such as adefovir and entecavir with a lower incidence of drug recurrence are preferable to lamivudine in the treatment of hepatitis-B-related decompensated cirrhosis. Although data are limited, combination therapy with agents such as lamivudine plus adefovir may be the best approach in patients with decompensated cirrhosis to maintain sustained virological

suppression and minimize the risk for drug resistance, which can precipitate acute deterioration of liver function. Combination therapy is particularly prudent in patients with a history of lamivudine resistance [91,100].

Currently, the combination of HBIG plus lamivudine or another nucleoside/nucleotide analogue is the most commonly used prophylactic regimen for patients infected with hepatitis B virus [91]. The use of lamivudine alone without HBIG is associated with a high reinfection rate of 22%–50% at 3 years after liver transplantation as a result of the selection of resistant mutants [101–103]. In low-risk patients with undetectable hepatitis B DNA at the time of liver transplantation, HBIG can be safely discontinued after short-term use (usually 12 months) following liver transplantation, with continued long-term antiviral therapy [104]. High-risk patients, including those with a high level of hepatitis B DNA without antiviral therapy or those with virological breakthrough or persistent viremia despite antiviral therapy, would likely require indefinite HBIG and maintenance antiviral therapy [91].

The use of a lower dosage of intramuscular HBIG in combination with lamivudine has also been evaluated as a cost-saving strategy in small pilot studies, with promising results in terms of the risk for hepatitis B recurrence [105,106]. Recently, the Australia and New Zealand group reported impressive results using a low dosage (400–800 IU/month) of intramuscular HBIG plus lamivudine in 147 patients with hepatitis B infection after liver transplantation [107]. The 5-year patient survival rate was 88%, and the actuarial risk of hepatitis B recurrence was only 4% at 5 years. The baseline hepatitis B DNA level was associated with hepatitis B recurrence. This strategy of low-dose HBIG given intramuscularly plus lamivudine appears to be highly effective and cost saving and should be further validated. More studies are also needed to evaluate the efficacy of newer antiviral agents in combination with HBIG as well as a combination of two antiviral agents in the prophylaxis of hepatitis B virus infection after liver transplantation.

Active immunization using standard or high-dose conventional hepatitis B vaccines to replace HBIG has been investigated as a potential strategy to prevent graft reinfection [108,109]. An earlier report showed encouraging results in selected patients at low risk of hepatitis B recurrence (negative hepatitis B DNA at the time of liver transplantation) who had been given HBIG prophylaxis for at least 18 months before receiving a series of three double doses of conventional recombinant hepatitis B vaccine. Fourteen of 17 patients (82%) developed a protective hepatitis B surface antibody titer of more than 10 IU/cm^3 [85]. However, subsequent studies reported low efficacy of this strategy with a response rate of less than 10% [91,109]. Consequently, active immunization should not be used in posttransplant patients as a means of preventing recurrent hepatitis B infection outside clinical trials.

Hepatitis C

Hepatitis C is the leading indication for liver transplantation in the United States and in Europe. The major problem concerning these transplant recipients is the high rate of graft reinfection with hepatitis C virus which occurs almost universally in these recipients, with histological evidence of hepatitis developing in about 40%–60% of patients at a median of 4–6 months after liver transplantation [91,110,111]. It is also increasingly evident that the course of posttransplant recurrent hepatitis C is more rapid when compared with that before liver transplantation. Between 10% and 40% of patients with recurrent hepatitis C virus infection progress to cirrhosis within the first 5 years after liver transplantation, and the median rate of fibrosis is estimated to be between 0.3 and 0.6 stages per year [110–113]. Some studies have reported that graft survival at or beyond 5 years following liver transplantation is reduced compared to patients without hepatitis C infection [114]. A severe form of recurrence, resembling the syndrome of fibrosing cholestatic hepatitis in patients infected with hepatitis B virus, has also been reported with recurrent hepatitis C [115]. Factors predictive of more severe recurrent disease and worse outcome after liver transplantation have not been fully elucidated, but those most consistently linked with more severe recurrent disease include older donor age [113,116–118], and treatment of acute rejection with OKT3 (Muromonab-CD3) or corticosteroid boluses [110,119–123]. Cytomegalovirus (CMV) infection has also been associated with more severe recurrent hepatitis C infection [124,125]. Other viral factors, including a high pretransplant hepatitis C RNA titer (at least 10^6 Eq/mL) [126] and genotype 1b [88,127], have also been suggested to correlate with more severe recurrent infection. Other studies, however, have not supported this association [128]. The type of calcineurin inhibitors in the immunosuppression regimen (cyclosporine [ciclosporin rINN] vs tacrolimus) does not appear to have any significant impact on the incidence or severity of hepatitis C recurrence [129]. The impact of mycophenolate mofetil on hepatitis C recurrence is also unclear. Additional studies are needed to further evaluate the impact of different immunosuppressive regimens as well as the use of new immunosuppressive agents on the course of recurrent hepatitis C.

The most common approach to the management of recurrent hepatitis C virus infection is to initiate antiviral therapy when there is histological evidence of recurrent disease [91,110,130]. Considerable variation exists among liver transplant centers in terms of the threshold for the disease severity according to the stage of fibrosis before treatment is initiated, in part because of the suboptimal treatment response rate and the significant side effects of treatment. The recommendation from an International Liver Transplantation Society Expert Panel Consensus Conference is to initiate treatment for patients with stage II fibrosis [112]. Combination therapy with pegylated interferon-α and ribavirin is the standard

treatment for hepatitis C in both the transplant and the nontransplant populations. A number of studies using standard interferon-α or pegylated interferon-α plus ribavirin for recurrent hepatitis C after liver transplantation, including two randomized controlled trials [131,132], have shown a sustained virological response rate of 12%–35% after about 48 weeks of therapy [131–136]. Poor patient tolerance and the effects of immunosuppression are important factors contributing to the suboptimal response in this population. Factors contributing to poor patient tolerance include renal insufficiency, anemia, and thrombocytopenia commonly observed in these patients especially in the early posttransplant period. The dosage of ribavirin used in these patients is typically less than that used in the nontransplant setting, in large part because of the anemia and reduced glomerular filtration rate associated with either cyclosporine or tacrolimus. Most patients require the support of growth factors, including erythropoietin and granulocyte colony-stimulating factor, during treatment.

Another approach that has been evaluated in several studies is preemptive therapy initiated between 2 and 8 weeks following liver transplantation [132,137,138]. The sustained response rate does not appear to be clearly better than that achieved with the administration of treatment later in the course when histological recurrence is established [130,137,138]. Furthermore, factors contributing to poor patient tolerance and the need for dose reductions, which include pancytopenia, anemia, and renal insufficiency, are often encountered with higher frequency and severity in the early postoperative period. Consequently, most experts do not recommend preemptive therapy [91,130]. Although interferon-α treatment has been suggested to cause acute rejection in the liver graft, the incidence and risk of this association have not been clearly defined [139]. In randomized controlled studies of interferon treatment compared with no treatment for recurrent hepatitis C [131,132], the incidence of acute rejection did not appear to be significantly higher in the treated group than in the control group.

The magnitude of the problem with recurrent hepatitis C infection following liver transplantation has led to a number of strategies being investigated in the hope of reducing the risk of graft reinfection. The University of Colorado group reported the use of a low, accelerating dose regimen (LADR) of interferon and ribavirin for patients with mildly decompensated cirrhosis due to hepatitis C awaiting liver transplantation in an attempt to achieve virological clearance before transplant [140]. The overall sustained virological response rate was 22%, and was much higher in patients with genotype 2 or 3 than in patients with genotype 1 (60% vs 11%, respectively). Sustained virological response to treatment before liver transplantation also correlated with absence of recurrent hepatitis C after transplantation. This strategy should only be considered in patients with mildly decompensated cirrhosis (Child's A and B) who are listed and ready for liver transplantation in the event of hepatic decompensation after treatment. A high rate of serious adverse events with this combination therapy has been reported in those patients infected with hepatitis C virus who have more advanced liver failure and are awaiting liver transplantation [141]. A randomized controlled study from the Adult-to-Adult Living Donor Liver Transplant Consortium (A2ALL) in the United States is in progress to determine the benefit of pegylated interferon and ribavirin therapy for patients with hepatitis C genotype 1 infection who are awaiting liver transplantation.

With the success of HBIG in the prophylaxis of hepatitis B virus infection after liver transplantation, several groups have examined the safety and efficacy of hepatitis C immunoglobulin (HCIG) to prevent hepatitis C reinfection [91]. However, a randomized controlled study did not show a significant benefit of HCIG in reducing the hepatitis C RNA level when compared to no treatment [142].

Transplantation of a hepatitis C-positive donor liver into a recipient with hepatitis C cirrhosis does not appear to result in a worse outcome in the initial years after liver transplantation [143], and may prove to be an important strategy for expanding the donor pool for liver transplantation. Whether patients infected with hepatitis C virus have worse results after living donor transplantation than after deceased donor liver transplantation remains highly controversial. In an analysis of the UNOS database comparing 279 living donor transplant recipients with 3955 deceased donor transplant recipients, the short-term graft survivals at 1 and 2 years appeared to be equal in the two groups [144]. According to the A2ALL study [145], the overall 3-year graft survival, but not patient survival, was significantly lower for live donor transplantation compared with cadaveric liver transplantation. However, the difference in graft survival between the two groups was limited to the first 20 live donor transplantation operations at each center, suggesting that limited experience and technical complications during the learning phase of live donor transplantation might have a significant contribution to the unfavorable outcome.

Hepatocellular carcinoma

Liver transplantation for hepatocellular carcinoma (HCC) in unselected patients, including those with extensive and bulky tumors, was associated with dismal outcome, primarily because of aggressive tumor recurrence [146]. The observation that small incidental tumors have no adverse impact on posttransplant survival compared to no tumors has shaped the development of restrictive tumor criteria to limit the risks for tumor recurrence after liver transplantation [146]. In the seminal study by Mazzaferro and colleagues from Milan, Italy [147], 35 patients who met the specific criteria of a solitary tumor not exceeding 5 cm or no more than three tumor nodules, none greater than 3 cm (Milan criteria) had excellent overall and recurrence-free survival rates of 85% and 92%, respectively, at 4 years after liver transplantation.

These criteria have been subsequently validated in a number of studies, showing overall 5-year patient survival rates to be consistently 70% or better [148]. The Milan criteria [147] have been incorporated into the UNOS modified staging classification for HCC [149] as T1 (one lesion 1.9 cm) and T2 (one lesion 2–5 cm, or two or three lesions all 3 cm). The adoption of the Milan criteria as selection guidelines for liver transplantation in the United States was largely responsible for the steady improvement in posttransplant survival in recent years according to UNOS data [150]. Currently, under the MELD system of organ allocation, HCC accounts for about 10% of all transplants in the United States [3], and this number roughly equals that for cholestatic liver disease (Fig. 92.5). Factors predicting recurrence of HCC after OLT have been evaluated in many published reports. The most consistently shown factors correlating with HCC recurrence include tumor stage based on size and number [147,151–153], vascular invasion [153–157], poorly differentiated histological grade [154–156], and high preoperative α-fetoprotein [152,153,155,157].

Despite excellent survival after liver transplantation for selected patients with HCC, tumor growth in the face of increased waiting time for liver transplantation in the United States presents a considerable challenge, as eventually, acceptable criteria for liver transplantation may be exceeded. As a result of the high dropout rate related to tumor growth in patients on the waiting list [158], the current MELD system for organ allocation is adjusted to give higher priority to patients with HCC who are at increased risk for exclusion based on tumor characteristics [159]. This system is designed to reduce the waiting time, and so the rate of dropout from the waiting list. When the HCC-adjusted MELD system of organ allocation was first implemented in 2002, there was an initial overestimation of the rate of dropout from the waiting list. Consequently, the adjusted MELD scores for these patients have been downgraded several times since then. Following the latest modification, only patients with T2 HCC are eligible for priority listing starting with a MELD score of 22. These patients are also eligible for upgrade of the priority score for every 3 months on the waiting list [149]. Patient with T1 HCC (single tumor mass < 2 cm in diameter) are no longer eligible for priority listing for liver transplantation because these patients are at low risk of dropout from the waiting list [158], and there is also a high rate of false radiological diagnosis with no tumor in the liver explant in patients with presumed T1 HCC undergoing liver transplantation [160].

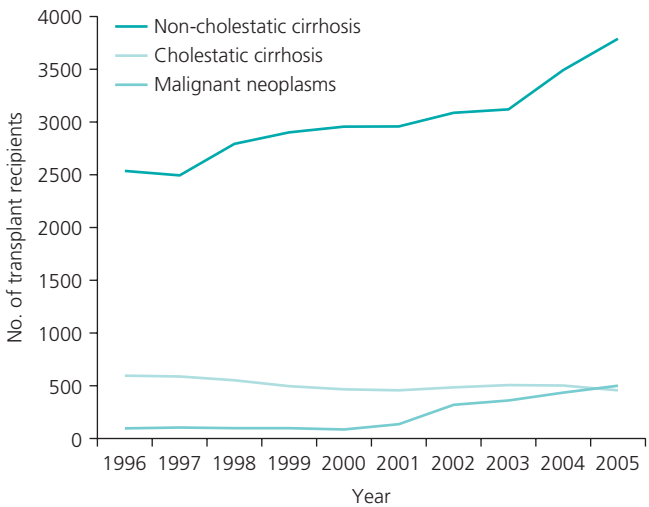

Figure 92.5 Liver transplantation in the United States according to major primary diagnosis. Noncholestatic cirrhosis includes viral hepatitis C and B, alcoholic and cryptogenic cirrhosis. Cholestatic liver disease/cirrhosis includes primary biliary cirrhosis and primary sclerosing cholangitis (but not biliary atresia). Malignant neoplasms are comprised mainly of hepatocellular carcinoma. Data from the Scientific Registry of Transplant Recipients [352].

To control tumor growth while waiting for a suitable organ, many liver transplant centers routinely use locoregional therapies, including chemoembolization, percutaneous ethanol injection, and radiofrequency ablation, as "bridging" procedures to liver transplantation [146]. However, the benefits of these procedures in reducing the rate of dropout from the waiting list and preserving the chance for successful liver transplantation, or to improve outcome following liver transplantation remain unproven [146,161,162]. Based on cost-effectiveness analysis, these treatments are recommended to slow tumor growth when the waiting time for liver transplantation is expected to be at least 6 months [146,162].

The ideas of expanding the conventional HCC criteria for liver transplantation and down-staging larger tumors to meet conventional criteria take center stage in a widespread debate [163–165]. The proposed University of California, San Francisco (UCSF) criteria represent a modest expansion of the tumor size limits beyond the Milan criteria (one lesion 6.5 cm, or two or three lesions all 4.5 cm with total tumor diameter 8 cm) [151]. Several groups have validated the UCSF criteria based on tumor pathology [152,166,167], but the ability of these criteria to serve as selection guidelines based on preoperative imaging has been questioned [167]. A prospective study is in progress to validate the UCSF criteria based on pre-operative imaging. Preliminary data from our institution have also shown that successful down-staging of large tumors by locoregional treatments can be achieved in the majority of highly selected patients, in association with excellent posttransplant outcome [164,168]. Data from longer follow-up with a larger cohort are needed to confirm these encouraging results.

Whether the results of living donor transplantation are the same as those with deceased donor liver transplantation for patients with HCC remains unclear. While studies from Asia reported similar outcome with living donor transplantation for patients with HCC meeting Milan or UCSF criteria [166,169], a retrospective study from the A2ALL group sug-

gested worse outcome following living donor transplantation when compared to deceased liver transplantation [170]. The inclusion of a high proportion of patients with advanced HCC beyond Milan criteria may be an important contributing factor to the high HCC recurrence rate in the group receiving living donor transplants. Concerns have also been raised that the short waiting time with living donor transplantation or under the MELD system would include patients with less favorable tumor biopsy results, who would have been selected out by the traditionally longer waiting time for liver transplantation [171]. To address this concern, a recent study showed no significant correlation between waiting time and the risk of HCC recurrence or survival following liver transplantation [171].

Hemochromatosis

Patients with hereditary hemochromatosis are at increased risk for the development of cirrhosis, liver cancer, cardiomyopathy, and diabetes [149]. Most cases of hereditary hemochromatosis have been linked to mutation in the *HFE* gene, including the homozygous C282Y mutation and the heterozygous C282Y/H63D mutation. Studies from the past 10 years have consistently demonstrated a less favorable outcome following liver transplantation for patients with hemochromatosis [173–178]. According to the National Hemochromatosis Transplant Registry involving 260 patients with end-stage liver disease and hepatic iron overload enrolled from 12 liver transplant centers [178], *HFE* mutation with homozygosity for the C282Y was identified in 14 patients (7.2%). Their 1- and 5-year survivals following liver transplantation were only 64% and 34%, respectively, which were significantly worse than in patients heterozygous for the C282Y/H63D mutation, as well as wild-type patients. Non-*HFE*-associated patients with hepatic iron overload also had significantly worse survival when compared with the overall population undergoing liver transplantation. Cardiac and infectious complications accounted for about half of the deaths in patients with hepatic iron overload following liver transplantation [178]. A high incidence of hepatic malignancies (27%) was also observed at the time of liver transplantation in one study [174]. The diagnosis of hemochromatosis was often not made until after liver transplantation [173,175,178], a factor that might have contributed to the poor outcome. Collectively, these studies suggest that hereditary hemochromatosis should be considered a controversial indication for liver transplantation. Once the diagnosis of hemochromatosis is confirmed, early initiation of phlebotomy may diminish the likelihood of posttransplant cardiac complications. Thorough cardiac evaluations with right heart catheterization and possibly endomyocardial biopsy are recommended before liver transplantation [173,175]. Cardiac dysfunction as the result of excessive iron infiltration should preclude liver transplantation in view of the high perioperative and late postoperative cardiac mortality [173,176,178].

Wilson disease

The hallmark of Wilson disease, a relatively rare, inherited autosomal recessive disorder of copper metabolism, is its highly variable clinical presentation [179,180]. The diagnosis of Wilson disease is suggested by a young age at presentation and the presence of low serum ceruloplasmin, neuropsychiatric symptoms, and Kayser–Fleischer rings on slit-lamp opthalmological examination, although atypical clinical presentations and the absence of these classic signs and are also common [179,180]. Wilson disease may present as fulminant hepatic failure with a high mortality when managed with medical treatment alone [181,182]. Such patients can be listed as UNOS status 1 for liver transplantation [183]. The presence of a Coomb negative hemolytic anemia and a serum alkaline phosphatase to serum bilirubin ratio of less than 2 is suggestive, but not diagnostic, of fulminant Wilson disease [175]. Nazer and colleagues have developed a useful prognostic score (based on serum bilirubin, serum aminotransferase levels, and prothrombin time), which stratifies patients with Wilson disease according to the risk of death without liver transplantation [184]. Recently, additional prognostic models have been tested for fulminant Wilson disease in adults and children showing good discriminatory power for outcome and need for liver transplantation in these patients. They include a MELD score of 30 [183], as well as a revised King's College Prognostic Index (based on aspartate aminostransferase, albumin, bilirubin, INR for prothrombin time, and white cell count) [185,186]. The neurological and psychiatric manifestations of Wilson disease improve in most but not all patients after liver transplantation [175,182,187].

Non-alcoholic fatty liver disease (NAFLD)

Nonalcoholic fatty liver disease (NAFLD) has been considered the hepatic manifestation of a metabolic syndrome related to insulin resistance, with central obesity as a major component [188,189]. NAFLD includes a spectrum of histological lesions ranging from benign steatosis to nonalcoholic steatohepatitis [188,189], the latter being increasingly recognized as a significant cause of cirrhosis [188–191]. Many patients with cryptogenic cirrhosis appear to have NAFLD as the etiology [190]. According to UNOS data [2,189], the proportion of patients with NAFLD undergoing liver transplantation has increased 35-fold from less than 0.1% in the period 1995–2000 to 3.5% in 2005. During the same time interval, the proportion of patients with cryptogenic cirrhosis undergoing liver transplantation decreased from 9.6% to 6.6%. It seems likely that more cases previously referred to as cryptogenic cirrhosis are recognized as resulting from NAFLD [189].

The adverse impact of obesity in association with NAFLD and other liver disease on morbidity and mortality following liver transplantation has been increasingly recognized. According to an analysis of UNOS data [192], patients who were

severely obese (with a body mass index [BMI] of 35) or morbidly obese (BMI 40) had a significantly greater risk of primary graft nonfunction and a higher 5-year mortality compared to patients who were not obese (BMI < 25). At the authors' institution, patients who are morbidly obese are required to lose weight to achieve a BMI of 40 before they are considered as potential candidates for liver transplantation.

Several reports have suggested that NAFLD may recur after liver transplantation [189,191,193]. This phenomenon has also been described in patients with cryptogenic cirrhosis following liver transplantation, with the presumption that NAFLD is the unrecognized underlying cause of their liver disease before liver transplantation [194,195]. The course of recurrent NAFLD may not be benign. In one study, 9 of 15 patients had recurrence of NAFLD after liver transplantation, and 2 of these patients had rapid progression to cirrhosis or liver failure requiring retransplantation [191]. Additional studies are needed to evaluate the long-term outcome of liver transplantation for NAFLD in a larger group of patients. Recurrent NAFLD after liver transplantation highlights the importance of host-dependent factors, as opposed to liver-dependent factors, in the pathogenesis of the disease. De novo development of NAFLD after liver transplantation in patients with other diagnoses and no risk factors for NAFLD has also been reported [196].

Other metabolic liver diseases

A number of other diseases in the category of inborn errors of metabolism have been successfully treated with liver transplantation [49,175]. The indication for liver transplantation is end-stage cirrhosis caused by some of these diseases, including α_1-antitrypsin deficiency [197], glycogen storage disease (types I, III, and IV) [198], cystic fibrosis [199], erythropoietic protoporphyria [200], and tyrosinemia [201]. At the other end of the spectrum, liver transplantation has been performed solely for the correction of nonhepatic manifestations of certain metabolic diseases in which the genetic defect is expressed in the liver in the absence of significant hepatic dysfunction. Examples include Crigler–Najjar syndrome [202], primary hyperoxaluria [203], familial amyloid polyneuropathy [204], and severe familial hypercholesterolemia [205].

Autoimmune hepatitis

Progression of autoimmune hepatitis to cirrhosis and liver failure requiring liver transplantation is usually seen in patients refractory to conventional immunosuppressive therapy and those who present late in the course of disease without previous diagnostic confirmation or appropriate therapy [206]. Acute, fulminant presentation of severe autoimmune hepatitis refractory to corticosteroid therapy has also been described, for whom status I listing for liver transplantation may be appropriate. Although the outcome of liver transplantation for autoimmune hepatitis is generally excellent, it is increasingly recognized that there is a risk for disease recurrence [207–210]. Bearing in mind a significant limitation with respect to the small number of patients in many single-center reports, and the differences in the definition of recurrent disease based on histology, autoantibodies, liver biochemical profiles, or a combination of these factors, the recurrence rate is estimated to be between 20% and 30% [207–210]. The diagnostic criteria for recurrent autoimmune hepatitis have not been well established. The utility of monitoring autoantibodies after liver transplantation is unclear, and most studies have found that these markers persist to some extent in all patients transplanted for autoimmune hepatitis. Published data on titer or persistence of the autoantibodies are insufficient for predicting recurrence or disease activity after liver transplantation [209]. Histological features of recurrent autoimmune hepatitis may be difficult to differentiate from those of acute cellular rejection. Risk factors for recurrent disease in some studies have included suboptimal immunosuppression, and HLA haplotypes DR3 and DR4 [208]. The use of tacrolimus vs cyclosporine as primary immunosuppression has not been shown to have a significant impact on the risk of disease recurrence [207]. Recurrent autoimmune hepatitis rarely develops in the first year after liver transplantation, presumably because of the higher level of immunosuppression used during this period [209,210]. The course of recurrent autoimmune hepatitis is typically indolent, and the histological features for recurrent disease rapidly resolve in most cases when adequate immunosuppression is restored [209]. One study, however, reported graft failure requiring retransplantation in 6 of 24 patients with recurrent autoimmune hepatitis and more than 1-year of follow-up [210].

Cholestatic liver disease

Patients with cholestatic liver disease, chiefly primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC), have traditionally been considered the best candidates for liver transplantation based on superior survival statistics [211,212]. The Mayo clinic risk scores for PBC [213] and PSC [214] have been widely used as prognostic models for predicting survival without therapeutic intervention. The MELD scoring system serves the role of identifying patients with PBC and PSC in need of liver transplantation and prioritizing them on the waiting list. Patients with cholestatic liver disease commonly present with pruritus, which can be severe and refractory to medical therapy [215], and metabolic bone disease with osteopenia predisposing to fractures [216]. No therapy other than liver transplantation has been shown to increase bone mineralization in patients with cholestatic liver disease [216,217]. Although bone loss continues in the first 3–6 months after liver transplantation, bone density then returns to pretransplant levels at 1 year, and may be restored to close to normal within 2–3 years after liver transplantation [217]. Liver transplantation is also effective for xanthomatous neuropathy, an unusual complication of cho-

lestatic liver disease. Biliary atresia is the most common indication for pediatric liver transplantation.

Primary biliary cirrhosis

PBC is characterized by progressive destructions of small intrahepatic bile ducts, leading to eventual cirrhosis and liver failure [218]. PBC is one of the five most common indications for liver transplantation in the United States, associated with superior patient survival of about 85% at 5 years after liver transplantation [212]. Ursodeoxycholic acid (UDCA) improves the biochemical profiles, especially the bilirubin level, in patients with PBC [218]. Some concerns have been raised that using the Mayo risk score, and possibly also the MELD score, in UDCA-treated patients may underestimate their mortality [219]. Although existing data are still inconclusive, UDCA appears to benefit survival in PBC and delay the need for liver transplantation [218,220].

It is widely accepted that PBC does recur in the allograft, with an estimated incidence of about 10%–20% after liver transplantation [207,221,222]. The diagnosis of recurrent PBC can only be made on histological criteria, which may be difficult to differentiate from other causes of bile duct damage in the allograft such as acute or chronic rejection and biliary complications. In a study from the Mayo Clinic using strict histological criteria for disease recurrence defined as the presence of a florid duct lesion or destructive lymphocytic cholangitis within a dense portal infiltrate, the incidence of recurrent PBC was reported to be 17% [221]. A large study from the United Kingdom involving 400 patients also reported a similar rate of recurrence [222]. Serum antimitochondrial antibody titer has not been shown to predict histological recurrence of PBC [221]. The risk of recurrence also does not appear to be different between tacrolimus and cyclosporine as primary immunosuppression [207]. To date, disease recurrence has had little impact on the quality of life or graft survival, and very few patients develop advanced stages of fibrosis or require retransplantation [207,221,222]. Whether UDCA alters the rate of progression of recurrent PBC has not been adequately studied.

Primary sclerosing cholangitis

PSC typically involves both the intrahepatic and extrahepatic bile ducts; with segmental biliary strictures, beading, and dilations. No medical therapy, including high dosages of UDCA, has clearly been proven to be effective in improving the natural history of PSC [223,224]. One of the indications for liver transplantation in PSC is recurrent bacterial cholangitis, which is often associated with bile duct stones or obstructing strictures. Endoscopic stenting or balloon dilation of strictures may benefit some patients, although controlled data are limited. With the extensive scarring of the diseased common bile duct, anastomosis to a Roux-en-Y limb of jejunum is the standard surgical approach at liver transplantation. Patients with PSC are also at risk for developing cholangiocarcinoma, with an estimated incidence of up to 20%–30% at the time of liver transplantation [225–227]. Establishing the diagnosis of cholangiocarcinoma in patients with PSC is often difficult. Neither brush cytology nor serum tumor markers including CA 19-9 are reliable diagnostic tools [228,229]. Fluorescence in situ hybridization from bile duct brushings and aspirates has been shown to improve the sensitivity over routine cytology in detecting cholangiocarcinoma in PSC [229]. Preliminary data on dynamic positron emission tomography scanning for detecting small cholangiocarcinoma in patients with PSC appears to be promising [230]. Survival after liver transplantation is reduced when occult cholangiocarcinoma is present [227,231]. About 70% of patients with PSC also have inflammatory bowel disease, and are at risk for developing colorectal cancer. There have been several reports of colorectal cancer diagnosed after liver transplantation in patients with PSC and ulcerative colitis [232,233]. Continued surveillance by yearly colonoscopy after liver transplantation to detect dysplasia is recommended.

The reported incidence of recurrent PSC after liver transplantation has ranged from 10% to 40% [234,235]. Distinguishing cholangiographic features of recurrent disease from some other conditions, such as ischemic strictures related to prolonged cold ischemia time, ABO incompatibility, and hepatic artery thrombosis can be difficult. In one study from the Mayo Clinic [235], nonanastomotic strictures of intrahepatic and extrahepatic bile ducts developing more than 90 days after liver transplantation defined cholangiographic recurrence, whereas fibroobliterative lesions and fibrous cholangitis were consistent with histological recurrence. Exclusion criteria included hepatic artery thrombosis, chronic ductopenic rejection, donor-recipient ABO incompatibility, and nonanastomotic strictures before day 90 posttransplant. The incidence of recurrence was 18% among 120 patients with PSC receiving liver transplantation, compared with 1% of a control group of 415 patients transplanted for other indications [235]. Recurrent PSC does not appear to impact adversely on patient or graft survival over the intermediate term [208].

Fulminant hepatic failure

Fulminant hepatic failure is traditionally defined as the development of hepatic encephalopathy within 8 weeks after the de novo onset of jaundice [236]. Subacute or subfulminant hepatic failure is observed in a small subgroup of patients in which encephalopathy develops later, up to 26 weeks after the onset of illness [237]. According to recent data from the US Acute Liver Failure Study Group, the predominant cause of fulminant hepatic failure in the United States is acetaminophen-induced hepatic injury [238]. Idiopathic liver failure possibly from an unidentified virus, other types of known viral hepatitis (hepatitis A, B, D, and E, but not hepatitis C) and idiosyncratic drug-induced liver injury comprise the next most common group [238], although differences exist between Europe, the United States, and

Eastern countries [239]. Patients with fulminant hepatic failure typically have no preexisting liver disease, but there are well-recognized examples of hitherto asymptomatic chronic liver disease, such as autoimmune hepatitis and Wilson disease, presenting with fulminant hepatic failure [240]. Acetaminophen-induced acute liver failure may be the result of intentional overdose or a so-called "therapeutic misadventure" [241]. Early diagnosis and administration of *N*-acetylcysteine as soon as possible are of paramount importance in reducing the risk of fulminant liver failure associated with acetaminophen. *N*-Acetylcysteine is proven to be effective when given in the first 24 h after acetaminophen overdose, but may still be of value 48 h or longer after ingestion [240]. Measurement of acetaminophen levels is of limited value in the setting of acute liver failure, and a low level should not dissuade one from treating the patient with *N*-acetylcysteine. A recent report has shown that measurement of serum acetaminophen–protein adducts improves the diagnostic yield of acetaminophen-induced liver failure [242].

Currently, about 6% of liver transplants in the United States are performed for patients with fulminant liver failure [2]. With improved supportive care for these critically ill patients, about 40% of patients with fulminant hepatic failure survive without liver transplantation [240]. Recent reports showed a high rate of spontaneous recovery (62%–68%) without liver transplantation in patients with acetaminophen-induced fulminant liver failure [238,241], but the chance of survival without liver transplantation was 25% or less in cases of drug reaction and indeterminate cause [238]. A variety of medical therapies, including charcoal hemoperfusion, hemodialysis, plasmapheresis, prostaglandin analogues, and corticosteroids have failed to improve outcome in controlled clinical trials involving patients with fulminant liver failure. The well-validated King's College prognostic criteria identify the subgroup of patients at highest risk of dying who should undergo liver transplantation as soon as possible [243] (Table 92.3). A coagulation factor V level of less than 20% (Clichy criteria) also appears to have significant discriminatory prognostic value in non-acetaminophen-induced fulminant hepatic failure [244,245]. A low serum phosphate as a marker for hepatic regeneration has been reported to predict a greater chance of recovery without liver transplantation in patients with acetaminophen-induced acute liver failure [246]. All these prognostic models are, however, imperfect in predicting the likelihood of spontaneous recovery vs the need for liver transplantation. Consequently, the decision of whether or not to proceed with liver transplantation remains a challenge in the management of these patients.

Early referral of patients with fulminant liver failure and also of patients with severe acute liver failure, even in the absence of altered mental status, to a liver transplant center is of paramount importance. Patients with fulminant liver failure should be listed for liver transplantation with the highest priority (UNOS status 1) as soon as they develop clinically evident hepatic encephalopathy [183]. Rapid deterioration and death, most commonly from multiorgan failure, cerebral edema, and sepsis, can occur within days after the development of stage 3 or 4 encephalopathy [239,240]. Intracranial pressure monitoring is commonly instituted in patients with grade 4 hepatic encephalopathy, but this procedure carries a significant risk for intracranial hemorrhage [247,248] and an alternative monitoring approach using the lumbar subarachnoid space is being assessed (Fix, OK, Pitts, LH, Davern, TJ and Bass, NM, unpublished results). At the authors' institution, patients deteriorating beyond stage 3 hepatic encephalopathy are electively intubated and ventilated with adequate sedation both to protect the airway and to prevent surges in intracranial pressure related to psychomotor agitation. Sustained elevation of intracranial pressure with cerebral perfusion pressure (mean arterial pressure – intracranial pressure) below 40 mmHg for at least 2 h despite treatment with mannitol and pentobarbital is associated with a very poor prognosis secondary to irreversible neurological damage and precludes liver transplantation [247]. In addition to mannitol and pentobarbital [240], hypothermia has also been shown to be of benefit in lowering the intracranial

Table 92.3 King's College prognostic criteria for fulminant hepatic failure

Prognostic factors	Predicted mortality rate (%)
Acetominophen-induced fulminant liver failure[a]	
pH < 7.3	95
Grade 3 or 4 encephalopathy, Prothrombin time > 35 s Serum creatinine > 3.5 mg/dL	67
Nonacetaminophen-induced fulminant liver failure[b]	
Prothrombin time > 35 s	100
Age < 10 or > 40 years	96
Bilirubin > 17.5 mg/dL	93
Jaundice for > 7 days before encephalopathy	97
Unfavorable etiology	90
idiosyncratic drug reactions	
Wilson disease	
non-A, non-B hepatitis	
halothane hepatitis	

a Liver transplantation is indicated for pH < 7.3 irrespective of the grade of encephalopathy; or prothrombin time > 35 s and creatinine > 3.5 mg/dL with grade 3 or 4 encephalopathy.
b Liver transplantation is indicated for prothrombin time > 35 s or any three of the remaining variables irrespective of the grade of encephalopathy.
Data from O'Grady [243]. The prothrombin time is converted to equivalent values in the United States.

pressure in these patients [249]. Faulty monitor function must be carefully excluded because false readings may result in erroneous decisions with respect to the patient's candidacy for liver transplantation [247]. The usual protocol for patients in hepatic coma with intracranial monitoring is to maintain cerebral perfusion pressure between 50 and 60 mmHg and intracranial pressure below 20 mmHg both before and during liver transplantation to ensure full neurological recovery after surgery [240,247].

The 1-year survival following liver transplantation for fulminant hepatic failure approaches 90% in the United States [212], perhaps reflecting advances in the care of critically ill patients and improved patient selection. Liver transplantation for fulminant hepatic failure is, however, limited by the severe shortage of cadaveric organ donors and by the very brief time available to obtain suitable organs. There has been considerable interest in the use of extracorporeal liver-support devices to provide temporary liver support, and serve as a "bridge" to liver transplantation. Results of some early studies were, however, disappointing in that no survival benefit could be demonstrated among patients so treated compared with those receiving supportive care only before liver transplantation [240], thus dampening the initial enthusiasm regarding this technology. A more recent multicenter trial did report improved short-term survival for a subgroup of patients with fulminant liver failure treated with a porcine hepatocyte-based bioartificial liver [250]. The application of extracorporeal liver support needs further research and validation [240]. Auxiliary orthotopic liver transplantation [251] is a special procedure in which part of the native liver is left in situ, and the reduced-size graft provides temporary support until subsequent regeneration of the native liver. Thereafter, the auxiliary graft is either surgically removed or allowed to atrophy following withdrawal of immunosuppression. Although auxiliary liver transplantation has the potential advantage of not subjecting patients to lifelong immunosuppression with its attendant risks, technical difficulties have prevented its widespread use for fulminant hepatic failure.

Evaluation for liver transplantation

Although the approach to the evaluation of patients for liver transplantation may vary according to the individual liver transplantation center, the principles are generally similar (Fig. 92.6). The evaluation process typically involves a multidisciplinary team including hepatologists, transplant surgeons, transplant nurse coordinators, social workers, and individuals with expertise in substance-abuse issues. The use of other consultants varies according to individual transplant centers and patient needs. The main roles of the transplant hepatologist are:

- to confirm that the patient has appropriate medical indications for liver transplantation
- to implement a plan for the management of the complications of liver disease
- to evaluate disease-specific issues that may potentially impact on outcome after liver transplantation
- to assess other comorbid conditions and possible contraindications to liver transplantation.

Surgical risks and technical considerations for liver transplantation need to be carefully evaluated, primarily by the transplant surgeon. Extensive portal and mesenteric venous thrombosis, previous abdominal surgery near the hepatic hilum, and severe obesity can make the transplant operation difficult, if not impossible. In some patients with a TIPS, extension or migration of the stent into the extrahepatic portal vein, the hepatic vein, or vena cava may compromise the success of liver transplantation [57]. Patients should be fully informed of the risks for liver transplant surgery, the possibility and likelihood of recurrent disease after liver transplantation, and the potential alternatives to liver transplantation. For instance, some patients with well-compensated or mildly decompensated cirrhosis may benefit from portal decompressive surgery for refractory variceal bleeding. Surgical resection for HCC may be an alternative to liver transplantation in some patients with well-compensated cirrhosis, a single lesion less than 5 cm, and no portal hypertension. Psychosocial assessment is an integral part of the liver transplant evaluation process to address substance-abuse issues, the risk for recidivism, compliance, and adequacy of social support. In addition to a thorough history and physical examination, an abdominal imaging study (ultrasonography with Doppler, computed tomography, or magnetic resonance imaging) to exclude intrahepatic or extrahepatic tumors and to evaluate hepatic vessel patency, and laboratory tests are part of the routine evaluation process.

Cardiac evaluation before liver transplantation is intended to exclude coronary artery disease, heart-valve disease, and cardiac failure from various etiologies, the extent of which may also depend on the cardiac risk factors present in the individual patient. Special attention should be given to the cardiac evaluation of patients with alcoholic liver disease and hemochromatosis because they are at increased risk for cardiomyopathy, whereas patients with diabetes, metabolic syndrome, and NAFLD are at higher risk for coronary vascular disease. A chest radiograph and arterial blood gas analysis are routinely performed in most transplant centers. Patients with α_1-antitrypsin deficiency, chronic tobacco use, or known or suspected intrinsic lung diseases should undergo full pulmonary function testing. It is also important to identify two pathophysiologically distinct pulmonary syndromes that are uncommon but clinically important among patients with cirrhosis. These are hepatopulmonary syndrome and portopulmonary hypertension [252]. Hepatopulmonary syndrome is characterized by arterial hypoxemia ($P_aO_2 < 70$ mmHg or alveolar–arterial gradient > 20 mmHg) and pulmonary capillary bed dilation supported by contrast echocardiography and

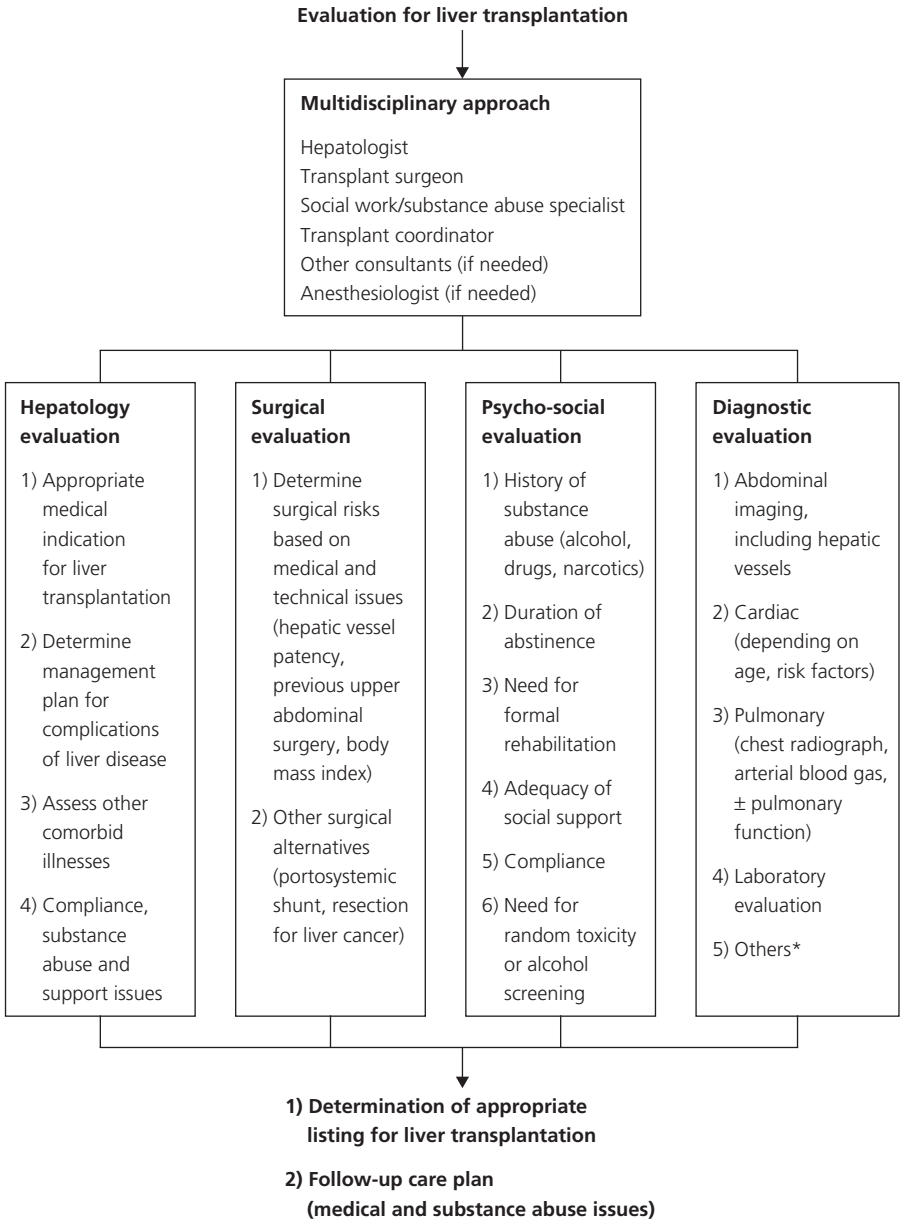

Figure 92.6 Principles in the evaluation of potential candidates for liver transplantation.

technetium macroaggregated albumin lung scanning [252]. Hepatopulmonary syndrome is reversible after liver transplantation, but a high perioperative mortality of about 30% has been reported in patients with a baseline P_aO_2 of 50 mmHg undergoing liver transplantation [253,254]. Portopulmonary hypertension is defined as a mean pulmonary arterial pressure (PAP) greater than 25 mmHg and pulmonary capillary wedge pressure of less than 15 mmHg [252,255]. The perioperative mortality associated with liver transplantation was reported to be 50% among patients with moderate portopulmonary hypertension (mean PAP between 35 and 50 mmHg) and 100% for those with severe portopulmonary hypertension (mean PAP 50 mmHg) [255]. Right heart catheterization is indicated to confirm the diagnosis when the estimated mean PAP is 35 mmHg by echocardiography [256]. Patients with mean PAP 35 mmHg and elevated pulmonary vascular resistance (> 3.0 Woods Units) should be considered for intravenous epoprostenol (prostacyclin) or other treatment protocols [252] in an attempt to decrease the PAP before liver transplantation [257,258].

Contraindications to liver transplantation

The commonly cited absolute and relative contraindications to liver transplantation, which also reflect the authors' opinion rather than a true consensus, are listed in Table 92.4. The absolute contraindications include severe comorbid medical illness such as cardiac and pulmonary diseases that are not reversible and adversely impact on the patient's short-term life

Table 92.4 Contraindications to liver transplantation

Absolute contraindications:
Severe, irreversible comorbid medical illnesses that adversely impact short-term life expectancy
Severe, untreated pulmonary hypertension (mean PAP ≥ 50 mmHg)
Extrahepatic malignancy (excluding some skin cancers)
Extensive hepatocellular carcinoma or with macrovascular or lymph node invasion
Uncontrolled systemic sepsis
Extensive portal vein and mesenteric vein thrombosis
Active alcohol or drug abuse
Noncompliance
Unacceptable risks for recidivism from drugs or alcohol
Severe, uncontrolled psychiatric disease
Relative contraindications:
Moderate pulmonary hypertension (mean PAP between 35 and 50 mmHg)[a]
Severe hepatopulmonary syndrome with P_aO_2 of ≤ 50 mmHg
Severe obesity (Body Mass Index ≥ 40)
Poor social support
Advanced age (≥ 70 years)
Cholangiocarcinoma[a]
HIV/AIDS[a]

a Liver transplantation has been performed in some transplant centers under an experimental treatment protocol.
AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus; PAP, pulmonary arterial pressure.

expectancy, and extrahepatic malignancies excluding certain skin cancers. Patients with advanced HCC and cholangiocarcinoma are generally excluded from liver transplantation, although some centers have performed liver transplantation on these patients under certain experimental treatment protocols. One example is the Mayo clinic protocol for cholangiocarcinoma using external-beam radiation therapy and neoadjuvant chemotherapy before liver transplantation in a highly selected group of patients, showing excellent 5-year survival of 82% [259]. This protocol may be more widely adopted by other transplant centers in the future.

As already described, patients with severe portopulmonary hypertension should not undergo liver transplantation because of an unacceptably high perioperative mortality. At the authors' institution and some other transplant centers, selected patients with moderate or severe pulmonary hypertension are placed on intravenous epoprostenol (prostacyclin) in an attempt to decrease the PAP before liver transplantation [257]. Systemic infections must be adequately treated before liver transplantation. Psychiatric and psychosocial contraindications include active substance abuse, high recidivism risk, noncompliance, and poorly controlled psychiatric illness. Poor social support is also a relative contraindication to liver transplantation. Technical contraindications include extensive thrombosis involving both the portal and mesenteric veins. Severe obesity, defined as a BMI of 35, was shown in a recent analysis of UNOS data to be associated with significantly worse survival after liver transplantation [192]. It is therefore important for these patients to lose weight before liver transplantation. At the authors' institution, patients who are morbidly obese are required to lose weight to achieve a BMI of 40 before they are accepted for liver transplantation.

Individuals infected with the human immunodeficiency virus (HIV) survive longer with current advances in highly active antiretroviral therapy (HAART). Whether they should be considered for liver transplantation remains a highly controversial issue. In the past few years, data on liver transplantation for HIV-infected patients have been reported by several centers in the United States (UCSF, Pittsburgh, Miami) and Europe, although the total number of patients in these studies is still relatively small [260]. In a small series from King's College, London, three of five patients with HIV and hepatitis C coinfection who received transplants died of aggressive recurrent hepatitis C infection between 6 and 25 months after the transplantation [261]. Another study from Barcelona, Spain including nine patients coinfected with HIV and hepatitis C showed no significant difference in 3-year actuarial patient survival compared to a control group [262]. In the largest series reported to date by the group from University of Pittsburgh [263], the 5-year posttransplant survival of 27 patients coinfected with HIV and hepatitis C was only 33%, compared with 72% for the HIV-negative, hepatitis C-positive controls. Recurrent hepatitis C, including three cases of fibrosing cholestatic hepatitis C infection, was a major cause of graft loss and mortality in this study [263]. Further studies with larger numbers of patients are needed to fully address the impact of hepatitis C on posttransplant outcome in this population. At present, liver transplantation for HIV-infected individuals should be restricted to centers with well-defined protocols for patient selection, managing HAART therapy and drug interactions, and treatment for recurrent disease.

Posttransplant management

Complications

Vascular complications

Hepatic artery thrombosis occurs in 2%–4% of all adult whole deceased donor liver transplants [264,265]. The incidence is approximately doubled after partial or split deceased donor liver transplants or living donor liver transplants [25,26,266,267]. Although risk factors for hepatic artery thrombosis include small hepatic arterial size, complex anatomy, the need for extension grafts, prolonged ischemic time, and hypercoagulable states have been identified [266], typically, the specific cause of individual cases is unknown

[268]. The presentation of hepatic artery thrombosis can be highly variable, ranging from clinical silence to frank hepatic necrosis. Diagnosis is usually suggested by Doppler examination of the hepatic vessels and confirmed by arteriography. If hepatic artery thrombosis is identified early after liver transplantation, operative exploration with thrombectomy may succeed in reestablishing arterial flow [268]. Since the blood supply of the biliary tree comes exclusively from the hepatic artery and ischemia frequently results in diffuse biliary strictures, often associated with episodic cholangitis, and less frequently, hepatic abscesses, retransplantation is often necessary [266]. Late hepatic artery thrombosis is more frequently occult and can have a more variable course because collateral blood supply may have developed. Management is dictated by the clinical scenario.

The second most common vascular complication is portal vein thrombosis, which can manifest solely as liver test abnormalities or can manifest with ascites, encephalopathy, or variceal bleeding [266]. Risk factors for portal vein thrombosis include jump graft reconstruction during transplantation, presence of portosystemic surgical shunts, and hypercoaguable states. Balloon dilation and stenting may be effective in some cases of portal vein stenosis, which abrogates the need for surgical revision or retransplantation [269]. Thrombosis or stenosis of the hepatic vein or the inferior vena cava with resultant outflow obstruction is generally uncommon. This complication however has a higher incidence in recipients with recurrent Budd–Chiari syndrome following liver transplantation [270], recipients of partial or split liver transplants either from a deceased or living donor [271], and livers implanted using the piggyback technique [272,273].

Biliary complications

Choledochocholedochostomy (end-to-end anastomosis) with or without a T-tube is the most frequently used biliary anastomosis in adult deceased donor liver transplantation. The alternative, a Roux-en-Y choledochojejunostomy, is used primarily in patients with preexisting bile duct abnormalities such as PSC and biliary atresia or in whom technical difficulty is encountered in fashioning a duct-to-duct anastomosis. In adult living donor liver transplantation, hepaticocholedochostomy is possible, typically when the graft has only a single duct. However, many right lobe grafts have more than a single bile duct, necessitating the use of Roux-en-Y hepaticojejunostomies. The use of T-tubes for duct-to-duct anastomoses or stents for choledochojejunostomy or hepaticojejunostomy is dictated by center practice. While these devices may have some therapeutic effect (prevention of leak or stricture), these devices are also inserted to ensure diagnostic access to the biliary tree [274].

The overall incidence of biliary complications after deceased donor whole liver transplantation ranges between 10% and 15% [275]. In a series of almost 1800 patients reported from the University of Pittsburgh [276], 80% of biliary complications were identified within the first 6 months after liver transplantation, and one-third were diagnosed in the first month. Bile leaks and biliary strictures account for 80% of biliary complications [275–277]. Many biliary complications, particularly those that occur early after transplantation, can be managed endoscopically, in the case of duct-to-duct anastomoses, or with interventional radiology, in patients with choledochojejunostomy or hepaticojejunostomy anastomoses [275,278,279]. Leaks occur most commonly at the anastomotic site, T-tube exit site, or the cut edge of reduced-size liver grafts. A bile leak results in a biloma or bile peritonitis, frequently complicated by superinfection. Nonoperative management with biliary stent insertion and percutaneous drainage is successful in most cases [278]. Surgical revision is typically reserved for failure of nonoperative strategies [278]. Biliary strictures occur most often at the anastomosis, presumably secondary to edema early after transplantation and local ischemia leading to scarring late after transplantation. Endoscopic biliary stenting with balloon dilation is generally successful in resolving early strictures and less successful in resolving late strictures [275]. Occasionally, diffuse stricturing of not only the extrahepatic but also the intrahepatic biliary tree develops. Although these are more frequent with allografts from ABO-incompatible or "donation after cardiac death" donors, or in the setting of insufficient hepatic arterial flow from thrombosis or stenosis, often, no definite etiology can be identified [280].

Biliary complications occur much more frequently after living donor liver transplantation, with an estimated incidence of 30%–40%. Graft preparation necessitates hilar dissection, which can inadvertently disrupt the biliary microcirculation. Moreover, the frequent occurrence of more than one hepatic duct also predisposes to complications. Similar to deceased donor transplantation, the majority of biliary complications after living donor transplantation are managed nonoperatively with stenting and biloma drainage, as needed, for leaks and stenting and dilation for strictures. The approach – endoscopic or transhepatic – is dictated by whether the anastomosis was to a duct or to a Roux-en-Y limb.

In summary, biliary complications remain fairly frequent, particularly after transplants from living donors or using donations after cardiac death. Although the overall impact of biliary complications on mortality is small because of improvements in diagnostic and therapeutic techniques strategies [278], they result in significant morbidity, including graft loss in 1%–3% of transplant recipients [278].

Recurrent disease in the allograft

Disease-specific recurrence following liver transplantation has already been reviewed. Disease recurrence is an important issue, particularly in light of the fact that retransplantation is associated with significantly worse survival compared to primary transplantation [281] and further depletes the limited donor pool. In general, recurrent autoimmune hep-

atitis and cholestatic liver disease have a minor impact on graft survival [208], whereas recurrent viral hepatitis has been a highly important cause of graft failure within the first 5 years following liver transplantation [266]. The use of HBIG and the addition of a nucleoside or nucleotide analogue have diminished the adverse impact of hepatitis B recurrence on graft survival [87–90,96–99]. The magnitude of the adverse impact of recurrent hepatitis C on graft survival, on the other hand, has become increasingly evident in the last few years. The problem related to liver transplantation for hepatitis C infection will likely worsen as many patients with hepatitis C infection are at risk for cirrhosis, liver failure, and HCC as the disease advances to the third and fourth decade following acute exposure of the chronically infected population (see Disease-specific issues and outcome after liver transplantation).

It is clear that all HCV recipients who are viremic at the time of transplant will have recurrent disease of variable and unpredictable severity. Currently, the most potent risk factor for aggressive recurrent disease is increased donor age. Interferon plus ribavirin therapy remains the only possible treatment for hepatitis C, but this treatment unfortunately is characterized by poor tolerability and low efficacy, particularly for unfavorable genotypes. In contrast, liver transplant candidates who are not viremic at the time of transplantation appear to be protected against recurrent disease. Currently, there are trials exploring the feasibility of pretransplant treatment, particularly for candidates who are less severely ill, such as those poised for living donor liver transplantation [140,141]. Despite improved outcome in recent years for liver transplantation among patients with HCC, many patients still succumb to recurrent HCC, which tends to be highly aggressive in immunosuppressed, posttransplant patients and is rarely curable by surgical resection or retransplantation. Better understanding of the mechanisms and predictors of tumor recurrence, refinements of the selection criteria for liver transplantation, and modification of organ allocation policies to reduce waiting time and the pretransplant risk of tumor dissemination may further improve the outcome for HCC.

The course of recurrent NAFLD has not been well characterized because of the small number of patients studied. It appears that the course is relatively benign, although some cases progress to cirrhosis and graft failure. The development of NAFLD following liver transplantation may occur not only in patients with this original diagnosis, but also in patients with different original diagnoses. Obesity and rapid weight gain in the posttransplant period may be important risk factors in these patients. Finally, alcoholic liver disease may recur with heavy alcohol intake in the posttransplant period. Surreptitious alcohol consumption should be considered in the diagnostic evaluation of unexplained graft dysfunction, especially among those with a history of heavy alcohol consumption before liver transplantation.

Medical complications of immunosuppression

Direct adverse effects of immunosuppressants

Clearly, an advantage of current immunosuppression strategies is the possibility to "mix and match" a variety of immunosuppressants, each with a distinctive toxicity profile, to minimize overall side effects. Most side effects occur in a dose-related manner and are amenable to management by dose reduction rather than by discontinuation. Some of the well-known direct adverse effects of the primary immunosuppressive agents are listed in Table 92.5. Corticosteroids are associated with a multitude of well-known side effects including hypertension, dyslipidemia, hyperglycemia/diabetes, osteoporosis, cataracts, weight gain, Cushingoid appearance, and mood alterations. Calcineurin inhibitors, tacrolimus, and cyclosporine share common side effects of nephrotoxicity, neurotoxicity, hypertension, hyperlipidemia, hyperkalemia, impaired glucose metabolism, and gastrointestinal disturbances. Neurotoxicity, decreased glucose tolerance, and gastrointestinal adverse effects are more common with tacrolimus whereas hypertension and hyperlipidemia are more common with cyclosporine. Hyperkalemia is usually managed with fludrocortisone [282]. Hair loss is specifically associated with tacrolimus whereas hirsutism and gingival hyperplasia are specifically associated with cyclosporine [283]. It is important to recognize that a long list of drugs can interfere with the metabolism of the calcineurin inhibitors (Table 92.6). Most interactions occur as a result of either competitive inhibition or induction of metabolism at the level of cytochrome P450 3A4. Increased drug levels can lead to toxicities whereas decreased drug levels can precipitate rejection. The primary adverse effect of immunosuppressants such as azathioprine, mycophenolate mofetil, and rapamycin is bone marrow suppression. Gastrointestinal toxicity, including a hemorrhagic gastritis, is also associated with mycophenolate mofetil. Prominent side effects of rapamycin include hyperlipidemia, ulceration of the oral mucosa, thrombocytopenia, anemia, and leukopenia. Less common but distinctive associations include peripheral edema and interstitial pneumonitis.

Among the most important complications of immunosuppression is the increased incidence of infections and malignancies, as well as renal dysfunction, cardiovascular abnormalities, and metabolic derangements. These are discussed in greater detail below.

Infectious complications

Over 50% of liver transplant recipients experience one or more episodes of infection in the postoperative period [284]. Historically, infectious complications account for most cases of death in the first year after liver transplantation [284]. The timetable of infection in all forms of solid-organ transplantation is most easily organized into three periods [285]: the first month, 1–6 months, and more than 6 months after transplantation. During the first posttransplant, month, conventional bacterial and fungal nosocomial infections predominate.

Table 92.5 Side effects of immunosuppressive drugs

Corticosteroids	Azathioprine	Mycophenolate mofetil	Rapamycin
Infection	Leukopenia	Leukopenia	Leukopenia

Opportunistic infections with various viral or fungal infectious agents occur most commonly between 1 and 6 months. Beyond 6 months after transplantation, as the degree of immunosuppression decreases, community-acquired infections or recurrent/persistent infections predominate.

With regard to specific infections and organisms, the typical bacterial infections in the early postoperative period are wound infections, indwelling catheter-based infections, and pneumonia with *Staphylococcus* and *Enterococcus* species as the most common pathogens [284]. Vancomycin-resistant *Enterococcus* has emerged as an important nosocomial pathogen in liver transplant recipients [286]. After the first month, viruses (such as CMV, herpes virus, Epstein–Barr virus), fungi, *Nocardia*, *Listeria*, tuberculosis, and *Pneumocystis carinii* pneumonia are important concerns [285]. Fungal infections usually present 1–6 months after liver transplantation. *Candida albicans* is the most common fungal pathogen, although there have been steep increases in the frequency of non-albicans *Candida* infections [287,288]. Invasive aspergillosis carries a high mortality, and its incidence among liver transplant recipients may be rising [289]. Other mycoses, such as cryptococcosis, coccidioidomycosis, and histoplasmosis, are rare except in cases of exposure in specific geographic endemic areas [284,285]. Oral nystatin, clotrimazole, or weekly fluconazole (Table 92.6) are the most frequently used agents for fungal prophylaxis [290]. *Pneumocystis carinii* pneumonia is

a Most interactions occur as a result of either competitive inhibition or induction of metabolism at the level of cytochrome P450 3A4.

very rare in liver transplant recipients because of highly effective long-term prophylaxis with trimethoprim–sulfamethoxazole [291].

Historically, CMV has represented one of the most important infectious complications after organ transplantation, causing mortality, morbidity, and heavy resource utilization [292,293]. However, the availability of oral antiviral agents and their use for prophylaxis [294–300] has reduced the incidence and severity of this complication. Distinction should be made between CMV "infection", which refers simply to the detection of the virus in tissue or body fluids, and CMV "disease", defined as CMV infection accompanied by symptomatic clinical manifestations [293]. Patients at highest risk for CMV infection and disease are those who are CMV-seronegative at the time of transplant and those treated with potent immunosuppression regimens [301]. Previously, the incidence of CMV disease was reported to be as high as 15%–40% but the overall incidence has decreased to below 15% [298,299]. The differential susceptibility of high-risk vs low-risk patients still persists. Historically, CMV disease occurred most commonly early after transplantation, within the first 3 months. The widespread use of prophylaxis has delayed the time of onset with CMV disease frequently occurring after cessation of prophylaxis [298,299]. Patients typically present with a "CMV syndrome" characterized by fever, malaise, arthralgia, myalgia, and hematological abnormalities such as leukopenia and thrombocytopenia. Clinical manifestations in liver transplant recipients can include fever, hepatitis, pneumonia, gastroenteritis, and chorioretinitis in descending order of frequency [301].

There are many available strategies to diagnose CMV infection. Histopathology depends on the identification of classic tissue intranuclear inclusion bodies (Cowdry type A). Conventional CMV culture from tissue or blood is slow and relatively insensitive. Its replacement, the shell vial assay, which uses a monoclonal antibody against the early CMV antigen, has improved sensitivity and has a rapid turnaround of less than 24 h. Several newer diagnostic assays are available, including:

- CMV antigenemia assay, which uses monoclonal antibodies to detect the viral pp65 antigen expressed on blood leukocytes
- polymerase chain reaction
- hybrid capture CMV DNA assay [293,302].

While these tests are highly sensitive and specific for detecting CMV infection, the specificity for predicting CMV disease is lower, in the 30% to 60% range, depending on the clinical manifestation [293,302]. The CMV antigenemia assay is the predominant diagnostic test used at the authors' institution because of the rapid turnaround time compared to the polymerase chain reaction assay.

Today, standard treatment of CMV disease is intravenous ganciclovir or oral valganciclovir for 14–21 days at the high treatment dosage, followed by 3–6 months at the low prophylaxis dosage. There is no evidence from controlled trials in solid organ transplantation that the addition of CMV immunoglobulin increases treatment efficacy [293]. Clinical response to intravenous ganciclovir is seen in the majority of patients. Of the 20% of patients with recurrent CMV infections, about two-thirds respond to a second course of ganciclovir treatment [303]. There is no consensus regarding the best regimen for CMV prophylaxis after liver transplantation. At the authors' institution, oral ganciclovir or valganciclovir is given to all liver transplant recipients for CMV prophylaxis. Reports have suggested no clear difference in efficacy between oral ganciclovir and valganciclovir for CMV prophylaxis in spite of the fact that the latter has higher oral bioavailability [296–298].

Posttransplant malignancies

De novo malignancy developing after transplantation has been a well-known complication of liver and other solid-organ transplantation [304,305]. The most common is skin cancer, followed by lymphoma/posttransplant lymphoproliferative disease (PTLD), cancer of the lip, Kaposi sarcoma, vulval and perineal cancers, hepatobiliary cancers, and sarcoma [305]. PTLD develops in about 2% of liver transplant

recipients in the first 5 years after transplantation under both cyclosporine and tacrolimus immunosuppression regimens [282,305]. PTLD most often occurs within the first year after liver transplantation, and involves the liver allograft in one-third of cases. The usual histology is B-cell-derived, large cell non-Hodgkin lymphoma. The association between PTLD and Epstein–Barr virus infection has been well documented [306]. Management of PTLD can be considered in a hierarchical fashion, beginning with withdrawal of immunosuppression and administration of antiviral agents such as ganciclovir/valganciclovir or interferon, through anti-B-cell agents such as rituximab, and culminating in conventional chemotherapy.

Renal, cardiovascular, and metabolic complications

Renal insufficiency is recognized as a major cause of long-term morbidity and mortality for all nonkidney solid organ recipients in general and for liver transplant recipients in particular. Previously, the cumulative incidence of end-stage renal failure necessitating hemodialysis or kidney transplantation was reported to be 5% at 5 years and 10% after 10 years [307,308]. However, the reported incidence of advanced chronic kidney disease appears to be much higher with 15% of liver transplant recipients having a glomerular filtration rate of below 30 within 5 years after transplantation [309]. The steepest decline in renal function is observed during the first 12–18 months after transplantation. Direct toxicity of the calcineurin inhibitors is believed to be a major contributing factor to posttransplant renal insufficiency [282,307,308]. The other prime risk factor is pretransplant renal dysfunction that, in the era of organ allocation according to the MELD score, is increasingly prevalent [310,311]. Pretransplant renal dysfunction can be acute, secondary to hepatorenal syndrome or acute tubular necrosis or chronic, most frequently secondary to various types of glomerulonephritis [307]. Although many instances of acute pretransplant renal dysfunction are, in theory, completely reversible shortly after transplantation, it is recognized that dysfunction lasting for several weeks before transplantation may not completely reverse [311–314]. The increasing use of induction immunosuppression [315] with a concomitant delay in the introduction of calcineurin inhibitors undoubtedly reflects an attempt to optimize renal recovery in the early posttransplant timeframe. Moreover, the steadily increasing use of mycophenolate mofetil as part of a triple immunosuppression regimen [315] may also facilitate relative sparing of toxicity from calcineurin inhibitors, although the safety and efficacy of such an approach has not been demonstrated by prospective randomized studies. Several single center studies have examined the safety and efficacy of mycophenolate mofetil and rapamycin as rescue therapy for liver transplant recipients who develop renal insufficiency several years after transplant. Results of reducing or discontinuing calcineurin inhibitors with concomitant initiation of mycophenolate mofetil and rapamycin have been mixed. From the safety perspective, some studies have reported acceptably low rates of acute or chronic rejection whereas others have observed high rates of acute or chronic rejection, some leading to graft loss. From the efficacy perspective, some studies have suggested benefit with improvement in renal function whereas others have suggested no benefit, surmising that renal dysfunction had become irreversible and therefore unaffected by late alterations in immunosuppression [316–318].

Hypertension is common after liver transplantation and may be related to renal insufficiency or immunosuppressive drugs. The incidence of hypertension appears to be lower with tacrolimus than cyclosporine [282]. The first-line agents for hypertension after liver transplantation have been β-blockers, both selective and nonselective (metoprolol, atenolol, and labetolol), and the dihydropyridine calcium-channel blockers (nifedipine, amlodipine, isradipine, felodipine, and nicardipine) [307]. With the exception of nicardipine, this group of calcium-channel blockers has no significant interactions with the calcineurin inhibitors, in contrast to that observed with the other groups of calcium-channel blockers such as verapamil or diltiazem (see Table 92.6). Second-line antihypertensive agents include β-adrenergic and α_1-adrenergic agents, loop diuretics, and angiotensin-converting enzyme inhibitors or angiotensin receptor blockers [307,308]. The use of the α-adrenergic agents such as clonidine and doxazosin is limited by their central nervous system toxicity, particularly drowsiness. It is best to avoid the angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in the first several months after transplantation when calcineurin inhibitors are being introduced and maintained at high levels because they may aggravate renal dysfunction and hyperkalemia [307]. About one-third of patients achieve effective control of their hypertension with a single agent, and another one-third require the addition of a second agent [307].

Obesity, diabetes, and hyperlipidemia occur commonly after liver transplantation, either singly or in combination [319,320]. In an analysis of about 800 adults from the NIDDK Liver Transplant Database, approximately 20% of nonobese liver transplant recipients became obese over the 2 years after liver transplantation [321]. Diabetes is present in about 5%–15% of patients with advanced cirrhosis awaiting liver transplantation [319]. These patients are at higher risk for posttransplant diabetes than those without diabetes before liver transplantation. Some patients develop short-term diabetes early after transplantation because of high-dose corticosteroids but this resolves once the corticosteroids are tapered. For those who remain diabetic, their management is not substantially different from management in the nontransplant setting, although the use of various oral agents that reduce insulin resistance, particularly those with potential hepatotoxicity, requires careful monitoring. Conflicting results have been reported with respect to the impact

of diabetes on medium- to long-term survival [319]. One study revealed a fourfold higher mortality among diabetic patients [322], whereas another study showed a higher survival rate in diabetics than nondiabetics [323]. A more consistent finding, however, is a higher incidence of bacterial and fungal infections after liver transplantation among diabetic patients compared to nondiabetic patients [319]. The intriguing observation from a few studies that the prevalence of diabetes after liver transplantation is higher among patients with hepatitis C infection and that diabetes is an independent risk factor for progressive recurrent hepatitis C needs to be further investigated [324–326].

Hyperlipidemia often occurs concurrently with obesity or diabetes mellitus. Experience has shown that hydroxymethylglutaryl-coenzyme A reductase inhibitors are both safe and efficacious for liver transplant recipients [327]. Other frequently used agents are, however, problematic. Cholestyramine interferes with gastrointestinal absorption of calcineurin inhibitors so its administration must be separated from that of calcineurin inhibitors. Niacin has multiple side effects and can be hepatotoxic.

Despite the increase in cardiac risk index for many of these patients after liver transplantation, long-term follow-up data regarding the risks and incidence for cardiovascular events and mortality following liver transplantation are only beginning to emerge. It is important to remember that liver transplant recipients are a highly selected population, one that has likely undergone extensive cardiovascular assessment as part of the pretransplant evaluation process. Therefore, in theory, they should have a lower prevalence of cardiovascular disease and a lower rate of cardiovascular events than age-matched and gender-matched controls. One study found that among patients who survived longer than 5 years after liver transplantation, the prevalence of cardiac disease was no higher than that in the nontransplant population in the United States [328]. Two other studies, on the other hand, reported cardiovascular events as the cause of 14%–24% of deaths beyond 1 year after liver transplantation [324,330]. Clearly, more studies with longer follow-up are needed. At present, it is important to try to aggressively correct potentially reversible cardiovascular risk factors following liver transplantation.

Immunosuppression

Induction agents

The historical aim of induction agents, typically an antibody preparation given for a short, predetermined course, was to rapidly and potently suppress the immune system around the time of transplantation. The primary short-term side effects associated with administration of these agents include a cytokine-release syndrome typically resulting in severe flu-like symptoms such as fevers, chills, headaches, myalgias, and diarrhea but sometimes involving hypotension or bronchospasm. The primary long-term side effects are those associated with "over-immunosuppression", an increased incidence of infections and malignancy, especially PTLD. While many or most programs used induction in the early era of liver transplantation when immunosuppressants were limited in both number and efficacy, the emergence of newer and more potent agents nearly eliminated all use of induction in the mid- to late 1990s [331–333]. However, there has been resurgence in the use of antibodies but with somewhat different aims – to facilitate minimization or elimination of a maintenance agent (most commonly steroids) or to delay the introduction of calcineurin inhibitors (most commonly in the setting of renal dysfunction) [334–339]. Studies are underway to explore the safety and efficacy of these strategies.

Antibody induction agents can be polyclonal (antilymphocyte globulin and equine or rabbit antithymocyte globulin) or monoclonal (Muromonab-CD3, which is also known as OKT3, the newer anti-interleukin-2 receptor antagonists, daclizumab and basiliximab, or alemtuzumab). Polyclonal preparations are γ-globulins isolated from animals that have been injected with human lymphocytes or thymocytes. Monoclonal preparations have specificities against the pan T-cell CD3 receptor (OKT3), the CD52 receptor (alemtuzumab), or the interleukin-2 receptor (basiliximab and daclizumab). Today, the primary polyclonal and monoclonal agents used in the United States are rabbit thymoglobulin and the anti-interleukin-2 receptor antibody preparations, respectively [333].

Maintenance agents

The typical maintenance immunosuppressive regimen consists of prednisone and a calcineurin inhibitor, with or without an antiproliferative agent. The immunological mechanisms of action for these and other immunosuppressive drugs used today are described briefly below and in greater detail elsewhere [340,341]. Although the specifics of maintenance immunosuppression differ according to the preference of individual transplant centers, the general strategy is to reduce the number and dosage of immunosuppressants with time, as long as there has been clinical stability. Center-specific protocols can specify different strategies based on the pretransplant diagnosis of liver disease, prescribing lower levels of maintenance immunosuppression for recipients with viral hepatitis and higher levels of maintenance immunosuppression for patients with autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, and possibly, fulminant hepatic failure.

Corticosteroids

Corticosteroids are nonspecific antiinflammatory agents that inhibit cytokine production and thereby prevent T-cell recruitment and activation. Typically, corticosteroids are started intraoperatively and given in large but rapidly tapering doses, reaching the maintenance dose of 5 mg/day within several weeks after transplantation. Frequently, corticosteroid

doses are then more gradually reduced such that the drug is completely discontinued sometime during the first posttransplant year. As evidenced by the decreasing percentage of recipients on corticosteroids at discharge from the transplant admission, there is a trend towards minimizing corticosteroids, giving them only in conjunction with induction immunosuppression or avoiding corticosteroids altogether [333,338,339,342].

Calcineurin inhibitors – cyclosporine and tacrolimus

Calcineurin inhibitors, first cyclosporine and then tacrolimus, have been the mainstay of immunosuppression for liver transplantation for nearly three decades [340,341]. Both drugs bind to cytosolic proteins termed immunophilins to form a complex that inhibits calcineurin, a critical enzyme in the production of interleukin-2 by T cells. Interleukin-2 has a major role in orchestrating the complex immune response through the recruitment and activation of not only T cells but also B-cell and natural killer cell populations and through induction of other cytokines.

The first available formulation of cyclosporine, Sandimmune, was notable for erratic bioavailability because its absorption was highly dependent on food intake, bile flow, and gastrointestinal mobility. The newer, microemulsion formulation products, Neoral and Gengraf, have a much more consistent bioavailability profile. Typically, calcineurin inhibitors are usually initiated immediately after liver transplantation. However, for patients with renal dysfunction, these agents, which have known nephrotoxicity, are often delayed, to optimize the recovery of renal function. Calcineurin inhibitors are typically continued indefinitely, albeit at lower doses. Discontinuation in the long-term is typically motivated by significant toxicity, most commonly, deteriorating renal function.

Azathioprine

Azathioprine is an antimetabolite, available since the late 1960s. As a derivative of mercaptopurine, it antagonizes purine metabolism thereby inhibiting DNA synthesis. Although it was frequently used as a maintenance immunosuppressant into the 1990s, it has been largely replaced by mycophenolic acid, which acts through a similar mechanism but has higher potency and lower toxicity.

Mycophenolic acid

Mycophenolic acid inhibits inosine monophosphate dehydrogenase, an enzyme that is essential for de novo purine synthesis, and thereby blocks DNA replication with some specificity in T and B lymphocytes, which are unable to use alternative salvage pathways. Currently, the drug is available as mycophenolate mofetil (MMF), a semisynthetic prodrug which is immediately released, or Myfortic, which is released in a delayed manner to ameliorate gastrointestinal side effects. Since the drug is inactivated by glucuronidation in the liver and then eliminated by the kidney, liver dysfunction results in higher exposure.

The use of mycophenolic acid, typically as a third maintenance agent in conjunction with corticosteroids and calcineurin inhibitors, has increased steeply during the past decade [333]. Now, more than 50% of all transplant recipients in the United States are discharged after transplantation on mycophenolic acid, although it is commonly discontinued sometime during the first posttransplant year when the risk of acute rejection has decreased substantially.

Rapamycin

Rapamycin is a macrolide antibiotic that blocks signal transduction of a multitude of growth factor receptors, inhibits ribosomal protein synthesis, and ultimately blocks cell cycle progression and proliferation. Since it is a potent immunosuppressant that lacks nephrotoxicity, there was great enthusiasm for exploring its appropriate use in not only kidney transplants but also liver transplantation. Early studies in liver transplantation, however, suggested an increased incidence of hepatic artery thrombosis, leading the United States Food and Drug Administration to issue the following black box warning: "The safety and efficacy of Rapamune (sirolimus) as immunosuppressive therapy have not been established in liver transplant patients, and therefore, such use is not recommended." Although later studies have to some degree allayed this fear, use of rapamycin early after transplantation as a maintenance immunosuppressant remains limited in the United States [333].

Acute and chronic rejection

Acute cellular rejection occurs in 30%–60% of all liver transplant recipients within the first year after transplantation with the majority of episodes within the first 4–6 weeks after transplantation [282,283,340,341,343]. It is generally thought to be a reaction to mismatches in class I and II major histocompatibility complex antigens [344]. Historically, in the study from the NIDDK Liver Transplant Database (343], acute rejection was not shown to exert an overall detrimental impact on patient and graft survival. Only the subgroup of patients with a severe episode of rejection defined by histological criteria was at higher risk for death or retransplantation [343]. These findings were in contrast to those in renal transplant recipients, in whom even a single acute rejection episode was associated with a significantly reduced graft survival. In the past decade, advances in immunosuppressive drugs have resulted in a progressive decline in the incidence of acute rejection episodes after liver transplantation [266]. A primary immunosuppressive regimen of a calcineurin inhibitor, mycophenolate mofetil, and prednisone is associated with a rejection rate of only about 30% [266]. Acute rejection is most commonly seen within the first 6 weeks, especially between days 4 and 14 after liver transplantation [282,283,340,341,343].

The incidence of acute rejection generally decreases with time after liver transplantation. The diagnosis is suggested by nonspecific elevations in the liver enzymes. Fever, leukocytosis, and eosinophilia may be present, but are also nonspecific. The other diagnostic considerations for elevated liver enzymes in the early postoperative period include "preservation/reperfusion" injury, hepatic artery thrombosis, and biliary complications. Histologically, acute cellular rejection is characterized by the triad of portal mixed cellular inflammation with predominantly lymphocytes, bile ductular injury, and subendothelial inflammation of the portal or terminal hepatic venules (endotheliitis) [345]. At least two of the three features are required for the diagnosis [345]. Eosinophils are commonly present in the mixed cellular infiltrate although this is a nonspecific feature.

The initial treatment for acute cellular rejection is usually high-dose methylprednisolone at 1000 mg/day for 2 days. In some centers, this intravenous treatment is followed by a tapering schedule of oral prednisone from over several weeks back to maintenance doses. Some centers, however, use only the intravenous bolus or the oral recycle. Steroid-resistant rejection occurs in 10%–20% of patients treated with cyclosporine, but the incidence is reported to be less than 10% with a tacrolimus-based immunosuppressive regimen [283]. Previously, Muromonab-CD3 (also known as OKT3), a murine monoclonal antibody to the CD3 receptor on T lymphocytes, was commonly used for the treatment of steroid-resistant acute cellular rejection. Muromonab-CD3 use is almost always accompanied by a cytokine-release syndrome, which can include fever, chills, bronchospasm, and, rarely pulmonary edema within the first hour after administration. This resolves within 4–6 h. Patients are given methylprednisolone, antipyretics, and antihistamines as a premedication regimen about 1 h before receiving muromonab-CD3 to relieve some of these symptoms. Aseptic meningitis is associated with muromonab-CD3 in 3%–5% of cases. Rabbit thymoglobulin, a polyclonal preparation generated against human thymocytes, has become the preferred agent, mostly because administration is associated with a much milder side effect profile. The use of either is associated with an increased incidence of serious infections, particularly CMV. Hyperacute rejection is a rare and devastating event mediated by preformed antibodies that bind to allogeneic epitopes on donor endothelial cells, leading to rapid graft failure within hours to days after liver transplantation [344]. It is most commonly due to ABO incompatibility.

Historically, chronic ductopenic rejection [346] was seen in about 10% of all liver transplant recipients but its incidence has decreased substantially with the availability of more potent immunosuppressants [347,348]. It is characterized by progressive loss of interlobular bile ducts and an obliterative arteriopathy [346]. Chronic rejection usually develops after multiple episodes of acute rejection, but may be seen after an unresolved episode of acute rejection or indolently over months to years after liver transplantation without a definite rejection episode. Chronic rejection is generally much more difficult to reverse than acute rejection [346,349,350,351] but again, the availability of potent immunosuppressants has improved treatment efficacy. Irreversible chronic rejection that results in diffuse stricturing of bile ducts in the allograft and cholestasis may require retransplantation.

Epidemiology of hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most frequent cause of cancer death worldwide, with an estimated 626 000 new cases per year [1]. Estimates from the International Agency for Research on Cancer for the year 2002 show worldwide age-specific incidence ratios of 15.8 cases per 100 000 per year in men and 5.8 cases per 100 000 per year in women [1]. As a result of the low overall cure rate for HCC, the worldwide age-specific mortality ratios are nearly identical to the incidence ratios at 14.9 deaths per 100 000 per year in men and 5.7 deaths per 100 000 per year in women. There are strong etiological associations with chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections, alcoholic cirrhosis, other causes of chronic liver disease, and dietary aflatoxin exposure. The strong associations with diseases and risk factors that have distinct geographic distributions and different frequencies within different ethnic groups produce a preferential distribution of cases of HCC to certain geographic regions and specific at-risk populations.

International variation in incidence of hepatocellular carcinoma

There is considerable international variation in rates of HCC. By region, the highest incidence is in eastern Asia, with age specific ratios of 36.9 per 100 000 in men and 13.4 per 100 000 in women. China, with the largest population in the region, had an estimated 346 000 cases of HCC in 2002, representing 55% of the total number of cases worldwide. Other regions of high incidence are subSaharan Africa, southeastern Asia, and southern Europe. The lowest incidence rates are found in northern Europe; North, Central and South America; south central Asia; and Australia/New Zealand. The regions of highest incidence in Asia and Africa have a high prevalence of chronic HBV infection as well as high-level exposure to dietary aflatoxins. These combined risk factors play a synergistic role in the development of HCC. Other combinations of risk factors that are important in the epidemiology of HCC include coinfection with HBV and HCV and alcohol use in individuals with chronic hepatitis from viral or other causes. Cigarette smoking and long-term use of oral contraceptives also appear to be independent risk factors for HCC [2]. The risk of development of HCC increases with age. The age distribution of cases of HCC also varies in different populations. A significant proportion of HCC occurs in young and middle-aged individuals at the peak of their productive lives. This results in a high public health and economic impact, particularly in the countries with the highest incidence rates. There is a 15- to 40-year lag time between development of chronic hepatitis or cirrhosis and diagnosis of HCC. This lag time is shorter in persons with active chronic hepatitis C, therefore the increasing prevalence of chronic hepatitis C has led to a decrease in the age of onset of HCC in many populations. For HBV-induced HCC, the age at acquisition of HBV infection is important because individuals who become infected in the perinatal period or in early childhood are more likely to develop chronic hepatitis or become chronic carriers, with an attendant increased risk of development of cirrhosis and HCC [3,4].

Gender variation in incidence of hepatocellular carcinoma

There is a significant effect of gender on the risk of development of HCC. The worldwide male to female incidence ratio is 2.7 : 1. In general, the male : female ratio is highest in the regions with the highest incidences of HCC. Higher levels of

androgen signaling may be associated with the increased risk of HBV-related HCC in men [5].

Epidemiology of hepatocellular carcinoma in North America

In the United States, there has been a well-documented increase in the number of cases of HCC over the past 20 years. Analysis of data from the Surveillance, Epidemiology, and End Results (SEER) database of the National Cancer Institute showed a 71% increase in incidence of histologically proven HCC from 1.4 per 100 000 population for the period from 1976 to 1980 to 2.4 per 100 000 for the period from 1991 to 1995 [6]. In particular, the incidence of HCC increased significantly among younger persons, aged 40–60 years old, during the period from 1991 to 1995 compared with earlier periods. Between 1981–1985 and 1991–1995, there was a 41% increase in the overall mortality rate from HCC. There is also an effect of gender on the incidence of HCC in the United States, with an incidence in men that is three times the incidence among women. There is a striking effect of race on the incidence of HCC in the United States. For the period from 1991 to 1995, Hispanics, Asians, Pacific Islanders, and Native Americans had the highest age-adjusted incidence of HCC, 7.4 per 100 000. For African-American men, the incidence was 6.1 per 100 000 per year, whereas for white men, it was 2.8 per 100 000. The incidence of HCC is highest among recent Asian immigrants to the United States, with age-standardized rates of 23.9 per 100 000 in Korean men and 5.5 per 100 000 in Korean women. These immigrant populations have a high prevalence of chronic HBV infection. Subsequent US-born generations typically have lower rates of chronic HBV infection and a lower risk for HCC [6]. In general, individuals of lower social class in urban US communities have a higher risk of HCC. This may be related to the inverse relationship of social class with prevalence of HBV infection and cigarette smoking.

Analysis of hospitalization rates for HCC in a population of US veterans showed that the recent increase in incidence of HCC was primarily the result of chronic HCV infection. Between 1993–1995 and 1996–1998, age-adjusted hospitalization rates for HCC associated with HCV increased threefold, from 2.3 per 100 000 in 1993–1995 to 7.0 per 100 000 in 1996–1998. During the same period, the age-adjusted hospitalization rates for HCC associated with HBV, alcoholic cirrhosis, and in persons without known risk factors remained relatively stable [7,8].

A number of recent studies have shown that diabetes is associated with development of HCC, with a relative risk of approximately 2.5 [9–11]. Diabetes exerts a synergistic effect with heavy alcohol use and also with viral hepatitis in increasing the risk of HCC in both African-Americans and whites in the United States [12]. Obesity, which is a risk factor for both diabetes and nonalcoholic steatohepatitis, is also associated with an increased risk of HCC [13]. Given the increasing rates of obesity and diabetes in the United States, these risk factors are likely to be increasingly important in the epidemiology of HCC during the next few decades.

Despite improvements in early diagnosis and management of HCC, survival of patients with HCC in the United States has not improved significantly over the past 20 years. A recent analysis of data from the SEER database showed that the overall 1-year relative survival rate increased from 14% in 1977–1981 to 23% in 1992–1996 [14]. However, 5-year relative survival rates did not change as much, increasing from 2% to 6%. Median survival after diagnosis increased only slightly, from 0.57 years in 1977–1981 to 0.64 years in 1992–1996. There were no significant influences of gender or ethnicity on survival. Most patients with HCC have advanced disease at the time of diagnosis. In the period from 1987 to 1991, only 0.8% of patients with HCC underwent radical surgery with curative intent; these patients had a significantly better survival than patients with untreated advanced disease, with a 1-year relative survival of 60% and a 5-year relative survival of 40%. In the same period from 1987 to 1991, 7.4% of patients underwent palliative surgery; these patients had a 1-year survival of 50% and a 5-year survival of 20%. The proportion of patients undergoing radical surgery in the later period from 1991 to 1996 was unchanged from the earlier period at 0.8%. These data suggested that screening programs aimed at identifying patients with HCC early enough to allow radical surgery were not widely practiced, were ineffective, or were not coupled with widespread availability of the specialized surgical skills needed for optimal radical surgery. The proportion of patients with HCC able to undergo radical surgery is probably also limited by the recognition in recent years that surgical outcomes in patients with cirrhosis and clinically significant portal hypertension are very poor [15]. There is an urgent need to develop methods of identifying the individuals who are at highest risk of developing HCC, to determine the optimal and most cost-effective screening methods to allow early diagnosis of HCC, and to provide access to specialized multidisciplinary management of HCC. In the 1992–1999 time period, there was a substantial increase in the proportion of individuals with HCC who received radical, potentially curative treatment to 13% of cases in the age group over 65 years of age, perhaps reflecting the results of efforts to enhance screening of at-risk individuals [16]. With substantial evidence accumulating that liver transplantation can effectively treat both early HCC and also replace the surrounding cirrhotic liver, there have been additional priority points awarded to patients with early HCC who are candidates for liver transplantation; consequently, the percentage of patients with HCC who are candidates for surgical resection or liver transplantation has increased further. These improvements in the management of HCC, particularly the increasing availability of liver transplantation for patients with early disease, are likely to result in further improvements in survival.

Etiology and risk factors for hepatocellular carcinoma

Chronic hepatitis B

There are 350 million chronic HBV carriers worldwide. The prevalence of hepatitis B surface antigen positivity ranges from high (> 8%) in Africa, Asia, and the Western Pacific, through intermediate (2%–7%) in Southern and Eastern Europe, to low (< 2%) in Western Europe, North America, and Australia. Fifty million new cases of HBV infection occur each year, of these, 5%–10% of adults and up to 90% of infants become chronically infected. In the United States, at least 250 000 persons contract hepatitis B each year. The predominant mode of viral transmission in a population varies with the prevalence of HBV infection. In low-prevalence countries, sexual contact among high-risk adolescents and adults is the predominant mode of transmission. In highly endemic countries, most HBV infections are contracted perinatally or in early childhood. Between one-fourth and one-third of individuals with chronic hepatitis B develop progressive liver disease. Cirrhosis develops in 0.1%–2% of patients with chronic hepatitis B each year, depending on the duration of HBV replication, the severity of disease, and the presence of coexisting infections or alcohol use. In individuals who develop cirrhosis, the risk of progression to HCC varies from 2% to 10% per year [17]. Both host and viral factors influence the natural history of chronic hepatitis B. Certain HBV strains predominate in HCC, suggesting that particular genotypes are more effective at initiating or promoting hepatocarcinogenesis [18]. Individuals with high serum HBV DNA levels are at substantially higher risk of developing cirrhosis and HCC than those with undetectable levels [19,20]. Vaccination of infants and at risk individuals decreases the prevalence of chronic HBV infection and the incidence of HCC [21]. However, there is no conclusive evidence that treatment of patients with high HBV DNA levels with antiviral agents decreases the risk of HCC.

Chronic hepatitis C

An estimated 170 million people are infected with HCV worldwide, and in some countries HCV has overtaken HBV as the major cause of HCC. HCV is an RNA virus that causes acute and chronic hepatitis. It is contracted through parenteral exposure to infected material. Those at highest risk for acquiring hepatitis C are recipients of contaminated blood transfusions, injection-drug users, people who snort cocaine with shared straws, and health-care workers at risk for needlestick and other exposures. Although the incidence of acute HCV infection has fallen dramatically in the United States during the past two decades, the prevalence of infection remains high (approximately 2.7 million Americans) because chronic hepatitis C develops in about 75% of those infected. Both acute and chronic hepatitis C are asymptomatic in most patients. Chronic hepatitis C is a slowly progressive disease that eventually results in severe morbidity in 20%–30% of infected persons. Virological features of HCV such as genotype and viral load are associated with progression and response to therapy [3]. There is a marked difference in the geographic distribution of HCV genotypes, with types 1, 2, and 3a being most frequently found in Western countries. Persistent hepatitis, with high average annual alanine aminotransferase levels, is a significant predictor of the development of HCC [22]. Individuals with active hepatitis, those with coinfections with HBV or human immunodeficiency virus (HIV) and persons with other causes of chronic liver disease such as alcoholic liver disease are more likely to develop liver-related complications. Persons with combined hepatitis B surface antigen positivity and chronic HCV infection are at particular risk of developing HCC [23]. HCV-positive individuals who are anti-hepatitis B core antigen-positive also have a higher prevalence of cirrhosis, lower HCV RNA levels, and an impaired ability to respond to interferon treatment [24].

HIV and HCV have shared routes of transmission so persons infected with HIV are at risk for coinfection with HCV. With the advent of highly active antiretroviral therapy, there has been decreased morbidity and increased survival of patients with HIV infection. As a result, HIV–HCV coinfected patients are living longer and are at increased long-term risk for hepatic cirrhosis, end-stage liver disease, and HCC [25].

After surgical resection of HCC, the presence of active hepatitis and hepatitis C viremia are risk factors for tumor recurrence. Prior treatment of hepatitis C with interferon is protective against the initial development of HCC or its recurrence after surgical resection. The protective effect of interferon is most marked in patients who respond to interferon treatment by clearing the virus and achieving a sustained virological response; there is no evidence of benefit in patients who do not clear the virus. In spite of the decreased risk of HCC after sustained virological response, the risk is still significant and continued surveillance for the early detection of HCC is warranted [26–32].

Dietary aflatoxin exposure

Dietary exposure to fungal aflatoxin is an important risk factor for development of HCC. Aflatoxin (derived from A*spergillus* fla*vus* toxin) is a mycotoxin produced by two fungal species, *Aspergillus flavus* and *Aspergillus parasiticus*. *Aspergillus flavus* is widespread in nature, occurring in soil and decaying vegetation, hay, and grains, particularly in conditions of high moisture content and high temperature. There are at least 13 different types of aflatoxin, with aflatoxin B_1 considered the most toxic. Epidemiological studies have indicated a relationship between aflatoxin intake and incidence of liver cancer in several countries [33,34].

Aflatoxins are metabolized in the liver by the cytochrome p450 and glutathione *S*-transferase enzyme systems. Aflatoxin

B_1 is a procarcinogen that is converted in the liver to the mutagenic metabolite aflatoxin B_1-8,9-exo-epoxide by hepatic microsomal cytochrome p450. Glutathione *S*-transferases and other phase II enzymes subsequently detoxify this DNA-reactive metabolite [35]. Interindividual differences in the biotransformation of dietary aflatoxins result in differing susceptibility to aflatoxin-induced carcinogenesis. The glutathione *S*-transferase M1 (*GSTM1*) gene exhibits genetic polymorphism, with a proportion of normal individuals having a homozygous deletion of the gene. Individuals living in regions where dietary aflatoxin levels are high who have the *GSTM1* null genotype are at increased risk of developing HCC [36]. The presence of additional high-risk genotypes in aflatoxin-metabolizing or DNA repair genes confers an even higher risk of development of HCC [37]. Aflatoxin exposure predisposes to mutations in the gene for p53, particularly a G to T transversion at codon 249, an event that contributes to the pathogenesis of HCC [38]. In many countries, particularly in tropical regions, grains, peanuts, beans, and other foods are harvested and stored under conditions that allow fungal growth and accumulation of high levels of aflatoxin. Measures are being instituted in many countries to decrease contamination of foodstuffs with aflatoxin. There are also efforts to develop drugs that enhance aflatoxin detoxification and excretion [39].

The carcinogenic potential of dietary aflatoxins is significantly increased by the presence of concomitant chronic HBV infection. In one study, persons negative for HBV had 0.01 cases of HCC per 100 000 persons per year per ng of aflatoxin B_1 ingested/kg body weight per day. In contrast, HBV-positive persons had 0.3 cases per year per 100 000 persons, a 30-fold higher risk than in the absence of hepatitis B surface antigen in the serum. Individuals with chronic HCV infection are also probably at increased risk from dietary aflatoxin [40].

Cirrhosis from alcohol and other chronic liver diseases

Cirrhosis from any cause, including chronic alcohol abuse, increases the risk of HCC. The HCC risk is higher for individuals with chronic hepatitis and ongoing hepatocellular injury. Therefore, individuals who stop drinking significantly reduce their risk of HCC. Similarly, persons with hereditary hemochromatosis and cirrhosis who are iron depleted by phlebotomy have a reduced risk of HCC. Certain causes of cirrhosis, such as autoimmune hepatitis, carry a relatively low risk of HCC [41].

Familial and genetic influences on risk of hepatocellular carcinoma

Particularly in areas of the world with a high incidence of HCC, a family history is a significant risk factor for HCC development [42]. The biological basis for this phenomenon is unknown. Epidemiological studies have suggested either the presence of a recessive allele that contributes to risk of HCC or a familial predisposition to a prolonged HBV replication phase [43,44]. Recent evidence from Taiwan has identified a potential susceptibility locus for familial predisposition to HBV-induced HCCs at chromosome 4q25, adjacent to the *LEF1* gene, which encodes a transcriptional effector of the Wnt signaling pathway [45]. In findings that may be related to the inherent ability to clear or suppress HBV infections, initial results suggest that HBV-infected individuals who carry the low-activity genotypes of major T helper type 1 cytokines or the high-activity genotypes of major T helper type 2 cytokines may be at particularly high risk for development of HCC [46]. Genetic polymorphisms of the carcinogen-metabolizing enzymes cytochrome P450 (*CYP*), *GSTM1*, and *N*-acetyltransferase (*NAT2*) as well as polymorphisms in the gene for p53 may also contribute to familial risk of HCC [47].

Factors associated with decreased risk of hepatocellular carcinoma

A number of recent epidemiological studies have identified factors that are associated with a decreased risk of progression of chronic liver disease or development of HCC. These factors include a high serum retinol level and high coffee consumption [48–53]. These findings may have future relevance for efforts at chemoprevention of HCC.

Pathogenesis of hepatocellular carcinoma

Oncogene activation and tumor suppressor inactivation play important roles in carcinogenesis. Oncogene activation occurs through transcriptional activation, gene amplification, or development of activating mutations of genes involved in cellular growth control. Tumor suppressor inactivation can occur through genomic deletions, translocations, or mutations or through epigenetic modifications such as promoter methylation. Normal human somatic cells have a finite life span in vivo and undergo senescence after a predictable number of cell divisions. Cellular senescence is triggered by the activation of two interdependent mechanisms. One mechanism leads to the induction of cell cycle arrest as a result of activation of two tumor suppressor genes, *p53* and *pRb*. The second mechanism is activated by a critical shortening of chromosomal ends as a result of the progressive shortening of the telomeres with each cell division. When both cell growth regulatory mechanisms are inactivated, unchecked cell division and progression to cancer occur. Cells that are turning over at higher than normal rates because of local growth factor up-regulation or chronic cell injury and regeneration, have a higher likelihood of developing genomic alterations that lead to oncogene activation or tumor suppressor inactivation [54]. Environmental exposure to carcinogens can also cause oncogene activation or tumor suppressor inactivation (Fig. 93.1). A number of approaches

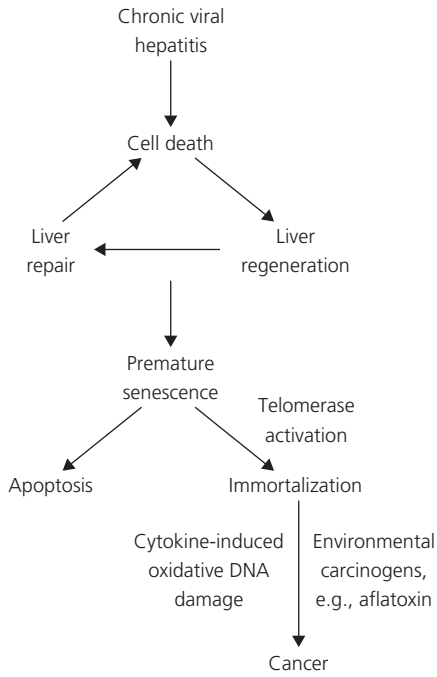

Figure 93.1 The role of chronic hepatitis with recurrent liver injury, regeneration, and repair in the development of hepatocellular carcinoma. Premature senescence of liver cells occurs by apoptosis. Cells undergoing telomerase activation escape apoptosis. The resulting immortalized cells are susceptible to the influence of oxidative and environmental carcinogen-induced DNA damage, leading to the eventual development of transformed neoplastic hepatocytes.

have been used to elucidate the molecular mechanisms of liver carcinogenesis. These include:

- the use of chemical tumor initiators and promoters in animal models
- studies of growth factors and their signaling pathways
- transgenic mouse models overexpressing cytokines, growth factors, or oncogenes
- studies of immune-mediated mechanisms of hepatocellular injury
- analysis of the molecular genetic changes that occur in HCCs, including studies of chromosomal allelic imbalance, comparative genomic hybridization, restriction landmark genomic scanning, and gene expression analysis using complementary DNA microarrays
- studies of the molecular consequences of HBV integration and the interaction of the protein products of the HBV and HCV with host cell processes.

These studies have contributed to our growing appreciation of the multiplicity of mechanisms and pathways that may contribute to the carcinogenic process in toxin-affected, chronically inflamed, or otherwise injured liver tissue. In cirrhotic livers, macroregenerative nodules with foci of hepatocyte dysplasia have been identified as preneoplastic lesions of HCCs. Histologically, dysplastic lesions are classified as small cell or large cell lesions or as foci of adenomatous hyperplasia; available evidence suggests that small cell dysplasia and adenomatous hyperplasia are the predominant preneoplastic lesions [55]. Unfortunately, we are still far from a unified, comprehensive understanding of liver carcinogenesis. This is in part because HCC is initiated in multiple genetic and environmental contexts and almost certainly emerges as a consequence of multiple possible pathways. The lack of a comprehensive view of the pathogenesis of HCC has also prevented the development of effective, targeted, preventive, or therapeutic interventions that are elegant and also simple enough to be applicable to the vast majority of patients with this disease. Recent analyses using genome-wide approaches and novel animal models have led to a better understanding of the major pathways involved in liver carcinogenesis and allowed initial attempts at subclassifying the apparently molecularly heterogeneous HCCs into distinct molecular and prognostic subtypes [56–60].

While the generally accepted paradigm of carcinogenesis is that malignant transformation occurs through the stepwise accumulation of genetic and epigenetic alterations that lead to the progressive acquisition of the cancer phenotypes, recent studies have led to the concept that a minimum number of molecular alterations leads to the acquisition of the key cancer phenotype, unconstrained cell proliferation. This "cancer platform" concept posits that growth-promoting oncogenic pathways generally also activate pathways of cellular senescence or apoptosis that limit their growth effects, producing a natural homeostasis of tissue mass. When activation of oncogenic events is coupled with inactivation of this "oncogene-induced apoptosis", unconstrained proliferation results. The other cancer phenotypes are then acquired secondarily through the interaction of the surrounding stroma with the growing mass of tumor cells [61,62]. The major regulator of oncogene-induced apoptosis appears to be the tumor suppressor p53, however, p53 action is accomplished through a network of regulatory molecules, which when disrupted individually or in combination can mimic the effects of p53, hence the observation that cancers are molecularly heterogeneous and there are multiple genes that contribute to the development of cancer. However, this new paradigm also suggests that targeting the key pathways that regulated unconstrained proliferation may have profound effects on tumor growth.

Another major advance in our understanding of cancer has come from the recognition that the primary events leading to unconstrained cell proliferation may occur in a small population of cancer stem cells from which the main bulk of a malignant tumor is derived through partial differentiation [63]. Consequently, to effectively induce tumor regression, therapeutic measures will have to target the key molecules and pathways that regulate unconstrained proliferation of the stem cell compartment. Experiments using mice in which *myc* oncogene expression is regulated by oral administration

of doxycycline have elegantly demonstrated the ability to induce HCC or to cause its regression through modulation of *myc* expression in a small stem cell compartment [64,65].

These studies hold great promise for allowing careful characterization of tumors and personalization of targeted therapies in the future.

Tumor suppressor genes

Tumor suppressor genes are normal cellular genes that, when homozygously inactivated, can contribute to tumor development. Tumor suppressor genes generally operate in a recessive manner, requiring loss of both copies for tumorigenesis, in contrast to oncogenes, which can exert their effects in a dominant fashion. Loss of heterozygosity (LOH) is loss of one allele in a tumor cell from a chromosomal region for which the individual's normal cells are heterozygous. LOH is detected using polymorphic DNA markers that can distinguish between the two alleles. If one allele of a tumor suppressor gene is inactivated by mutation, then deletion of the second allele, detected by LOH, is associated with loss of expression of the gene. Promoter hypermethylation also leads to decreased expression of tumor suppressor genes. DNA hypermethylation on CpG islands and DNA hypomethylation on pericentromeric satellite regions are early events during hepatocarcinogenesis. CpG island hypermethylation leads to decreased tumor suppressor gene expression, while pericentromeric hypomethylation results in chromosomal instability and deletions [66].

Known or putative tumor suppressor genes shown to be mutated or down-regulated in HCCs include *p53* [67], *RB* [68], *M6P/IGF2R* [69], *BRCA2* [70], *DLC1* [71,72], *p16* [73], *Smad2* [74], *Smad4* [74], *axin1* [75], *axin2* [76], *Parkin* [77], *SULF1* [78], Kruppel-like factor 6 [79–82], the IκB kinase (IKK) subunit *NEMO/IKKγ* [83], *Prickle1* [84], vitamin D binding protein, fibrinogen γ-chain, fibrinogen-like protein 1, metallothionein 1G, α_2-plasmin inhibitor [85], *DDX3* [86], and *TIP30* [87]. In human HCCs, LOH has been reported in multiple chromosomal regions, including 1p, 1q, 2q, 4q, 5q, 6q, 8p, 8q, 9q, 10q, 11p, 12p, 13q, 14q, 16q, and 17p [88,89]. A number of these regions contain known tumor suppressor genes, such as at 17p13.1 (*p53*), 6q26–27 (*M6P/IGF2R*), 8p21.3–22 (*DLC1*), and 13q12–q32 (*Rb* and *BRCA2*). For a few of these chromosomal loci, clinicopathological associations have been demonstrated, such as the association of LOH on chromosome 1p with early stage HCC [90] and that of LOH on chromosome 16q with progression of HCC [91]. In addition, patients with LOH at multiple regions have more advanced stage disease, less well-differentiated tumors, higher serum α-fetoprotein levels, and a worse prognosis [92]. Chronic HBV infection and integration of the HBV genome are also associated with high rates of genomic instability [93]. Comparative genomic hybridization (CGH) allows the identification of gains and losses of DNA sequences across the entire tumor genome. Analysis of HCC tumors and cell lines by CGH has revealed genomic DNA copy number gains on chromosomal arms 1p, 1q, 2q, 3q, 6p, 7p, 7q, 8q, 10p, 11q, 12q, 17q, 20p, and 20q. Recurrent losses have been found on 1p, 3p, 3q, 4p, 4q, 5q, 6q, 8p, 9p, 10q, 11q, 13q, 14q, 15q, 16q, 17p, 18q, 21q, and on the Y chromosome [94–101]. Significantly, a majority of the overrepresented regions harbor known protooncogenes, and half of the underrepresented regions coincide with sites of known or putative tumor suppressors [96]. Notably, comparison of CGH analysis of HCCs that are the result of HBV infection, as compared to HCC with non-viral etiology, has a lower frequency of loss at 4q, 16q, and 17p in nonviral HCC samples, suggesting that these abnormalities are associated with HBV infection [102]. CGH analyses also reveal a similar pattern of chromosomal alterations in HBV-induced and HCV-induced HCCs. Thus a subset of alterations may preferentially contribute to virus-induced carcinogenesis. In general, LOH and CGH studies have shown variable rates of chromosomal instability. Patient populations with low rates of virus-induced HCCs have lower levels of chromosomal instability than populations with high rates of virus-induced HCCs. Despite this variability, there is remarkable consistency in the locations of chromosomal instability, suggesting that particular gene targets are affected by genomic instability in HCC.

Investigation of gene mutations in the tumor suppressor gene *p53* in HCC has been particularly revealing because HCCs from patients with high dietary exposure to fungal aflatoxin B_1 have a high frequency of point mutations at the third position of codon 249 of the *p53* gene, resulting in a G : C to T : A transversion [103]. The frequency of this mutation in HCC increases in proportion with the level of dietary exposure to aflatoxins. A G : C to T : A transversion at the second position of codon 249 is often found in patients with chronic HBV or HCV infection. The occurrence of this mutation correlates with oxyradical exposure. Both of these mutations lead to decreased binding of p53 to its nuclear DNA targets [104]. Mutations in *p53* have been demonstrated in nonneoplastic liver cells in subjects from communities with high dietary aflatoxin B_1 exposure, suggesting that the mutations are early events in neoplastic transformation (Fig. 93.2). However, *p53* mutations can also occur late in tumor progression. The hepatitis B virus HBx gene product has also been shown to interact with p53 and to strongly inhibit p53 sequence-specific binding, leading to inhibition of p53-mediated apoptosis. Abnormalities in the *Rb* gene have been noted in association with *p53* mutations in advanced HCCs, particularly in poorly differentiated tumors, and *p53* and *Rb* mutations may have an additive effect in liver carcinogenesis [105]. HCCs from different populations show different frequencies of *p53* mutations. In Alaskan Indians, *p53* mutations are rare or absent, suggesting that a difference in environmental or host factors leads to a different mechanism of hepatocarcinogenesis [106]. In a conditional mouse model of HCC, loss of *p53* has been shown to be required for the

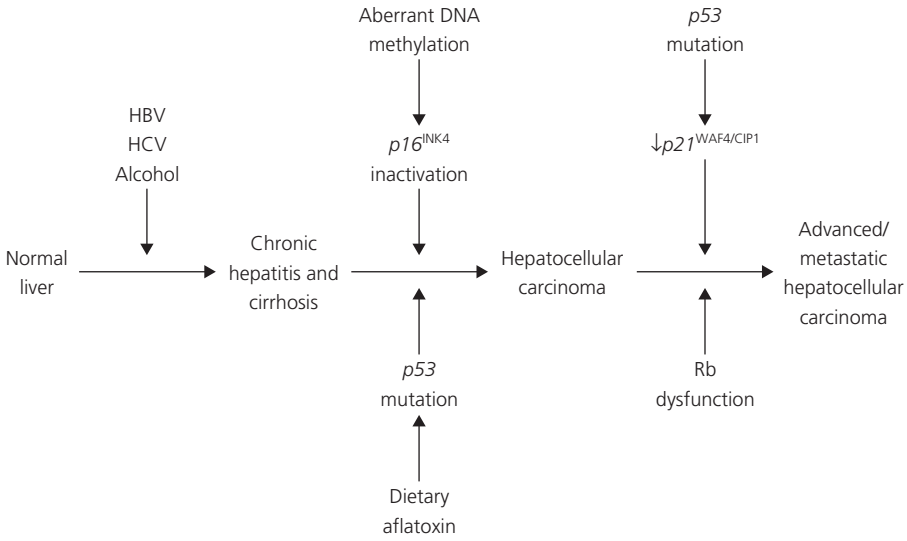

Figure 93.2 Major molecular pathways of hepatocarcinogenesis. Hypermethylation of the p16 gene promoter is one of the earliest changes in development of hepatocellular carcinoma. In regions with high dietary aflatoxin exposure, the development of p53 mutations also occurs early. In areas with low aflatoxin exposure, p53 and pRb pathway disruption occurs late in hepatocarcinogenesis.

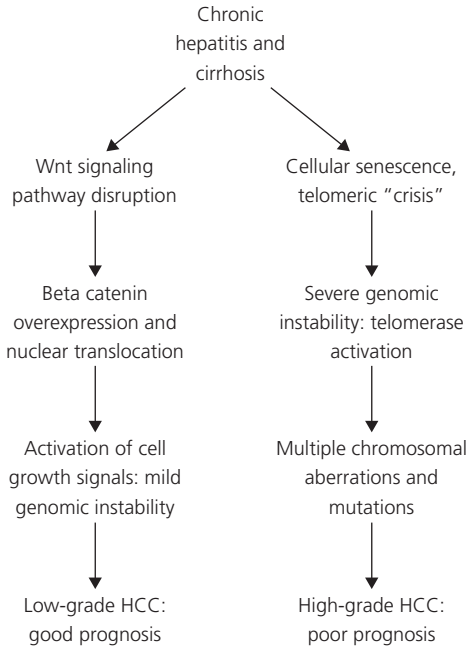

Figure 93.3 Two distinct pathways of liver carcinogenesis. Disruption of the Wnt signaling pathway occurs in approximately 25% of hepatocellular carcinomas. β-Catenin mutations prevent degradation of β-catenin and lead to accumulation of nuclear β-catenin. β-Catenin cooperates with the Tcf transcription factor to activate cellular growth control genes. Tumors with β-catenin mutations tend to have lower rates of genomic instability and to be lower grade tumors with a better prognosis.

maintenance of aggressive HCCs [107]. In this model, reactivation of endogenous p53 induced cellular senescence and an enhanced innate immune response that produced complete tumor regression. These studies underline the importance of p53 in restricting tumorigenesis. Molecular genetic studies show that HCC appear to fall into two groups, with either low or high levels of chromosomal changes [108]. In general, the group of tumors with low level chromosomal instability is also more likely to have disruption of the Wnt signaling pathway, with β-catenin mutations, low-grade histology, and a better long-term prognosis (Fig. 93.3). In contrast, tumors with high-level chromosomal instability are more likely to have *p53* mutations.

Promoter hypermethylation is an important cause of loss of expression of tumor suppressor genes in hepatocarcinogenesis. Genes inactivated by this mechanism include *p16* [109], *SOCS* [110], *TSLC1* [111], E-cadherin [112], *RASSF1A* [113], *NORE1B* [114], Fas-associated phosphatase-1 [115], and spleen tyrosine kinase [116]. In particular, *p16* inactivation by hypermethylation appears to be one of the earliest genetic events in hepatocarcinogenesis (Fig. 93.3) [117].

Oncogenes

Protooncogenes are cellular genes involved in the control of cell growth. Mutation, overexpression, or amplification of these genes leads to oncogenic activity that contributes to neoplastic transformation. Oncogenes known to be overexpressed in HCC include c-*fos* and c-*myc* [118], c-*erbB2* [119], c-*met* [120], β-catenin [121], gankyrin [122], and pituitary tumor-transforming gene-1/survivin [123,124]. Overexpression of c-*myc* is frequently a consequence of amplification of the c-*myc* locus in HCC [94]. Activation of the c-*myc* and c-*fos* oncogenes also occurs as a consequence of the transactivating function of the hepatitis B virus x protein (HBx) and the C-terminal truncated middle hepatitis B surface protein (MHBst) [125]. Oncogene activation may also occur through promoter hypomethylation [126], through pathways mediated by reactive oxygen species, or through protein kinase C or mitogen-activated protein kinase pathways. Processes mediated by reactive oxygen species or lipid peroxidation are also important in the pathogenesis of chronic liver injury induced by alcohol, genetic hemochromatosis, and α_1-antitrypsin deficiency.

Growth factors and growth factor signaling pathways

A number of different growth factors are involved in hepatocarcinogenesis. Insulin and insulin-like growth factors (IGFs) 1 and 2 promote hepatocyte growth. IGF-2 is frequently overexpressed in HCCs. In addition, insulin receptor substrate 1 (IRS-1), a cellular mediator of insulin-like growth factor signaling, is frequently overexpressed in HCCs [127]. Signaling events downstream of IRS-1 lead to activation of the mitogen-activated protein kinase cascade and to cell proliferation through up-regulation of cellular growth genes and inhibition of apoptosis [128]. Transforming growth factor-α (TGF-α) and the structurally related epidermal growth factor are another potent class of hepatocellular growth factors. TGF-α is overexpressed in the liver of patients with chronic hepatitis. As TGF-α levels are often increased in HCCs, it is likely that it contributes to cellular proliferation in cancer, and may be a factor in tumor initiation or progression in patients with chronic hepatitis. In a transgenic mouse model, TGF-α dramatically enhances c-*myc*-induced hepatocarcinogenesis by promoting the proliferation and survival of HCC cells [129]. The TGF-α/c-*myc* transgenic mouse model also shows hyperphosphorylation of the retinoblastoma protein pRb, which results in inactivation of pRb and release of E2F transcriptional activity, resulting in cell cycle progression and enhanced mitosis [130]. TGF-β_1 inhibits cell proliferation and promotes cellular differentiation, fibrogenesis, and apoptosis. Increased TGF-β_1 may create an environment in which selection of hepatocyte clones resistant to TGF-β_1-induced apoptosis occurs. The *Smad* genes are involved in TGF-β signaling and mutations in the *Smad2* and *Smad4* genes have been described in HCC [74]. Hepatocyte growth factor, the ligand for the c-*met* oncogene, activates the Akt/phosphatidylinositol-3 kinase pathway to suppress Fas-mediated cell death in human HCCs [131]. High molecular mass forms of basic fibroblast growth factor have also been shown to have a mitogenic effect on hepatocytes [132]. Recent studies suggest that the Ras, Jak/STAT, and Akt pathways are activated in the majority of HCCs [133]. As previously mentioned, there is substantial evidence for a significant role of Wnt pathway activation in hepatocarcinogenesis. Emerging evidence suggests that Wnt pathway regulation in HCC is complex, with differential effects of mutated β-catenin and Axin1 in different subclasses of HCCs [59,134]. There is also evidence for involvement of the hedgehog signaling pathway in hepatocarcinogenesis [135]. Clearly, multiple growth-promoting molecules are involved in hepatocellular carcinogenesis.

Telomere length and telomerase activity

Telomeres are specialized protein–DNA structures at the ends of chromosomes that contain long stretches of TTAGGG hexameric repeats. Telomeres prevent degradation of chromosome ends and end-to-end fusion with other chromosomes. Aging of somatic cells is associated with reduction in telomere length as a result of the inability of traditional DNA polymerases to completely replicate the end of the chromosomal DNA. In contrast, germ-line and neoplastic cells express telomerase, an enzyme that restores telomere length. There is progressive shortening of telomeres during progression from chronic hepatitis to cirrhosis and eventually to HCC [136]. This occurs as a consequence of the multiple cycles of cell injury, death, and regeneration that occur in injured liver, leading to premature hepatocellular senescence. Telomere shortening beyond a critical length leads to a proliferative block referred to as telomeric crisis, which is characterized by chromosomal instability, end-to-end fusions, and cell death. Stabilization of the telomeric DNA through either telomerase activation or the activation of an alternative mechanism of telomere maintenance is essential if the cells are to survive and proliferate indefinitely (Fig. 93.1) [137]. There is cross-talk between the oncogene and telomerase pathways, as c-*myc* has been shown to activate the telomerase gene promoter [138]; p53 dysfunction also cooperates with telomere-induced chromosomal instability in hepatocarcinogenesis [54]. Hepatocarcinogenesis is characterized by the evolution of clones of hepatocytes with increased telomerase expression and an immortalized phenotype [139]. Therefore, almost all HCCs show reactivation of telomerase activity [140].

Microsatellite instability

Microsatellite instability (MSI) is defined as a change of any length as the result of either insertion or deletion of repeating units in a DNA microsatellite within tumor genomic DNA when compared to normal tissue. This form of genomic instability is associated with defective DNA mismatch repair in tumors, which is important in the pathogenesis of the hereditary nonpolyposis colon cancer (HNPCC) syndrome and associated malignancies [141]. To date, six mismatch repair genes have been identified in humans: *hMLH1*, *hMSH2*, *hPMS1*, *hPMS2*, *hMSH3*, and *hMSH6*. Colorectal cancers may be characterized as having high-frequency MSI (MSI-H) if more than 30%–40% of more than five microsatellite loci analyzed show instability, low-frequency MSI (MSI-L) if less than 30%–40% of more than five loci analyzed show instability, or as being microsatellite stable (MSS) if 0% of loci show instability. Of sporadic colorectal cancers, 70% are MSS, 15% are MSI-L, and 15% are MSI-H. MSS or MSI-L colorectal cancers do not have an associated defective mismatch repair phenotype or the clinicopathological features of HNPCC tumors; instead they behave in the same manner as sporadic colon cancers. Clear criteria have not been defined for MSI in noncolonic tumors. To date, a number of studies have demonstrated either no instability or a relatively low frequency of low-level MSI in HCC [142,143]. As is the case with other noncolonic tumors, it is unclear whether this finding is of significance in the etiology or pathogenesis of HCCs or is instead simply a consequence of the generalized genomic instability found in cancer. It has

been suggested that cumulative low-level MSI at multiple loci leads to tumor progression. Further investigation is needed to resolve this potentially important question.

Chromosomal fragile sites

Chromosomal fragile sites are specific genetic loci which are susceptible to forming gaps, breaks, and rearrangements in metaphase chromosomes of cells cultured under conditions that inhibit DNA replication, such as treatment with the DNA α-polymerase inhibitor, aphidicolin. Fragile sites are grouped into "common" or "rare" classes based on their frequency of occurrence and the culture conditions required for their expression. So far, 89 common and 28 rare chromosomal fragile sites have been identified. Common fragile sites are present in all individuals. The most frequently observed common chromosomal fragile sites occur at 3p14.2 (*FRA3B*), 16q23 (*FRA16D*), 6q26 (*FRA6E*), 7q32 (*FRA7H*), and Xp22 (*FRAXB*) [144]. Common fragile sites span a distance of 250–1500 kilobases and display characteristics of unstable, highly recombinogenic DNA in vitro. In particular, they are preferred sites for sister chromatid exchanges, chromosomal deletions and rearrangements, integration of viral sequences and transfected plasmid DNA, and initiation of bridge breakage–fusion cycles, which lead to gene amplification. As a result of these characteristics and the frequent coincidence of fragile sites with chromosomal breakpoints in malignant cells, it has been hypothesized that fragile sites are involved in carcinogenesis [145]. The most convincing evidence of the potential significance of the fragile sites in carcinogenesis is the location of *FRA3B*, the most highly inducible common fragile site, at chromosome 3p14.2. This chromosomal region is frequently deleted in lung cancer, renal cell carcinoma, and pancreatic cancer, and is also the location of the fragile histidine triad (*FHIT*) gene [146]. The *FHIT* gene has been proposed to be a tumor suppressor and has been identified as a preferential target in HCC [147]. Additional fragile site genes, including the *FRA16D* gene *WWOX* (16q23) and the *FRA6E* gene *Parkin* (6q26), which are both located in regions at which there is increased LOH in HCC, encode proteins that have been shown to have tumor suppressor functions in HCC [77,148,149].

Angiogenesis

New vessel formation is required for the continual growth of the tumor and provides a gateway for cells to escape the confines of the primary tumor. HCCs are usually hypervascular and show evidence of active angiogenesis. Arteriolar density in the tumors correlates with angiographic vascularity and also with the proliferating cell nuclear antigen labeling index [150]. It has been shown that IGF-2 production is stimulated by hypoxia, and that IGF-2 in turn activates expression of vascular endothelial growth factor (VEGF), an important regulator of tumor angiogenesis [151]. IGF-2 has also been shown to directly stimulate angiogenesis. The hypoxia inducible factor (HIF-1) also plays a role in angiogenesis in HCC [152]. HIF-1 stimulates angiogenesis by activating transcription of the gene encoding VEGF. In parallel with the increase in angiogenic stimuli, it has been shown that the expression of collagen XVIII, the precursor of the antiangiogenic molecule endostatin, is decreased in larger and more vascular HCCs [153]. Antiangiogenic agents have been shown to be effective against HCC in mouse models, and initial results from clinical trials of antiangiogenic agents in human HCC suggest that they are of benefit [154–156].

Hepatitis B virus in the pathogenesis of hepatocellular carcinoma

Multiple mechanisms appear to contribute to HBV-induced hepatocarcinogenesis. Although persistent hepatitis with regenerative hepatocellular turnover and cirrhosis is presumed to play a significant role in HBV-induced carcinogenesis, a significant percentage of HBV-related HCCs occur in the absence of cirrhosis, suggesting a specific role for HBV in the development of these cancers. HBV integrates into the host genome in almost all patients with chronic hepatitis. Viral integration almost invariably precedes the development of HCC. HBV DNA appears to integrate into random sites in the human genome, however, with recent advances in molecular genetics, there is emerging evidence that, as with other viruses, viral integration preferentially targets specific genes or common chromosomal fragile sites [149,157,158]. Integrated HBV is thought to contribute to the pathogenesis of HCC through a number of potential mechanisms:

- by local genomic effects as a result of production of genomic instability and focal deletions and translocations
- by interruption of genes, leading to overexpression, suppression, or production of novel fusion transcripts
- by the transactivating effects of viral proteins, particularly the X and preS gene products.

Viral integration has been shown to result in deletions, translocations, and gene amplification at the site of integration [159]. In a number of cases, HBV integration has been shown to occur adjacent to or within genes involved in cell growth or apoptosis. Genes found at HBV integration sites include the retinoic acid receptor β-gene (*RARB*) [160], the cyclin A gene [161], and the sarco/endoplasmic reticulum calcium ATPase (*SERCA*) gene [162]. In the case of the *RARB* and cyclin A integrations, expression of a fusion transcript results in oncogenic effects [163,164]. Integration of HBV into the *SERCA* gene leads to accumulation of chimeric HBx/SERCA-1 proteins that induce apoptosis. HBx protein inhibits the function of the tumor suppressor p53 and activates cytoplasmic mitogenic signaling cascades, including the mitogen-activated protein kinase and the Janus family tyrosine kinase (JAK)/signal transducer and activators of transcription (STAT) pathways. HBx also interacts with transcription factors in the nucleus to transactivate multiple genes involved in cellular growth control, including the nuclear factor-κB (NF-κB),

activator protein 1 (AP-1), and serum response element (SRE) pathways [165]. The HBx protein has been shown to play a role in fibrogenesis. HBx interacts with Smad4 and stabilizes the complex of Smad4 with components of the basic transcriptional machinery, leading to enhanced transcriptional activity in response to TGF-β. In addition, confocal microscopy studies suggest that HBx facilitates and potentiates the nuclear translocation of Smads, further enhancing TGF-β signaling. This suggests that HBx-enhanced Smad-mediated signaling may contribute to HBV-associated liver fibrosis [166]. The hepatitis B surface and core genes and proteins may also play significant roles in hepatocarcinogenesis. It has been shown that a truncated C-terminal variant of the HBV S protein directly interacts with DNA and transactivates several cellular and viral promoters, including the c-*jun* and c-*fos* promoters [167]. Hepatocellular carcinoma has also been associated with HBV strains that have deletions or insertions in the HBV core promoter region, suggesting a role for changes in core protein expression in persistence of HBV infection, HBV integration, and carcinogenesis [168].

Hepatitis C virus in the pathogenesis of hepatocellular carcinoma

In patients with chronic HCV viremia, persistent liver damage with abnormal alanine aminotransferase levels plays an important role in the development of HCC. This may be the result of repeated cycles of liver cell injury and regeneration, resulting in premature cellular senescence and the development of genomic aberrations. However, in addition, it has been shown that individuals with persistent liver damage develop a population of HCV quasispecies which changes over time, whereas individuals with persistently normal aminotransferases have a stable infection with a single species of HCV [169]. Even within the same patient, tumor samples show greater variability in the core region of HCV isolates than is found in adjacent benign samples [170]. This phenomenon may be important in hepatocarcinogenesis, by allowing for selection of more oncogenic variants of the HCV core protein. In a transgenic mouse model, HCV proteins suppress Fas-mediated hepatocellular apoptosis, and may use this mechanism to maintain the persistence of HCV infection [171]. Of the seven HCV proteins, core protein and nonstructural (NS) proteins NS2, NS3, NS4A, NS4B, NS5A, and NS5B, the core protein is the most potent cellular signaling activator, causing activation of the NF-κB, AP-1, and SRE pathways and the mitogen-activated protein kinase/extracellular-regulated kinase cascade [172]. Activation of these cascades leads to cell proliferation. The HCV core protein has been shown to interact with the 14-3-3 protein, leading to activation of Raf-1 kinase [173]. The core protein also up-regulates Wnt-1 expression and stimulates hepatocyte growth [174]. The NS4B protein activates the NF-κB pathway, and the NS5A protein has been shown to repress the interferon-induced protein kinase, PKR. The envelope protein E2 is transcribed from the most variable region of the HCV genome, and is thought to allow the virus to escape from neutralizing antibodies, in addition, E2 also inhibits PKR and contributes to interferon resistance of HCV [175].

Surveillance for hepatocellular carcinoma

Surveillance in a population assumes that:

- the disease has an asymptomatic stage but if left alone will produce significant morbidity or mortality
- a high-risk population can be identified
- surveillance tests are inexpensive, noninvasive, and accurate
- clearly defined recall procedures exist
- effective therapy is available (Table 93.1).

For HCC almost all of these criteria can be met in principle. Patients with cirrhosis from alcohol abuse, viral hepatitis, hemochromatosis, α_1-antitrypsin deficiency, and primary biliary cirrhosis all have an increased incidence of HCC [176–180]. Asians and Africans who are chronic HBV carriers are also at significant risk for the development of HCC [181]. In contrast, HCC is unusual in Wilson disease,

Table 93.1 Criteria for instituting population surveillance

Criteria	Criteria met for HCC
Asymptomatic stage	Yes
Late stages are incurable and cause mortality	Yes
High-risk population	Yes, cirrhosis
Surveillance testing is inexpensive and noninvasive	Yes, ultrasonography
Established recall procedures	Yes
Effective therapy	Liver transplantation, surgical resection, ablative procedures; TACE[a]

a These therapies can only be applied on a selective basis, and the nontransplant therapies are fraught with recurrent disease.
HCC, hepatocellular carcinoma; TACE, transcatheter arterial chemoembolization.

autoimmune hepatitis, and primary sclerosing cholangitis [182–184]. In high-risk cirrhotic patients the incidence of HCC is 2%–6%, which is more than the calculated incidence of 1.5% that is thought to be the cutoff point needed for surveillance to be cost-effective [185]. Current guidelines recommend surveillance for all patients with cirrhosis of any etiology as well as for patients with chronic hepatitis B who are Africans over 20 years of age, Asian men of at least 40 years of age, Asian women of at least 50 years of age, or who have a family history of HCC [186]. Ultrasonography is relatively inexpensive, noninvasive, and accurate in the diagnosis of early stage HCC, and, therefore, it is recommended that ultrasonography be used to screen for HCC at 6-month intervals in patients with cirrhosis. This radiographic technique has a sensitivity of 70% and a specificity of 90% for identifying HCC in an asymptomatic population [187]. The 6-month interval time schedule comes from data on the doubling time of HCCs [188,189]. The utility of serum α-fetoprotein determinations in screening for HCC is diminished by the low sensitivity of the test for early-stage tumors, which are most amenable to potentially curative therapy, and recent guidelines discourage its use except in settings where expertise in liver ultrasound is not available or in overweight patients in whom ultrasound is less sensitive [186,190]; however, an elevated serum α-fetoprotein does identify patients at increased risk for developing HCC [191]. Current recommendations for recall procedures (the definition of an abnormal result and the procedure for investigating abnormal results) are based on studies of the size, growth, and imaging characteristics of early HCCs. Although cirrhotic nodules can be as large as 2 cm, most nodules less than 1 cm in size are not HCCs. Therefore, new nodules in a cirrhotic liver that are less than 1 cm in size should be followed with repeat ultrasound at 3- to 4-month intervals. If the nodules remain stable in size over 18–24 months, it is reasonable to presume that they are benign and resume standard surveillance every 6 months. Nodules 1 cm or greater in size should be evaluated further using cross-sectional imaging of the liver (see Diagnosis of hepatocellular carcinoma). Recent population-based studies of surveillance for HCC confirm that it is associated with the detection of disease at an earlier stage and enhanced survival [192].

Differential diagnosis, diagnosis, and staging of hepatocellular carcinoma

This section will focus on the differential diagnosis of liver mass lesions in the presence of cirrhosis. The major problem in cirrhosis is differentiating HCCs from macroregenerative nodules (MRNs), which are large nodules that form in the liver as part of the cirrhotic process. The presence of large MRNs is itself a risk factor for the development of HCC, and therefore, the distinction between MRNs and HCC is difficult. Indeed, nomenclature suggests that instead of MRN the term dysplastic nodule should be used [193]. The imaging hallmark of HCC is increased vascularity of the lesion as compared to the surrounding tissue in the arterial phase and "washout" of contrast from the lesion so that it is less enhancing than the surrounding nonneoplastic tissue in the portal venous and late venous phases. These characteristics have a 98% specificity for the diagnosis of HCC [194]. For lesions 1–2 cm in size, arterial enhancement and venous "washout" using two cross-sectional imaging modalities is considered necessary for a noninvasive diagnosis of HCC; for lesions greater than 2 cm in size both these characteristics found on one cross-sectional imaging modality are sufficient for noninvasive diagnosis (Fig. 93.4) [195,196]. Also, if the lesion is accompanied by an α-fetoprotein measurement greater than 400 ng/mL, the diagnosis of HCC is likely [196]. If these strict criteria are adopted, imaging misdiagnosis is unlikely. In a robust study, the diagnosis of HCC was established preoperatively without biopsy with an accuracy of 99.6%, sensitivity of 100%, specificity of 98.9%, and positive and negative predictive values of 99.3% and 100%, respectively [197]. In the absence of these noninvasive criteria for the diagnosis of HCC (Table 93.2), histological or cytological verification of the malignancy should be obtained. However, the risk of tumor seeding has been estimated to be 0.76%–5.1% [198–200], and a biopsy should only be performed if it will change therapy. Recent experience with the use of needle introducer sheaths, through which a cutting needle is passed into the tumor, suggests that they reduce the risk of tumor seeding [201]. Also, the false-negative rate (negative biopsy report in a patient with cancer) is approximately 10%. In many instances, expert clinicians may elect to proceed with surgery or an ablative therapy based on the presence of a clear-cut mass lesion in a cirrhotic liver because it is difficult to interpret a negative biopsy. The detection of small (< 1 cm) hypoechoic or hyperechoic nodules during ultrasonography of the liver should raise the suspicion of HCC. Hypoechoic nodules are consistent with neoplastic growth of tissue whereas hyperechoic nodules suggest the presence of steatosis within an early cancer. It is well established that many small HCCs contain fat, which is subsequently lost as the cancer progresses [202]. Therefore, both hypoechoic and hyperechoic lesions must be considered malignant in a cirrhotic liver until further characterized. However, pathological studies have shown that only approximately half of such nodules less than 1 cm in size are neoplastic. These small lesions, unfortunately, are too small to assess their vascularity by imaging studies or to reliably obtain tissue for pathological examination. It is recommended that these lesions be followed with serial imaging studies at 3- to 4-month intervals. Growth of the lesion or the development of contrast enhancement on cross-sectional imaging studies would signify the development of HCC. Ultrasound and spiral computed tomography (CT) or magnetic resonance imaging (MRI)

Figure 93.4 **(a)** Schematic representation of arterialization during hepatocellular carcinoma (HCC) development. **(b)** A contrast magnetic resonance imaging scan in the arterial phase showing enhancement of an early HCC. This pathological feature of HCC allows more accurate detection of malignant nodules. The technique of transarterial chemoembolization also relies on the preferential arterial vascularization of HCC rather than the normal hepatic parenchyma. **(c)** Delayed image showing venous phase washout of the small HCC shown in **(b)**. This phenomenon is accounted for by the later flow of contrast-carrying portal venous blood into the benign liver parenchyma, after the arterial flow has emptied out of the vascular HCC. Washout is highly specific for HCC in a cirrhotic liver.

Table 93.2 Noninvasive radiographic criteria for the diagnosis of hepatocellular carcinoma

Lesions 1–2 cm in size:	
Radiographic criteria	two coincident imaging studies demonstrating arterial hypervascularization and portal venous washout
Lesions > 2 cm in size:	
Radiographic criteria	one imaging study demonstrating arterial hypervascularization and portal venous washout

scans are the standard imaging modalities for the follow-up of these early and diagnostically challenging lesions.

Natural history of hepatocellular carcinoma

An understanding of the natural history of HCC is necessary for appropriate interpretation of the results of published treatment trials. The natural history of HCC is dependent on the severity of the underlying cirrhosis, tumor characteristics (i.e., size, growth rate, multicentricity, presence or absence of vascular invasion, pathological grade, and metastases), symptoms as manifest by the performance status of the patient, comorbid diseases, and the efficacy of treatment interventions.

Table 93.3 Prognostic stage classification systems for hepatocellular carcinoma

Classification	Parameters
BCLC	performance status constitutional symptoms vascular invasion extrahepatic spread
CLIP	Child–Turcott–Pugh stage tumor size or nodularity vascular invasion α-fetoprotein ≥ 400 mg/mL
GETCHC	Karnofsky index < 80% bilirubin ≥ 3 mg/dL α-fetoprotein > 35 mg/mL alkaline phosphatase > 2 × ULN vascular invasion
Okuda	ascites tumor size > 50% of liver albumin < 3 g/L bilirubin > 3 mg/dL

BCLC, Barcelona Clinic Liver Cancer; CLIP, Cancer of the Liver Italian Program; GETCHC, Group d'Etude et de Traitement du Carcinoma Hepatocellulaire; ULN, upper limit of normal.

Several prognostic classifications for HCC have been developed (Table 93.3). All of these are imperfect, in part because they do not take into account specific information on the tumor (e.g., information on the genetic changes or specific mechanisms involved in pathogenesis of the tumor), are based on information at the time of the initial diagnosis and, therefore, do not incorporate changes in prognostic variables over time, and are based on retrospective analysis. The first was developed by Kunio Okuda and colleagues and is simply known as the Okuda classification [203]. This classification takes into account hepatic factors (bilirubin, albumin, and ascites) and a single tumor factor (extent of liver replacement > 50% or < 50%). Given its relatively gross assessment of tumoral factors and absence of patient health parameters, this classification is seldom used in clinical assessment. The other three prognostic classifications take into account more refined assessments. The Barcelona Clinic Liver Cancer (BCLC) prognostic assessment takes into account the patient performance status, presence or absence of constitutional symptoms, vascular invasion, and extrahepatic spread [204]. The Cancer of the Liver Italian Program (CLIP) uses the Child–Turcotte–Pugh Score, tumor size and multicentricity, vascular invasion, and the serum α-fetoprotein to establish a prognosis [205,206]. The Group d'Etude et de Traitement du Carcinoma Hepatocellulaire (GETCHC) takes into account the Karnofsky index, serum bilirubin, α-fetoprotein, serum alkaline phosphatase, and vascular invasion [207]. It is clear from an assessment of these models that vascular invasion, poor performance status, and an elevated α-fetoprotein with tumor multicentricity are uniform poor prognostic parameters. The BCLC staging system has been externally validated by two groups and is the staging system of choice, having been endorsed by two professional societies (Table 93.4; Fig. 93.5) [208,209]. This classification system also predicts which patients will do well for extended periods of time. For example, using data from patients randomized to no treatment in well-designed randomized control trials, the BCLC group found that patients with unicentric disease, no symptoms, and no evidence for vascular invasion nor extrahepatic spread had a 50% 3-year survival [210]. This subgroup of patients with HCC are frequently those selected for locoregional therapies (see below) and the survival in the treatment groups is frequently no better than this untreated group of patients. This information on the natural history of HCC needs to be kept in mind when counseling patients and helping them select treatment options.

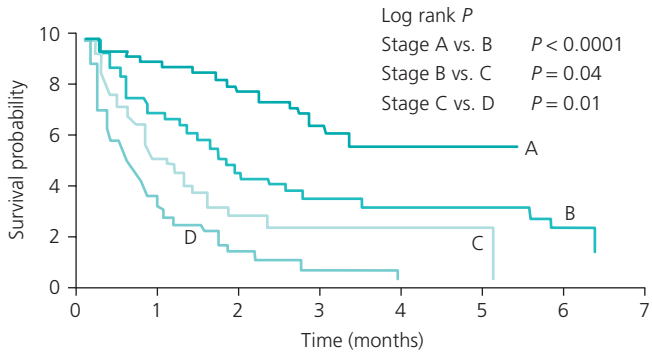

Figure 93.5 Staging of hepatocellular carcinoma. Survival as a function of Barcelona Clinic Liver Cancer stage. Modified from Marrero et al. [208].

Table 93.4 Barcelona Clinic Liver Cancer (BCLC) staging system

Stage	Tumor features	Liver features
Stage 0 (very early HCC)		
PST 0	Single < 2 cm	Child–Pugh A
Stage A (early HCC)		
PST 0	Single tumor	Child–Pugh A–B
PST 0	Three tumors, all < 3 cm	Child–Pugh A–B
Stage B (intermediate HCC)		
PST 0	Multinodular	Child–Pugh A–B
Stage C (advanced HCC)		
PST 1–2	Vascular invasion or extrahepatic spread	Child–Pugh A–B
Stage D (end-stage HCC)		
PST 3–4	Any	Child–Pugh C

HCC, hepatocellular carcinoma; PST, performance status.

Table 93.5 Clinical manifestations of symptomatic hepatocellular carcinoma

Presentation	Clinical syndrome
Tumor	malaise, anorexia, weight loss, night sweats
Hepatic decompensation	jaundice, ascites, variceal bleeding
Acute abdominal pain	tumor bleeding, capsular extension
Pyrexia	fever and leukocytosis
Metastases	brain, lung, or bone metastases
Cholestasis	large bile duct obstruction or diffuse infiltrating cancer
Paraneoplastic	↑ red blood cell mass, ↑ Ca^{2+}, ↓ glucose, diarrhea

Clinical manifestations of hepatocellular carcinoma

With better institution of surveillance strategies, most HCC will be identified at an asymptomatic stage. However, many patients continue to present with advanced HCC. The clinical manifestations of advanced HCC are protean and include decompensation of cirrhosis, tumoral symptoms, acute abdominal catastrophe due to intratumoral or peritumoral hemorrhage, cholestasis, fever of unclear etiology, paraneoplastic phenomena, and the metastatic presentation (Table 93.5). HCC may result in decompensation of cirrhosis by vascular invasion of the major portal vein or its large branches. This event worsens portal hypertension and frequently results in the development of ascites and refractory variceal bleeding. Infiltrating cancers in the liver also increase portal hypertension at the level of the sinusoids promoting ascites formation and variceal bleeding. Also, the diffuse infiltrating cancers further worsen hepatic function resulting in hyperbilirubinemia, coagulopathy, and encephalopathy. Even small cancers may be associated with hepatic decompensation either because advanced cirrhosis is frequently associated with HCC or because the small cancers have effects on the immune system or hepatic function in general. For example, approximately 20% of patients hospitalized with spontaneous bacterial peritonitis will have HCC [211]. As a result of this association, all hospitalized cirrhotic patients should have appropriate imaging studies to look for HCC.

Tumoral and acute presentations of HCC are less common than the presentation of hepatic decompensation. The tumoral presentations include anorexia, weight loss, general malaise, and painful hepatomegaly. The acute presentation is associated with spontaneous rupture of the cancer into the liver parenchyma, into the peritoneum, or extension through the capsule. Mortality is high with hemoperitoneum because of exsanguination. Selective acute arterial embolization of the bleeding artery is the preferred treatment for this complication. Patients with pain from tumor extension through the capsule likely have pain from this rupture event. The pain is usually acute, limited in time (< 24 h) and is usually assumed to be biliary colic. The screening ultrasound of the liver often unexpectedly identifies a liver mass when the patient seeks medical attention.

Cholestasis may result from tumor-associated extrinsic compression of the large bile ducts, tumor invasion of the large bile ducts, or miliary metastasis throughout the liver. Tumor invasion of the bile ducts can be associated with hemobilia and gastrointestinal bleeding [212]. The miliary pattern of metastases is usually associated with disproportionate high serum aminotransferases in addition to hyperbilirubinemia and jaundice.

Fever of unknown etiology is an unusual presentation of HCC [213]. Interestingly, the febrile episodes may be discrete episodes and associated with leukocytosis. Tumors need not be large to generate this symptom complex. Given the frequent difficulty in diagnosing HCC by a single imaging study, multiple imaging studies may be necessary to make the diagnosis of HCC in this context. In contrast to fever, night sweats are quite common in advanced HCC and portend a poor prognosis.

Paraneoplastic phenomena associated with HCC are rare but include hypercalcemia, erythrocytosis, hypoglycemia, thrombophlebitis migrans, arterial hypertension, and the syndrome of watery diarrhea, hypokalemia, and achlorhydria. The hypercalcemia is the result of production of a parathyroid hormone-like molecule, the erythrocytosis is due to erythropoietin generation by the tumor, and hypoglycemia is mediated by insulin-like growth factors [214]. Arterial hypertension is uncommon in advanced cirrhosis and its presence, therefore, should prompt imaging studies for HCC. In addition to the rare syndrome of watery diarrhea, hypokalemia, and achlorhydria, diarrhea without electrolyte abnormalities is relatively common in advanced HCC [214]. In children with hepatoblastomas, isosexual precocity may be a paraneoplastic syndrome [214]. In adults, feminization and gynecomastia are also associated with HCC, but these syndromes are often present in cirrhosis without HCC and are, therefore, difficult to attribute to HCC. Cutaneous manifestations of HCC are equally rare and include dermatomyositis, pemphigus foliaceous, and Leser–Trelat sign. The latter is the sudden onset of seborrheic dermatitis and freckles with a rapid increase in the number of the lesions accompanied by pruritus. Pityriasis rotunda (round or oval hyperpigmented scaly lesions) may be associated with HCC in black South Africans [214].

Metastatic complications of HCC are not dissimilar from the metastatic complications of other neoplastic diseases. However, HCC does have some unique metastatic presentations. One metastatic complication of HCC is dyspnea as the result of tumor pulmonary emboli, and another is headache associated with pituitary metastases [215]. Common sites for HCC metastases include the diaphragm with associated pleural effusions, bone metastases with pain, and regional lymph node metastases, which may be associated with abdominal

discomfort. In general, abdominal pain in patients with HCC is a poor prognostic symptom and usually indicates advanced disease.

Staging for selection of therapy

The staging procedure depends in part on the intensity of the selected treatment. A chest radiograph should be performed for all patients to exclude pulmonary metastases; at least two imaging studies should be carried out to stage intrahepatic disease and exclude vascular invasion (ultrasound, contrast CT, contrast MRI), and many centers will perform a CT scan of the chest and a bone scan if liver transplantation is being contemplated. It is important to note that abdominal lymphadenopathy is common in cirrhosis, especially the perihilar lymph nodes, and even more generalized lymphadenopathy occurs in hepatitis C. One therefore has to be very cautious in attributing lymphadenopathy to metastatic disease. In suspicious cases, the authors have found endoscopic ultrasound with fine-needle aspiration of hypoechoic lymph nodes useful for detecting metastatic involvement of lymph nodes. Finally, the dilemma of what to do with a small HCC remote from a portal vein thrombosis remains problematic. If tumor thrombosis is present, radical or ablative therapies are not effective; if the thrombus is bland, then these therapies may be contemplated. Many experienced centers use color-flow Doppler and ultrasound-guided fine-needle aspiration of the thrombus to make a decision [216–218]. The appearance of an arterial signal on the color-flow Doppler is most indicative of tumor thrombus as these lesions are frequently arterialized despite their residence in a vein. A negative color-flow Doppler along with a negative fine-needle aspiration would be strong evidence in favor of a bland thrombus.

Locoregional therapies

Locoregional approaches include surgical and percutaneous ablative techniques. The outcome of these therapies for HCC is dependent on several readily identifiable prognostic factors. Poor prognostic factors identified in numerous studies include unicentric tumors larger than 5 cm, multicentric disease with more than three lesions, especially if any of the lesions is larger than 3 cm in size, satellite lesions adjacent to the main tumor (a marker for tumor invasion and therefore metastatic potential), and vascular invasion [204]. In particular, invasion of the main portal vein or one of its segmental branches, a striking feature of HCC, is a relative contraindication to radical therapy.

Surgical approaches

Surgical resection is commonly accepted as the initial treatment of choice for localized HCC worldwide. Despite the acceptance of surgery for the treatment of HCC, there are no randomized controlled trials demonstrating its efficacy. This approach is limited in its application because few patients are suitable for partial hepatectomy because of tumor size, vascular invasion, multicentricity, the presence of portal hypertension, or overall hepatic functional reserve. Intrahepatic recurrence of HCC is common among patients who undergo apparently curative resection because the neoplastic potential of the nonresected liver remains unchanged. Indeed, the 5-year recurrence rate is 52% either as the result of de novo tumor recurrence or the progression of previously unrecognized intrahepatic metastases [15]. Hepatic decompensation is high in patients with any elevation of the serum bilirubin or evidence of portal hypertension (Fig. 93.6) [219]. A wedged hepatic venous pressure gradient above 10 mmHg is considered to be a contraindication for resection. However, few liver centers routinely perform this test and, instead, many surgeons use a platelet count of less than 100 000/fL (indicative of congestive splenomegaly) or the presence of varices on endoscopy or cross-sectional imaging studies of the abdomen (indicative of a wedge hepatic vein pressure gradient of at least 12 mmHg) as contraindications to surgery. Operation-related mortality is also high, especially in patients with limited hepatic functional reserve. Partial hepatectomy should therefore only be considered for patients without cirrhosis or those with mild liver disease (Child's A cirrhosis), normal portal pressure, and normal bilirubin [204]. A Model for End-Stage Liver Disease (MELD) score of 9 or greater has been shown to predict a significantly worse outcome after surgical resection for HCC [220]. The best outcomes are observed in patients with unicentric disease, no vascular invasion, tumors smaller than 5 cm, and relatively inactive liver disease. Given these selection criteria, it is estimated that only about 5% of patients with cirrhosis and HCC are candidates for surgical resection [221]. In this highly selected patient population, the best reported outcomes are 50% at 3 years [204]. This outcome is not that much different from the natural history of untreated, asymptomatic,

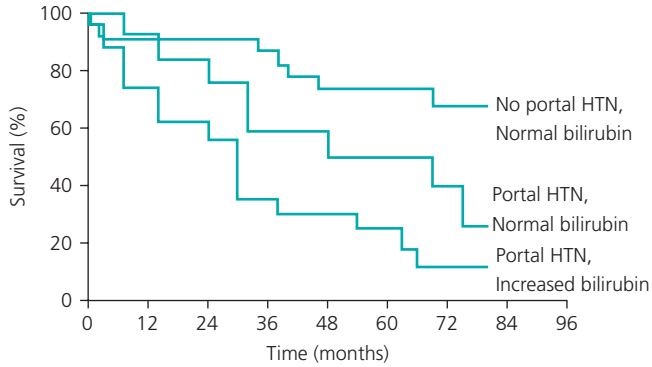

Figure 93.6 Hepatic decompensation leads to a worse outcome after surgical resection for hepatocellular carcinoma in patients with clinically significant portal hypertension and an increased serum bilirubin. Modified from Llovet et al. [15].

small, unicentric disease without vascular invasion or that obtained with ablative techniques (see above). Many hepatologists seldom advocate resection for HCC except in ideal candidates for these reasons. However, if appropriate adjuvant therapies or secondary chemopreventive agents could be developed then surgery would be a more attractive option. Along these lines, polyprenoic acid has been shown in a single study to decrease recurrence rates following surgical resection of HCC [222]. If these studies can be confirmed, the use of this agent should enhance outcomes following surgery or ablative therapies.

Orthotopic liver transplantation (OLT) for patients with HCC offers several advantages over partial hepatectomy. It can be employed for patients with all stages of liver disease and the cancer, the neoplastic potential of the underlying liver disease, and the liver disease itself are all therapeutically addressed at the same time. Indeed, numerous studies have demonstrated that in patients with unicentric disease smaller than 5 cm or with multicentric disease of up to three lesions with each lesion 3 cm or less, the results with liver transplantation are superb. For example, a study of 120 cirrhotic patients with HCC showed that transplanted patients with a maximum of two small (< 3 cm) nodules had improved survival without recurrence (83% at 3 years) compared to patients treated with partial hepatectomy (18% at 3 years) for tumors of the same size [223]. One large series found that HCC less than 5 cm in diameter or the presence of three or fewer tumors all less than or equal to 3 cm in diameter was associated with overall survival of 85% and disease-free survival of 92% at 4 years [224]. Subsequently, transplant centers throughout Europe and the United States have adopted these criteria in HCC patients for OLT. In the United States, patients with HCC are assigned additional MELD points with the goal of matching their dropout rate from tumor progression to that of patients with advanced liver disease who die while on the waiting list. Initial limited studies based on post-transplant pathological examination of explanted livers suggested that unicentric tumors with a capsule and without vascular invasion of up to 6.5 cm or multicentric tumors with up to three lesions, each no larger than 4.5 cm in size, having a total diameter of up to 8 cm, may do equally well with OLT; these are commonly referred to as the UCSF (University of California at San Francisco) criteria [225]. In addition, data from Germany suggest that very well-differentiated large tumors have acceptable outcomes following OLT [226]. Consequently, it has been suggested that the current guidelines of one lesion less than 5 cm or three lesions all less than 3 cm in diameter are restrictive criteria developed to assure the best outcomes, and should be reevaluated as more information becomes available. However, a recent study suggests that when applied before liver transplantation, the additional patients with disease stage beyond the Milan criteria who meet the UCSF criteria have a worse outcome; the 5-year survival was 46% in the patients meeting UCSF criteria but beyond Milan criteria compared to a survival of 60% in those meeting the Milan criteria [227]. In future, molecular staging techniques may allow optimal selection of the candidates who are most likely to have a recurrence-free survival after transplant. The most important limitation of OLT is an increasing organ shortage, which is problematic for several reasons. OLT for HCC removes livers from the common donor pool and may thus aggravate the situation for patients with end-stage cirrhosis. In addition, a long waiting period for a donor organ often allows a small tumor to become large or even metastatic. Indeed, the drop-out rate for patients initially meeting the criteria for OLT may be as high as 25% during 6 months of waiting time in the absence of therapy [15]. However, these patients were selected on the criteria that all lesions had to be identified by two imaging modalities, resulting in an understaging bias. In contrast, most transplant centers in the United States have an overstaging bias, which is to take the maximum number of lesions identified on any given study to be the actual number of tumors. Nonetheless, given the long waiting times for OLT, most centers prefer to treat the lesions before OLT to prevent tumor growth and dissemination. Ablative approaches, chemoembolization, or radioembolization are usually employed [228]. None of these therapies has been subjected to randomized controlled trials in combination with OLT and, therefore, the optimal approach remains to be ascertained.

In summary, tumor criteria identifying patients with HCC who are most likely to benefit from surgical approaches (resection and transplantation) have been established. Many experts feel that patients meeting criteria for surgical approaches should be offered this option as definitive therapy. In patients who are candidates for both resection and transplantation, the best outcomes are obtained with transplantation because of the high recurrence rate following liver resection [15]. However, if effective secondary chemoprevention therapies can be established, surgical resection may become preferred as it avoids the risks and need for long-term immunosuppression. In patients with HCV infection, this decision must be balanced against the risk of recurrent HCV and its sequelae. For patients who are not candidates for surgical approaches, locoregional forms of treatment are reasonable. These options include percutaneous alcohol injection, radiofrequency ablation, transcatheter arterial chemoembolization, and transcatheter arterial radioembolization and will be discussed in the following sections.

Percutaneous alcohol injection

Percutaneous alcohol injection (PEI) has become a widely accepted form of therapy for small, localized HCC. The advantage of PEI over other local ablative minimally invasive therapies is its relatively simple technique and low cost. PEI can be safely performed in patients who are not candidates for resection or OLT, even in the presence of advanced cirrhosis [229]. It is generally agreed that HCCs less than 3 cm

in size and with fewer than three nodules are suitable for PEI. The destruction of tumor cells by injection of absolute alcohol is probably the result of a combination of cellular dehydration, coagulative necrosis, and vascular thrombosis followed by tissue ischemia.

For PEI, sterile ethanol (95%) is slowly instilled throughout the tumor nodule under ultrasound or CT guidance. Since it is important to achieve uniform distribution of the ethanol, the injecting needle is usually placed at the far end of the lesion and then withdrawn in a stepwise fashion during the injection. For small lesions, a single treatment is often sufficient while larger lesions may require several treatments over a number of days. The extent of necrosis achieved is dependent on tumor size. Small nodules less than 3 cm in diameter are usually completely destroyed, larger tumors are only partially destroyed [230,231]. Patients should therefore be followed up regularly with spiral CT scans. PEI can be repeated for local recurrences and new lesions within the liver. PEI is associated with a complication rate of 1.7% and a 0.1% mortality rate. Patients may experience abdominal pain, which is often the result of leakage of ethanol into the peritoneal cavity and can be prevented by leaving the needle inside the lesion for 30 seconds or more after injection. A low-grade fever may be present for 1–3 days after the procedure because of tumor necrosis. Contraindications to PEI include massive ascites, coagulopathy, and obstructive jaundice, which increase the risk of postprocedural bleeding and bile peritonitis.

Long-term survival is as high as 70% at 3 years in patients with cirrhosis undergoing PEI for single HCCs less than 3 cm in diameter [230,231]. In the largest series published, Livraghi and colleagues reported survival rates in 746 cirrhotic patients with HCC treated with PEI [229]. In patients with a single tumor < 5 cm in diameter ($n = 462$), the 3- and 5-year survival rates, respectively, were 79% and 47% for patients with Child A stage disease, 63% and 29% for patients with Child B stage disease, and only 12% and 0% for patients with Child C disease. In patients with Child A cirrhosis, survival was much lower in those with multiple HCCs (35% at 5 years), single HCCs larger than 5 cm (30% at 5 years), and advanced HCCs (0% at 5 years). Unfortunately, there have been no prospective randomized controlled trials comparing PEI to surgical resection or transplantation for early-stage HCC. In a large retrospective study from Japan in which patients were matched for severity of the liver disease and stage of tumor, there was no significant difference in survival between patients treated with PEI and those undergoing surgical resection [232]. Long-term survival after PEI may therefore be equivalent to survival after surgical resection in a selected subgroup of patients with small tumors and mild cirrhosis. Similar to the results after surgical resection, tumor recurrence occurs in 50% of patients following PEI [233]. In summary, PEI is a safe, simple, and inexpensive treatment for patients with HCC. Although relatively few reports of long-term results are available, PEI seems to be an effective method for patients with single, small tumors. For this subgroup of patients, PEI might be equal to surgical resection with fewer complications and less procedure-related morbidity and mortality. However, more controlled studies comparing PEI to other treatment modalities are needed to better define its role in the management of HCC. Treatment of larger lesions is also possible, but is less likely to completely ablate the tumor and is therefore associated with higher rates of relapse and decreased survival.

Radiofrequency ablation

Radiofrequency ablation (RFA) is emerging as a preferred therapeutic method in the management of HCC. The first papers reporting ultrasound-guided RFA of hepatic tissue were published in 1990 and suggested that RFA could prove useful to create focal coagulative necrosis of hepatic tumors while sparing normal liver tissue [234]. Significant advances in equipment design have led to increasing success in the use of this method in the management of HCC. RFA destroys tissue by thermal energy generated with an alternating electric current generator that operates in the radiofrequency range from 200 to 1200 kHz. Like PEI, RFA is usually performed by a percutaneous approach in the outpatient department. After local anesthesia, a needle electrode is introduced through the skin under sonographic guidance and advanced into the center of the tumor. Treatment is guided by impedance measurements between components of the needle electrode. The goal of each procedure is to ablate the tumor and a small margin of normal tissue around the tumor. Depending on the equipment used, this is can be achieved in one or two short sessions (< 15 min) for lesions up to 5 cm. Large blood vessels act as a heat sink so RFA is not effective for lesions adjacent to large veins in the liver. It is also more technically difficult to treat lesions in segment 8 (lesions high in the dome of the liver) with RFA than with PEI. Spiral contrast enhanced CT scanning is usually used to assess tumor necrosis after RFA because ultrasound is usually not sensitive enough for this purpose. RFA can be repeated for residual tumor found on follow-up or for new tumor nodules that develop in the liver.

As experience with RFA has accumulated, the initially promising results have been largely confirmed. In 1995, Rossi and colleagues reported initial results from 24 patients with one or more tumor nodules smaller than 3 cm who were treated with intent to cure [235,236]. Complete tumor necrosis was achieved in all but two patients after one session; both patients successfully received additional thermal ablations. About half the patients had recurrence of the tumor during follow-up, which could be retreated in 70% of these patients. The survival rate was 95% the first year, 84% the second year, 67% the third year, and 45% the fourth and fifth years. Livraghi and colleagues used a large cohort of patients ($n = 112$) with small HCCs, less than 3 cm in diameter,

to compare the effectiveness of RFA with that of PEI [237]. Complete tumor necrosis was achieved in 90% of tumors with RFA in an average of only 1.2 sessions per tumor and in 80% of tumors with PEI in 4.8 sessions. However, in contrast to other series, four minor and one major complication were reported in patients treated with RFA; in contrast, no complications occurred in patients treated with PEI. One study suggests that RFA may be associated with a high rate of needle track seeding (12.5%) because of the large needle used in this approach, especially for high-grade and surface lesions [238].

Studies comparing PEI and RFA have shown superiority in outcome for patients treated with RFA [239]. More importantly, a randomized controlled trial comparing RFA with surgical resection yielded similar outcomes. Consequently, RFA is rapidly becoming a preferred approach for treatment of unicentric HCC less than 3 cm in diameter [240].

Transcatheter arterial chemoembolization

Transcatheter arterial chemoembolization (TACE) is a technique that uses angiography to selectively embolize the arterial supply to an HCC. A cytotoxic agent such as doxorubicin or cisplatin is mixed with lipiodol, gelfoam, or Ivalon particles to form a suspension that is then injected into the feeding artery of the tumor using an angiographic technique by way of the common femoral artery. This results in both selective ischemic and chemotherapeutic effects on the HCC. As a result of the dual blood supply of the liver, TACE causes minimal damage to normal liver parenchyma, because 80%–100% of the blood-flow to liver tumors, but only 20%–30% of the flow to normal liver, is supplied by the hepatic artery. After the procedure the suspension remains in the tumor, where the cytotoxic agent is slowly released to exert its effect. Although lipiodol serves a dual role in TACE by carrying the chemotoxic agent to the tumor and also embolizing the vasculature, it can remain in the lesion for prolonged periods of time and preclude adequate radiographic assessment of tumor necrosis by contrast-enhanced CT scanning. The relative contribution of the chemotherapeutic agents to treatment of HCCs compared to the simple ischemic effect of occluding the tumor vasculature has never been established.

Risks of TACE include contrast allergy, contrast-induced nephropathy, and bleeding or pseudoaneurysm formation at the catheter site. Most patients develop a postembolization syndrome with fever and right upper quadrant pain and are therefore hospitalized. Liver function tests can be elevated for up to 2 weeks. Major complications include hepatic abscess, which is most common in patients with a preexisting biliary–enteric anastomosis, hepatic artery dissection or thrombosis, and ischemic cholecystitis. The morbidity rate of TACE was 5.1% and treatment-related mortality rate was 4.1% in one retrospective study [241]. Advanced Child C stage cirrhosis is a relative contraindication for TACE because of the high risk of potentially fatal complications such as liver failure. Other contraindications include hepatic encephalopathy, biliary obstruction, portal vein occlusion, a surgical portosystemic shunt, a transjugular intrahepatic portosystemic shunt device, bilirubin greater than 5 mg/dL, international normalized ratio greater than 1.7, or creatinine more than 1.8.

The efficacy of TACE is determined by the size of the lesion. One study reported a survival rate of 100% at 3 years for tumors less than 2 cm in diameter, whereas 3-year survival was 0% for tumors greater than 5 cm [242]. TACE also avoids the risk of needle-track seeding so transplant centers often use TACE as a bridge to transplantation for HCC patients. It prevents progression of the lesions and potential micrometastases while the patient waits for a donor organ. In a pilot study at our institution, none of the transplant recipients pretreated with TACE developed recurrent HCC during a mean follow-up of more than 2 years [243]. More recent results confirm that patients who have a complete or partial response to pretransplant TACE, as assessed by CT, have substantially better 5-year survival rates (complete response, 85.7%, partial response 66.2%) than those with no response or with tumor progression (19.3%) [244]. The value of TACE as a palliative procedure for patients with intermediate stage HCC has been established in the past few years by the results of two randomized controlled trials that both confirmed increases in survival of patients receiving TACE when compared to untreated controls [245,246]. An analysis of the available randomized trials also confirmed the superiority of TACE [247].

Transcatheter arterial radioembolization

Transcatheter arterial radioembolization (TARE) is similar to TACE in that radiolabeled particles are infused into the hepatic artery and preferentially flow into the highly vascular HCCs, with relative sparing of the nontumorous liver, which is primarily supplied by the portal venous circulation. TARE is available in two variants, as yttrium-90-impregnated glass microspheres (TheraSpheres, MDS Nordion, Ottowa, ON) and as resin-based microspheres (Sir-Spheres, SIRtex Medical Limited, Wilmington, MA) [248,249]. There has been more published experience with TheraSpheres. Significant differences between TheraSphere administration and TACE include the fact that the Thera-Sphere microspheres have high specific activity and consequently a relatively small mass of beads is infused into the tumor vasculature. The beads therefore do not occlude the vasculature, as occurs with TACE, and TheraSphere treatment does not cause the tumor lysis syndrome that is typically induced by TACE [250]. TARE using TheraSpheres can therefore be administered to patients with HCC and portal vein thrombosis, which is typically a contraindication for the use of TACE. Since there is no tumor lysis syndrome and the emission of β-particles by yttrium-90 is limited to 1–2 mm from the microspheres, the treatment also has the advantage of being

administered on an outpatient basis. There are risks of radiation injury to the lungs or the adjacent gastrointestinal tract supplied by hepatic artery branches. Therefore, a planning angiogram is performed before the TheraSphere procedure in which any hepatic artery branches that supply the stomach or duodenum are occluded. During the planning angiogram a small dose of technetium-99-labeled macroaggregated albumin is injected into the hepatic artery distribution followed by a lung scan to quantify the percentage of infused radiation that is shunted to the lungs. A high lung shunt would lead to potential radiation lung injury from the radiolabeled microspheres and is a contraindication to therapy. The TheraSphere protocol has been shown in uncontrolled series to be effective for down-staging patients with intermediate stage HCC to resection, RFA, and as a bridge to liver transplantation. [251]. Additional studies, particularly randomized controlled comparisons of TARE with TACE, are needed to determine the optimal strategy for patients who are eligible for treatment using these modalities.

Systemic therapy

Four forms of systemic therapy have been applied to the treatment of advanced HCC without substantial efficacy, including cytotoxic therapy, immunotherapy, hormonal therapy, and gene therapy. Studies using new treatments that target molecular pathways involved in cancer growth and angiogenesis are being reported. With improvements in our understanding of the molecular pathogenesis of HCC, these new, targeted therapies hold promise for providing substantial improvements in the treatment of advanced HCC, adjuvant treatment of intermediate stage HCC in combination with surgery or locoregional therapies, secondary chemoprevention after surgery for cure, and primary chemoprevention in high-risk individuals.

Cytotoxic chemotherapy

HCC is extremely refractory to current available cytotoxic therapies. Moreover, the presence of cirrhosis with impaired clearance of drugs metabolized by the liver increases drug toxicity. Portal hypertension with leukocytopenia and thrombocytopenia also exacerbate drug-induced bone marrow toxicity. The overall response rate is < 20% for systemic chemotherapy given intravenously using either single or combined agents [252]. Intraarterial therapy also has not been shown to impact disease progression or survival [253]. There is therefore no current proven chemotherapeutic regimen for HCC.

Hormonal therapy

The presence of androgen receptors in HCC, the sexual dimorphism of the liver, and the male predominance of HCC led to the use of antiandrogen therapy for this cancer. Unfortunately, studies were negative and this approach was abandoned [254]. The presence of estrogen receptors in the liver also led to the use of tamoxifen (an antiestrogen) for the treatment of this disease. Initial studies suggested a survival benefit [255]. However, several randomized controlled trials and a metaanalysis of these trials have shown no survival benefit. Finally, HCCs express somatostatin 2 receptors, and administration of somatostatin appeared to improve the survival of patients with advanced HCC cancer in a pilot study [256]; however, subsequent randomized studies have shown no significant survival benefit [257–259].

Immunotherapy

Two forms of immunotherapy have been applied in HCC, using systemic therapy with interferon or employing lymphokine-activated natural killer cells. Although interferon was superior to no treatment or adriamycin in one study, this result was not reproduced in a second study [260]. Further, the administration of interferon in doses required for antitumoral effects was associated with a high rate of adverse side effects necessitating discontinuation of therapy. Lymphokine-activated killer cell therapy is associated with significant toxicity, is expensive, and difficult to implement [261]. Results with this approach have also been modest and, therefore, it has not been adopted as a therapeutic option.

Gene therapy

Gene therapy is rational for HCC because a transient transfection (e.g., liposome-mediated transfer of plasmid DNA constructs) or transduction (e.g., administration of a virus expressing the desired construct) may be sufficient to destroy the tumor cells. It also may be possible to effect selective tumor targeting using the α-fetoprotein promoter or angiography. In addition, bystander effects have been observed with all gene therapy strategies, indicating that not all cells have to be transduced. However, these goals have yet to be realized in the clinical context. Several trials, including those attempting to transfect HCC cells with wild-type p53, have evolved to human studies, but the results have been disappointing so far. Nonetheless, it is premature to abandon this approach and further developments are likely.

Targeted molecular therapies

Advances in our understanding of the molecular pathogenesis of epithelial cancers in general and HCC in particular have led to the recognition of specific molecular pathways that are deranged in cancer and that provide opportunities for targeted intervention. Growth-signaling pathways including the receptor tyrosine kinase signaling pathways and their downstream Raf kinase, mitogen-activated protein kinase, phosphatidylinositol-3/Akt kinase pathways, proangiogenic pathways activated by VEGF and mediated by the VEGF receptors, the Wnt signaling pathway, pathways leading to inactivation of multiple tumor suppressors, including the

methylation and histone deacetylase and the proteasomal protein degradation pathways, all represent rational targets for anticancer drug development. A phase II study of the Raf kinase and VEGF receptor kinase inhibitor sorafenib showed modest efficacy in HCC [154]. Subsequently, the first large phase III study of a receptor tyrosine kinase inhibitor in HCC, using sorafenib, was terminated early because of a presumed significant positive effect on patient survival. Sorafenib may become the treatment of choice for advanced HCC. The major toxicities are fatigue, a hand–foot skin rash, acne, and diarrhea. The study was conducted in patients with Child–Pugh class A disease, largely with BCLC stage C disease. The toxicity profile and efficacy in patients at Child–Pugh class B and C is unknown. This early positive result gives hope for additional future gains in the use of targeted agents for systemic therapy and prevention of HCC.

Summary

The selection of an appropriate treatment strategy for patients with HCC depends on careful tumor staging and assessment of the underlying liver disease (Fig. 93.7). All patients with localized HCC (involvement of one single lobe, no vascular invasion or extrahepatic disease) should be evaluated for the potentially curative therapy options partial hepatectomy or OLT. Candidates for partial hepatectomy must have no liver disease or Child stage A cirrhosis, normal portal pressure, and normal serum bilirubin. For patients not meeting these criteria, OLT should be considered if there is a solitary lesion less than 5 cm in size or three or fewer lesions less than 3 cm in size. Local ablative therapies such as PEI, RFA, TACE, and TARE offer palliation for patients with contraindications for surgical approaches. PEI and RFA are minimally invasive and can be used on an outpatient basis, usually for tumor nodules smaller than 3 cm. When used for small tumors, the survival rates can be similar to those achieved by partial hepatectomy. TACE may be used as an interim treatment for patients waiting for OLT or patients with BCLC stage 3 HCC. Given the paucity of efficacy data, there are no proven systemic chemotherapy regimens, immunotherapy approaches, or hormonal therapies that can be recommended. Early results suggest that we may be on the threshold of new advances in treatment of HCC using targeted therapeutics, especially sorafenib.

Amebic versus pyogenic abscess

This chapter describes the clinical presentation, imaging characteristics, laboratory findings, natural history, and response to treatment of hepatic abscess. Although there is considerable overlap in these features between amebic and pyogenic abscesses, the differences in epidemiology, associated conditions, treatment, and prognosis underscore the need for the physician to distinguish these entities. Effective management depends critically on prompt and correct definition of the abscess type.

Epidemiology

There are important differences in the epidemiology of amebic abscess, as it presents in the United States, and pyogenic abscess. Intestinal amebiasis is a necessary prelude to hepatic amebic abscess so patients with amebic abscess typically have emigrated from or traveled to areas where intestinal amebiasis is prevalent [1,2]. Ethnicity of the local patient population is important. For example, in a large series from Los Angeles, 92% of 457 patients with amebic liver abscess had Hispanic surnames, compared with 37% of the local patient population [3]. In contrast, ethnicity of patients with pyogenic abscess did not differ from that of the general hospital population. Another difference identified between amebic and pyogenic liver abscess in this series was a striking male predominance (84%) in those with amebic abscess, whereas the gender distribution in those with pyogenic abscess was about equal. The median age of patients with amebic abscess (28 years) was significantly lower than that of those with pyogenic abscess (44 years) [3].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Since the classic review by Ochsner and colleagues [4] in 1938, and after the introduction of antibiotics in the 1940s, the frequency of pyogenic liver abscess associated with intra-abdominal infection has diminished [5,6]. Although pylephlebitis (mostly due to appendicitis) accounted for 43% of cases of pyogenic liver abscess in the first decades of the 20th century [4], a series of patients from 1973 to 1993 indicated that in only 7% of cases was pyogenic liver abscess believed to be the result of portal bacteremia [7]. During the past few decades, biliary obstruction, both benign and malignant, has emerged as the most common etiology of pyogenic liver abscess, accounting for 50%–60% of cases in several recent series [7–9]. This trend undoubtedly reflects improvements in early diagnosis and management of extrabiliary abdominal infections attributable to modern imaging modalities and use of antibiotics. Over time the incidence of cryptogenic hepatic abscess has remained stable at ~20% of cases [4,7,10]. Several series suggest that diabetes mellitus may predispose to pyogenic liver abscess because 15%–25% of cases occur in patients with diabetes [3,7,8,11]. Finally, since the 1980s, it has become apparent that recipients of liver transplant allografts have an elevated risk for pyogenic liver abscess [12].

Clinical manifestations

Fever and right upper quadrant pain are the principal symptoms of hepatic abscess, both amebic and pyogenic. Fever is evident in virtually all patients. Although spiking fever and chills favor pyogenic abscess, these may be seen with amebic abscess. Pain is reported by 75%–90% of patients, is usually constant, is of variable intensity, and may exhibit pleuritic features with radiation to the right shoulder if diaphragmatic involvement is present [3,13–15]. Most patients have symptoms for less than 2 weeks before seeking medical care. Nonspecific symptoms, such as weakness, anorexia, nausea, and weight loss, are common. About one-third of patients with either type of liver abscess report diarrhea, and one-fourth have a nonproductive cough.

On physical examination, sequential measurements of body temperature should be made to detect fever. Hepatic enlargement and tenderness are typical, but not invariably present. Jaundice is rare in amebic abscess and, when present, should suggest biliary tract obstruction with pyogenic infection or underlying chronic liver disease. Percussion dullness, diminished breath sounds, or other chest findings at the right lung base are evident in 20%–30% of patients and suggest involvement of the superior portion of the right hepatic lobe. Occasionally signs of weight loss, dehydration, and anemia are evident [3,7,14,16].

Diagnosis and differential diagnosis

Imaging modalities

The clinical constellation of fever, right upper quadrant discomfort, and hepatic enlargement with tenderness should prompt an imaging study early in the diagnostic assessment. Depending on the age of the patient and level of clinical suspicion for cholelithiasis or biliary obstruction, either ultrasonography or computed tomography (CT) will be performed. These techniques facilitate discrimination of liver abscess from cholecystitis, bile duct obstruction, or pancreatitis. Radionuclide liver–spleen scanning after administration of a technetium 99m–sulfur colloid has been supplanted by ultrasonography and CT because the latter two are more sensitive for small lesions (less than 3 cm) and offer better precision in localizing lesions that may require percutaneous aspiration or drainage. Of note, lesions near the dome of the right hepatic lobe may be difficult to see by ultrasonography. Typically, on ultrasound abscesses appear as hypoechoic lesions, sometimes with internal echoes [17,18] (Fig. 94.1). CT scanning identifies abscesses as low-density lesions (Fig. 94.2), often with peripheral enhancement after intravenous administration of contrast, and may provide better definition of extrahepatic pathology associated with pyogenic abscess (e.g., appendiceal or diverticular abscess) [19]. Although both modalities are sensitive for detecting abscesses and biliary obstruction, neither can distinguish reliably between amebic and pyogenic abscesses [20–22]. Although less widely used, magnetic resonance imaging (MRI) also has high sensitivity for detection of hepatic abscess. Characteristically, liver abscesses are hypointense on T1-weighted images and hyperintense on T2-weighted images, and wall enhancement soon after gadolinium infusion is typical [23]. Both CT and MRI provide multiplanar imaging so these modalities may be particularly valuable when ultrasound findings are ambiguous or when coronal or sagittal images will help guide

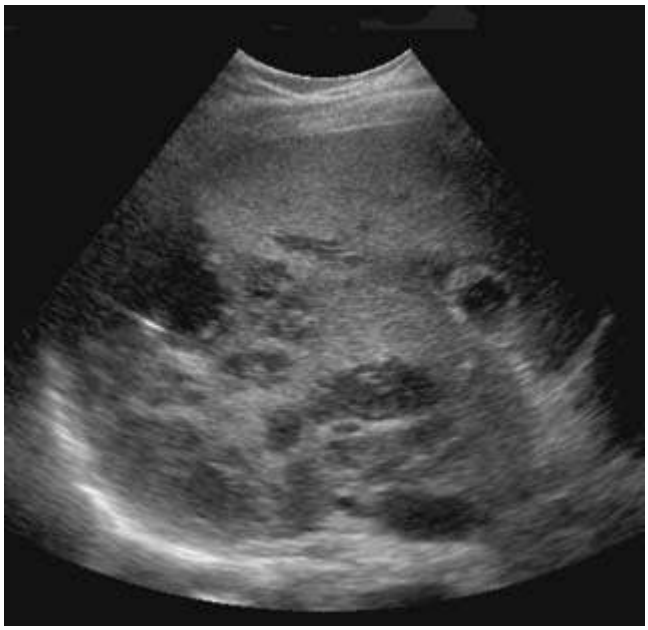

Figure 94.1 Sonogram of the right hepatic lobe showing multiple hypoechoic pyogenic abscesses. This image is from a 54-year-old man who developed multiple hepatic abscesses associated with sigmoid diverticulitis. Blood cultures obtained before antibiotic administration yielded *Bacteroides thetaiotaomicron*. Gram stain of abscess material obtained after antimicrobial therapy was initiated showed gram-positive cocci, gram-negative rods, and gram-positive rods. He was treated initially by percutaneous drainage and intravenous ceftriaxone and metronidazole. After clinical improvement, he was discharged home and completed uneventfully a several week course of oral ciprofloxacin and metronidazole.

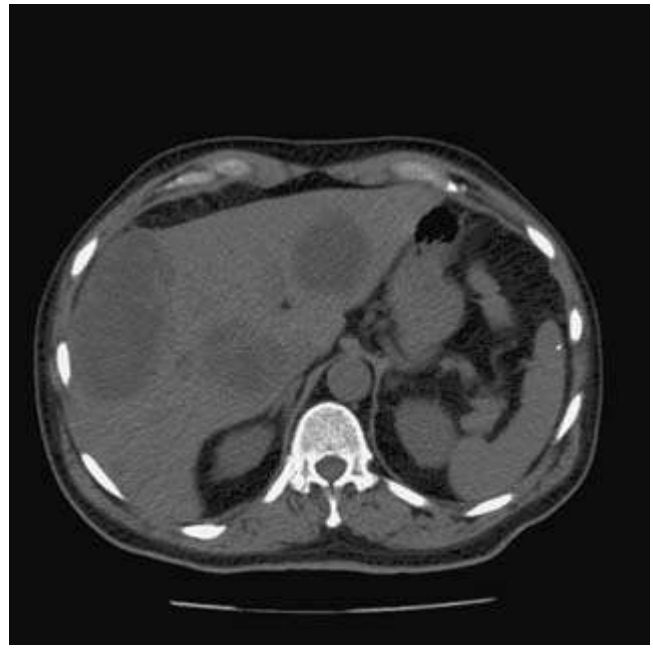

Figure 94.2 Computed tomography image showing numerous low-density lesions in both hepatic lobes in a 65-year-old man with colon carcinoma. *Streptococcus* (γ-hemolytic) was cultured from fluid obtained by abscess aspiration. His liver lesions were treated by aspiration without drain placement and by administration of levofloxacin and metronidazole. He improved and subsequently tolerated resection of his colonic lesion.

management of a lesion in the superior portion of a hepatic lobe [24]. Most abscesses, both amebic and pyogenic, occur in the right hepatic lobe. The presence of multiple abscesses strongly suggests pyogenic infection, as does identification of concomitant biliary tract obstruction. Chest radiographs in patients with an abscess adjacent to the diaphragm may show elevation of the right diaphragm, subpulmonic effusion, and right lower lobe atelectasis or infiltrate. It is well to remember that hepatic tumors may present with necrosis and secondary infection [25], mimicking a primary abscess.

Laboratory testing

Commonly employed blood tests are of limited utility in reaching a specific diagnosis of hepatic abscess. This being said, certain abnormalities are typically present. Leukocytosis (more than 10 000/mm^3) is present in more than 90% of patients. Mild anemia is common, with hemoglobin levels of less than 12 g/dL seen in two-thirds of patients. Mild to moderate elevation of serum alkaline phosphatase activity is typical but of little discriminating value in the absence of information from imaging studies [3,7,26].

Detection of antiamebic antibodies is of primary importance in diagnosis of amebic liver abscess. Although serological tests may rarely be negative very early in infection, more than 90% of patients with hepatic abscess develop antibodies to *Entamoeba histolytica* in high titer. A positive serological response to *E. histolytica* indicates tissue invasion by the parasite and not simply intestinal colonization. Both indirect hemagglutination and enzyme-linked immunosorbent assays are available [2,27]. Importantly, seropositivity does not distinguish current from prior disease. Persistence of antiamebic antibodies after resolution of amebic abscess (usually in diminishing titer) may lead to confusion in the differential diagnosis of a subsequent liver lesion, especially in areas in which infection is endemic [1,2,28–30].

A key element in diagnosis and treatment of pyogenic liver abscess is identification of the organisms in the abscess. Blood cultures are positive for bacteria in about 50% of patients so at least two separate specimens of blood should be taken for culture before administration of antibiotic agents. Most pyogenic abscesses are caused by enteric gram-negative aerobic rods, streptococci, and anaerobes. Although blood cultures typically identify a single organism, cultures from abscess aspiration are frequently polymicrobial [3,32,33]. Needle aspiration of an abscess is the best and most direct method to distinguish amebic from pyogenic abscess. Material from an amebic abscess is brown-red in color and typically is not particularly malodorous. A pyogenic abscess yields material that is creamy, tan-green in color, and often putrid, reflecting anaerobic infection. Gram stains of amebic abscess contents show neutrophils but no bacteria, unless secondary infection is present. Smears of pyogenic abscess contents usually identify at least one bacterial form. Meticulous handling of aspirated material to avoid exposure to air enhances the recovery and identification of anaerobic species. Reliable and complete identification of infectious agents ensures proper selection of an antibiotic treatment regimen [33].

Course and complications

Amebic abscess

Without treatment, amebic liver abscess tends to enlarge and ultimately extend through the diaphragm or rupture into the peritoneal cavity. Pleuropulmonary involvement is the most common complication [13,34–36]. On extension through the diaphragm, amebic empyema or lung involvement with development of hepatobronchial fistula may occur. Rupture into the right pleural cavity is less frequent than into the lung, probably because of fusion of the diaphragmatic and visceral pleura induced by inflammation. Erosion into a bronchus may be followed by expectoration of amebic pus and by amelioration of symptoms. This mechanism of abscess drainage affords an opportunity for spontaneous resolution. Less frequently seen is rupture into the pericardium, typically a complication of amebic abscess within the left hepatic lobe. This may be accompanied by retrosternal pain, a pericardial friction rub, and findings of cardiac tamponade, such as jugular vein distention with pulsus paradoxus. Historically, rupture into the pericardium has carried a high mortality [13,34].

When an amebic abscess ruptures abruptly into the peritoneum, diffuse abdominal pain and signs of peritonitis occur. Less frequently encountered is a contained abscess adjacent to the site of hepatic rupture. In neither instance is surgery required because cure typically results from antimicrobial therapy alone [13,35]. Other rare intraabdominal complications include rupture into bowel and hemobilia through formation of an arteriobiliary fistula.

Pyogenic abscess

The mortality rate associated with untreated pyogenic liver abscess approaches 100% [4,8,10]. As with amebic abscess, complications of pyogenic liver abscess include rupture and extension into the surrounding tissues, with pleuropulmonary involvement most common. In contrast to amebic peritonitis, should rupture into the peritoneum occur from a pyogenic liver abscess, mortality is very high without surgical management. Abscess-associated thrombosis within the portal vein (Fig. 94.3) or a hepatic vein is associated with anaerobic infections [5,6] and may lead to residual portal hypertension or the Budd–Chiari syndrome after otherwise successful treatment of the abscess. Patients with large or multiple pyogenic abscesses are at increased risk for developing infections at remote body sites as a result of bacteremia. Patients with polymicrobial abscesses have a higher mortality rate than do those with monomicrobial infections. In one series, all 14 patients who had two or more organisms isolated

Figure 94.3 Computed tomography image showing filling defects within the intrahepatic portal vein, scattered hepatic hypodense lesions, and free fluid within the abdominal cavity. These findings are compatible with septic pyelothrombophlebitis. This image is from a 44-year-old man who presented with sigmoid diverticulitis and pericolonic abscess. He was treated by segmental colectomy and his liver abscesses resolved without aspiration after prolonged antibiotic therapy. He was treated postoperatively with heparin, then coumadin. After 3 months of anticoagulation therapy, his portal vein thrombus resolved and there were no residual imaging abnormalities.

from blood cultures died [8]. Mortality appears to be higher in patients with pyogenic abscesses of biliary origin, probably because these patients tend to have multiple abscesses. Even with prompt diagnosis and treatment, the mortality rate from pyogenic liver abscess remains high, ranging from 10% to 30% [3,8].

Treatment

Liver abscess should be considered in any patient with fever, leukocytosis, pain in the right upper quadrant, and tenderness over the liver or right lower chest wall. Depending on the age of the patient and the nature of the discomfort and associated symptoms elicited by history, either ultrasonography or CT should be obtained. Either modality will detect reliably one or more hepatic lesions, with imaging characteristics suggesting abscess. Should jaundice or evidence for biliary obstruction be discovered, consideration of cholangiography and biliary decompression is appropriate. Regardless of whether amebic or pyogenic abscess is believed more likely, at least two sets of blood cultures should be obtained before administration of antimicrobial agents.

Amebic abscess

If the patient is a young man who has emigrated from or traveled to an area where amebiasis is endemic, who has a single lesion on an imaging study, and who does not appear toxemic, then amebic abscess is the more likely diagnosis. Stool specimens should be examined for amebic cysts and trophozoites and serum should be tested for *E. histolytica* antibodies. Treatment in adult patients should then be initiated with metronidazole, 750 mg given orally three times daily for 10 days [1,2,33]. An alternative regimen is chloroquine phosphate, 1000 mg (600 mg chloroquine base) given orally daily for 2 days, and then 500 mg (300 mg chloroquine base) given orally daily for 2–3 weeks [1,2,37]. Clinical improvement is expected within 3 days. After treatment with either of these tissue amebicides, therapy with a lumenal amebicide is appropriate to eradicate amebas within the bowel because these may cause relapsing or persisting infection. Iodoquinol, 650 mg given orally three times daily for 20 days, is the drug of choice for this purpose [37]; paromomycin is a satisfactory alternative [2,33]. Aspiration of the abscess is indicated if there is no clinical improvement within several days, if the diagnosis is in doubt, or if the abscess is large or located such that rupture is believed likely. Amebic pleural effusions are treated by aspiration and one of the amebicidal regimens. Amebic pericarditis is treated by pericardiocentesis and by aspiration of the (usually left lobe) hepatic abscess in addition to amebicidal antibiotics. Surgery is not indicated for uncomplicated amebic liver abscess but may be appropriate in some instances for rupture or, rarely, for failure of medical therapy alone [38]. Ultrasound-guided percutaneous drainage is effective and should obviate the need for surgical management in most cases [39]. In uncomplicated amebic liver abscess, the prognosis is good, with a mortality rate of about 1% [13]. Extension into the chest or pericardium increases mortality significantly, to 6% or 25%–30%, respectively [13,35].

Pyogenic abscess

If the patient is older, lacks a history suggesting risk for amebiasis, or has multiple lesions or bile duct obstruction on an imaging study, pyogenic abscess is more likely. After blood cultures have been obtained, treatment with a broad-spectrum antibiotic regimen is appropriate. The mixed nature of many pyogenic infections dictates that the initial empiric regimen should provide effective coverage against aerobic enteric bacilli, microaerophilic streptococci, and enteric anaerobes. Suitable regimens include ampicillin–sulbactam, piperacillin–tazobactam, cefoxitin, imipenem, or a third-generation cephalosporin plus metronidazole [33]. Previous instrumentation or obstruction of a patient's biliary tree and local patterns of bacterial antibiotic resistance should prompt broader coverage

or antibiotic selection to strengthen coverage against specific pathogens such as *Enterococcus* and *Pseudomonas* species [7]. In most instances, diagnostic aspiration for bacterial culture is appropriate. Ideally, this should occur before antibiotics are administered, but treatment should not be delayed injudiciously if prompt aspiration is not feasible. Although many choose to leave a drain in place after aspiration, several series have indicated that aspiration without catheter drainage (in concert with antibiotic therapy) is curative in most instances [3,7,9,16,40–47]. Antibiotic therapy alone should be employed only for those with multiple small abscesses not amenable to aspiration and for those with a contraindication to aspiration and drainage (e.g., coagulopathy) [48]. Surgical drainage, either open or laparoscopic [49], is appropriate for patients who fail to improve with percutaneous drainage and antibiotic therapy and for those who have an extrahepatic or biliary source of hepatic abscess in need of surgical treatment. It is important to note that resolution of abscess cavities (as determined by sequential imaging studies) typically lags behind clinical improvement in effectively treated patients. Thus, clinical judgment and not simply persistence of an abscess cavity should guide decision-making regarding the need for recurrent aspiration or operative drainage. Surgical intervention may ultimately be necessary in up to one-third of patients with pyogenic abscess [50,51]. Although percutaneous drainage and current antibiotic regimens have reduced mortality from pyogenic liver abscess significantly, it remains high (20%–40%) in patients with significant comorbidity, multiple abscesses, malignant biliary obstruction, and inadequate drainage [7,8].

Systemic circulatory disease

Ischemic hepatitis

Ischemic hepatitis or "shock liver" may occur as the result of reduction in systemic blood pressure with or without hypoxemia. Ischemic hepatitis often occurs in patients with underlying heart disease [1–3] and it has been suggested that right-sided heart failure with hepatic venous congestion predisposes to ischemic hepatitis because of systemic hypotension [3]. Decreased cardiac output may have cardiac causes, such as myocardial infarction, severe congestive heart failure, cardiac arrhythmias, severe cardiomyopathy, cardiogenic shock, constrictive pericarditis, or pericardial tamponade. Systemic causes of hypotension include septic shock or hypovolemia due to massive hemorrhage, extensive burns, or extravasation of fluid into the peritoneum, e.g., in acute pancreatitis.

The diagnosis is made on clinical grounds when there is systemic hypotension and severe and rapidly reversible elevation of serum aminotransferases in the absence of other causes of acute hepatitis. In addition to these features, a marked, rapid elevation of lactate dehydrogenase [4] with a low ratio of serum aminotransferase to lactate dehydrogenase is helpful in distinguishing ischemic hepatitis from acute viral hepatitis [5]. Serum aminotransferases are most commonly 20 or more times the upper limit of normal and an elevation less than 20 suggests the need for further confirmation of the diagnosis [6]. Concomitant renal hypoperfusion with elevation in creatinine and blood urea nitrogen are also usually present. The classic histological feature is centrilobular necrosis.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Congestive hepatopathy

Chronic passive congestion of the liver in congestive heart failure causes atrophy of hepatocytes in zone 3, sinusoidal congestion, and enlargement of sinusoidal endothelial fenestration. It has been suggested that the mechanisms leading to hepatocyte atrophy are pressure on the hepatocytes and perisinusoidal edema, which impairs the diffusion of oxygen and nutrients to hepatocytes [7].

Causes of congestive hepatopathy include chronic right-sided heart failure as the result of cardiomyopathy or valvular heart disease, constrictive pericarditis, and pulmonary hypertension. Clinical findings include a dull ache in the right upper quadrant, hepatomegaly, increased jugular venous pressure, and hepatojugular reflux. Liver tests are usually normal. Congestion will cause sinusoidal dilation in the centrilobular sinusoids with preservation of normal architecture in the periportal areas. Histologically this pattern is referred to as a "nutmeg" appearance. Centrilobular fibrosis may occur with long-standing disease, but frank cardiac cirrhosis is rare.

Treatment of both ischemic hepatitis and congestive hepatopathy is directed towards the underlying cardiopulmonary disease.

Hypoxia

Cases of presumed ischemic hepatitis may sometimes be the result of hypoxia rather than of decreased perfusion, although more commonly this will be the result of the combination of left-sided heart failure with chronic respiratory failure than the latter in isolation [8]. Primary pulmonary causes of hypoxemia leading to hepatocellular necrosis may include massive pulmonary embolus, end-stage chronic obstructive lung disease, or restrictive lung disease.

Budd–Chiari syndrome

Budd–Chiari syndrome (BCS) is the eponym for hepatic venous outflow tract obstruction, independent of the level or

mechanism of obstruction [9,10]. BCS is considered primary when the blockage is intrinsic to the vein and secondary when the obstruction or compression originates external to the vein. In the West, a pure hepatic vein obstruction is more common. In non-Western countries obstruction of the hepatic portion of the inferior vena cava (IVC) is more common than hepatic vein obstruction.

Membranous obstruction of the hepatic portion of the IVC is frequently seen in patients in countries such as South Africa, India, Japan, Nepal, and China, whereas in the West it is uncommon. The original theory was that the membrane was congenital, but current thinking is that it is a consequence of thrombus organization [11,12]. One of the initiating factors may be an infectious process. Patients with prothrombotic disorders also have a predisposition to obstruction of the hepatic portion of the IVC, but it is unknown why that particular section of the IVC is more vulnerable to thrombosis. Behçet disease is more likely to cause obstruction in the hepatic portion of the IVC than in the hepatic veins [13,14]. The symptoms of hepatic vein obstruction and obstruction of the hepatic portion of the IVC are the same.

Clinical features

Presenting signs and symptoms in patients with overt disease include fever, abdominal pain and tenderness, ascites, lower extremity edema, gastrointestinal bleeding, and hepatic encephalopathy, but any of these symptoms may be absent in symptomatic cases [15–17]. In obstruction at the level of the IVC, patients may develop distended subcutaneous veins across the abdomen, chest, and back, which form part of the collateral circulation; this finding is uncommon, but specific for IVC block. The presentation of BCS may be acute, acute-on-chronic, subacute, or chronic, although the last two presentations are more common. Severity of symptoms will depend on the extent of the involvement of the hepatic veins, the time-course over which the obstruction develops and the duration of untreated disease. Slower development of the obstruction or occlusion allows the formation of collaterals, which alleviates sinusoidal congestion. There is a wide spectrum of disease presentation. Concomitant portal vein obstruction is common in patients with severe forms of the disease [15,18–20]. Patients with an acute presentation are more likely to present with fulminant hepatic failure with coagulopathy, encephalopathy, and hepatorenal syndrome. Patients with a chronic presentation may present with chronic liver disease with (near-)normal aminotransferases, low albumin, and a prolonged prothrombin time. If there is extensive formation of collaterals or involvement of a single hepatic vein, the patient may have preservation of normal liver function and no ascites. BCS may be asymptomatic in up to 20% of cases [21]. The most common presentation is a history of vague complaints for less than 6 months and onset of ascites.

Serum aminotransferases and alkaline phosphatase may be normal or elevated. Serum albumin, serum bilirubin, and prothrombin can be normal or abnormal, and in some patients are markedly abnormal, although frank jaundice is relatively uncommon. The serum–ascites albumin gradient will be greater than 1.1 g/dL. An ascitic fluid protein concentration of greater than 3 g/dL is consistent with BCS, but may also occur with cardiac or pericardial disease.

The caudate lobe drains through the right inferior hepatic vein into the IVC, which develops thromboses less frequently, so that flow through the caudate lobe may become an important route of blood flow when there is occlusion of two or all three main hepatic veins. This increased flow leads to caudate lobe hypertrophy in about half of patients with BCS. Significant caudate lobe hypertrophy may compress the IVC behind it, complicating decompression by portacaval shunts (which are of course below the level of compression of the IVC).

Risk factors

Primary BCS is the result of an intrinsic venous process and the risk factors are those that lead to thrombosis or phlebitis. The major risk factors (Table 95.1) are chronic myeloproliferative diseases and prothrombotic coagulation disorders. Around 25%–30% of patients will have multiple concurrent risk factors [22,23]. Myeloproliferative disorders are the leading causal factor in 50% of patients [22,24–26]. The chronic myeloproliferative disorder most closely associated with hepatic vein thrombosis is polycythemia vera, whereas essential thrombocythemia is a less common cause. In a large series, 10% of patients with polycythemia vera, and 13% of patients with essential thrombocythemia, developed hepatic vein thrombosis [27]. None of the 232 patients with chronic myelogenous leukemia in this series developed thrombosis of the major abdominal vessels. The increased risk for hepatic vein thrombosis is linked to both overt and latent myeloproliferative disease.

In a recent series, one or more prothrombotic risk factors was identified in 87% of patients with BCS [22]. Two recent case series have identified factor V Leiden as an important risk factor [22,23], but these studies differed as to whether protein C deficiency was a risk factor. The prevalence of antithrombin deficiency, protein S deficiency, the G20210A prothrombin gene mutation, and the methylene-tetrahydrofolate reductase gene mutation in patients with hepatic vein thrombosis is similar to that expected for a healthy control population. Once BCS causes chronic liver disease, diagnosis of protein C deficiency, protein S deficiency, or antithrombin deficiency may be misleading because synthesis of these coagulation factors decreases as liver function declines; studies of family members may be needed to rule out these clotting disorders as a risk factor. Antiphospholipid antibodies are a risk factor for BCS and may be primary or related to one of the various connective tissue diseases. Oral contraceptives, pregnancy, and the puerperium are associated with an increased risk of BCS, but there will most commonly be a

Table 95.1 Risk factors for Budd–Chiari syndrome

Primary Budd–Chiari syndrome	Secondary Budd–Chiari syndrome
Myeloproliferative diseases	Hepatocellular carcinoma[a]
Polycythemia vera	Renal cell carcinoma[a]
Essential thrombocythemia	Adrenal carcinoma[a]
Prothrombotic coagulation disorders	Primary hepatic hemangiosarcoma
Factor V Leiden mutation	Epitheloid hemangioendothelioma
Protein C deficiency	Sarcoma of the inferior vena cava[a]
Antiphospholipid antibodies	Right atrial myxoma[a]
Prothrombin G20210A mutation	Hydatid cysts[a]
Oral contraceptives, pregnancy, puerperium	Amebic or pyogenic abscess[a]
Rare causes	Sarcoidosis
Behçet disease[a]	Trauma[a]
Paroxysmal nocturnal hemoglobinuria	Aspergillosis
Hypereosinophilic syndrome	Abdominal surgery
Granulomatis venulitis	
Ulcerative colitis	

a More commonly associated with membranous obstruction of the hepatic portion of the inferior vena cava than with obstruction at the level of the hepatic vein.

concurrent risk factor. Uncommon risk factors for BCS include paroxysmal nocturnal hemoglobinuria [28], postoperative complications, and Behçet disease. Although Behçet disease may cause hepatic vein thrombosis, it is more likely to cause obstruction of the IVC [13,14].

Procoagulants and anticoagulants circulate systemically throughout the vasculature. If the hemostatic balance of coagulation factors was the only determinant of thrombosis, then any change in the balance should have an impact on all vascular beds. As noted in the preceding paragraph, some of the prothrombotic disorders do and others do not cause hepatic vein thrombosis. Predisposition to thrombosis in a particular vascular bed is a characteristic feature of prothrombotic disorders. This selectivity of thrombosis for discrete segments of the vasculature may be the result of endothelial cell-dependent procoagulant and anticoagulant activities [29].

Secondary BCS is the result of a process originating outside the vein that compresses or invades the vein. The major causes are cancers and infections (Table 95.1). Some of the causes listed in Table 95.1 may cause obstruction at the level of the hepatic veins, but they are more commonly associated with obstruction of the hepatic portion of the IVC. Uncommon causes of secondary BCS are trauma with formation of an intrahepatic hematoma, granulomata caused by sarcoidosis, and aspergillosis invading hepatic veins [30].

Diagnosis

Imaging with Doppler ultrasound can make the diagnosis, although in some centers dual-phase computed tomography (CT) or magnetic resonance (MR) angiography may be needed to confirm the diagnosis (Table 95.2). Imaging may demonstrate obstruction or absence of flow at the level of the major hepatic veins or IVC; intrahepatic, capsular, or systemic col-

Table 95.2 Sequential steps in diagnostic imaging and therapy of Budd–Chiari syndrome

Sequential steps	Diagnostic imaging	Therapy
1	Doppler ultrasound	Anticoagulation
2	Magnetic resonance imaging	Angioplasty and stenting

TIPS, transjugular intrahepatic portosystemic shunt.

lateral formation; hepatic parenchyma with variegated appearance and nodularity; caudate lobe enlargement; ascites; or splenomegaly. If normal hepatic veins with phasic flow are detected, the diagnosis of BCS is excluded. In difficult cases angiography may be required to establish the diagnosis and to precisely localize the obstruction.

Ultrasound is superior to MR imaging (MRI) for the detection of intrahepatic collaterals [31]. MRI may be more accurate than venography for the characterization of solid endolumenal material [31]. In the older literature, CT did not provide a reliable assessment of the hepatic veins [31], but the accuracy of current CT technology has not yet been reported.

The value of liver biopsy for establishing prognosis or determining management is greatly limited by significant sample variation. Liver biopsy is, however, the only method to establish a diagnosis of BCS of the small intrahepatic veins. Liver biopsy findings in acute BCS include centrilobular and sometimes midlobular sinusoidal congestion, acute hemorrhage, and hepatocyte ischemia or drop out. Chronic outflow obstruction leads to hepatocyte dropout and bridging fibrosis between central veins with sparing of the portal tracts. Thrombi in the hepatic veins may have multiple layers, consistent with ongoing or recurrent thrombosis. Portal vein thrombosis occurs secondarily in some of the small branches of the portal vein and in the main portal vein in about 25% of cases. Areas of the liver subject to the most severe outflow obstruction demonstrate sinusoidal fibrosis. Benign regenerative nodules are common.

In addition to the diagnosis of BCS itself, the diagnostic work-up needs to uncover the predisposing factor(s). Frequently there are two or more causes, one of which may be a myeloproliferative disorder [22,23]. In this population, portal hypertension with hypersplenism and with gastrointestinal bleeding leading to iron deficiency anemia will obscure the peripheral blood changes of the myeloproliferative disorder in most patients [25], resulting in occult myeloproliferative disease. No single test is diagnostic in all patients with occult myeloproliferative disease [32–34]. Diagnosis may be made by demonstrating the 1849GmT point mutation (V617F) of the tyrosine kinase *JAK2* gene in myeloid cells [32–35], by demonstration of clusters of dystrophic megakaryocytes on bone marrow biopsy [36], or by endogenous erythroid colony formation in culture of bone marrow cells or circulating myeloid progenitor cells [25,37,38].

Management of primary Budd–Chiari syndrome

The sequential steps for management of BCS recommended by consensus statement reports in 2002 [10] and 2005 [9] are:

- anticoagulation, treatment of predisposing conditions, and prophylaxis for or treatment of complications of portal hypertension
- an active search for and treatment of short-length venous stenoses amenable to angioplasty or stenting
- transjugular intrahepatic portosystemic shunt (TIPS), if angioplasty or stenting is not possible or is unsuccessful
- if TIPS is unsuccessful, evaluate for liver transplantation (Table 95.2).

Treatment of condition predisposing to thrombosis

Myeloproliferative diseases should be treated, although therapeutic end points are not well defined. Phlebotomy alone will increase the risk of thrombosis in patients with polycythemia vera, whereas one nonrandomized trial has suggested a reduced risk of thrombosis in patients receiving phlebotomy plus hydroxyurea [39,40]. Hydroxyurea reduces the risk of thrombosis in patients with essential thrombocythemia [41].

Oral contraceptives are contraindicated. There are reports of successful pregnancies in patients on anticoagulation during pregnancy. Most other predisposing conditions for primary BCS will require anticoagulation.

If the predisposing condition is not curable, indefinite anticoagulation should be considered. Indefinite anticoagulation may improve survival for patients with a good prognosis, but may not for individuals with an intermediate or poor prognosis [15].

There are insufficient data to determine the benefit of thrombolytic therapy. The largest case series suggests that the best results may be obtained with local infusion of thrombolytic therapy rather than systemic treatment, after recent thrombosis and following partial recanalization by mechanical means [42]. However, these findings are based on a small retrospective study.

Angioplasty and stenting

Angioplasty, with or without stenting, should be considered in patients with focal or segmental obstruction. Patency may be better maintained in patients who remain on anticoagulants for at least 6 months [43]. Recurrent obstruction is more common after primary angioplasty than after primary stenting for both hepatic vein and IVC obstruction. Reobstruction may be less common after IVC stenting than after hepatic vein stenting [43].

Portosystemic shunting

Increased sinusoidal pressure and decreased liver perfusion in BCS lead to parenchymal necrosis, fibrosis, cirrhosis, and portal hypertension. Sinusoidal decompression performed before significant fibrosis and loss of liver function may stabilize disease progression. Other indications for decompression include refractory ascites and uncontrollable gastrointestinal hemorrhage. Options for decompression of obstruction in the hepatic vein include TIPS and surgical shunt. The goal of TIPS or of a surgical shunt is to create hepatofugal flow through the portal vein.

The use of TIPS for BCS has been increasing. Polytetrafluoroethylene-covered stents have a lower rate of dysfunction

than uncovered stents [44]. Bleeding complications of TIPS may be higher for BCS than for other chronic liver diseases, but the incidence of encephalopathy may be lower.

The availability of TIPS has greatly reduced the need for surgical shunts. There may not be any improvement in survival with a shunt unless patency of the shunt is maintained [45]. The choice of surgical shunt will often depend on the preference of the surgeon. If there is significant compression of the IVC by caudate lobe hypertrophy or substantial obstruction of the IVC by thrombosis or a web, pressure in the retrohepatic IVC may be higher than in the portal vein. Under these conditions shunts proximal to the obstructed IVC (portacaval or mesocaval shunt) may fail and a mesoatrial shunt should be considered. Side-to-side portacaval shunts, with direct anastomosis of the side of the portal vein to the side of the vena cava, have the highest patency rate but may make future liver transplantation more difficult: a portacaval shunt will require extensive dissection around the porta hepatis and reversal of the shunt is a major undertaking. Mesocaval shunts are technically less demanding and may facilitate surgery at the time of liver transplantation, but when performed with a synthetic graft they have a higher thrombosis rate than a side-to-side portacaval shunt.

Liver transplantation

Liver transplantation is the treatment of choice for acute BCS with fulminant hepatic failure and for end-stage liver disease after a chronic course. In more recent series of patients transplanted for BCS, survival rates have been much improved over earlier series. Three-year survival of 78%–88% and 5-year survival of 75% have been reported [46,47]. The improved survival is likely to be the result of earlier treatment after onset of symptoms and the recognition of the need for lifelong anticoagulation in most patients. Liver transplantation may cure one of the underlying predispositions, such as factor V Leiden, protein C deficiency, or antithrombin deficiency, but a thorough diagnostic work-up may reveal the presence of two or more remaining prothrombotic risk factors that will still require anticoagulation.

Portal vein thrombosis

After a review of the common risk factors, this section will separately review the acute and chronic phases of portal vein thrombosis.

Risk factors

A local precipitating factor can be identified in 30% of patients, whereas a systemic risk factor is present in 70%–80% [22,23,32] (Table 95.3).

The most common local precipitating factors include hepatoma, pancreatic cancer, and cirrhosis. Other local factors include: any abdominal malignancy; inflammatory processes in the abdomen such as pancreatitis, diverticulitis, appendicitis, cholecystitis, inflammatory bowel disease, or cytomegalovirus hepatitis that lead to a pylephlebitis; and abdominal trauma or surgery. Portal vein thrombosis in patients with malignancy may be the result of local tumor invasion or of a hypercoagulable state. Pancreatitis may cause portal vein thrombosis either through extrinsic compression of the portal vein by a pseudocyst or through pylephebitis secondary to acute pancreatitis. Cirrhosis may predispose to portal vein thrombosis because of sluggish blood flow through the liver in intrahepatic portal hypertension, but cirrhosis-related hepatocellular carcinoma may also manifest as portal vein thrombosis.

Table 95.3 Risk factors for portal vein thrombosis

Systemic risk factors	Local risk factors
Myeloproliferative diseases	*Abdominal malignancies*
Polycythemia vera	Hepatoma
Essential thrombocythemia	Pancreatic cancer
Inherited clotting disorders	Cirrhosis
G20210A prothrombin	*Inflammatory/infectious processes*
Antithrombin deficiency	Pancreatitis
Protein C deficiency	Diverticulitis
Protein S deficiency	Cholecystitis
	Appendicitis
	Cytomegalovirus hepatitis
	Inflammatory bowel disease
	Abdominal trauma and surgery

The major systemic risk factors are myeloproliferative diseases and inherited clotting disorders. About one-third of patients with portal vein thrombosis will have a primary myeloproliferative disease, notably polycythemia vera and essential thrombocythemia. As noted earlier in the chapter on the section for BCS, in most patients the myeloproliferative disease will be occult, i.e., not manifested in peripheral blood smears, because of hypersplenism and iron deficiency anemia. No one diagnostic test is sufficient to diagnose all cases of occult myeloproliferative disease. Diagnosis may be made by the presence of dystrophic megakaryocytes on bone marrow biopsy [36], endogenous erythroid colony formation in cultures of bone marrow or circulating progenitors [25], or the presence of the 1849GmT point mutation (V617F) of the tyrosine kinase gene *JAK2* in myeloid cells [32,34,48,49].

The inherited clotting disorders that predispose to portal vein thrombosis are the prothrombin gene mutation (factor II G20210), antithrombin deficiency, protein C deficiency, and protein S deficiency [22,23,32]. Inherited protein C, protein S, and antithrombin deficiency need to be distinguished from acquired deficiency because of impaired hepatic synthesis in liver disease. Factor V Leiden and hyperhomocysteinemia do not predispose to thrombosis of the portal vein. It is unclear why prothrombotic disorders predispose to

clotting in particular regions of the vascular bed. Endothelial cells in various organs and even within organs show tremendous heterogeneity [50]. The selectivity of a prothrombotic disorder to predispose to clotting in a particular vascular bed may be related to specific procoagulant and anticoagulant activity of the endothelial cells in that particular segment of the vasculature [29].

Analogous to BCS, most patients will have two or more risk factors for portal vein thrombosis.

Acute portal vein thrombosis

Clinical presentation

The most common presenting symptom of acute portal vein thrombosis is abdominal or lower back pain. When there is partial occlusion of the vein, symptoms are milder, whereas the intestinal congestion of a complete obstruction leads to severe, continuous colicky pain. The patient may develop an ileus with abdominal distention, but without other features of intestinal obstruction. Other symptoms include nonbloody diarrhea and a persistent fever. Laboratory tests may reveal a transient increase in serum aminotransferases, but liver function is otherwise preserved. Acute portal vein thrombosis is reversible with recanalization or development of a cavernoma.

Propagation of the thrombus into the mesenteric venous arches may lead to intestinal ischemia or even infarction. In the presence of mesenteric vein thrombosis, patients may develop severe pain lasting longer than 5–7 days, bloody diarrhea, and ascites. With progression to intestinal infarction patients may develop renal insufficiency, acidosis, and respiratory dysfunction. Without timely surgical intervention, transmural intestinal infarction will lead to perforation, peritonitis, sepsis, and death.

In a patient with acute portal vein thrombosis with high fever, chills, and right upper quadrant pain, a pylephlebitis is likely. The patient should be evaluated for an abdominal infection as the precipitating event. In this setting, liver abscesses are common and blood cultures are usually positive for enteric organisms.

Diagnosis

CT scan before contrast injection can demonstrate hyperattenuating material in the lumen of the vessel and CT after contrast injection demonstrates the lack of lumenal enhancement, increased arterial and decreased portal phase enhancement of the liver [51,52]. If CT is not readily available, Doppler ultrasound can demonstrate hyperechoic material in the portal vein, distention of the vein, and lack of flow. Either CT or MR angiography can be used to demonstrate propagation of the thrombus into the mesenteric circulation.

Management

The three treatment goals in acute portal vein thrombosis are to recanalize the obstructed vessel, to diagnose and treat the predisposing factor, and, if there are indicators of infection, to treat the infection.

Recanalization rarely occurs spontaneously, but partial or complete recanalization may occur in 40% and 50%, respectively, of patients on anticoagulation [53]. Therapy can be initiated with low-molecular-weight heparin and then switched to oral anticoagulation. Anticoagulation should be given for at least 3 months. Long-term anticoagulation should be considered for patients with a predisposing risk for clotting that cannot be cured, with extension of the thrombus into the mesenteric circulation, or in whom the mesenteric thrombus does not recanalize. The current literature suggests that recanalization rates with thrombolytic therapy are similar to those with anticoagulation alone, but with a much higher incidence of complications. A work-up should be initiated to find the source of infection in patients with fever or leukocytosis, but even if the source of infection cannot be documented antibiotics should be considered in these patients. Intestinal infarction requires emergent laparotomy to resect necrotic bowel.

Prompt institution of anticoagulation will significantly improve the prognosis. Outcome is dependent on recanalization of the portal and mesenteric veins and prevention of intestinal infarction. Recanalization of the portal vein and at least one of its branches will prevent portal hypertension. Intestinal infarction will be prevented if extension of the thrombus into the mesenteric circulation can be prevented or if the mesenteric vein is recanalized. Rarely, patients with intestinal ischemia may develop intestinal strictures and present with small bowel obstruction at a later time point. With prompt diagnosis and treatment before intestinal infarction, the outcome is good. Overall mortality is around 10% and this is mainly the result of postoperative complications or the predisposing condition [54].

Chronic portal vein thrombosis

Clinical presentation

In the developed nations, portal vein thrombosis is increasingly being recognized during the acute phase [53]. The most common presenting features of chronic portal vein thrombosis are splenomegaly or variceal hemorrhage due to portal hypertension. Patients with cirrhosis who develop a chronic portal vein thrombosis may present with worsening ascites. Recanalization of the portal vein clot leads to formation of small tortuous collateral veins, so-called cavernomatous transformation, which is the hallmark feature of chronic portal vein thrombosis. Initially patients will develop extensive collaterals throughout the upper gastrointestinal tract, portal hypertensive gastropathy, and splenomegaly. Some patients will have a tender enlarged liver. Blood flow to the liver from the hepatic artery and from perihepatic varices is usually adequate to maintain normal liver function. However, ascites or encephalopathy may be transiently present after a gastrointestinal bleed, during sepsis, or with unrelated renal

failure. With complete obstruction of the portal vein, enlarged biliary veins can compress large bile ducts, leading to portal cholangiopathy. About 10% of patients have hepatopulmonary syndrome [55].

In the absence of cirrhosis, liver tests are usually normal. Prothrombin time may be moderately prolonged. Patients who develop portal cholangiopathy may have cholestasis.

Diagnosis

The diagnostic feature of chronic portal vein thrombosis is cavernomatous transformation. Ultrasound, CT, or MRI will demonstrate the presence of a cluster of small irregular collateral vessels and the absence of the main portal vein and its main branches. Doppler ultrasound, CT or MRI before and after contrast can detect both the size and the patency of the portal vein. Hepatic arteries are usually enlarged and the caudate lobe may be enlarged.

Management

The most common presenting symptom of portal vein thrombosis is variceal hemorrhage. Acute variceal bleeding may be managed endoscopically. Prevention of recurrent variceal bleeding can be addressed with endoscopic band ligation or β-blockers. Patients with cavernomatous transformation who do not present with variceal hemorrhage should be screened for varices. The two options for intractable variceal hemorrhage are shunt surgery and TIPS. Shunt surgery in this population carries an increased risk of thrombosis of the shunt and should be performed with larger veins [56]. TIPS may be considered for intractable bleeding, but is not technically feasible in most patients [57].

Given the risk of variceal hemorrhage on one hand and extension of thrombosis on the other, the question arises as to the risk–benefit ratio of anticoagulation. Three retrospective studies have found no increase or a decreased incidence of gastrointestinal hemorrhage with anticoagulation [58–60] with a significantly decreased risk of recurrent thrombosis [60]. In 2005, a consensus panel recommended that anticoagulation should only be considered in patients with a permanent prothrombotic condition [9]. Long-term anticoagulation should be considered for patients with chronic portal vein thrombosis without cirrhosis, who have no contraindication for anticoagulation, who have received adequate treatment or prophylaxis for varices, and who either have a permanent prothrombotic condition or who have extension of the thrombus into the mesenteric circulation [61].

Patients with jaundice or biliary symptoms due to portal cholangiopathy may be treated by endoscopic retrograde cholangiopancreatography and stent placement after extraction of any stones. Half of these patients will not have recurrent symptoms when the stent is removed [62]. Recurrence will require a repeat procedure. If a surgical approach is deemed necessary, biliary decompression should be coupled with portal decompression.

Outcome is largely related to complications from portal cholangiopathy and transformation of a myeloproliferative disease to leukemia or myelofibrosis. In a 5-year follow-up study, fewer than 5% of patients died from either gastrointestinal hemorrhage or intestinal infarction. The prognosis may be worse in patients with extension into the mesenteric circulation [59].

Portal vein thrombosis in cirrhosis

Much of the preceding applies to portal vein thrombosis in cirrhotics, but a few special considerations apply to this population.

The risk of portal vein thrombosis increases with the severity of cirrhosis. The most common risk factor in cirrhosis is hepatocellular carcinoma. Evaluation of inherited deficiency of antithrombin, protein C, and protein S is complicated by acquired deficiency because of decreased hepatic synthetic function and evaluation of family members may be needed to make the diagnosis.

Splenectomy and surgical portosytemic shunting markedly increase the risk of portal vein thrombosis in this population. It is unclear whether treatment of varices precipitates the development of portal vein thrombosis or whether severe portal hypertension that leads to varices also predisposes to portal vein thrombosis.

Long-term anticoagulation should be considered for patients with compensated cirrhosis, a permanent prothrombotic risk factor and adequate treatment or prophylaxis for gastrointestinal hemorrhage [61]. In patients with decompensated cirrhosis with portal vein thrombosis, anticoagulation should only be instituted in a transplant center [61].

Sinusoidal obstruction syndrome (hepatic venoocclusive disease)

In 1920 and again in 1945, papers were published describing a novel liver disease [63,64]. The most striking histological feature was occlusion of the central veins and it was subsequently named hepatic venoocclusive disease [65]. Clinicopathological studies have demonstrated that the central veins are not occluded in up to 45% of patients [66,67] and experimental studies have shown that the disease process originates in the sinusoids [68,69]. Based on these findings, investigators in this field have proposed renaming this disorder sinusoidal obstruction syndrome (SOS) [70].

Pathogenesis

In contrast to most liver diseases, SOS presents with features of portal hypertension, followed subsequently by evidence of parenchymal dysfunction. This is indicative of the primary circulatory nature of the disease. Experimental studies indicate that drugs that cause SOS target the sinusoidal endothelial cell [68,71–73]. Sinusoidal endothelial cells become

rounded and gaps form within and between these cells [68]. This permits blood to enter into the space of Disse and dissect off the sinusoidal lining cells, which then embolize downstream and block sinusoidal flow [69]. Interventions that preserve the integrity of the sinusoidal endothelial cell lining completely prevent the development of SOS [74,75], confirming the sinusoidal origin of the disease.

Risk factors

The original descriptions of SOS were the result of ingestion of herbal teas ("bush tea disease") or foodstuffs contaminated with pyrrolizidine alkaloids, particularly in protein-malnourished individuals. In many parts of the world, ingestion of pyrrolizidine alkaloids is still the major cause of SOS. In North America and Western Europe the most frequent cause of SOS is myeloablative conditioning in preparation for hematopoietic stem cell transplantation (bone marrow transplantation), either high-dose combination chemotherapy or chemotherapy plus irradiation [67,76–78]. SOS may occur after long-term immunosuppression with azathioprine or treatment with 6-thioguanine [79–84]. It is also seen after treatment with chemotherapeutic agents unrelated to stem cell transplantation and has been associated with drugs such as gemtuzumab ozogamicin, actinomycin D, dacarbazine, cytosine arabinoside, 6-thioguanine, and urethane [85–89]. Treatment of Wilms tumors with actinomycin D carries a significant risk for SOS and this risk is greater in right-sided Wilms tumors or when actinomycin D is combined with abdominal irradiation [90,91]. The risk of gemtuzumab ozogamicin is particularly high when the drug is given in close temporal proximity to myeloablative conditioning therapy [88,92]. In a small series of patients, an interval of less than 3.5 months between gemtuzumab ozogamicin and myeloablative conditioning lead to a 90% incidence of SOS [92].

Clinical presentation

The classic features of SOS are hyperbilirubinemia, right upper quadrant pain of liver origin or hepatomegaly, and weight gain. The course of disease is protracted in SOS as a result of chronic exposure to pyrrolizidine alkaloids, whereas SOS in the setting of stem cell transplantation evolves more rapidly. In patients treated with cyclophosphamide-containing conditioning regimens, onset is within 10–20 days of initiation of treatment [77]. In other conditioning regimens onset of SOS may occur later than for cyclophosphamide-containing regimens [93].

Diagnosis

A tentative diagnosis can be made based on the presenting features in the setting of hematopoietic stem cell transplantation with a conditioning regimen that is hepatotoxic, but the importance of ruling out other conditions cannot be overemphasized. The differential diagnosis in this population includes (hyper)acute graft-versus-host disease; cholestatic jaundice caused by sepsis; fluid-overload caused by renal failure, congestive heart failure, or vigorous fluid resuscitation; medication-induced cholestasis; and liver involvement by viral or fungal infections seen during immunosuppression. More than one of these conditions may occur simultaneously in this population so that it can be difficult to determine which disease is the predominant cause of a particular sign or symptom. Up to 10%–20% of patients with liver dysfunction in the first 10–20 days after stem cell transplantation cannot be diagnosed with certainty based on clinical grounds [94,95].

Two groups of investigators developed clinical criteria used to diagnose SOS after hematopoietic stem cell transplantation that were intended for clinical research purposes (Table 95.4). However, application of these criteria requires careful exclusion of other causes. According to the criteria published by the Seattle investigators, two of three findings must occur within 20 days after transplantation: bilirubin greater than 2 mg/dL, tender hepatomegaly, and weight gain greater than 2% as the result of fluid accumulation. These criteria were developed for SOS caused by conditioning regimens that contain cyclophosphamide and the temporal criterion may not apply to regimens without cyclophosphamide. The Baltimore criteria require bilirubin to be greater than 2 mg/dL and two of three other findings: (usually painful) hepatomegaly, greater than 5% weight gain, and ascites.

Imaging studies can confirm hepatomegaly and ascites and can exclude biliary obstruction and tumor invasion into the hepatic parenchyma or vasculature, but there is not a single imaging feature that by itself is diagnostic. Imaging features that are highly suggestive of SOS include reversal of portal

Table 95.4 Criteria for diagnosis of sinusoidal obstruction syndrome

Seattle criteria [127]	Baltimore criteria [78]
Diagnosis requires two of three criteria within 20 days of transplantation: • bilirubin > 2 mg/dL • hepatomegaly or pain of liver origin • > 2% weight gain due to fluid retention	Hyperbilirubinemia (> 2 mg/dL) plus at least two of the following three findings: • (tender) hepatomegaly • > 5% weight gain • ascites

venous flow, gallbladder wall edema, attenuation of hepatic venous flow, and, perhaps, increased resistive index of hepatic artery flow.

The main differential diagnosis that might warrant a liver biopsy is (hyper)acute graft-versus-host disease. In a moderately or severely ill patient in whom the diagnosis is uncertain, a transvenous liver biopsy with hepatic venous pressure gradient using the occlusive balloon technique may help to distinguish SOS from graft-versus-host disease. In the setting of stem cell transplantation, a hepatic venous pressure gradient greater than 10 mmHg has a specificity of more than 90% and positive predictive value greater than 85% [96].

Prevention

Prevention is largely limited to identification of those at high risk for SOS, who may then be limited to less hepatotoxic alternatives. The major risk factors are hepatitis C, hepatic fibrosis, previous exposure to a myeloablative regimen, and previous history of SOS. Cirrhosis is an absolute contraindication to a myeloablative regimen.

Nonmyeloablative regimens are used to treat malignancy through a graft-versus-tumor effect. These regimens do not appear to have a risk for SOS and reduce immediate transplant-related mortality, but may have more late complications than myeloablative regimens [97,98]. For patients at significant risk for SOS, non-myeloablative regimens seem to be the best approach. Even with nonmyeloablative regimens, patients with cirrhosis have an increased risk of death from liver decompensation [98]. Lower doses of total body irradiation [99] and pharmacokinetic monitoring followed by targeted dosing of drugs such as cyclophosphamide [100,101] and busulfan [102–105] may also lower the risk of SOS. Adjustment of busulfan dosing based on plasma concentrations has been shown in some studies to be beneficial, but this could not be confirmed in a number of studies (see review [106]). The value of therapeutic monitoring of busulfan may depend on other factors, such as the age of the patient, the underlying disease, and the other drugs in the conditioning regimen [106]. Investigators from Seattle have shown benefit from metabolism-based dosing of cyclophosphamide, but it remains to be seen whether this will become more widely available and whether it will indeed reduce the risk of fatal SOS. Other approaches to avoiding SOS caused by myeloablative regimens include reversing the order of drugs in the busulfan–cyclophosphamide regimen (i.e., cyclophosphamide first) [107] or avoiding cyclophosphamide-containing regimens altogether.

Prophylactic treatment has been tried with heparin, low-molecular-weight heparin, prostaglandin E, and pentoxifylline, but none of these compounds have been shown to reduce the incidence of fatal SOS (see review [70]). The largest randomized controlled trial found no benefit for ursodeoxycholic acid [108], but a recent metaanalysis reported that ursodeoxycholic acid was beneficial in SOS [109]. The likely explanation for the apparent benefit is that SOS commonly occurs in conjunction with cholestatic liver disease, which may improve with ursodeoxycholic acid.

Treatment

The majority of patients with SOS recover spontaneously. Patients with severe SOS are deeply jaundiced, but commonly lack some of the features of liver failure, such as hyperammonemia, cerebral edema, and prolonged international normalized ratio. Death is usually the result of multiorgan failure with renal and pulmonary failure. Supportive care requires maintenance of fluid and electrolyte balance. Extravascular fluid overload is treated with diuretics in conjunction with paracentesis, hemodialysis, and hemofiltration when indicated for respiratory impairment due to ascites.

Defibrotide is an experimental compound that has been tried for a variety of vascular diseases. It is a single-stranded polydeoxyribonucleotide with antithrombotic, antiischemic, and thrombolytic effects and that reduces leukocyte accumulation. Uncontrolled clinical trials in moderate to severe SOS have been promising, but randomized controlled trials have not yet been performed.

TIPS decompresses portal pressure and relieves ascites, but does not improve the outcome of SOS [110–112]. Liver transplantation may be considered in patients who develop SOS after hematopoietic stem cell transplantation for a benign disease or whose underlying malignancy is expected to have a good outcome (e.g., chronic myelogenous leukemia in chronic phase). However, liver transplantation is not indicated when the risk of recurrent malignancy is high.

Prognosis

Diagnostic criteria for SOS and fatal SOS vary between transplantation units. These differences may account for the wide range in published case fatality rates [77,78,113–115]. Two large studies with cyclophosphamide-containing regimens reported a 70% recovery rate from SOS [77,113] and a study of SOS due to other alkylating agents reported an 84% recovery rate [93]. For patients who develop SOS due to cyclophosphamide-containing regimens, outcome can be predicted based on bilirubin level and weight gain using published graphs [116].

Adaptation to heterogeneous perfusion

The current consensus is that there are a variety of pathological lesions and clinical manifestations that are the result of uneven perfusion of the liver [117–120]. According to this hypothesis, these lesions (Table 95.5) are a single entity with a common pathogenesis, but a range of presentations. These lesions include nodular regenerative hyperplasia, partial nodular transformation, incomplete septal cirrhosis, and idiopathic noncirrhotic intrahepatic portal hypertension.

Table 95.5 Lesions due to heterogeneous perfusion of the liver

Liver lesions	Morphology [118]
Nodular regenerative hyperplasia	Monoacinar nodules composed of hyperplastic hepatocytes diffusely distributed throughout the liver, no surrounding fibrous septa
Partial nodular transformation	Multiple nodules that are several centimeters in diameter, composed of hyperplastic hepatocytes, encompassing several portal tracts, located in perihilar region
Incomplete septal cirrhosis	Large, diffusely distributed nodules, bordered by incomplete slender fibrotic septa; septa extend from periportal or perivenular fibrosis; spacing between portal tracts and between portal tracts and central veins is abnormal
Idiopathic non-cirrhotic intrahepatic portal hypertension	No nodular lesions; portal tracts are fibrotic, thin fibrotic septa may be present, if present then bridging fibrosis is subcapsular; sinusoidal dilation is common

More than one of these lesions may be found in some patients, supporting the concept that these lesions are a spectrum of responses with a shared etiology. By definition, these lesions occur in the absence of cirrhosis or chronic liver diseases that might lead to cirrhosis.

The concept of liver lesions caused by heterogeneous perfusion was first described for nodular regenerative hyperplasia [120]. The hypothesis is that impaired perfusion in some of areas of the liver leads to atrophy with apoptotic or atrophic hepatocytes and reactive hyperplasia in adjacent areas with preserved blood flow.

Risk factors

Underlying predispositions include collagen vascular diseases, clotting disorders, myelo- and lymphoproliferative diseases, some immunological disorders, and a variety of drugs and toxins (Table 95.6). Although the diseases and predisposing factors vary greatly, a shared element is the ability to potentially impair the circulation at the venous or sinusoidal level. Inflammation of the hepatic artery in collagen vascular diseases or immune complex diseases may lead to inflammatory destruction of adjacent portal veins [121,122]. Prothrombotic disorders may cause thrombosis in either the venous or sinusoidal circulation [117]. Azathioprine and myeloablative conditioning therapy for stem cell transplantation may impair the sinusoidal circulation by damage to sinusoidal endothelial cells [72,73].

Table 95.6 Conditions leading to heterogeneous perfusion of the liver

- Antiphospholipid syndrome
- Myasthenia gravis

Drugs and toxins
- Anabolic steroids
- Azathioprine
- Myeloablative conditioning regimens for stem cell transplantation
- Oral contraceptives
- Oxaliplatin
- Thoratrast
- Toxic oil syndrome
- 6-Thioguanine

Clinical presentation

The clinical presentation can vary from asymptomatic disease diagnosed at autopsy to decompensated liver disease. Nodular regenerative hyperplasia is an uncommon clinical diagnosis. Large autopsy series have found a prevalence of nodular regenerative hyperplasia of around 2.5% of the population [119,120], demonstrating that most cases of nodular regenerative hyperplasia are asymptomatic. The most common symptoms of overt disease are bleeding varices and splenomegaly as the result of portal hypertension. Liver function is usually preserved, so that hypoalbuminemia and ascites are uncommon. Decompensated liver disease or frank liver failure may be precipitated by severe gastrointestinal hemorrhage or by another concurrent disease. The most common liver test abnormalities are mild elevations of alkaline phosphatase, aspartate aminotransferase, or alanine aminotransferase. Morphology of lesions attributed to heterogeneous perfusion of the liver is described in Table 95.5.

Treatment

In the vast majority of patients, no treatment is needed for the liver disorder itself, although the underlying predisposing condition or precipitating factor may require therapy. Manifestations of portal hypertension are treated along conventional lines.

Peliosis hepatis

Peliosis hepatis is a rare abnormality characterized by blood-filled cystic lesions in the hepatic parenchyma distributed irregularly throughout the liver. The peliotic cavities range in

Table 95.7 Conditions associated with peliosis hepatis

AIDS/*Bartonella* infection
Tuberculosis
Myeloproliferative diseases
Leukemia
Lymphoma
Multiple myeloma
Macroglobulinemia
Anabolic steroids
Oral contraceptives
Azathioprine
Arsenic
Thoratrast
Vinyl chloride
6-Thioguanine

size from less than 1 mm to several centimeters. Although most common in the liver, peliotic lesions may also occur in the spleen, abdominal lymph nodes and bone marrow.

Risk factors

Risk factors for peliosis hepatis include drugs, AIDS, tuberculosis, lymphoma, multiple myeloma, leukemia, and myeloproliferative disorders (Table 95.7). Historically, peliosis was found at autopsy in patients with chronic wasting illnesses, in particular tuberculosis and cancer. In patients with acquired immunodeficiency syndrome (AIDS), infection with *Bartonella henselae* or *Bartonella quintana* may cause peliosis as well as bacillary angiomatosis.

The initial change in peliosis hepatis seems to be sinusoidal dilation, followed by formation of cavities without sinusoidal endothelial cells [123,124]. Eventually the endothelial lining may be restored in parts of the peliotic cavities. Studies in AIDS patients most clearly support the concept that peliosis is initiated by damage to sinusoidal endothelial cells. In AIDS patients, *Bartonella* bacilli can be detected by electron microscopy in sinusoidal endothelial cells of peliotic lesions [125] and there is disruption of the sinusoidal endothelial cell lining [123].

Peliosis caused by some drugs (azathioprine, 6-thioguanine, oxaliplatin, urethane) may also be the result of direct damage to sinusoidal endothelial cells. These drugs have been linked to other disorders that are thought to be the result of damage to sinusoidal endothelial cells and in some cases up to all four lesions (i.e., peliosis, SOS, nodular regenerative hyperplasia, and sinusoidal dilation) have been described within the same liver. Azathioprine and oxaliplatin have been associated with all four lesions; 6-thioguanine has been linked to peliosis, nodular regenerative hyperplasia, and SOS; and urethane has been associated with peliosis and SOS. Other drugs (glucocorticoids, methotrexate, anabolic steroids, vitamin A, oral contraceptives) cause peliosis through an as yet undefined mechanism.

One might speculate that, analogous to AIDS, infection with *Bartonella* sp. may play a role in some of the other risk factors that cause immunosuppression, such as tuberculosis, cancer, malnutrition, and glucocorticoid therapy. However, *Bartonella* spp. have not been documented in peliosis in these disorders.

Clinical presentation

Peliosis hepatis is usually a silent disease. There are reports of portal hypertension, ascites, cholestasis, and liver failure. Rupture of a lesion may lead to either a hepatic hematoma or an intraperitoneal hemorrhage that may progress rapidly to shock and death. If the precipitating cause of peliosis is withdrawn or resolves, there is regression of the lesions. Diagnosis may be made by Doppler ultrasound, CT, or MRI [50,126].

Introduction

Hepatocyte transplantation, liver-directed gene therapy, and artificial liver assist devices are being developed in a parallel but interdependent manner. For example, hepatocyte transplantation can be used as a vehicle for liver-directed gene therapy. On the other hand, gene transfer can be used to expand hepatocytes in culture for transplantation and abrogation of the immune response. This article will provide a short overview of advances, as well as the remaining hurdles in these areas.

Hepatocyte transplantation

Orthotopic liver transplantation has significantly improved the prognosis for patients with acute or end-stage liver failure, or potentially lethal inherited metabolic disorders. Because of the expense, complexity, and associated morbidity and mortality of this procedure, hepatocyte transplantation is being explored as an alternative. Hepatocyte transplantation is performed by percutaneous or transjugular injection into the portal vein, spleen, or peritoneal cavity so this procedure is less invasive than liver transplantation. As the host liver remains intact, the loss of graft function should not worsen liver function. While intact livers must be transplanted shortly after procurement, isolated liver cells may be cryopreserved for later use [1]. The success of hepatocyte transplantation in experimental animals has encouraged clinical trials of this procedure at several institutions. Potential indications for hepatocyte transplantation include acute or chronic liver failure and inherited metabolic disorders. Hepatocytes could be used as a vehicle for ex vivo gene therapy of inherited metabolic disorders. Hepatocyte transplantation is also being considered for rescuing patients from radiation-induced liver damage following radiotherapy for liver tumors.

Treatment of liver-based metabolic diseases

Hepatocyte transplantation has been shown to correct several liver-based metabolic disorders in animals. The Gunn rat, an animal model of Crigler–Najjar syndrome type 1, lacks bilirubin-uridine diphosphate-glucuronosyltransferase (UGT1A1) activity and consequently, exhibits toxic levels of hyperbilirubinemia 1 [2]. Gunn rats and Nagase genetically analbuminemic (NAR) rats have been studied extensively in hepatocyte transplantation experiments. Transplantation of normal donor hepatocytes has ameliorated the metabolic abnormality in both animal models [3]. In the absence of cirrhosis, hepatocytes injected into the splenic pulp or infused into the portal vein engraft in the liver, where they integrate into the hepatic cords and function throughout life [4,5]. Hepatocyte transplantation has resulted in partial correction of metabolic disorders in low-density lipoprotein receptor-deficient [6] Watanabe heritable hyperlipidemic rabbits (an animal model of familial hypercholesterolemia), the Long–Evans Cinnamon rat (an animal model for Wilson disease) [7], the *mdr2* mouse (a model of progressive familial intrahepatic cholestasis type 3) [8], the *spf-ash* mouse (a model of ornithine transcarbamylase deficiency) [9], the $Agxt^{-/-}$ mouse (a model for primary hyperoxaluria-1) [10], and the hyperuricemic Dalmatian dog [11].

Although many biologically active liver proteins are present in excess, the expectation that liver-based metabolic deficiencies could be corrected by the transplantation of a very

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

small number of hepatocytes did not materialize. Repeated hepatocyte infusions can improve the response to transplantation [12], but more dramatic results have been obtained by progressive repopulation of the host liver by engrafted hepatocytes.

Massive repopulation of the liver

Studies in fumarylacetoacetate hydrolase (FAH) mutant mice (a model of hereditary tyrosinemia type I) showed that transplanted normal hepatocytes can spontaneously repopulate the liver of animals, in which hepatocytes are dying because of a metabolic disorder [13]. A small number of hepatocytes from normal mice, engrafted into the livers of FAH mutant mice, almost completely replace the native liver cells [13]. However, the transplant recipients remain susceptible to the development of hepatocellular carcinomas, despite extensive repopulation of their livers with normal hepatocytes. Therefore, risk of cancer or recurrent disease should be an important consideration in the clinical application of hepatocyte transplantation for a given disease. A small number of other metabolic diseases that provide a competitive repopulation advantage to donor cells include Wilson disease and α_1-antitrypsin deficiency. Unfortunately, in many cases, the liver disease is so advanced at the time of diagnosis that the structural damage to the host liver poses a hurdle to successful treatment by hepatocyte transplantation.

For most metabolic diseases, where host hepatocytes do not die spontaneously, strategies are being developed to inhibit host hepatocyte regeneration, while providing a proliferative stimulus to the transplanted cells by partial hepatectomy, induction of Fas-mediated apoptosis of host hepatocytes, or administering pharmacological doses of thyroid hormone [14,15]. A plant alkaloid, retrorsine blocks the hepatocyte cell cycle and has been used for this purpose [16]. As retrorsine is potentially carcinogenic, X-irradiation of the liver has been utilized as part of the preparative regimen [17,18]. Transplantation of normal hepatocytes from congeneic donor rats into Gunn rats that had undergone partial hepatectomy and hepatic irradiation resulted in complete normalization of serum bilirubin levels. Functional correction was also shown in a mouse model of primary hyperoxaluria type 1, where hepatic irradiation was combined with expression of hepatocyte growth factor by gene transfer, in lieu of partial hepatectomy [10]. It is possible that with detailed analysis in large animals, including nonhuman primates, preparative hepatic irradiation could find clinical application as a preparative regimen to expand donor hepatocytes after transplantation in patients with liver-based metabolic disorders.

Hepatocyte transplantation in patients with inherited metabolic disorders

Patients with ornithine transcarbamylase deficiency [19,20], α_1-antitrypsin deficiency [21], glycogen storage disease type 1a [22], infantile Refsum disease [23], factor VII deficiency [24], bile salt export protein deficiency (PFIC2) [25], and Crigler–Najjar syndrome type 1 [26] have been transplanted with allogeneic hepatocytes. Partial improvement in the metabolic syndrome has been documented in several of these diseases. In a patient with glycogen storage disease type 1a, hepatocyte transplantation resulted in improved glycemic control, and in the child with infantile Refsum disease, serum dihydroxycoprostanoic acid levels remained improved for more than a year after transplantation.

Unequivocal evidence of function of transplanted human hepatocytes was obtained in a 10-year-old patient with Crigler–Najjar syndrome type I (UGT1A1 deficiency) [26,27]. After transplantation, the serum bilirubin level fell by 50%, hepatic bilirubin glucuronidating activity increased from pretransplantation levels that were essentially unmeasurable to approximately 5% of normal and bilirubin glucuronides were excreted in bile. Allograft rejection was prevented with standard tacrolimus therapy. The procedure was not associated with any significant complications. Continued function of the engrafted cells was documented for nearly 3 years after transplantation. After this, the patient underwent partial liver organ transplantation because of continued requirement for phototherapy and slowly rising bilirubin levels [25].

Hepatocyte transplantation for patients with acute liver failure

Conceptually, hepatocyte transplantation should be particularly suitable for treating acute liver failure, because the liver remains architecturally normal and retains considerable restorative potential. Hepatocyte transplantation can rescue rodents with acute liver failure induced by hepatotoxins, liver ischemia, or 90% hepatectomy [28,29] and prevent the development of intracranial hypertension in pigs with acute, ischemic liver failure [30]. However, the outcome of hepatocyte transplantation in patients with acute liver failure has been disappointing, except, when used as a bridge to liver transplantation.

In the first clinical study, seven patients with fulminant liver failure were injected with human fetal hepatocytes into the peritoneal cavity. Some of the recipients recovered from encephalopathy [31]; the survival of patients with grade III hepatic encephalopathy was superior to that observed in the untransplanted control group. Since long-term survival of hepatocytes following direct injection into the peritoneum has not been shown, investigators in the United States have used other sites. Ethical concerns have led to the use of adult hepatocytes rather than fetal cells. In one study, seven potential transplant candidates received hepatocyte infusion through the splenic artery, five of these survived to undergo orthotopic liver transplantation [32]. In other studies, patients who were not candidates for organ transplantation were transplanted with hepatocytes by infusion into the portal vein for engraftment in the liver [33,34]. Engrafted hepatocytes were found in the spleens and livers of some of

the transplant recipients, and there are anecdotal reports of improvement in ammonia, prothrombin time, encephalopathy, cerebral perfusion pressure, and cardiovascular stability. Complications have been few, but include transient hemodynamic instability during intraportal hepatocyte infusion, sepsis, and embolization of hepatocytes into the pulmonary circulation [35]. Portal hypertension as a result of transplantation through the portal vein has been generally transient. Although the results suggested that the transplanted hepatocytes provided some benefit, unequivocal evidence for engraftment and function of the transplanted cells has not been obtained. Part of the problem could be that relatively small numbers of hepatocytes were transplanted in many of the patients.

In contrast to the situation in animal models of acute liver failure, liver regeneration is significantly inhibited in patients with acute liver failure [36]. Since injections of bone marrow cells and hepatocyte lysates have also been shown to affect animal survival, hepatocyte transplantation in the animal models might have helped by enhancing the regeneration of the host liver, rather than through functional engrafted cells. Based on studies with a mouse model of acute liver failure that more closely parallels the clinical situation [37], it is likely that multiple hepatocyte infusions over time may be required for improved patient survival.

Treatment of chronic liver failure

Studies in experimental animals

Because of the difficulty in generating animal models of stable and irreversible liver cirrhosis causing hepatic failure, most studies on evaluating hepatocyte transplantation for chronic liver failure have been performed in other animal models of hepatic encephalopathy. Intrasplenic transplantation of hepatocytes in rats with end-to-side portacaval shunt resulted in improvement of behavioral score, partial correction of the amino acid imbalance [38], and prevention of hepatic coma induced by ammonium chloride administration [39]. The engrafted hepatocytes proliferated in the spleen, organizing into structures resembling hepatic chords.

Hepatocyte transplantation has been shown to improve many of the physiological abnormalities associated with decompensated liver failure in rats with end-stage liver cirrhosis, induced by chronic administration of phenobarbital and carbon tetrachloride. Hepatocyte transplantation also prolonged the survival of these animals [40]. Transplantation of hepatocytes into cirrhotic livers results in a severe and prolonged increase in portal pressure [41]. While some transplanted hepatocytes migrate into cirrhotic nodules following intraportal infusion, it is unlikely that enough cells can engraft in the cirrhotic liver to significantly affect liver function. Moreover, it is unclear whether the transplanted cells could function normally within the deranged structure of the cirrhotic nodules. For these reasons, in the studies on cirrhotic rats, hepatocytes were engrafted in the spleen.

Clinical experience

The initial clinical trial was performed on 10 Japanese patients with liver cirrhosis to test the hypothesis that the functional failure of hepatocytes within the cirrhotic liver is the result of the deranged architecture of the organ. Between 10 million and 600 million hepatocytes harvested from their own left lateral liver segments were injected directly into the spleen, or infused into the splenic artery or the portal vein. In one patient, ascites and encephalopathy eventually resolved and engrafted hepatocytes were detected in the spleen by technetium-99m(Sn)-*N*-pyridoxyl-5-methyltryptophan radioisotope uptake 11 months after transplantation [42]. Subsequently, in the United States, infusion of up to 10^{10} allogeneic donor hepatocytes into the splenic artery in patients with decompensated chronic liver disease was shown to be well tolerated and associated with improvement in encephalopathy, hepatic protein synthesis, and renal function [35]. Nuclear scanning demonstrated the presence of engrafted hepatocytes in the spleen.

If extrahepatic hepatocyte transplantation proves to be effective in improving liver function, it could be performed in combination with transjugular intrahepatic portosystemic shunt to relieve portal hypertension. However, the risk for hepatocellular carcinoma would persist, and routine surveillance would still be needed. Unfortunately, the improvement of liver function following hepatocyte transplantation in patients with chronic liver failure has been relatively modest, compared with that observed in animal models. The discrepancy may have resulted from the fact that hepatocytes were transplanted by injection into the splenic pulp in rats, whereas they were infused into the splenic artery of the patients [35]. In fact, hepatocytes infused in the arterial bed of rats are lost rapidly [43]. Consistent with this, in patients, only a few hepatocytes were found in the spleen after infusion into the splenic artery.

Ongoing issues

Technically, the number of hepatocytes that can be transplanted at any one time is limited. Using present techniques, less than 30% of transplanted cells engraft in the liver. A better understanding of the factors that allow hepatocyte engraftment might reduce the need for repeated cell infusions and multiple donors. The most important issue limiting the application of hepatocyte transplantation is the availability of donor livers, which is reduced by competition for use in whole organ transplantation. The ability to cryopreserve and bank hepatocytes might allow the pooling of cells from multiple donors, increasing cell availability for transplantation. Unfortunately, cryopreserved liver cells have not yet been shown to engraft as well as fresh hepatocytes [44] and the viability of human hepatocyte cryopreserved by current methods is variable.

Despite some progress in growing primary hepatocytes in culture [45], only hepatocytes that have been immortalized

by gene transfer are capable of long-term growth and correcting metabolic abnormalities in liver failure after transplantation [39,46]. An alternative solution for the scarcity of human donor cells is the transplantation of xenogeneic hepatocytes [47]. Studies in both rodents and primates indicate that xenogeneic hepatocytes are not susceptible to the immunological processes that lead to hyperacute rejection of vascularized whole organ xenografts [48]. However, xenograft survival in humans has been of such short duration that whether organs or tissues from another species will function adequately to replace human organ function remains uncertain [49]. It is also a concern that xenogeneic liver cells could transfer infectious agents to the recipient and, potentially, beyond [50]. On the other hand, it is possible, that transplanted nonhuman hepatocytes could be resistant to recurrent infection by human-specific viruses, such as hepatitis C virus.

Finally, it is difficult to detect early rejection of the transplanted hepatocytes and new, noninvasive approaches to the detection of donor hepatocytes, such as magnetic resonance-based methods, are needed [51].

Liver-directed gene therapy

Goals of liver-directed gene therapy

Targets of liver-directed gene therapy include both inherited metabolic disorders and acquired conditions, such as infectious and neoplastic diseases, cirrhosis of the liver, and immune rejection of transplants. Liver-directed gene therapy could be used for diverse purposes. Gene products that are missing in inherited disorders could be replaced by transferring transcription units expressing those proteins. In other cases, certain genes could be overexpressed for specific therapeutic benefits, such as treatment of cirrhosis by expression of metalloproteases. The large size of the liver and its capability to secrete proteins into the plasma could be exploited to generate extrahepatic proteins, such as coagulation factors or hormones. Proteins that are normally expressed at extrahepatic sites could be expressed in the liver for specific purposes. For example, the catalytic subunit of the apolipoprotein B messenger RNA (mRNA) editing enzyme (APOBEC-1), which is expressed normally in the intestinal epithelial cells, could be expressed ectopically in the liver to switch the hepatic apolipoprotein production from apolipoprotein B-100 to apolipoprotein B-48, thereby reducing the generation of low-density lipoproteins [52]. Similarly, PDX, a homeobox protein that is responsible for pancreatic differentiation, could be expressed in the liver, to switch the hepatocyte phenotype to an insulin-generating phenotype [53]. Gene transfer to the liver could be used to generate pharmacological gene products, such as vaccines, single chain antibodies, dominant negative proteins, immunomodulatory substances, and pro-apoptotic or antiapoptotic proteins. On the other hand, nucleic acids may be used to inhibit the expression of deleterious proteins, such as viral proteins or mutant α_1-antitrypsin. This could be accomplished by transferring synthetic antisense RNAs, ribozymes or small interfering RNAs. Genes could be transferred to express antisense RNAs [54], ribozymes, short hairpin RNAs (shRNAs), micro RNAs (miRNAs), or dominant negative proteins [55]. Finally, technologies are being developed to correct mutations within endogenous genes in intact organisms. This could be accomplished by targeted replacement of the defective gene [56], or by site-directed correction of a target genomic sequence [57]. These newer strategies permit the repaired gene to remain under the control of the endogenous promoter, whereby physiological regulation is retained. Table 96.1 is a partial list of inherited and acquired disease targets for liver-directed gene therapy.

Table 96.1 Some hepatic disorders that are targeted for gene therapy

I. Inherited liver disorders
Crigler–Najjar syndrome type I
Familial hypercholesterolemia and other lipid metabolic disorders
Maple syrup urine disease
Progressive familial intrahepatic cholestasis
Phenylketonuria
Tyrosinemia
Mucopolysaccharidosis VII
α_1-Antitrypsin deficiency
Ornithine transcarbamylase deficiency
Wilson disease
Glycogen storage diseases, e.g., von Gierke disease and Pompe disease
II. Inherited systemic disorders
Hemophilia A and B
Oxalosis
III. Acquired disorders
Infectious diseases, e.g., hepatitis B and C
Malignant neoplasms: hepatomas, cholangiocarcinomas, metastatic tumors
Extrahepatic tumors (inhibition of neovascularization)
Cirrhosis of the liver
Allograft or xenograft rejection

Gene therapy for cancer

Like other therapeutic approaches, the target is to eliminate the tumor cells while minimizing the damage to normal cells. Gene transfer could be used to kill the tumor cells or inhibit their growth, reduce the vascular supply to tumors, generate immune response against tumor cells, or augment the effect of chemotherapy and radiotherapy. Enhancement of apoptosis of the tumor cells could be promoted by expressing *p53*, a sentinel gene of the cell cycle [58]. Tumor killing is attempted by transferring "suicide genes," such as the herpes simplex virus thymidine kinase (HSV-TK), which converts a prodrug,

ganciclovir, to its active phosphate derivative [59], or cytosine deaminase and purine nucleoside phosphorylase (which converts fludarabine to a diffusible toxic metabolite) [60]. The activated toxin, such as ganciclovir phosphate, may diffuse to neighboring cells, killing them by "bystander effect". Toxicity to normal cells could be reduced by tumor-specific delivery through tagging the DNA to a monoclonal antibody, such as that directed against AF-20, a 180-kDa, tumor-specific cell surface glycoprotein, expressed in hepatoma cell lines [61], and by using tumor-specific promoters (e.g., α-fetoprotein or carcinoembryonic antigen) to drive the expression of transgene. In an alternative approach, E1B-mutant adenoviruses that are capable of replicating in tumor cells deficient in functional p53, have been used in an attempt to kill tumor cells [62], although the replication of these mutant adenoviruses may not necessarily depend on the absence of p53.

Direct killing of the tumor cells by topical expression of toxic gene products does not eliminate those at metastatic sites. As tumor growth requires neovascularization, inhibition of new blood vessel formation by angiostatin or endostatin may retard the growth of both primary and metastatic tumors [63,64].

Permanent elimination of the tumor cells may require a host immune response against tumor-specific "neoantigens" that are not expressed by normal cells. Specific tumor antigens, such as those from melanoma cells, may permit DNA-based tumor vaccination. The host immune response against the neoantigens may be feeble because of inadequate presentation of the antigens by antigen-presenting cells. Genetic manipulation of antigen-presenting cells may augment the host immune response against tumor cells. Secretion of cytokines, such as transforming growth factor-β or interleukin-10, by large tumors may suppress the immune response [65]. "Debulking" the tumor by surgery, radiofrequency ablation, radiotherapy, chemotherapy, or gene therapy may enhance the immune response. Currently, gene therapy for cancer has the greatest potential as an adjunct to chemotherapy or radiotherapy. Irradiation enhances the number of tumor cells transducible by recombinant viruses. Transgene expression could be driven by promoters that are stimulated by irradiation [66]. On the other hand, inhibition of the expression in the tumor cells of radioprotective proteins, such as ATM (*a*taxia *t*elangiectasia *m*utated), could increase their radiosensitivity.

Gene therapy for infectious diseases

Nucleic-acid-based approaches are being explored for both prophylaxis and treatment of hepatic viral infections. DNA vaccination [67] eliminates the possibility of the vaccines being contaminated by microbes or other organic material. The injected DNA itself serves as an adjuvant, enhancing the immune response. For viral antigens that are presented poorly, the antigenic peptides may be expressed directly in antigen-presenting cells by gene transfer. Gene transfer may also be used to express cytokines that promote the antigen-presenting cell proliferation and maturation of T cells to helper T cells. In a different approach, termed intracellular vaccination, single chain antibodies or antibody fragments may be expressed within the cells to make them resistant to viral infections [68].

Gene therapy can also be used to interfere with the virus life cycle by introducing synthetic antisense RNAs, ribozymes, or DNA ribonucleases (see below). Ribozymes, antisense RNAs, shRNAs, miRNAs, or dominant negative proteins [69] can also be expressed within the target cells by gene transfer.

Gene therapy for inherited disorders

As many inherited disorders are caused by the abnormality of a single gene, the effect of gene therapy can be evaluated directly and precisely in these conditions. For this reason, although the inherited disorders are much less common than acquired diseases, single gene abnormalities continue to be important targets of liver-directed gene therapy. Table 96.1 contains a partial list of inherited disorders that are targets of gene therapy.

Methods of gene transfer to the liver

Genes may be delivered to the liver by isolated hepatocytes, termed ex vivo gene therapy, or by delivery of the gene into the intact liver. Hepatocyte transplantation-based methods have been discussed above. Here we will consider methods of delivering genes to the intact organism, using replication-deficient recombinant viruses or nonviral vectors. For gene transfer to hepatocytes, important considerations include the attainable infectious titer, ability of the virus to infect nondividing cells, integration into the host genome, repeatability of administration, and safety of the vector system. Frequently used methods of gene transfer to the liver are listed in Table 96.2. Some commonly used recombinant viral vectors are described below.

Vectors based on recombinant viruses

Retrovirus-based vectors

The complementary DNA (cDNA) generated from the RNA genome of retroviruses is integrated into the host genome and transmitted to the progeny of the transduced cells [70]. Oncoretroviruses, particularly, Moloney murine leukemia virus, are used commonly for generating recombinant vectors (Figs 96.1 and 96.2). The viral genes are replaced by target transgenes, but the packaging signal (ψ) is retained [71]. The viral proteins are provided in *trans* by "packaging cell lines," generating a replication-deficient recombinant virus. The range of species that recombinant retroviruses can infect is determined by the envelope protein. The host range can be expanded by engineering the viral envelope to contain proteins, such as the G protein of the vesicular stomatitis virus. Inside the cell, the RNA genome is reverse-transcribed into double-stranded DNA, which is transported to the nucleus

Table 96.2 Characteristics of liver-directed gene therapy methods

Method	Integration and persistence	In vivo gene transfer efficiency to liver	Liver-specificity	Immunological and other issues
Recombinant viral vectors:				
Murine leukemia-based retroviruses	Integration is required	Requires mitosis Low efficiency in quiescent cell types, e.g., hepatocytes	None	Non-immunogenic Difficult to obtain very high titers Envelope can be pseudotyped with other proteins to increase stability and broaden host range
Lentivirus-based retroviruses	Integration is required	Can infect non-dividing cells, but cell cycling may be needed Low to intermediate efficiency for liver	None	Non-immunogenic Difficult to obtain very high titers Envelope can be pseudotyped with other proteins to increase stability and broaden host range
Adeno-associated virus	Can exist in both episomal and integrated forms	Can infect quiescent and dividing cells Low to intermediate efficiency for liver	None	Causes humoral immune response Can be grown at high titers Site-specificity of integration of the wild-type virus is lost in the absence of *rep* Can undergo lytic cycle in the presence of helper proteins Limited packaging space
Simian virus 40	Can exist in both episomal and integrated forms	Infects both quiescent and dividing cells High efficiency	None	No significant immune response Can be grown at high titers Limited packaging space
Adenovirus	Episomal Can persist for several months in the absence of host immune response	Efficiently infects both dividing and non-dividing cells Very high efficiency for liver	Liver targeted	Evokes both humoral and cell-mediated host immune response Viral gene deletion reduces primary immunogenicity, but does not permit repeated injection Host tolerization permits repeated gene transfer
Hybrid viruses	Combines advantages of different viruses	Efficiency of adenoviral vectors is combined with persistent nature of other viruses	Liver targeted	Adenoviral proteins provided in *trans* may evoke immune response Site-specific integration or episomal replication may be possible
Non-viral vectors:				
Injection of naked DNA or RNA	Transient	Intermediate efficiency	Liver targeted	Probably nonimmunogenic
Receptor or liposome-mediated plasmid delivery	Transient	Low efficiency	Liver targeted	Probably nonimmunogenic
Oligonucleotides designed to form DNA triplex or to convert single nucleotides	Permanent	Low efficiency	Liver targeted	Nonimmunogenic

and is integrated into the host genome. This process requires mitosis of the host cell; this is infrequent in hepatocytes of the adult liver. To overcome this obstacle, immunoretroviruses, particularly lentiviruses, which form preintegration complexes that can be translocated into nondividing nuclei, are being explored for liver-directed gene therapy [72].

Recombinant adenovirus

Adenoviruses are large, linear, double-stranded DNA viruses. Adenoviruses types 5 and 2 are commonly used for preparing gene transfer vectors. Recombinant adenoviruses can be generated at high titers, can infect both dividing and quiescent cells, and on intravenous administration in rodents,

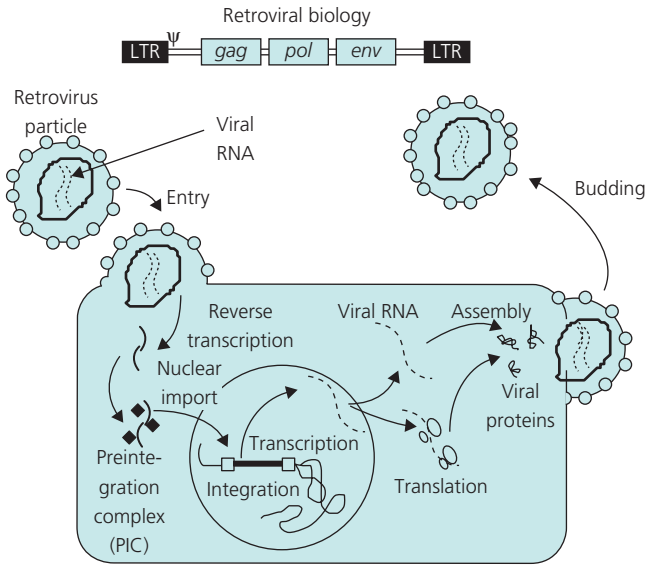

Figure 96.1 Life cycle of wild-type Moloney murine leukemia virus. The RNA genome of the virus consists of the retroviral genes, *gag*, *pol*, and *env*, flanked on the 5′ and 3′ ends by the "long terminal repeats" (LTRs), consisting of a promoter, enhancers, and polyadenylation signals. Sequences upstream to the 5′ LTR contain the packaging signal (ψ) that is needed for packaging of the viral RNA genome into viral particles. After entry into the infected cell, the RNA genome undergoes reverse transcription and the DNA transcript is incorporated into a preintegration complex (PIC), which is imported into the nucleus. Dissolution of the nuclear envelope, which occurs during mitosis, may be needed for this step. The proviral DNA is then integrated into the host genome. The entire unspliced transcript provides the new viral genome, which is packaged with the viral proteins expressed from the integrated proviral DNA. The assembled virus buds out and is ready to infect another cell.

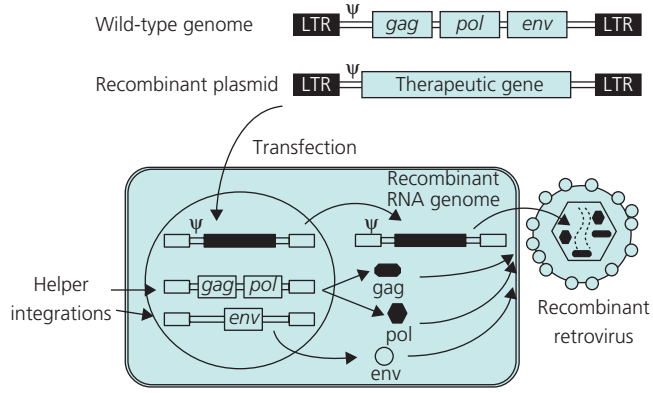

Figure 96.2 "Domestication" of the Moloney murine leukemia virus. The packaging cell is stably transfected with multiple DNA segments expressing different viral proteins (gag, pol, and env). A DNA version of the viral genome is cloned into a plasmid. All viral genes are replaced by target transgene, but the packaging signal (ψ) is left intact. The recombinant plasmid is transfected into the packaging cell, which provides the viral proteins in *trans*. The viral RNA genome can be assembled with the viral proteins because of the presence of the packaging signal, ψ. The assembled recombinant virus buds out of the packaging cell into the culture medium. The recombinant virus can infect other cells but is replication-incompetent because of the lack of the viral genes.

localize preferentially to the liver [73]. The adenoviral receptor, coxsackievirus and adenovirus receptor (CAR), is highly concentrated in rodent liver, but less so in the human liver. It is therefore unclear whether the high gene transfer efficiency observed in the rodent liver will be replicated in human liver.

Recombinant adenoviral vectors are produced by inserting the transgene into the early region-1 (*E1*) gene, which encodes transcription factors required for the expression of adenoviral genes. The recombinant virus is generated in packaging cells that provide the *E1* gene products in *trans*. All adenoviral genes may be deleted to increase the "stuffing space" and to reduce immunogenicity by preventing any possibility of expression of viral proteins [74]. These "gene-deleted" or "gutless" vectors require helper adenoviruses to provide the structural proteins in *trans*.

Strong immunogenicity of the viral antigens limits the clinical application of adenovectors. Many human subjects have preexisting immunity against adenoviruses from natural infection. In addition, there can be innate immune response after administration of adenovectors in humans. Neutralizing antibodies generated after the first injection block gene transfer following subsequent administrations of adenovector. Cytotoxic lymphocytes against adenoviral antigens attack the adenovirally infected host cells, causing liver damage and rapid loss of the transgene after secondary gene transfer [75]. Despite the deletion of all viral genes, the helper-dependent, gutless adenovectors retain their immunogenicity by virtue of the capsid proteins in the input virus [76], thereby frustrating the attempts at repeated gene transfer. Adenovectors are being generated from nonhuman strains of adenoviruses that are antigenically different from human adenoviruses, so that vectors based on different adenoviral strains can be used serially to express a transgene.

Development of an effective immune response requires costimulatory interaction between antigen-presenting cells and cytotoxic lymphocytes through the B7–CD28 and CD40–CD40 ligand interactions. Although inhibition of the B7–CD28 costimulation by injecting cytotoxic T-lymphocyte antigen 4–immunoglobulin (CTLA4–Ig) alone does not permit repeated administration of adenovectors [77], coexpression of CTLA4–Ig along with the target transgene permits multiple administration of the recombinant adenovirus [78]. Alternatively, host tolerance toward adenoviral proteins can be induced by injecting recombinant adenoviruses in utero or in newborn rats [73], inoculating adenoviral proteins into the thymus of young adult rats [79], or orally administering small doses of adenoviral proteins [80]. However, safety concerns

persist regarding tolerization of humans to adenoviral antigens, because wild-type adenoviruses are pathogenic to humans.

Herpes simplex virus 1

Herpes simplex virus type 1 is a 150-kilobase (kb) double-stranded DNA virus with a broad host range [81] and the ability to infect nondividing cells. However, long-term gene expression in the liver has not been achieved with the available herpes simplex virus vectors.

Recombinant baculovirus

The *Autographa californica* nuclear polyhedrosis virus is usually employed for generating recombinant proteins in insect cells [82]. Interestingly, among mammalian cells, hepatocytes can be infected by baculovirus vectors and the transgene expression can be driven by mammalian promoters. Hybrid viruses, consisting partly of baculoviral sequences, are being evaluated for *in vivo* application.

Recombinant adeno-associated virus

Adeno-associated virus (AAV) is a human parvovirus with a single-stranded DNA genome encapsidated in an icosahedral shell ~ 25 nm in diameter. The genome is approximately 5 kb long and contains two open reading frames. The reading frame on the left encodes replication proteins whereas the right-hand open reading frame encodes capsid proteins. AAV is a dependent parvovirus that relies on coinfection by adenovirus or herpes viruses or genotoxic stimuli, e.g., ultraviolet light or irradiation [83] for a productive, lytic infection. In the absence of helper viruses, wild-type AAV integrates preferentially on the q13.4-ter arm of human chromosome 19 [84] and remains latent in the host genome. Of the capsid proteins, VP1, VP2, and VP3, the key structural component VP3 constitutes nearly 80%–90% of the virion shell. VP1 contains a phospholipase A2 (PLA2) domain required for infectivity. Recombinant AAV vectors require the 145-base-pair (bp) terminal repeats of the AAV genome whereas all other viral factors can be provided in *trans* for production (Fig. 96.3). Following the initial development of an infectious AAV type 2 (AAV-2) clone in 1982 [85], rAAV-2 vectors have gained popularity in gene therapy applications, and have been tested in preclinical studies and clinical trials for a variety of diseases [86]. Binding of AAV-2 to a heparin sulfate proteoglycan at the cell surface is required for its internalization. The 145-bp inverted terminal repeats are needed for integration into the host genome. Following introduction into cells, recombinant AAV vectors persist mainly as episomes. The viral Rep protein, which directs the site specificity of AAV integration into chromosome 19, is absent in the recombinant vectors, which, therefore, lose the ability to integrate and remain in the nucleus as episomes [87].

Initial studies of intramuscular administration of AAV-2-based vectors for delivering coagulation factor IX in patients with hemophilia B resulted in low levels of protein production [88]. Infusion of higher doses of the recombinant virus into the portal vein of factor IX-deficient dogs resulted in the appearance of 5% of normal levels of factor IX activity in plasma [89]. The efficiency of AAV-mediated cancer gene therapy could be augmented when used in combination with conventional tumor therapies, such as irradiation or chemotherapy [90]. Later studies showed that various AAV serotypes have distinct tissue tropism, depending on their capsids. To date, 11 different serotypes, AAV-1 to AAV-11, and over 100 variants have been isolated from human and nonhuman tissues [91]. Of these 11 serotypes, AAV serotypes 1–9 are being developed as gene therapy vectors. As the AAV-2 genome is well-characterized, it has been cross-packaged with capsids of other serotypes to increase the efficiency of gene transfer. AAV-2/AAV-8 hybrids are particularly efficient for transferring genes into hepatocytes, although the pancreas, heart, and skeletal muscles are additional targets of this hybrid vector.

While recombinant AAV vectors persist for up to a year as episomes in hepatocytes, they are eventually lost because of their episomal nature. AAV vectors cause humoral and cellular immune responses, which are hurdles to readministration of a single vector. However, it may be possible to use vectors of alternative capsid serotypes for repeat administration. Attempts are being made to generate AAV vectors with the desired characteristics by mutagenesis of the capsid genes, based on known structural characteristics. An alternative approach is to use random DNA recombination, which leads to viral diversity in nature. Using DNA shuffling techniques, the process of evolution can be accelerated to generate vectors

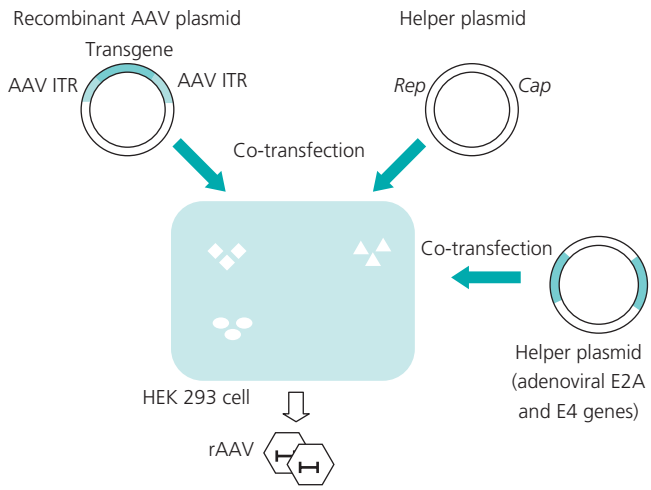

Figure 96.3 Generation of recombinant adeno-associated viruses (AAV). To generate AAV vectors, two plasmids, one containing the transgene, flanked by the inverted terminal repeats (ITRs) and the other encoding rep, cap, and adenoviral proteins, are cotransfected into 293 cells, which provide adenoviral E1A in *trans*. The recombinant virus is "rescued" by infection with a helper adenovirus (*E1A*-deleted) or, more commonly, by transfecting a plasmid that expresses adenoviral proteins.

with certain desired attributes, such as the ability to avoid recognition by antibodies and cytotoxic lymphocytes, or to transfer genes into specific tissues with high efficiency [92].

Despite several advantages of recombinant AAV vectors, the small stuffing space offered by the small virus limits the size of cDNA that can be accommodated within these vectors. To overcome this problem, the split AAV vector technology has been used to expand the packaging capacity of AAV through head-to-tail dimerization. Essentially, two recombinant vectors are generated. A 5′ vector includes the enhancer/promoter cassette and a half-intron carrying a splice donor site. A complementing 3′ vector contains another half-intron carrying a splice acceptor site linked with the cDNA encoding the target gene and a polyadenylation signal. Following coinfection into cells (e.g., 293 cells), genomes of the 5′ and 3′ vectors dimerize together, thereby expressing the target gene [93].

Simian virus 40-based vectors

Simian virus 40 (SV40) is a non-enveloped virus of the papova family with a 5.2-kb double-stranded DNA genome. The large (Tag) and small (tag) T antigens are transcription factors required for the expression of the viral structural genes, VP1, VP2, and VP3. The recombinant vector is generated by replacing the *Tag* genes of the viral genome by the target transgene. Various lengths of the structural genes can also be deleted to make additional stuffing space. The recombinant viral genome is transfected into a helper cell line (e.g., COS cells that provide Tag in *trans*). Absence of the *Tag* gene makes the recombinant virus replication deficient and markedly reduces its immunogenicity. Up to 4.7 kb of exogenous DNA can be inserted into SV40 vectors, which can be generated at 10^9 infectious units (IU)/mL and concentrated to 10^{12} IU/mL [94,95]. Recombinant SV40 integrates into the genome of both dividing and nondividing cells. The range of target cells is broad and includes hepatocytes and bone marrow cells [94,95].

Nonviral vectors

Liposomes, lipoplexes, and polyplexes

Non-viral vectors comprise:

- lipid-based delivery systems, e.g., lipid microcapsules (liposomes) or lipid-nucleic acid complexes (“lipoplex”)
- polycations, e.g., poly-L-lysine (PLL), polyethylenimine (PEI), polyglucosamines, lipopolyamines, and cationic peptides
- polycation–lipid hybrids (“Lipopolyplex”).

DNAs are usually compacted with polycations before lipid encapsulation into liposomes or formation of complexes with lipids. Lipopolyplex particles are smaller than the liposomes or lipoplexes and provide greater protection of the nucleic acids from degradation by nucleases. Cationic lipid transfecting agents (e.g., lipofectamine, 1,2-dioleolyl-3-trimethylammonium-propane), and cationic polymers, (e.g., PLL and PEI), provide relatively effective transfection [96], but are inefficient in the presence of plasma and too toxic for use in vivo. To target the gene delivery to hepatocytes, the gene transfer vehicles have been modified to include ligands that are endocytosed by hepatocyte-specific receptors, such as, the asialoglycoprotein receptor (ASGPr). Galactose-terminated peptides (e.g., asialoorosomucoid) or galactose can be conjugated to PLL or PEI for hepatocyte-specific gene delivery [97]. Similarly, liposomes composed of galactocerebrosides serve as ligands for the ASGPr by way of the galactose residues [98]. Incorporation of nuclear localization signal peptide motifs on plasmid constructs enhances their translocation to the nucleus [99].

Nucleic acid transfection generally has a transient effect in vivo; this may be sufficient when using synthetic antisense RNAs or ribosymes. A long-term effect is possible if the DNA integration can be enhanced by some mechanism, e.g., using the transposon–transposase system, or if the transfected nucleic acid triggers a permanent change, e.g., site-directed gene repair. Some specific applications of nonviral gene transfer methods are discussed below.

Ribozymes, antisense RNA, and DNA ribonucleases

Ribozymes are RNA enzymes that hybridize to complementary RNA sequences and catalyze endoribonucleolytic cleavage, causing rapid degradation of the RNA molecule [100]. For hairpin ribozymes the presence of a guanosine residue immediately downstream to the cleavage site is essential, but the effect is enhanced by a GUC sequence. Hammerhead ribozymes require only a UA, UC, or UU dinucleotide for cleavage. Ribozymes can be synthesized and packaged for cellular uptake, or expressed in cells from transfected DNA.

Hammerhead [100] and hairpin [101] ribozymes have been shown to inhibit the production of hepatitis B and hepatitis C viruses in cells. Antisense oligonucleotides targeted to a 5′-untranslated region of hepatitis C virus were transferred to a differentiated human hepatoma cell line HuH7 using ASGPr–polylysine complexes, resulting in specific inhibition of the hepatitis C vrus-directed protein synthesis in the cells [101]. Multiple sites within the hepatitis C virus RNA genome may be targeted simultaneously using a series of ribozymes expressed from a single vector, thereby inhibiting the emergence of drug-resistant mutants [102]. Hepatitis B virus, a partially double-stranded DNA virus, replicates through a pregenomic RNA intermediate, which could also be a target for ribozyme-based RNA cleavage [100].

DNA ribonucleases are synthetic single-stranded DNAs comprising a 15-nucleotide catalytic domain, flanked by two RNA-binding domains, that catalyze RNA cleavage with a greater efficiency than ribozymes [103]. DNA ribonucleases against the hepatitis C viral genome can specifically cleave the viral RNA. DNA ribonucleases designed to cleave hepatitis B virus RNA transcript substantially inhibit viral gene expression [104].

Small inhibitory RNAs, short hairpin RNAs, and micro RNAs

The introduction of single-stranded siRNAs and shRNAs that express siRNAs within cells has ushered an exciting era in down-regulation of gene expression as a therapeutic strategy in liver diseases. Synthetic single-stranded siRNAs can be transfected into cells to inhibit the translation of specific mRNAs and to destabilize the mRNA. However, for in vivo gene therapy, it is more convenient to use vectors to express shRNAs that are processed in the cell into siRNAs [105]. The most vigorously investigated targets are hepatitis B and hepatitis C viruses [106], although other disease targets are also being explored. Plasmid or viral vectors are used to express shRNAs, usually from polymerase III promoters (e.g., U6 or H1). However, the use of polymerase II promoters may also be feasible [107]. A recent advance in gene silencing has involved modification of the stem sequence of miR-30 miRNA hairpins to achieve gene knockdown [108]. Modified miR-30 can achieve more effective knockdown than shRNA-based methods and can be expressed readily from polymerase II promoters. A number of natural miRNA hairpins have been found to exist in clusters of multiple identical or different copies [105], suggesting that polycistronic transcripts might naturally enhance the efficiency of target gene repression or result in linked multigene repression. Simple multihairpin designs have been shown to exhibit improved knockdown efficiency compared with single hairpin constructs [108]. Gene knockdown technologies using shRNAs and miRNAs are likely to progress to clinical trials [106].

Homologous recombination

Site-specific recombination of DNA could be a precise means of repairing mutated or damaged DNA. Several proteins, including homologues of yeast recombination proteins rad51 or rad52, are important in the homologous recombination in higher eukaryotes [109]. Although used extensively in cultured cells, the process is inefficient and has rarely been successful in vivo [110]. As homologous recombination is cell cycle-regulated, it occurs extremely infrequently in quiescent cells, such as hepatocytes [111].

Triplex DNA

This method is based on the formation of a triple-DNA by the binding of an exogenous single-stranded nucleic acid to the major groove of a homopurine region of the double-stranded genomic DNA [112]. The polypurine regions must be guanine rich and 12–14 nucleotides in length for adequate triplex formation to occur. Conventionally, cross-linking agents, such as psoralen or other mutagens, are covalently attached to the triplex-forming oligonucleotide [112]. After intercalation of the psoralen at the target 5′-ApT-3′ site, ultraviolet irradiation causes cross-linking of the thymines in the two strands. This substrate is then repaired by endogenous cellular DNA repair mechanisms, producing the characteristic T : A to A : T transversions. Single-strand DNAs with cross-linking agents can also be used to promote insertions and deletions at target through the excision repair pathway [113]. Target sequence constraints limit the application of this method in vivo. Bifunctional oligonucleotides comprising regions that form triple-helical structures as well as conventional Watson and Crick base pairs have partly overcome this hurdle in cultured cells [114].

Single nucleotide modification

A method that uses the cells' mismatch repair machinery to correct single base mutations has been introduced. A synthetic oligonucleotide is generated that is complimentary to the targeted genomic DNA, except at a single mismatched base. The majority of the successful studies have utilized a DNA/RNA chimera. The RNA component, consisting of 2′-*O*-methyl-RNA residues, is included to increase the strength of hybridization with the targeted DNA sequence. The mismatch between the oligonucleotide and the genomic DNA triggers the mismatch repair system of the cell, so that the genomic mutation is permanently corrected. In *Escherichia coli* strains that are deficient in specific repair proteins [115], this approach was shown to require RecA and MutS, proteins involved in DNA pairing and mismatch repair, respectively, suggesting the involvement of both the homologous recombination and mismatch repair pathways. Both recombination and mismatch repair pathways are evolutionarily conserved. Extracts of human hepatoma cells (HuH-7) containing the mismatch repair protein hMSH2 can complement MutS-deficient *E. coli* in converting the mutant aminoglycoside resistance gene. Wild-type p53 may inhibit the initial pairing step in this repair process by inhibiting the pairing activity of RecA and its human homologue Rad51 [116].

In intact rats, RNA–DNA chimeric oligonucleotides were delivered to the liver by receptor-mediated endocytosis, using lactosylated PEI or galactocerebroside-containing liposomes. In initial studies, a Ser365Arg conversion of the rat factor IX gene was achieved with significant frequency [117]. Subsequently, the guanosine base deletion in the bilirubin-uridine diphosphate-glucuronosyltransferase (*UGT1A1*) gene in jaundiced Gunn rats was repaired at a frequency that was sufficient to express detectable enzyme activity in the liver and reduce serum bilirubin levels significantly [118]. Nucleotide insertion was verified by differential hybridization, Southern blot analysis, and Western blot analysis. Tagalakis and colleagues demonstrated a high level of conversion of the gene expressing human apolipoprotein E-2 in a transgenic mouse to apolipoprotein E-3 after intraperitoneal injection of an RNA–DNA chimeric oligonucleotide [119]. In addition to hepatocytes, the RNA–DNA chimera has been used successfully for site-directed gene conversion of the apolipoprotein A-2 gene in human lymphocytes [119], the nonsense

mutation of carbonic anhydrase II in nude mouse primary kidney tubular cells [120], and the missense mutation in the tyrosinase gene in albino mouse melanocytes [121].

Transposon-based gene integration

Transposable genetic elements (transposons) are ubiquitous in eukaryotic genomes and are capable of moving from one chromosomal location to another by a "cut-and-paste" mechanism. The Emmons laboratory characterized five transposable elements from fish that were similar in structure to the Tc1 transposon of the nematode *Caenorhabditis elegans* [122]. These transposons of the *Tc1/mariner* superfamily consist of short inverted repeats that flank an open reading frame, encoding a transposase. Ivics and associates generated a synthetic transposable element from defective copies of an ancestral Tc1-like fish transposon. This transposon was termed *Sleeping Beauty*, because it had remained dormant for millions of years during evolution and became functional only after correcting mutations that had accumulated over many generations [123]. It is a 1.6-kb element, flanked by 250-bp terminal inverted repeats. DNA sequences, flanked by the terminal inverted repeats, can efficiently integrate into mammalian cellular genome, provided the transposase is expressed in the same cell. The integration occurs at TA dinucleotide sites, which are duplicated on insertion of the transposable element [123]. The coding region of human factor IX has been inserted into the genome of hepatocytes of factor IX-deficient hemophilic mice by cotransfection of one plasmid containing the factor IX transcription unit flanked by the inverted repeats and another plasmid expressing the *Sleeping Beauty* transposase [124].

Extracorporeal liver assist devices

The fact that some patients with acute liver failure recover spontaneously led to the idea that patient survival could be improved by providing metabolic support until the liver had had time to regenerate. During the 1960s and early 1970s, ex vivo and in situ cross-circulation with animal and human livers was shown to improve clinical and biochemical parameters in animal models of liver failure and in uncontrolled human trials [125]. However, without the option of transplantation, there was no evidence of increased survival. In the 1980s the life-saving effects of liver transplantation in fulminant hepatic failure were shown, resulting in expanding demand for a finite number of donor organs, increasing the difficulty of obtaining suitable organs in a timely manner. The concept of temporary liver support as a "bridge" to successful liver transplantation emerged. Since coagulopathy, renal failure, encephalopathy, and cerebral edema negatively affect the prognosis after liver transplantation, survival could improve if these complications could be held at bay while waiting for a suitable organ. Liver assist devices have been considered also for use in acute exacerbation of chronic liver failure to alleviate encephalopathy following gastrointestinal bleeding or to prevent hepatorenal syndrome, and for intractable pruritus caused by cholestatic liver disease. Many of these patients are not transplant candidates so the potential for liver assist devices to improve survival is limited.

Many liver support systems are in the development stage but only a few have been tested in clinical series. Although the survival benefit of these devices in patients with acute liver failure is yet to be shown unequivocally in controlled, randomized trials, much progress has been made in the bioengineering of artificial liver support systems. Hepatic support systems comprise three basic groups:

- cell-free liver assist devices
- entirely biological systems, such as extracorporeal liver perfusion
- hybrid bioartificial devices, which include both nonbiological and biological components.

A brief discussion of these devices follows.

Cell-free liver assist devices

To substitute for the detoxification and excretion functions, hemodialysis [126], exchange transfusion [127], and hemoperfusion [128] through charcoal or resins have been attempted during the past 40 years, without consistent beneficial outcomes. Currently, two such systems are available for clinical use, the molecular absorbent recirculating system (MARS) and the Prometheus system. A third, the BioLogic-DT plasma filter system, has been extensively evaluated in patients but is no longer available [129]. In the last of these, the patient plasma comes into contact with a powdered charcoal suspension [128]. Many putative toxins that are thought to contribute to the complications of hepatic failure bind to the charcoal in vitro. Clinical trials have suggested improvement in patients with decompensated chronic liver disease, but studies in acute hepatic failure did not show any benefit over standard clinical management [130].

Of the two systems available for use in patients, there is most experience with MARS (Fig. 96.4). MARS is a cell-free system in which an albumin-enriched dialysate is passed through an anion exchange resin column and a charcoal column, and recirculated through the dialysis unit. This system effectively reduces plasma bilirubin and bile acid concentrations in patients with cholestasis. As standard dialysis is included in the circuitry, some water-soluble substances are also removed [131]. Use in several hundred patients has suggested that treatment with this system may improve encephalopathy scores and the hemodynamic status, thereby increasing urine output in hepatorenal syndrome reducing ascites [129]. Significant improvement in cases of acute-on-chronic decompensation was documented in controlled trials [129]. Patients with fulminant hepatic failure have been bridged to transplantation and cases of primary graft hypofunction have been supported until recovery with the

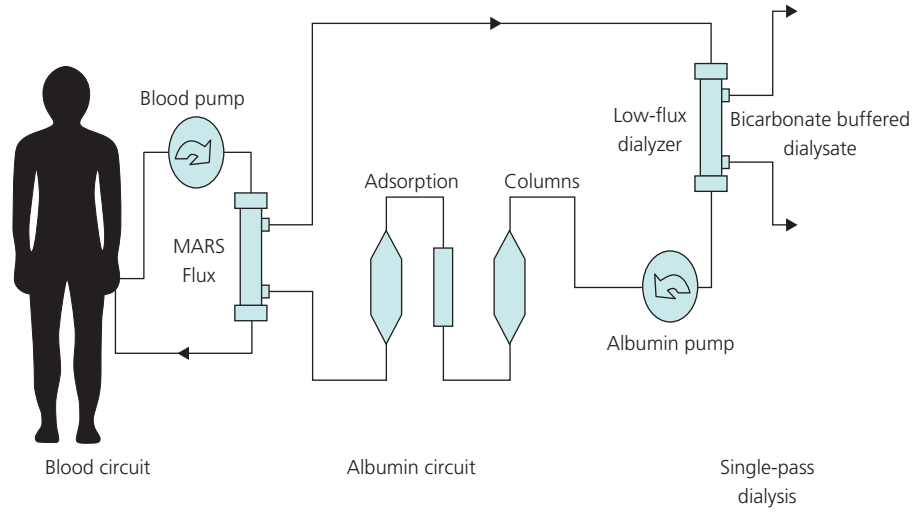

Figure 96.4 The MARS (molecular absorbent recirculating system) unit, a cell-free liver assist device. An albumin-enriched dialysate is passed through a series of absorption columns, including an anion-exchange resin column and a charcoal column, and recirculated through the dialysis unit.

MARS system [132,133]. MARS has also been used in cases of intractable pruritus due to cholestatic liver disease with clear improvement in itching and in some cases, but not all, a durable response, eliminating or reducing symptoms for weeks [134]. Based on a similar principle to MARS there have been case reports of proprietary single-pass albumin dialysis (SPAD) systems where the albumin-enriched dialysate is discarded rather than "scrubbed" and recycled [135].

The Prometheus system relies on fractionated plasma separation (filter cut-off 250 kDa) and passage of the patients' plasma proteins (mostly albumin) through two adsorption columns of neutral resin adsorber followed by an anion exchange resin [136,137]. The cleansed plasma is then returned to the primary dialysis circuit. The blood then passes through a high-flux dialyzer before being returned to the patient. Similar to previous systems, Prometheus has been demonstrated to remove putative toxins, both protein-bound and water-soluble, that accumulate in hepatic failure [138,139]. In comparative studies with MARS, Prometheus showed higher efficiency for removal of urea and bilirubin and similar efficiency for bile acid clearance [140,141]; however, MARS improved the hyperdynamic circulatory changes seen in some patients whereas Prometheus did not [142]. Safety profiles were comparable between the two systems.

Although these results are encouraging, the cell-free plasma detoxification systems cannot substitute for the metabolic and synthetic functions of the liver. Therefore, other liver support systems including liver tissues or liver-derived cells are being developed.

Extracorporeal liver perfusion

Otto and colleagues in 1958 demonstrated that allogeneic extracorporeal liver perfusion could reduce plasma ammonia in hyperammonemic dogs [143]. Eiseman and colleagues [144] were the first to apply this concept in patients using both human and xenogeneic livers. By 1994, 87 cases treated with extracorporeal perfusion using porcine liver or human cadaver livers had been reported [145]. At the University of Nebraska, 14 patients received extracorporeal liver perfusion using eight human and eight pig livers. Of the 10 patients who were considered suitable for transplantation, nine were "bridged" to liver transplantation [146]. In one study, livers from transgenic pigs expressing human CD55 and CD59 to limit hyperacute rejection were used for the management of two patients with fulminant hepatic failure [147]. Although controlled trials of extracorporeal liver perfusion have not been carried out, the complete recovery of three patients and the prolonged survival of some patients suggest improvement over conventional treatment. However, even the best results using extracorporeal liver perfusion are not equal to that of liver transplantation. Membranes, filters, and tubings included in the circuitry may activate leukocytes, leading to cytokine release. Since immunosuppression is avoided to reduce the risk of sepsis, humoral and cellular rejection can occur. Finally, perfusion of the extracorporeal organ with systemic, rather than the portal blood may reduce hepatic function. Logistic hurdles to extracorporeal perfusion include the limited availability of human donor organs and the difficulty of procuring porcine livers, unless an institution maintains its own colony. Concerns over safety and efficacy of porcine organs persist.

Hybrid bioartificial liver support devices

Standardized machinery, including bioreactors containing metabolically active hepatocytes, has been in development over the last 20 years. Initially, Matsumara used a device containing liver cell suspension to treat one patient [148], but it is recognized that hepatocytes function more effectively when anchored to a surface. In a clinical trial on patients with acute liver failure, perfusion of patient plasma over porcine hepatocytes attached to Biosilon microcarriers, 37 of the 59 patients recovered, but only 25% of those with

grades 3 and 4 encephalopathy survived [149]. The hepatocytes lost function after a few hours of application. Other systems that use hepatocytes cultured onto stacked flat surfaces [150] or three-dimensional structures [151] have been designed but not yet tested in clinical studies. The largest clinical experience is with systems consisting of a large number of cellulose-acetate hollow fibers packaged into plastic cartridges. The intralumenal and the extralumenal compartments can be perfused independently. In all devices undergoing clinical trial, the intralumenal compartment is used for perfusion of blood or plasma, and the hepatocytes are inoculated into the extralumenal compartment, although Nyberg and colleagues have designed an experimental system in which gel-entrapped hepatocytes are packed within the intralumenal compartment [152].

Sussman and colleagues employed C3A cells, a human hepatoblastoma-derived cell line, grown to confluence in the extralumenal compartment of hollow fiber cartridges in their Extracorporeal Liver-Assist Device (ELAD) [153]. Whole blood from patients was perfused through the intralumenal compartment. Although initial uncontrolled observations in 11 patients with acute hepatic necrosis were encouraging, a pilot control trial demonstrated no difference in outcome compared to a control group receiving conventional supportive therapy [154]. In this study, the survival rate was surprisingly high in both the treatment (78%) and the control (75%) groups, probably because of the inclusion of patients with early stages of acute liver failure.

Demetriou and associates used cryopreserved primary pig hepatocytes, attached to collagen-coated microcarriers in their device, the Bioartificial Liver (BAL) also known as HepatAssist (Fig. 96.5) [155]. In this device, hepatocytes are introduced into the extralumenal compartment of hollow fiber cartridges and the intralumenal compartment is perfused with patient plasma that has been previously circulated through a charcoal column to remove toxins in the "hepatic failure" plasma. Each cartridge functions for 6 h, but the course may be repeated several times. In 2004 the results of a randomized multicentered controlled trial using this device in acute liver failure were published [156]. A total of 171 patients (86 controls and 85 BAL) were enrolled at 11 US and nine European centers. All patient had fulminant or subfulminant hepatic failure (FHF/SHF) or primary nonfunction (PNF) following transplantation and all had advanced encephalopathy, grades III or IV. Thirty-day survival was not significantly different between the treated and control groups but using a time-dependent proportional hazard model to control for the effect of liver transplantation, it was shown that the mortality of FHF/SHF (excluding the PNF patients) was almost halved for the BAL treatment group ($P = 0.048$).

A third hybrid hollow fiber system, Modular Extracorporeal Liver Support (MELS), uses woven polyether-sulphone capillaries that exit from the bioreactor in discrete bundles, so that different bundles can serve separate functions such as plasma flow and oxygenation [157]. The three-dimensional structure is claimed to improve the function of the cultured hepatocytes. CellModule bioreactors containing primary porcine hepatocytes were used to treat eight patients with liver failure, all of whom were carried through to successful transplantation [158]. Primary human hepatocytes obtained from cadaver donor organs were used, leading to encouraging results in 12 patients with acute failure [159]. Several other hybrid hepatic support systems have been used in preliminary human studies of hepatic failure [160–163].

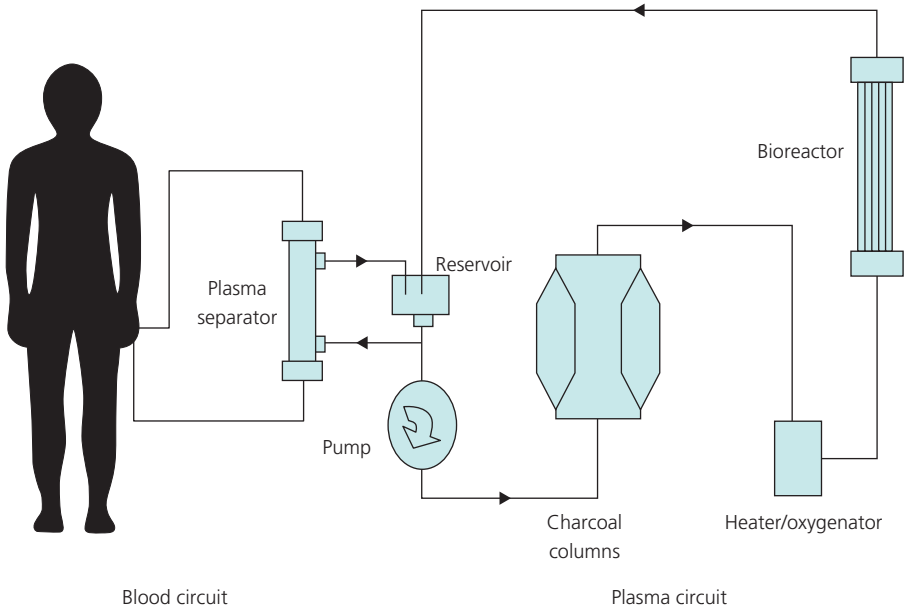

Figure 96.5 The HepatAssist device, example of a hybrid liver assist device. Plasma is separated from blood cells and passed through a charcoal column being perfused through the intralumenal compartment of a hollow fiber bioreactor. The extralumenal space of the bioreactor is packed with cryopreserved primary pig hepatocytes, attached to collagen-coated microcarriers.

Hurdles that need to be overcome for the development of extracorporeal liver support

Currently, porcine livers are the main source of the biological component of artificial liver devices. Limitations of using xenogeneic sources include hyperacute or delayed immune response to the cells or their products, and concerns regarding the presence of infectious organisms, such as the porcine endogenous retrovirus. The use of human hepatocytes would be logical, but is limited by donor organ shortage. Therefore, more progress is needed for generating human hepatocytes that can be expanded in vitro. The potential sources, including embryonic stem cells, hepatocyte progenitors, fetal hepatocytes, and genetically engineered immortalized hepatocytes, are being explored actively.

Preclinical evaluation of extracorporeal liver assist devices has been limited by the lack of animal models of fulminant hepatic failure that fully represent the clinical course of acute liver failure in patients. The relatively low incidence of acute liver failure makes it difficult to perform a detailed clinical evaluation of a hepatic support system at any one center, on the other hand, multicenter trials add to the variables to be considered in the trial design. The wide spectra of etiology, severity at presentation, and rapidity of progression of acute liver failure complicate the standardization of entry criteria and randomization. The level of encephalopathy in patients is difficult to quantify. Since liver transplantation is known to improve survival fulminant hepatic failure, the extracorporeal hepatic support may be applied only until a donor organ becomes available, making the data analysis difficult. However, even if the present generation of devices does not prove sufficiently efficacious, the experience gained will undoubtedly help in the future development of an effective extracorporeal liver support.

Pathology of transplantation, 2476

This chapter describes the morphological changes of various disease processes that are relevant in attempting to interpret a needle biopsy of the liver. Attention is drawn to the changes that are most important in analyzing a liver biopsy to arrive at a diagnosis and differential diagnoses. Sections in other chapters deal with more detailed analysis of these disease processes.

The first step in liver biopsy interpretation is recognition of the lobular architecture differentiating normal from fibrosis, cirrhosis, and noncirrhotic nodular regeneration. Systematic analysis of the hepatic lobule starts with the examination of the portal tract, followed by terminal hepatic veins, and the assessment of the parenchyma and the sinusoidal spaces. Based on this analysis, the following differentiations are made:

- acute versus chronic
- parenchymal versus biliary disease
- possible etiological factors
- if neoplastic, benign versus malignant, and primary versus metastatic.

Technique of liver biopsy

Obtaining liver tissue for histological examination has been useful for diagnostic and prognostic purposes since the 19th century [1]. Several approaches can be taken, using a number of available biopsy needles, each with specific advantages and shortcomings.

The most common method of liver biopsy is transcutaneous (transthoracic or subcostal) with or without ultrasound or computed tomography (CT) guidance [2,3]. Occasionally, the clinical circumstance prevents the transcutaneous route and alternative methods should be considered. The most common of these situations are summarized in Table 97.1. Alternatively, patients with coagulopathy can be biopsied transcutaneously after infusion of platelets and fresh frozen plasma [3,4]. Patients with inherited bleeding disorders such as hemophiliacs can be biopsied transcutaneously, provided they are infused with the appropriate coagulation factors and are followed by experienced hematologists during the peri-biopsy period [5].

Table 97.1 Reasons for avoiding the transcutaneous liver biopsy route

Clinical situation	*n*	Percentage of patients
Ascites	37	9
Abnormal coagulation	213	52
Ascites + coagulopathy	81	20
End-stage renal disease	18	4
Obesity	20	5

From Smith et al. [4].

The transjugular route appears superior in yield and safer than percutaneous biopsy in patients with renal disease undergoing hemodialysis [6].

Needle types

Needles used for liver sampling rely either on suction (Menghini, Klatskin, and Jamshidi) or cutting technique (Tru-Cut and Vim Silverman) [3]. The latter technique is applied with a spring-load mechanism (Quick-core, Cook Medical, Bloomington, IN; BioPince, Angiotech Medical, Denmark; or INRAD, SE Kentwood, MI) that allows a specific length of tissue, usually 15–20 mm, to be retrieved with a minimum of needle manipulation in the liver parenchyma [7]. In cirrhotic

Table 97.2 Advantages and disadvantages of different biopsy needles

Biopsy needle	Size (gauge)	Advantages	Disadvantages
Jamshidi	17	Long cores with minimal needle insertion	Fragmented tissue with increased fibrosis
Tru-Cut	16	Rare fragmentation, large core	17–20 mm maximum length in one pass, less tissue than other needles
Inrad, BioPince	16 or 18	Rare fragmentation, large core, adjustable throw up to 34 mm length with one pass	Long throw, more procedural pain

From deMan et al. [23].

livers, cutting techniques result in less fragmented specimens than the suction technique (Table 97.2). Most percutaneous liver biopsies result in the retrieval of sufficient liver tissue for diagnosis (see below) after a single pass, but more than one pass is required in 4%–12% of patients [2,8]. Although in our institution, the intercostal approach has been preferred, the subcostal approach with an 18G needle has been shown to result in adequate samples with similar frequency of adverse events [9].

Imaging for liver biopsy

The use of real-time imaging (ultrasound being more cost-effective than CT) or ultrasound X-marking of the entry site prior to biopsy has significantly decreased the percentage of patients who experience pain requiring analgesia (50%–35%) [2,3,8] as well as the chance of hospitalization [2]. A decrease in mortality has not been shown [2,8]. but the sample size required to show a difference would be exceedingly large.

Surgical approaches

Laparoscopic liver biopsy may be indicated in patients with ascites as hemostasis is carried out after liver sampling by the surgeon. The technique has the advantage of offering visual inspection of the liver surface and biopsy of focal lesions [10]. One study suggested that the diagnosis of cirrhosis was increased with minilaparoscopic biopsy, owing to the visual diagnosis of a nodular liver surface [10].

Percutaneous approach

Liver biopsy is usually performed with an unsedated patient given a local anesthetic injection at the site of needle entry [11]. In our institution, oral or sublingual temazepam is administered at the patient's request. Some physicians administer intravenous midazolam prior to biopsy. The patient is marked by ultrasound, either at the bedside or in the imaging department, where a mark is made in deep expiration. We ask the technician to indicate the angle of entry to avoid large vessels and gallbladder. After the procedure approximately 50% of patients have some epigastric or right shoulder pain [11]. Oral or intravenous analgesia is then administered. A history of intravenous drug abuse (IVDA) has been associated with pain medication use [11]. Typically 98%–99% of patients can be discharged after a 3-h observation. Some radiology departments reimage the patient after the biopsy and if no hematoma is noted and the patient has no or minimal symptoms, discharge is carried out after 1 h [12].

Adequacy of specimen

Failure to obtain tissue occurs in 1%–3% of biopsies [11]. In addition, several studies have addressed the issue of the appropriate biopsy length for an accurate diagnosis. Typically a biopsy length of less than 10 mm and with less than six portal tracts is considered inadequate, although this depends on the indication [1]. For example, it may be possible to diagnose acute cellular rejection with a small biopsy but not to stage fibrosis accurately. At the other end of the spectrum a length greater than 25 mm and including at least 11 portal areas is usually considered adequate [1]. Little has been written about the needle gauge; a 14G needle is likely to retrieve a thicker specimen with conceivably a better assessment of fibrosis stage. But a larger needle is also more likely to be associated with more complications.

Complications

The estimated percentage of patients that need admission after a liver biopsy is approximately 2%. The most common causes are severe pain (2%), hemoperitoneum (0.04%), hemobilia (0.01%), and sepsis (0.01%) [13,14]. Hemo-, pneumo-, or hydrothorax was reported in 0.07% of cases [13]. Perforations of other organs such as gallbladder, lung, colon, kidney, or adrenal gland have all been described [2,8,13]. Pancreatic tissue has been observed together with liver tissue.

Biopsy of malignant liver masses is associated with a small but significant probability of seeding the track with neoplastic cells: the percentage varied from 1% in hepatocellular cancer (HCC) to 19% with colorectal metastasis [15,16]. The vast majority of complications occur within the first 3 h after biopsy, so a 3–6-h monitoring period is usually carried out, with a friend or family member to take charge of the patient for 24 h [14]. A study describing 629 high-risk patients,

including HIV infection [17], reported an unusually high (0.5%) mortality rate after liver biopsy. The finding of delayed bleeding (> 24 h) in 70% of patients who bled was also unusually high. Death has been reported in 1 per 1000–10 000 cases, and basically is always due to massive hemoperitoneum, and most often associated with cirrhosis or malignancy [13,18]. The risk of bleeding appears to increase with the number of passes, associated severe systemic disease including infections, and the use of heparin or corticosteroids [17]. Typically only two passes are customarily allowed [18]. There is little difference in the complication rates that occur with trainees versus attending physicians [11,14,18,]. However, the former tend to retrieve less satisfactory specimens compared with the latter [18]. In the radiological literature, experience with ultrasound-guided percutaneous liver biopsy was not a factor regarding specimen adequacy or complications [19]. There are some differences in specimen adequacy and complications with suction, cutting, or spring-load techniques [2,8]. The impact of a lower needle gauge (14G vs 16 or 18G) or the use of "plugging" devices on the risk of complications is unsettled [3].

Alternatives to liver biopsy

Two main approaches have been taken to evaluate fibrosis (and inflammation) in the hepatic parenchyma. The first is by modeling of blood tests that estimate fibrosis; some are easily obtained (AST/platelets ratio [APRI], Forns, Fib-4, cirrhosis discriminant score [CDS]) [20]. Others are proprietary and cost about $200 per test. These tests have a far better predictive value for lower fibrosis levels and, depending on the cutoff used, may only save liver biopsy in 20%–25% patients with hepatitis C [21]. Further validation needs to be obtained in other types of liver disease. The other approach is to estimate fibrosis by assessing hepatic stiffness using an ultrasound wave. The results are integrated with a Fibroscan (Echosens, Paris) machine. A study noted a negative predictive value of 99% for cirrhosis when the liver stiffness was less than 9.2 kPa in patients with hepatitis B and C and alcoholic and nonalcoholic liver diseases [22]. Unfortunately, prediction of earlier stages was not reported. Thus it appears that with a few exceptions, liver biopsy will remain the most accurate, although not perfect, way to assess necrosis, inflammation, and fibrosis of the liver.

Processing of liver biopsy tissues

Fixation and processing techniques vary from laboratory to laboratory; however, the most commonly used fixative is 10% buffered formalin. For crisp nuclear details and rapid fixation, we use B5 solution containing 6 g of mercuric chloride and 2.074 g of hydrated sodium acetate dissolved in distilled water and mixed with 10 mL of 40% formaldehyde (pH 5.8) at time of use. Embedding in plastic resins such as Araldite, compared with paraffin embedding, improves the ability to obtain thin (2–3 μm) sections with greater cytological details, such as cellular mitochondria or microvesicular fat [24]. Besides regular hematoxylin and eosin (H & E) stains, the most useful routine stains are Masson trichrome for collagen (Fig. 97.1), periodic acid–Schiff (PAS) for glucose, diastase-digested PAS for glycoprotein (i.e., α_1-antitrypsin) (Fig. 97.2), iron stain (Fig. 97.3), Shikata orcein stain for hepatitis B surface antigen (HBsAg) (Fig. 97.4), and copper-binding proteins (Fig. 97.5) and reticulin stain for identification of cord sinusoidal structures. Other special stains that are helpful in diagnosis are those for acid-fast and fungal organisms

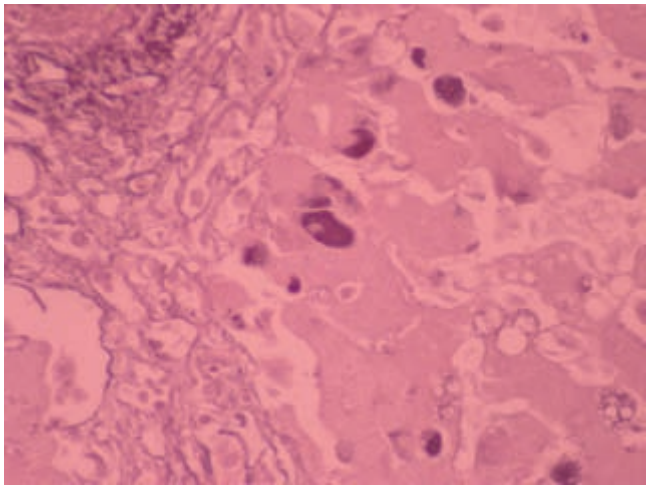

Figure 97.4 Shikata stain demonstrating the presence of HBsAg in the hepatocytes in chronic hepatitis B virus. (Original magnification × 200.)

in cases of granulomas; phosphotungstic acid–hematoxylin for fibrin in disseminated intravascular coagulation or necrosis in cases of Q fever; rubeanic acid for copper; and immunoperoxidase stains for viral proteins, α_1-antitrypsin, α-fetoprotein, factor VIII, and others.

Special requirements

Frozen sections of fresh or fixed tissue are needed to demonstrate fat with oil red "O" stain in cases of Reye syndrome, fatty liver of pregnancy, and fat-soluble vitamin A in Ito cells in hypervitaminosis A. For quantitative analysis of hepatic copper or iron, a part of the tissue needs to be saved either fixed or fresh frozen prior to processing for paraffin embedding. Electron microscopic examination is not a routine necessity and is used for special studies.

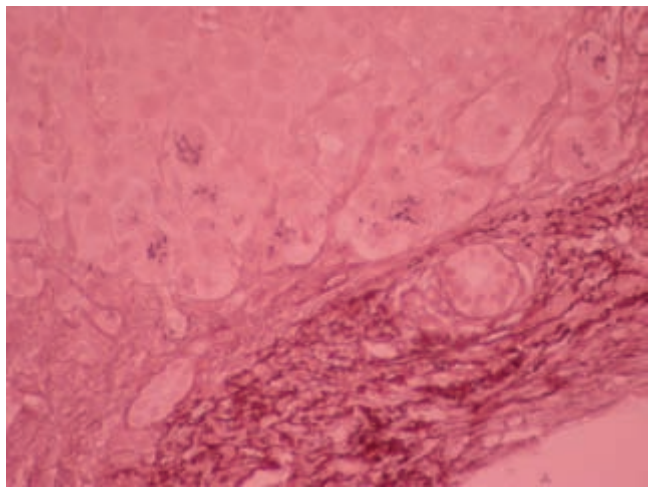

Figure 97.5 Shikata stain demonstrating dark-black granules of copper-binding protein in periseptal hepatocytes in Wilson disease. (Original magnification × 200.)

Systematic approach to the review of liver biopsies

The biopsy section should be reviewed on a low-power field to screen all fragments present in the section. At this time, an evaluation of the overall architecture is made. Regularly placed portal tracts and hepatic venules with their proper relationship constitute normal architecture. The portal areas can be expanded with fibrosis. When there are fibrous septa from portal to portal or to perivenular areas with formation of regenerative nodules, a diagnosis of cirrhosis is made (Fig. 97.1). In nodular regenerative hyperplasia, the parenchyma exhibits regenerative nodules compressing the adjacent hepatic cords without fibrous tissue around them (Fig. 97.6).

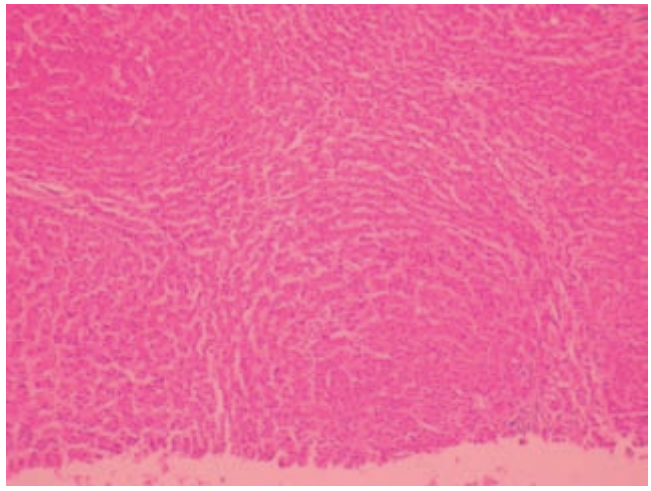

Figure 97.6 Nodular regenerative hyperplasia demonstrating regeneration of parenchyma compressing the surrounding parenchyma without fibrous septa formation. (H & E stain; original magnification × 40.)

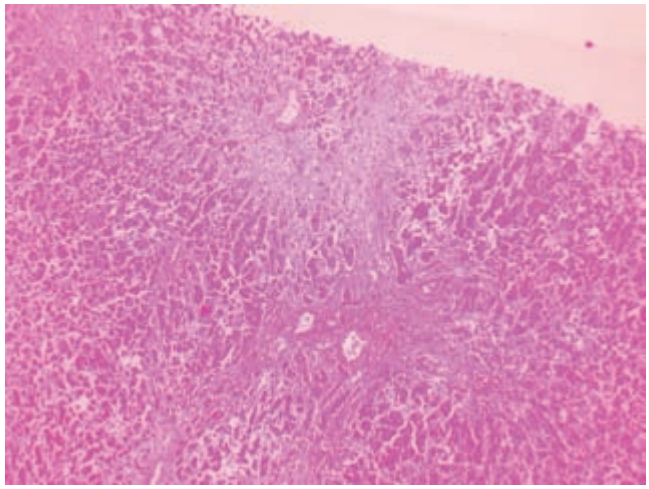

Figure 97.7 Submassive hepatic necrosis with collapsed perivenular reticulum network. (H & E stain; original magnification × 40.)

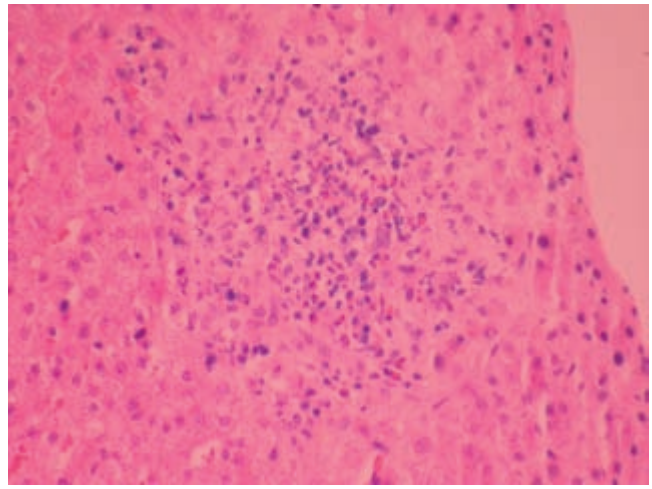

Figure 97.10 Portal area with increased number of eosinophils in a case of early rejection of orthotopic liver transplantation. (H & E stain; original magnification × 200.)

Collapsed reticulin fibers can be differentiated from true fibrosis by reticulin and trichrome stains. When there is confluent or submassive liver necrosis, there is loss of hepatocytes from hepatic cords resulting in a collapsed or compressed reticulum network. If this occurs in the perivenular region, it can mimic fibrosis (Fig. 97.7). Immediately following the overall assessment of the hepatic architecture, special attention is paid to each of the elements of the hepatic lobule.

Portal areas

Enlargement of the portal tracts can be due to either cellular infiltration or fibrosis. Cellular infiltrate can be of inflammatory reactive changes, such as in a variety of viral, drug-induced, or autoimmune types of hepatitis, or neoplastic infiltrate, such as lymphomas. Inflammatory infiltrates are further categorized as acute with neutrophils, usually seen in acute cholangitis with orientation around the dilated ducts due to biliary obstruction (Fig. 97.8) or diseases such as oriental cholangiohepatitis. Predominantly eosinophilic infiltrates, not oriented to the ducts, can be seen in allergic drug reactions (Fig. 97.9), parasitic diseases, and acute rejection following liver transplantation (Fig. 97.10). Among the inflammatory infiltrates of mononuclear type, mainly plasma cells are seen in autoimmune chronic hepatitis (Fig. 97.11), mixed mononuclear cells are seen in viral-induced chronic hepatitis, and cells oriented around the bile ducts are seen in primary

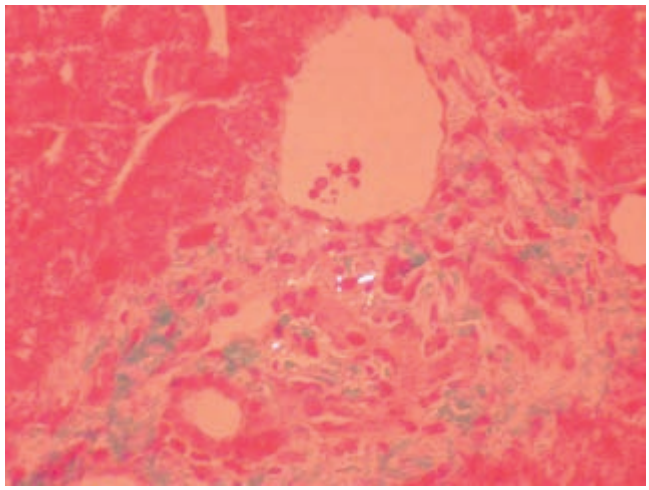

Figure 97.12 A portal area under polarizing light to demonstrate polarizable crystals in an intravenous drug user. (H & E stain; original magnification × 200.)

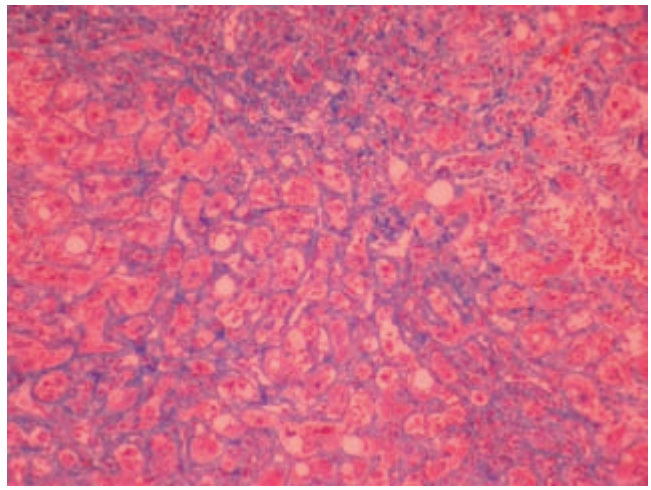

Figure 97.14 Arachnoid portal fibrosis with periportal extension of collagen in chronic alcoholic liver disease. (Masson trichrome stain; original magnification × 100.)

biliary cirrhosis. Portal tracts may contain granulomas due to various etiologies, as well as hypertrophic macrophages with phagocytosed pigments, such as iron or foreign material. Polarizable talc crystals are often seen in intravenous drug abusers (Fig. 97.12). The pattern of portal fibrosis varies with the type of disease. For example, in chronic biliary tract diseases the fibrosis is often periductal, concentric, and lamellar (Fig. 97.13) in nature, whereas in chronic alcoholic liver disease it is arachnoid with irregular extension into the parenchyma (Fig. 97.14). Bile ducts are involved in acute as well as chronic disease processes. In acute cholangitis, usually due to mechanical obstruction, there is dilation of the duct with periductal edema and polymorphonuclear leukocytes infiltrating the duct epithelium and within the duct lumina (Fig. 97.8). In chronic biliary obstruction there is bile duct proliferation and biliary fibrosis with periductal orientation (Fig. 97.15). Periductal concentric fibrosis is also seen in sclerosing cholangitis (Fig. 97.16). There is a chronic inflammatory reaction involving the duct epithelium in the early stages of primary biliary cirrhosis (PBC) (Fig. 97.17) and, in the late stage, the ducts are absent. Similar changes are seen in chronic rejection of a liver transplant. Anomalous duct changes include Meyenburg complexes (Fig. 97.18) and cystic disease such as Caroli disease. Paucity of bile ducts is seen in intrahepatic biliary atresia, whereas biliary fibrosis and bile duct proliferation are seen in extrahepatic biliary

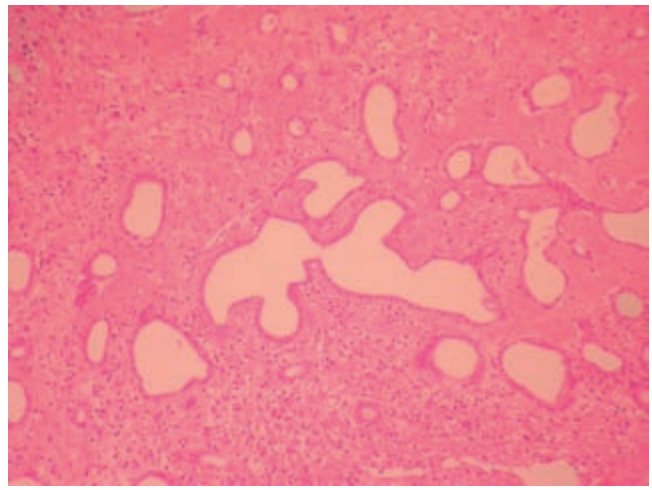

Figure 97.18 A few dilated duct structures with abnormal epithelium surrounded by loose collagen representing Meyenburg complex. (H & E stain; original magnification × 100.)

atresia (Fig. 97.19). Portal veins are thin-walled vascular structures, and are increased in number and dilated in portal hypertension (Fig. 97.20). There is inflammation and thrombosis of portal veins in pyelophlebitis. Primary or metastatic tumors can be seen in the portal venous structures. The hepatic artery can reveal hyalinization in diabetics. Polyarteritis nodosa and giant cell arteritis can produce a typical inflammatory reaction involving the arterial wall (Fig. 97.21). There is arterial hypoplasia in congenital hepatic fibrosis. In Osler–Weber–Rendu syndrome there is an increase in abnormal vascular channels suggestive of arteriovenous shunting (Fig. 97.22). There is deposition of amyloid on the arterial wall in systemic amyloidosis.

Terminal hepatic venules

Terminal hepatic venules are thin, endothelial-lined vascular spaces without collagen deposition. There is perivenular fibrosis in most types of alcoholic liver disease (ALD) (Fig. 97.23). Endophlebitis with inflammatory reaction of terminal hepatic venules is seen in acute rejection of liver transplants (Fig. 97.24). In Budd–Chiari syndrome, there is obliteration of the terminal hepatic veins along with hemorrhagic necrosis of the perivenular hepatocytes and dilation of sinusoids (Fig. 97.25).

Hepatic parenchyma

The hepatic parenchyma should be evaluated with orientation to the three zones of Rappaport. Zone 3, or the perivenular

zone, is most susceptible to anoxic changes and most drug-induced liver necrosis occurs here. Acute alcoholic injury, as well as acute viral hepatitis, reveals a predominance of zone 3 involvement. Periportal cell necrosis can be seen in some cases of acute type A viral hepatitis, in ferrous sulfate toxicity, and in toxemia of pregnancy. The term *spotty necrosis* is used when there are small scattered foci of hepatocytolysis replaced by a small group of hyperplastic Kupffer cells. Confluent necrosis occurs when a larger number of liver cells, such as an entire zone, is necrotic (Fig. 97.26). Submassive and massive necrosis are more severe forms. In submassive necrosis, entire lobules are involved with sparing of a few periportal hepatocytes, whereas in massive necrosis no viable hepatocytes are present (Fig. 97.27). The term granulomatous necrosis is used when the area of necrosis is well circumscribed and comprises a compact arrangement of macrophages, lymphocytes, and plasma cells (Fig. 97.28). This differs from true granulomas in lacking epithelioid cells and multinucleated giant cells. Coagulative necrosis denotes eosinophilic change of hepatocytes with loss of nuclei and maintenance of reticulin without inflammatory infiltration. This is seen in anoxia (Fig. 97.26) or toxic necrosis due to halothane or acetaminophen (Figs 97.29 and 97.30).

Parenchymal inclusions

The most common pigment seen in the liver cells is lipochrome or lipofuscin (wear-and-tear pigment) prominent in zone 3. Hemosiderin pigment is usually seen in periportal

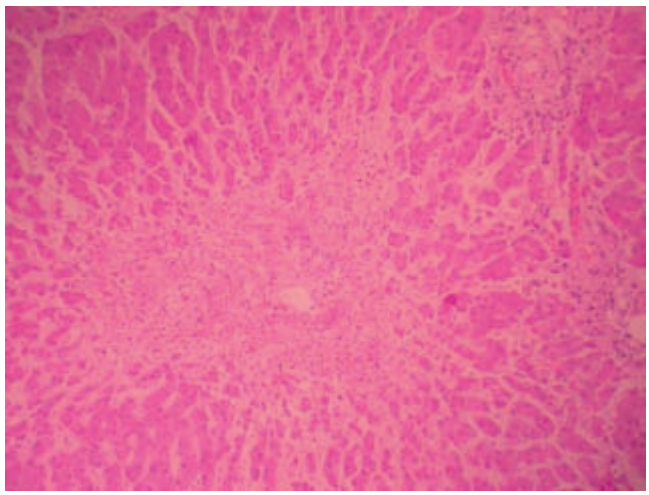

Figure 97.29 Acetaminophen toxicity resulting in perivenular coagulative necrosis without hepatocyte swelling. (H & E stain; original magnification × 100.)

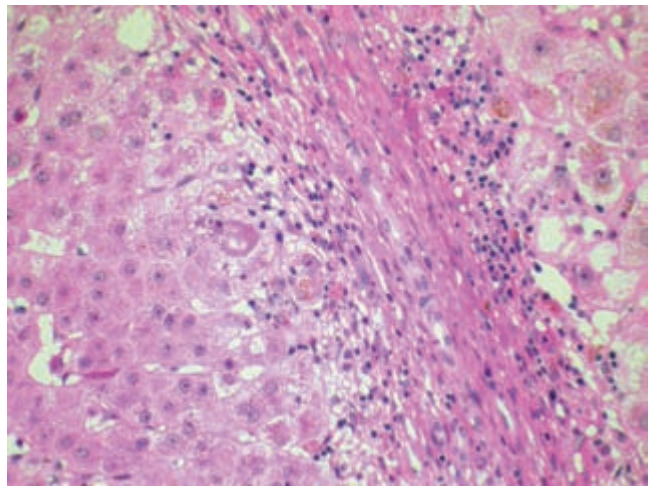

Figure 97.32 A periportal hepatocyte containing Mallory hyaline in primary biliary cirrhosis. (H & E stain; original magnification × 200.)

hepatocytes (Fig. 97.3). Bile can be seen in the hepatocytes and Kupffer cells but often it is associated with canalicular bile plugs. Mallory hyalin is seen as eosinophilic clumpy, ropy material in hepatocytes that are hydropic. It represents aggregates of intermediate filaments. In acute ALD, hyaline necrosis is associated with neutrophilic infiltrates usually in perivenular areas (Fig. 97.31). Mallory bodies can be seen in periportal hepatocytes in chronic biliary diseases such as primary biliary cirrhosis or chronic obstruction (Fig. 97.32). Another eosinophilic inclusion body that is often spherical but of variable size is the α_1-antitrypsin globule, which is seen in heterozygous or homozygous deficiency of α_1-antitrypsin resulting in accumulation of the protein in hepatocytes. This is also seen in periportal hepatocytes. These globules are PAS-positive with resistance to diastase digestion (Fig. 97.2). In some cases of ALD, giant mitochondria that are spherical or needle-shaped can be seen in hepatocytes (Fig. 97.33). Among the viral inclusions, ground-glass hepatocytes with excessive HBsAg in chronic hepatitis B virus (HBV) infection, nuclear and cytoplasmic inclusions of cytomegalovirus (CMV), and nuclear inclusion of herpes simplex are important.

Cord pattern

Hepatocytes are arranged in a radial fashion alternating with the sinusoidal blood spaces. In cases of diffuse cell swelling, this pattern is altered. When there is uniform cell enlarge-

ment with crisp nuclei and the cells are arranged in a cobblestone formation, it indicates focal regenerative activity (Fig. 97.34). A diffuse cobblestone pattern is seen in persistent viral hepatitis.

Nuclear changes

Nuclear changes of hepatocytes include dysplasia, defined as enlargement of a group of cells with a high nuclear to cytoplasmic ratio (Fig. 97.35). Nuclear polyploidy means irregularity and enlargement of individual cell nuclei. Nuclear membrane invagination and glycogen vacuolization are other frequent changes (Fig. 97.36). Syncytial change represents multinucleated liver cells, often seen with neonatal hepatitis (Fig. 97.37).

Sinusoidal spaces and lining cells

In chronic passive congestion and outflow obstruction, the sinusoids in zone 3 are dilated along with atrophy of hepatocytes (Fig. 97.38). In left-sided heart failure, red cells traverse the space of Disse and enter the hepatic trabecula (Fig. 97.39). Focal sinusoidal dilation can be seen in space-occupying lesions in the adjacent parenchyma. Collagen deposition in the space of Disse eventually leads to narrowing and occlusion of sinusoidal spaces (Fig. 97.40). This is commonly seen in ALD, hypervitaminosis A, chronic outflow obstruction including constrictive pericarditis, and inferior vena cava web lesions, as well as in methotrexate toxicity. In amyloidosis there is deposition of amyloid either as a reticular type or globular amyloid in the space of Disse (Figs 97.41 and 97.42).

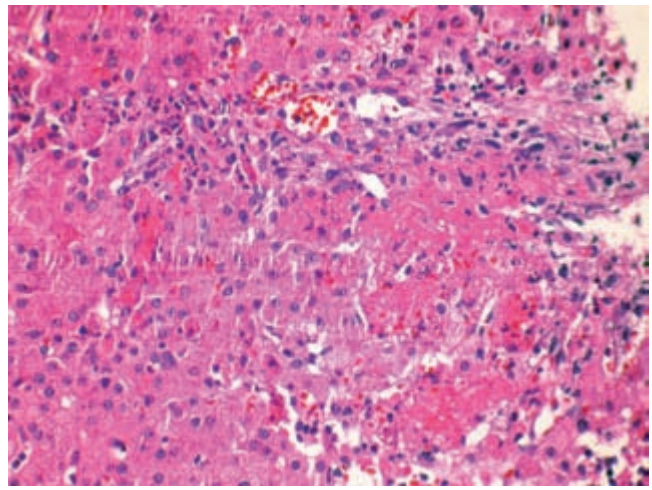

Figure 97.46 Periportal sinusoidal space filled with fibrin thrombi in toxemia of pregnancy. (H & E stain; original magnification × 100.)

Hypertrophy of Kupffer cells is seen in many inflammatory diseases of the liver, but is most striking in salmonellosis (Fig. 97.43). Stellate cells or Ito cells are located in the space of Disse; they are the storage cells of retinoids (vitamin A metabolites). Through a process of activation, these cells become myofibroblasts causing sinusoidal fibrosis (Fig. 97.44). Peripheral circulating cells are visualized in sinusoidal blood spaces. Atypical cells of mononucleosis, leukemic cells, and cells of hairy cell leukemia can be seen (Fig. 97.45). Fibrin thrombi are seen packed within the sinusoids in disseminated intravascular coagulation and in toxemia of pregnancy (Fig. 97.46). Sickled red blood cells are often seen in small clumps within the sinusoidals in sickle-cell anemia (Fig. 97.47).

Cholestasis

Bile stasis can be within the lobules in dilated biliary canaliculi or in periportal cholangioles or bile ducts. Cholestasis in zone 3 is often associated with biliary obstruction or drug-induced injury (Fig. 97.48), whereas periportal (zone 1) bile stasis is seen in late stages of primary biliary cirrhosis. Simple cholestasis with no associated morphological changes of bile ducts is seen in conditions such as benign recurrent intrahepatic cholestasis, benign postoperative cholestasis, pregnancy, and administration of drugs such as estrogen or anabolic steroids, as well as in bacterial sepsis.

Fat

Two major types of fatty changes can occur in hepatocytes:

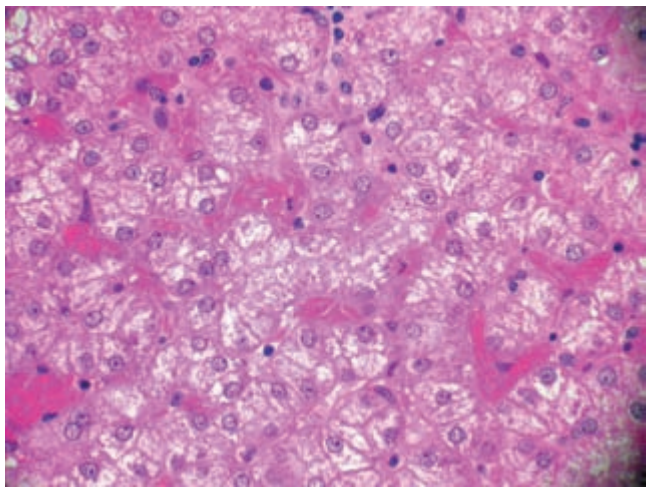

Figure 97.47 Clumps of sickled red blood cells packed in the sinusoidal spaces. (H & E stain; original magnification × 200.)

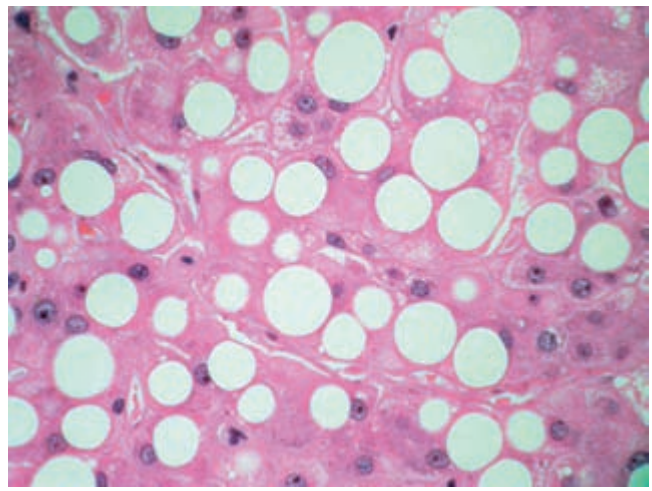

Figure 97.49 Macrovesicular fatty change of hepatocytes in alcoholic liver disease. (H & E stain; original magnification × 200.)

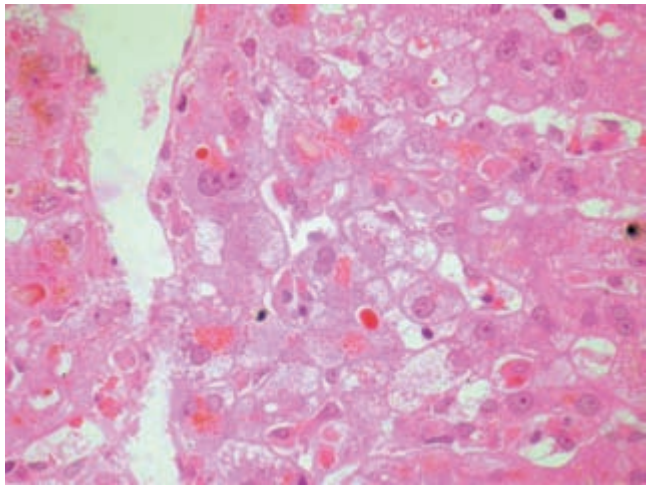

Figure 97.48 Cholestasis in dilated canaliculi in zone 3 in chlorpromazine-induced liver disease. (H & E stain; original magnification × 200.)

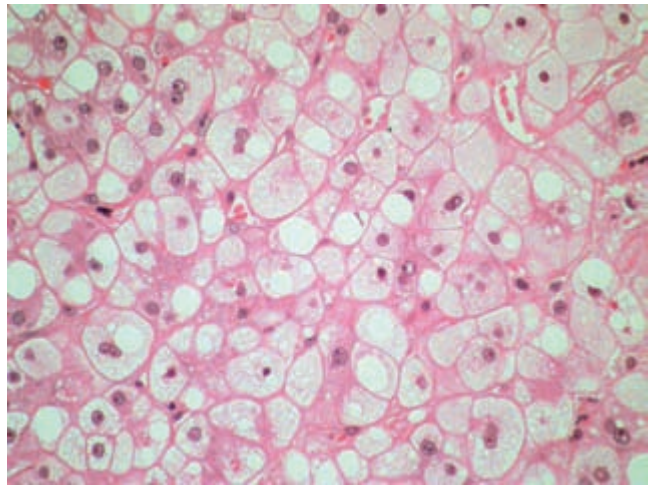

Figure 97.50 Diffusely enlarged hepatocytes with foamy fatty change in acute alcoholic liver disease. (H & E stain; original magnification × 100.)

macrovesicular and microvesicular types. Macrovesicular fat droplets appear as a large vacuole dislocating the nucleus and the cytoplasmic material to the periphery of the cell. Macrovesicular fatty change involving zone 3 is often seen in ALD (Fig. 97.49) and also in diabetes mellitus and in obesity. Steroid-induced fatty change involves all zones. Microvesicular fat, composed of small droplets of fat, sometimes appears as foamy change of the cytoplasm, without displacement of the hepatic nucleus. This is seen in alcoholic foamy degeneration, fatty liver of pregnancy, tetracycline toxicity, Reye syndrome, and in valproic acid toxicity (Fig. 97.50).

Terminal hepatic venules and venous outflow

The most common pathological change of terminal hepatic venules is perivenular and obliterative sclerosis seen in alcohol-induced liver injury (Fig. 97.23). Similar fibrosis can also be seen in Budd–Chiari syndrome and other causes of outflow obstruction, such as constrictive pericarditis, inferior vena caval obstruction, or web lesions. Endotheliolitis or inflammatory cell infiltration of terminal hepatic venules is a feature of acute rejection of liver transplants (Fig. 97.24).

Space-occupying lesions of the liver

Primary tumors: benign and malignant

These can be neoplastic lesions, cysts, or abscesses. A CT- or ultrasound-guided liver biopsy can result in a sample that is diagnostic of the lesion present. Cysts and abscesses are usually aspirated. Among the benign solid mass lesions, focal

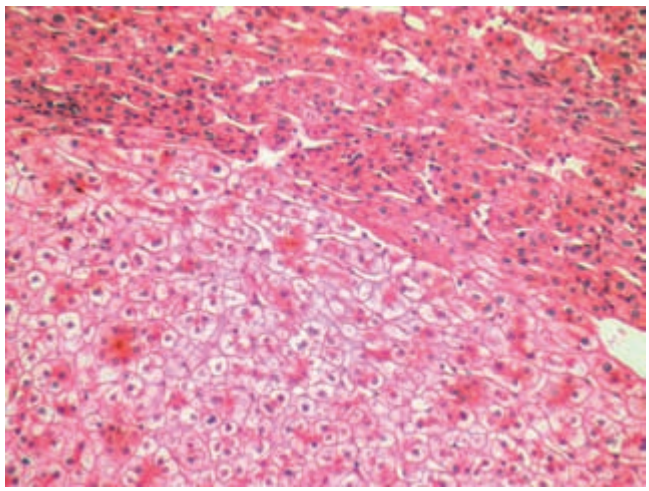

Figure 97.51 Liver cell adenoma with clear cells and the adjacent normal parenchyma. (H & E stain; original magnification × 100.)

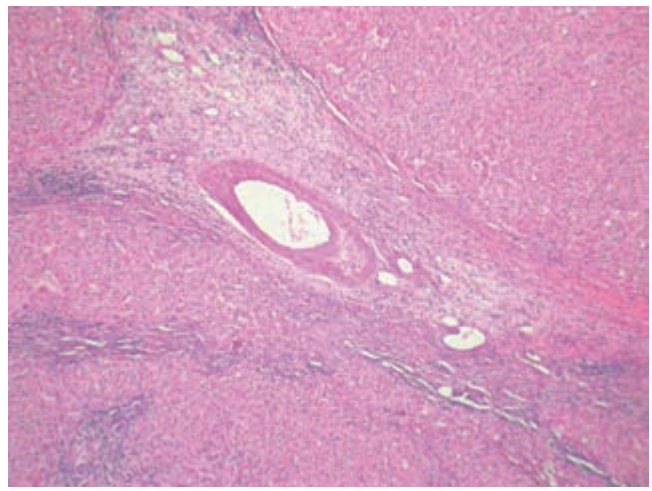

Figure 97.53 Focal nodular hyperplasia (FNH) with central stellate scar. (H & E stain; original magnification × 40.)

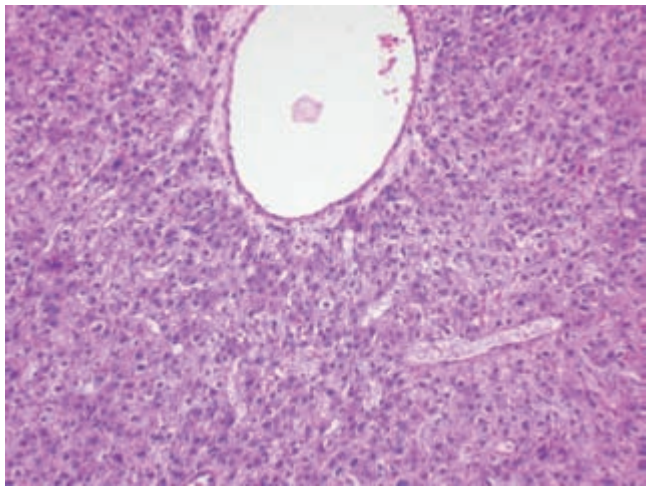

Figure 97.52 Liver cell adenoma with thick-walled vessels and lack of portal tracts. (H & E stain; original magnification × 100.)

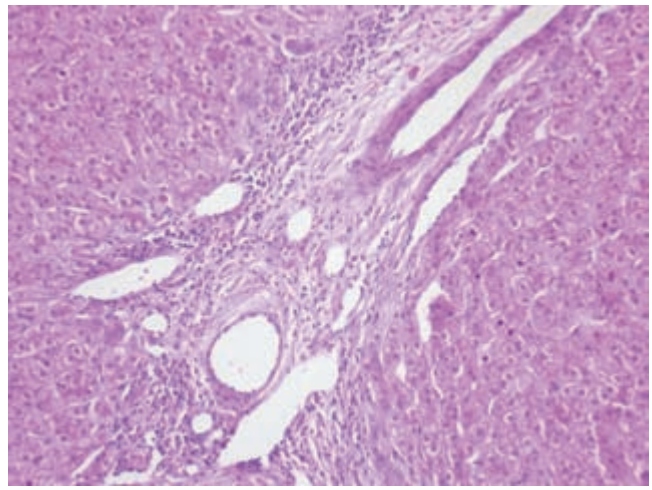

Figure 97.54 Focal nodular hyperplasia (FNH) with the scar exhibiting lack of bile ducts and presence of vascular structures. Liver cells are uniform and regenerative in appearance. (H & E stain; original magnification × 100.)

nodular hyperplasia is one of the most common and must be differentiated from liver cell adenoma [25,26]. Liver cell adenoma does not have a capsule but compresses adjacent parenchyma (Fig. 97.51). The tumor cells are benign with normal nuclear-to-cytoplasmic ratios, and with lack of portal tracts and terminal veins in the lesions. There are prominent, thick-walled arteries present along the edge of the tumor (Fig. 97.52). Focal nodular hyperplasia has a typical central stellate scar with loose vascularized fibrous tissue containing atypical ductal elements along the periphery of the scar (Fig. 97.53). This lesion also lacks normal portal areas and terminal hepatic veins (Fig. 97.54). Among the primary malignant neoplasms of the liver, hepatocellular carcinoma (HCC) is the most common form [27]. Other forms include cholangiocarcinoma and angiosarcoma. The tumor cells of the majority of typical HCCs have a trabecular pattern with increased numbers of cell thicknesses forming finger-like projections into vascular spaces. These trabeculae are lined by endothelial cells and surrounded by vascular spaces (Fig. 97.55). The tumor can have focal acinar changes with secretory material in the lumina. Sclerosing hepatic carcinoma is a variant with a dense collagenized stroma (Fig. 97.56). The fibrolamellar variant has lamellar strands of collagen separating thin cords of large eosinophilic neoplastic hepatocytes [28] (Fig. 97.57). Cholangiocarcinomas are composed of neoplastic ductal elements surrounded by dense fibrous stroma [27] (Fig. 97.58). The tumor is clearly demarcated from the surrounding liver.

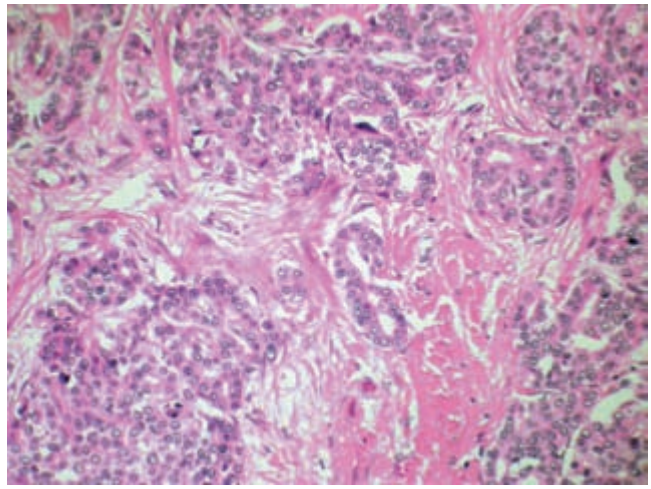

Figure 97.58 Neoplastic ductal structures with fibrous stroma in cholangiocarcinoma. (H & E stain; original magnification × 100.)

Nodular regenerative hyperplasia (NRH)

This is a rare form of hyperplasia of liver cells with formation of nodules without fibrous septa [29]. Microscopically, the hyperplastic nodules are better identified on low power exhibiting compression by the surrounding parenchyma (Fig. 97.6). A reticulum stain outlines these nodules, which can vary from small and microscopic to large, up to 23 cm. Patients with NRH may have evidence of portal hypertension.

Metastatic tumors

Metastatic tumors in the liver can be easily diagnosed from an ultrasound-guided needle biopsy. The tumor cells usually grow into the adjacent sinusoids, compressing and separating the hepatic trabeculae (Fig. 97.59). Examination of the junction between the tumor and nontumorous tissue is useful in differentiating HCC from metastatic tumors. In HCC, the tumor cells merge into the hepatic cords where there is a transition from normal to neoplastic cells (Fig. 97.60). In metastatic tumors, as mentioned earlier, the tumor grows into the sinusoidal spaces.

Granulomas

Granulomas are identified in the liver at a rate of 25% of all liver biopsies in most of the large centers [30]. The most common cause of epithelioid granulomas in the liver is sarcoidosis (Fig. 97.61). Among infectious agents causing granulomas in the liver, the most common are *Mycobacterium tuberculosis, Mycobacterium avium intracellulare*, Q fever, and brucellosis

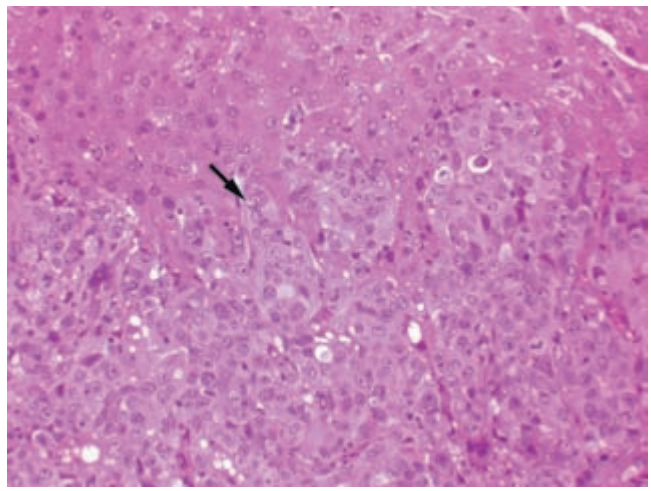

Figure 97.59 Metastatic, poorly differentiated adenocarcinoma infiltrating into the sinusoids. (H & E stain; original magnification × 200.)

(Figs 97.62–97.64). Rare fungal infections such as blastomycosis and coccidioidomycosis are the next most common causes. Parasitic infections such as schistosomiasis with hepatic granulomas are common in some endemic areas of the world. Epithelioid granulomas are well circumscribed and comprise multinucleated giant cells, epithelioid cells, and lymphocytes along the periphery. Granulomatous lesions, which are not true granulomas, are small punched-out areas of hepatic necrosis with aggregates of macrophages and lymphocytes without epithelioid cell formation. These lesions are seen in viral infections (e.g., CMV, Epstein–Barr virus [EBV]), rickettsial infections (e.g., Q fever), and in liver injury caused by drugs such as phenytoin, allopurinol, phenylbutazone, and sulfonamides. Some of these drugs can also elicit an epithelioid reaction with true granuloma formation (Fig. 97.65). Hepatic granulomas can also be associated with Hodgkin disease, post-jejunoileal bypass, and PBC (Fig. 97.17). Some unique features useful in the differential diagnosis of hepatic granulomas include:

- a central vacuolated space with a fibrin ring in granulomas [31] of Q fever representing the so-called "donut" lesions (Fig. 97.64)
- demonstrations of acid-fast and fungal organisms using special stains
- the presence of eosinophils in granulomas associated with drug reactions, parasitic diseases, and Hodgkin disease

Differential diagnosis of cirrhosis

Based on its morphological features, cirrhosis of the liver can be classified as alcoholic, nonalcoholic, biliary, and cardiac cirrhosis. Based on the size of the regenerative nodules, a broad distinction is made between micronodular (< 3-mm nodules) and macronodular (> 3-mm nodules) cirrhosis. A typical alcoholic cirrhosis is a micronodular type diagnosed by the presence of dense, broad, fibrous scars with small parenchymal nodules exhibiting sinusoidal collagenosis (Fig. 97.1). Fat, alcoholic hyaline, and other acute changes due to alcohol can be superimposed. Mild chronic inflammatory reaction of a nonspecific nature can be present in the fibrous septa without periseptal or parenchymal activity. Cirrhosis due to hemochromatosis, also a micronodular cirrhosis, is characterized by the presence of hemosiderin deposition in the parenchymal cells as well as in the fibrous septa and in bile duct epithelia. There is a striking lack of inflammatory process in this type of cirrhosis. Nonalcoholic cirrhosis, usually of macronodular type, is a broad category where the cirrhosis is the end result of chronic hepatitis of various etiologies. Fibrous septa are relatively thin and vascularized and reveal prominent chronic inflammatory infiltration. The inflammation extends into the periseptal parenchyma, which exhibits a varying degree of necroinflammatory activity. In biliary cirrhosis, the fibrous septa reveal a character-

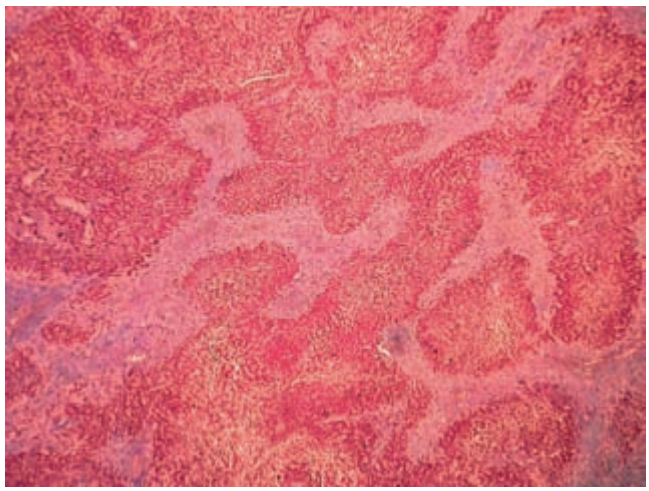

Figure 97.67 Jigsaw-puzzle appearance of biliary cirrhosis. (Masson stain; original magnification × 40.)

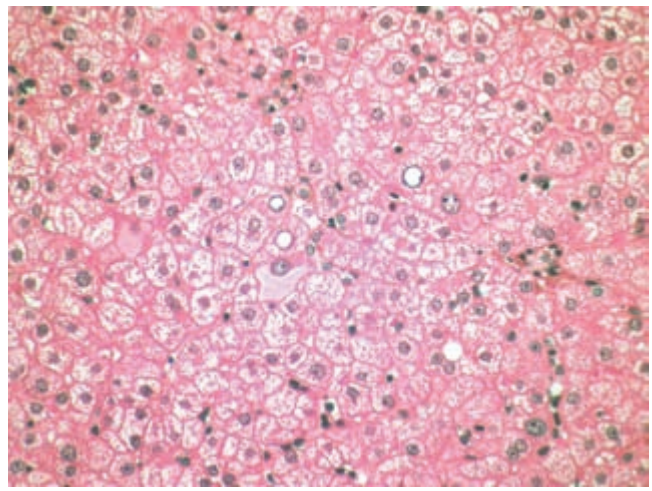

Figure 97.68 Scattered ground-glass cells in chronic hepatitis B. (H & E stain; original magnification × 100.)

istic lamellar pattern and extend from portal to portal areas leaving islands of parenchyma. This is best described as a jigsaw puzzle-like appearance (Fig. 97.67). Cardiac cirrhosis, in contrast, has a reverse lobular pattern, as the perivenular fibrous areas form septa leaving the portal areas relatively uninvolved. Following a morphological identification of the type of cirrhosis, an etiological diagnosis is attempted. The morphology of alcoholic cirrhosis can also be seen in post-jejunoileal bypass liver disease. Among the etiologies of nonalcoholic cirrhosis, chronic HBV infection can be diagnosed by the presence of ground-glass cells (Fig. 97.68) and significant dysplastic changes of the hepatocytes (Fig. 97.35). Autoimmune hepatitis can be suspected as the etiology if there is a predominance of plasma cells among the portal and parenchymal infiltrates (Fig. 97.11). In addition, areas of collapse may exist even in the cirrhotic stage in these cases. Wilson disease can be suggested if there is evidence of increased hepatic copper and copper-binding protein (Fig. 97.5). In cases of biliary cirrhosis, absence of bile duct elements with the presence of lymphoid infiltrates in the septa is suggestive of primary biliary cirrhosis, whereas evidence of bile duct proliferation with or without acute cholangitis is suggestive of biliary obstruction leading to cirrhosis. Cirrhosis in infants and children due to α_1-antitrypsin deficiency, intra- or extrahepatic biliary atresia, and in cystic fibrosis involving the liver also appears biliary in nature. Clinical, laboratory, and radiological data are needed to arrive at a more accurate etiological diagnosis of cirrhosis in most cases.

Specific liver diseases

Necroinflammatory diseases

Acute viral hepatitis

Regardless of the etiological agent, typical perivenular hepatocytolysis, extreme hydropic swelling of the hepatocytes, marked Kupffer cell hyperplasia, and mononuclear exudative reaction in the parenchyma as well as the portal tracts are found in cases of acute viral hepatitis [32] (Figs 97.69 and 97.70). Numerous acidophilic bodies are also present. The acidophilic bodies represent individual hepatocytes undergoing necrosis with cytoplasmic condensation and nuclear pyknosis. Cholestasis may or may not be present. The hepatocytes in zone 1 usually reveal uniform hydropic change suggestive of regeneration. Portal tracts are expanded with inflammation without fibrosis (Fig. 97.70). Some of the following specific changes are associated with different viral agents. Acute type A hepatitis can exhibit a periportal accentuation of the necrosis [33]. Enteric (hepatitis E virus, HEV) acute hepatitis tends to have prominent acinar changes with hepatocytes arranged around dilated biliary canaliculi resembling rosettes throughout the lobules [34] (Fig. 97.71). In acute hepatitis due to delta (hepatitis D virus, HDV) agent, the presence of hepatitis D antigen (HDAg) can be demonstrated by immunoperoxidase. When the necrosis in acute viral hepatitis (AVH) is severe, it involves the entire zone 3 and is called confluent necrosis. When the necrosis involves zones 2 and 3 and part of zone 1 with hepatocytes remaining viable in the periportal zones, it is classified as submassive necrosis. Massive necrosis is the term used when the necrosis involves all zones without any viable hepatocytes.

Chronic viral hepatitis

Terminology

Chronic hepatitis is the universal terminology used for all liver biopsies obtained from patients whose virological markers persist for more than 6 months in the presence of abnormal liver enzymes. Terms such as persistent hepatitis, chronic active hepatitis, chronic lobular hepatitis, and so forth are no longer used by pathologists. The diagnosis of

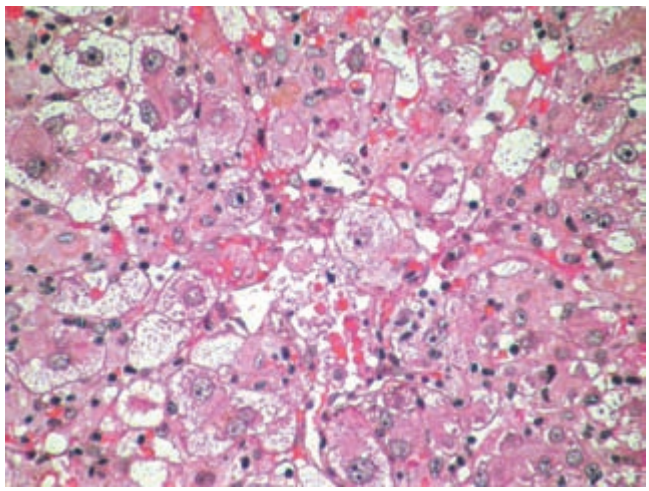

Figure 97.69 Perivenular zone in acute viral hepatitis demonstrating hydropic hepatocytes, hepatocytolysis, inflammatory exudate, and rare acidophilic bodies. (H & E stain; original magnification × 200.)

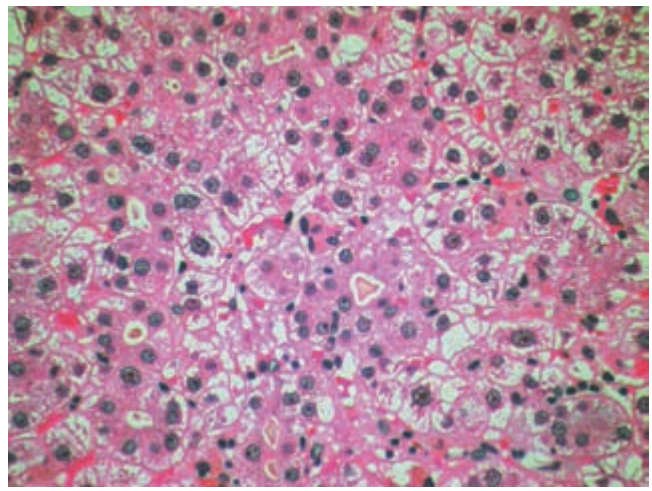

Figure 97.71 Prominent acinar transformation of hepatocytes in enterically transmitted acute hepatitis, type E. (H & E stain; original magnification × 200.)

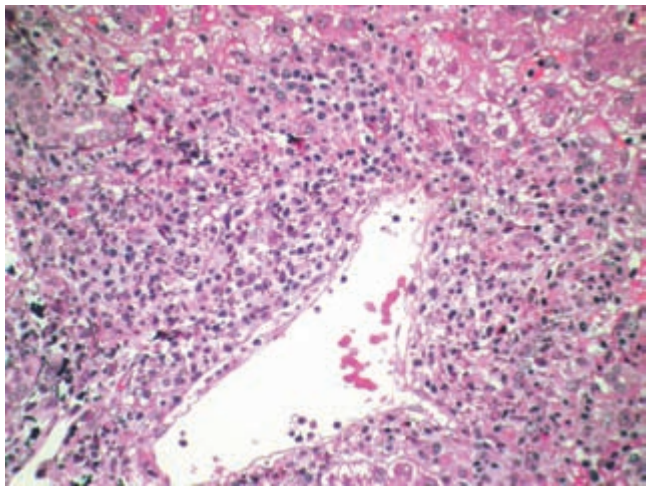

Figure 97.70 Portal area in acute viral hepatitis with mononuclear infiltration extending to the periportal regions. (H & E stain; original magnification × 200.)

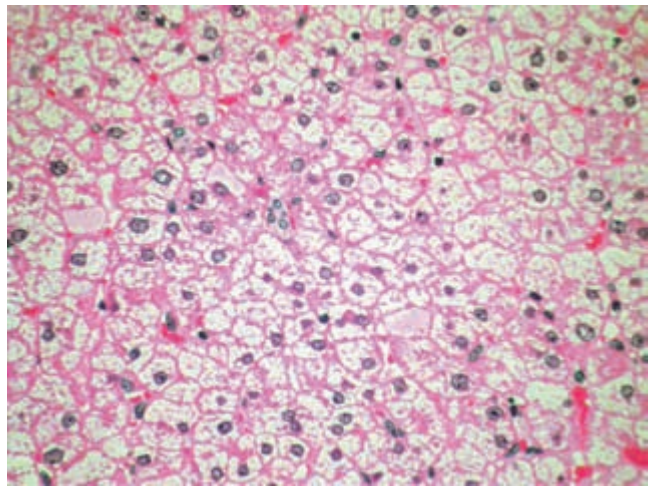

Figure 97.72 Uniform cobblestone appearance of parenchyma in chronic hepatitis, type B. A few ground-glass cells are seen. (H & E stain; original magnification × 200.)

"chronic hepatitis" is further elaborated by adding the name of the causative virus (i.e., type B, type C, or type D) and by adding the assessment of necroinflammation and fibrosis by a semiquantitative method, using grades (0–4) and stages (1–4) as proposed by Ludwig [35]. Detailed quantitation assessments have included many scoring systems; the most commonly used are those devised by Knodell and colleagues and Ishak and colleagues, and the Metavir scoring system [36–38]. *Knodell scoring* has a total of 18 for necroinflammation including lobular, periportal, and portal inflammation, and a total of 4 for fibrosis (0–4). The *Ishak scoring system* has more details for necroinflammation (0–18) and expanded scores for fibrosis (0–6). *Metavir scoring* is simpler with a combination score for inflammation including periportal and lobular activity (A0–A3) and a fibrosis score on a scale of F0–F4.

The most common morphological features of chronic viral hepatitis are portal fibrosis, portal and periportal mononuclear inflammation, and necroinflammatory changes within the parenchyma with an irregular distribution between one lobule and another. There is also regenerative activity in an irregular distribution (Figs 97.72 and 97.73). Lymphocytes and Kupffer cells are seen cuffing around the target hepatocytes (Fig. 97.74). The degree of necrosis depends on the disease activity – more severe in exacerbations or reactivation and less so in quiescent stages. Fibrosis progresses to cirrhosis and the periseptal inflammatory activity continues with

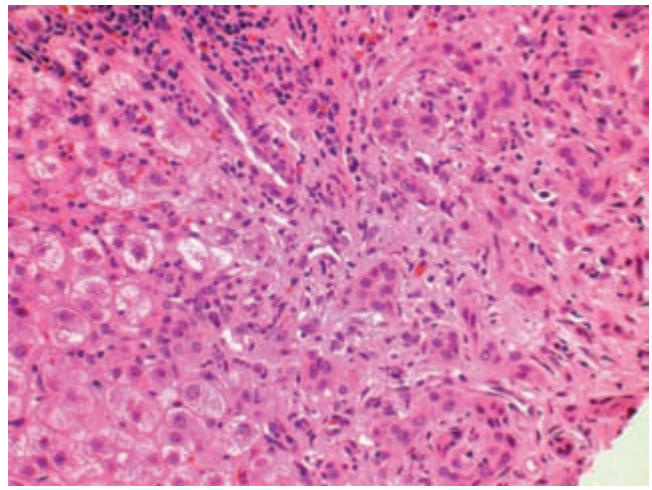

Figure 97.76 Atypical bile ducts in a portal tract of chronic hepatitis C. (H & E stain; original magnification × 200.)

cirrhosis. The term piecemeal necrosis is used to describe the periportal extension of mononuclear inflammation in association with hepatocytolysis involving the limiting plate. In chronic hepatitis B there is significant nuclear dysplasia (Fig. 97.35). In cases of chronic hepatitis C the following unique features are seen in most cases: macrovesicular fatty change, mild sinusoidal collagenosis in the periportal areas, prominent lymphoid reaction of portal areas, and moderate to marked atypia of the bile duct epithelium [39] (Figs 97.75 and 97.76). In cases of chronic hepatitis B immunoperoxidase can be used to stain for the viral proteins such as hepatitis B core antigen (HBcAg), HBsAg, and hepatitis B e antigen (HBeAg) [40]. The HBsAg protein is also demonstrable using Shikata orcein stain or Victoria blue (Fig. 97.4). In chronic hepatitis D virus infections HDAg is demonstrable by immunoperoxidase techniques [41] (Fig. 97.77).

Autoimmune etiology

In addition to the features of chronic hepatitis already described, the changes unique to autoimmune chronic hepatitis (the term *lupoid hepatitis* is used by some, but should be discouraged as it is not related to systemic lupus erythematosus) are:

- the presence of significant numbers of plasma cells among the portal and the parenchymal infiltrates (Fig. 97.11)
- evidence of collapse and striking degree of periportal as well as perivenular necrosis
- trapped hepatocytes in the fibrous portal or septal areas [42].

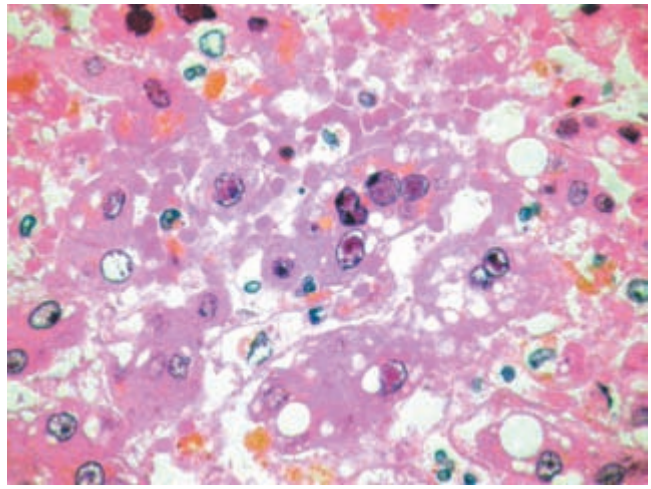

Figure 97.80 Intranuclear inclusions of Cowdry type A of herpes simplex seen in hepatocytes. (H & E stain; original magnification × 200.)

Necroinflammatory changes are minimal in patients on steroid therapy with good response.

Other viral infections

A mononucleosis pattern of hepatitis can be seen in hepatitis due to EBV, CMV, and some cases of hepatitis C virus (HCV) [43]. In this form, the hepatocytes are not swollen and the cord pattern is maintained. There is striking sinusoidal lymphocytosis, many of these cells being atypical in nature (Fig. 97.78). There is portal infiltration by the same type of cells. In addition, there is multifocal punched-out hepatocytolysis (Fig. 97.28) without confluent or zonal necrosis. Rarely, epithelioid granuloma can be seen. In immunocompromised individuals, the CMV infection results in an abundance of virally infected cells with typical nuclear inclusion bodies in the bile duct epithelium or reticuloendothelial cells. Following an orthotopic liver transplantation, CMV infection causes typical microabscess formation with the polymorphonuclear leukocytes surrounding the cells with viral inclusion bodies [44,45] (Fig. 97.79). Viral antigen in CMV hepatitis in these cases is demonstrable using immunochemical methods. Herpes simplex infection of the liver is rarely encountered in liver biopsies, because the prothrombin time is too prolonged for a biopsy in these patients. However, the typical changes consist of large, discrete, irregular zones of coagulative necrosis of parenchymal cells with the presence of eosinophilic intranuclear inclusions in the viable hepatocytes at the margins of necrosis [46] (Fig. 97.80).

Alcoholic liver disease

Changes in liver biopsies due to alcohol can be broadly divided into acute cellular damage and its characteristic features, and chronic, slowly progressive changes with evidence of chronic liver disease.

Acute changes

The most common form of acute damage is seen as fatty change of a macrovesicular type with or without cholestasis. The patients present with large fatty change with or without jaundice. Needle biopsy reveals large vacuoles of macrovesicular fat involving the perivenular hepatocytes (Fig. 97.49). Occasionally, the entire lobule is uniformly involved. Cholestasis and sinusoidal fibrosis may be seen. Acute foamy fatty change (FFC) represents a variant of acute alcoholic hepatitis [47]. The perivenular hepatocytes are enlarged with foamy or microvesicular fat (Fig. 97.50). The nucleus is central in location and the cells may exhibit abnormal giant mitochondria visible as eosinophilic round bodies (cherry bodies) (Fig. 97.33). Sinusoidal collagen deposition can be prominent in the perivenular zones. Foamy fatty change can also be seen in association with the classic acute sclerosing hyaline necrosis (ASHN) in patients with alcoholic hepatitis [48]. The morphological hallmarks of ASHN are:

- hydropic hepatocytes with cytoplasmic Mallory hyaline bodies
- neutrophil reaction around these cells with hyaline necrosis (Fig. 97.31)
- sclerosis of the terminal hepatic venules with sinusoidal collagenosis.

Other microscopic features, such as fatty change, cholestasis, and portal fibrosis with arachnoid extension, can also be part of this morphology. Other uncommon biopsy findings of acute ALD include lytic necrosis of liver cells, in which the hepatocytes are extremely hydropic with lysis and fusion of adjacent cells, and acute portal reaction, in which there is prominent neutrophilic reaction within the portal tract without any orientation to the bile ducts. These portal tracts often have classic arachnoid fibrosis.

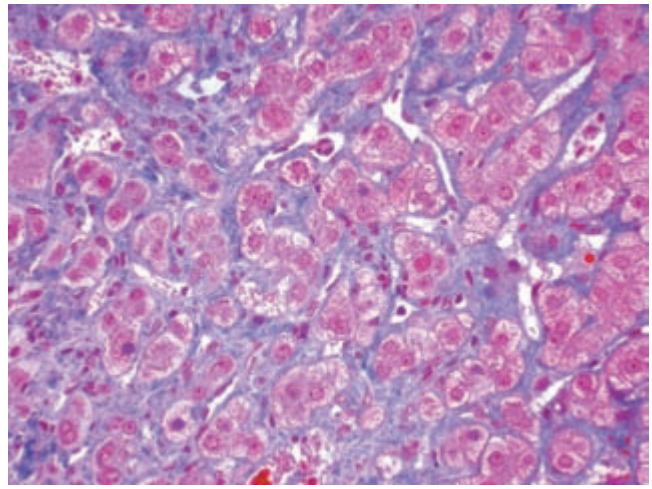

Figure 97.81 Diffuse interstitial fibrosis in chronic alcoholic liver disease. (Masson stain; original magnification × 100.)

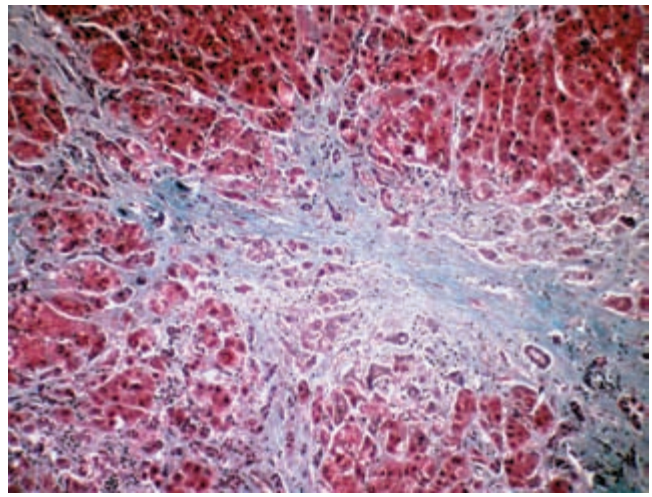

Figure 97.82 Marked perivenular fibrous scarring with mild portal fibrosis and lack of regenerative nodules in progressive perivenular fibrosis of alcoholic etiology. (Masson stain; original magnification × 100.)

Chronic alcohol-induced liver damage

This primarily manifests as fibrosis. Three forms of progressive fibrosis are seen in the liver [49]:

- portal and perivenular fibrosis leading to fibrous septa formation, resulting in cirrhosis with small regenerative nodules (Fig. 97.1)
- diffuse interstitial fibrosis with collagen extending throughout the lobule encircling individual hepatocytes and without parenchymal regeneration or septal formation (Fig. 97.81)
- progressive perivenular fibrosis with dense scar-like collagen involving zone 3 with relatively minimal portal fibrosis (Fig. 97.82).

In the early stages of development of cirrhosis the fibrous septa appear thin, with larger pseudolobules or parenchymal nodules. There is evidence of prominent intranodular sinusoidal fibrosis. As the disease progresses, the septa become denser and wider, and the nodules become subdivided into smaller nodules, with continued sinusoidal fibrosis in the periseptal regions. In advanced stages, there is extensive scarring with islands of parenchymal nodules scattered within. Masson trichrome and PAS stains clearly outline this ratio of fibrous tissue to the parenchyma. Following an established state of cirrhosis, if there is prolonged abstinence from alcohol, the regenerative parenchymal nodules enlarge, pushing the fibrous septa centrifugally with a remarkable reduction in the amount of collagen both within the parenchyma and the septa. At this inactive stage, it is difficult to identify

alcohol as the initial agent responsible for the cirrhosis. Any of the acute cellular changes described previously can occur superimposed on a cirrhotic or fibrotic liver. The distribution of Mallory hyaline, neutrophilic infiltrate, or fatty change may be irregular and focal, not uniform. When there are additional complications, such as anoxia due to variceal bleeding or general anesthesia, typical coagulative necrosis can be seen within the central zone of the cirrhotic nodules.

Differential diagnosis

Nonalcoholic steatohepatitis (NASH) or nonalcoholic fatty liver disease (discussed in the next section) are unrelated to alcohol or any other recognized cause of liver disease, but most often present as progressive liver disease with histological features resembling alcoholic liver disease [50,51]. Identical morphological changes of ASHN can be seen in Indian childhood cirrhosis, liver disease secondary to jejunoileal bypass surgery for morbid obesity, and drug-induced reactions in patients receiving amiodarone [52]. Mallory bodies without accompanying neutrophilic reaction can be seen in a number of conditions such as Wilson disease, primary biliary cirrhosis, chronic biliary obstruction, and in livers bearing HCC (in either the tumor or nontumor cells). Sinusoidal collagen deposition typical for ALD can be seen in a moderate degree in chronic HCV hepatitis, hypervitaminosis A, and methotrexate toxicity. A much more localized perivenular fibrosis can be seen in venous outflow obstruction such as Budd–Chiari syndrome. Studies of serological testing for HCV have identified a high prevalence (> 50%) of chronic HCV infection among those with ALD. In many of these patients, the liver biopsy reveals features of both ALD and chronic hepatitis of HCV type. There is an increased degree of chronic inflammatory infiltrate in the portal tracts or fibrous septa with spillover to the periseptal parenchyma.

Nonalcoholic fatty liver disease (NAFLD)

This covers the spectrum from fatty liver to nonalcoholic steatohepatitis (NASH) and to end-stage cirrhosis. Although these are not necessarily sequential, they represent increasing gravity of the disease process. Morphological features of NAFLD (Figs 97.83 and 97.84) include steatosis (both macrovesicular and microvesicular), ballooning change of hepatocytes and perisinusoidal fibrosis predominantly in zone 3 in adults and in zone 1 in children, and lobular inflammation including mononuclear cells and neutrophils. A finding of Mallory hyaline (MH) within the hepatocytes with ballooning change, neutrophilic infiltrates, megamitochrondria, and pericentral fibrosis are all features of NASH as well as ASH (alcoholic steatohepatitis). However, MH is usually more abundant in ASH. Several scoring systems have been described to assess the severity and stage of NAFLD. These include microvesicular and macrovesicular steatosis, perivenular and periportal sinusoidal fibrosis with or withoutnecroinflammation, and Mallory bodies. Degree of necroinflammation and

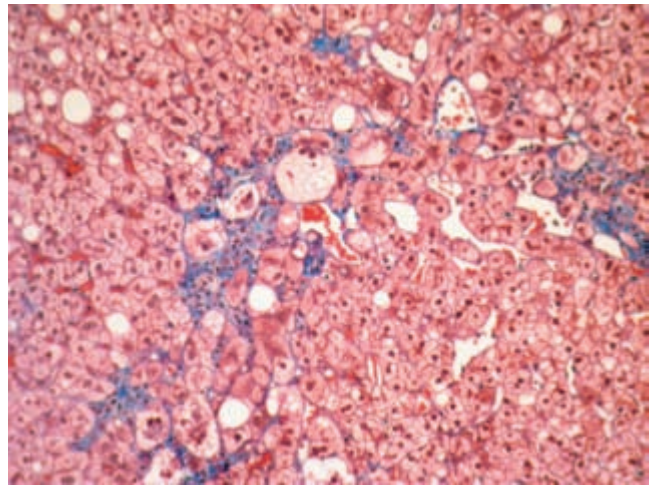

Figure 97.83 Perisinusoidal collagen in nonalcoholic steatohepatitis (NASH). (Masson trichrome stain; original magnification × 100.)

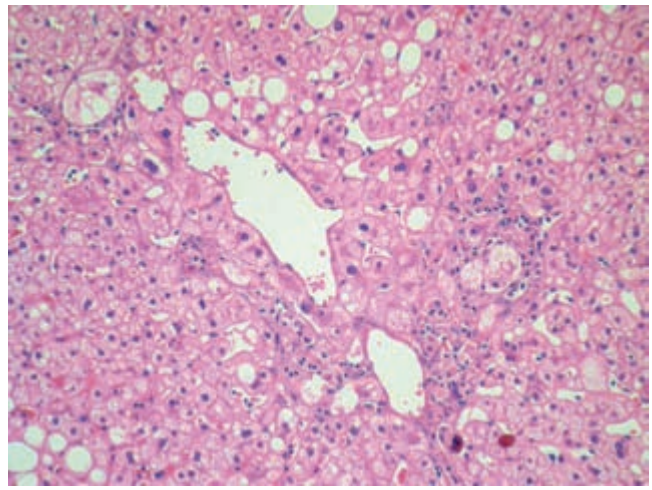

Figure 97.84 Hepatocytes with ballooning change and Mallory bodies in nonalcoholic steatohepatitis (NASH). (H & E stain; original magnification × 100.)

ballooning changes (scale of 1–3) as well as fibrosis (1–4) have been graded by a system developed by Brunt and colleagues [51]. Subsequently, a NASH clinical research network group has proposed a scoring system called the NAFLD activity score, or NAS [53]. This scores the sum of steatosis (scale of 0–3), lobular inflammation (0–2), and ballooning of hepatocytes (0–2). A score greater than 5 is diagnostic of NASH, whereas a score of less than 3 excludes NASH. The fibrosis stage is on scale of 0–4, with 1 = perisinusoidal or periportal; 2 = perisinusoidal and periportal; 3 = bridging fibrosis; and 4 = cirrhosis. Although other features such as MH and megamitochrondria are often seen in NASH, these features are associated with hepatocyte ballooning change, which is a component of the NAS system and therefore these features are not independently added to the scoring system.

Biliary diseases

Mechanical duct obstruction

Mechanical obstruction of the bile duct is often diagnosed without a liver biopsy. When the various procedures, such as ultrasound, endoscopic retrograde cholangiopancreatography (ERCP), and others, are inconclusive, a liver biopsy is performed. The changes can be divided into parenchymal and portal. Although the predominance of one type of change over the other varies from patient to patient, the earliest change might be parenchymal cholestasis in the perivenular hepatocytes. This is followed by canalicular dilation with bile plug formation. The hepatocytes become hydropic with a reticular rarefaction of the cytoplasm termed "feathery degeneration." The portal tracts reveal edema with loose fibrous tissue around dilated bile ducts. Portal inflammatory reaction includes polymorphonuclear leukocytes (PMNs) and mononuclear cells. An orientation of PMN infiltration around the bile duct, and within the duct lumen, strongly suggests mechanical duct obstruction (Fig. 97.8). Prolonged biliary obstruction results in marked cholangiolar proliferation as well as periductal fibrosis (Figs 97.13 and 97.15). Long-standing obstructions can result in disappearance of the ducts resembling PBC. During the acute stage, drug-induced cholangitic and cholestatic reaction, acute viral hepatitis of cholestatic type, impaired regeneration syndrome, changes due to parenteral hyperalimentation, and septic shock should be considered in the differential diagnosis. Biliary fibrosis and cirrhosis follow if there is continued duct obstruction (Fig. 97.67).

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC)

The diagnosis of PBC based on a needle liver biopsy might be difficult if adequate portal tracts are not present in the specimen. In addition to the classic destructive duct lesions with marked lymphoplasmacytic infiltrates, the presence of granulomas, absence of ducts in small portal tracts, hydropic changes of periportal hepatocytes containing Mallory hyaline and copperbinding protein (Shikata-positive granules), and periportal cholestasis are all helpful morphological features in diagnosing PBC [54]. A staging system of 1–4 has been used by some; briefly, the histological hallmarks of each of these stages are as follows:

- Stage 1: destructive changes of interlobular bile ducts with or without granulomas
- Stage 2: proliferation of atypical ductules mostly along the periportal areas
- Stage 3: absence of interlobular bile ducts in most of the portal tracts and portal-to-portal bridging fibrosis
- Stage 4: cirrhosis.

However, in many patients the biopsies reveal changes overlapping between different stages [55].

Diagnosis of PSC is much more difficult in needle biopsies of liver. A wide range of pathological changes from minimal portal fibrosis and inflammatory reaction, changes of biliary obstruction secondary to extrahepatic sclerosing cholangitis, to typical marked concentric periductal fibrosis with chronic inflammation can be seen [56] (Fig. 97.16). Radiological studies are necessary for definitive diagnosis.

Drug-induced liver diseases

Liver biopsy interpretation should always consider the possibility of drug-induced changes as a differential diagnosis [57]. A careful history of drug intake should be considered prior to final morphological diagnosis.

Parenchymal changes

Parenchymal changes resembling acute viral hepatitis are seen in both isoniazid- and methyldopa-induced hepatic damage (Fig. 97.85). Changes resembling mononucleosis pattern are seen in liver disease induced by diphenylhydantoin, paraaminosalicylic acid, and, occasionally, sulfonamides (Fig. 97.86).

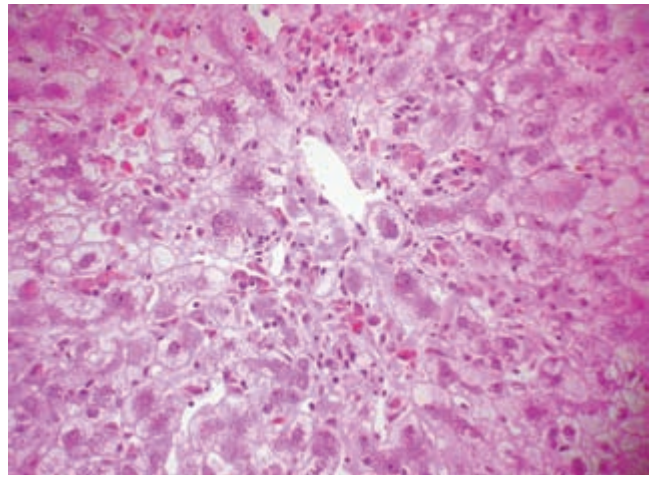

Figure 97.85 Hepatitis-like activity resembling acute viral hepatitis in Aldomet-induced hepatotoxicity. (H & E stain; original magnification × 200.)

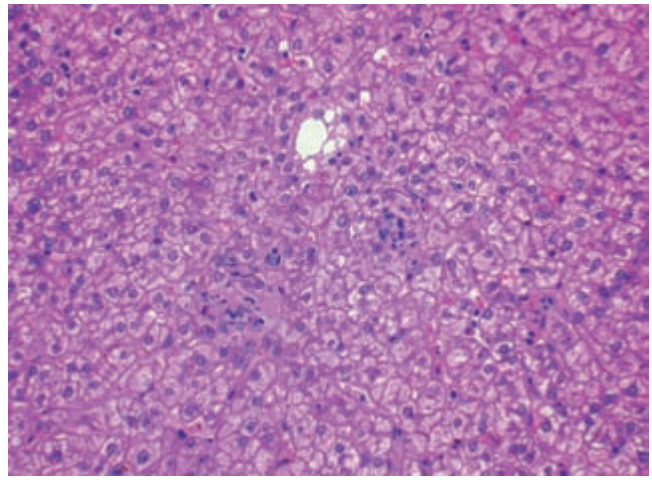

Figure 97.86 Dilantin-induced hepatic changes resembling mononucleosis. (H & E stain; original magnification × 100.)

Coagulative necrosis without much inflammatory reaction is seen in acetaminophen- and halothane-induced damage (Figs 97.29 and 97.30). The necrosis is typically in perivenular and mid-zonal locations. Periportal coagulative necrosis is seen in ferrous sulfate poisoning. Fatty change of a microvesicular type is caused by tetracycline and valproic acid. This is accentuated in zone 3, resembling alcoholic FFC. Macrovesicular fatty change is most commonly seen with corticosteroid and methotrexate use. Carbon tetrachloride and tritetrachlorethylene toxicity results in fatty change as well as liver cell necrosis without inflammatory changes. Hepatocyte necrosis with Mallory body formation can be seen with amiodarone, perhexilene maleate, and with synthetic estrogen preparations used for prostatic carcinoma. Parenchymal cholestasis in zone 3 without inflammation or necrosis can be seen with the use of anabolic steroids and with oral contraceptives. Cholestasis with mild hepatocellular necrosis is associated with total parenteral hyperalimentation, antibiotics such as erythromycin, penicillin, sulfonamides, nitrofurantoin, oral hypoglycemic agents, tranquilizers such as chlorpromazine (Fig. 97.48), antihypertensive agents, captopril, gold therapy, and some antineoplastic agents. Some of these drugs, such as sulfonamides, cause granulomatous necrosis in addition to cholestasis. Rare cases of allopurinol-induced submassive hepatic necrosis have been reported. Morphological patterns of CAH can result from hepatotoxicity from nitrofurantoin, methyldopa, oxyphenisatin, dantrolene, papaverine, and, occasionally, isoniazid. A number of drugs can elicit granulomatous reactions in the liver. Phenylbutazone and sulfonamides cause granulomas resembling sarcoidosis, either portal or parenchymal. Allopurinol, Dilantin, quinidine, nitrofurantoin, methyldopa, Pronestyl, and, rarely, isoniazid can cause a granulomatous reaction, consisting of punched-out areas of hepatocytolysis replaced by hyperplastic Kupffer cells, lymphocytes, and other inflammatory cells in a circumscribed fashion resembling a granuloma. Among the drugs causing hepatocyte inclusions, a ground-glass appearance can be caused by cyanamide, and proliferation of smooth endoplasmic reticulin (SER), resulting in a similar appearance, by phenobarbital, chlorpromazine, and Dilantin [58].

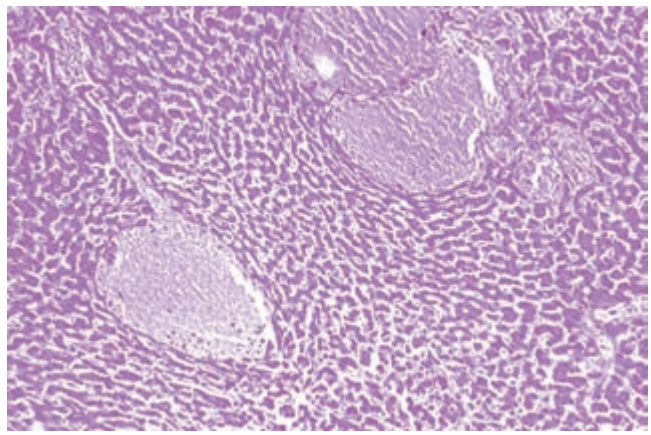

Figure 97.87 Peliosis hepatis with blood-filled spaces without endothelial lining. (H & E stain; original magnification × 100.)

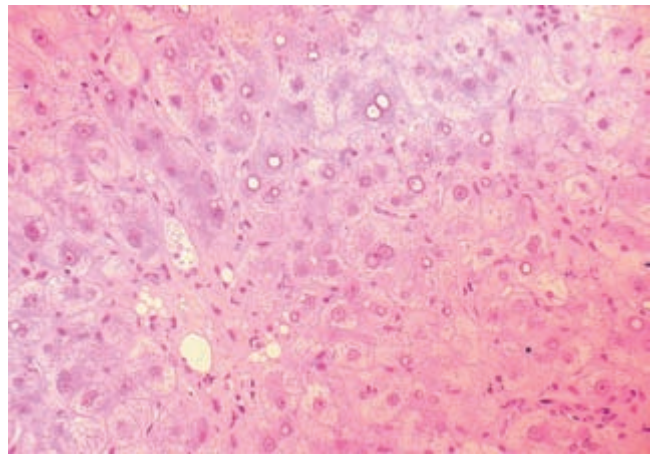

Figure 97.88 Sinusoidal fibrosis and nuclear dysplastic changes in methotrexate toxicity. (H & E stain; original magnification × 400.)

Portal tract changes

Oral hypoglycemic agents and tranquilizers mentioned previously, as well as allopurinol, can cause variable degrees of portal inflammation and bile duct epithelial abnormalities, resembling mechanical duct obstruction or PBC. Dilantin toxicity results in a mononucleosis pattern along with a portal inflammatory reaction with a predominance of eosinophils (Fig. 97.9). Allopurinol causes portal eosinophilia with a cholangitic reaction.

Vascular changes

These include sinusoidal dilation following administration of oral contraceptive agents or anabolic steroids, and in azathroprine therapy, and peliosis hepatis seen in anabolic steroid and methyl testosterone treatment (Fig. 97.87). Venous outflow occlusion with its hepatic morphological changes can be seen as follows: perivenular sclerosis with sinusoidal collagenosis resembling alcohol is associated with hypervitaminosis A, methotrexate (Fig. 97.88), azathioprine, and certain antineoplastic drugs, such as mitomycin C. Venoocclusive disease with coagulative necrosis and severe congestion in zone 3 is seen in toxicity due to bush tea containing pyrrolizidine alkaloids, as well as toxicity resulting from 6-thioguanine and azathioprine. Hepatic vein thrombosis leading to Budd–Chiari syndrome has been associated with prolonged use of oral contraceptives (Fig. 97.25).

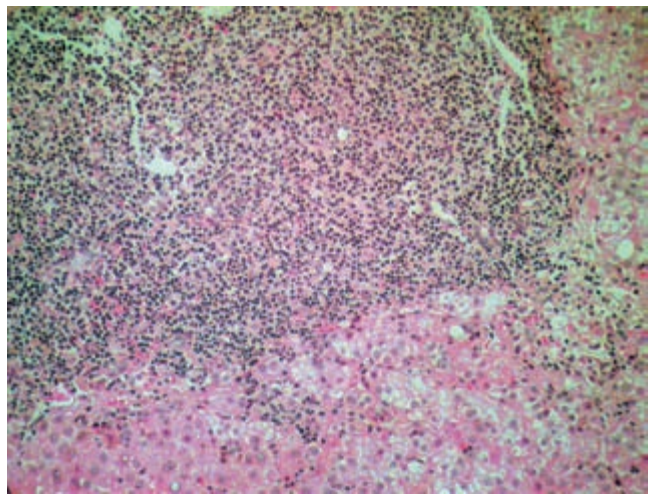

Figure 97.89 Portal infiltrate in non-Hodgkin lymphoma. (H & E stain; original magnification × 100.)

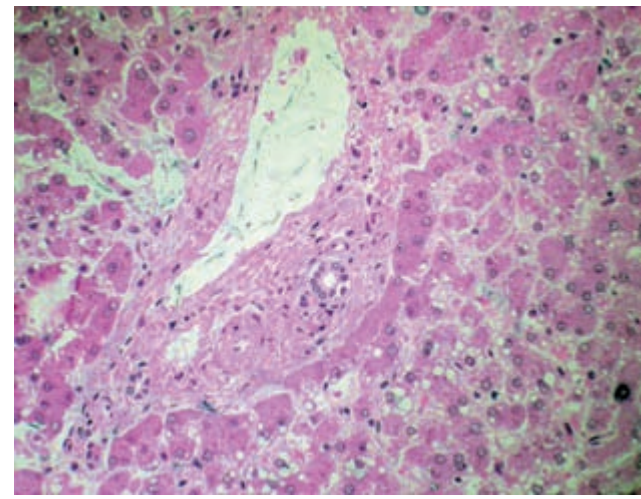

Figure 97.91 Portal area with lymphopenia in a patient with AIDS. (H & E stain; original magnification × 200.)

Liver biopsy changes in systemic diseases

Hematopoietic system

Lymphomas with hepatic involvement reveal monomorphic portal infiltrates of neoplastic lymphocytes (Fig. 97.89). Bile ducts and parenchymal cells are not involved. However, in Hodgkin disease, the portal infiltrate, including atypical or typical Reed–Sternberg cells, seems to produce destructive lesions of bile ducts (Fig. 97.90). In addition, epithelioid granulomas of a nonneoplastic nature are seen in both portal and lobular zones. Cholestasis can also be a prominent feature in Hodgkin disease. Liver biopsies in leukemias reveal immature neoplastic white cells in the sinusoidal spaces as well as in the portal zones (Fig. 97.45). Hairy-cell leukemia exhibits typical leukemic cells in the sinusoidal spaces as well as infiltrating the parenchyma. Sickle-cell disease can be diagnosed by identifying clumped red cells as well as sickled cells in the sinusoidal spaces (Fig. 97.47). Disseminated intravascular coagulation manifests as fibrin thrombi within the sinusoidal spaces.

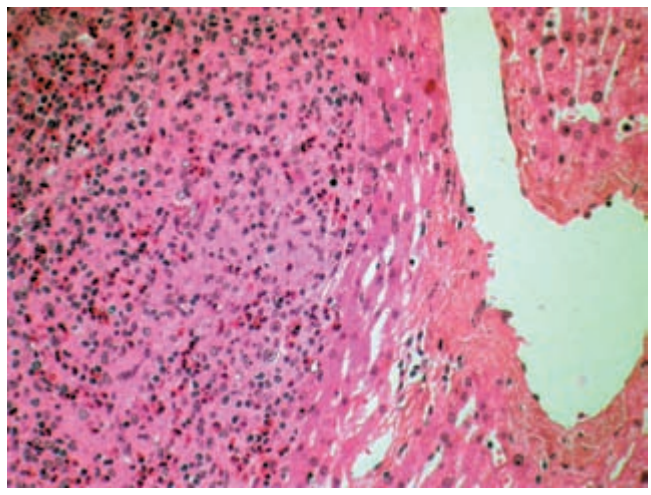

Figure 97.90 Portal infiltrate in Hodgkin lymphoma with an atypical Reed–Sternberg cell. (H & E stain; original magnification × 200.)

Acquired immunodeficiency syndrome (AIDS)

Liver biopsies in patients with AIDS should be examined for evidence of opportunistic infections commonly seen in these patients. In general, the portal areas are relatively lymphopenic, in spite of the inflammatory processes in the liver [59] (Fig. 97.91). *Mycobacterium avium–intracellulare* (MAI) infection in these patients typically results in numerous clusters of bloated Kupffer cells, appearing foamy and containing numerous acid-fast stainable organisms (Fig. 97.63). No true granulomas are seen. Similarly, fungal infections such as cryptococcosis reveal a lack of granuloma formation in the presence of organisms identified by special stains and cultures. Viral inclusion bodies of CMV and herpes simplex involving either the reticuloendothelial cells or duct epithelium cells, or parenchymal cells can be seen. Cryptosporidiosis involving the biliary system can be identified by examining the lumenal surface of the duct epithelial cells using special stain such as Giemsa (Fig. 97.92). Sclerosing cholangitis identified in patients with AIDS has been described as a sequela of CMV and cryptosporidiosis of the biliary system [60]. In patients with Kaposi sarcoma elsewhere in the body, liver biopsy can also exhibit the presence of the tumor [61] (Fig. 97.93). Because these patients are on a number of drugs on a long-term basis, hepatotoxic changes due to the drugs should also be considered in the differential diagnosis.

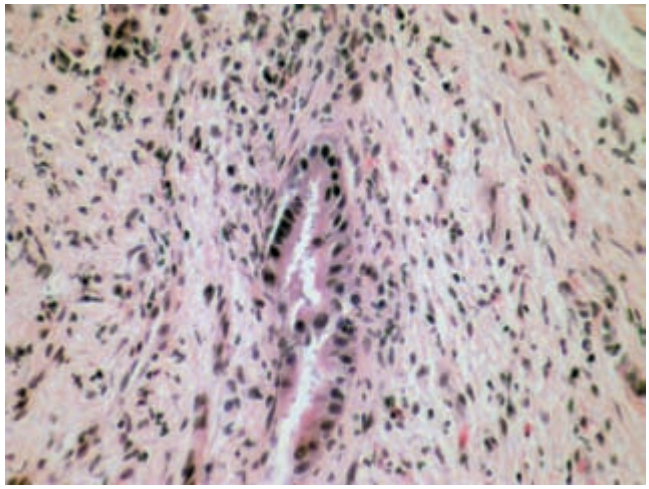

Figure 97.92 Bile duct epithelium along the lumenal surface demonstrates the presence of cryptosporidiosis, which are 3–4-μm size. (H & E stain; original magnification × 400.)

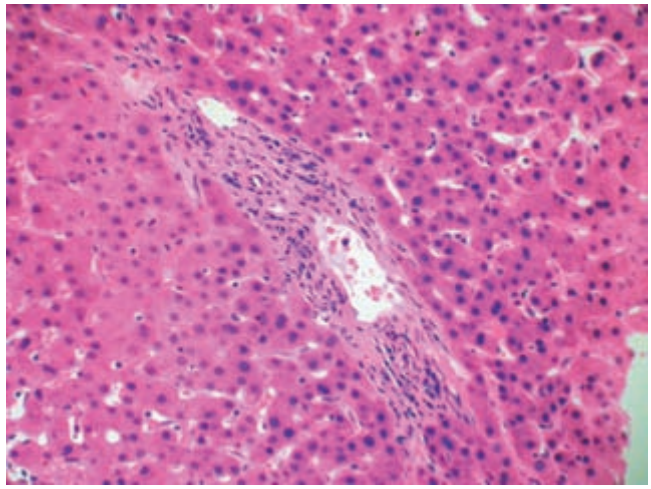

Figure 97.95 Portal inflammatory infiltrate with loss of bile ducts in chronic rejection. (H & E stain; original magnification × 200.)

Pathology of transplantation

Allograft rejection

Acute rejection is a common event seen in varying degrees in 70% of allografts. The histological characteristics, as described by Snover and colleagues [62], include portal inflammatory infiltration, inflammation and destructive changes of interlobular bile ducts, and endothelialitis involving hepatic and portal venous structures (Fig. 97.94). Portal inflammation consists of activated lymphocytes or "immunoblasts," neutrophils, and eosinophils. These cells are seen infiltrating the epithelial cells of interlobular bile ducts. In addition, the duct epithelium reveals pyknosis of the nuclei, hydropic changes, and disruption of basement membrane. Endothelialitis is exhibited as lymphocytes attached to the venous endothelium and infiltrating through the subendothelium. The hallmark of chronic rejection consists of progressive destruction and eventual loss of bile ducts [63] (Fig. 97.95). In addition, there is perivenular cholestasis and multifocal hepatocytolysis. There is also evidence of obliterative vascular lesions involving hepatic arteries and arterioles. Chronic rejection is less common than acute rejection and occurs in about 4% of graft recipients.

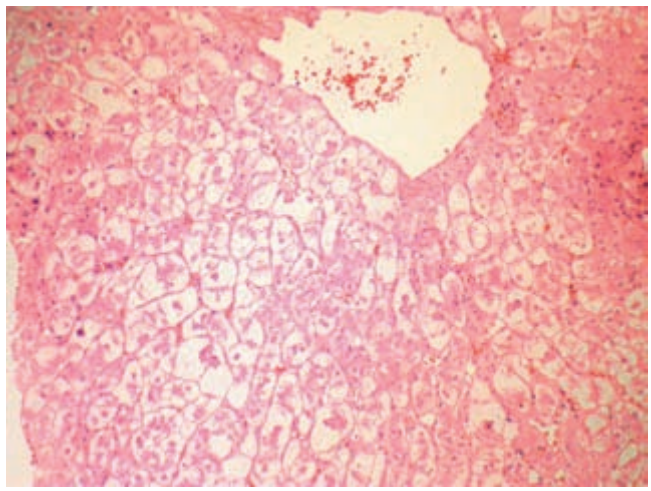

Figure 97.96 Marked ballooning of the hepatocytes in acinar zone 3 representing harvest injury. (H & E stain; original magnification × 100.)

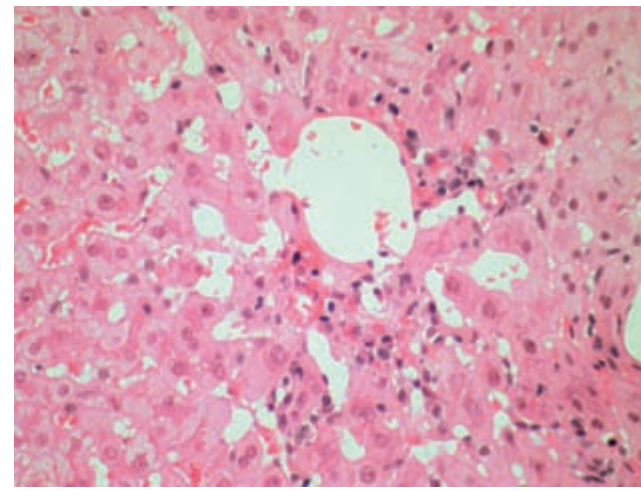

Figure 97.97 Perivenular zone with necroinflammatory changes in recurrent acute hepatitis B infection of allograft. (H & E stain; original magnification × 200.)

Harvest or preservation injury

In the majority (54%) of orthotopic hepatic grafts, there is marked ballooning of the hepatocytes in acinar zone 3 (Fig. 97.96). This usually occurs in the first 2 weeks and in some patients as early as 48 h. This is often associated with cholestasis and high serum alanine aminotransferase (ALT) levels. Ischemia is considered one of the pathogenetic factors. Ballooning without associated necrosis has a better prognosis and is not a sign of graft rejection. Among the other features included under preservation injury are microvesicular fatty change and mild acidophilic degeneration of the hepatocytes.

Cytomegalovirus hepatitis

Cytomegalovirus hepatitis in allografts is often associated with parenchymal microabscesses, seen as small aggregates of neutrophils in the hepatic lobule. Infected cells have large eosinophilic intranuclear inclusions. Immunoperoxidase stains demonstrate these inclusions clearly.

Recurrent hepatitis B in allograft

Liver allograft recipients who had chronic hepatitis B with cirrhosis invariably develop recurrence of hepatitis B infection of the graft. The recurrence usually develops after more than 3 months but can occur earlier in association with an accelerated course. The recurrent HBV infection is similar to that seen in non-liver-graft patients. The acute process consists of lobular disarray and ballooning hepatocytes with necroinflammatory changes (Fig. 97.97). Portal areas reveal inflammatory hyperplasia without any evidence of bile duct epithelial changes or vascular endothelial damage. At this early stage, HBcAg is demonstrable in the hepatocytes by immunoperoxidase stains. Although the acute events can be self-limited, viral infection is never cleared and invariably leads to chronic infection, with progressive increase in the expression of viral antigens in the liver. A unique variant of recurrent hepatitis in the allograft is termed *fibrosing cholestatic hepatitis* [64]. The characteristic pathological changes include periportal fibrosis with thin strands of pericellular collagen, cholestasis, and ballooning of hepatocytes with apoptotic necrosis. There is an abundance of HBsAg and HBcAg demonstrable in hepatocytes. Lymphocytic infiltrates are minimal. This morphology has been associated with a poor outcome. Chronic hepatitis and cirrhosis are the eventual outcomes.

Recurrent hepatitis C

Reinfection of allografts is universal but the disease progression varies widely. Acute changes can be seen as early as 80–90 days posttransplant. They include sinusoidal lymphocytosis, acidophilic bodies, and lobular disarray. Portal lymphoid aggregates, progressive fibrosis, and changes similar to chronic HCV in the non-transplant setting are seen in later stages. A small percentage (2%–10%) of patients with recurrent HCV develop severe fibrosing cholestatic hepatitis similar to that seen in recurrent HBV [65].

Graft-versus-host disease

Graft-versus-host disease is seen in association with bone marrow transplantation and less often with other solid organ transplantation [66]. In the acute stage, there is evidence of hepatocellular necrosis and endothelialitis. In chronic stages, there is extensive bile duct damage and the interlobular bile duct epithelium shows cytoplasmic vacuolization, nuclear hyperchromasia, and atypia. Destructive bile duct changes resemble PBC.

Embryology of the abdominal cavity

Abdominal cavity

Knowledge of the embryology of the abdominal contents is imperative to understanding the pathophysiology of the various congenital and structural anomalies of the abdominal cavity. The abdominal or peritoneal cavity is formed from a large intraembryonic coelomic cavity during the fourth week of embryonic development. The cells of the somatic mesoderm lining the intraembryonic coelomic cavity become mesothelial and form the parietal layer of the serous membranes lining the outside of the peritoneal, pleural, and pericardial cavities. In a similar manner, the cells of the splanchnic mesoderm layer form the visceral layer of the serous membranes covering the abdominal organs, lungs, and heart [1]. During the fifth to seventh weeks of development, the pleuroperitoneal folds fuse with the septum transversum, and the mesentery of the esophagus thus separates the thoracic cavity from the abdominal cavity. In the cephalic and caudal parts of the embryo, the primitive gut (an endodermal-lined cavity) forms a blind-ending tube, the foregut and the hindgut, respectively. The middle part, the midgut, remains temporarily connected to the yolk sac by means of the vitelline duct or yolk stalk. The upper gastrointestinal tract develops from the foregut and includes the esophagus, stomach, duodenum, liver, gallbladder, and pancreas. The midgut develops into the small bowel and the right and transverse colons. Development of the hindgut forms the left colon, sigmoid, rectum, and the upper part of the anal canal.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Development of the foregut, midgut, and hindgut

During embryonic development, the foregut rotates 90° clockwise around its longitudinal axis, causing the left side of the stomach to face anteriorly and its right side posteriorly (Fig. 98.1). The foregut blood supply is the celiac artery.

The development of the midgut is characterized by rapid elongation of the gut and its mesentery, resulting in the formation of the primary intestinal loop. Over its entire length, the midgut is supplied by the superior mesenteric artery. As a result of this rapid elongation and the simultaneous expansion of the liver, the abdominal cavity of the fetus becomes too small to contain all the intestinal loops. These loops enter the extraembryonic coelomic cavity in the umbilical cord, forming a physiological umbilical herniation during the sixth week of development (Fig. 98.2). Coincident with this rapid growth, the midgut rotates 270° counterclockwise around the axis of the superior mesenteric artery. At about the third month, the herniated intestinal loops return to the abdominal cavity. The proximal portion of the jejunum is the first part to reenter, and it comes to lie on the left side, whereas the primitive cecum is the last to reenter and descends into the right iliac fossa.

The hindgut gives rise to colon and rectum past the distal third of the transverse colon as well as the upper part of the anal canal. The junction of the endodermal and ectodermal parts of the anal canal is formed by the pectinate line, which is found just below the anal columns. The endoderm of the hindgut also gives rise to the internal lining of the bladder and urethra. The hindgut blood supply is the inferior mesenteric artery.

Mesenteries of the abdominal cavity

During the development of the peritoneal cavity, the splanchnic mesoderm covers the developing gut. Eventually, most of this ventral mesentery is resorbed, except for a small portion between the liver and the stomach that persists as the

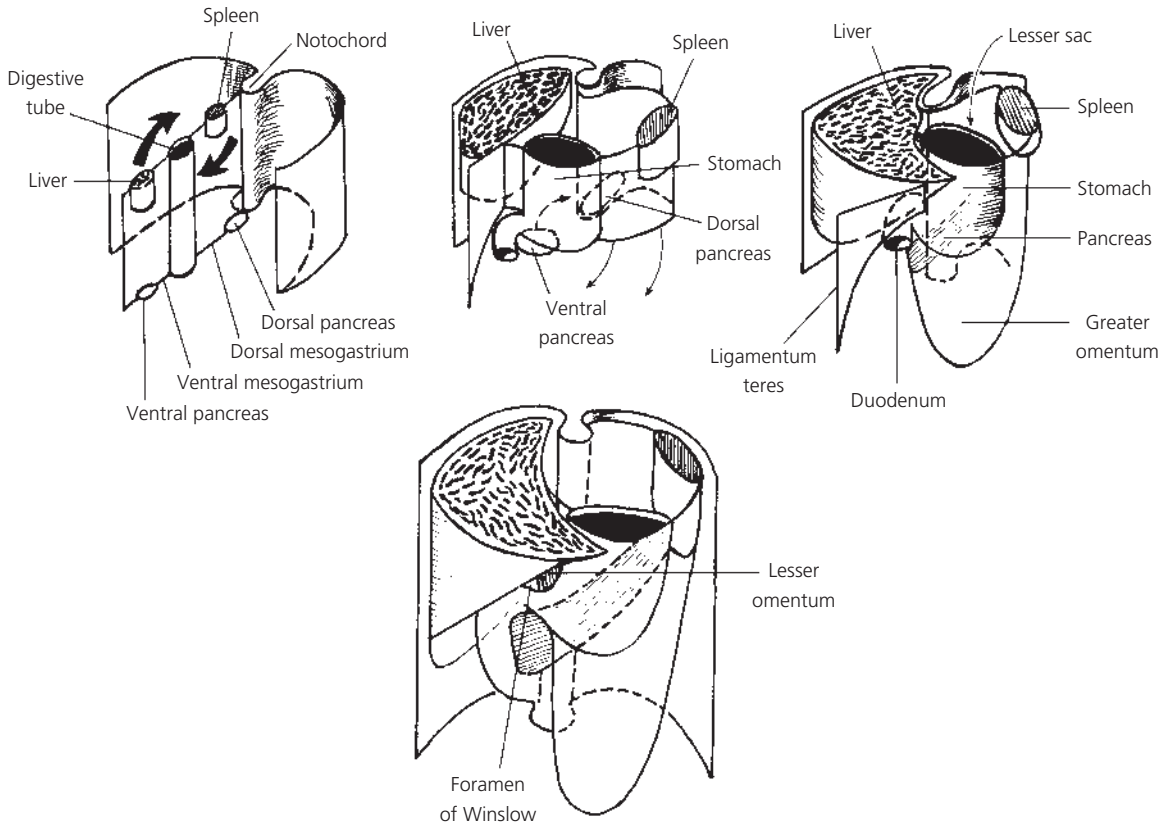

Figure 98.1 Embryonic development of the foregut. The organs of the upper gastrointestinal tract rotate 90° clockwise (when viewed from above) in a transverse plane. Originally, ventral structures like the liver and ventral pancreas are situated to the right, and posterior organs such as the spleen and dorsal pancreas and the dorsal aspect of the future stomach are positioned to the left side of the abdominal cavity. The dorsal mesogastrium elongates and folds to the left to form the greater omentum.

gastrohepatic ligament (or lesser omentum) (see Fig. 98.1), and the ligaments of the liver, i.e., the coronary, falciform, and teres. The dorsal mesogastrium remains and changes in position and size; the spleen is positioned to the left, the pancreas is situated posteriorly, and the space within the mesogastrial fold becomes the lesser sac. The dorsal mesogastrium enlarges, forming the greater omentum, which drapes anteriorly. As the midgut elongates during development, the dorsal mesodermic attachment elongates as well and forms the mesentery. The right colon adheres to the posterolateral abdominal wall and becomes retroperitoneal; the rest of the midgut is intraperitoneal.

Anatomy of the abdominal cavity

The abdominal cavity in the adult is defined by the diaphragm superiorly, the abdominal walls laterally, and the pelvis inferiorly. The peritoneal covering is the endodermal investment of the surface of the organs of the abdominal cavity. The pancreas, parts of the duodenum, right and left colon, and the rectum, being retroperitoneal, are only covered anteriorly by peritoneum. The organs are supported by thickened bands of peritoneum: the gastrohepatic, gastrosplenic, splenorenal, and splenocolic ligaments. The liver is suspended from the diaphragm also by the falciform and coronary ligaments and is joined to the abdominal wall by the ligamentum teres that contains the remnant of the umbilical vein.

The abdominal cavity has three compartments: lesser sac, supramesocolic, and inframesocolic. The lesser sac is limited by the stomach and gastrocolic ligaments anteriorly; by the spleen, splenorenal, and gastrosplenic ligaments on the left side; and by the pancreas and duodenum posteriorly (see Fig. 98.1). The lesser sac communicates with the rest of the abdominal cavity through the foramen of Winslow. The boundaries of the foramen are the liver superiorly, hepatic pedicle anteriorly, duodenum and pancreas inferiorly, and the retroperitoneum posteriorly.

The supramesocolic compartment lies cephalad to the transverse mesocolon and contains the duodenum, pancreas, liver, spleen, and lesser sac. The inframesocolic compartment contains the small intestine, colon, and suspensory ligaments of the spleen and liver. The area between the colon and the inferior margin of the liver is called the Morison pouch and

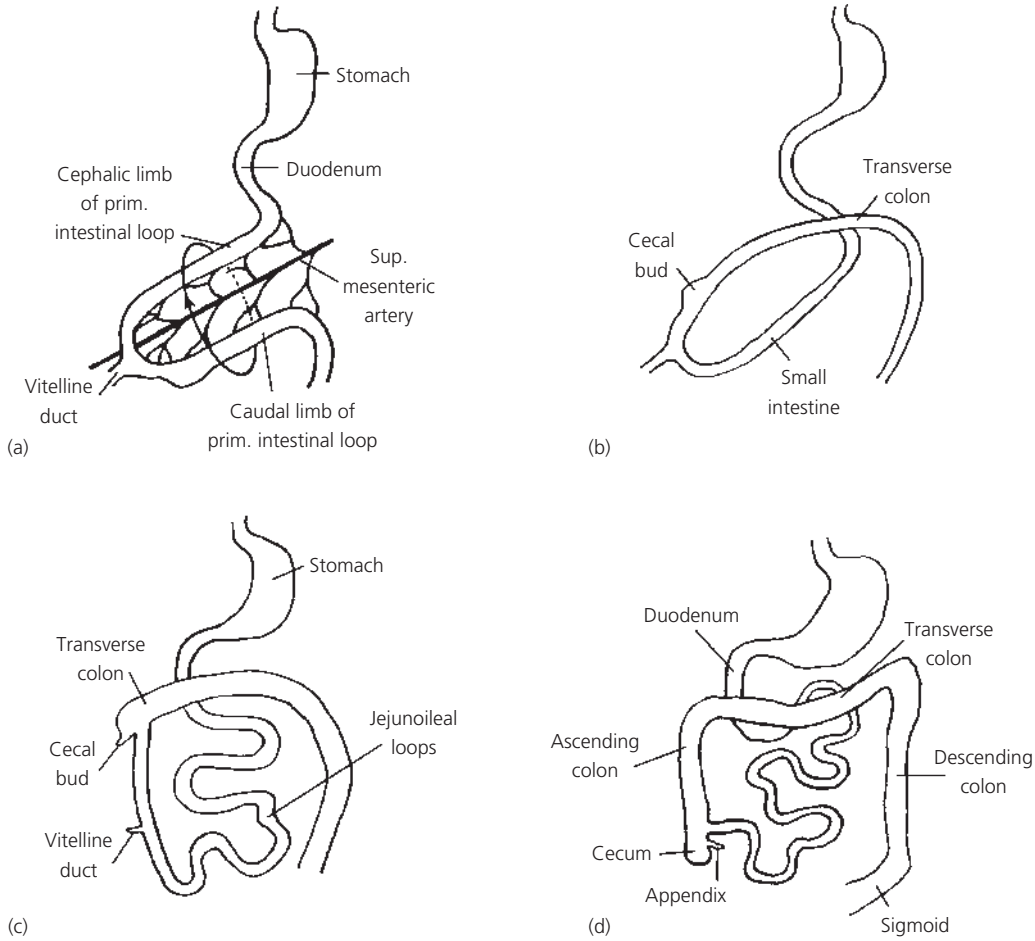

Figure 98.2 Embryonic development of the midgut. **(a)** Schematic drawing of the primary intestinal loop before rotation (lateral view). The superior mesenteric artery forms the axis of the loop, and the arrow indicates the counterclockwise rotation around this axis. **(b)** Similar views as in **(a)** showing the primary intestinal loop after 180° counterclockwise rotation. The transverse colon is shown as passing in front of the duodenum. **(c)** Anterior view of the intestinal loop after the 270° counterclockwise rotation. Note the cecal bud in the right upper quadrant. **(d)** Similar views as in **(a)** with the intestinal loops in the final position. Cecum and appendix are now in the right lower quadrant. Adapted from Sadler [1].

acts as a potential space for fluid accumulation. In addition, fluid can accumulate along the pouches created by the right and left parietocolic peritoneal coverings.

The inferior limit of the peritoneum covers the pelvic urogenital organs and the inguinal region. Most inferiorly is the pouch of Douglas, a peritoneally covered pouch between the rectum and uterus in females and the rectum and bladder in males.

The anatomy of the inguinal region (the groin) is complex and is discussed in the section Groin hernias.

Congenital anomalies

In the embryo, the abdominal cavity is too small to accommodate the intestines, and a physiological herniation occurs into the umbilical cord with return of the intestines to the abdominal cavity by the 10th week. *Omphalocele* (Fig. 98.3a) is failure in the growth of the coelomic walls with a large herniation of the abdominal viscera into the base of the umbilical cord. The herniated viscera are covered by a sac composed of amnion. The incidence of omphalocele is estimated to be 1 in 6000 to 1 in 10 000 live births. *Gastroschisis* (Fig. 98.3b) is a similar anomaly, but the defect in the abdominal wall is located lateral to the umbilicus and is caused by failure of closure of the abdominal wall. No sac is present to cover the herniated intestines, and the size of the defect is often smaller. In gastroschisis, the intestines can be inflamed and thickened, and the mesentery may be foreshortened. The incidence of gastroschisis is 1 in 3200 to 1 in 10 000 births, with some male predominance; associated congenital anomalies include incomplete rotation and fixation of the midgut in 40% of cases.

(a) (b)

Figure 98.3 (a) Omphalocele with large herniation of the abdominal viscera. Note the amnionic sac covering the viscera. **(b)** Gastroschisis with defect lateral to the umbilicus. Note that the herniated intestines are engorged and discolored and that no sac is present.

At least 50% of infants with omphalocele have associated anomalies of the skeleton, gastrointestinal tract, or nervous or genitourinary system [2]. Ultrasound can detect these defects prenatally, and vaginal delivery is safe for all newborns except those with the biggest omphaloceles, which may contain liver [3]. Both conditions are surgical emergencies of the newborn. The airway should be managed first, and a nasogastric sump tube should be placed to prevent intestinal distention. If present, the sac is painted with antiseptic solutions, and the herniated contents are kept moist and covered with warm, moistened, saline-soaked gauze and plastic to prevent dehydration and desiccation. Alternatively, the entire lower torso can be covered by a plastic intestinal bag. Once stable, an operation is needed to reduce the herniated viscera and perform a fascial closure. If necessary, the viscera are wrapped in a sheet of silicone (Silastic chimney) that is sutured to the abdominal wall, allowing time for growth of the abdominal wall and eventual reduction of the herniation.

Remnants of the omphalomesenteric (vitelline) duct may present as abnormalities related to the abdominal wall or remain asymptomatic for long periods. An *umbilical sinus* results from the continued presence of the umbilical end of the duct and can result in persistent drainage and infection at the umbilicus. Persistence of the entire duct is heralded by passage of enteric contents from the umbilicus, and excisional treatment avoids complications of intussusception or volvulus. Cystic remnants should be excised if seen at operation or if presenting as an infection at the umbilicus. *Meckel diverticulum* results when the intestinal end of the vitelline duct persists. This is a true diverticulum, composed of all layers of the intestinal wall.

Congenital diaphragmatic hernias

The diaphragm appears in the third week of development as a septum transversum that separates the thorax from the abdomen. The diaphragm is derived from the following structures: the septum transversum, which forms the tendinous part of the diaphragm; the pleuroperitoneal membranes; the muscular components from the lateral and dorsal body walls; and the mesentery of the esophagus, which forms the crura of the diaphragm (Fig. 98.4a). A diaphragmatic hernia is one of the more common malformations of the newborn (1 in 2200) and is most frequently caused by failure of the pleuroperitoneal membranes to separate completely the peritoneal and pleural cavities posteriorly [4].

Posterolateral hernia (hernia of Bochdalek) is usually large and on the left side; the intestinal loops, stomach, spleen, and part of the liver may enter the thoracic cavity (Fig. 98.4). The presence of abdominal viscera in the chest results in compression of the heart and hypoplasia of the lung. Animal models have shown that long-term compression of the lung leads to abnormal development of the lung and the pulmonary vascular bed [5]. The neonate presents with acute respiratory distress; the heart, mediastinum, and lungs are displaced to the right, and the abdomen may be scaphoid. Respiratory sounds are absent on the affected side, and heart sounds may be audible in the right chest. The diagnosis is easily made with a chest radiograph showing one or more air–fluid levels in the left thorax, displacement of the mediastinum, and loss of the sharp diaphragmatic line separating the thorax and abdomen (Fig. 98.4b). Radiological studies with water-soluble contrast show the intraabdominal contents in the left chest. Lung hypoplasia results in acute respiratory distress and is the main cause of death in these patients. Bowel obstruction, strangulation, and other gastrointestinal malformations can result in other complications. Mortality depends on the age of the patient, associated malformations, and most importantly the degree of lung hypoplasia. Mortality rates are as high as 50% in those infants requiring emergency operations during the first week of life but decrease to 10% in infants with a higher degree of lung maturity. Extracorporeal membrane oxygenation is

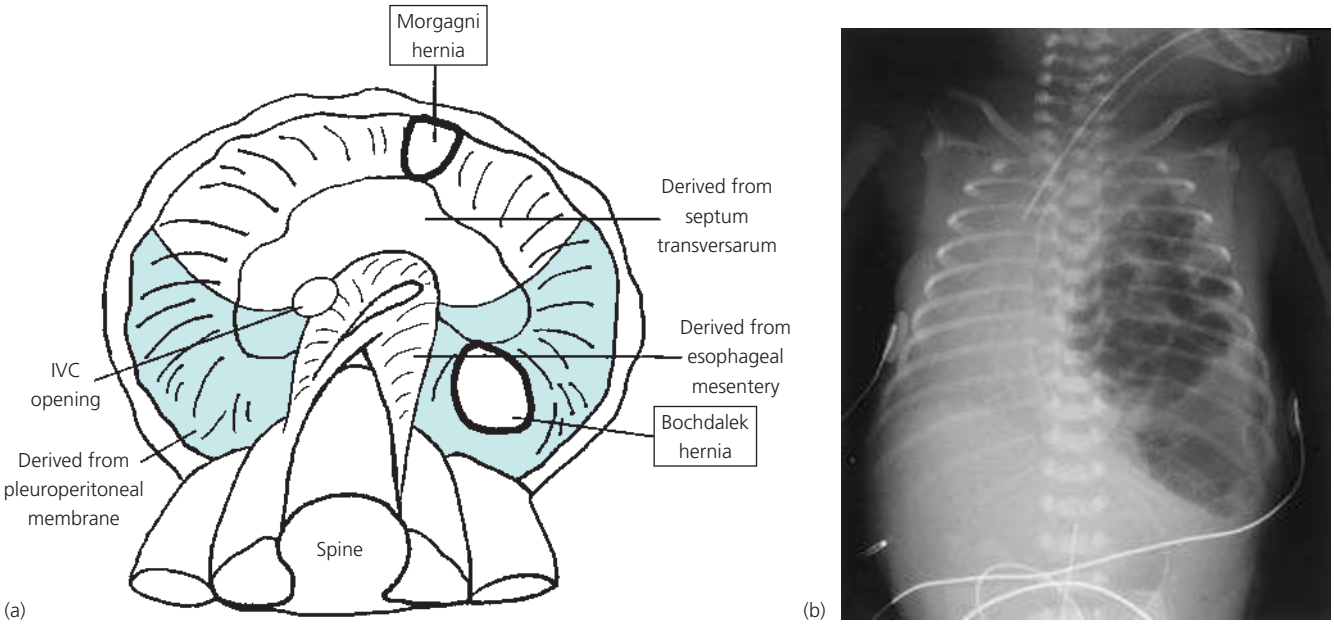

Figure 98.4 Development of the diaphragm and congenital diaphragmatic hernia. **(a)** Abdominal surface of the diaphragm and the derivation of the components during development. The pleuroperitoneal membranes, the septum transversum, and the esophageal mesentery form the diaphragm. A Bochdalek hernia forms when there is a posterolateral defect. Morgagni hernias are less common and are present anteriorly. **(b)** Chest radiograph of a child with a congenital posterolateral (Bochdalek) diaphragmatic hernia on the left. The mediastinum is displaced to the right by the intestinal loops present in the left chest.

used in some instances to support the maturing lungs before and after repair of the hernia [6].

Occasionally, a small part of the muscular fibers of the diaphragm fails to develop, and a hernia may remain undiscovered until later in life. Such a defect is seen in the anterior portion of the diaphragm and is known as a *parasternal hernia* (hernia of Morgagni; see Fig. 98.4a). These hernias are usually small and can contain stomach, omentum, colon, or small intestine with a peritoneal covering.

Umbilical hernias of childhood

Herniation of intraabdominal viscera through the umbilicus is an *umbilical hernia*. A congenital defect in the umbilical ring during development of the abdominal wall results in this hernia. Congenital umbilical hernias are more common in black and male infants, most not reaching maximal size until the infant is 1 month of age. The younger the neonate, the more common this congenital deformity, reaching 20% in premature infants. Predisposing conditions include Down syndrome, gargoylism, amaurotic familial idiocy, cretinism, Beckwith–Wiedemann syndrome, and diseases that increase intraabdominal pressure. This type of hernia has a high propensity to reduce and heal spontaneously, so that repair is generally not indicated in children younger than 3 years of age [7]. Large or symptomatic hernias, especially with incarceration or strangulation, require immediate attention.

Hernias of the abdominal cavity in adults

> Hernia is a protrusion of any viscus from its proper cavity (Sir Astley Cooper, 1804).

Hernias are composed of a herniated viscus, the hernia sac, and the opening of the hernia (the hernial ring) (Fig. 98.5). The hernial sac is the internal wall of the hernia lined by peritoneum. An external hernia comprises a viscus abnormally located outside the abdomen; an internal hernia is when the viscus is abnormally located within the intraabdominal space. Any viscus can become part of a hernia, but most commonly a segment of intestine is partially or completely herniated.

A *Richter hernia* occurs when only a portion of the wall of the herniated bowel is included in the hernia (Fig. 98.5). Such a hernia is unique in that it can strangulate without causing complete small bowel obstruction. Herniation of two adjacent loops through the same hernial opening is called a *Maydl hernia* (Fig. 98.5). This kind of hernia is dangerous because the closed loop may perforate, leading to peritonitis. A *sliding hernia* is when a partially retroperitoneal structure (such as colon) is part of the wall of the hernial sac (Fig. 98.5). The symptoms of hernias depend on a number of factors, such as the exact viscus that is herniating, the location of the herniated bowel (i.e., jejunum or ileum), and whether there is a full or partial strangulation. When omentum alone is strangulated within a hernia, obstruction of the gut does not occur.

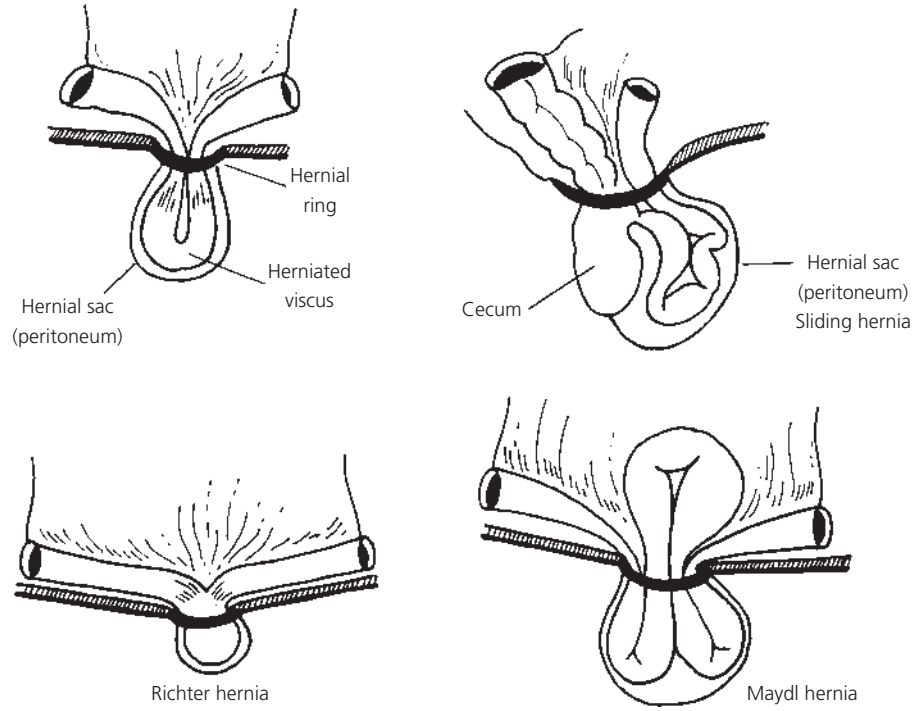

Figure 98.5 Different types of intestinal hernias.

A *reducible hernia* occurs when the hernial sac contents return to the abdominal cavity spontaneously or with external manipulation. The major complications of hernias are incarceration, bowel obstruction, and bowel strangulation. A complication is more likely to occur if the hernial opening is small and in hernias in which the bowel has access to the sac. Bowel incarceration greatly increases the chance that strangulation will occur. An *incarcerated hernia* occurs when the hernial contents cannot be dislodged from the sac. Incarceration occurs when there are adhesions from the hernial contents or around the opening of the hernia, making reduction impossible, or when there is edema or contortion of the hernial contents such that hernial contents once entered into the sac cannot exit. A hernia, reducible or incarcerated, becomes a *strangulated hernia* when the blood supply to the herniated viscus is compromised.

Epidemiology

Hernias are common occurrences; 5% of people have a spontaneous abdominal hernia during their lifetime. Many people also develop secondary hernias, most frequently at the site of a previous incision or injury to the abdominal wall. Hernia is the most common cause of intestinal obstruction worldwide, and in the USA it is the third most common cause. In surgical practice, 10%–15% of all procedures are related to hernias. Of all hernias, 90% are incisional, umbilical, or inguinal hernias. Groin hernias account for 85% of all hernias (Table 98.1). Indirect inguinal hernias are the most common, followed by direct inguinal hernias. Incisional hernias develop in 3%–5% of all abdominal operations and represent 7% of abdominal wall hernias. Internal hernias are uncommon and have been seen in 0.5% of autopsies.

There is a male to female prevalence in inguinal hernias of about 7 : 1, whereas there is a female dominance in femoral, umbilical, and incisional hernias of about 2 : 1. Although femoral hernias are seen more commonly in females, the most common hernia in women still remains an indirect inguinal hernia.

Pathophysiology

Our understanding of the pathophysiology of inguinal hernias has changed over the years. In the past, indirect hernias were attributed at least in part to a patent processus vaginalis, which is present in many infants and up to 25% of young children. However, more recent studies have shown the inguinal ring and any patent processus vaginalis to close with a valve-like effect because of tension on the abdominal wall musculature when there is increased intraabdominal pressure [8]. In cases of indirect inguinal hernia, this valve-like effect may become ineffective, allowing a viscus to enter the patent processus vaginalis [9]. Chronic injury in the form of traumatic overstretching of muscles and aponeurotic structures undoubtedly contributes to hernia formation, although rigorous scientific studies have not been performed. Clinicians often see the onset of herniation related to such activities as extreme athletics or conditions associated with increased intraabdominal pressure such as pregnancy, chronic cough, chronic obstructive pulmonary disease, obstructive uropathy, massive ascites, or obstipation from colorectal cancer.

In cases of incisional hernias, infection or tension during the wound healing or scar remodeling phase can lead to weakened musculoaponeurotic tissue, which in turn leads to herniation at a later date. Some studies have shown altered collagen formation and breakdown in tissue samples from the inguinal floor of patients with hernias [10].

Diagnostic considerations

Most abdominal wall hernias are detected using history and physical examination. The patient needs to be questioned regarding the presence of a bulge, conditions that make the bulge appear and disappear, and any associated pain or gastrointestinal symptoms. History of any previous hernias, abdominal wall incisions, or a family history of any connective tissue disorder such as Marfan syndrome should be sought. A review of systems to include any of the above-mentioned causes of intraabdominal pressure should be obtained because failure to recognize these factors will increase the chance for recurrence if repair is undertaken. A complete physical examination of the abdomen and rectum should be done, including a prostate examination and testing of the stool for occult blood. All scars should be noted. The examination is best initiated with the patient in the standing position because gravity tends to pull the intraabdominal contents into hernias. If no bulge is obvious, a Valsalva maneuver is used to increase intraabdominal pressure. If a bulge is seen, a gentle attempt to reduce the hernia can be made with the patient standing or in the recumbent position. Examination of the area in the recumbent position often allows better palpation of the hernial defect and opening.

Radiographic studies are rarely needed but may be useful in cases in which the abdominal wall fat layer prevents accurate diagnosis. Ultrasound is rarely helpful, but in some cases it can delineate the abdominal wall musculature and note the presence of air or peristalsing bowel. Computed tomography (CT) is good at detecting abdominal and pelvic defects; use of the Valsalva maneuver may sometimes be helpful during imaging [9,11].

Specific types of hernia

Epigastric hernias

Epigastric hernias occur in the midline of the abdominal wall between the umbilicus and the xiphoid in 5% of the population (males more than females). Most epigastric hernias are asymptomatic. An area of congenital weakness in the linea alba allows protrusion of bowel, omentum, or just preperitoneal fat. Symptoms range from a small painless nodule below the xiphoid to epigastric pain with exertion or rarely small bowel obstruction. Diagnosis is easy if the hernia is large but can be difficult if there is a small hernia in an obese patient. Tenderness while palpating the linea alba with elevation of the head can sometimes be produced in small hernial protrusions. These hernias should be surgically repaired. About 20% of patients have multiple hernial defects in other locations along the linea alba [12] and this should be taken into consideration at the time of repair.

Umbilical hernias

Umbilical hernias in adults often occur in obese people, multiparous women, and patients with ascites. The diagnosis is usually self-evident with a protuberant mass at the umbilicus. Incarceration of omentum or small bowel is common, and up to 30% of cases present with strangulation of bowel. Of patients with ascites and end-stage liver disease, 40% have umbilical hernias. In this setting, ulceration and perforation of the hernia can lead to peritonitis with a high mortality rate [13]. Discoloration or ulceration of overlying skin heralds imminent rupture. Umbilical hernias in adults generally need surgical repair. Small defects can be repaired primarily if there is no tension; defects larger than 3 cm should be repaired with prosthetic mesh or by using some other method to ensure tension-free repair (e.g., release of the lateral fascial attachments). Patients with ascites should have their ascites controlled before repair, otherwise the repair will likely fail. In some cases of refractory ascites, portacaval shunt or transjugular intrahepatic portacaval shunt allows successful surgical herniorrhaphy after the ascites has disappeared. Alternatively, concomitant peritoneovenous shunt and herniorrhaphy should be considered to prevent breakdown of the repair [14]. Liver transplantation is another alternative in the appropriate candidate.

Groin hernias

Hernias of the groin are the most common of all hernias. The inguinal anatomy is defined superiorly by the arch of the aponeurosis of the transversus abdominis muscle and inferolaterally by the upper ramus of the pubis and the psoas muscle. The inguinal canal is about 4 cm in length and is located

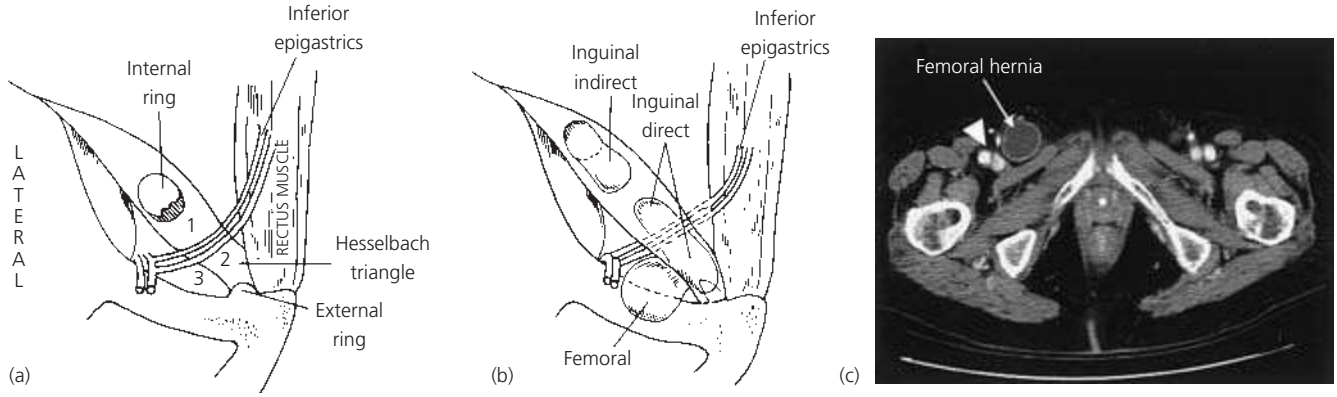

Figure 98.6 The right inguinal region. **(a)** Schematic anatomy showing internal and external rings and Hesselbach triangle. Spaces where hernias occur include Hesselbach triangle (2), the inguinal canal (1, 2), and the femoral space (3). **(b)** The most common groin hernias are direct and indirect hernias above the inguinal ligament and femoral hernias below the inguinal ligament. **(c)** Computed tomography of an incarcerated femoral hernia on the right. Note that a loop of small intestine is present medial to the femoral vessels; the vessels are marked by a white arrowhead.

just above the inguinal ligament between the internal and external rings (Fig. 98.6). The inguinal canal contains the spermatic cord in males (vas deferens, spermatic artery and vein, and cremasteric muscle) and the round ligament in females, in addition to the ilioinguinal nerve. The superior entrance to the inguinal canal is the internal ring (the deep inguinal ring) and is an outpouching of the transversalis fascia lateral to the inferior epigastric vessels. The external ring is a slit-like opening between the diagonal fibers of the aponeurosis of the external oblique muscle (Fig. 98.6a). The anterior wall of the inguinal canal is composed mainly by the aponeurosis of the external oblique. The superior wall is formed by the arching fibers of the internal oblique and transverse abdominal muscles, otherwise called the conjoined tendon. The inferior wall is formed by the inguinal ligament (the folded aponeurosis of the external oblique) that forms a shallow ledge, and more medially by the lacunar ligament along the pectineal line of the pubis. The inguinal ligament is the landmark between the abdomen and thigh. It is fixed medially to the pubis and laterally to the anterosuperior spine of the ilium and fascia of the thigh. The pectineal ligament (Cooper ligament) lies between the pubic tubercle and the femoral vein. The posterior wall (floor) is formed mainly by transversalis fascia; medially, this wall is reinforced by formation of the conjoint tendon (inguinal falx), the merging of the internal oblique and transverse abdominal aponeuroses. The floor or the posterior wall has no intrinsic strength, and as the fibers of the transversalis fascia deteriorate, a direct hernia results [15]. The Hesselbach triangle is bounded by the inguinal ligament inferiorly, the inferior epigastric vessels laterally, and the lateral border of the rectus medially (Fig. 98.6a). A weakness in the floor of this triangle (the transversalis fascia) results in a direct inguinal hernia. Hernias protruding lateral to the Hesselbach triangle are termed *indirect hernias* (Fig. 98.6b). Inguinal hernias include direct and indirect hernias found above the inguinal ligament, and femoral hernias are found below the inguinal ligament in the femoral canal. The inferior epigastric artery serves as an important defining anatomical landmark. Indirect hernias originate lateral to this artery and protrude into the inguinal canal along the spermatic cord. Direct hernias are located medial to the inferior epigastric artery and come through a weakened inguinal floor composed of the transversalis aponeurosis and fascia (Fig. 98.6). A *pantaloon hernia* is composed of both direct and indirect components. *Sliding hernias* have one wall composed of colon or bladder. A special type of indirect inguinal hernia containing a Meckel diverticulum is *Littré hernia*.

The main symptom of groin hernia is a bulge in the inguinal area that appears intermittently or with increased intraabdominal pressure. Pain is usually mild; local pain or colicky abdominal pain is suggestive of incarceration or strangulation. Palpation should be performed in the standing and recumbent position and using Valsalva maneuver to sustain increased intraabdominal pressure. Both sides of the groin and scrotum should be examined. To perform a digital examination, the index finger is introduced into the inguinal canal through the external inguinal ring by invaginating the skin in the area (Fig. 98.7). Using the index finger, the external inguinal ring is first palpated, and with a small further push the internal ring can be palpated. Using this simple technique, an indirect hernia can be felt exiting the internal ring at the fingertip, and a direct hernia can be felt more medial to the finger. In femoral hernias the inguinal canal has no hernia, but a mass is felt below the inguinal ligament in the medial thigh near the saphenofemoral junction, medial to the femoral vein. Obesity makes the examination difficult, especially in detection of femoral hernias, and radiological studies may be helpful [16] (Fig. 98.6c).

The differential diagnosis of an inguinal bulge includes lipoma, tumors, lymphadenopathy, abscess, cysts, endometrial

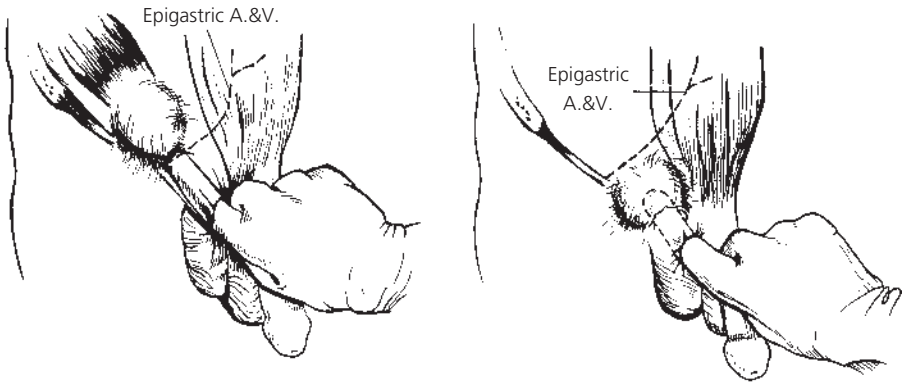

Figure 98.7 Digital examination of inguinal hernias. **(a)** Indirect inguinal hernias are palpated in the inguinal canal at the fingertip. **(b)** Direct inguinal hernias are palpated on the sides of the examiner's finger.

deposits, testicular torsion in an undescended testicle, hydrocele, varicocele, pseudoaneurysm, and saphenous varix. Strangulated hernia can present with signs and symptoms of small bowel obstruction with the addition of a painful, tender, or tense swelling in the groin. Without an operation, it is difficult to determine whether bowel loops are strangulated; therefore, all painful tense hernias should be considered strangulated and repaired imediately. Because both strangulated inguinal and femoral hernias require urgent operations, differentiating them is of intellectual but not practical interest [17].

Surgical treatment is generally recommended for most inguinal and femoral hernias, because of the chance of strangulation (5% in indirect hernias and up to 30% in femoral hernias). Watchful waiting may be a reasonable option in men whose inguinal hernias are minimally symptomatic. In one randomized study of 336 patients assigned to watchful waiting over the subsequent 4 years, two required surgery due to strangulation or small bowel obstruction caused by the inguinal hernia; and 23% of patients assigned randomly to watchful waiting chose to have their hernias repaired in the 2-year period of the study, most commonly due to increase in pain [18]. Elective repair can be undertaken as outpatient surgery using general anesthesia, spinal anesthesia, intravenous sedation, or local anesthesia alone. Repair of the hernia requires delineation of anatomy, identification of the hernia sac, and reduction of sac contents. Indirect hernia sacs are ligated at the level of the internal inguinal ring; direct hernia sacs are pushed below the repair site. Suitable native tissue can be used for repair. The modified Bassini repair apposes the shelving edge of the inguinal ligament to the conjoint tendon (inguinal falx), the merging of the internal oblique and transverse abdominal aponeuroses. The Shouldice repair is similar but uses an overlapping technique with two rows of sutures. The McVay repair involves opening the inguinal floor and approximates the conjoint tendon and transversalis fascia to the pectineal ligament (Cooper ligament); this repair is suitable for femoral hernias. Relaxing incisions of the anterior rectus sheath are used to reduce tension on repairs using native tissue.

Polypropylene mesh repair is now widely used as standard repair for all direct and larger indirect hernias. The Lichtenstein repair involves overlay of the mesh along the inguinal floor underneath the spermatic cord; the mesh is sutured to the shelving edge of the inguinal ligament, the pubis medially, and the internal oblique fascia superiorly. A slit in the mesh allows passage of the spermatic cord [19]. Recurrence rates are thought to be somewhat lowered by the use of mesh, but a higher risk for infection must be taken into consideration [20].

The laparoscopic approach to repair of hernias has been popularized. A transabdominal or preperitoneal approach can be taken, and knowledge of anatomical considerations is key [21] (Fig. 98.8a). The transabdominal, preperitoneal, and totally extraperitoneal repairs are the most commonly used laparoscopic approaches [22]. After reducing the hernia contents, the repair is performed by securing a sheet of polypropylene mesh over the internal aspect of the inguinal floor and internal ring area using surgical clips or staples (Fig. 98.8b,c). Proponents of laparoscopic inguinal hernia repair cite advantages such as improved cosmesis, less postoperative discomfort, earlier return to work, and easier repair of bilateral hernias. The laparoscopic approach also has disadvantages. Complications related to laparoscopy, such as intestinal or vascular injury during trocar insertion, potential for adhesions, the need for general anesthesia, and increased cost, are potential downsides of laparoscopic repair. Prospective randomized trials have been performed showing advantages of laparoscopic repair for one or more of the above-cited parameters [23–25]. Larger randomized studies [26] have shown some benefit in terms of less pain and more rapid return to work, but the same authors have shown more recurrences and higher costs in the laparoscopic repair groups [27]. Overall, many surgeons still feel the potential risks associated with laparoscopy and the increased cost outweigh the advantages and do not routinely recommend laparoscopic hernia repair. The laparoscopic approach has been recommended by some surgeons as ideal for repair of recurrences, for bilateral hernias, and for patients who need to return to a very active lifestyle rapidly [20,28].

(**c**) After reduction of the hernia, the polypropylene mesh is secured over the inguinal floor using surgical clips or staples.

Pelvic hernias

The intestine can herniate through the pelvic floor (weakness, perhaps, from multiparity or previous trauma) in areas such as the obturator foramen, the greater or lesser sciatic foramen, or the perineal muscle. The most common of these hernias is the *obturator hernia*. The obturator foramen is covered by a membrane except for one small area, and herniation occurs when the intestine (usually ileum) enters the foramen through this small defect and into the obturator region of the thigh (Fig. 98.9). This hernia is seen more commonly in females (male to female ratio of 1 : 6), on the right side, and in the sixth decade of life. Bilateral hernias can be seen, albeit rarely [29]. Most obturator herniations present with acute intestinal obstruction with no previous signs or symptoms. Occasionally, dysesthesias occur in the medial thigh because of compression of the obturator nerve. The Howship–Romberg sign (pain in the medial thigh radiating to the knee or hip exacerbated with extension, adduction, or medial rotation of the thigh) is present in 50% of the patients. A tender mass may be palpated near the obturator canal on rectal or vaginal examination. Radiological studies may show a gas shadow in the region of the obturator foramen; a small loop of intestine in this region can be also seen on CT [29]. Surgical treatment using a transabdominal approach is indicated in all cases [30,31].

Sciatic hernias are extremely rare and can present with a slowly enlarging mass in the gluteal fold area. A CT scan is often needed for diagnosis, and treatment is surgical using a transabdominal or combined transabdominal and gluteal approach. *Perineal hernias* occur through the pelvic floor musculature, and symptoms can vary but are usually related to a protruding mass in the perineal area, worst with standing. These hernias can be seen after removal of the rectum in abdominoperineal resection for rectal carcinoma. Repair is undertaken using a transabdominal approach; polypropylene mesh may be needed.

Lumbar hernias

The posterior abdominal wall has two naturally weak areas. The superior triangle of Grynfeltt–Lesshaft, also called the lumbocostoabdominal triangle, is the most common site for lumbar herniation. This area is bordered by the 12th rib, the posterior border of the internal oblique, and the anterior border of the sacrospinalis. The inferior triangle of Petit or lumboiliac abdominal triangle is limited by the iliac crest, the anterior border of the latissimus dorsi, and the posterior border of the external oblique muscle.

Lumbar hernias are seen most commonly in men and are congenital (20%), acquired (50%), or due to trauma (25%), for example rib fractures or removals, iliac crest fractures, or

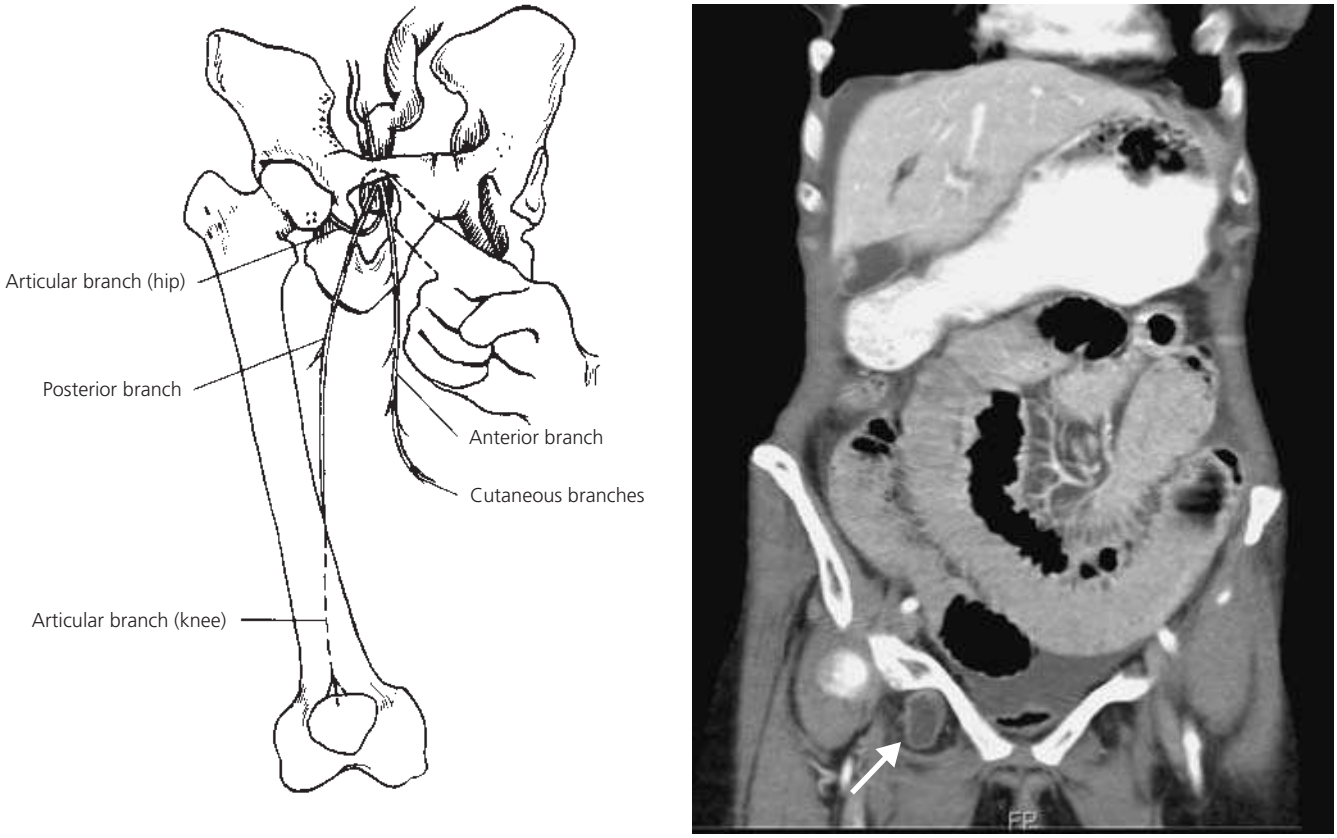

Figure 98.9 Rectal or vaginal palpation of the obturator foramen may confirm the existence of an obturator hernia. Adapted from Nyhus LM, Condon RE (eds). Hernia. Philadelphia: JB Lippincott, 1978. **(b)** Computed tomography of an obturator hernia; white arrow points to small intestine trapped in the hernia.

removal of a segment of iliac crest for bone grafting [12]. These hernias are usually left-sided. Symptoms usually include a tender mass or pain in the lumbar area or radiating to the pelvis. Lumbar hernias should be surgically fixed when first noted because they tend to enlarge, and larger hernias are more difficult to repair.

Spigelian hernias

A Spigelian hernia is rare, occurring through the linea semilunaris, lateral to the rectus abdominis, with protrusion through the external oblique fascia. Spigelian hernias occur in elderly people, are often small and difficult to diagnose, and always present below the arcuate line of Douglas. Symptoms include local pain or discomfort worsened by increased intraabdominal pressure. Diagnosis can be made with ultrasound or CT if physical examination is difficult because of obesity or if differentiation is needed from abdominal wall tumor [32]. Surgical repair is needed because of the risk for incarceration; the results are excellent.

Diaphragmatic hernias

Acquired diaphragmatic hernias are the result of blunt or penetrating trauma. Most hernias occur on the left, and herniated viscera can include stomach, spleen, colon, or the left lobe of the liver. Herniation and traction on the mesentery can lead to nausea, vomiting, diaphoresis, and general abdominal discomfort. Respiratory symptoms occur if there is lung or mediastinal compression. Some patients present years after a traumatic injury [33].

The diagnosis is based on physical examination with dullness to percussion along the left chest; chest radiography shows abdominal viscera or a nasogastric tube curled in the thorax (Fig. 98.10). CT can be useful in visualizing defects with protruding viscera [34]. If the index of suspicion is high for a diaphragmatic injury, normal radiological studies should not deter laparoscopy or surgical exploration of the diaphragm [35]. All diaphragmatic hernias should be fixed on diagnosis to avoid strangulation or acute respiratory distress. Chronic herniations may be best approached transthoracically to allow release of intrathoracic adhesions, although most can be repaired transabdominally.

Internal hernias

An internal hernia is a protrusion of any intraperitoneal viscus into a compartment within the abdominal cavity. There is no hernia sac, and frequently the herniated viscus is

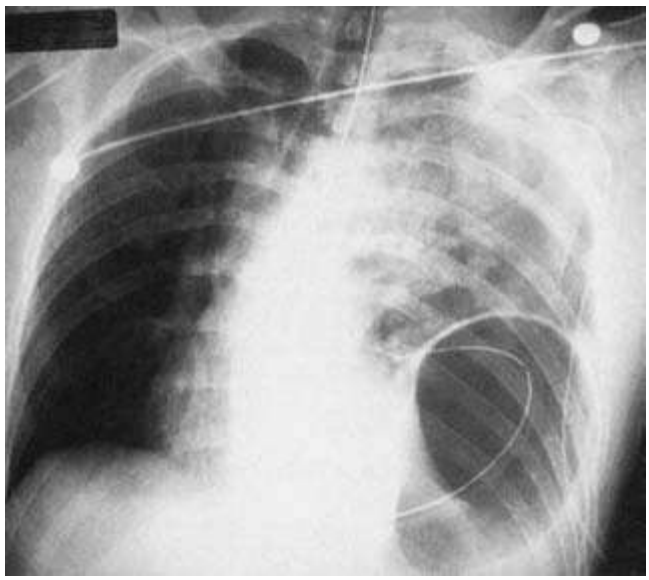

Figure 98.10 Traumatic hernia of the diaphragm on the left. The diaphragmatic line has disappeared and the gastric fundus is in the left thoracic space. The contour of the nasogastric tube should be noted in the left chest.

entering a known anatomical space or foramen; some hernias occur in surgically created or congenital defects. In one review, 0.2%–0.9% of cadavers had incidentally noted internal hernias, most commonly paraduodenal (53%), followed by pericecal (13%) and the foramen of Winslow (8%), and supravesical and intersigmoid hernias (6%–7% each) [36].

Most symptoms are intermittent, and patients often present with small bowel obstruction or signs and symptoms of strangulation. Radiological studies are not always helpful, and the differential diagnosis must include foreign bodies, intestinal volvulus, adhesions, and tumors [37,38]. Surgical treatment is needed and includes reduction of the herniated viscus and repair of the defect.

Paraduodenal hernias

The left paraduodenal fossa of Landzert is a peritoneal pocket located lateral to the fourth portion of the duodenum and posterior to the inferior mesenteric vein. A left paraduodenal hernia (75%) results from dorsal malrotation of the midgut resulting in a hernial opening with the inferior mesenteric artery covering the anterior margin. A right paraduodenal hernia (25%) is formed by incomplete rotation of the midgut such that the small intestine is in a sac covered anteriorly by the mesocolon and the superior mesenteric artery. The cecum remains in the right upper quadrant and is attached to the right abdominal wall by thickened parietocolic peritoneal bands of tissue called Ladd bands.

Signs and symptoms are elusive and can include any signs associated with chronically incarcerated hernias. Contrast radiography shows stasis and delay in transit with large portions of small bowel trapped in one anatomical position. Surgical correction is necessary, and damage to the small bowel vasculature should be carefully avoided.

Hernias of the foramen of Winslow

Herniation of a mobile cecum and distal ileum can occur into a larger than usual foramen of Winslow. Signs and symptoms are vague but can include crampy epigastric pain relieved with flexion of the torso. Radiographic studies show a gas-filled loop of bowel behind the stomach and pushing the stomach anteriorly and to the left. Surgery with reduction and cecopexy may be needed.

Pericecal hernias and intersigmoid hernias

The distal ileum can pass through a defect in the cecal mesentery occupying the right paracolic gutter. Most present with right lower quadrant pain with or without small bowel obstruction. Intersigmoid hernias are composed of herniated small bowel present in the peritoneal pocket between the two loops of sigmoid. These hernias are usually picked up incidentally at operation or during a radiological study such as barium enema or CT [38].

Transmesenteric and transomental hernias

About 5%–15% of internal hernias occur through defects in the mesentery or the omentum. Transmesenteric hernias occur most commonly in children, along the mesentery of the jejunum. Prenatal ischemic events may be the causative agent because the area of defect is often associated with atretic segments of intestine. Symptoms of small bowel obstruction may develop, and surgery is required at diagnosis.

Iatrogenic hernias

Iatrogenic hernias result from alteration of intraabdominal anatomy, most often at surgery. Internal herniation can be related to surgical defects created by prior operations, e.g., in the paracolic or paraileal spaces adjacent to end stomas, or in a retroanastomotic location. Of iatrogenic hernias, 75% manifest in the first postoperative year.

Retroanastomotic hernias

A retroanastomotic hernia occurs through any defect in the mesenteric space left open after completion of an intestinal anastomosis. Hernias can occur after a Billroth II anastomosis in the space between a gastrojejunostomy and the posterior abdominal wall. Most patients present with intestinal obstruction and require immediate surgical correction. The presentation will generally be indistinguishable from other causes of intestinal obstruction, so that an accurate preoperative diagnosis is rarely made. Surgical repair of the defect should be performed along with resection of any nonviable bowel. If discovered incidentally at the time of laparotomy for other reasons, such defects should be repaired to avoid future problems.

Given the rapidly increasing number of patients undergoing gastric bypass operations, herniation and volvulus associated with the new anatomy created by Roux-en-Y gastric bypasses deserves special mention. These hernias used to be quite rare and rarely reported, but now appear to be a major cuase of morbidity and mortality after open or laparoscopic gastric bypass. Retrocolic/retrogastric herniation of most of the small intestine has been reported due to internal herniation at the mesenteric defect of the jejunojejunostomy after both laparoscopic and open gastric bypass surgery [39]. This unusual but not rare complication is potentially life-threatening due to possible ischemic necrosis of most of the small bowel as well as perforation of the gastric remnant, which is almost uniformly fatal. Internal hernias appear to be more common after laparoscopic Roux-en-Y gastric bypasses, possibly due to the relative lack of postoperative adhesions. Patients with retrocolic placement of the Roux limb appear to be at highest risk of herniation [40]. Patients often present with intermittent abdominal pain, small bowel obstruction and normal radiological studies, including contrast studies and CT scans, but can also present with signs and symptoms of an intraabdominal catastrophe. One retrospective analysis of 2000 consecutive patients who underwent laparoscopic Roux-en-Y gastric bypass found 63 patients with such internal hernias requiring operative intervention, an incidence of 3.1%. The site of internal herniation included 44 in the mesocolon, 14 in the jejunal mesentery, and five in the space of Petersen. Of these patients, 20% had normal small bowel series or CT scans [41]. In one study of laparoscopic gastric bypass procedures, the overall incidence of internal hernias was 6.0% of patients with retrocolic procedures and 3.3% of patients with antecolic procedures. Most were in the Petersen defect (55.9%) and at the enteroenterostomy site (35.3%), while 23% of patients with internal hernia were diagnosed in the early postoperative period (2–58 days) and 77% were diagnosed at a later date, up to 3 years after the original surgery [42]. In another study, volvulus and ischemia requiring resection of small intestine was present in over 50% of patients with transmesenteric hernias, and absence of the *whirl sign* and other radiological signs of bowel ischemia did not exclude volvulus or ischemia [43]. Diagnosis of internal herniation in this patient population remains extremely challenging given the relative lack of experience with this situation and because of extreme obesity leading to difficulty with reliability of both physical examination and laboratory findings. A high index of suspicion, diligent patient evaluation with special attention to symptoms, early abdominal CT scanning, communication with the surgical team involved with the patient's gastric bypass (if different from current physician team), and urgent operative intervention are necessary to achieve a successful outcome. All defects must be closed to minimize the risk of hernia, whether antecolic or retrocolic [44].

Incisional hernias

Incisions of the abdominal wall result in future herniation 2%–5% of the time. Multiple factors are responsible for a postoperative incisional hernia, including defective suture material, undue tension on the sutured fascia, obesity, previous incisions, infections, seromas or hematomas, malnutrition, and smoking [45]. Different incisions have different rates of future herniation. Midline incisions have the highest rates; paramedian and transverse incisions have lower rates of herniation. Incisional hernias can range in size from 1 cm to large hernias containing nearly all the intestines. With increasing popularity of laparoscopic surgery, attention needs to be paid to all trocar site defects larger than 0.5 cm to avoid future herniation.

The diagnosis of incisional hernia is usually evident by history as well as physical examination. The hernial ring is often palpable with the edges of the muscle retracted laterally. Incisional hernias often incarcerate but tend not to strangulate. Operative repair should be undertaken in most patients. For many years, the repair of incisional hernia was associated with a high recurrence rate. Most recurrences are thought to be due to infection, insufficient dissection and exposure of other defects, or closure under excess tension. Tension should be avoided at the time of repair, and prosthetic mesh is often needed. The introduction of synthetic prosthetic materials has provided the opportunity to perform a tension-free repair, thereby reducing the rate of recurrence [45]. In addition, musculoaponeurotic flaps are used along with relaxing incisions in cases in which prosthetic material is best avoided. Natural tissue substitutes, such as fascia lata or pig small intestinal submucosa, are also being used to repair incisional hernias [46].

Therapy, 2500
Specific considerations, 2501

Intraabdominal abscesses and fistulae are complications that arise from a variety of abdominal and pelvic processes. They should be approached as specific clinical entities, with close attention to the underlying etiology. In the past, most abscesses and fistulae required open surgical therapy. However, the modern therapeutic approach includes sophisticated diagnostic imaging, percutaneous or endoscopic aspiration and drainage, and medical therapy, leaving fewer cases requiring aggressive surgery. A thorough understanding of the pathogenesis, diagnostic options, and therapeutic strategies will lead to more efficient and effective care of complex cases.

Epidemiology

The most common cause of intraabdominal abscesses are complications of abdominal operations, penetrating trauma, perforations of the gastrointestinal tract, diseases of the pancreas or biliary system, and infections of the male and female genitourinary tracts [1]. Half to three-fourths of intraabdominal abscesses arise in the postoperative setting with most resulting from a documented anastomotic leak [2]. The causes of nonsurgical intraabdominal abscesses include diverticulitis, appendicitis, inflammatory bowel disease, pancreatitis, perforated peptic ulcers, and perforated visceral carcinomas. The incidence of intraabdominal abscesses appears to be decreasing, but the overall mortality remains high at 10%–30% [3,4]. Intraabdominal abscesses are being increasingly seen in elderly or immunocompromised patients where their detection and management may be difficult [1].

A gastrointestinal fistula is defined as an abnormal communication between the gastrointestinal tract and another epithelialized surface such as the skin or an adjacent loop of bowel. Gastrointestinal fistulae can be further subdivided into congenital and acquired [5]. Congenital gastrointestinal fistulae are the result of embryological processes (e.g., tracheoesophageal fistula) and are most commonly encountered in the neonatal period and childhood. These are not considered further in this chapter. Acquired fistulae can be classified by their anatomical origin and end point, and are either internal (e.g., enteroenterofistula) or external (e.g., enterocutaneous). Functionally, they are separated into low output (< 500 mL/day) or high output (> 500 mL/day). Most occur in the postoperative setting due to inadvertent organ injury, failure of an anastamosis, or in proximity to a drain, tube or other foreign body. Posttraumatic fistulae can be due to direct injury or be associated with an open abdominal wound. Fistulae form in the setting of inflamed tissue as in Crohn's disease, pancreatitis, or post irradiation. Finally, malignant or necrotic tissue can form fistulae, particularly if they are adjacent to bowel or the abdominal wall [2,6]. Acquired fistulae in adults are often either the cause or the consequence of intraabdominal abscesses and therefore are considered together.

Pathophysiology

Intraabdominal abscesses

Intraabdominal abscesses develop as a result of localization of diffuse peritonitis, in which case they may reside in dependent regions of the peritoneum such as the pelvis, perihepatic spaces or the paracolic gutters, or as a result of localized abscess around an area of trauma, surgery, or adjacent to a diseased organ. An intraabdominal abscess is a well-defined collection of inflammatory cells and bacteria, either viable or nonviable, that is walled off from the rest of the peritoneal cavity by inflammatory adhesions, omentum, abdominal viscera, or the gut [6]. Intraabdominal abscesses typically arise when previously sterile visceral organs or abdominal spaces are seeded by bacteria. The majority of visceral organ abscesses result from hematogenous seeding, whereas the majority of

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

abscesses in the peritoneal space result from perforation of an abdominal viscus or dehiscence of a surgical anastamosis [2,6]. Abscesses in the retroperitoneal space can result from both perforation of the gastrointestinal tract and lymphatic or hematogenous spread. The location of abscesses varies by series depending on the etiologies. In one large series, 20% were perihepatic, 44% were in the right lower quadrant, 14% in the left lower quadrant, and 14% in the pelvis [7].

When pyogenic bacteria enter a previously sterile anatomical space, they trigger an acute inflammatory reaction. Numerous leukocytes are drawn to the infection to contain and eradicate the invading bacteria. This leads to the formation of an abscess cavity consisting of a localized region of edema, neutrophils, and necrotic tissue [6]. An abscess cavity typically consists of three distinct histological layers. The center of an abscess consists of necrotic leukocytes and the necrotic cells of the infected tissue. This necrotic center is surrounded by a second layer of preserved neutrophils. Outside this region, there is a third layer characterized by vascular dilatation and fibroblastic reaction. It is this zone of vascular dilatation that gives a mature abscess its characteristic *ring enhancement* during contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) [8]. The central devascularized area of necrotic cells and bacteria has no blood flow and is difficult to reach with antibiotics. Abscesses often require percutanous or surgical drainage in addition to antibiotic treatment.

Intraabdominal abscesses are typically polymcrobial. Anaerobes can be found in 60%–70% of cases. In one series, *Bacteroides fragilis* was the most common pathogen, with anaerobic cocci and clostridia found in 50%. Other common bacteria include *Escherichia coli*, *Klebsiella/Enterobacter* group, *Proteus* spp., *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and enterococci [1,9–11].

Gastrointestinal fistulae

The pathophysiology of gastrointestinal fistulae is incompletely understood. In some settings it is likely that disruption of the normal tissue planes creates a path of least resistance that then perpetuates effluent from a lumenal organ. The effluent itself may inhibit normal healing of the tract. The tissue planes could be disrupted by a foreign body (e.g., gastrostomy tube), inflammation (e.g., pancreatitis), infection, surgery, or tumor. In some conditions such as Crohn's disease, downstream intestinal strictures create a high-pressure region facilitating the fistula [2]. However, only approximately 50% of Crohn's fistulae in the terminal ileum are associated with a downstream stricture, and perianal fistulae are not usually associated with significant rectal or anal stenosis [12–14]. The molecular mechanisms underlying fistula formation are poorly understood, although in Crohn's disease and postirradiation fistulae, matrix metalloproteinases play a local role in matrix degradation [15,16]. Infection likely contributes in many settings as fistula formation is commonly associated with an abscess or local tissue infection. Local ischemia may play a role especially in the postoperative setting. Finally, patient factors including nutritional status and concomitant medications contribute to fistula formation and delay spontaneous closure [17,18].

Anatomical considerations

The peritoneal and retroperitoneal compartments consist of a series of communicating compartmentalized potential spaces that determine the site and clinical symptoms associated with gastrointestinal abscesses and fistulae (Fig. 99.1). The potential space between the visceral and parietal peritoneum defines the peritoneal space. The organs within the peritoneal cavity are connected and supported by ligaments including omenta and mesenteries [8]. The ligaments define the potential spaces in the peritoneum.

Key structures limit or localize infection in the abdomen. The greater omentum joins the greater curvature of the stomach to the colon and then extends downward anterior to the small bowel. The small bowel mesentery is a broad fan-shaped fold of peritoneum that connects the jejunum and ileum to the posterior abdominal wall. It originates at the duodenal jejunal flexure (ligament of Treitz) in the left upper quadrant and extends diagonally to the ileocecal junction in the left lower quadrant. The transverse mesocolon is the mesentery that extends from the ventral surface of the pancreas to the transverse colon.

The region near the liver has two major potential spaces: the perihepatic space and the lesser sac (omental bursa). These two spaces communicate via the epiploic foramen (foramen of Winslow). The perihepatic space extends superiorly to the junction of the bare area of the liver and the diaphragm and is the site of subphrenic abscesses. The posterior subhepatic space projects cephalad into the recess between the liver and the right kidney. This recess constitutes the hepatorenal fossa (pouch of Morrison). The hepatorenal fossa is the most dependent portion of the subhepatic space when the patient is supine and consequently is a common site for the accumulation of intraperitoneal fluid collections. Intraperitoneal inflammation can cause the lesser sac to seal off from the remainder of the peritoneal space. As a result, abscesses in the main cavity rarely enter the lesser sac and abscesses in the lesser sac usually do not spread to the rest of the peritoneal space [2,8].

Inferior to the small bowel mesentery the potential space extends down into the pelvis as the pouch of Douglas (also called the rectouterine space in women and the rectovesical space in men). The pouch of Douglas is the most dependent portion of the peritoneal cavity in both the erect and supine positions, and is a common site of abscess formation after bowel perforation. The right and left pericolic gutters border the ascending and descending colon, respectively. These form important tracts for infected fluid between the lower and upper abdomen. Finally, the retroperitoneum is a potential

space that is also separated into regions defined by fascia. The anterior pararenal space contains most of the pancreas and the retroperitoneal portions of the duodenum, ascending colon, and descending colon. Soft tissue of the retroperitoneal space facilitates the development of fistulae.

Clinical manifestations

Intraabdominal abscesses

Classically, patients with intraabdominal abscesses have fever, abdominal pain, anorexia and malaise. The symptom complex can vary widely based on the underlying etiology, location of the abscess in the abdomen, and patient factors. The fever is usually intermittent and spiking, and may be associated with intermittent bacteremia. Abdominal pain may be localized to the region of the abscess. An abscess that is associated with the parietal peritoneum may produce localized pain, tenderness, and a palpable mass. Abscesses within the mesentery or between bowel loops may produce diffuse, poorly localized visceral pain, and a mass may be more difficult to appreciate. Subphrenic abscesses can cause shoulder pain, tachypnea, cough, and hiccups. Pelvic abscesses may cause tenesmus, diarrhea, or urinary retention. Lumbar or ileopsoas muscle pain may be present. Retroperitoneal abscesses cause fewer symptoms than an intraperitoneal process. Patients with intraabdominal abscesses usually appear ill, and fever, tachycardia and tachypnea are common. Vascular collapse and a classic picture of septic shock may be present, but is rare. Abdominal examination may or may not localize the region of the abscess. Peritoneal signs may be present but are not common. Abdominal distention and decreased bowel sounds suggest an ileus. Pelvic abscesses can often be palpated during rectal or vaginal examination. A pleural effusion may be associated with a subphrenic abscess. Involvement of the psoas muscle may cause pain on flexion of the hip (psoas sign).

Patients may have minimal signs and symptoms of an intraabdominal abscess. History and physical examination can be more difficult in obtunded patients, and may underestimate pathology in elderly patients or patients on antibiotics, narcotics, or steroids. Intraabdominal abscesses may be difficult to distinguish from the underlying disease process in patients with Crohn's disease or diverticulitis for example. Finally, an intraabdominal abscess in a postoperative patient may be difficult to detect. Therefore, a high index of suspicion needs

to be maintained when evaluating patients with diseases or clinical settings where the development of intraabdominal abscesses occurs commonly.

Laboratory examination usually demonstrates leukocytosis with a classic left shift. Bacteremia may be present and should be sought with at least three blood cultures. Urine examination may reveal white or red blood cells due to irritation of the ureters or bladder. Serum bilirubin may be elevated if sepsis is present. Amylase may be elevated if a lesser sac abscess is present. Chest radiography will often show a pleural effusion on the side of the subphrenic abscess. An elevated diaphragm and atelectasis of the adjacent lung may be present. Plain abdominal radiographs may reveal air–fluid levels, gas bubbles localized outside the intestinal tract, or if the abscess is large, displacement of bowel loops.

Gastrointestinal fistulae

Clinical manifestations of gastrointestinal fistulae vary widely depending on the underlying etiology and the organs in communication. Internal enteroenterofistulae may be relatively asymptomatic and without physiological consequences if they span a short segment of bowel. Fistulae to the skin from the stomach or duodenum can result in fluid and electrolyte losses, hypochloremic hypokalemic metabolic alkalosis, and skin breakdown. Loss of pancreatic secretions from pancreatic fistulae can result in metabolic acidosis and maldigestion of nutrients. The presence of activated digestive enzymes in fistulae effluent can cause significant skin breakdown.

Sepsis can accompany fistula development as the fistula may rupture into the peritoneal cavity or cause an abscess at a distant site. Alternatively, a fistula can present as a draining surgical wound or a localized abscess that then continues to drain. Pain can accompany fistula formation, or pain may decrease as the fistula itself decreases pressure in an abscess or in a bowel segment upstream of a stricture as occurs in Crohn's disease [1,2,17,18].

Diagnostic studies

Over the last several decades, CT has become the imaging method of choice for evaluating intraabdominal abscesses [19–21]. Other modalities such as ultrasound, MRI, and nuclear imaging can play an important role in complex cases, in specific clinical indications (e.g., ultrasound for tuboovarian abscess), or when there are relative contraindications to CT (e.g., pregnancy).

Radiography and fluoroscopy

Plain film radiography has low sensitivity and specificity for detecting an intraabdominal abscess. However, several nonspecific findings suggest the presence of an abscess, including a mass effect on the bowel or adjacent organs, a mottled extralumenal gas collection, and loss of fat/soft tissue interfaces [8,19]. Occasionally, fluoroscopy can be used to direct injection of sterile water-soluble contrast into a drain that has been previously placed into an abscess cavity. This is done in order to determine the size of the residual abscess cavity and therefore the continued need for the drain. Overpressurization of an abscess cavity during injection can result in rigors and even sepsis, so patients are often premedicated with antibiotics prior to this procedure. Drain injections should be reserved for special circumstances such as identifying a potential fistulous communication between the abscess cavity and an abdominal organ.

Ultrasound

The physics of sound transmission severely limit ultrasound's ability to detect intraabdominal abscesses. When sound strikes an interface between soft tissue and gas, nearly all of the sound is reflected [22] and therefore ultrasound cannot "see" gas collections. Consequently, ultrasound cannot be used to find abscesses among multiple air-filled loops of bowel [8]. Further, ultrasound can not easily distinguish a gas-containing abscess from an air-filled bowel loop. Finally, the lack of commercially available contrast agents for ultrasound often makes it nearly impossible to differentiate an abscess cavity from a postoperative seroma or hematoma.

Despite these limitations, ultrasound is the primary imaging modality in specific situations such as the evaluation of tuboovarian abscess [23]. Transabdominal ultrasound is able to visualize the pelvic structures because of the excellent sonographic window provided by a fluid-filled urinary bladder. Transvaginal scanning allows the operator to bring the ultrasound probe into close apposition with the pelvic structures, often avoiding interference from gas-filled loops of bowel. Ultrasound can also be used to guide real-time imaging for needle aspiration and catheter drainage, but this should generally only be performed after a diagnostic CT has excluded additional abscesses and better defined the location of adjacent bowel [8] (Fig. 99.2).

Nuclear medicine

Over the past few decades, nuclear medicine/radionuclide image has been largely supplanted by anatomical imaging modalities, and has evolved a complementary role as a problem-solving tool [24]. Three major radionuclide markers are utilized in the imaging of infectious and inflammatory disease processes: gallium 67 citrate, technetium 99m-labeled leukocytes, and indium 111-labeled leukocytes. Of these three agents, ^{111}In-labeled leukocytes are the most appropriate for the localization of intraperitoneal abscesses because the label does not demonstrate physiological uptake in normal bowel. While spatial resolution is limited, it can provide important physiological data about the infectious or inflammatory status of fluid collections and soft tissue stranding seen on CT. This information can be valuable for differentiating postoperative changes from infection. In addition, leukocyte imaging

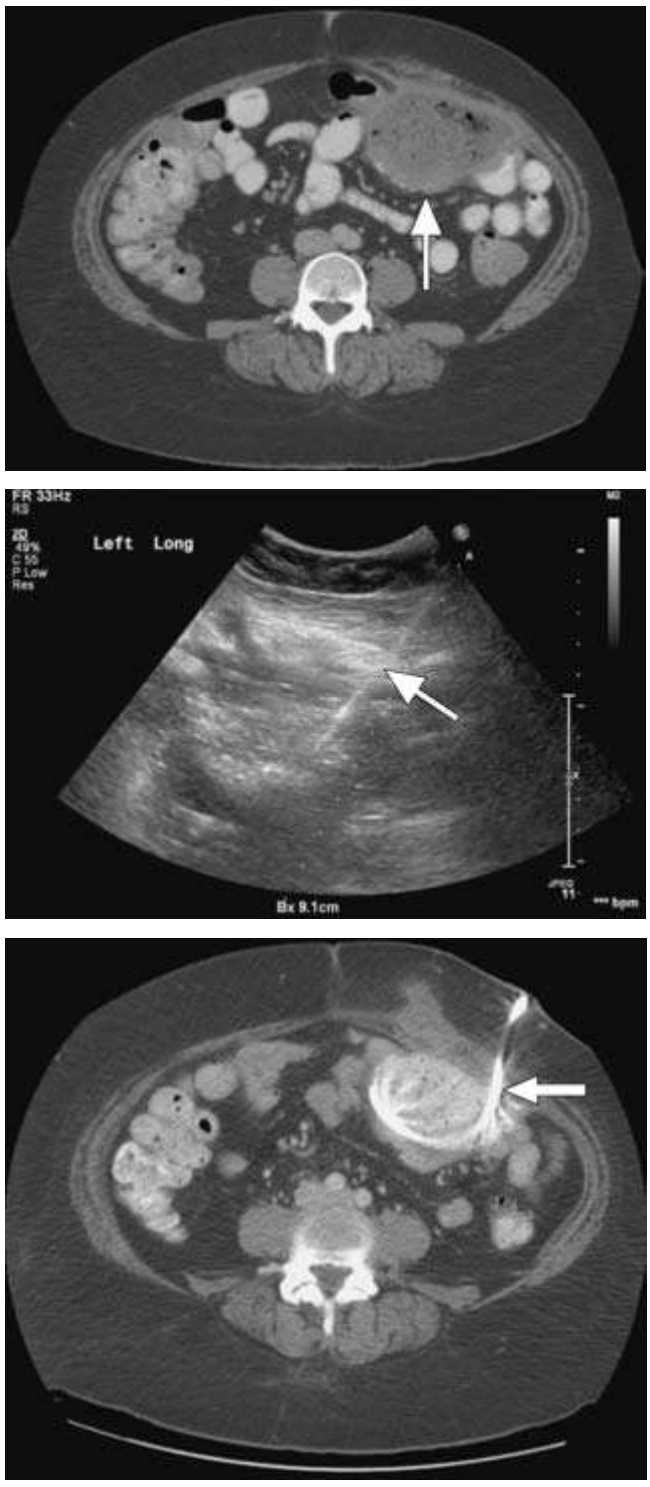

Figure 99.2 **(a)** A patient with a prior history of diverticulitis presents with a rim-enhancing fluid collection containing mottled gas in the left lower quadrant consistent with an abscess (arrow). **(b)** Under ultrasound guidance, a needle (arrow) was introduced into the abscess and brown turbid fluid was aspirated. A drainage catheter was subsequently placed. **(c)** Follow-up CT scan reveals the drainage catheter in the abscess cavity. There is now oral contrast in the abscess cavity consistent with internal fistulization with adjacent bowel.

has proven superior to anatomical imaging for determining if prostheses (e.g., vascular prosthetics, orthopedic hardware) have been seeded by bacteria from an intraabdominal process [24].

Magnetic resonance imaging

Technical issues limit routine application of MRI in the abdomen, but this may change with rapid advances in magnetic resonance technology. Magnetic resonance sequences are relatively slow, especially when compared with the speed of modern CT. Motion artifact results in "ghosting," an imaging phenomenon that can blur images [25,26]. Respiratory motion can often be overcome by breath-holding and respiratory gaiting, although this is difficult in ill patients. The random motion produced by peristalsis also significantly hinders attempts to identify abscesses among bowel loops [25]. The air–fluid–fat interface, as well as surgical clips and metallic objects, cause further artifacts [26]. Many limitations of traditional MRI are being overcome by modern techniques such as magnetic resonance enterography and magnetic resonance colonography, although these techniques have limited availability [27,28].

MRI serves an important problem-solving role for distinguishing small hepatic abscesses from cysts and cavernous hemangiomas that are too small to characterize by CT [29]. In addition, MRI provides exquisite detail of the retroperitoneal and pelvic structures and is a superb imaging modality for perianal abscesses and fistulae [30,31] (Fig. 99.3).

Computed tomography

CT has an accuracy of over 90% in detecting intraabdominal abscesses [19,20,32]. Several findings on CT are highly suggestive of an intraabdominal abscess including loculation, ring enhancement, and gas (Fig. 99.4). The very low attenuation mottled gas collections seen on CT can either result from a gas-producing infection or from gas that has escaped from an adjacent gastrointestinal perforation. In a solid organ with no recent operative intervention, the presence of a gas-containing fluid collection is virtually pathognomonic of an abscess [33].

Ideally, CT of the abdomen and pelvis should be performed with intravenous and oral contrast when evaluating for abscess. The use of iodinated intravenous contrast can help differentiate an inflamed rim-enhancing abscess from a sterile loculated fluid collection such as a seroma. Unfortunately, due to renal failure or allergy many patients cannot receive intravenous contrast. While the lack of intravenous contrast can reduce the accuracy of CT for abscess evaluation, it should not preclude the performance of a CT scan for this indication.

The administration of an appropriate positive oral contrast is important for identifying and characterizing abscess cavities adjacent to loops of bowel. Positive oral contrast is defined as any agent that is higher in attenuation than water, i.e., the traditional barium and iodine-based agents. Without any oral

contrast or with some of the newer water-density contrast agents, it can be very difficult to differentiate fluid in the bowel lumen from extralumenal fluid collections like abscesses. In addition, the presence or absence of spillage of oral contrast into the abdominal cavity can help differentiate a bowel perforation from an abscess. Therefore, whenever possible, positive oral contrast should be administered to allow adequate opacification of the entire bowel.

Imaging fistulae

Diagnostic imaging plays an important role in the triage and treatment of patients with gastrointestinal fistulae. Gastrointestinal fistulae may be associated with chronic disease processes, or a more acutely life-threatening processes (e.g., intraabdominal abscess and dehiscence of surgical anastamoses). Accordingly, the imaging workup can be divided into the acute and chronic phases. Acutely ill patients or patients with peritoneal signs are the most likely to benefit from plain film radiography, because it is a rapidly available test that is quite sensitive for free air as in an uncontained bowel perforation. Contrast-enhanced CT may be utilized as a first-line agent to evaluate acutely ill patients, because it can rapidly assess the entire abdomen for associated conditions like intraabdominal abscesses and perforations. In addition, newer multislice CT scanners are often able to define larger fistulous and sinus tracts without any additional imaging.

In subacutely and chronically ill patients, more specialized and time-consuming examinations (e.g., MRI, fistulography, small bowel follow-through) can provide greater anatomical detail regarding the presence and extent of smaller fistulae. These tests are more specifically tailored to evaluate fistulae and can provide valuable information to guide medical and surgical intervention focused specifically on fistula treatment.

A hybrid approach combining cross-sectional imaging studies (e.g., CT and MRI) with more traditional studies (e.g., fistulography and contrast fluoroscopy) can provide complementary information. Such a hybrid/multimodality approach to fistula imaging is becoming more common as imaging technology advances [8] (Fig. 99.5).

Fistulography

Fistulography has traditionally been a first-line test for imaging of cutaneous gastrointestinal fistulae. This is a relatively

Figure 99.5 **(a)** Inflamed terminal ileum (arrow) demonstrating marked wall thickening in a patient with Crohn's disease. There is an enhancing gas-containing tract (arrowhead) between the terminal ileum and the sigmoid colon which was suspicious of an enterocolic fistula. **(b)** A small bowel follow-through was performed which demonstrated that the tract seen on CT was a blind-ending sinus tract (arrowhead). The small bowel follow-through was able to detect subtle ileocecal fistulae (small arrows) that were not visible on the conventional CT of the abdomen and pelvis. The terminal ileum is markedly narrowed secondary to Crohn's involvement (large arrow).

simple test that involves placing a catheter into the fistulous opening and gently instilling water-soluble contrast [34]. The contrast instillation is typically observed under fluoroscopy in order to define the fistulous tract and communications with any organs or abscess cavities. Because of the risk of pressurizing an abscess cavity or the biliary tree and possibly inducing sepsis, some institutions elect to premedicate patients with broad-spectrum antibiotics prior to fistulography. Fistulography has proven relatively inaccurate and unreliable in perianal fistulae [35,36], and has been replaced by MRI, and to a lesser extent endoanal ultrasound, for the evaluation of perianal Crohn's disease and fistula-in-ano [30,31,37].

Therapy

Intraabdominal abscesses

Drainage is the mainstay of therapy for intraabdominal abscesses. Advances in imaging have allowed detailed localization and description of the abscess, and often clues as to the underlying etiology. Abscesses can usually be distinguished from normal structures such as the bowel lumen or sterile collection of fluid or blood by contrast agents and by comparison of different imaging techniques. Aspiration of the contents is critical to confirming the diagnosis of an abscess and providing guidance as to the choice of antibiotic regimen. CT- or ultrasound-guided drainage is being used increasingly in appropriate clinical settings with good results. Requirements for optimal percutaneous catheter drainage include:

- an abscess that can be approached adequately via a safe percutaneous route
- an abscess that is unilocular
- an abscess that is not vascular and the patient has no coagulopathy
- joint radiological, surgical, and medical evaluation with adequate back-up for any complications
- the possibility of dependent drainage for the percutaneously placed drain [1,8].

When these criteria are met, percutaneous drainage is successful in 80%–90% [38,39]. Attempts at drainage of loculated, poorly organized, multiple or extensive collections are less successful. The complications in most series range from 5% to 15% and include septicemia, hemorrhage, peritoneal spillage, and fistula formation [38,39]. Percutaneous drainage may be associated with less morbidity and mortality than surgical treatment [1,40].

Antimicrobial therapy should be started as soon as appropriate samples are collected; typically this occurs before drainage. Initial antibiotic therapy is directed at the anaerobes, especially *B. fragilis* and Enterobacteriaceae. The antibiotic regimen should be adjusted based on in vitro testing of the organisms isolated from the blood or purulent material. Repeated cultures of blood and fluid collections may be necessary during prolonged illnesses, as changes in the pathogenic organisms can occur during therapy. Small abscesses can occasionally be treated with antibiotics alone without drainage [1,2].

Supportive care for ill patients with intraabdominal abscesses is important and includes attention to fluids and electrolytes, gastrointestinal drainage with a nasogastric tube for patients with ileus or obstruction and, when necessary, blood transfusion and respiratory support.

An operative approach to an intraabdominal abscess should be considered if there is bowel perforation as in a postsurgical anastamotic leak or traumatic perforation [2]. In addition, laparotomy may be indicated if the purulent collection is large or complex, or if there is suspicion of necrotic or severely compromised organ, such as necrotic bowel. Finally, decompressive laparotomy may rarely be indicated in extreme cases of acute increase in intraabdominal pressure, which itself can lead to multiorgan failure and shock [2].

Gastrointestinal fistulae

The treatment of gastrointestinal fistulae depends on the anatomy, the underlying etiology, and the physiological consequences [17,18,41]. The treatment approach is based on

Table 99.1 Factors influencing spontaneous closure of gastrointestinal fistulae

Favorable	Unfavorable
Tract < 2 cm	Tract > 2 cm
Intestinal continuity	Diseased adjacent bowel
Absence of obstruction	Distal obstruction
Postoperative/anastamotic	Malignancy, Crohn's disease, radiation
Low fistula output (< 500 mL/day)	High fistula output (> 500 mL/day)
No sepsis	Sepsis
Serum albumin > 2.5 g/dL	Serum albumin < 2.5 g/dL
Well-nourished patient	Malnourished patient
Short duration	Chronic duration
Origin: pancreaticobiliary, colon	Origin: gastric, small bowel

careful imaging to define an underlying organ leak or infection. External fistulae with their origins in the stomach, pancreas, small bowel, or colon are the most common. General treatment principles include adequate external drainage, control of infection, and intensive nutritional support and replacement of nutrient and electrolyte losses. In the case of traumatic or postsurgical fistulae, 4–8 weeks of intensive nutritional and medical therapy should be continued to allow spontaneous closure [2]. Factors affecting spontaneous closure of fistulae are listed in Table 99.1. When surgery is undertaken general principles include resection of the fistula, serosal patching or internal drainage of the fistula, correction of any associated pathology, and provision of adequate wound coverage [2].

Management of nutrition is highly important to successful closure of the fistula, as wound healing mechanisms are necessary for closure of fistulae to occur [17,18,41]. The issue of enteral versus parenteral feeding is an ongoing discussion. Based on the critical care literature, the enteral route should be employed when possible as it is more effective in improving nutritional state, with beneficial effects on wound healing and possible favorable effects on gut mucosal integrity [42–45]. Further, enteral nutrition avoids metabolic, infectious, and other safety concerns associated with total parenteral nutrition (TPN) [46]. Historical data on gastrointestinal fistulae clearly demonstrate improved outcomes in the TPN era [47–49]. However, randomized trials have not been performed, and the exact effects of TPN are difficult to determine from these studies. The concept that bowel rest is beneficial is based on a 30%–50% decrease in gastrointestinal secretions in patients on TPN and receiving nothing by mouth [50]. However, while bowel rest will improve fluid and electrolyte management, data supporting spontaneous fistula closure or other significant outcomes are largely lacking [17]. TPN is generally reserved for patients with high-output fistulae (> 500 mL/day), when the patient is unable to tolerate enteral nutrition, or when there is distal obstruction. If oral feeding is used, it is recommended that calorie counts and nutritional assessment be performed to ensure that nutritional needs are being met. Enteral feeding bypassing or directly through the fistula has been reported [51].

High-output fistulae are less likely to close spontaneously than low-output fistulae. This observation underlies the practice of decreasing fistula output, although the evidence that decreasing output improves spontaneous closure is less convincing [17]. It is common to increase the salt and glucose content of oral fluids similar to the management of short bowel syndrome. Proton pump inhibitors and slowed bowel transit using antimotility agents are used. Somatostatin, or its longer half-life analogue octreotide, is widely used to decrease gastrointestinal secretions, although the data supporting its use are mixed. A number of controlled trials of somatostatin or octreotide have compared these agents to standard treatment alone [17,52]. Most trials showed a reduction in the time to fistula closure, although only one study showed a significant improvement in the spontaneous closure rate. Somatostatin may be more effective than octreotide, but the difficulty with constant infusion compared with subcutaneous administration favors octreotide.

Specific considerations

Appendiceal abscesses

A periappendiceal abscess or phlegmon is present in 2%–4% of patients presenting with typical signs and symptoms of acute appendicitis; the incidence is higher if symptoms have been present for several days [53,54] (see Fig. 99.4). Immediate appendectomy is technically difficult and associated with high morbidity. Imaging should be performed to confirm the diagnosis and percutaneous drainage should be considered. Antibiotic coverage for bowel flora should accompany percutaneous drainage [55,56]. After primary nonsurgical treatment, the recurrence rate is less than 10%, and is often associated with an appendicolith. Whether interval appendectomy should be performed after primary nonsurgical

management of an appendiceal abscess is less clear. There is an approximately 2% risk of missed serious diagnosis of cancer or Crohn's disease with a nonsurgical approach. A recent metaanalysis favors a nonsurgical approach without interval appendectomy, but stressed the importance of follow-up with colonoscopy or imaging especially for patients over age 40 [57].

Diverticular abscesses

Complicated diverticulitis occurs when there is an abscess or phlegmom, fistula, stricture, bowel obstruction, or peritonitis and occurs in approximately 25% of patients with acute diverticulitis. In patients with a diverticular abscess but without peritonitis, the size of the abscess is an important determinant of outcome. Abscesses less than 4 cm can be treated effectively with bowel rest and broad-spectrum antibiotics [58,59]. Several recent studies of percutaneous drainage demonstrate that, for larger abscesses, percutaneous drainage with antibiotics improves the patient's clinical course [58,60–64] (see Fig. 99.2). Most patients with complicated diverticulitis require hospitalization and may require repeat imaging to confirm improvement in the radiographic findings. This is particularly true in immunocompromised patients including elderly patients or patients on steroids who may have a paucity of symptoms or clinical findings. A more thorough discussion of recurrence rates and operative management can be found in Chapter 61.

Crohn's-related intraabdominal abscesses and fistulae

Abscesses occur in up to 20% of patients with Crohn's disease [12,14]. They can arise from any involved region of the gut, with the terminal ileum being the most common. They commonly arise postoperatively at the site of an anastamosis. Approximately 50% arise proximal to a narrowed area, resulting in a relative high-pressure region. An abscess is formed if the infection is walled off by inflamed tissue and mesentery. If there is an adjacent bowel loop or an adherent scar, an enteroenterofistula or an enterocutaneous fistula may form. Enterovesical or enterovaginal fistula form in some patients. Fistulae and abscesses in the perianal region present particular clinical and diagnostic considerations that are described in Chapters 57 and 66.

Abdominal abscesses are best identified with CT using intravenous and positive oral contrast. Management of intraabdominal abscesses in Crohn's disease is complicated by the underlying pathology and the immunosuppressive medications used to treat serious Crohn's disease [12]. Percutaneous drainage and antibiotics may successfully treat the immediate infection, but half of patients treated nonoperatively will ultimately require surgery [65]. The use of potent immunosuppression in the setting of an abscess creates a difficult clinical dilemma, especially inpatients presenting with an abscess and intestinal obstruction or near obstruction. Generally, parenteral steroids or anti-tumor necrosis factor (TNF) therapy are deferred until the abscess is drained and antibiotics are ongoing. It is anticipated, but not proven, that treatment with disease-modifying therapy earlier in the course of the disease will prevent complications such as strictures, abscesses, and fistulae and reduce the occurrence of these difficult situations.

Data on medical therapy for Crohn's fistulae are derived from studies that include predominantly patients with perianal disease, with fewer patients in each series having internal or other fistulae. Corticosteroids are not effective in closing fistulae. Antibiotics are indicated if there is infection present, and leads to healing in some patients, but is not definitive therapy for most. Controlled trials of azathioprine and 6-mercaptopurine demonstrate efficacy in fistula closure and improved symptoms [66,67]. Other agents such as tacrolimus also show efficacy [68]. The most robust data on fistula closure of all types suggests the use of anti-TNF therapy, where closure rates approach 60% [14,69,70]; most fistulae reopen when the therapy is stopped. A combined approach of medical (commonly anti-TNF therapy) and limited surgical therapy is commonly used and often successful [66,67,71]. Medical therapy for fistulae is considered in Chapter 57 in more detail.

Gastric fistulae

Most cases of gastric fistulae are postsurgical. In past decades, surgery for ulcer disease was the most common cause, with ischemia and anastamosic tension considered the major factors. Gastric fistulae are more commonly the result of long-term gastrostomy tube placement. Fistulae in this setting are related to the duration of tube placement and nutritional status of the patient [72]. The rate of gastrocutaneous fistulae following operations for nonmalignant conditions such as ulcer disease, reflux, and obesity is 0.5%–3.9% [2]. With the increasing rate of surgical therapy for obesity, it is anticipated that obesity surgery will be a more common cause of gastrocutaneous fistulae in the future. Spontaneous gastrocutaneous fistulae are uncommon, but may result from ulcer disease, ischemia, radiation, and cancer. The effluent from a gastrocutaneous fistula can be high volume, and result in hypochloremic hypokalemic metabolic alkalosis and skin breakdown. These symptoms may be improved with high-dose proton pump inhibitors, and good skin care. Treatment is generally surgical, but endoscopic approaches have been utilized [73,74].

Pancreatic abscesses and fistulae

A pancreatic abscess is a devastating complication of severe necrotizing pancreatitis. It is typically considered when a patient with severe acute pancreatitis has CT findings suggesting pancreatic necrosis. Development of a pancreatic abscess occurs late in the course of acute pancreatitis, occurring in the second or third week in 40%–70% of patients

[75]. Persistent fever, elevated white blood cell count, sepsis, bacteremia, or failure to demonstrate improvement raises the index of suspicion for a pancreatic abscess. Data including a recent metaanalysis favor prophylactic antibiotics to reduce the mortality and morbidity of pancreatic necrosis [75]. As with abscesses in other abdominal sites, percutaneous aspiration to document infection and refine antibiotic therapy is recommended [76,77]. Surgical therapy for pancreatic abscess is associated with high mortality, and therefore minimally invasive laparoscopic, radiographic or endoscopic techniques for debridement and drainage have been tried [78,79]. Surgical therapy remains the standard, but patient factors and local experience and expertise may determine the exact approach. Necrotizing pancreatitis and pancreatic abscess are discussed in more detail in Chapter 68.

A pancreatic fistula develops as a complication of severe acute pancreatitis or trauma or as a result of surgery to the pancreas. Endoscopic retrograde cholangiopancreatography is used to determine pancreatic duct anatomy and establish continuity; a pancreatic duct stent can improve drainage in certain settings. CT can also help to delineate anatomy and rule out abscess or other pathology that could affect drainage. Pancreatic fistulae may be high volume and may have significant metabolic consequences, with bicarbonate loss resulting in acidosis and malabsorption occurring due to loss of digestive enzymes. Duodenal ulcers can occur due to diversion of the alkaline pancreatic secretions from the duodenum. Fluid and electrolyte management, proton pump inhibitor therapy, and pancreatic enzyme replacement are used. Octreotide is effective in decreasing fistula volume and may improve spontaneous closure rates [17,52]. Nonoperative therapy is generally successful and only 10%–30% of patients require surgery for fistula closure [2].

Peritoneum

Embryology, anatomy, and physiology

The peritoneum is the mesothelial lining of the peritoneal cavity and its contained viscera. Embryologically, it develops from the primitive celom, which is formed by a splitting of the lateral mesoderm into somatic and splanchnic layers [1]. The parietal peritoneum, derived from the somatic layer, lines the abdominal cavity, diaphragm, and pelvis. The visceral peritoneum, from the splanchnic layer, covers the intraperitoneal organs and forms the mesenteries by which they are suspended.

The peritoneum and mesentery are supplied mainly by the splanchnic blood vessels and, to a lesser extent, by branches of the lower intercostal, lumbar, and iliac arteries. Differences arise in the innervation of the visceral and parietal peritoneum, which lead to different perceptions of painful stimuli. The visceral peritoneum receives afferent innervation from the autonomic nervous system and responds primarily to traction and pressure; painful stimuli are perceived as a poorly localized, dull pain. In contrast, the parietal peritoneum is innervated by both somatic and visceral afferent nerves; noxious stimuli are perceived as a localized, sharp pain with rebound tenderness.

The peritoneum, with a total surface area of approximately 2 m^2, serves as a bidirectional dialysis membrane through which the passage of both large- and small-molecular-weight solutes is accomplished predominantly by simple passive diffusion [2,3]. Factors that can alter absorption include intraabdominal pressure, temperature, pH, increased portal pressure, lymphatic blockade, and scarring of the peritoneum [4,5]. The peritoneum contains a complex multileveled defense system that provides an innate immune system to protect against inflammatory processes [6,7]. This system consists mainly of mechanical clearance of the peritoneal cavity; sequestration mechanisms, such as fibrin trapping of bacteria activation of complement, particularly C3a and C5a, which stimulate neutrophil chemotaxis; and the bacteria-killing actions of polymorphonuclear neutrophils and macrophages. The disease processes of the peritoneum discussed in this section include inflammation of the peritoneum (i.e., peritonitis), primary mesothelioma, and pseudomyxoma peritonei.

Peritonitis

Peritonitis involves a local or generalized inflammation of the parietal and visceral peritoneum. With the development of broader-spectrum antibiotics, newer anesthetic techniques, and modern preoperative and postoperative monitoring in the intensive care unit, the mortality from peritonitis has been greatly reduced; however, despite these advances, peritonitis remains a formidable challenge confronting physicians.

Peritonitis can be classified as either *primary* or *secondary*. Primary peritonitis is less common and involves a spontaneous infection of preexisting ascites in the absence of any obvious intraabdominal source [8,9]. The spectrum of bacteria causing this syndrome and the patient population primarily affected has changed. Spontaneous bacterial peritonitis is more common in adults than in children and shows no differential gender incidence. The group most commonly affected, formerly children with nephrosis, is adults with cirrhosis. Whereas gram-positive organisms formerly caused most of these infections, gram-negative enteric bacteria account for 60%–80% of organisms in ascitic fluid cultures, with *Escherichia coli* and *Klebsiella pneumoniae* the most common species [10]. Primary, or spontaneous, peritonitis is discussed in Chapter 90.

Secondary peritonitis is caused by diseases of or injury to the intraabdominal organs causing a mechanical break in the gastrointestinal tract [11]. Acute suppurative peritonitis,

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

granulomatous peritonitis, and chemical (aseptic) peritonitis belong to this category and are discussed in this section.

Acute suppurative peritonitis

Etiology

Spillage of intestinal contents into the peritoneal cavity as a result of primary intraabdominal disease (e.g., perforated peptic ulcer, appendicitis, diverticulitis, perforated carcinoma), penetrating trauma, or iatrogenic perforation after instrumentation or radiological procedures is the usual cause of acute suppurative peritonitis [12,13].

Clinical manifestations

Abdominal pain, which may be sudden in onset if associated with a perforated viscus, is the predominant symptom [14]. Characteristically, patients with peritonitis lie supine with knees flexed and with frequent and limited intercostal respirations. Examination of the abdomen of a patient with generalized peritonitis reveals distention and bowel sounds that are either hypoactive or absent. Of the various physical findings of peritonitis, tenderness and muscle guarding are the most important. Tenderness is often maximal over the organ in which the process originated; however, as the inflammation spreads, tenderness may be present over the entire extent of the peritoneum. Rebound tenderness, defined as the sudden and severe pain produced with the release of the hand after deep abdominal palpation, is often described as a useful adjunct in the diagnosis of the acute abdomen. This test, however, elicits no more information than that obtained from a careful and gentle examination of the abdomen and, furthermore, may cause unexpected and undue pain to the patient. Symptoms associated with acute suppurative peritonitis include anorexia, nausea that is often accompanied by vomiting, fever (38°C–40°C), and signs of hypovolemia (e.g., tachycardia, dry mucous membranes, and hypotension). Typical diagnostic findings in patients with acute peritonitis include a leukocytosis, often with an increased number of bands in the differential count. Radiographic findings are usually nonspecific, with evidence of a paralytic ileus of both the small bowel and colon in some patients. Free air under the diaphragm may be seen in an upright chest radiograph if a ruptured viscus is the cause (Fig. 100.1). Although conventional plain radiographs remain as a first-line investigation, extraluminal air is identified in only 50%–70% of cases [15]. Computed tomography (CT) is recognized to be more sensitive for the detection of free air with reported sensitivities of 70%–100% [15]. The improved sensitivity of CT allows for the detection of free air that would not normally be detected with conventional plain films. Furthermore, indirect findings of bowel perforation such as phlegmon, abscess, or free peritoneal fluid can easily be detected with CT imaging [16]. Generally, the diagnosis of acute suppurative peritonitis is based on clinical manifestations and a thorough physical examination; laboratory and radiological procedures serve mainly in a confirmatory role.

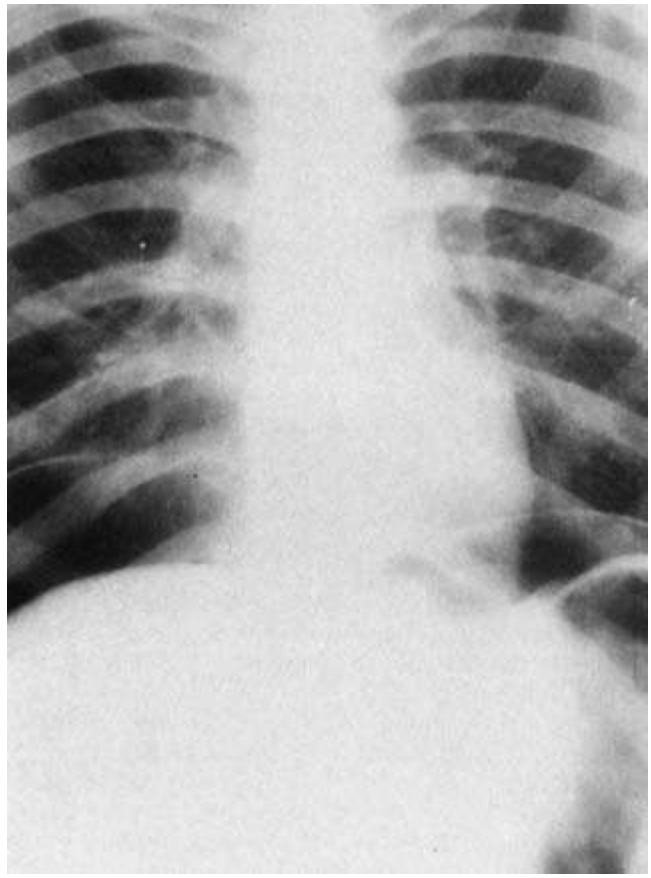

Figure 100.1 Upright chest radiograph demonstrates free air under both diaphragms after perforation of a duodenal ulcer. Courtesy of Charles J. Fagan, MD, Galveston, TX.

Clinical course and complications

Usually, suppurative peritonitis has an abrupt onset and a relatively short course with a rapid progression. Mortality results from fluid shifts and systemic endotoxin, which may cause hypovolemia and septic shock. Early diagnosis with prompt surgical intervention and aggressive preoperative and postoperative management is essential to reduce the morbidity and mortality from multiple organ system failure resulting from untreated peritonitis [17–20].

Treatment

The hallmarks of treatment include resuscitation with intravenous fluids to restore normal physiology, broad-spectrum antibiotics, and operative management to control the source of peritoneal contamination and irrigate the peritoneal cavity (Table 100.1).

Resuscitation involves aggressive administration of isotonic crystalloid fluids (e.g., Ringer's lactate) to correct hypovolemia

Table 100.1 Treatment of acute suppurative peritonitis

Restore normal physiology
Fluid resuscitation
Correct electrolyte imbalances
Supplemental O_2
Monitoring (e.g., vital signs, urine output, CVP, PCWP)
Broad-spectrum antibiotics
Operative intervention
Control the source of infection
Irrigate peritoneal cavity
Planned reoperations if source of infection not controlled
Investigational adjuvant therapies
Immunostimulation (e.g., administration of biological response modifiers, vaccination)
Immunorepletion (e.g., administration of antiendotoxin antibody)
Immunoabrogation (e.g., cytokine antagonism, inhibition of prostaglandin synthesis)

CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure.

and electrolyte imbalances. Careful monitoring of the response to rapid fluid resuscitation is necessary, particularly if large fluid volumes are required or the patient has impaired cardiac reserve. Monitoring usually entails frequent assessment of vital signs, hourly measurement of urine output, and frequent determination of central venous pressure or, preferably, placement of a Swan–Ganz catheter for pulmonary capillary wedge pressure and pulmonary artery pressure determinations in an intensive care unit. Oxygen may be administered to overcome the mild hypoxemia that is commonly present, and nasogastric intubation is required to decompress the stomach.

Antibiotics play an important, albeit adjuvant, role in the management of patients with peritonitis. To be effective in the treatment of peritonitis, antibiotic therapy must be initiated before and continued during and after surgical therapy. In addition, broad-spectrum antimicrobial therapy should be directed toward both aerobic and anaerobic pathogens. The combination of an aminoglycoside (e.g., gentamicin or tobramycin) with clindamycin has long been considered the "gold standard" in the treatment of intraabdominal infections. However, concerns about nephrotoxicity have prompted investigators to evaluate the use of single agents (e.g., third-generation cephalosporins, broad-spectrum penicillins with β-lactamase inhibitors and carbapenems) in the treatment of intraabdominal infections. A number of single and combination drug choices have been recommended, all with comparable efficacy, by the Surgical Infection Society for the treatment of intraabdominal infections [21,22]. A more recent Cochrane review demonstrated no difference in morbidity and mortality when single agents were compared to combination regimens; however, the combination of fluoroquinolones/antianaerobes and cephalosporins/β-lactamase inhibitors did appear to be statistically more effective [23].

Expeditious surgical intervention remains the mainstay of treatment [24]. After an adequate period to ensure resuscitation, laparotomy should be performed to irrigate the peritoneal cavity copiously and to repair the rupture. Aerobic and anaerobic cultures should be obtained to ensure appropriate antibiotic coverage. If the source of infection is not eliminated, the debridement is incomplete, or definitive abdominal closure cannot be accomplished, staged laparotomies may be required for redebridement, removal of abdominal packs, and repeat irrigation until the source of infection is controlled and abdominal closure is obtained. In this situation, the placement of a large abdominal zipper can greatly facilitate abdominal opening and closing. Other procedures that have been described, but found not to be beneficial, include continuous postoperative irrigation with Tenckhoff catheters and radical peritoneal debridement. Recently, laparoscopy has been used as both a diagnostic and a therapeutic modality in selected patients with peritonitis [25–27]; the future role and possible advantages of laparoscopy compared with a formal laparotomy remain to be defined.

The clinical syndrome of sepsis results from a systemic host response to infection that, in turn, triggers the cytokine cascade. A number of cytokines have been identified and are generally classified as either proinflammatory (e.g., tumor necrosis factor-α [TNF-α] and interleukin-1 [IL-1]) or anti-inflammatory (e.g., IL-10 and IL-1 receptor antagonist). It is generally accepted that a careful balance exists between proinflammatory and antiinflammatory cytokines; a disruption in this balance leads to an exaggerated immune response resulting in multiple organ system failure and possibly death. Therefore, novel agents directed at immunomodulation offer an attractive area of research and may offer new therapies in the treatment of sepsis. One such approach has focused on neutralizing the proinflammatory cytokine TNF-α using monoclonal anti-TNF antibodies. Three large clinical trials (i.e, the North American Sepsis Trials [NORASEPT I and II] and the International Sepsis Trial [INTERSEPT]) were conducted to test the efficacy of anti-TNF therapy in the treatment of severe sepsis [28–30]. These trials generated some conflicting results, but overall, anti-TNF therapy was noted to have possible survival benefits in a select subgroup of patients (e.g., patients in septic shock) when administered early (< 24 h from the onset of symptoms). Other approaches to immunomodulation are under investigation. One such approach is the use of interferon-γ, granulocyte–macrophage colony-stimulating factor and intravenous immunoglobulins to promote monocyte activity [31]. These have demonstrated encouraging results in small studies; however, large randomized trials are needed to test the clinical efficacy of these modalities in sepsis. Finally, anticoagulant therapies, such

as tissue-factor-pathway inhibitors and activated protein C, have emerged in the treatment of sepsis [31]. While these therapies may not be regarded as true immunomodulators, research has suggested that the coagulation cascade interacts with various inflammatory pathways. A recent large, multicenter placebo-controlled trial has demonstrated significantly increased survival following infusion of recombinant human activated protein C [32].

Granulomatous peritonitis

Etiology

Granulomatous peritonitis is a disease process characterized by peritoneal inflammation that is associated with formation of granulomas and an increased incidence of adhesions. The disease most commonly associated with granulomatous peritonitis is tuberculosis [33,34]. Other, less common, causes include fungal (e.g., *Candida*, *Histoplasma*), amebic, and parasitic infections [35–37]. Iatrogenic causes of granulomatous peritonitis also occur, usually related to the presence of glove lubricants (e.g., talc, cornstarch) or cellulose fibers from gauze, surgical drapes, or gowns within the peritoneum [38].

Tuberculous peritonitis

Epidemiology

After years of a decreasing incidence of tuberculosis in the United States, there has been a general reemergence of this disease secondary to an increase in cases of acquired immunodeficiency syndrome (AIDS) and an increase in the number of immigrants [39–44]. Cases of tuberculosis have decreased in the United States since 1984 but the number of new cases worldwide has increase approximately 20% [45]. The recent appearance of multidrug-resistant strains of tuberculosis is particularly disturbing [44,46,47]. In addition to patients with AIDS, other groups at high-risk include poorly nourished, debilitated patients, patients requiring ambulatory peritoneal dialysis, and those with cirrhosis, diabetes, or malignancy [48,49].

Etiology

Tuberculous peritonitis is a form of abdominal tuberculosis that can involve the omentum, intestinal tract, liver, spleen, or female genital tract in addition to the parietal and visceral peritoneum. It accounts for approximately 11%–16% of extrapulmonary cases [50]. The overall incidence of abdominal tuberculosis in the United States is about 0.5%–1% of all cases of tuberculosis [33,34]. Tuberculous peritonitis is usually associated with a primary focus of tuberculosis elsewhere. This primary focus is usually the lung; however, only about one-third of cases have clinical or radiographic evidence of pulmonary tuberculosis. The pathological organism, *Mycobacterium tuberculosis*, can gain entry to the peritoneal cavity by one of three mechanisms: transmurally from diseased bowel, from tuberculous salpingitis, or, more commonly, by hematogenous spread from a pulmonary focus [33,34].

Clinical manifestations

Generally, the onset is insidious, with more than 70% of patients having had symptoms for more than 4 months before definitive diagnosis. The most common symptoms are constitutional and include fever, anorexia, weakness, malaise, and weight loss. Abdominal distention caused either by ascites or by partial obstruction may be present. On examination, the abdomen is diffusely tender in most patients; however, the classic doughy abdomen is rarely found. Tuberculous peritonitis should be suspected in high-risk or immunocompromised patients with ascites, fever, unexplained generalized symptoms, and diffuse abdominal pain or tenderness [33,34].

Differential diagnosis and diagnostic studies

Routine laboratory and radiographic studies are rarely diagnostic. A normal leukocyte count is present in most patients, and anemia is found only occasionally. Tuberculin skin tests are usually positive in patients with tuberculous peritonitis; however, a negative result is of no help in excluding the disease. Chest radiographs are abnormal in 80% of patients and include findings of pleural effusions or pulmonary infiltrates. Radiographs of the abdomen are seldom of benefit; however, a CT scan may be useful in identifying thickened bowel and ascites.

Examination of the peritoneal fluid may prove useful (see Chapter 90). In patients with tuberculous peritonitis, the protein content characteristically exceeds 3.0 g/dL, and glucose concentration is below 30 mg/dL in more than 80%. Most patients have a leukocyte count higher than 250 cells/mm^3 and a relative lymphocytic pleocytosis. Acid-fast stains are rarely positive unless at least 1 L of ascitic fluid is obtained, concentrated by centrifugation, and then examined. To compound the diagnostic problem, bacterial cultures of *M. tuberculosis* often require 4–6 weeks of incubation. For these reasons, much attention has been given to the development of a rapid diagnostic test for tuberculosis. Promising new approaches include adenosine deaminase, polymerase chain reaction, ligase chain reaction, and enzyme-linked immunosuorbent assays [48,51]. Although these tests hold great potential, a number of issues surround their routine use including cost, availability, and low predictive value.

The diagnosis of tuberculous peritonitis is often suggested by findings at laparoscopy or laparotomy. With reported sensitivities of 100% and low complication rates, laparoscopy with biopsy is considered the gold standard in diagnosing peritoneal tuberculosis [33,52]. Tuberculous peritonitis is characterized by stalactite-like fibrinous masses from the parietal peritoneum; in addition, the peritoneum may be studded with small granulomas.

The differential diagnosis of tuberculous peritonitis is variable, depending on the acuteness of the symptoms. In patients with a prolonged history, tuberculous peritonitis most commonly is confused with Crohn's disease or carcinoma. In patients presenting acutely, the differential diagnosis must

include such entities as acute appendicitis, cholecystitis, perforated ulcer, and salpingitis.

In summary, the diagnosis of tuberculous peritonitis is often difficult to make and requires an initial suspicion based on the clinical presentation (i.e., fever, anorexia, and abdominal pain) in combination with findings of a nonexudative ascites. It is crucial that a suspected diagnosis be confirmed by open or laparoscopy-assisted biopsy before committing the patient to a long-term treatment regimen with multiagent therapy.

Clinical course and therapy

Before the advent of chemotherapy, the mortality from tuberculous peritonitis was as high as 60%; the disease is, for the most part, readily curable with the available agents. Current recommendations for tuberculous peritonitis follow the principles of treatment for pulmonary tuberculosis. Treatment consists of a regimen of isoniazid, rifampin, pyrazinamide, and ethambutol for 6 months. Therapy should be prolonged for patients who exhibit a slow response to treatment. Although not proven experimentally, corticosteroids for 2–3 months may be beneficial in preventing the formation of dense fibrous adhesions, which could lead to bowel obstruction. The most worrying feature of the resurgence of tuberculosis has been the recent outbreaks of multidrug-resistant isolates that often fail to respond to isoniazid and rifampicin, the two cornerstone antituberculosis drugs [39–44,46,53]. Treatment of patients with multidrug-resistant tuberculosis should ideally be managed by physicians with expertise in drug-resistant disease.

Chemical (aseptic) peritonitis

Etiology

Peritoneal inflammation can result from spillage of irritant materials that are initially sterile; with time, secondary bacterial contamination occurs with signs and symptoms similar to those of acute suppurative peritonitis. Most of the substances that cause a chemical peritonitis are capable of acting as adjuvants to promote the growth of bacterial contaminants. These agents include bile, usually resulting from open or laparoscopic biliary tract operations without adequate external drainage, from inadvertent injury to the biliary tract, or from external trauma [54–56]; urine, from intraperitoneal bladder rupture [57]; and chyle, which occurs secondary to injuries of large lymphatic vessels during operations on retroperitoneal organs [58]. In addition, spillage of barium sulfate, secondary to perforation of the gastrointestinal tract from diagnostic procedures, results in a severe peritoneal irritation, and, in combination with accompanying enteric bacteria, poses a lethal threat to the patient [59,60].

Treatment

The same principles that apply to the management of acute suppurative peritonitis also apply to the treatment of chemical peritonitis. Adequate intravenous fluids to replace the peritoneal fluid sequestration and antibiotics are followed by laparotomy to irrigate the abdomen and control the source of the peritoneal contamination.

Peritonitis as a complication of chronic peritoneal dialysis

Etiology

Continuous ambulatory peritoneal dialysis (CAPD) has gained increasing acceptance as an efficacious and cost-effective alternative to chronic hemodialysis in patients with end-stage renal disease. It is estimated that, in the United States alone, about one-fourth of the more than 100 000 dialysis patients use CAPD. Despite its obvious advantages, the most common complication of CAPD is infectious peritonitis resulting from bacterial contamination of the peritoneal cavity [61]. Even with better patient education regarding sterile techniques and proper cleaning around the catheter site, peritonitis in this group of patients is the major source of morbidity and the largest single cause of patient failure on CAPD. Although the incidence of peritonitis varies with the institution, peritonitis as a complication of CAPD averages 1.1–1.3 episodes per patient-year of treatment [61,62].

Epidemiology

The most frequent portals of entry for bacteria in CAPD patients include the exit site of the dialysis catheter and the tunnel through which the catheter traverses the abdominal wall. Infection usually occurs as a result of a break in aseptic technique with secondary contamination. Other possibilities for contamination include hematogenous or lymphatic dissemination from a septic focus originating from the patient. In contrast to other types of peritonitis, CAPD-related peritonitis usually is caused by a single organism, in most cases by gram-positive cocci (*Staphylococcus epidermidis*, *Staphylococcus aureus*, streptococci, and enterococci) [61–65]. Gram-negative bacteria account for about 25% of all cases of CAPD peritonitis, with the most common being *E. coli* and *Pseudomonas aeruginosa*. The presence of anaerobic organisms or a mixed flora should raise suspicion of an intestinal perforation or other intraabdominal disease as the cause of peritonitis. Fungal peritonitis is relatively uncommon but remains the most serious type of infective peritonitis in CAPD patients because of treatment difficulties [66]. At least 20 different fungal species have been cultured; however, *Candida albicans* and *Candida tropicalis* remain the most common.

Clinical manifestations

The severity of symptoms is dependent on the infecting organism; however, the signs and symptoms in most patients with CAPD peritonitis are clinically less severe than those in patients with suppurative peritonitis. Some cases may even be asymptomatic and detected only by the presence of a cloudy effluent. The predominant symptom found in

patients is a diffuse abdominal pain, usually associated with a lowgrade fever and leukocytosis. Other symptoms may include hyperhydration, diarrhea, hypotension, and pressure pain above the catheter tunnel. Characteristically, a turbid dialysis effluent is found in nearly all cases of CAPD peritonitis.

Diagnosis

The diagnosis of CAPD peritonitis is based on both clinical and laboratory findings [61,65,67]. The clinical diagnosis should be based on the presence of two of three criteria: abdominal pain or tenderness, a turbid dialysate containing more than 100 neutrophils/mm^3, and a positive culture from the peritoneal fluid. Even if the patient's history and examination are consistent with the diagnosis of peritonitis, it is essential that the dialysate be evaluated to confirm the diagnosis and to identify the causative organisms. In some centers, the use of bacteria-concentrating techniques yielded positive cultures in more than 90% of cases.

Therapy and clinical course

Of patients with CAPD peritonitis, 70%–80% can be treated successfully on an outpatient basis without hospitalization or interruption of dialysis [61,63–66,68–70]. CAPD peritonitis is treated most effectively by intraperitoneal administration of antibiotics. The initial choice of antibiotics should be broad enough to cover the most common pathogens causing CAPD peritonitis and then should be changed according to susceptibility testing. Recently, the International Society for Peritoneal Dialysis (ISPD) has altered its recommendations for empirical therapy of peritonitis. Current recommendations include a first-generation cephalosporin for gram-positive organisms, a third-generation cephalosporin for gram-negative organisms, and a combination of first- and third-generation cephalosporins when no organism is identified [65]. Aminoglycosides may be substituted for treatment of gram-negative organisms in patients with residual urine output of < 100 cm^3/day. Furthermore, ISPD no longer recommends the routine use of vancomycin; however, this recommendation remains controversial. In addition to antibiotics, heparin also is added to the dialysis bag to reduce fibrin formation and, thereby, the incidence of postinfective adhesions. Indications for catheter removal include persistence of peritonitis after 4–5 days of treatment and the presence of fungal or tuberculous peritonitis, fecal peritonitis, or severe skin infection at the catheter site.

Peritonitis in the immunocompromised host

Etiology and diagnosis

The AIDS epidemic and the increasing use of immunosuppressive therapy for cancer, autoimmune disease, and multiple organ transplantation procedures have combined to increase greatly the incidence of opportunistic infections of the gastrointestinal tract [53,71]. The differential diagnosis of abdominal pain in AIDS is broad and involves both AIDS- and non-AIDS-related disorders (see Chapter 104) [71–73]. Perforation of the small bowel or colon secondary to cytomegalovirus enteritis is a frequent cause of peritonitis in patients with AIDS [74,75]. Other organisms reported to cause peritonitis in these patients include *Mycobacterium avium-intracellulare*, *M. tuberculosis*, *Cryptococcus neoformans*, *Strongyloides* spp., and *Leishmania* spp. [71–74,76–78].

Clinical manifestations and treatment

Immunocompromised patients with peritonitis usually present with severe abdominal pain as the predominant symptom, like patients with suppurative peritonitis. Principles of management include emergent laparotomy and resection of the involved portion of bowel, intravenous fluid resuscitation, and broad-spectrum antibiotics.

Primary mesothelioma

Incidence and etiology

Primary mesotheliomas, arising from mesenchymal and epithelial components, are uncommon. The reported incidence in the United States is only 2.2 cases per million population; however, studies suggest that the incidence is increasing throughout the world and especially in industrialized countries [79–83]. Only 20%–40% of mesothelioma occurs in the peritoneum, with most of these tumors originating from the pleura. Malignant mesothelioma is linked to exposure to asbestos, and there is a strong association with occupations that require workers to handle or work in proximity to asbestos, such as those in the textile, insulation, building, demolition, and shipyard industries [81,82,84–86]. There is a latency period of 20–40 years from significant asbestos exposure to development of mesothelioma; two-thirds of the patients are diagnosed at 45–64 years of age, and there appears to be a male predominance. Crocidolite is considered the most oncogenic type of asbestos, whereas the oncogenic potential of chrysotile is still debated. Although asbestos is the predominant cause of this disease, other etiological agents may be associated with primary mesothelioma, including genetic factors, use of the angiographic contrast material Thorotrast (thorium dioxide), radiation exposure, and recurrent peritonitis.

Clinical manifestations

The clinical presentation is nonspecific, with the predominant complaint being abdominal pain present in the epigastrium or right upper quadrant. Other symptoms include nausea and vomiting, malaise, fever, weight loss, diarrhea, and anemia. Ascites is the most common physical finding and occurs in 90% of patients. Peritoneal mesotheliomas can produce and secrete a variety of ectopic hormones, including antidiuretic hormone, growth hormone, and insulin-like factors, which can produce associated paraneoplastic syndromes with symptoms of hypoglycemia, hyponatremia, thrombocytosis, and increased production of fibrin-degradation products

[79–82,86]. Interestingly, peritoneal mesothelioma has been described in association with other synchronous neoplasms such as colorectal cancer.

Differential diagnosis and diagnostic studies

Malignant mesothelioma is a difficult malignancy to diagnose early [79–82,86,87]. Mesotheliomas are generally firm, white tumors that present as individual nodules studding the peritoneal surface and tend to spread over the surface of the intraabdominal organs, eventually encasing the viscera. Ultrasound and CT studies can suggest the diagnosis, demonstrate the extent of tumor, and also aid in directed biopsy of suspicious lesions; however, in most cases, the diagnosis is confirmed after diagnostic laparoscopy or laparotomy.

Microscopic and immunohistochemical studies are available to aid in the diagnosis [88,89]. Immunohistochemistry is useful for two reasons:

- to determine whether the mesothelial cells present are benign or malignant
- to distinguish mesothelioma from an adenocarcinoma.

The typical analysis of a suspected mesothelioma should include electron microscopy, periodic acid–Schiff (PAS) stain, Alcian blue stain to detect hyaluronic acid, and an anticarcinoembryonic antigen (anti-CEA) antibody stain. Ultrastructural features on electron microscopy include long, slender microvilli and diffuse cytoplasmic or perinuclear distribution of tonofilaments. Mesotheliomas lack intracellular mucin on PAS stains, should produce negative results on anti-CEA antibody stain, and often stain positively for hyaluronic acid. In contrast, adenocarcinomas often stain positively for mucin and CEA and do not contain hyaluronic acid. Well-characterized monoclonal and polyclonal antibodies hold great promise for improving the diagnostic accuracy [90]. Recent studies indicate that staining with calretinin, a member of the family of calcium-binding proteins, and cytokeratin 5/6 appear to be the most sensitive and specific positive members for distinguishing between malignant epithelial mesotheliomas (positive staining) and metastatic adenocarcinomas (negative staining) [89]. Among the antibodies that are considered to be negative members for mesothelioma, MOC-31, CEA, and BG-8 seem to be the best diagnostic discriminators. Other useful negative markers include B72.3, Leu-M1, Ber-EP4, and thrombomodulin. Immunostaining for N-cadherin and E-cadherin appears to be promising in the diagnosis of mesothelioma. Another useful marker is epithelial membrane antigen, which has been shown to be of value in distinguishing between benign and malignant mesotheliomas. Additional molecular studies that may serve as useful adjuncts to the diagnosis include the identification of high levels of the platelet-derived growth factor (PDGF) in malignant mesotheliomas [90]. Another promising area of research involves gene expression microarray analysis [91]. Microarray data may help to identify single genes or gene expression patterns that will aid in diagnosis and predicting prognosis.

Less common primary peritoneal neoplasms that should be included in the differential diagnosis include benign papillary mesotheliomas, benign fibrous mesothelioma, adenomatoid tumors, and multicystic peritoneal mesothelioma [81,82].

Genetic factors

With the advances in molecular techniques and the ability to identify genetic abnormalities in various tumors, studies have focused specifically on potential genetic abnormalities in mesotheliomas [79,80,84,85,91–93]. The accumulation of numerous chromosomal deletions in a number of mesotheliomas suggests a multistep process of tumorigenesis, characterized by the loss or inactivation of various tumor suppressor genes. Genetic abnormalities that have been identified include frequent deletions of specific sites within chromosome arms 1p, 3p, 6q, 9p, 13q, 15q, and 22q [92,93]. Loss or mutation of the $p16^{Ink4a}$ tumor suppressor gene at 9p21 has been noted with high frequency (~ 85%) and may contribute to the pathogenesis of these tumors. In addition, another recurrent theme of genetic abnormalities in mesotheliomas is mutation or allelic loss of neurofibromatosis type 2 (*NF2*), a tumor suppressor gene, at 22q12. Recent studies have identified the presence and expression of simian virus 40 (SV40) in a number of mesotheliomas [94,95]. SV40 large T antigen has been shown to inactivate the tumor suppressor gene products Rb and p53, suggesting the possibility that asbestos and SV40 could act as cocarcinogens in mesothelioma. Furthermore, circulating antibodies to SV40 antigens have been described, raising the possibility that the immune system may be modulated to treat patients with mesothelioma. Finally, expression of growth factors, including PDGF-A and PDGF-B, insulin-like growth factors I and II, and transforming growth factors α and β, has been identified in these tumors. A possible paracrine/autocrine role for PDGF has been postulated because the PDGF receptor is expressed in a number of mesotheliomas. Continued studies are required to determine whether these genetic abnormalities play a role in the pathogenesis and progression of the mesothelioma tumors and may serve as potential targets for novel treatment strategies.

Treatment and prognosis

Therapy for mesothelioma has proved disappointing, mainly because of the advanced stage of the disease at diagnosis and the local aggressiveness of the tumor [96,97]. Rarely can surgery be performed for a curative resection; rather, laparotomy serves to establish a tissue diagnosis and to perform palliative procedures such as bypassing obstructive lesions or tumor debulking. Chemotherapy offers little improvement in overall patient survival. Doxorubicin, alone or in combination with other antineoplastic agents, achieves the best, albeit a minimal, response. Studies suggest that surgical cytoreduction and multimodality therapy, especially with paclitaxel and cisplatin chemotherapy, may confer a survival

advantage. In addition, there is emerging evidence of improved patient survival using hyperthermic intraperitoneal infusion of the chemotherapeutic agent in patients with primary peritoneal mesotheliomas [98–100]. Radiation therapy has been used in combination with intracavitary instillation of various chemotherapeutic agents or with systemic chemotherapy but with only minimal success.

Future directions for the management of mesothelioma include the use of IL-2, interferon-γ, TNF-α, monoclonal antibodies, and cancer vaccines, which may prove beneficial when used in combination with other therapies. The results of recent trials suggest potential benefits of chemoimmunotherapy for the treatment of mesothelioma. Novel treatment strategies under investigation include the introduction of the herpes simplex virus thymidine kinase gene into the mesothelioma so that growth is inhibited after administering ganciclovir and the transfection of antisense oligonucleotides to the growth factors PDGF-A or -B [79,80,101,102]. Multiple obstacles, including transfection efficiency and proper vector construction, must be overcome before these types of gene therapy protocols will be clinically beneficial. The prognosis for mesothelioma of the peritoneum is poor. Death usually occurs within 12–14 months of the diagnosis from progressive gastrointestinal tract obstruction and debility.

Pseudomyxoma peritonei

Incidence and etiology

Pseudomyxoma peritonei is a rare condition manifested by diffuse, gelatinous implants of the peritoneal cavity and omentum arising from mucinous neoplasms of either the appendix or ovary. The reported incidence of pseudomyxoma peritonei is approximately 2 in 10 000 laparotomies. The vast majority of female patients with pseudomyxoma peritonei have disease in both the appendix and ovary; therefore, there is no general agreement regarding the tissue of origin. Recent applications of immunocytochemistry and genetic analysis by polymerase chain reaction strongly suggest that most cases are the result of metastases from appendiceal neoplasms [103–105].

Clinical features and diagnosis

Women between 45 and 55 years of age make up about 75% of patients with pseudomyxoma peritonei. This is usually an unexpected diagnosis made at laparotomy for a preoperative diagnosis of appendicitis or ovarian tumor. Patients can present with an increasing abdominal girth secondary to mucinous ascites or intestinal obstruction, abdominal pain, or a mass in the abdomen [105–107].

Histologically, pseudomyxoma peritonei is characterized by a benign appearance with simple columnar epithelium containing mucin-filled vacuoles [107,108]. Certain features, noted on sonography or CT scan, are characteristic for this disease. Sonographic findings include multiple intraperitoneal multilocular cysts and ascitic septation. A characteristic CT finding of pseudomyxoma peritonei is "scalloping" of the hepatic and bowel margins secondary to extrinsic compression by ascitic spaces containing gelatinous material (Fig. 100.2). The role of magnetic resonance imaging (MRI) in diagnosing pseudomyxoma remains to be defined. T2-weighted images accentuate differences between mucinous and fluid ascites; however, a major disadvantage of MRI is the added expense compared with CT scan.

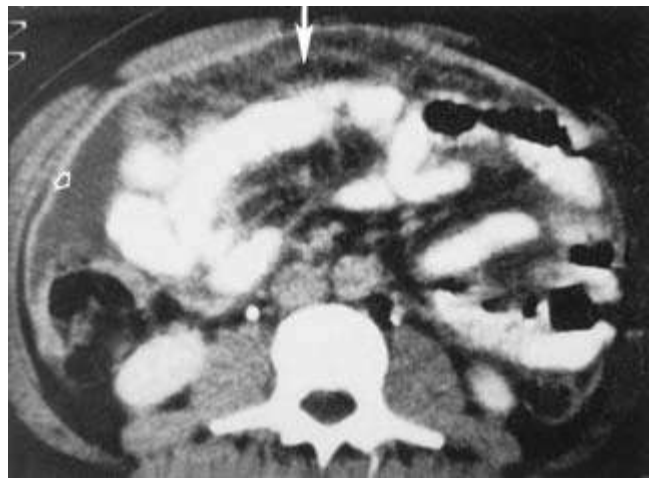

Figure 100.2 Computed tomography scan demonstrates large gelatinous masses (arrows) in a patient with pseudomyxoma peritonei. Courtesy of Charles J. Fagan, MD, Galveston, TX.

Treatment and prognosis

Pseudomyxoma peritonei is a low-grade malignancy that rarely metastasizes or invades contiguous viscera. The treatment of pseudomyxoma peritonei is primarily surgical, with aggressive debulking of all intraabdominal tumor and omentectomy [109]. In addition, because of the usual involvement of both the appendix and the ovaries, it is recommended that appendectomy and bilateral oophorectomy be performed in all patients. Recurrence occurs in about 75% of patients; repeat laparotomies are indicated for recurrent disease. Recently, new strategies in the treatment of this disease have included a chemotherapy regimen with surgical treatment [81,110–112]. These reports suggest a survival advantage using early postoperative chemotherapy (intraperitoneal or systemic) combined with cytoreductive surgical treatment compared with repeated surgical procedures in the absence of chemotherapy. Radiation treatment, mucolytic agents, and phototherapy have been described but appear to be of little benefit [113]. Long-term survival is about 54% at 5 years, with death occurring usually as a result of extensive peritoneal disease and intestinal obstruction.

Retroperitoneum

The retroperitoneum is the space behind the abdominal cavity extending from the posterior peritoneum and the mesenteries to the spinal column and the psoas, quadratus lumborum, and transversus abdominis muscles. It extends superiorly from the diaphragm and inferiorly to the levator muscles of the pelvis. The retroperitoneum is divided into the anterior compartment, which contains the pancreas, duodenal loop, and the ascending and descending colon, and the posterior compartment, which contains the perinephric space with the kidneys, ureters, and adrenal glands and an extensive network of vessels, lymphatics, and neural structures. The space also contains fatty and areolar tissue and connective tissue.

Modern diagnostic techniques, such as ultrasonography, CT scan, MRI, and arteriography, have greatly enhanced our ability to diagnose and treat pathological processes in the retroperitoneum; however, this region remains elusive. Early clinical manifestations are nonspecific so pathological processes become relatively advanced before producing symptoms. Retroperitoneal disease processes often present as a mass. (The differential diagnosis of retroperitoneal masses and other disease processes is shown in Table 100.2.) This section specifically discusses retroperitoneal hemorrhage and infections, idiopathic retroperitoneal fibrosis, and primary neoplasms of the retroperitoneal space. In addition to these clinical entities, fluid collections consisting of lymph, gastrointestinal secretions (e.g., duodenal, pancreatic), bile, or urine also may collect in this space, usually secondary to iatrogenic or traumatic injuries [114,115]. A CT scan or ultrasound may be a useful diagnostic imaging study; percutaneous drainage with fluid analysis may aid in further establishing the diagnosis and, in certain instances, may be useful in the treatment.

Table 100.2 Differential diagnosis of retroperitoneal masses and disease processes

Benign soft tissue tumor
Malignant
Sarcoma
Germ cell-derived neoplasm
Lymphoma
Lymph node metastases
Aortic aneurysm
Retroperitoneal fibrosis

Retroperitoneal hemorrhage

The most common etiology for retroperitoneal bleeding and hematoma is secondary to traumatic injuries associated with pelvic or vertebral fractures, avulsion of the vascular pedicle of the kidney, or penetrating injuries [115–118]. Other causes for hemorrhage may be secondary to anticoagulation therapy, acute pancreatitis, spontaneous hemorrhage into an adrenal gland or retroperitoneal tumor, ruptured aortic aneurysm, and ruptured ureteral or ovarian veins during pregnancy. In addition, massive retroperitoneal hemorrhage has been associated with femoral vein catheterization and liposuction [119–121].

If hemorrhage occurs quickly and in significant amounts, signs of hypovolemic shock may be present. Signs of retroperitoneal hemorrhage that may occur late include pain felt most in the abdomen and back and ecchymosis of the flank (Grey Turner sign). Laboratory examination may demonstrate a low hematocrit. Evaluation of the retroperitoneal hemorrhage may include plain films of the abdomen, which can show obliteration of the psoas shadow. A CT scan may be useful in the stable patient to evaluate the possible etiology and extent of the hemorrhage (Fig. 100.3).

Treatment of retroperitoneal hemorrhage is secondary to the specific etiology. For example, retroperitoneal hemorrhage

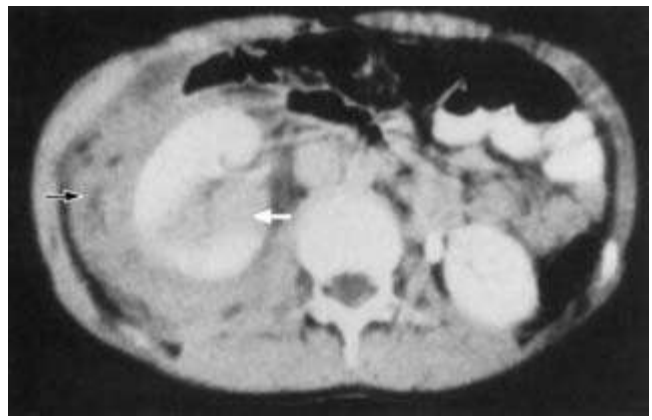

Figure 100.3 Computed tomography scan demonstrating a large retroperitoneal hematoma (open arrow) due to blunt injury to the kidney (closed arrow). Courtesy of Melvyn H. Schreiber, MD, Galveston, TX.

secondary to a pelvic fracture may be treated by fracture stabilization or arteriography and embolization of the bleeding vessel. Vascular injuries or a ruptured abdominal aortic aneurysm require emergent surgical intervention and control of the ongoing hemorrhage.

Retroperitoneal infections

Abscesses in the retroperitoneal space are normally secondary to diseases of surrounding abdominal organs, the urinary tract, or the vertebral column [112,122–126]. Most commonly, the abscesses result from perforated diverticular disease or colonic cancer, appendicitis, acute pancreatitis, penetrating duodenal ulcer, or biliary tract disease. A psoas abscess may occur secondary to intraabdominal or vertebral infections; extension from Crohn's disease, appendicitis, colon diverticulitis, and cancer are the most frequent causes. Primary bacterial infections in the retroperitoneal space can occur but are rare. Except for the Gerota fascia, there are no anatomical boundaries to the retroperitoneal space; therefore, abscesses can be large, extend bilaterally, and present late in their course. As a result, retroperitoneal abscesses may be associated with higher mortality.

Clinical manifestations include fever, chills, anorexia, and weakness; pain in the lower back and abdomen, thigh, or flank is present in about 60% of the patients. A palpable mass may be present on physical examination. Leukocytosis is often noted as the most common laboratory abnormality. The CT scan is the most useful diagnostic test to establish the diagnosis (Fig. 100.4); CT-guided percutaneous needle aspiration of the abscess may allow for bacteriological examination so that an appropriate antibiotic treatment regimen can be chosen based on the specific organisms and sensitivities. Depending on the etiology, percutaneous drainage may be the effective treatment for some of these collections; surgical drainage is required secondary to inadequate fluid evacuation. Coliform organisms and *S. aureus* are the most common organisms encountered. Other organisms can occur rarely and include *M. tuberculosis*, which most commonly effects the urinary tract or spine; opportunistic fungi (e.g., *Candida*, *Aspergillus*, *Cryptococcus* species) may spread to the retroperitoneum, particularly in patients who are immunocompromised. Actinomycosis or retroperitoneal infections with *Nocardia* organisms can be the result of secondary extension from a primary focus. For example, actinomycosis may be secondary to perforation of the appendix or colon and nocardiosis may be associated with a pulmonary infection.

Retroperitoneal fibrosis

Etiology and epidemiology

Retroperitoneal fibrosis is an uncommon disease process characterized by progressive nonspecific inflammation and fibrosis of connective and adipose tissue in the retroperitoneal space [127–131]. This process originates just below the level of the aortic bifurcation near the sacral promontory and then spreads throughout the retroperitoneum with extension bilaterally along the aorta and inferior vena cava. Symptoms are the result of gradual compression of the tubular structures in the retroperitoneal space, particularly the ureter.

Retroperitoneal fibrosis was first described by the French urologist Albarran in 1905 [127]. The initial description of retroperitoneal fibrosis in the English literature is credited to Ormond in 1948 [128]. In fact, idiopathic retroperitoneal fibrosis is often referred to as Ormond disease. Retroperitoneal fibrosis is relatively uncommon, with an instance of 1 in 200 000. There appears to be an overall male predominance of 2 or 3 to 1, with presentation usually in the fifth and sixth decades of life. The etiology of this disease is, for the most part, not known. A number of factors have been postulated to contribute to this disease process, including extravasation of urine, surgery, and nonspecific gastrointestinal inflammatory diseases, including Crohn's disease; however, most cases of retroperitoneal fibrosis are considered idiopathic (Table 100.3). Various medications have been associated with retroperitoneal fibrosis as a side effect. Methysergide, an antiserotonin drug, is the best-described agent in which the occurrence of retroperitoneal fibrosis has been clearly linked [132]. Other drugs implicated in this fibrotic process include ergotamine, pergolide, hydralazine, methyldopa, and, β-adrenergic blocking agents such as metoprolol [133]. An immune etiology for retroperitoneal fibrosis has been suggested, particularly because an association with other immune-mediated connective tissue disorders such as systemic lupus erythematosus, Hashimoto thyroiditis, Raynaud disease, systemic vasculitis, and ankylosing spondylitis has been demonstrated in certain cases [134,135]. In addition, amelioration of symptoms can occur with corticosteroid treatment. In some patients, retroperi-

toneal fibrosis can occur secondary to severe retroperitoneal infection (e.g., pancreatitis) or inflammatory aortic aneurysms and in response to neoplasms, most commonly Hodgkin lymphoma, sarcomas, carcinoid tumors, and certain adenocarcinomas [136].

Pathology

Retroperitoneal fibrosis appears grossly as a woody, white, fibrous plaque, which, as it progresses, surrounds the ureters and vascular structures in the retroperitoneum [129–131]. Early microscopic features include active chronic inflammation occurring with abundant lymphocytes, plasma cells, and macrophages interspersed with fibroblasts and collagen bundles [129,130]. As the disease progresses, the tissues become relatively acellular with scattered calcifications, an abundant collagen deposition, and fibrous scarring.

Clinical manifestations

The symptoms of retroperitoneal fibrosis are generally nonspecific, the most common symptom being a dull, constant pain localized to the back or flank [127–131]. This pain may radiate to the lower abdomen, groin, or anteromedial aspect of the thigh. Other symptoms include anorexia, nausea, diarrhea, fever, and weight loss; patients may present with hypertension. Laboratory abnormalities may include a leukocytosis, an elevated erythrocytic sedimentation rate, and elevated alkaline phosphatase levels. As the disease progresses, late complications of retroperitoneal fibrosis occur as the result of encasement and compression of the tubular retroperitoneal structures, most commonly involving the ureters, and eventually leading to azotemia, renal insufficiency, and possible renal failure. Lower extremity edema may occur from compression of lymphatics and venous obstruction [137]. The aorta can be involved, albeit uncommonly, with symptoms consistent with arterial insufficiency (e.g., claudication, rest pain). Rarely, this fibrotic process may involve the duodenum, the common bile duct, or colon, resulting in obstruction [129,130,138–140].

Differential diagnosis and diagnostic studies

The differential diagnosis of retroperitoneal fibrosis includes retroperitoneal hemorrhage, primary neoplasms, and metastasis to the retroperitoneum. Imaging studies useful in establishing the diagnosis of retroperitoneal fibrosis include an intravenous pyelogram, in which a triad of classic findings have been described: delayed excretion of contrast material with hydronephrosis, narrowing of the ureters at approximately the L4–5 level, and a medial displacement of the ureters (Fig. 100.5) [129,130]. In fact, this medial deviation of the ureters was considered a pathognomonic sign of retroperitoneal fibrosis, in contrast to retroperitoneal neoplasms in which deviation of the ureters normally occurs laterally. Recent studies, however, indicate that medial deviation is not a constant finding in patients with retroperitoneal fibrosis. The CT scan has emerged as the procedure of choice for the diagnosis and follow-up of patients with retroperitoneal fibrosis [130,141]. Findings include a periaortic soft tissue mass of variable thickness that envelops the retroperitoneal structures, with obliteration of the fat plane between the mass and adjacent psoas musculature. Increasingly, MRI has been used to assess retroperitoneal fibrosis, particularly using T2-weighted images to delineate the stage of the disease more clearly (Fig. 100.6) [140,142–144]. The

Figure 100.6 Axial T2-weighted magnetic resonance scan demonstrating a periaortic soft tissue mass (arrow) that obliterates the fat plane in a patient with retroperitoneal fibrosis. Courtesy of Greg Chalchub, MD, Galveston, TX.

advantages of MRI compared with CT are a more exact anatomical definition because of multiplanar capability and the avoidance of nephrotoxic contrast agents.

Treatment

Goals of treatment include establishing the diagnosis, relieving the obstruction (usually involving the urinary tract), and preventing progression of the disease. Medications associated with retroperitoneal fibrosis should be discontinued. Surgical management is directed at ureterolysis for ureteral obstruction with intraperitoneal transposition of the ureters. Other maneuvers described to prevent recurrence of the ureteral obstruction include wrapping the ureters in omental fat or interposing retroperitoneal fat between the ureters and the fibrosis [145,146]. The use of laparoscopic ureterolysis in selected cases has been described with good results in short-term follow-up [147]. Symptoms caused by venous obstruction are best treated nonoperatively, with elevation and elastic support of the leg eventually resulting in the development of collateral circulation. The medical management of retroperitoneal fibrosis includes corticosteroids, which are effective in the early, active inflammatory stage. Other immunosuppressive drugs, such as azathioprine and cyclophosphamide, also have been used with varying success [148,149]. Recently, two prospective observational trials have demonstrated remission of retroperitoneal fibrosis with steroid treatment [150,151]. In one trial, remission was achieved in 11 of 12 patients with prednisolone alone whereas, in the second trial, seven patients were successfully treated with a combination of prednisolone and mycophenolate–mofetil. Recent studies suggest that tamoxifen, a nonsteroidal antiestrogen agent, may be effective in regression of the fibrotic process and amelioration of symptoms secondary to increased synthesis and secretion of transforming growth factor-β, an inhibitory growth factor [152]. In patients with idiopathic retroperitoneal fibrosis without renal compromise and effective ureterolysis, the prognosis is excellent with long-term success rates exceeding 90% [129].

Retroperitoneal neoplasms

Etiology and pathology

Tumors in the retroperitoneal space arise from mesodermal, neuroectodermal, or embryonic remnants, including fat, connective tissue, fascia, muscle, nervous tissue, lymph vessels, and lymph nodes. Malignant tumors are about four times more prevalent than benign neoplasms, with the most common neoplasms being malignant lymphomas or liposarcomas [153,154]. Other malignant neoplasms in this area include other types of sarcomas, such as liposarcoma and leiomyosarcoma [155–157]. Of the benign tumors, the most frequent are lipomas. Most patients presenting with primary retroperitoneal tumors are in the fifth or sixth decades of life, although about 15% of these tumors are found in children aged younger than 10 years. In addition to primary tumors of retroperitoneal structures, the retroperitoneum is also a common site for metastasis, primarily lymphatic metastasis from neoplasms of abdominal organs.

Clinical manifestations

Retroperitoneal tumors can grow to a large size before becoming symptomatic [153,154]. Early symptoms are normally vague or lacking and may include fatigue, weakness, weight loss, abdominal discomfort, and a sense of fullness or abdominal heaviness. Nausea and vomiting and a change in bowel habits may occur with intestinal compression. Swelling of the lower extremities may occur secondary to obstruction of lymphatics or venous return. Larger tumors can cause pain radiating to both thighs as a result of involvement of the lumbar and sacral nerve roots. Rarely, patients may present with hypoglycemia. The most common physical finding is the presence of a nontender abdominal mass.

Differential diagnosis and diagnostic studies

Primary retroperitoneal tumors should be differentiated from other masses in this region, including renal lesions, pancreatic cysts and tumors, malignancies of the gastrointestinal tract, ovarian tumors, and cysts of the omentum and mesentery. The CT scan is a useful imaging modality to identify the mass, determine its size and origin, and assess its relationship, proximity, and invasion of surrounding structures (Fig. 100.7) [158]. In addition, CT-guided needle biopsy can often provide a histological diagnosis preoperatively. MRI has become increasingly important as a diagnostic tool for retroperitoneal neoplasms [144,159,160]; it provides a better degree of definition between the mass, surrounding muscle groups, and vascular structures compared with CT (Fig. 100.8). Before surgery, angiography provides important information about the vasculature supplying the neoplasm. The main

value of barium studies is to delineate primary intestinal malignancies from retroperitoneal tumors.

Treatment

Surgical excision offers the greatest prospect for cure and remains the best option for treatment of these retroperitoneal malignancies [161,162]. Some retroperitoneal tumors are benign and are cured by complete excision. Treatment of malignant tumors involves surgical resection or radiation or a combination of the two modalities. With the exception of lymphomas, chemotherapy appears to offer little to the multimodal management of these tumors. It is important to remember that even though the overall prognosis for malignant retroperitoneal tumors is relatively low, en bloc resection of a primary malignancy can achieve 5-year survival rates of more than 60%. Furthermore, debulking procedures can provide symptomatic relief and may offer a better response rate to radiation therapy in the postoperative period in patients with tumors that cannot be excised because of size or invasion of surrounding structures. Malignant tumors have a recurrence rate in the range of 30%–50% over a 3-year period.

Mesentery and omentum

During fetal development, the splanchnic mesoderm forms the mesentery covering the developing gut [1]. The greater omentum, which extends from the greater curvature of the stomach caudally to fuse with the transverse colon and mesocolon, develops from the dorsal mesogastrium. The omentum and mesentery are rich in lymphatics and blood vessels and provide a major source of macrophages and lymphocytes to aid in the removal of foreign material or infection in the abdominal cavity. The small bowel mesentery contains the lymphatic and vascular network responsible for transporting all of the nutrients absorbed from the small bowel. Primary diseases of the mesentery and omentum are relatively uncommon. This section will describe some of the diseases that primarily or prominently involve the omentum, mesentery, or both mesenchymal structures (Table 100.4).

Mesenteric panniculitis and retractile mesenteritis

Incidence and etiology

Mesenteric panniculitis (also called primary liposclerosis, lipogranuloma, isolated lipodystrophy, and mesenteric Weber–Christian disease) is a nonspecific, rare inflammatory process involving the adipose tissue of the mesentery [163,164]. This process includes a spectrum of diseases, from inflammatory to fibrotic lesions, which have been called mesenteric panniculitis and retractile mesenteritis, respectively. Possible etiologies include trauma, autoimmunity, infection, ischemia, previous abdominal surgery, or abdominal malignancy, but in the majority of cases, the precise etiology is not known.

Pathology

Gross pathological findings include a diffusely thickened and rubbery mesentery, usually as a solid mass in the root of the mesentery or as several adherent masses. Microscopic findings include excessive growth of normal fat, with subsequent degeneration, fat necrosis, and xanthogranulomatous inflammation with lipid-laden macrophages, infiltration with

histiocytes, lymphocytes, and occasional foreign body giant cells, leading to fibrotic scarring and calcification [163].

Clinical manifestations

Patients with mesenteric panniculitis generally present in middle or late adulthood (average age 53 years). There is a slight male predominance. When symptomatic, patients may present with cramping abdominal pain, which may be local or generalized; weight loss; nausea and vomiting; and low-grade fever. Patients may occasionally present with findings consistent with an acute abdomen. Approximately 60% of patients present with a palpable abdominal mass noted by physical examination; the remainder of patients present with an incidental mass noted at examination or laparotomy [163,164]. The differential diagnosis includes a wide range of mesenteric pathologies such as mesenteric lymphoma, fat necrosis, primary or secondary mesenteric tumors, and mesenteric fibromatosis. In certain instances, an abdominal aortic aneurysm may be considered because of the transmission of aortic pulsations to the anterior abdominal wall [165].

This diagnosis can be suspected by various radiographic studies. Plain radiographic findings include displacement of intestinal segments and extrinsic compression of the bowel. Findings by CT scan include fat density masses arising from the mesentery, surrounding mesenteric vessels, displacing bowel loops without evidence of invasion, a left-sided orientation, a hypodense fatty halo surrounding nodules and vessels, and a hyperattenuated stripe [166] (Fig. 100.9). Ultrasonography has also been successfully used as a diagnostic tool in these patients [167].

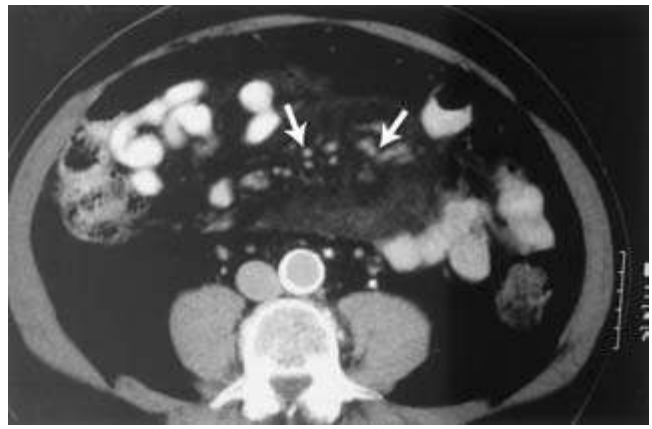

Figure 100.9 Computed tomography scan of mesenteric panniculitis demonstrating a fat-density mass surrounding mesenteric vessels with a characteristic "fatty halo" surrounding the vessels (arrows). Courtesy of Luis B. Morettin, MD, Galveston, TX.

Over time, some cases of mesenteric panniculitis progress to retractile mesenteritis characterized by a thickened mesentery that is fibrotic and retracted. There may also be mesenteric pseudocysts from fat necrosis. Rarely, there is involvement of the colonic mesentery, and fewer than 5% of patients have retroperitoneal involvement. Symptoms include continuous abdominal pain, fever, and weight loss. Some patients develop small bowel obstruction, mesenteric thrombosis, and lymphatic obstruction with ascites, steatorrhea, or protein-losing enteropathy.

Treatment and prognosis

Patients with mesenteric panniculitis should undergo biopsy of the lesion to rule out malignancy. This may be accomplished laparoscopically or by an open procedure. Resection of the entire mass is usually not possible and should not be attempted. In patients with symptomatic progressive sclerosing or retractile mesenteritis, dramatic responses have been reported after treatment with progesterone, prednisone and azathioprine or with cyclophosphamide [168–170]. Experience with these immunosuppressive agents is too small to determine their efficacy in this usually self-limiting disease. Surgical diversion or bypass is indicated for symptomatic relief in cases where extrinsic bowel obstruction because of mesenteric inflammation and scarring has occurred. The prognosis for mesenteric panniculitis is usually good but depends on the underlying disease processes.

Mesenteric fibromatosis

Incidence and etiology

Fibromatous proliferation of the mesentery, called mesenteric fibromatosis or mesenteric desmoid, is a rare and noninflammatory condition [171]. These mesenteric lesions can infiltrate the surrounding structures and, similar to desmoid tumors in other locations, tend to recur locally, although they have never been reported to metastasize. The majority of the reported cases have been associated with familial adenomatous polyposis syndromes (in particular, Gardner syndrome). Mesenteric fibromatosis affects about 3% of patients with familial adenomatous polyposis and 14%–29% of patients with Gardner syndrome [172,173]. This process has also been reported after abdominal surgery, trauma, prolonged estrogen intake, and pregnancy [171]. In addition, it may occur as a primary condition (primary mesenteric fibromatosis) in the absence of predisposing factors.

Clinical manifestations

Patients with mesenteric fibromatosis may present with an asymptomatic abdominal mass on physical examination or with a mesenteric mass at laparotomy. Symptoms of intestinal obstruction are the most common complaint. Aggressive mesenteric desmoids can become infiltrative and can involve mesenteric vessels, leading to intestinal infarction and perforation. The radiographic features of mesenteric fibrosis are generally nonspecific. The desmoid tumor appears as a solid mass by ultrasound. CT scan shows a nonenhancing mass with soft tissue density. At laparotomy, desmoids are found to involve the mesentery of the small bowel or transverse mesocolon, and the most common site is the base of the small bowel mesentery [174,175]. These lesions can be difficult to differentiate from low-grade sarcoma and can lead to misdiagnosis at operation and extensive small bowel resection.

Treatment and prognosis

In the past, the treatment of choice for patients with mesenteric desmoids has been wide local excision, but, unlike extraabdominal desmoids, no clear evidence exists showing a benefit from negative margins on the rate of recurrence of mesenteric fibromatosis. Furthermore, the severity and frequency of complications, recurrence rates as high as 85%, and relatively good long-term survival in unresectable patients lead some to reserve resection for patients suffering from complications secondary to desmoid tumors (e.g., obstruction, perforation, or fistula formation) [176,177].

There are anecdotal reports of successful treatment with prostaglandin inhibitors (i.e., sulindac or indomethacin) and antiestrogens (e.g., tamoxifen) alone and in combination [178,179]. Cytotoxic chemotherapy with dactinomycin, vincristine, and cyclophosphamide, and radiotherapy have been utilized, individually or in combination, with variable success [180–182].

Cysts and tumors of the mesentery and omentum

Mesenteric and omental cysts

Incidence and etiology

Cysts of the mesentery and omentum are uncommon lesions, with an incidence of about 1 case for every 140 000 general hospital admissions and about 1 per 20 000 pediatric hospital admissions [183,184]. These cysts represent benign proliferation of ectopic lymphatics lacking communication with the normal lymphatic system [185]. Although they are most commonly found in the small bowel mesentery, they can occur anywhere along the gastrointestinal tract. Some authors differentiate between mesenteric/omental cysts and cystic lymphangiomas.

Clinical manifestations

Cystic lymphangiomas characteristically are found in children (mean age, 6–10 years) and are frequently large and almost always symptomatic, usually presenting with abdominal distention, pain, or vomiting, and occasionally with an acute abdomen mimicking appendicitis [184]. Lymphangiomas are most often located in the small bowel mesentery but occasionally may be found in the mesocolon, the omentum, or, more rarely, the retroperitoneum. They may be single or multiple.

In contrast to cystic lymphangiomas, the mean age of presentation of patients with nonlymphangiomatous mesenteric

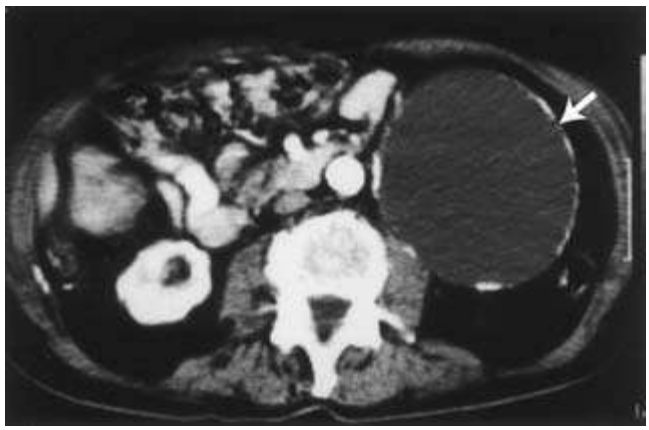

Figure 100.10 Computed tomography scan of a large lymphatic cyst arising from the mesentery (arrow). Courtesy of Luis B. Morettin, MD, Galveston, TX.

cysts is 44 years [186]. These cysts include nonpancreatic pseudocysts, enteric cysts, and mesothelial cysts. As many as one-third of the nonlymphangiomatous cysts may be located in the omentum, and only 25% are symptomatic.

Diagnosis and treatment

The identification of an intraabdominal cystic mass can be obtained by radiographic studies. Plain radiographs often demonstrate a mass displacing bowel gas and may demonstrate proximal dilation of the bowel. Ultrasonography, CT, and MRI may demonstrate the multilocular or unilocular nature of the cysts, which may have homogeneous or nonhomogeneous contents (Fig. 100.10). Of the three imaging modalities, ultrasonography probably yields the most information for the least expense.

Surgical resection represents the definitive diagnosis and treatment for these lesions. Percutaneous aspiration and biopsy are not warranted because they are not likely to provide a definitive diagnosis and may lead to infection or rupture of the cyst. Total excision of the cystic lymphangioma requires resection of adjacent attached abdominal organs (usually segments of small bowel) in a majority of cases, but most other types of mesenteric cysts can simply be excised [185,186]. Rarely, the location of the cyst precludes complete resection and requires drainage or marsupialization. However, this is usually associated with a high recurrence rate [187,188]. Recent reports have begun to emerge demonstrating that mesenteric and omental cysts can be effectively treated using a laparoscopic approach [189–191].

Solid tumors of the omentum and mesentery

Incidence and etiology

Primary tumors of the omentum and mesentery are exceedingly rare and may arise from any of the cellular elements that constitute these tissues [192]. By far the most common types of tumors that involve the omentum and mesentery are malignant tumors that arise from intraabdominal viscera, such as the ovaries, stomach, colon, or pancreas, and secondarily involve the omentum or mesentery through metastasis or direct invasive extension.

Clinical manifestations

Patients may present with a constellation of nonspecific or vague complaints; however, the most consistent presenting feature of omental and mesenteric tumors is a palpable abdominal mass that is often movable, often associated with pain, and sometimes associated with ascites or vomiting [192,193]. Plain abdominal radiographs and gastrointestinal contrast studies can demonstrate intestinal displacement and are useful in excluding the intestine as the origin of the tumor. A CT scan usually identifies the location of the mass within the mesentery or omentum and can exclude other organs as the origin of the mass; However, CT is nonspecific with regard to the diagnosis [158].

Treatment

The treatment of primary omental and mesenteric tumors is surgical excision, if possible. The malignant tumors of the mesentery and omentum spread by local invasion and by peritoneal implantation and kill by involvement of vital abdominal organs. Surgery always should be considered in patients with symptoms of bowel obstruction or ischemia.

Metastatic tumors of the mesentery are more common than primary mesenteric tumors and are usually the result of enlarged lymphomatous or carcinomatous lymph nodes. In addition, malignant midgut carcinoid tumors often metastasize or spread directly to the mesentery and exhibit pronounced fibrosis causing mesenteric shortening, angulation, and fixation of the bowel, which can result in bowel obstruction and intestinal infarction [34,194,195]. Surgical palliation of patients with metastatic carcinoid tumors is warranted because of the indolent behavior of these tumors.

Mesenchymal tumors (e.g., leiomyomas or gastrointestinal stromal tumors) of the gut wall are also treated by surgical resection. The gastrointestinal stromal tumors may express gain-of-function mutations of the *c-kit* protooncogene, which encodes a tyrosine kinase receptor. If the stromal tumor stains positive for *c-kit*, the tumor appears to be responsive to the inhibitor imatinib (Gleevec). Recently, a large Phase III trial was completed which demonstrated significant overall survival when compared to conventional chemotherapy [196].

Nutritional assessment

Most methods used to evaluate nutritional status are aimed at identifying specific nutrient deficiencies or protein–energy malnutrition. The diagnoses and treatments of specific nutrient deficiencies are usually straightforward. For example, potassium deficiency can be identified by measuring the serum potassium concentration and can be corrected by oral or intravenous potassium supplementation. In contrast, the diagnosis of protein–energy malnutrition is more complicated. Commonly used indicators of nutritional status have been validated by linking nutritional indicators with clinical outcome; patients with abnormal indicators have a worse outcome than patients with normal indicators. However, all indicators are influenced by illness or injury, so it is difficult to separate the contribution of malnutrition from that of the illness itself. Therefore, if nutritional status is linked to the severity of disease, patients who are "malnourished" may have a poor outcome simply because they are sicker than patients who are "well nourished." Moreover, nutritional therapy may not improve outcome unless malnutrition is an independent contributor to adverse medical events.

Nutritional assessment techniques

Specific nutrient deficiency

A careful history and physical examination, routine blood tests, and selected laboratory tests based on the history and physical examination findings can be used to diagnose specific macronutrient, mineral, vitamin, and trace mineral deficiencies (Tables 101.1–101.3) [1].

Protein–energy malnutrition

Ideally, nutritional assessment is used to identify those patients who will benefit from nutritional support. However, the indicators used to assess protein–energy malnutrition have been validated by determining their relationship to clinical outcome rather than to the response of patients to nutritional therapy.

Body mass and composition

In general, unintentional weight loss is associated with an adverse clinical outcome [2]. However, the assessment of changes in body weight can be confounded by errors in recall and changes in body water. Anthropometry, the measurement of triceps and subscapular skinfold thickness, provides an index of body fat and muscle mass, which is compared with the values in standard tables. Although the interpretation of these data may be limited by differences in age and ethnicity between patients and the standard population, interrater variability, and hydration, markedly abnormal values (below the 5th percentile) usually predict a poor clinical outcome. Body muscle mass can also be assessed in the clinical setting by measuring the urinary creatinine excretion [3]. Patient values can be compared with those in tables indicating an expected amount of creatinine excretion in relationship to height in subjects consuming a meat-free diet [1]. The body mass index (BMI), which is obtained by dividing weight (kilograms) by the square of the height (meters squared), can help identify patients at increased risk for medical complications (Table 101.4).

Serum protein concentrations

The concentrations of several plasma proteins, particularly albumin, correlate with clinical outcome: a low plasma albumin concentration is associated with an increased incidence of

Table 101.1 Some physical signs of nutritional deficiency

	Finding	Deficiency
Hair	Thin, sparse	Protein, zinc, biotin
	Flag sign (transverse depigmentation)	Protein, copper
	Easy pluckability	Protein
Nails	Spoon-shaped (koilonychia)	Iron
	No luster, transverse ridging	Protein–energy
Skin	Dry, scaling (xerosis)	Vitamin A, zinc
	Seborrheic dermatitis	Essential fatty acids (EFAs), zinc, pyridoxine, biotin
	Flaky paint dermatosis	Protein
	Follicular hyperkeratosis	Vitamin A, vitamin C, EFAs
	Nasolabial seborrhea	Niacin (B-1), pyridoxine (B-6), riboflavin (B-2)
	Petechiae, purpura	Vitamin C, vitamin K, vitamin A
	Pigmentation, desquamation	Niacin (pellagra)
	Pallor	Folate, iron, cobalamin, copper, biotin
Eyes	Angular palpebritis	Riboflavin
	Blepharitis	B vitamins
	Corneal vascularization	Riboflavin
	Dull, dry conjunctivae	Vitamin A
	Bitot spots	Vitamin A
	Keratomalacia	Vitamin A
	Fundal capillary microaneurysms	Vitamin C
	Ophthalmoplegia	Thiamin (Wernicke encephalopathy)
Mouth	Angular stomatitis	B vitamins, iron, protein
	Cheilosis	Riboflavin, niacin, pyridoxine, protein
	Atrophic lingual papillae	Niacin, iron, riboflavin, folate, cobalamin
	Glossitis (scarlet, raw)	Niacin, pyridoxine, riboflavin, folate, cobalamin
	Decreased sense of taste and smell	Vitamin A, ?zinc
	Swollen, bleeding gums	Vitamin C
Glands	Parotid enlargement	Protein
	"Sicca" syndrome	Ascorbic acid
	Thyroid enlargement	Iodine
Heart	Enlargement, tachycardia, high-output failure	Thiamin (wet beriberi)
	Small heart, decreased output	Protein–energy
	Cardiomyopathy	Selenium
	Cardiac arrhythmias	Magnesium, potassium
Extremities	Edema	Protein, thiamin
	Muscle weakness	Protein–energy, selenium
	Bone and joint tenderness (child)	Vitamin C, vitamin A
	Osteopenia, bone pain	Vitamin D, calcium, phosphorus, vitamin C
Neurological	Confabulation, disorientation	Thiamin (Korsakoff psychosis)
	Decreased positional and vibratory senses, ataxia	Cobalamin, thiamin
	Decreased tendon reflexes	Thiamin
	Weakness, paresthesia	Cobalamin, pyridoxine, thiamin
	Mental disorders	Cobalamin, niacin, thiamin, magnesium
Other	Delayed wound healing	Vitamin C, protein, ?zinc, ?EFAs
	Hypogonadism, delayed puberty	Zinc
	Glucose intolerance	Chromium

Table 101.2 Clinical laboratory tests for detection of vitamin deficiency

Vitamin	Test	Source	Reference range (units)[a] Marginal	Deficient	Usefulness
B-1	Transketolase ratio	RBC	1.16–1.24	> 1.25	+ When severe
	Thiamin	Serum		< 12.7 (nmol/L)	Direct measure
	Thiamin	Urine		< 27 (μg/g creatinine)	
B-2	GSH-reductase ratio	Serum	1.20–1.40	> 1.40	Body stores
	Riboflavin	Urine	27–79	< 27 (μg/g creatinine)	Recent intake
B-6	AST activity ratio	RBC	1.70–1.85	> 1.85	Body stores
	Pyridoxal 5-PO_4	Plasma	20–30	< 20 (nmol/L)	Stores, sensitive
	4-Pyridoxic acid	Urine		< 3.0 (μmol/day)	Recent intake
	Total vitamin B-6	Urine		< 0.5 (μmol/day)	Recent intake
Niacin	*N*-methylnicotinamide	Urine	0.5–2.5	< 0.5 (mg/g creatinine)	Recent intake
	2-Pyridone	Urine	2.0–3.9	< 2.0 (mg/g creatinine)	Recent intake
Folate	Folic acid	Plasma	3.0–5.9	< 3.0 (ng/mL)	Stores + intake
	Folic acid	RBC	140–159	< 140 (ng/mL)	Body stores
Folate or B-12	Homocysteine	Plasma	12–15	> 15 (μmol/L)	Function
B-12	Cobalamin	Serum	150–200	< 150 (pg/mL)	Body stores
	Methylmalonic acid	Serum		> 376 (nmol/L)	Function
	Holotranscobalamin II	Serum	40–60	> 60 (pg/mL)	Function
C	Ascorbic acid	Serum	11–23	< 11 (μmol/L)	Recent intake
	Ascorbic acid	WBC	10–20	< 10 (μg/10^8 cells)	Stores
A	Retinol	Plasma	10–19	< 10 (μg/dL)	Stores + intake
	Retinol-binding protein	Plasma		< 50 (mg/L)	Function
D	25-OH vitamin D	Serum	12–25	< 12 (nmol/L)	Body stores
	1,25-dihydroxyvitamin D	Serum	48–65	< 48 (pmol/L)	Function
E	α-Tocopherol	Serum	5.0–7.0	< 5 (μg/mL)	Body stores
	α-Tocopherol/total lipid	Serum	0.8–1.0	< 0.8	Preferred
	H_2O_2 hemolysis	RBC	10–20	> 20 (%)	Function
K	Prothrombin time	Plasma	1.5–2.0	2.0 (s over control)	Function
	Phylloquinone			< 0.35 (nmol/L)	Recent intake

a Precise values may vary between laboratories.
AST, aspartate aminotransferase; GSH, reduced glutathione; RBC, red blood cells; WBC, white blood cells.

medical complications [4,5]. Illness or injury, however, rather than malnutrition per se, are responsible for hypoalbuminemia in sick patients [6]. Inflammation and injury decrease albumin synthesis, increase albumin degradation, and increase albumin transcapillary losses. Specific gastrointestinal, renal, and cardiac diseases can increase albumin losses through the gut or kidney. Wounds, burns, and peritonitis cause losses from surface tissues. Nutritional support itself does not usually alter serum albumin levels [7]. Serum concentrations of transferrin, retinol-binding protein, and thyroxine-binding prealbumin are also affected by inflammation, so that they are unreliable as a measure of protein–energy malnutrition.

Immune system function

The total circulating lymphocyte count and delayed cutaneous hypersensitivity to skin test antigens have been used as clinical indicators of malnutrition. Although depression of circulating lymphocytes (< 200/mm^3) and anergy assessed by delayed cutaneous hypersensitivity are associated with a poor clinical outcome, they are not specific for nutritional deficiency and are affected by specific diseases, injury, and certain drugs.

Subjective global assessment

The subjective global assessment involves a focused history and physical examination to determine the adequacy of

Table 101.3 Laboratory detection of micronutrient mineral deficiency

Nutrient	Test	Source	Reference range (units)[a]	Usefulness
Iron	Iron	Serum	50–200 (μg/dL)	Poor measure of body stores
	Total iron-binding capacity	Serum	245–400 (μg/dL)	
	Iron-binding saturation		15–50 (%)	Insensitive for iron status
	Transferrin	Serum	200–400 (μg/dL)	Preferred over TIBC if available
	Ferritin	Serum	12–300 (ng/mL)	Measures body stores: high specificity when stores low, poor sensitivity
Zinc	Zinc	Plasma	20–130 (μg/dL)	Poor specificity for body stores
	Zinc tolerance test	Plasma	> Twofold increase over baseline at 2 h	For malabsorption
Copper	Copper	Serum	55–175 (μg/dL)	Insensitive for body stores
	Ceruloplasmin	Plasma	10–60 (mg/dL)	Independent of body stores
Selenium	Selenium	Serum	100–340 (ng/mL)	Insensitive for body stores
	Glutathione peroxidase	Plasma	455–800 (U/L)	More sensitive for body stores

a May vary in different laboratories.
TIBC, total iron-binding capacity.

nutrient intake and the possible effect of malnutrition on body composition and organ function (Fig. 101.1) [8,9]. In addition, it includes an analysis of the patient's future ability to ingest adequate nutrients. The findings of the history and physical examination are subjectively weighted to rank patients as well nourished, moderately malnourished, or severely malnourished. Patients who are judged to be severely malnourished are at high risk for medical complications and adverse outcome [8,10].

There is no "gold standard" for determining nutritional status. All current approaches are influenced by the severity of illness and have been validated by assessing clinical outcome rather than by nutrition-specific parameters. Therefore, current nutritional assessment techniques identify sick patients. Although it is often assumed that "malnourished" patients will benefit from nutritional support, this assumption has not been documented in prospective randomized clinical trials [11].

Choosing the route for nutritional support

The decision to initiate nonvolitional nutritional support is complex and involves a clinical assessment of the patient's nutrient intake, body fat and protein mass, protein and energy requirements, severity of illness, and anticipated duration of inadequate volitional intake. Once it has been decided that nonvolitional nutritional support is indicated, the route of nutritional support must be considered. The usual course is to choose the oral or enteral route when this approach can be used effectively and safely. There are several reasons for this choice. First, enteral nutrition may provide nutrients that are not available from parenteral nutrition. The best example of this principle is the provision of short-chain fatty acids to the colonic mucosa through the bacterial degradation of fiber or unabsorbed carbohydrate. The provision of this important colonic energy source may maintain colonic function [12]. Second, it is felt that lumenal nutrients may prevent atrophy in the small intestinal mucosa. Atrophy occurs in rats fed by

A History

1 Weight change

Overall loss in past 6 months: amount = _____ kg

Change in past week: _____ increase

_____ no change

_____ decrease

2 Dietary intake change (relative to normal)

_____ No change

_____ Change: duration = _____ weeks

type: _____ suboptimal solid diet _____ full liquid diet

_____ hypocaloric liquids _____ starvation

3 Gastrointestinal symptoms (that persisted > 2 weeks)

_____ none _____ anorexia _____ nausea _____ vomiting _____diarrhea

4 Functional capacity

_____ No dysfunction (e.g., full capacity)

_____ Dysfunction: duration = _____ weeks

_____ working suboptimally

_____ ambulatory

_____ bedridden

5 Disease and its relation to nutritional requirements

Primary diagnosis (specify) _____

Metabolic demand (stress) _____ none _____ low _____ moderate _____ high

B Physical (for each trait specify: 0 = normal, 1+ = mild, 2+ = moderate, 3+ = severe)

_____ loss of subcutaneous fat (triceps, chest)

_____ muscle wasting (quadriceps, deltoids, temporals)

_____ ankle edema, sacral edema

_____ ascites

_____ tongue or skin lesions suggesting nutrient deficiency

C SGA rating (select one)

_____ A = Well nourished (minimal or no restriction of food intake or absorption, minimal change in function, weight stable or increasing)

_____ B = Moderately malnourished (food restriction, some function changes, little or no change in body mass)

_____ C = Severely malnourished (definitely decreased intake, function, and body mass)

Figure 101.1 Subjective global assessment (SGA) of nutritional status. Adapted from Klein et al. [11].

parenteral nutrition, but the importance of this phenomenon in humans is still uncertain [13]. Finally, enteral feeding may be safer than parenteral nutrition [14–16].

If oral or enteral feeding is chosen, intestinal motility and the absorptive surface must be adequate. Other disorders that interfere with enteral feeding include severe diarrheal illnesses, extensive inflammatory bowel disease, acute gastrointestinal bleeding, conditions that will require abdominal surgery in the near future, obstructing small bowel or colonic lesions, and acute inflammation of the pancreas or biliary tract. Guidelines have been developed that provide useful and practical information for the clinician [17,18]. The guidelines for use in specific disorders, such as AIDS, are practical modifications of the generalized guidelines, with special emphasis on the problems of feeding patients with that disorder [19]. However, the clinician should not rely on a set pattern of guidelines for decisions regarding nutritional support. The published guidelines should be used as resource material to aid in the clinical judgment required for each patient.

Enteral nutrition

The availability of so many different types of nutritionally complete diets and defined formulas makes it possible for many hospitalized patients to receive adequate nutrient intake by oral or enteral tube feedings.

Whole-food diets include a regular hospital diet and diets modified in either consistency (e.g., clear-liquid, full-liquid, pureed, and soft diets) or nutrient content (e.g., low-residue, low-fat, low-sodium, low-protein, and high-fiber diets). In many cases, nutrient intake can be increased by encouraging the ingestion of ordinary food and by avoiding missed meals and unpalatable diets. Many patients eat more if they are given assistance at mealtimes and provided with desired foods, and if some food is supplied by relatives and friends is allowed.

Defined formulas are commercially made products with a known "defined" nutrient composition (Table 101.5). These formulas can be divided into five categories: feeding modules,

Table 101.5 Classification of commercially available enteral nutrition products

Modular type	Indication	Examples
Intact protein	Standard	Boost, Ensure, Isosource, Nutren 1.0, Osmolite, Peptinex 1.0, Peptinex 1.5, Peptinex DT, Resource
	Volume-restricted	Boost Plus, Ensure Plus, Isosource 1.5, Jevity 1.5, Nutren 1.5, Nutren 2.0, Resource 2.0
	High-protein	Boost High Protein, Isosource HN, Nutren Replete, Osmolite 1, Osmolite 1.5, Promote
	Disease-specific	Boost Diabetic, Diabetisource AC, Ensure Plus, Glucerna, Juven, Nepro, Novasource Pulmonary, Novasource Renal, Nutren Glytrol, Nutren Pulmonary, NutriHep, Oxepa, Pulmocare, Renalcal, Suplena
	Immunonutrition	Crucial, Impact, Impact Advanced Recovery, Impact Glutamine, Impact with Fiber, Perative, Pivot 1.5, TraumaCal
	Fiber supplement	Ensure Fiber, Fibersource, Jevity 1, Nutren 1.0 Fiber, Nutren ProBalance, Nutren Replete Fiber, Promote With Fiber, Resource Benefiber
	Milk-based	Carnation Instant, Carnation Instant No Sugar Added, Resource Instant Breakfast, Resource Milkshake
Elemental	Digestion-impaired	Crucial, Peptamen, Vivonex TEN, Vital HN, Optimental, Peptinex, FAA free amino acid diet
Protein-limited	Protein supplement	Additions (526 kcal/100 g), Resource Beneprotein (357 kcal/100 g)
CHO-limited	CHO supplement	Resource Benecalorie (800 kcal/100 g), Polycose liquid (10 kcal/5 mL), Polycose powder (380 kcal/100 g)
Fat-limited	Fat supplement	MCT oil (830 kcal/100 g)

Note: caloric density ranges from 1.0 to 1.5 kcal/mL for the intact protein and elemental products, except for the volume-restricted products, in which the caloric density is 1.5–2.0 kcal/mL and is often identified in the product name by number.
CHO, carbohydrate.

monomeric formulas, oligomeric formulas, polymeric formulas, and disease-specific formulas. Feeding modules consist of single nutrients, such as protein (intact protein, hydrolyzed protein, or crystalline amino acids), carbohydrate (glucose polymers), or fat (long-chain or medium-chain triglycerides), that can be used to supplement a specific diet or be part of a modular enteral system composed of several nutrient modules.

Monomeric (elemental) formulas contain nitrogen in the form of free amino acids and usually only small amounts of fat (< 5% of total calories). Therefore, these formulas can be useful in patients who require an extremely low-fat diet. However, monomeric formulas are hyperosmolar, unpalatable, and more expensive than polymeric formulas, and in the absence of pancreatic insufficiency, they are absorbed no better than oligomeric or polymeric formulas [20].

Oligomeric (semielemental) formulas contain hydrolyzed protein in the form of small peptides and sometimes free amino acids. Fat represents 5%–40% of energy content as either long-chain triglycerides or a combination of long-chain and medium-chain triglycerides. Data from several studies suggest that oligomeric diets can reduce diarrhea and other gastrointestinal side effects in critically ill patients [21] and in patients receiving abdominal irradiation and chemotherapy [22]. However, the purported clinical benefits of oligomeric formulas require confirmation in large prospective clinical trials before precise recommendations regarding their use can be made.

Polymeric formulas contain nitrogen in the form of whole proteins. These formulas can be categorized into three groups: blenderized food formulas, milk-based formulas, and lactose-free formulas. Milk-based formulas usually contain milk as a source of protein and fat and tend to be more palatable than other defined diets. Although milk-based formulas can be problematic for lactose-intolerant patients, they are often tolerated when infused continuously to decrease the load of lactose delivered to the intestine at any one time. Lactose-free formulas are the most commonly used polymeric formulas in hospitalized patients, and many modifications in protein and fat content are available. Disease-specific formulas have been designed for patients who have specific illnesses, including hepatic insufficiency, renal insufficiency, pulmonary insufficiency, diabetes, and severe metabolic stress. In general, the clinical superiority of these formulas over less expensive, standard polymeric enteral formulas remains controversial. However, branched-chain amino acid-enriched formulas may permit greater nitrogen intake in selected patients with chronic protein-intolerant hepatic encephalopathy (see "Nutritional support in the hospitalized patient with gastrointestinal disease"), and renal failure formulas contain much smaller amounts of sodium, potassium, phosphorus, and magnesium than standard formulas.

Over the last 10 years more than 500 articles have been published addressing the benefits and risks of immunonutrition. Immunonutrition formulas are supplemented with one or a combination of immune stimulants, such as arginine, glutamine, omega-3 fatty acids, and nucleotides (Table 101.5). A metaanalysis of randomized clinical trials comparing immunonutrition to standard products concluded there were no significant effects on mortality, infectious complications,

length of stay, or time on the ventilator in critically ill patients [23]. A higher mortality rate has been observed in septic patients receiving immunonutrition when compared with similar patients receiving parenteral nutrition [24]. However, a significant reduction in infectious complications and length of stay was observed in elective surgery patients. Interpreting the data on immunonutrition is hampered by differing study populations, inconsistent use of blinding, the use of different control feeds, and small sample sizes.

A positive caloric balance is necessary to optimize and sometimes to achieve positive nitrogen balance, and to incorporate amino acids into new protein. To achieve this goal, the ingestion of about 25–35 kcal/g of protein (105–146 kJ/g) (~ 150–200 kcal/g [630–835 kJ/g] of nitrogen) is required. This ratio is based on the derivation of 10%–15% of caloric needs during catabolism from protein degradation.

Oral rehydration therapy

Patients with protracted vomiting or diarrhea can lose excessive amounts of fluid and electrolytes. Oral rehydration therapy enhances sodium and water absorption by stimulating sodium/glucose cotransport in the small intestine. Oral rehydration therapy has been demonstrated to have considerable clinical benefits in patients with severe gastrointestinal fluid and mineral losses, such as those with cholera-induced diarrhea, high-output ostomies, and short bowel syndrome [25–31].

A variety of oral rehydration solutions are available (Table 101.6). The World Health Organization developed a solution based on the results of studies in patients with cholera [30]. The glucose component of an oral rehydration solution should be provided at concentrations between 70 and 150 mmol/L. Higher concentrations of glucose can be deleterious because the increase in osmolality may reduce water absorption. Making the solution hypotonic by replacing glucose with rice solids or other polymeric forms can decrease stool output compared with isotonic solutions [26–29]. In patients with short bowel syndrome ending in a jejunostomy, net sodium and fluid balance is related to jejunal length. Patients with less than 100 cm of jejunum are usually net secretors, whereas those with more than 100 cm of jejunum are usually net absorbers [31]. The use of oral rehydration therapy can markedly decrease ostomy output and convert some patients from net secretors to net absorbers. In these patients, the consumption of electrolyte replacement drinks containing 60 mmol or less of sodium per liter causes a negative sodium and fluid balance, whereas the balance becomes positive after the ingestion of solutions containing 90 mEq/L and is maximal at concentrations of 120 to 160 mEq/L [32,33]. Sport drinks and commercially made defined liquid formula diets do not contain an adequate amount of sodium for maximal fluid absorption in patients with severe short bowel syndrome and a jejunostomy.

Tube feeding

General principles

Enteral tube feeding is useful in patients who have a functional gastrointestinal tract but who cannot or will not ingest adequate nutrients. Many approaches to tube feeding are possible (e.g., nasogastric, nasoduodenal, nasojejunal, gastrostomy, jejunostomy, pharyngostomy, esophagostomy tubes) and depend on physician experience, clinical prognosis, anticipated duration of feeding, patency and motility of the gut, risk for aspiration of gastric contents, and patient preference.

Short-term feeding (< 6 weeks) can be achieved by the placement of a soft, small-bore nasogastric or nasoenteric feeding tube. These tubes are made of silicone or polyurethane and can be left in place without the tissue irritation or pressure

Table 101.6 Characteristics of selected oral rehydration solutions

Product	Na (mEq/L)	K (mEq/L)	Cl (mEq/L)	Citrate (mEq/L)	kcal/L	CHO (g/L)	mOsmol/kg
Equalyte	78	22	68	30	100	30	305
CeraLyte 70	70	20	98	30	165	40	235
CeraLyte 50	50	20	40	30	240	60	240

necrosis caused by larger polyvinyl chloride tubes. Many patients are able to eat with the tube in place, which permits the use of tube feeding to supplement oral intake. Nasogastric feeding is usually the most appropriate route, but orogastric feeding can be used in cases of nasal injury or gross nasal deformity. Nasoduodenal or nasojejunal feeding is useful in patients with gastroparesis. In addition, by taking advantage of the barrier function of the pyloric and gastroesophageal sphincters, nasoenteric feeding may decrease the incidence of aspiration in high-risk patients. However, the prevention of aspiration by feeding beyond the pylorus has not been proved in clinical trials.

Most patients who require long-term tube feeding (> 6 weeks) should have a gastrostomy or jejunostomy tube placed. These tubes can be placed endoscopically, radiologically, or surgically, depending on the clinical situation and local expertise. Percutaneous endoscopic gastrostomy can be performed within 30 min and is successfully completed in more than 90% of attempts [34]. Gastrostomy tubes can be placed percutaneously without endoscopy by inserting the catheter directly into the stomach by a peel-away sheath introduced over a previously placed J-wire guide [35]. This approach is particularly useful in patients with an obstructing lesion of the esophagus or hypopharynx that prevents passage of an endoscope or a gastrostomy tube bumper. A summation of data from several large series suggests that percutaneous endoscopic gastrostomy tube placement is associated with mortality in 0.5%, major complications (peristomal leakage with peritonitis, necrotizing fasciitis of the anterior abdominal wall, gastric hemorrhage) in 1%, and minor complications (minor wound infections, stomal leaks, tube extrusion or migration, aspiration, gastrocolic fistula, ileus, fever) in 8% of patients [36]. Jejunal tube placement can be achieved by threading a tube through an existing gastrostomy or by percutaneous endoscopic jejunostomy in patients with previous partial or total gastrectomy [37–41].

Surgical gastrostomy is more expensive than percutaneous endoscopic gastrostomy unless the tube is placed during an operation performed for another reason. A jejunostomy tube may also be placed at the time of abdominal surgery and consists of a subserosal tunnel or needle catheter jejunostomy. Gastrostomy and jejunostomy tubes can also be placed by using laparoscopic techniques.

Administration of tube feeding

Patients with feeding tubes in their stomach can often tolerate intermittent gravity feedings, in which the total amount of daily formula is divided into four to six equal portions that are infused by gravity over 30–60 min. The patient's upper body should be elevated by more than 30° during and for at least 1 h after feeding. Intermittent feedings are useful for patients who cannot be positioned with the head of the bed continuously elevated or who require greater freedom from feeding. However, patients who experience nausea and early satiety with bolus gravity feedings may require continuous infusion at a slower rate. Patients who have gastroparesis often tolerate gastric tube feedings when they are started at a slow rate (e.g., 10 mL/h) and advanced by small increments (e.g., 10 mL/h every 8–12 h). However, patients with severe gastroparesis require passage of the feeding tube tip past the ligament of Treitz. Continuous infusion should always be used when feeding directly into the duodenum or jejunum to avoid distention, abdominal pain, and dumping syndrome.

Complications

Mechanical, metabolic, and gastrointestinal complications can occur in patients receiving tube feedings. Although the placement of nasogastric tubes is usually safe, tubes can be misplaced, particularly in unconscious patients. Intubation of the tracheobronchial tree has been reported in up to 15% of patients, and intracranial placement can occur in patients with skull fractures. Feeding tubes can cause nasopharyngeal erosions, pharyngitis, sinusitis, otitis media, pneumothorax, and gastrointestinal tract perforation.

Small-diameter nasogastric tubes (e.g., 8F or 9F) are usually used to lessen nasopharyngeal irritation. These small tubes often become occluded by inspissated feedings or pulverized medications given through the tube. Frequent flushing of the tube with 30–60 mL of water and avoiding the administration of pill fragments whenever possible help maintain patency. Many techniques for unclogging tubes have been published and include the gentle infusion of small quantities of carbonated beverage, pancreatic enzymes, and 95% ethyl alcohol into the tube. In addition, commercially made products can be obtained that either dissolve or mechanically remove the obstruction. Metabolic complications, such as hypokalemia, hyponatremia, hypophosphatemia, and hyperglycemia, can occur [40]. Patients should be monitored for metabolic abnormalities, particularly severely malnourished patients during the initial refeeding period.

Gastrointestinal side effects of tube feedings include nausea and vomiting, pulmonary aspiration, abdominal pain, and diarrhea. Diarrhea is the most common complication and occurs in 30%–50% of critically ill patients receiving tube feedings. Diarrhea is often caused by antibiotic use [41] and the use of liquid medications and elixirs that contain nonabsorbable carbohydrates, such as sorbitol [42]. Patients with normal gastrointestinal tract function can tolerate larger volumes of tube feedings. In one study, tube feeding did not cause diarrhea in healthy subjects until it was given at rates exceeding 200 mL/h [43]. Several case reports have also documented an association between small bowel necrosis and jejunal feedings in critically ill patients [44]. Most of these patients were receiving pressors to maintain an adequate blood pressure, suggesting that the increased oxygen requirements associated with feeding can cause ischemia in patients whose intestinal blood flow is unable to increase.

Parenteral nutrition

In some patients, enteral feedings are either contraindicated or cannot be provided in sufficient quantities to meet nutritional requirements. In these cases, parenteral nutritional support can be a valuable adjunctive and sometimes lifesaving therapy. Certainly, patients who are unable to ingest "adequate" nutrients for a "prolonged" period of time require nutritional therapy to prevent the adverse effects of malnutrition. However, the precise definitions of "adequate" and "prolonged" are not clear and are likely to differ from patient to patient depending on the amount of body energy stores and lean body mass, the presence of preexisting medical illnesses, and the level of metabolic stress. The use of parenteral nutrition is often recommended if enteral intake has been, or is anticipated to be, inadequate for 5–10 days [45]. However, carefully performed, well-designed, prospective randomized clinical trials to support the efficacy of this approach for many clinical situations are few in number [46]. Therefore, the use of parenteral nutrition requires a careful integration of data from pertinent clinical trials, clinical expertise in the illness or injury being treated, a reasonable estimate of the anticipated duration of inadequate food intake, clinical expertise in nutritional therapy, and input from patients and their families.

Central parenteral nutrition

General principles

The ability to use a central vein to supply nutrient requirements for growth and maintenance was realized more than 30 years ago when catheters were inserted into the superior vena cava of beagle dogs to provide the sole source of nutrients for 72–256 days [47]. Today, the use of central parenteral nutrition (CPN), also known as *total parenteral nutrition* (TPN), is commonplace. Although percutaneous infraclavicular subclavian vein catheterization with advancement of the catheter tip to the junction of the superior vena cava and right atrium is the most commonly used technique for catheter placement, many other approaches have been successfully performed when the subclavian vein is not accessible, including internal jugular, basilic, saphenous, and femoral veins, and even thoracotomy with direct insertion into the right azygos vein [48] or the right atrial appendage [49]. In addition, peripherally inserted central venous catheters can be used to provide CPN. In this approach, insertion by a physician is not required, and the technique cannot cause pneumothorax or traumatic injury to arteries or nerves, but it is associated with an increased risk for thrombosis if the catheter tip is placed proximal to the superior vena cava [50].

Parenteral nutrient solutions provide all the basic nutrient requirements, including fluids, proteins, carbohydrates, fats, minerals, trace elements, and vitamins (Table 101.7). The lipid component can be piggybacked to the primary nutrient mixture, or a total nutrient admixture can be prepared, which reduces handling costs and potential breaks in sterility. However, total nutrient admixtures prevent visible inspection for particulate matter. Invisible calcium and phosphorus precipitates have caused fatal pulmonary emboli in patients receiving parenteral nutrition [51]. Therefore, pharmacy standards regarding physicochemical compatibility should be closely followed in all patients receiving CPN, and in-line filters should be used with all parenteral nutrient solutions. Even a careful inspection of clear nutrient solutions cannot detect small microprecipitates, which can obstruct small pulmonary capillaries [52].

The specific formulation prescribed for a patient depends on the patient's estimated nutrient requirements and ability to tolerate specific nutrients without adverse effects. The patient's protein, energy, and fluid requirements are the most important initial considerations in designing the appropriate parenteral formulation. Protein requirements are met by infusing standard solutions composed of crystalline amino acids containing 40%–50% essential and 50%–60% nonessential amino acids, usually with little or no glutamine, glutamate, aspartate, asparagine, tyrosine, and cysteine. Most hospitalized patients require between 1.0 and 1.5 g of protein per kilogram body weight per day. Some amino acid solutions have been modified for specific disease states, such as those enriched in branched-chain amino acids (advocated for patients with hepatic encephalopathy) and those containing 67%–100% essential amino acids (advocated for patients with renal insufficiency). However, the clinical superiority of these formulations over standard amino acid solutions has not been well documented in clinical trials [53,54].

The major sources of energy are glucose and lipid. However, infused amino acids are also oxidized and should be included in the estimate of energy provided as part of the parenteral formulation. Glucose (dextrose) is usually the predominant energy source in CPN formulations and is the required fuel for erythrocytes, white blood cells, bone marrow, and renal medulla (~ 40 g/day) and the preferred fuel for the brain (~ 120 g/day). Each gram of hydrated dextrose provides 3.4 kcal (14.2 kJ) and is readily oxidized unless excessive amounts are infused. In stable postoperative patients, increasing the rate of glucose infusion up to, but not more than, 7 mg/kg/min increases the rate of glucose oxidation [55,56]. Lipid emulsions contain soybean oil or a combination of soybean and safflower oil triglycerides, egg yolk phospholipids as an emulsifying agent, and glycerin to maintain isosmolarity. These emulsions provide energy and are a source of essential fatty acids, linoleic and linolenic acids. Lipid calories are as effective as additional glucose calories in conserving body nitrogen economy and supporting protein metabolism once absolute tissue requirements for glucose have been met [57,58]. The optimal percentage of calories that should be infused as fat is not known. At least 5% of total calories should be given as lipids to prevent essential

Table 101.7 Delivery of nutrients during total (central) parenteral nutrition

Nutrient	Formulation for delivery	Frequency, suggested dose
Water	Diluent in base solution	Daily, 2–3 L
Amino acids	3.5%–10% solutions of crystalline amino acids in base solution or 3:1 mixtures	Daily, 12%–24% of total kcal
Carbohydrate	20% dextrose in base solution or 3:1 mixtures	Daily, 55%–65% of total kcal
Phospholipid	10%–30% soybean/safflower oil emulsion in 3:1 mixtures (1.1–3.0 kcal/mL)	Daily to weekly, 20%–25% of total kcal
Essential fatty acids	3:1 mixtures i.v., corn oil orally (5–15 mL), or topical skin application	Daily to weekly, ~ 11 g/day (1%–2% of kcal/day)
Vitamins A, D, E, C, B complex	Multivitamin preparation in base solution	Daily or q.o.d., 10 mL
Vitamin B-12	Injection s.c. (1 mg/mL) or oral tablet	Monthly (1 mg s.c.) or daily (100 µg/day orally)
Vitamin K	Aqueous colloidal solution	Weekly, 10 mg s.c.
Sodium	Amino acid solutions and NaCl/acetate added	Daily, 60–120 mEq
Potassium	Amino acid solutions and KCl added	Daily, 30–80 mEq
Chloride	Amino acid solutions and Na/KCl added	Daily, 80–140 mEq
Calcium	Calcium gluconate added to base solution	Daily, 4.6–9.2 mEq
Magnesium	Amino acid solutions and $MgSO_4$	Daily, 8.1–24.3 mEq
Phosphorus	Na/K phosphate added to diluted base solution	Daily, 12–24 mmol
Iron	Iron dextran added separately to maintain stores	Monthly, titrated to needs
Trace minerals	Trace mineral solutions	Daily, 1 mL

Note: Each component of total parenteral nutrition can be ordered separately, according to patient need. The amino acid concentration is chosen according to the need for nitrogen. Lipid is not needed beyond the requirement for essential fatty acids but is often provided daily to restrict volume.
i.v., intravenously; q.o.d., every other day; s.c., subcutaneously.

fatty acid deficiency. The rate of lipid emulsion infusion should probably not exceed 0.7 kcal/kg/h because most complications associated with lipid emulsion infusions have been reported when more than 1.0 kcal/kg/h (0.11 g/kg/h) was provided [59]. Lipid emulsion infusion, containing ω-6 polyunsaturated fatty acids (PUFAs), can cause pulmonary dysfunction [60], hepatic phospholipidosis [61], impaired immune system function [62], pancreatitis [63], decreased platelet aggregation [64], fat overload syndrome [65], and hypersensitivity reactions [66–68]. Therefore, olive oil-based lipid emulsions and medium- and long-chain triglyceride lipid emulsions are being developed [69,70]. Together, carbohydrate and lipid should provide 25–35 kcal/g of protein to optimize incorporation of amino acids into new protein.

Complications

Mechanical, infectious, metabolic, and gastrointestinal complications are associated with the use of CPN. Administering CPN under the guidance of experienced teams decreases the incidence of most complications [71]. Percutaneous insertion of a central venous catheter can damage local structures and cause pneumothorax, brachial plexus injury, subclavian and carotid artery puncture, hemothorax, thoracic duct injury, and chylothorax. In addition, the catheter can be sheared off, become occluded, or cause subclavian vein or superior vena cava thrombosis [72–74].

Catheter-related sepsis is the most common serious complication in patients receiving CPN; even when meticulous care is provided, catheter-related sepsis occurs in up to 4% of hospitalized patients [75]. Multiple-lumen central catheters that are used for CPN are associated with an increased incidence of infections compared with single-lumen catheters [75]. Catheter-related sepsis should be considered in all patients in whom a fever or leukocytosis develops while they are receiving CPN. The catheter tunnel and exit site should be carefully inspected, and any exit site drainage should be cultured. Blood cultures should be obtained from the central line and a peripheral vein. The presence of subcutaneous infection along the catheter tunnel or clinical toxicity (e.g., hypotension) without another known source of infection is

an indication for immediate catheter removal. If no evidence of tunnel infection or clinical toxicity is found, the catheter can remain in place, and empirical antibiotic therapy should be started through the central venous catheter. Blood cultures should be obtained again in 48–72 h to ensure clearance of bacteremia. The catheter should be removed from patients who have blood cultures that are positive for fungus or *Staphylococcus aureus,* polymicrobial infection, persistent or recurrent catheter-related bacteremia, or persistent fever without another suspected source of infection [76].

The metabolic complications observed in patients receiving parenteral nutrition are usually caused by inappropriate nutrient administration resulting in nutrient excesses or deficiencies or both. Parenteral nutrition has a propensity to cause hyperglycemia in hospitalized patients. Since 2001, there exists good evidence that even minor elevations in blood glucose (BG) levels in intensive are unit (ICU) patients lead to increased mortality when compared with true normoglycemia (BG 80–110 mg/dL) [77,78]. In the less stressed patient a BG goal of less than 150 mg/dL may be more appropriate as there have been no clinical trials published in this patient group. Blood glucose should be kept below a concentration of 120 mg/dL in pregnant patients to avoid the complications of gestational diabetes and large-for-gestational-age births. Metabolic bone disease, including osteopenia and osteomalacia, has been observed in patients receiving long-term (> 3 months) CPN [79].

Several hepatobiliary abnormalities have been observed in patients receiving CPN, and these are usually more severe and more frequent in infants than in adults [80]. Hepatic abnormalities include alterations in liver biochemistries, steatosis, steatohepatitis, lipidosis and phospholipidosis, cholestasis, fibrosis, and cirrhosis. Most hepatic abnormalities occur early and are transient, but in a small subset of patients receiving long-term (> 16 weeks) CPN, progressive and more serious liver disease develops [81]. Biliary abnormalities include acalculous cholecystitis, gallbladder sludge, and cholelithiasis, and these usually occur in patients receiving relatively prolonged (> 4 weeks) courses of CPN. Acalculous cholecystitis has been reported in about 5% [82], cholelithiasis in about 30%, and gallbladder sludge in up to 100% [83] of patients receiving prolonged CPN. The pathogenesis of acalculous cholecystitis is unclear. Gallbladder stasis is an important contributing factor in the pathogenesis of gallbladder sludge and stones.

Maintaining regular gallbladder contractions by either enteral feedings or cholecystokinin injections prevents gallbladder sludge and gallstone formation [84,85].

Peripheral parenteral nutrition

Peripheral parenteral nutrition (PPN) consists of a mixture of nutrients containing a final concentration of 5%–10% dextrose, 2%–5% amino acids, electrolytes, and vitamins and minerals. This crystalloid solution is mixed with a 10% or 20% lipid emulsion as an all-in-one admixture, or the lipid emulsion can be piggybacked to the distal port of the intravenous infusion line. To ensure that adequate calories can be given in a reasonable volume, the lipid component usually provides approximately half of the total calories.

The use of a peripheral vein to provide nutritional support avoids many of the mechanical and infectious complications of CPN but is associated with a high risk for thrombophlebitis, which occurs in up to 94% of patients [86]. However, the use of PPN has become possible in many patients since the development of safe isotonic lipid emulsions and a better understanding of the causes of PPN-induced thrombophlebitis.

Several factors are important in the pathogenesis of thrombophlebitis in patients receiving PPN [87,88]:

- the osmolality, pH, and lipid content of the PPN solution, and the presence of particulate matter
- the diameter, length, and composition of the catheter
- the duration, rate, and volume of the infusion
- the diameter and anatomical position of the vein
- the insertion technique.

Adherence to the following principles can increase the life of a single infusion site to more than 10 days in many patients:

- provide at least 50% of total energy as a lipid emulsion, add 500–1000 U of heparin and 5 mg of hydrocortisone per liter of solution, and add sodium hydroxide if needed to achieve a pH of 7.4
- insert a fine-bore 22- or 23-gauge polyvinyl pyrrolidine-coated polyurethane catheter in as large a vein as possible in the proximal forearm with use of a sterile technique
- place a 5-mg glyceryl trinitrate ointment patch over the infusion site
- infuse the PPN solution with a volumetric pump and keep the total infused volume below 3500 mL
- filter the solution with an in-line 1.2-μm filter.

Home parenteral nutrition

The ability to provide parenteral nutrition at home was first demonstrated in 1970 [89]. In 1992, approximately 40 000 patients (120 per million residents) received home parenteral nutrition (HPN) in the United States [90], a tenfold higher rate than that in Europe (1–12 per million residents) [90–92]. Patients with benign diseases have a much better outcome than those with terminal illnesses. Patients with benign gastrointestinal disease and receiving HPN have a better outcome and decreased HPN days spent in the hospital than those with terminal illnesses. In addition, it has been reported that patients with benign disease and receiving HPN had a 5% 1-year mortality compared with 80% of their counterparts with terminal illnesses [93].

HPN is usually given through an implantable subcutaneous port or a catheter inserted in the subclavian vein and tunneled subcutaneously to exit on the anterior chest. Nutrient formulations are infused for 8 to 12 h overnight to

allow patients to be active during the day. Intravenous lipids may not be necessary for patients who eat and are able to absorb adequate amounts of fat, whereas others may receive 20%–30% of their calories as a lipid emulsion. The development of multichamber bags with an extended shelf life allows the delivery of more CPN bags to home patients at one time [94]. The most serious common complication is catheter-related sepsis, most often caused by *S. aureus* or *Staphylococcus epidermidis*. However, a 5-year review of HTPN patients demonstrated a 50% decline in the incidence of catheter-related sepsis from 1997 to 2001 [95]. Nonetheless, venous thrombosis, chronic liver disease, cholelithiasis, and metabolic bone disease are all associated with the prolonged use of HPN.

Nutritional support in the hospitalized patient with gastrointestinal disease

The major purpose of nutritional therapy is to prevent or correct specific nutrient deficiencies and to prevent the adverse effects of protein–energy malnutrition. Nutritional support has also been proposed as a primary therapy for patients with certain gastrointestinal diseases, such as inflammatory bowel disease and hepatic encephalopathy. In this section, we review the available data evaluating the clinical efficacy of nutritional support in patients with gastrointestinal diseases. Whenever possible, only the data from prospective randomized clinical trials are considered because this approach is the most reliable technique for evaluating the usefulness of therapy.

Short bowel syndrome

Patients who have undergone massive intestinal resection often require nutritional support for optimal function and survival. The length of the remaining jejunum, the presence of the ileocecal valve, and whether the colon is intact are critical determinants of the need for nutritional support [96]. In general, patients with a jejunostomy and less than 90 cm of jejunum, or those with a colon in continuity but less than 50 cm of jejunum, are likely to require parenteral nutrition. Providing nutrients with continuous nighttime tube feedings [97] or fluid and electrolytes with oral rehydration therapy [32] (see "Oral rehydration therapy" above) can sometimes decrease or eliminate the need for parenteral therapy.

Inflammatory bowel disease

Enteral nutrition

Three metaanalyses of published prospective randomized clinical trials concluded that enteral nutrition is not as effective as corticosteroids. In addition, no benefit of elemental over nonelemental formulas was noted [98–100]. The true clinical efficacy of enteral nutritional therapy has not been evaluated because no study has compared patients receiving dietary therapy with an untreated control group. However, the overall remission rate reported with enteral nutrition therapy is about 60% [98,99], which is higher than the range of 20%–40% reported for placebo-treated patients with moderate disease [101,102].

Parenteral nutrition

Data from several prospective randomized clinical trials found that "bowel rest" is not necessary to achieve clinical remission in patients with active Crohn's disease; patients who received TPN plus bowel rest fared no better than those receiving TPN plus oral/enteral feeding [103,104]. A beneficial effect of TPN in patients with Crohn's disease or ulcerative colitis has not been demonstrated in prospective randomized clinical trials. No significant differences in clinical response rates were found in hospitalized patients with severe disease exacerbations who were randomized to receive TPN and steroid therapy or an oral/enteral diet and steroid therapy [105–107]. Nonetheless, TPN may be useful in patients with severe inflammatory bowel disease who cannot eat because of prolonged ileus or who might benefit from bowel rest because of severe diarrhea or anticipated surgery.

Specific nutrient therapy

Fish oil supplementation may produce a modest decrease in the activity of ulcerative colitis [108,109], may help to lower the steroid dose, and may prevent early but not late relapse [110], but it is not effective by itself. Two prospective randomized clinical trials of maintaining clinical remission in patients with Crohn's disease have shown both success [111] and failure [112]. Short-chain fatty acids have not been shown to be effective for rectal disease in ulcerative colitis [113].

Gastrointestinal fistulae

No prospective randomized clinical trials have evaluated the efficacy of TPN, but "bowel rest" may improve the clinical outcome of selected patients with fistulae. Before the use of TPN, mortality in patients with gastrointestinal fistulae was caused by malnutrition, fluid losses, and peritonitis. A retrospective analysis of patients with small bowel fistulae showed an improved outcome for those who received nutritional support [114]. Anastomotic fistulae at sites of recent resection in Crohn's disease may close permanently with TPN and bowel rest, although octreotide therapy may also be necessary for success in some patients [115]. However, fistula closure is not well maintained after an oral diet is reinstituted in patients with active disease at the origin of the fistula, or with postfistula obstruction.

Growth failure in children

Total parenteral nutrition or oral/enteral supplemental feedings can initiate catch-up growth, resulting in marked increases in height and weight, in children with inflammatory bowel disease and growth failure [116–119]. In fact, even intermittent enteral feeding can improve growth [120,121].

Acute pancreatitis

Most patients with acute pancreatitis are unable to eat because oral feeding can cause abdominal pain and increase serum amylase and lipase concentrations. Nonetheless, nutritional support is not useful in patients with mild or moderate pancreatitis because of the rapid resolution of symptoms and ability to begin oral feeding within several days. In addition, no benefit of parenteral nutrition compared with enteral nutrition has been demonstrated in patients with mild or moderate pancreatitis [122], and in one study, the use of TPN was associated with a higher prevalence of catheter-related sepsis and insulin requirements [123]. However, nutritional support may be necessary in about 10%–20% of patients with pancreatitis who have severe and complicated disease when a prolonged period of starvation is anticipated.

It has been shown that it is possible to provide enteral feeding to patients who have mild to moderate [122] or severe [124–126] pancreatitis, without causing an exacerbation of symptoms, when feeding is delivered distal to the ligament of Treitz into the upper jejunum. Moreover, in prospective randomized clinical trials that compared enteral with parenteral nutritional therapy in patients with severe pancreatitis, those who were randomized to receive enteral nutrition showed a greater reduction in acute-phase-response proteins, a greater improvement in disease severity scores, and fewer medical complications than those given parenteral nutrition [124]. These findings led to the recommendation by an international consensus conference to provide nutrition support by jejunostomy feedings rather than CPN in patients with severe acute pancreatitis [127]. However, it is not known whether enteral feeding was beneficial or whether parenteral feeding was harmful because no study included an unfed control group.

Providing a portion of total calories as lipid can help prevent hyperglycemia in glucose-intolerant patients with pancreatitis. However, it is important to ensure adequate triglyceride clearance because hypertriglyceridemia induced by infusion of fat emulsions can cause a relapse of pancreatitis [63].

Liver disease

Alcoholic hepatitis

One prospective randomized clinical trial compared PPN with an anabolic steroid, oxandrolone, or the combination for 21 days and found no change in mortality but improved Child–Pugh scores in those receiving PPN plus oxandrolone [128,129]. In another study, nutritional therapy improved liver function and reduced early mortality (1- and 6-month) in a subgroup with moderate "malnutrition" or liver disease [130]. No improvement was noted in the group with severe disease. It is clear that these markers correlate with the severity of liver disease and with clinical outcome [131].

Alcoholic cirrhosis

Several prospective randomized clinical trials showed that enteral nutrition in patients hospitalized for complications of cirrhosis led to an improved clinical status [132–134]. A single study showed that enteral feeding of a branched-chain amino acid formula reduced mortality [135]. However, the ad lib diet group ingested only about half the calories of the enterally fed group, and the control group had an unusually high mortality rate (47%).

Hepatic encephalopathy

In a metaanalysis of nine prospective randomized clinical trials evaluating the use of TPN enriched with branched-chain amino acids in patients with acute encephalopathy [53], recovery from encephalopathy was improved during short-term (7–14 days) treatment. However, the variability in mortality rates was so great that no conclusion could be reached regarding that outcome measure. No benefit of branched-chain amino acid therapy was detected in the one study that compared a group that received branched-chain amino acid-enriched TPN with a control group that received standard amino acids. Studies of the use of enteral solutions containing branched-chain amino acids in patients with chronic encephalopathy have yielded conflicting results. However, the studies with the largest number of patients showed clinical benefits in protein-intolerant patients [136].

Micronutrient deficiency and treatment

Tissues that proliferate rapidly (skin, oral and gastrointestinal mucosa, hair, bone marrow) or in which metabolic rates are high (muscle, gastrointestinal mucosa) are at greatest risk for signs of deficiency at an early stage. Clues regarding deficiency come from a history of reduced intake or increased losses (or of conditions that make those situations more likely), physical examination findings, and results of laboratory tests that ideally determine body stores of the nutrient. The signs and symptoms of nutritional deficiency in adult patients are listed in Table 101.1. The laboratory values for the major vitamins and minerals are listed in Tables 101.2 and 101.3. A more detailed discussion of these nutrients and the assessment of their status can be found in general references [1,137,138].

Sodium (Na^+)

Deficiency

Sodium depletion usually presents with symptoms of dehydration because of concomitant water loss. Severe depletion presents with nausea, vomiting, exhaustion, cramps, seizures, and ultimately cardiovascular collapse. On the physical examination, mucosal xerosis, sunken eyeballs, and mental confusion can be present, but none of these are specific findings. In older patients, other explanations are often present for all these signs [139]. Orthostatic hypotension is often used to estimate the intravascular volume and is defined as a

systolic blood pressure below 20 mmHg or a diastolic blood pressure below 10 mmHg within 3 min after standing, with or without a rise in the heart rate of 5 to 10 beats/min [140]. The signs of total body sodium excess are weight gain and edema. The presence of either of these would not reflect sodium deficiency. If sodium deficiency is the result of increased gastrointestinal or cutaneous losses, the urine osmolality is increased and the urine sodium concentration is less than 10 mEq/L. If sodium deficiency is the result of diuretic therapy, the urine osmolality is decreased and the urine sodium concentration is more than 10 mEq/L.

Assessment

The serum sodium concentration primarily reflects water, not sodium, balance. Thus, any serum concentration is possible when deficiency is present, depending on the relative deficits of water and sodium. If hyponatremia is present but the cause is not apparent, the serum osmolality should be measured. In hospitalized patients, hyponatremia is most often the result of dilution by excess free water, not depletion of sodium. The free water excess is usually caused by cardiac, hepatic, or renal insufficiency or by overly enthusiastic fluid administration and is accompanied by edema and weight gain. When normovolemia is present, the hyponatremia may be caused either by inappropriate secretion of antidiuretic hormone or by displacement of sodium osmoles with elevated glucose or urea as osmoles.

Treatment

When signs of volume depletion are present, at least a 10% reduction in extracellular fluid volume has occurred [141]. The sodium deficit can be estimated as follows: Na deficit (mEq) = ([Na desired] − [Na observed]) × 0.6 × weight (kg). Sodium is usually replaced with NaCl (1 g = 17 mEq Na), either orally, enterally, or parenterally. Symptomatic hyponatremia (e.g., seizures, lethargy) is treated with intravenous 0.9% NaCl or occasionally with hypertonic (3% or 5%) NaCl. Sodium infusion should be designed to increase the serum concentration by 1 mEq/h until it reaches 120 mEq/L. Too rapid restoration has been associated with permanent neurological deficits resulting from central pontine myelinolysis. When sodium depletion is accompanied by hypernatremia or normonatremia, the appropriate amount of water should be supplied along with the sodium to achieve or maintain a normal serum sodium concentration. Chronic losses from diarrhea, vomiting, or ileostomy should be treated in adults with an oral rehydration solution that provides a carbohydrate source along with adequate sodium, so that Na/solute-coupled cotransport can occur and maximize the rate of sodium repletion. These solutions are discussed in the section "Enteral nutrition" above. Sodium toxicity can result from excessive administration of NaCl. Symptoms of toxicity include vomiting, diarrhea, peripheral vascular collapse, respiratory depression, and death.

Potassium (K^+)

Deficiency

Hypokalemia (< 3.5 mEq/L) rarely is caused by decreased intake but can result from shifts between the extra- and intracellular compartments of the body occurring while the total body potassium remains normal. This shift can be caused by alkalosis and the administration of glucose or insulin. Alternatively, decreased body stores result from increased renal excretion or intestinal losses, with subsequent shift of potassium from extra- to intracellular compartments. Loss of gastric contents by vomiting produces hypovolemia and metabolic acidosis, leading to increased renal K^+ loss. Increased K^+ loss from diarrhea produces hypovolemia, but with metabolic acidosis, yet can still produce hypokalemia from Na^+–K^+ exchange in the colon. Other causes of renal losses include mineralocorticoid excess, some antibiotics, and, rarely, renal tubular acidosis. In pure deficiency states, each decrease of 1 mEq/L corresponds to a loss of 200–300 mEq of body potassium. The loss of 5%–10% of body stores is usually tolerated without symptoms, but when serum levels fall below 3.0 mEq/L, weakness, paresthesias, confusion, cramps, myalgias, and cardiovascular abnormalities can occur [142].

Assessment

The normal serum level of potassium is 3.5–4.5 mEq/L and reflects both body stores and the availability of glucose as an energy source. Red blood cell hemolysis or extreme leukocytosis without hemolysis can result in spurious hyperkalemia. Total body potassium deficit cannot be estimated accurately especially by urinary K^+([K^+]u), as that merely reflects the renal response to circulating volume, pH, or plasma K^+ ([K^+]p) (Table 101.8). The transtubular K^+ concentration gradient (TTKG) is a simple calculation that can provide a semiquantitative measure of K^+ secretion in the cortical collecting duct (CCD) [143]: [K^+]ccd = [K^+]u/(Osm_u/Osm_p), the urine–plasma osmolality ratio. If the urine osmolality exceeds that of plasma, then TTKG = [K^+]ccd/[K^+]p, and it can be used to assist in the differential diagnosis of hypokalemia. TTKG is correlated with plasma aldosterone levels in hypokalemic patients.

Treatment

Treatment should be provided if symptoms are attributed to the hypokalemia, or if other conditions, such as chronic liver disease, are present that would exacerbate the hypokalemia. Alkalosis tends to lower the serum potassium concentration, whereas acidosis raises it. Thus, alkalosis can be treated first before the addition of potassium salts, but the same should not be done when acidosis is present. Oral replacement should be used if possible because this allows the serum potassium concentration to rise slowly in equilibrium with the intracellular compartment. Either food or supplement (Table 101.9) sources should be used. Foods rich in K^+ (> 400 mg/serving) include cantaloupe, potato, dried fruits, avocado, skim milk, banana, fruit juices, and many fruits. The administration of

Table 101.8 Expected values for tests that are helpful in the differential diagnosis of hypo- or hyperkalemia

Test	Normal	Hypokalemia	Hyperkalemia
24-h K^+ excretion	60–80 mmol/day 6–8 mmol/mmol creatinine	< 10 mmol/day < 1–1.5 mmol/mmol creatinine	> 150 mmol/day > 10–15 mmol/mmol creatinine
Urinary Na^+/K^+	2.3–2.7	GI loss 2.5–2.6 Diuretics 2.6	Aldosteronism 1.4
Spot urine K^+	Variable due to K^+ secretion and water reabsorption	Diarrhea < 20 Renal > 20	Variable
TTKG	2–5	Diarrhea < 2 Diuretics 5–10 Vomiting 2–5	Aldosteronism > 10

GI, gastrointestinal; TTKG, transtubular potassium concentration gradient.

Table 101.9 Oral potassium products comparison chart

Dosage forms	Potassium salt(s)	Brand names	Potassium content	Comments
Liquid	Potassium chloride	Various	10, 15, 20, 30, 40 mEq/15 mL	Rapid absorption, low frequency of gastrointestinal ulceration, unpleasant taste
	Mixture of potassium acetate/bicarbonate/citrate	Trikates, Tri-K	45 mEq/15 mL	Preferred forms in patients with delayed gastrointestinal transit time, avoid nonchloride salts in metabolic alkalosis
Powder	Potassium gluconate Potassium chloride Mixture of potassium bicarbonate/citrate	Kaon Various Various	20 mEq/15 mL 15, 20, 25 mEq/packet 25, 50 mEq/packet	Must be dissolved in water before use, avoid nonchloride salts in metabolic alkalosis
Effervescent tablets	Potassium chloride	Various	25, 50 mEq/tablet	
Sustained-release capsules, tablets	Potassium chloride	Various	8, 10, 20 mEq/capsule	Wax matrix or polymer-coated crystals in gelatin capsule, bioequivalent to liquid forms, avoid in patients with delayed gastrointestinal transit time, poorly effective in short bowel syndrome
Salt substitutes	Potassium chloride	Adolph's, Morton's, Nu-Salt, No Salt, various	Powder 50–70 mEq/tsp	Inexpensive dietary source, prescribe specific amount to avoid hyperkalemia; contraindicated in oliguria, severe renal disease

St. Louis: Facts and Comparisons, 1992:16; and Stanaszek WF, Romankiewicz JA. Current approaches to management of potassium deficiency. Drug Int Pharm 1985;19:176.

20–40 mEq at a time up to four times a day is safe. The chloride salt is preferred when renal or gastric losses account for the hypokalemia. When hypokalemia is secondary to diarrhea, one of the alkalinizing salts (e.g., citrate, acetate, bicarbonate) is preferred. The slow-release, matrix, and microencapsulated forms are better tolerated than liquid preparations. The slow-release forms have reduced the risk of small bowel ulcers and strictures but may not be useful for patients with short bowel syndrome. For intravenous therapy, the infusion rate should not exceed 20 mEq/h unless cardiac monitoring is included. The chloride salt is usually best for intravenous therapy, except when phosphate is used for treating the associated hypophosphatemia of diabetic ketoacidosis. In the presence of acidosis, potassium acetate is the best choice. Hyperkalemia should be avoided during therapy because levels above 8.0 mEq/L carry a severe risk

for cardiac dysfunction, including bradycardia, asystole, and ventricular fibrillation. Skeletal muscle weakness, areflexia or hyperreflexia, paralysis, and fatigue may also occur at these high levels.

Calcium

Deficiency

The conditions that cause hypocalcemia requiring calcium supplementation include vitamin D deficiency, failure of vitamin D synthesis or action, hypoparathyroidism, hypomagnesemia, severe acute pancreatitis, malabsorption syndromes, neoplasms with osteoblastic metastases, and medications, including aminoglycosides, cisplatin, calcitonin, furosemide, mithramycin, phosphates, and anticonvulsants [144]. Acute manifestations include tetany, altered myocardial function and arrhythmias, hyperreflexia, paresthesias, seizures, mental status changes, and choreoathetotic movements. The electrocardiogram shows prolonged Q–T intervals with normal QRS complexes. Chronic deficiency may not be associated with hypocalcemia. With a total body content of 1000 g and a net daily loss of 100 mg/day, a 20% decrease in body stores (which could be easily detected) would take 2000 days, or about 6 years, to develop. Osteopenia usually presents with fractures or bone pain. However, patients identified as being at high risk for the development of osteopenia should begin treatment well before this occurs. Risk factors include cigarette smoking, family history of osteoporosis, sedentary lifestyle, long-term glucocorticoid therapy, long-term anticonvulsant therapy, early surgical or natural menopause (< 50 years), and testicular failure (secondary to drug therapy or disease).

Assessment

Recent intake or absorption is assessed by 24-h urinary calcium [137]. At levels of absorption above 2 mg/kg (corresponding to an intake of 6 mg/kg), urinary calcium equals absorbed calcium. When absorption is low, urinary calcium levels do not decline proportionally, unlike the levels of sodium, potassium, magnesium, and phosphorus, all of which are better absorbed with better-regulated urinary excretion. Urinary calcium is used primarily to determine that absorption is low and to follow the patient after oral replacement is begun, to ensure that absorption becomes normal and that hypercalciuria does not ensue. Urinary calcium excretion of more than 300 mg/day is an indication to reduce the dose of calcium (or vitamin D). Serum calcium is tightly regulated and only falls below normal when severe deficiency occurs. Pseudohypocalcemia can be caused by hypoalbuminemia and by gadolinium administration, a treatement that precipitates calcium [145]. Body stores of calcium are assessed by bone densitometry, with many centers using dualenergy x-ray absorptiometry. The accuracy of this method is equal to that of quantitative computed tomography and is sensitive to changes of 9%–12% in bone mass [146]. Results must be compared with those of age- and gender-matched controls and are useful for diagnosis and following the response to therapy. Bone densitometry should be used to screen all patients at high risk for the development of osteopenia and to guide treatment decisions for selected postmenopausal women, but it is not recommended for routine screening. Serum calcium and alkaline phosphatase levels do not become abnormal until total body calcium depletion is severe.

Treatment

Treatment of acute symptomatic hypocalcemia is required immediately to prevent laryngospasm, seizures, and cardiac arrhythmias. A total of 200–300 mg of elemental calcium should be given intravenously over 5 min as 1 g of calcium chloride or 2–3 g of calcium gluconate (10 mL of 10% calcium gluconate = 1 g of calcium). This should be followed by an infusion of calcium of 0.5–2.0 mg/kg/h [144,147]. The serum calcium should normalize in 6–12 h while the vital signs and electrocardiographic activity are monitored. Patients with chronic hypocalcemia or osteopenia on the basis of poor intake or absorption should be treated with oral supplements of up to 2.5–3.0 g/day given in divided doses. The best dietary source of calcium is milk, and this can be used if clinically tolerated. Otherwise, a number of oral calcium salts are available that vary in elemental calcium content (Table 101.10) [148]. Calcium carbonate is used most often because of the high percentage of elemental calcium, but it is rather insoluble. If the urinary calcium does not increase with calcium carbonate, another, more soluble salt (e.g., calcium gluconate) may be tried, with or without the addition of vitamin D. People who take calcium supplements may be at risk for ingesting lead, although the amount of lead in bone meal has dropped as a consequence of a decrease in the levels of environmental lead from gasoline and paint. When tested by the Natural Resources Defense Council, many of the 20 major brands of calcium supplements marketed in California contained enough lead to increase the average intake of 5–10 µg by 50% [149]. The supplements tested that were lowest in lead content (< 0.5 µg per dose) were Children's Mylanta, Posture-D High Potency Calcium with Vitamin D, and Tums 500 Calcium Supplement.

When malabsorption is present, the doses of vitamin D used are large (25 000–50 000 IU given from once a week to daily). Alternatively, the more soluble forms of vitamin D, especially 1,25-dihydroxyvitamin D, may be effective. Treatment programs must be individualized and monitored closely. Thiazides can decrease the urinary loss of calcium (thereby rendering the urinary determination less meaningful) but also increase the urinary loss of magnesium. Thus, their use in patients with osteopenia must be carefully considered. Supplemental calcium may predispose some individuals to kidney stones but decreases the risk for oxalate stones in patients with short bowel syndrome. The develop-

Table 101.10 Selected oral calcium supplements

Salt in mineral supplements	Percentage of elemental calcium	Tablet size (mg)	Amount of calcium per tablet (mg)
Calcium carbonate	40		
Caltrate + D (200 IU)		1500	600
Os-Cal 500 + D (200 IU)		1250	500
Tums Ultra		1000	400
Viactin (100 IU D)		1250	500

Cheese, soft	1 oz	~ 175
Tofu	1/2 cup	~ 250
Broccoli, boiled	1/2 cup	36
Kale, cooked	1/2 cup	47

D, vitamin D; 1 cup = 8 fl oz (240 mL); 1 oz = 28 g.

ment of calcium toxicity in patients with malabsorption is rare but can occur in patients with osteopenia and normal absorption, especially if they are also receiving supplemental vitamin D. Hypercalcemia can cause anorexia, nausea, constipation, polyuria, fatigue, weakness, confusion, lethargy, decreased deep tendon reflexes, shortened Q–T and prolonged P–R interval and QRS complex duration, and cardiac arrest [147].

Magnesium

Deficiency

Symptomatic magnesium deficiency is usually the result of decreased absorption or increased losses in the urine or from the gastrointestinal tract, especially in patients with extensive small bowel resection [150]. Excessive urinary loss, usually caused by decreased tubular reabsorption, occurs in a variety of circumstances [151]. Medications that promote renal loss include diuretics, aminoglycosides, cyclosporine (ciclosporin), amphotericin B, cisplatin, and digitalis [152]. Increased renal losses also occur in hypercalcemia, volume expansion, tubular dysfunction, acute and chronic alcoholism, diabetes mellitus, hyperparathyroidism, and hypophosphatemia. Magnesium deficiency may occur in type 2 diabetes mellitus and precede the diabetes. Added magnesium may improve diabetic control if the serum levels are low initially [153]. Hypomagnesemia caused by a shift of magnesium from the extracellular to the intracellular compartment may result from feeding, treatment of diabetic ketoacidosis, parathyroidectomy, acute pancreatitis, and correction of acidosis in renal failure. Hypomagnesemia is often associated with and can be a cause of hypocalcemia, hypokalemia, and hypophosphatemia [153]. Hypomagnesemia can present as tremor, myoclonic jerks, ataxia, tetany, ventricular dysrhythmias, tachycardia, hypotension, cardiac arrest, apathy, depression, delirium, hallucinations, and psychosis [154]. The signs and symptoms of hypomagnesemia are often a consequence of the hypocalcemia resulting from the same condition (e.g., malabsorption) or of the decreased parathyroid hormone secretion that occurs when hypomagnesemia is severe.

Assessment

In the absence of excess fecal or renal losses, urinary excretion reflects intake and absorption of magnesium [138]. When the serum magnesium is low in patients with short bowel syndrome, the urinary magnesium excretion may

also be low and perhaps more sensitive than the serum magnesium [155]. Serum magnesium concentrations do not correlate well with total body stores, but it is reasonable to assume that depletion is present when the serum concentration is less than 1.0 mg/dL [152]. Because magnesium is primarily an intracellular ion, the best indicator of depletion may be a measurement of the content in white cells, although only a few studies have compared this value with those in other tissue pools [138]. A load test for magnesium depletion has been described, but its usefulness has not been satisfactorily documented.

Treatment

Moderate to severe deficiency should be treated parenterally, especially if tetany or ventricular arrhythmias are present. An intravenous loading dose of 4 to 8 mmol should be given first, followed by 25 mmol/day thereafter until the plasma magnesium is above 0.4 mmol/L [156]. If hypocalcemia or hypokalemia is present, magnesium should be replaced first. Repletion is best achieved with slow, continuous infusions to avoid rapid increases in urinary excretion. Replacement should be monitored closely with serial serum concentrations and evaluation of deep tendon reflexes. Hypermagnesemia (> 3.0 mg/dL) should be avoided because vasodilation, nausea, vomiting, drowsiness, lethargy, hypotension, bradycardia, depressed deep tendon reflexes, and a prolonged P–R interval can develop.

Patients with mild deficiency or ongoing magnesium losses should receive foods rich in magnesium or an oral supplement. A variety of magnesium salts are available, but many of them, especially the oxide and hydroxide, are virtually insoluble (Table 101.11). Because magnesium is poorly absorbed, it is best to give it in frequent small doses. Potassium-sparing diuretics such as spironolactone decrease urinary magnesium losses and may be useful, especially in patients who are also hypokalemic. However, some patients will require parenteral supplements. Outpatients unresponsive to oral therapy can be treated with intramuscular injections of 2.0 mL of 50% magnesium sulfate solution (8.1 mEq) in each buttock at intervals as needed.

Table 101.11 Magnesium products comparison chart

Product	Dosage forms[a]	Magnesium content (mEq/g)[b]	Comments
Magnesium carbonate	Tablet, 250 mg	23.7	Poorly soluble, low absorption
Magnesium, chelated	Tablet, 500 mg	8.2	Amino acid chelate; sodium-free, oral use only
Magnesium chloride	Solution, 200 mg/mL	9.8	Used i.v. or orally as a 5% solution; alternative to parenteral $MgSO_4$
	Enteric-coated tablet, 535 mg		Sold as Slo-Mag
Magnesium citrate	Solution, 60 mg/mL	4.4	Oral use only
Magnesium gluconate	Tablet, 500 mg, 1000 mg/5 mL	4.8	Very soluble, well absorbed
Magnesium hydroxide	Suspension, 40–80 mg/mL	34.0	Readily available in combination antacid formulations; start with 5-mL suspension or 1 tablet, increase as tolerated to four times daily; may require gastric acid to be absorbed; inexpensive
	Tablet, 600 mg		
Magnesium lactate	Sustained-release tablet, 700 mg	9.8	Sold as Mag-Tab SR
Magnesium oxide	Capsule, 140 mg Tablet, 250 mg, 400 mg, 420 mg, 500 mg	49.6	Poorly soluble; net absorption low, especially in malabsorption
Magnesium sulfate	Solution, 10%, 12.5%, 50%	8.1	Use i.v., i.m., or p.o.

a Magnesium products exhibit variable absorption; increase dose incrementally until no further rise in serum magnesium occurs or until diarrhea ensues. Oral magnesium alleviates diarrhea in some patients with malabsorption.
b 1 mEq = 12 mg = 0.5 mmol Mg.
i.m., intramuscularly; i.v., intravenously; p.o., orally.

Phosphorus

Deficiency

Most patients in whom clinical evidence of hypophosphatemia develops have an underlying wasting condition [157,158], such as malabsorption, malnutrition of any cause, cancer, or chronic alcoholism. Causes of hypophosphatemia include increased urinary losses, shifts of serum phosphorus into the intracellular compartment, and reduced absorption. Absorption is decreased with the use of phosphate-binding antacids, vitamin D deficiency, and parathyroid hormone deficiency. Renal loss is increased in metabolic alkalosis, diuretic therapy, renal tubular dysfunction, osmotic diuresis, hyperparathyroidism, and long-term corticosteroid therapy [156]. When carbohydrate is administered or when phosphate-rich lean tissue is restored and insufficient phosphorus is available, serum levels can fall [156]. Signs and symptoms of hypophosphatemia include hemolytic anemia (serum phosphorus concentration < 0.5 mg/dL), rhabdomyolysis (< 1.0 mg/dL), and other complications that occur with lesser degrees of depletion, including platelet dysfunction, metabolic acidosis, peripheral neuropathy, central nervous system dysfunction, metabolic encephalopathy, and cardiac failure. Most cases of hypophosphatemia appear to be associated with intercompartmental shifts of phosphorus rather than with decreases in the total body pool, although this distinction is not easy to make.

Assessment

The normal serum phosphorus concentration is 2.5–4.5 mg/dL. Levels lower than 1.0 mg/dL usually cause symptoms [156,157].

Treatment

If hypophosphatemia is the result of therapy with phosphate-binding medications (antacids, sucralfate), stopping the medication is sufficient. If oral or enteral intake is possible, supplementation for other causes of a serum phosphate level below 2.5 mg/dL can be provided with milk (1000 mg or 32 mmol/quart (0.9 L) of skim milk) or with other oral preparations in doses of 2–3 g/day (e.g., Neutra-Phos K or Uro-KP Neutral with 250 mg or 8.0 mmol per capsule or dose of powder). Most of the oral preparations, however, cause diarrhea (secondary to lactose intolerance in the case of milk and the phosphate content in the others), which may limit their use in patients with malabsorption. Intravenous supplementation should be limited to those who cannot take oral preparations or who have severe hypophosphatemia (< 1.0 mg/dL). The exact amount needed to restore serum phosphorus cannot be predicted because severe hypophosphatemia may occur with normal body stores of phosphorus. The dose of intravenous phosphate can be adjusted to serum phosphorus levels and to body weight (Table 101.12). When hypocalcemia or renal failure is present, great caution should be used in administering phosphate by any route, but especially intravenously. Too rapid administration can cause calcium phosphate precipitation in renal tubules and other tissues.

Table 101.12 Intravenous phosphorus repletion protocol according to body weight

	Single phosphorus dose (mmol)		
	Body weight (kg)		
Serum [P] (mg/dL)	40–60	61–80	81–120
< 1.0	30	40	50
1.0–1.7	20	30	40
1.8–2.2	10	15	20

A single dose restores serum [P] to normal within 24 h in 76% of patients.

Iron

Deficiency [158,159]

For clinicians, the sequelae of the last stage of iron deficiency, when stores are depleted and anemia occurs, are equated with iron deficiency. However, the role of delivering oxygen to the tissues is dependent not only on hemoglobin concentration but also on the ability of iron-containing proteins in mitochondria to process the oxygen. Such changes may account for the symptoms more prevalent in children (i.e., anorexia, decreased resistance to infection, and reversible protein-losing enteropathy) and for other features not easily explained by anemia, such as angular stomatitis, atrophic lingual papillae, koilonychia, and behavioral or cognitive changes [160]. Cognitive changes have been correlated with low hemoglobin levels in dieting adults, although it is not clear whether the iron was causative [161]. When anemia develops, weakness and pallor predominate. Iron supplements can decrease fatigue in women who are not anemic (mean ferritin concentration 10.5 μg/L), showing that iron deficiency can be recognized and treated preclinically [162].

Assessment

The hemoglobin and hematocrit are the initial and best screening tests [163], but the results should be interpreted with caution. The patient's age and gender have to be considered in assessing the iron status of any individual. Moreover, hemoglobin concentrations can be altered by dehydration or overhydration, chronic inflammation or infection, protein–calorie malnutrition, cobalamin or folate deficiency, hemoglobinopathies, and pregnancy. Thus, hemoglobin is at best an indirect index of the iron status. The ferritin levels in serum are directly proportional to marrow iron stores and

inversely proportional to transferrin levels, with each milligram per liter representing 10 mg of storage iron. Low levels of serum ferritin (< 15 ng/mL) in the presence of anemia nearly always reflect decreased iron stores, and values up to 35 ng/mL are suggestive [1]. However, ferritin levels can be elevated in cases of acute and chronic inflammation, cobalamin or folate deficiency, leukemia or lymphoma or other tumors, alcohol intake, and hyperthyroidism. Thus, values between 15 and 100 ng/mL can be seen in patients with iron deficiency. Serum iron levels alone are not a good measure of the iron status because they do not reflect a stable body pool. About 35 mg is turned over in the plasma each day, and levels can change rapidly in response to acute inflammation. In iron deficiency, serum transferrin levels rise whereas iron levels fall, so that the percentage of saturation falls below 15%. When chronic inflammation, infection, or liver disease is present, serum transferrin levels fall. Transferrin synthesis is downregulated by iron status at the level of translation, so that transferrin levels are elevated in iron deficiency. Thus, a low percentage of saturation in the presence of low transferrin levels does not reflect iron deficiency but rather the anemia of chronic inflammation. Table 101.13 outlines the predictive value of the usual tests in iron deficiency compared with anemia of chronic inflammation [163].

How to proceed when ferritin values are above 35 ng/mL is not clear, and transferrin receptors have been suggested as a possible aid [164]. The amount of uptake of transferrin into cells is regulated by alterations in the number of soluble transferrin receptors (sTfR) on the surface of cells and is most dependent on marrow erythropoiesis activity [164], although intracellular concentration of iron is also important. The highest concentration of transferrin receptors is on cells with the greatest need for iron, such as reticulocytes. A truncated form of the receptor is found in human plasma bound to transferrin, and its content is elevated in iron deficiency, even if mild and of recent onset. The levels of transferrin receptor are not affected by inflammation or liver disease, because cytokines and other factors suppress erythropoiesis through inhibition of erythropoietin production. Thus, the levels of transferrin receptor can be used to distinguish iron deficiency from the anemia of chronic disease. Normal sTfR levels average 5.0 ± 1.0 mg/L, but the lack of an international standard makes comparison of laboratory values difficult. Receptor levels are also increased when erythropoiesis is stimulated by hemolysis or ineffective erythropoiesis.

Table 101.13 Serum tests that differentiate anemia of chronic inflammation (ACI) from iron deficiency anemia (FeD)

Serum test	ACI	FeD	Both
Iron	↓	↓	↓
Transferrin	↓ or NL	↑	↓
Transferrin saturation	↓	↓	↓
Ferritin	↑	↓	↓ to NL
Soluble transferrin receptor (sTfR)	↓	↑	NL to ↑
sTfR/log ferritin	< 1	> 2	> 2
Cytokine levels	↑	NL	↑

NL, normal.

Treatment

Oral iron is available in a wide variety of preparations as a single nutrient or in combination with other vitamins and minerals. The amount used is not important so long as it is adequate to replenish body stores, with an assumption of 20% absorption at the start of treatment for iron deficiency. The approximate percentages of the preparations as elemental iron are as follows: sulfate anhydrous, 30%; sulfate $7H_2O$ hydrated, 20%; fumarate, 33%; and gluconate, 11.6%. The dose should be calculated based on the elemental iron content. A standard dosing schedule is ferrous sulfate (65 mg of elemental iron) two to three times a day between meals. Side effects include nausea, indigestion, diarrhea, and abdominal cramping and can limit the amount that can be ingested. Side effects may be less common when slow-release forms are used, but the iron may be made less available by delaying release to beyond the duodenum, the site of maximal absorption. The total iron deficit can be determined roughly by calculating the amount needed to replenish hemoglobin, with an additional gram for repleting tissue stores: iron deficit (mg) in males = body weight (lb) × (15 – hemoglobin [g/dL]) + 1000. A hemoglobin value of 12 or 13 g/dL can be used for females, 14 or 15 g/dL for males. If 10% absorption throughout therapy is assumed, the total dose required can be calculated. Once the daily tolerable supplement is determined for a patient, the length of treatment necessary to replete the stores can be calculated. Oral preparations should be continued for 1–3 months after the hemoglobin level is restored to allow for restoration of other tissue stores. Parenteral iron is used only when oral iron is not tolerated or effective. Iron dextran (50 mg/mL) is available for intramuscular or intravenous use. The total dose required to replete stores is based on the patient's weight and hemoglobin level:

$$\text{Total iron (mg)} = 0.3 \times \text{body weight (lb)} \times 100 - \frac{\text{hemoglobin (g/dL)} \times 100}{14.8}$$

The intravenous route is safe when the iron is diluted in normal saline solution and administered over 2–3 h [165] (Table 101.14). A test dose of 25 mg of iron dextran should be given initially, and the daily dose should not exceed 100 mg if one wishes to minimize the risk for side effects. A test dose is not required for the other parenteral iron preparations. However, medium-dose (100–400 mg) or high-dose (500–

Table 101.14 Parenteral iron therapy

Parameter	Iron dextran	Sodium ferric gluconate	Iron sucrose
Product	INFeD (100 mg/2 mL) DexFerrum (100 mg/2 mL) Desferal (500 mg/vial)	Ferrlecit (62.5 mg/5 mL)	Venofer (100 mg/5 mL)
Test dose	Required	Not required	Not required
Recommended dose	100 mg/day to repletion	125 mg/dialysis session × 8 doses May repeat p.r.n. for ferritin < 100 ng/mL and Tf saturation < 26%	100 mg 1–3 times/week × 10 doses – repeat p.r.n.
Maximal dose	May give to full replacement	10 mL (25 mg)	5 mL (100 mg)
Method	Diluted in 250 mL–1 L over 4–6 h	Undiluted 12.5 mg/min Diluted in 100 mL NS over 60 min	Undiluted up to 20 mg/min, or diluted in 100 mL NS over > 15 min
TPN compatible	Nonlipid solutions	Not studied	Not studied
Limitations	Stop oral iron Do not exceed calculated dose	↓ Dose by 50% for ferritin > 100 ng/mL, or Tf saturation > 35% Hold dose for ferritin > 500 ng/mL or Tf saturation > 50%	Same as Fe gluconate

Adapted from Kumpf [165] and Aronoff [167].

1000 mg up to full replacement) regimens of iron dextran can be used safely and more conveniently, provided adequate precautions are taken and the patient is observed during the infusion [165]. Anaphylaxis is extremely rare when iron dextran is given in this way. However, the patient should be closely supervised and parenteral iron given with caution to anyone with asthma or allergy. Epinephrine (adrenaline) should be available for acute hypersensitivity reactions, and antihistaminics can be given for symptoms of urticaria, rashes, sweating, dizziness, headache, nausea, and fever. Ferric gluconate is the preparation preferred by some experts [166]. All parenteral iron preparations are fairly safe, with the incidence of serious adverse events ranging from 0.4% to 2.5% [167]. Most patients with Crohn's disease who require parenteral iron will respond, but erythropoietin can enhance the response [168].

Zinc

Deficiency

Zinc deficiency is difficult to identify, because plasma zinc is an insensitive predictor of zinc status; thus, deficiency is probably underdiagnosed. Overt deficiency in otherwise healthy individuals is not reported in the United States, but the growth of children can be limited by inadequate dietary zinc [169]. Patients with gastrointestinal disease (Crohn's disease, short bowel syndrome), cystic fibrosis, pancreatic insufficiency, or chronic diarrhea from any cause are at increased risk for zinc deficiency because of increased losses in the stool and decreased intake [170]. Diarrheal stool contains about 17 mEq of zinc per liter, in excess of the recommended dietary allowance (RDA). Other conditions predisposing to zinc deficiency include cirrhosis, sickle cell anemia, pregnancy, pica, and penicillamine treatment [171]. Clinical manifestations include growth retardation (in children), skin lesions on the face and limbs (which can vary from moist and pustular to seborrheic and acneiform), alopecia, diarrhea, apathy, night blindness, and possibly poor wound healing and loss of taste. However, the single double-blinded study of the effect of zinc supplements on taste and smell dysfunction did not support a role for zinc [171].

Assessment

None of the available methods reliably reflects either recent intake or absorption or body stores. The fasting plasma concentration is most often used, but it correlates poorly with total body zinc except when the patient is severely deficient. Most zinc in blood is in red cells, so that even small amounts of hemolysis can alter plasma zinc. Most plasma zinc is bound tightly to α_2-macroglobulins or loosely to albumin. Thus, hypoproteinemia can lower zinc levels. The plasma level may be falsely low because it can be decreased by many other factors, such as stress, infection, polypharmacy (displacing

zinc from albumin), and corticosteroids [1,138]. Levels below 50 μg/mL are often associated with some symptoms, and patients with levels below 30 μg/mL nearly always have some manifestation of deficiency. Metallothionein is a zinc/copper-binding protein that is reduced in zinc deficiency, and its red cell content has been low when zinc plasma levels were normal, perhaps reflecting a functional zinc pool [172]. At present, however, if zinc deficiency is suspected, it is best diagnosed by the symptomatic response to zinc therapy.

Treatment

Zinc is available as a single nutrient and as a component of many multivitamin and mineral preparations. Zinc supplementation should be provided to persons at risk for the development of deficiency, as well as to those with symptomatic deficiency [173]. Zinc sulfate (67 mg or 220 mg) contains 15 or 50 mg of elemental zinc. Thus, unlike a single dose of other minerals, a single dose of zinc exceeds the RDA, and oral therapy is usually sufficient although absorption is only about 20%. Parenteral zinc therapy is also available as the sulfate or chloride. Zinc is safe to use; the minimum oral toxic dose is 500 mg/day [1]. Long-term ingestion of high doses (450 g/day) can induce copper deficiency [174]. Zinc supplements have reduced the incidence, prevalence, duration, and severity of diarrhea and pneumonia in children from developing nations, presumably because the availability of dietary zinc in such regions is limited [175]. Because of its effect in diarrhea of children, zinc has been added to some oral rehydration solutions. Zinc does not appear to help in treatment of the common cold [176]. Supplemental zinc decreases measures of iron status in patients with low iron reserves [177]. Although zinc is not usually considered a toxic metal, a familial syndrome of hyperzincemia is associated with recurrent infections, hepatosplenomegaly, inflammatory skin lesions, arthritis, and anemia [178].

Copper

Deficiency

Copper deficiency in adults is rare. It can occur in patients receiving TPN without copper supplementation and in patients treated with chelating agents, such as D-penicillamine, with or without large doses of zinc [179]. Premature infants, malnourished or malabsorbing patients, and persons with Menkes syndrome, an inherited defect in copper absorption, are at higher risk for the development of deficiency [180]. Neutropenia, anemia, diarrhea, and scurvy-like bone changes can occur, but detection of early deficiency can be difficult [181]. A clinical myelopathy similar to subacute combined degeneration is being increasingly reported with severe copper deficiency [182]. Copper supplementation should also be considered for patients with increased gastrointestinal fluid losses, especially from chronic biliary tract fistulae, because biliary secretion is the major excretory route for copper [179].

Assessment

Laboratory assessment of copper status is difficult because serum concentrations do not correlate well with tissue levels. Because 80% of copper is bound to ceruloplasmin (each milligram binds 3.3 μg of copper) and the rest to other proteins, the level does not correlate with intake [183]. However, tissue copper levels are relatively stable and change slowly. Thus, when deficiency occurs, the plasma level often falls earlier than the tissue levels. Normal levels are increased by estrogens or oral contraceptives, pregnancy, and acute and chronic infections. Levels are decreased in nephrosis, Wilson disease, and any cause of protein malnutrition. Free copper levels are more instructive than total levels and can be estimated by calculating bound copper (bound copper = ceruloplasmin [μg/dL] × 3) and subtracting it from the total. Values below 25 μg/dL are normal [184]. This calculation is more sensitive in detecting elevated copper levels (as in Wilson disease) than in detecting copper deficiency.

Treatment

Oral supplementation can be provided by the copper sulfate in multivitamin and mineral preparations, which contain 0.4 mg of elemental copper per milligram of copper sulfate. The daily dose of 2–3 mg is adequate to treat deficiency in adults. The suggested maintenance intravenous dose is 0.3–1.5 mg/day, but the dose should be reduced to 0.15 mg/day for patients with cholestasis [185]. To treat deficiency, 2 to 3 mg/day has been given intravenously, repeated thrice weekly until the ceruloplasmin level normalizes, usually in about 10 days. There is a large margin of safety in using copper supplements, but acute oral ingestion of more than 15 mg of elemental copper produces nausea, vomiting, diarrhea, abdominal cramps, and mucosal ulceration. At larger doses, hemolysis, gastrointestinal bleeding, azotemia, and jaundice can occur. The treatment of toxicity includes gastric lavage and 1 g of D-penicillamine per day [186].

Thiamin (vitamin B-1)

Deficiency

Deficiency of thiamin may be caused by decreased intake or increased tissue utilization, or by a combination of factors. Thus, the usual clinical settings include pregnancy, chronic alcoholism, malabsorption syndromes, chronic nausea and vomiting, prolonged febrile illnesses, and chronic renal dialysis. The total requirement is usually more than 1 mg/day in adults, and the total stores are only about 30 mg, so deficiency can develop fairly rapidly. In parts of the world where polished rice is the staple cereal in the diet, beriberi (weakness, paresthesias, high-output cardiac failure) is seen. In the United States, where food thiamin is abundant, the deficiency syndrome is often seen in conjunction with deficiency of other B vitamins. Symptoms and signs include peripheral neuropathy, limb weakness, cerebellar dysfunction, subacute necrotizing encephalomyelopathy, and Wernicke encephalopathy

(apathy, confusion, ataxia, photophobia, nystagmus, paralysis of upward gaze). Signs of deficiency may worsen if glucose is given without thiamin. If lactic acidosis is also present, signs of heart failure may develop [187]. Thiamin deficiency should be considered in the differential diagnosis of lactic acidosis.

Assessment

Recent intake or absorption, but not body stores, is correlated with urinary excretion. The amount excreted is greater during childhood, when growth is rapid, so the result (micrograms of thiamin per gram of creatinine) must be compared with the values in age-matched controls. Body stores are measured either directly in blood or serum by high-performance liquid chromatography or by the erythrocyte transketolase assay, which measures a thiamin-dependent enzyme activity. The activity coefficient of the enzyme is determined by the activity in the presence and absence of added thiamin. In deficiency states, more stimulation occurs, and the activity coefficient is above 1.25 [138].

Treatment

Thiamin hydrochloride is available as a single nutrient in oral and parenteral forms and as a constituent of almost all multivitamin preparations. Adults with mild deficiency should receive 10–20 mg intramuscularly or 25–50 mg orally twice daily for 1 week, followed by an oral maintenance dose of 2–5 mg/day. Benfotiamine (*S*-benzoylthiamine-*O*-monophosphate) is a lipid-soluble thiamin analogue that achieves plasma levels five times that of comparable doses of thiamin [188]. There is no clinical correlation with these higher plasma levels. Critically ill patients, especially those with central nervous system manifestations of deficiency, should receive doses of 50–100 mg twice daily intravenously for 3 days, followed by oral supplementation of 5–30 mg/day until a normal diet is resumed. The thiamin should be given before any carbohydrate is administered to avoid enhancing the deficiency. Because thiamin deficiency is often associated with deficiencies of other B vitamins, multiple vitamins should be given. Rare responses to parenteral thiamin include feelings of warmth, tingling, pruritus, nausea, sweating, and anaphylactic reaction [189]. It has been suggested that thiamin improves energy levels during exercise and in the elderly, and cognition in Alzheimer disease, but the few studies performed do not support these conclusions [190].

Riboflavin (vitamin B-2)

Deficiency

Riboflavin deficiency usually occurs along with deficiencies of other B vitamins, especially in patients with malabsorption and chronic alcoholism. Early symptoms relate to oral or eye lesions. Angular stomatitis (maceration and fissuring of the mucocutaneous junction at the angles of the mouth), cheilosis (inflammation of the lips), glossitis, geographic tongue, seborrhea-like dermatitis, pruritus, photophobia, corneal vascularization, and visual impairment may occur. The differential diagnosis of the lip lesions includes poorly fitting dentures with malocclusion, allergy (e.g., lipstick, toothpaste), and iron deficiency anemia. Other vitamin B deficiencies can cause the tongue lesions. Some of these symptoms occur in vitamin B-6 deficiency because the oxidase necessary to produce functional vitamin B-6 is riboflavin-dependent [191].

Assessment

Urinary excretion correlates well with intake because the vitamin is excreted unmetabolized. With fasting or prolonged bed rest, urinary excretion can be falsely elevated. Levels below 40 μg/g of creatinine signify extremely low intake in an adult. Body stores of riboflavin are assessed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase in the blood. An activity coefficient above 1.2 (stimulated/control activity) signifies deficiency [138].

Treatment

Deficiency can be treated with 5–10 mg/day orally, along with other vitamins [192]. When malabsorption is present, a prophylactic dose of 3 mg/day is recommended, usually as part of a multivitamin preparation. Riboflavin may cause a yellow-orange appearance to the urine but is remarkably nontoxic.

Niacin (vitamin B-3)

Deficiency

Because of the niacin supplementation of grains and breads, the classical deficiency syndrome of pellagra (dermatitis, dementia, diarrhea) is rare in the United States. Deficiency is seen most often in patients on a diet of meat, cornmeal, and molasses, with chronic alcoholism, malabsorption syndromes, or carcinoid syndrome, in which a large amount of tryptophan (niacin precursor) is converted instead to serotonin. Pellagra rarely occurs in the carcinoid syndrome, and when it does it can be overcome with oral niacin. Hartnup disease is associated with a defect in tryptophan absorption and can also predispose to deficiency [193]. Isoniazid therapy can lead to deficiency because hydrazines form adducts with pyridoxal phosphate. The last enzyme in the conversion of tryptophan to nicotinic acid, kynureninase, requires pyridoxal, thereby linking the deficiency of these two vitamins. Moreover, isoniazid resembles nicotinic acid and acts as an inhibitor. In niacin deficiency, the dermatitis occurs over exposed areas and is scaly. Twenty percent of patients get dyssebacea, referring to plugs of inspissated sebum projecting from deleted orifices of sebaceous glands, appearing first along the alae nasi, spreading over the nose, and then the forehead, lips, and chin. It is not inflammatory, and is unrelated to sunlight, unlike the dermatitis, and can precede the dermatitis by weeks. Painful tongue and angular stomatitis are seen but may be caused in part by accompanying riboflavin deficiency. Diarrhea is probably caused by the direct

effect of niacin deficiency on epithelial cell function. Central nervous system dysfunction includes irritability, headache, insomnia, psychosis, hallucinations, and seizures.

Assessment

The urine content of the niacin metabolite *N*-methylnicotinamide reflects intake and absorption and is less than 0.5 mg/g of creatinine in adults with deficient intake. No test is available for body stores of niacin, although the results of one study in young men suggested that an erythrocyte ratio of nicotinamide adenine dinucleotide (NAD) to nicotinamide adenine dinucleotide phosphate (NADP) below 1.0 might reflect deficiency [138].

Treatment

Isolated niacin deficiency is unusual in the United States, so treatment with other B vitamins often accompanies niacin replacement. Depending on their severity, the symptoms of pellagra respond to oral doses of 100–500 mg of niacin per day [193]. Mental, gastrointestinal, and oral symptoms clear rapidly, but the resolution of skin lesions may require weeks to months. Large doses of nicotinic acid (1–3 g/day) used to treat hypercholesterolemia can cause flushing, pruritus, burning sensations, nausea, vomiting, heartburn, diarrhea, dizziness, and tachycardia. Hyperglycemia and increased serum aminotransferase and bilirubin levels can occur at doses as low as 750 mg of nicotinic acid per day [194].

Pyridoxine (vitamin B-6)

Deficiency

Because vitamin B-6 is abundant in foods and is produced by colonic bacteria, dietary deficiency is rare. It is most often reported as a result of treatment with pyridoxine antagonists, especially isoniazid, hydralazine, oral contraceptives, dopamine, and D-penicillamine. Rarely, deficiency occurs in chronic alcoholism or malabsorption, usually in association with deficiencies of other B vitamins. The clinical manifestations include peripheral neuropathy, seborrheic dermatitis around the eyes and nasolabial folds, and oral lesions (angular stomatitis, cheilosis, glossitis), similar to those seen in riboflavin and niacin deficiencies. Seizures and sideroblastic anemia may also occur [195]. Hyperhomocystinuria has been identified as an independent risk factor for vascular disease and may be caused in part by a deficiency of cystathionine synthase, the vitamin B-6-dependent enzyme that catalyzes the conversion of homocysteine to cystathionine. Twelve large-scale randomized studies have examined the effect of B-vitamin supplementation on cardiovascular risk, and shown that homocysteine levels can be normalized, but any effect on clinical outcomes is still uncertain [196]. It is premature to recommend the use of these supplements to alter atherogenesis in this subset of patients with hyperhomocystinemia [197]. Low vitamin B-6 levels have been associated with an increased risk for first venous thrombosis in a single study [198], so it is not inconceivable that vitamin supplementation might carry some risk on its own.

Assessment

Recent intake is reflected by the urinary excretion of metabolites. A low intake correlates with excretion of less than 500 μg of 4-pyridoxic acid per day. Body stores are measured by the erythrocyte aminotransferase index, with a determination of enzyme activity in the presence and absence of pyridoxal phosphate. Deficiency is correlated with an erythrocyte aspartate aminotransferase (E-AST) index above 2.2. Alternatively, pyridoxal phosphate can be measured in whole blood (50–120 nmol/L) or plasma (> 30 nmol/L), although the levels associated with deficiency have not been precisely determined [138].

Treatment

Pyridoxal phosphate is available in both oral and parenteral forms. Suspected deficiency should be treated with 50–150 mg/day orally, especially when neuropathy is present. A multiple vitamin preparation containing 2–5 mg of pyridoxine should be added to provide the other B vitamins. Some experts suggest such a supplement for all patients on isoniazid and similar inhibitors, whereas others suggest supplements only for those patients at high risk for the development of neuropathy. Pyridoxine is used in large doses for isoniazid overdose, *Gyromitra* (monomethylhydrazine) mushroom poisoning, and hydrazine overexposure [199]. When pyridoxal phosphate is ingested in large amounts (2–6 g/day), a peripheral neuropathy may develop [200]. Pyridoxine antagonizes levodopa by stimulating the decarboxylation of dopa to dopamine. Therefore, patients taking levodopa should limit their pyridoxine intake to less than 5 mg/day [201].

Folate

Deficiency

Folate deficiency is associated with poor socioeconomic and dietary conditions, especially with chronic alcoholism (usually > 80 g/day) and malabsorption syndromes. Alcohol can increase urinary folate excretion [202]. Deficiency also results from competition for absorption (sulfasalazine), long-term anticonvulsant therapy (usually years), increased utilization (pregnancy, hemolytic anemia, leukemia, chronic myelofibrosis), and inhibition of dihydrofolate reductase (the enzyme that converts folate to the active coenzyme) by methotrexate, trimethoprim, and pyrimethamine [203]. A cerebral folate deficiency syndrome can be produced by folate receptor antibodies in infants, older children, and occasionally in adults, resulting from blocked folate transport into the brain [204]. Serum and erythrocyte folate levels and serum homocysteine are normal, but 5-methyltetrahydrofolate concentration in the cerebrospinal fluid is low and accounts for the developmental and neurological abnormal-

ities. If folate stores are normal initially, symptoms will appear in about 4 months. The primary manifestation of classical folate deficiency is macrocytic anemia, often accompanied by thrombocytopenia and leukopenia. Other symptoms may include glossitis, diarrhea, fatigue, and possibly (but uncommonly) neurological signs.

Two other significant forms of folate deficiency occur in the absence of classical evidence of deficiency. Women consuming too little folic acid during early pregnancy are at increased risk for delivering children with neural tube defects. The Dietary Reference Intake Committee has confirmed the recommendation of the US Department of Health and Human Services that all women capable of becoming pregnant ingest 400 μg of synthetic folic acid daily [203]. Hyperhomocystinemia can be caused by folate deficiency if it is not accompanied by elevated methylmalonic acid levels. High levels of homocysteine are correlated with an increased risk for myocardial infarction in some studies, in about 10% of patients [197]. Although the folate levels are normal, the hyperhomocystinemia can be corrected by supplemental folate, but it is not clear that the risk for heart disease is altered. The epidemiological data implicating homocysteine as a factor in cardiovascular risk are strong, but data from some prospective interventional studies have been less consistent [197,205]. Although a low folate status is a strong determinant of elevated total homocysteine levels, the folate status was not associated with homocysteine levels [143], nor with an increased risk for coronary atherosclerosis [206]. These data are consistent with overrating of homocysteine as a risk factor for heart disease. Similarly, the importance of homocysteine and folate levels as risk factors for stroke is probably small [207].

Assessment

Because folate deficiency develops during decreased intake or absorption, the first laboratory abnormality to develop is a decrease in the serum folate (2–6 ng/mL), which is sensitive to changes in intake [138]. Values below 2 ng/mL are usually associated with megaloblastic anemia and decreased tissue reserves. Because about 50% of serum folate is bound to albumin, hypoalbuminemia can produce falsely low serum folate levels. Body stores of folate can be measured by red cell folate more accurately than by serum folate. Both red and white cells contain much more folate than serum does, so hemolysis or a leukemoid reaction can falsely elevate the serum folate. When both serum folate (< 2 ng/mL) and red cell folate (< 140 ng/mL) are low, folate deficiency is the cause. When cobalamin deficiency is present, folate may not be well utilized in 15%–25% of cases, so serum folate rises and red cell folate falls. Multilobed polymorphonuclear cells and macrocytic anemia develop after tissue folate levels fall [138]. Serum homocysteine levels above 30 μmol/L are consistent with folate deficiency if the methylmalonic acid levels are normal.

Treatment

Oral folate supplements are available in tablets up to 1 mg, but the unreduced pteroylglutamic acid is the form used. Most of this form is excreted unchanged or after degradation, so the dose of this supplement cannot be compared with the true folate requirements. Folinic acid (5-formyltetrahydrofolate) is needed for treating the cerebral folate syndrome. The parenteral route is used only if oral therapy is not possible or malabsorption is severe. A reticulocyte response is seen in 3–5 days, and a peak response occurs in 5–10 days. The 400-μg dose found in multivitamin preparations is usually adequate as maintenance therapy for patients with malabsorption or alcoholism. For patients on sulfasalazine or with hemolytic anemia, a dose of 1 mg/day is suggested. Folate can lower plasma homocysteine, but the data do not yet support a preventive role for folate in cardiovascular disease, stroke, or other chronic diseases [205–208]. Betaine (trimethylglycine) is a methyl donor, approved by the US Food and Drug Administration (FDA) for the treatment of homocystinuria, that does lower plasma homocysteine, but not more so than folate [209]. Foltx (folic acid 2.5 mg, cyanocobalamin 1 mg, and pyridoxine 25 mg) is an over-the-counter preparation promoted for hyperhomocysteinemia, but its benefit compared with existing preparations is unknown. Folate is remarkably nontoxic. Large doses (> 100 times the RDA) can precipitate convulsions in patients treated with phenytoin [210]. Giving folate to a patient with cobalamin deficiency corrects the anemia but does not prevent irreversible neurological damage. The tolerable upper intake level (UL) for folate of 1000 μg/day has been challenged because all but eight cases of masking neurological progression (not just worsening anemia) in vitamin B-12 deficiency occurred in patients taking more than 5 mg of folate per day [211].

Cobalamin (vitamin B-12)

Deficiency

A dietary deficiency of cobalamin occurs only in lacto-ovo-vegetarians who do not consume any food of animal origin. The most common causes in adults are gastric lesions (especially the atrophic gastritis associated with pernicious anemia or gastrectomy), lesions or resection of the terminal ileum (especially in Crohn's disease), and bacterial overgrowth. Gastric pathology accounts for well over half the cases. An increasingly common cause of low serum cobalamin levels is AIDS. The significance of the low levels is not always clear, but some patients manifest subtle alterations in mental and cognitive abilities [212]. Reversible chorea and dystonia have been reported as a result of cobalamin deficiency [213]. Deficiency also occurs rarely in patients with severe chronic pancreatitis, congenital deficiency of the carrier protein transcobalamin II (TCII), or an inability to utilize food-bound cobalamin in the absence of other gastric pathology [214]. Symptoms are insidious and develop over 2–3 years, sooner if malabsorption is the cause. A sore

tongue, paresthesias, anorexia, loss of taste, diarrhea, dyspepsia, hair loss, impotence, irritability, and psychiatric illness (e.g., depression) can be present. Numbness and tingling, especially in the lower extremities, can progress to loss of vibratory sensation, loss of coordination, muscle weakness, and atrophy, and memory disturbances can develop [215]. Macrocytic anemia with megaloblastic bone marrow and multilobed nuclei in the polymorphonuclear leukocytes is frequently, but not always, present. The macrocytic anemia must be differentiated from chronic liver disease and from hypothyroidism. Many patients, especially those who are elderly, present with neurological symptoms and signs in the absence of anemia assessment.

Assessment

The diagnosis of cobalamin deficiency is usually suspected on the basis of hematological findings [216]. The serum concentration of cobalamin usually correlates with body stores. Unlike the folate concentration, the cobalamin concentration in red cells is no higher than that in serum, so hemolysis is not a cause of falsely elevated values. In humans, only a small proportion of cobalamin is carried on TCII, the protein that delivers the vitamin to the tissues. Thus, there can be a stage at which the serum level is normal (cobalamin is bound to haptocorrin) but tissue levels are low. Falsely high levels can be seen in leukocytosis (release of haptocorrin, increasing the total serum binding capacity) and in acute liver disease (release of body stores). Conversely, serum levels can be low when body stores are normal. Protein deficiency can lower serum levels without affecting tissue delivery if the TCII levels are normal. Levels are low in pregnant women because of dilution and redistribution of binding proteins. Serum cobalamin levels below 150 pg/mL (110 pmol/mL) are always associated with deficiency if causes of falsely low levels are not present (folate or protein deficiency, pregnancy). Levels between 150 and 200 pg/mL should be considered suspect and should lead to further testing with methylmalonic acid and homocysteine levels, correlation with abnormal hematological or neurological findings, or both. A subtle presentation of cobalamin deficiency is especially likely in elderly patients [217]. In doubtful cases, a therapeutic trial with cobalamin is safe, and reversal of the abnormal findings is diagnostic.

Biochemical tests for cobalamin deficiency can clarify cases in which the serum cobalamin levels combined with the clinical picture are not definitive. The workup should also include a careful neurological examination. The serum can be assayed for metabolites that increase when the function of the two cobalamin-dependent enzymes is impaired: methylmalonyl-CoA mutase (methylmalonic acid increased) and methionine synthase (homocysteine increased). Folate deficiency leads to an increase in homocysteine levels (> 20 µmol/L) but not in methylmalonic acid levels, whereas cobalamin deficiency increases methylmalonic acid (> 390 nmol/L) as well [218]. Methylmalonic acid levels can be elevated in the absence of cobalamin deficiency when renal insufficiency is present. Because TCII is the protein that delivers cobalamin to tissues but accounts for less than 10% of serum cobalamin binding, low holo-TCII concentrations have been reported as the earliest sign of negative cobalamin balance [89]. This test is not used routinely. The selection of the various tests for cobalamin deficiency depends on the stage of deficiency suspected (Table 101.15). Early sensory neuropathy can be linked to cobalamin deficiency by evidence of myelopathy obtained by spiral magnetic resonance imaging (MRI) [219].

Because abnormal serum measurements of cobalamin metabolism precede the late manifestations of tissue damage, it is recommended that populations at risk are screened.

Table 101.15 Laboratory tests in sequential stages of cobalamin deficiency

	Stage of cobalamin deficiency				
Parameter	**None**	**I**	**II**	**III**	**IV**
Cbl balance	Normal	Negative balance of stores	Depletion (early)	Tissue damage (late)	
Serum holo-TCII	> 60 pg/mL	Low	Low	Low	Low
Serum Cbl	> 201 pg/mL	> 201 pg/mL	> 201 pg/mL	Low	Low
Serum MMA	< 376 nmol/L	< 376 nmol/L	< 376 nmol/L	High	High
Serum Hcy	< 15 µmol/L	< 15 µmol/L	< 15 µmol/L	High	High
RBC folate	> 160 pg/mL	> 160 pg/mL	> 160 pg/mL	> 140 pg/mL	> 100 pg/mL
Neurological symptoms	None	None	None	Sometimes	Frequent
MCV	Normal	Normal	Normal	Normal	High
Hemoglobin	Normal	Normal	Normal	Normal	Low

Cbl, cobalamin; Hcy, homocysteine; MCV, mean corpuscular volume; MMA, methylmalonic acid; RBC, red blood cell; TCII, transcobalamin II.
Adapted from Herbert VD. Round Table Series 66. London: Royal Society of Medicine Press, 1999.

These include strict vegetarians, persons older than 65 years of age with decreased food intake, and patients with any of the following: unexplained neurological or psychiatric symptoms or anemia, long-term use of proton pump inhibitors, autoimmune diseases, AIDS, previous gastric surgery, Crohn's disease of the ileum, and malabsorption from any cause. Screening should be done with serum holo-TCII measurements if available, either alone or in conjunction with serum cobalamin. If serum cobalamin alone is used and values below 350 pg/mL are obtained, metabolite assays should be performed if cobalamin deficiency is suspected clinically. The combination of a serum cobalamin value below 350 pmol/mL and an elevated methylmalonic acid concentration has a specificity of 98% for cobalamin deficiency [220].

Intake or absorption should be assessed only when clinically indicated. If gastric atrophy is demonstrated by biopsy, or if gastrectomy is known from the history or the radiographic findings, it is not usually necessary to confirm the absence of intrinsic factor by a Schilling test. Urinary excretion of less than 5% labeled cobalamin is diagnostic of malabsorption, whereas excretion of more than 10% labeled cobalamin is normal, but many results are indeterminate (5%–10%) [1,138]. This lack of sensitivity is also a factor in deciding whether to proceed with the test. The two major causes of a falsely normal Schilling test result are an erroneous value (intertest variability can be as high as 30%–50%) and malabsorption of food cobalamin, presumably because of an inability of gastric proteases to liberate the vitamin. The Schilling test must be performed with labeled food cobalamin (usually in liver or scrambled eggs) to make the diagnosis because the standard Schilling test uses free cobalamin. However, the commercially available versions of the test have not been uniformly standardized.

Treatment

If cobalamin deficiency is caused simply by decreased intake without malabsorption, 3–6 μg of oral cobalamin per day will suffice. However, if malabsorption is present, either because of lack of intrinsic factor or of intestinal disease, then losses of up to 10 μg/day must be allowed for. Deficiency is treated with 100 to 1000 μg/day for 5–10 days, followed by at least 300 μg/month, given by subcutaneous injection, indefinitely. Alternatively, oral or sublingual cobalamin can be given with equal efficacy (2 or 1 mg/day, respectively) to take advantage of the inefficient (~ 1%) absorption of the vitamin in the absence of intrinsic factor [221]. Nasal spray and nasal gel formulations of cyanocobalamin (Nascobal) are available, in the recommended dose of 500 μg once per week [222]. Although normal cobalamin levels can be restored by larger doses, no studies have documented equal efficacy with the much more expensive nasal preparation. Increased well-being is noted within 24 h of initiating treatment, painful glossitis improves in 48 h, and reticulocytosis begins in 5 to 7 days. Serum folate falls rapidly. The reversal of neurological signs may take 6 months or more. No significant toxicity has been reported with therapeutic doses of oral or parenteral cobalamin.

Ascorbic acid (vitamin C)

Deficiency

Scurvy develops in 2–3 months if the diet is deficient in ascorbic acid. It occurs in the United States only rarely, usually in cases of chronic alcoholism, malabsorption, or food faddism. Early symptoms are weakness, lassitude, irritability, aching joints and muscles, and weight loss. Later, perifollicular hyperkeratotic papules appear on the buttocks, thighs, and legs, followed by petechiae on the lower legs [223]. In advanced deficiency, the gums become swollen, red, and spongy and hemorrhaging occurs, especially from the gums and in the skin and muscles. Anemia is common. No deficiency syndrome other than scurvy has been reported.

Assessment

Plasma ascorbate levels reflect recent intake. Thus, a low serum concentration precedes clinical scurvy [138]. Low levels do not necessarily denote scurvy, however. Levels can be falsely low in patients with chronic inflammatory diseases, in cigarette smokers, after severe emotional stress, and in women taking oral contraceptives. Levels below 0.2 mg/dL (11 μmol/L) denote deficient intake or absorption; that level is reached in 3–5 months. Leukocyte ascorbate concentration is better correlated with body stores (< 150 μmol/L represents a high risk for deficiency), but the assay is technically difficult and requires large blood samples. Because the diagnosis of scurvy should be made quickly, plasma ascorbate is the initial test of choice.

Treatment

Scurvy may respond to as little as 10 mg of vitamin C per day, but doses between 60–100 mg/day and 250 mg four times daily are recommended to replenish body stores. Large doses of ascorbic acid (2–6 g/day) have been reported to cause diarrhea, promote the formation of renal oxalate stones, increase the excretion of basic drugs by acidifying the urine (e.g., tricyclic antidepressants), decrease the excretion of acidic drugs (e.g., aspirin), and interfere with many laboratory tests, including the fecal tests for occult blood that depend on oxidation of the substrate for a positive reaction. However, the reports of clinically adverse effects with supplemental vitamin C have largely not been substantiated in normal healthy populations [224]. However, despite small benefits regarding the duration and severity of rhinovirus infection in experimental settings, there is no evidence that vitamin C reduces the incidence or severity of the common cold in the general population [225]. Epidemiological studies have noted an inverse relationship between serum levels and coronary artery disease, hypertension, cataracts, and carcinomas, but no evidence for benefit from intervention has been found

[226]. It is not indicated to recommend supplemental vitamin C for these conditions.

Biotin

A dietary deficiency of biotin is rare [203,227], but it can be caused by excessive consumption of raw egg white, which contains avidin, a biotin-binding glycoprotein. The serum assay is available, but is complex, involving high-performance liquid chromatography combined with avidin binding. The effects of deficiency include anorexia, nausea, dermatitis, alopecia, mental depression, and organic aciduria. Symptoms disappear with doses of 0.15 to 0.3 mg parenterally, or with 0.2–10 mg/day orally for a few days. No adverse effects of such treatment have been reported.

Pantothenic acid

Definite clinical deficiency has not been reported in humans, probably because the vitamin is so abundant in foods [203]. The "burning feet" syndrome seen in malnourished patients may respond to pantothenic acid, but it is unclear whether this represents a specific deficiency. If deficiency is suspected, 10 mg of calcium pantothenate can be used.

Vitamin A [228,229]

Deficiency

Vitamin A deficiency is usually the result of decreased intake or of fat malabsorption. Contributing factors include impaired conversion of carotenoids to vitamin A (in mucosal disease), decreased storage capacity (in liver disease), decreased levels of serum transport proteins (in liver disease or protein malnutrition), and increased urinary losses (in cancer, tuberculosis, or urinary tract infections) [228].

Inadequate intake is rare in the United States, but the number of new cases of corneal disease caused by vitamin A deficiency worldwide approaches 1 million each year [229]. It takes about 2 years to deplete hepatic stores. Symptoms of deficiency are night blindness, xerophthalmia, follicular hyperkeratosis, altered taste and smell, increased cerebrospinal fluid pressure, and increased infections [230]. When zinc deficiency is also present, the effect on visual adaptation may be magnified.

Assessment

The intake of both carotene and vitamin A is reflected in the serum levels. Decreased intake is reflected in serum vitamin A levels between 10 and 20 μg/dL [138]. A level below 10 μg/dL indicates deficiency. Low carotene levels are meaningful only if carotene is being ingested in the diet because there are no body stores of carotene. In severe liver disease and chronic infection, serum vitamin A levels may fall because retinol-binding protein is not produced in normal amounts. However, carotene levels tend to rise because less carotene is converted to vitamin A in these conditions. Vitamin A can be elevated with normal carotene levels in patients ingesting excess amounts of vitamin A or in patients on chronic hemodialysis because of a decreased conversion of retinol to retinoic acid. Elevated carotene levels with normal retinol are seen in persons ingesting excess amounts of carotene and also in patients with anorexia nervosa, hypothyroidism, hyperlipidemia, or the hypercholesterolemia of diabetes [138].

Treatment

Vitamin A is provided in the form of free retinol. Deficiency states respond to daily oral doses of the vitamin of between 5000 and 50 000 IU. Intramuscular delivery can also be used [1]. Because of their antioxidant properties, carotenoids have been implicated in many chronic diseases often linked with vitamins E and C, the other vitamin antioxidants [223]. However, no convincing evidence is yet available to support supplementation with any antioxidant vitamins, carotenoids, or preformed vitamin A to prevent malignancies or cataracts. Some data suggest that vitamin A may help children with infections to grow [231]. Doses of vitamin A suggested for patients with severe malabsorption are 50 000 IU/day for young infants (0–6 months), 100 000 IU for older infants (6–12 months), and 200 000 IU for children over 1 year of age. Doses of vitamin A above the RDA are contraindicated in pregnant women because of the potential for teratogenicity. The minimum daily dose that is toxic to patients without malabsorption is 25 000–50 000 IU. Toxicity is correlated with serum levels of vitamin A above 1000 μg/dL. Symptoms of chronic toxicity include dry mouth and mucous membranes, skeletal pain, increased cerebrospinal fluid pressure, alopecia, anorexia, irritability, hepatic dysfunction, exophthalmos, and hypercalcemia. Carotene cannot be converted to retinol fast enough for even large doses to produce retinol toxicity.

Vitamin D (cholecalciferol)

Deficiency

Vitamin D deficiency secondary to inadequate intake is rare in the United States, in part because milk products are fortified with the vitamin. Even persons who do not consume dairy products usually obtain adequate sunlight exposure to prevent vitamin D deficiency. However, in elderly persons with little exposure to sunlight, decreased vitamin D intake or synthesis along with inadequate calcium intake may contribute to a high incidence of bone fractures [232]. Deficiency should be considered in any patient with steatorrhea (malabsorption of dietary vitamin and polar metabolites by the enterohepatic circulation) or severe liver disease (decreased 25-hydroxylase activity) or kidney disease (lack of 1α-hydroxylase), as well as in patients with Crohn's disease or previous ileal resection [233]. Vitamin D deficiency causes hypocalcemia and hypophosphatemia, which result in increased parathyroid hormone secretion and bone demineralization. In time, this sequence leads to osteomalacia in adults and rickets in children and can be an unrecognized

factor in acute hip fracture [234]. Tetany results from severe hypocalcemia, and muscle weakness is correlated with hypophosphatemia and depletion of muscle phosphate. Patients with risk factors for the development of osteopenia (cigarette smoking, family history, sedentary lifestyle, long-term glucocorticoid therapy, long-term anticonvulsant therapy, early menopause, testicular failure) should be followed even more carefully if they are at risk for vitamin D deficiency. Long-term alcohol abuse is also an overlooked cause of osteoporosis in men [235]. Risk factors for metabolic bone disease in patients with liver disease include female gender, Caucasian race, estrogen deficiency, low–normal BMI, corticosteroid use, and tobacco abuse [236].

Assessment

The 25-hydroxyvitamin D serum level is low when body stores, intake, or endogenous production of the vitamin are low [237]. Thus, this parameter is satisfactory for assessing vitamin D status with respect to deficiency and toxicity. However, the assay is variable: the competitive protein binding assay gives results some 20%–30% higher than the radioimmunoassay (RIA) [166]. Levels of 32 μg/L (80 nmol/L) have been advocated as the upper range of normal, based on the ability to restore plasma parathyroid hormone (PTH) concentrations to normal [238,239]. The production of 25-hydroxyvitamin D is not closely regulated and rises or falls as its substrate is made available. The concentration in serum is 5–10 times that in other tissues except for adipose tissue. It is bound in serum to a binding protein that is normally only 5% saturated, and the half-life is long (24 h). Thus, recent exposure to sunlight or increased oral intake are reflected in the serum level. Levels are low in dietary deficiency, decreased absorption, lack of sunlight, prematurity, and severe liver disease; low levels are also associated with drugs that alter the metabolism (e.g., anticonvulsants). High levels are seen in growing children, conditions in which parathyroid hormone levels are elevated, sarcoidosis, and some forms of idiopathic hypercalciuria.

Patients at risk for deficiency should be followed with periodic measurements of the serum 25-hydroxyvitamin D level, as well as bone density and 24-h urinary calcium measurements, to assess the status of calcium stores and intake (see "Calcium" above). 1,25-Dihydroxyvitamin D can also be measured in the serum. The production of this isoform is closely regulated, but by extracellular ionized calcium not by vitamin D stores, unless the latter are extremely low. The level of this vitamin correlates with vitamin D function more than with stores. Serum 1,25-dihydroxyvitamin D levels are low in profound vitamin D deficiency, chronic renal disease, hypoparathyroidism, vitamin D-resistant rickets type I, and osteolytic conditions not caused by increased PTH levels (cancer, hyperthyroidism). Primary hyperparathyroidism, vitamin D-resistant rickets type II, and pregnancy are conditions in which levels are elevated. Hypervitaminosis D elevates 25-hydroxyvitamin D levels markedly, but 1,25-dihydroxyvitamin D levels are little affected. Table 101.16 provides suggested guidelines for evaluating the vitamin D status.

Treatment

Oral vitamin D does not maintain the vitamin D status as well as endogenous vitamin D; the latter is released more constantly from the skin and is not converted so rapidly to other isomers by the liver, to which virtually all orally administered vitamin D is exposed following absorption. Nonetheless, oral supplements are needed sometimes, especially in patients with fat malabsorption, uremia, long-term corticosteroid use, and possibly postmenopausal osteoporosis, although the proper place of vitamin D supplementation in the management of osteoporosis is still uncertain. Adults with vitamin D deficiency should receive 0.1–0.2 mg (4000–8000 IU) of cholecalciferol daily by mouth. Much larger doses should be used if malabsorption is present, although the exact dose needed may vary widely. Theoretically, the more polar forms, 25-hydroxyvitamin D (calciferol) and 1,25-dihydroxyvitamin D (calcitriol), should be useful in patients with malabsorption [240,241], but the absorptive advantage is probably not sufficient to justify the great increase in cost. Analogues of vitamin D are available for use in chronic renal failure, being designed to decrease the hypercalcemic effect while restoring bone mass [242]. Paricalcitol

Table 101.16 Suggested guidelines for evaluating vitamin D status

Test	Deficient	Low	Acceptable	High
25-Hydroxyvitamin D				
(nmol/L)	≤ 30	< 60	≥ 80	> 200
(ng/mL)	≤ 12	< 24	≥ 32	> 80
1,25-Dihydroxyvitamin D				
(pmol/L)			48–100	
(pg/mL)		20–42		
24-h urinary calcium (mg/kg)	< 2		> 2	
Bone density (SD below mean)	> 2.5	> 2	1–1.5	

(19-nor-1α-25-dihydroxyvitamin D-2) also improves survival from cardiovascular and infectious causes of death. The efficacy of treatment should be assessed by periodic measurement of the 25-hydroxyvitamin D level, with the dose adjusted to keep the serum level within the normal range. In patients with malabsorption, one should determine that the function of vitamin D has also been restored – that is, that calcium absorption has been normalized – by bringing the 24-hour urinary calcium into the normal range. The risk for toxicity in patients with malabsorption is extremely slight. In other patients, hypercalcemia and hypercalciuria may develop. The estimated minimal toxic daily oral dose for healthy adults is 0.125 mg (5000 IU) [1,232]. Nausea, anorexia, itching, polyuria, abdominal pain, constipation, bone pain, metallic taste, and dehydration may be present early, followed by other manifestations of hypercalcemia. Vitamin D toxicity is reversible if renal damage is not severe.

Vitamin E

Deficiency

Deficiency of vitamin E is uncommon in humans. Persons at risk include newborns and premature infants, patients with fat malabsorption or biliary obstruction, and food faddists. Vitamin E does not cross the placenta well and is poorly absorbed in newborns. Severe fat malabsorption in cystic fibrosis, abetalipoproteinemia, short bowel syndrome, biliary obstruction, and excessive mineral oil ingestion can lead to deficiency [243]. Unsteady gait, tremor, weakness, ophthalmoplegia, pigmentary retinopathy, and proprioceptive impairment have been noted in adult malabsorptive syndromes, along with red cell hemolysis. A similar progressive neurological syndrome has been reported in children with cholestatic liver disease [244].

Assessment

Deficiency can be documented by a low serum α-tocopherol concentration (< 11.6 μmol/L or < 5.0 μg/mL) [89]. Because the vitamin is carried in serum by lipoproteins, the plasma concentration of vitamin E is low in any hypolipidemic state. Therefore, the ratio of α-tocopherol to total lipid (triglyceride + cholesterol) is a more accurate indicator of vitamin E status than is the vitamin level alone [245]. Ratios of more than 0.8 mg of α-tocopherol per gram of total lipid or more than 0.22 mg of α-tocopherol per gram of cholesterol are normal. Ethane and pentane are generated through the peroxidation of *n*-3 and *n*-6 fatty acids, respectively. Breath ethane has been used to evaluate the vitamin E status and follow therapy in children because the level rises with deficiency [246].

Treatment

Large oral doses of D-α-tocopherol acetate, up to 600 mg (800–900 IU) per day, are needed, especially in patients with malabsorption. A water-soluble form of the vitamin (D-α-tocopherol-PEG-1000 succinate) is available over the counter as Liqui-E [247]. This compound forms micelles when given in doses above 25 mg/kg/day and may assist in the absorption of other fat-soluble vitamins. The results of the use of vitamin E to treat chronic diseases have been mixed, but overall are negative for heart disease, either alone or in combination with other antioxidants [248]. The American Heart Association consensus statement does not recommend the routine use of vitamin E [249]. Data for protection by vitamin E in prostate and other cancers is still inconclusive [250]. No consistent ill effects are seen with up to 3200 IU (2112 mg) per day in healthy persons. At doses from 100 to 1100 mg/day, oxidation of vitamin K to its active form can be inhibited, and high-dose vitamin E may be problematic in patients with bleeding disorders. However, the use of 800–1200 IU/day had no effect on the prothrombin time of patients on warfarin therapy [190].

Vitamin K

Deficiency

Nutritional deficiency of vitamin K is uncommon in adults because of the large amount in foods and because bacteria synthesize the vitamin in the intestinal lumen. Deficiency is most commonly the result of fat malabsorption, often compounded by poor intake and diminished liver function or decreased bile excretion [251]. Inhibition of bacterial biosynthesis by broad-spectrum antibiotics can be important. Deficiency is manifested by easy bruising and clotting abnormalities.

Assessment

The most commonly used clinically applicable test for vitamin K deficiency is the one-stage prothrombin time. The clotting factors tested (II, V, VII, and IX) are all responsive to vitamin K except for factor V. Factor VII has the shortest half-life and is the usual rate-limiting factor. The prothrombin time does not test vitamin K stores and is abnormal when deficiency is present, when the synthesis of clotting factors is impaired by liver disease, or when factors are consumed in intravascular coagulation. Thus, the test is nonspecific. Response of the prothrombin time to 5–10 mg of parenteral vitamin K for 2 to 3 days confirms the presence of a deficiency state. Plasma phylloquinone reflects recent intake, but is not a good measure of body stores. Determination of the urinary α-carboxyglutamic acid (Gla) level may be even more sensitive because it tests a function of vitamin K, and the level can be low when blood coagulation is normal [252]. Plasma levels of Gla proteins may be useful in detecting deficiency of vitamin K but have not been widely used. These proteins include undercarboxylated prothrombin (PIVKA-II) and carboxylated/undercarboxylated osteocalcin [8].

Treatment

Long-term therapy with doses titrated to the prothrombin time (~ 2 mg daily or every other day) should be restricted to patients with malabsorption. Patients on anticoagulant

therapy should eat a well-balanced diet with consistent intake of vitamin K, avoiding fluctuations of high-content foods (egg yolk, vegetable oils, green leafy vegetables). For anticoagulant overdose, 1–2.5 mg oral phytomenadione (vitamin K-1) will decrease the international normalized ratio (INR) from 5–9 to 1–5 in 24–48 h [253]. For an INR greater than 10, a 5-mg initial dose of vitamin K-1 is recommended. The vitamin is available for subcutaneous or intramuscular injection at 2 or 10 mg/mL. Vitamin K is not a component of any multivitamin preparation and must be prescribed individually.

History and physical examination, 2564
Gastrointestinal complications of obesity, 2564
Systemic complications of obesity, 2565
Treatment of obesity, 2565
Complications of weight loss, 2571
Conclusions, 2571

Obesity is defined as an excessive amount of body fat arising from an excess energy intake that exceeds energy expenditure. Accurate measurement of body fat requires expensive and sophisticated techniques not readily available to physicians. The body mass index (BMI) correlates closely with the mass of adipose tissue [1] and therefore constitutes an acceptable estimate of body fat. The BMI represents an index of the relationship between height and weight (calculated as weight in kg divided by height in m^2 or as weight in pounds multiplied by 704 divided by height in inches squared). It is used as a clinical tool to identify overweight (BMI between 25 and 29.9 kg/m^2) and obese (BMI > 30 kg/m^2) patients. This BMI classification is primarily based on several epidemiological studies that assessed the relationship between BMI and mortality and found that men and women with a BMI greater than 30 kg/m^2 are at increased risk of health hazards and mortality [2] (Table 102.1).

According to the most recent National Health and Nutrition Examination Survey (NHANES 2003–2004), the prevalence of obesity among adults in the United States was 32.9% and the prevalence of obesity and overweight was 66.2% (Table 102.2). The number of obese adults has doubled from 1980 to 2000 and the number of morbidly obese (BMI > 40) has quadrupled. More than 300 000 deaths per year are attributed to obesity [3] and poor diet and physical inactivity may soon overtake tobacco as a leading cause of death in the United States [4]. Furthermore, because of the substantial rise in the prevalence of obesity and its life-threatening complications, we may experience a potential decline in life expectancy in the United States in the 21st century [5].

Obesity has particular relevance to gastroenterologists because of the associated causality with different gastrointestinal diseases. Gastroenterologists should be knowledgeable in the treatment of obesity (dietary interventions and pharmacological treatment) and in the treatment of patients presenting with complications after bariatric surgery. This chapter reviews the complex mechanisms that regulate food intake and body weight, comorbidities in particular those involving gastrointestinal and hepatic complications associated with obesity and the clinical approach to the patient with obesity.

Regulation of energy storage, intake, and expenditure

Concept of energy homeostasis

Fat is the primary form of energy storage. According to the first law of thermodynamics, the amount of stored energy is equal to the difference between energy intake and energy expenditure. This law applies to any biological system, including the human body. Weight gain results from an imbalance in homeostatic mechanisms that, in normal conditions, maintain the difference between intake and expenditure close to zero. A very small imbalance over a long period of time can have a large cumulative effect. To keep a perfect balance between energy intake and expenditure, homeostatic mechanisms rely on neural signals that emanate from adipose tissue, endocrine, neurological, and gastrointestinal systems and are integrated by the central nervous system (CNS) [6,7] (Fig. 102.1). The CNS subsequently sends signals to multiple organs in the periphery to control energy intake and expenditure and maintain energy homeostasis over long periods of time.

Gastrointestinal hormones and food intake

The gastrointestinal neuroendocrine system plays a substantial role in regulating food intake and maintaining energy homeostasis. Specialized enteroendocrine cells contain chemoreceptors that are sensitive to nutrients present in the chyme as it progresses through the gastrointestinal tract [8]. In response to different classes of nutrients, the enteroendocrine

Table 102.1 Classification of weight by BMI, waist circumference, and associated disease risk

BMI (kg/m^2)	Classification	Disease risk[a] Men ≤ 102 cm (≤ 40″) Women ≤ 88 cm (≤ 35″)	Disease risk[a] Men > 102 cm (> 40″) Women > 88 cm (> 35″)
< 18.5	Underweight	–	–
18.5–24.9	Normal	–	–
25.0–29.9	Overweight	Increased	High
30.0–34.9	Obese class I	High	Very high
35.0–39.9	Obese class II	Very high	Very high
≥ 40	Obese class III	Extremely high	Extremely high

cells secrete peptides that act either as hormones by entering the bloodstream or in a paracrine fashion by diffusing through the extracellular fluid to adjacent cells. Most of these peptides stimulate satiety with the exception of ghrelin, which has an orexigenic effect.

Cholecystokinin

Cholecystokinin (CCK) is the prototypical satiety hormone, produced by I cells in the duodenum and jejunum. It is secreted in response to the presence of nutrients within the gut lumen, specifically fat and protein [9]. The satiating effect of CCK is mediated by the vagus nerve. The activated vagus in turn stimulates cells in the brainstem (nucleus tractus solitarius) leading to signals to other areas of the brain (paraventricular nucleus and ventromedial hypothalamus) that cause the individual to stop eating [10]. CCK also has endocrine effects on the gastrointestinal system and the CNS, which may be important in stimulating satiety. These include contraction of the pylorus, inhibition of gastric emptying and possibly direct binding to CCK receptors in the area postrema at the base of the fourth ventricle [11].

Peptide tyrosine tyrosine, pancreatic polypeptide and neuropeptide Y

Peptide tyrosine tyrosine (PYY), pancreatic polypeptide (PP), and neuropeptide Y (NPY) are all members of the pancreatic polypeptide family. NPY, a potent short-term stimulus of appetite, is released from NPY neurons in the arcuate nucleus (Fig. 102.1). PYY is secreted by L cells in the distal ileum and colon and is present in two forms, PYY(1–36) and PYY(3–36). PYY release from the gastrointestinal tract is proportional to the caloric density of the ingested nutrients, primarily lipids and carbohydrates [12]. When administered peripherally, PYY(3–36) has been shown to reduce food intake in rodents, primates, and in normal weight and obese humans [13,14]. PP is secreted from specific pancreatic islet cells in response to a meal. Several reports have shown a reduction in food intake after peripheral administration of PP [15,16] (Fig. 102.1).

Glucagon-like peptide-1 and oxyntomodulin

Glucagon-like peptide-1 (GLP-1) is derived from the post-translational modification of proglucagon in the enteroendocrine L cells in the ileum and colon. The secretion of GLP-1

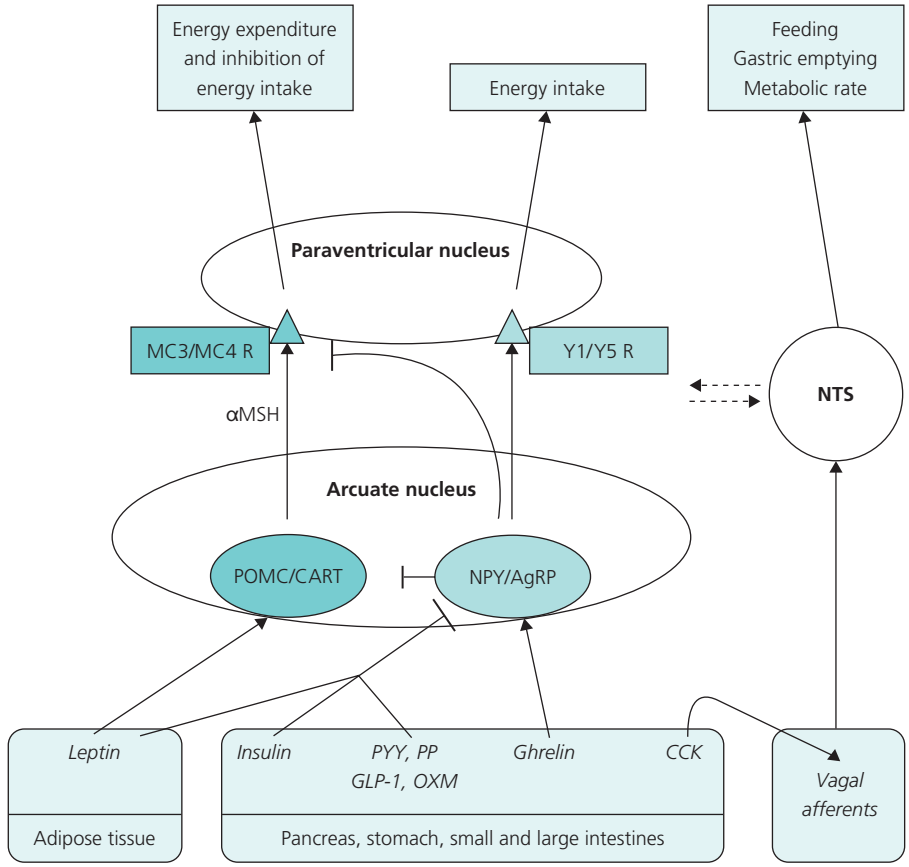

Figure 102.1 Pathways of regulation of food intake. Representation of potential action of gut peptides on the hypothalamus. Primary neurons in the arcuate nucleus contain multiple peptide neuromodulators. Appetite-inhibiting neurons (dark purple) contain proopiomelanocortin (POMC) peptides such as α-melanocyte-stimulating hormone (αMSH), which acts on melanocortin receptors (MC3 and MC4) and cocaine- and amphetamine-stimulated transcript peptide (CART), whose receptor is unknown. Appetite-stimulating neurons in the arcuate nucleus (light purple) contain neuropeptide Y (NPY), which acts on Y receptors (Y1 and Y5), and agouti-related peptide (AgRP), which is an antagonist of MC3/4 receptor activity. Integration of peripheral signals within the brain involves interplay between the hypothalamus and hindbrain structures, including the nucleus tractus solitarius (NTS), which receives vagal afferent inputs. Inputs from the cortex, amygdala, and brainstem nuclei are integrated as well, with resultant effects on meal size and frequency, gut handling of ingested food, and energy expenditure. →, direct stimulatory; ⊣, direct inhibitory; PYY, peptide tyrosine tyrosine; PP, pancreatic polypeptide; GLP-1, glucagon-like peptide-1; OXM, oxyntomodulin; CCK, cholecystokinin. Adapted from Badman & Flier [7], with permission from the American Association for the Advancement of Science.

results from direct nutrient stimulation in the distal small intestine as well as indirect neurohumoral stimulation in proximal regions of the small intestine [17]. A major action of GLP-1 is to help stimulate insulin secretion during a meal. GLP-1 also has an anorectic effect in healthy [18], diabetic [19], and obese [20] human subjects. The peripheral administration of GLP-1 is thought to elicit satiety by its inhibitory effects on gastrointestinal transit and reduced gastric emptying [21].

Oxyntomodulin is another peptide derived from proglucagon's posttranslational processing in L cells. It is also an anorectic peptide and reduces caloric intake in humans. Part of its anorectic effect may result from suppression of plasma ghrelin levels [22].

Amylin

Amylin is a peptide secreted by pancreatic B cells in parallel with insulin secretion during meals. The peptide inhibits gastric emptying and gastric acid secretion. Several reports showed a decrease in meal size after systemic administration of amylin [23,24]. Pramlintide, an amylin analogue, has been shown to induce weight loss in diabetic patients [25].

Leptin

Leptin is an adipocyte-derived factor that plays a dominant role in the central regulation of food intake and energy balance by signaling adipose energy reserve to the brain [26]. Leptin is secreted by subcutaneous adipose tissue in response to fat storage or overfeeding. Leptin is also produced in extra-adipose sites such as placenta, skeletal muscle, and stomach. Up to 25% of circulating leptin derives from fundic glands in the stomach [27]. Leptin has the ability to reduce food intake and body weight [28] by suppressing the expression of NPY, a potent appetite stimulatory peptide, and increasing the expression of α-melanocyte-stimulating hormone, which acts to decrease appetite (Fig. 102.1). In contrast, leptin deficiency reduces energy expenditure [7]. The effects of gastric leptin are probably similar to the adipocyte-derived leptin [28]. Although total leptin deficiency is responsible for the obesity seen in the *Ob/Ob* mouse [7], the majority of obese humans actually have elevated leptin levels [29], suggesting an end-organ decreased response to the peptide.

Ghrelin

Unlike the satiety hormones discussed so far, ghrelin is an orexigenic or "appetite" hormone that stimulates hunger [30].

It is primarily synthesized and secreted from the fundic area in the stomach but can also be produced by cells in the duodenum, ileum, cecum, and colon. Plasma levels of ghrelin rise during fasting, peak (to double the baseline concentration) immediately before meals and fall rapidly after a meal, suggesting a role as a meal initiator [31]. The role of ghrelin in obesity in not clear because, unlike what one would expect, ghrelin levels tend to be low in obese humans, only increasing after dietary weight loss [32].

History and physical examination

History taking should be the first step in the evaluation of the obese patient. A review of the patient's lifestyle including eating habits and physical activity may provide helpful information as to why the patient is obese. Eating disorders are a relative contraindication for the treatment of obesity and require the intervention of a specialist in the area. Binge eating is reported more frequently in women with higher BMI [33]. Information about the age at onset of obesity, recent weight changes, previous attempts of weight loss with details of the modalities followed, and family history of obesity is important. A search for drugs that can promote weight gain such as steroid hormones (glucocorticoids, progesterone), neurotropic and psychotropic medications (lithium, antidepressants, phenothiazines), and antidiabetic medications (sulfonylureas, insulin, thiazolidinedione) should be carried out and if possible alternatives should be offered. A review of systems should look for symptoms of secondary causes of obesity such as hypothyroidism, Cushing syndrome and polycystic ovarian syndrome. Attention should be directed to medical conditions associated with obesity like diabetes, hyperlipidemia, hypertension, coronary artery disease, and osteoarthritis. The physician should be aware of symptoms and signs of sleep apnea (loud snoring, daytime fatigue, and morning headaches) and the patient should be referred accordingly. From the gastroenterologist's perspective, a search for symptoms related to gastrointestinal complications of obesity should be undertaken. Those can range from conditions such as gallstones and gastroesophageal reflux disease (GERD) to more serious cases involving cirrhosis or malignancies.

Physical examination should start with the measurement of the height and weight, and calculation of BMI to categorize the risk and severity of obesity. Clinical judgment is necessary in assessing a muscular patient because the BMI may overestimate the degree of fatness. The excess body fat in obese persons may be distributed in an android or gynecoid pattern. Measurement of the patient's waist circumference is important to assess the abdominal distribution of adipose tissue, which by itself is associated with an increased risk of medical complications [34]. Women and men with a waist circumference greater than 88 cm (35 inches) and 102 cm (40 inches), respectively are considered at increased risk for diabetes and other complications of obesity independent of their BMI. Blood pressure should be checked with an appropriately sized cuff. Other key features in the clinical assessment include looking for signs of secondary causes of obesity and conditions that are caused by obesity. Particular attention should be given to the examination of the thyroid gland and the search for signs of hypothyroidism and Cushing syndrome. Hyperinsulinemia, which is typically associated with obesity, can be manifested by acanthosis nigricans around the neck and axilla. Laboratory evaluation should screen for complications of obesity and associated conditions such as nonalcoholic steatohepatitis, type 2 diabetes, and hyperlipidemia that are not necessarily detected on physical examination. Thyroid-stimulating hormone level should be measured to rule out hypothyroidism.

Gastrointestinal complications of obesity

Esophageal disease

The prevalence of GERD and GERD-related complications, particularly erosive esophagitis, Barrett esophagus, and esophageal adenocarcinoma, has been increasing over the past 20 years [35]. Several reports link this increase to the obesity epidemic. The association between reflux symptoms and obesity has been examined in several cross-sectional studies. Most of these studies showed a significant positive association [36–38] with an increased risk ranging from 1.5- to 3-fold in obese subjects, whereas other studies showed no significant link [39,40]. The association between obesity and erosive esophagitis was examined in multiple case–control, cross-sectional, and cohort studies [41–44]: most reports showed a positive association with adjusted odds ratios ranging from 1 to 2.1 in overweight and 1.6 to 14.6 in obese patients.

The incidence of esophageal adenocarcinoma has increased in parallel with that of obesity in the past 15 years, which prompted the performance of several studies looking at an association between them [44–46]. Estimates from pooled studies showed a 2.1-fold increase in the overall risk of esophageal adenocarcinoma in patients with a BMI greater than 25 compared to subjects with a normal BMI [44].

Gallbladder disease

Obesity is an important risk factor for gallbladder disease. Data from the Nurses Health Study demonstrated that the risk for symptomatic gallstones increases linearly with BMI. A twofold and a sevenfold increase in risk for symptomatic gallstones was noted in women with BMI greater than 30 and BMI greater than 45, respectively [47]. Several other epidemiological studies have found the same positive association between BMI and the risk of gallstones [48,49]. The mechanism of gallstone formation in obese individuals involves an increase in cholesterol saturation index and a decreased

response to cholecystokinin [50]. The risk of gallbladder cancer increases with gallstones, hence obesity increases this risk [51].

Pancreatic disease

The increased risk of pancreatitis in obesity is thought to be explained by the increased risk of cholelithiasis. Acute pancreatitis is more severe in overweight and obese subjects [52]. There is an increase in the incidence of infectious complications as well as in the length of hospitalization in obese individuals.

Obesity has also been associated with pancreatic cancer but it has been difficult to determine whether this association is direct or secondary to the association of obesity to diabetes, the latter being an established risk factor for pan-creatic cancer. A metaanalysis estimated that obese subjects have a 20% increase in the risk of developing pancreatic cancer when compared to people with a normal body weight [53].

Liver disease

Liver damage can be increased when liver disease occurs in the setting of obesity. This has been shown in chronic hepatitis C, alcoholic liver disease, and toxin-induced liver disease [54,55]. The most common liver abnormality associated with obesity is nonalcoholic fatty liver disease (NAFLD). Several studies have demonstrated a strong link between obesity and NAFLD. There is an increase in prevalence of NAFLD with BMI increase in both genders and in all races. Furthermore, liver biopsies from morbidly obese individuals performed at the time of bariatric surgeries demonstrated NAFLD in over 80% of cases [56]. NAFLD is a spectrum of conditions that range from steatosis at one end to cirrhosis at the most serious end of the spectrum. Nonalcoholic steatohepatitis (NASH) is an intermediate stage in this spectrum, characterized by hepatocyte injury and death accompanied by infiltration of acute and chronic inflammatory cells. NAFLD is the hepatic consequence of insulin resistance and the associated metabolic syndrome that leads to a relative overproduction of proinflammatory mediators [57]. It has also been suggested that hyperleptinemia plays a role in the occurrence of fibrosis by activating hepatic stellate cells (the source of hepatic collagen) [58]. NAFLD is usually diagnosed when patients are referred for further evaluation of abnormal liver enzymes or when fatty infiltration is detected on an abdominal imaging study performed for other reasons. Serum aspartate aminotransferase, alanine aminotransferase, and γ-glutamyl transferase are usually increased less than fourfold and do not correlate with the severity of the condition. The main target in the treatment of NAFLD is the improvement of insulin sensitivity, which can be achieved by dietary modifications and by pharmacological treatment. A gradual weight loss of 10% or more of body weight can correct abnormal liver chemistries and decrease liver size, fat content, and features of steatohepatitis but the impact on the long-term outcome and the progression of the disease remains unknown. Several small clinical trials looking at the efficacy of pharmacological agents such as insulin-sensitizing agents (metformin, troglitazone), lipid-lowering agents (gemfibrozil, atorvastatin), antioxidants (vitamin E), tumor necrosis factor-α-inhibiting agents, and ursodeoxycholic acid showed conflicting results and their impact on the natural progression of the disease remains unknown [59].

Colon disease

Several cohort and case–control studies have looked at the association between obesity and colorectal cancer and a positive association was noted especially in men, with an increased risk of about 1.5- to 3-fold [44,60]. The association was found to be weaker in women, especially older and postmenopausal women [61]. The risk of colon polyps is also increased about twofold in obese individuals [44,62] and appears to be higher in men than in women.

Irritable bowel syndrome

Gastrointestinal motility is regulated by some of the gut peptides involved in feeding behaviors. Hence, the association between irritable bowel syndrome (IBS) and obesity is worth studying. Few studies have examined this association: one demonstrated a significant increase in some IBS symptoms (constipation, diarrhea, straining, and flatus) in obese patients and another showed a threefold increase in the risk of IBS with obesity [63]. Further studies are needed to confirm this association.

Systemic complications of obesity

Since the 1990s, the obesity epidemic has generated a rapid increase in the metabolic syndrome. The metabolic syndrome is defined as the constellation of insulin resistance (manifested by type 2 diabetes or glucose intolerance), visceral adiposity (resulting in abdominal obesity and increased waist circumference), hypertension, and dyslipidemia [64]. One of the direct consequences of metabolic syndrome and obesity is an increase in the prevalence of diabetes, hypertension, and dyslipidemia leading to a two- to threefold increase in cardiovascular disease [64,65] (Fig. 102.2).

Treatment of obesity

Treatment guidelines

Determination of BMI and waist circumference and the search for comorbid conditions (such as cardiovascular risk factors) help in assessing the degree of overweight and the overall risk status. The next step is to assess how motivated the patient is to lose weight and their degree of understanding of obesity as a disease, its causes, its consequences, and

If not motivated, urge weight maintenance and manage comorbidities
Develop a treatment plan based on Table 102.4

the treatment options, and to discuss any previous unsuccessful treatments and the reasons for failure of those treatments [66] (Table 102.3).

The initial goal of the treatment is a 10% reduction of body weight from baseline. A reasonable time line to achieve this reduction is 6 months of therapy. Further weight loss can be attempted later if indicated [66]. Depending on the degree of overweight and the overall risk status of the patient, different modalities are available to the clinician to achieve the weight loss target. These include lifestyle modifications (dietary interventions and physical activity), pharmacotherapy, and surgical interventions (Table 102.4). Efforts to maintain the

achieved weight loss should be put in place through a weight maintenance program involving dietary and behavioral therapy along with physical activity.

Lifestyle modifications

Dietary interventions

To induce weight loss, a calorie deficit must be achieved. Balanced diets should contain a minimum of 1000–1200 kcal per day and provide adequate amounts of all essential nutrients. An average loss of 500 kcal per day should produce a weight loss of about 450 g (1 lb) weekly. There is evidence that weight loss of 5%–15% of initial weight is enough to reduce the risks of dyslipidemia, diabetes, and hypertension associated with obesity [67].

The role of dietary fat in the development of obesity has been studied extensively. Almost all dietary guidelines recommend a reduction in the daily intake of fat to 30% of energy intake or less regardless of weight status. On the other hand, despite a decrease in consumption of fat in the past 30 years, the rate of obesity has risen to an all-time high [68]. This shows that reducing the percentage of fat alone will not produce weight loss unless combined with a reduction of total calories. Furthermore, a metaanalysis of six clinical trials (comparing low-fat to other types of weight-reducing diets) showed that low-fat diets were no better or worse than other weight-reducing diets for achieving sustained weight loss [69]. Despite the controversial role of low-fat diet in the treatment of obesity, the National Institutes of Health (NIH) recommend a low-calorie diet consistent with a step I or II diet (depending on the patient's risk status) in which fat constitutes 30% or less [66].

The popularity of low-carbohydrate diets (Atkins, Sugar Busters, Zone, South Beach) has been increasing since the late 1990s. These diets result in a rapid initial weight loss explained by sodium diuresis secondary to ketosis caused by glycogen mobilization in the presence of carbohydrate restriction.

Very-low-calorie diets are diets that provide 500–800 kcal per day. Despite an impressive short-term success, these diets provide no greater weight loss at 1 year than do low-calorie diets (1000–1500 kcal per day) [70].

Portion-controlled, vitamin/mineral-fortified meal replacements have been increasingly used as part of low-calorie diets. These diets using meal replacements are marketed now by several manufacturers and used as components in several large-scale clinical trials. A metaanalysis of trials utilizing these diets showed significant weight loss (7%–8% of body weight) at 3 months and 1 year [71].

Several epidemiological studies looked at the magnitude of weight loss with the different types of diets discussed above. A recent randomized trial comparing four different diets [very-low-carbohydrate (Atkins); macronutrient balance controlling glycemic load (Zone); calorie restriction (Weight Watchers); very-low-fat (Ornish)] with a design intended to simulate their use in a real-world setting [72]. A trend toward higher dropout rates was noted after 1 year with the very low-carbohydrate and very low-fat diets than with the more moderate diets. Average weight loss at 1 year was approximately 4–7 kg (in those who completed the study), and was similar among the four diets. In the intention-to-treat analysis, mean weight loss was similar for all four diets and was more modest (2.1–3.3 kg). Dietary adherence rates were low for all diets and were more important predictors of weight loss. This study illustrates the difficulty of achieving significant weight loss with dietary therapy in a real-world setting.

Physical activity

Physical activity is a key component of any long-term weight loss therapy and weight maintenance program. Physical activity modestly contributes to weight loss in overweight and obese adults. It may also decrease abdominal fat and it increases cardiorespiratory fitness [66]. The combination of a low-calorie diet and increased physical activity produces greater weight loss than diet alone or physical activity alone. Adults should accumulate at least 30 minutes of moderate intensity physical activity on most days of the week.

Behavior therapy

The role of behavior therapy is to alter the eating and activity habits of an obese patient and overcome barriers to compliance with dietary therapy and increased activity [66]. It can be achieved either on an individual basis or in group settings (the latter being less expensive). Behavior therapy can produce a weight loss in the range of 10% of baseline weight over 4 months to 1 year [66,73] but most patients return to baseline weights in the absence of continued intervention. Specific behavioral strategies include self-monitoring, stress management, stimulus control, positive reinforcement, and social support. Self-monitoring consists of recording dietary habits (types, amounts, caloric values, nutrient composition) and physical activity habits (frequency, intensity). Stress management through coping strategies, meditation, and relaxation techniques can defuse situations leading to overeating. Stimulus control includes avoiding stimuli that may encourage eating and situations associated with little amount of exercise. Positive reinforcement through the use of rewards for specific actions encourages behavior change. Social support (family members, friends) can assist in maintaining motivation and providing positive reinforcement [66].

Pharmacotherapy

Antiobesity drugs are indicated as adjuncts to diet and physical activity for patients with BMI of 30 or above in the absence of obesity-related risk factors or diseases, and for patients with BMI of at least 27 in the presence of such conditions [66]. Usually drugs are used after nonpharmacological treatment has been attempted for 6 months with unsatisfactory results of weight loss (less than 450 g per month).

Table 102.5 Medications for the treatment of obesity

Medication	Typical dosing	Classification	Common adverse effects
Medications approved by the FDA specifically for weight loss indication			
Phentermine	15–37.5 mg/day	Adrenergic agent	Tachycardia, hypertension
Sibutramine	10–15 mg/day	Serotonergic/adrenergic	Hypertension, tachycardia
Orlistat	120 mg three times/day	Lipase inhibitor	Malabsorption, steatorrhea
Medications approved by the FDA for other indications but shown to have weight loss effect			
Bupropion	150–300 mg/day	Depression	Anticholinergic; agitation
Metformin	500–1000 mg/day	Type 2 diabetes	Hepatic oxidative injury
Topiramate	50–100 mg/day	Seizure disorder	Cognitive impairment
Zonisamide	400–600 mg/day	Seizure disorder	Cognitive impairment

FDA, Food and Drug Administration.

Pharmacotherapy for obesity underwent a gigantic turn in the 1990s when Weintraub et al. showed that the combination phentermine-fenfluramine (Phen-fen) induces a sustained weight loss for more than 3 years [74]. Fenfluramine was subsequently withdrawn from the market because of an association with valvular heart disease and pulmonary hypertension. Sibutramine and orlistat are the two medications currently approved in the United States for long-term use. Several others, including phentermine, are approved for short-term use but are often used off-label for longer periods of time. Studies are underway regarding new promising antiobesity agents. Other drugs approved for indications other than obesity have been shown to induce some weight loss (Table 102.5).

Sibutramine

Sibutramine (Meridia) is a serotonin and norepinephrine reuptake inhibitor and a weak dopamine reuptake inhibitor. Increasing the availability of these neurotransmitters in the CNS results in appetite suppression. Placebo-controlled trials showed 5%–8% weight reduction after 6 months of sibutramine treatment compared with 2%–4% weight loss in subjects receiving placebo [75,76]. Of note, most of these trials include dietary or exercise interventions for subjects in both the treatment and placebo groups, which likely explains the weight loss in the placebo group. In one study, continued treatment for up to 2 years was associated with some weight regain (approximately 50% of the initial weight loss); however, around 25% of subjects who continued to take sibutramine maintained their reduced weight for the entire 2 years of observation [77]. Side effects of sibutramine include hypertension and tachycardia, therefore routine clinical monitoring of vital signs is recommended. Other less dangerous adverse effects include headache, insomnia, dry mouth, and constipation.

Orlistat

Orlistat (Xenical) alters fat metabolism by inhibiting pancreatic lipase. As a result, ingested fat is not completely digested. Taken with a meal, orlistat can inhibit the absorption of up to 30% of ingested fat [78]. Clinical trials demonstrated that orlistat treatment in conjunction with nutritional counseling results in weight loss of 8%–10% at 1 year, compared with 6% with placebo [79,80]. Extension of the treatment with 2 years results in weight regain of approximately one-third of the initial weight loss (compared with regain of two-thirds with placebo) [79,80]. The use of orlistat is associated with gastrointestinal side effects that include flatulence, steatorrhea, increased stool frequency, fecal incontinence and oily rectal discharge [81]. Malabsorption can be associated with a deficiency in the fat-soluble vitamins A, D, E, and K. Patients on orlistat should receive a daily supplement containing these vitamins given at least 2 h before or after each dose of orlistat [81]. Furthermore, vitamin D levels should be measured before and periodically during orlistat therapy [81]. Few cases of orlistat-induced severe hepatotoxiciy and hepatic failure have been reported [82,83].

Phentermine

Phentermine is an adrenergic reuptake inhibitor that works as an appetite suppressant. It is approved for use over 12 weeks or less. Because phentermine is an adrenergic agonist, it can be associated with tachycardia and hypertension. A weight loss of 1.8 kg (4 lb) over 4 weeks is considered an acceptable therapeutic response [81]. Other noradrenergic agents approved by the Food and Drug Administration (FDA) for short-term use in the treatment of obesity include diethylpropion, phendimetrazine, and benzphetamine [84]. Studies using this class of medications demonstrated up to 10-kg weight loss when compared with placebo [84].

Rimonabant

Rimonabant (Acomplia) is a cannabinoid receptor antagonist. Animal studies have shown that the cannabinoid-1 receptor plays a role in appetite and body weight regulation [85]. Rimonabant has been studied as a potential treatment for both obesity and smoking cessation. In a randomized trial comparing rimonabant to placebo, subjects who took 20 mg rimonabant experienced an average weight loss of 6.6 kg whereas subjects who took placebo lost on average 1.8 kg. Furthermore, improvements in waist circumference, high-density lipoprotein, triglycerides, and insulin resistance were noted with rimonabant [86]. Two other recent randomized controlled trials showed similar effects of rimonabant on weight loss and associated metabolic risk factors [87,88]. In one of the trials, weight regain was noted in subjects who were switched to placebo after 1 year while those who continued on 20 mg rimonabant experienced sustained weight loss at 2 years [88]. Side effects of rimonabant include depression, nausea, headache, dizziness, and diarrhea.

Drugs approved for other indications

Bupropion, a psychotropic agent used in the treatment of depression, is associated with a modest weight loss in the range of 4%–5% when compared with placebo [89]. Similarly, the antidiabetic agent metformin has been associated with weight loss in the range of 4% of the initial body weight over 1–2 years [81]. Topiramate and zonisamide, both anticonvulsant drugs, have been shown to induce some weight loss (up to 6% of the initial body weight with zonisamide) [81].

Over-the-counter products

Over-the-counter dietary supplements are widely used by individuals attempting to lose weight. Such supplements include ephedra (no longer available in the United States to treat obesity), green tea, chromium, chitosan, ginseng, and guar gum. The use of these agents should be discouraged because of the lack of evidence of their efficacy and safety [90].

Surgical therapy

Bariatric surgery is indicated for carefully selected patients with clinically severe obesity (BMI ≥ 40 or BMI ≥ 35 with comorbid conditions) when less invasive methods of weight loss have failed [66]. To be considered effective, a bariatric procedure should result in a sustained excess weight loss of more than 50% and resolution of comorbid conditions. Bariatric surgeries can be divided into two varieties, malabsorptive and restrictive, depending on the mechanism by which weight loss is induced.

Malabsorptive procedures include jejunoileal bypass, biliopancreatic diversion, and biliopancreatic diversion with duodenal switch. These procedures induce weight loss by shortening the length of functional small bowel segment. Profound weight loss can be achieved with these malabsorptive procedures but significant metabolic abnormalities occur, including protein calorie malnutrition and various macronutrient deficiencies [91]. As a result of these dangerous consequences, malabsorptive procedures have been replaced by the restrictive procedures: Roux-en-Y gastric bypass (RYGB), vertical banded gastroplasty (VBG), and laparoscopic adjustable gastric banding (LAGB). RYGB is primarily restrictive but has also some malabsorptive characteristics.

RYGB is accomplished by creating a small, 15–20 mL, gastric pouch and a Roux-en-Y gastrojejunostomy (Fig. 102.3a), hence restricting food intake and at the same time inducing some malabsorption by bypassing the distal stomach, the duodenum, and a variable length of jejunum. RYGB is the most common bariatric procedure performed in the United States. More weight loss is achieved with this procedure than with VBG [92,93]. On average, 50%–75% of excess weight loss is achieved after 1–2 years [94]. Complications of the gastric bypass procedure include stomal stenosis, marginal ulcers, staple line disruption, dilatation of the bypassed stomach, internal hernias, dumping syndrome, and malabsorption of nutrients. RYGB can be performed laparoscopically and results in similar sustained weight loss compared to the open approach [91]. Advantages of the laparoscopic approach include a lower incidence of incisional hernia and wound infection, faster recovery and shorter hospital stay [94,95].

VBG is a purely restrictive procedure that involves creating a gastric pouch by stapling the gastric fundus and placing a circumferential band around the pouch. VBG was the most commonly performed procedure before the advent of gastric bypass (Fig. 102.3b). The average excess weight loss at 3–5 years is around 30%–50% [96]. These more modest long-term results compared with RYGB, along with the significant adverse events associated with VBG (GERD, vomiting, solid food intolerance), explain the decline of popularity of this procedure. Postoperative complications requiring intervention include staple line disruption, stomal stenosis, band erosion, band disruption, and pouch dilatation.

LAGB is another purely restrictive procedure that involves placing a tight, adjustable prosthetic band around the proximal stomach (Fig. 102.3c). The prosthetic band is connected to an infusion port that is placed in the subcutaneous tissue and is accessible with a needle. Injection of saline into the port leads to increased restriction. Advantages of LAGB include technical ease of placement, lack of anastomosis, adjustability (deflation of the port), and reversibility (band removal). Because of its simplicity and lower rate of complications, this procedure has largely replaced VBG, especially in Europe and Australia. Despite initial disappointing data in the United States [97], subsequent studies showed excess weight loss similar to the Australian and European experience, in the range of 45%–75% [98–101].

Patients undergoing bariatric surgery should be followed by a multidisciplinary team including medical, behavioral, and nutritional experts. Gastroenterologists should assess the patient preoperatively and manage any chronic gastrointestinal

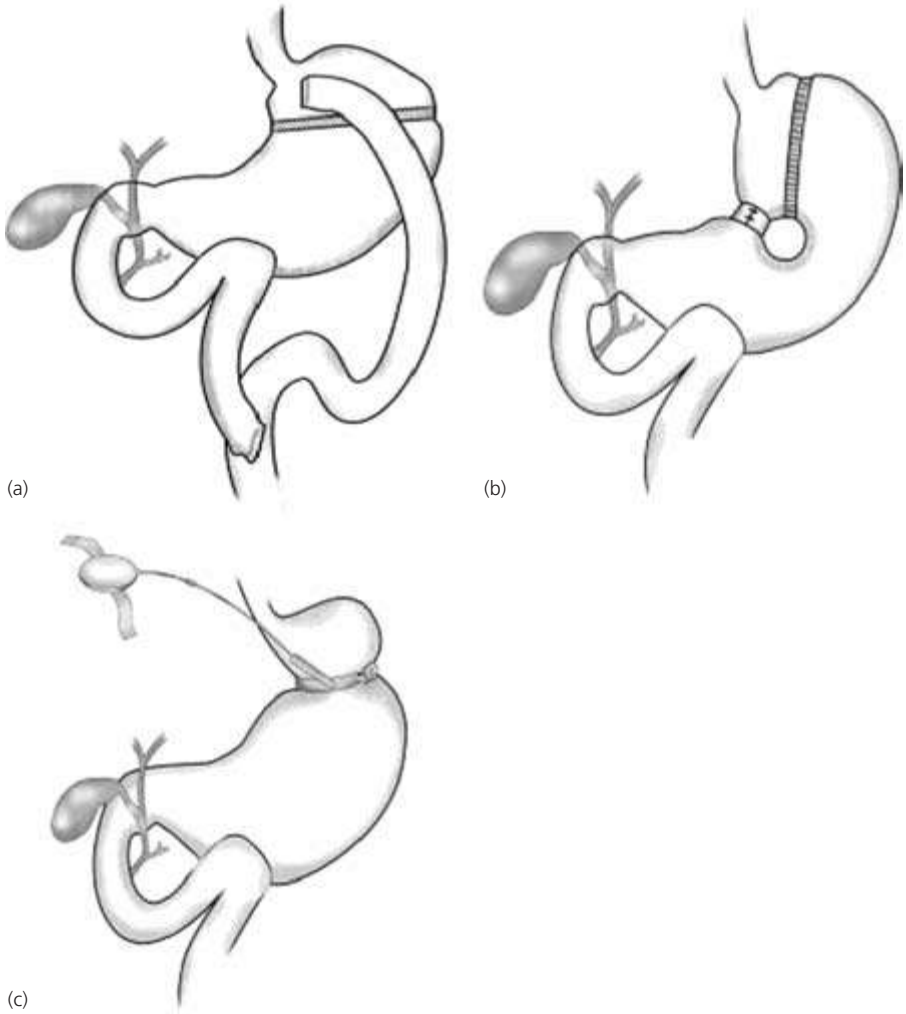

Figure 102.3 Types of bariatric surgeries: **(a)** Roux-en-Y gastric bypass; **(b)** vertical banded gastroplasty; **(c)** laparoscopic adjustable gastric banding. Redrawn from Brolin [118], with permission from the American Medical Association.

disorders that may complicate the postoperative care. For example, attention should be paid to detecting any gastric, pancreatic, or biliary diseases preoperatively because the alteration of the anatomy with some of the performed surgeries makes parts of the gastrointestinal tract (distal stomach, biliary tree) inaccessible to endoscopic and radiological procedures. Patients should be screened for iron deficiency anemia before surgery and gastrointestinal blood loss should be excluded to avoid confusion after surgery. Fatty liver disease is present in most morbidly obese patients requiring surgery and 3%–7% of these patients have cirrhosis [102]. Portal hypertension and the presence of varices (esophageal and/or gastric) are contraindications to gastric operations and should be excluded before surgery [103].

Gastroenterologists also have a role in the management and follow-up of the bariatric surgery patients postoperatively. Complications of surgery usually present as nausea, vomiting, pain, bleeding, diarrhea, and constipation. Immediately after the surgery, these symptoms are probably directly associated with the operation and are often managed by the surgical team. Later on, the gastroenterologist may get involved to deal with complications indirectly related to the surgery, such as anastomotic ulceration, band erosion, stricture, and fistula, which may require endoscopic therapy. Depending on the type of operation, some nutritional complications may occur. Iron, vitamin B-12, and calcium deficiencies can be seen with gastric bypass.

Endoscopic therapy

Minimally invasive endoscopic treatment for obesity is an attractive option, especially in patients who do not respond to lifestyle modifications and pharmacotherapy but are not candidates for bariatric surgery. Various intragastric space-occupying devices have been evaluated for short- and long-term use. In 1985 the FDA approved the Garren–Edwards gastric bubble [104], an air-filled bubble floating in the stomach that is inserted through the esophagus using a gastric tube. Because of a lack of significant weight loss in sham-controlled studies and significant complications such as gastric erosions, gastric ulcers, Mallory–Weiss tear, and esophageal

lacerations, this device was abandoned and is no longer commercially available. Several subsequent modifications to the device failed to show improvement in efficacy. More recently, the Bioenterics intragastric balloon (BioEnterics Corp., Carpinteria, CA, USA) has been widely used internationally but not yet in the United States. It consists of a soft, saline-filled balloon placed endoscopically to partially fill the stomach mimicking an intragastric bezoar. Mean excess weight loss with Bioenterics intragastric balloon is reported to be 38%–48% after 4–6 months [105]; however, only a minority of patients has sustained weight reduction after balloon removal [106]. In a recent sham-controlled study, the difference in mean weight loss between patients with Bioenterics intragastric balloons and controls was not significant (10.4% and 9%, respectively) at 3 months [107]. Complications are less frequent with the Bioenterics intragastric balloon than with earlier balloons. They include intolerance to the balloon, vomiting, abdominal pain, esophagitis, and gastric ulcers and erosions [104].

Future endoscopic approaches will aim to duplicate bariatric surgical procedures. Ongoing animal work is directed at attempting gastric partitioning (the equivalent of VBG). Preclinical work is also being undertaken to refine an endoscopic gastrojejunostomy technique [104].

Complications of weight loss

During rapid weight loss, the risk for cholesterol gallstone formation increases [108]. Patients with higher initial BMI and greater absolute rate of weight loss seem to have the highest risk of gallstone formation. The mechanism of this increase in gallstone formation involves an increase in the cholesterol saturation index and in the crystallization promoting proteins (mucin) and a decrease in gallbladder motility with low-calorie low-fat diet [109–111]. Once an individual has lost weight and maintained weight loss, the risk of gallstone formation decreases. Some surgeons recommend the performance of cholecystectomy at the time of gastric bypass surgery because of the high incidence of gallbladder disease in the seriously obese and to avoid postoperative complications as a result of gallstones [112]. More recently, the use of ursodeoxycholic acid has been shown to reduce the risk of gallstone formation in the first 6 months after bariatric surgery [113]. Another complication of rapid and large weight loss is the occurrence of liver disease. Two weight loss studies, one involving patients undergoing gastroplasty and the other involving patients on a very low-calorie diet, showed a decrease in the prevalence of steatosis but an increase in the prevalence of steatohepatitis with the fall of BMI [114,115]. The risk of liver damage may be related to the rapidity of weight loss, which determines the rate of increased delivery to the liver of free fatty acids from lipolysis of adipose triglycerides [116].

Conclusions

Obesity has become a major health problem in most industrialized nations. It has particular relevance to gastroenterologists because of their involvement in managing the associated gastrointestinal disorders, their role in the evaluation and treatment of obese patients before and after bariatric surgery, and their potential future role in the endoscopic therapy for obesity. By becoming actively involved in the management of obesity, gastroenterologists can provide a valuable clinical service to their patients.

Each year an estimated 5 million US citizens are affected by an eating disorder [1]. The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) classifies eating disorders into those of childhood and those of adolescence and adulthood [2]. The former category includes pica, rumination disorder, and feeding disorder of infancy or early childhood. The latter includes anorexia nervosa (AN), bulimia nervosa (BN), and "eating disorder – not otherwise specified." This chapter will focus on the two prominent eating disorders of adolescence and adulthood, namely AN and BN. Because patients with eating disorders "won't eat," their unwillingness to resume "normal" eating is usually considered evidence of an underlying psychological disorder. The coexistence of obsessiveness, an altered body image, hyperactivity, anxiety, and depression further support this viewpoint. Accordingly, patients with an eating disorder are commonly referred to a psychiatrist for treatment. There is, however, a growing body of evidence that many of the features of eating disorders may be maladaptive physiological responses to caloric restriction. In this chapter, we will review AN and BN, emphasizing this biological perspective.

Epidemiology

About 0.5%–1% of adolescent and young adult females in the United States have a diagnosis of AN, with a lifetime incidence as high as 3.7% [2]. Bulimia nervosa is diagnosed slightly more often, with a reported prevalence of 1.5% [3]. Eating disorders are more common in females, by a ratio of 10–20:1 ratio [4]. Nearly 75% of individuals manifest features of their eating disorder while in adolescence [5], with the average age of onset for AN being 15 years [6]. Increasingly, late-onset cases are being recognized [7].

A dramatic rise in the incidence of eating disorders during the 20th century was reported for the United States, Western Europe, and Japan [8–10]. Some have questioned this conclusion after a critical review of epidemiological data [11,12]. Although long assumed to be more prevalent in industrialized than nonindustrialized societies [1], cases of AN are being increasingly reported in Nigeria, leading some to claim that its prevalence may be as common in African populations as in Western countries [13,14]. Rieger et al. argue against the validity of two often-cited assumptions regarding the weight concerns of anorexics, namely, that these concerns are specifically a contemporary, Western manifestation of the condition or that the increasingly recognized prevalence of AN in non-Western societies is solely attributed to their adopting Western ideals of thinness [15].

Although eating disorders can be found in all ethnic and socioeconomic groups in the United States [16–18], the majority of cases are diagnosed in middle- to upper-middle-class families [5]. They are more common in Caucasians (up to 95% in some series of patients) and Asians [4]. The increasing incidence of eating disorders is said to parallel a significant increase in dieting by adolescent girls and young women. Other risk factors for developing an eating disorder have been proposed and include a family history of an eating disorder, history of past sexual abuse, previous substance abuse, and type 1 diabetes mellitus [19].

Recognizing eating disorders

Anorexia nervosa

Cases of AN have been described in medical writings dating back 300 years [20]. Increasing attention was given to AN

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

in the 1900s, with various etiologies for the condition proposed during that time [21]. Three distinct components were proposed by Hilde Bruch in 1962 as the principal hallmarks of the disease [22]:
- a distorted body image
- alteration in perception of signals of hunger and satiety
- an overwhelming feeling of ineffectiveness.

She also described a preoccupation with food and eating in anorexics [20]. In the absence of an underlying organic disease, she proposed that AN was a mental disorder [22]. This is the model that is used today as the classic approach to understanding AN.

The overarching abnormality that characterizes AN is an unwillingness to maintain an appropriate bodyweight. The diagnosis is driven by clinical criteria, which have been expanded and incorporated within DSM-IV. The four diagnostic criteria for AN under DSM-IV include:
- bodyweight < 85% of expected
- intense fear of weight gain
- inaccurate perception of own body size or weight
- amenorrhea in postmenarcheal females [8] (Table 103.1).

Bulimia nervosa (BN)

This condition was first described as a clinical entity in 1979 [23]. In addition to excessive concern about weight or body shape, which is similar to AN, patients diagnosed with BN also have recurrent episodes of binge-eating followed by inappropriate compensatory activities, such as vomiting. Four diagnostic criteria for BN are listed in DSM-IV:
- recurrent binge eating (at least twice per week for 3 months)
- recurrent purging, excessive exercise, or fasting (at least twice per week for 3 months)
- excessive concern about bodyweight or body shape
- the absence of anorexia nervosa (Table 103.1).

Although a common component, vomiting is not mandatory to the diagnosis. Other compensatory activities that may be employed in BN include abuse of laxatives, diuretics, or enemas, or excessive exercise or fasting. Because fasting behavior can be encountered in BN, just as binge–purge behavior can be seen in AN, the phenotypic expression of these two conditions can exhibit considerable overlap.

Table 103.1 Diagnostic criteria for anorexia nervosa and bulimia nervosa

A. Anorexia nervosa
1. Inability to maintain a minimally appropriate bodyweight, as indicated by bodyweight < 85% of expected for age
2. Intense fear of weight gain
3. Disturbance in the perception of one's own body shape, size, and weight
4. Amenorrhea lasting for three consecutive months in females who are postmenarche

B. Bulimia nervosa
1. Recurrent episodes of binge eating as defined by eating an excessively large amount of food within a discrete period of time, with these episodes often associated with individuals feeling a lack of control over their eating
2. Recurrent, inappropriate, compensatory behaviors to avoid weight gain (e.g., self-induced vomiting, misuse of laxatives, diuretics, enemas, or other medications, or excessive exercise)
3. Binging and purging behaviors occur at least twice a week for 3 months
4. Body shape and weight unduly influence one's self-evaluation

Adapted from American Psychiatric Association [8], with permission.

Could anorexia nervosa and bulimia nervosa share an underlying pathophysiology?

Bulimics and anorexics are different in one conspicuous way: bulimics are normal weight, whereas anorexics are underweight. In addition, cycles of binge eating and subsequent compensation, such as cathartic-induced purging and vomiting, are necessary for the diagnosis of BN. However, could this separation by phenotype be an artificial one? In her original description of AN, Bruch included binging and purging behavior as a part of the condition [22], and Russell presented bulimia as a special form of anorexia [23]. Could there be a common etiology?

Sodersten et al. suggest that AN and BN represent a continuum of the same underlying process [24]. Furthermore, there is a newer diagnostic category of "eating disorder – not otherwise specified" [8], which suggests a difficulty in drawing a clear distinction between AN and BN in some individuals. The significant overlap between AN and BN is further highlighted in DSM-IV by its attempts to subclassify eating disorders. Anorexia nervosa can be divided into a restricting type and a binge-eating/purging type [8]. Similarly, BN can be classified as either a purging type or nonpurging type. This chapter will discuss the different eating disorders as different clinical manifestations of the same disease, falling within a spectrum of phenotypes for the same underlying pathophysiological process. We will use the term anorexia nervosa (AN) broadly to cover the range of eating disorders described in DSM-IV.

Three cardinal features of eating disorders

Distorted body image

Ever since Bruch described a distorted body image as a core feature in AN [22] there has been debate about the specific nature of this disturbance [25]. Generally, two components

have been described as making up this body-image dysfunction, namely a perceptual body size distortion and a cognitive evaluation dissatisfaction [25]. A perceptual distortion is manifested as an abnormality in accurately gauging one's body size. A cognitive evaluation dissatisfaction involves a negative attitude towards one's size, that is, body dissatisfaction. Although a distorted body image has long been associated with eating disorders, there are data that argue against this feature being specific to individuals with eating disorders. One study reported greater body uneasiness and inappropriate attitudes towards eating in participants of recreational sports, such as body-building, dancing, and gymnastics, which emphasize muscularity and thinness [26]. In some individuals, might a distorted attitude of body image take root in the fact that a specific body shape may be a required component of their recreational endeavors or occupations? Other studies have reported increased body dissatisfaction in female dieters who do not have an eating disorder [27–29], particularly when hungry [30] and after consumption of a high-caloric drink, such as a milkshake [31,32]. These data support the view that body dissatisfaction is not unique to patients with an eating disorder.

Alteration in processing of signals of hunger and satiety

Patients with eating disorders have reported low levels of hunger and heightened levels of fullness [33]. Although these findings suggest an alteration in how the brain processes signals of hunger and satiety as a contributing cause of an eating disorder, experiments in obese subjects suggest another possible explanation [34]. Specifically, after a 3-week, near-fasting diet of only 840 kJ/day (200 kcal/day), hunger scores in these obese patients decreased to nearly zero, which argues that prolonged food deprivation leads to physiological loss of the desire to eat [35]. In states of malnutrition, delayed gastric emptying may account for early satiety [36], raising the possibility that loss of hunger and greater satiation may not be unique to patients with an eating disorder.

A period of diminished food intake often precedes binge eating [37]. Observations from prisoners of war after World War II have provided some insight into feelings of satiety during the resumption of eating after prolonged starvation. When refeeding of the prisoners was undertaken, they demonstrated lower levels of satiety and dramatically increased rates of food intake, with this increased drive to eat lasting for several weeks [38]. Thus, resumption of caloric intake after long-term food deprivation may be associated with a diminished satiation and binge-eating in some instances [37].

Feelings of ineffectiveness and other psychological changes

Bruch described a paralyzing feeling of "ineffectiveness" in her anorexic patients, creating a sense of helplessness, passivity, and fear of losing control [39]. Many other psychological disturbances have been associated with AN, including irritability, depression, phobias, inertia, magical thinking, difficulty with concentration, and insomnia [40]. The coexistence of depression or dysthymia has been reported in 50%–75% of patients [41]. In one series, about two-thirds of patients with an eating disorder had one or more lifetime anxiety disorders, with obsessive-compulsive disorder being the most common, affecting ~ 40% of anorexics [42]. An increased risk of substance abuse and personality disorders has also been described [2]. Because anxiety disorders, often with features of obsessive-compulsive features, have long been recognized as a common feature of AN, some assert that these are different phenotypic expressions of related mental illnesses and that there may be an evolution from one phenotype to another. Sodersten et al. questioned the hypothesis that an underlying genotype would manifest as an obsessive-compulsive disorder (OCD) during childhood, with a phenotypic progression to AN during adolescence, and then ultimately to an anxiety disorder later in life, by citing the higher incidence of OCD in boys, which contrasts with a higher incidence of AN in girls [43]. In general, increased rates of psychological distress, including feelings of ineffectiveness, have been described in dieters, demonstrating that these feelings are not unique to patients with an eating disorder [44,45].

Natural history of eating disorders

There are no formal definitions regarding what constitutes recovery from an eating disorder [46], which creates some ambiguity when comparing data on long-term outcomes. The goals of treatment are generally said to be two-fold: weight gain and normalization of eating patterns. It is reported that about half of individuals with AN will recover from their illness, 30% will demonstrate residual symptoms (which may fluctuate over time), and 10% will demonstrate more severe, persistent, and unrelenting symptoms [47]. The remaining 10% will eventually die from complications of AN, giving an overall mortality rate of 0.56% per year [48]. Others have reported an even lower rate of sustained remission, of only 33% [49]. During one long-term follow-up study lasting 21 years, 16% of patients died of disease complications [50].

Regarding bulimic activity, studies suggest that patterns of aberrant eating habits usually wax and wane over the course of many months to years. Similar to AN, 50% of bulimics will eventually recover from their illness. Twenty to thirty percent suffer continued, persistent symptoms. An additional 30% who had achieved remission experience a relapse [51]. Mortality in eating disorders is most commonly associated with complications of severe malnutrition.

Biology of response to caloric restriction

A fluctuating food supply challenges the homeostasis of all animals. As such, semistarvation is a key stressor. What is the expected response to this stress? How does this response compare with the changes seen in AN? Similarities between the biology of malnutrition in underfed, otherwise normal individuals and those with eating disorders have been described [52]. The body's two main physiological imperatives necessary for survival during starvation are provision of a continual supply of energy to the brain, in the form of glucose, and conserving the body's protein stores [53–55]. The physiological changes described in starvation associated with AN are analogous to those changes seen in many other states of malnutrition and starvation.

Energy expenditure

The resting energy expenditure (REE) of the body is decreased as lean body mass is reduced during the starvation of AN. This may, at least partly, be influenced by diminished secretion of thyroid hormones (T_3 and T_4). The muscle unit in an anorexic patient also expends less energy than normal muscle, with a consequent decreased efficiency in work performed [56]. Following refeeding, undernourished muscle demonstrates a "superefficiency." The total energy expenditure (TEE) is similar in anorexics and controls, and for this to be the case there must be an increase in activity-related energy expenditure to offset a reduced REE [57]. The decreased REE and improved economy of muscle function allows anorexics to maintain an increased level of activity with relative conservation of energy.

Using the body's stored calories during inadequate caloric intake

A regular supply of nutrients is normally required to ensure access to all three forms of energy for the body: fat, carbohydrates, and protein. During periods when the body's energy needs are not being met by oral intake, stored fat, protein, and glycogen are mobilized to make up this shortcoming. As starvation progresses, the body switches from primarily using glucose, derived from amino acids by gluconeogenesis, to using ketone bodies, derived from fatty acids [58]. The fat stores harbor a much greater potential to meet the body's energy needs than glycogen or protein. Most tissues can utilize fatty acids and ketone bodies, except nervous tissue, erythrocytes, and the immune system, which still need glucose. The plasma ketone levels rise dramatically with advancing starvation. When plasma levels reach a certain threshold, the brain can begin using ketone bodies as an alternative energy source [59]. Likewise, with advanced starvation, muscle tissue adapts so it can utilize ketone bodies and free fatty acids for energy, which induces a perpetual low-insulin state. The body strives to conserve its protein stores. Early in the process of starvation, 10 g N/day is lost from protein stores, falling to 3 g N/day once the body shifts to the utilization of ketones and fatty acids as the primary energy source [60].

Searching for calories in the face of starvation

Throughout history, food has been inconsistently available to humans, with periods of famine and starvation that vary in length. During famine, the need for survival will reinforce behavior that is conducive to this end. Increased physical activity, increased focus and preoccupation with food, and the motivational drive from "obsessive" thinking and thoughts of desperation would all serve the individual well, from an evolutionary standpoint, in the pursuit of food.

Hyperactivity

Keys published one of the sentinel works examining the effects of starvation in humans [61]. This study enrolled 36 male conscientious objectors to significant caloric deprivation (~ 40% of normal intake) for an average of 168 days. These individuals were normal weight at baseline and young (range 20–33 years), and lost 24% of their baseline bodyweight down to an average body mass index (BMI) of 17.5. The effects of prolonged semistarvation were recorded in detail. During their caloric restriction, the subjects were reported to have increased levels of hyperactivity.

Similar behavior has been described in eating disorders. Remarkably, despite weight loss and food deprivation, patients with eating disorders often exhibit exaggerated levels of physical activity [62]. This is a phenomenon that is seen in experimental animals as a response to food deprivation [60]. The rat model has been the best studied, in which the imposition of food restriction on rats leads to increased activity [62]. When an exercise wheel is available, rats deprived of food will use the wheel to the point of markedly accelerating weight loss. From an evolutionary perspective, this would be an advantageous response in the face of a food shortage.

Impulsivity and obsession

An evolutionary adaptation to resource scarcity is a heightened sensitivity to risk. As a self-protective mechanism, impulsive behavior may convey an advantage, as the appropriate adaptation to scarcity of food [63]. In his 1950 study, Keys observed markedly altered behavior in his semistarved subjects, including hyperirritability, impulsive behavior, and violent ideations, which emerged with progressing weight loss [43,61]. He also reported depression in many of the malnourished subjects, and during their refeeding there was a linear relationship between improved nutritional status and improved symptoms of depression. Sodersten et al. explain

that an "obsession" with food would make sense during a period of significant food deprivation [43]. With ongoing starvation, a preoccupation with food would prompt the individual to devote more time to searching for food. Therefore, might the obsessive thinking associated with an eating disorder represent an understandable adaptation to food deprivation, rather than indicating a true psychiatric illness [43]?

The presence of anxiety in those with eating disorders is also well described. A fear of becoming fat is listed as a key diagnostic criterion in DSM-IV [8]. Can the anxiety in AN be explained as a correlate of a fear of becoming fat? Sodersten et al. propose that the cognitive recognition of an "obsession" with food, which arises with extreme fasting, may transform into a fear of acting on this obsession, in which case obesity becomes the undesirable outcome to avoid [43]. The desire to avoid an aversive outcome (i.e., becoming fat) can become reinforced by the preoccupation with food seen in eating disorders, and this persistent desire becomes anxiety-provoking.

Mechanisms explaining hyperactivity and anxiety in anorexia nervosa

Role of low blood glucose

The stress of restricted-feeding regimens on rats and the resulting hyperactivity has received significant attention since it was first reported in 1954 [64]. In this original description, the rats demonstrated abnormal behaviors similar to obsessive-compulsive behaviors witnessed in semistarved humans with AN. In these experiments, gastric ulcers were seen as another sign of stress. Takeda et al. subjected rats to 7 days of a food-restricted diet while allowing for continued access to either water or a glucose solution of varying concentration [65]. Prevention of hypoglycemia with glucose consumption inhibited many of the stress-induced outcomes in the rats, suggesting that hypoglycemia is one of the driving forces for the abnormal behavioral and physical responses in this rat model.

"Obsessive" behavior and OCD have long been recognized in individuals with AN [41,66]. Diminished food intake, weight loss, and hyperactivity are often elements of OCD, as they are in AN. Elevated cerebrospinal fluid (CSF) levels of corticotropin-releasing hormone (CRH) and vasopressin are found in patients with AN and patients with OCD, suggesting a common disturbance [67,68]. Based on positron emission tomography (PET) scans showing alterations in glucose metabolism in the brains of individuals with OCD [69], abnormally low serum glucose levels may play a role in the pathogenesis of OCD.

Role of hypoleptinemia

As the neuroendocrinology of the body's adaptation to starvation has become better understood, the role of leptin in this process has been a source of tremendous interest. Leptin was discovered in 1994 as a secretory product of adipose tissue. The original studies showed that leptin-deficient mice were subject to overeating and obesity [68], so leptin was assumed to mediate a negative feedback to prevent overeating. Subsequent studies in humans failed to confirm leptin deficiency to be a cause of human obesity [70]. Our understanding of leptin is evolving, and it is known to be an important mediator of some biological changes of starvation [70–72].

Serum leptin levels are generally higher in obese individuals [70]. By contrast, starvation is associated with low levels of leptin. Leptin levels drop dramatically after only 2–3 days of restricted nutritional intake [72,73]. Low leptin levels act as a signal to the hypothalamus of a reduced-energy state [71,74]. As the control center of many hormonal pathways, the hypothalamus directs a shift from energy use to energy conservation. Levels of thyroid and reproductive hormones fall. Studies of healthy men who fasted for as little as 2–5 days reported reduced serum luteinizing hormone (LH) and testosterone concentrations [75,76]. The role of leptin in hormonal feedback control was demonstrated when exogenously administered recombinant leptin (r-metHuLeptin) prevented the fall in LH and testosterone levels seen with fasting [72]. In contrast to the fall in sex hormone levels, levels of stress hormones rise as part of an attempt to mobilize energy stores. Likewise, growth hormone (GH) levels rise, but without a corresponding rise in insulin-like growth factor-1 (IGF-1). During starvation, GH induces lipolysis, which allows utilization of the body's alternative energy reserves. Because IGF-1 levels remain low, the body's energy-consuming, growth-related pathways are not stimulated [74]. As a whole, the body is diverting energy to pathways most critical for survival.

Intense exercise is associated with amenorrhea in many female athletes [77]. The combination of strenuous physical activity and inadequate nutritional intake creates a relative energy deficiency. This energy imbalance results in a hypothalamic amenorrhea. Leptin has been implicated as a regulatory agent in this process. These athletes have a low-leptin state, similar to the semistarved state of AN, which results in lower levels of sex hormones, thyroid hormones, and IGF-1, but increased secretion of cortisol and GH [78–80].

In addition to leptin, adipose tissue secretes a number of other biologically active proteins, often referred to as adipocytokines. Adiponectin is one such protein that is receiving increasing attention; it is involved in regulating energy homeostasis and glucose and lipid metabolism [81]. Adiponectin levels are low in obese individuals [82], and weight reduction increases the serum concentration of adiponectin in obese rats and humans [83,84]; therefore, its plasma level rises with a decreasing BMI. Several studies have reported elevated plasma adiponectin in AN [85,86], but at least one

other study has described lower levels of adiponectin in AN and BN compared with normal-weight controls, regardless of BMI [81]. However, these levels were restored after weight gain in the anorexic group, suggesting that feeding behavior may also influence adiponectin levels in eating disorders. A complex interplay of low leptin and high adiponectin exists in AN, mediating insulin sensitivity, neuroendocrine abnormalities, and osteopenia [87].

Leptin secretion may increase with the resumption of eating after a prolonged fast [88]. Such increased secretion limits food intake and may arrest weight gain as a means of averting obesity, which would be the undesirable outcome of an overcorrection in caloric intake after a period of starvation. It is suggested that by this mechanism leptin might be a factor in the relapse of anorexia in some patients [88]. Several studies have also identified a role for hypoleptinemia in hyperactivity and impulsivity in rats and humans [89,90]. This is corroborated by animal data showing that intracerebroventricular administration of leptin suppresses the hyperactivity associated with the semistarvation state in rats [91].

Role of elevated neuropeptide Y

The body strives for homeostasis with regard to its weight by either stimulating or suppressing the drive to eat through changes in the signals from the gut and energy stores [92]. Anorexia nervosa does not function in this way. It is a condition of starvation, yet anorexics are not intrinsically stimulated to eat. Some have suggested that the actions of many orexigenic (stimulating food intake) and anorexigenic peptides are more complex than initially appreciated and may be partially dependent on the physiological context [43].

One of the best recognized orexigenic peptides is neuropeptide Y (NPY). High leptin levels reduce the production of NPY by the hypothalamus, which would be the expected result for the hyperleptinemia of obesity [93]. Yet, this does not lead to less eating for many of these individuals. The classic theory of bodyweight regulation asserts that external signals are processed by hypothalamic centers, which then adjust food intake. Reduced leptin levels induce an upregulation of orexigenic peptides, including NPY, which should increase nutritional intake [94–96]. In AN, however, these changes do not stimulate eating [93,97].

Insights from animal data suggest a different biological action of NPY that may explain why higher levels of an orexigenic peptide may not be associated with stimulation of food intake. Food deprivation increases the level of NPY mRNA in the hypothalamic arcuate nucleus of female rats. The most striking characteristic of these rats was that they engaged in progressively more running as food deprivation continued, and those provided with an exercise wheel lost more weight than animals without access to an exercise wheel [98]. Administration of a NPY Y1 receptor antagonist to rats blunted the effect that food deprivation had on stimulating wheel running, demonstrating the role of NPY in the hyperactivity response [99]. Correspondingly, increased physical activity was reproduced with intracerebroventricular administration of NPY to these rats without stimulating increased food intake. Interestingly, in the situation of food-deprived rats that did not have access to an exercise wheel, but did have continual access to food, exogenous NPY did stimulate food intake [98]. These results are consistent with the suggestion of Morley et al. in 1987 that NPY may have a stimulatory effect on behavior [100]. These findings in experimental animals, whereby NPY (an orexigenic peptide) paradoxically decreases food intake in the setting of stimulating physical activity, fit into a model of a complex interplay of behavioral, physiological, and biochemical adaptations to starvation in humans [101].

Neuropeptide Y has also been implicated in food-anticipatory activities, including hoarding behavior [102–105]. Evolutionarily, such anticipatory behavior has been explained as a logical precursor to the impending search for food. Anorexics have been reported as engaging in similar anticipatory behavior [106].

Explanation for female predominance

Is there an explanation as to why women are so much more susceptible to developing an eating disorder than men? Differences in energy homeostasis and utilization of substrates between the genders have been claimed [107]. Studies have also asserted that there is a difference between men's and women's abilities to withstand starvation [61,107,108]. Sodersten et al. reported such a difference in a cohort of 30 (17 women and 13 men) high-school-aged subjects. The quantity of food consumed by each gender was measured at baseline and then after skipping two successive meals. After this short-term fast, the amount consumed by the male subjects on resuming eating was markedly greater than their baseline, whereas the women actually ate less food after this short-term fast [24]. The authors felt this might suggest an inherent difficulty for females to compensate for a period of fasting by increasing their food intake. Therefore, dieting may be more risky for females than males. Dieting may start an individual down the road of reduced caloric intake leading to physiological changes of starvation. Once this progression begins, it may be particularly difficult for females to reverse this process.

Medical complications of eating disorders

Potentially serious medical complications may result directly from the malnutrition associated with food deprivation, and indirectly from metabolic derangements following purging

Table 103.2 Laboratory abnormalities seen in eating disorders

Anorexia nervosa
Hypokalemia, hyponatremia, metabolic alkalosis
Metabolic acidosis
Hypoglycemia
Mildly increased creatinine
Anemia, thrombocytopenia
Mild leukopenia
Low erythrocyte sedimentation rate
Mildly increased hepatic aminotransferases
Mildly increased serum proteins
Hypercholesterolemia
Low alkaline phosphatase
Decreased TSH, T_3, and T_4
Decreased FSH, LH, and prolactin
Elevated cortisol
Low magnesium, phosphorus, and zinc levels
Carotenemia
Bulimia nervosa
Hypokalemia, hyponatremia, hypochloremic alkalosis
Metabolic acidosis
Hypoglycemia
Azotemia
Elevated cortisol
Increased prolactin
Low magnesium

FSH, follicle-stimulating hormone; LH, luteinizing hormone; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone.

Peptic ulcer disease
Superior mesenteric artery syndrome
Renal
Prerenal azotemia
Mesangial sclerosis
Nephrolithiasis
Endocrine
Amenorrhea
Decreased libido
Osteopenia and pathological fractures
Impaired functioning of the hypothalamic–pituitary–adrenal axis
Diabetes insipidus
Hypothermia
Increased growth hormone accompanying low levels of insulin-like growth factor (IGF-1)
Decreased insulin production
Metabolic
Decreased metabolic rate
Increased β-hydroxybutyrate
Immunological
Decreased cell-mediated immunity
Granulocyte dysfunction
Decreased serum complement
Altered cytokine levels

behaviors common to these patients. Although still controversial, most investigators in this area support the idea of an increased risk of premature death in people with eating disorders, with a mortality odds ratio (OR) of 10.5 (95% confidence interval [CI], 5.5–15.5) [109]. The medical complications of eating disorders are generally identical to those reported in healthy individuals placed on a semistarvation diet, with changes affecting every organ system, including the skin, digestive, cardiovascular, respiratory, skeletal, renal, immune, and endocrine systems [110,111] (Tables 103.2 and 103.3).

Gastrointestinal complications

Hypogeusia (decreased taste acuity), delayed gastric emptying, loss of digestive capacity, and constipation are the most common complications of the digestive tract in anorexics and bulimics [112–114]. A reduced sensitivity to sweet, salty, sour, and bitter flavors was demonstrated in anorexics [115]. Individuals who specifically employed vomiting as their primary means of purging, also demonstrated a similar loss of sensation on the tongue [116], perhaps related to the frequent exposure of their mouths to the acidity of the gastric contents. In addition, low serum levels of zinc, copper, and

triiodothyronine (T_3 hormone), which many anorexics demonstrate, have been implicated as influencing taste [115]. Often, there is also a loss of dental enamel [117,118], with an increased rate of caries formation and increased sensitivity to hot, cold, and acidic foods [119,120].

Numerous studies have documented a delay in gastric emptying in AN [121–124]. A lack of food in the stomach may cause the delay [125]. Gastric smooth muscle atrophy may result from protein malnutrition [126]. Other proposed mechanisms include the presence of gastric dysrhythmias [124] and a reflexive inhibition of gastric emptying by the rectal distention of constipation [127]. The data are somewhat conflicting as to whether weight gain improves the delay in gastric emptying: some studies demonstrated improvement after weight gain [128–130] whereas others did not [124,125]. Delayed gastric emptying is associated with symptoms of bloating, early satiety, and abdominal distention [125,128,130]. These symptoms may prove to be an impediment to refeeding and weight gain, as eating may increase physical discomfort and exacerbate bloating and distention, reinforcing a perception of feeling "fat" [113]. A similar association of delayed gastric emptying with BN has also been reported in some studies [131,132], but not in others [125,133,134]. Geliebter et al. report that bulimics require a larger volume of gastric balloon distention to produce a feeling of fullness [131]. Proposed explanations for this include abnormalities in gastric relaxation and diminished release of the anorexigenic signal cholecystokinin (CCK) [135–137].

Constipation is also a common problem encountered in AN, with diminished oral intake contributing to this. Anorexics frequently complain also of bloating and abdominal distention [113,127]. Whole-gut transit times were found to be delayed in AN and BN compared with controls [127], and an association with abnormalities in anal canal resting pressure and rectal sensation have also been suggested [138]. The delayed colonic transit times improved with refeeding.

Cardiovascular complications

Potentially the most serious cardiac complication in AN is the prolongation of the Q–T interval, a marker for certain arrhythmias and sudden cardiac death [139]. Several studies have linked AN with a prolonged Q–T interval [140–143] and an increased risk of ventricular arrhythmias [142]. Bradycardia and hypotension are two additional abnormalities associated with AN. One series showed that 100% of anorexics had a sinus bradycardia with a heart rate of less than 60 beats/min compared with controls [144]. Several causative mechanisms for this bradycardia have been proposed, including vagal hyperactivity of starvation [143,145,146] and reduced secretion of T_3 hormone [143]; electrolyte abnormalities, a decrease in myocardial glycogen stores, and myocardial cell atrophy may be additional aggravating factors [141].

Endocrine complications

The hormonal changes that are observed in AN are best understood as an adaptation to malnutrition and starvation rather than a manifestation of a primary endocrinopathy [147]. Normal hypothalamic functioning is impaired in the setting of a significant energy deficit. The role of leptin in this process has already been described (see "Role of hypoleptinemia" above). Whereas amenorrhea is the consequence of this hypotropic hypogonadism in women, males manifest a diminished libido [148]. Teleologically, the body is attempting to divert energy from the reproduction pathway to other processes more crucial for survival. The hypothalamic dysfunction of AN also disrupts thyroid hormone secretion, with the resulting hypothyroidism contributing to lower body temperature, lethargy, dry skin, constipation, and bradycardia.

Feeding is a chief regulator of the daily rhythms of the hypothalamic–pituitary–adrenal (HPA) axis, which mediates secretion of plasma corticosteroids [52]. Persistently elevated serum cortisol levels are reported in anorexics, with an abolition of the normal daily circadian rhythm observed in healthy individuals. Similarly, an elevated 24-hour urinary cortisol has been described in bulimics [149]. There is blunting of the CRH-induced response of adrenocorticotrophic hormone (ACTH) and cortisol in AN and BN [149–151]. Because bulimics are normal in weight, these changes may be independent of BMI. Yet, many of the changes do largely reverse with increased nutritional intake. As is seen in AN, CRH hypersecretion is also described in depression and is suggested as a common pathogenic mechanism to explain some of the clinical similarities of these conditions [150].

Anorexia nervosa is also associated with reduced bone mineral density in adolescent and adult females [152–154]. Although the degree of estrogen deficiency may be similar in AN and other causes of hypothalamic amenorrhea, anorexics have a much greater reduction in bone density, which observation argues for other contributing factors [155], such as malnutrition, excessive exercise, hypercortisolemia, acquired GH resistance, and low levels of IGF-1 [151,154]. Secretion of GH by the pituitary is nutritionally regulated and stimulates hepatic secretion of IGF-1, which functions as a bone trophic factor. However, IGF-1 levels remain low in AN, despite elevated levels of GH [151].

Treatment

Basic approach to treatment

A multidisciplinary team, including an internist, psychiatrist, dietician, and also, in some cases, a gastroenterologist, endocrinologist, and psychotherapist, is advocated as the optimal approach in managing eating disorders [156]. Intervention and counseling by the primary physician alone are adequate in only a few cases involving younger patients with a short duration of symptoms. Most patients, particularly those with more serious and long-standing symptoms, benefit from referral to a psychiatrist who is knowledgeable about eating disorders [149]. Indications for mandatory psychiatric referral include a failure to respond to current treatment with clinical deterioration, significant underlying depression with suicidal behavior, or serious family issues.

It is reported that 50% of patients with AN can be successfully treated in the outpatient setting [157]. Patients with a higher probability of successful outpatient treatment include those who are younger, have a shorter duration of disease, and have cooperative families. There are no randomized controlled trials (RCTs) comparing inpatient with outpatient treatment to guide this decision [158]. A structured, inpatient program is recommended for those who are 25%–30% below a healthy bodyweight [159].

The general physician's primary role is nutritional management, which includes following serial weights and labs, educating, counseling, and recognizing the need for referral [149]. Initial treatment for AN should focus on medical stabilization and weight restoration [156]. Adequate nutritional replacement can be achieved by the oral route in most; only in rare instances is nasogastric feeding or hyperalimentation needed. As a rule, caloric supplementation is progressively increased to achieve weight gain. In severely malnourished individuals, the clinician must be cautious with the rate of nutrition reintroduction to avoid the electrolyte abnormalities and other complications of the refeeding syndrome.

A multivitamin preparation with vitamin D and supplemental calcium should be part of the nutrition plan. Exogenous estrogen and progesterone have not demonstrated any meaningful improvement over placebo in bone density [160]; these agents should not be given to adolescents who are still growing. Excessive exercise should be discouraged [161]. A crucial component of a nutritional rehabilitation program is to correct the patient's distorted views towards eating and dieting [149].

Psychiatric approach: treatment directed at psychological change

The association of eating disorders with other psychiatric diagnoses is well described, such as anxiety and AN, or depression and BN. Many of the tools and treatments traditionally used for these psychiatric conditions have been tried for eating disorders, particularly in the setting of individuals with coexisting psychiatric diagnoses [162]. Selective serotonin reuptake inhibitors (SSRIs) are commonly used in the treatment of both AN and BN. Randomized controlled trials of fluoxetine have not established clear efficacy with improved clinical outcomes for AN [163–168]. Severely malnourished individuals have diminished synaptic release of serotonin (5-hydroxytryptamine; 5-HT), which may account for a decreased effect of the SSRIs in AN [156]. As a general rule, the American Psychiatric Association does not endorse

the use of SSRIs in the treatment of significantly underweight patients with AN [169]. Published reviews on the pharmacological management of AN acknowledge that no medication to date has demonstrated a significant impact on weight gain or the psychological features of AN [170,171]. However, although evidence about their efficacy in AN is lacking, SSRIs are well tolerated and are frequently employed as therapy directed at depressive and obsessive-compulsive symptoms [156]. For BN there is better evidence that high-dose fluoxetine decreases binging and purging and may reduce relapse at 1 year [172].

The efficacy of other psychotropic drugs in eating disorders has been examined. For example, amitriptyline, cyproheptadine, and clomipramine did not demonstrate consistent clinical improvement in AN [173–175]. However, limited data suggest that the tricyclic antidepressants (TCAs) may reduce vomiting episodes in BN [172]. The TCAs are associated with constipation, hypotension, and certain cardiac arrhythmias, side effects that are particular concerns in AN. Furthermore, based on anecdotal experience, antianxiety and "atypical" antipsychotic medications have been tried in some patients with AN [176].

Many forms of behavioral interventions have been tried for eating disorders, including cognitive, dynamic, family, individual, and group therapy. One study suggested that cognitive behavioral therapy (CBT) reduced the rate of relapse and led to improved outcomes in those who had already achieved inpatient weight gain [177]. The efficacy of CBT in the acute setting of still-underweight anorexics is less clear [171]; yet, in general, CBT is assumed to be helpful in AN [178]. For BN there is relatively better evidence that CBT should be the primary treatment [172]. Family therapy has not been shown to be effective in adolescents suffering from AN [179], but may be beneficial in younger patients with a shorter duration of symptoms [180,181]. Overall, the research on psychotherapy in AN is limited [182], and the combination of pharmacological and behavior therapy has not been thoroughly studied [171].

The course of AN is often protracted, with suboptimal long-term outcomes in many [47,183]. The framework on which most treatment is based is that an eating disorder is an inherent psychiatric abnormality. In many instances, this approach has resulted in only marginal improvements. Perhaps developing a new framework to understand eating disorders will open new avenues, down which future treatment may be directed.

Biological approach: treatment directed at the response to starvation

Anorexia nervosa may primarily represent a perturbation in the biological response to caloric restriction, which is an alternative framework for trying to understand the diagnosis. The cascade of events in this process is as follows. Voluntary caloric restriction is undertaken, perhaps prompted by societal influences, or the subject's occupation or athletic pursuits. As a pronounced energy and nutritional deficit develops, hypoleptinemia ensues, influencing the body's hypothalamus-directed hormonal axes [74]. Levels of NPY rise in response to hypoleptinemia, driving hyperactivity [98]. Hypoglycemia also may contribute to impulsive behavior. Furthermore, the individual is driven to continue the pattern of decreased food intake and hyperactivity by the activation of the dopaminergic reward pathway in the brain [184]. It is hypothesized that these behaviors become entrenched within the individual, as a perceived "reward" leads to conditioning of these behaviors. In patients experiencing the acute physiological consequences of malnutrition, it may not be surprising that a traditional approach of medication and psychotherapy is often only minimally effective in changing behavior [185,186].

Can a biological framework for understanding AN lead to more effective treatments? Anorexics often demonstrate significantly increased levels of exercise and participation in sports, even predating their diagnosis [187]. Increased physical activity may be a crucial component in the pathogenesis and progression of AN. The euphoria associated with physical activity is well described and, thus, serves as a positive driver to the perpetuation of the eating disorder [188]. Hyperactivity seems then to be a key component of AN, because increased physical activity results in a greater metabolic demand, and this alone hampers efforts to successfully gain weight. In the rat model of AN, providing access to an exercise wheel while instituting food restriction, was key for beginning the cycle of uncontrollable weight loss [98]. In the rat given NPY, stimulated eating (the expected effect of an orexigenic peptide) was suppressed when the animal had access to an exercise wheel but was unmasked when the wheel was removed [98]. Thus, the two main physiological risk factors for AN and BN may be dieting and hyperactivity [188]. Although treatment recommendations for anorexics often include discouraging overly excessive exercise, might treatment outcomes in AN be more successful if strict attention is given to limiting increased physical activity, so as to alter the physiological response to NPY?

Intriguing preliminary research exists in which investigators utilized a biological framework for understanding AN to devise an innovative, multifaceted treatment program [186,189]. Their approach used a computerized device to help patients relearn how to eat and how to recognize satiety. Patients' activity was strictly limited. They were also treated with external warmth, which some studies suggest further reduces activity and anxiety in the individual [91,186,190]. A randomized trial from 2002 reported that 75% of patients treated in this manner were able to achieve a normal BMI over an average of 14 months of follow-up [186]. Even more remarkably, only 10% of enrollees demonstrated relapse after 5 years. The authors felt that these results support the contention that a conceptual shift to a more biologically

based treatment program, including strict attention to controlling physical activity, is needed to improve clinical outcomes in treating eating disorders.

104 Complications of AIDS and other immunodeficiency states

Phillip D. Smith, Edward N. Janoff

Role of the gastrointestinal mucosa in HIV-1 pathogenesis, 2588
Diarrheal diseases, 2588
Biliary disorders, 2601
Pancreatitis, 2601
Gastrointestinal bleeding, 2602
Gastrointestinal neoplasms, 2602
Anorectal disease, 2602
Other immunodeficiency states, 2603

The gastrointestinal tract plays a fundamental role in the pathogenesis of the acquired immunodeficiency syndrome (AIDS). Consequently, it is not surprising that gastrointestinal complications are common in patients infected with human immunodeficiency virus-1 (HIV-1), the causative agent of AIDS (Table 104.1). Infectious processes, particularly in resource-limited settings, comprise the majority of these complications and are responsible for relentless morbidity and, in some cases, mortality [1,2]. This chapter focuses on the intestinal infections and key gastrointestinal syndromes associated with AIDS and other common immunodeficiency states.

Role of the gastrointestinal mucosa in HIV-1 pathogenesis

All HIV-1 infections, excluding those acquired parenterally, are transmitted across a mucosal surface [3]. In addition to their role in HIV-1 transmission, mucosal surfaces participate in many key events in HIV-1 pathogenesis. First, mucosal cells are probably involved in selecting from the pool of inoculated viruses the phenotypically and genotypically restricted HIV-1 that is transmitted in acute infections [4–6]. Second, mucosal (lamina propria) lymphocytes are the initial target cell for HIV-1 infection [7–9]. Third, HIV-1 replication occurs in the mucosa [10–13], a microenvironment containing an abundance of cytokines capable of enhancing HIV-1 replication in infected cells [14]. Fourth, the subsequent decline in the number of circulating $CD4^+$ T lymphocytes, a fundamental characteristic of AIDS, begins in the intestinal mucosa [15–19]. Finally, local and systemic reduction in $CD4^+$ T cells, and related cellular and humoral perturbations, predispose the gastrointestinal tract mucosa to an array of opportunistic infections and neoplasms. Consequently, the crucial role of mucosal immunity in HIV-1 infection has gained prominent consideration in vaccine strategies designed to prevent HIV-1 transmission [20,21].

Diarrheal diseases

HIV-1-related diarrhea may first occur during the syndrome of primary HIV-1 infection 1–4 weeks after virus inoculation [22–25]. This mononucleosis-like syndrome, characterized by fever, sore throat, rash, lymphadenopathy, fatigue, weight loss, and myalgias, occurs in 30%–90% of persons acutely infected with HIV-1 and lasts for 1–3 weeks. Acute, self-limited diarrhea occurs in approximately one-third of persons with the syndrome [24]. Less frequent gastrointestinal manifestations of acute HIV-1 infection include thrush and ulcerations of the oral cavity, esophagus, and rectum, as well as enteropathy and weight loss. Resolution of the syndrome coincides with seroconversion and decline in the level of circulating virus [24].

Chronic diarrhea, defined as two or more loose or watery stools per day for at least 1 month, is common in patients with clinically apparent AIDS. Such patients have lower numbers of circulating $CD4^+$ T lymphocytes and a higher incidence of extraintestinal opportunistic infections than patients without diarrhea, indicating a causal relationship between the immunosuppression and the diarrhea. When an enteric pathogen is not detected, the diarrhea has been termed "AIDS enteropathy" [25,26]. The ability of the HIV-1 transactivating factor protein (Tat) to induce epithelial cell ion secretion without direct infection of the cells suggests a potential mechanism for diarrhea associated with the AIDS

Table 104.1 Major gastrointestinal complications of AIDS

Diarrhea:	Acute HIV-1 syndrome, infectious enteritis/colitis, drug-induced and AIDS enteropathy
Biliary disorders:	Acalculous cholecystitis, sclerosing cholangitis and papillary stenosis
Pancreatitis:	Drugs (pentamidine and dideoxyinosine), infections
Gastrointestinal bleeding:	Upper tract: infectious esophagitis, Kaposi sarcoma and lymphoma Lower tract: infectious colitis, idiopathic colonic ulcers, non-Hodgkin lymphoma and Kaposi sarcoma
Neoplasms:	Non-Hodgkin lymphoma and Kaposi sarcoma
Anorectal disease:	Anus: condylomata, infection, fistula, fissure and squamous cell carcinoma Rectum: nonspecific proctitis, infectious proctitis and perirectal abscess

AIDS, acquired immune deficiency syndrome; HIV-1, human immunodeficiency virus type 1.

enteropathy [27]. However, among HIV-1-infected persons with diarrhea, vigorous microbiological evaluation frequently reveals an identifiable pathogen [28–32]. Important causes of diarrhea in HIV-1-infected persons include opportunistic and nonopportunistic infections and, during the last decade, antiretroviral therapy as well. Diarrhea in HIV-1-infected persons is associated with wasting and decreased survival in infants as well as adults [33,34]. In addition to the effect of diarrheal illness on the individual, the resultant loss of the ability to work and the high cost of providing health care are major drains on the financial resources of families and ultimately society in developing as well as developed countries.

Diagnostic evaluation

A vigorous diagnostic evaluation in HIV-1-infected patients with severe chronic diarrhea is usually justified, because pathogen-specific therapy can reduce the volume and frequency of the diarrhea [28,29]. Increased awareness of the infectious processes involving the gastrointestinal tract (Table 104.2) and improved diagnostic techniques have led to the identification of enteric pathogens in 44%–85% of patients with AIDS who have diarrhea [28–32]. A gastrointestinal pathogen is more frequently identified in symptomatic patients who also have weight loss and fewer than 100 $CD4^+$ T cells/mm^3 than in those patients without weight loss and with more than 100 $CD4^+$ T cells/mm^3, indicating that patients with more severe illness and greater immunosuppression are more likely to have an identifiable enteric pathogen [30,35–37]. Two or more enteric pathogens may coexist in approximately 25% of patients with AIDS who have diarrhea [38].

Step 1

Evaluation begins with a thorough history, including a review of the patient's drugs. In North America and Europe, antimicrobial agents and antiretroviral drugs are among the most common causes of gastrointestinal symptoms and diarrhea.

Table 104.2 Sites of infections in the gastrointestinal tract in HIV-1-infected persons

Organ	Pathogens
Esophagus	*Candida albicans*, herpes simplex virus, cytomegalovirus
Stomach	Cytomegalovirus, *Mycobacterium avium* complex
Biliary tract	Cytomegalovirus, *Cryptosporidium*, microsporidia, *Isospora belli*
Gallbladder	Cytomegalovirus, *Crytosporidium*, microsporidia, *Isospora belli*
Pancreas	Cytomegalovirus, *Mycobacterium avium* complex, herpes simplex virus
Small intestine	*Cryptosporidium*, microsporidia, *Isospora belli*, *Cyclospora*, *Mycobacterium avium* complex, *Salmonella* spp., *Campylobacter jejuni*, cytomegalovirus
Colon	Cytomegalovirus, *Mycobacterium avium* complex, *Shigella* sp., *Clostridium difficile*, *Campylobacter jejuni*, *Histoplasma capsulatum*, adenovirus, enteroaggregative *Escherichia coli*
Rectum	Herpes simplex virus, lymphogranuloma venereum, papillomavirus

HIV-1, human immunodeficiency virus type 1.

In addition, the increased use of antimicrobial agents in HIV-1-infected patients may be associated with increased rates of *Clostridium difficile*-associated diarrhea [39,40]. In the largest retrospective review of bacterial diarrhea in HIV-1-infected persons, *C. difficile* has become the most commonly identified bacterial pathogen in the United States [32]. The geographic region(s) in which a patient has resided or traveled is important because some AIDS-defining pathogens are endemic or more common in certain geographic regions, e.g., *Histoplasma capsulatum* in the Mississippi valley [41], *Cryptosporidium parvum* and *Isospora belli* in developing countries [42,43], and rotavirus in Australia [44,45] and Peru [31].

Step 2

After the history and physical examination, up to three stool specimens are cultured for *Salmonella* spp., *Shigella* spp., and *Campylobacter jejuni*, which are among the most common bacterial diarrheal pathogens identified in persons with and without HIV-1 infection [31,32,46,47]. *Aeromonas*, *Yersinia*, and *Escherichia coli* 0157:H7 are not more common among patients with AIDS, so stool samples are not routinely cultured for these bacteria. Each specimen is also examined for ova and parasites using saline, iodine, trichrome, and acid-fast preparations of direct or concentrated samples of stool. Antigen detection assays for *Giardia lamblia* and *Cryptosporidium* are increasingly available in clinical laboratories. Stool is assayed for *C. difficile* toxin, but because approximately 10% of patients without AIDS but with *C. difficile* infection are toxin-negative, stool is cultured for *C. difficile* when the bacterium is suspected despite a negative toxin assay [48]. The identification of enteric pathogens by stool examination alone in up to 55% of HIV-1-infected patients with diarrhea [29,49] underscores the importance and cost effectiveness of stool examination as the initial diagnostic test [50]. When fever is present, blood cultures are obtained for *Salmonella* spp., *Shigella* spp., and *C. jejuni* because bacteremia may accompany these infections at increased rates in HIV-1-infected persons.

Step 3

When stool examination does not reveal a potential pathogen or when therapy for the identified pathogen(s) does not improve symptoms, we perform esophagogastroduodenoscopy (EGD) and colonoscopy to inspect the mucosa and obtain biopsies for histopathological and microbiological evaluation. Small bowel fluid from HIV-1-infected patients rarely contains parasites [51] or excessive levels of bacteria ($> 10^4$/mL) [52], so we do not aspirate fluid from the small intestine to diagnose parasitic or bacterial overgrowth. Among HIV-1-infected patients with diarrhea and pathogen-negative stool studies, a diagnosis was obtained in 26% of patients by EGD [51], in 50% by EGD plus sigmoidoscopy [26], and in 44% by EGD plus colonoscopy [36]. The diagnostic yield of an endoscopic procedure is significantly greater for patients with $CD4^+$ T-cell counts below 500 cells/mm^3 [30], especially counts lower than 100 cells/mm^3 [36], and weight loss greater than 10 kg [53]. The diagnosis of cytomegalovirus (CMV) colitis, microsporidiosis, *Mycobacterium avium* complex, *Histoplasma capsulatum*, and adenovirus is made most frequently in such patients, who typically have advanced disease. Endoscopic procedures are an important adjunct to the diagnostic evaluation of unexplained chronic diarrhea in HIV-1 disease, and the diagnostic yield is greater for patients with more profound immunosuppression and severe diarrhea.

Step 4

When Steps 1–3 do not yield a detectable pathogen or when therapy is ineffective, glutaraldehyde-fixed tissue specimens obtained during Step 3 can be evaluated by electron microscopy for microsporidia (duodenal biopsies), and adenovirus and enteroaggregative bacteria (colon biopsies). The cost required to perform electron microscopy should be weighed against the low prevalence of these pathogens.

Approach to therapy

During the diagnostic evaluation of diarrhea, many patients without febrile, inflammatory, or bloody diarrhea benefit from supportive therapy with fluids, electrolytes, and antimotility agents. However, because the array of opportunistic and nonopportunistic pathogens that cause diarrhea in HIV-1-infected patients is extensive (Table 104.3), and drug-related side effects and drug interactions are common, specific antimicrobial therapy is preferable to empiric therapy [54]. In this regard, many microorganisms are resistant to, or develop resistance to, antimicrobial agents, necessitating close monitoring with in vitro drug susceptibility testing. Importantly, diarrhea and the AIDS cholangiopathy are often multifactorial in etiology, and, therefore, treatment may be only partially beneficial. Nevertheless, long-term suppressive therapy is often necessary for infections that reactivate or recur after treatment. Although specific antimicrobial therapy and supportive care can enhance the quality of life and duration of survival in many patients, highly active antiretroviral therapy (HAART) has obviated the need for antimicrobial therapy for some pathogens, as described next.

Highly active antiretroviral therapy

A major advance in the therapeutic management of HIV-1 infection has been the development of HAART, which combines reverse transcriptase inhibitors (RTI) and protease inhibitors (PI) and, more recently, fusion and integrase inhibitors, and HIV coreceptor antagonists (Table 104.4). RTIs include nucleoside analogues (NRTIs), such as zidovudine, and non-nucleoside analogues (NNRTIs), which inhibit the ability of HIV-1 RNA to encode viral DNA. The PIs block the cleavage of HIV-1 Gag-Pol polyprotein precursor into structural core proteins and enzymes (reverse transcriptase, integrase, and protease), causing the production of abnormal

Table 104.3 Opportunistic and nonopportunistic pathogens in the gastrointestinal tract in HIV-1 infection

	Opportunistic	Nonopportunistic
Bacteria	*Salmonella* sp. *Shigella flexneri* *Campylobacter jejuni* *Mycobacterium avium* complex Enteroaggregative *Escherichia coli*	*Clostridium difficile*
Protozoa	*Cryptosporidium parvum* *Enterocytozoon bieneusi* *Septata intestinalis* *Cyclospora cayetanensis* *Isospora belli*	*Giardia lamblia* *Entamoeba histolytica*
Viruses	Cytomegalovirus Herpes simplex virus Adenovirus Picobirnavirus/Astrovirus[b]	Rotavirus[a] Norwalk virus
Fungi	*Histoplasma capsulatum* *Candida albicans*	

a Nonopportunistic in United States and Africa, but more common in HIV-1-infected persons in Australia and Europe.
b More common in patients infected with HIV-1 with diarrhea; pathogenesis under investigation.
HIV-1, human immunodeficiency virus type 1.

viral proteins and noninfectious virions. HAART regimens typically include three or more agents, usually two NRTIs and one PI, along with one or more of the newer agents for patients with drug-resistant infections, to diminish or ablate viral replication, prevent the development of resistance, and enhance the recovery of immunological competence [55–59]. Consequently, HAART has dramatically reduced the rate of death [60] and the incidence of many systemic and gastrointestinal opportunistic infections, especially cryptosporidiosis [61,62], microsporidiosis [62], and enteric CMV disease [63], as well as oral candidiasis [64], in patients with HIV-1 infection, probably as the result of the inhibition of HIV-1 replication and the resultant recovery of immune function. Coinciding with the increased use of HAART, *C. difficile*-associated diarrhea [32] and medication-associated diarrhea [65] have emerged as leading causes of diarrhea in HIV-1-infected persons. The recovery of immune function takes several months so rates of opportunistic infections decline most prominently after 2 months of antiretroviral therapy. Prophylactic antimicrobial therapy may be discontinued in most patients on HAART when the number of $CD4^+$ lymphocytes has increased to 200 cells/mm^3 and remained at this level for more than 12–24 weeks [66–68].

A spectrum of toxicities is associated with antiretroviral drugs, but many antiretroviral agents have prominent side effects: nausea, vomiting, and diarrhea (Table 104.4). These toxicities occur more frequently among patients with advanced HIV-1 disease ($CD4^+$ T cells < 200 cells/mm^3) [3]. The PIs such as nelfinavir are associated with higher rates of diarrhea than are more recent agents, such as lopinavir/ritonavir [69]. Pancreatitis and hepatic toxicity also may occur with some agents. Many of the toxic effects of antiretroviral medications are dose-dependent, and dose reduction may allow the continuation of therapy. However, because optimal antiretroviral activity is usually dose-dependent, particularly for PIs, changing antiretroviral agents may be preferable to lowering doses. Drug resistance may develop so virological status should be monitored. The management of overlapping toxicities, side effects and complications associated with anitretroviral agents requires in-depth knowledge of the agents and close patient monitoring.

Bacterial infections

Salmonella spp., *Shigella* spp., and *Campylobacter jejuni*

The gram-negative bacteria, both *S. enteritidis* (particularly in the United States) and *S. typhimurium* (particularly in Africa) [70–72], *Shigella flexneri* [73–75] (although *Shigella sonnei* is more comon in the general population), and *C. jejuni* [76,77], cause a similar clinical illness in HIV-1-infected persons. This syndrome may be characterized by chronic or recurrent diarrhea, abdominal cramps, and fever. During symptomatic infection, the stool frequently contains fecal leukocytes and either gross or microscopic blood, although noninflammatory diarrhea may also be present. Each of these bacterial infections occurs more often, causes more prolonged or recurrent diarrhea, and is more commonly associated with bacteremia and antibiotic resistance in HIV-1-infected persons than in seronegative persons. The *C. jejuni* may cause visible mucosal inflammation. *Campylobacter* sp. other than *C. jejuni* have been detected in HIV-1-infected patients with diarrhea [78], but a causative role for these species in the diarrhea awaits confirmation.

Diagnosis

These bacteria are diagnosed by culture of the organism in a stool specimen. The blood should also be cultured when diarrhea is accompanied by fever.

Treatment

The drug of choice for infection with *Salmonella* spp. is ceftriaxone or ciprofloxacin, for *Shigella* spp. ciprofloxacin is used, and for *C. jejuni* erythromycin or ciprofloxacin is used (Table 104.5). Because recurrence is common and drug resistance may develop, repeat culture of stool and blood (when bacteremia occurs) and drug sensitivity testing are used to monitor the therapeutic response, particularly when symptoms persist.

Table 104.4 Gastrointestinal complications of antiretroviral therapy and potential interactions with other medications used in gastrointestinal medicine

Type of medication	Medication	Trade name	Primary gastrointestinal toxicity[a]	Gastrointestine-associated drug interactions
Antiretroviral				
• Nucleoside analogue RTI (NRTI)	Zidovudine (AZT, ZDV)	Retrovir	Anorexia; nausea (4%–26%); vomiting (3%–8%); rare hepatitis, steatosis, lactic acidosis	Activity may be inhibited by ribavirin
	Didanosine (ddI)	Videx; Videx EC	Indigestion; diarrhea (16%); pancreatitis (4%–8%); ↑ALT/AST (6%–20%); rare steatosis and lactic acidosis	Potential increased rate of pancreatitis with pentamidine, azathioprine; buffers associated with ↓ absorption of itraconazole, ketoconazole, dapsone; tetracycline, ciprofloxacin; ddI levels ↑ with ranitidine, ganciclovir
	Zalcitabine (ddC)	HIVID	Stomatitis (self-limited) (2%–17%); pancreatitis (0.5%–9%)	Few; possible ↑ neuropathy with metronidazole, disulfuram
	Stavudine (d4T)	Zerit	Diarrhea (33%), nausea/vomiting (26%), abdominal pain (23%); ↑ALT/AST (65%); significant GI symptoms and hepatic abnormalities in 4%–10%; rare lactic acidosis and pancreatitis	Few; possible ↑ neuropathy with ethanol; ribavirin may increase activity (in vitro data)
	Lamivudine (3TC)	Epivir	Limited; mild and transient diarrhea, nausea, abdominal pain; rare pancreatitis, steatosis, and lactic acidosis	Few
	Abacavir (ABC)	Ziagen	Nausea (45%), diarrhea (25%), vomiting (15%) and abdominal pain (15%) may decrease over weeks of therapy; hypersensitivity reaction with fever ± rash, malaise, nausea, vomiting, ↑ALT/AST in 2%–5% within 1 month	None reported
	Emtricitabine (FTC)	Emtriva	Minimal toxicity; occasional nausea; diarrhea and nausea; rare pancreatitis, steatotis, and lactic acidosis	
	Tenofovir (TDF)	Viread	Well tolerated; occasional nausea, vomiting, diarrhea, flatulence, abdominal distention, anorexia	
• Nucleotide analogue RTI	Adefovir dipivoxil	(Preveon)	Usually mild nausea, diarrhea, occasional vomiting (1%–8%); ↑ALT/AST (4%); (renal toxicity 38%)	None reported
Combinations	ZDV/3TC	Combivir	See individual agents	
	ZDV/3TC/ABC	Trizivir	See individual agents	
	3TC/ABC	Epzicom	See individual agents	
	FTC/TDF	Truvada	See individual agents	
• Non-nucleoside RTI (NNRTI)	Nevirapine (NVP)	Viramune	Nausea, vomiting; ↑ALT/AST (1%; lower if begin with 2 weeks at lower dose); isolated ↑GGT common; (rash most common, ≈ 10%)	
	Delavirdine (DLV)	Rescriptor	Nausea (7%); diarrhea (4%); ↑ALT/AST (≤ 5%); (rash most common; usually transient)	Level ↓ with rifampin, rifabutin (P-450 system) and antacids (↑ gastric pH); level ↑ with clarithromycin, rifabutin, cisapride
	Efavirenz (EFV)	Sustiva	Most common: transient rash and CNS symptoms of headache, dizziness, impaired concentration; some nausea, vomiting, diarrhea, ↑ALT/AST	Avoid cisapride; should not be taken within 2 h of antacids; not recommended with clarithromycin; (interacts with other PI)
	Etravirine (TMC125)	New agent; not released	Initial GI symptoms not greater than control regimens	
	EFV/FTC/TDF	Atripla	See individual agents	

• Protease inhibitors (PI)[b] (most PI metabolized by liver)	Saquinivir (SQV)	Invirase	Nausea, diarrhea, abdominal pain, dyspepsia (5%–10%)	Cisapride contraindicated; SQV level ↑ with ketoconazole, clarithromycin; SQV level ↓ with rifampin, rifabutin; clarithromycin level ↑ with SQV; (interacts with other PI)
	Ritonavir (RTV)	Norvir	Nausea, diarrhea, vomiting, anorexia, abdominal pain (20%–40%), esp. in first few weeks of therapy; Taste perversion (10%); Increased triglycerides (60%, but > 1500 mg/dL in 2%–8%); ↑ALT/AST (10%–15%), esp. with NRTI; fewer complications when used only at lower doses for boosting levels of other PIs	Cisapride contraindicated; caution with dronabinol, ondansetron, cimetidine, promethazine, corticosteroids; RTV level ↑ with ketoconazole, itraconazole; RTV level ↓ with rifampin; clarithromycin, erythromycin, rifampin, rifabutin levels increased with RTV; (interacts with other PI)
	Indinavir (IDV)	Crixivan	Nausea, vomiting, diarrhea, abdominal pain (4%–15%); Increased indirect bilirubin (10%); (nephrolithiasis 5%–10%)	Cisapride contraindicated; IDV level ↓ with rifabutin; IDV level ↑ with ketoconazole; rifabutin level ↑ with IDV; (interacts with other PI)
	Nelfinavir (NLF)	Viracept	Diarrhea (usually mild) (2%–19%)	Cisapride and rifabutin contraindicated; NLF levels ↓ with rifampin; rifabutin levels ↑ with NLF; (interacts with other PI)
	Amprenavir	Agenerase	Mild diarrhea, nausea, vomiting (7%–33%); fatigue; taste disorder; (rash 18%);	Cisapride and rifampin contraindicated; Amprenavir levels ↓ with rifabutin; rifabutin levels ↑ with amprenavir; (interacts with other PI)
	Fosamprenavir (FPV)	Lexiva	Nausea, diarrhea, vomiting; mouth numbness; ↑ALT/AST; (rash common 19%)	As above; cytochrome P450 and CYP3A4 inhibitor[b]
	Lopinavir-Ritonavir (LPV/RTV)	Kaletra	Diarrhea (10%–20%); nausea, vomiting, stomach pain; ↑ALT/AST (8%)	Similar to other PI
	Atazanavir (ATV)	Reyataz	Occasional GI symptoms and ↑ALT/AST; elevated indirect bilirubin/jaundice (7%–9% but subclinical)	As above; cytochrome P450 and CYP3A4 inhibitor[b]
	Tipranavir (with ritonavir)	Aptivus	Nausea, vomiting, diarrhea, fatigue, and headache (rates similar to those with comparator PIs); ↑ALT/AST (> 10%) and occ. fatal hepatic failure	Avoid drugs that are metabolized by or induce CYP34A
	Darunavir (DRV/RTV) (with ritonavir)		Nausea, vomiting, diarrhea, fatigue, and headache (rates similar to those with comparator PIs); ↑ALT/AST (2%–3%)	Avoid drugs that are metabolized by or induce CYP34A
• Fusion inhibitors	Enfuvirtide	T20; Fuzeon	Decreased appetite; ↑ALT/AST; (local injection and systemic hypersensitivity reactions)	Does not affect cytochrome P450
• Other	Interleukin-2	Proleukin	Diarrhea, abdominal pain, stomatitis (7%); nausea; vomiting; isolated ↑ bilirubin (8%); ↑ALT/AST; acalculous cholecystitis; constitutional flu-like symptoms (fever, chills, muscle/joint pain) (45%)	
	Hydroxyurea	Hydrea	Nausea (12%); ↑ALT/AST (2%); stomatitis (8%); diarrhea; occasional anorexia, vomiting, diarrhea, constipation (myelosuppression; rash)	
	New classes: – entry inhibitors (CCR coreceptor)	Maraviroc	Limited to date	
	– integrase inhibitors	Raltegravir	Limited to date	
	– maturation inhibitors			

a Rates may vary among studies.

b As with other inhibitors of cytochrome p450 system, specifically CYP 3A4, protease inhibitors should not be given with cisapride (Propulsid), astemizole (Hismanal), terfenadine (Seldane), midazolam (Versed), or triazolam (Halcion), or ergot derivatives.

Table 104.5 Therapy for intestinal infections in HIV-1-infected adults

Pathogen	Treatment	Alternative treatment
Protozoal:		
Cryptosporidium	Nitazoxamide 500 mg b.i.d. × 14 days	Paromomycin 500 mg q.i.d./1000 mg b.i.d. × 14 days
Microsporidium sp.	Albendazole 400 mg b.i.d. × 4 weeks (*Septata intestinalis*)	Fumagillin 60 mg/day (*Enterocytozoon bieneusi*); Nitazoxanide 1000 mg b.i.d.
Isospora belli[a]	Trimethoprim-sulfamethoxazole 1 DS[b] q.i.d. × 10 days	Pyrimethamine 25 mg + leucovorin acid 5–10 mg/day × 10 days Ciprofloxacin 500 mg b.i.d. × 10 days, then b.i.d. × 3 weeks Maintenance: 1 TMP-SMX q.d. or 3 ×/week
Giardia lamblia	Metronidazole 250 mg t.i.d. × 5 days	Tinidazole 2 g single dose Furazolidone 100 mg q.i.d. × 7–10 days
Cyclospora	Trimethoprim-sulfamethoxazole 1 DS q.i.d. × 10 days	
Viral:		
Cytomegalovirus[a,c,d]	Ganciclovir 5 mg/kg i.v. q12h × 3–4 weeks Valganciclovir 900 mg b.i.d. with food × 3–4 weeks	Foscarnet 60 mg/kg i.v. q8h or 90 mg i.v. q12h × 2–3 weeks
Herpes simplex[a,c,d]	Acyclovir 200–800 mg 5/day × 7–14 days	Foscarnet 40 mg/kg i.v. q8h × 3 weeks
Adenovirus	NA[e]	
Rotavirus[f]	NA	
Astrovirus	NA	
Picobirnavirus	NA	
Bacterial:		
Salmonella sp.[a,d]	Ceftriaxone 1–2 g q.d. × 7 days Ciprofloxacin 500 mg b.i.d. × 7 days	Amoxicillin 1 g t.i.d. × 7–14 days Trimethoprim-sulfamethoxazole 1 DS b.i.d. × 10–14 days
Shigella flexneri[a,f]	Ciprofloxacin 500 mg b.i.d. × 3–7 days Ampicillin 500 mg q.i.d. × 5 days	Trimethoprim-sulfamethoxazole 1 DS b.i.d. × 3–14 days Ceftriazone 1–2 g q.d. × 7 days
Campylobacter jejuni[a,d]	Erythromycin 500 mg q.i.d. × 7 days Ciprofloxacin 500 mg b.i.d. × 7 days	Tetracycline 500 mg q.i.d. × 7 days
Mycobacterium avium complex[a,d]	Clarithromycin 500–1000 mg b.i.d. Rifabutin 300 mg p.d., and Ethambutol 15–25 mg/kg q.d.	Azithromycin 500 mg q.d.
prophylaxis:	Clarithromycin 500 mg q.d. or Azithromycin 500 mg q.d.	Ribabutin 300 mg q.d.
Clostridium difficile Bacteriosis[f]	Metronidazole 500 mg p.o. t.i.d. × 7–10 days Ciprofloxacin 500 mg b.i.d. × 4 weeks	Vancomycin 125 mg p.o. q.i.d. × 10–14 days
Fungal:		
Histoplasma capsulatum[a]	Amphotericin B 0.7 mg/kg i.v., q.d. × 3–14 weeks (or liposomal AmB 3 mg/kg/day i.v.) (maintenance phase up to 12 weeks)	Itraconazole 200 mg b.i.d. × 4–8 weeks[g]

All treatments are per os unless otherwise indicated. Treatment of all diarrheal syndromes should include supportive care, particularly repletion of fluids and electrolytes. Use of loperamide, lomotil (diphenoxylate-atropine) or paregoric an option with noninflammatory untreatable chronic infections, such as adenovirus, astrovirus, picornavirus, and calicivirus. Use of effective antiretroviral therapy is important initial and supportive therapy for many opportunistic infections, including *Cryptosporidium*, *Microsporidium*, herpes simplex virus, *M. avium* complex, etc.

a Chronic suppression at reduced dosage may be necessary.

b Double-strength tablet.

c Reduce dosage for decreased creatinine clearance.

d Resistance may develop; susceptibility testing necessary.

e Not available.

f Pathogenicity in human immunodeficiency virus type 1 infection under investigation.

g Also maintenance regimen.

b.i.d., twice a day; DS, double-strength; i.v., intravenous; p.o., orally; q8h, 8-hourly; q12h, 12-hourly; q.d., each day; q.i.d., four times a day; t.i.d., three times a day.

Mycobacterium avium complex

Mycobacterium avium complex (MAC) comprises two acid-fast, obligate, intracellular bacteria: *M. avium* and *M. intracellulare*. The gastrointestinal tract is the likely portal of entry for MAC, and exposure is common in all persons, as the organisms are ubiquitous in the environment. In immunocompetent hosts, MAC is not an enteric pathogen, but immunosuppressed HIV-1-infected patients ($CD4^+$ T cells < 100 cells/mm^3) are highly susceptible to infection. Macrophages are an important reservoir for the bacteria, and during HIV-1 infection macrophages phagocytose MAC, but appear unable to kill them. The organism up-regulates the macrophage HIV-1 production in dual-infected cells [79] and alters macrophage function [80].

MAC is the most common cause of systemic bacterial infection in HIV-1-infected persons in the United States. MAC is much less common in Africa and Haiti. End organ involvement and bacteremia usually do not occur until the number of circulating $CD4^+$ T cells declines to below 100 cells/mm^3. Gastrointestinal tract disease, which is usually a manifestation of disseminated infection, may be associated with diarrhea, abdominal pain, malabsorption, weight loss, and fever, with or without night sweats [81,82]. Concomitant hepatomegaly or splenomegaly with anemia as the result of MAC infection is often present. The numerous mycobacteria typically present in the gastrointestinal tract mucosa suggest that MAC contributes to the associated gastrointestinal symptoms. Endoscopic abnormalities are nonspecific and include erythema, friability, erosions, and fine white nodules. Occasionally, an inflammatory mass, which can be mistaken for a tumor, is the major gastrointestinal manifestation. The small intestine is reported to be involved more often than the colon [81], but this may reflect endoscopic access. Histological examination shows diffuse infiltration of the lamina propria by macrophages filled with bacilli. Granulomas are usually absent or poorly developed, possibly because of the impaired chemotactic activity of monocytes in patients with AIDS [83].

Diagnosis

The diagnosis of MAC is based on the identification of typical acid-fast organisms in stool or gastrointestinal biopsy specimens (fixed and touch preparations) [81,82]. Culture of gastrointestinal tissue may increase the positivity rate compared to acid-fast staining alone [84]. Isolation and speciation are achieved by culture of organisms from stool and biopsy specimens. Although the incidence of both pulmonary and extrapulmonary *Mycobacterium tuberculosis* infections is increased among HIV-1-infected persons, intestinal involvement is uncommon.

Treatment

Although initial trials of anti-tuberculosis agents proved disappointing, improved results with newer multi-drug regimens provide reason for cautious optimism in treating MAC [85]. Combination regimens have produced more sustained benefit, but such regimens are expensive, have adverse effects, and are often difficult to tolerate. The current recommended three-drug therapy is two anti-mycobacterial agents, including a macrolide azole agent and rifabutin, and a third agent, such as ethambutol [86]. For prophylactic therapy when the $CD4^+$ T-cell number falls below 50 cells/mm^3, clarithromycin or clarithromycin plus rifabutin are effective; MAC disease occurred in 9% and 7% of patients treated with clarithromycin alone or with combination therapy, respectively [87]. For patients on HAART who respond with an increase in the number of $CD4^+$ lymphocytes to more than 100 cells/mm^3 for more than 3–6 months with sustained suppression of HIV-1 plasma RNA for the same period, prophylactic therapy may be discontinued.

Clostridium difficile

The gram-positive bacterium *C. difficile* is an important pathogen in the differential diagnosis of diarrhea in persons with HIV-1 infection. During the first decade of HAART, *C. difficile* emerged in the United States as the most common bacterial cause of diarrhea among HIV-1-infected persons [32]. Risk factors for *C. difficile*-associated diarrhea in HIV-1-infected persons include recent antimicrobial therapy (particularly clindamycin and pyramethamine) and hospitalization [88], risk factors similar to those in immunocompetent persons without HIV-1 infection [89]. Failure to generate specific antibodies to *C. difficile* toxins, important mechanisms of defense, and resolution of infection, may be compromised during HIV-1 infection [90] and predispose severely immunocompromised persons with HIV-1 infection to *C. difficile*-associated diarrhea. Importantly, the rate for *C. difficile*-associated diarrhea is significantly higher for persons with more advanced HIV-1 infection, particularly persons with clinical AIDS [32]. Although asymptomatic carriage occurs, *C. difficile* infection in HIV-1-infected persons is commonly associated with profound watery diarrhea, abdominal pain and tenderness, fever, leukocytosis, and the presence of fecal leukocytes and occult blood. Infection with *C. difficile* is among the most common bacterial causes of diarrhea in HIV-1-infected persons in the United States [32,91] but the severity of the clinical illness and the response to therapy appear to be similar to those of seronegative subjects [92,93]. Thus, *C. difficile* is a frequent, but nonopportunistic, pathogen associated with diarrheal illness in HIV-1-infected patients.

Diagnosis

The diagnosis of *C. difficile*-associated diarrhea or colitis is based on the presence of diarrhea during antimicrobial use and the detection of either *C. difficile* toxin or organisms in stool or endoscopically confirmed pseudomembranous colitis. The potential usefulness of stool culture is underscored by the higher rates of positive stool cultures (90%–97%)

compared with positive toxin assays (70%–73%) in HIV-1-seronegative subjects with *C. difficile* infection [48,94], although asymptomatic carriage is well-described. Newer toxin assays show increased sensitivity for toxins A and B and are capable of detecting toxin A variant strains of *C. difficile* [95].

Treatment

Metronidazole and vancomycin are highly effective for the treatment of *C. difficile* infection in HIV-1-infected persons (Table 104.5).

Enteroaggregative bacteria

Intestinal infection with enteroaggregative *E. coli* has been reported in HIV-1-infected persons in the United States and Africa [96,97]. The bacterium adheres to enterocytes predominantly in the colon and ileum, where focal areas of epithelial cell injury (effacement, displaced microvilli, necrosis) are associated with attached bacteria. Accumulation of inflammatory cells in the epithelium or lamina propria is minimal or absent. Enteroaggregative *E. coli* have been identified more frequently in stool from HIV-1-infected adults with diarrhea than in stool from asymptomatic seropositive subjects [98]; the mechanism of the diarrhea is not known. Therapeutic eradication of the bacteria with ciprofloxacin has been associated with restoration or improvement of diarrheal symptoms [99].

Protozoan infections

Cryptosporidium parvum

Cryptosporidium parvum is a unicellular, spore-forming coccidian protozoan taxonomically related to *Isospora*, *Toxoplasma*, *Sarcocystis*, and *Cylospora* [100]. Early in the AIDS epidemic, cryptosporidia were present in approximately 20% of AIDS patients with diarrhea in the United States [28,29,101] but in as many as 55% of AIDS patients in developing countries such as Zaire and Haiti [35]. Persistent infection occurs predominantly in HIV-1-infected patients with more than 200 cells/mm^3 [102,103]. A relatively common cause of self-limited mild diarrhea in immunocompetent persons [101,104,105], cryptosporidiosis-associated disease may be characterized by chronic, debilitating diarrhea in patients with AIDS. The diarrhea can be voluminous, nonbloody, and watery; abdominal cramps, anorexia, malaise, and weight loss are also prominent symptoms. Asymptomatic carriage may occur [106], but symptoms of dehydration and wasting are more common. Malabsorption of both fat and carbohydrate is associated with cryptosporidiosis. Rarely, *Cryptosporidium* may spread to the biliary tract, leading to biliary tract obstruction (see below). The parasite has been identified throughout the gastrointestinal tract, developing within a parasitophorous vacuole beneath the epithelial cell membrane but outside the cytoplasm. Despite its ability to cause severe disease, the spectrum of *Cryptosporidium*-associated symptoms is broad, may vary over time, and is strongly influenced by the level of immunosuppression [107].

Diagnosis

Infection with *Cryptosporidium* is easily identified in stool microscopically with a modified acid-fast stain. Concentration of stool by zinc sulfate or sucrose flotation enhances the detection of rare or infrequent oocysts during intermittent shedding. A single stool examination was sufficient to diagnose 96% of cases in one retrospective study [108]. When *Cryptosporidium* is suspected despite negative stool examination, hematoxylin & eosin-stained tissue specimens obtained by endoscopy can reveal the parasite. Biopsy of the terminal ileum has a higher sensitivity (91%) than that of the duodenum (53%) for the detection of the parasite [109]. Sensitive and specific antigen detection assays for stool are also commercially available.

Treatment

Despite anecdotal reports of successful treatment of cryptosporidiosis in HIV-1-infected persons with spiramycin, bovine colostrum, transfer factor, somatostatin, and zidovudine, therapy with these agents has not been consistently effective, and controlled clinical trials have not yet been performed. Paromomycin, a nonabsorbable aminoglycoside, was shown to be no more effective than placebo for HIV-1-associated cryptosporidiosis [109]. Nitazoxamide, which has induced parasitological cure and complete resolution of the diarrheal syndrome in a high proportion of patients [110,111], is a reasonable first-line agent for HIV-1-infected patients with cryptosporidiosis. Somatostatin may reduce the frequency and volume of *Cryptosporidium*-associated diarrhea, but therapy is complicated by the requirement that the drug be given chronically several times daily and either intravenously or subcutaneously. As noted above, HAART appears to decrease the incidence, severity, and duration of *Cryptosporidium* infections [61,112].

Microsporidia

Microsporidia are spore-forming, obligate intracellular protozoa that infect the small intestine (*Enterocytozoon bieneusi*), small intestine with dissemination (*Septata intestinalis*), liver (*Encephalitozoon cuniculi*), and cornea (*Encephalitozoon hellem*). The parasite has distinctive ultrastructural features; many organisms at different stages of development can be identified in the same enterocyte, causing cytopathic effect [113] (Fig. 104.1). *Enterocytozoon bieneusi* infects only enterocytes in the small intestine. *Septata intestinalis*, which is ultrastructurally distinct from *E. bieneusi*, also infects epithelial cells but can penetrate into the lamina propria, infect macrophages and disseminate to other organs such as the kidney [114–116]. Microsporidia were initially identified exclusively in HIV-1-infected persons, but the parasite has been diagnosed in seronegative liver and renal transplant recipients [117,118]

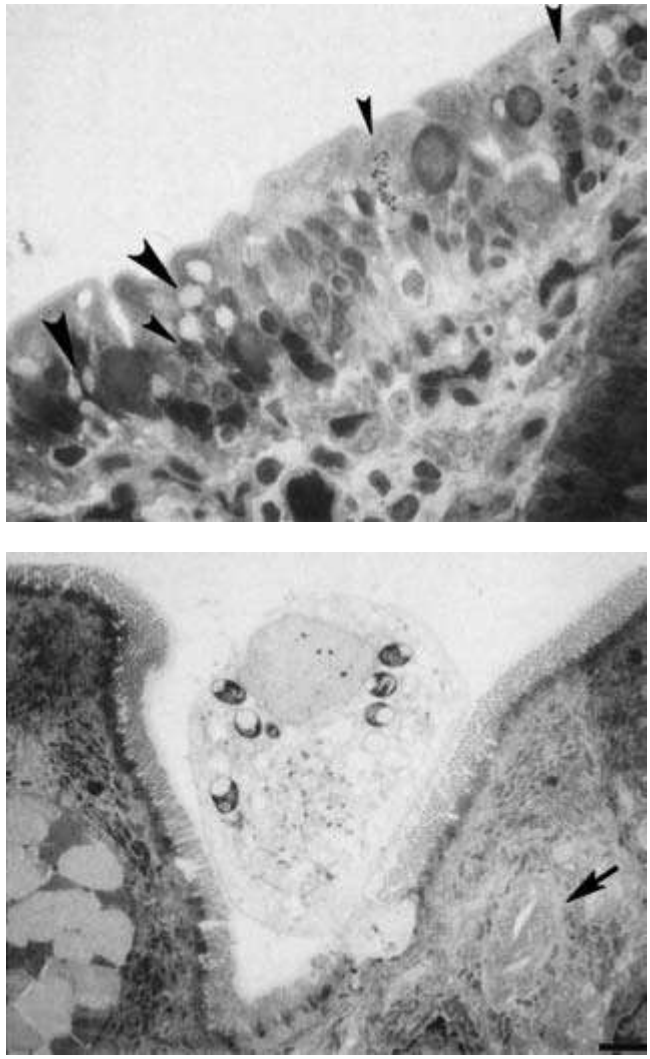

Figure 104.1 **(a)** Densely stained microsporidial spores are detected in the cytoplasm of several epithelial cells by light microscopic examination of an intestinal biopsy from a patient with microsporidiosis (semithin plastic section; methylene blue-azure II and basic fuchsin stain, original magnification × 630). **(b)** Electron micrograph shows a necrotic intestinal enterocyte containing six microsporidial spores in the final stage of being sloughed into the lumen (original magnification × 10 000). Courtesy of Dr Jan M. Orenstein.

and infrequently in immunocompetent persons [119]. In resource-limited settings in South America, intestinal microsporidiosis is associated with poor sanitary conditions as well as low (< 400) $CD4^+$ cells/mm^3 [120].

Infection with the parasite is associated with chronic, watery, nonbloody diarrhea of variable severity, frequently with substantial fluid and weight loss. Microsporidiosis has been reported to cause 40%–50% of the cases of unexplained diarrhea among patients with HIV-1 infection [121], but microsporidia infection is not invariably accompanied by diarrhea [122]. *Enterocytozoon bieneusi* is equally common in HIV-1-infected patients with and without diarrhea. The highest density of *E. bieneusi* is located in the jejunum [123], where the parasite infects enterocytes and may cause villus atrophy. The organism has been associated with AIDS-related biliary tract disease, including acalculous cholecystitis, cholecystitis with cholelithiasis, and cholangitis, presumably by ascending the proximal small intestine to infect the biliary tract, as discussed below.

Diagnosis

The diagnosis of microsporidiosis is based on the identification of the parasite in small intestinal tissue or fluid. Biopsies should be taken at the most distal site, where the parasite burden is the highest. Because of their small size, poor staining qualities, and minimal associated inflammation, microsporidia were formerly diagnosed exclusively by transmission electron microscopy. Microsporidia can be identified by light microscopy in semi-thin plastic sections of small intestinal biopsies stained with methylene blue-azure II-basic fuchsin, touch preparations of mucosa stained with Giemsa, and stool specimens stained with a small modified trichrome (chromotrope 2R) stain. One light microscopic technique appears to obviate the need for electron microscopy in over 50% of cases, and a combination of any two techniques obviates the need in more than 75% of cases [38]. A rapid fluorescence technique based on Uvitex 2B binding to chitin, a component of the spore wall, is reportedly effective for detecting microsporidia [121]. However, because Uvitex 2B binds to any chitin-containing microorganism, morphological evaluation may be necessary to confirm the diagnosis. A polymerase chain reaction assay using primers for the ribosomal RNA gene of *E. bieneusi* and *S. intestinalis* to identify microsporidia in tissue specimens is not widely available [124].

Treatment

Curative therapy for microsporidiosis is not available. Albendazole, a benzimidazole derivative related to mebendazole, induces improvement in or resolution of symptoms in patients with microsporidia infection (Table 104.5) and appears to be more effective against *S. intestinalis* than *E. bieneusi* [116,125]. Patients on HAART have shown both improvement and resolution of diarrheal symptoms due to microsporidia infection. Nitozoxanide is another therapy with potential efficacy for these infections.

Isospora belli

Isospora belli is an obligate, intracellular coccidian parasite that resembles Cryptosporidium in its life cycle and small intestinal habitat. In the early years of the AIDS epidemic, *I. belli* was identified in fewer than 3% of AIDS patients in the United States but in up to 15% of patients in developing nations such as Haiti and Zambia [43,126]. Isosporosis is typically a chronic illness characterized by profuse, nonbloody,

watery diarrhea that may be indistinguishable from the diarrheal illness associated with cryptosporidia and microsporidia infections. Weight loss of at least 10% may occur during the months before diagnosis [43,127]. Nausea and abdominal cramps also typically accompany the illness; fever and vomiting are less frequent. In Haitian patients, dehydration requiring hospitalization has been reported in nearly 50% of patients [43]. Steatorrhea and eosinophilia may also be present. Histology usually shows inflammation associated with some degree of villus atrophy; in contrast to *Cryptosporidium*, *I. belli* may invade the mucosa. Although concentrated in the small intestine, *I. belli* has been identified throughout the gastrointestinal tract and has been associated with biliary disease, specifically acalculous cholecystitis. Rarely, the organism disseminates to extraintestinal sites, including mesenteric and tracheobronchial lymph nodes.

Diagnosis

The diagnosis of *I. belli* is established by the identification of the typical highly refractile, spherical oocysts (containing two sporoblasts) in stool using the modified Kinyoun acid-fast stain. Stool concentration may be necessary to detect infrequent or rare oocysts.

Treatment

The most effective therapeutic agent for *I. belli* is trimethoprim-sulfamethoxazole (Table 104.5). Because infection recurs in as many as 50% of cases following treatment, prolonged or repeat therapy with this agent may be required to suppress clinical illness.

Cyclospora cayetanensis

Cyclospora are obligate, intracellular coccidian parasites with morphological and staining characteristics of a cyanobacterium-like organism [128,129]. The spherical cyst-like organisms measure 8–10 μm in diameter and on modified acid-fast staining resemble *Cryptosporidium*. The *Cyclospora* oocyst has two sporocysts, each containing two sporozoites, distinguishing the parasite from the larger *I. belli* [128]. Both sexual and asexual forms occur in small intestinal epithelial cells, suggesting that the organism can complete its life cycle in a single host. The organism has been identified in persons with diarrhea from Latin America (primarily Peru), the Caribbean, Southeast Asia, Eastern Europe, and the United States. In immunocompetent persons, the diarrhea is typically abrupt in onset, watery, and prolonged (lasting a mean of 6 weeks) but self-limited. The histopathology of the small intestine in patients with *Cyclospora*-associated diarrhea shows acute and chronic inflammation, surface epithelial disarray, and varying degrees of villous atrophy and crypt hyperplasia. *Cyclospora* infection in persons with AIDS is associated with prolonged or relapsing diarrhea and weight loss as great as 10% [129,130]. Diffuse, cramping abdominal pain accompanies the diarrhea in over half of patients and fever in a third. *Cyclospora* outbreaks have been associated with contaminated drinking water and imported raspberries [131,132].

Diagnosis

Modified Kinyoun stain is used to identify *Cyclospora* oocysts in a concentrated fresh stool sample; oocysts appear as 8–9-μm, acid-fast, granular spheres.

Treatment

Trimethoprim-sulfamethoxazole appears to be effective therapy for *Cyclospora* infection [129] (Table 104.5).

Giardia lamblia and *Entamoeba* species

In immunosuppressed HIV-1-infected patients, *Giardia lamblia* does not cause more frequent or severe infection than in seronegative persons and responds appropriately to antimicrobial therapy with metronidazole [133]. A retrospective case review showing that a small proportion of HIV-1-infected persons exposed to *Entamoeba histolytica* develop *E. histolytica* colitis or liver abscess warrants prospective study [134].

Viral infections

Cytomegalovirus

CMV is a double-stranded DNA virus in the herpesvirus group. After initial infection, which in immunocompetent persons is usually asymptomatic, the virus enters a latent, nonproductive phase in circulating mononuclear cells [135]. Consequently, serious organ disease due to CMV infection is extremely rare in immunocompetent persons, with only 34 such cases having been reported by 1996 [136]. When the host becomes immunosuppressed, virus is reactivated, leading to replication and cell lysis. Replication occurs in the nuclei of permissive cells, and virus accumulates in nuclear and cytoplasmic inclusions, producing cell enlargement and the characteristic nuclear and cytoplasmic inclusions. In the immunosuppressed host, CMV has been detected in intestinal mononuclear, epithelial, endothelial, and smooth muscle cells [137]. The local inflammatory response appears to involve CMV-induced release of proinflammatory cytokines [138,139].

The clinical manifestations of CMV disease in the gastrointestinal tract include esophagitis, gastritis, small intestinal enteritis, and, less frequently, acalculous cholecystitis, papillary stenosis, sclerosing cholangitis, pancreatitis, and appendicitis. Colitis appears to be the most common manifestation of enteric CMV disease [46,140]; among AIDS patients with colitis or enteritis, CMV has been identified in biopsies in 45% of patients [46]. CMV colitis is characterized by diarrhea, fever, and weight loss. Abdominal pain and hematochezia are also frequently present and help distinguish CMV colitis from the protozoan diarrheal illnesses described above. The colon appears to be particularly susceptible to
