Figure 104.2 (a) Endoscopic visualization of mucosal ulceration and inflammation in a patient with cytomegalovirus colitis. Light microscopic view of a colon biopsy from the same patient shows ulceration and hemorrhage **(b)** and infiltration by inflammatory cells **(c)**, many containing cytomegalic inclusions. (**b**,**c**, hematoxylin & eosin: **b**, original magnification × 30; **c**, original magnification × 62). From Smith et al. [138], with permission from the American Society for Clinical Investigation.

progression to ischemic necrosis and perforation during CMV infection. Regardless of whether diarrhea is present, CMV-associated disease of the biliary tract (usually without icterus or pruritus) should be included in the differential diagnosis of abdominal pain, nausea, and vomiting in patients with AIDS. Endoscopic findings that suggest CMV-induced disease range from localized hyperemia through hemorrhagic erythema to superficial or deep ulceration (Fig. 104.2).

Diagnosis

CMV should be suspected when endoscopic or colonoscopic visualization show discrete, often hemorrhagic, erosions or ulcerations with normal intervening mucosa in an HIV-1-infected patient. Colitis may be patchy in approximately 40% of cases and involve only the right colon or cecum in 18% [140], underscoring the importance of colonoscopy in the diagnostic evaluation of colitis in an HIV-1-infected patient. The diagnosis of CMV gastrointestinal disease is established by the histopathological identification of large (cytomegalic) mononuclear, endothelial, or epithelial cells containing intranuclear or cytoplasmic inclusions with surrounding inflammation [141] and confirmed by immunocytochemical staining, *in situ* hybridization, or DNA amplification.

Treatment

Ganciclovir and foscarnet are the drugs of choice for the treatment of CMV (Table 104.5). Because these agents are virustatic and not virucidal, recurrent CMV disease is common after the cessation of therapy. Ciclovovir is a new nucleoside analogue with potent prolonged *in vivo* activity against CMV in patients with CMV retinitis, but the agent has not been studied in patients with gastrointestinal CMV disease. The availability of valganciclovir, an oral form of ganciclovir with substantial bioavailability (≈ 50%–60%), has been of substantial value in controlling CMV disease in a range of immunocompromised patients, both for primary and maintenance therapy.

Herpes simplex virus

Herpes simplex virus (HSV) is also a double-stranded DNA virus in the herpesvirus group. Latent in sensory nerve ganglia, HSV reactivation during immunosuppression leads to spread of the virus along sensory nerve pathways to mucocutaneous sites where the virus next spreads among epithelial cells by lysis, releasing virions that infect and lyze adjacent cells. Reactivation increases HIV-1 levels in plasma. Gastrointestinal HSV disease is confined to the perianal region, distal rectum, and esophagus. The perianal lesions range from small, unrecognized mucosal ulcers or fissures to chronic, deeply ulcerated necrotic lesions that cause localized pain but not diarrhea [142]. Involvement of the rectum (proctitis) is often associated with perianal disease. Proctitis manifests as severe anorectal pain, tenesmus, constipation, inguinal lymphadenopathy, and, less often, difficulty with urination and sacral paresthesias. Such symptoms may also be associated with proctitis in seronegative homosexual men. Diarrhea is not associated with typical proctitis, although the mucopurulent discharge may be misinterpreted as diarrhea. Proctocolitis, which occurs when the proctitis extends proximally into the distal sigmoid colon, can cause mild diarrhea associated with hematochezia, but the predominant symptoms are generally those of the proctitis. Overall, HSV proctocolitis is a rare cause of diarrhea in HIV-1-infected persons [132].

Diagnosis

Anoscopy and sigmoidoscopy are required to diagnose HSV proctitis and proctocolitis, respectively. Typical lesions begin as small vesicles, these progress to erosions that coalesce

into diffuse ulcers. Diagnosis is predicated on the cytological identification of intranuclear (Cowdry type A) inclusions in cells within the lesion and is confirmed by virus isolation.

Treatment

Acyclovir and related agents are the drugs of choice (Table 104.5) for HSV infection. Recurrent HSV is common so long-term suppressive therapy may be necessary. Despite increased use of suppressive acyclovir therapy, increased acyclovir-resistant HSV (type 2) has not been reported [143].

Adenovirus

Adenovirus is a double-stranded non-enveloped DNA virus that is well recognized as a cause of morbidity and mortality in immunocompromised persons such as recipients of stem cell and organ transplants [144]. In HIV-1-infected patients, adenovirus has been isolated from various body sites and may induce hepatic necrosis, but intestinal involvement is rare. In the United States, adenovirus excretion is equally common in HIV-1-infected patients with and without diarrhea [45]. In contrast, 23% of Australian HIV-1-infected patients with diarrhea reportedly excrete adenovirus compared to 5.4% without diarrhea [44]. Adenovirus has been identified with transmission electron microscopy and culture in inflamed colonic tissue of patients with AIDS with chronic, watery, nonbloody, nonmucoid diarrhea [145]. Weight loss was also a prominent symptom. Endoscopically, the colonic mucosa showed areas of discrete, often raised, erythematous lesions that were several millimeters in diameter. Light microscopy showed chronic inflammation surrounding epithelial cells containing large, amphophilic intranuclear, but not cytoplasmic, inclusions. Adenovirus appeared to infect only epithelial cells, especially goblet cells, sparing lamina propria cells, which are frequent targets of CMV. At the ultrastructural level, adenovirus was associated with degeneration, death, and focal necrosis of infected epithelial cells, some of which had been extruded into the lumen (Fig. 104.3). Although adenovirus can cause pathogenic changes in the colonic mucosa, a causal relationship between adenovirus and diarrhea has not been established. An array of antiviral agents has been used in immunocompromised patients with adenovirus infection, but only treatment with cidofovir, a cytosine analogue with nephrotoxicity, has been associated with a significant reduction in adenovirus-associated mortality [144].

Astrovirus, picobirnavirus, and rotavirus

Prospective evaluation of chronic diarrhea in HIV-1-infected persons indicated an association between the presence of astrovirus and picobirnavirus and diarrhea in HIV-1-infected persons [146], but further epidemiological and clinical studies are needed to define the role of these viruses in HIV-1 disease. Rotavirus is not associated with diarrhea in HIV-1-infected patients in the United States [29,45,146] or Africa

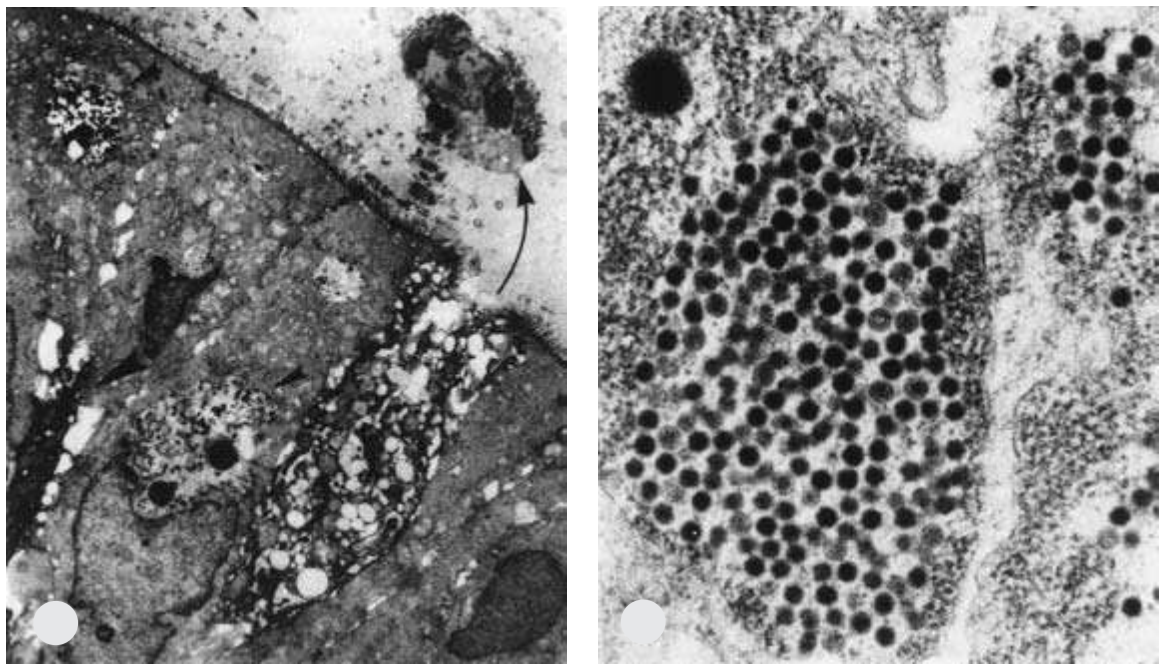

Figure 104.3 **(a)** Transmission electron micrograph of a colonic biopsy specimen from a patient with adenovirus colitis shows a nucleus from a necrotic enterocyte extruded into the lumen (arrow). Adjacent cells have foci of disrupted cytoplasm containing secondary lysosomes (original magnification × 34 000). **(b)** Higher magnification of a portion of the extruded nucleus in **(a)** shows numerous hexagonal virions characteristic of adenovirus (original magnification × 49 000). From Janoff et al. [145], with permission from Elsevier.

(Zaire) [147,148], but it is the predominant virus detected in the stools of Australian HIV-1-infected homosexual men with diarrhea [44] and is common in HIV-1-infected adults with diarrhea in Peru [31]. These findings suggest geographic variation in the prevalence of rotavirus-associated diarrhea in HIV-1-infected persons, but additional studies are needed.

Fungal infections

Histoplasma capsulatum

Histoplasma capsulatum is a dimorphic fungus that exists as a mycelial form with septate branching hyphae that contain readily airborne and infectious spores and a yeast form present in tissue macrophages. The organism is endemic in the central region of the United States and some tropical, subtropical areas, including Central and South America, where bird excrement provides microfoci of infection.

Disseminated *H. capsulatum* is the most common of the endemic mycoses in HIV-1-infected persons with $CD4^+$ T-cell counts less than 100 cells/mm^3 who reside in endemic areas [149–151]. Gastrointestinal involvement generally reflects disseminated disease, which is primarily the result of reactivation of quiescent infection. Among persons with disseminated *H. capsulatum*, gastrointestinal involvement has been detected in approximately 70% of cases by evaluation of biopsy specimens, but gastrointestinal symptoms are present in only about 10% of patients [152]. Symptoms include diarrhea, weight loss, fever, and abdominal pain, which often accompany respiratory symptoms. *Histoplasma* skin lesions are uncommon in patients in the United States but occur in up to 85% of patients in Brazil, possibly as the result of genetic differences between the *H. capsulatum* strains in the United States and those in Latin America [153]. Most patients with gastrointestinal manifestations of *H. capsulatum* have colonic involvement. Colonoscopy in such patients may show inflammation, ulcerations, or fungating mass lesions.

Diagnosis

The histological examination of Giemsa-stained sections shows small yeast-like cells within macrophages or histiocytes. When infection is intense, the organism is not difficult to identify. However, the diagnosis of histoplasmosis is established by culture. Serological detection of complement fixing antibodies to *H. capsulatum* mycelial antigens provides supportive evidence for infection.

Treatment

Amphotericin B is the drug of choice for disseminated histoplasmosis (Table 104.5). The recommended initial course of therapy in HIV-1-infected persons is amphotericin B 0.5–0.7 mg/kg intravenously daily for 4–8 weeks, or longer, depending on the clinical response. Long-term therapy with amphotericin B (50–80 mg intravenously every 2 weeks) is also highly effective in suppressing relapses after initial treatment [150]. Itraconazole may also be effective for milder disease and chronic suppressive therapy. The role of caspofungin acetate, a fungicidal echinocandin, is under evaluation.

Biliary disorders

HIV-1-infected persons and patients with AIDS may develop cholecystitis and cholangitis as the result of cholelithiasis and the same gram-negative bacteria that cause biliary tract disease in seronegative persons. In addition, HIV-1-infected persons are susceptible to a spectrum of biliary tract disorders related to opportunistic pathogens (Tables 104.2 and 104.3) and lymphoma, referred to collectively as the AIDS cholangiopathy. The disorders associated with infection include acalculous cholecystitis, biliary tract obstruction due to stenosis of the distal common bile duct, and narrowing and irregularity of the intrahepatic and extrahepatic bile ducts, associated most commonly with *Cryptosporidium* or CMV in the gallbladder and bile duct papillary stenosis and sclerosing cholangitis [154,155]. Other opportunistic pathogens implicated etiologically in biliary tract disease include *Enterocytozoon bieneusi*, *Septata intestinalis*, *Isospora belli*, and *Pneumocystis carinii* [156–158]. Endoscopic retrograde cholangiography is the most effective diagnostic tool for evaluating the extent of the disease and excluding other processes, such as cholelithiasis. Sphincterotomy is an effective therapeutic modality for relieving the obstruction and pain. Rarely, HIV-1-associated non-Hodgkin lymphoma may cause sclerosing cholangitis, resulting in a similar clinical syndrome. The long-term prognosis of HIV-1-infected patients with hepatobiliary cholangiopathy is similar to that of patients without the syndrome.

Pancreatitis

Pancreatitis is an important gastrointestinal complication in patients with HIV-1 infection. Autopsy studies have identified an array of opportunistic pathogens, including viruses (CMV and HSV), fungi (*Cryptococcus neoformans*), bacteria (*Mycobacterium*) and protozoa (*Toxoplasma gondii*), as well as neoplasms (non-Hodgkin lymphoma and Kaposi sarcoma), in the pancreas [159]. Although CMV and tuberculosis may cause clinical pancreatic disease [160,161], most infectious and neoplastic processes involving the pancreas in HIV-1-infected persons are subclinical. In contrast, drug-induced pancreatic disease is a common cause of clinical pancreatitis among persons with HIV-1 infection [162]. The two most common drugs implicated in HIV-1-associated pancreatitis are pentamidine and dideoxyinosine. Pentamidine-induced disease, which may occur with either inhaled or parenterally administered drug, causes mild to severe, and even fatal, pancreatitis. Dysregulation of glucose metabolism is common in this setting, although pentamidine itself may

cause dysregulation in the absence of clinical pancreatitis [163]. Dideoxyinosine therapy may induce pancreatitis in up to 10% of patients [164,165]; occasionally, dideoxyinosine-induced pancreatitis is fatal. Low-level hyperamylasemia (serum amylase level less than three times the upper limit of normal) may occur in patients with AIDS despite the absence of underlying pancreatic disease [166,167]. After antiretroviral drug-induced pancreatitis has been excluded, the presentation, evaluation, and management of acute pancreatitis in HIV-1-infected persons are similar to that in seronegative persons.

Gastrointestinal bleeding

Upper gastrointestinal bleeding is uncommon in HIV-1-infected persons, who are as likely to bleed from HIV-1-related etiologies as non-HIV-1 causes. The most common HIV-1-related causes are viral esophagitis, gastroduodenal lymphoma, and MAC disease of the proximal small intestine [168,169]. Regarding viral esophagitis, HSV is the most common cause of bleeding. Unlike HIV-associated CMV colitis, CMV esophagitis is rarely associated with significant bleeding [170,171].

Similar to the low prevalence of bleeding in the upper gastrointestinal tract, intestinal and colonic bleeding in HIV-1-infected persons is uncommon. Although the differential for lower gastrointestinal tract bleeding includes traditional causes, opportunistic infections are, in our experience, the most common etiology for bleeding from the lower gastrointestinal tract in persons with HIV-1 infection. In contrast to the esophagus, where HSV is the most common infection associated with bleeding, lower tract bleeding is more frequently caused by CMV [172]. Typically, bleeding is slow and associated with abdominal pain and diarrhea; bleeding from CMV colitis is rarely severe, but may be associated with intestinal perforation [173]. Other HIV-1-related causes of lower gastrointestinal tract bleeding include non-Hodgkin lymphoma, unusual infections, such as *Histoplasma capsulatum*; and idiopathic ulcerations. The approach to diagnosis and management of gastrointestinal bleeding in HIV-1-infected patients is similar to that in seronegative persons.

Gastrointestinal neoplasms

Kaposi sarcoma and non-Hodgkin lymphoma are the most common gastrointestinal neoplasms associated with HIV-1 infection. Recognized formerly as a rare neoplasm of the skin in older men of Jewish or Eastern European origin, Kaposi sarcoma emerged in the 1980s as one of the most common opportunistic processes heralding the AIDS epidemic. Although the incidence of Kaposi sarcoma has declined dramatically in recent years [174], the tumor remains an important gastrointestinal malignancy in HIV-1-infected, immunosuppressed, homosexual and bisexual men; Kaposi sarcoma occurs rarely in those who acquire HIV-1 intravenously or through heterosexual contact. Human herpesvirus 8 is etiologically linked to the development of Kaposi sarcoma [175–178]. Histologically, the tumor is characterized by the proliferation of spindle-shaped endothelial cells in a stroma of proliferating abnormal vessels, fibroblasts, and infiltrating leukocytes. The local presence of angiogenic growth factors, human herpesvirus 8, and impaired immunosurveillance mechanisms appear to predispose the gastrointestinal tract to Kaposi sarcoma formation.

Endoscopically, Kaposi sarcoma begins as a small, hyperpigmented plaque or macule, progressing to a violaceous nodule and eventually a tumor-like mass. In the early stage of the AIDS epidemic, visible tumor was identified in the gastrointestinal tract in 40%–50% of patients with AIDS [179,180]. Although the tumor may be more common in the upper tract, Kaposi sarcoma occurs throughout the gastrointestinal tract. Oropharyngeal Kaposi sarcoma is highly suggestive of upper tract involvement. The vast majority of persons with enteric Kaposi sarcoma are asymptomatic; consequently, therapy for gastrointestinal lesions is rarely necessary. Interferon-α and doxorubicin treatment have been associated with tumor regression [181,182]. Unusually large tumors that cause bleeding, obstruction, or perforation can be treated emergently with radiation therapy. Antiretroviral therapy likely has a positive impact on the incidence and progression of this tumor.

Among HIV-1-infected patients with non-Hodgkin lymphoma, the most frequently involved gastrointestinal sites are the colon (46%), ileum (39%), and stomach (23%) [183]. Symptoms associated with gastrointestinal lymphoma include abdominal pain, weight loss, obstruction, and bleeding [183–185]. The presence of latent and replicating Epstein–Barr virus DNA in the lymphomas of patients with AIDS suggests that lymphoproliferative lesions in the gastrointestinal tract could represent the outgrowth of Epstein–Barr virus-transformed or modulated mucosal B cells [186]. Chemotherapy, surgery, radiotherapy, or combination therapy have not substantially improved the survival of HIV-1-infected persons with gastrointestinal lymphoma.

Anorectal disease

Anal complications associated with HIV-1 disease include perianal condylomata, infection, fissure, fistula, and squamous cell carcinoma. These complications occur predominantly in HIV-1-infected homosexual and bisexual men. Homosexual men, particularly those who are HIV-1-positive, have a high incidence of anal infection with human papillomavirus (HPV) [187], which has been implicated as a risk factor for anal condylomata and anal squamous cell carcinoma

[188]. The link between HPV, particularly types 16 and 18, and anal carcinoma may be through the ability of the virus to induce local dysplasia in a high proportion (15%) of immunosuppressed, HIV-1-infected homosexual men [189]. The role of cytological screening for HPV and local HPV-related lesions is under investigation and is recommended by some authorities. Although quadrivalent vaccine against papillomavirus has been shown to reduce the incidence of HPV-associated anogenital diseases in young women [190], the vaccine has not yet been evaluated for efficacy in men, particularly those with HIV-1 infection. Perianal infection is commonly caused by HSV, but involvement of the rectal mucosa is rare (see section on herpes simplex virus). Rectal complications of HIV-1 infection include nonspecific proctitis (rectal inflammation in the absence of an identifiable pathogen [191]) and infectious proctitis due to *Chlamydia trachomatis*, *Treponema pallidum*, *Neisseria gonorrhoeae*, or HSV [192]. Perirectal abscess in HIV-1-infected persons is often idiopathic [193] or may be associated with HPV [194,195] or CMV [196] infection.

The initial presentation of anorectal disease includes dyschezia (pain on defecation), bleeding, drainage from the anal canal, palpable mass, and sepsis syndrome (local pain and fever). Dyschezia usually results from ulcerative lesions in the anal canal caused by infection, abscess, fissure, hemorrhoids, or neoplasm. A palpable mass suggests neoplasm. When the mass is tender and accompanied by fever, perirectal abscess is the most likely differential diagnosis. Tenesmus, urgency, and frequent small-volume stools suggest proctitis. Perianal drainage is usually caused by a fistulous tract or, less commonly, severe proctitis. Careful inspection, palpation of the perianal area and anal canal, and visualization of the rectum are mandatory components of the anorectal evaluation. Biopsy is performed for microbiological evaluation and histological examination, and computerized tomography is helpful for staging neoplasms and evaluating perirectal abscess. Symptomatic treatment, pathogen-specific antimicrobial therapy, and surgery in selected patients [197] are effective for most nonmalignant anorectal lesions. Anorectal neoplasms are treated with radiation therapy, chemotherapy, and, when localized, surgical resection [198].

Other immunodeficiency states

Hematopoietic stem cell transplant recipients

Gastrointestinal disease is an important cause of morbidity and mortality in recipients of allogeneic hemopoietic stem cell or solid organ transplants. Hematopoietic stem cell transplantation, in which recipients receive donor bone marrow or peripheral blood stem cells, is performed to cure hematological malignancies and certain nonmalignant disorders of blood cells. Along with donor progenitor cells, $CD4^+$ and $CD8^+$ αβ T cells are transferred into the recipient. Although the αβ T cells reconstitute T-cell immunity and eradicate malignant cells in the recipient, they also attack recipient nonself antigens in host tissues in a process known as graft-versus-host disease [199]. Stem cell transplantation is further complicated by the need for immunosuppressive therapy, which impairs immune reconstitution and increases the risk of infection. Consequently, Recipients of stem cell transplantation experience more frequent and more severe gastrointestinal disease than solid organ (kidney, liver, heart, lung) recipients, mainly as the result of graft-versus-host disease and more profound neutropenia and cell-mediated immune deficiency.

Acute graft-versus-host disease occurs usually within 3–4 weeks after transplantation, and often involves the skin, liver, lung, and intestine. Intestinal disease presents as severe watery diarrhea that may be accompanied by anorexia, nausea, vomiting, abdominal pain, and gastrointestinal bleeding. [200,201]. The latter may involve the esophagus, stomach, and small intestine and is usually caused by CMV infection, graft-versus-host disease itself, and vascular ectasias (stomach) [202]. When rash and jaundice are also present, graft-versus-host disease is likely. However, because the gastrointestinal symptoms are nonspecific, the diagnosis of acute graft-versus-host disease is confirmed by the presence of single-cell apoptosis of the epithelium, crypt distortion, and abscesses with minimal or no inflammation [203,204] (Fig. 104.4) in endoscopically obtained biopsy specimens. Chronic graft-versus-host disease, which is less common than acute graft-versus-host disease, typically occurs 3–12 months after marrow transplantation. The major gastrointestinal manifestations of chronic graft-versus-host disease include mucositis of the oral cavity, dysphagia as the result of esophageal desquamation and stricture, and small bowel dysmotility associated with bacterial overgrowth [205–207].

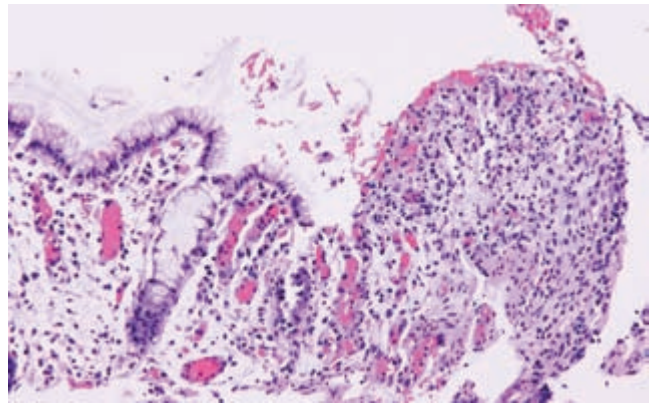

Figure 104.4 Intestinal biopsy from a patient with graft-versus-host disease shows frequent epithelial cell apoptosis in the basal zone of the crypts, crypt degeneration and loss, edema, and ulceration (× 20). Courtesy of Dr N. Jhala.

Solid organ transplant recipients

In contrast to recipients of hemopoietic stem cell transplants, the gastrointestinal complications of solid organ recipients are mainly infections. Among lung transplant recipients, for example, 51% developed operative and nonoperative gastrointestinal complications [208]. The nonoperative complications included esophagitis, gastritis, colitis, enteritis, peptic ulcer disease, gastrointestinal bleeding, cholecystitis, diverticulitis, and Ogilvie syndrome; 65% of these processes were caused by infections, excluding cholecystitis and diverticulitis.

The frequency and severity of infections diagnosed in transplant recipients varies considerably, depending on the factors listed in Table 104.6. As discussed above, stem cell transplant recipients have more frequent and more severe enteric infections than solid organ transplant recipients. The amount of time elapsed since the transplant operation also has an important influence on the development of gastrointestinal complications [208–210]. During the first month after transplantation, marrow recipients are vulnerable to fungal and bacterial infections as a consequence of cytoreductive therapy, whereas during the same period organ recipients are more susceptible to the complications of surgery and surgery-related procedures. One month after marrow transplantation, acute graft-versus-host disease should be in the differential diagnosis of diarrhea. Between 1 and 6 months after transplantation, both stem cell and solid organ recipients are highly susceptible to gastrointestinal infections caused by viruses, including CMV, adenovirus, HSV, varicella zoster virus, and rotavirus (children); fungi, such as *Candida* spp. and *Histoplasma capsulatum* [211,212]; bacteria, particularly *Clostridium difficile*; and, less commonly, parasites, such as *Cryptosporidium* [213–215]. CMV infection is an important complication of transplantation because it affects up to 25% of organ transplant recipients [216–218], causes major gastrointestinal morbidity in such patients [219], and is associated with a marked increase in mortality among transplant recipients [220]. The presence of graft-versus-host disease in hemopoietic stem cell transplant recipients also significantly increases the risk of CMV disease, and, conversely, CMV infection increases the risk of graft-versus-host disease [221]. After 6 months, stem cell and organ transplant recipients may develop gastrointestinal manifestations of chronic graft-versus-host disease. Susceptibility to an array of enteric pathogens also increases after 6 months (Table 104.7). In addition, recipients of bone marrow or organ transplants are susceptible to the gastrointestinal complications of chemotherapy, radiation therapy, and typhlitis.

Table 104.6 Factors that influence the development and management of gastrointestinal infections in transplant recipients

Type of transplantation
Hematopoietic stem cell vs solid organ
Time since transplantation
< 1 month: fungal and bacterial infections
~ 1 month: acute graft-versus-host disease
1–6 months: viruses, especially cytomegalovirus
> 6 months: chronic graft-versus-host disease; enteric pathogens; chemotherapy and radiation therapy complications
Prevalence of potential pathogens in the environment
Prevalence of latent infections in the donor and host before transplantation
Especially cytomegalovirus
Level of immunosuppression
Profound suppression/hematopoietic stem cell recipients
Type of immunosuppressant (less with cyclosporine [ciclosporin rINN])
Availability of diagnostic tests
Transplant center vs community hospital
Rigor of diagnostic evaluation for enteric pathogens
Transplant center vs community hospital

Pathogens endemic to certain regions may be more common in transplant recipients. For example, *Strongyloides stercoralis*, which is more prevalent in the southeastern part of the United States, has been reported in renal transplant recipients in that region [222,223] and in Brazil. Similarly, *Histoplasma capsulatum* infections are more common in transplant recipients in the midwestern and southeastern part of the United States. Although amebiasis and malaria are common in immunocompetent persons in the tropics, *Entamoeba histolytica* and *Plasmodium falciparum* infections appear not to be more common in organ (renal) transplant recipients in the same region [224]. In addition, the prevalence of latent infections in the donor and host before transplantation strongly influences the development of infection by the same pathogen after transplantation. For example, among bone marrow and liver transplant recipients, the highest rate of symptomatic CMV infection occurs when the donor is seropositive and the recipient is initially seronegative and the lowest rate when both the donor and recipient are seronegative [225–227]. The relative risk for death 1 year after transplantation is also affected by the presence of latent CMV infection. One year after liver transplantation, the highest relative risk (4.56-fold) for death occurred when the donor was CMV-seropositive and the recipient was CMV-seronegative [220]. In addition, the more profound the immunosuppression, as in bone marrow transplant recipients, the more severe the infections. The rate of infectious complications is also affected by the type of immunosuppressive regimen. Compared with recipients of heart transplants, who received conventional immunosuppressive therapy, recipients who received cyclosporine (ciclosporin rINN) had lower rates of complications and morbidity due to CMV and HSV [217].

Table 104.7 Gastrointestinal pathogens in immunocompromised subjects[a]

Site	Viral	Parasitic	Fungal	Bacterial
Oral cavity	Herpes simplex virus Epstein–Barr virus		*Candida* sp.	
Esophagus	Herpes simplex virus Cytomegalovirus		*Candida* sp. *Histoplasma capsulatum*	*Mycobacterium tuberculosis* *Pseudomonas aeruginosa*[b] *Lactobacillus acidophilus*[b] *Streptococcus* sp.[b] *Staphylococcus* sp.[b] *Bacillus* sp.[b]
Small intestine	Cytomegalovirus Rotavirus Adenovirus Coxsackievirus Astrovirus Calicivirus Picobirna/parvovirus	*Giardia lamblia* *Cryptosporidium parvum* *Strongyloides stercoralis* Microsporidia[b], *Cyclospora*[c]	*Aspergillus* sp. *Histoplasma capsulatum*	*Salmonella* sp. *Campylobacter* sp. *Aeromonas* sp.
Colon	Cytomegalovirus Herpes simplex virus[c]	*Entamoeba histolytica*	*Histoplasma capsulatum* *Aspergillus* sp.	*Clostridium difficile* *Campylobacter* sp. *Shigella* spp.
Liver	Cytomegalovirus Herpes simplex virus		*Candida* sp.	*Mycobacterium* sp.

a Excluding persons infected with human immunodeficiency virus type 1.
b Rare.
c Proctitis.

Finally, the availability of diagnostic tests and the rigor with which patients are evaluated for enteric pathogens have strong influences on the detection of gastrointestinal pathogens in immunocompromised patients.

Neutropenia

A reduction in the absolute number of circulating neutrophils to less than 1000 cells/mm^3 is associated with increased susceptibility to infections. When the level of neutrophils declines to less than 500 cells/mm^3, normal host defense against endogenous gastrointestinal flora is substantially impaired. Neutropenic patients are far more likely to present with fever and sepsis from gram-negative bacteria and fungemia than with primary gastrointestinal syndromes. Importantly, the intestinal flora is the source of most bacteremias in neutropenic patients [228,229], and approximately 15% of such patients have polymicrobial infections [230]. Data suggest that the risk for the development of bacteremia in neutropenic patients colonized with potential gram-negative bacterial pathogens is up to 200-fold greater than the risk in noncolonized patients; for this reason, some clinicians advocate surveillance cultures of mucosal and other surfaces [228]. However, the clinical responses to the presence of such colonization are not well characterized nor have the beneficial consequences been validated.

Three gastrointestinal syndromes may complicate neutropenia: oral infections, anorectal infections, and enterocolitis. The oral manifestations of neutropenia include gingivitis, periodontitis, and oral ulcers. These complications occur most commonly when the neutrophil count declines below 500 cells/mm^3 [231–234]. Anorectal disease is an important and life-threatening complication of neutropenia and is discussed above (see section on anorectoal disease).

Necrotizing enterocolitis typhlitis, also referred to as neutropenic enterocolitis and the ileocecal syndrome, is an infrequent complication of chemotherapy-induced neutropenia in patients with leukemia or lymphoma [235,236]. The etiology of necrotizing enterocolitis is thought to be the consequence of chemotherapy-induced mucosal injury that promotes local infection by enteric bacteria [230]. In a minority of cases, the neutropenia is caused by the hematological disease itself, such as aplastic anemia and multiple myeloma. Necrotizing enterocolitis has been associated with *Clostridium septicum* sepsis in several cases [237], suggesting that local infection with this gas gangrene-producing bacterium may be involved in the pathogenesis of the syndrome

in some patients. Typically, patients present with right lower quadrant pain, diarrhea, lower gastrointestinal bleeding, and fever. The syndrome should be recognized early because the characteristic cecal inflammation may progress to life-threatening necrosis and perforation, in which case surgical intervention is imperative. A clinical condition consistent with necrotizing enterocolitis also has been reported in HIV-1-infected patients, except that neutropenia may be absent [238]. However, some patients with necrotizing enterocolitis, particularly those with HIV-1 infection, have been managed conservatively with broad-spectrum antibiotics, bowel rest, fluids, and close radiographic and computed tomographic monitoring [237].

Small bowel transplantation, 2628

Immunodeficiency diseases and the gut

The gut epithelium represents the largest surface area where the host interacts with the environment, separating the lumen from the internal milieu. This structure is vulnerable to access by infectious material. Strategic mucosal defense requires a precisely regulated mucosal immune system supported by a variety of nonimmunological protective factors, such as gastric acidity, digestive enzymes, peristalsis, mucus secretion, epithelial cell regeneration, and the mutually competitive interactions of the gut flora [1].

The importance of effective mucosal defense is underscored by the frequency of mucosal infections. Mucosal infections are a major cause of mortality in children under 5 years of age; *Helicobacter pylori* is the most common infection in humans; and diarrheal infectious disease alone accounts for about 3 million deaths among children worldwide annually. A wide spectrum of opportunistic infections occurs in patients with immune deficiencies. Patients with milder, more selective forms of immune deficiency (e.g., immunoglobulin A [IgA] deficiency), however, are frequently free of infectious complications. The nonimmunological mucosal defenses, as well as the functional reserve of the immune system, probably account for the resistance of these patients to infection. In addition, immune deficiencies may predispose to autoimmunity and opportunistic cancers.

Classification of immunodeficiency disorders

Primary immune deficiencies (congenital or acquired) are rare and result from intrinsic defects in the cellular or secretory components of the immune system, whereas secondary immune deficiencies are common and may arise from a diversity of conditions, including immunomodulatory drugs, protein-calorie malnutrition, protein-losing enteropathy, cancer, and age-related immune senescence. The most important secondary immunodeficiency disorder is acquired immunodeficiency syndrome (AIDS), which is discussed separately in Chapter 104.

Considerable advances in basic immunology have been made by studying the primary immunodeficiencies. About 100 of these are recognized and in most cases the genetic and molecular basis is understood [2–4]. The current classification of primary immunodeficiencies is summarized in Table 105.1. Several new conditions are included, such as the hereditary periodic fevers including familial Mediterranean Fever, because these conditions have been shown to be inborn errors in the regulation of innate immunity [5]. It is noteworthy that the list of molecular defects is increasing as new immune deficiencies in mice with various targeted gene deletions are discovered. Conditions of particular gastroenterological importance are discussed in this chapter. A representative list of opportunistic or recurring gastrointestinal infections that commonly occur in patients with different primary immunodeficiency syndromes is shown in Table 105.2.

X-linked (congenital or Bruton) hypogammaglobulinemia

This is the prototypic syndrome of a pure B-cell or humoral immunodeficiency. It occurs in males, although rarely in females. The genetic defect results from mutations in the cytoplasmic signal transduction molecule, Bruton tyrosine kinase (Btk) [2,3]. Serum levels of all immunoglobulins are less than 100 mg/dL, and there is an inability to make functional serum antibodies. An intrinsic B-cell defect with a maturation block in preB-cell to B-cell differentiation is present [2,3]. The preB cells fail to express functional immunoglobulin M (IgM) on the cell surface because of an inability to rearrange immunoglobulin light-chain genes. PreB cells are

Table 105.1 Categories of primary immunodeficiency syndromes

Category	Examples/Comments
Combined T-cell and B-cell deficiencies	Highly heterogeneous and result in a severe clinical phenotype
Predominantly antibody defects	B-cell defects that usually present with recurrent bacterial infections, e.g., X-linked agammaglobulinemia, common variable immunodeficiency, selective immunoglobulin deficiency
Defined syndromes of immunodeficiency with nonimmunological features including syndromes with defects in DNA repair	For example, Wiskott–Aldrich syndrome, ataxia-telangiectasia, chronic mucocutaneous candidiasis
Diseases of immune dysregulation	Defects in apoptosis leading to lymphoproliferation or autoimmunity
Defective phagocytic cell function/number	For example, chronic granulomatous disease, leukocyte adhesion deficiency
Defects in innate immunity	Mannose-binding protein deficiency
Autoinflammatory disorders and Blau syndrome (NOD2 mutations)	Includes the hereditary periodic fever syndromes, e.g., familial Mediterranean fever
Complement deficiencies	Defects in early components of pathway are associated with lupus-like autoimmunity; defects in terminal components are linked with infections (notably *Neisseria*); defects in the lectin pathway initiated by mannose-binding lectin are associated with recurring infections; defects in C1 esterase inhibitor cause hereditary angioedema.

Table 105.2 Gastrointestinal infections in immunocompromised hosts

Site	Infection	Examples/comment
Oroesophageal	Candidiasis	*C. albicans* and non-*albicans*
	CMV	
	HSV	
Gastric	*Helicobacter pylori*	
	Adenovirus	
	Bacillary angiomatosis	*Bartonella* spp.
Small intestine	Adenovirus	
	Mycobacteria (tuberculosis and atypical mycobacteria)	
	Fungi	*Histoplasma capsulatum*
	Parasites	*Giardia lamblia*
		Cryptosporidium spp.
		Microsporidium spp.
		Isospora belli
		Entamoeba spp.
		Strongyloides stercoralis
Large bowel	CMV	
	Clostridium difficile	
	Tuberculosis	
	Spirochesosis	*Brachyspira* spp.

CMV, cytomegalovirus; HSV, herpes simplex virus.

present in bone marrow in normal numbers, but circulating B cells are absent and peripheral lymphoid tissue is hypoplastic with rare or absent plasma cells. The thymus and T-cell function are normal.

Patients usually present with recurrent pyogenic infection during infancy (after the disappearance of maternal immunoglobulin G [IgG]) or in early childhood. The respiratory and gastrointestinal tracts are the most frequent sites of infection

[6,7]. Gastrointestinal infections occur in 30% of patients [7]. These are usually infectious diarrheal episodes commonly caused by *Campylobacter* species. Giardiasis can cause severe mucosal damage and steatorrhea in these patients, but it is responsive to therapy and is surprisingly uncommon. Perirectal abscess formation and small bowel bacterial overgrowth may also occur. In asymptomatic patients, rectal biopsy characteristically reveals an absence of plasma cells and a mild lamina propria neutrophil infiltrate with early crypt abscess formation. This may lead to an erroneous diagnosis of chronic colitis. Although cellular immunity is normal, these patients are susceptible to certain virus infections, notably hepatitis and enteroviral infections including chronic meningoencephalitis and poliomyelitis [6]. There is an increased risk of malignancy, particularly lymphomas and leukemias. Treatment consists of parenteral immunoglobulin replacement.

Selective IgA deficiency

Selective IgA deficiency is the most common primary immune deficiency with a variable prevalence in different ethnic groups, in the range of 1 in 500 to 1 in 3000 [2,3]. Its occurrence is usually sporadic, but occasionally familial. Most patients lack both serum and secretory IgA1 and IgA2. The basic defect is not known, and there may be etiological heterogeneity as well as clinical heterogeneity. Occasionally IgA deficiency may be transient, and a large number of drugs including phenytoin, penicillamine, and sulfasalazine have been linked with reversible deficiency [8].

Although IgA deficiency is associated with a wide range of conditions, mainly recurrent infections of mucosal tissues and autoimmune disorders (Table 105.3), a majority of IgA-deficient individuals are asymptomatic and are free of a complicating disease. The associations with celiac disease and pernicious anemia may be partly the result of a common linkage of IgA and such diseases with human leukocyte antigen (HLA) B8/DR3. In one case, IgA deficiency with malabsorption and villous atrophy was associated with an IgG antibody to intestinal epithelial cells and a favorable response to cyclophosphamide [9].

When infections occur in IgA deficiency, they are usually recurrent bacterial and viral sinopulmonary disorders; the gastrointestinal tract is seldom involved. Giardiasis occurs in IgA-deficient subjects, but unlike pan-hypogammaglobulinemia, its frequency is probably the same as in the general population. When persistent or recurrent infections occur, it suggests associated immunological defects, such as deficiencies of IgG subclasses, particularly IgG2 and IgG4, which have been found in some patients with IgA deficiency [8]. Jejunal biopsy is usually morphologically normal in selective IgA deficiency, with an absence or paucity of IgA-producing cells and an increase in IgM-secreting cells. This may be an important compensatory response because IgM can bind to secretory component.

Table 105.3 Disorders that may occur in association with immunoglobulin A (IgA) deficiency

Gastrointestinal manifestations and associations:
None (usually)
Infections, especially giardiasis (may not be any more common than in general population)
Gluten-sensitive enteropathy (IgA prevalence in celiac disease is 1:50)
Pernicious anemia
Vitamin B-12 deficiency secondary to bacterial overgrowth
Intrinsic factor deficiency
Nodular lymphoid hyperplasia
Food allergy (increased serum antibodies to food antigens but clinical disease apparently rare)
Crohn's disease (IgA deficiency prevalence reported to be 1:73)
Disaccharidase deficiencies (unproven association)
Extraintestinal manifestations and associations of IgA deficiency:
Non-organ-specific autoimmune disorders (e.g., collagen vascular diseases)
Atopy
Malignancy (lymphomas, carcinoma reported but extent of risk is unclear and probably low)
Risk of anaphylaxis if given IgA-containing solutions, including blood

Most patients with IgA deficiency require no treatment. Replacement with serum IgA is futile because only locally produced IgA is transported into the lumen. Parenteral administration of IgA-containing blood products may be contraindicated because of the risk of anaphylactic reactions due to anti-IgA antibodies. Whether patients should be screened routinely for IgA antibodies is unclear because the titer of antibody is not well correlated with the risk of anaphylaxis to blood products. Prophylactic IgG therapy for IgA deficiency is either hazardous or ineffective, although some clinicians have reported a beneficial effect [10]. Patients with recurring infections should be screened for IgG subclass deficiency, but can usually be managed with prophylactic or periodic antibiotics without requiring immunoglobulin replacement.

Secretory component deficiency

Secretory component is a glycoprotein receptor on the basolateral surface of the mucosal epithelial cell that is essential for the transepithelial delivery of IgA and IgM from the lamina propria to the lumen. Deficiency of secretory component is rare, and affects not only lumenal IgA levels but also any compensatory effects of IgM. In isolated case reports, it has been associated with intestinal candidiasis and diarrhea [11,12]. Administration of IgA-rich bovine colostrum may result in symptomatic improvement.

Common variable hypogammaglobulinemia ("acquired" or late-onset hypogammaglobulinemia)

Common variable hypogammaglobulinemia is second to selective IgA deficiency as the most common primary immuno-

deficiency in adults and is the most common symptomatic primary immunodeficiency. Its variable phenotype and immunological heterogeneity have hindered identification of the underlying defect(s). It comprises a group of disorders in which there is defective terminal differentiation of B lymphocytes in the majority of patients and probably represents distinct diseases with differing immunopathogeneses [8,13]. Most cases are sporadic, but the condition can be familial.

Clinically, common variable hypogammaglobulinemia may be similar to X-linked (Bruton) agammaglobulinemia, but differences include the later age of onset, less severe infections, the fact that the lymphoid tissue (tonsils, lymph nodes, and spleen) may be normal or enlarged, and the association with autoimmune and granulomatous disease in some patients [13]. The chronic granulomatous disorder resembles the noncaseating lesions of sarcoidosis but is distinct from the chronic granulomatous disease associated with defects in neutrophil function. Patients usually present in the second or third decade with either recurrent respiratory tract infections (most commonly pneumococci, staphylococci, and *Haemophilus influenzae*) or diarrhea and steatorrhea (Table 105.4). Up to 60% of patients have chronic recurrent diarrhea; two-thirds of these have malabsorption. Enteroviral infection of the central nervous system is rare. Giardiasis is a particularly common cause of symptoms in common variable hypogammaglobulinemia, but unlike in normal individuals, it may be persistent and lead to extensive mucosal damage with steatorrhea and malabsorption [14]. It is usually reversible with appropriate anti-*Giardia* therapy. Other parasitic infections, such as cryptosporidiosis and strongyloidiasis, occur less commonly. Patients with common variable hypogammaglobulinemia are susceptible to bacterial enteric pathogens including *Shigella*, *Salmonella*, and *Campylobacter* species (*C. jejuni* and *C. fetus*), which occasionally may mimic ulcerative colitis. Bacterial overgrowth may also occur.

In some patients, sprue-like changes may be found on intestinal biopsy, and giardiasis should always be ruled out. True gluten-sensitive enteropathy has not been well documented in common variable hypogammaglobulinemia. Jejunal biopsy generally shows a paucity of plasma cells in the lamina propria, unlike sprue. When the mucosa is flat, an enteropathy refractory to a gluten-free diet is likely. Other intestinal inflammatory disorders that have been reported in common variable hypogammaglobulinemia include Crohn's disease and idiopathic ulcerative jejunitis [8,13,14].

In one-third of patients with common variable hypogammaglobulinemia, atrophic gastritis and pernicious anemia develop, with an increased risk of gastric cancer [15]. Differences from classic pernicious anemia include the absence of mucosal plasma cells, lack of autoantibodies, involvement of the entire gastric mucosa, and normal rather than elevated serum gastrin levels. Defective gastrin release in response to bombesin or food has been reported as a highly specific means of distinguishing common variable hypogammaglobulinemia from other forms of hypogammaglobulinemia [16].

Chronic liver disease has occurred in 10%–15% of patients with common variable hypogammaglobulinemia due to hepatitis C or another non-A, non-B hepatitis virus acquired from previous plasma infusion. It has not been a problem with the use of the licensed intravenous immunoglobulin preparations. Other potential causes of hepatobiliary disease include autoimmune hepatitis, cholelithiasis, sclerosing cholangitis, and biliary cryptosporidiosis.

Nodular lymphoid hyperplasia is frequently found in common variable hypogammaglobulinemia, but it does not occur in X-linked hypogammaglobulinemia and is rare in selective IgA deficiency. The lymphoid nodules usually involve the small intestine but may affect the colon, rectum, and stomach. The nodules consist of large lymphoid follicles with germinal centers within the lamina propria. Plasma cells are either absent or markedly diminished. The lymphoid hyperplasia is thought to reflect B cells unable to undergo full differentiation to immunoglobulin-screening plasma cells. Localized forms of nodular lymphoid hyperplasia may occur in apparently immunocompetent individuals, particularly in the large bowel. In children and adolescents, a self-limited lymphoid hyperplasia in the terminal ileum is a frequent radiological finding. Although there is an increased incidence of lymphomas in common variable hypogammaglobulinemia, intestinal nodular lymphoid hyperplasia per se does not appear to be premalignant. Almost all patients with common variable hypogammaglobulinemia require parenteral immunoglobulin replacement therapy.

Table 105.4 Disorders that may occur in association with common variable hypogammaglobulinemia

Gastrointestinal:
Giardia lamblia infection
Small bowel bacterial overgrowth
Viral gastroenteritis (e.g., rotavirus)
Infectious diarrheas (*Campylobacter*, *Salmonella*, *Shigella*)
Secondary disaccharidase deficiency
Pernicious anemia, atrophic gastritis, gastric carcinoma
Gluten-sensitive sprue
Sprue refractory to gluten-free diet
Autoimmune enteropathy
Nodular lymphoid hyperplasia
Extraintestinal:
Increased incidence of generalized lymphomas
Increased incidence of autoimmune diseases
Recurrent respiratory tract infections
Chronic granulomatous disorder

Congenital thymic hypoplasia (DiGeorge syndrome)

DiGeorge syndrome, the most common contiguous-gene deletion syndrome in humans, is associated with defective formation of the third and fourth pharyngeal pouches during embryogenesis. It is characterized by absent T-lymphocyte function, hypoparathyroidism, and cardiovascular abnormalities, particularly of the aortic arch. The syndrome is the result of deletions in the short arm of chromosome 22, and several studies have implicated the transcription factor *TBX1* as a key candidate gene, although other genes have a contributory role [17]. Presentation is usually with neonatal tetany or seizures. There may be unusual facies. Other structures developing at the same stage of embryogenesis also may be affected; for example, esophageal atresia may occur. Other gastrointestinal manifestations include candidiasis, chronic diarrhea, and partial villous atrophy with malabsorption.

Chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis represents a spectrum of clinical syndromes in which there is an increased susceptibility to chronic *Candida* infections of the mucosa, skin, and nails [18]. Most patients become infected with other organisms in addition to *Candida* species. There is variability in the mode of inheritance (autosomal recessive and sporadic), age of onset (early or late), and frequency of association with autoimmune disorders such as pernicious anemia and endocrinopathies, including Addison disease, diabetes mellitus, hypothyroidism, and hypoparathyroidism. The latter subset of patients comprise the autoimmune polyglandular syndrome type 1 or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, a recessive disorder caused by mutations in the *AIRE* (autoimmune regulator) gene [19].

Most patients develop infections before the age of 5 years, but some may have the onset of *Candida* infections in adulthood. *Candida* infection most commonly involves the oropharyngeal mucosa, but involvement of the esophagus also may occur and may be present in the absence of oral lesions. Esophageal strictures, nutritional deficits, and the endocrinopathies account for most of the morbidity and mortality associated with the disease. More commonly the skin lesion is a sharply demarcated scaly erythematous macular rash; less commonly it may be granulomatous. Nails of the hands and toes are frequently involved. The *Candida* infection is usually superficial, involving the epidermis, but does not penetrate the dermis or become systemic.

A variety of defects in T-cell function have been described. Autoantibodies may precede the development of endocrinopathies. The development of endocrine abnormalities is often insidious, and it is important to evaluate patients regularly for endocrine function. Chronic mucocutaneous candidiasis does not respond well to topical antifungal therapy; systemic agents are usually required. Immunological reconstitution with therapeutic benefit has been achieved with transfer factor alone or in combination with fetal thymus transplantation.

Severe combined immunodeficiency syndromes

Severe combined immunodeficiency (SCID) is the most severe form of primary immunodeficiency and represents a syndrome caused by several distinct genetic defects, characterized by profound deficiency of T- and B-lymphocyte function and sometimes of natural killer cells [2,3,20]. At least seven different forms of SCID are recognized in humans, and the genetic defect responsible has been identified in some of these. The most common form of SCID (60% of cases) is X-linked. It is caused by defective cytokine signaling as the result of a mutation of the common cytokine receptor γ-chain, a component of the receptors for interleukin-2 (IL-2), IL-4, IL-7, IL-9, and IL-15. The remaining SCID cases are autosomal recessive, most of them as the result of deficiencies of purine-degradation enzymes, such as adenosine deaminase and nucleoside phosphorylase. Mutations in the gene for Janus kinase 3 (*Jak3*), which transduces the receptor signal from the common γ-chain, also cause autosomal recessive SCID, as do mutations in the gene encoding the γ-chain of the IL-7 receptor. Another variant of SCID is reticular dysgenesis, in which there is a coexisting deficiency of granulocytes.

Clinically, the syndrome presents in early infancy with severe life-threatening infections, chronic diarrhea, malabsorption, and failure to thrive. Graft-versus-host disease (GVHD) as the result of transplacentally acquired maternal lymphocytes may occur during the neonatal period. There is increased susceptibility to viral infections, including cytomegalovirus, and chronic rotavirus infection may account for the intractable diarrhea in some patients. Jejunal biopsy reveals absent plasma cells, and in some cases there is partial villous atrophy with numerous periodic acid–Schiff-positive macrophages in the lamina propria. A high incidence of gastroesophageal reflux has been reported in association with SCID [21]. Without a bone marrow graft, the clinical course is rapidly fatal. Results with gene therapy have been encouraging, despite suboptimal initial results in adenosine deaminase deficiency [22].

Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome is an X-linked recessive condition of variable severity characterized by eczema, thrombocytopenia, recurrent infections, progressive defects in T-cell function, and a poor antibody response to polysaccharide antigens. Atopy with elevated immunoglobulin E (IgE) levels is common. The underlying defective gene encodes the Wiskott–Aldrich syndrome protein, a member of a family of proteins responsible for signal transduction from the cell membrane to the actin cytoskeleton in hemopoietic cells [23]. Gastrointestinal manifestations include hemorrhage, chronic diarrhea, malabsorption, and nonspecific colitis. Without treatment, patients die from hemorrhage or the develop-

ment of Epstein–Barr virus-induced lymphoma. Stem cell transplantation is the only curative therapy for Wiskott–Aldrich syndrome, particularly if it is performed within the first 5 years of life [24].

Ataxia telangiectasia

Ataxia telangiectasia is an autosomal recessive, multisystem disorder. There are defective DNA repair mechanisms, cell cycle abnormalities, frequent chromosomal abnormalities, increased sensitivity to ionizing radiation, and predisposition to cancer. The gene responsible for this syndrome (*ATM*) encodes a product similar to phosphatidylinositol-3-kinases, which are involved in signal transduction and cell-cycle control [24]. The most prominent clinical features are progressive cerebellar ataxia, oculocutaneous telangiectasia, chronic recurrent sinopulmonary infections, and a high incidence of malignancy. The immune deficiency is variable and affects both cellular and humoral elements. IgA deficiency occurs in over 50% of patients and may be associated with IgG2 subclass deficiency. Malignancies are the most common cause of death. They are usually lymphoreticular, but adenocarcinomas also occur. Other gastrointestinal complications are not common in ataxia telangiectasia. Mild abnormalities of liver function may occur, and levels of α-fetoprotein are elevated.

Phagocytic cell defects: chronic granulomatous disease

Intrinsic defects in neutrophils, monocytes, and macrophages include several disorders of cell locomotion, adhesion, chemotaxis, killing, and metabolism [25]. Numerically, the most important of these and the most frequently encountered in gastroenterology is chronic granulomatous disease.

Chronic granulomatous disease represents a group of disorders of phagocytic cell oxidative metabolism. There are several variants of the basic defect in oxidase function, and more than one mode of genetic transmission [25]. In its classic form, inheritance is X-linked and is caused by mutations in the gene coding for the β-subunit of cytochrome β558, which is the catalytic redox entity of nicotinamide adenine dinucleotide phosphate (NADPH) and responsible for generating superoxide in phagocytes. More rarely, chronic granulomatous disease may be transmitted in an autosomal recessive or dominant pattern caused by mutations in the β-subunit of cytochrome β558 or in cytosolic proteins required for the activation of NADPH.

The respiratory burst associated with stimulation of phagocytes is lacking. This results in defective microbicidal activity because of the failure to generate toxic oxygen metabolites such as hydrogen peroxide. There is a markedly increased susceptibility to pyogenic and fungal infections, including staphylococci, *Serratia marcescens*, *Salmonella*, gram-negative enterococci, and *Candida* and *Aspergillus* species. There is particular susceptibility to infections with catalase-positive organisms. In contrast, catalase-negative organisms such as pneumococci, streptococci, and lactobacilli are not major pathogens in chronic granulomatous disease because they do not destroy their endogenous hydrogen peroxide and thereby contribute to their own demise [25,26].

The condition classically presents during infancy, although variants of the disease may present later. Every organ is vulnerable to infection, and the associated granulomas occur throughout the body. They consist of plasma cells, lymphocytes, macrophages, and occasional multinucleated giant cells without organisms. A second type of granuloma occurs in which hyphal elements of fungi are found in giant cells. Pigmented, lipid-bearing tissue histiocytes are also found.

Hepatic and gastrointestinal disorders are a prominent feature of chronic granulomatous disease. Hepatomegaly is common, with liver abscess formation in more than 30% of patients. *Staphylococcus aureus* is the most common organism in the abscesses, which often require surgery and may be recurrent.

Gastrointestinal presentations of chronic granulomatous disease may mimic Crohn's disease, and commonly include chronic gingivitis and stomatitis, perianal abscesses with fistulae, *Salmonella* gastroenteritis, diarrhea, and malabsorption. The characteristic granulomas and pigmented histiocytes may be found in patients with no gastrointestinal symptoms. In some patients the granulomatous reaction leads to stricture formation, most commonly in the gastric antrum. Although surgical treatment may be required, resolution of strictures following antibiotic therapy is well known, and aggressive antimicrobial therapy is the treatment of first choice.

Complement deficiency: hereditary angioedema (C1 esterase inhibitor deficiency and nondeficiency syndromes)

Deficiency states involving individual complement proteins are associated with a high incidence of infectious (particularly neisserial) and autoimmune disorders [2]. Deficiency of the complement regulator C1 esterase inhibitor is the most common complement deficiency state and the major one in which gastrointestinal symptoms are prominent.

Hereditary angioedema is characterized by recurrent, self-limited attacks of circumscribed nonpitting, subepithelial edema in the skin and mucous membranes [27,28]. The skin lesions are painless, and, unlike urticaria, pruritus is absent. The onset of symptoms is variable, although most patients have their first episode in childhood. A positive family history is common. Attacks may develop over hours and may last from hours to several days, often precipitated by minor local trauma, dental extractions, infections, and surgery. There is frequently initial awareness of a tingling sensation in the affected area, and a faint macular or serpiginous erythema may precede the swelling. The most serious manifestation is laryngeal edema, which may lead to fatal airway obstruction. Gastrointestinal involvement is common and includes colicky abdominal pain, vomiting, and watery diarrhea. Significant

intestinal fluid loss can occur, leading to hypotension and shock. Fever and leukocytosis are notably absent. The abdomen may be tender but not rigid. Bowel sounds may be increased. Barium studies during an attack may show the "stacked coin" appearance of mucosal edema. The lesions consist primarily of circumscribed edema without inflammatory cellular infiltrates. The edematous segment of bowel can cause intussusception. When gastrointestinal symptoms precede other manifestations, or occur in isolation, the diagnosis is often delayed, and many of these patients have been subjected to unnecessary abdominal surgery.

Hereditary angioedema is transmitted in an autosomal dominant manner. In approximately 85% of patients, the levels of C1 esterase inhibitor (C1-INH) are low because of heterozygosity for a non-expressed C1 inhibitor allele. In a minority of patients, levels of the inhibitor protein are normal but it is functionally defective because of heterozygosity for a nonfunctional C1 inhibitor allele. A third, estrogen-dependent, inherited form of angioedema has been described with no defect in C1-INH [29]. This is transmitted in an autosomal dominant manner but may be X-linked in some cases. Episodes of angioedema are indistinguishable from those associated with other forms of the disease, but occur only during pregnancy or with the use of exogenous estrogens. Acquired forms of angioedema caused by increased catabolism of C1-INH are clinically similar to the hereditary disorders occurring particularly in patients with lymphoproliferative disorders and collagen vascular diseases [27]. Drugs such as angiotensin-converting enzyme inhibitors may also cause angioedema.

The pathogenesis of angioedema is not fully understood, but the increased vascular permeability may be mediated by kinins. C1-INH prevents autoactivation of C1 and inhibits activated Hageman factor and kallikrein. The diagnosis, in most cases, is confirmed by quantitative and qualitative analysis of C1-INH. In addition, levels of C4 are secondarily reduced between attacks and nearly absent during attacks. A consensus approach to the management of angioedema has been published [27]. Infusion of C1-INH concentrate is effective for severe attacks whereas prophylaxis includes avoidance of estrogens and prompt treatment of infections and the graded use of antifibrinolytic agents (tranexamic acid or ε-aminocaproic acid) or attenuated androgenic steroids, such as danazol and stanozolol.

Secondary immunodeficiency of gastroenterological importance

Immunodeficiency due to protein loss may be a component of any severe inflammatory condition in the gastrointestinal tract; examples include protein-losing gastroenteropathy (e.g., Ménétrier disease) and extensive Crohn's disease. However, the more severe cases of gastrointestinal protein loss occur in the setting of primary lymphangiectasia or secondary lymphatic obstruction (see Chapter 83). Protein-calorie malnutrition leads to significant depression of cell-mediated immune function. This may occur in association with malignancy, particularly lymphoreticular tumors. Iatrogenic immunosuppression is an increasingly common cause of secondary immunodeficiency (e.g., in patients undergoing organ transplantation or reversible IgA deficiency with drugs such as sulfasalazine, penicillamine, and phenytoin) The increased susceptibility to *Candida* and other infections with corticosteroid use is well established but it is less well known that corticosteroids are the most common cause of superinfection with *Strongyloides stercoralis* [30]. The signficance of mucosal immune senescence in humans is uncertain. Reduced mucosal resistance and risk of bacterial overgrowth in older adults are probably multifactorial. Nonimmunological risk factors in the elderly include motility disturbances, achlorhydria, comorbidity, polypharmacy, and antibiotic use with altered enteric flora [31].

Neutropenic enterocolitis

Neutropenic colitis, also called necrotizing enterocolitis, ileocecal syndrome, and typhlitis (from the Greek *typhlos* meaning "blind sac" or cecum), may occur with neutropenia of any cause, but is most common following chemotherapy, occurring in about 6% of patients treated for leukemia [32,33]. It usually begins 7–10 days after chemotherapy, and affects primarily the ileocecal region with clinical manifestations ranging from abdominal discomfort, vomiting, distention, diarrhea, and tenderness to local or generalized peritonitis after perforation. Secondary sepsis as the result of bacterial translocation is common. The organism traditionally associated with neutropenic colitis is *Clostridium septicum* but other clostridial and non-clostridial species from the normal flora are more frequently isolated in blood cultures [33]. Diagnosis requires a high index of suspicion – many cases are diagnosed postmortem. Radiological findings include dilated bowel loops, air–fluid levels, mural thumbprinting, and pneumatosis. Barium studies are generally avoided because of the risk of perforation. Recommended management includes fluid and electrolyte replacement, broad-spectrum antibiotic coverage, and restoration of neutrophil count with granulocyte colony-stimulating factor [34]. Depending on the severity, surgery may be required.

Food allergy (hypersensitivity)

Immunological hypersensitivity to foodstuffs was shown in the early part of the 20th century, but the issue of food allergy has become controversial and confusing for several reasons. These include the lack of adherence to standardized terminology, failure to distinguish food allergy from other forms of adverse food reaction, and widespread use of unsubstantiated or inappropriate tests for food allergy by some practitioners and commercial outlets. The development of

scientifically sound experimental approaches has advanced our understanding of the pathogenesis of food allergy, improved diagnostic management of the problem, and clarified and standardized the terminology regarding the spectrum of adverse reactions to foods [35–37].

Classification and prevalence

The terms *food allergy* and *food hypersensitivity* may be used interchangeably but should be reserved for those reactions that have been shown to be mediated by the immune system (Table 105.5). *Food intolerance* is a term that should be used to describe nonimmunologically mediated adverse reactions to food or food additives that may closely mimic acute allergic reactions. Reactions to food additives, such as sulfites, salicylates, and tartrazine, may be more common and as important as allergy to natural food components (see Table 105.5). Some foods may produce adverse reactions by multiple mechanisms in different individuals, including allergic reactions to milk proteins or, rarely, to contaminant antibiotics, or they may result from lactose intolerance or fat intolerance.

The spectrum of nonimmunologically mediated food intolerance is wide (see Table 105.5) and includes food avoidance, which may arise for various reasons, including faddism, anorexia nervosa, or even dysgeusia. Common causes of dysgeusia include medications (mostly halogen salts), menopause, and depression.

Community surveys indicate that at least 20% of adults believe that they have an adverse reaction to some food. When tested objectively, using blinded food challenges, the majority of complaints cannot be reproduced; estimates closer to 1% are more realistic [35–38]. Most adverse reactions to food are probably not immunologically mediated. The prevalence of true food allergy is more common in atopic individuals and in children, but declines with age. Estimates of the frequency of food allergies in children are about 5%, although cows' milk allergy may be more common [36]. As with other forms of allergy and immune-mediated disorders, there appears to be an increasing prevalence of food allergy in industrialized countries; this is particularly true with peanut allergy [39]. In adults, food allergy is a well-documented entity, but is uncommon. True food allergy is a most unlikely diagnosis in adults presenting with new onset of gastrointestinal symptoms in the absence of a strong atopic background or without a history of food allergy since childhood.

Table 105.5 Differential diagnosis of adverse reactions to foods[a]

Immunologically mediated:
Early: immunoglobulin E-mediated
Delayed: late-phase reactions, immune complex-mediated or cell-mediated immunity (e.g., celiac disease, most cases of cows' milk allergy)
Nonimmunologically mediated:
Idiosyncratic
Gastrointestinal (e.g., lactase deficiency)
Systemic (e.g., glucose 6-phosphate-dehydrogenase deficiency)
Pharmacological (e.g., caffeine, tyramine, serotonin, alcohol, histamine)
Toxic (e.g., aflatoxins, botulism, mushroom toxins)
Infectious (e.g., salmonellosis)
Other contaminants and additives
Antibiotics, pesticides
Dyes (e.g., tartrazine)
Flavorings and preservatives (e.g., monosodium glutamate [Chinese restaurant syndrome], sulfites, benzoate, nitrites, and nitrates)
Gastrointestinal disorders (e.g., peptic ulcer, cholelithiasis)
Psychological (e.g., phobias, avoidance, faddism)

a This list is intended to be representative and is not comprehensive.

Immune response to dietary antigens

Small amounts of antigenic macromolecules normally penetrate the gastrointestinal mucosal barrier and reach the systemic circulation, occurring more in early life and in conditions causing disruption of the mucosal defenses. Uptake of antigenic material and presentation to the mucosal immune system may occur by three main routes [40]. First, the specialized microfold or M cells that overlie lymphoid follicles are adapted to sampling lumenal antigens and delivering them to dendritic cells for presentation to T cells. Second, the surface enterocytes lining the intestine are also capable of presenting antigens, and can selectively stimulate suppressor T cells in vitro. Although the significance of enterocyte-mediated uptake and processing of antigens in vivo is unclear, preferential stimulation of suppressor cells could be an important mechanism preventing hypersensitivity to dietary antigens. Finally, antigen sampling occurs across the epithelium by dendritic cells, which are capable of extending to the lumen without disrupting epithelial tight junctions.

When dietary antigen engages the immune system, there may be a local secretory IgA antibody response, but a systemic immune response seldom occurs. Most commonly, a state of immunological tolerance develops. Oral tolerance is a state of specific immunological unresponsiveness that occurs following oral ingestion of antigen, and significantly regulates immune responses to dietary antigens [40–42]. Immune responses that are most easily suppressed or tolerated by feeding proteins are IgE-mediated and delayed-type hypersensitivity responses. Not surprisingly, these are the major immunological reactions mediating food allergy. Stated differently, food allergy or hypersensitivity represents a breakdown in oral tolerance. Mechanisms responsible for the induction and maintenance of oral tolerance appear to involve activation of regulatory T cells. The molecular mediators include suppressive cytokines, particularly transforming growth factor-β. Moreover, the liver appears to down-regulate systemic immune responses to dietary antigens, and

the enteric flora have an obligatory role in the establishment of immune tolerance [40].

Although sensitization to food allergens usually occurs after exposure through the oral route in infancy, sensitization may also occur through extraintestinal routes. This has been described in children with peanut allergy who may have been sensitized to peanut protein by topical application to skin rashes of medicines containing peanut oil [43]. Sensitization may also arise because of cross-reactivity against other protein allergens.

Susceptibility to food allergy is genetically influenced but environmental determinants also play a role. All forms of allergy, including food allergies, are more common in developed countries, linked with improved sanitation and changes in the pattern of exposure to childhood infections. Some enteric infections may have a protective effect against food allergy, although the relationship is complex because enteric infections may also act as an adjuvant for responses to ingested antigens [44].

Food allergens and pathogenesis of food allergy

Most food hypersensitivity reactions are caused by a relatively small number of foods, notably milk, soy, eggs, nuts (peanut, tree nuts such as Brazil nut and walnut), fish, shellfish, and wheat. Whereas age-related loss of sensitivity is common with milk and eggs, this is less likely with allergies to nuts or seafood which are, therefore, more common in adults. For several of these foods, the specific allergen epitope has been molecularly defined [45,46]. Many food allergens are heat-stable and acid-stable, are resistant to proteolysis, and have the appropriate size with a molecular weight in the range of 10–70 kDa for bridging IgE on the surface of mast cells. Their immunogenicity may be retained or modified with food processing, digestion, and cooking (for example peanuts appear to be more allergenic if roasted).

Since food-labeling regulations vary in different countries, allergens may be hidden in processed foods [47]. With the development of transgenic foods, it is also important to be aware that food allergens may be transferred by genetic manipulation [46].

Food-allergic or hypersensitivity reactions are either immediate (IgE-mediated, type I hypersensitivity) or delayed (late-phase IgE-mediated, immune complex-mediated, and cell-mediated). Immediate or IgE-mediated hypersensitivity reactions account for the majority of immunologically mediated adverse reactions to foods. Delayed-type hypersensitivity is involved in the pathogenesis of gluten-sensitive enteropathy; so it is distinct from food allergy in its pathogenesis (see Chapter 50).

The wheal and flare reaction that occurs in some individuals after intradermal injection of a food allergen is the result of the presence of food-specific IgE antibodies on the surface of cutaneous mast cells; adjacent IgE molecules are cross-linked by the allergen and trigger degranulation of the mast cell. This phenomenon along with the uptake of intact food allergens across the mucosal barrier was elegantly demonstrated almost 80 years ago [48]. Nonallergic subjects after intradermal injection with serum from fish-sensitive patients developed wheal and flare reactions at the injection site on ingestion of fish, showing that such antigens can reach and trigger mast cells at extragastrointestinal sites.

Studies in mast cell-deficient murine models of food hypersensitivity have confirmed the central role of mast cells and their interaction with other cells including nerves, epithelial cells, and eosinophils, in the pathogenesis of food allergy [49]. This is illustrated in Fig. 105.1. Eosinophils may partially mediate the late phase of food allergic reactions within the gut mucosa in experimental animals and may contribute to allergy-related dysmotility syndromes [36]. Interleukin-5 and the eosinophil chemokine eotaxin are the primary mediators of eosinophil recruitment to the mucosa [37,50].

Clinical features of food allergy

Symptoms usually occur within minutes of ingestion but may be delayed several hours. Systemic anaphylaxis is the most serious manifestation of food hypersensitivity and may be the first presentation. Cofactors such as aspirin ingestion or exercise may have a profound effect on the clinical expression of food hypersensitivity and postprandial, exercise-induced systemic anaphylaxis has been described. More commonly, a variety of less severe and usually transient symptoms may be experienced. The organs primarily affected are the skin (eczema, urticaria), the respiratory tract (rhinitis, asthma), and the gut [36,37,51].

Gastrointestinal symptoms are nonspecific and range from edema and pruritus of the lips, buccal mucosa, and pharyngeal mucosa to vomiting, cramping, distention, and diarrhea, depending on the level of the gut primarily affected. Symptoms primarily involving the buccal or lingual mucosa (oral allergy syndrome) are particularly common and may not be associated with other gastrointestinal manifestations. Chronic diarrhea and malabsorption may arise as a result of non-IgE-mediated delayed hypersensitivity reactions, such as in food protein enteropathies and celiac disease (see Chapter 50). Cows' milk hypersensitivity in infants may cause occult bleeding or frank colitis. Food allergy is not responsible for most cases of irritable bowel syndrome but should be considered in the small subset of patients with a strong history of atopy. The importance of taking a careful history is confirmed by studies showing that symptoms can discriminate irritable bowel from food allergy [52]. Evidence for IgG-mediated adverse reactions to foods has been found in some patients with irritable bowel syndrome [53]. There is no convincing evidence for food allergy in the pathogenesis of inflammatory bowel disease. Links between food allergy and other syndromes including esophageal reflux and dysmotility appear important in children and have been reviewed elsewhere [65] and in Chapter 33.

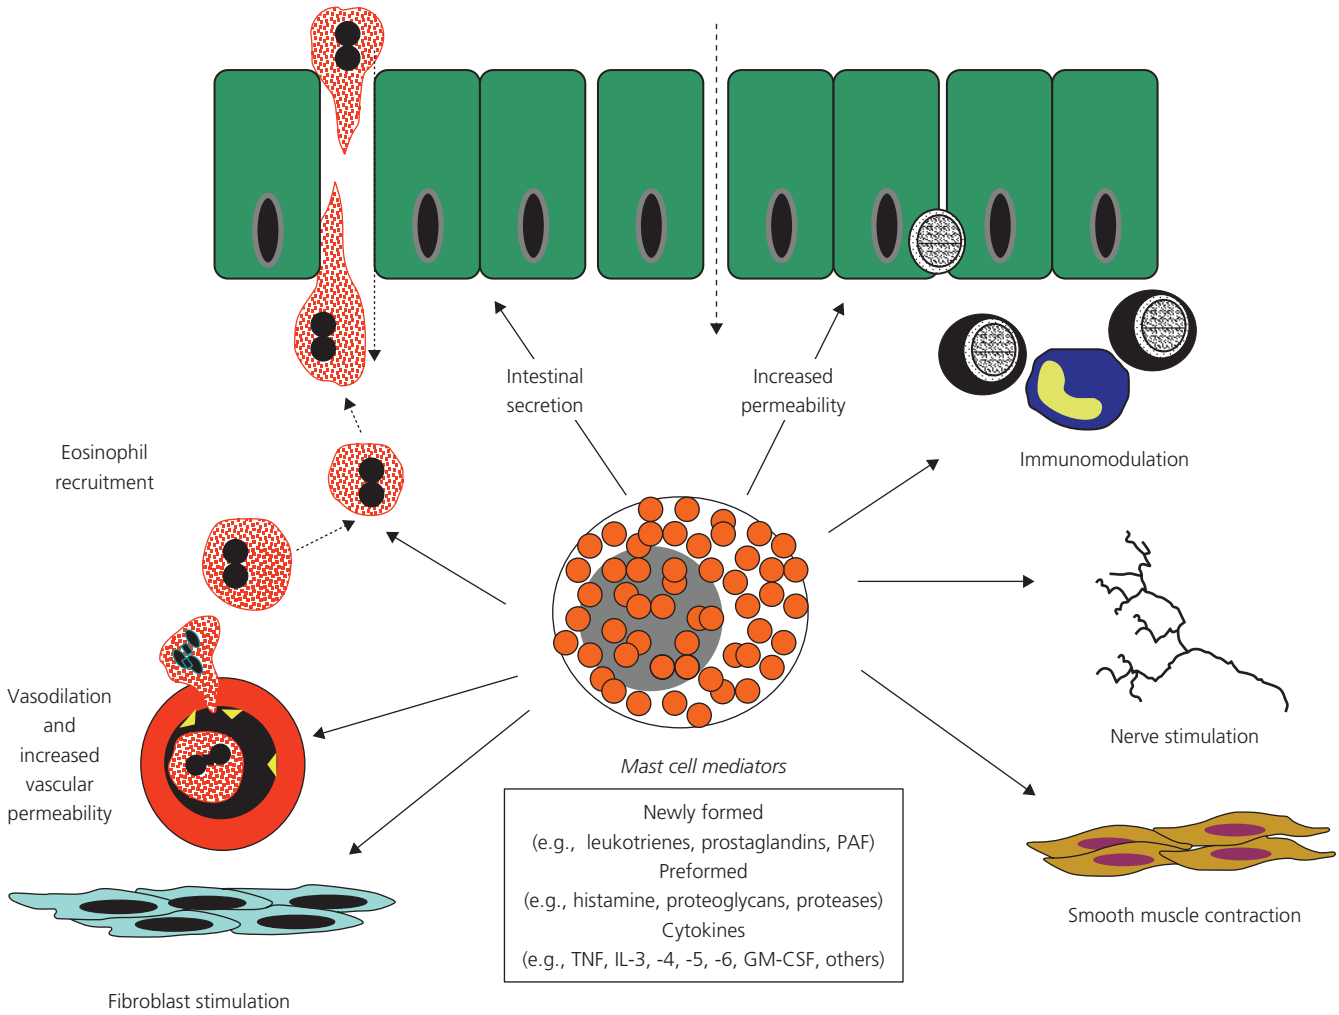

Figure 105.1 Mast cell mediators and potential consequences of their release. Mediator release is triggered when adjacent immunoglobulin E (IgE) antibodies on the surface of the mast cell are bridged by binding to an allergen. Mast cell secretion may also be stimulated by a variety of other endogenous and exogenous factors, including activated complement components (C3a and C5a), neuropeptides, bee venom, polymyxin, ionomycin, and opiates. GM-CSF, granulocyte macrophage-colony stimulating factor; IL, interleukin; PAF, platelet activating factor; TNF, tumor necrosis factor.

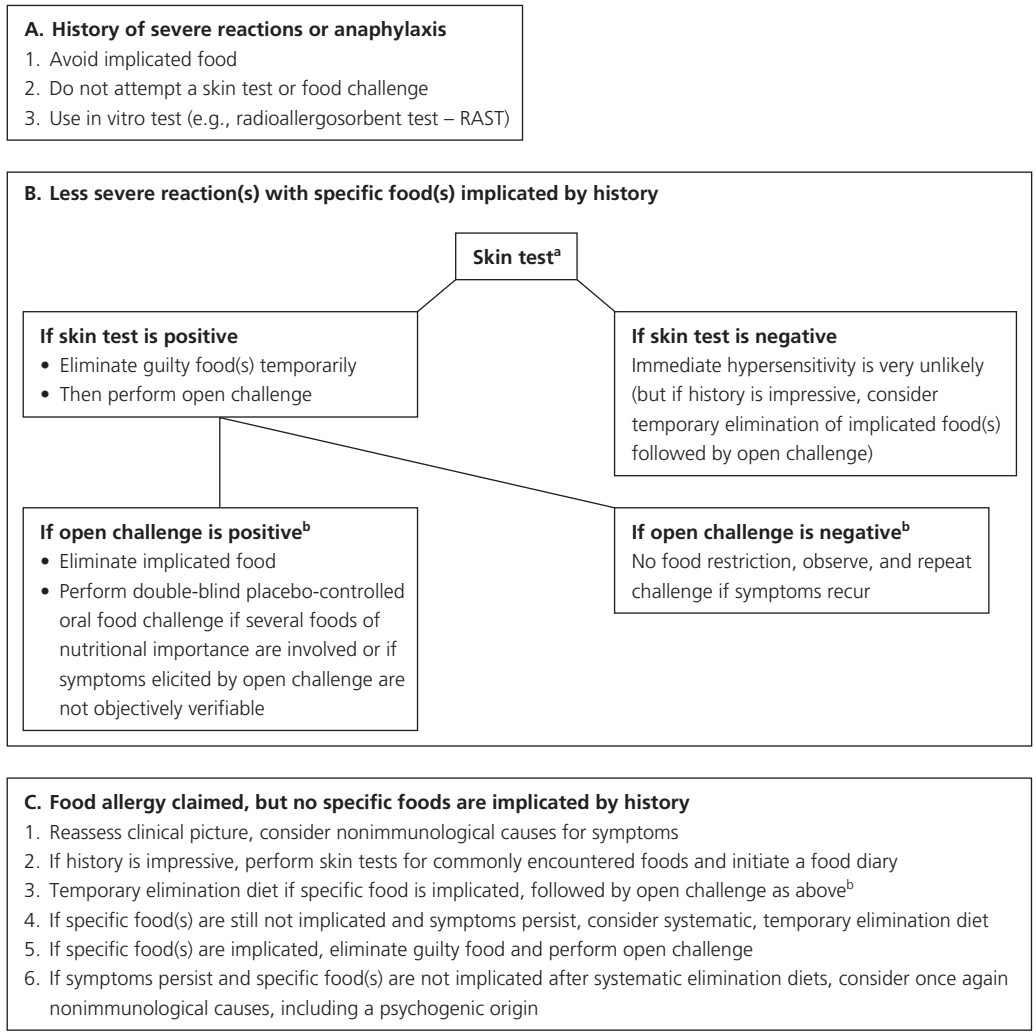
Evaluation of the patient with suspected food allergy

Only a small number of adult patients referred with a supposed food allergy have a reproducible, immunologically mediated adverse reaction to food [54–56]. A careful and objective assessment is important not only to detect preventable disease in such patients but also to offset inappropriate and potentially harmful dietary restriction in others. Although the differential diagnosis of food-related symptoms is broad (see Table 105.4), a detailed history and physical examination will often indicate the correct diagnostic category.

The definitive criteria for the diagnosis of food allergy are reproducible induction of the patient's symptoms after ingestion of the implicated food coupled with evidence for an immunological mechanism. A general diagnostic guideline is shown in Fig. 105.2. In practice, the diagnostic approach should be individualized, and the rigor with which one attempts to prove the diagnosis will be influenced by several factors, such as the age of the patient, the nature and nutritional importance of the food implicated, the likely reliability of the patient's history and compliance with challenge test protocols, and the severity of the symptoms. For example, patients who are thought to be allergic to several major food groups require an accurate confirmation of the diagnosis because of the inconvenience and potential danger of malnutrition with prolonged, complicated restriction diets. In contrast, patients with only episodic symptoms triggered by uncommonly encountered or nonessential foods should be instructed to avoid such foods and do not require rigorous food challenges. For reliable patients with a clear history of objectively verifiable symptoms and signs, an open challenge may suffice. The patient with vague or subjective complaints,



a Prick technique with fresh food or commercial extract.

b Depending on nature of the food and the ease with which it can be camouflaged, a single blinded challenge may be performed in preference to open challenge.

Figure 105.2 General guidelines for the investigation of adult patients with suspected food allergy.

self-diagnosed as an adverse reaction to food, poses the greatest difficulty. In adults, particularly the nonatopic individual, the likelihood of such symptoms being the result of food allergy is small. Prolonged investigative evaluation beyond simple screening tests may not be appropriate or desirable for these patients.

Food challenges and skin testing with food antigens can trigger potentially serious and even fatal anaphylaxis in a small percentage of patients. Such diagnostic tests should be performed only by experienced physicians and only in a facility equipped to address serious allergic reactions.

Skin tests and in vitro assays

For practical purposes, the demonstration that an adverse reaction to food is immunologically mediated involves the demonstration of IgE antibodies specific for the implicated food allergen. Direct skin testing with the prick technique with food extract and control solution is a simple and sensitive method of detecting specific mast cell-bound IgE antibodies [36]. If properly performed, a negative skin test indicates that immediate hypersensitivity to the food tested is highly unlikely. However, a positive test (wheal diameter > 3 mm larger than that of the control wheal) merely indicates the presence of sensitizing antibodies and not necessarily the presence of clinical food hypersensitivity, which can be confirmed conclusively only by food challenge (see Fig. 105.2).

Skin testing should not be attempted if the clinical history indicates there is a substantial risk of anaphylaxis; instead, an in vitro assay for the presence of allergen-specific IgE in the serum should be used. Assays for IgE antibodies to several of

the known food allergens include the commercially available radioallergosorbent test and enzyme-linked immunosorbent assay kits. Less commonly used is the basophil histamine release assay, which is performed mainly in research laboratories. There is no place for the nonvalidated, so-called cytotoxicity food allergy test, which is still widely advertised in the lay press [57].

Elimination diets

Systematic elimination of different foods and the use of a food/symptom diary may help identify foods to which a patient might be allergic. Resolution of symptoms and recurrence with reintroduction of selected foods is consistent with a diagnosis of food hypersensitivity. If multiple or several major food groups are implicated, confirmation should be obtained by controlled food challenge. The design of the diet, particularly the degree of food restriction, will depend on the patient's history and the number of potential food allergens thought to be involved. Ideally, the design of the diet should involve an experienced dietitian. Reintroduction of the implicated food(s) should be supervised by a physician because anaphylaxis can occur in some patients during food challenge following elimination trials.

The most restrictive elimination diet is an elemental diet. Elemental diets are unappealing but on a short-term basis they may be diagnostically useful in patients claiming to have allergies to multiple foods, or where the possibility of food allergy is a major concern but no specific food has been implicated by the clinical history. Persistence of symptoms on such a diet excludes food allergy from the differential diagnosis. If symptoms resolve on an elemental diet, various foods may be reintroduced in a systematic fashion.

Food challenge

A double-blind, placebo-controlled oral food challenge is the most reliable and unbiased method for determining if symptoms are related to a specific food. However, like direct skin testing, oral food challenge is only required in a minority of patients and is contraindicated in patients with a history of food-related anaphylaxis [54–56]. Dehydrated foods are most convenient for diagnostic challenges because they can easily be disguised in a variety of vehicles or gelatin capsules, and are commercially available. Guidelines for the performance of food challenges have been published [58]. The double-blind, placebo-controlled food challenge is time consuming and expensive so "single-blinded" or "open" challenges are more convenient initial tests to use in selected cases to rule out food allergy or to help identify those who require a double-blind challenge (see Fig. 105.2).

Direct challenge of the intestinal mucosa with food antigen extracts using colonoscopy has been used to identify patients with intestinal allergy. Mucosal wheal and flare reactions are recorded semiquantitatively and tissue biopsy specimens are examined for mast cell and eosinophil activation. As with skin testing, positive and negative controls are required and similar safety considerations must be applied [59].

Treatment and prevention of food allergy

Most patients can be reassured that they will outgrow their food allergy, although allergies to seafood and especially peanut, which is the most common cause of severe food allergy in adults, may be exceptions. The only acceptable treatment of food allergy is avoidance of the offending food. Patient education is the best means of ensuring dietary compliance. Expert instruction and supervision by an experienced dietitian reduce the likelihood of inadvertent ingestion of allergens. Attention to food labels is important and the European parliament has issued a directive regarding specific ingredients considered to be allergenic which must be indicated on food labels. Drug therapy with antihistamines and corticosteroids has only a secondary role in the management of symptoms caused by inadvertent ingestion of food allergens. Parenteral immunotherapy (hyposensitization) with food extracts has been disappointing. Monoclonal anti-IgE antibodies that bind to the Fc region of IgE, interfere with its binding to mast cells and basophils, and down-regulate the expression of the receptor, have had promising results in patients with peanut allergy [60]. There is evidence to suggest that breast-feeding until infants are 6 months old may have a protective effect against the development of food allergy [61]. The potential prophylactic role of altering the enteric microflora with probiotics is an active area of investigation [62].

Eosinophilic gastrointestinal disorders

Recognition of a spectrum of eosinophilic gastrointestinal disorders has increased remarkably over the past decade. This has been accompanied by an improved understanding of the biology of the eosinophil and its potential role in host defense and tissue injury [50]. Homing to the gut is under separate control to that responsible for other inflammatory cells and appears to be independent of the endogenous flora [63]. IL-5 is the principal eosinophil growth factor whereas the eotaxins are the chemokines responsible for tissue recruitment of eosinophils. The secretory products of eosinophils include cytotoxic cationic proteins, proteases and ribonucleases, neuropeptides such as substance P, leukotrienes, chemokines, and proinflammatory cytokines. Eosinophils are normally present in the lamina propria of all segments of the gastrointestinal tract with the exception of the normal esophagus. Therefore, it is particularly noteworthy that eosinophilic infiltration of the esophagus has been increasingly recognized, particularly in children but also in adults, in the setting of gastroesophageal reflux syndromes, food allergy, and as isolated causes of dysphagia and dysmotility. The topic of eosinophil esophagitis is dealt with separately in Chapter 33.

Eosinophilic gastroenteritis

Pathophysiology

Eosinophilic gastroenteritis is probably not a single entity but rather a heterogeneous collection of disorders of varied causes with similar clinicopathological features [50,63,64]. Allergic phenomena, particularly food hypersensitivities, have been proposed to account for eosinophilic gastroenteritis but the evidence is limited in many patients. Although food hypersensitivity (usually to milk) may be found in children with eosinophilic gastroenteritis, the response to dietary elimination is often disappointing. Some patients have no atopic symptoms, and fewer than half of all patients with eosinophilic gastroenteritis have a positive family history of allergy. Studies of experimental models of allergic intestinal disorders have demonstrated the role of the eosinophil chemokine, eotaxin, and of eosinophils in mediating intestinal injury including neuronal damage [50]. Other cytokines particularly IL-5 but also IL-3 and granulocyte–macrophage colony-stimulating factor promote the persistence of the eosinophil infiltration within the gut [64].

Clinical manifestations

The clinical manifestations of eosinophilic gastroenteritis depend on the gastrointestinal site primarily affected and the layer of bowel wall predominantly involved. The stomach and intestine are most commonly involved, but the disease may affect any part of the gastrointestinal tract as well as the pancreatic and biliary tree. When the predominant involvement is mucosal, the condition behaves like other forms of inflammatory bowel disease, with diarrhea, cramping, postprandial nausea, vomiting, and periumbilical pain. If the eosinophilic infiltration is extensive, there may be malabsorption, weight loss, protein-losing enteropathy, blood loss, and anemia. In preadolescents, growth retardation may occur. A low level of peripheral eosinophilia occurs in most cases. Stools may be positive for occult blood, although frank hematochezia is rare. Charcot–Leyden crystals secondary to lumenal extrusion of eosinophils may be seen. Detection of these distinctive hexagonal bipyramidal crystals may be easier with fluorescence microscopy than conventional light microscopy. Although characteristic of eosinophilic involvement in inflammation, they may also be derived from basophils and are not specific for allergic reactions, being found in parasitic and other causes of inflammation including idiopathic inflammatory bowel disease. Quantification of mediators such as eosinophil cationic protein and eosinophil protein X within stool samples promises to be an alternative diagnostic strategy. Definitive diagnosis of mucosal eosinophilic gastroenteritis is made by barium radiography and gastric and small bowel biopsy. A diffuse mucosal pattern with nodules or intralumenal masses and a sawtooth mucosal pattern may be noted in the small bowel. A widening of small bowel segments may be seen secondary to mesenteric nodal involvement. Gastric lesions may have a cobblestone appearance in the antrum and thickening of mucosal folds. Small bowel biopsies may be diagnostic, showing a diffuse infiltration of the mucosa with eosinophils. However, because eosinophilic gastroenteritis may present as a patchy intestinal disease, multiple biopsies at different levels of the gastrointestinal tract should be performed.

When eosinophilic gastroenteritis predominantly involves the muscularis layer of the intestine, the clinical presentation consists of intestinal obstruction with nausea, vomiting, pain, and abdominal distention. Barium studies of the upper gastrointestinal tract will usually demonstrate irregular narrowing of the distal antrum or small bowel. Endoscopic mucosal biopsy may not be helpful. Occasionally, isolated infiltration of esophageal muscle may be seen with symptoms and manometry evaluations suggestive of achalasia. Rarely, the eosinophilic infiltration is predominantly serosal and may be associated with eosinophilic ascites or pleural effusions.

Differential diagnosis

Diseases associated with peripheral eosinophilia in addition to mucosal eosinophilic infiltrates may mimic idiopathic mucosal eosinophilic gastroenteritis. The most frequently encountered is the hypereosinophilic syndrome, characterized by diffuse gastrointestinal involvement, frequent peripheral eosinophilia, and eosinophils in several other organs. Periarteritis nodosa may be associated with a peripheral eosinophilia, and abdominal pain and nodular masses in the stomach and small bowel may be seen on radiography. This condition may be distinguished from eosinophilic gastroenteritis by the systemic nature of the inflammatory process and by the eosinophilic infiltrate localized to the perivascular region. The nodular polypoid mucosal findings on radiographs in periarteritis nodosa are secondary to ischemia and inflammation rather than eosinophilic infiltration. Intestinal parasitism (hookworm, *Ascaris*, *Strongyloides*, *Toxocara*, *Trichuris*, *Capillaria*, and *Trichinella* species) causes peripheral eosinophilia and gastrointestinal symptoms, including diarrhea and abdominal pain. The diagnosis is usually suggested by the clinical history and confirmed by stool analysis and examination of a duodenal aspirate. Protozoal infections such as amebiasis and giardiasis are not associated with eosinophilia. Finally, intramural collections of mature eosinophils, most commonly in the stomach, are often seen in eosinophilic granuloma. These patients present with symptoms of gastric obstruction. The isolated nature of the granuloma may help distinguish this disorder.

The second major category of diseases that may mimic eosinophilic gastroenteritis clinically and radiologically includes inflammatory and infiltrative disorders, such as gastrointestinal lymphoma, scirrhous carcinoma of the stomach, and Crohn's disease. These conditions may be associated with a mild increase in eosinophils histologically.

Treatment

There is no specific treatment for eosinophilic gastroenteritis. An attempt to identify a specific environmental or food aller-

gen may be considered if there is a convincing history of symptoms triggered by food and if there is a strong background of atopy. In most adult patients, a specific food will not be implicated, and prolonged investigation with elimination diets is not appropriate. If necessary, a trial of an elemental diet can quickly eliminate a role for food hypersensitivity. Oral corticosteroids, 20–40 mg prednisolone/day are effective in most patients. A short course of 7–10 days usually produces clinical remission, although repeat and more prolonged courses may be required. Depending on disease distribution, a topically active corticosteroid, such as budesonide with controlled small bowel release, may be optimal. The long-term prognosis for patients with eosinophilic gastroenteritis is generally favorable, and the disease course is one of waxing and waning severity. Occasionally, the use of total parenteral nutrition is required to manage patients with severe disease and symptoms that are refractory to steroids. Segmental resection of the intestine is not curative. Promising therapeutic developments include the use of leukotriene inhibitors and monoclonal antagonists against eotaxin and IL-5.

Gastrointestinal complications of organ transplantation

Gastrointestinal complications are common in patients undergoing transplantation, particularly hemopoietic stem cell transplantation. Complications include toxicity of conditioning protocols (radiation or chemotherapy) before bone marrow grafting; acute and chronic GVHD; and opportunistic infections due to immunodeficiency associated with both the induction procedure and graft-versus-host reactions [65,66]. Some of the clinical and diagnostic characteristics that help distinguish these entities in the setting of bone marrow transplantation are shown in Table 105.6.

Intestinal disease secondary to conditioning protocols

Conditioning protocols which include both chemotherapeutics and high-dose radiation are capable of injuring rapidly dividing cell populations and producing intestinal cell death (see Table 105.6). Enterocyte death occurs immediately during the conditioning and up to 3 weeks elapses before there is mucosal regeneration. Both the small and large intestine are damaged during this process, although the epithelium of the small intestine is more susceptible to this form of cell death [67]. Anorexia, cramping, and abdominal pain, with watery diarrhea, may develop. During healing, there is atypia of cell nuclei and regeneration of crypt cells, but the surface epithelium is normal. This histopathological picture is important in helping distinguish this entity from acute GVHD or secondary viral infections [68,69]. The time of onset following bone marrow transplantation is a helpful clue, and rectal biopsy with negative stool cultures is the most important diagnostic test (see Table 105.6). Treatment consists of supportive measures and parenteral nutrition.

Graft-versus-host disease

GVHD is common after hemopoietic stem cell transplantation, occasionally occurs after organ transplantation, and is

Table 105.6 Gastrointestinal complications of bone marrow transplantation

	Secondary to induction protocol	Acute GVHD	Chronic GVHD
Time to onset after BMT (days)	0–20	20–80	>80
Clinical features	Anorexia, abdominal pain, diarrhea	Diarrhea (large volume), abdominal pain ± skin rash ± liver disease	Dysphagia, oral ulcers, diarrhea
Radiographic changes	Not helpful	Mucosal edema, mucosal ulcers, pneumatosis	Esophageal strictures and webs
Endoscopy or manometry	Nonspecific	Normal → erythema → mucosal sloughing; stomach and rectum are spared	Upper esophageal bands and webs; lower third of esophagus is spared
Histology: source and changes	Rectal: atypia of cell nuclei, crypt cell regeneration	Early → rectal; crypt cells/apoptosis Late → mucosal disintegration	Esophagus: neutrophil infiltration, basal layer necrosis
Differential diagnoses	Intestinal infection, esophagitis, early GVHD	Infection, drug effect	Peptic esophagitis, infection – *Candida*, herpesvirus, CMV
Stool findings	Negative for pathogens	Negative for pathogens, cellular debris, increased protein	Negative for pathogens

BMT, bone marrow transplantation; CMV, cytomegalovirus; GVHD, graft-versus-host disease.

rare after blood transfusion. Acute GVHD is characterized by epithelial cell death mainly in the gastrointestinal tract, liver, and skin, whereas chronic GVHD is characterized by fibrosis and atrophy of these and other organs [65,68]. The pathophysiology of GVHD is a multiphase process beginning with damage to the intestinal mucosa during the conditioning, pretransplant period. This causes increased permeability and translocation of bacterial products such as lipopolysaccharide with the generation of inflammatory cytokines that upregulate adhesion molecules and major histocompatibility complex (MHC) antigens on host tissues. This is followed by activation of $CD4^+$ donor T cells that recognize disparities with the recipient MHC proliferation and amplify the process by further release of T helper type 1 cytokines (e.g., tumor necrosis factor-α, IL-12, and interferon-γ) and activation of cytotoxic lymphocytes. Different subsets of memory T cells expressing distinct adhesion molecules home separately to the gut and skin. Activation of these alloreactive donor T cells within the tissues is followed by clonal expansion (expansion phase). This is followed by cytokine and chemokine release ("cytokine storm"), which leads to the recruitment of additional inflammatory cells (effector phase). The cytokine profile of acute GVHD is predominantly T helper type 1 but type 2 cytokines also contribute and feature more prominently in chronic GVHD, although there is considerable overlap in the immunopathogenesis of acute and chronic GVHD [65,70]. The central role of intestinal injury in the pathogenesis of GVHD is supported by evidence for reduced severity of GVHD with nonmyeloablative conditioning protocols. It also provides the rationale for use of "cytokine shields" such as keratinocyte growth factor and IL-11 to fortify the mucosal barrier [65,71].

Acute GVHD

Acute GVHD may be staged on the basis of damage to the skin (dermatitis), gut (mucositis, enteritis), and liver. A moderate to severe degree of acute GVHD develops in 30%–50% of patients with sustained bone marrow engraftment. The condition appears to be increasing although this may reflect more liberal use of endoscopic biopsy surveillance [72]. The onset or continuance of profuse, watery diarrhea 3 weeks following bone marrow transplantation is indicative of intestinal acute GVHD. The severity of the intestinal condition generally parallels that of the skin and liver involvement, although profound gastrointestinal symptoms can occur without any gross skin or liver changes.

The clinical picture, when severe, includes anorexia, vomiting, buccal mucositis, abdominal pain, intestinal bleeding, protein loss, and secondary infection (see Table 105.6). High-volume diarrhea may occur, and the amount of fluid generated is an index of extent and severity of disease activity. Extensive disease may be associated with up to 10 L of diarrheal fluid loss per day. The large stool volume may lead to distention and pain. Distention of the bowel may be exacerbated by opiate analgesics, which should be used with caution. The symptoms of GVHD are not specific so vigilance is required for other complications, particularly infections. The most common cause of gastrointestinal bleeding in these patients is esophagitis and gastric erosions. However, when a discrete ulcer develops, cytomegalovirus infection is an important consideration. Medical treatment of such lesions is often unsatisfactory, and if bleeding is persistent, surgical resection may be required.

Features that distinguish acute GVHD from the enteritis associated with the induction protocol include an erythematous, maculopapular skin rash over the palms, soles, and trunk, as well as liver test abnormalities, including hyperbilirubinemia. The diagnosis of acute GVHD may be made with confidence approximately 3 weeks following bone marrow transplantation if there is evidence of a functioning graft and if there is watery diarrhea accompanied by a diffuse skin rash and jaundice (see Table 105.6). The patient who presents with gastrointestinal symptoms but without jaundice or skin rash represents a much more difficult diagnostic challenge. Other diagnostic considerations include an opportunistic intestinal infection and the residual effects of the chemoradiotherapy conditioning lasting beyond the usual 3-week period. A combination of stool examinations, barium radiographic studies, endoscopy, and histopathology may be helpful (see Table 105.6).

The stool usually contains large amounts of cellular debris and red and white blood cells. Protein loss in the stool may be sufficiently severe to lead to profound hypoalbuminemia. The absence of pathogens in the stool is important but does not necessarily rule out an infection of the gastrointestinal tract.

Barium radiography may be helpful in the differential diagnosis and in establishing extent of disease. Widespread changes may occur, including mucosal and submucosal edema, pneumatosis cystoides intestinalis, and mucosal ulcerations. These radiological findings may also be consistent with other conditions, such as cytomegalovirus enteritis and the effects of acute radiation. The acute radiological features may return to normal, or in some cases they may progress to a chronic segmental, ribbon-like appearance, usually in the small intestine.

Endoscopic appearances may be normal or may show patchy erythema or extensive mucosal sloughing. These lesions are most prominent in the ileum, cecum, and ascending colon, with relative sparing of the gastric and rectal mucosa. Histological changes seen in biopsy samples from advanced or severe lesions may not be as diagnostically useful as those from early lesions. Therefore, endoscopic biopsy samples should be taken from intact mucosa as well as from areas involved with gross inflammation. The earliest change seen on light microscopy is apoptosis of individual cells in the intestinal crypts (Fig. 105.3). This is diagnostic, if obtained from normal-appearing mucosa at least 20 days following transplantation. Inflammatory cells or microorganisms are not present in the adjacent mucosa. Later, the histopathology

Figure 105.3 Rectal biopsy specimen taken after bone marrow transplantation from a patient with acute graft-versus-host disease shows apoptotic bodies (arrows). This necrosis of individual cells within the crypt is the first change seen on light microscopy and is characteristic of acute graft-versus-host disease if found after day 20, when damage from chemoradiation therapy has resolved.

can progress to a total denudation of the mucosa; the apoptosis lesion is no longer evident, and changes are not specific. The site of greatest diagnostic yield for endoscopic biopsy is a matter of some debate with some centers favoring colorectal biopsy and others sampling the segment of gut suggested by the patients symptoms [65,68].

Management of intestinal acute GVHD consists of nutritional support, maintenance of fluid and electrolyte balance, steroid and immunosuppressive treatment, and vigilance for secondary infectious complications. Common opportunistic pathogens include astrovirus, *Clostridium difficile*, and adenovirus [73]. For patients with severe high-volume diarrhea, subcutaneous administration of octreotide may provide relief. To improve long-term survival, doses ranging up to 2 mg/kg of prednisone, for up to 1–2 weeks, may be used. Cyclosporine (ciclosporin rINN) may be used in combination with specific anti-T-cell monoclonal antibodies and anti-tumor necrosis factor-α therapy with infliximab is effective. A subset of patients with intestinal GVHD do not progress to severe multisystem disease and can be managed more conservatively with less toxic drug strategies, including topically active steroids, thereby minimizing the risk of opportunistic infections [74]. Prevention of GVHD can be achieved by prior removal of mature donor T lymphocytes from the bone marrow graft. Unfortunately, this is associated with reduced graft survival. To circumvent this, strategies for nonmyeloablative conditioning with reduced mucosal toxicity and removal of more specific subsets of effector cells coupled with various immunosuppressive regimens are increasingly studied [65,75].

Chronic GVHD

Chronic GVHD is a multisystem disorder that occurs 80–400 days after allogeneic transplantation (see Table 105.6). The majority of patients have previously had acute GVHD. However, approximately one-fourth of the patients with chronic GVHD have had no clinical indications of any previous acute graft-versus-host illness. The pathogenesis is poorly understood but is thought to represent either an end-stage of alloreactivity in which the reactive donor T cells have evolved to a T helper type 2 phenotype (in contrast to the type 1 predominance of acute GHVD), or it might represent a T-cell-mediated autoimmune process [65].

There is a wider spectrum of disorders in chronic GVHD than in acute GVHD. The pattern of gastrointestinal involvement also differs with more proximal involvement in chronic GVHD. Skin, liver, and gastrointestinal tract are again prominently involved but the oropharynx, lungs, eyes, and musculoskeletal system may also be affected [65]. The clinical features resemble those of sicca syndrome and systemic sclerosis. Gastrointestinal involvement occurs particularly in the oral mucosa (mucositis), esophagus, and small intestine. Esophageal symptoms of dysphagia with weight loss are common presenting gastrointestinal manifestations [76]. Patients with skin involvement (hyperpigmentation and scleroderma-like changes) frequently, but not always, have esophageal involvement. Dysphagia with chronic esophageal reflux can lead to chronic lung disease. Small bowel involvement with chronic GVHD is characterized either by a patchy fibrosis of the lamina propria and submucosa, or by bacterial overgrowth as a result of stasis and dysmotility. This latter abnormality responds to oral broad-spectrum antibiotics.

As with other immunosuppressed conditions, opportunistic gastrointestinal infections are a constant threat posttransplantation and must always be considered in the differential diagnosis. The combination of radiology, esophagoscopy with biopsy, and manometry may be required to distinguish between esophageal involvement with chronic GVHD and reflux peptic disease of the esophagus. Endoscopic lesions of

chronic GVHD can range from generalized desquamation of the upper and midesophagus to web-like fibrous bands [76]. Manometry with pH monitoring shows a nonspecific motor abnormality and a decreased ability to clear acid from the esophagus. In contrast to peptic esophagitis, the distal esophagus is usually spared in chronic GVHD. Histological changes within the esophagus include infiltration with neutrophils and lymphocytes with necrosis of individual cells of the basal mucosa, similar to the changes found in the skin and oral mucosa. Submucosal fibrosis may be found, but there are no muscle or neural abnormalities. In the colon, the changes may be similar to those of ulcerative colitis but mucosal biopsies may be unhelpful in some cases because many of the fibrotic changes are submucosal [69]. A recent report describes intestinal thrombotic microangiopathy after bone marrow transplantation which presents with bleeding and which may be mistaken for chronic GVHD. The distinction is important because the treatments differ [77].

In contrast to acute GVHD, the treatment of chronic GVHD is frequently satisfactory. Early diagnosis and drug therapy have prevented much of the disability associated with this condition. Prednisone alone or in combination with azathioprine has been effective. Aggressive antireflux therapy is important for reducing the symptoms associated with esophageal involvement. However, fibrosis tends to be progressive, and esophageal dilation may be required for treatment of webs and strictures.

The liver in GVHD

In acute GVHD, liver involvement is manifested by cholestasis and mild hepatocellular necrosis. Hepatic failure is uncommon. Although liver abnormalities may be the presenting feature of acute GVHD, skin and intestinal GVHD are usually evident by the time jaundice occurs, and diagnosis is relatively clear when these multisystem manifestations arise at least 3 weeks following bone marrow transplantation. Within the first 2–3 weeks after transplantation, venoocclusive disease secondary to chemoradiotherapy may be a more important diagnostic consideration, whereas throughout the posttransplant period, GVHD must be distinguished from, or may coexist with, several other causes of hepatotoxicity. These include parenteral nutrition, viral infections, drug-induced liver damage (such as immunosuppressants, antibiotics, and antifungals), hypotension, and sepsis.

Biochemical abnormalities as the result of liver complications of GVHD include a marked elevation in serum alkaline phosphatase followed by hyperbilirubinemia, but serum transaminases are elevated to a lesser extent. Liver biopsy is hazardous because of the risk of bleeding from thrombocytopenia in bone marrow transplant patients, but may be helpful, particularly where additional causes of liver disease are suspected. Histological changes of GVHD within the first week after the onset of biochemical abnormalities are nonspecific and consist of a mild lobular hepatitis with variable eosinophilic necrosis of hepatocytes and necrosis of biliary epithelium. Subsequently, the changes become more characteristic; one of the earliest features is attachment of lymphocytes to vascular endothelium followed by lymphocytic infiltration of the portal areas, pericholangitis and then destruction of small bile ducts and proliferation of ductules. The histological picture may evolve into one of profound chronic cholestasis with portal inflammation and fibrosis. Progression to liver failure may occur but most patients with severe GVHD die of infection or other complications before this. At least half of the patients who survive severe acute GVHD develop chronic GVHD and most of these will have liver involvement. In contrast to the mixed hepatocellular–bile duct damage of acute GVHD, the liver damage in chronic GVHD is predominantly portal with dense plasmacytic infiltration, loss of small bile ducts, and cholestasis.

A variant hepatic GVHD has also been described. This presents with an acute hepatitis rather than the cholestatic picture described above. Serum transaminases are greatly elevated and liver biopsy shows that in addition to lymphocytic infiltration of the portal triad and bile duct destruction, there is loss of the limiting plate and lobular inflammation with lymphocytic infiltration, pericentral necrosis, and acidophil bodies [78].

Small bowel transplantation

Transplantation of the small bowel is a realistic therapeutic strategy for patients with intestinal failure in whom continued parenteral nutrition is no longer a safe option (see also Chapter 53). These will usually be patients with complications of parenteral nutrition such as advanced liver disease or loss of venous access as the result of catheter sepsis or venous thrombosis. Intestinal failure in adults is generally the result of short bowel syndrome following resection for conditions such as Crohn's disease or infarction associated with trauma or hypercoagulable states. In children, congenital disorders such as atresia or necrotizing enterocolitis are the most common indications for small bowel transplantation. Since the topic is covered separately under short bowel syndromes in Chapter 53, the principal immunological features will be discussed here.

Improvements in the success rate for intestinal transplantation have been largely the result of the introduction of potent immunomodulatory agents; patient and graft survival rates are comparable with those of lung transplantation and approaching those of liver and heart transplantation [79–81]. In adults, the reasons for graft loss are rejection, thrombosis/ischaemia, and sepsis whereas infection followed by rejection are the main causes of death [80,81]. Contrary to what had been expected, GVHD, albeit more common than

with solid organ transplants, has not been a major obstacle with small bowel transplantation [79–81].

The basis of graft rejection is recipient T-cell reactivity against a variety of polymorphic donor antigens (alloantigens), the most important of which are encoded within the MHC, but other non-MHC antigens are also contributory. Much of the risk of rejection of a small bowel graft is attributed to the expression of MHC antigens within the abundant lymphoid tissue of the gut. Recruitment of activated T cells into the graft leads to target cell death by several mechanisms including direct lysis, induction of apoptosis, and the generation of proinflammatory cytokines [82]. Rejection predisposes to sepsis because of loss of mucosal barrier function. This is compounded by potent immunosuppression with the risk of opportunistic infections, particularly cytomegalovirus enteritis, and a subsequent lymphoproliferative disorder that is probably related to Epstein–Barr virus infection. Distinguishing rejection from infections and other pathology may be difficult, particularly because the rejection process is often focal or patchy. Multiple endoscopic biopsies are required to monitor the progress of the graft. Crypt cell apoptosis characterizes acute rejection, whereas chronic rejection is associated with fibrosis, focal ulceration, and obliterative arteriopathy [83]. Recipient lymphocytes infiltrate the lamina propria of the graft and replace donor lymphoid cells within weeks to months. The rejection reaction is associated with local production of T helper type 1 cytokines including tumor necrosis factor-α and interferon-γ, and targets mainly the crypt epithelium and local endothelium. Neither the morphology nor the cytokine response is specific to the rejection process. Vigilance and careful attention to detail are required, and the degree of immunosuppression to prevent rejection must be balanced against the risk of opportunistic infection.

Outcomes of small bowel transplantation are likely to continue to improve with the development of strategies that promote transplantation tolerance requiring minimal immunosuppression. Promising strategies include the use of highly selective immunomodulatory agents, mixed hemopoietic chimerism, and induction of regulatory T cells, but the redundancy and reserve within the immune response implies that a multifaceted approach will be needed [82,84].

With longer survival of intestinal grafts additional complications may be anticipated. One outcome that has been particularly informative has been the recurrence of Crohn's disease in the intestinal graft [85]. Although this must be carefully distinguished from GVHD, it provides insight into the pathogenesis of Crohn's disease. In contrast to the sustained resolution of Crohn's disease following bone marrow transplantation [86], recurrence of Crohn's disease following transplantation of the end organ is consistent with the view that the fundamental defect in Crohn's disease does not reside exclusively in the gut and probably reflects a dysregulated immune response to enteric flora.

106 Parasitic diseases: protozoa

Ellen Li, Samuel L. Stanley Jr

Extracellular protozoan parasites, 2632 Intracellular protozoan parasites, 2641

Protozoan parasitic infections of the gastrointestinal tract are being increasingly recognized as an important public health problem in the United States. They were the most frequently identified etiological agents in water-borne disease outbreaks in 1991 through 1994 [1]. The reasons for the apparent increased prevalence of intestinal parasites in the United States include the continuing immigration of people from developing countries in southeast Asia, the Caribbean, and Central America; the expanded use of day-care facilities, which are breeding grounds for any fecally-orally transmitted pathogens; a growing problem with fecally contaminated food and water supplies; the increased recognition of parasites as pathogens of patients with AIDS; and the development of improved stool examination techniques [2].

The intestinal protozoan pathogens include both parasites that are extracellular, such as *Giardia lamblia*, *Blastocystis hominis*, and *Entamoeba histolytica*, and the intracellular spore-forming parasites *Cryptosporidium parvum, Cyclospora cayetanensis*, and *Isospora belli*. This latter group of organisms have emerged as important pathogens in immunocompetent individuals as well as in patients with AIDS. The most commonly detected protozoan pathogen in stool specimens in the United States is *G. lamblia* [2] (Table 106.1), with *B. hominis* the next most commonly detected, although the latter's role in intestinal disease remains controversial. The prevalence of infection increases during the summer months [3]. This may be related to increased exposure to recreational water during these months. Because conventional microscopic examination of the stool for ova and parasites is time-consuming and expensive, special requests for microscopic examinations may need to be made to the laboratory. In some hospitals only fecal immunoassay(s) directed against *Giardia* and *Cryptosporidium* species may be performed when stool ova and parasite testing is requested. Stool microscopic examinations may be performed in clinical laboratories only if specifically requested. In some cases in which infection is suspected on clinical grounds, stool examination may not be revealing, and endoscopy may be necessary to make the diagnosis. It is important for the gastroenterologist to know what the likely organisms are and whether specific requests need to be made for stool microscopic examinations.

Table 106.1 Intestinal protozoan parasites detected by stool examination in the United States

Organism	Percentage of stool specimens containing the organism
Giardia lamblia	7.2
Blastocystis hominis	2.6
Entamoeba histolytica	0.9
Dientamoeba fragilis	0.5
Cryptosporidium spp.	0.2

The results of 216 275 stool specimens examined for intestinal parasites by state public health laboratories in 1987 are shown. Only organisms detected at a level of more than 0.1% of the stools are listed. Adapted from Kappus et al. [2].

Extracellular protozoan parasites

Amebiasis: *Entamoeba histolytica*

E. histolytica is the causative agent of human amebiasis. The clinical manifestations of human amebiasis range from asymptomatic disease to invasive disease manifested as amebic colitis or liver abscess. Although Brumpt postulated in 1925 that there were two morphologically indistinguishable species of *E. histolytica* – one that could cause disease and a second that could not [4] – only in the 1990s did molecular genetic analyses confirm data from isoenzyme studies and clearly establish that there are two genetically distinct but morphologically identical species [5,6]: *E. histolytica*, which can cause invasive amebiasis, and *E. dispar*, a harmless commensal.

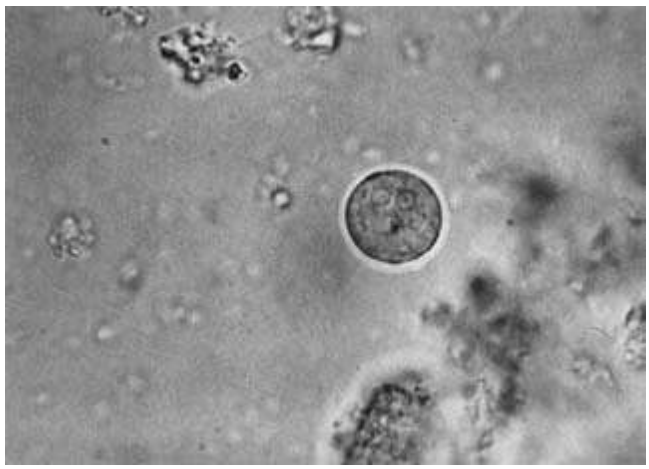

Figure 106.1 *Entamoeba histolytica* cyst from stool specimen stained with iodine. The cyst contains four nuclei and measures 9–25 μm in diameter. Courtesy of Centers for Disease Control and Prevention, Atlanta, GA.

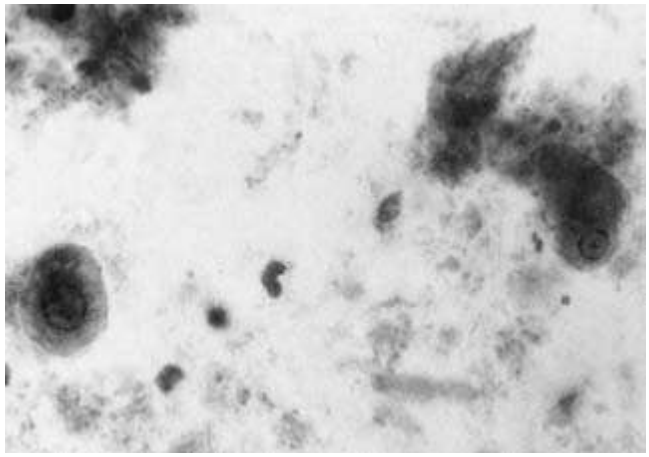

Figure 106.2 *Entamoeba histolytica* trophozoites in stool. Note ingested red cells and the single nucleus (trichrome stain). Courtesy of Centers for Disease Control and Prevention, Atlanta, GA.

The life cycle of *E. histolytica* consists of two stages: the cyst (host infective stage) (Fig. 106.1) and the trophozoite (host tissue invasive stage) (Fig. 106.2). No host other than humans is implicated in the life cycle, although natural infection of primates has been reported [7]. The disease is most commonly acquired by ingestion of food or water contaminated with feces containing the cyst form of the parasite, but venereal transmission through fecal–oral contact also occurs. Prompted by still-undefined stimuli in the intestinal tract, the cysts excyst and then form by nuclear and cytoplasmic division a total of eight trophozoites. The trophozoites are the motile feeding forms of the parasite and contain a single nucleus and pseudopodia. Trophozoites are the causative agents of invasive disease but play no role in the transmission of disease, owing to their rapid degeneration outside the body and destruction by gastric acidity. *E. histolytica* trophozoites multiply by binary fission, and they encyst, producing uninucleate cysts, which then undergo two successive nuclear divisions to form the characteristic quadrinucleate cysts.

Epidemiology

It has been estimated that 500 million people are infected with either *E. histolytica* or *E. dispar* [8]. In asymptomatic individuals, the prevalence of *E. dispar* infection is about 7- to 10-fold higher than that of *E. histolytica* infection. Forty million individuals infected with *E. histolytica* develop disabling colitis or extraintestinal abscesses, resulting in 50 000 deaths annually. Among parasitic diseases, only malaria and schistosomiasis result in more deaths than amebiasis [8].

High prevalence rates of amebiasis (both *E. histolytica* and *E. dispar*) are found in developing regions, including Central and South America, the Indian subcontinent and Indonesia, and sub-Saharan and tropical Africa [8–10]. A prospective study of a cohort of almost 300 children living in a slum region of Dhaka revealed that almost 40% acquired a new *E. histolytica* infection during the 12-month study period, but only 3% of the infections were associated with dysentery [9]. A serological study of the inhabitants of Mexico City demonstrated that 8.4% had been infected with *E. histolytica* in the previous 5–10 years [10]. The prevalence of colonic disease is equal between men and women, but amebic liver abscesses and other extraintestinal disease are 3–10 times more common in men. Children, especially neonates, and pregnant and postpartum women have an increased risk for severe disease and death. Malignancy, malnutrition, and treatment with corticosteroids are other risk factors for more severe disease.

In developed countries of Europe and North America, amebic infection is generally confined to certain high-risk groups, including recent travelers and immigrants, inmates of mental institutions, and sexually active homosexual men [11]. However, it should be noted that even in these populations, most individuals are infected with *E. dispar* rather than *E. histolytica* [12,13].

There is conflicting evidence regarding naturally acquired immunity to amebiasis. In the study of Bangladeshi children, some children showed resistance to the acquisition of a new *E. histolytica* infection that was associated with the presence of stool immunoglobulin A (IgA) antibodies to an *E. histolytica* antigen [9]. However, the effect was relatively short lived, and almost 20% of the children in the study had more than one episode of amebiasis during the 1-year study period [9]. These data, along with anecdotal reports of multiple episodes of amebic liver abscess in the same individual, suggest that naturally acquired immunity to amebiasis is, at best, short lived and may occur in only a small proportion of infected individuals [14,15].

Pathogenesis and pathology

Invasive disease is characterized by ulcerations of the intestinal mucosa, which extend into the submucosa. Trophozoites invading laterally through the submucosa, relatively sparing the overlying epithelium, give rise to the classic flask-shaped ulcer of amebiasis [16–20]. In some cases, amebic invasion through the mucosal and submucosal layers and subsequent dissemination through the portal circulation to the liver result in the formation of liver abscesses. Factors implicated in tissue invasion and destruction by the organism include:

- adhesion of amebic trophozoites to host epithelial cells through a galactose-binding lectin [21]
- release of cysteine proteases [22–26]
- amebic contact-dependent cytolysis of host cells by means of amebapore (a pore-forming protein that resembles NK-lysin from natural killer and cytotoxic T cells) [27,28]
- amebic phagocytosis and motility [29,30].

Sequencing of the *E. histolytica* genome (strain HM1:IMSS) has led to the identification of 9938 predicted genes, each averaging 1.7 kb in size, comprising ~ 49% of the genome (24 Mb) [31]. Ten percent of the sequence reads consisted of one of 25 different types of repeating transfer RNA (tRNA) unit, containing between one and five tRNA types per unit. Redundancy has also characterized many of the genes encoding suspected or proven *E. histolytica* virulence factors, including the cysteine proteinases, amebapores, and the intermediate subunit of a galactose-binding lectin. The repetitive nature and the high AT content of the genome have made it difficult to generate a map of the genome. Nonetheless, a number of key observations have been made from the genome project. First of all, although introns were thought to be rare in *E. histolytica* genes, 25% of the putative genes contained introns. The genome project has also led to the delineation of a new repertoire of signal transduction pathways in *E. histolytica*. But there was no evidence of a mitochondrial genome, consistent with the observation that trophozoites do not contain mitochondria. Instead, the parasite derives its energy from glycolysis and fermentation. Many of these genes seem to represent cases of recent prokaryotic to eukaryotic transfer. Finally, it has been noted that *E. histolytica* possesses an essentially complete complement of the genes known to be required for meiosis, although thus far there have been no confirmed sightings of amebic sex [32].

Expression profiling has been utilized to examine host response to amebic infection in the liver and the colon [33,34]. *E. histolytica* DNA microarrays have been generated to examine virulence factors and amebic responses to host factors [35–37]. Proteomic analysis has been applied to examine phagosome biogenesis in *E. histolytica* [38,39] and to identify novel virulence factors [40].

Clinical manifestations

Intestinal disease

The clinical manifestations of intestinal amebiasis range from asymptomatic infection to mild diarrhea to classic dysentery with abdominal pain, tenesmus, and bloody stools [41–43]. The presentation is generally subacute, with most individuals symptomatic for less than 1 month. Dysentery is a hallmark of invasive amebic infection, and stools that are not grossly bloody almost invariably contain occult blood, consistent with the invasive pathophysiology. Rarely, patients may present with a more fulminant colitis with severe bloody diarrhea and fever [44]. These patients have diffuse abdominal tenderness but usually do not present with a rigid surgical abdomen, although up to 75% of these patients may have peritonitis secondary to leakage through the severely diseased colon. Fulminant colitis is associated with a high (> 50%) rate of mortality. The risk for developing this syndrome is greater in children, pregnant women, and patients taking corticosteroids. Toxic megacolon is a rare but often fatal complication that is associated with administration of corticosteroids to patients with intestinal amebiasis. Unusual presentations of intestinal amebiasis include chronic non-dysenteric infection – in which symptoms of diarrhea, abdominal pain, and weight loss persist for years – and appendiceal involvement. The differential diagnosis of invasive intestinal amebiasis includes infection with *Shigella*, *Campylobacter*, and other invasive bacteria, as well as pseudomembranous colitis secondary to *Clostridium difficile*, cytomegalovirus colitis, ischemic colitis, and inflammatory bowel disease. Because of the similarities in symptoms between amebiasis and inflammatory bowel disease [45], amebiasis should be excluded by examination of stools or amebic serology in all patients before a diagnosis of inflammatory bowel disease is made and especially before corticosteroid therapy is begun.

Rarely, a localized amebic colonic infection results in a segmental mass of granulation tissue forming an ameboma. Amebomas are found, in decreasing order of frequency, in the cecum, ascending colon, rectosigmoid, transverse colon, and descending colon, and they can be detected on physical examination as a tender palpable mass. The ameboma can be mistaken for a carcinoma on barium enema. Amebic strictures are most commonly observed in the anus, rectum, or sigmoid colon and must be differentiated from those due to lymphogranuloma venereum (*Chlamydia*) or malignancy.

Extraintestinal disease

The most common manifestation of extraintestinal amebiasis is amebic liver abscess [46–49]. Patients often present with fever and right upper quadrant pain, leukocytosis, and abnormal liver test results, with an elevated alkaline phosphatase level being the most common finding (> 75% of individuals). Hyperbilirubinemia is uncommon, and severe jaundice may indicate bacterial superinfections of the abscesses. Concurrent diarrhea occurs in only one-third of the patients. In about half the patients with amebic liver abscess, hepatomegaly and point tenderness of the liver are prominent on physical examination. Most patients have a single abscess, usually in the right lobe. Multiple abscesses

are observed more commonly in patients with an acute presentation. With early diagnosis and treatment, the mortality of uncomplicated liver abscess is less than 1%. Most of the complications are related to rupture of the amebic liver abscess, which occurs most commonly into the chest (10%–20%), but also into the peritoneum (2%–7%) or pericardium (rare, often from a left lobe abscess). The development of a bronchopleural fistula presents as a cough productive of the odorless, brown anchovy-paste-like necrotic contents of the liver abscess. Amebas are usually not detectable in the necrotic material. Before the availability of effective antiamebic therapy, formation of such a fistula was a good prognostic sign for a spontaneous cure because it provided drainage of the abscess.

Amebic brain abscess occurs rarely but has a high associated rate of mortality. There have been case reports describing genitourinary involvement, including perinephric abscesses, splenic abscesses, infected rectal cysts, rectovaginal fistulae, cervical ulcers, uterine involvement, and vaginal lesions [50]. Cutaneous amebiasis is a rare complication and generally involves the perineum and genitalia as a complication of intestinal disease [51].

Diagnosis

The diagnosis of intestinal amebiasis (Table 106.2) still rests primarily on microscopic demonstration of cysts or trophozoites in the stool or in scrapings or biopsy samples obtained by sigmoidoscopy or colonoscopy. Because organisms may be excreted intermittently or may be unevenly distributed in the fecal specimen, at least three stool specimens on separate days should be examined to detect 85%–95% of the infections. Barium studies, laxatives, bismuth-containing preparations, antidiarrheal agents, and antibiotics can interfere with detection of the organism. Problems with microscopy include the misidentification as *E. histolytica* of other *Entamoeba* species and leukocytes that have ingested red cells, and the inability to distinguish between *E. histolytica* and *E. dispar*. In patients with mild bowel complaints, whose symptoms do not appear consistent with invasive amebiasis, care must be taken in the interpretation of a positive microscopic examination for amebic cysts or trophozoites. Fecal antigen detection assays that can distinguish between *E. histolytica* and *E. dispar* infections have been developed for commercial use; however, their efficacy in areas where disease is not endemic has been questioned [51–55]. Because *E. dispar* infections are not associated with seroconversion, amebic serology may be a useful adjunct in assessing the patient, especially in areas where *E. histolytica* is not endemic.

Sigmoidoscopy should generally be performed in patients presenting with dysentery. Endoscopy should be performed without previous bowel preparation to increase the chance of detecting amebas in the colonic mucus [56]. Discrete shallow-based ulcers covered with yellow or white exudate with intervening areas of edematous mucosa are often found in invasive amebic colitis. However, the endoscopic appearance of amebic colitis may be indistinguishable from inflammatory bowel disease, diffuse mucosal erythema, granularity, and friability, or from pseudomembranous colitis secondary to *C. difficile* infection with pseudomembranes [44]. Multiple biopsy samples or scrapings should be taken from the ulcer edge, exudate, and intervening mucosa [44,56]. The diagnostic yield from endoscopic biopsy samples or scrapings is high. Trophozoites are usually easily identified in these specimens by routine light microscopy, but immunohistochemical staining for *E. histolytica* may further increase the yield [44].

Serology is an important tool in the diagnosis of amebic liver abscess and can help confirm the diagnosis of intestinal amebiasis [57]. Because antiamebic antibodies may persist for months and years after the eradication of infection, a positive serology requires more rigid clinical and diagnostic correlation in endemic areas. Indirect hemagglutination is the most sensitive assay, which yields positive results in 90%–100% of subjects with liver abscess, 75%–90% of subjects with symptomatic intestinal infection, and 5%–50% of subjects with asymptomatic infection. Enzyme-linked immunosorbent assay (ELISA) kits for the serodiagnosis of amebiasis are also available. Because serological tests may be negative early in the course of an acute infection, it is important to repeat the serology 5–7 days later. Recombinant antigens have been used for diagnosis and may offer improved specificity for acute infection [58–60].

An imaging procedure should be performed in all suspected cases of amebic liver abscess. Right upper quadrant ultrasonography is usually the least expensive initial procedure. The usual appearance is a round or oval-shaped hypoechoic lesion with no wall echoes. On abdominal computed tomography (CT), the abscesses usually appear as well-defined low-density lesions. The differential diagnosis of space-occupying lesions in the liver includes bacterial (pyogenic) liver abscess, hydatid cyst, or tumor. Amebic serology usually establishes or excludes the diagnosis of amebic liver abscess. Ultrasonographic or CT-guided needle aspiration of the abscess can be performed to rule out a pyogenic abscess if the results of serology are nondiagnostic or if the clinical condition of the patient requires an immediate diagnosis. Concomitant pyogenic and amebic infections are unusual at the time of the initial presentation, but bacterial superinfection may occur after repeated aspirations or open drainage. Amebas are rarely recovered in the aspirate. Because of the risk for spillage and anaphylaxis, aspiration should be avoided if there is suspicion of a hydatid cyst.

Treatment

Patients with *E. histolytica* infection should receive antiamebic therapy, but there is no evidence that patients with *E. dispar* infection require treatment [42,61]. If assays that distinguish between infection with *E. histolytica* and *E. dispar*

Table 106.2 Morphology of human gastrointestinal protozoan parasites

	Stool	Intestinal biopsy
EXTRACELLULAR		
Ameboid		
Entamoeba histolytica	Trophozoite 10–20 μm; pale, round nucleus with small central karyosome; cyst 9–25 μm, four nuclei; morphologically indistinguishable from *E. dispar*; with ELISA, fecal antigen detection of trophozoite antigen can distinguish *E. histolytica* from *E. dispar*; serology may be useful adjunct	Trophozoites but not cysts seen invading colonic mucosa, causing colonic ulcerations
Blastocystis hominis (pathogenicity is controversial)	Organisms 6–40 μm, round with large central body or vacuole	
Flagellates		
Giardia lamblia	Trophozoite pear-shaped, 10–20 μm long, characteristic face-like image secondary to two nuclei, each with prominent karyosome; cyst oval, 7–10 μm long; direct fluorescence antibody test available in many laboratories for detection of cysts. Fecal immunoassays are routinely used to detect *Giardia* in many US hospitals	Trophozoites seen most commonly on duodenal mucosal surface but also on jejunal and ileal biopsy; histology usually normal, but villous atrophy seen in severe infections
Dientamoeba fragilis	Ameboid in shape, flagella not visible, 5–15 μm, 1–2 nuclei; no known cyst form	
Ciliates		
Balantidium coli (rare)	Trophozoite 50–200 μm in length, motile; cysts are rarely seen in stool and are 50–75 μm in diameter	Trophozoites can invade colonic mucosa, causing ulceration
INTRACELLULAR (coccidia)		
Cryptosporidium parvum	May need to submit special request to the laboratory; with modified acid-fast stain, oocysts stain uniformly, are round, 4–6 μm, contain four sporozoites, which may or may not be visible; measurement with micrometer to differentiate from *Cyclospora*; direct fluorescence assay may be helpful in detecting cysts	Intracellular forms seen as 4-μm extracytoplasmic dots on the apical surface of enterocytes; highest yield in the proximal small intestine, but also in ileum and colon
Isospora belli	May be observed on wet preparation; may need to submit special request to laboratory; with modified acid-fast stain, oocysts stain uniformly, appear oval, 20–30 μm, with two sporocysts, each containing four sporozoites	Intracellular forms seen as 20-μm intracytoplasmic inclusions within the enterocyte on light microscopy; distribution may be patchy
Cyclospora cayetanensis	May be observed on wet preparation; may need to submit special request to laboratory; with modified acid-fast stain, oocysts stain variably, resemble cryptosporidia oocysts but are larger, 8–10 μm; contains two sporocysts each with two sporozoites; the oocysts autofluoresce under UV light (365 nm); measure with micrometer to distinguish from cryptosporidia	Intracellular forms difficult to observe on light microscopy; intracellular forms have been observed on electron microscopy as intracytoplasmic inclusions

ELISA, enzyme-linked immunosorbent assay.

are unavailable, treatment decisions must be based primarily on the clinical presentation. The goals of treatment are to cure invasive disease and eradicate intestinal carriage of the organism. Metronidazole and tinidazole are the drugs of choice for patients with invasive intestinal disease or amebic liver abscess (Table 106.3). Metronidazole is highly efficacious (90% cure rate in many studies) and is relatively well tolerated. Despite widespread use of this drug, *E. histolytica* resistance to metronidazole has not been a problem to date. Intestinal disease is generally treated for 5–10 days. Antibiotic therapy of liver abscess is similar; however, 2.4 g of metronidazole taken as a single dose for 2 days has been reported to be more effective in a small group of patients [62]. Common side effects of metronidazole include nausea, headache, metallic taste, and abdominal discomfort; ataxia, confusion, insomnia, and paresthesias may occasionally occur. Patients should avoid alcoholic beverages owing to the disulfiram-like properties of metronidazole. The most serious side effects involve the central nervous system (psychosis, seizures), which mandate cessation of the drug. Rapid recurrence of these symptoms after readministering the drug has been reported [63]. The drug is available for intravenous administration

Table 106.3 Antibiotic therapy for amebiasis

Drugs	Adult dosage	Pediatric dosage
Lumenal agents[a]		
Paromomycin (Humatin)	30 mg/kg/day orally in three divided doses for 7 days	25 mg/kg/day orally in three divided doses (maximum 2 g/day) for 7 days
Iodoquinol (Yodoxin)	650 mg orally t.i.d. for 20 days	30–40 mg/kg/day in three divided doses (maximum 2 g/day) for 20 days
Agents for invasive amebiasis[b]		
Metronidazole	750 mg orally t.i.d. for 5–10 days 500 mg i.v. every 6 h for 5–10 days	30–50 mg/kg/day orally in three divided doses for 5–10 days 15 mg/kg i.v. load followed by 7.5 mg/kg every 6 h (maximum 2250 mg/day)
Tinidazole	2 g/day for 3–5 days	50 mg/kg/day (children > 3 years of age)
Dehydroemetine[c] (Mebadin)	1–1.5 mg/kg/day i.m. for 5 days (maximum 90 mg/day)	1–1.5 mg/kg/day i.m. for 5 days (maximum 90 mg/day)

a Lumenal agents are used primarily for the treatment of nondysenteric amebiasis and to eradicate intestinal colonization after treatment of invasive amebiasis (colitis and liver abscess).
b Treatment of amebic colitis, liver abscess, and other invasive disease is followed by a complete course of a lumenal agent to eliminate intestinal colonization.
c Available only through the US Centers for Disease Control and Prevention: telephone 404-639-3670 or 404-639-3356; nights and emergencies, 404-639-2888.
i.m., intramuscularly; i.v., intravenously; t.i.d., three times daily.

in patients who are unable to take medications by the oral route. Tinidazole may be more effective than metronidazole and is prescribed at a dose rate of 2 g/day for 3–5 days [64].

In the critically ill patient with fulminant amebic colitis, there may be some advantage in adding a second agent, dehydroemetine, for the first 2–3 days of therapy. Although there are no controlled trials to support such combination therapy, dehydroemetine offers a rapid amebicidal effect that could be beneficial in severe disease. The short course of therapy is designed to lessen the risk for cardiotoxicity. Dehydroemetine, which is preferred to the parent compound, emetine, because it may be less toxic, is available in the United States only from the Centers for Disease Control and Prevention. Because bacterial peritonitis resulting from leakage of the diseased colon is a frequent complication of fulminant amebic colitis, antibacterial therapy should also be initiated in these patients [42]. As in other patients with dysentery, antidiarrheal agents should not be administered.

After treatment of invasive intestinal or extraintestinal amebic disease is complete, administration of a lumenal agent is generally started to eradicate intestinal carriage of the organism. Three drugs have proven efficacy as lumenal agents: diloxanide furoate (no longer available in the United States), paromomycin, and iodoquinol (Table 106.3). The side effects of paromomycin are diarrhea and gastrointestinal side effects. Rare dose-related neurological toxicity, including optic neuritis, has been reported with iodoquinol. It is controversial whether a lumenal agent is necessary in conjunction with metronidazole treatment because courses of metronidazole of 10 days or longer may be effective in eradicating intestinal carriage [65]. Because about 10%–15% of patients treated with any of these agents fail to eradicate intestinal carriage, a follow-up stool examination after completion of therapy is recommended.

Most cases of colonic and extracolonic amebiasis can be managed medically. Even in cases of fulminant colitis, it is unclear whether these patients benefit from surgery unless toxic megacolon is present [42]. Further interventions are generally reserved for prevention of complications resulting from perforation of the colon and rupture of liver abscesses. Possible indications for aspiration of an amebic liver abscess as an adjunct to medical therapy include extremely large abscesses in which rupture is felt to be imminent, abscesses in the left lobe of the liver (because of the greater risk of rupture into the pericardium), and treatment failure, in which fever and pain persist after 3–5 days of appropriate therapy. Aspiration can generally be accomplished percutaneously. Surgical drainage should be reserved for large left lobe abscesses that cannot be reached percutaneously. It is important to note that amebic liver abscess cavity may resolve slowly and that successfully treated abscess cavities may increase in size over the first few weeks. Most abscesses resolve by 6 months, but 10% of patients may have abnormal ultrasonographic findings more than 1 year after therapy. The persistence of a cavity alone is not an indication for aspiration or for administering another course of antibiotics.

Positive ameba stool examinations may be encountered in patients with minimal bowel complaints as well as in AIDS patients with diarrhea who do not have symptoms or findings consistent with invasive disease. Most of these cases represent infection with *E. dispar*, rather than *E. histolytica*, and do not require therapy. However, it is recommended that asymptomatic cyst passage of pathogenic strains of *E. histolytica* be treated because these patients may subsequently develop invasive disease or transmit the organism to close contacts. At the present time, our recommendation is to treat all patients in areas of nonendemicity whose stool examination results are positive, particularly because stool examinations are rarely conducted in the absence of any intestinal symptoms. This practice may change after widespread acceptance of tests that can differentiate between *E. histolytica* and *E. dispar*.

Despite legitimate concerns about administering metronidazole in pregnancy, women who develop symptomatic amebic colitis during pregnancy should receive metronidazole because of their increased risk for fulminant colitis. A long-term follow-up study of women given metronidazole for therapy of *Trichomonas* during pregnancy reported no adverse outcomes [66]. However, in the case of the pregnant woman with a positive stool examination result, but without evidence of invasive disease (a setting in which infection with *E. dispar* is most likely), treatment with paromomycin, a nonabsorbable aminoglycoside, could be initiated with close follow-up of the patient [67].

Giardia lamblia

Giardia lamblia (also termed *G. intestinalis* and *G. duodenalis*) is a flagellated protozoan initially described by van Leeuwenhoek in 1681 and by Lambl in 1859. The clinical spectrum of human giardiasis includes asymptomatic carriage, acute self-limiting diarrhea, and, rarely, persistent diarrhea that may fail to respond to appropriate therapy even in immunocompetent individuals. *Giardia* infection can cause intestinal malabsorption, and in children this may be associated with retardation of growth and development.

Giardia spp. are among the most primitive of all eukaryotes [68]. The life cycle consists of two stages: the trophozoite and the cyst (Fig. 106.3). Infection is initiated by ingestion of as few as 10–100 cysts [69]. The cysts excyst in the proximal small intestine, releasing two trophozoites that multiply by binary fission. Trophozoites attach to the intestinal mucosa through an attachment organelle called the *ventral disk*. The life cycle is completed by excystation, an event that may be induced by exposure to a mildly alkalotic pH of 7.8, intralumenal conjugated bile salts, or decreasing levels of cholesterol [70,71].

Epidemiology

Giardia is cosmopolitan in distribution, and prevalence rates are estimated to be as high as 2%–5% of populations in the industrialized world and a staggering 20%–30% of individuals in some regions of the developing world. *Giardia* is one of the most frequently identified intestinal parasites in the United States and was the most commonly implicated pathogen in water-borne disease outbreaks during the past 30 years [12]. Although recognized as a common pathogen, it is less well appreciated that *Giardia* can cause illness serious enough to require hospital admission, with the number of admissions for giardiasis rivaling that for shigellosis [72].

High-risk groups for giardiasis include infants and young children, particularly those attending day-care centers, individuals who have traveled outside the United States, people exposed to infected water sources, and homosexual men [73]. Reporting of giardiasis as a nationally notifiable disease

in the United States began in 2002 [74]. The total number of reportable cases was approximately 20 000 per year between 1998 and 2002. The highest number of case reports received were for children aged 1–9 years and adults aged 30–39 years. The peak incidence was during the early summer through early fall months coinciding with the summer recreational water season [74]. *Giardia* has been implicated in multiple outbreaks of diarrheal illness associated with ingestion of contaminated drinking water and recreational water sources [1,75]. Many of these outbreaks were associated with unfiltered water systems in which the only treatment was chlorination, a tribute to the ability of the cysts to survive in fresh water and their relative insensitivity to chlorination. Although contamination of recreational water sources may occur from animals, and humans can be infected by *Giardia* from animal sources [76], evidence does not generally support zoonotic transmission as a major risk for human infection [77]. Transmission of *Giardia* does not occur exclusively by ingestion of contaminated water; food-borne transmission has been described in several outbreaks [78].

Pathogenesis and pathology

Despite intensive investigation, the pathogenesis of human giardiasis is incompletely understood. In contrast to *E. histolytica*, *Giardia* causes disease without penetrating the epithelium or surrounding tissues, and infection is not typically associated with significant mucosal inflammation. Giardiasis causes diarrhea through multiple mechanisms, including intestinal malabsorption, hypersecretion, loss of epithelial barrier function, and intestinal hypermotility [79–81]. *Giardia* induces loss of brush-border surface area and impairment of disaccharidase activity, thus contributing to malabsorption. The observation that microvillous injury is not observed in athymic mice infected with *Giardia* suggests that this injury is not due solely to parasite attachment or virulence factors and strongly implicates the role of T cells [82]. A 58-kDa enterotoxin has been implicated in stimulating chloride secretion [83,84]. Disruption of epithelial tight junctions and increased rates of epithelial apoptosis contribute to the loss of epithelial barrier function observed in cell culture and animal models of giardiasis [79,80,85,86].

Infecting strains may differ in their virulence [87–90]. One phenotypic difference between *Giardia* strains is their susceptibility to host intestinal proteinases, and resistance may depend on the form of variant surface protein expressed by the parasite [88]. The *Giardia* human isolates can be divided into two major genotypes, assemblage A and assemblage B, based on genetic and biological differences [68]. Assemblages A and B share less than 90% nucleic acid identity at many homologous loci, and some investigators have proposed that they be considered as separate species [90]. It has been suggested that assemblage B genotypes are associated with a more severe diarrhea, but this remains to be confirmed in further studies [91–94]. Genome sequence information from the *Giardia* genome project [95] will continue to provide important insights into *Giardia* genes with respect to their biological function and the evolution of eukaryotic processes [32,95].

There is strong experimental and clinical evidence that secretory antitrophozoite antibodies are important and contribute to clearance of the parasite from the intestinal tract [96–98]. For example, individuals with immunoglobulin deficiencies are at significantly higher risk for chronic *Giardia* infection [99,100]. Although animal studies suggest that cell-mediated immunity could play a role in host defense against *Giardia* [101], children with a severe T-cell deficiency due to thymic aplasia (Di George syndrome) or purine nucleoside phosphorylase deficiency are not more susceptible to giardiasis, and their morbidity is comparable with that in immunocompetent children. The clinical course of giardiasis does not appear to be altered in patients infected with the human immunodeficiency virus (HIV) [102]. Ingestion of maternal antibody in breast milk appears to provide infants with protection from symptomatic disease but does not stop the establishment of *Giardia* infection [103].

Clinical manifestations

Studies of human volunteers suggest that the incubation period for symptomatic disease is 1–2 weeks [69,88]. It is important to note that the onset of symptoms may precede the excretion of cysts in stool by more than 1 week [104]. The clinical presentation is varied and can be classified in one of three syndromes: asymptomatic carrier state, acute self-limiting diarrhea, and chronic diarrhea. Asymptomatic infection is probably the most common outcome of *Giardia* infection [105,106]. In individuals who develop symptoms, the most common presentation is that of diarrhea with watery foul-smelling stools, often with abdominal distention, flatulence, nausea, flatus, anorexia, and vomiting. Blood and mucus in the stool are rare. Low-grade fever also may be observed, and in some individuals, fatigue and malaise or headache may be prominent.

Although infection is self-limiting in most healthy individuals, a significant proportion (25%–30%) come to medical attention because of chronic diarrhea, often with features of steatorrhea and weight loss. Malabsorption of vitamins A and B-12, proteins, and D-xylose is not unusual, and more than 50% of symptomatic individuals report weight loss of greater than 4.5 kg (10 lb) [107,108]. It is important to note that secondary lactase deficiency may persist for several weeks after eradication of *Giardia* infection, necessitating the dietary restriction of lactose. This can be confused with recurrent or relapsing infection.

Protracted disease is more frequent in young children and in those individuals with an underlying humoral immunodeficiency syndrome and nodular lymphoid hyperplasia [99,100,108,109]. This syndrome is most commonly associated with patients who have common variable immunodeficiency

and occasionally with selective immunoglobulin A deficiency. However, *Giardia* infection also has been associated with nodular lymphoid hyperplasia in the absence of overt humoral immunodeficiency. Extraintestinal disease is rare, but there are case reports of individuals with gastritis, reactive arthritis, biliary tract disease, and urticaria [110–113]. Gastric giardiasis may be seen in patients with achlorhydria.

Diagnosis

The diagnosis of *Giardia* infection (Table 106.2) should be considered in any patients with prolonged diarrhea, particularly if they have been exposed to children in day care, were exposed to potentially contaminated water, or report a history of recent travel. Stool parasitological exam has traditionally relied on microscopic examination. However, this is a labor-intensive method and relies on the availability of skilled technicians for reading stool parasite smears. Consequently many hospitals offer enzyme immunoassay methods for screening stools for *Giardia* and *Cryptosporidium*, and a microscopic exam is not performed unless the clinician specifically requests this exam or provides the laboratory with a detailed clinical history [114]. Multiple stool samples collected on different days may be required to obtain more than 90% sensitivity in detecting *Giardia* infection [115]. Barium studies are not useful and may even hamper detection of the organism in stool. The experience of the laboratory staff in the microscopic recognition of *G. lamblia* also has an important impact on the sensitivity of microscopic examination of stools. A direct fluorescent antibody test can be used as a rapid alternative confirmatory test instead of routine microscopy [114]. When the diagnosis cannot be made by examination of stool, intestinal aspiration, intestinal biopsy, or brush cytology may be indicated [116]. One advantage of biopsy is that it may provide additional information regarding associated bowel pathology, such as nodular lymphoid hyperplasia. An alternative approach is to treat empirically for giardial infection before subjecting the patient to more invasive tests. The nonspecificity of symptoms associated with chronic *Giardia* infection and the similarity to symptoms observed in irritable bowel syndrome may contribute to delayed and missed diagnoses [117]. The differential diagnosis includes infection by other protozoan organisms, enteric viruses, and noninvasive bacteria. In patients with malabsorption, the differential diagnosis includes other causes of steatorrhea and malabsorption as well as inflammatory bowel disease. Serology has not proved helpful in the diagnosis of giardial infections.

Treatment

Metronidazole and tinidazole are the drugs of choice (Table 106.4) for the treatment of giardiasis [118]. Tinidazole is superior to metronidazole when given in a single dose. Furazolidone is somewhat less effective than metronidazole, but it is available in a liquid preparation that is widely used in children in the United States. Albendazole has been shown to exhibit some efficacy in the treatment of giardiasis, and it may prove useful for administration to children in less developed countries for the simultaneous treatment of intestinal helminths and *Giardi* [119]. None of the above agents is recommended for use during pregnancy. Paromomycin, a nonabsorbable aminoglycoside with antigiardial activity, has been suggested as a possible drug for use in pregnant women. Nitazoxanide has been licensed to treat patients over 1 year of age. It has not been shown to be more efficacious than the nitroimidazoles, but may have a role in treating metronidazole-resistant giardiasis [120]. This medicine has not been studied in pregnant women, but is not expected to be harmful.

A major problem in treating patients with *Giardia* infection is the recurrence of symptoms after standard courses of therapy. This may be secondary to persistent infection because of resistant organisms, or may occur in patients in whom reinfection cannot be documented and in whom an immunodeficiency, such as hypogammaglobulinemia, is not present. One possibility is secondary lactase deficiency, which may persist despite eradication of infection. Patients who have persistent symptoms after single-drug therapy may benefit from treatment with another agent from a different class of drugs, or combination therapy [118,120].

Although symptomatic patients infected with *Giardia* should receive therapy, the treatment of asymptomatic carriers is not routinely recommended. This particularly pertains to control of infection within day-care centers. A longitudinal

Table 106.4 Drug treatment of giardiasis

	Adult dosage	Pediatric dosage
Metronidazole	250 mg t.i.d. for 5–7 days	5 mg/kg/day for 10 days
Tinidazole	2 g single dose	50–75 mg/kg single dose
Nitazoxanide	500 mg orally b.i.d. for 3 days	Age 12–47 months: 100 mg orally b.i.d. for 3 days Age 4–11 years: 200 mg orally b.i.d. for 3 days
Furazolidone	100 mg q.i.d. for 7–10 days	2 mg/kg t.i.d. for 7–10 days

b.i.d., two times daily; q.i.d., four times daily; t.i.d., three times daily.

study of asymptomatic children in a day-care center indicated that excretion of *Giardia* cysts is well tolerated, and in the setting of a high rate of reinfection, treatment of asymptomatic children may lead to recurrent courses of therapy with potentially toxic drugs [121].

Blastocystis hominis

Blastocystis hominis is a unicellular protozoan parasite detected in 10%–20% of stools examined by microscopy (Table 106.2). Its life cycle is unknown, and controversy surrounds its taxonomy and pathogenicity [122,123]. Symptomatic patients with high concentrations of *Blastocystis* parasites (more than 10 organisms per high-power [400 ×] field) were more likely to be coinfected with other enteric pathogens [124]. This may explain why the treatment of *Blastocystis* with iodoquinol and metronidazole appears to be more effective in relieving the symptoms of infected patients than in eliminating the infection [124]. Alternatively, there may be distinct strains of *B. hominis* differing in their pathogenic potential, which could explain the poor correlation between infection and symptomatic disease. One study suggested that *Blastocystis* infection was associated with disease only in immunocompromised individuals [124]. Symptomatic *Blastocystis* infection should be considered a diagnosis of exclusion, and if symptoms persist after therapy, there should be a further investigation for other causes of intestinal disease [125]. Optimum therapy has not been established, but metronidazole and trimethoprim sulfamethoxazole have been used when treatment is deemed necessary [126].

Dientamoeba fragilis

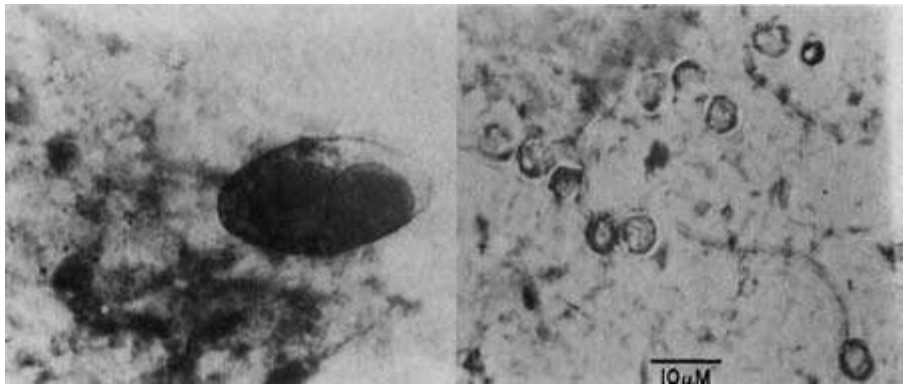
Dientamoeba fragilis is a protozoan parasite that is being increasingly identified in stool samples (Table 106.2) [127]. No known cyst form of *D. fragilis* has been identified and its life cycle and mode of transmission are unknown. Molecular phylogenetic studies indicate that *D. fragilis* is not an amoeba but a flagellate that has permanently lost its flagella, and is closely related to the trichomonads. Symptoms ascribed to *D. fragilis* infection are similar to those observed in patients with irritable bowel syndrome, including mild diarrhea, abdominal pain, anorexia, and fatigue. Fever, irritability, weight loss, nausea, and vomiting are occasionally reported, and an associated eosinophilia has been described [128]. The pathogenic potential of this organism remains uncertain, because the organism is detected in asymptomatic patients and in patients harboring other suspected pathogens. It has been proposed that *D. fragilis* is transmitted in the ova of *Enterobius vermicularis*, because some studies have observed a high level of coinfection, but subsequent studies have rejected this hypothesis. In several reports, symptomatic individuals become free of symptoms when the parasite was eradicated [127]. Attempts to introduce infections in animals or human volunteers have been unsuccessful. If symptomatic infection is diagnosed, adults should be treated with diiodohydroxyquin (650 mg three times daily for 3 weeks), or tetracycline (500 mg four times daily for 1 week) as an alternative. In children, metronidazole is recommended (30–50 mg/kg/day orally in three divided doses for 5–10 days). Paromomycin (25 mg/kg/day orally in three divided doses for 5–7 days) is also a reasonable alternative.

Balantidium coli

Balantidium coli is a ciliated protozoan parasite and is a rare cause of intestinal disease (balantidiasis) in humans (Table 106.2). Disease outbreaks in humans are associated with close exposure to pigs and their feces [129]. Outbreaks in institutions associated with poor hygiene or coprophagia have also been reported [130], as have water-borne outbreaks. Humans are probably relatively resistant to *B. coli* infection, but malnutrition, achlorhydria, and poor hygiene predispose to disease. The spectrum of disease ranges from asymptomatic carriage, through watery diarrhea, to active colitis with bloody mucus-laden stools. *B. coli* infection is also a rare cause of appendicitis [131,132]. *B. coli*, like *E. histolytica*, can invade the colonic mucosa and spread through submucosal layers, causing colonic ulcerations. Misdiagnosis as ulcerative colitis has been reported [133]. Rarely, colonic perforation occurs with resultant peritonitis [134]. Extraintestinal disease, with lung or liver involvement, is a rare complication [133]. Diagnosis is made by observing the motile trophozoites in stool saline mounts under low-power microscopy [129]. Cysts are much less frequently seen in human infections. Optimum therapy remains uncertain, but tetracycline (500 mg four times daily for 10 days) is recommended by most authorities. Iodoquinol (650 mg three times daily for 3 weeks) is an appropriate alternative.

Intracellular protozoan parasites

The AIDS epidemic has played an important role in the recognition of intracellular spore-forming parasites as important gastrointestinal protozoan pathogens [135]. Organisms from the genera *Cryptosporidium*, *Cyclospora*, and *Isospora* can cause an acute, self-limited diarrheal illness in immunocompetent hosts and a severe chronic diarrhea in patients with AIDS and other forms of immune dysfunction. The similar life cycles of these organisms may account for their similar clinical presentations. *Cryptosporidium*, *Cyclospora*, and *Isospora* are all intracellular pathogens that can replicate asexually within the enterocyte to produce a merozoite stage, which can autoinfect other enterocytes, leading to a rapid spread of the infection within the epithelium. All three pathogens also undergo a sexual stage that leads to the generation of cysts or spores, which are sloughed into the gut lumen and excreted in the stool. For *Cryptosporidium*, formation of the infectious sporozoite can take place within the host, which can autoinfect other enterocytes. However, for *Cyclospora* and *Isospora*,



(a) (b)

Figure 106.4 **(a)** Modified Kinyoun stain of *Isospora belli* cyst in stool. Note that the ellipsoid shapes are larger (20–33 μm × 12–15 μm) than the oocysts of *Cryptosporidium* or *Cyclospora* (4–10 μm). Immature oocysts contain a single sporocyst; mature oocysts contain two. **(b)** Modified Kinyoun stain of *Cryptosporidium* oocyst in stool. From DeHovitz JA, Pape JW, Boncy M, Johnson WD. Clinical manifestations and therapy of *Isospora belli* infection in patients with the acquired immunodeficiency syndrome. N Engl J Med 1986;315:88, with permission from the Massachusetts Medical Society.

formation of the infectious sporozoite must take place outside the host.

Enzyme immunoassays are routinely used to screen stools for cryptosporidia [114]. Many laboratories no longer routinely screen for *Cyclospora* or *Isospora* in their analysis of stool samples for parasites. The modified acid-fast stain may be the most useful for distinguishing among the three genera (Fig. 106.4). The distinction is important because infections with *Cyclospora* and *Isospora*, but not *Cryptosporidium*, respond well to antibiotic treatment.

Microsporidia are spore-forming protozoa that have been recognized as causing widespread infection in patients with AIDS (see Chapter 104). Because they do not appear to be significant pathogens in immunocompetent hosts, they are not discussed further in this chapter.

Cryptosporidium

Cryptosporidium species were originally described in the stomach and intestine of asymptomatic mice by Tyzzer in 1907 [136]. *C. parvum* was recognized as a cause of diarrhea in animals but was not identified as a human pathogen until 1976 [137,138]. Initially, most of the reported *C. parvum* infections were in patients with AIDS [139]. However, with improved methods of stool diagnosis and better understanding of the clinical disease, cryptosporidiosis has emerged as an important cause of diarrhea in normal hosts as well. *C. hominis* was identified in 2002 as a distinct *Cryptosporidium* species infecting humans [140]. *C. hominis* is restricted to humans, but *C. parvum* can infect other mammals. Most human *Cryptosporidium* infections involve either *C. parvum* or *C. hominis*; however, other *Cryptosporidium* species traditionally associated with animals (*C. meleagridis*, *C. felis*, and *C. muris*) have also been isolated from humans [141]. *Cryptosporidum* species were originally classified as coccidia, but subsequent evidence suggests that they should be placed in a distinct taxonomic group [142].

Epidemiology

Human cryptosporidiosis is found worldwide in both industrialized and developing countries and in both rural and urban areas. The parasite is transmitted by ingestion of oocysts that are excreted in the feces of infected humans or animals, from person-to-person spread, by ingestion of contaminated food and water, and, as a zoonosis, by contact with infected (primarily farm) animals. Direct person-to-person transmission may occur by fecal–oral spread related to sexual practices. The prevalence of *Cryptosporidium* infection is highest in young children and immunocompromised individuals. The stool positivity rate is higher in developing countries (1%–22%) than in industrialized countries, where cryptosporidia are identified in the stool of 0.3%–4% of individuals with diarrheal illnesses [143–145]. In developing nations, there is a high rate of asymptomatic carriage, and in some studies, the prevalence of stool positivity for *Cryptosporidium* in control patients approached or exceeded that observed in children with diarrhea [145]. Based on serological studies, exposure to *Cryptosporidium* is relatively common even in industrialized countries, with as many as 15%–36% of individuals seropositive [118,145–149]. *C. parvum* also infects cattle, and individuals with occupational exposures, such as dairy farmers, have a higher prevalence of seropositivity [148]. In developing countries, the seroprevalence is even higher, with 65% to nearly 100% of individuals possessing antibodies to *C. parvum* in parts of Latin America [149]. Cryptosporidiosis is among the most common causes of diarrhea in patients with AIDS, with an annual incidence of 5%–10%. Severe cases of cryptosporidiosis also can be seen in individuals with other forms of immunodeficiency, such as hypogammaglobulinemia, and in those patients who are receiving immunosuppressive drugs for malignancies, autoimmune diseases, or organ transplantation [118,145]. The reader is referred to Chapter 104 for a more detailed discussion of *Cryptosporidium* infection in immunocompromised hosts.

In developing countries, a significant portion of disease transmission may arise from person-to-person spread within families, with transmission rates comparable with those of *Shigella* [150]. In industrialized countries, day-care centers represent a source for outbreaks and sporadic infections. A cross-sectional study showed that 1.8%–3.8% of children

in day-care centers are infected, but rates are much higher (27%–59%) among children in centers experiencing an outbreak of *C. parvum* disease [151]. Infections occur primarily in diaper-wearing children, who serve as a potential nidus for secondary infection of the surrounding community. The risk for secondary transmission within a household is low (5%) when the index case involves an adult [152]. Person-to-person spread within the hospital setting also has been reported [153].

Water-borne outbreaks of *C. parvum* infection are a major threat to public health and have been associated with contaminated drinking water and recreational waters [75,143,144]. These outbreaks underscore the resistance of *Cryptosporidium* oocysts to chlorination and the difficulties in removing the organism by filtration. Food-borne outbreaks of cryptosporidiosis have also been reported, and have been associated with ingesting unpasteurized apple cider, unpasteurized milk, chicken salad, and raw produce [118,145]. Cryptosporidiosis has also been associated with travel, particularly to south-central Asia [154].

Pathogenesis and pathology

Cryptosporidium sporozoites emerge from the ingested oocysts after undergoing sexual recombination. Time-lapsed video-microscopy has demonstrated that the sporozoites invade epithelial cells within 30 s after contact [155]. However, the parasite remains at the cell surface within a membrane-bound compartment without entering deep into the cytoplasm. Parasite-induced epithelial cell apoptosis induces inflammatory mediators [156,157]. The potential mechanisms by which cryptosporidia cause diarrhea include disruption of the epithelial barrier (resulting in malabsorption), induction of inflammatory mediators, or release of parasite enterotoxins that stimulate intestinal secretion [145].

The complete genome sequences for *C. parvum* and *C. hominis* have been reported [158,159]. The two genomes are similar with only 3%–5% sequence divergence. Analysis of the protein-coding genes indicates that both aerobic and anaerobic metabolic pathways are available, but that the latter consists of an alternative electron transport system in a simplified mitochondrion. The parasite lacks the enzymes for the synthesis of key biochemical building blocks. Consistent with its need to import essential nutrients from the host cell, the genome encodes multiple transporters.

On histological examination of intestinal biopsy specimens from infected individuals, a variety of nonspecific changes can be seen, including villous atrophy (partial or complete) and crypt hyperplasia with increased numbers of lymphocytes, macrophages, plasma cells, and, less commonly, neutrophils in the lamina propria [160]. However, many patients show normal duodenal biopsy specimens, despite chronic diarrhea [160]. There appears to be an association between the extent of malabsorption and intestinal injury and the intensity of the infection (based on oocyst excretion) [161]. The prolongation of infection in immunocompromised patients and in animal models suggests that CD4 (helper) T cells and interferon are critical to the control of infection [145,157,162–164]. One of the remarkable consequences of the availability of highly active antiretroviral therapy (HAART) has been a significant reduction in the cases of cryptosporidiosis seen in HIV-infected individuals [165].

Clinical manifestations

The clinical spectrum of the disease is wide and includes asymptomatic carriage, a self-limited diarrheal illness in immunocompetent individuals, and a relentless, severe, watery diarrhea in some immunocompromised individuals. In a study of 29 healthy volunteers, the median infective dose of *C. parvum* was estimated to be 132 oocysts, with a mean incubation period of 9 days (range 5–22 days) [166]. As few as 30 oocysts caused infection in some subjects. The infectivity was therefore comparable with that of *Giardia* cysts. Subjects with diarrhea excreted more oocysts over the course of the infection than did subjects without diarrhea [167]. In a study of 21 healthy volunteers, the median infective dose of *C. hominis* was 10 and 83 oocysts using clinical and microbiological definitions of infection respectively [168]. The mean incubation period was 5.7 days (range 2–10 days). The infectivity of *C. hominis* was similar to that of *C. parvum*. In contrast to *C. parvum*, *C. hominis* elicited a serum IgG response in most infected persons.

The predominant symptom in intestinal cryptosporidiosis is diarrhea, which is often accompanied by abdominal cramps and varies greatly in severity from individual to individual. Some patients have scant intermittent diarrhea, whereas others (more often immunocompromised individuals) experience voluminous watery diarrhea that can approach the quantities seen with cholera (> 10 L/day). Mucus may be present in stools, but bloody diarrhea is rare, and white blood cells are usually not found in stools from patients with cryptosporidiosis. Accompanying symptoms may include nausea, fatigue, general malaise, anorexia, vomiting, and low-grade fever. The duration of illness in immunocompetent individuals ranged from 2 to 26 days in one study [169], with a mean of 12 days, but more prolonged illness is not unusual [150]. Transient relapse of watery diarrhea has been observed in immunocompetent hosts, particularly in the massive outbreak of water-borne *Cryptosporidium* infection that occurred in Milwaukee [152]. Extraintestinal disease is rare in immunocompetent individuals, but pancreatitis and cases of reactive arthritis have been reported in previously healthy adults [170,171]. Cholecystitis is seen in up to 10% of patients with cryptosporidiosis and AIDS but is rare in immunocompetent patients.

The differential diagnosis for cryptosporidiosis in immunocompetent hosts includes other protozoan infections (e.g., *Cyclospora cayetanensis, Giardia lamblia*, and *Isospora belli*), bacterial infection (e.g., *Salmonella, Shigella, Campylobacter, Yersinia,*

Clostridium difficile, and enterotoxigenic *Escherichia coli* in patients with a history of travel to developing countries), and viral infections (e.g., rotavirus and Norwalk viruses).

Diagnosis

The diagnosis of *Cryptosporidium* infection should be suspected in individuals with diarrhea lasting longer than 3 days. Patients should be questioned with respect to recent travel, exposure to children in day care, the state of their drinking water, ingestion of unpasteurized milk or fruit juices, exposure to recreational water, and exposure to animals, particularly cattle. Many laboratories routinely use commercial enzyme immunoassay methods to detect *Cryptosporidium* antigens in the stool [114]. At least two stools should be obtained on two different days to reach a sensitivity of over 90% [115]. In some laboratories, positive results using enzyme immunoassays are confirmed by immunofluorescent assays [116]. In the human volunteer studies, organisms could be detected using a more sensitive flow cytometric assay in stool samples that were negative by enzyme immunoassay or immunofluorescent assays [168]. The US Environmental Protection Agency has developed methods of concentrating the organisms from water involving filtration, centrifugation, and immunomagnetic separation, but these methods are not applied in clinical microbiological laboratories [172]. It is important to make a diagnosis in the interest of public health, although disease is generally self-limiting in immunocompetent hosts.

For those unusual cases in which *Cryptosporidium* infection is suspected, but the major symptoms are abdominal cramps or abdominal pain without significant diarrhea, stool specimens are more likely to be negative, and a duodenal aspirate with biopsy, combined with lower endoscopy and terminal ileum biopsy, may have a higher diagnostic yield [173].

Treatment

For immunocompetent individuals, the disease is self-limiting, and symptomatic treatment (replacement of lost fluids) is the cornerstone of therapy. Nonspecific antidiarrheal therapies, such as antimotility agents, may provide some relief for individual patients. Most antimicrobial agents investigated for cryptosporidiosis have demonstrated mixed success. The most promising agent is nitazoxanide, which is licensed for the treatment of giardiasis and cryptosporidiosis in children [174,175].

Cyclospora cayetanensis

In the early 1990s, diarrhea associated with an organism variously described as a large cryptosporidium, blue-green algae, cyanobacterium-like body, or coccidian-like body was reported [176]. The organism was identified as a species of *Cyclospora* by Ortega and colleagues [177], who successfully induced sporulation and excystation of oocysts obtained from individuals with diarrhea. Electron microscopic studies of the organisms in enterocytes revealed that they possessed morphological features of coccidians of the phylum Apicomplexa [178], and a molecular phylogenetic analysis confirmed that *Cyclospora* is a coccidian parasite closely related to protozoa of the *Eimeria* genus, which are known pathogens of birds [179].

Epidemiology

Cyclospora species are distributed widely but appear to be more common in tropical and subtropical areas. Originally, disease was described primarily in travelers to endemic areas, but with greater awareness of the parasite, indigenous disease in endemic areas and outbreaks in areas of low endemicity are being more widely recognized [180]. Prevalence rates as high as 11% have been reported in nonnative residents of an endemic area, and 18% of young children (1 month to 2 years of age) in poor regions of Peru had oocysts in their stool [180,181]. In the United States and the United Kingdom, surveys of stool specimens during nonoutbreak periods reveal that the prevalence of positive stools is less than 0.5% [176].

One of the most important biological properties affecting the epidemiology of *Cyclospora* is that the oocysts in freshly excreted stool are noninfectious! The oocysts must sporulate outside the host before infection of the next host can occur. Consequently transmission is not likely to occur by person-to-person contact. The environmental conditions required for oocysts to sporulate are not well understood. The ingestion of water or fresh produce containing sporulated oocysts of *Cyclospora* is the major mode of transmission. In North America there have been over 12 documented food-borne outbreaks involving *Cyclospora*. This number is unprecedented in the experience with other protozoan parasites. The types of fresh produce implicated in such outbreaks have included raspberries, mesclun, basil, and snow peas that were potentially imported from Central and South American countries [176,182]. Produce should be thoroughly washed before being eaten to decrease the risk of transmission.

Pathogenesis and pathology

Limited information is available on how *Cyclospora* causes disease in humans. Thus far infections have not been established in animals models or human volunteers [176,183]. Disease appears to involve primarily the small intestine, and documented impaired D-xylose absorption suggests that the proximal small intestine may be an important target for infection [184,185]. Electron microscopic studies of jejunal biopsy samples have demonstrated that the sporozoite, trophozoite, schizont, and merozoite stages of the organism are present within parasitophorous vacuoles in the cytoplasm of infected enterocytes [178]. In contrast to cryptosporidia, the *Cyclospora* are intracytoplasmic in the apical supranuclear region, rather than extracytoplasmic at the lumenal surface of the enterocyte. Villous blunting has been observed on endoscopic biopsies obtained from patients with active *Cyclospora* infection,

which could be mistaken for celiac disease or tropical sprue [186–188].

Clinical manifestations

The clinical manifestations range from asymptomatic illness to prolonged, nonbloody diarrhea associated with loss of appetite, fatigue, and weight loss [176]. Whereas infected children in endemic areas are asymptomatic or have relatively mild symptoms, infected nonimmune adults developed a more severe and prolonged illness. In untreated nonimmune patients remitting–relapsing symptoms may persist for weeks to months, with fatigue and malaise being the most persistent symptoms. The average incubation period is estimated to be 7 days, but may be as short as 1–2 days [176]. The mean duration of oocyst shedding has been found to be 23 days [176]. Symptoms of diarrhea and fatigue may persist after organisms are no longer detectable in stool samples; conversely, individuals may continue to shed oocysts after symptoms have disappeared. Although cyclosporiasis can be prolonged and frequent relapses are common, disease appears to be self-limited in immunocompetent hosts. Complications can include malabsorption, Reiter syndrome, and possibly Guillain–Barré syndrome [176].

Diagnosis

A high index of suspicion is needed to make the diagnosis because stools are not routinely processed for detection of this organism. It is important for the physician to communicate with the laboratory to determine how the stool should be collected and whether it should be sent to a reference laboratory. *Cyclospora* infection should be suspected in patients with prolonged diarrhea accompanied by marked fatigue and malaise, particularly those with a recent history of travel. Patients should also be questioned regarding their intake of fresh produce. Diagnosis depends on the detection of oocysts by the microscopic examination of stool samples using acid-fast staining methods or ultraviolet fluorescence microscopy (Fig. 106.5; see also Table 106.2). Because excretion of oocysts may be intermittent, multiple stool samples should probably be examined before excluding the diagnosis of *Cyclospora* infection. The diameter of oocysts in stained specimens can distinguish *Cryptosporidium* oocysts (4–6 μm) from the larger (8–10 μm) *Cyclospora* oocysts.

Diagnosis of cyclosporiasis also has been made by light microscopic examination of duodenal and jejunal aspirates obtained during endoscopy and examined as wet mounts, or, probably more efficiently, as acid-fast-stained samples. Smears also can be examined under ultraviolet fluorescence microscopy, looking for the characteristic blue fluorescence. Identification of the parasite by light microscopy in a duodenal biopsy specimen has been reported, but in general this has not been a high-yield approach for diagnosis. If the diagnosis is suspected endoscopic biopsies should be sent in special fixative for electron microscopy [178].

Treatment

Immunocompetent patients can be treated successfully with few or no relapses with trimethoprim (TMP)–sulfamethoxazole (SMX) (i.e., co-trimoxazole; 160 mg TMP + 800 mg SMX) twice daily for 7–10 days [176]. Alternative treatments for persons allergic to sulfa drugs have not been established. Ciprofloxacin has been reported to demonstrate efficacy [189]. There is an anecdotal report that an immunocompetent sulfa-allergic patient infected with *Cyclospora* failed ciprofloxacin treatment but subsequently responded to nitazoxanide [190].

Isospora belli

Isospora belli is a coccidian protozoan that was first recognized as an intestinal parasite of humans more than 80 years ago in military forces stationed overseas and in outbreaks of diarrhea in institutionalized individuals [191,192]. Molecular phylogenetic analysis indicates that *Isospora* spp. are most closely related to *Toxoplasma* and *Neospora* [193,194].

Isospora infection is more common in individuals residing in developing countries and is relatively rare in immunocompetent individuals in the United States. Sporadic small-scale outbreaks of *Isospora* infection have been seen in mental institutions and day-care centers within the United States, but more widespread outbreaks, such as as ones seen with *Cryptosporidium* and *Cyclospora*, have not been reported [195]. *Isospora* is an important cause of diarrhea (~ 15%) in individuals with AIDS in developing countries but accounts for only 0.2% of diarrhea cases in AIDS patients within the United States [196]. *Isospora* is sensitive to TMP–SMX, and one reason for the lower prevalence of isosporiasis in AIDS patients within the United States may be the widespread use of TMP–SMX as prophylaxis for *Pneumocystis carinii* infection. There is no evidence of significant zoonotic transmission of

the organism. Like *Cyclospora* but unlike *Cryptosporidium*, oocysts are excreted unsporulated or partially sporulated. The major mode of transmission is therefore by ingestion of water or food contaminated with sporulated oocysts.

The manifestations of *Isospora* infection are similar to those seen with both *Cyclospora* infection and cryptosporidiosis: watery, nonbloody, noninflammatory diarrhea that is often accompanied by abdominal cramps, fatigue, weight loss, anorexia, and occasionally fever [195]. The incubation period is relatively short (2–3 days), and infection is generally self-limited but may be prolonged (months to years) even in immunocompetent hosts. In contrast to cryptosporidiosis and cyclosporiasis, a peripheral eosinophilia may be seen in individuals with isosporiasis. Diarrhea may be more severe in young children than in adults. Villous atrophy and crypt hyperplasia have been observed in small intestinal biopsies of immunocompetent patients. Extraintestinal infections have been observed primarily in AIDS patients, but one has been reported in an immunocompetent patient [197].

Because stools are not routinely processed for detection of this organism, the physician must specifically request the laboratory to process the stool. The diagnosis can be made by detection of the *Isospora* oocysts in feces using light microscopy (Table 106.2). Shedding of oocysts is intermittent, and multiple stool samples may need to be examined. Charcot–Leyden crystals and eosinophils are occasionally seen in stool samples from individuals with isosporiasis [195]. There are case reports of individuals who had negative stool tests but in whom organisms were detected by histological examination of small intestinal biopsy specimens [198].

The drug of choice for the treatment of *Isospora* infection is TMP–SMX (160 mg TMP + 800 mg SMX four times daily for 7 days, followed by 10 days of 160/800 mg twice daily). In patients with severe malabsorption, parenteral administration may be required to achieve therapeutic drug levels [197]. In the sulfa-allergic patient pyrimethamine alone may be used.

107 Parasitic diseases: helminths

Carlos Seas, Martin Montes, A. Clinton White Jr

Intestinal nematodes (roundworms), 2651
Trematodes (flukes), 2659
Cestodes, 2661

Helminth parasites, or worms, are multicellular eukaryotic organisms that are common inhabitants of the human gastrointestinal track. Throughout human history, parasitism with helminths has been a normal part of the human condition [1–3]. Only with the development of improved standards of sanitation, housing, and food preparation in the 20th century did the prevalence of these infections decrease in wealthy countries. In contrast, the total number of infected individuals continued to increase throughout most of the 20th century. Data from the late 20th century highlighted the previously unrecognized burden of morbidity, focusing on the role of helminths in chronic malnutrition, anemia, and accompanying cognitive defects, leading to the recognition that intestinal helminths are neglected tropical diseases of global public health importance [4,5].

Helminths are multicellular members of the animal kingdom, large enough to be visible to the human eye at some point in their life cycle. Parasites have different morphological forms that vary with the host and environment and most have an obligate one-way life cycle. In contrast to most microorganisms, helminths do not typically reproduce within the human host. Thus, the parasite burden is largely a reflection of the infecting dose and host control of infection. Interestingly, the population structure of worm burden in communities is typically overdispersed, i.e., most of the worms live in a small portion of the population. Most of this pattern appears related to genetic predisposition [6].

Helminths are categorized into three major groups: nematodes, trematodes, and cestodes. Nematodes are roundworms with a tubular gut including both a mouth and anus. There are two groups of flatworms: trematodes and cestodes. Trematodes, or flukes, are flat leaf-shaped organisms with a blind gut. All require an obligate freshwater snail host. The cestodes, or tapeworms, typically have two distinct forms. The adult forms a tapeworm in the gut of the definitive host and possesses an attachment organ (scolex) and segments (proglottids). While not having a separate gut, the external surface shares many features with the mammalian digestive tract. The proglottids are hermaphroditic, containing both ovaries and testes. The larval forms develop as cystic lesions in the tissues of the intermediate host. Some species have a second intermediate host. Many parasites use humans as an obligate host in their life cycle. In addition, related animal parasites often infect people and cause human disease. Zoonotic infections are noted with all the major nematodes groups as well as some trematodes and cestodes. The major human intestinal helminths and their treatment are detailed in Table 107.1.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Intestinal nematodes (roundworms)

Ascaris lumbricoides

Ascaris lumbricoides is the most common human helminth infection, with one-fifth of all humans infected. Adult females live inside the host for about 1 year, producing 200 000 ova daily. Humans acquire infection by ingestion of contaminated food or water. Larvae are released in the small intestine, penetrate the intestinal wall, and migrate to the lung and up the trachea. They are subsequently swallowed, and complete their development within the lumen of the small intestine.

Epidemiology

Approximately 1.2 billion people are infected with *Ascaris*, with 100–300 million symptomatic infections and 60 000 deaths annually [3–5,7]. Most infections occur in tropical and subtropical areas of the world, especially in Asia. The peak prevalence occurs between ages 5 and 15 years. Ascariasis is thought to cause growth deficit, lactose intolerance, malabsorption of vitamin A, malnutrition, impaired cognition, and impaired physical fitness in developing countries [5,7–9]. Much of the variability in worm burden reflects host genetic susceptibility [6].

Table 107.1 Helminth infections involving the human gastrointestinal tract and their treatment.

Nematode	Drug	Adult dose	Pediatric dose
Nematodes (roundworms)			
Ascaris	Albendazole	400 mg, single dose	400 mg, single dose
	Mebendazole	100 mg, twice daily for 3 days	100 mg, twice daily for 3 days
		500 mg, single dose	500 mg, single dose
	Pyrantel pamoate	11 mg/kg (maximum 1 g) for 3 days	11 mg/kg (maximum 1 g) for 3 days
	Levamisole	2.5 mg/kg, single dose	2.5 mg/kg, single dose
Hookworm	Albendazole	400 mg, single dose	400 mg, single dose
	Mebendazole	100 mg, twice daily for 3 days	100 mg, twice daily for 3 days
	Pyrantel pamoate	11 mg/kg (maximum 1 g) for 3 days	11 mg/kg (maximum 1 g) for 3 days
	Levamisole	2.5 mg/kg, single dose, repeat after 7 days in heavy infection	2.5 mg/kg, single dose, repeat after 7 days in heavy infection
Strongyloides	Ivermectin	200 µg/kg for 1–7 days	200 µg/kg for 1–7 days
Trichuris	Mebendazole	100 mg, twice daily for 3 days	100 mg, twice daily for 3 days
	Albendazole	400 mg for 3 days	400 mg for 3 days
Enterobius	Albendazole	400 mg, single dose, repeat in 2 weeks	400 mg, single dose, repeat in 2 weeks
	Mebendazole	100 mg, single dose, repeat in 2 weeks	100 mg, single dose, repeat in 2 weeks
	Pyrantel pamoate	11 mg/kg (maximum 1 g), repeat in 2 weeks	11 mg/kg (maximum 1 g), repeat in 3 weeks
Trichinella	Albendazole	400 mg, twice daily for 8–14 days	400 mg, twice daily for 8–14 days
	Mebendazole	200–400 mg three times daily for 3 days, then 400–500 mg three times daily for 10 days	200–400 mg three times daily for 3 days, then 400–500 mg three times daily for 10 days
Ancylostoma (cutaneous larva migrans)	Ivermectin	200 µg/kg, single dose	200 µg/kg, single dose
	Albendazole	400 mg daily for 3 days	400 mg daily for 3 days
Visceral larva migrans	Albendazole	400 mg, twice daily for 5 days	400 mg, twice daily for 5 days
	Mebendazole	100–200 mg, twice daily for 5 days	100–200 mg, twice daily for 5 days
Anisakiasis	Surgical removal is the treatment of choice. Mebendazole or albendazole for 1–5 days has been effective in some cases		
Baylisascariasis	Albendazole	25–40 mg/kg daily for 28 days	25–40 mg/kg daily for 28 days
Angiostrongylus costaricensis	Ivermectin?		
Capillariasis	Albendazole	400 mg daily for 10 days	400 mg daily for 10 days
	Mebendazole	200 mg, twice daily for 20 days	200 mg, twice daily for 20 days
Tremadotes (flukes)			
Schistosoma spp. *S. mansoni*, *S. haematobium*, *S. intercalatum*	Praziquantel	40 mg/kg in two doses on a single day	40 mg/kg in two doses on a single day
S. japonicum or *S. mekongi*	Praziquantel	60 mg/kg in three doses on a single day	60 mg/kg in three doses on a single day
Fasciola	Triclabendazole	10 mg/kg, one to two doses	10 mg/kg, single dose
Other flukes	Praziquantel	25 mg/kg three times daily for 1 day	25 mg/kg three times daily for 1 day
Cestodes			
Adult tapeworms			
Hymenolepis nana	Praziquantel	25 mg/kg, single dose	25 mg/kg, single dose
	Nitazoxanide	500 mg, twice daily for 3 days	100–500 mg, twice daily for 3 days
	Niclosamide	2 g, single dose	50 mg/kg, single dose
Taenia saginata or *T. solium* taeniasis, or other tapeworms	Praziquantel	5–10 mg/kg, single dose	5–10 mg/kg, single dose
	Nitazoxanide	500 mg, twice daily for 3 days	100–500 mg, twice daily for 3 days
	Niclosamide	2 g, single dose	50 mg/kg, single dose

Table 107.1 (*cont'd*)

Nematode	Drug	Adult dose	Pediatric dose
Larval cestodes (cysticercosis, hydatid disease)			
Neurocysticercosis	Albendazole Plus steroids or neurosurgery	400 mg, twice daily for 8 up to more than 30 days	7.5 mg/kg, twice daily for 8 up to more than 30 days
Echinococcus granulosus	Albendazole Alone, +PAIR, or +surgery	400 mg, twice daily for > 10 weeks	7.5 mg/kg, twice daily for > 10 weeks
Echinococcus multilocularis	Surgical resection plus albendazole	400 mg, twice daily for 2 years up to lifelong	7.5 mg/kg, twice daily for 2 years up to lifelong

PAIR, *p*uncture, *a*spiration, *i*njection of scolicidal agent, and *re*-aspiration.

Clinical manifestations

With low worm burdens, patients are typically asymptomatic or may note passage of an adult worm, which can reach a length of 40 cm [7]. Most symptoms attributed to *Ascaris* (abdominal pain, nausea, and diarrhea) are difficult to differentiate from those of other endemic diseases. Intestinal obstruction may result from a massive parasite burden, particularly in children, who present with abdominal distention, abdominal pain, and poor oral tolerance [10,11]. The adult *Ascaris* may migrate upward to the oropharynx to be eliminated by the nasal or oral route, or may travel to the biliary tract, causing cholangitis, hepatic abscesses or pancreatitis, particularly in adults [12–14]. During the migration of larvae through the lungs patients may experience bronchospasm, and transient pulmonary infiltrates accompanied by eosinophilia.

Diagnosis, treatment, and prevention

Typical ova found in the stools with direct saline preparations or the Kato–Katz method are sufficient to make the diagnosis (Figs 107.1 and 107.2). Adult worms may be found in the stool, biliary tract and pancreatic duct. *Ascaris* can be visualized by ultrasound or computed tomography (CT) as cylindrical shapes with a slow and nondirectional movement [15].

Albendazole and mebendazole are the first-line drugs (see Table 107.1). Levamisole, pyrantel pamoate, and nitazoxanide are alternatives. Endoscopic extraction coupled with antiparasitic thrapy is the treatment of choice for biliary tract involvement. Ascariasis can be prevented by sanitation and promoting good hygienic practices. However, these measures are difficult to implement in endemic areas. Mass community treatment programs can dramatically decrease disease prevalence and reduce transmission [7,16–18].

Hookworm

Hookworm infections are mainly caused by *Ancylostoma duodenale* and *Necator americanus*, and are considered among the most common parasitic infections in tropical countries [3,5,19,20]. Humans are infected by skin contact with the filariform infective larval stage of the parasite. The most common penetrating sites are the hands and feet; from these sites the larva migrates to the lung where it usually resides for about 10 days. The larvae migrate up the trachea from the lungs and are swallowed. The adult worms develop in the small intestine. Adult hookworms are 1 cm long and pass approximately 30 000 eggs per day [19,21]. Each adult worm attaches to an intestinal villus, aspirates a plug of tissue from the villus tip, secretes inhibitors of the host coagulation and platelet pathways, and ingests blood. Periodically, the parasites will move to other villi. The main consequence of hookworm infection is intestinal blood losses due to ingestion by the parasite or villus damage. Infections with *A. duodenale* results in loss of approximately 0.2 mL/day per adult hookworm, significantly more than noted with *N. americanus* (~ 0.03 mL/day per adult hookworm) [19]. Occasionally, filariform larvae of *A. duodenale* may be ingested causing nausea, vomiting, and pharyngeal irritation [20].

Epidemiology

Hookworms are widely distributed, with *N. americanus* more widespread than *A. duodenale*. More than 700 million humans are infected with hookworms globally, with the greatest burden of disease in sub-Saharan Africa and Asia. Infection is more prevalent in males, but women and children are more vulnerable to the chronic sequelae (anemia and iron deficiency). Approximately 44 million pregnant women are infected. Poor sanitation, walking barefoot, and the use of human

excrement as fertilizers contribute to transmission in developing countries.

Clinical manifestations

The main clinical manifestation of hookworm infection is anemia due to iron deficiency, resulting from blood losses induced by parasite feeding. *Ancylostoma* induces more profound anemia than *Necator*. Hypoalbuminemia also follows the chronic infection and results in protein malnutrition. Typically, patients with chronic infection complain of severe pallor, dyspnea, fatigue, palpitations, and poor school performance. Increase maternal mortality, prematurity, low birthweight, and reduced lactation have been reported [5,20,21].

Most infections are asymptomatic or mildly symptomatic. Epigastric pain and tenderness as well as nausea are among the most commonly reported abdominal symptoms. Papular and pruritic skin eruptions may follow exposure to the filariform larvae. Mild cough, sore throat, and rarely pneumonitis may accompany larval lung migration. Eosinophilia, anemia and hypoalbuminemia are common [19].

Diagnosis, treatment, and prevention

Stool examination for eggs is usually adequate to make the diagnosis (see Figs 107.1 and 107.2). There is no clinical need to differentiate between hookworm species. Anthelminthic treatment includes albendazole, mebendazole, or pyrantel pamoate (see Table 107.1). If the patient is anemic, iron supplementation is usually needed as well. Improving sanitary conditions, promoting good hygienic practices, treatment of infected persons, and use of footwear can prevent transmission. However, the main current control strategy is mass chemotherapy of children [5,16,17,19,21]. Novel vaccines are under clinical evaluation.

Trichuris trichiura (whipworm)

Trichuris trichiura is the third most common soil-transmitted helminth, infecting 600 million with high prevalence rates in China, India, East Asia, and Central Africa [3,5]. Humans are infected by the ingestion of embryonated ova. The larvae are liberated from the eggs, migrate to the large intestine, and mature over 3 months. Each adult female produces approximately 20 000 eggs per day.

Epidemiology

Trichuris trichiura has a worldwide distribution but is especially prevalent in Africa, Asia and Latin America. The severity of infestation varies within a community resulting in an overdispersed distribution, with most of the worm burden occurring in a subgroup of individuals who are more likely to manifest disease [5].

Clinical manifestations

The adult parasite lives preferentially in the cecum, but the whole large intestine can be infected. The anterior end of the adult burrows inside the mucosa and submuocsa, leaving the posterior end visible in the lumen. Low-burden infections are typically asymptomatic [5,22]. In heavy infections, the inflammatory reaction to the attached nematode leads to colitis, dysentery, and rarely rectal prolapse. Heavy infections are most common in children below 10 years of age, who present with diarrhea and growth retardation. Colonic obstruction and perforation have been reported. Eosinophilia is the most frequent laboratory abnormality.

Diagnosis, treatment, and prevention

The diagnosis is confirmed by identifying ova in the stool (see Figs 107.1 and 107.2) [23]. Mebendazole or albendazole are first-line drugs for therapy (see Table 107.1), but should be given as a multidose regimen because single-dose therapy with albendazole is not consistently effective [24]. Mass deworming programs with single dose of albendazole fail to eliminate heavy infestations [16–18]. Adequate sanitary disposal of human feces, proper hygiene, and preparation of food reduce transmission.

Strongyloides stercoralis

Strongyloides is capable of completing its life cycle inside a single human host, allowing infection to persist for decades or to progress to life-threatening hyperinfection [25]. Adult female parasites live in the intestinal wall, where the ova hatch, releasing the rhabditiform larvae, which migrate into the lumen and pass in stools. In the environment, larvae molt into the filariform larvae, which infect the human host by penetrating through intact skin. The larvae then migrate via the bloodstream to the lungs, into the alveoli, up the tracheobronchial tree, and are swallowed. The adult female worms invade the small intestinal wall, where they produce eggs asexually. Some of the rhabditiform larvae molt into invasive forms prior to being excreted, and are capable of reinvading via the intestinal wall or perianal skin (autoinfection). The number of filariform larvae is increased in some immunocompromised individuals (e.g., those taking corticosteroids), leading to a hyperinfection syndrome. Some of the rhabditiform larvae convert to free-living adult males and females, which produce ova that hatch and mature to filariform larvae in the soil.

Epidemiology

Estimates of infected people range from 3 million to over 100 million, with a consensus estimate of approximately 60 million [26]. Endemic areas include most tropical areas of Africa, Asia, and Latin America. High prevalence areas include Southeast Asia and the Amazon basin [27–29]. Lower rates are noted in the southern USA, southern and eastern Europe, and Japan.

Strongyloides stercoralis can produce life-threatening hyperinfection in people with altered host defense, especially associated with corticosteroid treatment. A high prevalence of

S. stercoralis and increased severity of disease has been observed in people concurrently infected with human T-cell lymphotrophic virus type 1 (HTLV-1) [30–33]. Spontaneous secretion of interferon-γ by HTLV-1-infected mononuclear cells or increased regulatory T cells may suppress protective granulocyte and interleukin (IL)-5 responses [31,34].

Hyperinfection has also been reported in association with organ transplantation, malignancies (especially lymphoma and leukemia), other immunosuppressive therapy, protein-calorie malnutrition, visceral leishmaniasis, lepromatous leprosy, and other debilitating conditions [35,36]. However, hyperinfection has only rarely been associated with human immunodeficiency virus infection [37,38].

Clinical manifestations

A maculopapular rash or linear urticaria, called larva currens, may occur at the time of skin penetration or as a consequence of autoinfection [25,36,39,40]. The pulmonary phase of strongyloidiasis can be associated with cough, shortness of breath, wheezing, fever, transient pulmonary infiltrates, and eosinophilia, but is usually asymptomatic in chronic infection [41]. Eosinophilia is common in normal hosts with strongyloidiasis.

The adult worms of *S. stercoralis* often produce epigastric or diffuse abdominal pain or diarrhea [25,39,40]. This may be accompanied by occult blood in stool. With heavy infections, vomiting, malabsorption, steatorrhea, and weight loss can occur. Upper endoscopy may reveal edema or discoloration of the stomach or duodenum. The colon may have edema, ulceration, or tears [42]. Eosinophilic granulomatous enterocolitis, pseudopolyposis, and inflammatory mass lesions have also been reported.

Strongyloides hyperinfection is characterized not only by multisystem involvement [25,36]. The clinical manifestations are highly variable. Lung disease may be the only site involved clinically [43]. Pulmonary involvement results from the migration of large numbers of larvae through the lungs, causing bronchospasm, pulmonary hemorrhage, pneumonia, and respiratory failure [41,44]. Pulmonary symptoms include cough, shortness of breath, wheezing, and hemoptysis. Hyperinfection may progress to the acute respiratory distress syndrome, often with bilateral infiltrates seen on chest radiograph. Others have primarily intestinal symptoms.

As the filariform larvae penetrate the intestines and migrate, they can carry Gram-negative bacteria and *Enterococcus*, which adhere to their surface, leading to bacterial infections with enteric organisms or polymicrobial bacteremia, meningitis, peritonitis, or endocarditis [25,35,36,45]. The mortality rate with *S. stercoralis* hyperinfection may exceed 50%.

Diagnosis, treatment, and prevention

The diagnosis of strongyloidiasis is confirmed by identifying larvae in stool, tissues, or secretions (see Fig. 107.2) [25,46]. Eosinophilia is frequently present, but may be absent in immunocompromised hosts. Direct microscopic examination of stool for the organisms is insensitive (only 30% positive in a single sample) because larval output is low and intermittent. Concentration techniques such as the Baermann sedimentation method improve the sensitivity only modestly. The agar plate method is more sensitive. In hyperinfection syndrome, the number of larvae is greatly increased, facilitating the identification of larvae in stool as well as other tissues, with organisms frequently found in sputum, bronchoalveolar lavage fluid, intestinal biopsies, and biopsies of other tissues. The poor sensitivity of parasitological tests led to the development of several immunodiagnostic assays [25,46]. In endemic areas, enzyme-linked immunosorbent assay (ELISA) can be used as a screening method to rule out infection [29,39,47]. Assays using recombinant antigens appear to be more specific [48].

Ivermectin is the treatment of choice for strongyloidiasis [49]. A single dose of 200 μg/kg is adequate in uncomplicated cases. Relapses have been reported with all these drugs, especially in HTLV-1 coinfected patients, in whom a second round of therapy is recommended. In hyperinfection, patients should be treated with daily therapy for up to 1 week. Veterinary parenteral preparations can be used in severe cases. Thiabendazole, while also effective, has frequent side effects and is no longer manufactured in the USA. Comparative trials have demonstrated that albendazole is less effective than ivermectin, but albendazole may be used as an alternative if ivermectin and thiabendazole are not available [50,51]. Prevention of strongyloidiasis depends on improved standards of living and personal hygiene. Patients infected with HTLV-1 and those initiating corticosteroid therapy from endemic areas should be screened for *Strongyloides* infection.

Enterobius vermicularis (pinworm)

Enterobius vermicularis or pinworm is prevalent worldwide [52]. Humans acquire the infection by ingesting ova. The larvae escape the eggs, molt twice in the small intestines, and develop into adults in the colon. The adult female is approximately 1 cm long and lives in the large intestine. At night, the adult females crawl to the perianal area (Fig. 107.3), where they lay 10 000 eggs per night. The eggs adhere to perianal skin, causing pruritis. Transmission occurs via the hands of infected individuals.

Epidemiology

Children are at the highest risk of infection. Overcrowding, poor sanitary conditions, and household contact are factors associated with transmission. The infection is overdispersed, with the greatest burden of infection occurring in a minority of individuals [52].

Clinical manifestations

Anal pruritus is the main clinical manifestation, but dermatitis and bacterial superinfections can result from scratching

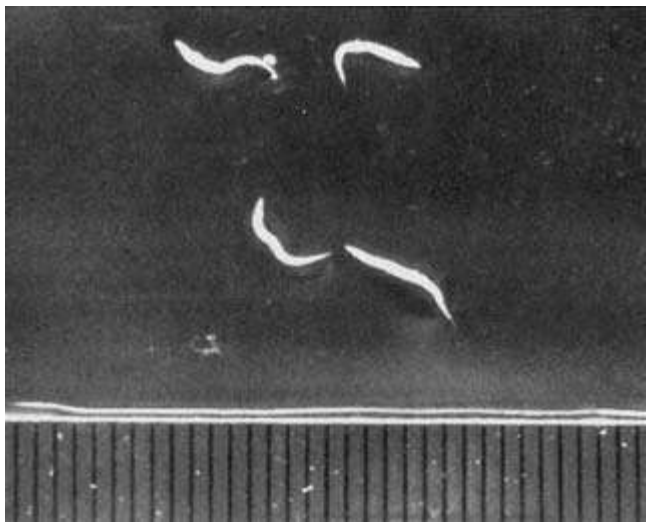

Figure 107.3 Adult female *Enterobius vermicularis* (pinworms) may be found on the perianal skin or occasionally on the surface of stools. Adult female pinworms are 8–13 mm long and 0.3–0.5 mm wide. (The scale is in millimeters.) From Smith JW, Ash LR, Thompson JH Jr, et al. Intestinal helminths. In: Atlas of Diagnostic Medical Parasitology Series. Chicago: American Society of Clinical Pathologists, 1984.

the area. Enuresis, insomnia, and rarely nausea and abdominal pain may occur. Appendicitis has been attributed to obstruction of the appendix by adult pinworms. Infection of the female genital tract is well recognized, causing vulvovaginitis in prepubertal girls; more infrequently cervical granulomas, salpingitis, and ovarian abscess have been reported. Peritonitis may result from intestinal perforation leading to ectopic localizations.

Diagnosis, treatment, and prevention

The recommended diagnostic approach is to apply adhesive transparent tape over the perianal skin area early in the morning and identifying ova microscopically (i.e., Scotch Tape test; see Fig. 107.1). The sensitivity is improved when several samples are taken. Direct stool examination is insensitive. Adult worms are occasionally identified on sigmoidoscopy or colonoscopy.

Albendazole, mebendazole, and pyrantel pamoate are the recommended antiparasitic drugs (see Table 107.1). Household members should also be treated. Reinfection is common. Hand hygiene and washing of bedclothes and underwear are recommended. Repeated treatment is often needed.

Trichinella

Trichinosis is a food-borne zoonosis of worldwide distribution. While animals are also infected, humans are particularly prone to clinical illness after eating improperly cooked meat infested with the larval stage of the parasite, mostly from pork, bear, horse and boar [53–56]. The larvae are released and mature in the small intestine over 2 weeks. Female adults deposit larvae, which invade the mucosa, travel through the bloodstream, and encyst in skeletal muscles [56]. The life span of an adult is several weeks, during which time a single female worm may produce approximately 1500 larvae.

Epidemiology

The disease is acquired only by ingestion of meat [55–57]. In Arctic North America, outbreaks are associated with the ingestion of bear meat. Molecular techniques have identified different groups: one, with five species and three genotypes, encapsulates in the host; the other, with three distinct species, does not encapsulate [55,57]. The worldwide incidence has declined, but outbreaks are still reported [53,54,58–60].

Clinical manifestations

The acute phase coincides with the intestinal and migratory phases of parasite development, with nausea, vomiting, abdominal pain, and diarrhea as the main complaints. Later, 1–3 weeks after exposure, fever, myalgia, facial or periorbital edema, and conjunctivitis are prominent symptoms [56,61–63]. Striated muscles are mainly affected during this phase, but cardiac and extraocular muscles are also infected. The central nervous system, kidney, and skin may also be infected.

Diagnosis, treatment, and prevention

The clinical picture, exposure history, and eosinophilia suggest the diagnosis. Several serological tests including ELISA are available, but antibodies may not be present until 3–5 weeks after infection [56,64]. Muscle biopsy is sometimes needed for diagnosis.

Albendazole or mebendazole is the drug of choice for the treatment of acute trichinosis [56,62]. Steroids are recommended in more severe forms of the disease. Trichinosis can be prevented by properly cooking pork or other potentially contaminated meat to at least 71°C (160°F). Meat less than 15 cm thick can be rendered safe if frozen at –23.3°C (–10°F) for 10 days.

Anisakiasis

Anisakiasis is an acute disease caused by fish ascarids (*Anisakis simplex*, *Anisakis physeteris*, *Pseudoterranova decipiens*) [65,66]. Humans are infected by eating undercooked marine fish containing the larval stage of the parasite, including cod, herring, rockfish, sardines, anchovies, salmon, tuna, mackerel, red snapper, and squid. The classical clinical presentation is with severe abdominal pain, nausea and vomiting developing minutes or hours after ingesting a contaminated fish. The diagnosis is usually confirmed by observing larva in the stomach by upper endoscopy [65–67]. Small intestinal involvement presents with localized invasion, edema, and even obstruction. Allergic manifestations may dominate the clinical picture. The diagnosis is confirmed by observing the worms at endoscopy or bowel resection. Larvae in the

stomach can be extracted with biopsy forceps. Anisakiasis is prevented by filleting freshly caught fish before larvae penetrate muscle, by cooking fish to 60°C (140°F) for at least 10 min, or by freezing for 24 h at –20°C (–4°F).

Visceral larva migrans and ocular toxocariasis

Toxocariasis is caused by two species of zoonotic ascarids of dogs and cats: *Toxocara canis* and *Toxocara catis* respectively [68,69]. The two main clinical syndromes are visceral larva migrans and ocular toxocariasis. Humans become infected by ingesting ova excreted by the definitive hosts into the environment. After ingestion of ova, the larvae penetrate the intestine and into tissues, but they are unable to enter the lung aveoli. Instead, the larvae continue to migrate through the host tissues until they eventually die. Children are most commonly affected. The disease is more frequently reported from developing countries with tropical and subtropical climates [68,69].

The clinical manifestations are characterized by fever, hepatomegaly, and eosinophilia. Other symptoms include abdominal pain, diffuse arthralgia, rash, and wheezing [68,69]. Pulmonary infiltrates are also observed. Neurological involvement is noted less frequently [70,71]. Ocular toxocariasis is characterized by unilateral involvement with retinal granulomatous lesions, causing visual defects, ocular pain and strabismus and, with chronic disease, retinal detachment [68,69,72,73]. The diagnosis is suspected on clinical grounds and confirmed by serological ELISA using parasite excretory/secretory antigens. The mainstay of treatment is the use of anti-inflammatory medications (e.g., prednisone 0.5–1.0 mg/kg). Antiparasitic drugs improve the response in visceral larva migrans, but should generally be avoided in ocular larva migrans. Albendazole is the treatment of choice. Thiabendazole and ivermectin are less effective. Ocular larva migrans requires a longer duration of therapy (4 weeks) and may require doses of albendazole of 800 mg twice a day. Control measures include deworming dogs and preventing defecation of dogs in areas where children play.

Baylisascariasis

The raccoon ascarid *Baylisascaris procyonis* can also cause a larva migrans syndrome with a predilection for the central nervous system [66,74]. Neurological involvement is characterized by fulminant eosinophilic meningoencephalitis, which is associated with very high mortality and significant neurological sequelae among survivors [75]. Visceral and ocular larva migrans have also been reported. Diagnosis is confirmed by measuring specific antibodies in serum and cerebrospinal fluid with ELISA. Thiabendazole or albendazole are recommended; ivermectin seems to be ineffective [75]. Steroids may be beneficial.

Cutaneous larva migrans

Cutaneous larva migrans or creeping eruption is a zoonosis caused by hookworms of dogs (*Ancylostoma caninum*) or cats (*Ancylostoma braziliense*). Like human hookworms, the filariform larvae penetrate the skin and cause a dermatitis characterized by serpiginous, papulovesicular, erythematous, and pruritic lesions as they migrate through the skin and subcutaneous tissues. Cutaneous larva migrans is prevalent in tropical and subtropical areas of the Caribbean, Africa, Latin America, the southern coasts of North America, and Southeast Asia. Transmission in developing countries occurs in both urban and rural settings [76]. The disease is also becoming more frequently recognized among travelers [77]. The diagnosis is made on clinical grounds. A single dose of ivermectin, or albendazole, is the drug of choice (see Table 107.1).

Ancylostoma caninum and eosinophilic enteritis

Ancylostoma caninum, the dog hookworm, has been identified as a cause of eosinophilic enteritis, generally a rare condition but quite common in northeastern Australia [67,78]. The findings include eosinophilic infiltration of the intestine, aphthous ulceration of the ileum, regional lymphadenopathy, and peripheral blood eosinophilia. Infection may be asymptomatic or cause abdominal pain. The diagnosis is made by finding the immature adult worm at endoscopy or by serological evidence of *A. caninum* infection. Albendazole or mebendazole are likely to be effective therapies.

Gastrointestinal angiostrongyliasis and other strongylids

Angiostrongylus species are strongylid nematodes whose normal hosts are rodents [79]. *Angiostrongylus cantonensis* was formerly limited to Southeast Asia and the Pacific, but has now been introduced into Jamaica and the US Gulf Coast, causing eosinophilic meningitis. *Angiostrongylus costaricensis* is endemic in rodents from California to South America. Adult worms reside in mesenteric arteries of rodents. Humans and rodents acquire infection by ingesting infected intermediate hosts (slugs, or their slime) on vegetation. Sporadic human disease is initially described among children and outbreaks in adults in Central America [79,80]. Recent studies from Brazil suggest that there may be widespread infection and underdiagnosis [81,82].

The parasites localize to the ileocecal region causing a granulomatous arteritis with eosinophilic infiltration in the ileocecal region that can result in thrombosis, local infarction, and bowel perforation [79]. The clinical manifestations vary from a visceral larva migrans-like syndrome to an acute abdomen, with nausea, vomiting, right lower quadrant pain, and fever. A right lower quadrant mass may be documented by palpation or visualized on radiographic studies of the ileocecal region. Eosinophilia and leukocytosis are common. Neither ova nor larvae are found in the stools of humans. Surgery is often necessary, and the diagnosis is often only made when adult worms or ova are identified in surgical specimens. Ivermectin, thiabendazole, and diethylcarbamazine are active against the worms in rodents, but there are

no data on their efficacy in people. Cooking slug-infested vegetables and hand washing can prevent infection.

Other strongylid parasites (*Trichostrongylus*, *Mammomonogamus*, *Oesophagostomum*, *Ternidens*) rarely cause human infection, but present with abdominal pain and eosinophilia [66].

Capillariasis

Capillariasis is an emergent zoonotic infection caused by three species of *Trichuris*-like organisms: *Paracapillaria philippinensis*, *Capillaria hepatica* and *Capillaria aerophilia* [66,67]. Humans are infected by eating uncooked freshwater or brackish fish containing infectious larvae; fish-eating birds are the definitive hosts. The parasite reproduces in humans, potentially achieving very high loads. The disease in endemic in the Philippines, Japan, Taiwan, India, Iran, and Egypt [66,67,83].

The clinical features are watery diarrhea, abdominal pain, malabsorption, and weight loss. Massive infestation may cause jejunal stricture and intestinal pseudoobstruction. The diagnosis is made by identifying the distinctive features of ova. Albendazole is the drug of choice, but mebendazole is an alternative. Proper cooking of fish prevents infection.

Trematodes (flukes)

Trematodes, or flukes, are flatworms (phylum Platyhelminthes, subphylum Trematoda) and require a freshwater snail as an intermediate host. Some use a second intermediate host. The blood flukes (genus *Schistosoma*) are among the most common human helminths. *Schistosoma mansoni* and *Schistosoma japonicum*, and the less common *Schistosoma intercalatum* and *Schistosoma mekongi*, live in mesenteric venules and cause intestinal and liver pathology. *Schistosoma haematobium* primarily affects the urinary tract. *Schistosoma* species enter through intact skin when humans come in contact with fresh water. Other pathogenic trematodes are foodborne, acquired by eating the second intermediate host (e.g., freshwater fish/crustaceans) or aquatic plants (*Fasciola* and *Fasciolopsis buski*). The liver/biliary flukes include *Clonorchis sinensis*, *Opisthorchis viverrini*, *Fasciola hepatica*, and *Metorchis conjunctus*. The intestinal flukes include *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai*. The organisms of the genus *Paragonimus* develop primarily in the lung.

Schistosoma species

Human schistosomiasis results from infection with one of five species of blood flukes of the genus *Schistosoma*, and is a major global public health problem. Each species of *Schistosoma* infects a specific freshwater snail [84]. The cercarial forms are released from the snail into fresh water, contact potential hosts, and enter human skin when contact is made with fresh water during bathing, fishing, or other water-related activities. The cercariae then shed their tail and the resulting schistosomulae invade the vasculature and migrate to the portal circulation, or in the case of *S. haematobium* the venous drainage of the urinary tract. *Schistosoma mansoni* migrates to the superior mesenteric veins and *S. japonicum* to the inferior mesenteric veins. The adult worms live as pairs within mesenteric venules, with the adult female surrounded by the male canal. Adult worms can live as long as 30 years in humans. Beginning 2–8 weeks after infection, the females begin to shed ova (approximately 300 ova daily for *S. mansoni* and up to 3500 daily for *S. japonicum*). The ova induce a granulomatous response, which facilitate migration through the intestinal or bladder wall allowing the ova to be excreted in stool or urine. Miracidia are released when ova hatch in fresh water and complete the life cycle by penetrating the surface of the appropriate snail host.

Epidemiology

An estimated 200 million people worldwide are infected with schistosomiasis [85–88]. *Schistosoma mansoni* is endemic in Africa, parts of Latin America, and scattered foci in the Middle East. Transmission is associated with dams, reservoirs, and irrigation systems. *Schistosoma intercalatum* is found in areas of western and central Africa. *Schistosoma japonicum* is endemic in the Far East, China, coastal river valleys in Japan, numerous islands in the Philippines, and Indochina, where it has a number of nonhuman hosts, including cows, dogs, and pigs. *Schistosoma mekongi* is found along the Mekong River in Indochina. In most areas, *Schistosoma* infection usually occurs in childhood and prevalence peaks between ages 10 and 20 years [89]. Updated information on the prevalence and epidemiology of schistosomiasis is available at http://www.who.int/ctd/schisto/epidemio.htm.

Clinical manifestations

Cercarial invasion is usually asymptomatic in local populations, but can cause a mild, pruritic, papular dermatitis termed cercarial dermatitis (swimmers itch) at the site of penetration [86,88,90]. The rash may last up to a few weeks. Acute schistosomiasis, or Katayama fever, was first described among people with *S. japonicum* infection, but can occur with other *Schistosoma* species [86,88–91]. The time from infection to onset of systemic symptoms ranges from 2 to 12 weeks and coincides with the initial production of ova. Katayama fever, a serum sickness-like syndrome thought to result from a hypersensitivity reaction to egg antigens, is characterized by fever, malaise, urticaria, abdominal discomfort, diarrhea, weight loss, cough, wheezing, mild hepatosplenomegaly, lymphadenopathy, and eosinophilia [88,91,92]. Some patients present with pulmonary infiltrates, which may reflect eosinophilic pneumonia, genital involvement (e.g., hematospermia), or spinal cord disease [93–95]. Symptoms can persist for several months.

Chronic schistosomiasis results from the granulomatous inflammatory response to the schistosome ova. For species

other than *S. haematobium*, eggs are deposited in mesenteric vessels, carried to the liver or intestines through the portal circulation, or reach the lungs or other sites by way of the systemic circulation. The pathology varies with the worm burden and the host immune response to the ova. A complex mix of Th1 and Th2 cytokines leads to varying degrees of inflammation and fibrosis [96].

Inflammation, hypertrophy, and ulceration of the mucosa characterize intestinal disease caused by *Schistosoma* [86,89,97]. Intestinal involvement is often asymptomatic, but infected people may experience abdominal pain, diarrhea, and occult or gross blood in their stools. Intestinal polyps, ulceration, and strictures may be encountered late in disease. There is also increasing evidence that chronic disease even with few symptoms is associated with malnutrition [4].

Ova that reach the liver elicit a granulomatous inflammatory response. Important components of the granulomas include eosinophils, lymphocytes, macrophages, and granulocytes. Advanced liver disease may also include fibroblasts, collagen, and giant cells [86,88,89]. A subset of individuals progress to severe "pipe-stem" portal fibrosis with presinusoidal portal hypertension with relatively preserved hepatic function. Hepatomegaly and splenomegaly are common in heavily infected persons. The parenchyma and liver function are preserved until late in the disease, but patients coinfected with hepatitis viruses, especially hepatitis C, may develop frank cirrhosis. Bleeding (from esophageal and rectal varices or intestinal granulomatous lesions) and ascites are complications of advanced hepatosplenic schistosomiasis.

Portosystemic shunting of ova to the pulmonary vasculature can cause granulomas and fibrosis may progress to chronic obliterative arteritis, pulmonary hypertension, and eventually cor pulmonale. Granulomatous responses to eggs are occasionally encountered in other organs, including the gallbladder (causing cholecystitis and cholelithiasis) and genital tract (causing cervicitis) [98]. Schistosomiasis also has been associated with prolonged or relapsing *Salmonella* bacteremia [99].

Schistosoma haematobium resides primarily in venules of the vesical plexus, but on occasion it too involves the gastrointestinal tract in association with acute appendicitis or asymptomatic appendiceal calcification [88,100].

Diagnosis, treatment, and prevention

The diagnosis of schistosomiasis is usually made by identifying ova in feces, urine or biopsy material (see Figs 107.1 and 107.2) [86,88]. Katz think smears are more sensitive than direct stool examination. Diffuse smears or patchy mucosal hyperemia, friability, and occasionally schistosomal polyps may be observed at colonoscopy [101]. Rectal biopsy may be necessary to document low-level infections. Histological examination may reveal ova even in the absence of macroscopic abnormalities. Ultrasonography has been widely used to assess hepatosplenic involvement and responses to therapy [102]. With hepatic disease, ultrasound may reveal dilation of the portal vessels and characteristic periportal fibrosis (so called "clay-pipe" or Symmer fibrosis), which correlates with parasite burden and hepatic pathology. Serological assays are available and provide suggestive evidence of schistosomiasis. In acute infection, antibody can often be detected prior to excretion of ova. The main serological test used in the USA is a FAST-ELISA [103]. The sensitivity is poor for *S. japonicum* and species-specific immunoblot assays may be more sensitive and specific. Antibodies may persist and cannot distinguish active from prior infection. Antigen detection assays can also prove helpful [104].

Praziquantel 40 mg/kg in one dose is recommended for the treatment of all *Schistosoma* species, except *S. japonicum* and *S. mekongi*, which should be treated with two doses of 30 mg/kg (see Table 107.1) [49,88]. Praziquantel is effective in killing the parasite and can decrease periportal fibrosis, hepatomegaly, and splenomegaly, but treatment does not reverse all the effects of chronic schistosomiasis. The response rate is lower in early infection and some cases may require a second dose. Second-line drugs include oxamniquine (*S. mansoni*) and metrifonate (*S. haematobium*). Endoscopic sclerotherapy or surgical decompression have been used successfully to treat bleeding esophageal varices due to portal hypertension.

Control measures in endemic areas include improved sanitation and disposal of human feces, avoidance of contaminated fresh water, use of molluscicides, and mass treatment programs. Chlorination of swimming pools and letting water stand for 24 h prior to bathing can prevent infection in travelers. Recent studies suggest that mass chemotherapy, particularly when directed at schoolchildren may decrease prevalence in many endemic areas, but this approach may not work as well in areas of zoonotic disease [4,105].

Liver flukes

Clonorchis and *Opisthorchis*

Clonorchis sinensis and *Opisthorchis viverrini* are found in Japan, China, Indochina, South Korea, and Taiwan [106–109]. *Opisthorchis felineus* and *Opisthorchis guayaquilensis* are found in Russia/Central Asia, and South America respectively. *Metorchis conjunctus* is found in North America. Humans become infected when they eat raw or incompletely cooked fish containing the infectious metacercariae. The released larvae mature into adults and migrate through the sphincter of Oddi to enter the biliary tract. Adult worms reside in small and middle-sized intrahepatic bile ducts, although they can also be found in extrahepatic ducts, the gallbladder and pancreatic ducts. Flukes may have prolonged life spans of up to 30 years. Eggs are released into the bile and passed in the stool. The eggs hatch in fresh water and are ingested by the snail intermediate host. Cercarciae emerge from the snail and infect freshwater fish, the second intermediate host, and transform into the metacercarcia form in the fish musculature.

Acute infection may present with fever, abdominal pain, and eosinophilia, but is not typically noted with Asian infections [108]. Slight liver enlargement and tenderness may be observed at the onset of infection. The major pathological changes of chronic infection manifest in the bile ducts: desquamation of the biliary epithelium, followed by hyperplasia, adenomatous proliferation, and later fibrosis and stricture of the bile ducts. The clinical manifestions of chronic infections are variable, ranging from asymptomatic to dyspepsia, abdominal pain, anorexia, hepatomegaly, icterus, edema, and diarrhea. Cholangitis, cholelithiasis, chronic cholecystitis, and pancreatitis have been noted. Cholangiocarcinoma is a potential long-term complication and is more common with *O. viverrini*.

The diagnosis of biliary flukes is based primarily on the identification of ova in the stool or bile (see Fig. 107.1). Ultrasonographic examination may reveal liver enlargement; dilation, sludge, or thickening of the wall of the gallbladder; dilation of the intrahepatic bile ducts; or evidence of cholangiocarcinoma [110,111]. Endoscopic retrograde cholangiopancreatography (ERCP) may show small irregular filling defects in the common bile duct, tortuosity and irregular dilation of the intrahepatic ducts, or blunting of the terminal branches of the biliary tree [109]. Praziquantel is the drug of choice for the treatment of *C. sinensis* and *O. viverrini*, but triclabendazole may also be effective [106,109,112].

Fasciola hepatica

Fasciola hepatica is found in most sheep- and cattle-raising areas of the world [108,113]. Snails are the intermediate host. Humans become infected when they eat wild watercress, alfalfa, or other aquatic plants contaminated with encysted metacercariae. Larvae excyst in the small intestine, penetrate the gut wall, migrate through the peritoneal cavity to the liver, and enter the liver through the capsule. They burrow through the human liver for periods of 6–9 weeks before finally penetrating into the bile ducts, where they spend their adult lives. Acute infection is characterized by fever, hepatomegaly, abdominal pain, weight loss, anemia, and eosinophilia [108,114–116]. Jaundice, biliary colic, and cholangitis are characteristics of chronic disease. Diagnosis of acute infection rests on a typical clinical scenario, supported by characteristic radiological findings, and demonstration of specific antibody. Multiple low-density lesions are observed on CT. Lesions are subcapsular, arrayed in tracts, and slowly evolve [114,116]. Serological tests for antibodies to either excretory/secretory antigens or recombinant proteins can confirm the diagnosis of acute infection [108,117]. In chronic infection, ova or adult worms may be identified in bile, duodenal aspirates, or stool. Therapeutic failures are common in patients with *F. hepatica* treated with praziquantel, and triclabendazole is now the drug of choice for fasciolasis (see Table 107.1) [112,115,118]. Nitazoxanide may also work in chronic infection [119]. Cure can also be achieved by removing the adult worms by ERCP [120].

Intestinal flukes

The intestinal fluke *Fasciolopsis buski* has as its definitive hosts humans, hogs, and occasionally dogs and a snail intermediate host. It is endemic in Asia [108,112]. The adult flukes attach to the mucosa of the upper small intestine and release ova into the feces. Cercariae encyst on water plants such as the water caltrop, water hyacinth, water chestnut, or water bamboo, which are ingested raw by humans. Inflammation, ulceration, and mucosal abscesses may develop in the small intestine. Epigastric pain, nausea, and diarrhea of varying severity are reported, but many people are asymptomatic. The diagnosis is made by identifying ova in the stool. Praziquantel is recommended for treatment.

Many species of the trematode family Heterophyidae (including *Heterophyes heterophyes* and *Metagonimus yokogawai*) and Echinostomatidae (including *Echinostoma* species) are parasites of humans and other fish-eating mammals [108]. The first intermediate hosts are snails, and the second intermediate hosts freshwater or brackish-water fish. Humans become infected from eating raw or inadequately cooked fish. *Heterophyes heterophyes* is encountered in the Middle East and Asia. Colicky pain, abdominal tenderness, and diarrhea may be noted by those with heavy infections. Eosinophilia may be present. *Metagonimus yokogawai* is found primarily in the Far East, where it is associated with the formation of egg-related granuloma at distant foci, such as the heart or central nervous system. *Echinostoma* species are found in Southeast Asia, where they cause inflammation in the intestines, with abdominal pain, diarrhea, and eosinophilia. Intestinal fluke infections are typically diagnosed by finding ova in the feces. Praziquantel is the treatment of choice. Infection can be prevented by eating only thoroughly cooked fish.

Cestodes

Cestodes (phylum Platyhelminthes, subphylum Cestoda) are tapeworms with adult stages and larval stages (e.g., cysticercosis or hydatid disease) [121]. The adult tapeworms are segmented worms that contain a scolex (attachment organ), a neck region where the segments are formed, and segments termed proglottids. Chains of proglottids comprise the body of the adult worm. The external proglottid surface functions as the parasite gut. As the proglottids mature, they develop both male and female sexual organs. The terminal proglottids contain the ova, which shed into the environment.

Taenia saginata (beef tapeworm)

Taenia saginata is a common human tapeworm endemic in most of the world. When people ingest raw or poorly cooked beef containing viable cysticerci, the 1–2 mm scolex, which has four muscular suckers but no hooks, evaginates and attaches to the intestine. The chain of proglottids forms from the scolex and reaches 4–25 m in length. The proglottids

gradually enlarge; mature gravid proglottids are usually 16–20 mm in length and 5–7 mm in width. The uterine stem has 12–30 main lateral branches on each side. When bovines ingest the ova, embryos hatch and invade the intestinal mucosa, migrate through the bloodstream, and develop into larval cysticerci in the muscles. This cystic ovoid structure measures 7–10 mm by 4–6 mm and contains an invaginated scolex. Ova are shed in feces or, more commonly, as gravid proglottids actively crawl out of the anus. The ova of *Taenia solium* and *T. saginata* are morphologically indistinguishable.

Epidemiology

Worldwide, 45–60 million people are thought to be infected with *T. saginata*. Contamination of pastures with human feces or untreated sewage leads to bovine cysticercosis. Infection is most important in tropical and subtropical cattle-raising areas of Africa, the Middle East, Europe, Asia, and South America [122,123]. The prevalence of human infection is less than 1% of stool examinations in most areas, but recent studies have identified prevalence rates of over 20% in East Africa, Bali, and Tibet [123]. The incidence of taeniasis in the USA is very low but transmission does occur.

Clinical manifestations

Taenia saginata usually causes few symptoms [123]. Common symptoms include sensing gravid proglottids migrating from the anus, abdominal pain, nausea, weakness, and loss of weight [122,123]. Rarely, intestinal obstruction or symptoms related to ectopic localization of proglottids have been seen. Some patients have significant eosinophilia, but most do not.

Diagnosis

Diagnosis is made by identifcation of the ova, scolex, or proglottids. Multiple stools are required to detect ova, since they are infrequently found on a single fecal examination, even when enhanced by concentration methods. Cellulose tape swabs applied to the perianal skin, as used for the diagnosis of *Enterobius* infection, is more sensitive than fecal concentration [124]. The eggs of *T. saginata* and *T. solium* cannot be differentiated morphologically. The scolex of *T. saginata* is differentiated easily from *T. solium* by the absence of hooks. However, the scolex is usually not recovered, even after successful treatment. Polyethylene glycol salt purgatives improve recovery of the scolex [125]. Examination of gravid proglottids is the main method for determining species, by counting the main branches of the uterine stem: counts of 13 or fewer branches on one side of the stem are considered diagnostic for *T. solium*; counts of 14 or greater are diagnostic for *T. saginata*.

Antigen detection tests are sensitive for taeniasis, but are not widely available and cannot distinguish the species [126]. Polymerase chain reaction (PCR) has been useful in diagnosing *T. saginata* in field situations [123]. Occasionally, tapeworms are identified as a ribbon-like defect in the barium column during contrast studies of the gastrointestinal tract.

Treatment and prevention

Praziquantel is the primary medication used to treat *T. saginata*. Niclosamide is also effective, but currently is not widely available. Nitazoxanide can also be used to treat taeniasis [127]. *Taenia saginata* infection can be prevented by avoiding raw or undercooked beef. Meat inspection is effective in detecting all but light infections. Cooking beef to a temperature of 56°C (133°F) kills cysticerci. Vaccines to prevent bovine *T. saginata* cysticercosis are feasible, but development has been slowed by limited commercial interest [128].

Taenia asiatica (Asian pork tapeworm)

Taenia asiatica is endemic in East and Southeast Asia. The proglottids are morphologically similar to those of *T. saginata*, such that it was only recognized as a separate species in 1993 [123,129]. Unlike *T. saginata*, the scolex contains a rostellum (like *T. solium*) but no hooks (like *T. saginata*). *Taenia asiatica* cysticerci are mainly found in the liver of pigs [129]. Humans become infected when they ingest cysticerci, which develop into the intestinal adult form.

Epidemiology

Asian taeniasis has been identified in Taiwan, Korea, China, the Philippines, Vietnam, Thailand, Indonesia, and Malaysia [123]. The prevalence of infection varies among regions, e.g., zero to 21% of people in various parts of Indonesia are infected.

Clinical manifestations, diagnosis, treatment, and prognosis

The clinical manifestations, diagnosis, and treatment of *T. asiatica* appear similar or identical to those of *T. saginata*. Human *T. asiatica* infection can be prevented by avoiding ingestion of undercooked liver and other viscera.

Taenia solium (pork tapeworm and cysticercosis)

Taenia solium infection has two distinct forms in the human host: taeniasis (tapeworm infection) and cysticercosis (tissues infected with the larval cysticercus) [130,131]. Neurocysticercosis refers to cysticercosis involving the central nervous system and is now recognized as a major cause of neurological disease worldwide. Humans develop the tapeworm form after ingesting undercooked pork containing cysticerci. The scolex evaginates, attaches to the intestinal wall, and develops chains of proglottids. The tapeworms are typically several meters long. Eggs or gravid proglottids are shed intermittently into stool. Pigs acquire the infection by ingesting eggs or proglottids from human fecal material. Once ingested, the larvae emerge from the eggs, penetrate the wall of the gut, enter the bloodstream, and migrate to many tissues, where they develop into cysticerci. Taeniasis is acquired by ingest-

ing undercooked pork and is closely associated with pig-raising areas in endemic countries. Cysticercosis is acquired from human tapeworm carriers, who often harbor eggs on their hands and fingernails. The eggs can autoinfect the tapeworm carrier or infect other people.

Epidemiology

Between 50 and 100 million people are infected with cysticercosis, but far fewer with intestinal taeniasis. Nearly all areas where pigs are raised with access to human fecal material are endemic for cysticercosis [132]. Currently, porcine cysticercosis remains highly endemic in Latin America, sub-Saharan Africa, South and Southeast Asia, as well as parts of Korea, China, Indonesia, and Papua New Guinea. In the USA, porcine cysticercosis is very rare, but human neurocysticercosis is widespread among immigrants from endemic countries [133,134].

Clinical manifestations

Taeniasis typically causes few symptoms. The most specific symptom is noting proglottids passed in the stool. The proglottids appeared flattened (typically 0.3–0.5 cm wide by 1–2 cm long and 1 mm thick). Each segment has 13 or fewer uterine branches. Unlike *T. saginata*, the proglottids are usually single and are not often noted to be motile.

Cysticercosis can present with a wide range of symptoms and signs depending on the location of the parasites and the host inflammatory response. Even neurocysticercosis presents with a range of syndromes that differ in pathogenesis, clinical manifestations, prognosis, and management [131,135–138]. The most common presentations of neurocysticercosis are seizures and hydrocephalus.

Diagnosis

Taeniasis has traditionally been diagnosed by examining stool for proglottids or ova. The sensitivity of stool microscopy for ova is only 26% [139]. Species identification requires collection of the proglottids, which can be facilitated by treating the patient with polyethylene glycol [125]. The proglottids of the two species can be distinguished by counting the number of uterine branches, which are lower for *T. solium*.

Antigen detection assays are more sensitive and specific but are not widely available and cannot distinguish *Taenia* species [123,139]. ELISAs to identify serum antibodies to *T. solium* tapeworm-stage antigens may be more sensitive than stool-based tests and seem to be quite specific for the *T. solium* tapeworm stage [140]. However, the antibody may persist after treatment. PCR assays can also be used to improve sensitivity and specificity [141].

Diagnosis of neurocysticercosis requires neuroimaging studies and serological confirmation [142]. The preferred serodiagnostic test is the enzyme-linked immunotransfer blot (EITB) employing semipurified parasite glycoproteins [131,142,143].

Treatment

Experts agree that neurocysticercosis represents a spectrum of disease that differs in optimal management. Symptomatic therapy with antiepileptic drugs for seizures and surgery for hydrocephalus are the mainstay of therapy. There is an emerging consensus among experts about the proper role of antiparasitic drugs and corticosteroids in the management of neurocysticercosis [136–138,144]. Patients with parenchymal cysticerci should usually be treated with a course of albendazole plus a simultaneous course of corticosteroids [137]. If patients have a history of seizures and calcified lesions, they should generally be treated with antiepileptic therapy indefinitely. Elective endoscopic removal of the cysticercus is the treatment of choice for ventricular neurocysticercosis, but some patients require emergency diversion of cerebrospinal fluid via a ventriculostomy or placement of a ventriculoperitoneal shunt.

Prevention

Taeniasis can be prevented by adequate cooking or freezing of infected pork, but meat inspection does not work in areas where pigs are slaughtered informally. Mass chemotherapy of endemic populations for human tapeworm carriage or porcine cysticercosis has resulted in significant short-term decreases in prevalence [145], although prevalence rates rapidly increase unless there is continued mass treatment. Development of an effective vaccine against cysticercosis may be the best hope for eradication of the disease. There are promising studies that this will be possible for human or porcine cysticercosis [146].

Diphyllobothrium species (fish tapeworm)

Diphyllobothrium species typically have fish-eating birds, marine mammals, bears, dogs, and foxes as definitive hosts, but people can also be infected when they eat raw or undercooked fish [122,123]. *Diphyllobothrium latum* infects approximately 9 million individuals worldwide, mostly in Europe, South America and Asia [147]. *Diphyllobothrium pacificum* infects humans in Japan and South America, and *Diphyllobothrium nihonkaiense* has been found in Pacific salmon in Japan and Europe [123].

The scolex of *D. latum* possesses has two deep grooves that allow it to attach to the intestines. The worm may reach a length of 15 m. The gravid proglottids have a rosette-shaped central uterus. The ova are shed into the fecal stream, develop in fresh water, hatch, and are ingested by copepods. Fish ingest the infected copepod, and the larval stages develop into the plerocercoid stage in the muscles of fish. Smaller fish are eaten by larger species, and people are infected from ingesting undercooked pike, perch, turbot, lake trout, whitefish, and salmon. The prevalence of infection increases with age in endemic areas [123]. Higher endemicity is associated with eating freshwater fish raw, lightly salted, or pickled without cooking.

Clinical manifestations

Most infections are asymptomatic or patients may notice proglottids in their stool. Nonspecific gastrointestinal complaints and megaloblastic anemia may occur in infected individuals [122,123]. Megaloblastic anemia caused by *D. latum* infection is seen mainly in patients older than 50 years in Finland. Comparison of nonanemic infected patients with uninfected controls revealed an increase in the symptoms of fatigue, weakness, craving for salt, lack of well-being, dizziness, and numbness of the extremities in the infected group. Significant gastrointestinal symptoms occur infrequently. Episodes of intestinal obstruction have been associated with the vomiting of masses of tapeworms. Eosinophilia is rare.

Diagnosis, treatment, and prevention

Identification of the characteristic ova (oval in shape, operculated, about 60 µm across) or proglottids provides the diagnosis. The parasite produces nearly 1 million eggs per day, and ova are usually detected easily by fecal examination. Treatment with praziquantel is highly effective. An alternative medical treatment would be niclosamide. Tapeworm-related anemia is reversible by treating the infection, but the affected child should be supplemented initially with vitamin B-12. A significant reduction in the transmission of *D. latum* followed introduction of sewage treatment and targeted drug treatment of human infections. Raw and undercooked fish should not be consumed in areas where there is a possibility of larval infection. Larvae do not survive in fish that is either cooked for 5 min or more at no less than 55°C (131°F) or frozen for at least –10°C (14°F) for 8–72 h [147].

Dipylidium caninum (dog tapeworm)

Dipylidium caninum, the common tapeworm of dogs and cats, also infects infants and young children [122,123]. Transmission occurs through the accidental ingestion of infected fleas (*Ctenocephalides* species) or body lice (*Trichodectes* species). While usually asymptomatic, infection may be associated with decreased appetite, abdominal discomfort, or perhaps diarrhea. The gravid proglottids are excreted in feces or migrate actively from the anus. The eggs are liberated as the proglottid disintegrates. Several species of flea serve as intermediate hosts. Development of the tapeworm's larval stages takes place as the larval flea metamorphoses into an adult. When the flea is ingested by the definitive host, the adult worm develops in the small intestine. Infection of dogs and cats is common throughout the world. *Dipylidium caninum* has also been found in a variety of wild canines and felids. However, reports of dipylidiasis in humans in the USA are uncommon [148,149].

Diagnosis, treatment, and prevention

Frequently, in infants, the only evidence of infection is the finding of proglottids in stool or in an infant's diapers. Abdominal pain, diarrhea, irritability, and pruritus have been recorded in symptomatic children. The small motile proglottids that migrate from the anus can be confused with pinworms. Examination of stool may be negative since proglottids may disintegrate on the walls of the specimen container. Treatment with praziquantel is effective. An alternative treatment is niclosamide. Infected dogs and cats should also be treated. Flea control requires the use of appropriate insecticides on pets. In addition, particular attention must be given to carpets and areas where pets sleep because these are the sites of development of the larval fleas.

Hymenolepis nana (dwarf tapeworm)

Hymenolepis nana, the dwarf tapeworm, is common throughout the world and is maintained by direct fecal–oral transmission from person to person [122,123]. Adult worms measure 1–5 cm in length and are less than 1 mm in width. Gravid proglottids disintegrate within the intestine, and ova are found in the feces. The oval-shaped eggs measure 30–50 µm in diameter and contain a six-hooked embryo within two envelopes. Larval stages develop in insect intermediate hosts after ingestion of the eggs. If people ingest the ova, larval stages develop in the intestinal villi in 4–5 days and then break into the lumen and develop into adult worms. Ova appear in feces 2–4 weeks after infection. An identical organism found in rodents may be a separate species. The rodent strains are alternatively called *Hymenolepsis fraterna* or *Hymenolepsis nana* var. *fraterna* [123,150]. The rodent strain occasionally infects humans. Human infection is acquired by the ingestion of eggs shed by a tapeworm carrier. Humans serve as both intermediate and definitive hosts in this direct cycle. Poor hygienic habits, overcrowding, lack of running water, and any other factor that fosters fecal–oral transmission enhance transmission via this route.

Epidemiology

Hymenolepsis nana is a common parasite of rats, mice, and people worldwide, with 50–75 million people infected [122,123]. Prevalence is higher in some urban areas. Stool surveys from endemic areas commonly show prevalence rates of 5%–25%, which may approach 50% in children aged 4–10 [82].

Clinical manifestations, diagnosis, treatment, and prevention

Most infections are asymptomatic. Heavy worm burdens have been associated with abdominal pain, diarrhea, malnutrition, growth retardation, and lethargy [122,123]. Detecting the characteristic eggs in fecal material by examining direct saline wet mounts or by concentration techniques is not usually difficult. However, a single examination is not always adequate to rule out infection. Praziquantel is effective in treating *H. nana* infection. Nitazoxanide is a reasonable alternative therapy; efficacy is about 75%–82% [151,152]. Family mem-

bers should be examined and treated if infected. *Hymenolepsis nana* infection is rarely severe and responds well to appropriate treatment.

Transmission of *H. nana* infection could be largely eliminated if proper methods of personal hygiene and disposal of human waste could be invoked throughout the world. Infected food handlers should always be treated and monitored to ensure that treatment has been successful. Stored food should be protected from rodents and insects.

Echinococcus granulosus and related species (cystic hydatid disease)

Human cystic hydatid disease results from infection with the larval stages of parasites of the genus *Echinococcus* [153–158]. The disease in humans and the intermediate hosts is called hydatid disease and is classified based on morphology of the larval stages: cystic echinococcosis is caused by *Echinococcus granulosus* and related organisms, alveolar echinococcosis by *Echinococcus multilocularis*, and polycystic echinococcosis by *Echinococcus vogeli* or *Echinococcus oligarthrus*.

Based on morphology, all cases of cystic hydatid disease were thought to be caused by a single species. However, genetic studies have demonstrated 10 separate genotypes that infect different intermediate hosts [154,155,157]. Most human infections are caused by the sheep strain; other strains can also cause human infection. The life cycles of the species of *Echinococcus* are similar, but the geographic distribution, types of hosts, and morphology of the parasites differ significantly. The adult tapeworms of the sheep strain develop in dogs, which may host thousands of tapeworms. The adult tapeworm is 3–8 mm long and has two to five segments. When sheep or humans ingest ova from infected dogs, the embryos hatch in the intestine, penetrate the intestinal wall, and gain access to the portal circulation. The embryos most commonly develop in the liver or lungs, where they become the cystic larval structures called hydatid cysts. A hydatid cyst is composed of an outer acellular membrane that is lined by a thin cellular germinal membrane. Structures called brood capsules grow from the germinal membrane and form protoscolices. Each protoscolex has the potential to become the scolex of an adult worm if eaten by a dog or to form a daughter cyst if the cyst ruptures into tissues. Host tissues produce a pericyst of compact collagen-rich host tissue around its exterior. In older cysts, daughter cysts may develop within the primary cyst cavity.

Epidemiology

Echinococcus granulosus sheep strain is found in most areas where sheep are raised [154,155,157–159]. In the past, the impact was significantly underestimated compared with other illnesses [160]. One of the highest morbidity rates is seen in rural Africans in Kenya and Uganda, where people live in close association with their dogs. The custom of feeding sheep viscera to sheep dogs maintains foci of infection.

Clinical manifestations

Most infected with *E. granulosus* have a single unilocular cyst, but multiple cysts are seen in 15%–30% of patients [154,157,161]. The most common site for cysts is the liver. In clinical series, approximately one in five cases have a pulmonary cyst often with a concurrent liver cyst. The proportion outside the liver is lower in population-based screening [162]. Approximately 10% of cysts are found in sites other than the liver or lung, including spleen, kidney, peritoneum, genitourinary tract, bone, muscles, heart, eye, and brain. Liver cysts grow approximately 1–3 cm in diameter each year, but pulmonary cysts grow more rapidly [162].

There is a wide spectrum of symptoms in cystic hydatid disease depending on the number, size, and location of the cysts [154,157,161]. Cysts in liver or lung are often asymptomatic for years. Symptomatic intrahepatic cysts cause right upper quadrant or epigastric pain, hepatomegaly, nausea, and vomiting. Cyst rupture may be precipitated by a traumatic event and may cause a range of symptoms, including fever, abdominal pain, hypotension, and allergic manifestations, including eosinophilia, urticaria, and anaphylaxis. Rupture into the biliary tract may cause cholangitis.

Intact pulmonary cysts are typically asymptomatic [154,157,161]. Leakage may cause cough, chest pain, dyspnea, and hemoptysis. Fever may be present especially with a secondary bacterial infection. When pulmonary cysts rupture into a bronchus, the patient may describe coughing up portions of the membranes, which may resemble grape skins, or noting a salty taste.

Diagnosis

The diagnosis of cystic echinococcosis usually is suspected on the basis of clinical or radiological findings plus a history of residence in an endemic area. About half of patients with hepatic cysts have abnormal liver enzyme results. Eosinophilia is typically low grade or absent. The initial diagnosis of cystic hydatid disease is based on imaging findings. An unruptured pulmonary hydatid cyst has a sharply demarcated, round or oval border but may be surrounded by atelectasis [154,157,161]. After the cyst has ruptured into a bronchus, a crescent-shaped air layer may be seen that is virtually diagnostic. In addition to the arc of air between the parasite and the host cyst wall, air in the cyst lumen also may be present.

Cysts in the liver are usually easily visualized and measured with ultrasound, CT, or magnetic resonance imaging (MRI). A World Health Organization (WHO) staging system has been developed that has been used to define management (Fig. 107.4) [163]. Stage CL cysts are unilocular collections without a discrete wall and with uniform anechoic contents, but this is not specific for *Echinococcus*. Stage CE1 cysts display a dense wall and may have internal echos. This so-called hydatid sand is due to protoscolices within the cyst. CE2 cysts have internal septae or daughter cysts, forming a

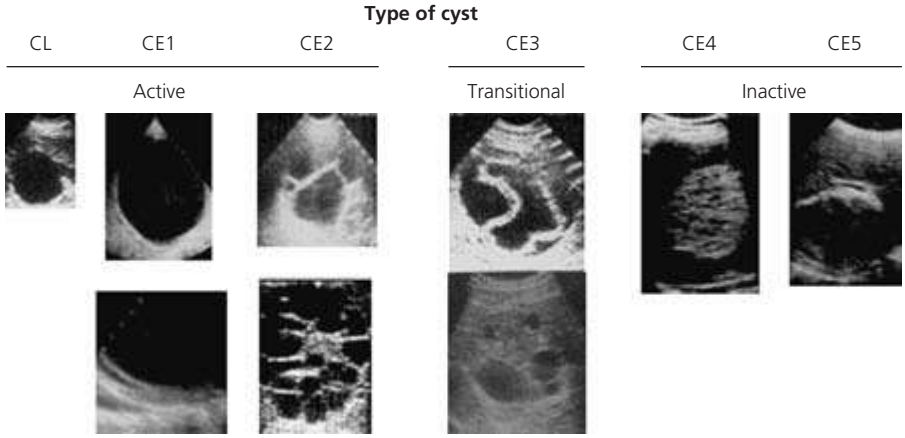

Figure 107.4 Ultrasound stages of cystic hydatid disease. From World Health Organization Informal Working Group on Echinococcosis [163], with permission from Elsevier.

honeycomb pattern, that are highly characteristic of hydatid cysts. CE3 cysts demonstrate detachment of the cyst wall or early collapse. CE4 cysts demonstrate inhomogeneous material instead of a cyst cavity. CE5 cysts demonstrate a thick rim of calcification. Radiographically apparent cyst wall calcification occurs only in liver or spleen cysts and generally takes more than 5–10 years to develop. Bone cysts typically produce radiolucencies without periosteal reaction. MRI offers little advantage over CT for the imaging of cysts except in the central nervous system.

Serological tests can be useful in confirmation of the diagnosis [154,157,161]. Antibody tests using crude antigen of either *E. granulosus* or *E. multilocularis* tested by ELISA, indirect hemagglutination, and fluorescent antibody assays are positive in 50%–90% of cases. False-negative results are more common in patients with pulmonary, brain, and splenic cysts. The available tests may cross-react with cysticercosis or other parasitic infections. Thus positive results should be confirmed by a more specific test (e.g., immunoblot assay or looking for the specific Arc 5 pattern by gel diffusion).

Treatment and prognosis

Experts now suggest that treatment should vary based on the location of the cyst or cysts, the nature and size of the cysts, the condition of the patient, and available expertise. Treatment modalities include surgery, antiparasitic chemotherapy, percutaneous drainage termed PAIR (*p*ercutaneous *a*spiration, *i*ntroduction of scolicide, and *r*easpiration), and watch and wait [154,157]. In contrast to the older reliance on surgery, a recent prospective study found that only 10% of children with hepatic cysts required surgery over the subsequent 5 years [164].

Albendazole and mebendazole have been used for chemotherapy [154,157,164–166]. While older series emphasize the low cure rate, approximately one-third of hepatic cysts will resolve in response to benzimidazoles and 30%–50% improve. Many of the residual lesions were subsequently shown to be nonviable. Albendazole is now thought to be the treatment of choice for small (< 5 cm) CL, CE1, and perhaps CE3 lesions [154,157]. Chemotherapy has also been successful for small pulmonary cysts [167]. However, there is a high failure rate with chemotherapy alone for larger lesions in either the liver or the lung. Albendazole is thought to be more effective than mebendazole. Albendazole is typically given at 10–15 mg/kg daily in two daily doses continued for 3–6 months. Side effects may include neutropenia, elevated liver enzymes, and alopecia. Prospective studies of surgically removed specimens show that protoscolices can remain viable for up to 3 months, which is the minimum duration of chemotherapy [166,168]. Treatment failures can be managed by further chemotherapy, PAIR, or surgery. In some cases, PAIR may demonstrate that protoscolices are no longer viable even with persistent lesions.

The PAIR technique is less invasive than the traditional surgical approaches [157,169–172]. Results have been similar to those of surgery but with fewer complications. PAIR is thought to be the treatment of choice for uncomplicated CL and CE1 lesions larger than 5 cm and for CE3 lesions. CE2 lesions can be treated with a modification of PAIR that employs a larger-bore catheter and drainage [171,173]. PAIR should be performed after initiation of albendazole chemotherapy. To limit spillage, aspiration should generally pass through solid tissue (e.g., liver) rather than directly into the cyst. The cyst fluid should be examined for protoscolices or hooks (to confirm the diagnosis). Prior to injection of scolicidal agents, the cyst fluid should be checked for bile staining (by dipstick or by injection of contrast medium) since scolicidal agents cause sclerosing cholangitis if injected into the biliary tract. Alcohol or hypertonic saline are used as scolicidal agents in this procedure. Contraindications to PAIR include communication with the biliary tract, inaccessibility, superficial cysts, and cysts that are free in the abdomen, heart, brain, or spine. If the cyst communicates with the biliary tract, contrast media, which are mildely scolicidal, can be used to further define the communication.

Surgery remains the treatment of choice for complicated disease and some CE3 lesions [154,157,161]. Rupture of the cyst contents at the time of surgery carries a risk of disseminated echinococcosis and a small risk of anaphylaxis at the time of operation. Surgical approaches have included pericystectomy (removal of the entire cyst and a rim of surrounding tissues), resection of the involved organ, simple drainage, omentoplasty, and capitonnage. More radical procedures are associated with fewer relapses at the cost of more perioperative complications. However, laparoscopic approaches have recently been reported to be associated with a high success rate and less morbidity [172,174]. Chemotherapy with albendazole with or without praziquantel is now routinely performed [157,166]. With chemotherapy, pressure within the cyst may be reduced and removal of cyst membranes and contents will be facilitated. In addition, treatment decreases the likelihood of secondary cyst development [168]. Pulmonary cysts have been treated successfully surgically, medically, and with PAIR.

Prevention

Control programs for cystic hydatid disease have met with variable success [156–158]. *Echinococcus granulosus* was eliminated from Iceland by banning home slaughter of sheep. Banning of home slaughter, education, arecolic purging of dogs, and treatment of infected dogs with praziquantel have led to eradication in New Zealand and Tasmania. However, these eradication programs required significant resources and have been less successful elsewhere. A recombinant vaccine has proven highly effective in field studies, but awaits implementation [158]. Other tools in development include copro-antigen tests to detect infected dogs and improved therapy for ovine infection.

Other *Echinococcus* species

Echinococcus multilocularis is the cause of alveolar hydatid disease [154,155,157,161,175]. Humans are an incidental host in a life cycle that typically involves foxes as definitive hosts (but also wolves and occasionally domestic dogs) and rodents as intermediate hosts. The larval parasite does not form a large cystic structure but grows by progressive external budding. The laminated membrane and host pericyst are thin. The larval mass slowly enlarges and replaces liver tissue much as a malignancy does. *Echinococcus multilocularis* is endemic in arctic and alpine areas, including western China, central Europe, and scattered foci in North America. In recent years, disease is emerging in much of central Europe. The larvae may invade contiguous structures and rarely metastasize. Human infection almost invariably involves the liver, but may spread to adjacent tissues or metastasize to the brain. The larval mass grows slowly, with a typical latent period of 5–15 years prior to clinical presentation. Thus, clinical disease is rare in children. Diagnosis involves imaging studies with serological confirmation. Management requires surgical resection along with prolonged chemotherapy. Comprehensive reviews of epidemiology, clinical manifestations, diagnosis, and management are available [154,155,157,161,175,176].

Echinococcus vogeli is a parasite of bush dogs and feral dogs in South America. [157]. The intermediate hosts are rodents (pacas, agoutis, spiny rats). When humans are infected, the germinal membrane grows externally to form additional cysts, and septae develop within the original cyst. This manifestation is the polycystic variety of hydatid disease. A rare cause of polycystic hydatid disease in humans has been attributed to *E. oligarthrus*, a fourth species that is found as adult tapeworms in wild felids such as pumas and jaguars. The intermediate hosts are the same as those for *E. vogeli*. Most infections occur in Central and South America. Polycystic hydatid disease is limited to South and Central America, where fewer than 100 human infections have been reported. Initial management should include albendazole.

I MISCELLANEOUS

108 Gastrointestinal and hepatic manifestations of specific genetic disorders

Elizabeth M. Petty

Practicing genetic medicine, 2673
Well-defined genetic disorders with prominent gastrointestinal or hepatic manifestations, 2675
Common gastrointestinal and hepatic disorders with complex genetic causes, 2710

Genetic contributions to the pathogenesis of many gastrointestinal (GI) and hepatic disorders are being increasingly recognized. Recognition of a well-understood genetic contribution to a GI or hepatic disease may have an impact on clinical management and have significant implications for other family members. To recognize genetic contributions, review of a comprehensive family history, relevant medical history, and related medical records (e.g., pathology reports, laboratory studies, clinical summaries) of the patient and, in some cases, of affected family members, is needed.

The family history may reveal a specific Mendelian inheritance pattern (e.g., autosomal dominant, autosomal recessive, X-linked recessive, or X-linked dominant) or non-Mendelian mode of inheritance (mitochondrial/maternal/cytoplasmic or imprinted) that suggests a major inherited genetic contribution. Even such major genetic contributions to GI or hepatic disease may be difficult to recognize if a family is small, no history about biological relatives is available, significant genetic heterogeneity exists, common phenocopies (sporadic conditions that mimic inherited disorders) occur, variable expressivity of manifestations is present, incomplete penetrance is possible, or a new mutation causes the disease. Determining genetic contributions to GI or hepatic diseases that are multifactorial (e.g., where significant environmental or epigenetic factors interact with an individual's underlying genetic constitution) or polygenic (e.g., where several genetic factors, including multiple modifying genes, interact to contribute to disease susceptibility) can be even more challenging. Despite such challenges, it is clinically relevant to assess genetic contributions to the disease process.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

The purposes of this chapter are:

- to provide a basic framework as to when, how, and why to consider genetic factors
- to briefly review several well-known genetic syndromes, most of which are highly penetrant, single-gene disorders with Mendelian patterns of inheritance, that may present with significant GI or hepatic manifestations.

Some of these genetic conditions present in infancy (e.g., some inborn errors of malabsorption), whereas others are characterized by adult-onset presentation (e.g., some colon cancer syndromes). Awareness of these syndromes is needed to ensure appropriate diagnoses and medical management for affected individuals. For example, an adult with Ehlers–Danlos syndrome type IV (the "vascular type" of Ehlers–Danlos syndrome – an autosomal dominant syndrome characterized by type III collagen abnormalities) who presents with sudden severe abdominal pain, must be immediately evaluated and treated, when needed, for bowel rupture and arterial dissection to reduce disease-associated morbidity and early mortality.

Most diseases presented in this chapter are summarized in an abbreviated table format for easy reference. More comprehensive discussions of the pathophysiology and treatment for common GI and hepatic diseases mentioned in this chapter are covered in more detail elsewhere in this text (see the references for each topic, Part III of the textbook and the Index). For more information about less common genetic conditions, several excellent genetic textbooks and online genetic databases are referenced for additional, more detailed, information about the particular syndromes and diseases [1–5]. Specifically, the *Online Mendelian Inheritance of Man* (OMIM) National Center for Biotechnology Information database (*http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM/*), *GeneReviews* at the *GeneTests* website (*http://www.genetests.org/*), and the Center for Disease Control's HuGE Net (*http://www.cdc.gov/genomics/hugenet/reviews.htm*) are excellent online

database references that provide regularly updated information about many genetic syndromes and include more detailed up-to-date reference lists. Information for this chapter was obtained through online searches of these databases with review of their key references and genetic textbooks [4,5]. Genetic contributions to common GI and hepatic conditions that have complex multifactorial or polygenic etiologies (e.g., inflammatory bowel disease, cirrhosis) are covered in other disease-specific chapters throughout this text (see Index).

Practicing genetic medicine

Clinicians must understand basic genetic principles to provide accurate diagnostic, prognostic, and therapeutic services for individuals with genetic conditions and their at-risk relatives. Once the genetic basis of a disease is recognized, preventive screening, medical or surgical management, genetic counseling, patient and family education, and referrals can be implemented as appropriate. DNA testing is available for dozens of conditions that have prominent GI or hepatic manifestations and the list will continue to grow. With completion of the Human Genome Project and identification of the genetic codes for all of our estimated 25 000 human genes, genomic knowledge relevant to the clinical practice of gastroenterologists and hepatologists will continue to be revealed at an unprecedented pace. Genetic testing can serve various purposes, from molecular confirmation of a suspected disease to facilitation of management and recurrence risk counseling, as in the case of hemochromatosis, or, predictively, to more accurately predict one's own risk of developing colon cancer. The practice of genomic medicine with utilization of genetic testing has already become standard of care in many areas of clinical medicine.

An example of this is seen in familial adenomatous polyposis (FAP), most often a highly penetrant, autosomal dominant condition caused by deleterious mutations in the adenomatous polyposis coli gene (*APC*) located on the long arm of chromosome 5 (see Chapter 64). In its classic form, individuals with one copy of a mutated *APC* gene will develop colon cancer in early to mid adulthood after having hundreds to thousands of polyps that began developing in adolescence. At-risk individuals benefit from genetic counseling, education, and testing to better understand and reduce their risks of developing cancer. In up to 90% of affected individuals, causative *APC* mutations can be detected, allowing robust and reliable predictive testing for at-risk family members. Specific preventive management strategies (e.g., serial colonoscopies, colectomies) can greatly reduce the risk of colon cancer in mutation carriers. Individuals lacking the mutation that segregates in affected family members, are spared the high risk of developing early-onset colon cancer and do not need the surveillance and surgical interventions recommended for mutation carriers. It is therefore both clinically and economically desirable to offer predictive genetic testing to individuals at risk for a highly penetrant, late adolescent/early adult-onset disorder such as FAP, where interventional management can significantly reduce morbidity and early mortality. In contrast to the highly penetrant *APC* mutations responsible for classic FAP, recognition of a relatively common polymorphism associated with a hypermutable tract of DNA in the *APC* gene in Ashkenazi Jews confers only a mildly increased risk of colon cancer in individuals with the polymorphism. An autosomal form of adenomatous polyposis colon cancer has been recognized in association with *MYH* gene mutations. Understanding the relative risks for colon cancer associated with various gene mutations is critical for patients because it may have profound effects on clinical management and predictive risk assessment. With increased understanding of genetic mechanisms in health and disease, the availability of clinically useful genetic tests will continue to grow and, ultimately, individually targeted molecular-based therapies may become a reality for many disorders. Testing for specific genetic polymorphisms in drug-metabolizing enzymes is already being used to predict clinical outcomes of treatment with common chemotherapy agents in cancer patients.

Issues in genetic counseling, education, and testing will be raised throughout this chapter. Genetic counseling involves discussing the natural history of the condition as well as diagnostic, prognostic, recurrence risk, medical management, genetic testing, and related psychosocial issues with appropriate referral to support systems and educational resources. Board-certified medical geneticists and genetic counselors provide the bulk of genetic counseling through specialized genetic clinics, which are available through most academic medical centers. The growth of genetic knowledge, however, will require that virtually all health-care professionals become comfortable with providing some basic level of genetic counseling in the future.

Increasingly more sensitive, specific, and cost-effective genetic tests continue to be developed so detailed discussion of specific genetic tests will not be addressed here. It is important, however, to understand that each test has its own analytic validity and clinical utility and that the specificity and sensitivity will vary considerably depending on the particular type of genetic test and the disease being studied. For some disorders, such as hereditary nonpolyposis colorectal cancer or Lynch syndrome, an adult-onset, autosomal dominant disease with genetic heterogeneity, clinicians must decide between a number of different kinds of available molecular assays to identify the most appropriate, sensitive, specific, and cost-effective test for any one individual or family. Online genetic testing laboratory databases, such as *GeneTests*, for health-care professionals, provide up-to-date information on laboratories that offer research or clinical genetic testing for

diseases with a genetic component [2]. Individuals needing more information should consult with local genetic centers and gather up-to-date information provided by national disease-associated organizations.

Whereas DNA-based genetic tests may have high clinical utility when evaluating an individual for a genetic condition, this is not always the case. Consider, for instance, a disease like neurofibromatosis type I (NF1), an autosomal dominant, neurocutaneous disorder that may have significant GI symptoms as the result of the mass effect of intraabdominal plexiform neurofibromas or of vascular ischemia in the intestinal vascular bed. Current genetic testing for NF1 is about 90% sensitive – less sensitive than a good clinical genetics examination in a classically affected adult. DNA testing in an individual with known NF1 who presents for management of their GI symptoms offers no direct clinical benefit to the patient because no relevant genotype/phenotype correlations exist that would provide insights into their management. Testing for NF1 mutations, however, may be useful if the individual is interested in prenatal testing or if the patient has young children where the diagnosis cannot be firmly established by clinical examination.

In all cases, genetic testing encompasses more than a simple laboratory analysis and should include pretest counseling and education, provision of informed consent, accurate interpretation and discussion of implications, follow-up after test results, and posttest education, management, and support (Table 108.1). This is especially important when molecular testing is used to more accurately determine a healthy individual's genetic risk for developing a disease, as in predictive testing of an asymptomatic individual who, by virtue of their family history or their ethnicity, is at risk of having inherited a particular mutation. Such testing is employed in the evaluation of inherited colon cancers, as described previously.

Table 108.1 Foundations for the appropriate use of genetic tests

DNA testing encompasses more than just the laboratory test. Tests must:
Be ethically applied with respect for genetic privacy and patient autonomy
Demonstrate analytic validity, clinical utility, and high-quality (sensitivity and specificity) with a high positive predictive value
Be cost-effective and yield results that will benefit the patient from a medical or psychosocial standpoint
Be accompanied by accurate patient education, counseling, and follow-up care
Prior to testing:
Conduct a comprehensive medical evaluation including family history
Perform a risk analysis regarding the potential for the diagnosis of a particular syndrome
Review the current literature regarding the positive predictive value of genetic testing for that condition
Determine what gene should be studied
Evaluate available tests and laboratories for reported sensitivity and specificity
Provide the patient with education about the disease process
Provide risk estimates of gene inheritance, susceptibility for disease, and potential related medical problems
Determine how the test results may modify the patient's risk
Discuss test specifics including costs, benefits, risks, and limitations
Provide counseling regarding various outcomes of test results and the resulting implications for patient or family members
Discuss management options including alternative approaches to genetic testing
Explore any psychosocial concerns including impact on self-esteem, relationships, potential for discrimination, and implications for other family members
At the time of testing:
Obtain and document informed consent after patient has been adequately educated about the test and has agreed to proceed with testing knowing potential benefits, risks, and limitations related to medical and psychosocial implications
Ensure that an appropriate specimen is properly collected, and shipped or delivered to the laboratory
Determine how results will be presented to the patient
When test results are available:
Interpret tests based on knowledge about known genotype–phenotype correlations, the clinical course of affected family members, the medical evaluation of the patient, and other environmental or hormonal risk factors for the patient
Provide the patient with counseling and education regarding results
Refer patient and family for appropriate support and education
Provide follow-up and medical surveillance, chemoprevention, and management as appropriate
Offer evaluations to other at-risk family members as appropriate

Well-defined genetic disorders with prominent gastrointestinal or hepatic manifestations

Malabsorption disorders

Some genetic syndromes involve defects of intestinal absorption (Table 108.2). Most are disorders of brush border enzymes or transport proteins that transfer sugars, amino acids, electrolytes, lipids, vitamins, and minerals from the gut lumen into the circulation. There may be malabsorption of a singular, specific substance, such as in lactase deficiency, or general malabsorption of several substances, such as in Hartnup disease. The other large group of genetic malabsorption syndromes involves disorders of the exocrine pancreas. Cystic fibrosis is most common, followed in frequency by the Shwachman–Bodian syndrome and the much rarer Johanson–Blizzard syndrome; the last two have normal sweat chloride tests.

Defects in carbohydrate metabolism

Congenital lactase deficiency

Patients with congenital lactase deficiency (i.e., disaccharide intolerance II) present with watery diarrhea, usually after the first milk feed. Lactase, an enzyme with lactase and phlorizin hydrolase activity, is virtually absent in the duodenal mucosa of affected infants, but the duodenum is otherwise histologically and enzymatically normal. The human lactase-phlorizin hydrolase gene, *LCT*, maps to chromosome 2q21.

Later-onset lactase deficiency

Lactase activity is generally around 10% of maximal activity in adults with later-onset lactase deficiency. Approximately three-fourths of non-white adults are lactase-deficient and 5%–30% of white persons, depending on ethnicity, have some degree of lactase deficiency. In ethnic groups where late-onset lactase deficiency is common (e.g., > 50% prevalence), affected individuals between 1 and 5 years of age often present with diarrhea and crampy abdominal pain after the ingestion of foods containing lactose. In white persons with hypolactasia, symptoms generally arise during adolescence. The diagnosis is most often confirmed by the noninvasive techniques of oral lactose tolerance tests or breath tests.

Since adult lactase activity variation in different ethnic groups is independent of lactose intake, the differences are largely genetic. There is a decreased amount of active brush border lactase, which is probably regulated by gene expression. Two phenotypes have been described: type I is characterized by a decrease in actase-phlorizin hydrolase messenger RNA; type II is characterized by abnormal posttranslational processing of lactase-phlorizin hydrolase, with abnormal retention of the protein in the endoplasmic reticulum. Hypolactasia is an autosomal recessive syndrome but parents of affected children are commonly affected because the gene alterations for hypolactasia are present in the population at high prevalence, resulting in homozygotes marrying heterozygous carriers.

Congenital lactose intolerance

Congenital lactose intolerance is a serious autosomal dominant disorder characterized by vomiting, failure to thrive, dehydration, renal tubular acidosis, disaccharidiuria, aminoaciduria, liver damage, cataracts, and brain damage in infancy. Unlike congenital lactase deficiency, it can be fatal unless diagnosed and managed promptly. It is caused by the abnormal absorption of lactose in the stomach rather than the duodenum. Lactose is hypothesized to be toxic to the liver and brain, analogous to the toxicity of galactose-1-phosphate in galactosemia. Treatment consists of lactose avoidance. The disorder spontaneously resolves between 12 and 18 months of age.

Sucrose–isomaltose malabsorption/disaccharide intolerance I

The autosomal recessive sucrose–isomaltose malabsorption disorder (i.e., sucrase–α-dextrinase or intestinal disaccharidase deficiency) presents with symptoms similar to lactase deficiency, except that they are triggered by sugar, not milk. Symptoms range from severe diarrhea in infants to occasional stomach upset in adults. Ingestion of sweetened foods and fruits provokes symptoms but tolerance to the sugars increases with age. Starch is generally well tolerated. In general, homozygotes have severe enzyme deficiency with lifelong symptoms, but heterozygotes with intermediate enzymatic activity may have mild symptoms as infants and no symptoms as adults. The disorder affects 10% of the Inuit of Greenland but only 0.2% of North Americans. The diagnosis is made using the same techniques as are used in lactase deficiency. Ingesting fresh baker's yeast that has sucrase activity, preferably on a full stomach, can ameliorate the symptoms after sucrose ingestion.

Studies suggest that the primary defect involves sucrase with secondary effects in isomaltase. Defects in various aspects of intracellular processing of the enzyme complex have been demonstrated: endoplasmic reticulum accumulation, blocked Golgi transport, and transport of a catalytically altered enzyme to the cell surface, illustrating the heterogeneity of this relatively uncommon, autosomal recessive disorder. The sucrase–isomaltase gene (*SI*) maps to chromosome 3q25–26.

Glucose–galactose malabsorption

The autosomal recessive condition of intestinal monosaccharide transport deficiency has a similar presentation to intestinal disaccharidase deficiency. In glucose–galactose malabsorption, diarrhea and dehydration occur after ingestion of carbohydrates containing one or more of these sugars. Tolerance to these sugars improves with age. Acidic stools, containing glucose and galactose, suggest the diagnosis. Some patients

Table 108.2 Genetic disorders of intestinal malabsorption

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Defects in carbohydrate metabolism				
Congenital lactase deficiency (disaccharide intolerance II)	AR	2q21 *LCT*	Watery diarrhea within the first 10 days of life	Possibly less cardiovascular disease due to avoidance of dairy products
Adult lactase deficiency or hypolactasia (disaccharide intolerance III)	AR	2q21 *LCT*	Abdominal pain, bloating, diarrhea after lactose ingestion	Present in > 75% of non-white and about 20% of white population
Congenital lactose intolerance	AD	2q21 upstream of LCT	Vomiting and diarrhea	Failure to thrive, dehydration, renal tubular acidosis, disaccharidiuria, aminoaciduria, liver damage, cataracts, and brain damage
Sucrase isomaltase deficiency (disaccharide intolerance I)	AR	3q25–26 *SI*	Variable symptoms, from severe diarrhea in infancy to stomach upset in adults after sucrose ingestion	Start well tolerated
Glucose–galactose malabsorption	AR	22q13 *SGLT1/SLC5A1*	Bloating, abdominal pain, and diarrhea after ingestion of most carbohydrates	Mild defect in renal tubular absorption of glucose
Fanconi syndrome with intestinal malabsorption and galactose intolerance	AR	3q26 *SLC2A2*	Poor appetite, generalized malabsorption	Impaired galactose metabolism, normal glucose absorption, slow weight gain, retarded psychomotor development, and abnormal renal tubular function
Trehalase deficiency	AR	11q23 *TREH*	Diarrhea and vomiting after ingestion of trehalose-containing foods (e.g., insects, mushrooms)	Rare in white Americans, found in 10%–15% of cDNA isolated in Inuit of Greenland
Defects in amino acid transport				
Iminoglycinuria	AR	?	None	A membrane transport defect causing excess excretion of proline, hydroxyproline, and glycine – often no clinical consequence but may be mental retardation and gyrate atrophy; frequency among whites, 1 in 15 000
Hartnup disease	AR	11q13 *HND*	None	Intermittent, red, scaly, pellagra-like rash after sun exposure; cerebellar ataxia, psychiatric disorders, low or subnormal intelligence, massive aminoaciduria of neutral and aromatic amino acids; US incidence of 5 per 100 000
Cystinuria I	AR	2p16 *SLC3A1*	None	Renal tubule and intestinal epithelium transport abnormalities of all dibasic amino acids; nephrolithiasis due to insolubility of cystine in urine; US incidence of 1 in 15 000
Cystinuria II, III	AR	19q13 *SLC7A9*		
Lysinuric protein intolerance (dibasic aminoaciduria I and II)	AR	7q31 *SLC7A7*	Vomiting and diarrhea after ingestion of cows' milk	Hyperammonemia, failure to thrive, organomegaly, mental retardation, lens opacities, elastic skin, and sparse hair

Blue diaper syndrome	AR	?	None	Hypercalcemia, nephrocalcinosis, and indicanuria due to intestinal tryptophan transport defect
Oasthouse syndrome	AR	?	Diarrhea	White hair, hyperpnea, seizures, mental retardation, and an odor of an oasthouse (i.e., kiln for drying hops)
Lowe oculocerebrorenal syndrome	XLR	Xp26 *OLRL*	None	Cataracts, mental retardation, vitamin-D-resistant rickets, glaucoma, generalized aminoaciduria and organic aciduria; death from renal failure; impaired intestinal and renal absorption of lysine and arginine; mapped to *Xq*; carrier detection possible
Lysine intolerance	AR	7q31 *SLC7A7*	Episodic vomiting, rigidity	Coma in infancy relieved by low-protein diet; hyperammonemia and high lysine and arginine levels, apparently due to defective L-lysine: NAD-oxidoreductase activity in liver
Lysine malabsorption syndrome	AR	?	Impaired intestinal absorption of lysine	Physical and mental retardation; hyperlysinuria and hypolysinemia, probably due to lysine transport defect
Glutamate–aspartate transport defect (dicarboxylic aminoaciduria)	AR	9p24	None	Defective intestinal and renal transport of glutamic and aspartic acids, leading to moderate hyperprolinemia and hypoglycemia
Disorders of electrolyte absorption				
Congenital chloride diarrhea	AR	7q22–31 *SLC26A3A*	Voluminous, chloride-containing, watery stools	Polyhydramnios, premature birth, hypochloremia, hypokalemia, metabolic alkalosis, growth retardation
Congenital sodium diarrhea	AR	?	Voluminous, sodium- and bicarbonate-containing stools	Polyhydramnios, premature birth
Microvillus inclusion disease	AR	?	Severe, watery diarrhea	No polyhydramnios or premature birth
18-Oxidation defects of aldosterone	AR		Vomiting, intestinal salt wasting	Dehydration, hypernatremia, and hypokalemia; deficiencies of 18-hydroxylase and 18-hydroxysteroid dehydrogenase
Congenital adrenal hyperplasia	AR	6p21 *CYP21*	Intestinal salt wasting	Deficiency in any one of several enzymes in cortisol synthesis; virilization, renal salt losing, or hypertension
Hypomagnesemia	AR XLR	3q27 *CLDN16*	Primary intestinal malabsorption of magnesium	Hypomagnesemia, hypocalcemia, seizures, and tetany in newborn period
Defects in intestinal protein absorption				
Intestinal lymphangiectasia	AD	?	Intestinal loss of protein, dilated lymphatic spaces in small bowel and partial villous atrophy	Neonatal edema, high incidence of stillbirth, congenital malformations, lymphopenia, hypogammaglobulinemia, skin energy, dysproteinemia, leg edema and ulcers in males
Aplasia cutis congenita with intestinal lymphangiectasia	AR	?	Intestinal loss of protein	Aplasia cutis congenita of the vertex, nonpitting limb edema, hypoproteinemia, lymphopenia
Protein-losing enteropathy	AR	?	Diarrhea, abdominal pain, ascites, intestinal loss of protein	Edema, growth retardation, clubbing, hypoproteinemia, iron-deficiency anemia, no lymphopenia; hepatic vein stenosis can lead to Budd–Chiari syndrome

Table 108.2 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Epidermolysis bullosa lethalis with pyloric atresia	AR	17q24 *ITGB4*	GI symptoms may dominate the clinical picture; pyloric atresia, diarrhea, and protein-losing enteropathy	Bilateral pyelonephrosis due to stenosis at the uterovesical junctions; prenatal diagnosis by ultrasound, demonstrating dermal–epidermal separation at the lamina lucida in the fetal skin
Vascular hyalinosis	AR	?	Diarrhea, rectal bleeding, malabsorption, protein-losing enteropathy	Progressive hyalinosis of the capillaries, arterioles and small veins of the GI tract, kidneys, and brain; poikiloderma and graying of the hair in the 20s
Hereditary lymphedema I, II	AD	5q35.3 *FLT4* 16q24.3 *MFH1/FOXC2*	Loss of albumin through the intestines	Severe edema below the waist; onset at birth; paucity of lymph nodes above the inguinal ligaments; distinct from hereditary lymphedema II, which has onset at puberty
Defects in fat absorption				
Familial amyloidosis polyneuropathy type 1	AD	18q11–12 *TTR*	Abnormal GI motility with resultant bacteria overgrowth and malabsorption of bile acids; initial constipation followed by bouts of diarrhea	Progressive sensorimotor neuropathy beginning in the lower extremities; orthostatic hypotension, and impotence
Abetalipoproteinemia	AR	4q22–24 *MTTP*	Steatorrhea with malabsorption of fat, poor weight gain, impaired absorption of fat-soluble vitamins	Beginning in the second decade; peripheral neuropathy, cerebellar ataxia, atypical retinitis pigmentosa, mild to moderate anemia, and acanthocytes; coagulopathy and low serum lipid values
Anderson disease	AR	Xq22	Steatorrhea with malabsorption of fat	Growth retardation; low serum lipid values
Familial hypobetalipoproteinemia	AD	3q22–21 *APOB* 4q24 *MTTP*	Mild fat malabsorption	Low serum levels of low-density lipoprotein and high-density lipoproteins; normal triglycerides
Wolman disease	AR	10q24–25 *LIPA*	Intestinal malabsorption	Death usually in infancy; tissue accumulation of cholesterol esters and triglycerides in liver, adrenals, spleen, lymph nodes, bone marrow, small intestines, lungs, and thymus; prenatal diagnosis made by amniocytes demonstrating enzyme deficiency
Cholesterol ester storage disease	AR	10q24–25 *LIPA*	Intestinal malabsorption	Similar to Wolman disease, with later onset and milder symptoms
Wolman disease with hypolipoproteinemia and acanthocytosis	AR	?	Intestinal malabsorption	Similar to Wolman disease; also features hypolipoproteinemia and acanthocytosis
Storm syndrome	AD	?	Fat malabsorption	Early, progressive, calcific cardiac valvular disease; loss of eyebrows and eyelashes; premature thinning and graying of hair; taut skin over hands and face

Groll–Hirschowitz syndrome	AR	?	Diminished gastric motility due to a vagal nerve abnormality; multiple diverticula with jejunoileal ulceration; malabsorption of fat and intestinal loss of protein	Progressive sensory neuropathy; nerve deafness with onset in the first three decades
Glucose-stimulated secretory diarrhea with common variable immunodeficiency	AD	?	Severe, watery diarrhea; malabsorption of fat, bile acids, vitamin B-12, and xylose	Combined immunodeficiency syndrome; perfusion studies show glucose-stimulated secretion of water, sodium, and chloride in the jejunum and ileum, with normal transport for bicarbonate and mannitol
Exocrine pancreas abnormalities				
Cystic fibrosis	AR	7q31 *CFTR*	Intestinal malabsorption, steatorrhea, pancreatitis	Thickened secretions, respiratory infections, infertility
Shwachman–Bodian/Diamond syndrome	AR	7q11 *SBDS*	Steatorrhea, intestinal malabsorption	Incidence of 1 in 250 000 births; poor growth, recurrent respiratory infections, moderate dwarfism with dysplastic metaphyseal changes
Johanson–Blizzard syndrome	AR	15q15–21 *UBR1*	Intestinal malabsorption	Aplasia or hypoplasia of the nasal alae, upswept frontal hair, widely spaced teeth, congenital deafness, hypothyroidism, postnatal growth retardation, mental retardation, midline ectodermal scalp defects, absent permanent teeth, and genitourinary and anorectal abnormalities; insulin-requiring diabetes in adulthood
Cartilage–hair hypoplasia (metaphyseal chondrodysplasia, McKusick type)	AR	9p13 *CHH*	Intestinal malabsorption, Hirschsprung disease	Dwarfing syndrome with radiographic changes called metaphyseal dysostosis; fine, sparse, light-colored hair, anemia, susceptibility to chicken pox, and malignancies
Asphyxiating thoracic dystrophy (Jeune syndrome)	AR	15q13	Intestinal malabsorption	Skeletal dysplasia with marked involvement of the rib cage causing asphyxia; polydactyly, chronic nephritis, cystic changes of liver, kidneys, and pancreas
Pearson marrow–pancreas syndrome	mt	mt	Intestinal malabsorption	Refractory anemia requiring transfusion; thrombocytopenia, neutropenia, and hepatic dysfunction
Lipase or colipase deficiency	AR	10q26 *PNLIP*	Steatorrhea with malabsorption of fat-soluble vitamins	Stature is within normal limits; responds to exogenous administration of lipase or colipase
Trypsinogen deficiency	AR	7q32qter *PRSS1*	Diarrhea	Failure to thrive, edema, hypoproteinemia with normal sweet electrolytes, imperforate anus
Enterokinase deficiency	AR	21q21 *PRSS7*	Diarrhea	Similar to trypsinogen deficiency; favorable response with pancreatic enzyme replacement
Congenital pancreatic hypoplasia	AR	13q12 *IPF1*	Diarrhea	Exocrine and endocrine insufficiency, intrauterine growth retardation, and early-onset type I (insulin-dependent) diabetes
Cystinosis	AR	17p13 *CTNS*	Diarrhea	Intralysosomal storage of cystine, leading to pancreatic exocrine and endocrine insufficiency in long-term survivors; corneal deposits with photophobia and corneal erosions, ovarian failure, hypothyroidism, confusion, short-term memory loss, cerebral atrophy, Fanconi syndrome, and renal failure; myopathy and CNS involvement; prenatal diagnosis by studies of cystine uptake and retention by chorionic villi. Heterozygotes have six times the normal free cystine concentration. Three types are known: infantile nephropathic, late-onset or adolescent nephrohepatic, and benign or adult nonnephrohepatic

Table 108.2 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Disorders of vitamin and mineral assimilation				
Imerslund–Grasbeck syndrome	AR	10q12 *MGA1*	Malabsorption of vitamin B-12 not corrected with exogenous intrinsic factor	Chronic, relapsing megaloblastic anemia; no antibodies to intrinsic factor or gastric parietal cells; proteinuria and malformations of the urinary tract
Folic acid transport defect	AR	?	Malabsorption of folic acid	Defect in transport of folic acid into CNS, causing seizures; mental retardation and movement disorder; megaloblastic anemia corrected by parenteral administration of folic acid
Pseudovitamin D deficiency	AR	12q14	Defective calcium absorption	Several subtypes; responds to large doses of vitamin D; rickets and short stature, myopathy, hypocalcemia and hypophosphatemia; distinct from X-linked vitamin-D-resistant rickets
Familial isolated deficiency of vitamin E	AR	8q13 *TTPA*	No evidence of fat malabsorption; selective defect in vitamin E absorption	Ataxia, areflexia, loss of proprioception; increased serum lipids, xanthelasmata, and xanthomas of the Achilles tendon; neurological symptoms may improve with administration of vitamin E. Heterozygotes may manifest tendinous xanthomas and elevated serum cholesterol levels.
Menkes syndrome (kinky hair disease)	XLR	Xq12–13 *ATP7A*	Defective intestinal copper absorption	Light-colored kinky hair, growth retardation, severe neurological impairment, metaphyseal changes, tortuosity of vessels, bladder diverticula; low serum copper and ceruloplasmin levels
X-linked cutis laxa (occipital horn syndrome)	XLR	Xq12–13 *ATP7A*	Defective copper absorption	Occipital bony prominences; short, broad clavicles, fused carpal bones, hooked nose, long philtrum, multiple bladder diverticula, varicosities, inguinal hernias, joint laxity; low serum copper and ceruloplasmin levels; allelic with Menkes syndrome
Hereditary iron-handling disorder	AR	?3	Selective iron malabsorption	Microcytic anemia unresponsive to oral iron therapy, partial response to intramuscular iron dextran
Acrodermatitis enteropathica	AR	8q24.3 *SLC39A4*	Intermittent diarrhea caused by zinc malabsorption	Bullous dermatitis, failure to thrive; alopecia of scalp, eyebrows, and eyelashes; thymic hypoplasia; improvement with zinc supplementation
Hemochromatosis	AR	6p21 *HFE*	Iron overload caused by increased absorption in the intestine; symptoms relate to the degree of iron overload in specific tissues and are often milder in menstruating females. Liver disease.	Findings may include fatigue, cirrhosis, cardiomyopathy, arthritis, and darkening of skin color, and may be relieved or prevented in the earliest stages by scheduled phlebotomy, thus highlighting the usefulness of presymptomatic DNA testing.

AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system; GI, gastrointestinal; mt, mitochondrial; XLR, X-linked recessive.

also have a mild defect in renal tubular reabsorption of glucose. It is clinically distinguished from disaccharidase deficiency because there is no significant rise in plasma glucose during a glucose–galactose oral tolerance test. Treatment consists of substituting fructose for other dietary carbohydrates. The transport mechanism in the small intestine is dysfunctional where the mucosa is unable to take up glucose and galactose. Mutations in the glucose–galactose transporter gene (*SGLT1*, also known as *SLCA5A1* – solute carrier family 5), which maps to chromosome 22q13, are responsible for the condition.

Trehalase deficiency

Trehalase deficiency, an autosomal recessive disorder characterized by diarrhea and vomiting after ingestion of trehalose-containing foods, is rare in white Americans but is found in 10%–15% of the Inuit of Greenland. Trehalose is a disaccharide found in insects and mushrooms. Deficiency can be detected by oral tolerance tests. The gene encoding human renal trehalase (*TREH*) encodes a brush border membrane glycoprotein and maps to 11q23.

Defects in amino acid transport

Proteins are normally absorbed by two major mechanisms: transport of liberated free amino acids by group-specific sodium-dependent amino acid transport systems and uptake of unhydrolyzed peptides independent of the specific entry mechanisms. At least three major group-specific active transport systems exist: monoamine monocarboxylic (neutral) amino acids; dibasic amino acids and cystine; and dicarboxylic (acidic) amino acids. The genetic disorders of amino acid absorption involve deficiencies in one or more of these transport mechanisms.

Iminoglycinuria

Iminoglycinuria occurs as part of autosomal recessive inborn errors of imino acids (i.e., proline and hydroxyproline) and glycine absorption in the kidneys and consists of five subtypes, two of which also involve the intestine. It is also a benign, normal finding in infants younger than 3–6 months of age. The malabsorption condition is often asymptomatic but has been associated with mental retardation and gyrate atrophy of the choroid and retina. When any of the three amino acids is ingested, excretion of the other two increases, indicating a group-specific defect. Some homozygotes show no L-proline defect. At least four alleles for the disorder are suspected but the degree of locus heterogeneity is unknown. The reported frequency among the white population is about 1 in 15 000, giving a heterozygote frequency of about 2%. Obligate heterozygotes may be hyperglycinuric. A rare autosomal dominant form of glycinuria with oxalate nephrolithiasis, seen most often in Ashkenazi Jews, may be a distinct form of iminoglycinuria that predisposes to urolithiasis.

Hartnup disease

Hartnup disease is a rare heterogeneous autosomal recessive disorder with an incidence of 5 cases per 100 000 individuals. It causes virtually no symptoms in more than 90% of affected persons in the United States, probably reflecting the consumption of an adequate diet in this population. In symptomatic individuals, an intermittent, red, scaly, pellagra-like rash after sun exposure and attacks of cerebellar ataxia, sometimes accompanied by psychiatric disorders and seizures, develop in childhood. Low-normal or subnormal intelligence has also been reported. The main feature is massive aminoaciduria involving neutral and aromatic monoamine monocarboxylic amino acids sharing a common proximal renal tubule reabsorption mechanism. Patients have diminished capacity for jejunal absorption of these amino acids because of a brush border transport defect, causing retention of the amino acids in the intestine, which allows intestinal bacteria to convert them into dipeptide decomposition products, some of which are absorbed. Diminished tryptophan absorption causes inadequate nicotinamide synthesis, resulting in pellagra. Dipeptide decomposition is toxic to the central nervous system, and coupled with pellagra, produces the neuropsychiatric manifestations. A nutritional deficiency results from the diminished availability of essential amino acids. Liver biopsy shows extensive fatty liver without infiltration of inflammatory cells or fibrosis. Patients are treated by the administration of niacin. The gene, *HND*, maps to chromosome 5p15.

Cystinuria

Cystinuria is a rare autosomal recessive disorder characterized by cystine, lysine, ornithine, and arginine transport abnormalities in the renal tubule and intestinal epithelium. The clinical manifestations are confined to nephrolithiasis resulting from the insolubility of cystine in the urine. Expression of the disease peaks in the second and third decades. Men are more severely affected than women. Its incidence in the United States is 1 in 15 000 individuals but its incidence is 1 in 2500 among Israeli Jews of Libyan origin. Three forms of cystinuria are recognized. Identification of radiopaque stones that present as hexagonal cystine crystals in the urine leads to the diagnosis of all types. Type classification is based on excretion rates of amino acids in obligate heterozygotes. Type I heterozygotes excrete no excess amino acids, type IIIs excrete up to twice the normal amount, and type IIs (the rarest form) excrete of 9–15 times the normal amount.

Type I cystinuria maps to chromosome 2p16 where the culprit gene, *SLC3A1*, was identified. The type II and III cystinuria gene, *SLC7A9*, maps to chromosome 19q13. Treatment is directed at reducing the urinary cystine by increasing urine volume, urine alkalinization to increase solubility, and, as needed, reducing free cystine excretion by additional medical therapy.

Lysinuric protein intolerance/dibasic aminoaciduria II

Lysinuric protein intolerance, or dibasic aminoaciduria II, is a rare but serious autosomal recessive disorder beginning in infancy when cows' milk is introduced. It is characterized by abnormal transport of dibasic amino acids across the basolateral membranes of intestinal and renal tubular cells. Symptoms include vomiting, diarrhea, failure to thrive, severe growth retardation, hepatosplenomegaly progressing to cirrhosis, lens opacities, mental retardation, sparse and brittle hair, osteopenia, intermittent stupor, and sometimes hyperextensible skin and joints. It is caused by the malabsorption of arginine, lysine, and ornithine as demonstrated after oral protein loading. Reduced tubular reabsorption of these amino acids also occurs in the kidney with demonstrable lysinuria. Some heterozygotes manifest partial intestinal malabsorption after an oral protein load.

Quantitative plasma amino acids reveal low levels of arginine, lysine, ornithine, leucine, and tyrosine; normal serine and citrulline levels; and elevated glutamine and alanine levels. Dibasic aminoaciduria without cystinuria, impaired intestinal absorption of basic amino acids, and protein intolerance are diagnostic features. Hyperammonemia results from deficient hepatic uptake of the amino acids producing a deficiency of some intermediate products of the urea cycle. Treatment consists of protein restriction with citrulline and lysine supplements. Some of the abnormalities resolve on this therapy. It is caused by mutations in the amino acid transporter gene, *SLC7A7*, which maps to chromosome 14q11.

Blue diaper syndrome

Blue diaper syndrome is a rare autosomal disorder of intestinal, but not renal, tryptophan transport. Infants present with failure to thrive, recurrent fever, infections, irritability, and constipation in addition to the bluish discoloration of the diapers. Hypercalcemia and nephrocalcinosis also occur because of increased absorption of calcium. The unabsorbed tryptophan is converted to indoles by bacteria in the intestine. The indoles are absorbed and converted to indican in the liver. Indican, when oxidized, becomes indigo blue in the urine. The differential diagnosis includes the blue-green discoloration that can occur from a pigment manufactured by *Pseudomonas aeruginosa*.

Methionine malabsorption syndrome (oasthouse urine disease)

This autosomal recessive condition of methionine malabsorption is often called oasthouse urine disease because affected patients excrete urine containing α-hydroxybutyric acid, a product of the bacterial metabolism of methionine that has the odor of an oasthouse (a kiln for drying hops). The clinical features include white hair, blue eyes, hyperpnea, seizures, diarrhea, and mental retardation. Individuals will have a positive ferric chloride test on analysis of their urine in addition to α-hydroxybutyric aciduria. A methionine-free diet improves the symptoms.

Disorders of electrolyte absorption

Four genetic causes of intestinal electrolyte and water imbalances are well characterized: congenital chloride diarrhea, congenital sodium diarrhea, microvillus inclusion disease, and disorders of aldosterone metabolism causing significant salt wasting.

Congenital chloride diarrhea

Congenital chloride diarrhea is an autosomal recessive disorder that may present in utero with polyhydramnios, presumably caused by in utero diarrhea. The infant may be premature and exhibit abdominal distention. Frequent voluminous, watery, high-chloride-containing stools are produced, leading to hypochloruria, hypokalemia, and metabolic alkalosis. The secretory diarrhea in this condition results from a deficiency in intestinal brush border chloride–bicarbonate exchange. With later presentations, or inadequate replacement therapy, growth failure is noted. The family of one young boy with the disorder required donations of disposable diapers by a diaper manufacturer because this was the boy's largest nonreimbursable "medical" expense. Affected adults have a history of watery diarrhea since birth with numerous hospital admissions for dehydration and electrolyte abnormalities, glucose intolerance, gout, proteinuria, and mild renal function impairment. The chloride content of the stools and characteristic serum electrolyte changes are diagnostic. Treatment consists of administering prostaglandin inhibitors and potassium chloride. The gene for this condition, *SLC26A3*, maps to chromosome 7q22-q31.

Congenital sodium diarrhea

Congenital sodium diarrhea is an autosomal recessive disorder that presents similarly to congenital chloride diarrhea with polyhydramnios, prematurity, and voluminous, watery, high sodium- and bicarbonate-containing stools in the first days of life. Treatment consists of replacement of sodium bicarbonate. Perfusion studies show that the jejunum is in a net secretory state, with abnormal intestinal sodium–hydrogen exchange activity.

Microvillus inclusion disease

Microvillus inclusion disease is an autosomal recessive disorder involving the brush border membrane, which results in severe congenital fluid and electrolyte malabsorption and causes severe refractory diarrhea in early infancy. Unlike sodium and chloride diarrheas, polyhydramnios is not present prenatally. Microvillus inclusion disease likely results either from defective brush border assembly and differentiation or from an error of intracellular transport. Localization of the cytoplasmic inclusions to the microvillus membrane in

villus cells is revealed by electron microscopic examination. Rectal biopsy is used for early diagnosis. Therapies such as octreotide, clonidine, and epidermal growth factor have had limited success. It has been suggested that the only therapy to reduce fluid losses may be enterectomy. Survival is unusual after 2 years of age. Small bowel transplantation may become the best available treatment.

Intestinal defects in protein absorption

Many genetic syndromes demonstrate selective protein malabsorption as outlined in Table 108.2. Most involve abnormalities of the intestinal lymphatic system with intestinal lymphangiectasia, protein-losing enteropathy, and vascular hyalinosis. A rare association of protein-losing enteropathy with neurofibromatosis has been described. This patient had massive protein loss from a localized segment of small intestine with possible neurofibromatosis involvement of the mesenteric vessels.

Intestinal defects in lipid absorption

Several important genetic disorders may present in adults with lipid malabsorption. Many are caused by inborn errors of apolipoprotein or lipid metabolism. Familial amyloidosis polyneuropathy is also an important disorder with onset in adulthood that may present with lipid malabsorption. The clinical features common to most of these syndromes are caused by a deficiency of fat-soluble vitamins. Neurological symptoms may be present because of a deficiency of vitamin E, and a coagulopathy may be caused by vitamin K deficiency.

Familial amyloidosis polyneuropathy

The amyloid protein in familial amyloidosis polyneuropathy type 1 is composed of abnormal transthyretin molecules. Transthyretin is a plasma protein that transports thyroid- and retinol-binding proteins. Systemic deposition of this abnormal protein causes a progressive stocking sensorimotor neuropathy that usually begins in the lower limbs. The autonomic nervous system may also be involved, causing orthostatic hypotension, impotence, and abnormal GI motility presenting as initial constipation followed by episodic diarrhea. Malabsorption of bile acids is common and appears to be the result of GI motility dysfunction from the autonomic neuropathy, with resultant bacterial overgrowth, rather than from the amyloid deposits in the intestinal mucosa. This is an autosomal dominant condition that can be presymptomatically diagnosed by looking for mutations in the transthyretin gene, *TTR*, on chromosome 18q11-12.

Abetalipoproteinemia

The principal GI symptom of abetalipoproteinemia, an autosomal recessive disorder, is malabsorption of fat, often beginning in infancy with steatorrhea and poor weight gain. The disorder is often misdiagnosed as celiac disease. Histopathological analysis of the small bowel shows normally formed villi with lipid-engorged enterocytes. Impaired absorption of fat-soluble vitamins is responsible for many of the clinical features. Neurological symptoms usually begin in the second decade and include peripheral neuropathy and cerebellar ataxia. An atypical presentation of retinitis pigmentosa with decreased night and color vision may also develop, as does mild to moderate anemia, usually with hemolysis. There may be an iron or folate deficiency because of malabsorption and there is usually a coagulopathy caused by decreased vitamin K stores. The total cholesterol values are in the range of 20–50 mg/dL and triglyceride values are also very low, with little postprandial increase. There are no chylomicrons, very-low-density lipoproteins, low-density lipoproteins, or apolipoprotein B particles, the major structural apolipoprotein for these lipids.

Treatment consists of avoidance of fat and the administration of fat-soluble vitamins. Heterozygotes are asymptomatic with normal plasma lipids. The genetic defect is in the microsomal triglyceride transfer protein gene, *MTTP*, on chromosome 4q24 that mediates the intracellular transport of membrane-associated lipids. *MTTP* mutations cause defects in the ability of the liver and intestines to assemble or secrete apolipoprotein B.

Familial hypobetalipoproteinemia

Familial hypobetalipoproteinemia is thought to be an autosomal dominant fatty liver disorder lacking neuroocular features caused by low levels of apolipoprotein-β. Truncated versions of the normal apolipoprotein B gene, *APOB*, on chromosome 2p24 have been reported in some families where affected individuals have low levels of high-density and low-density lipoproteins, normal triglycerides, mild fat malabsorption, and defective chylomicron clearance. Genetic studies suggest that mutations in one allele of *MTTP*, which maps to 4q24, may also be responsible for some cases; confirming the genetic heterogeneity of this condition.

Anderson disease/lipid transport defect of the intestine

Individuals with Anderson disease, an autosomal recessive lipid transport defect of the intestine characterized by hypobetalipoproteinemia with accumulation of apolipoprotein B-like protein in intestinal cells, present with fat malabsorption with steatorrhea and growth retardation. They lack the significant acanthocytosis and the neuroocular symptoms of abetalipoproteinemia. Low-density lipoprotein particles are present in the plasma, but there is a failure of chylomicron formation. Enterocytes from intestinal biopsies show numerous fat droplets, and monoclonal antibody staining reveals the presence of apolipoprotein B48, the form produced by the intestine. Defective glycosylation of apolipoprotein B48 has been observed, which may underlie the absence of formation and secretion of chylomicrons.

Wolman disease and cholesterol ester storage disease/lysosomal acid lipase deficiency

Wolman disease is a severe autosomal recessive disorder, often fatal in infancy, where cholesterol esters and triglycerides accumulate in the liver, adrenal gland, spleen, lymph nodes, bone marrow, small intestine, lungs, and thymus because of lysosomal acid lipase deficiency. Death results from intestinal malabsorption. Cholesterol ester storage disease is a late-onset disorder with milder manifestations. It also involves lysosomal acid lipase deficiency and is allelic with Wolman disease. The culprit lysosomal acid lipase gene (*LIPA*) maps to chromosome 10q24-25. Prenatal diagnosis has been performed by enzyme assay in cultured amniocytes. DNA-based testing is available through a laboratory in Germany.

Exocrine pancreas abnormalities (see also Chapter 72)

Defects in protein and fat absorption are more commonly caused by abnormalities of the exocrine pancreas. Examples include deficiencies of specific pancreatic exocrine enzymes, cystic fibrosis, the Shwachman–Bodian syndrome, and the Johanson–Blizzard syndrome. Table 108.2 lists genetic syndromes manifesting with exocrine pancreas insufficiency.

Cystic fibrosis

Cystic fibrosis (CF) is a common autosomal recessive disorder in the Caucasian population, occurring with a frequency of about 1 in 2500 births. The classic disorder is characterized by viscous secretions and dysfunction of multiple exocrine glands, leading to pancreatic insufficiency, malabsorption, chronic pulmonary infection with emphysema, and a high chloride concentration in sweat. Milder mutations of the gene, *CFTR*, may result only in male infertility owing to congenital bilateral absence of the vas deferens or chronic pancreatitis. Only the GI manifestations of CF are reviewed here. CF remains a leading cause of malabsorption in white children in developed countries. More than one-half of patients with CF survive to adulthood and develop many of the GI complications with time. In fact, the majority of patients with classic CF have some degree of pancreatic insufficiency leading to achylia. Many are born with insufficiency and require enzyme replacement therapy by their first birthdays. Because the pancreatic secretions are abnormal, the pancreatic ducts become blocked, leading to destruction of the distal ducts. Proximal to these clogged ducts, autodigestion and inflammation lead to fibrosis and ultimately to exocrine insufficiency. The result is malabsorption, primarily of fats and fat-soluble vitamins, which causes malnutrition, susceptibility to hemorrhage caused by lack of vitamin K, tetany caused by hypocalcemia from losses in the stool, and neurological problems caused by vitamin E deficiency. Treatment consists of pancreatic enzyme replacement. The islets of Langerhans may become secondarily affected by fibrosis of the pancreas, leading to glucose intolerance or clinical diabetes, which is similar to non-insulin-dependent diabetes (type II), in approximately 50% of patients with CF.

Approximately 25%–30% of CF patients also develop focal biliary cirrhosis. In 2%–5% of these cases, multilobular biliary cirrhosis with portal hypertension may develop. Thick secretions plug the bile ducts, leading to inflammation and fibrosis. There is usually a history of pancreatic insufficiency in these cases.

The earliest clinical manifestation of CF may be meconium ileus, occurring in approximately 10%–15% of patients, caused by the lack of fluid in the small intestine because of a lack of pancreatic secretion or defective intestinal epithelial secretion. Gastrografin enema or oral *N*-acetylcysteine may resolve the obstruction; if not, surgery is necessary. A similar abnormality occurring later in life, called the distal intestinal obstruction syndrome, may occur in 10%–20% of CF patients, causing symptoms of colicky pain and constipation. These symptoms may be relieved with Golytely, mineral oil, an increase in pancreatic enzymes, or *N*-acetylcysteine. Rectal prolapse occurs in approximately one-fourth of patients before 2 years of age, but it usually does not occur in patients receiving pancreatic enzyme replacement therapy.

The responsible gene, *CFTR*, maps to chromosome 7q31 and encodes the cystic fibrosis transmembrane regulator protein, which forms a cAMP-regulated chloride channel. More than 1000 *CFTR* mutations have been described. The sensitivity of mutation testing varies depending on an individual's ethnicity, however, with up to 96% of mutant chromosomes detectable in affected Ashkenazi Jews and less than 70% of mutant chromosomes detected in African Americans with most commercially available mutation testing products.

The most common mutation in white patients of Northern European descent is δF508, a deletion of the amino acid residue phenylalanine at codon 508, occurring in 70% of CF patients. Most of the non-δF508 mutations are relatively rare, affecting less than 1%–10% of CF patients. Some *CFTR* genotypes are associated with pancreatic sufficiency or insufficiency, suggesting that the genotype at the *CFTR* locus is responsible for susceptibility to pancreatic insufficiency. δF508 and the common mutation among Ashkenazi Jews, *W1282X*, are examples of pancreatic insufficiency alleles. Preconceptual testing and prenatal testing are readily available. As of 2001 the American Colleges of Medical Genetics and Obstetrics and Gynecology recommend that all white couples considering parenthood and pregnant women be routinely offered DNA carrier testing.

Shwachman–Diamond/Shwachman–Bodian syndrome

The Shwachman–Diamond/Shwachman–Bodian syndrome, also called congenital lipomatosis of the pancreas, is an autosomal recessive disorder and the second most frequent pancreatic cause of malabsorption in childhood with an incid-

ence of 1 in 250 000 births. Symptoms include poor growth, intestinal malabsorption, steatorrhea, and recurrent respiratory infections, which present within the first few years of life. Dysplastic changes in the metaphyses of long bones lead to a moderate dwarfism. Patients may suffer from a pancytopenia caused by bone marrow dysfunction and are at increased risk for hematological malignancies. The pancreatic enzyme replacement required in infancy may not be necessary later. The responsible gene, *SBDS*, maps to chromosome 7q11.l

Johanson–Blizzard syndrome

In addition to pancreatic insufficiency with malabsorption, the autosomal recessive Johanson–Blizzard syndrome is characterized by aplasia or hypoplasia of the nasal alae, upswept frontal hair, widely spaced teeth, congenital deafness, hypothyroidism, postnatal growth retardation, mental retardation, midline ectodermal scalp defects, and absent permanent teeth. Genitourinary and anorectal abnormalities have also been described. Autopsy findings have shown almost complete replacement of the pancreas with fat and a paucity of islet cells. Death in childhood often results from malabsorption-related complications. Survival to adulthood is rare but possible if continuous enzyme replacement is instituted. Insulin-requiring diabetes is a feature in adulthood, similar to the situation for CF patients, presumably because of the loss of β-cells. It is the result of mutations in a gene important in the ubiquitin-ligase E3 pathway, *UBR1*, which maps to the long arm of chromosome 15.

Cartilage-hair hypoplasia/metaphyseal chondrodysplasia, McKusick type

Cartilage-hair hypoplasia (i.e., metaphyseal chondrodysplasia, McKusick type) is an incompletely penetrant autosomal recessive dwarfing syndrome (average adult height is 107–157 cm) with changes visible on radiographs called metaphyseal dysostosis. Other features include fine, sparse, light-colored hair, anemia, malabsorption caused by pancreatic insufficiency, Hirschsprung disease, and a susceptibility to chickenpox. Malignancies, specifically lymphoma, are more frequent in affected individuals. The *CHH* gene maps to chromosome 9p13.

Asphyxiating thoracic dystrophy/Jeune syndrome

Asphyxiating thoracic dystrophy, also called Jeune syndrome, is an autosomal recessive skeletal dysplasia that is often lethal in the perinatal period caused by involvement of the rib cage leading to severe asphyxia. Mildly affected individuals survive to adulthood. Other features include polydactyly, chronic nephritis, and intestinal malabsorption because of pancreatic insufficiency. Cystic changes occur in the kidney, liver, and pancreas. This syndrome shares clinical features seen in two other genetic syndromes, Ellis–van Creveld and renal–hepatic–pancreatic dysplasia syndromes.

Disorders of vitamin and mineral assimilation

This heterogeneous group of disorders displays widely variable manifestations dependent on the specific vitamin or mineral involved. Some disorders of vitamin and mineral metabolism can be appropriately treated by adequate replacement therapy.

Imerslünd–Grasbeck syndrome (see also Chapter 51)

Imerslünd–Grasbeck syndrome is an autosomal recessive disorder of chronic relapsing megaloblastic anemia caused by malabsorption of vitamin B-12. It is not corrected with exogenous intrinsic factor, differentiating it from intrinsic factor deficiency and transcobalamin II deficiency. No antibodies to intrinsic factor or gastric parietal cells are detected. The defect appears to be located between the attachment of B-12 to the surface of the ileal cell and the binding to transcobalamin II. In some cases, the defect is a selective failure of intrinsic factor transcytosis; in others, it may be the absence of an ileal receptor; and in others, the defect is unknown. Associated features include proteinuria and malformations of the urinary tract and persistent proteinuria.

The gene for this disorder, *MGA1*, maps to 10p12.2. Treatment consists of monthly intramuscular doses of 250 μg hydroxycobalamin or intramuscular doses every 2–3 months of 1000 μg hydroxycobalamin. The proteinuria does not usually respond. Mental retardation may ensue from delay of treatment so siblings of an affected person should be screened.

Menkes syndrome (see also Chapter 51)

Menkes syndrome, also called kinky hair disease, is an X-linked recessive disorder of copper metabolism caused by a defect in the intestinal absorption of copper owing to mutations in the *ATP7A* gene on chromosome Xq12-13. This affects copper-dependent enzymes in the body, producing a phenotype that is characterized by light-colored and kinky hair, growth retardation, severe neurological impairment with focal cerebral and cerebellar degeneration, changes in the metaphyses of the long bones, tortuosity of vessels, and bladder diverticula. Most patients die between 6 months and 3 years of age. Affected patients with milder allelic forms of the disease have survived to adolescence. Low serum copper and ceruloplasmin levels are reliable diagnostic findings. Heterozygotes may be detected by the finding of pili torti (i.e., kinky hair).

X-linked cutis laxa/occipital horn syndrome

X-linked cutis laxa/occipital horn syndrome mutations are caused by mutations in *ATP7A*, on chromosome Xq12-13, making it allelic with Menkes syndrome. It is characterized by occipital bony prominences (occipital horns), short broad clavicles, fused carpal bones, pectus deformities, a hooked nose with a long philtrum, multiple large diverticula of the bladder, varicosities, inguinal hernias, joint laxity, and diarrhea. Serum levels of copper and ceruloplasmin are low.

Acrodermatitis enteropathica (see also Chapter 110)
Acrodermatitis enteropathica is an autosomal recessive disorder of zinc malabsorption that presents with intermittent alopecia of the scalp, eyebrows, and eyelashes as well as diarrhea, dermatitis, and failure to thrive. Islet cell hyperplasia, absence of the thymus, and absence of germinal centers with plasmacytosis of the lymph nodes and spleen are noted at autopsy. Low serum and urinary levels of zinc and serum alkaline phosphatase (i.e., a zinc metalloenzyme) are helpful but not 100% sensitive in making the diagnosis. Oral zinc therapy has been successful in ameliorating symptoms. Ultrastructural abnormalities of the Paneth cells of the small intestine (i.e., cells that usually contain high concentrations of zinc) or a trial of oral zinc supplementation with good clinical response may provide evidence for the diagnosis in cases with normal serum zinc levels. Mutations in the intestinal zinc-specific transporter gene, *SLC39A4*, which maps to chromosome 8q24.3, have been implicated in the disease.

Hemochromatosis (see also Chapter 86)
Hemochromatosis is one of the most common autosomal recessive disorders with a carrier frequency of 1 in 10 individuals and affecting between 1 in 200 to 1 in 400 individuals of Northern European descent. An entire chapter, Chapter 86, is devoted to this condition. In homozygotes, increased absorption of iron in the small intestine results in an excess of iron deposited in many organs, ultimately resulting in organ failure in some individuals. Serious manifestations of hemochromatosis include cirrhosis, diabetes, cardiomyopathy, arthritis, hepatomas, and hypogonadotropic hypogonadism. Symptoms vary considerably among individuals. These may be minimal in individuals with chronic or episodic blood loss (e.g., menstruating women) and more severe in men with a high content of iron in their diet. Generally, symptoms begin in adulthood, after several years of increase in iron absorption.

The gene, *HFE*, maps to the human leukocyte antigen (HLA) region of chromosome 6p21, and has been cloned. One predominant mutation, Cys282Tyr, accounts for between 80% and 90% of mutant chromosomes, making DNA testing relatively straightforward. Homozygotes diagnosed early or when asymptomatic can be closely monitored and managed to prevent symptoms of iron overload. In addition to DNA diagnosis, liver biopsy along with serum iron, total iron-binding capacity, and ferritin levels may be helpful in the diagnosis. Treatment continues to include phlebotomy for individuals with increased iron levels. Other forms of hemochromatosis, caused by other factors, exist.

Chronic diarrhea syndromes not characterized by malabsorption

Several genetic disorders featuring chronic, recurrent diarrhea are not associated with a specific malabsorption syndrome. Many of the inherited immunodeficiency disorders involving T-cell antigens, T-cell antigen receptors, B cells, and immunoglobulin and complement deficiencies are characterized by a chronic diarrhea. Inherited colitis syndromes, neurological disorders, and endocrinopathies may also feature chronic or recurrent diarrhea as a common manifestation. Many of the polyposis syndromes may present with complaints of chronic diarrhea. Table 108.3 briefly summarizes those disorders that may be more commonly encountered by the clinician.

Recurrent gastrointestinal bleeding syndromes

Recurrent acute or occult GI hemorrhage should raise suspicion for a variety of genetic disorders (Table 108.4). These include structural abnormalities, such as the polyposis syndromes (e.g., Peutz–Jeghers syndrome, Gardner syndrome); vascular abnormalities, such as those that occur in vascular malformation syndromes and connective tissue disorders (e.g., hereditary hemorrhagic telangiectasia syndrome, Ehlers–Danlos syndrome); and disorders of the hematological system that may involve platelets, clotting factors, or abnormalities in fibrinolysis. The polyposis syndromes are reviewed elsewhere (see Chapter 64).

Many of the structural and vascular abnormality syndromes that cause GI bleeding belong to a group of disorders called the phakomatoses or genodermatoses, including NF1, basal cell nevus syndrome, Gardner syndrome, hereditary hemorrhagic telangiectasia, Klippel–Trenaunay–Weber syndrome, and Peutz–Jeghers syndrome. *Phakos* means spots, and these disorders have characteristic spotty or patchy cutaneous lesions. Other common features include a major vascular component to some lesions, involvement of the skin and central nervous system, and autosomal dominant inheritance patterns, often with significant variable expressivity and a high new mutation rate.

Many genetic hematological disorders predispose to GI bleeding. Deficiencies of clotting factors may result in a bleeding diathesis. von Willebrand disease and combined deficiency of factor VII and VIII are autosomal dominant disorders that may present with recurrent GI bleeding. The most common factor deficiency is factor VIII deficiency, better known as hemophilia A, an X-linked condition occurring with a frequency of 1 in 10 000. This disorder usually presents with hemarthroses that result in a chronic arthropathy, deep muscle hematomas, frank hematuria, and spontaneous intracranial bleeds. GI bleeding is not a common complication.

Abnormalities in fibrinolysis may also predispose to GI bleeding. Deficiencies of the anticlotting factors, protein C, protein S, and antithrombin III, can cause portal vein thrombosis, which can be complicated by ruptured esophageal varices.

Several genetic disorders are associated with abnormal platelet number or function predisposing to increase GI bleeding. Glanzmann thrombasthenia (i.e., platelet glycoprotein IIb-IIIa deficiency) is an autosomal recessive bleeding

Table 108.3 Diarrhea syndromes

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Immunodeficiency syndromes				
T3 T-cell antigen deficiency	AD	11q23	Nonspecific malabsorption	
T-cell antigen receptor deficiency, zeta subunit	AD	1q22–q23 *CD3Z*	Anorexia, diarrhea; small bowel shows absence of villi	Failure to thrive, pneumonia
Bare lymphocyte syndrome (BLS)	AR	19q13 *RFX1*	Severe, persistent diarrhea	A member of the severe combined immunodeficiency syndromes (SCID); mucocutaneous candidiasis, interstitial pneumonitis, and bacterial infections. In BLS type 1, the defect is the lack of HLA class I molecules. In type 2, there is a lack of HLA class I and II molecules. BLS seems to involve defects that affect gene expression.
Agammaglobulinemia, Swiss type, X-linked severe combined immunodeficiency disease	XLR	Xg13 *IL2RG*	Chronic diarrhea	Susceptibility to infections, thymic hypoplasia, and severe thrush
IgA and IgG2 deficiency	?AD	6q21	Nonspecific malabsorption	Infections, atopy, autoimmune disorders; association with HLA-BB; stronger association with neutral amino acids at the 57 position of HLA-DQ β-chain
κ-Light chain deficiency	AD	2q12 *IGKC*	Diarrhea	Recurrent respiratory infections
Deficiency of complement component 5	AD	9q34	Intractable diarrhea	General seborrheic dermatitis, recurrent local and systemic infections (gram-negative), and marked wasting
Wiskott–Aldrich syndrome	XLR	Xp11 *WAS*	Bloody diarrhea	Eczema, thrombocytopenia, susceptibility to infections; death by age 10; lymphoreticular malignancies. Therapy consists of bone marrow transplant. Carriers have a defect in platelet oxidative phosphorylation. Frequency is 4 per million male births; prenatal diagnosis possible with closely linked DNA markers.
Hereditary mucoepithelial dysplasia	AD	?	Diarrhea in infancy; esophageal stenosis or webs	Periorofacial flat, red mucosal lesions, follicular keratosis, photophobia, and nystagmus in infancy; keratitis, pannus, and cataracts; fibrocystic lung disease and cor pulmonale in adulthood; nonscarring alopecia; vaginal, oral, or urinary Papanicolaou smears show large immature cells containing vacuoles and strand-shaped inclusions. Mild mucocutaneous candidiasis, increased susceptibility to bacterial infection, possibly hypoadrenocorticism
Colitis syndromes				
Lethal cutaneous photosensitivity and colitis	AR	?	Severe colitis, refractory diarrhea	Early cutaneous photosensitivity; skin lesions are erythematous and vesicular, normal plasma zinc
Enterocolitis	AR	?	Bloody diarrhea	Death within a few weeks; very rare
Hermansky–Pudlak syndrome	AR	10q23 *HPS*	Inflammatory bowel disease, usually in Puerto Ricans	Oculocutaneous albinism with bleeding tendency, restrictive lung disease, pigmented reticular cells, defect in platelet ADP release, causing prolonged bleeding time and defective platelet aggregation

Table 108.3 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Neuropathy syndromes				
Charcot–Marie–Tooth disease (AD CMT1A most common and several other forms exist)	AD, AR, or XLR	17p *CMT1A* 1q22 *CMT1B-MPZ*	Chronic diarrhea, nausea, and vomiting	Begins with a motor and sensory neuropathy involving the distribution of the peroneal nerve; loss of reflexes and trophic changes may occur; pes cavus is common; significant genetic heterogeneity
Fatal neonatal radiculoneuropathy	AR	?	Chronic diarrhea	Prenatal polyhydramnios, floppy infant, distal muscle weakness, areflexia, opisthotonic posturing, autonomic instability, rare variant of infantile spinal-muscular atrophy
Endocrinopathy syndromes				
Multiple endocrine neoplasia type 1 (MEN1)	AD	11q13 *MEN1*	Severe peptic ulcer disease and chronic diarrhea secondary to gastrinomas	Pituitary, parathyroid, and pancreatic adenomas; bronchial and duodenal carcinoid; malignant schwannomas
Polyglandular autoimmune syndrome type 1	AR	22q22	Diarrhea	Triad of Addison disease, hypoparathyroidism, and chronic mucocutaneous candidiasis; frequently associated with chronic active hepatitis, pernicious anemia, and primary hypogonadism; IDDM and thyroid disease are infrequent
IDDM-secretory diarrhea syndrome	XLR	Xp11–q13 *FOXP3*	Severe secretory diarrhea	Newborn presentation of brittle IDDM; death in infancy from septicemia, malnutrition, and poor diabetes control
X-linked diarrhea, poly-endocrinopathy, fatal infection syndrome	XLR	Xp11–q13 *FOXP3*	Intractable diarrhea	Eczema, hemolytic anemia, diabetes or thyroid autoimmunity; increased susceptibility to viral infections
Miscellaneous syndromes				
Systemic infantile hyalinosis	AR	4q21 *CMG2/ANTXR2*	Diarrhea in infancy	Early thickening and focal nodularity of the skin, causing reduced mobility and joint contractures; gum hypertrophy and osteoporosis, failure to thrive, and recurrent infections. Histopathology shows deposits of hyaline in the skin, muscle, GI tract, and endocrine glands.
Rapadilino syndrome	AR	8q24.3 *RECQL4*	Diarrhea	Radial and patellar aplasia or hypoplasia, absence of thumbs, dislocation of joints, long face with narrow palpebral fissures, long slender nose, small chin, unusual ears, cleft or high-arched palate, small stature, normal intelligence
Hyperphosphatemia, polyuria, and seizures	AR	?	Vomiting, diarrhea due to hyperphosphatemia	Seizures, intermittent polyuria, and hyperphosphatemia occurring together or separately; irritability, anorexia, high-pitched cry, carpopedal spasm, and overt tetany secondary to hyperphosphatemia
Dutch-type perodic fever	AR	12q24	Diarrhea during attacks; otherwise minimal abdominal symptoms; no serositis	Recurrent attacks of fever, headache, and swollen glands; leukocyte count of 10 000–20 000 cells/μL.
Fatal infantile diarrhea with abnormal hair	AR	?	Severe diarrhea preceded by excoriated buttocks	Large, low-set simple ears; flat nasal bridge, large mouth, and wooly, easily removed hair; hepatic fibrosis, hemosiderosis, and islet cell hyperplasia; increased serum galactose. Consider Menkes syndrome in differential diagnosis.
Erythroderma desquamativa of Leiner	AR	?	Severe diarrhea	Susceptibility to infection, lymphatic hypoplasia, and increase in reticular cells of the lymph nodes.

AD, autosomal dominant; AR, autosomal recessive; GI, gastrointestinal; HLA, human leukocyte antigen; IDDM, insulin-dependent (type I) diabetes mellitus; IgA, immunoglobulin A; XLR, X-linked recessive.

Table 108.4 Recurrent gastrointestinal bleeding syndromes

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Polyposis syndromes		see Chapter 64		
Neurofibromatosis type I (NF1)	AD	17q11 *NF1*	GI bleeding, secondary to ulceration of intestinal neurofibromas	Multiple café au lait macules, neurofibromas, axillary and inguinal freckling, multiple Lisch nodules, optic gliomas, bony dysplasia of the sphenoid and long bones; associated neoplasms include pheochromocytoma, meningiomas, and malignant degeneration of neurofibromas
Neurofibromatosis type III (NF3)?	AD	?17q11 *?NF1*	GI bleeding caused by ulceration of intestinal neurofibromas	None of the other features seen in NF1
Multiple endocrine neoplasia type 1 (MEN1)	AD	11q13 *MEN1*	GI bleeding caused by peptic ulcer disease secondary to gastrinomas	Triad of pancreatic (i.e., insulinomas and gastrinomas), parathyroid, and pituitary adenomas; disease gene located on chromosome 11q
Muir–Torre syndrome	AD	3p21.3 *MLH1*	GI bleeding secondary to multiple primary carcinomas of the colon, duodenum, and larynx	Keratoacanthomas of the face; multiple sebaceous tumors
Macrocephaly, multiple syndrome lipomas, and hemangiomas (see text for syndrome names)	AD	10q23 *PTEN* 10q22 *BMPR1A*	Multiple visceral hemangiomas and intestinal hamartomas predispose to GI bleeding	Macrocephaly, pseudopapilledema, multiple hemangiomas involving the skin; males may have hyperpigmented macules on the penis
Cutis laxa type	AR, AD	5q23–31 *FNBL5*	Diverticula of the GI tract that are susceptible to bleeding (X-linked cutis laxa also features of GI diverticula)	Diaphragmatic and other hernias, diverticula of the urinary tract, and pulmonary emphysema
Small intestinal diverticulosis	AR	?	Small bowel diverticula and ulcerative colitis predispose to GI bleeding	Possible increase in autoimmune disorders, including rheumatoid arthritis, thyroiditis, and nonviral hepatitis

Table 108.4 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Diverticulosis of bowel, hernia, and retinal detachment	AR	?	Diverticula of large or small bowel	Femoral or inguinal hernias, diverticula of bladder, myopia, strabismus, and retinal detachment
Williams syndrome	AD	7q11 *ELN*	Risk for GI bleeding caused by diverticulosis; constipation	Supravalvular aortic stenosis, elfin face, dental abnormalities, infantile hypercalcemia, growth and mental deficiency; estimated frequency of 1 in 10 000
Ehlers–Danlos syndrome (many subtypes with significant genetic heterogeneity)	AD	Type IV 2q31 *COL3A1*	Bowel and large vessel rupture, more common in type IV	Classic type (I and II): soft, extensible skin; lax joints, easy bruisability, atrophic scarring, hernias, and premature birth. Vascular type (IV) caused by type III collagen defect, thin, translucent skin
Pseudoxanthoma elasticum	AR and AD	6p13 *ABCC6*	Abnormal vasculature causes GI and urinary tract bleeding; hematemesis is common	Pseudoxanthomatous changes of the skin of the flexural areas; angioid streaks of the retina
Hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu syndrome)	1-AD	9q34 *ENG* 12q13 *ALK-1*	Mucocutaneous telangiectases with acute or chronic blood loss	Epistaxis, cutaneous telangiectasias, arteriovenous malformations in the lung, liver, and brain
Klippel–Trenaunay–Weber syndrome	Sporadic/AD	5q13.3 VG5Q	Diffuse cavernous hemangiomas of the colon causing GI bleeding	Varicose veins, large cutaneous hemangiomas with hypertrophy of underlying soft tissues and bone
Blue rubber bleb nevus syndrome	AD	?	Hemangiomas of the nasopharynx and GI tract	Hemangiomatous skin lesions of the trunk and upper extremities
Idiopathic colonic varices	AD	?	GI bleeding from colonic varices in the absence of portal hypertension	
Hermansky–Pudlak syndrome	AR	10q23 *HPS*	Inflammatory bowel disease and defective platelet aggregation predispose to GI bleeding	Partial albinism, restrictive lung disease; common in Puerto Ricans
Cutaneous photosensitivity and colitis	AR	?	GI bleeding secondary to severe colitis; refractory diarrhea	Early cutaneous photosensitivity, causing erythematous, vesicular lesions of the skin

AD, autosomal dominant; AR, autosomal recessive; GI, gastrointestinal.

diathesis with deficient clot retraction and abnormal platelet morphology. Mucosal bleeding is typical, and gingival bleeding, epistaxis, and laryngeal bleeding are common features. An autosomal dominant form of Glanzmann thrombasthenia has similar features. Bernard–Soulier syndrome (i.e., platelet glycoprotein Ib deficiency) is an autosomal recessive bleeding disorder characterized by unusually large platelets and a prolonged bleeding time. The platelet membrane is abnormal and lacks a receptor, glycoprotein Ib, involved in the adhesion of platelets to subendothelium and von Willebrand factor; patients are susceptible to mucosal bleeding. Thromboxane synthase deficiency, leading to platelet aggregation abnormalities, is an autosomal recessive disorder that may present with petechiae, bruising, epistaxis, hematuria, or massive GI bleeding. The Hermansky–Pudlak syndrome is also characterized by abnormal platelets and is discussed in a later section of this chapter.

Neurofibromatosis (see also Chapter 64)

Of the two major types of neurofibromatosis, NF2 is not typically associated with significant GI manifestations. NF1 and a probable allelic variant of NF1, previously called NF3, known as familial intestinal neurofibromatosis, can be associated with GI hemorrhage because of ulceration of neurofibromas in the lumen of the bowel. Major characteristics of NF1 include multiple cutaneous café au lait macules, multiple neurofibromas or plexiform neurofibromas, axillary or inguinal freckling, optic gliomas, multiple Lisch nodules (i.e., iris hamartomas), and bony dysplasia of the sphenoid or long bones. Occasionally, an individual with NF1 may present with obstructive GI symptoms secondary to having large internal plexiform neurofibromas extending throughout their thoracoabdominal cavity. Arterial occlusive disease also has been reported in NF and may be the underlying etiology of GI complaints in affected individuals.

NF1 is an autosomal dominant disorder displaying significant intrafamilial and interfamilial variability and occurs in 1 per 4000 persons of all ethnic groups. New mutations are thought to account for up to 50% of affected individuals. The large NF1 gene maps to chromosome 17q12. DNA-based diagnostic testing detects approximately 90% of mutations. The National Neurofibromatosis Foundation (and its local chapters) provides educational materials, support, and newsletters to families and physicians.

Hereditary hemorrhagic telangiectasia/Osler–Weber–Rendu syndrome

Hereditary hemorrhagic telangiectasia (HHT) is a genetically heterogeneous autosomal dominant disorder of high penetrance characterized by mucocutaneous telangiectases. Two major genetic forms, HHT1 and HHT2, are recognized. The usual presenting feature is epistaxis occurring at puberty. The cutaneous telangiectases appear later, usually between 5 and 20 years of age. Blood loss from the mucosal lesions in the gut can be chronic or acute. Larger vessel involvement is common. Pulmonary arteriovenous malformations occur in approximately 15%–20% of individuals, especially in those families with HHT1 whose disease is caused by mutations in the endoglin gene, *ENG*, on chromosome 9q34, and may lead to embolic complications or high-output cardiac failure. HHT2 maps to 12q13 where mutations have been identified in *ALK-1*. Arteriovenous malformations occur less often, in the cerebral and hepatic vessels.

Klippel–Trenaunay–Weber syndrome

The Klippel–Trenaunay–Weber syndrome is usually sporadic, but may be autosomal dominant. It is characterized by varicose veins and large, cutaneous hemangiomas with hypertrophy of the underlying bones and soft tissues. Diffuse cavernous hemangiomas of the colon are found in 1%–12.5% of patients and can sometimes cause significant GI bleeding. Partial colectomy with endoscopic laser ablation of residual abnormal colonic mucosa has been successful in the management of this complication. Mutations in or gain-of-function translocation involving *VG5Q*, which maps to chromosome, 5q3.13, have been identified.

Blue rubber bleb nevus syndrome

The blue rubber bleb nevus syndrome is an autosomal dominant disorder characterized by the presence of easily compressible bladder-like, hemangiomatosis skin lesions that refill quickly after compression and have the look and feel of rubber nipples. The sites most commonly involved are the trunk and upper extremities, but the mucosa of the nasopharynx and GI tract, particularly the small bowel, can be affected. Bleeding is an important complication of these lesions. Nocturnal pain and regional hyperhidrosis may also be features of this disorder.

Ehlers–Danlos syndrome

Connective tissue disorders in which the integrity of structural tissues is impaired may predispose to GI bleeding. Ehlers–Danlos syndromes (EDS) are a heterogeneous group of connective tissue disorders affecting the skin, ligaments, joints, blood vessels, and internal organs, depending on the structural protein or modifying enzyme affected. There are six major subtypes of EDS that have been described, most of which are autosomal dominant, although the dermatospraxis and kyphoscoliosis forms are autosomal recessive. The nomenclature for EDS subtypes has been revised to define the "classic" forms, EDS I and EDS II (where EDS II is a milder form) as characterized by soft, velvety, hyperextensible skin, lax joints, easily bruised skin, atrophic scarring, venous varicosities, hernias, and prematurity caused by rupture of fetal membranes. GI bleeding caused by hollow organ (i.e., bowel) and arterial rupture is not a usual manifestation but may occur. Some cases of EDS I and EDS II have demonstrated alterations in the type V collagen gene, *COL5AI*, which

maps to chromosome 9q. An increased incidence of irritable bowel syndrome and diverticulitis has been observed in some individuals with the hypermobility type of EDS, also known as EDS type III, but specific risks for these GI symptoms in EDS have not been established.

The "vascular" form of EDS, also known as EDS IV, is associated with increased morbidity and early mortality caused by bowel and large vessel ruptures. Individuals most often have thin, fragile skin with easily visible veins and friable tissues. They bruise easily, have tight skin over the fingers, face, and ears (acrogeria), and hyperextensible distal interphalangeal joints. Defects in the type III collagen gene, *COL3A1*, which maps to chromosome 2q31, are responsible for the phenotype. Unfortunately, no specific treatment is available for EDS IV and it is not uncommon for individuals to die during late adolescence or early adulthood owing to rupture of the bowel, large arterial vessels, or uterus during pregnancy. Cases have been reported where the ruptured bowel could not be appropriately repaired at surgery owing to the extensive friability of the tissue that was unable to adequately hold sutures. Analysis of skin fibroblasts for type III collagen synthesis and secretion has been the diagnostic method of choice for vascular EDS although direct DNA sequencing is available. When a specific DNA mutation is identified in a family, sensitive DNA-based mutation testing can be done. Unfortunately, even with early diagnosis, no specific therapy is available to prevent rupture of hollow organs and vessels. However, appropriate genetic counseling about risks and strategies to minimize catastrophic complications, especially during pregnancy, can be offered to individuals.

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum primarily affects the skin of the neck, axillae, and other flexural areas; the Bruch membrane of the eye, resulting in angioid streaks on funduscopic examination and ultimate retinal detachment with visual loss; and the arteries, producing GI and urinary tract hemorrhage, precocious calcification, and occlusive vascular changes. Recurrent, severe hematemesis was the presenting feature of one of the first reported cases. Hematemesis is much more common than melena; superficial hemorrhages and erosions may be seen in the stomach. Bleeding tends to occur as early as the first decade of life, before the skin and eye changes are evident. Pregnant women are more susceptible to bleeding.

The diagnosis is made on the basis of clinical examination but there is widely variable expression. Allelic autosomal dominant and autosomal recessive forms have been reported. The dominant types are characterized by peau d'orange skin changes, severe vascular complications, severe choroiditis, angioid streaks, retinal detachment, macular or focal changes in the skin (which may be very stretchy), myopia, a high-arched palate, blue sclerae, and loose joints. The recessive types may be clinically similar. Patients have been reported with generalized skin changes with no ocular or vascular abnormalities.

Mutations in the multidrug resistance gene, *ABCC6* (ATP-binding cassette, sub-family C, member 6), on chromosome 6p13 have been identified in individuals with both autosomal dominant and autosomal recessive forms of the disease.

Syndromes characterized by hamartomas, macrocephaly, multiple lipomas, or hemangiomas

(see also Chapter 64)

A collection of several allelic autosomal dominant syndromes, including Bannayan–Zonana syndrome, Bannayan–Riley–Ruvalcaba syndrome, Cowden syndrome, Riley–Smith syndrome, and Ruvalcaba–Myhre–Smith syndrome, present with similar features but exhibit genetic variability as well as both locus heterogeneity. Typical features include macrocephaly, pseudopapilledema, multiple lipomas, multiple hemangiomas involving the skin and viscera, thyroid nodules, and intestinal hamartomatous polyposis. The latter two features create a susceptibility to GI hemorrhage. Males may have diagnostic hyperpigmented macules on the penis. High birth weight and length are typical, but growth levels off at 6–7 years of age. There may be delayed motor development, autistic features, cognitive delays, and lifelong problems with coordination. Seizures have been reported from intracranial hemorrhage caused by arteriovenous malformations; such arteriovenous malformations may also lead to extremity overgrowth, necessitating amputation. In adults, higher incidences of breast, thyroid, colon, renal, endometrial, and skin cancers have been reported, making this a cancer predisposition syndrome for which preventive screening and management should be employed.

Mutations in the *PTEN* gene, a tumor suppressor gene first identified in association with Cowden syndrome that maps to chromosome 10q23, have also been demonstrated in individuals with Bannayan–Riley–Ruvalcaba, Bannayan–Zonana, Riley–Smith, and Ruvalcaba–Myhre–Smith syndromes, demonstrating that these are indeed, allelic conditions. Mutations in the *BMPR1A/ALK3* gene, a member of the transforming growth factor-β/*BMP* superfamily, on 10q22, have been identified in some families with these conditions. They have also been noted in some kindreds with the inherited juvenile polyposis syndrome, a similar but distinct hamartoma syndrome with an increased predisposition to colon cancer. Mutations in the *MAD4/DPC4* gene located on 18q21 have been associated with familial juvenile polyposis, although early reports suggested that juvenile polyposis can be caused by mutations in the *PTEN* gene. Atypical juvenile polyps with mixed features of hamartomas and adenomas are characterized by a variant of the juvenile polyposis syndrome known as the hereditary mixed polyposis syndrome. This form maps to chromosome 6q16. Further molecular characterization of

the hamartomatous syndromes is needed to more precisely clarify the relationships between these conditions. It has been suggested that if *PTEN* mutations are identified in a patient that the most useful diagnosis may be the "*PTEN* hamartoma syndrome" to reduce the confusion associated with the multiple allelic syndromes that have been associated with *PTEN* alterations.

Cutis laxa

Several genetically heterogeneous forms of cutis laxa have been described. Cutis laxa type I is an autosomal recessive disorder characterized by abnormalities of the elastic tissue and features diaphragmatic and other hernias; diverticula of the GI and urinary tracts, which are susceptible to bleeding; and pulmonary emphysema, which may lead to cor pulmonale. Death usually occurs in the first year of life. Mutations in *FNBL5* on the long arm of chromosome 5 have been implicated in some forms of the diease. The second less severe form is characterized by prenatal and postnatal growth deficiency, large fontanelles with delayed closure, congenital hip dislocation, and lax joints. Diminished elastin production has been verified in these patients, and quantification reveals decreased elastin messenger RNA, perhaps caused by decreased rates of transcription or degradation of unstable transcripts. A dominant form of cutis laxa also associated with mutations in the *FBLN1* gene or the elastin, *ELN*, gene, does not have the visceral manifestations characteristic of the recessive forms. X-linked cutis laxa is discussed in the section on disorders of vitamin and mineral assimilation because it is associated with copper abnormalities. All forms of the syndrome also feature diverticular disease of the GI tract, increasing the possible risk for GI hemorrhage.

Hermansky–Pudlak syndrome

Hermansky–Pudlak syndrome is an autosomal recessive disease that occurs most frequently in Puerto Rico, where the prevalence is 1 in 2000 individuals. It is a storage disorder of a ceroid-like substance and is associated with features of partial albinism, restrictive lung disease, and a platelet abnormality. There is a deficiency of the granule storage pool in platelets, causing defective ADP release, which leads to a prolonged bleeding time and defective platelet aggregation. Inflammatory bowel disease with an onset between the ages of 12 and 30 years is also common in Puerto Rican patients. The combination of inflammatory bowel disease and defective platelets contributes to the occurrence of GI bleeding in these patients. The gene for this disorder, *HPS*, maps to chromosome 10q23.

Intestinal motility or pseudoobstruction disorders

(see also Chapter 47)

Intestinal pseudoobstruction may result from intrinsic enteric myopathies and neuropathies or from generalized muscular and neurological disorders. This section reviews the genetic disorders that feature abnormal intestinal motility or pseudoobstruction in each of these categories. These disorders are summarized in Table 108.5.

Intestinal pseudoobstruction is suggested by recurrent signs and symptoms of intestinal obstruction in the absence of mechanical obstruction, as proven by appropriate radiological, endoscopic, or surgical investigations. The presence and severity of complications depend on the individual's age, site of involvement, and degree of functional impairment. In the adult, a long-standing history of symptoms suggesting GI motility dysfunction – such as dysphagia, early satiety, and constipation or diarrhea – may precede the onset of acute symptoms. Patients usually present in the second to fourth decades of life with complaints of abdominal pain, distention, and sometimes vomiting. Malnutrition is common and results from decreased food intake, impaired digestion, or malabsorption. Infants with these disorders usually present with acute, severe, obstructive symptoms of abdominal pain and distention after feeding. Reflux esophagitis and aspiration pneumonia caused by impaired gastroesophageal motility is also common in infants.

After mechanical obstruction has been ruled out, diagnostic studies to evaluate pseudoobstruction include esophageal and intestinal manometry, gastric emptying studies, and full-thickness biopsy with silver stains. Esophageal manometry shows aperistalsis and incomplete relaxation of the lower esophageal sphincter. Intestinal manometry usually shows a hypomotile pattern. Gastric emptying studies show a delay for solids and a variable pattern for liquids. Silver stains delineate neuropathic from myopathic forms. Detection of subclinically affected family members at risk can be accomplished with these diagnostic techniques.

Visceral myopathy syndromes

Clinical GI manifestations of the visceral myopathic and neuropathic forms of intestinal pseudoobstruction are similar. In the myopathic form, there may be other evidence of myopathy, such as megacystis, vesicoureteral reflux, ophthalmoplegia, ptosis, and small intestine diverticulosis. Pathogenetic mechanisms of GI manifestations include degenerative changes and thinning of intestinal smooth muscle, especially of the longitudinal layers; the enteric neurons are normal. A mitochondrial myopathy associated with intestinal pseudoobstruction caused by a visceral myopathy has been described. Some forms of visceral myopathy may be mitochondrial myopathies. Diagnosis of a mitochondrial myopathy can often be made by a Gomori trichrome-stained skeletal muscle biopsy, which shows the characteristic ragged, red fibers, or by analysis of respiratory chain enzymes. There are no well-documented reports of a mitochondrial DNA mutation responsible for intestinal pseudoobstruction. The reported familial cases are autosomal dominant or recessive, lacking the maternal pattern of transmission seen with mitochondrial

Table 108.5 Intestinal motility and pseudoobstruction disorders

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Visceral myopathies				
Visceral myopathy with megaduodenum or megacystitis	AD	?	Intermittent abdominal pain, distention, vomiting, constipation, and diarrhea, usually presenting in the 1st to 2nd decade	Megacystitis occurs without obstruction but with vesicoureteral reflux, predisposing to urinary tract infections; diagnosis often made in adults. Family study can prevent unnecessary diagnostic surgery for symptomatic relatives
Visceral myopathy with external ophthalmoplegia	AR	?	Chronic diarrhea, abdominal distention and pain, dilated duodenum and jejunum with diverticulosis	Ptosis, ophthalmoplegia, proximal muscle weakness, and atrophy; mitochondrial myopathy may accompany or be responsible for disorder, usually adult onset
Megacystitis–microcolon–intestinal hypoperistalsis syndrome	AR	15q24 *PABPN1*	Microcolon and dilated small intestine with symptoms of obstruction; abdominal distention and bilious vomiting	Symptom onset in infancy; marked dilation of the bladder, hydronephrosis, external appearance of prune belly, multiple cardiac rhabdomyomas; 4 : 1 female preponderance, possibly due to increased severity in males; prenatal diagnosis by ultrasound identifying distended GI tract and bladder; death usual by 3 years from malnutrition of sepsis
Hereditary internal anal sphincter myopathy	AD	?	Severe anal pain, constipation	Onset in 3rd to 5th decades; noncompliant, thickened internal anal sphincter
Duchenne muscular dystrophy	XLR	Xp21 *DYS*	Bloating, abdominal fullness, delayed gastric emptying, acute gastric dilation, chronic intestinal pseudoobstruction	Skeletal muscle degeneration, causing severe debilitating weakness caused by deficiency of the gene product dystrophin
Myotonic dystrophy	AD	19q13 *DM*	Problems with swallowing, aspiration, and constipation; more severe complications occur with congenital myotonic dystrophy with gastroparesis; subacute obstruction, megacolon, and constipation	Delayed muscular relaxation, ptosis, cataract, gonadal atrophy, cardiac, conduction defects, and male pattern baldness; disease gene localized to chromosome 19p; maternal transmission associated with more severe phenotype of congenital myotonic dystrophy with mental retardation, neonatal hypotonia, and facial diplegia
Oculopharyngeal muscular dystrophy	AD	14q11–13	Dysphagia	Ptosis; weakness and wasting of facial, neck, and distal limb muscles; mitochondrial abnormalities seen on electron microscopy
Kearns–Sayre syndrome	mt deletions	mt	Swallowing difficulties	Progressive external ophthalmoplegia, pigmentary retinopathy, cardiac conduction defects caused by cytochrome C oxidase deficiency; deletions in the mitochondrial DNA responsible for the phenotype; all reported cases are sporadic
Visceral neuropathies				
Deficiency of argyrophil myenteric plexus	AR ?AD	?	Intermittent abdominal pain, distention and vomiting, functional intestinal obstruction; short, small intestine, malrotation, and pyloric hypertrophy caused by failure of the development of the myenteric plexus	Ataxia, abnormal pupillary reflexes, dysarthria, absent deep tendon reflexes, peripheral neuropathy and autonomic neuropathy; eosinophilic nuclear inclusions in the myenteric neurons, brain, spinal cord, and celiac plexus ganglia

Microcolon	AR	?	Obstruction, abdominal distention, vomiting	Aganglionosis of the entire colon and distal small intestine leads to microcolon; may be secondary to congenital atresia or mechanical obstruction (e.g., meconium ileus)
Hirschsprung disease microcephaly, and iris coloboma	AD multifactorial	10q11, others *RET, others*	Aganglionic megacolon with constipation and abdominal distention	Risks to family members increase with severity and number of female relatives affected
Hirschsprung disease, microcephaly, and iris coloboma	AR	?	Aganglionic megacolon	Microcephaly, hypertelorism, iris coloboma, submucous cleft palate, short stature, learning problems; similar features described in chromosome deletion syndromes; high-resolution karyotype recommended
Hirschsprung disease with bilateral bicolored irides	AR	22q13 *SOX10* 20q13 *EDN3*	Aganglionic megacolon	Heterochromia, two distinct colors present in the same iris
Hirschsprung disease with polydactyly, renal agenesis, and deafness	AR	?	Aganglionic megacolon	Polydactyly, unilateral renal agenesis, hypertelorism, and congenital deafness
Hirschsprung disease with ulnar polydactyly, polysyndactyly of big toes, and ventricular septal defect	AR	?	Aganglionic megacolon	Ulnar polydactyly, polysyndactyly of big toes, and ventricular septal defect
Hirschsprung disease with hypoplastic nails and dysmorphic facial features	AR	?	Aganglionic megacolon	Hypoplastic nails, minor dysmorphic facial features, bilateral hydronephrosis, imperforate anus, inguinal hernia; death in infancy
Hirschsprung disease and Ondine curse	?AR ?AD	?	Short segment and total colonic aganglionosis	Idiopathic, congenital hypoventilation; possible abnormality of the neural crest
13q-syndrome	Chromosomal		Aganglionic megacolon	Growth deficiency, microcephaly, mental deficiency, abnormal facies with prominent nasal bridge, hypertelorism, ptosis, epicanthal folds, microphthalmia, colobomas, retinoblastoma, prominent maxilla, prominent, slanting, low-set ears, micrognathia, hypoplastic or aplastic thumbs, cardiac defects, club feet, hypospadias, cryptorchidism
Down syndrome	Chromosomal	Trisomy 21	Aganglionic megacolon in 5.9% of cases	Hypotonia, protruding tongue, joint laxity, short stature, mental retardation, speckling of irides (i.e., Brushfield spots), small ears, flat facial profile, upslanting palpebral fissures, redundant neck skin, single transverse palmar crease, 5th finger clinodactyly, hypothyroidism; leukemia in 1% of cases
Cartilage–hair hypoplasia (metaphyseal chondrodysplasia, McKusick type – several types of metaphyseal chondroplasia exist)	AR	9p13 *CHH*	Megacolon with constipation	Dwarfing syndrome with radiographic changes called metaphyseal dysostosis; fine, sparse, light-colored hair, anemia; susceptibility to chickenpox and malignancies
Waardenburg–Shah syndrome	AR	20q13	Intestinal obstruction with dilated proximal ileum, collapse of distal ileum and colon	White forelock, white eyebrows and eyelashes, isochronia irides (i.e., mosaic pattern in light brown irides)

Table 108.5 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Waardenburg syndrome	AD	2q35 *PAX3*	Short segment aganglionosis megacolon	Dystopia canthorum, broad nasal root, white forelock, white skin patches, deafness. This and the Waardenburg–Shah syndrome may represent a single dominant gene with pleiotropic effects. A more severe phenotype exists in homozygotes
Familial achalasia and diffuse esophageal spasm	AR		Retrosternal discomfort, progressive dysphagia, intermittent regurgitation, diverticulosis of the esophagus	Severity varies in family members. HLA studies suggest an immunogenetic mechanism in the pathogenesis of this disorder.
Achalasia–microcephaly syndrome	AR	?	Onset of dysphagia and regurgitation due to achalasia in early childhood	Microcephaly and mental deficiency
Congenital deafness with vitiligo and achalasia	AR	?	Dysphagia and regurgitation caused by achalasia	Deafness, short stature, and vitiligo; variable expressivity; some family members with only vitiligo and achalasia
Groll–Hirschowitz syndrome	AR	?	Dysphagia, nausea, diverticula of the small bowel	Cachexia; protein and fat malabsorption, progressive sensory neuropathy, tachycardia, and abnormal GI motility secondary to vagus nerve involvement; progressive nerve deafness, with neurological deficit ascribed to a process of demyelinization
POLIP syndrome (myoneuro-gastrointestinal encephalopathy)	mt	mt	Severe GI dysmotility caused by visceral neuropathy with chronic malabsorption and malnutrition	Progressive sensorimotor peripheral neuropathy, cranial neuropathy (i.e., external ophthalmoplegia and deafness), abnormal cerebral and cerebellar white matter, endoneural fibrosis and demyelination, ragged red fibers in skeletal muscles, partial defect of cytochrome C oxidase
Familial dysautonomia (Riley–Day syndrome)	AR	9q31–33	Dysphagia, emesis, and aspiration pneumonia	Failure to thrive, dehydration secondary to GI manifestations, autonomic instability
Hereditary coproporphyria (for other porphyrias see Chapter 87)	AD	3q12 *CPO*	Nausea, vomiting, abdominal pain and distention, constipation caused by autonomic neuropathy	Pruritic skin blisters, weakness and paresthesias of the extremities caused by a peripheral neuropathy, elevated fecal coproporphyrins with normal erythrocyte uro-1-synthase and α-aminolevulinic acid dehydratase
Multiple endocrine neoplasia type 2b (MEN-2B)	AD	10q11 *RET*	Chronic constipation with megacolon or diarrhea, frequently developing before the endocrine neoplasms	Neuromas from lips to rectum; prominent lips, nodular tongue, thickened eyelids, medullary thyroid carcinoma, pheochromocytoma, marfanoid habitus
Optiz G syndrome	AD, XLR	22q11, Xp22	Esophageal dysmotility and laryngeal tracheal clefts causing swallowing difficulties; imperforate anus	Mild to moderate mental deficiency, hypertelorism, widow's peak, hypospadias, cryptorchidism, bifid scrotum, and hernias

AD, autosomal dominant; AR, autosomal recessive; GI, gastrointestinal; HLA, human leukocyte antigen; mt, mitochondrial; XLR, X-linked recessive.

DNA mutations. If a mitochondrial myopathy is involved, it is likely that the disease gene responsible in most cases resides in the nucleus.

Duchenne muscular dystrophy

Duchenne muscular dystrophy is an X-linked disorder characterized by skeletal muscle degeneration causing atrophy and weakness. The incidence in male births is about 1 in 3500. Onset of symptoms usually begins before 5 years of age, with progressive symptoms of muscle weakness, toe walking, waddling gait, pseudohypertrophy of the calves, and difficulty in rising from sitting and in climbing stairs. By puberty joint contractures and scoliosis develop and most patients require use of a wheelchair. Death usually occurs in the early 20s from respiratory infections or heart failure. Laboratory studies show elevated serum levels of aldolase, lactate dehydrogenase, and creatine kinase. Common GI symptoms include abdominal pain and distention, delayed gastric emptying, acute gastric dilation, and chronic intestinal pseudoobstruction. The large disease gene, encompassing over 2 Megabases of DNA, responsible for Duchenne muscular dystrophy maps to Xp21 and encodes a protein found in skeletal muscle called dystrophin, which helps stabilize the cytoskeleton of skeletal muscle. Dystrophin is often lacking in affected boys and partially deficient in female carriers. DNA diagnosis is readily available. The majority of mutations are large deletions that can be easily detected by polymerase chain reaction-based DNA diagnostic methods. Prenatal DNA diagnosis, in vitro fertilization with donor eggs, and preimplantation diagnosis with in vitro fertilization are viable options for families wishing to prevent the birth of an affected child. Obviously, improved treatments are desperately needed and many hope that efforts in gene therapy will lead to more human trials in the near future.

Myotonic dystrophy

Myotonic dystrophy is an autosomal dominant disorder characterized by delayed muscular relaxation, facial weakness and muscle atrophy, ptosis, cataracts, gonadal atrophy, cardiac conduction abnormalities, and male pattern baldness. Significant GI complications are caused by abnormal functioning at all levels of the GI tract, from the pharynx to the anal sphincters; this results from degenerative changes in smooth muscle and fatty infiltration, causing problems with swallowing, aspiration, and constipation. The more severe phenotype of congenital myotonic dystrophy only occurs with alleles of maternal origin. The congenital form, often inherited from a mildly affected mother, features mental retardation, hypotonia, facial diplegia, gastroparesis, subacute intestinal obstruction, megacolon, and constipation.

The disease gene maps to 19q13 and involves a CTG trinucleotide repeat in the three untranslated regions of the gene. Unaffected individuals have 5–27 copies of the repeat, whereas affected individuals have minimally 50 or more repeats with severity increasing as the repeat copy number increases to several kilobases. Expansion of the repeat can occur in subsequent generations, providing a molecular basis for the clinical phenomenon of anticipation (i.e., earlier clinical onset of disease in subsequent generations) in this disorder. DNA testing is sensitive, specific, and relatively easy to perform, thereby providing a specific way to confirm a suspected clinical diagnosis noninvasively. Other disorders presenting with myotonia caused by different genetic alterations can present with GI symptoms similar to those previously described.

Kearns–Sayre syndrome

Kearns–Sayre syndrome is a mitochondrial disorder characterized by progressive external ophthalmoplegia, pigmentary retinopathy, cardiomyopathy, and cardiac conduction defects; weakness of facial, trunk, and extremity muscles; and deafness, small stature, electroencephalographic changes, and increased cerebrospinal fluid protein. GI symptoms relate to the pharyngeal muscle weakness experienced by affected individuals, causing swallowing difficulties and dysphagia. The mitochondrial mutations characteristic of this disorder are deletions ranging in size from 2 to 7 kilobases and can be easily detected by analysis of mitochondrial DNA.

Visceral neuropathy syndromes

The visceral neuropathic forms of intestinal pseudoobstruction are characterized by abnormal pupillary reflexes, ataxia, and dysarthria; peripheral nervous system abnormalities, including absent deep tendon reflexes and impaired vibratory and position sense; and autonomic neurological abnormalities such as inappropriate blood pressure responses to phenylephrine, Valsalva maneuver, upright posture, and lack of sweating on warming. One type is also associated with basal ganglia calcification and mental retardation. Histological sections of tissues stained with a silver stain reveal degenerative changes of myenteric plexus neurons.

Hirschsprung disease (see also Chapter 56)

Hirschsprung disease is probably a multifactorial disorder that usually occurs as an isolated congenital anomaly but may be a syndromic association of several genetic conditions (see Table 108.4). With isolated Hirschsprung disease, the risk to family members increases with severity (i.e., length of GI tract involved) and the number of affected relatives, especially female relatives. Empiric risk estimates are 7.2% for the siblings of affected women and 2.6% for the siblings of affected men. Complex segregation analysis demonstrated Mendelian inheritance patterns when the length of affected bowel was considered. Cases with aganglionosis beyond the sigmoid colon had a mode of inheritance that was compatible with an autosomal dominant trait with incomplete penetrance. Cases with aganglionosis no more proximal than the sigmoid colon had inheritance patterns consistent with multifactorial inheritance or autosomal recessive inheritance

with very low penetrance. Isolated, nonsyndromic familial forms of the disease have demonstrated mutations in the *RET* protooncogene, which maps to chromosome 10q11.

Familial achalasia and diffuse esophageal spasm

Familial occurrence of achalasia, an autosomal recessive disorder, involves the esophagus, causing symptoms of progressive dysphagia, retrosternal discomfort, and intermittent regurgitation. The cause of achalasia is unknown. Diverticulosis of the esophagus may also occur. The severity of the disorder exhibits intrafamilial variability. Esophageal ganglion cells and dorsal motoneurons of the vagal nucleus are decreased, and there is Wallerian degeneration of the vagus nerve.

Familial dysautonomia

Familial dysautonomia, also called Riley–Day syndrome, is an autosomal recessive disorder, involving the autonomic nervous system that is most prevalent in the Ashkenazi Jewish population, with an incidence of about 1 in 3500 individuals. It is characterized by autonomic instability, including lack of tearing, emotional lability, paroxysmal hypertension, increased sweating, cold hands and feet, corneal anesthesia, red blotching of the skin, and drooling. GI manifestations include oropharyngeal incoordination, abnormal esophageal motility and decreased lower esophageal sphincter pressure, prolonged gastric emptying, and gastroesophageal reflux, all of which result in dysphagia, emesis, and aspiration pneumonia. Affected individuals are reluctant to eat and suffer from dehydration and failure to thrive. Fundoplication and gastrostomy has some documented benefit in these cases. Diagnosis is determined by a lack of axon flare after intradermal injection of histamine, absence of fungiform papillae on the tongue, miosis of the pupil after instillation of methacholine chloride (2.5%), absent deep tendon reflexes, and diminished tear flow. The disease gene, *IKBKAP*, maps to chromosome 9q31 and linkage disequilibrium is present within Ashkenazi Jews, with a high-risk haplotype recognized.

Mechanical obstruction and malformation syndromes

Most genetic disorders that cause mechanical obstruction are related to congenital malformations, and in general they have more importance in the pediatric population than they do for adults. However, as noted earlier in this chapter, some disorders with potential mass effects, such as large abdominal plexiform neurofibromas in NF1, may cause mechanical obstructive symptoms in rare instances. Another more common genetic cause for mechanical obstruction not caused by malformation is meconium ileus seen in 10%–15% of CF patients. The anatomic site or sites of developmental malformation in these syndromes is usually restricted to derivatives of the embryological foregut, midgut, and hindgut. In a rostral to caudal distribution, Table 108.6 reviews genetic malformation syndromes that may present with symptoms secondary to a mechanical obstruction.

Chronic abdominal pain syndromes

Many genetic syndromes can present with recurrent bouts of abdominal pain, including familial Mediterranean fever (FMF), Fabry disease, hereditary angioneurotic edema, hereditary fructose intolerance, and the hereditary pancreatitis syndromes (Table 108.7). Although these syndromes (except for FMF) are relatively rare; making the correct diagnosis in a symptomatic individual may prevent unnecessary and invasive procedures and may similarly benefit other family members. The porphyrias are also associated with significant recurrent abdominal pain as discussed in Chapter 56.

Familial Mediterranean fever

FMF is an autosomal recessive disorder with protean manifestations and an obscure cause that has a frequency of approximately 1 in 2700 in Israel, a country in which it has been studied extensively. Half of affected individuals are of Sephardic Jewish descent, about 20% are Armenian, 20% are Turkish or Arabic, and the remaining patients are Italian, Greek, or of Ashkenazi Jewish descent. FMF occurs rarely in Northern Europeans. Approximately 50% of patients do not have a positive family history.

Manifestations usually appear during childhood or adolescence and are characterized by brief episodic febrile attacks, recurring at varying intervals and associated with painful inflammation involving a variety of serosal surfaces, including the abdomen, chest, joints, and skin, lending the alternative name of recurrent familial polyserositis. Attacks last typically for 1–2 days and occur once or twice each month. The natural history of the attacks can vary considerably, even in an individual patient. Clinical features include fever, abdominal pain, and signs of peritonitis in most patients. The peritonitis is nonspecific so other acute febrile conditions must be considered, such as appendicitis, cholecystitis, pancreatitis, and intestinal obstruction. Less constant features include pleuritic pain, mild arthritis of the large joints, and a transient erysipelas-like skin lesion on the lower extremities. In 1% of patients, meningitis also occurs. Arthritis is an episodic monarthritis or oligoarthritis of the large joints, mimicking oligoarthritic forms of juvenile rheumatoid arthritis with attacks usually lasting days to weeks. They may last for months and can be associated with radiographic changes of periarticular osteopenia without erosions.

Laboratory test results are nonspecific during the attacks of pain and fever. The leukocyte count averages 16 000 cells/μL but may be as high as 40 000 cells/μL. The erythrocyte sedimentation rate increases, as do other acute-phase reactants. Albuminuria and microscopic hematuria also occur. Radiographic studies may show bowel edema and air–fluid levels in the small bowel, causing confusion with obstruction. The

Table 108.6 Mechanical obstruction and malformation syndromes

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features/comments
VATER association	Sporadic	?	Tracheoesophageal fistula with esophageal atresia and anal atresia	Vertebral defects; radial, renal, and cardiac abnormalities
Hiatal hernia and congenital short esophagus	AD	?	Gastroesophageal reflux, esophagitis	
Galloway syndrome	AR	?	Reflux with vomiting of feedings from birth	Microcephaly, large ears, nephrotic syndrome, renal microcystic dysplasia and focal glomerulosclerosis; death by age 3 years
Tracheoesophageal fistula with or without esophageal atresia	?Multifactorial	?	Aspiration, dysphagia	
Leiomyoma of vulva and esophagus	AD?	?	Dysphagia caused by an obstructing lesion (e.g., leiomyoma)	Vulvar lesions, clitoromegaly caused by leiomyoma involvement at its base
Abnormal hands, feet, short palpebral fissures, microcephaly, and esophageal or duodenal atresia	AD	?	Polyhydramnios, duodenal atresia secondary to annular pancreas, tracheoesophageal fistula	Microcephaly, upslanting, short palpebral fissures, fifth finger clinodactyly, syndactyly of fourth and fifth toes
Familial short rib syndrome, Beemer type	AR	?	Pyloric stenosis, short bowel, malrotation	Short stature, short ribs, severe respiratory failure, hydrops
Epidermolysis bullosa dystrophica, Hallopeau–Siemens type	AR	3p21 *COL7A1*	Mucosal surfaces may be involved with bullae, leading to esophageal stricture and perforation	Destructive bullae develop on hands, feet, elbows, and knees with secondary joint contractures; conjunctiva and cornea may be involved caused by excessive collagenase activity; disease gene maps to chromosome 11q
Epidermolysis bullosa lethalis with pyloric atresia	AR	17q11–q34 *ITGB4* *ITGA6*	Membranous diaphragmatic obstruction at the pylorus, diarrhea, protein-losing gastroenteropathy	Bilateral stenosis at the uterovesical junction, causing hydronephrosis; prenatal diagnosis by demonstration of dermal–epidermal separation at the lamina lucida level in fetal skin
Pyloric atresia	AR	?	Dysphagia	Congenital pyloric atresia due to reduction of the pylorus to a fibrous band or obstruction from a membranous diaphragm
Pyloric stenosis	AD, multifactorial	12q24.2 *NOS1*	Projectile vomiting at about 1 month of age	Recurrence risk of about 10% for male relatives and 2% for females; male predominance
Smith–Lemli–Optiz syndrome	AR	7q31 *SLO*	Vomiting secondary to pyloric stenosis, failure to thrive	Dysmorphic facial features, microcephaly, mental retardation, hypotonia, hypospadias, syndactyly of second and third toes, defect in cholesterol metabolism, low total cholesterol, may respond to increased cholesterol intake
Familial intrathoracic gastric volvulus	AD	?	Sharp, epigastric discomfort, occult blood loss, liquid dysphagia	? Same as hiatus hernia
Duodenal atresia	AR	?	Bilious vomiting	May be seen in Down syndrome (5.9% of cases)
Annular pancreas	Ad	?	GI obstruction with vomiting caused by duodenal stenosis	

Table 108.6 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Jejunal atresia	AR	?	Abdominal pain and distention	Agenesis of the mesentery leading to distal small bowel coming straight off cecum and twisting around the marginal artery, creating an apple-peel appearance seen at surgery; primary abnormality may be obliteration of the superior mesenteric artery
Volvulus of midgut	AD	?	Abdominal pain, distention, and constipation	Present in infancy or early childhood; atresia of the ascending colon may be present
Fryns syndrome	AR	?	Duodenal atresia, pyloric hyperplasia, malrotation and common mesentery in about 50% of patients	Diaphragmatic defects, lung hypoplasia, cleft lip and palate, cardiac defects, renal cysts, urinary tract malformation, distal limb hypoplasia, hypoplastic external genitalia, Dandy–Walker brain anomaly, agenesis of the corpus callosum
Lissencephaly syndrome	AR vs. chromosomal deletion	17p13 *PAFAH1B1*	Midgut, malrotation, gastric volvulus	Postaxial and preaxial ray defects; renal anomalies
Multiple intestinal atresia	AR	?	Multiple atretic lesions from stomach to anus	Intraluminal calcifications seen on radiographs
Cornelia de Lange syndrome	Sporadic AD	3q26 *CDL1*	Intestinal atresia in a minority of patients	Hirsutism, synophrys, broad nasal root, micrognathia, malformed ears, abnormal hands, congenital heart disease, severe mental retardation; 2%–5% recurrence risk
Anosacral anomalies	X-linked	?	Imperforate anus	Anterior sacral meningocele, anal canal duplication cyst
Imperforate anus	X-linked	?	Imperforate or ectopic anus	Rectovaginal fistula, hypospadias, hearing loss
Townes–Brocks syndrome	AD	16q12 *SALL1*	Imperforate anus	Triphalangeal thumbs and other anomalies of the hands and feet, mild, sensorineural deafness, lop ears, renal anomalies
Cat-eye syndrome	Chromosomal	22q11	Imperforate anus	Vertical pupil caused by iris coloboma, preauricular tags or fistulae, cardiac and urinary tract abnormalities, mental deficiency; extra chromosomal material, probably a derived dicentric chromosome 22
Optiz G syndrome	AD	XLR 22q11, Xp22	Imperforate anus, pharyngeal incoordination with regurgitation	Mild to moderate mental deficiency, hypertelorism, widow's peak, hypospadias, cryptorchidism, bifid scrotum, hernias
Rieger syndrome	AD	4q25–26 *RIEG*	Anal stenosis	Iris coloboma, broad nasal root, umbilical malformation, glaucoma
Ulnar mammary syndrome	AD	12q24 *TBX3*	Anal atresia and pyloric stenosis	Abnormalities of the fourth and fifth fingers, hypoplastic ulna, small penis, delayed puberty, obesity

AD, autosomal dominant; AR, autosomal recessive; GI, gastrointestinal; VATER, vertebral defects, imperforate anus, tracheoesophageal fistula with esophageal atresia, and radial and renal dysplasia; XLR, X-linked recessive.

Table 108.7 Chronic or recurrent abdominal pain syndromes

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features/comments
Familial Mediterranean fever	AR	16p13 *MEFV*	Recurrent bouts of abdominal pain	Recurrent fever, pain in chest and joints caused by a serositis; elevated leukocyte count, erythrocyte sedimentation rate, renal amyloidosis; mapped to chromosome 16p
Fabry disease	XLR	Xq22 *GLA*	Abdominal pain	A lysosomal storage disease caused by α-galactosidase deficiency; accumulation of lipoid material in the skin, corneas, vessels, kidneys, heart, and ganglion cells of the autonomic nervous system; skin lesions called angiokeratoma characteristic but nonspecific
Hereditary angioneurotic edema	AD	11q11–13 *C1NH*	Abdominal pain	Choking, laryngeal edema; c1 esterase inhibitor deficiency is underlying defect; androgens useful in prophylaxis against attacks; mapped to chromosome 11p
Hereditary fructose intolerance	AR	9q22 *ALDOB*	Abdominal pain, vomiting after fructose ingestion	Kidney and liver damage, growth retardation, coma and death on chronic exposure to fructose; caused by aldolase B deficiency; mapped to chromosome 9q
Hereditary pancreatitis	AD	7q32-ter *PRSS1* 7q31 *CFTR*	Severe abdominal pain	Fever, elevation of serum amylase, pancreatic insufficiency, diabetes, pseudocyst; hemorrhagic pleural effusions and portal or splenic vein thrombosis possible
Deficiency of pancreatic stone protein (PSP)	AD	7q35 *PRSS1* *SPINK1*	Chronic calcifying pancreatitis	PSP inhibits $CaCo_3$ crystal growth; PSP gene maps to chromosome 2p
Familial hypertrophy of the sphincter of Oddi	AD	?	Chronic pancreatitis	Rare but a surgically correctable cause of pancreatitis
Pancreatitis, sclerosing cholangitis, and sicca complex	AR	?	Pancreatitis	Dry eyes and mouth; HLA-DR3 associated with primary sclerosing cholangitis
Lipoprotein lipase deficiency	AR	8q22 *LPL*	Recurrent attacks of abdominal pain, chronic pancreatitis	Massive hyperchylomicronemia on a normal diet; hepatosplenomegaly, eruptive xanthomas, lactescent plasma; early atherosclerosis not a feature; heterozygotes show slight hyperlipernia, maps to chromosome 8p
Apolipoprotein C-II deficiency	AR	19q13 *APOC2*	Chronic pancreatitis	A necessary cofactor for lipoprotein lipase; clinically and biochemically similar to lipoprotein lipase deficiency except xanthomas and hepatosplenomegaly are less common
Glycogen storage disease type 1 (Von Gierke disease)	AR	17q21 *G6PT*	Chronic pancreatitis caused by hyperlipidemia, hepatosplenomegaly, hepatic adenomas, which may undergo malignant degeneration	Defect in glucose-6-phosphatase; hypoglycemia, lacticacidemia and ketonemia; hyperlipidemia causing xanthomas; hyperuricemia causing gout, renal insufficiency and proteinuria. Dietary therapy consists of continuous nocturnal infusions and frequent administration of raw cornstarch; survival to adulthood is reduced
Homocystinuria (cystathionine β-synthase deficiency)	AR	21q22 *CBS*	Pancreatitis with pseudocyst formation	Marfanoid habitus, ectopia lentis, osteoporosis, arterial and venous thromboembolic events, elevated urine methionine and homocystene

AD, autosomal dominant; AR, autosomal recessive; HLA, human leukocyte antigen.

diagnosis is made in patients with the appropriate ethnic background, who have typical, self-limited, and recurrent attacks of fever and abdominal pain.

The most severe feature of this disease is the progressive accumulation of a specific protein, known as amyloid fibrillar protein, in the kidney, which manifests clinically as a nephropathy. There is considerable ethnic variation in the incidence of amyloidosis in FMF. Amyloidosis occurs least frequently in Armenians with the disorder, even though FMF occurs most commonly in Armenians (1 in 400). Amyloidosis occurs commonly in non-Ashkenazi Jews (1 in 2400) and is most common in Moroccan Jews in Israel (up to 30%). In some patients, the amyloidosis develops before any other clinical sign. The genetic or environmental factors that account for these differences in the incidence of amyloidosis are not clear. The amyloidosis appears to be a phenomenon secondary to the periodic inflammation, because its occurrence is reduced by colchicine therapy.

Colchicine (0.6 mg), administered orally, two to three times per day, is an effective treatment in the prevention of the acute febrile attacks of the disease. A low-fat diet (20 g/day) may also prevent the attacks. Colchicine does not allay symptoms if taken during attacks. Some patients use it intermittently to forestall attacks when they recognize that one is imminent.

FMF seems to involve a genetically determined defect in the regulation of inflammatory responses. Research into the cause of FMF has included studies of suppressor T cells, leukocyte chemotaxis, lysosome release from neutrophils, and immunoglobulins, all without a definitive identification of the pathophysiological defect. The FMF susceptibility gene, *MEFV* or the pyrin gene, maps to chromosome 16p13, and both diagnostic and predictive testing of at-risk family members is possible. Although clinical heterogeneity exists, as reflected by the different prevalence rates of renal amyloid in different ethnic groups, there is no evidence for locus heterogeneity, because the FMF gene is linked to the same locus in the non-Ashkenazi Jewish and Armenian populations.

Fabry disease/diffuse angiokeratoma

Fabry disease, also called diffuse angiokeratoma, is an X-linked recessive lysosomal storage disorder caused by a deficiency of α-galactosidase. Deposition of lipoid material in several tissues is responsible for the characteristic findings. These include: attacks of pain in the abdomen and extremities (probably caused by lipid changes in ganglion cells of the autonomic nervous system), vascular lesions in the fundi of the eye and the kidney, corneal opacities, a hypertrophic cardiomyopathy, and characteristic skin lesions of a vascular nature called angiokeratoma. Symptoms may present in adulthood, and death usually occurs after renal failure in midadulthood. Female heterozygotes may have renal insufficiency and proteinuria, and rarely have skin lesions.

α-Galactosidase activity is deficient in the leukocytes of male patients, and carrier females can be identified because of decreased activity. Several mutations in the α-galactosidase gene, *GLA*, at Xq22 in patients with Fabry disease have provided the definitive evidence to indicate that this is the gene for Fabry disease. Enzyme replacement therapy is available to treat affected individuals.

Hereditary angioneurotic edema

Hereditary angioneurotic edema is an autosomal dominant disorder that affects the respiratory and GI tracts. Symptoms of choking occur because of airway edema that can be precipitated by acts of trauma, such as tracheal intubation. GI symptoms include abdominal pain, nausea, vomiting, and diarrhea. Barium studies during an acute attack show bowel wall edema. Associated findings include an increased incidence of autoimmune disorders.

Deficiency of C1 esterase inhibitor is the underlying pathophysiological defect in these patients. This protein regulates the first component of complement (C1) by inhibition of the proteolytic activity of its subcomponents C1r and C1s, preventing activation of C4 and C2 by C1s and inhibiting other serine proteases, including plasmin, kallikrein, and the coagulation factors XIa and XIIa. Low levels of C4 and normal levels of C1 are characteristic of hereditary angioneurotic edema. These low levels of C4 are responsible for the increased incidence of systemic lupus erythematosus, glomerulonephritis, and vasculitis among these patients. Heterozygotes have about 10%–20% of the normal levels of C1 inhibitor rather than the expected 50%, possibly because of complex formation of the activated C1 inhibitor and activated C1 or because of increased catabolism of the protein. Androgens are effective in stimulating increased synthesis of C1 inhibitor from the normal allele and are useful for prophylaxis against attacks. Concentrates of C1 inhibitor are useful in acute attacks.

The C1 inhibitor gene, *C1NH*, maps to chromosome 11q11–q13. Two clinically indistinguishable types of hereditary angioneurotic edema are described. Patients with type 1 have a deletion of the C1 inhibitor gene or a truncated transcript, and patients with type 2 have a single base substitution.

Hereditary fructose intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder caused by a deficiency of aldolase B (i.e., fructose-1-phosphate aldolase). This enzyme is expressed in tissues that metabolize fructose: the liver, kidney, and small intestine. It catalyzes the reversible cleavage of fructose-1-phosphate into dihydroxyacetone phosphate and glyceraldehyde. After fructose, sorbitol, or sucrose ingestion, patients with HFI present with severe abdominal pain, vomiting, and hypoglycemia. Liver and kidney damage, growth retardation, coma, and even death may result from chronic ingestion of fructose. Most patients with HFI learn to avoid foods containing fructose. Problems arise when they are unable to

avoid them, as during infancy, or if given intravenous fructose- or sorbitol-containing infusions for dehydration resulting from diarrhea and vomiting associated with illness, a practice carried out in some European countries. Intravenous fructose loading tests and measurement of aldolase B activity in liver biopsy specimens are methods used for the diagnosis of HFI.

The aldolase B gene, *ALDOB*, maps to chromosome 9q22. It consists of nine exons that code for 363 amino acids. At least 10 mutations have been described; three missense mutations of *A149P*, *A147D*, and *N334K* account for 87% of alleles in the European HFI population and 68% in the North American population. The *A149P* mutation is the most common and widespread, accounting for 58% of HFI alleles in Europe and 55% in North America. Linkage studies suggest that the *A149P* allele arose once during evolution and spread through the mechanism of genetic drift, rather than occurring several times in different populations. Testing for the common mutations with amplified DNA specimens against a panel of allele-specific oligonucleotides would be an appropriate initial diagnostic approach that could identify most patients in a noninvasive manner.

Hereditary pancreatitis syndromes (see also Chapter 72)

Hereditary pancreatitis is an autosomal dominant disorder that is similar clinically to nonfamilial chronic pancreatitis. Steatorrhea and recurrent attacks of severe abdominal pain, fever, and marked elevation of serum amylase levels are characteristic. The elevated amylase level differentiates the disorder from FMF. The mean age at onset is 13 years. Between 5% and 10% of affected persons have pancreatic insufficiency, diabetes, and pseudocysts. As in nonsyndromic pancreatitis, emotional stress, alcohol, or a diet that is rich in fat can precipitate an attack.

The disorder exhibits 80% penetrance. The gene for hereditary pancreatitis is the cationic trypsinogen gene, *PRSS1*, which maps to chromosome 7q32-qter. One predominant mutation in codon 117 results in an arginine to a histidine substitution that can easily be detected by restriction digestion. Codon 117 is a trypsin-sensitive site and when the arginine 117 cleavage site is replaced by histidine, trypsin continues to activate trypsinogen and other zymogens, ultimately leading to pancreatitis secondary to autodigestion of the pancreas. Mutations in the cystic fibrosis gene, *CFTR*, have also been associated with chronic pancreatitis when present in heterozygotes in association with the variable number of thymidines in intron 8, specifically the *5T* allele.

Other genetic syndromes involving obstruction of the pancreatic duct, such as secretory pancreatic stone protein deficiency, familial hypertrophy of the sphincter of Oddi, or sclerosing cholangitis, pancreatitis, and sicca complex, can present as cases of familial or recurrent pancreatitis. Recurrent pancreatitis caused by a submucosal ampullary tumor has also been described in a patient with neurofibromatosis. Cases of hereditary or recurrent pancreatitis may be caused by genetic disorders of triglyceride metabolism, leading to hypertriglyceridemia, such as lipoprotein lipase deficiency, apolipoprotein C-II deficiency, and familial hypertriglyceridemia.

Gastrointestinal neoplasm syndromes (see also Chapters 36, 54, 64, 65)

Exciting and important applications of genetics to oncology and gastroenterology have led to the elucidation of genetic contributions to many GI malignancies. Details about GI and hepatic malignancies are further described in Chapters 36, 54, 64, 65, 93. Genetic disorders have been associated with malignancies in the esophagus, stomach, small and large bowel, pancreas and rectum as summarized in Table 108.8 and the general features that suggest an inherited predisposition to cancer are presented in Table 108.9. Although most cancers are sporadic, approximately 10% are caused by the inheritance of an autosomal dominant germ-line mutation in a tumor suppressor or DNA recognition and repair gene leading to a significantly increased risk of developing cancer at a relatively early age. The clinical features of GI malignancies are covered in many other chapters of this volume and will not be discussed further here. An outline of genetic syndromes that are associated with increased risks for GI tract neoplasms is given in Table 108.10. Predictive genetic testing and early preventive management may be useful for several of these conditions (Table 108.11). Increasingly, prognostic genetic tests will be used in oncology to help direct clinical management of patients.

Syndromes associated with benign hepatic masses or cysts

Many genetic conditions are associated with benign hepatic masses or cysts. While the hepatic manifestations often do not result in significant clinical symptoms, recognition of the hepatic manifestations may be helpful in making the diagnosis of the genetic syndrome. Of the many multisystemic genetic syndromes that may be associated with benign hepatic lesions, the autosomal dominant disorders polycystic kidney disease, tuberous sclerosis complex, and von Hippel–Lindau syndrome are three conditions where clinical recognition is of paramount importance to ensure that affected patients receive appropriate medical management. von Hippel–Lindau syndrome is presented in Table 108.10.

Polycystic kidney disease

There are both autosomal dominant and autosomal recessive polycystic kidney diseases. In general, autosomal recessive polycystic kidney diseases present very early in life, whereas the autosomal dominant forms generally present later with progression to end-stage renal disease around the fifth decade of life. While the main manifestations of polycystic kidney disease involve multiple cysts in the kidneys bilaterally with

Table 108.8 Specific cancer sites in the gastrointestinal tract of the hereditary cancer predisposition syndromes[a]

Site of cancer	Genetic condition/syndromes[b]	Gene(s) or locus (loci)[c]
Colon	Familial adenomatous polyposis (FAP)	*APC*
	Hereditary breast/ovarian cancer	*BRCA1, BRCA2*
	Hereditary nonpolyposis colon cancer (HNPCC)	*MSH2, MLH1, PMS1, PMS2, MSH6*
	Juvenile intestinal polyposis syndrome	*SMAD4, PTEN*
	Peutz–Jeghers syndrome	*STK11*
Esophageal	Familial Barrett esophageal cancer	?
	Familial keratosis/tylosis with esophageal cancer	*TOC*
Pancreas	Familial pancreatic cancer	*SMAD4*
	Hereditary breast/ovarian cancer 2	*BRCA2*
	Hereditary melanoma	*CDKN2, CDK4*
	HNPCC	*MSH2, MLH1, PMS1, PMS2, MSH6*
	Li–Fraumeni syndrome	*TP53*
Small bowel	FAP	*APC*
Stomach	Familial gastric cancer	*CDH1*
	HNPCC	*MSH2, MLH1, PMS1, PMS2, MSH6*
	Li–Fraumeni syndrome	*TP53, CHK2*

a Syndromes are listed alphabetically, not in order of frequency of cancer at that site.
b Other cancer predisposition syndromes may be associated less frequently with cancer at any of the sites.
c While the main genes implicated to date for each cancer predisposition syndrome are listed, additional genes will likely be discovered that may contribute to the syndrome.

Table 108.9 Findings suggestive of an inherited cancer predisposition syndrome

A clear inheritance pattern is suggested in the family history
One particular type of cancer, or a limited number of different cancers, segregates in the family
Cancer diagnoses occur at earlier ages when compared with the onset in the general population
Family member has an identified genetic mutation associated with a cancer predisposition syndrome
There is an unusual constellation of tumor(s)
Multiple primaries in a single individual
Bilateral cancers in paired organs of an individual
Occurrence of relatively rare cancers not commonly seen in the general population clustering within a family
Multiple recognized precursor lesions are present in the individual or family members
Cancers are associated with other nonmalignant physical features or medical problems
Constellation of cancers or other features that are part of a known cancer predisposition syndrome

renal failure, hepatic cysts and colon diverticula may also develop. In addition, patients with the autosomal dominant form of adult polycystic kidney disease may have vascular complications including a high risk of intercranial aneurysms and an increased prevalence of cardiac valve disease. In general, the hepatic cysts are asymptomatic but the kidney cysts progress to end-stage renal disease in later adulthood.

There is locus heterogeneity for autosomal dominant polycystic kidney disease with mutations in the *PKD1* gene at chromosome 16p13 and *PKD2* gene at chromosome 4q21–q23. In addition, there have been some families reported that do not map to either the chromosome 16 or chromosome 4 locus, suggesting that there is at least one additional gene that predisposes to autosomal dominant polycystic kidney disease. In general, management of the disease consists of management of the renal complications with dialysis and kidney transplants.

Tuberous sclerosis complex

Tuberous sclerosis complex is a multisystemic autosomal dominant disease with significant variable expression among affected individuals, even those within the same family. Several cutaneous features, including facial angiofibromas, hypopigmented macules, Shagreen patches, subcutaneous

Table 108.10 Intestinal neoplasm syndromes

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Keratosis palmaris et plantaris with esophageal cancer	AD	17q24–25	Esophageal cancer	Palms and soles are diffusely hyperkeratotic; onset in first year of life; low serum vitamin A level in some cases; distinct from keratosis palmaris et plantaris familiaris because of the esophageal cancer association
Dyskeratosis congenita	XLR	Xq28 *DKC*	Leukoplakia of the oral mucosa and sometimes of anal mucosa	Cutaneous pigmentation, continuous lacrimation caused by atresia of the lacrimal ducts, nail dystrophy, testicular atrophy, thrombocytopenia and anemia, opportunistic infections
Neurofibromatosis type I (NF1)	AD	17q12 *NF1*	Malignant degeneration of intestinal neurofibromas, duodenal carcinoid containing somatostatin	Multiple café au lait macules, neurofibromas, axillary and inguinal freckling, multiple Lisch nodules, optic gliomas, bony dysplasia of the sphenoid and long bones; associated neoplasms include pheochromocytoma, meningiomas and malignant degeneration of neurofibromas
Neurofibromatosis type III (NF3)	AD	?17q12 ?*NF1*	Malignant degeneration of intestinal neurofibromas	None of the other features seen in NF1
Carney triad	?AD		Gastric leiomyosarcomas	Pulmonary chondromas and paraganglionomas; all cases are sporadic
Basal cell nevus syndrome (Gorlin–Goltz syndrome)	AD	9q22 *PTCH*	Hamartomas of the stomach	Many basal cell nevi usually appear at puberty, rarely at birth. Basal cell nevi may develop at sites of therapeutic amounts of ionizing radiation. Associated neoplasms include medulloblastoma, astrocytoma, and ovarian fibroma. Other features include mild prognathism, lateral displacement of the inner canthi, frontal and biparietal bossing, odontogenic keratocysts of the jaw, kyphoscoliosis, abnormal cervical spine, calcified falx cerebri, short fourth metacarpal, and palmar and plantar pits
Cowden syndrome (multiple hamartoma syndrome)	AD	10q23 *PTEN*	Hamartomatous polyps of the intestines	Multiple hamartomas of the skin, mucous membranes, breast, and thyroid; verrucous skin lesions of the face and limbs; papules of the gingiva and buccal mucosa, multiple facial trichilemmomas, macrocephaly; females have high frequency of breast cancer
Cronkhite–Canada syndrome	unknown	?	Intestinal polyposis	Diffuse skin hyperpigmentation, alopecia, fingernail changes; all cases sporadic with no proof of genetic basis; possible phenocopy for the genetic polyposis syndromes; unclear if genetic
Multiple lipomatosis	AD	12q15 ?others	Gastrointestinal lipomas	Multiple subcutaneous lipomas, cytogenetic abnormalities within the lipomas are common. If chromosome 12q is involved, there is a tendency for malignant degeneration.

Table 108.10 (*cont'd*)

Condition	Inheritance pattern	Chromosome location/gene locus	Gastrointestinal manifestations	Other features and comments
Multiple endocrine neoplasia type I (MEN1)	AD	11q13 *MEN1*	Severe peptic ulcer disease caused by Zollinger–Ellison syndrome secondary to gastrinoma; duodenal carcinoid in some cases	Triad of pancreatic (i.e., insulinomas, gastrinomas), parathyroid, and pituitary adenomas; intrafamilial uniformity of tumor types usual; MEN2 lacks pancreatic adenomas and has pheochromocytomas; MEN1 disease gene localized to chromosome 11q
Multiple endocrine neoplasia type IIb (MEN2B)	AD	10q11 *RET*	Multiple true neuromas throughout the GI tract; megacolon and colonic diverticulosis common; duodenal carcinoid in some cases	Hypertrophy of lips and thickened eyelids from neuroma, pheochromocytoma, medullary thyroid cancer; prophylactic thyroidectomy indicated; no parathyroid disease; disease gene is localized to chromosome 10
Intestinal carcinoid	AD	see *MEN*	Familial incidences of appendiceal and ileal carcinoid reported	Duodenal carcinoid seen in MEN1, MEN3, and NF1
Pancreatic carcinoma	AD	9p21 p16	Pancreatic acinar carcinoma	No history of pancreatitis or tumors at other sites
von Hippel–Lindau disease	AD	3p25–26 *VHL*	Pancreatic cysts and pancreatic carcinoma	Cardinal features are angiomas of the retina and hemangioblastoma of the cerebellum. Other features include hypertension caused by pheochromocytoma; hypernephroma-like renal tumors; polycythemia due to renal tumor or cerebellar hemangioblastoma; hemangiomas of the spinal cord, lungs, and adrenals; cysts of the pancreas, liver, and kidneys; and epididymal cystadenomas. The gene has been mapped to chromosome 3p, and direct mutational analysis is available in about 15% of cases.
Ataxia-telangiectasia (AT)	AR	11q22 *ATM*	Pancreatic carcinoma	Progressive cerebellar ataxia; telangiectases, especially of the conjunctiva; susceptibility to sinopulmonary infection, oculomotor apraxia; strong predisposition to malignancy, especially leukemias. Heterozygotes for AT are also at an increased risk for malignancy. Female heterozygotes exposed to certain types of ionizing radiation are at increased risk for breast cancer. The disease gene maps to chromosome 11q.
Muir–Torre syndrome	AD	2p22 *MSH2* (3p-MLH1)	Multiple, primary, carcinomas of the colon, duodenum, and larynx	Keratoacanthomas of the face, multiple sebaceous tumors

AD, autosomal dominant; AR, autosomal recessive; GI, gastrointestinal; XLR, X-linked recessive.

Table 108.11 Examples of the use of DNA testing and ancillary studies in the evaluation of cancer predisposition syndromes

DNA testing is standard of care in the evaluation
Example: von Hippel–Lindau (VHL) syndrome:
DNA-based testing of *VHL* gene
Very specific, sensitive with a high positive predictive value
Has become standard of care to determine if an asymptomatic individual inherited the condition
Childhood testing appropriate and important
Other studies useful in the baseline evaluation of a patient with a VHL mutation:
Imaging studies:
Abdominal ultrasound or CT examination of kidneys, adrenals, liver (teenagers, adults)
MRI of the brain and spine (teenagers, adults)
Laboratory studies:
Urinalysis (children, teenagers, adults)
BUN and creatinine (children, teenagers, adults)
Urinary catecholamine metabolites or plasma metanephrine (children, teenagers, adults)
Focused examinations in addition to general physical examination:
Testicular examination (teenagers, adults)
Ophthalmological examination (children, teenagers, adults)
Detailed neurological examination (children, teenagers, adults)
Audiology

DNA testing is widely used, readily available, and helpful in the evaluation
Example: Familial adenomatous polyposis:
DNA-based testing of *APC* gene
> 90% sensitive; false-negative test results possible, identification of a mutation in an affected family member improves predicative value of test in asymptomatic individuals
May be appropriate to do DNA testing before any other baseline evaluations of patient
Testing in children is appropriate
Other studies useful in baseline evaluation of individuals with mutation or at-risk asymptomatic individuals where mutation status is not known or cannot be determined with certainty:
Imaging studies:
Colonoscopy
Laboratory studies:
Complete blood count
Occult fecal blood test
Focused examinations in addition to general physical examination:
Detained cutaneous examination
Ophthalmological examination
Comprehensive neurological examination

DNA testing is of limited clinical value
Example: Tuberous sclerosis (TS):
DNA-based testing of *TSC1* or *TSC2* genes
Locus heterogeneity decreases test sensitivity and predictive value
Not widely employed in the diagnostic evaluation of patients given clinical diagnosis often easily recognizable
Childhood testing may be appropriate if specific mutation is detected in an affected parent
Other studies are usually needed to determine if individuals have TS and assess baseline systemic involvement in affected individuals:
Imaging studies:
Head CT or MRI (any age)
Renal ultrasound (any age)
Chest radiograph (any age)
Echocardiogram (any age)
Laboratory studies:
Urinalysis (children, teenagers, adult)
BUN and creatinine
Focused examinations in addition to general physical examination:
Wood lamp examination of the skin (all age)
Ophthalmological examination (children, teenagers, adults)
Detailed neurological examination (all ages)

BUN, blood urea nitrogen; CT, computed tomography; MRI, magnetic resonance imaging.

nodules, café au lait spots, and subungual fibromas, suggest the diagnosis. Retinal patches and astrocytomas can be identified on ophthalmology examinations. Dental examinations reveal pitted dental enamel and gingival fibromas. More serious complications include cardiac rhabdomyoma, which may present early in childhood or infancy and neurological problems as the result of subependymal nodules, cortical tubers, and intracranial calcification that can be detected with head imaging studies and may lead to infantile spasms, seizures, and mental retardation in a significant number of patients. Cysts and angiomyolipomas are often seen in the kidneys and may also be identified in the livers of patients. The lesions in the liver are usually asymptomatic. In addition, lymphangiomyomatosis can also be identified in the lung and it is important to identify them in women of childbearing age. Patients are at increased risk for renal carcinoma.

There is locus heterogeneity for this autosomal dominant condition with mutations in the *TSC1* gene on chromosome 9q34 and mutations in the *TSC2* gene at chromosome 16p13 accounting for the vast majority of cases. Although this condition is autosomal dominant, many patients are thought to possess new mutations and, therefore, there may be no family history of this disease. The *TSC* genes encode proteins that function as tumor suppressors.

Disorders of bile pigment metabolism

Several genetic disorders of bile pigment metabolism have been described. Although they vary in severity and clinical symptoms, most present with some degree of jaundice. The most commonly observed disorders are presented in Table 108.12.

Examples of inborn errors of metabolism with hepatic manifestations (see also Chapter 87)

Most of the inborn errors of metabolism are autosomal recessive or X-linked recessive disorders that present with multisystemic complications. Many are associated with a variety of hepatic findings including storage of precursor metabolic products, cirrhosis, or hepatomegaly. Classic metabolic diseases involving the GI tract and the liver are discussed in Chapter 109. Many so-called metabolic disorders have been presented earlier in this chapter (i.e., hereditary fructose intolerance, Fabry disease, hemochromatosis). A few additional diseases will be discussed subsequently to further illustrate the scope of different hepatic and GI manifestations that may be associated with inborn errors of metabolism. Although many inborn errors of metabolism present early in infancy or childhood, some do not present until later years.

Wilson disease

Wilson disease is an autosomal dominant disorder caused by mutations in the ATPase copper ion transporting β-polypeptide gene (*ATP7b*) which is associated with high nonceruloplasmin-bound serum copper levels. High urinary copper levels are also seen, as well as a low serum ceruloplasmin. Patients present with a variety of neurological and abdominal complaints. Often the onset of symptoms is in late childhood, adolescence, or early adulthood. Neurological symptoms include dementia, poor motor coordination, personality changes, dystonia, dysarthria, tremors, dysphagia, and decreased concentration. The main abdominal findings that can occur involve the liver and may include atypical hepatitis, cirrhosis, hepatomegaly, hepatic coma, and high liver copper levels. Esophageal varices can also arise. Renal tubular dysfunction and kidney stones may be seen. Loss of protein, amino acids, glucose, uric acid, phosphates, and calcium is often identified in the urine. Hypoparathyroidism and hemolytic anemia may also be observed. One characteristic ophthalmological finding is Kayser–Fleischer rings.

The diagnosis is based on analyzing serum copper levels and ceruloplasmin. *ATP7b* gene mutations lead to a dramatic build up of intracellular hepatic copper with subsequent and significant hepatic and neurological abnormalities. The gene maps to 13q14-q21. Treatment involves reducing serum copper levels. Agents including penicillamine and zinc have been successful in decreasing plasma copper levels.

Medium-chain acyl-coenzyme A dehydrogenase deficiency

Medium-chain acyl-coenzyme A dehydrogenase (MCAD) is a relatively common autosomal recessive inborn error of fatty acid metabolism frequently seen in populations with the homozygote frequency estimated to be 1 in 6500 to 1 in 20 000, depending on ethnic background. White subjects of Northern European decent exhibit the highest frequency of MCAD-deficient genotypes. Patients deficient for MCAD are at high risk of hypoglycemia, vomiting, lethargy, encephalopathy, cardiorespiratory arrest, hepatomegaly, seizures, apnea, and sudden death in infancy. In fact, patients with this condition often die undiagnosed with sudden infant death syndrome. Long-term outcomes may include developmental and behavior abnormalities, muscle weakness, cerebral palsy, and attention deficit disorder. Most often, infants are born healthy but present with symptoms after a fast or illness. It is in these times of metabolic stress caused by fasting or infection when the demands for fatty acid oxidation are high and patients may present with progressive symptoms. The MCAD gene is located on chromosome 1p31 and encodes an enzyme that is responsible for the metabolism of medium-chained fatty acids. Newborn screening for this condition is offered in several states, as recognition of the condition at the time of birth may allow for prevention of symptoms and sudden infant death syndrome by treating infections promptly and avoiding fasting conditions. Supplemental treatment, including carnitine therapy, may also be beneficial.

Table 108.12 Genetic disorders of bile pigment metabolism

Condition	Inheritance pattern	Chromosome location/gene locus	Hepatic and gastrointestinal manifestations	Other features and comments
Defects in bilirubin metabolism or processing				
Crigler–Najjar syndrome type I	AR	2q37 *UGT1A1*	Unconjugated hyperbilirubinemia with normal liver histology and routine liver function tests; no bilirubin uridine diphosphoglucuronate glucuronsyltransferase activity	Jaundice with kernicterus, rare in population, phenobarbital does not reduce serum bilirubin levels, liver transplant has been curative in affected patients
Crigler–Najjar syndrome type II	AR	2q37 *UGT1A1*	Unconjugated hyperbilirubinemia with milder elevations than in Crigler–Najjar type II with normal liver histology and routine liver function tests; up to 10% of normal bilirubin uridine diphosphoglucuronate glucuronsyltransferase activity	Usually benign jaundice without kernicterus
Gilbert syndrome	AR	Variant promoter of *UGT1A1*	Benign mild unconjugated hyperbilirubinemia with normal liver histology and routine liver function tests; up to 40% of normal bilirubin uridine diphosphoglucuronate glucuronyltransferase activity	Common (3%–7% of population) inherited form of mild chronic fluctuating unconjugated hyperbilirubinemia
Dubin–Johnson syndrome	AR	10q23–24 *MRP2* (*ABCC2*)	Predominantly conjugated hyperbilirubinemia with black liver grossly and dark pigments in centrilobular areas on histology; routine liver function studies normal except bilirubin	Chronic benign nonhemolytic mild jaundice
Rotor syndrome	AR	22q13 SGLT1 or SLC5A1	Predominantly conjugated hyperbilirubinemia with normal liver and routine liver function studies normal except bilirubin	Increased urinary coproporphyrin
Progressive familial intrahepatic cholestasis: type I, Byler disease, type II, and type III	AR	Type I: 18q21 *FIC1* Type II: 2q24 *SPGP* (*ABCB II*) Type III: *MDR3* (*ABCB4*)	Type I associated with life-threatening cholestasis first described in Amish-Mennonite community; type II has a similar phenotype but seen more commonly in European and Middle East populations; type III causes severe cholestasis due to progressive destruction of small bile ducts	All may present with very severe disease and limited treatment options are available
Alagille syndrome	AD	20p12 *JAGGED*	Congenital developmental anomaly of the hepatobiliary system characterized by paucity of bile ducts and resulting in infantile cholestasis in some cases	Other features include characteristic mild facial dysmorphisms, butterfly vertebrae, posterior embryotoxon of eye, and cardiac anomalies

AD, autosomal dominant; AR, autosomal recessive; ABC, ATP-binding cassette transporter. For a regularly updated website of human ABC transporters with links, see http://www.med.rug.ml/mdl/humanabc.htm

Tyrosinemia

Tyrosinemia type 1 is an autosomal recessive condition caused by mutations in the fumarylacetoacetate hydrolase (*FAH*) gene, which maps to chromosome 15q23–q25 and is required for the metabolism of tyrosine. Build up of tyrosine in the body can create multiple problems including failure to thrive, hypertrophic cardiomyopathy, renal Fanconi syndrome, renal failure, kidney stones, rickets, muscle weakness, episodic paralysis and peripheral neuropathy, abnormal blood coagulation studies, and a variety of abdominal problems. Hepatic problems that may occur include hepatomegaly, liver failure, cirrhosis, and associated ascites. Pancreatic islet-cell hypertrophy may also occur, as may splenomegaly. Gastrointestinal bleeding and paralytic ileus may also occur. Analysis of plasma amino acids is diagnostic. In addition, elevated α-fetoprotein, hypoglycemia, and hypophosphatemia can also be detected.

Symptoms are highly variable and patients may have a progressive course that rapidly leads to hepatic failure whereas others may have acute and chronic hepatic crises. Hepatocellular carcinomas occur at high frequency in affected patients. The highest incidence of this condition is in the Saguenay-Lac St Jean region of Quebec, Canada, and Northern Europe. Patients with this condition are often described as having an unusual "cabbage-like" odor.

α_1-Antitrypsin deficiency

α_1-Antitrypsin is an autosomal recessive condition with multiple allelic forms. Homozygotes for the *PiZ* form and some other much rarer variants are at a high risk of developing emphysema, particularly if they smoke, in early adulthood. These patients account for approximately 1% of all patients with emphysema. About 10% of the ZZ homozygotes develop liver failure that often leads to fatal childhood cirrhosis. This is the result of an abnormal polymerization of the Z antitrypsin where the abnormal molecule has been poorly secreted in forms insoluble intracellular inclusions that are presumably toxic. In general, the infantile liver abnormalities occur when there is a less than 20% deficiency of the enzyme. Laboratory findings include a low serum α_1-antitrypsin (Pi) deficiency and abnormal liver function tests. Mutations in the protease inhibitor 1 gene on chromosome 14q32 are responsible for the phenotype. Again, multiple different mutations have been identified and different alleles are associated with different degrees of severity of disease. In the most severe form with hepatic failure in infancy, liver transplant has been used to treat this condition.

Common gastrointestinal and hepatic disorders with complex genetic causes

In addition to the many monogenic, mendelian genetic disorders with GI and hepatic manifestations previously reviewed in this chapter, there are several common disorders whose genetic susceptibilities are inherited in a more complex or multifactorial mode. These disorders include conditions such as pernicious anemia, celiac disease (Chapter 50), inflammatory bowel disease (Chapter 57), cirrhosis, gallstone disease, peptic ulcer (Chapter 40), and sporadic colon cancer (Chapter 65). Common diseases often show familial aggregation caused by genetic factors or the combination of genetic and environmental factors. They also exhibit associations with certain genetic markers, often with specific HLA genotypes. Studies of family aggregation, twin data, subclinical markers, and genetic markers have been essential in demonstrating the importance of genetic determinants in the development of these common diseases. Many of the common complex gastrointestinal conditions are seen more frequently in specific genetic syndromes. For example, inflammatory bowel disease has been reported in individuals with Turner syndrome, Hermansky-Pudlak syndrome, glycogen storage disease type Ib, various immunodeficiency disorders, secretory immunoglobulin deficiency, gammaglobulinemia and hypogammaglobulinemia, selective immunoglobulin A deficiency, Chédiak–Higashi syndrome, deficiency of C2, hereditary angioedema, and chronic granulomatous disease. Further elucidation of genetic contributions to common nonmendelian GI and hepatic conditions will undoubtedly improve our understanding of their pathophysiology and may ultimately lead to susceptibility testing and preventive management for some of these conditions, at least in some populations in the near future. All of these common complex GI and hepatic conditions are discussed in great detail in other chapters of this text (see Index) and will not be further discussed here.

References

The following online genetic databases and comprehensive genetic textbooks were used as the sources for all information contained in this overview chapter that summarizes salient features. Specific detailed references for each disease are found in these sources with the *OMIM* and *GeneTests/GeneReviews* databases being most comprehensive and up to date. Information from *OMIM* and *GeneTests/GeneReviews* and its links was used to gather information and generate tables.

Systemic diseases are commonly manifest by gastrointestinal signs or symptoms. The liver or gut may be the principal targets of the disease process or simply indirectly affected; in either case, the gastrointestinal manifestations may be the cause for seeking medical attention. The purpose of this chapter is to examine the systemic disorders that have well-recognized gastrointestinal manifestations and to stress their more important effects on the digestive system.

Cardiovascular diseases

Aortic stenosis

Aortic stenosis predominantly affects men in middle to late life [1], and has been associated with an increased incidence of gastrointestinal bleeding [2], often attributed to angiodysplasias of the gut (Heyde syndrome) [3,4]. Although case series suggest that 15%–41% of patients with bleeding angiodysplasias also have hemodynamically significant aortic stenosis, no such relationship is found when aortic stenosis is sought in patients with nonbleeding colonic angiodysplasias [5]. Thus, the validity of the association between the two conditions has been questioned [6], and probably lies more with the now recognized (below) changes in blood coagulation associated with the abnormal valve that makes the angiodysplasias commonly in the elderly bleed.

Lesions identified by angiography or endoscopy (fiberoptic or capsule) can be incriminated as the bleeding source if active hemorrhage is observed. Endoscopic cautery, angiographic embolization, and intestinal resection remain standard therapy for active bleeding [7]. Aortic valve replacement has resulted in the cessation of bleeding in some cases [8], but the angiodysplasias persist [9]. A probable mechanism is that the majority of patients with severe aortic stenosis have an acquired type 2A von Willebrand syndrome characterized by a deficiency of the largest multimers of von Willebrand factor and impaired shear-induced platelet aggregation, and this is improved by porcine valve replacement [10,11]. There are no evidence-based medical alternatives to surgery.

Congestive heart failure

Impairment of the heart's ability to fill or empty the left ventricle results in inadequate perfusion of tissues and a consequent inability to maintain tissue metabolic demands. Ischemia and hypertension are the most common causes, but valvular heart disease, cardiomyopathies, anemia, and hypermetabolic states (e.g., thyrotoxicosis and sepsis) may be seen [12]. Heart failure leads to congestion of the splanchnic venous bed, causing anorexia, nausea, bloating, and abdominal pain. Mesenteric ischemia of the bowel due to low flow states is not uncommon in such patients [13]. Rarely, venous congestion is sufficiently severe to produce weight loss, diarrhea, malabsorption, protein-losing enteropathy [14,15], and the clinical picture of cardiac cachexia. Hepatic congestion secondary to right heart failure (Fig. 109.1) may mimic biliary tract disease or hepatitis because of jaundice, right upper quadrant pain, hepatomegaly, abnormal liver enzyme levels,

low protein ascites, and prolongation of the prothrombin time [16]. Prolonged congestion rarely progresses to cardiac cirrhosis [17].

The increasingly effective, but complex, medical therapy of left ventricular failure [18] can produce gastrointestinal side effects (Table 109.1). Mainstays are the angiotensin-converting enzyme (ACE) inhibitors, which are generally well tolerated, but may cause mild diarrhea. Rarely, ACE inhibitors have been associated with bowel obstruction due to angioedema of the intestine, caused by increased bradykinin levels [19]. Angiotensin II receptor blockers can also cause angioedema. Digoxin is less commonly used and causes anorexia, nausea, and vomiting in many patients [20]. Digoxin-associated constriction of splanchnic vessels may contribute to intestinal ischemia [13]. Severe pancreatitis has been attributed to a variety of diuretics, including thiazides, furosemide, and ethacrynic acid [21]. Oral potassium supplements have been implicated in esophagitis, ulcers, and, rarely, intestinal strictures [22].

Coronary artery disease

Although the incidence of coronary artery disease (CAD) has decreased markedly since 1990, it remains the most prevalent cause of death in the United States. It is not uncommon for the initial presenting symptoms of angina or infarction to mimic gastrointestinal disease (epigastric pain or pressure, heartburn), which at times is confusing to both patient and physician. Once the diagnosis of CAD is certain, its treatments may lead to gastrointestinal problems.

Smooth muscle relaxants (calcium channel antagonists, nitrates) improve coronary blood flow but also relax the lower esophageal sphincter and have been associated with the epidemic of gastroesophageal reflux disease (GERD) and esophageal adenocarcinoma over the past two decades [23]. Constipation is also prevalent with the calcium channel antagonists, and attention to bowel function is important. Statins are associated with constipation and elevations of transaminases, but only rarely severe hepatotoxicity [24]. There is no reason to withhold statins from patients with mild liver function abnormalities (e.g., nonalcoholic steatohepatitis [NASH], hepatitis C), but test monitoring should be more rigorous [25]. An interesting association between statin use and reduced risk of colorectal cancer needs confirmation [26].

Aspirin is a foundation in the prevention of myocardial infarction [27,28]. In all trials, there is a small but consistent increase in the risk of gastrointestinal bleeding in the aspirin-treated groups. Although the risk of gastrointestinal bleeding is dose related, even daily doses below 100 mg per day cause irreversible inactivation of platelet prostaglandin synthetase for 7–10 days [29]. Epidemiological studies suggest that the concurrent use of nitrovasodilators reduces this risk substantially [30]. Ticlopidine and clopidogrel, other antiplatelet agents, appear to be more effective than aspirin, are effective in preventing restenosis of coronary stents, are used with increasing frequency, and have a lower risk of gastrointestinal bleeding [31].

Gastrointestinal complications of cardiac bypass surgery (acalculous cholecystitis, acute pancreatitis, mesenteric ischemia, hepatic necrosis, and others) occur more commonly in the elderly and those requiring dialysis [32] Gastrointestinal complications are recognized more frequently as higher-risk patients with multiple comorbidities are chosen for the surgery.

Chromosomal abnormalities and other genetic disorders

Abetalipoproteinemia

Abetalipoproteinemia is an autosomal recessive condition that causes severe hypolipidemia, diarrhea, fat malabsorption, growth failure, retinitis pigmentosa, acanthocytosis, and cerebellar ataxia. The growth failure and diarrhea can be

Table 109.1 Gastrointestinal side effects of drugs for cardiovascular disease

Medication class	Examples	Indication	GI side effects
Selective inhibitor of α-adrenergic agonist	Doxazosin mesylate, Terazosin	HBP	Nausea (C)
Adrenergic stimulants	Clonidine, methyldopa	HBP	Nausea/vomiting (C); hepatotoxicity (R)
α/β-Adrenergic blockers	Labetalol	HBP	Nausea/vomiting (C); dyspepsia/GERD (UC); hepatoxicity (R)
Angiotensin converting enzyme inhibitors	Enalopril, lisinopril	HBP, CHF	Diarrhea/dyspepsia (UC); ileus/pancreatitis (R); hepatotoxicity (R)
Angiotensin II receptor antagonists	Losartan, irbesartan	HBP, CHF, arrhythmias	Constipation (UC); diarrhea (UC)
Antiarrhythmics			
Group 1	Mexilitene, Quinidine, Disopyramide		Nausea/vomiting (C); diarrhea (C); constipation (C)
Group 2	See Beta-blockers		
Group 3	Sotalol, Amiodarone		Nausea/vomiting (C); abnormal liver tests (C);
Group 4	See Calcium channel antagonists		hepatotoxicity (UC)
Beta blockers	Atenolol, metoprolol	CAD, HBP	Diarrhea (UC)
Calcium channel antagonists	Verapamil, Diltiazam, Nifedipine	HBP, CAD	GERD (C); nausea (C); constipation (C); hepatotoxicity (R)
Hypolipidemic agents			
Bile acid binding resins	Cholestyramine	CAD	Dyspepsia (C); flatulence (C); constipation (C)
Cholesterol absorption	Ezetimibe	CAD	Diarrhea (UC); inhibitors
Fibric acid derivative	Gemfibrozil	CAD	Dyspepsia (C); abnormal liver tests (UC); cholestatic jaundice (R)
HMG-CoA reductase inhibitors abnormal liver tests (C); hepatotoxicity (R)	Lovastatin, simvastatin	CAD	Constipation (UC);
Nicotinic acid	Nicotinic acid	CAD	Dyspepsia (C); abnormal liver tests (UC)
Inotropic agents	Digoxin	CHF, arrhythmias	Mesenteric ischemia (R)
Vasodilators, coronary	Nitrates	CAD, CHF	GERD (UC)
Vasodilators, systemic	Hydralazine, Minoxidil	CAD, HBP, nausea/ vomiting(C); diarrhea (C); constipation (UC)	

C, common; CAD, coronary artery disease; CHF, congestive heart failure; GERD, gastroesophageal reflux disease; GI, gastrointestinal; HBP, high blood pressure; HMG-CoA, 3-hydroxyl-3-methyl-glutaryl-CoA; R, rare; UC, uncommon.

improved with a diet modified to contain medium-chain triglycerides. Children with the disease can develop severe neurological disease from vitamin E deficiency, and fat-soluble vitamins must be monitored and replaced. The disorder is a result of mutations of the microsomal triglyceride transfer protein [33], and with current molecular technology it can be differentiated from a variety of hypobetalipoproteinemias caused by truncation-producing mutations of the apolipoprotein B-100 gene [34] and from chylomicron retention disease.

Down syndrome

Down syndrome (chromosome 21 trisomy) can be associated with multiple gastrointestinal anomalies, the presence of which predicts higher mortality [35]. Infants with duodenal stenosis and atresia present with vomiting, abdominal distention, and the "double bubble" sign on abdominal radiography. Less complete obstructions from fenestrated duodenal membranes may present later in life as a cause of vomiting [36]. Esophageal abnormalities include tracheoesophageal fistula, esophageal stenosis, and gastroesophageal reflux.

Imperforate anus, Hirschsprung disease, and malrotation of the intestine have been described. Celiac disease has a relatively high prevalence in these patients [37]. The high incidence of hepatitis A and B infection in patients with Down syndrome has been reduced with early vaccination.

Fabry disease

Anderson–Fabry disease, an X-linked glycosphingolipidosis, is caused by mutations in the gene encoding the lysosomal exoglycosidase α-galactosidase A (α-Gal A), with the resulting deposition of ceramide trihexose in the lysosomes of endothelial, neural, and smooth muscle cells. Diagnosis is made by skin biopsy, measurement of α-Gal A in leukocytes, and genetic studies. Gastrointestinal manifestations are present in most affected men and in 29% of female carriers and include episodic constipation, diarrhea, nausea and vomiting, and abdominal pain, and, rarely, intestinal ischemia and perforation. The cause of these symptoms may be related, in part, to impaired autonomic function and vascular insufficiency. The advent of enzyme replacement therapy with α-Gal A has afforded these patients regression of gastrointestinal symptoms and substantial improvement in functionality [38–40].

Familial Mediterranean fever

Familial Mediterranean fever (recurrent polyserositis) is a recessive disease that is common in populations of Eastern Mediterranean origin. The gene responsible for familial Mediterranean fever has recently been cloned and designated *MEFV*. Three missense mutations have been identified and can be screened for using an amplification-refractory mutation system assay [41]. The target organ appears to be the blood vessel, and vasculitis can be present. Clinical manifestations begin in childhood and include attacks of fever, synovitis, severe abdominal pain suggesting an acute surgical emergency, or pleurisy [42].

The diagnosis is suspected when patients of Mediterranean extraction with a positive family history present with recurrent episodes of chest or abdominal pain, peritoneal signs, arthritis, fevers, and leukocytosis. The patient may have undergone previous fruitless diagnostic workups, including laparotomy. Frequent complications include AA amyloidosis, degenerative arthritis, renal vein thrombosis, and narcotic addiction [42]. Treatment with colchicine has been beneficial in preventing and ameliorating acute attacks [43].

Gaucher disease

Type 1 (nonneuronopathic or "adult") Gaucher disease is a rare autosomal recessive disease caused by a deficiency of glucocerebrosidase and resulting in the amassing of an insoluble glucocerebroside in the lysosomes of macrophages. Adults present with hepatosplenomegaly, thrombocyto-penia, and pathological bone fractures. Ascites or esophageal varices, which occasionally may bleed massively, have been described (Fig. 109.2). Definitive diagnosis relies on assaying β-glucerebrosidase actitivity [42]. Improvement in hepa-tosplenomegaly and overall function can be achieved with either enzyme replacement therapy with small doses of mannose-terminated glucocerebrosidase (alglucerase) or substrate reduction therapy with an inhibitor of glucosylceramide synthetase, attenuating the synthesis of glucocerebroside the substrate of the deficient glucocerebrosidase (oral miglustat) [42,43].

Hepatic porphyrias

The hepatic porphyrias are a group of inherited metabolic disorders of heme synthesis. The acute hepatic porphyrias include acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, and δ-aminolevulinic acid (ALA) dehydratase deficiency. They are characterized by attacks of abdominal pain (commonly with vomiting and constipation) associated with hypertension, neuropathy, and neuropsychiatric disturbance that may last days to months. The abdominal pain is severe, may be associated with signs of peritoneal inflammation on physical examination, and can lead to unnecessary abdominal surgery. The peripheral neuropathy is manifest as pain in the extremities but may progress to a motor neuropathy. Photosensitivity occurs only in variegate and coproporphyria. Attacks can be precipitated by medicines (barbiturates, dilantin, alcohol), menstruation, malnutrition, or other medical or surgical illnesses [44].

Sequence analyses of the genes for the enzymes of heme biosynthesis have revealed the porphyrias as highly heterogeneous, with multiple mutations underlying each type. All but ALA dehydratase deficiency are inherited as an autosomal dominant trait and are associated with increased urinary excretion of porphobilinogen (PBG) and ALA (Table 109.2). In patients with ALA dehydratase deficiency excretion of PBG is normal but ALA is elevated [44]. Once the diagnosis is made, genetic counseling should be undertaken; patients

Table 109.2 The hepatic porphyrias

Disorder	Abdominal pain	Skin lesions	Biochemical markers	
			Urine	Feces
Acute intermittent porphyria	+	0	High PBG and ALA	0
Variegate porphyria	+	+	High PBG, ALA, and coproporphyrin	High protoporphyrin and coproporphyrin
Hereditary coproporphyria	+	+	High PBG, ALA, and coproporphyrin	High coproporphyrin
ALA dehydratase deficiency	+	0	High ALA with normal PBG	0
Porphyria cutanea tarda	0	+	High uroporphyrin	0

This table does not list all the biochemical abnormalities, but rather serves as a guide to indicate which measurements are most critical in evaluating a particular porphyria. ALA, delta-aminolevulinic acid; PBG, porphobilinogen. (Adapted from Bloomer JR. The hepatic porphyrias. Gastroenterology 1976;71:689)

are told to avoid precipitating factors and are placed on a high-carbohydrate diet. Acute attacks may be ameliorated by infusion of glucose, hematin (being replaced by heme arginate in Europe) [44], which suppresses ALA synthetase. Treatment of seizures has been difficult because many antiepileptic medications increase the hepatic metabolism of heme and can precipitate attacks. Gabapentin does not have this effect and seems to be safe and effective as a treatment for seizures in this setting [45].

Porphyria cutanea tarda (PCT) is inherited as an autosomal dominant trait, but its clinical presentation as a disease may depend on a number of other genetic and environmental factors. It is associated with prominent dermal photosensitivity and mechanical sensitivity without abdominal pain and also with alcoholic liver disease, hemochromatosis (or other disorders of iron overload), and hepatitis B and C. In PCT, urinary excretion of PBG is normal and the disease is differentiated from variegate and coproporphyria by the increased urinary excretion of uroporphyrins. Abstention from alcohol, phlebotomy or deferioxamine to reduce iron overload, low-dose chloroquine, and interferon–ribaviron treatment of hepatitis C all have reduced symptoms [46].

Hereditary angioedema

Hereditary angioedema is a rare autosomal dominant inherited deficiency of activated C1 inhibitor, a plasma protein that prevents uncontrolled intravascular activation of complement. Low serum C4 and an assay showing absent serum C1 inhibitor confirms the diagnosis [47].

The major clinical feature is episodic, self-limited, nonpitting swelling of the orofacial region, larynx, extremities, and gastrointestinal tract. Angioedema is distinguished from urticaria in that it is asymmetric and burns rather than itches. Edema in the cervical region can compromise the upper airway. Abdominal attacks are characterized by colic, bloating, and nausea and vomiting secondary to enteric mucosal edema, and can occur in the absence of peripheral or orofacial angioedema. Barium studies demonstrate "thumbprinting." Bradykinin is felt to be the main if not the sole mediator responsible for the edema. Treatment with synthetic androgens (e.g., danazol or methyltestosterone) increases the levels of C1 esterase inhibitor and can ameliorate or prevent attacks. Where available, infusions of C1 inhibitor concentrates are the treatment of choice for emergent attacks [47]. Premedication with C1 inhibitor concentrate or antifibrinolytic agents (e.g., ε-aminocaproic acid, tranexamic acid) should be considered before oropharyngeal manipulations such as upper endoscopy [48].

Hyperlipidemias

The familial hyperlipidemias are a collection of inherited disorders of lipid metabolism characterized by elevated plasma lipid levels. The epidemiological association with atherosclerotic vascular disease is clear. Only disorders that predispose to high levels of triglycerides (> 1000 mg/dl but usually > 2000 mg/dl) are associated with acute pancreatitis [49]. Many of these patients, particularly if overweight or diabetic, will develop fatty liver associated with abnormal serum liver enzyme levels, and will have nonalcoholic steatohepatitis on biopsy. The use of oral contraceptives during the third trimester of a pregnancy and highly active antiretroviral therapy (HAART) therapy for human immunodeficiency virus (HIV) are associated with an increased risk of developing severe dyslipidemia and pancreatitis [50].

In the past 5 years multiple studies have demonstrated the safety and beneficial effect of lipid-lowering medication on the primary and secondary prevention of coronary disease and stroke. Statins [3-hydroxy-3-methylglutaric acid (HMG-CoA) reductase inhibitors], fibrates, and niacin are commonly employed in combination in difficult to manage dyslipidemias. Hepatotoxicity is rare, but clinically unimportant elevations of aminotransferases occur in 1%–2% of the treated population. Asymptomatic elevations of aminotransferases to twice the upper limit of normal can be monitored without stopping medication. When clinically indicated, statins should not be withheld from patients with minor

transaminase elevations (e.g., NASH) but tests of liver function should be performed within the first 1–2 months of initiating therapy and every 6 months thereafter [24,25].

Bile acid-binding resins such as cholestyramine cause abdominal fullness, flatulence, and constipation in 30% of patients. These symptoms usually respond to dose reductions or the addition of psyllium or prune juice. Nicotinic acid, especially at doses > 2000 mg/day, has been implicated in more common hepatotoxic reactions than statins. Gemfibrozil may cause severe abdominal pain, and is associated with increased frequency of gallstones [51].

Niemann–Pick disease

Niemann–Pick disease is a rare, inherited lipid storage disease that principally afflicts people of Jewish ethnicity. The enzyme sphingomyelinase is absent or nonfunctional, leading to the accumulation of sphingomyelin in the lysosomes of reticuloendothelial cells. Affected infants manifest severe neurological disease, hepatosplenomegaly, and hepatic failure and do not survive to adulthood. Survival of patients with type B Niemann–Pick disease to adulthood is common but may be associated with cirrhosis and portal hypertension [52].

Tangier disease

Tangier disease is a rare codominant inherited deficiency of plasma α-lipoprotein. The genetic defect has been localized to chromosome 9q31. ABCA1, a cell membrane protein, mediates the active efflux of excess cholesterol from cells and is mutated in Tangier disease. Affected patients exhibit reduced total cholesterol, low high-density lipoproteins, and elevated plasma triglycerides. Accumulation of cholesterol in the reticuloendothelial system results in enlarged orange or red tonsils, lymphadenopathy, peripheral neuropathy, hepatosplenomegaly, and yellow–orange patches in the colonic mucosa [53,54].

Turner syndrome

Turner syndrome (X chromosome monosomy, or mosaicism) occurs in 1:2500 live female births and presents with a variety of external somatic features, of which short stature and gonadal dysgenesis are almost invariably present. Gastrointestinal hemorrhage resulting from intestinal vascular malformations, an increased incidence of inflammatory bowel disease and celiac sprue, and a greater risk of anorexia nervosa have been described [55]. Mild elevation of alkaline phosphatase may be seen. This cholestasis is not related to the chronic use of estrogens for the gonadal dysgenesis [56].

von Hippel–Lindau disease

von Hippel–Lindau disease (VHL) is an autosomal dominant inherited disorder characterized by hemangioblastomas of the retina and central nervous system, renal cell carcinoma, pheochromocytoma, and endolymphatic sac tumors with marked phenotypic variability. Heterogeneous germline mutations lead to the absence of the VHL protein, resulting in uncontrolled production of vascular endothelial growth protein and the formation of blood vessels [57]. Pancreatic disease is found in three-quarters of the affected individuals. The most common lesions found were cysts, serous cystadenomas, and neuroendocrine tumors. These lesions rarely cause symptoms and require surgical intervention only when very large [58].

Connective tissue diseases

Ehlers–Danlos syndrome

Ehlers–Danlos syndrome is a collection of inherited diseases affecting collagen synthesis. Nine different subtypes are described, although gastrointestinal involvement is common only in types I (gravis) and IV (arterial). Patients with type I disease have fragile, hyperelastic skin and hyperextensible joints. They often complain of bleeding gums and easy bruising after even minor trauma. Severe gastrointestinal bleeding from mucosal lesions occasionally occurs [59].

Ehlers–Danlos syndrome type IV is unique in that hyperelastic skin is lacking and joint hyperextensibility is less prominent. Ecchymoses, thin skin with visible vessels, and "cigarette paper" scars are common, however. Cultured fibroblasts that synthesize abnormal type III procollagen molecules or the identification of or a mutation in the gene for type III procollagen (*COL3A1*) confirms the diagnosis. Most complications occur after age 20. The defect in type III collagen synthesis leads to multiple aneurysms, including in splanchnic arteries, rupture of which results in intraabdominal bleeding. Spontaneous perforation of the bowel, particularly the sigmoid colon, is common and a cause of death. Tissue fragility and poor wound healing with dehiscence contribute to surgical mortality. Repeated perforations are seen [60].

Mixed connective tissue disease

Mixed connective tissue disease (MCT), or overlap syndrome, is a heterogeneous autoimmune disorder which may present with clinical features of lupus, scleroderma, and polymyositis. Gastrointestinal manifestations may resemble any of those described (see below) for the aforementioned rheumatoid diseases. However, the most common manifestations are esophageal symptoms of heartburn and dysphagia, with either distorted proximal or distal esophageal motility. Treatment with corticosteroids may improve the swallowing abnormality [61].

Polymyositis and dermatomyositis

Polymyositis and dermatomyositis are rheumatological diseases characterized by inflammation of striated and, to a lesser extent, smooth muscle. Muscle biopsy is needed for diagnosis. A characteristic skin rash accompanies dermatomyositis. The gastrointestinal tract may be affected through-

out its entire length, but the proximal esophagus is usually involved. Gastric and esophageal emptying is compromised in many patients, who may complain of dysphagia, aspiration, regurgitation, early satiety, and bloating [62].

Colonic pseudodiverticula and pneumatosis intestinalis may develop. Constipation is a common complaint. Acute inflammation of smooth muscle may result in gut wall edema, ulceration, or perforation. There is an association between dermatomyositis and malignancy – colon cancer seems to be prevalent, and colonoscopic screening is therefore appropriate [63].

Progressive systemic sclerosis

Progressive systemic sclerosis (PSS) or scleroderma is characterized by vasculitis of small arteries and fibrosis of skin and other organs. Gastrointestinal manifestations are found in most patients. Tightening of the perioral skin with restricted ability to open the mouth and impaired taste sensation may contribute to malnutrition. Esophageal involvement, present in 70%–80% of patients, is associated with more severe Raynaud phenomenon, skin abnormalities, and autonomic dysfunction [64,65]. Smooth muscle atrophy leads to absent or low-amplitude esophageal contractions that are most prominent in the mid and distal esophagus and weakening of the lower esophageal sphincter, leading to both reflux of acid and retarded clearance of the refluxed material. In addition, gastric emptying is commonly delayed, further increasing acid reflux [66]. The result is the most severe type of symptomatic reflux and erosive esophagitis. Evaluation of dysphagia may be difficult in advanced cases as it may be impossible to distinguish primary dysmotility from stricture. Endoscopy should be the primary diagnostic modality. Dilation of a stricture can substantially improve swallowing. The risk of developing strictures is high, and patients should be maintained indefinitely on an adequate amount of proton pump inhibitor to suppress heartburn.

In those PSS patients with upper gastrointestinal bleeding, endoscopy may reveal telangiectasia [67] or gastric antral vascular ectasia (watermelon stomach). Chronic iron deficiency anemia, persistent occult blood in the stool, and recurrent melena and hematemesis are common manifestations. Cautery with heater probe or laser may reduce recurrent bleeding [68].

The small intestine is frequently involved, causing severe morbidity. Hypomotility, dilation, pseudodiverticula, and thickening of the bowel are common [69]. Stasis, pseudoobstruction, and bacterial overgrowth may produce anorexia, abdominal distention, postprandial periumbilical pain, malabsorption, diarrhea, steatorrhea, and weight loss. The bacterial overgrowth may be worsened by the need for effective inhibition of acid secretion because of concomitant gastroesophageal reflux. Erythromycin, cycled antibiotics, and octreotide may reduce symptoms, but many patients require home parenteral nutrition.

Figure 109.3 Wide-mouthed pseudodiverticula are present in a patient with scleroderma.

Delayed colonic transit and impaired anal sphincter function have been demonstrated in patients with PSS [70]. Pseudodiverticula (Fig. 109.3) and telangiectasias are common. Constipation, pseudoobstruction, and volvulus may develop. Fecal incontinence and rectal prolapse are particularly disabling symptoms. Pneumatosis cystoides intestinalis may be found and is probably due to excessive hydrogen production by intestinal bacteria, altering the partial pressure of nitrogen in the intestinal wall [69]. Careful attention to bowel function has an important role in extending the patient's functionality. Patients with the CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, telangiectasias) variant of PSS are at risk for the development of primary biliary cirrhosis [71].

Pseudoxanthoma elasticum

It has been found that mutations in the *ABCC6* gene encoding for the multidrug resistance-associated protein 6 cause pseudoxanthoma elasticum [72]. The disease is characterized by plaques resembling xanthomata on the skin and angioid streaks on the fundus. Degeneration of elastic fibers in visceral blood vessels results in ineffectual vasoconstriction and vessel retraction after injury, predisposing to gastrointestinal bleeding [73]. Yellow raised plaques similar in appearance to the skin lesions have been identified in the stomach during endoscopy [74]. The best therapy for bleeding is uncertain.

Rheumatoid arthritis

Rheumatoid arthritis is a chronic systemic disease characterized by a deforming symmetrical polyarthritis and the presence

of serum rheumatoid factors. It most commonly afflicts women between the third and seventh decades of life and has a prevalence of about 1% in the United States [75]. Gastrointestinal manifestations are common and protean. Involvement of the temporomandibular joint impedes chewing. Sicca syndrome, when present, is accompanied by stomatitis and gingivitis. Heartburn and dysphagia are not as common as in PSS or MCT disease. Secondary amyloidosis may occur in patients with long-standing rheumatoid arthritis, may involve any portion of the gastrointestinal tract, may be manifest by chronic diarrhea, and can be diagnosed by endoscopic gastroduodenal biopsies [76].

Vasculitis is less common than in other rheumatic diseases; however, both small and large vessels may be involved in the setting of severe arthritis, subcutaneous nodules, high titers of rheumatoid factor, and depressed serum complement levels. Necrotizing vasculitis of the mesenteric vessels may result in intestinal ischemia, bleeding, and infarction [77]. Cholecystitis, appendicitis [78], perisplenitis, splenic infarction, pancreatitis, and hepatic arteritis have been described.

Iatrogenic illness results in the most common gastrointestinal manifestations in patients with rheumatoid arthritis. Chronic administration of salicylates or nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit both cyclooxygenase 1 and 2 (COX-1 and COX-2) produce gastroduodenal erosions and ulcers, as well as hypocoagulability. Although these lesions can be associated with anorexia, nausea, and abdominal pain, many patients are asymptomatic [79]. Significant gastrointestinal bleeding or perforation occurs in about 1%–2% each year [80]. Of these adverse events, 40% are the consequence of lower gastrointestinal (GI) ulceration or perforation [81]. The risk of bleeding is increased substantially (up to 9%–10%) in frail older patients who (a) are taking certain NSAIDs (e.g., piroxicam), (b) are taking higher doses of any NSAIDs, (c) have a previous history of gastrointestinal bleeding or ulcers, (d) are using steroids or aspirin with an NSAID, or (e) have concomitant cardiopulmonary disease [82].

Under ideal circumstances, a patient with rheumatoid arthritis would be treated with joint-sparing immunotherapy alone (e.g. methotrexate, anti-tumor necrosis factor [TNF]) and would not require chronic NSAIDs. In practice, however, many continue to have pain and inflammation that respond only to NSAIDs. In such patients, the use of selective COX-2 inhibitors (celocoxib) has been associated with decreased dyspepsia and bleeding. Because of the availability of inexpensive generic proton pump inhibitors (PPIs), which will also protect the stomach, and the concerns about increased cardiovascular events with the coxibs, many patients are prescribed a PPI along with non-selective NSAIDs.

Methotrexate is commonly used to modify the disease progression of rheumatoid arthritis. Nausea and vomiting are common side effects that during the first year of therapy limit the use of this efficacious medication. Decreased renal function (because of either kidney disease or aging) increases the risk of side effects, and high-dose folic acid supplementation is protective [83]. Although chronic therapy with low-dose methotrexate can result in hepatic fibrosis, the risk of developing cirrhosis is small in young nonobese patients who do not abuse alcohol. Hence, the clinical value of obtaining periodic liver biopsies is controversial [84,85]. As many patients with rheumatoid arthritis also have chronic hepatitis C, it is comforting to know that using the TNF-α compounds does not appear to worsen the viremia or liver biochemistries [86]. The toxic effects of gold preparations are discussed in the section on heavy metal toxicity.

Seronegative spondyloarthropathies

The seronegative spondyloarthropathies are a collection of rheumatic diseases including ankylosing spondylitis, psoriatic arthritis, the reactive arthritides (e.g., Reiter syndrome), arthritis associated with inflammatory bowel disease, and Whipple disease. Serum rheumatoid factor is lacking, but most patients are human leukocyte antigen (HLA) B27 positive, and many have recurrent oral and genital ulcers [87]. Patients with reactive arthritis frequently have an antecedent gram-negative enteric or chlamydial infection [88]. Many have chronic gastrointestinal symptoms (e.g., mild diarrhea, abdominal cramps), and most patients have endoscopic or histological evidence of ileocolonic inflammation that sometimes resembles Crohn's disease [89].

Sjögren syndrome

Sjögren syndrome results from immune-mediated destruction of exocrine glands and is characterized by keratoconjunctivitis sicca (dry eyes and mouth). Atrophy of the salivary glands leads to a lack of alkaline saliva, which can worsen acid reflux. In addition, esophageal dysmotility and mucosal webs are found [90]. Gastric atrophy, protein-losing enteropathy, and celiac disease [91] are reported in these patients. There is a strong association with the development of primary biliary cirrhosis [92]. An association with autoimmune pancreatitis has been reported [93].

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease that is characterized by arthritis, myalgias, fever, rash, lymphadenopathy, renal disease, polyserositis, and central nervous system involvement. Abdominal pain is common in SLE and has a broad differential diagnosis. Inflammation of serosal surfaces may produce lupus peritonitis [94], which is usually self-limited but may be associated with ascites. Self-limited peritonitis is difficult to distinguish from intestinal ischemia or perforation secondary to mesenteric vasculitis [95]. Pancreatitis, sometimes severe, and perhaps related to vasculitis, has been associated with SLE. Lupus enteritis is a common cause of admission to hospital [96], and SLE may present with terminal ileitis, and can

be confused with Crohn's disease [97]. Malabsorption and protein-losing enteropathy with lymphangiectasia are documented [98]. Although clinically significant liver disease is uncommon in SLE, many patients have hepatomegaly and abnormal liver enzyme levels. Drug-induced hepatotoxicity is probably the most common underlying cause [99]. Differentiation from autoimmune hepatitis with systemic features of SLE can be difficult. Other drugs, such as azathioprine, may produce similar abnormalities. Hepatic vasculitis is a rare cause of liver disease, which in extreme cases has resulted in liver rupture [100].

Dermatological diseases

Blue rubber bleb nevus syndrome

Blue rubber bleb nevus syndrome is characterized by rubbery, blue nevi on the skin and gastrointestinal hemangiomas. The gastrointestinal hemangiomas can result in hemorrhage and iron deficiency anemia, may be the lead point of intestinal intussusceptions, and are commonly identifiable at the time of upper or lower endoscopy. Actively bleeding lesions can be cauterized, or the vessel can be occluded during angiography [101–103].

Cowden syndrome

Cowden syndrome is an autosomal dominant disease characterized by ectodermal, mesodermal, and endodermal hamartomatous neoplasms. Patients manifest small papular lesions on the skin and oral mucosa. Diffuse esophageal glycogenic acanthosis may be characteristic of the syndrome [104]. There is a strong propensity for thyroid goiter, thyroid cancer, and, in women, breast cancer. Mutations of the tumor-suppressor gene *PTEN* have been found [105]. Multiple hamartomatous polyps of various sizes can develop from the esophagus to the colon, but have a low potential for malignant degeneration. The hamartomas can cause chronic gastrointestinal blood loss and partial intestinal obstruction [106] (see Chapter 64).

Epidermolysis bullosa

Epidermolysis bullosa is a group of diseases in which minor trauma disrupts the cohesion between epidermis and dermis, resulting in the formation of vesicles or bullae. Adult forms of this entity include epidermolysis dystrophica with either dominant or recessive inheritance and epidermolysis simplex of dominant inheritance.

Lingual scarring and microstomia occur as a consequence of injury to the oropharyngeal mucosa during the eating of solid foods [107]. Clinically significant esophageal disease is seen more commonly in recessive epidermolysis dystrophica. Odynophagia and dysphagia are common because esophageal bullae lead to erosions, ulcers, pseudodiverticula, shortened esophagus, webs, strictures, and obstruction, most commonly in the cervical esophagus. Eating a soft or puréed diet may limit mechanical injury to the esophagus, but endoscopic placement of a gastrostomy tube may be needed. Strictures respond to repetitive ballon dilation. Bougienage should probably be avoided because the shearing forces could perpetuate injury [108].

Hereditary hemorrhagic telangiectasia

Hereditary hemorrhagic telangiectasia (HHT, Osler–Weber–Rendu disease) is an autosomal dominant condition found in 1–2 per 100 000 population. Mutations in the endoglin and ALK-1 genes cause the two recognized disease types, HHT1 and HHT2. HHT is associated with the formation of telangiectasias, aneurysms, and arteriovenous malformations (AVMs) throughout the body. Cutaneous telangiectasia usually appears after the second or third decade of life and is located most frequently on the face, lips, nares, tongue, ears, and hands. Pulmonary AVMs occur only in HHT1 while HHT2 has milder disease manifestations [109].

Epistaxis is the most common form of bleeding, with gastrointestinal hemorrhage developing in 10%–40% of patients [110]. Upper and lower GI endoscopy have been amplified by capsule endoscopy in localizing lesions [111,112]. Hepatic vascular malformations cause arterioportal and intrahepatic portosystemic shunts, resulting in high-output congestive heart failure. Hepatomegaly, hemobilia, portal hypertension, esophageal varices, hepatic encephalopathy, bruit, and cardiomegaly have been noted. Elevated alkaline phosphatase and bile duct lesions similar to Caroli disease or sclerosing cholangitis can be encountered [113].

Iron deficiency anemia is common and may require continuing oral or parenteral iron replacement or even transfusions. Endoscopic coagulation can effectively control life-threatening hemorrhage from a visible intestinal vascular malformation. In many cases, however, the bleeding site cannot be localized, and, in the absence of an evidence-based medical therapy, chronic transfusion or iron therapy is initiated. When large intrahepatic arteriovenous fistulae result in high-output congestive failure, embolization of these vessels or ligation of select branches of the hepatic artery may result in improvement of the failure, but infarction of the liver. Liver transplantation has been employed in severe cases [113].

Neurofibromatosis

Neurofibromatosis (von Recklinghausen disease) is a dominantly inherited disease. The gene frequency is 1 in 3000 births. Cutaneous diseases comprise café au lait spots and neurofibromas, which rarely transform into sarcoma [114]. Polypoid neurofibromas can be present throughout the gastrointestinal tract, and it has been suggested that the Auerbach myenteric plexus may be the source of the tumors [115].

Neurofibromas occasionally cause gastrointestinal bleeding and obstruction presenting as melena and abdominal

pain. Gastrointestinal stromal tumors are commonly found in patients with neurofibromatosis [116].

Pemphigus

Pemphigus is a group of diseases characterized histologically by acantholysis, resulting in bullae formation. Pemphigus vulgaris, the most common variant, is characterized by circulating immunoglobulin G (IgG) antibodies to desmoglein 3 [117]. D-Penicillamine, which is used in the management of Wilson disease, can cause pemphigus, although this is rare. Pemphigus vulgaris can involve the esophagus, endoscopy showing blisters or erosions in the upper esophagus and linear red streaks along the entire organ, but treatment of the pemphigus with steroids regresses the esophageal disease [118].

Psoriasis

Psoriasis is not associated with gastrointestinal disease; however, difficult psoriasis is often controlled by prolonged methotrexate administration. At the doses used, this drug carries a risk of potentially serious hepatotoxicity, including fatty liver, hepatic fibrosis, and cirrhosis. This risk has probably been overstated, with only 8% developing advanced fibrosis with cumulative doses > 6000 mg [119]. Where available, monitoring with assays of type III procollagen has replaced serial liver biopsies to detect early hepatic damage [120].

Stevens–Johnson syndrome

Stevens–Johnson syndrome is an uncommon, but severe, hypersensitivity reaction characterized by a diffuse rash (erythema multiforme) that may progress to an exfoliative dermatitis. It is fatal in about 5% of cases [121]. This syndrome is often accompanied by fever and mucositis of both the gut and the respiratory tract. Etiological agents include drugs (e.g., sulfonamides, allopurinol, anticonvulsants, NSAIDs) and infectious agents. The oropharyngeal mucosa frequently exhibits erosions and mucosal sloughing, although the entire gut may be involved in severe cases. Oropharyngeal pain may be severe enough to limit oral intake. Mucosal injury may result in dysphagia, odynophagia, abdominal pain, and gastrointestinal bleeding [122]. Esophageal stricture has been reported as a sequela of the Stevens–Johnson syndrome [123]. The syndrome is commonly associated with abnormal liver tests and hepatotoxicity.

Management is similar to that provided for major burns, and patients with extensive loss of skin should be managed in intensive care. Treatment includes identification and elimination of the inciting factors, rehydration, nutritional support, antibiotics, and vigilance for respiratory problems and secondary infections. Complete recovery may take several weeks [121–123].

Sweet syndrome

Sweet syndrome is an uncommon condition, seen in women more than men, characterized by the acute eruption of tender, erythematous, nonulcerating plaques and nodules. Nodules on the legs can mimic erythema nodosum. Diagnosis is defined by the histological presence of neutrophilic infiltration and leukocytoclasis on skin biopsy. The latter findings also are found in pyoderma gangrenosum, which, in contradistinction, is represented clinically by ulcerating plaques with violacious edges. As with pyoderma, a strong association of Sweet syndrome with both ulcerative colitis and Crohn's disease has been noted. Also reported are mouth ulcerations and an association with myeloma, myeloid leukemia, and adenocarcinoma of the colon [124].

Tylosis

Tylosis is a rare autosomal dominant disorder characterized by thickening of the skin on the palms and soles (focal nonepidermolytic palmoplantar keratoderma) (Fig. 109.4). Late-onset tylosis (type A) is associated with squamous cell carcinoma of the esophagus. The causative locus, located on chromosome 17q25.1, has been termed the tylosis esophageal cancer (TOC) gene [125], and has also been associated with sporadic esophageal cancer [126]. The esophageal mucosa forms papillomas. Affected persons have about a 90% probability of developing esophageal carcinoma by the age of 65, and should be screened with endoscopy and biopsies [127].

Figure 109.4 Hyperkeratosis of the palm and leg may be indicative of tylosis.

Urticaria

Urticaria is a reactive inflammatory vascular dermatosis characterized by vasodilation, increased vascular permeability, and extravasation of protein and fluids into the dermis, resulting in the characteristic peau d'orange wheals. Urticaria of less than 6 weeks' duration is usually related to inciting allergic factors. Chronic cases are usually idiopathic. Only a minority of patients with chronic urticaria will have systemic mastocytosis, which may be signaled by the more classical urticaria pigmentosa, flushing, and diarrhea [128]. Intial reports of an association with *Helicobacter pylori* infection appear unfounded [129]. Implicated in the pathophysiology of both acute and chronic urticaria is the release of histamine and other inflammatory mediators. Gastrointestinal manifestations have been reported in a number of patients suffering from chronic urticaria and include abdominal pain, gastroduodenitis, peptic ulcer, and enteric mucosal "hives" [128].

Endocrinological disorders

Acromegaly

Acromegaly is a disorder whose clinical manifestations result from excessive growth hormone (GH) and insulin-like growth factor 1 production, usually a result of a pituitary adenoma. Rarely, carcinoid and pancreatic islet cell tumors can secrete a GH-releasing factor that leads to acromegaly. Although patients manifest enlargement of the tongue, enlargement of the other organs of the digestive system is unusual, and hepatosplenomegaly thus would warrant further investigation [130]. It has become accepted that patients with acromegaly are at greater risk for colorectal neoplasia, although this idea is controversial, and they should therefore undergo routine screening guidelines by colonoscopy after the age of 50 [131].

When GH secretion cannot be normalized by ablation of the adenoma, long-acting octreotide can control symptoms. As a consequence of the disease and the chronic use of the somatostatin analog, patients are at increased risk of developing gallstones. It has been suggested that this may be accounted for by (a) slow-transit constipation, leading to increased formation of deoxycholic acid, and (b) impairment of postcibal cholecystokinin release and gallbladder contraction [132,133]. For this reason, reducing the lithogenicity of the bile with ursodeoxycholic acid may be considered.

Addison disease

Addison disease results from insufficient production of both mineralosteroids and corticosteroids by the adrenals. Gastrointestinal symptoms are common in untreated Addison disease. The prominent clinical features include anorexia, vomiting, weight loss, abdominal pain, apathy, hypotension, hyponatremia, and hyperkalemia [134]. Addison disease of autoimmune etiology is associated with atrophic gastritis, antibodies against H^+,K^+-ATPase and intrinsic factor, and uncommonly achlorhydria and pernicious anemia. Subclinical Addison disease may present with increased transaminase levels [135].

Autoimmune polyendocrine syndromes

The autoimmune polyendocrinopathies are a diverse group of inherited diseases that share a common immunonological theme: the loss of immunological tolerance to a peptide within a molecule found in a specific organ. Hypoparathyroidism is present in most patients with the autosomal recessively inherited autoimmune polyendocrine syndrome type I, as is candidiasis, and Addison disease [136]. Mutations in *AIRE* (an autoimmune-suppressor gene) cause the syndrome, with presentation early in life. Associated manifestations include gonadal failure, type IA diabetes, gastric parietal cell atrophy and pernicious anemia, and malabsorption with steatorrhea [137]. The type II autoimmune endocrinopathy is more common, occurs later in life, presents as idiopathic hypotension (adrenal failure), and results in the development of hypothyroidism. As more is understood about the nature of these illnesses, the larger the number of patients that are classified under a broad diagnostic umbrella [136].

Cushing syndrome

Overproduction of adrenal corticosteroids caused by oversecretion of adrenocrticotrophic hormone (ACTH) from a pituitary adenoma, or by ACTH ectopically produced in islet cell or small cell lung cancers, leads to the typical redistribution of fat (buffalo hump, central obesity, Cushingoid facies) that identifies the Cushing syndrome. Gastrointestinal manifestations, other than transaminase elevations from hepatic steatosis, are unusual. However, an uncommon type of an ACTH-independent Cushing syndrome, which is food dependent, deserves comment. Hypercortisolism in these patients is induced by an overexpression of gastric inhibitory polypeptide (GIP) receptors in the adrenal cortex. Eating stimulates GIP secretion, GIP binds to the receptors in the adrenal gland, and abnormal cortisol synthesis and secretion is initiated [138].

Diabetes mellitus

Diabetes mellitus is a common metabolic disease resulting in primary hyperglycemia. Insulin-dependent diabetes mellitus (IDDM) is caused by a genetically mediated immune destruction of the pancreatic β-cells, whereas the eight times more common non-insulin-dependent diabetes mellitus (NIDDM) is caused by insulin resistance at the effector cell. Non-insulin-dependent diabetes mellitus is more prevalent in Hispanic groups of Mexican origin, in Native Americans, and in some Asian–Pacific Island groups. For a variety of inadequately understood socioeconomic, genetic, and cultural reasons, diabetes-related morbidity and mortality are also more common among minorities [139]. Abdominal complaints (Table 109.3) are common, nonspecific to diabetes, and may not relate directly to the diabetes [140].

Table 109.3 Gastrointestinal manifestations of diabetes mellitus

Organ	Symptoms	Pathophysiology
Esophagus	Odynophagia	Candidiasis; autonomic neuropathy, causing dysmotility
Stomach	Bloating, nausea/vomiting	Transient dysmotility due to hyperglycemia or fixed gastroparesis
Small bowel	Bloating, diarrhea, weight loss	Celiac sprue, bacterial overgrowth caused by autonomic neuropathy and dysmotility
Colon	Constipation	Autonomic dysfunction
Biliary system	Increased frequency of cholelithiasis	Altered bile acids due to dysmotility and/or bacterial overgrowth; genetic concordance of diabetes, obesity, and cholelithiasis
Liver	Abnormal liver tests, hepatomegaly	Fatty liver with or without steatonecrosis
	Abdominal pain	
	Acute pain	Diabetic neuropathy, pancreatitis, cholecystitis, mesenteric ischemia
	Chronic pain	Diabetic neuropathy, mesenteric angina

Acute abdominal pain associated with nausea and vomiting is a frequent accompaniment of acute diabetic ketoacidosis and resolves with normalization of blood sugar. Persistent, severe abdominal pain may signal that the ketoacidosis is the consequence of some other serious intraabdominal process. Acute pancreatitis, cholecystitis, intestinal ischemia, appendicitis, and diverticulitis must always be considered.

Later stages of the disease may entail gastrointestinal symptoms of a chronic and irreversible nature. Many of the chronic symptoms are believed to result from visceral autonomic neuropathy, which is thought to be a consequence of a metabolic dysfunction of peripheral nerves caused by prolonged hyperglycemia. When blood sugar is maintained within a normal range by frequent daily administration of insulin, the onset of neuropathy is delayed and established neuropathy is improved [141].

Although clinical manifestations of esophageal dysfunction, often mild pyrosis and dysphagia, are unusual, abnormal esophageal motor function is common in both IDDM and NIDDM [142]. Esophageal dilation, reflux, and delayed esophageal emptying may be seen radiographically. Changes demonstrated manometrically may include feeble peristaltic pressure waves that are at times multipeaked or multiphasic, increased frequency of nonperistaltic contractions, and decreased lower esophageal sphincter pressure.

New-onset odynophagia in the diabetic patient should suggest the presence of *Candida* esophagitis. Oral thrush accompanies *Candida* esophagitis in no more than 50% of patients, but when present it is an indication for an empirical trial of an antifungal agent such as fluconazole. If odynophagia persists, or if oral thrush is not present, diagnostic upper endoscopy should be undertaken. The most common visual finding is that of cream-colored plaques scattered throughout the esophagus. The diagnosis is made through endoscopic biopsy and brushing of the plaques. Nausea and vomiting are common in patients with uncontrolled hyperglycemia and do not necessarily mean that the patient has the fixed vagal autonomic neuropathy seen in IDDM patients with gastroparesis diabeticorum. Hyperglycemia, even that induced in normal volunteers using the glucose clamp technique, disrupts normal myoelectric activity in the stomach. There is an inverse relationship between gastric emptying and blood glucose concentration [143]. These alterations in gastric myoelectric activity result in gastric dilation, slow peristalsis, and delayed gastric emptying. Increased pyloric resistance and small intestinal dysmotility [144] also slow transpyloric flow. The patient's diabetes must be under optimal control before investigations are undertaken for gastroparesis.

Symptoms of gastroparesis include early satiety, bloating, heartburn, persistent nausea, and paroxysmal vomiting of undigested food 3–4 h after eating. Physical examination may demonstrate a succussion splash as well as findings of peripheral neuropathy. Patients are predisposed to the formation of gastric bezoars from indigestible food. Yet most diabetic patients who have diabetes with abnormalities of gastric emptying have no symptoms [145]. Classical gastroparesis is defined by finding more than 1000 mL of gastric contents after awakening in the morning or by demonstrating a massively dilated stomach on routine abdominal radiographs or upper gastrointestinal series. Endoscopy supports the diagnosis by confirming the absence of structural gastric outlet obstruction and revealing a substantial gastric residue after an overnight fast. Other causes of gastroparesis that may be more treatable, such as hypocalcemia, hypothyroidism, or medications (e.g., narcotics, tricyclic antidepressants), must be excluded. Subtle gastric emptying dysfunction can be documented by gastroscintiscanning but must be interpreted with caution as abnormalities are found commonly in asymptomatic diabetics [145].

Central to the treatment of diabetic gastric emptying disorders is the optimal normalization of blood glucose, modification of concomitantly prescribed medications, and correction of any electrolyte abnormalities. In young women with IDDM eating disorders are common, and are associated with

noncompliance, underdosing of insulin to achieve weight loss, and poor metabolic control. Symptoms can mimic gastroparesis. If the eating disorder is not treated progression of microvascular complications is more common [146].

Therapy with prokinetic agents can be disappointing in advanced gastroparesis. The central dopaminergic and peripheral cholinergic effects of metoclopramide to accelerate gastric emptying may be short-lived because of tachyphylaxis. Although not available in the United States, domperidone (up to 20 mg four times daily) can result in longer-lasting improvement in symptoms despite a variable effect on tests of emptying, without the risk of the parkinsonian side effects of metoclopramide [147]. Although erythromycin improves gastric emptying in diabetic patients, it has not been helpful in the long-term management of gastroparesis. Surgery to improve gastric drainage should not be considered, but gastric pacing may be helpful in selected cases. Repeated measurements of gastric emptying are not useful because they do not discriminate well between symptomatic and asymptomatic patients and do not predict the response to treatment [148].

Diarrhea and fecal incontinence occur commonly in advanced IDDM [149]. The diarrhea is watery, painless, and commonly nocturnal. It can remit after days or months, but recurrence is frequent. Although intestinal autonomic neuropathy may be the cause in as many as 50% of cases, other, more treatable, causes must be excluded. Celiac disease, which is found more commonly in patients with IDDM, can be screened for with tissue transglutaminase antibodies. Pancreatic insufficiency and bacterial overgrowth should also be considered in the differential diagnosis. Fecal incontinence is commonly due to anal sphincter dysfunction and decreased rectal sensation [150], but a flexible sigmoidoscopy will exclude proctitis.

Once other causes have been cleared, idiopathic diabetic diarrhea is treated with good glucose control, opiates, and bulk-forming agents containing psyllium. Some patients may improve with clonidine hydrochloride, an α_2-adrenergic agonist, which possibly stimulates an increase in intestinal fluid absorption by enhancing adrenergic activity [151]; however, this medication may induce hypotension. Other patients with suspected bacterial overgrowth may respond to cycled antibiotic therapy. Diarrhea control and biofeedback training [152] may provide complete or partial relief of fecal incontinence.

Severe constipation associated with colonic motor abnormalities [153] occurs in 20% of patients with diabetes and neuropathy. The onset of constipation is often insidious. Management includes the use of a variety of nonstimulant laxatives.

Patients with diabetes can develop chronic abdominal pain secondary to thoracic radiculopathy. The pain is present constantly, is unilateral, and may or may not be associated with paresthesia or hypesthesia. Antidepressant drugs such as amitriptyline or desipramine may help control painful diabetic neuropathy [154].

Diabetes may lead to a large, poorly functioning gallbladder that has a predilection for cholelithiasis [155]. Contrary to previous assumptions, patients with diabetes with acute cholecystitis may not have a substantially increased risk of complications compared with the general population [156]. Thus, diabetes mellitus is not an indication for prophylactic cholecystectomy.

Hepatomegaly and fatty liver are frequent findings, especially in patients with poorly controlled blood sugar, hyperlipidemia, and obesity. In a minority of such patients, nonalcoholic steatonecrosis can develop, presenting with mild elevation of transaminases. Progression to cirrhosis is recognized, but weight reduction and diabetes control can normalize liver tests [157].

Endometriosis

Endometriosis is defined as the presence of endometrial glands and stroma outside the uterine cavity and musculature. The disorder is common to women during the years they menstruate, and it is associated with severe perimenstrual lower abdominal pains and infertility. Since bowel function is commonly abnormal around the period, the pains can be difficult to distinguish from irritable bowel syndrome or diverticulitis. Most endometriosis takes the form of plaques of tissues on the serosal surface of the bowel lying in the pelvis in close proximity to the uterus and ovaries.

When intestinal endometriosis infiltrates into the deeper layers of the bowel, it can cause symptoms. Deeper infiltration can lead to obstruction of either the small or large bowel. Penetration of the mucosa can cause lower gastrointestinal bleeding, which may occur only during menstruation, but most patients do not characterize symptoms as cyclic. Treatment is surgical and bowel resection may be necessary if implants are deep [158,159].

Hyperparathyroidism

Hyperparathyroidism is a disorder of calcium and phosphate metabolism due to the excess secretion of parathyroid hormone. Primary hyperparathyroidism is caused by adenomatous or hyperplastic change in the parathyroid gland and may be associated with inherited multiple endocrine adenopathies (see below). Primary hepatic tumors have been reported to do this more commonly [160]. Secondary forms of the diseases occur when there is a tendency toward hypocalcemia, such as chronic renal failure. Symptoms that are probably consequences of high serum calcium concentrations include anorexia, nausea, vomiting, constipation, and abdominal pain. Hypercalcemia induces gastric hypersecretion, and likely predisposes to peptic ulcer formation [161]. Pancreatitis can develop when hypercalcemia is moderate to severe [162].

Hypoparathyroidism

Hypoparathyroidism, or low serum ionized calcium from whatever cause, can lead to neuromuscular irritability. Gastrointestinal manifestations can include abdominal pain, intestinal tetany, diarrhea, steatorrhea, and intestinal pseudoobstruction [163]. The steatorrhea may be secondary to pancreatic insufficiency due to insufficient endogenous cholecystokinin release following a meal.

Hyperthyroidism

Excessive circulating thyroid hormone causes hyperthyroidism. Although several disorders can induce this syndrome, 60%–80% of the cases are a consequence of Graves disease, an autoimmune disease. The symptoms of hyperthyroidism include nervousness, palpitations, heat intolerance, excessive perspiration, fatigue, weakness, dyspnea, and eye complaints. Despite having an enhanced appetite and hyperphagia, patients usually experience weight loss because of their hypermetabolic state [164]. The most common physiological effect on the gastrointestinal system is an alteration in gastric and intestinal motility, resulting in dyspepsia and shortened small bowel and colonic transit time [165]. This, as well as the increased consumption of fat, may result in steatorrhea and increased stool frequency, but rarely frank watery diarrhea. Hyperthyroidism should be excluded in all patients with new-onset diarrhea. There is also a high incidence of atrophic gastritis and hypochlorhydria or achlorhydria. Moderate to severe hyperthyroidism can be associated with hepatic dysfunction. Increases in blood alkaline phosphatase, transaminases, and bilirubin have been attributed to liver injury. In many cases, passive congestion of the liver secondary to heart failure could be the underlying mechanism [166]. Autoimmune-type thyroid diseases can flare up when chronic hepatitis is treated with interferon [167]. Propylthiouracil and methimazole, used in the treatment of thyrotoxicosis, can induce serious liver damage [168,169].

Hypothyroidism

Hypothyroidism results from a deficiency of thyroid hormone. Most cases are a consequence of thyroid gland dysfunction resulting from Hashimoto thyroiditis or therapy of hyperthyroidism. Symptoms include weakness, dry skin, swelling of the extremities, mental aberrations, coarse voice, paresthesias, and muscle cramps. Patients have a decrease in metabolism and experience anorexia with moderate weight gain. Motility is slowed throughout the gastrointestinal tract [165]. Intestinal transit is slowed, usually manifest as constipation and abdominal distention. Rarely, intestinal pseudoobstruction or megacolon results [170]. The gallbladder also may dilate and contract poorly.

Ascites, usually having a high protein concentration, is a rare complication of myxedema. It can be associated with histological changes in liver architecture suggestive of central congestive fibrosis, without congestive heart failure [171]. The ascites resolves after appropriate thyroid replacement therapy.

Granulomatous diseases

Granulomas are dynamic, usually focal inflammatory processes composed of macrophages and other inflammatory cell types. Many factors such as infectious agents, silica, metals complexed to macromolecules, and immune complexes can evoke a granulomatous response. Even when there is a known nidus, the cause of a granuloma is not always evident on histological examination.

Many infectious and noninfectious diseases are associated with granuloma formation in the liver and intestines (Table 109.4) [172,173]. The significance of these associations is complicated by the observation that granulomas are present in 3%–10% of liver specimens obtained at abdominal surgery or autopsy. The etiology of granulomas can, at times, be ascertained when bacteria, ova, or mineral crystals are identified within individual lesions. Some granulomas have distinctive morphology, such as the ring granuloma that is commonly found in hepatic Q fever, although ring granulomas have been described in other conditions [174]. Serological testing, culture of the involved tissue, or clinical presentation may provide the diagnosis in other circumstances.

In industrialized societies, the illnesses most commonly associated with hepatic granulomas are sarcoidosis and tuberculosis (see below) (Table 109.5). Primary biliary cirrhosis, drug-induced liver disease, and occasionally other primary liver diseases account for some of the remaining cases. In many patients, it is not possible to identify an etiological factor or an associated disease. Patients may be asymptomatic or may present with fever, fatigue, hepatosplenomegaly, and jaundice. Granulomatous hepatitis is suggested by a disproportionately high alkaline phosphatase with a normal biliary system on imaging. Diagnosis requires a liver biopsy that is cultured and examined histologically. The process rarely progresses to extensive hepatic fibrosis and cirrhosis, although sarcoidosis can lead to portal hypertension.

Causes of granulomatous inflammation of the intestines are less well characterized (see Table 109.4). In the United States, Crohn's disease and lymphoma are overwhelmingly the most frequent diagnoses, but a rare case of intestinal tuberculosis may be encountered. All these diseases can have a chronic course, presenting with abdominal pain, fever, fatigue, weight loss, diarrhea, and gastrointestinal bleeding. All have a predilection for the terminal ileum and can result in intestinal strictures [175].

When a specific cause of the granulomatous inflammation is defined, treatment is directed at eliminating the offending agent. Lesions that defy diagnosis or which are of unknown cause present special problems. Many patients are asymptomatic and require no therapy. Unusual conditions such as

idiopathic granulomatous hepatitis frequently respond to corticosteroid administration.

Sarcoidosis

Sarcoidosis is a systemic disorder that is characterized by noncaseating granulomas in pathological specimens. The age-adjusted annual incidence of sarcoidosis in the United States is 10.9/100 000 for whites and more than three times higher in African Americans. In addition, the disease affects blacks more acutely and more severely than people of other races. Genetic factors appear to play a part in the pathogenesis as it is likely that the host develops an exaggerated cellular immune response and the formation of granulomas when exposed to a variety of antigenic stimuli [176].

Although the most common sites of involvement are the lungs and the intrathoracic lymphatic system, evidence of the disease in the liver will be found in 40%–70% of cases. Hepatic sarcoidosis is usually manifest by fever, hepatomegaly, and

elevated alkaline phosphatase, and may be the most obvious clinical manifestation when pulmonary disease is subtle [176,177]. Typically the noncaseating granulomas are scattered throughout the liver, but confluent granulomas may be present. It is in the patient with severe hepatic sarcoidosis and confluent granulomas that scarring, portal hypertension, and hepatic dysfunction can result. A chronic cholestatic syndrome mimicking primary biliary cirrhosis is due to a granulomatous cholangiopathy with consequent ductopenia. Imaging studies may be normal, show a diffuse hepatopathy, demonstrate nodular lesions that can be mistaken for malignancy, and rarely show extrahepatic biliary obstruction due to lymphadenopathy or bile duct strictures [178,179]. Treatment commonly uses steroids, but progression to cirrhosis and liver failure many ensue. Liver transplantation can be considered, but recurrence of sarcoidosis in the allograft is the norm [180].

Although symptomatic disease in the liver, spleen, and abdominal lymphatics is common in sarcoidosis, involvement of the gastrointestinal tract is rare. The stomach is the most common site and may be defined by thickened gastric folds, nodularity, ulcers, or erosions [181]. As small bowel and colon disease is so rare, the demonstration of typical granulomatous ileocolitis in a patient with known sarcoidosis should still be followed and treated as presumed Crohn's disease.

Tuberculosis

Approximately one-third of the world's population is infected with the causative organism of tuberculosis (TB), *Mycobacterium tuberculosis*, with over 8 million new cases annually. Despite an average annual decline in incidence in the United States of 5.8%/year from 1953 to 1985, the number of new cases of tuberculosis increased 20% over the next 7 years as a result of the HIV/AIDS epidemic and immigration, and diminished TB control [182]. Although extrapulmonary TB occurs in about 20% of cases, in the United States the gastrointestinal tract is involved in only 2% [183].

Tuberculosis may involve any portion of the gastrointestinal tract. At presentation, abdominal pain, fever, and weight loss are the most common symptoms, and have usually been present for months. A mass is palpable in the right lower quadrant in 25% of cases. In the United States, Crohn's disease, colon cancer, lymphoma, and even amebiasis will be considered before TB. As the therapy for Crohn's disease (e.g., anti-TNF-α therapy) can suddenly worsen TB, the importance of considering TB in the differential diagnosis is evident. The diagnosis of tuberculosis should be considered if the disease has been documented elsewhere in more typical locations (e.g., the chest radiograph shows characteristic lesions, exudative ascites and peritoneal disease are recognized, tubercular tuboovarian disease is present) in a high-risk patient (e.g., malnourished, immigrant from a developing

country, a patient with AIDS, an alcoholic patient). Tubercular granulomas may have distinct histological features: They tend to coalesce and are larger than 400 μm; they often contain giant cells that are numerous and large; and caseation, although rare in the liver and intestine, should suggest tuberculosis. In the unusual case, histological staining, polymerase chain reaction (PCR), or culture may identify acid-fast bacilli. Treatment follows accepted protocols [184–186].

Peritoneal disease with ascites is common in countries in which TB is endemic. In the United States, TB peritonitis is associated with poverty, homelessness, alcoholism, and malnutrition. Abdominal distention, fever, weight loss, and abdominal pain in a patient with the appropriate risk factors should raise the suspicion for the disease. The chest radiograph will be abnormal in 50%, but active pulmonary TB will be present in only 15%. Paracentesis will usually show a high protein (> 2.5 g/dL) fluid with a low albumin gradient (< 1.1 g/dL). Examination of the fluid for acid-fast bacilli is positive in less than 3% of cases, and cultures are positive in 20%. Adenosine deaminase activity > 33 U/L has excellent sensitivity and specificity. In nonendemic countries, laparoscopy with peritoneal biopsies may be needed for diagnosis, whereas a therapeutic trial is commonly employed in areas with a higher prevalence of TB [187].

Heavy metal toxicity

Arsenic poisoning

Arsenic poisoning is endemic in many parts of the world, including North America, as a result of environmental contamination. Arsenic compounds continue to be used commercially, particularly in the preservation of wood, mining, and the manufacture of glass and metal [188].

Acute arsenic poisoning results in a reversible inactivation of sulfhydryl-containing enzymes. Cellular oxidative processes are blocked and tissue hypoxia ensues. Patients present with severe colicky abdominal pain, nausea, vomiting, profuse diarrhea, malodorous ("garlicky") breath, dysphagia, hepatomegaly, jaundice, and circulatory collapse. Quantities of 100–300 mg may be fatal in an adult. Quantitative measurement of 24-h urinary arsenic excretion is the only reliable test to confirm arsenic poisoning. Treatment includes gastric lavage, chelation therapy (e.g., British anti-Lewisite [BAL, dimercaprol] or D-penicillamine), and cardiorespiratory support [188].

Chronic arsenic toxicity often manifests as nonspecific symptoms, including weakness, nausea, diarrhea, or constipation. Macular skin pigmentation, leukoderma, keratotic lesions of the palms and soles, pancytopenia, edema, peripheral vascular disease, neuropathy, cirrhosis, and accompanying presinusoidal portal hypertension may appear alone or in combination [189,190]. The diagnosis of chronic arsenic intoxication is made by measuring arsenic levels in tissue samples (e.g., hair, nails). An association with cutaneous, hematological, respiratory, and hepatic malignancies (angiosarcoma) has also been suggested [191].

Gold

Gold preparations (e.g., gold sodium thimalate, auranofin) have long been used as disease-modifying treatment of rheumatoid arthritis. Adverse effects include aplastic anemia, proteinuria, rash, stomatitis, and diarrhea [192]. The last effect is particularly common with auranofin, an oral preparation that increases intestinal permeability and decreases intestinal transit time.

Rarely, gold can induce a severe enterocolitis, with markedly ulcerated small and large intestinal mucosa. The clinical picture can mimic ulcerative jejunoileitis seen in celiac sprue, or small intestinal lymphoma. The clinical course may be protracted and, if the relationship to gold therapy is not appreciated, there may be a need for laparotomy. Gold should be withdrawn as soon as the condition is recognized. Severe, reversible cholestatic hepatitis has also been reported [193].

Lead poisoning

Lead poisoning remains the most common form of heavy metal intoxication, often producing vague, nonspecific, and transient symptoms. Inner-city children in major metropolitan areas are at particularly high risk of lead-based paint ingestion. The diagnosis should be considered in patients with abdominal complaints and a history of occupational or environmental exposure, such as ingestion or removal of lead-based paints, manufacture of batteries or jewelry, welding, automobile radiator repair, and eating from painted dishes acquired abroad [194].

Common symptoms include recurrent severe abdominal pain (lead colic), oral ulcers, constipation, stocking–glove paresthesias, psychiatric symptoms, and a metallic taste in the mouth. Physical findings include a gingival lead line (absent in edentulous patients) and peripheral neuropathy. Anemia and renal dysfunction also may be evident at presentation [195]. Lead inhibits enzymes involved in the synthesis of heme, and secondary porphyria, characterized by elevated ALA and other porphyrin metabolites in the urine, may result.

Blood lead concentrations are an unreliable predictor of body lead stores, as they reflect only recent exposure. The diagnosis of lead intoxication is best established by measuring 72-h urine lead levels after administration of calcium disodium edetate [196]. Treatment of lead poisoning with parenteral or oral [190] chelating agents is usually successful if the diagnosis is made in time.

Hematological disorders

Hemoglobinopathies

Sickle cell anemia is an autosomal recessive disease of hemoglobin synthesis (hemoglobin SS). Eight percent of the

African American population of the United States are heterozygotes; hence, as many as 15 of every 100 000 African Americans may be affected. Under conditions of low oxygen tension, erythrocytes containing hemoglobin SS deform (sickle), and become lodged in capillary beds, causing widespread venous congestion, thrombosis, and microinfarction and leading to the clinical vasoocclusive "crisis" [197].

In addition to diffuse pains throughout the long bones of the body, abdominal pain and intestinal ileus are common during the acute crisis. It is often difficult to distinguish a sickle cell crisis from other gastrointestinal emergencies such as cholecystitis, appendicitis, bowel infarction, and bowel obstruction. Moreover, these intraabdominal illnesses themselves may provoke a sickle cell crisis. The absence of bone or pleuritic pain is suggestive of a primary intraabdominal cause. Sickle cell crises often resolve in less than 4 days. Hence, abdominal symptoms of longer duration also should raise the possibility of a primary abdominal illness [198].

Acute crisis can selectively affect the liver with hepatic infarcts, causing pain, fever, and transaminase elevation. Chronic sickling causes cholelithiasis, cholecystitis, and chronic passive congestion. The common use of hypertransfusion programs to lower the risk of recurrent stroke places these patients at high risk of hemosiderosis [199]. A combination of these factors can lead to progressive liver injury, with significant fibrosis and cirrhosis developing by adulthood [200]. Splenomegaly is frequent in the early stages of the disease, but "autosplenectomy," caused by repeated splenic infarctions, often results in a shrunken, fibrotic, or calcified spleen. Hyposplenism will be documented by the presence of Howell–Jolly bodies in the peripheral blood smear and signals an increased risk from encapsulated organisms, such as pneumococci and bacteroids [197].

Patients with beta-thalassemia are characterized by a relative overproduction of alpha-globin chains, consequent ineffective hematopoiesis, and severe anemia. Current therapy has depended on transfusion therapy. Iron overload of tissue, which is fatal if not treated, is the most important complication of this disease. In patients not receiving transfusions, the enormous erythroid expansion leads to abnormally regulated iron absorption and increases in body iron burden ranging from 2 to 5 g per year. Regular transfusions may double this burden [201]. Iron-induced liver disease, often aggrevated by chronic hepatitic C, is a common cause of death in adults. This can be delayed by adequate deferoxamine therapy monitored by frequent quantitative measurement of liver iron stores with liver biopsy [202].

Hemolytic uremic syndrome/thrombotic thrombocytopenic purpura

The hallmarks of the hemolytic uremic syndrome (HUS) are hemolysis, thrombocytopenia, and acute renal failure. Although most common in children, all age groups are affected because thrombotic thrombocytopenic purpura (TTP) is likely the same illness manifesting with fever and central nervous system sequelae in patients over 40 years of age. Both are now grouped under the thrombotic microangiopathies. Antecedent gram-negative enteric infections with *Salmonella*, *Shigella*, and *Campylobacter* species have been associated with HUS/TTP [203]. In the past decade, verotoxin-producing strains of *Escherichia coli*, especially serotype O157:H7, appear to be responsible for most reported cases. It must be remembered that only a small minority (5% of patients with symptomatic enteritis in a recent outbreak) of patients with these foodborne illnesses develop HUS/TTP [204]. Thrombotic thrombocytopenic purpura has also been reported in some patients undergoing solid organ transplantation, associated with the use of cyclosporine (ciclosporin) or tacrolimus [205].

The pathophysiology connecting enteric infections and medications with the hematological consequences is poorly understood. The cellular pathogenesis of both HUS and TTP appears to involve diminished activity of the von Willebrand factor-cleaving protease (ADAMTS13), leading to an accumulation of ultralarge von Willebrand factor multimers [206,207]. Endothelial cell injury (perhaps mediated by endotoxins or cytokines) followed by thrombotic microangiopathy in the glomerulus and the gastrointestinal mucosa are consistent features (Fig. 109.5) [208,209]. Similar thrombotic angiopathy has been reported in gastric antral vascular ectasia syndrome (GAVE) (see Chapter 112). Thus, TTP should be included in the differential diagnosis of patients with endoscopic changes of GAVE and in whom biopsies show microscopic thromboses [210].

The spectrum of gastroenterological symptoms ranges from gastroenteritis, through segmental colitis mimicking Crohn's disease or ischemia, to fulminant colitis with toxic megacolon or colonic perforation. Bowel disease almost always

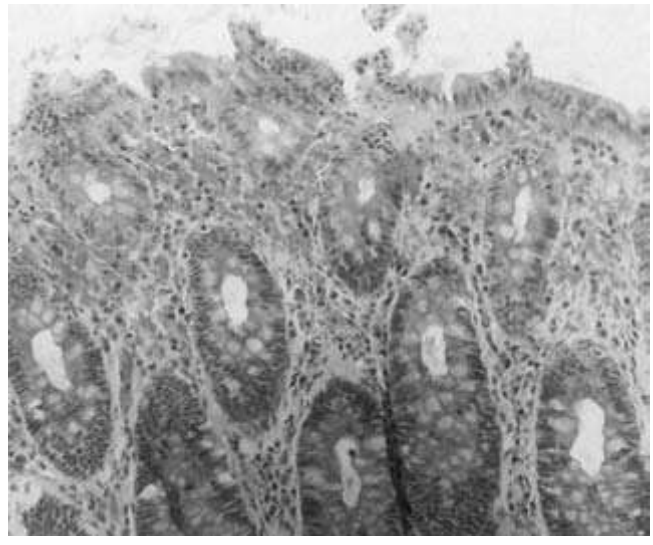

Figure 109.5 Colonic biopsy specimen from a patient with hemolytic uremic syndrome shows intravascular coagulation and thrombotic microangiopathy. (H & E stain; original magnification × 16.)

precedes the development of HUS [209]. The disease is usually self-limited, although the course may be prolonged, and fatalities occur. There is now evidence that early treatment of the enteric infection with antibiotics increases the risk of developing HUS/TTP, and should be avoided [211]. Treatment focuses on general support and dialysis when needed. In adults with neurological changes (e.g., TTP) plasmapheresis can be life-saving [208,209].

Hypercoagulable states

Hypercoagulability is an important cause of gastrointestinal morbidity. Spontaneous thrombosis of the mesenteric veins can cause intestinal ischemia and infarction (see Chapter 114) while thrombosis of the portal vein can lead to portal hypertension and variceal hemorrhage (see Chapters 32 and 128) and of the hepatic veins can result in ascites and the Budd–Chiari syndrome (see Chapter 44). Oral contraceptives, pregnancy, SLE, myeloproliferative disorders (see below), cancer, and surgery all are associated with a hypercoagulable state and a consequent propensity for venous thrombosis. Antithrombin III deficiency [212] and protein C deficiency are inherited (autosomal dominant) disorders associated with recurrent venous thrombosis. Factor V Leiden mutation, resulting in thrombophilia attributable to activated protein C resistance, has been associated with small bowel infarctions [213], hepatic vein occlusion during pregnancy [214], and an increased risk of venous thrombosis in patients with inflammatory bowel disease [215]. Once the cause is identified, most affected patients require lifelong therapy with warfarin to prevent recurrent vascular catastrophe.

Hypocoagulable states

Deficits of coagulation factors

Deficiencies of coagulation factors may be inherited or acquired and when severe are associated with bleeding tendencies. The best known of the inherited factor deficits is hemophilia A, an X-linked disorder of factor VIII synthesis. Other inherited forms include hemophilia B (Christmas disease or factor IX deficiency) and factor XI deficiency. Gastrointestinal bleeding occurs in all these diseases. It may be mucosal, intramural, or intraabdominal and may involve virtually any part of the gastrointestinal tract. Bleeding can be spontaneous or follow trauma or surgery. Upper gastrointestinal hemorrhage has multiple potential causes in these patients, including varices, because of the increasing incidence of chronic liver disease from blood-borne hepatitis viruses. If deemed important in the management of such patients, transjugular liver biopsy can be performed safely [216]. Endoscopy can be undertaken safely in hemophiliac patients after correction of factor VIII level to 0.4 U/mL [217,218].

Platelet abnormalities

Platelet defects also may result in severe bleeding diatheses that manifest as gastrointestinal bleeding. von Willebrand disease, the Bernard–Soulier syndrome, and Glanzman thrombasthenia are inherited diseases of platelet adhesion and aggregation associated with prolonged bleeding times. Aspirin and other drugs (e.g., penicillins, cephalosporins) interfere with platelet function by irreversibly inhibiting COX-1 activity and prolong the bleeding time for up to 5–7 days [219]. The importance of these drugs in reducing morbidity and mortality after heart attack, stent placement, and stroke is clear, and they should be stopped prior to endoscopy only with extreme caution.

Plummer–Vinson–Kelly syndrome

The Plummer–Vinson–Kelly syndrome is characterized by dysphagia, esophageal webs, and iron deficiency anemia. Middle-aged women are most commonly affected. Glossitis, dyspepsia, atrophic gastritis, diarrhea, hoarseness, and paresthesias are frequently present [220]. An association with postcricoid esophageal cancer has been reported. The syndrome is rarely seen, which may reflect the improved identification and treatment of iron deficiency anemia.

Metabolic disorders

Capillary leak syndrome

Capillary leak syndrome is a rare episodic illness of variable severity characterized by increased small vessel permeability and fluid shifts [221]. Its association with systemic toxicity, sepsis, and administration of a number of recombinant protein medications, including interleukin 2 and granulocyte–macrophage colony-stimulating factor (GM-CSF), supports the contention that it is mediated directly by cytokines [221,222]. In addition to edema, hemoconcentration, hypotension, and a monoclonal gammopathy, patients can experience severe nausea, vomiting, and diarrhea secondary to impaired fluid absorption in the gastrointestinal tract. Therapy with aminophylline and terbutaline has been reported to ameliorate the syndrome in some patients [223].

Systemic amyloidoses

The systemic amyloidoses are a group of diseases characterized by the widespread extracellular deposition of insoluble fibrillar proteins. Classification of amyloidosis is based on the precursor plasma proteins that form the fibril deposits. Two types of primary systemic amyloidosis are recognized: AL (immunoglobulin light chain related in patients with plasma cell dyscrasia) and ATTR (familial transthyretin associated). Secondary amyloidosis is formed from serum amyloid A, an acute-phase reactant formed in response to inflammation. It is termed AA and caused by chronic infectious or inflammatory diseases, such as tuberculosis and rheumatoid arthritis [224].

The range of organs infiltrated is greatest in AL amyloidosis, with the kidney and heart most commonly involved. The

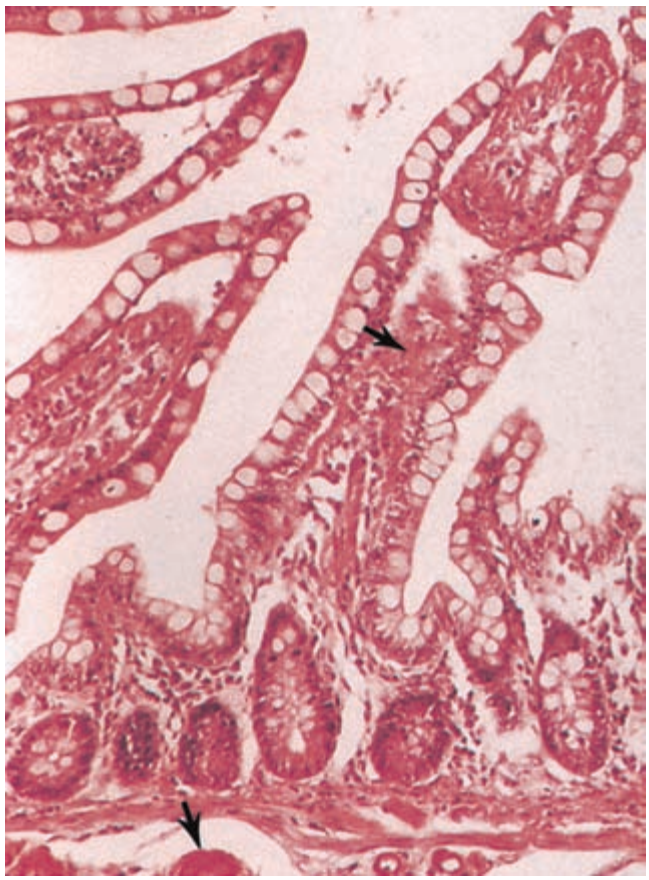

Figure 109.6 Amyloid infiltration of the small intestine (arrows). (Congo red stain; original magnification × 200.)

gastrointestinal tract may be involved at any site. Infiltration of the tongue results in macroglossia, a feature that is uncommon in the ATTR and AA forms of the disease. Gastric infiltration can produce prominent gastric folds, but resulting gastric outlet obstruction, ulcer, and bleeding are uncommon [225].

Amyloid can accumulate in the intestine and mesentery, causing coarsening of the valvulae conniventes (Fig. 109.6), retroperitoneal fibrosis, protein-losing enteropathy, and intestinal obstruction. Autonomic dysfunction can lead to stasis, bacterial overgrowth, and malabsorption [226]. This is also a common feature of the ATTR type. Intestinal ischemia has also been reported [227].

High alkaline phosphatase can signal amyloid deposition in the liver. Hepatomegaly but not splenomegaly is common in AL amyloidosis [228]. Hepatosplenomegaly is more common in AA amyloidosis, but liver failure and portal hypertension are uncommon [229]. Ascites may result from nephrotic syndrome-induced hypoproteinemia. Pancreatic involvement occasionally produces exocrine pancreatic insufficiency and steatorrhea.

The diagnosis of amyloidosis is based upon clinical suspicion and tissue biopsy of the affected organ. A safe and simple procedure, obtaining a sample of subcutaneous fat, has replaced the blind rectal biopsy recommended in the past. Treatment of the underlying disease process, if present, may result in amyloid regression, but this is not the rule. Stem cell transplant after high-dose chemotherapy is helpful in selected patients [230].

Neoplastic disorders

Cancer cachexia

Cancer cachexia, a common manifestation of advanced neoplasms, is characterized by marasmus with anorexia, early satiety, weight loss, anemia, and edema (see Chapter 49). Nutritional evaluations find an elevated basal metabolic rate and increased energy expenditure associated with systemic catabolism of muscle and adipose tissue [231]. Such tumor-induced, treatment-related malnutrition is the proximate cause of death in 20%–30% of patients with cancer, but it also complicates the delivery of adequate antineoplastic therapy and markedly impairs the quality of life [232].

In exploring the cellular mediators of cancer cachexia, two groups of compounds have been suggested. Materials produced by tumors with hormone-like properties that result in the direct catabolism of host tissues, such as angiotensin II and proteolysis-inducing factor (PIF), form one group [233,234]. The second group is the proinflammatory cytokines such as tumor necrosis factor alpha, interleukin 6 (and 1), and gamma-interferon [235].

The literature regarding the efficacy of nutrition support in cancer patients has been critically reviewed, and no clear benefit was found [236]. Megestrol acetate [237] and eicosapentanoic acid [234] have been shown to improve appetite and modestly increase weight.

Consequences of chemotherapy

Constipation

Patients with cancer commonly develop constipation as a consequence of factors such as decreased physical activity, reduced fluid intake, depression, drugs used in treatment, and changes in diet. Effective pain management may lead to the use of potent narcotics, all of which lead to constipation. Close attention to bowel function as opioids are being started will reduce the number of later problems with obstipated and impacted patients, who occasionally require hospital admission [238]. Metabolic disorders and intestinal luminal narrowing secondary to tumor growth or radiotherapy can also cause constipation. Constipation may result from hypercalcemia related to ectopic production of parathyroid-like hormone by neoplasms. Rarely, malignancy, particularly small cell carcinoma of the lung, produces a paraneoplastic visceral neuropathy that results in aberrant motor activity throughout the gastrointestinal system [239].

Although attention to diet is important, there are limitations to the amount of fibrous food the cancer patient will

tolerate. Reversal of established opioid constipation requires agents that increase peristalsis, such as senna derivatives (see Chapter 41), but polyethylene glycol can also be effective.

Diarrhea

Diarrhea is common immediately after potent chemotherapy. In adults, diarrhea may be a self-limited consequence of mucositis, but other causes need to be considered. *Clostridium difficile* colitis is a common cause. The spore-forming organism is found on the environmental surfaces of oncology units [240], and antibiotics are ubiquitous. Because sigmoidoscopy is avoided in neutropenic patients, identification of the toxin-forming *C. difficile* in stools should lead to treatment with metronidazole or vancomycin. In uncomplicated cases (no fever no blood in stool, negative cultures and toxin assays) loperamide up to 16 mg a day can reduce the frequency of diarrhea [241].

Mucositis

Damage of the oral and gastrointestinal mucosa (mucositis) is a common accompaniment of current chemotherapy regimens, and frequently leads to severe pain, inanition, diarrhea, and increased risk of severe infection. The pathobiology of the lesion is unknown, although a number of growth factors are currently under study and show promise. Currently, standard therapy includes close attention to oral hygiene, analgesia, infection identification and management, and the provision of parenteral nutrition when required [242].

Nausea and vomiting

Nausea and vomiting, common after chemotherapy, exacerbate inanition and malnutrition. Inadequate management of these symptoms is a common reason for discontinuation of potentially effective chemotherapy or the unwanted conversion of outpatient to inpatient chemotherapy. Cancer chemotherapy causes two main phases of vomiting: an intense, acute phase of emesis that occurs almost immediately following administration of anticancer drugs; and a delayed phase of nausea and vomiting of longer duration [243]. It appears that the acute vomiting is mediated by serotonin (5-hydroxytryptamine, 5-HT) binding to 5-HT3 receptors in the central nervous system, triggering emesis. High doses of intravenous 5-HT3 receptor antagonists (e.g., ondansetron, granisetron, dolasetron, palonosetron) with dexamethasone are most effective in treating acute-phase vomiting [244]. The addition of an oral neurokinin-1 antagonist (aprepitant) to this regimen has been found to decrease delayed vomiting and improve response with subsequent cycles of a highly emetogenic cisplatin-based chemotherapy [245]. A wide variety of antiemetics of differing effects and costs is available to the clinician [246]. Because the cost of newer pharmaceuticals needs to be matched against the increased total cost of therapy, and new drugs outpace the publishing industry, readers may find this frequently updated approach to acute and delayed emesis at the website of the National Comprehensive Cancer Network (www.nccn.org/professionals/physician_gls/PDF/antiemesis.pdf) valuable.

Anticipatory vomiting can be difficult to control once initiated. The development of emesis induced by the sights and sounds of the setting in which chemotherapy is provided is more likely to occur in patients with pretreatment anxiety, posttreatment dizziness, delayed nausea and vomiting, and severe nausea and vomiting [247]. Behavioral therapy has been shown to be effective once anticipatory vomiting has developed [248].

Hematological malignancies

Heavy-chain diseases

The heavy-chain diseases are rare lymphoplasma cell proliferative disorders associated with the production of abnormal monoclonal heavy chains without associated light chains. α-Heavy-chain disease (Mediterranean lymphoma), the most common of these entities, is seen in two forms: pulmonary and enteric. The former is more common in the United States, and it rarely exhibits gastrointestinal manifestations. The latter is found principally in the Mediterranean region. Infiltration of the small intestine and abdominal lymph nodes by malignant B cells and α-heavy chains produces abdominal pain and masses, vomiting, weight loss, malabsorption, steatorrhea, and hypocalcemia [249]. Additional complications include obstruction, intussusception, and intestinal perforation. Diagnosis is established by small bowel biopsy. If diagnosed early in the course of disease antibiotics can be helpful [250].

Leukemias

Both acute and chronic leukemias can involve the gastrointestinal tract. The gastrointestinal manifestations result chiefly from leukemic infiltration of the luminal gut and liver, or they are a consequence of therapy. Gingivitis is caused by leukemic invasion of the gums and causes oral pain and bleeding. Leukemic infiltration of the esophagus, stomach, intestine, or colon produces mucosal or intramural lesions that may cause dysmotility, obstruction, bleeding, or enterocolitis [251]. Hepatosplenomegaly and portal hypertension are additional complications of leukemic infiltration. Rarely, an illness indistinguishable from fulminant hepatitis occurs [252]. Subcapsular splenic hemorrhage and splenic rupture have been reported, particularly in acute lymphoblastic leukemia [253].

Induction chemotherapy for leukemia can induce an often fatal syndrome characterized by acute abdomen, paralytic ileus, diarrhea, and gastrointestinal bleeding. Development of this syndrome often is attributed to neutropenic enterocolitis or typhlitis, a severe inflammatory process that involves the distal small bowel, cecum, or appendix (Fig. 109.7) [254]. The etiology of the disease is unknown. Diarrhea (sometimes bloody), right lower quadrant pain or tenderness, nausea, and vomiting are the usual presenting features, developing

Figure 109.7 Typhlitis involves terminal ileum and cecum in a patient with acute myelogenous leukemia.

over hours to days. The differential diagnosis includes infectious colitis caused by *C. difficile*, cytmegalovirus (CMV), and other organisms, appendicitis, Ogilvie syndrome, and ischemia. Patients at risk must be observed carefully for evidence of perforation.

Lymphoma

As many as 10% of patients with non-Hodgkin lymphoma originating from a nongastrointestinal site develop involvement of the gastrointestinal tract [255]. Obstruction, bleeding, abdominal masses, and perforation are among the more frequently recognized clinical features. Invasion of the liver and spleen is frequent, commonly presenting with fever and elevated alkaline phosphatase. Lymphoma in the liver can mimic acute hepatitis and fulminant hepatic failure [256]. Mantle cell lymphomas can present as multiple lymphomatous polyposis and resemble the familial adenoma syndromes until biopsy is obtained [257]. Primary digestive tract lymphoma of the stomach (see Chapter 67) and the intestine (see Chapter 78) are discussed elsewhere.

Clinically evident gastrointestinal involvement in Hodgkin disease is infrequent, although a substantial proportion of patients who die from this illness are found at autopsy to have hepatic involvement (Fig. 109.8) [258]. Presinusoidal portal hypertension can result from either increased intrahepatic blood flow as a consequence of splenomegaly or intrahepatic infiltration with malignant cells. When the luminal gut is involved, thickened mucosal folds are common (Fig. 109.9).

Multiple myeloma

Multiple myeloma results from a monoclonal neoplastic proliferation of plasma cells and usually affects middle-aged and older people. Osteolytic lesions of the skeleton, hypercalcemia, anemia, monoclonal gammopathy, and renal disease are characteristic findings. When the gastrointestinal tract is invaded, plasmacytomas form, with attendant abdominal pain, ulceration, bleeding, or obstruction. The lesions can be detected radiographically or endoscopically [259] and may look like peptic ulcer disease or colon cancer. Amyloidosis is a well-recognized complication of myeloma (see section on metabolic diseases). Involvement of the liver and spleen results in hepatosplenomegaly and, rarely, portal hypertension. Jaundice can be caused by infiltration of the liver parenchyma or obstruction of the biliary tree [260].

Figure 109.8 Hodgkin disease infiltrating the liver. Reed–Sternberg cells are present (arrows). (H & E stain; original magnification × 25.)

Myeloproliferative disorders

Myelofibrosis with myeloid metaplasia is associated with bone marrow fibrosis and extramedullary hematopoiesis in the spleen and liver, and presents with marked hepatosplenomegaly and progressive anemia. Portal hypertension, associated with ascites or variceal hemorrhage, occurs in about 7% of patients. The portal hypertension can be

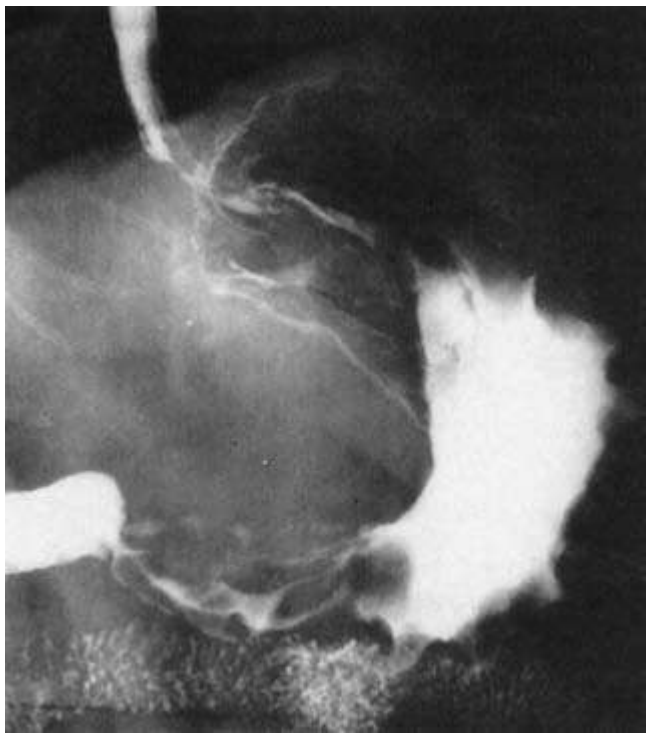

Figure 109.9 Hodgkin disease infiltrating the stomach. Thick folds in antrum and fundus.

due to the increased portal flow through the enlarged spleen and obliteration of small portal venules, and is resolved with splenectomy. Patients can also develop acute left upper quadrant abdominal pain due to splenic infarction [261].

Paroxysmal nocturnal hemoglobinuria is characterized by intravascular hemolysis that is manifest by episodes of hemoglobinuria and life-threatening venous thrombosis. In a large cohort of such patients seen over a 30-year period at one hospital [262], the most common sites of venous thrombosis were the hepatic and mesenteric veins. This was also the most common cause of death. All such patients should be on long-term anticoagulation.

Polycythemia vera affects middle-aged people and is characterized by an increased red cell mass. Many patients have associated thrombocytosis. The erythrocytosis and hyperviscosity syndrome lead to plethora, headache, vertigo, dizziness, visual disturbances, vascular ischemia, and venous thrombosis [263]. Budd–Chiari syndrome may develop as a consequence of hepatic vein thrombosis. Hepatosplenomegaly resulting from extramedullary hematopoiesis and bleeding esophageal varices secondary to portal vein thrombosis and increased blood flow through the giant spleen are described.

Primary or essential thrombocytosis is characterized by platelet counts greater than $10^6/mm^3$ but without an increase in the red cell mass. This condition must be differentiated from the secondary thrombocytosis that accompanies inflammation and iron deficiency. Platelet aggregation defects predispose to gastrointestinal bleeding or thrombosis. Hepatosplenomegaly is evident in many patients [264] and is caused by extramedullary hematopoiesis or Budd–Chiari syndrome.

Waldenström macroglobulinemia

Waldenström macroglobulinemia is an IgM-secreting variant of multiple myeloma that is characterized by the presence of macroglobulin (monoclonal IgM) in the serum. Osteolytic lesions are seen less commonly than in myeloma, whereas lymphadenopathy and hyperviscosity are more prominent. Massive hepatosplenomegaly results from infiltration by plasma cells. The deposition of large amounts of IgM in the intestinal lamina propria and mesenteric lymph nodes can impair absorption [265], resulting in diarrhea and steatorrhea.

Nonhematological malignancies

Gynecological malignancies

The treatment of cancer of the cervix, depending on stage of disease, usually involves a combination of a hysterectomy, chemotherapy, and radiation therapy. Because any invasion of the bowel can abort attempts at exenteration procedures [266], a change in bowel habit or blood in the stool should lead to a colonoscopy before operation. Most gastrointestinal consequences of cervical cancer relate to the sequelae of radiation therapy. The risk of more severe radiation-induced bowel complications, such as obstruction or fistula formation, is doubled when adjuvant radiotherapy follows, rather than precedes, hysterectomy [267]. Although most radiation-induced bowel disease occurs in the first 2 years after radiotherapy, illness can occur at any time in the next several decades (see Chapter 115).

Ovarian cancer can produce gastrointestinal complications by local extension and frequently encases the abdominal viscera. Intestinal obstruction, either because of direct invasion of bowel by peritoneal metastases or as a consequence of radiotherapy, is a common and disabling clinical complication [268]. In many terminally ill patients, palliation of vomiting can be a distressing management problem that is beyond the capabilities of reconstructive surgery. Options for palliation include the use of a percutaneous endoscopic gastrostomy for venting [269] and the use of intraluminal stents to bypass extrinsic compression [270]. Refractory malignant ascites also can be an important cause of ovarian cancer morbidity, requiring repeated paracentesis.

Metastases to the ovary from gastrointestinal malignancies (Krukenberg tumors) may be difficult to distinguish from primary ovarian cancer by noninvasive imaging modalities. Typically, these tumors are bilateral, asymmetrically large, and solid. Almost all are mucinous signet ring tumors from the stomach, pancreas, and colon, all with poor prognosis [271].

Malignant melanoma

Malignant melanoma is a common malignancy whose prevalence is increasing. Although metastases to the gastrointestinal

tract are commonly revealed at autopsy, fewer than 9% of melanoma patients are diagnosed with gastrointestinal involvement while living [272]. The small intestine, stomach, and colon are most commonly involved, but the liver, pancreas, and gallbladder also can be affected. Although most patients remain asymptomatic, complications include abdominal pain, anorexia, gastrointestinal hemorrhage, and intestinal perforation. In appropriate circumstances, surgical intervention to alleviate significant gastrointestinal complications is warranted and may prolong survival [273].

Mastocytosis

Mastocytosis is a rare disorder characterized by the clonal proliferation of mast cells into the skin (urticaria pigmentosa) and other organs, including the intestines and liver. Common symptoms are headache, pruritus, flushing, dizziness, wheezing, and tachycardia. Serum tryptase and urinary histamine excretion are elevated. Gastrointestinal dysfunction develops more commonly than previously thought, resulting in abdominal pain, nausea, diarrhea, fecal urgency, malabsorption, gastritis, and peptic ulcers [274]. Rubbing cutaneous lesions or drinking alcohol may precipitate symptoms. Symptoms probably develop secondary to the release of many mast cell products, such as histamine, leukotrienes, and platelet-activating factor. Many patients have liver disease, manifested by hepatosplenomegaly, portal hypertension with ascites, and abnormal liver tests. Liver biopsy shows portal fibrosis, nodular regeneration, and venoocclusive disease. Diagnosis and therapy are controversial and should be performed in centers capable of genetic analysis of bone marrow [275].

Metastatic disease to the gastrointestinal tract

Intestinal metastasis from tumors originating in locations outside the gastrointestinal system can induce significant symptoms. Abdominal pain, obstruction, and bleeding are common consequences. Other than melanoma, malignancies derived from organs such as the breast, lung, and thyroid [276] can metastasize to the intestines and on occasion are diagnosed by endoscopic biopsies. In approximately half of patients with Kaposi sarcoma, an accompaniment of AIDS, intraoral or intestinal involvement develops (Fig. 109.10) [277].

Renal cell carcinoma

Renal cell carcinoma (hypernephroma) can directly invade into, or metastasize to, the intestinal tract, causing bleeding [278] and obstruction. Resection of the primary tumor has been associated with regression of metastatic lesions. Nonmetastatic hepatic dysfunction (Stauffer syndrome) is usually manifest by abnormal alkaline phosphatase and prolongation of the prothrombin time [279], and it is associated with hepatic sinusoidal dilation [280]. It is possible that in some cases the elevated phosphatase derives from the tumor itself and does not denote hepatic dysfunction.

Figure 109.10 Kaposi sarcoma of the lower extremities.

Neuromuscular disorders

Autonomic dysfunction

The autonomic nervous system supplies every organ in the body, and dysfunction is associated with orthostatic hypotension, erectile problems, urinary retention, and temperature deregulation. Abnormal gastrointestinal function of the sympathetic and parasympathetic pathways in primary neurological disorders such as Parkinson disease, pandysautonomia, and paraneoplastic syndrome is manifested by vomiting, small bowel bacterial overgrowth, intestinal pseudoobstruction, fecal incontinence, and constipation (Table 109.6) [281,282]. A number of gastrointestinal diseases can produce dysautonomic symptoms, particularly advanced liver disease [283]. Antibodies to ganglionic acetylcholine receptors have been found in a group of patients with idiopathic dysautonomia, suggesting an autoimmune etiology for some [284].

A common association with the neurological diseases characterized by autonomic dysfunction is postprandial hypotension. Marked reduction in blood pressure after a meal may result in syncope, weakness, angina pectoris, nausea, and falls. The pathophysiology is complex and includes inadequate sympathetic nervous system compensation for meal-induced splanchnic pooling of blood, impaired baroreflex

Table 109.6 Gastrointestinal manifestations of neuromuscular disorders

Disorder	Symptoms	Causes
Amytrophic lateral sclerosis	Dysphagia with aspiration and inanition	Oropharyngeal dysfunction
Autonomic dysfunction	Vomiting; bloating	Decreased gastric emptying
Small bowel bacterial overgrowth	Constipation	Small bowel/colonic pseudoobstruction
Dementia syndromes	Dysphagia, aspiration, feeding problems	Oropharyngeal dysfunction
Migraine	Vomiting, abdominal pain, diarrhea	Secondary to headache attack
Multiple sclerosis	Dysphagia with aspiration; constipation	Oropharyngeal dysphagia
Prolonged transit time, decreased gastrocolic reflex, difficulty in transferring for toileting	Fecal incontinence	Decreased perception of rectal distention, decreased anal sphincter function
Muscular dystrophies, oculopharyngeal	Dysphagia with aspiration; GERD; fecal incontinence	Oropharyngeal dysfunction; LES dysfunction; decreased anal sphincter tone
Duchenne muscular dystrophy	Nausea/vomiting; abdominal distention; constipation	Decreased gastric emptying; prolonged transit time; pseudoobstruction
Myasthenia gravis	Dysphagia	Oropharyngeal dysfunction
Myotonic dystrophy	Dysphagia/aspiration; bloating, constipation; fecal incontinence	Myotonic contractions of the tongue and pharynx; prolonged transit time; decreased anal sphincter tone
Parkinson disease	Dysphagia, constipation	Oropharyngeal dysfunction
Decreased colonic motility, impaired defecation, anticholinergic medications		
Spinal cord disorders	Heartburn, bloating; constipation; fecal incontinence	High number of lesions impairs gastric and small bowel transit; decreased rectal sensation; impaired voluntary control of defecation and anal sphincter

GERD, gastroesophageal reflux disease; LES, lower esophageal sphincter.

function, and peripheral vasodilation secondary to vasodilatory gastrointestinal peptides and insulin secretion. Similar symptoms are also seen in the elderly without more global dysautonomia [285].

Dementia syndromes

Patients with dementia syndromes, such as Alzheimer disease, multiinfarct dementia, and Huntington disease, exhibit gastrointestinal symptoms related to oropharyngeal dysfunction, with dysphagia for solids and liquids and an increased risk of aspiration and progressive inanition and malnutrition. Diminished recent memory and disorientation impede rapid diagnosis of common and often easily recognized medical problems.

In advanced terminal neurological diseases, difficult decisions must be made pertaining to providing or withholding enteral feedings that must be delivered by nasogastric tube, gastrostomy, or jejunostomy. These techniques of enteral alimentation permit more effective, longer administration of defined enteral diets that can prolong the end stage of patients in a severely demented or "vegetative" state. Enteral support through feeding tubes is a form of medical treatment that is not necessarily mandatory for all patients in such condition, and indeed would not be the choice of most competent patients living in a nursing home [286–288]. Percutaneous endoscopic gastrostomy is an easily applied, safe (but not perfectly so [289]), and popular method of administering enteral feeding. Jejunostomies should be used only in patients with severe gastroesophageal reflux, in whom they may provide additional protection against aspiration pneumonia.

Hiccups

Hiccups (or singultus) are intermittent, involuntary, spasmodic contractions of the diaphragm and accessory muscles of respiration that lead to abrupt ending of inspiration by airway closure at the glottal level. Transient hiccups are a common phenomenon often associated with overindulgence in food or drink, and they can be dealt with effectively by a variety of home nostroms and traditional remedies. Hiccups become a medical problem when they are prolonged and unresponsive to the usual approaches. Prolonged hiccups lasting for weeks or months are seen more commonly in men and can lead to insomnia, inanition with weight loss, and occasionally suicide [290].

Particularly if the hiccups continue while the patient is sleeping, an organic cause should be sought. The potential causes of protracted hiccups are extensive and include foreign bodies in the ear canal, cervical tumors or adenopathy, central nervous system disease, metabolic disease (diabetes, uremia, hyponatremia), alcoholism, and chest (tumors or inflammation in the mediastinum, pericardium, pleural space, or diaphragm) disease. Gastrointestinal diseases associated

with protracted hiccups include gastroesophageal reflux, gastric obstruction with distention, and stomach or esophageal tumors. Many of these problems can be defined with a careful history and physical, plain films of the chest or abdomen, and routine blood work. Further diagnostic studies may require computed tomography (CT) of the chest, abdomen, and central nervous system, endoscopy, and otolaryngology and neurology consultations. For many patients, a specific causal etiology may not be found [291].

In a practical sense, the most immediate problem confronting the clinician is how to abort the protracted hiccups. Assuming that the usual home remedies (e.g., breath holding, drinking water) have been unsuccessful, local stimulation of the pharynx with a nasogastric tube might be tried. Continued hiccups would lead to sequential trials of medications, none of which has been evaluated in randomized trials. Baclofen, a centrally acting antispasticity agent, has been effective in dosages of 5–60 mg a day orally [292]. The dopaminergic antagonists (chlorpromazine, metoclopramide, haloperidol), amitriptyline, carbamazepine, diphenylhydantoin, quinidine, and nifedipine have all successfully stopped protracted hiccups [293].

Migraine

Migraine is a periodic headache syndrome that usually begins early in life. Well-defined visual, sensory, or motor dysfunction may precede or accompany the headache. Gastrointestinal manifestations are almost universal and include nausea, vomiting, crampy abdominal pain, and diarrhea. The nausea and vomiting may impede the use of oral medications during an attack. Sumatriptan, a commonly employed antimigraine medication, and a selective 5-hydroxytryptamine-1 receptor agonist, has been associated with the development of ischemic colitis [294].

Migraine equivalents such as cyclic vomiting [295] and abdominal migraine [296] are encountered, particularly in childhood. The diagnostic criteria include recurrent stereotypic attacks of either intractable vomiting or upper abdominal pain, the absence of abdominal symptoms between attacks, a family history of migraine, and response to specific migraine therapy. Only occasionally are these symptoms accompanied by headache or prodrome. Nortriptyline has been used with some efficacy in adults to prevent attacks of vomiting.

Multiple sclerosis

Multiple sclerosis (MS) is a focal demyelinating disorder of the central nervous system. Whipple disease can mimic the clinical presentation of MS. Epidemiological studies suggest that patients with inflammatory bowel disease (IBD) have an increased risk of developing demyelinating diseases [297], as do patients receiving anti-TNF therapy [298]. Oropharyngeal dysphagia is common, but in population-based studies constipation and fecal incontinence are the most serious and disabling problems for MS patients. Constipation is a problem for more than two-thirds of MS patients, while about 25% experience fecal incontinence weekly [299]. Causes of constipation are multiple, including difficulty in transferring to commode, increased segmenting contractions that lead to prolonged transit time [300], and diminished gastrocolic response to a meal. Abnormalities of anal sphincter function and diminished perception of rectal distention contribute to the incontinence [301].

Careful attention to bowel function can markedly improve the quality of life of a patient with an MS. Having an occupational therapist evaluate the home environment to improve access to a commode, judicious use of fiber in the early stages of disease, and a strict bowel regimen that uses digital stimulation or glycerin suppositories and enemas to avoid impaction are all useful. Stimulant laxatives may increase bowel spasm and cause unpredictable bowel explosions that always are associated with incontinence and further lack of control.

Muscular dystrophies

Muscular dystrophies are inherited myopathies featuring progressive weakness and muscle wasting. Although generally thought of as involving only the skeletal muscle, several forms have been associated with motor disturbances of the gastrointestinal system. Ptosis and dysphagia are the principal manifestations of oculopharyngeal muscular dystrophy. Radiographic abnormalities reflecting the global degeneration of skeletal muscle include altered clearance of barium from the pharynx, delayed initiation of swallowing, aspiration, and nasopharyngeal regurgitation [302]. The external anal sphincter is also nonfunctional.

Duchenne muscular dystrophy is an X-linked recessive disorder that usually presents with initial proximal skeletal muscle weakness by the age of 5 years, progressing to incapacitation and death by the third decade of life. Gastrointestinal symptomatology includes nausea, vomiting, abdominal distention, and constipation. Acute gastric dilation [303] and intestinal pseudoobstruction have been reported [304].

Myotonic dystrophy

Myotonic dystrophy is an autosomal dominant, slowly progressive condition, with symptoms presenting in the third decade of life. The distinctive features are delayed relaxation of muscle after initial contraction, muscle wasting of a characteristic pattern, frontal baldness in men, testicular atrophy, dysarthria, and cataracts. Studies have found abnormal muscle function throughout the gastrointestinal tract. Common symptoms are abdominal pain, dysphagia, emesis, chronic or episodic diarrhea, and fecal incontinence. One-fourth of the patients consider their gastrointestinal symptoms the most disabling consequence of the disease [305].

Weak or myotonic contractions of the tongue and pharynx can result in oropharyngeal dysphagia and aspiration. Delayed gastric emptying, prolonged intestinal transit, and abnormal anal sphincter function also may develop [306,307].

Parkinson disease

Parkinsonism is characterized by progressive rigidity, tremor at rest, bradykinesia, and diminished postural reflexes. Autonomic dysfunction is common. Although 10%–15% of cases occur in the third and fourth decades of life, the prevalence of the disease increases exponentially in the elderly, being higher than 3% among those over the age of 65. Asians and African Americans are less likely to develop the disease than the white population. Regularly observed pathological changes include degeneration of pigmented brain stem nuclei, which contain distinctive eosinophilic intracytoplasmic inclusions termed Lewy bodies. Dementia is common and loss of sympathetic ganglia and parasympathetic neurons in the enteric nervous system has been documented [308].

Gastrointestinal dysfunction is common and clinically important in Parkinsonian patients. Dysphagia, bloating, nausea, constipation, and defecatory dysfunction are common symptoms. Over 50% of patients have swallowing disorders. For many, pharyngeal swallowing dysfunction documented on swallowing studies is similar to that seen after stroke or with amyotrophic lateral sclerosis. Gastric emptying is disordered in many patients, and is associated with abnormal myoelectric activity [309]. The gastroparesis may lead to malnutrition, it may also be responsible for some of the motor fluctuations seen with levodopa therapy. The therapy that appears to be most effective in reducing these symptoms, domperidone [310], is not available in the United States.

Constipation characterized by colonic inertia is associated with depletion of dopaminergic neurons in the muscularis externa, decreased colonic motility, and alteration of puborectalis and anal sphincter function. Constipation is aggravated by the anticholinergic effects of antiparkinsonian medications. The use of stimulant laxatives is common. Pelvic floor dyssynergia is frequently documented, and straining to defecate complicates the constipation [311]. A daily bowel regimen with the use of glycerin suppositories can be helpful.

Spinal cord disorders

Acute spinal cord injury is commonly associated with ileus, and patients are at increased risk of gastrointestinal bleeding [312]. Nasogastric suction and prophylaxis with continued acid suppression or sucralfate are warranted. After surviving the acute injury, constipation and fecal incontinence are almost universal and are a major source of disability and depression [313]. Over time, laxative dependence and dilated colon develop, and the increased time to generate a movement occupies a great deal of the patient's day. Rectal sensation, voluntary control of defecation, and normal anal sphincter function are lost [314]. Loss of sympathetic coordination leads to slow transit [315]. A carefully designed bowel program that includes laxatives, manual distention of the rectum to stimulate the intact defecation reflex, and careful attention to assistance in transfer to a commode or low toilet can be helpful. Although a few patients may be aided by anterior sacral root stimulators [316], in many patients a colostomy can substantially improve the quality of life [317].

Other neuromuscular diseases

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by progressive loss of motor neurons (perhaps as a consequence of mitochondrial injury [318]), muscle atrophy, and weakness. Dysphagia will ultimately be present in all patients and is due to discoordination of the entire pharyngeal and upper esophageal swallowing mechanisms. Rapid nutritional disintegration is common, speeding the potential for respirator dependence. Studies demonstrate that placement of a percutaneous endoscopic gastrostomy (PEG) is safe, rapidly improves nutrition, and seems to improve quality of life in ALS patients [319]. Delayed gastric emptying has been reported, and if present might necessitate the use of jejunal feeding.

A variety of mitochondrial DNA defects have been identified that lead to a global and progressive degeneration in muscles and gastrointestinal symptoms that are not dissimilar to ALS. These have been termed the mitochondrial myopathies and, as with ALS, management of dysphagia and bowel dysfunction are central to the quality of life of the patients [320,321].

Residual swallowing problems are common in patients who have had a stroke. The consequences are impaired nutritional intake, decreased quality of life, and a risk of aspiration pneumonia. Pharyngeal motor dysfunction and a delay in swallowing initiation are common after acute stroke. Vocal cord mobility is reduced, with resulting reduction in airway protection. Swallowing therapy may help maintain oral intake in some cases [322]. Commonly, a choice must be made with dysphagic stroke patients as to whether and when to provide nutrition via nasogastric feeding or percutaneous gastrostomy. A recent randomized trial confirmed that early enteral feeding marginally increases early survival, but at the expense of increasing the proportion of patients surviving with a poor functional outcome. Outcomes after endoscopic gastrostomy were not as favorable as with nasogastric feeding [323].

Myasthenia gravis is an autoimmune disorder of the neuromuscular junction that is a treatable cause of oropharyngeal dysphagia [324]. Some patients have coexisting immunodeficiency states and may have intestinal villus atrophy and increased susceptibility to enteric infections [325]. Stiff man syndrome consists of symmetrical, progressive stiffness and painful spasm of axial musculature. Dysphagia may develop, possibly related to muscle spasm of the cricopharyngeus and upper esophagus [326].

Nutritional disturbances

Malnutrition

Malnutrition results from famine, war, poverty, natural disasters, poor dietary habits, and chronic disease. Kwashiorkor

identifies the protein-deficient patient with an adequate intake of calories, exmplified in developed countries by the catabolic patient after trauma, infection, or burn. Typically such patients are characterized by a persistent edematous state. Marasmus syndromes are causally related to a deficiency in total caloric intake, the starved patient [327]. Diarrhea and infection are common manifestations of the terminal malnutrition. Malnutrition causes both humoral and cellular immunodeficiency, which renders the mucosa susceptible to bacterial overgrowth and infection by various pathogens, such as parasites, toxigenic bacteria, and viruses. Atrophy of the intestinal mucosa and pancreas contributes substantially to development of the diarrheal state. Hepatomegaly may develop in conjunction with fatty liver, and pancreatic enzyme secretion may be reduced by over 80% [328]. In Western countries, chronic alcoholism and chronic liver disease are common causes of malnutrition [329,330].

The indications for the delivery of nutrients by the enteral and parenteral route as well as the efficacy of nutritional supplementation in malnourished, hospitalized patients are unproved [331]. Recent weight loss of more than 10% of body weight, the inability to eat for 5–7 days in an undernourished patient or for 10–14 days in a well-nourished patient, and a hypercatabolic state (e.g., burn) are generally proposed criteria for initiation of nutritional supplementation [236], especially in critically ill patients. Both parenteral and enteral formulations can provide all essential nutrients, but the enteral route is preferred whenever the gastrointestinal tract is functional [332].

Refeeding of extremely malnourished patients should be done gradually to permit mucosal and metabolic adaptation and to avoid exacerbation of diarrhea. Many patients will need pancreatic enzyme supplementation. Too rapid refeeding with high-calorie solutions that are rich in carbohydrates can lead to death by precipitating severe hypophosphatemia, hypokalemia, and hypomagnesemia and by intensifying other metabolic disturbances [333].

Obesity

Over 50% of adult Americans weigh more than 10% above ideal body weight, and obesity-related conditions are estimated to contribute to more than 300 000 deaths annually. Detailed evaluation of this topic can be found in Chapter 22.

Organ transplantation and complications

Bone marrow transplantation

Most of the gastrointestinal complications that occur after bone marrow transplantation (BMT) relate to graft-versus-host disease (GVHD) and the consequences of chemotherapy (see above). Overt gastrointestinal bleeding is uncommon (7.4%) in such patients when sucralfate or histamine H_2 antagonists are given prophylactically. Endoscopy usually does not define an isolated lesion and carries a 19% risk of inducing clinically relevant bacteremia [334]. Antibiotic prophylaxis should be given, and the risk and benefit of endoscopy should be considered before initiating the procedure.

A suppressed immune system predisposes the BMT recipient to life-threatening infections. Bacterial and fungal infections of the gastrointestinal tract are more common during the initial 30 days, whereas viral and parasitic infections are observed more often after day 30 [335]. Oropharyngeal and esophageal thrush occur frequently. Herpesvirus infections and CMV are common and may involve any portion of the gastrointestinal tract. Acute diarrhea is most commonly caused by GVHD, but *C. difficile* infection can cause severe, prolonged diarrhea [336]. Diagnosis depends on appropriate stool studies.

Graft-versus-host disease

Allogeneic stem cell BMT preceded by myeloablative high-dose chemotherapy conditioning can cure hematological malignancies but is associated with a high mortality. Acute GVHD (see Chapter 129) is the major cause of death. Recently, the use of nonmyeloablative conditioning (spurred by the concept that the curative potential of BMT relies on the killing of the recipient's malignant cells by the graft's T-cells and that newer highly immunosuppressive conditioning regimens cause less epithelial damage) have demonstrated reduced GVHD without reducing the curative potential of stem cell BMT [337,338].

The earliest sign of GVHD is the onset of a severe watery, secretory diarrhea. Anorexia, nausea, vomiting, jaundice, gastrointestinal bleeding, and abdominal pain may also be present, and 10%–20% have either severe hemorrhage or perforation [339]. Although less common, chronic GVHD may also cause gastrointestinal symptoms. The diagnosis is best made by endoscopy with biopsy, a relatively safe and simple procedure (Fig. 109.11). Tissue typically demonstrates apoptosis and gland destruction, sparse inflammatory infiltrate, and granular eosinophilic debris in dilated glands. The granular debris may be the most specific feature but is not seen commonly [340]. Oral beclomethasone dipropionate and prednisone have been found to be more effective than prednisone alone in treating intestinal GVHD [341].

Hepatic venoocclusive disease

Liver damage secondary to cytoreductive therapy is common after BMT. The most prominent site is the terminal hepatic venule. Venoocclusive disease is manifested by hyperbilirubinemia, hepatomegaly or right upper quadrant pain, and sudden weight gain within 20 days of transplantation without other cause. Pretransplant aminotransferase elevations, high-dose cytoreductive therapy, and persistent fever are independent risk factors. There is no clearly defined therapy for venoocclusive disease, which, when severe, is associated with multiorgan failure and death [342].

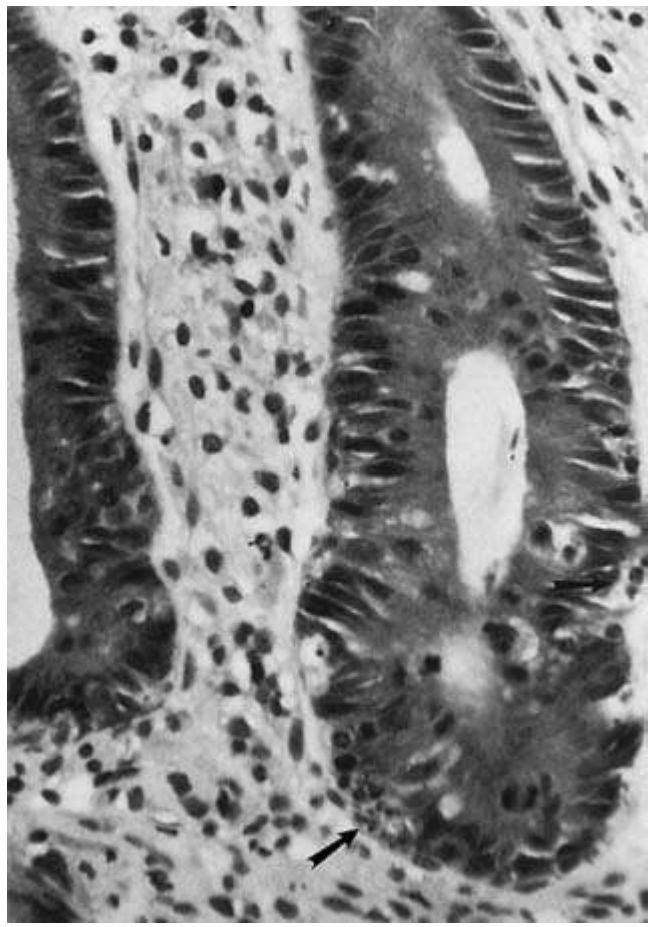

Figure 109.11 Rectal biopsy specimen shows crypt cell degeneration, which is the characteristic lesion of graft-versus-host disease. (H & E stain; original magnification × 100.)

Heart transplantation

The most common severe gastrointestinal complications after heart transplant include upper gastrointestinal bleeding, pancreatitis, cholecystitis, and bowel perforation. An increased risk for pancreaticobiliary disease persists for 1 year after the operation [343]. Although there is no evidence of an increased risk of colorectal cancer or adenomatous polyps in patients post transplant, nor any evidence-based guideline to follow, the chronic immunosuppression dictates a vigilant approach to colorectal cancer screening.

Lung transplantation

The risks of lung transplantation are similar to those noted after other solid organ transplants; however, several reports have described a high frequency of postoperative colonic perforation [344,345]. Because mortality is related directly to the duration of delay in diagnosis after symptoms are noted and symptoms may be blunted secondary to immunosuppression, careful evaluation for abdominal distention with plain films of the abdomen may help to guide clinical decisions. Because of the extensive mediastinal dissection required during heart–lung transplants, vagal injury can occur, leading to dysphagia and gastric stasis. Fortunately, there are few important clinical sequelae of the nerve injury [346]. Fatal hyperammonemia has been reported to occur uncommonly after lung transplantation, and is associated with hepatic glutamine synthetase deficiency [347].

Renal transplantation

Patients who undergo renal transplantation commonly develop gastrointestinal complications [348]. Peptic ulcer disease with hemorrhage or perforation was common when high doses of prednisone were used, but is much less common in the cyclosporine era. More effective medical therapies exist for ulcers, making surgical intervention less common [349]. Intestinal ischemia, diverticulitis with perforation, CMV-induced gastroduodenitis and colitis, intestinal tuberculosis, and intraabdominal abscesses are increasingly common [350]. Infection with hepatitis C and B is common in dialysis patients who develop chronic renal failure. After transplantation, the immune suppression may accelerate the course of chronic hepatitis (particularly hepatitis B) and fulminant hepatitis may occur [351].

Pregnancy

Pregnancy is accompanied by a variety of physiological changes, many of which have been attributed to the effects of progesterone or α-human chorionic gonadotropin on gastrointestinal motility and displacement of the viscera by the gravid uterus. Common gastrointestinal symptoms of pregnancy include altered appetite, pica, ptyalism, gingivitis, vomiting, dyspepsia, heartburn, constipation, and hemorrhoids. Management of symptoms with pharmaceuticals is complicated by a paucity of clinical studies in humans demonstrating safety for the fetus. These issues are dealt with in detail in Chapter 50.

Liver disease

Although the liver functions normally in pregnancy, palmar erythema and spider nevi are often observed, perhaps as a result of elevated steroid hormones. Serum alkaline phosphatase and leucine aminopeptidase levels are increased, attributable to placental production. Other liver enzyme levels are normal. Jaundice is infrequent, but when it occurs it is most often the result of intrahepatic cholestasis of pregnancy (ICP) [352]. Cholestasis presents in the second or third trimester as severe generalized pruritus that worsens at night. Marked increases in alkaline phosphatase and serum bile acids with normal γ-glutamyltransferase (GGT) are characteristic. A subgroup with raised GGT is associated with heterozygous *MDR3* mutations [353]. In Chile, ICP has been associated with a decrease in blood selenium level, suggesting

environmental causes [354]. There is an increased risk of stillbirths and premature births. Ursodiol can help control the pruritus, but its effects on the outcome of pregnancy are uncertain [355]. Prophylactic vitamin K should be administered parenterally to avoid postpartum bleeding [352].

The HELLP syndrome is a variant of severe preeclampsia characterized by hemolysis, elevated liver enzymes, and low platelets. Its features suggest a thrombotic microangiopathic process, and it must be distinguished from acute fatty liver of pregnancy, hemolytic–uremic syndrome, and thrombotic thrombocytopenic purpura [356]. Acute fatty liver and HELLP have been associated with the presence of long-chain 3-hydroxyl coenzyme A dehydrogenase deficiency in the infants of these mothers [357]. Marked elevations of transaminases are unusual and may suggest complicating hepatic vein thrombosis or fulminant liver failure, or spontaneous intrahepatic hemorrhage and hepatic rupture with an increased mortality [358]. Despite studies suggesting high fetal and maternal mortality with the HELLP syndrome [356,359], recent studies have noted greatly improved outcomes when interdisciplinary teams (that included a hepatologist) have managed the patients aggressively with expeditious delivery [360,361].

Acute fatty liver of pregnancy resembles Reye syndrome and usually occurs in young primigravida or multiparous women in the third trimester. Vomiting, right upper quadrant pain, and a viral-like syndrome are common early. Jaundice, encephalopathy, and acute renal failure then supervene. In contrast to the HELLP syndrome, hypofibrinogenemia, hypoglycemia, and hypoprothrombinemia are common [360]. Microvesicular fat accumulated in the central zone is seen on liver biopsy, but the diagnosis is based on clinical presentation and biopsy is rarely needed. When acute fatty liver is present, the pregnancy should be terminated promptly. Maternal and fetal mortality has been reduced to less than 5%, and survivors have no long-term liver disease [360,361].

Conception and viable pregnancy in patients with chronic liver disease is uncommon and fraught with complications. Patients with established portal hypertension have an increased risk of variceal hemorrhage during the third trimester of pregnancy with consequent increase in both fetal and maternal mortality. Prophylactic variceal ligation with ablation of varices or transvenous intrahepatic portal shunt should be considered [362].

Psychological disorders

Eating disorders

Anorexia nervosa

Anorexia nervosa is a potentially fatal eating disorder characterized by severe voluntary weight loss, altered body image, and morbid fear of obesity that primarily affects adolescent females [363]. Anorexia nervosa may carry a mortality of up to 9%. Gastrointestinal complaints are seen in more than half of patients, but multiple systems are involved secondary to the starvation. Delayed gastric emptying that contributes to a feeling of bloating and early satiety is common, but it usually resolves with a return to normal body weight [364]. Serum levels of trace metals such as zinc and copper are commonly depressed, and hypophosphatemia may supervene during refeeding. In severe cases, parenteral feeding may be needed. Details of evaluation and management are found in Chapter 35.

Bulimia

Bulimia is a distinct syndrome characterized by cyclic binge eating, followed by self-induced vomiting, fasting, laxative abuse, or excessive exercising to promote weight loss [365]. In contrast to anorexia, severe weight loss and multisystem involvement are rare. Common gastrointestinal symptoms include bloating, flatulence, constipation, abdominal pain, borborygmi, and nausea. Binge eating causes acute gastric dilation, which can result in gastric rupture. Vomiting is associated with dental enamel erosion, parotitis, esophagitis, Mallory–Weiss tears, and esophageal rupture [366]. Although pancreatitis may occur, hyperamylasemia in patients with bulimia is most often caused by increased salivary-type amylase. Treatment is directed at the underlying psychiatric diagnosis.

Rumination

Although frequently reported in children, rumination is uncommon in adults who are not developmentally disabled. It is characterized by daily effortless regurgitation of undigested food and may be associated with prominent weight loss. Screening for other eating disorders is important. Delays in diagnosis and the concomitant overuse of diagnostic tests are common. Esophageal and upper gastrointestinal studies are normal. There is no clearly effective medical therapy other than reassurance and psychiatric consultation [367].

Munchausen syndrome

Munchausen syndrome is the repeated seeking of medical care for factitious and purposefully self-generated illness. In contrast to hysteria, the symptoms are subject to "conscious" control. Patients have feigned many gastrointestinal diseases, including abdominal emergencies, hematemesis, hematochezia, and inflammatory bowel diseases [368]. Satisfactory treatment of this syndrome is rare.

Pulmonary disorders

α_1-Antitrypsin deficiency

α_1-Antitrypsin (AAT) deficiency is a recessively inherited condition that is the most common genetic cause of liver disease in children. The most frequent mutation leading to AAT

arises in the *SERPINA 1* gene [369]. It is also associated with emphysema (the most common cause of death), chronic liver disease, and hepatocellular cancer in adults. The ZZ phenotype has been associated most frequently with severe disease [369]. Adult patients can be screened effectively by serum AAT levels. Those with an AAT level below 80 mg/mL should undergo AAT phenotyping [370]. Liver disease tends to manifest late in life, and liver biopsy reveals inclusion bodies containing entangled polymers of mutant Z AAT in the endoplasmic reticulum of hepatocytes in the periportal areas, a finding unrelated to the severity of the liver disease [371]. Liver transplantation is an effective form of therapy for patients with severe liver disease [369].

Asthma/chronic cough

Asthma is a common cause of disability and death that is characterized by varying degrees of bronchial constriction. GERD is present in three-fourths of asthmatic patients [372] and may be worsened by the use of asthma medications (theophylline, β-adrenergic agonists) that lower esophageal sphincter pressure, although GERD also may substantially complicate the course of the lung disease. Worsened wheezing is thought to result from the aspiration of gastric contents, although reflex bronchial constriction has also been suggested as a mechanism [373]. Pyrosis as well as other symptoms of GERD, asthma onset in middle age, the presence of nocturnal gasping, cough, and wheezing, and the absence of coincident allergy or eosinophilia are clues to a possible association with GERD [374]. When GERD-induced asthma is suspected, 24-h ambulatory pH monitoring can confirm severe reflux [375]. Therapy of GERD in this setting usually requires the strict exclusion of eating before bedtime and prolonged potent acid inhibition with proton pump inhibitors [374,376]. Because of uncertainties in demonstrating a causal relationship between asthma and GERD, antireflux surgery should be considered carefully [377].

Chronic idiopathic cough is commonly associated with GERD [378]. Even in the absence of heartburn, acid may trigger nocturnal cough or laryngospasm. Laryngospasm may be mistaken for asthma unless appropriate pulmonary function tests are employed. Evaluation and management are the same as for asthma.

Consequences of mechanical ventilation and respiratory failure

Respiratory failure and mechanical ventilation may be complicated by gastrointestinal bleeding from erosive gastritis and ulcer disease. Associated coagulopathy further increases the risk of overt hemorrhage. It is important to emphasize the infrequency of this complication when it is monitored prospectively in large populations [379]. This said, prophylactic suppression of acid secretion with H_2 antagonists or proton pump inhibitors in critically ill patients at high risk of bleeding (expectation of remaining on mechanical ventilation for > 48 h) reduces the incidence of stress ulcerations [380] and should be instituted. It has been suggested, however, that raising the gastric pH might permit colonization of the stomach by pathogenic bacteria, which, in turn, may predispose to nosocomial ventilator-associated pneumonia. This is controversial, and careful attention to a general preventive strategy is likely to be more helpful than arbitrarily switching to sucralfate [381]. Administering sucralfate alone through a nasogastric tube may expose the patient to an increased risk of erosive esophagitis because gastric pH remains low [382].

Acute exacerbation of chronic respiratory failure is a common cause of ischemic hepatitis. In contrast to the severe hypertransaminitis seen after circulatory arrest, of which severe hypotension is the proximate cause, in patients with acute on chronic respiratory failure the cardiac index is increased. The cause of the hepatic damage is a combination of severe arterial hypoxemia and elevated central venous pressure [383]. This has also been noted in a patient with severe obstructive sleep apnea [384].

Cystic fibrosis

Cystic fibrosis (CF) is the most common inherited disease among Caucasians in North America, with an incidence of about 1 per 2000. Mutations in the CF transmembrane conductance regulator gene [385] on the long arm of chromosome 7 lead to an underlying defect in mucosal cAMP ion and water transport. A net shift in fluid from the lumen results in viscous secretions and duct obstruction in the respiratory tract, salivary glands, pancreas, intestinal lumen, and biliary tree [386].

The presence of viscous secretions in the intestinal lumen has important clinical consequences. Affected infants may present with meconium ileus, intussusception, distal intestinal obstruction syndrome (DIOS), intestinal atresia, volvulus, and perforation. Chronic constipation is common and may lead to rectal prolapse. Adults with CF who have a severe genotypic expression of the regulator gene commonly present with DIOS [387]. Mineral oil or acetylcysteine may be effective. Recurrent use of gastrointestinal lavage with Golytely also may be helpful in reducing the symptoms of bloating and distention that characterize DIOS [388].

Symptomatic gastroesophageal reflux is common in children who have CF. Contributing factors are decreased saliva production, gastrointestinal hypomotility, chronic cough, and the need for postural drainage of pulmonary secretions [389]. Standard antireflux therapy is usually effective. As more patients survive to adulthood, complications of GERD, such as stricture and Barrett esophagus [390], will be seen with greater frequency.

Essentially all patients have severe nutritional impairment caused by pancreatic insufficiency and manifested by steatorrhea and malabsorption of nonfat nutrients. Protein–calorie malnutrition is aggravated by the catabolic state induced by chronic respiratory tract infections but may also contribute to

worsening lung disease. Improvement of exercise tolerance and pulmonary function can result from enteral/parenteral nutritional support, pancreatic enzyme replacement, and fat-soluble vitamin supplementation [391,392]. Although the use of large doses of high-potency pancreatic enzymes has caused a fibrosing colitis manifested by bloody diarrhea associated with diffuse narrowing of the colon with rectal sparing [393], the bulk of evidence supports the use of pancreatic enzyme supplementation to treat pancreatic insufficiency in CF [394]. As survival to adulthood becomes more common, new problems are recognized. Symptomatic osteomalacia is a common sequela of chronic steatorrhea, 25-hydroxyvitamin D levels should be monitored, supplemental calcium and vitamin D should be provided [395], and medications for osteopenia considered. A greater than expected incidence of malignancies of the digestive tract has been found [396]. Thus, persistent or unexplained gastrointestinal symptoms should be investigated carefully.

Focal biliary cirrhosis is common and asymptomatic, but about 10% of children with CF develop confluent biliary cirrhosis and progressive portal hypertension. If variceal bleeding occurs, banding or portosystemic shunting would be the therapeutic modalities of choice. Ursodiol improves liver function tests, but it is unclear whether fibrosis is retarded. Improvements in surgical techniques have allowed CF patients with end-stage cirrhosis to undergo liver or combined liver and lung transplantation successfully [397].

Renal disorders

Chronic renal failure

Chronic renal failure is associated with a number of gastrointestinal disturbances. Dysgeusia, a metallic taste in the mouth, and fetor uremia are often noted by uremic patients. Parotitis and sicca syndrome commonly occur in uremic patients, further limiting compliance with fluid restriction and impairing nutrition.

Renal failure is commonly associated with anorexia, nausea, vomiting, and epigastric pain. Endoscopy should be carried out to exclude ulcer or gastritis. Because uremia is associated with gastric emptying abnormalities [398], however, symptoms may be alleviated by using agents such as metoclopramide. Gastrointestinal bleeding has multiple possible causes [399], but, in contrast to patients with normal renal function, arteriovenous malformations are particularly prevalent. Peptic ulcer disease, gastritis, esophagitis, and duodenitis may be managed as in patients without renal failure. The diagnosis of *Helicobacter pylori* infection is difficult in uremic subjects and relies on histological methods rather than the breath test [400]. Duodenal pseudomelanosis is an idiopathic condition in which pigmentation develops in the proximal duodenal mucosa (Fig. 109.12). There are no known symptoms attributable to this syndrome.

Figure 109.12 Duodenal biopsy specimen from a patient with pseudomelanosis duodeni shows the deposition of pigment within lamina propria macrophages.

Uremic patients may develop abdominal pain, constipation, pseudoobstruction, and intussusception. Important factors in the development of constipation include oral fluid restriction and the use of antacids that contain aluminum hydroxide. Diarrhea secondary to a variety of causes is also common. Fecal impaction must be excluded. Although conditions such as bacterial overgrowth and pseudomembranous colitis must be considered, the cause of many cases remains idiopathic. The incidence of pancreatitis in chronic renal failure is unknown [398]. Elevation of serum amylase is common but should not necessarily be attributed to impaired renal clearance, especially if the level exceeds twice the upper limit of normal [401]. Intestinal ischemia has been associated with systemic calciphylaxis [402].

Uremic patients can develop hepatic friction rubs without other manifestations of liver disease. Elevated alkaline phosphatase in such patients can be of intestinal origin and may not be indicative of bone disease or cholestasis. Chronic hepatitis B and C are common, and may complicate the ability to provide effective dialysis and kidney transplantation [403].

Treatment with lamivudine for hepatitis B and interferon for hepatitis C can be undertaken with caution in such patients.

Hemodialysis

Diarrhea and the inability to gain weight may be manifestations of inadequate dialysis. A few patients on long-term hemodialyis can develop severe obstipation, colonic pseudo-obstruction, and spontaneous perforation of the colon [404]. Serum lipase levels can increase significantly after heparin administration and thus have reduced specificity for the diagnosis of pancreatitis in this setting [405]. Idiopathic refractory exudative ascites occurs in a few patients, is difficult to treat medically, and commonly resolves with kidney transplantation [406].

Peritoneal dialysis

Patients undergoing continuous ambulatory peritoneal dialysis are commonly subject to an easily treatable form of bacterial peritonitis. Differentiating this condition from peritonitis associated with important intraabdominal pathology (bowel perforation, ischemic bowel, appendicitis) can be difficult because polymicrobial infections can occur without important gastrointestinal pathology [407], and pneumoperitoneum is common after dialysis. Pneumoperitoneum not associated with perforated viscus was found in 4% of one series, and may take weeks to resolve [408].

Polycystic kidney disease

Polycystic kidney disease (PKD) is an autosomal dominant disorder associated with abnormal genes (*PKD1*, *PKD2*) that have been localized to chromosome 16. Polycystic kidney disease accounts for about 10% of the chronic dialysis population [409]. Significant inter- and intrafamilial differences in the severity of phenotypic expression appears to relate to modifier loci on the gene [410]. Hepatic cysts are an important manifestation of PKD. The frequency of coincident hepatic cysts increases with age, and the large cysts are more common in women who have had multiple pregnancies. Despite large cysts, hepatic parenchymal volume is preserved, as is liver function [411]. Hepatic cysts can become infected, large cysts can obstruct the biliary tree, and early intervention with both antibiotics and percutaneous drainage is needed [412]. An association with congenital hepatic fibrosis has been reported [413].

Substance abuse

Alcohol

Alcohol consumption can increase lower esophageal sphincter (LES) pressure, reduce the frequency of esophageal peristaltic contractions, and delay esophageal emptying. High-amplitude peristaltic contractions have also been noted (nutcracker esophagus) [414]. These alterations in function may result in chest pain and esophagitis. Chronic alcohol ingestion increases the risk of esophageal cancer.

Alcohol produces acute and chronic gastritis by disruption of the gastric mucosal barrier. Binge drinking can result in gastric erosions and severe hemorrhage. Chronic use, however, seems to protect against development of serious mucosal injury. Recent epidemiological studies suggest that the concomitant use of alcohol and NSAIDs [415], or of alcohol and warfarin [416], potentiates the risks of severe GI bleeding or perforation compared with the use of either of these drugs alone.

Alcoholism may result in diarrhea and malabsorption. Alcohol increases small intestinal transit, decreases brush border enzyme activity, and impairs absorption of nutrients. Acute exposure of the small bowel to alcohol causes altered mucosal and microvascular permeability [417]. Chronic pancreatitis, the spectrum of chronic alcoholic liver disease, protein–calorie malnutrition, and vitamin deficiencies are contributing factors (see Chapter 94).

Amphetamines

The social use of ecstasy (methylenedioxymethamphetamine, MDMA) and amphetamines has become widespread in the United States. These drugs induce euphoria, intensify emotions, and have become a staple of the "rave" culture. In excess, these drugs cause anxiety, hallucinations, chest pain, palpitations, coma, subarachnoid hemorrhage, and death [418]. A panarteritis that is similar to polyarteritis nodosum (but antineutrophil cytoplasmic antibody [ANCA] negative), with associated mesenteric ischemia, is reported [419]. As with cocaine hepatotoxicity, liver dysfunction is common, caused by both immune-mediated mechanisms and hyperthermic liver injury, and therapy for severe cases is largely supportive [420].

Cocaine

The use of cocaine and related metabolites is widespread. Anorexia and diarrhea are common. Cocaine use can result in gastric ulcerations with perforation [421], retroperitoneal fibrosis, and intestinal ischemia with infarction [422]. Severe liver injury is almost always associated with rhabdomyolysis and hyperthermia. The zone of hepatic necrosis will vary depending on other drugs being used [423]. The practice of smuggling cocaine in condoms concealed in the digestive system can result in intestinal obstruction and death.

Narcotics

Narcotic administration for abuse or for pain relief frequently results in physical dependency, with resulting physical symptoms on withdrawal. Gastrointestinal symptoms of withdrawal include anorexia, nausea, vomiting, and abdominal pain. These symptoms may be difficult to distinguish from structural gastrointestinal disorders. Narcotics delay gastric emptying and intestinal transit, and suppress intestinal secretion

of water and electrolytes [424]. Slow colonic peristalsis frequently induces constipation, which can be a long-standing problem [425]. If the narcotics must be continued, stimulant laxatives are frequently required.

Parenteral administration of illicit drugs can result in chronic viral hepatitis, cirrhosis, and hepatic abscess. Injected contaminants such as talc can cause hepatic granulomas.

Vasculitides

Behçet disease

Behçet disease is a systemic illness of unknown etiology characterized by necrotizing vasculitis and most commonly described in people of Middle Eastern and Japanese extraction. Common manifestations include orogenital ulcerations, eye inflammation, skin lesions, arthritis, and migratory thrombophlebitis. Gastrointestinal tract involvement is uncommon [426]. A curious and virtually pathognomonic sign is the development of pustules at the site of needle punctures.

Oral lesions resemble aphthous ulcers and may be single or multiple. Esophageal ulcerations are common, but infrequently cause symptoms. The most frequent extraoral manifestations of gastrointestinal involvement are segmental inflammation and focal deep ulceration of the ileocecal region and colon, resembling Crohn's disease. Intestinal bleeding or perforation may result. Therapy is similar to that of Crohn's disease, with immunomodulating medications often ameliorating the disease. Resection of severely diseased segments of the gut may be required, but postoperative recurrence is common [427,428].

Other than symptomatic Budd–Chiari syndrome, involvement of the liver and spleen is rare. Typically, affected patients have cavernous transformation of the portal vein, associated with portal vein, inferior vena caval, and hepatic venous thrombosis. Definable coagulopathies have not been defined as the cause of the thrombosis, suggesting the primary importance of vasculitis. Once established, the presence of Budd–Chiari syndrome in the patient with Behçet disease indicates a poor prognosis [429,430].

Churg–Strauss syndrome

Churg–Strauss syndrome is a systemic vasculitis characterized by the presence of asthma, hypereosinophilia, and necrosis with extravascular eosinophil granulomas. Common symptoms other than the asthma are weight loss, fever, myalgias, arthralgias, and vasculitic skin lesions. Small to medium-sized vessels are involved, and ANCAs are commonly detected. Corticosteroids, alone or in combination with cyclophosphamide, will usually induce clinical remission, but recurrence is common [431,432].

Gastrointestinal manifestations are common, and when present are associated with a poor prognosis [431]. They include nausea, vomiting, abdominal pain, gastrointestinal hemorrhage, perforation, cholangiopathy, and cholecystitis, are related to mesenteric vasculitis, and are similar to those found in polyarteritis nodosa. Mesenteric ischemia with ulceration and perforation is reported. On occasion a case may be identified on endoscopic biopsy [433].

Cryoglobulinemia

Cryoglobulinemic vasculitis is caused by immune complexes of mixed cryoglobulins in the walls of venules, capillaries, and arterioles, which incites acute inflammation. Mixed cryoglobulins, rheumatoid factor, and low levels of C4 are typically found in the serum. The most frequent clinical manifestations are purpura, arthralgias, and nephritis (the main cause of morbidity). Cryoglobulinemia occurs in a variety of clinical settings, such as lymphoproliferative disorders, infections, and autoimmune diseases, or as an idiopathic process. However, cryoglobulinemic vasculitis is almost always associated with chronic hepatitis C [431].

Gastrointestinal illness, such as recurrent episodes of crampy abdominal pain, enterocolitis, and, rarely, small or large bowel ischemia, has been reported. When possible, the effective treatment of the hepatitis C infection with interferon-ribaviron will abolish the vasculitis [434].

Giant cell arteritis

Giant cell arteritis is a granulomatous disease that usually involves large-sized arteries, including the aorta and the temporal arteries. The disease usually occurs in the elderly and is associated with the clinical syndrome of polymyalgia rheumatica. Disseminated fibrinoid necrosis of smaller vessels can result in visceral ischemia, abdominal pain, nausea, anorexia, weight loss, bleeding, and perforation. Disturbances of liver function are common and have been attributed to hepatic artery involvement [435] and hepatitis associated with fibrin ring granulomas [436].

Henoch–Schönlein purpura

Henoch–Schönlein purpura is a vasculitis syndrome with a peak age of onset in childhood, characterized by systemic deposition of IgA-dominant immune complexes in small vessels. The classic triad of symptoms includes a palpable purpuric rash, abdominal cramping, and hematuria that typically begins after an upper respiratory infection [431]. In Henoch–Schönlein purpura, ANCAs are absent. Most children have a self-limited disease without chronic sequelae. Any part of the gastrointestinal tract may be affected. Gastrointestinal symptoms include abdominal pain, vomiting, diarrhea, intestinal obstruction, and intussusception and can precede the onset of the characteristic purpuric rash [437]. The bowel may be edematous and show evidence of submucosal or subserosal hemorrhage. Radiographic findings include thickening of small bowel folds (Fig. 109.13), colonic wall edema, and intussusception. Whether corticosteroids actually improve outcomes is controversial [438].

Figure 109.13 Henoch–Schönlein purpura. Thickened folds in the second part of the duodenum.

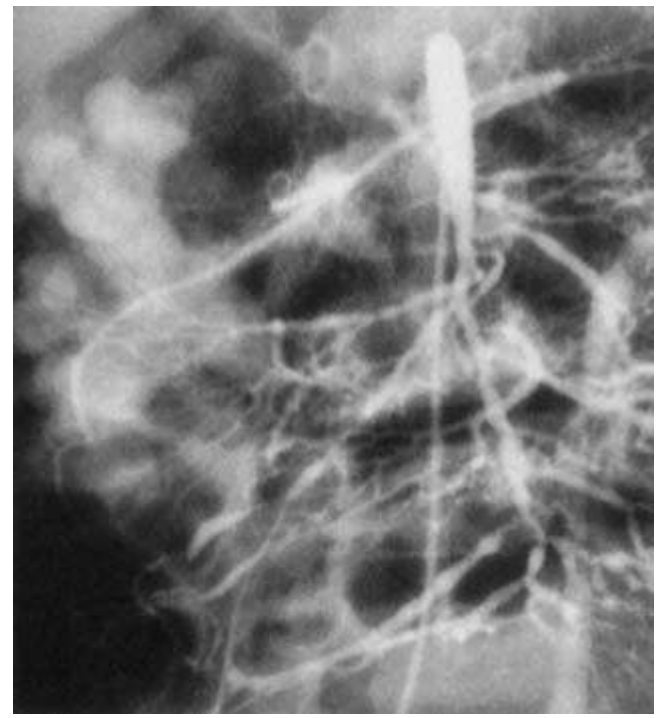

Figure 109.14 Polyarteritis nodosa. Typical aneurysmal dilation of small and medium-sized arteries.

Polyarteritis nodosa

Polyarteritis nodosa (PAN) is a systemic necrotizing vasculitis that affects small and medium-sized arteries of nearly every organ system, giving rise to a wide spectrum of clinical findings. Recently distinguished from PAN, microscopic polyangiitis is an ANCA-positive systemic vasculitis of small-size vessels, smaller than arteries, characterized by rapidly progressive glomerulonephritis and pulmonary involvement that is usually absent in PAN. The absence of necrotizing granulomatous inflammation separates this entity from Wegener granulomatosis and Churg–Strauss syndrome. The gastrointestinal manifestations of the two disorders are similar [431].

Many cases of PAN are associated with hepatitis B infection. Fever, weight loss, arthralgias, subcutaneous nodules, hypertension, and peripheral neuropathy are common. Gastrointestinal complaints are present in about one-third of patients, usually secondary to visceral ischemia. Polyarteritis nodosa is the most common cause of localized vasculitis of the gastrointestinal tract, and when present carries a poor prognosis [439]. The most common clinical manifestations are epigastric pain, nausea, anorexia, mucosal ulceration, intestinal bleeding, and diarrhea [440]. Appendicitis, cholecystitis, pancreatitis [441], cataclysmic intraabdominal hemorrhage, bowel obstruction, and liver infarction have been reported. Typical aneurysmal dilation of small and medium-sized arteries on arteriography (Fig. 109.14) may provide a diagnosis. Corticosteroid and cyclophosphamide therapy have improved the overall survival of these patients dramatically [442].

Wegener granulomatosis

Wegener granulomatosis is an ANCA-positive, small-vessel vasculitis characterized by granulomatous inflammation involving the respiratory tract and necrotizing vasculitis of small to medium-sized vessels. Glomerulonephritis is common. Manifestations of upper airway disease are sinus pain and purulent drainage, nasal mucosal ulceration, and otitis media. Tracheal inflammation causes stridor and may lead to dangerous airway compromise. Chest radiographs commonly show nodular radiographic densities, and, unlike Churg–Strauss syndrome, there is no asthma [431].

Odynophagia secondary to esophageal vasculitis, manifest as punched-out ulcers in the esophagus, has been reported [443]. Granulomatous inflammation of the stomach may be mistaken for Crohn's disease [444]. The associated vasculitis may result uncommonly in intestinal or colonic ischemia, bleeding, and perforation [445].

Many diseases can involve both the skin and the gastrointestinal tract. Primary disorders of the gut such as inflammatory bowel disease can initially manifest in the skin, and primary skin disorders such as pemphigus vulgaris may present with mucosal lesions. It is important that specialists in both disciplines be aware of how cutaneous lesions may be reflective of gastrointestinal diseases. This chapter reviews the skin lesions that may be associated with specific gastrointestinal complaints or known pathological processes. If a dermatological lesion or diagnosis is suspected, dermatological consultation is suggested to assist in diagnosis and management.

Inflammatory bowel disease

Chronic nonspecific ulcerative colitis and Crohn's disease are associated with a host of immunological abnormalities. Although the role of circulating immune complexes in producing extraintestinal manifestations has been debated (see Chapters 7, 50, 52, 57 and 59), it is not surprising that numerous reactive inflammatory vascular dermatoses occur in patients with these diseases.

Erythema: generalized, localized and annular

Reactive inflammatory vascular dermatoses comprise a spectrum of inflammatory blood vessel reactions that occur in association with internal disease [1]. These range from generalized or local erythema (macular blanchable lesions characterized histologically by simple vasodilation and mild inflammation) to urticarial lesions, erythema multiforme, and vasculitis characterized by palpable purpuric lesions with histological leukocytoclasis and fibrinoid necrosis of blood vessel walls. Table 110.1 summarizes the various types of vessel-based inflammatory lesions that may occur in patients with gastrointestinal disease.

Urticaria and angioedema

Urticaria is a raised, peau d'orange, cutaneous vascular reaction characterized by dermal edema and erythema in which, by definition, individual lesions resolve within 24 h [1]. Similar lesions occurring in a deep dermal or subcutaneous location are called angioedema. In patients with inflammatory bowel disease [2], urticaria is usually drug induced or results from some cause other than bowel disease. Hereditary or acquired C1 esterase deficiency is associated more with angioedema than urticaria; abdominal pain caused by mucosal edema may occur. Chronic urticaria affects primarily middle-aged women and is characterized by the occurrence of daily hives (individual lesions still resolve within 24 h) for longer than 6 weeks. Two specific conditions, urticarial vasculitis and a syndrome of urticarial lesions occurring in the setting of a serum sickness-like illness lasting longer than 24 h, are not, by definition, true urticaria. A skin biopsy should be performed on urticarial lesions that last longer than 24 h to exclude vasculitis. The cause of chronic urticaria in an individual patient may be difficult to establish. Several practical approaches have been published [3]. Treatment of urticaria consists of an attempt to eliminate the cause and relieve signs and symptoms with around-the-clock antihistamine therapy.

Erythema multiforme

Erythema multiforme is an acute, self-limiting, mucocutaneous syndrome characterized by targetoid cutaneous lesions

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Table 110.1 Erythematous vessel-based eruptions in patients with gastrointestinal disease

Clinical pattern	Common associations
Generalized erythema	
Morbiliform (macules and papules) Scarlatiniform (confluent)	Drug or transfusion reaction; viral exanthem
Palmar erythema	Nonspecific: oral contraceptive therapy; pregnancy, chronic liver disease, collagen-vascular diseases
Annular erythema	
Erythema migrans: often a single expanding lesion following a tick bite	Lyme disease
Erythema annulare centrifugum: multiple lesions, central clearing with rim of scale	Underlying infection; inflammatory disease
Erythema gyratum repens: rare "wood grain" pattern	Occult carcinoma: lung, stomach, esophagus
Urticaria	
Transient red wheals	Idiopathic, drug, food hypersensitivity; underlying infection; collagen-vascular disease
Erythema multiforme (EM)	
EM minor: target lesions	
EM major: mucous membrane	Drug reaction; infections (*Mycoplasma* species, herpes simplex, other); underlying inflammatory disease
Erythema nodosum	
Tender red nodules on legs and elsewhere	Underlying inflammatory disease (e.g., bowel disease, sarcoidosis); drug reaction

that may be accompanied by serum sickness-like signs and symptoms (e.g., fever, arthralgias) [4]. Erythema multiforme minor refers to a form of the syndrome in which patients have a finite number of acrally located typical target lesions and, in general, lack mucosal lesions and other symptoms. Erythema multiforme major represents a more severe disease, and is termed *Stevens–Johnson syndrome* if the patient has significant mucosal involvement [4]. Patients with toxic epidermal necrolysis, which may overlap with severe Stevens–Johnson syndrome, have a burn-like appearance. Toxic epidermal necrolysis is usually drug induced and may be associated with a 30% rate of mortality.

Well-documented causes of acute erythema multiforme include drugs (e.g., sulfonamides, phenytoin, penicillin), herpes simplex, *Mycoplasma* infections and other infections (e.g., tuberculosis), as well as a host of underlying diseases [4]. Typical erythema multiforme has been described in patients with inflammatory bowel disease [2]. Complications of erythema multiforme major may affect the gastrointestinal tract and may be severe in toxic epidermal necrolysis. Esophagitis and esophageal stricture have been reported. There is considerable evidence that most cases of recurrent erythema multiforme minor are induced by recurrent herpes simplex infections [4].

Therapy for erythema multiforme has not been assessed in a double-blind trial. Systemic corticosteroids are often prescribed for adults with erythema multiforme major in whom infection has been excluded. Ophthalmological consultation for eye involvement and aggressive topical care are required to prevent secondary infection.

Erythema nodosum

Erythema nodosum is characterized by the occurrence of tender nonulcerative nodules, most often on the legs, resulting from inflammation in the subcutaneous fat (Fig. 110.1). Usually, these nodules last 3–6 weeks and affect the anterior lower legs in a symmetric distribution. Patients may have associated signs and symptoms, including fever, malaise, arthritis, and arthralgias [5].

Erythema nodosum has been well established as an extraintestinal manifestation of ulcerative colitis, Crohn's disease, and infectious colitis such as that caused by *Yersinia enterocolitica* [1]. The incidence of erythema nodosum in patients with ulcerative colitis was 7% in one large series, but the incidence in Crohn's disease is lower [5]. Other well-documented conditions associated with erythema nodosum include drugs (e.g., estrogen, sulfonamides), infections (e.g., bacteria, viruses, fungi, chlamydia, acid-fast bacteria, spiro-

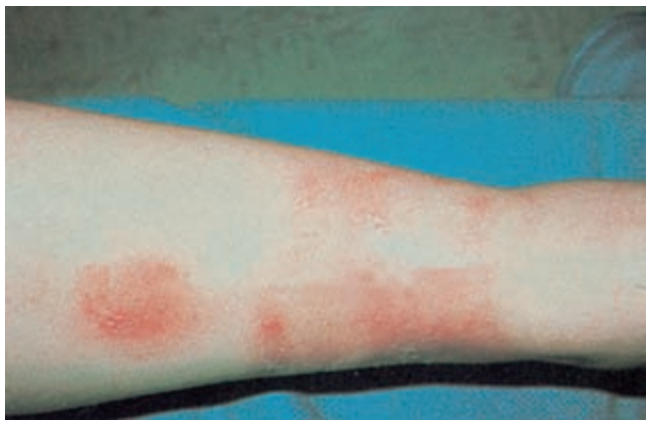

Figure 110.1 Tender nodules of erythema nodosum occurring in association with ulcerative colitis.

chetes), malignant diseases, and other diseases, including Behçet disease and sarcoidosis [5]. An immune complex-mediated mechanism affecting vessels in the septal panniculus has been proposed, although the exact pathogenesis of erythema nodosum remains unknown.

Treatment of erythema nodosum in patients with inflammatory bowel disease is directed at the underlying disease. Nonsteroidal antiinflammatory drugs or even acetaminophen may alleviate the systemic symptoms.

Vasculitis

The term *cutaneous small vessels vasculitis* (CSVV) has been used to refer to a form of vasculitis affecting postcapillary venules with the histopathological findings of endothelial swelling, neutrophilic invasion of blood vessel walls, leukocytoclasis (karyorrhexis of nuclei of neutrophils), extravasation of erythrocytes, and fibrinoid necrosis of blood vessel walls [6]. It presents as palpable purpura and may go by other names such as leukocytoclastic vasculitis, Henoch–Schönlein purpura (which is actually a subgroup with IgA-containing immune complexes), allergic angiitis, and hypersensitivity vasculitis. Larger-vessel involvement characterizes polyarteritis nodosa, granulomatous vasculitis (e.g., Wegener syndrome, Churg–Strauss syndrome), and giant-cell arteritis.

CSVV has been proposed as a cutaneous model for circulating immune complex-mediated vessel damage [6]. The central and peripheral nervous system, synovium, pleura, pericardium, gastrointestinal tract, and kidney may act as filters for complexes with the similar end result of necrotizing lesions [6].

Between 39% and 61% of patients with CSVV do not have a precipitating cause that can be identified. Drugs, infections (e.g., hepatitis B, streptococcal infection), and diseases associated with immune complexes (e.g., collagen vascular diseases, cancers, chronic active hepatitis) account for most of the identified associations. Crohn's disease [7] and ulcerative colitis [8] have both been clearly described in association with necrotizing venulitis and occasionally with granulomatous vasculitis [9].

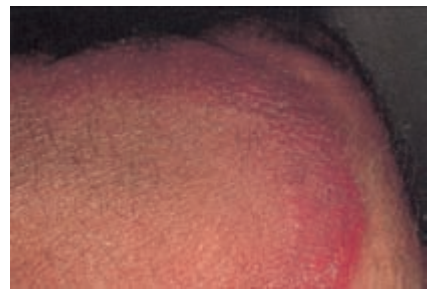

Figure 110.2 Typical lesions over joints in a patient with erythema elevatum diutinum.

Prognosis in all forms of vasculitis depends on the internal organ involvement. Treatment should be directed at the underlying disease. Severe vasculitis may require acute therapy with high-dose systemic corticosteroids, or pulse cyclophosphamide, or both. Low-dose weekly methotrexate, azathioprine or, for larger-vessel vasculitis, cyclophosphamide may be important adjuvant therapies. Oral colchicine or sulfone drugs (e.g., dapsone) may be used for primarily cutaneous vasculitis [6].

Erythema elevatum diutinum

Erythema elevatum diutinum is a chronic fibrosing dermatosis characterized by juxtaarticular, persistent, symmetric, firm, tender, red to yellow-brown papules and plaques on the extensor surfaces of extremities (Fig. 110.2). It is believed to be caused by immune complexes. Early histological features include leukocytoclastic vasculitis, subepidermal fibrin deposition, and dermal papillary edema. A storiform proliferation of dermal spindle cells with fibrosis and foci of neutrophils or neutrophilic vasculitis characterize older lesions. Besides inflammatory bowel disease and celiac disease, it has been associated with rheumatoid arthritis, pyoderma gangrenosum, diabetes mellitus, paraproteinemias, and dermatitis herpetiformis, as well as chronic infections including streptococcal, mycobacterial, and human immunodeficiency virus (HIV) infections [10]. Oral dapsone therapy is the treatment of choice.

Pyoderma gangrenosum

Pyoderma gangrenosum is a misleading designation for an idiopathic ulcerating cutaneous disease. Theories range from a forme fruste of vasculitis to a cell-mediated reactive process [6]. Typically, fully evolved lesions have a dusky purple, undermined border and heal with cribriform scarring (Fig. 110.3) [6]. Lesions may demonstrate the pathergy phenomenon: the rapid extension of the lesion after trauma such as surgical debridement.

The diagnosis of pyoderma gangrenosum is a clinical diagnosis of exclusion. Bacterial, fungal, mycobacterial, and other infections, as well as vasculitis, squamous cell carcinoma, iododerma, bromoderma, and factitial disease, must be

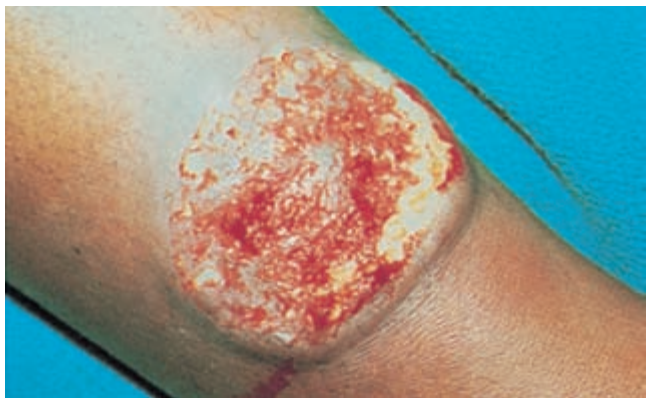

Figure 110.3 Pyoderma gangrenosum in a patient with Crohn's disease.

excluded histologically with appropriate special stains and cultures from biopsy specimens. More than 50% of patients with typical pyoderma gangrenosum do not have an associated disease. However, the association with inflammatory bowel disease is one of the best known and should be considered and excluded in every patient with pyoderma gangrenosum [11]. Other associated conditions include chronic active and chronic persistent hepatitis, polyarthritis including rheumatoid arthritis, and myeloproliferative disorders.

Aggressive therapy is often required because the disease can spread rapidly and can predispose patients to sepsis or inanition and even death. Systemic corticosteroids in high doses, immunosuppressive agents, and sulfones are the mainstays of treatment. Antibody therapy with antitumor necrosis factor α may be useful [12].

Oral manifestations

As many as 30% of patients with ulcerative colitis have oral lesions, including aphthae and angular stomatitis [2], whereas specific lesions (i.e., granulomas) of Crohn's disease affect the mouth and lips more rarely. Granulomatous lip lesions of Crohn's disease may be confused with Melkersson–Rosenthal syndrome, a condition in which granulomatous cheilitis occurs in association with facial nerve palsy. Granulomatous oral lesions may be nodular or show a cobblestone pattern [13]. *Aphthae* (canker sores) are nonspecific mucosal lesions that may be the most common oral lesions in patients with inflammatory bowel disease (Fig. 110.4). Simple aphthae occur in up to 25% of healthy persons. Patients with numerous, almost constant, oral aphthae (complex aphthosis) should be evaluated to exclude inflammatory bowel disease and Behçet disease [14].

Angular cheilitis (perléche and angular stomatitis) may occur as a manifestation of nutritional deficiency or, more commonly, as a manifestation of oral candidiasis. *Pyostomatitis vegetans* is a papular eruption of the oral mucosa that produces a cobblestone and eroded appearance. This distinctive oral disease is associated with Crohn's disease or ulcerative colitis in most patients [15].

Figure 110.4 Tender erythematous papules and plaques on the upper extremities in a patient with Sweet syndrome.

Sweet syndrome

Sweet syndrome, also known as acute febrile neutrophilic dermatosis, is characterized by the abrupt onset of tender cutaneous erythematous papules and plaques (Fig. 110.5). Fever and peripheral blood neutrophilia may also occur. Disease onset frequently follows a nonspecific infection of the respiratory or gastrointestinal tract and is believed to represent a hypersensitivity reaction. Sweet syndrome has been reported in association with acute infections, myelodysplastic and other malignant diseases, and inflammatory bowel disease [16]. Histological specimens show a neutrophil vascular reaction with dermal inflammatory neutrophilic infiltrates and leukocytoclasis with no fibrinoid change in vessel walls.

Cutaneous lesions are typically located on the upper extremities, head, and neck. They may ulcerate, become purulent, and resemble lesions of pyoderma gangrenosum. Many dermatologists view Sweet syndrome and pyoderma gangrenosum as representing a continuum along a spectrum of disease, and considerable overlap between these two diseases occurs. Like pyoderma gangrenosum, the disease responds to therapy with prednisone or other immunosuppressive agents, although often therapy with oral dapsone alone is adequate.

Figure 110.5 Aphthous ulcer involving the tongue in a patient with Behçet disease.

Figure 110.6 Finger clubbing.

Nail abnormalities

Finger clubbing is a nail disorder caused by enlargement of the soft tissues of the distal digit. The nail plate is enlarged and excessively curved (Fig. 110.6), with greater than 180° widening of the angle between the proximal nail fold and the nail plate (angle of Lovibond). Secondary bilateral clubbing has been associated with pulmonary, cardiac, gastrointestinal, infectious, and endocrine diseases. In Crohn's disease and ulcerative colitis, the hyponychial angle can be significantly correlated with disease activity [17]. Finger clubbing in patients with Crohn's disease has been reported to regress after resection of macroscopic disease. Clubbing usually develops over years but sometimes may develop subacutely, generating pain.

Miscellaneous skin lesions

Although certain reactive dermatoses occur more commonly in patients with inflammatory bowel disease, many reports exist of single-case associations of a given dermatosis with Crohn's disease or ulcerative colitis. Metastatic Crohn's disease, which is the occurrence of noncaseating granulomas remote from the gastrointestinal tract in patients with Crohn's disease, has been well described at a host of cutaneous sites [18,19]. Lesions are usually ulcers, papules, or nodules. Pustular vasculitis, which can occur with inflammatory bowel bypass syndrome, is discussed in the section Bowel-associated dermatosis/arthritis syndrome. Details of other less common associations can be sought in review articles [2,7], as well as in classical reports of large patient population surveys [20,21]. Table 110.2 provides an overview.

Table 110.2 Some cutaneous associations of Crohn's disease and ulcerative colitis

Erythemas (including annular erythemas)
Urticaria
Erythema nodosum

Psoriasis
Exfoliative erythroderma
Vitiligo
Lichen nitidus
Lichen planus

Rheumatological diseases

Rheumatoid arthritis, systemic lupus erythematosus, and dermatomyositis

A review of skin manifestations of rheumatoid arthritis, systemic lupus erythematosus, and dermatomyositis [22,23] is beyond the scope of this review. Gastrointestinal involvement is usually related to vasculitis and is similar to that described earlier. Chapter 109 describes the gastrointestinal manifestations of rheumatic diseases.

Antiphospholipid syndrome

This disorder is characterized by recurrent venous or arterial thrombosis with typical laboratory abnormalities (elevated levels of antibodies against membrane anionic phospholipids or their associated plasma proteins, or evidence of a circulating anticoagulant). It can occur as a primary disease or in association with systemic lupus erythematosus or another rheumatic or autoimmune disorder. Dermatological manifestations include livedo reticularis, purpura, and infarcts/ulceration. Gastrointestinal involvement is usually related to vasculitis.

Scleroderma

Scleroderma is a cutaneous or multisystem disease of unknown origin. A localized cutaneous form (morphea) is characterized by plaque, gyrate, generalized, or linear dermal sclerosis. The systemic form may be considered as a continuum of disease severity, the extremes of which are the milder CREST variant (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) and a more severe progressive systemic sclerosis [24]. Most patients with systemic scleroderma have the CREST variant. Although patients with CREST can become critically ill with

any of the varied manifestations of systemic scleroderma, they generally are middle-aged or older women who have a chronic course and die with, not of, their disease. Esophageal reflux should be treated to reduce esophageal fibrosis. Sclerosis occurs acrally and periorally and can affect the trunk. A salt-and-pepper postinflammatory pigment change is particularly noticeable over sclerotic areas in darker-skinned patients. Telangiectasias are described as being box-like or mat-like and occur on the hands, face, oral mucosa, and other sites [25]. The progressive systemic sclerosis type of systemic scleroderma occurs with an explosive onset. The dermal sclerosis is dramatic, but CREST features are often absent or are present to a lesser degree. The systemic and gastrointestinal features of scleroderma are discussed in Chapters 31, 47, and 109.

Behçet disease

Behçet disease is a complex multisystem disease first described by and named after a Turkish dermatologist. Because there is no pathognomonic laboratory test for the diagnosis, several sets of diagnostic criteria have been proposed. The O'Duffy criteria require that patients without inflammatory bowel disease or collagen vascular disease must have oral aphthosis (canker sores) plus at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis, and meningoencephalitis [26]. The exclusion of patients with inflammatory bowel disease is crucial because patients with bowel disease may have recurrent aphthosis and (especially those with HLA-B27 antigen) are best considered as having the Reiter disease/HLA-B27 spectrum of diseases rather than Behçet disease [27].

The oral lesions in Behçet disease are aphthae and can easily be distinguished from the psoriasiform oral lesions of Reiter disease [27]. Genital aphthae resemble oral aphthae (Fig. 110.7). Recurrent herpes simplex must be excluded by culture or by immunoperoxidase study of biopsy material. Cutaneous pustular vasculitis lesions show either leukocytoclastic vasculitis or a neutrophilic vascular reaction histologically [28]. Other lesions have been described that are similar to those seen in erythema nodosum, Sweet syndrome, or pyoderma gangrenosum.

Certain ocular changes have been described in these patients, although posterior uveitis (i.e., retinal vasculitis) is the most important manifestation. The synovitis produces an asymmetric, migratory, nonerosive oligoarthritis. Many neurological manifestations have been reported. Vascular involvement such as aneurysms, arterial occlusions, venous occlusions, and varices may occur, and they can prove fatal. The principal gastrointestinal manifestations are aphthae, which can occur at any gastrointestinal site. Changes similar to those in inflammatory bowel disease have been described but, as has been discussed, these may occur in HLA-B27-positive patients with a Reiter-like illness and aphthae.

Bowel-associated dermatosis/arthritis syndrome

Approximately 20% of patients in one report developed a characteristic syndrome after jejunoileal bypass surgery [29] that included pustular vasculitic cutaneous lesions, arthritis, and serum sickness-like features. Clinically and histopathologically, the skin lesions resembled the pustular vasculitis lesions seen in Behçet disease. This operation has essentially

Figure 110.7 Early genital aphtha showing features of pustular vasculitis in a patient with Behçet disease.

Figure 110.8 Bowel-associated dermatosis/arthritis syndrome. Pustular vasculitis lesions in a patient with a blind loop after Billroth II surgery.

Figure 110.9 Amyloidosis. Note the perirectal amyloid nodules in this patient with multiple myeloma.

been abandoned; however, we expanded the concept to include patients who have not had bypass surgery but who have either inflammatory bowel disease or the occurrence of a blind loop after Billroth II surgery [30].

The cutaneous lesions occur in crops, with each episode lasting 1–2 weeks and occurring at intervals of 1 month to several months (Fig. 110.8). Lesions similar to those seen in erythema nodosum may occur. Fever, myalgias, chills, flu-like symptoms, gastrointestinal upset, and arthralgias or nonerosive arthritis are often associated. Circulating immune complexes have been postulated to mediate this syndrome [29] and serum enhancement of neutrophil migration may mediate the cutaneous lesions [31].

The bowel bypass syndrome can be cured by restoration of normal bowel anatomy (see Chapter 53). Treatment of the underlying disease is necessary to control the syndrome in patients with inflammatory bowel disease. Systemic antibiotic therapy with metronidazole, tetracycline, or erythromycin has proved beneficial in controlling cutaneous and systemic manifestations of this syndrome. Systemic corticosteroid therapy and oral dapsone are also effective therapies.

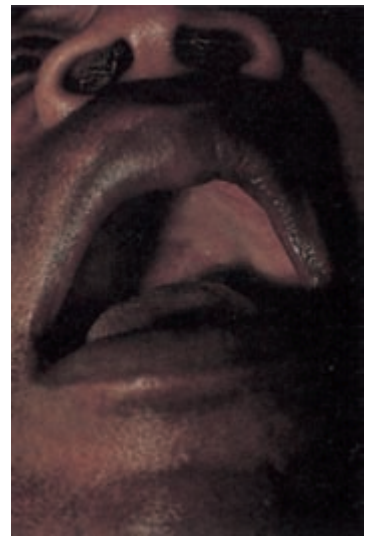

Figure 110.10 Typical telangiectasia of hereditary hemorrhagic telangiectasia.

Amyloidosis

Amyloidosis is a group of syndromes characterized by the extracellular deposition of an abnormal protein with certain staining properties and electron microscopic features. Primary amyloidosis, also called light chain-related systemic amyloidosis [32], often occurs in patients with multiple myeloma. Macroglossia, cutaneous papules, plaques, and nodules occur with pinch purpura (Fig. 110.9). Patients with primary amyloidosis have frequent gastrointestinal, cardiac, renal, and other multisystem involvement. Skin biopsy of a cutaneous lesion in primary amyloid is virtually diagnostic of the disease.

Patients with secondary (AA) amyloidosis do not have cutaneous involvement [33]. This pattern is associated with underlying disease, such as chronic inflammatory bowel disease, tuberculosis, leprosy, chronic osteomyelitis, or familial Mediterranean fever. Biopsy of normal skin reveals amyloid deposits in fewer than one-third of patients, whereas small bowel or colonic mucosal biopsy samples are positive in more than 75%–85% of patients.

Skin disease and gastrointestinal bleeding

Vascular abnormalities

Hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease)

This autosomal dominant trait is characterized by telangiectasis, aneurysms, and arteriovenous malformations that can affect mucocutaneous areas as well as internal organs [34]. The mucocutaneous hallmark for the syndrome is 1–3 mm telangiectatic mats resembling those seen in patients with scleroderma (Fig. 110.10). These lesions can affect the lips, tongue, face, hands, chest, and feet [34] (see Chapter 112).

Blue rubber bleb nevus syndrome

Blue rubber bleb nevus syndrome is a rare autosomal dominant condition with blue, subcutaneous, rubbery, compressible, sometimes painful nodular vascular malformations that are up to 10 cm in diameter [35]. These vascular malformations are not true hemangiomas. They occur in the small intestine or colon but have also been observed in the oropharynx, nasopharynx, esophagus, stomach, peritoneal cavity, mesentery, liver, lung, glans penis, eye, and central nervous system [36]. Gastrointestinal bleeding and intussusception may occur (see Chapter 112).

Kaposi sarcoma

Most publications since the early 1980s regarding Kaposi sarcoma have focused on the epidemic form of the disease, associated with acquired immunodeficiency syndrome (AIDS) [37] (see Chapter 104). An endemic form has long been recognized in Africa, and the third variant is the classic type, which occurs primarily in persons of Mediterranean ancestry.

The tumor in all groups is derived from proliferating endothelial cells. The cutaneous lesions vary from reddish-purple macules to large vascular tumors. In the slowly progressive classic form of the disease, lesions begin on the feet or lower legs of affected patients (who are typically elderly men) and extend proximally, becoming associated with severe peripheral edema. The most common site of internal involvement, but usually not a prominent feature, is the gastrointestinal tract. Sites affected, in decreasing frequency of involvement, include the small intestine, stomach, esophagus, and colon [38]. Extensive hemorrhage or partial bowel obstruction can occur. Other organs that may be affected include lymph nodes, larynx, spleen, liver, and lungs. Most patients with the classic form of Kaposi sarcoma die with, and not of, their disease.

Malignant atrophic papulosis (Degos disease)

Malignant atrophic papulosis (Degos disease) is a rare, idiopathic, usually lethal disease with characteristic lesions that affect the skin, gastrointestinal tract, and central nervous system [39]. The cutaneous lesions are discrete painless papules with umbilicated porcelain-white centers surrounded by telangiectatic rims. Histologically, these lesions reveal an atrophic epidermis with a wedge-shaped dermal scar that is broader at the top than at the bottom [40]. Gastrointestinal involvement may lead to massive gastrointestinal bleeding and to death (see Chapter 112). Current evidence is against an immunopathogenesis in this disease [40]. There is no effective therapy, and visceral involvement may be fatal.

Diseases of connective tissue

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum is a genetic disorder characterized by cutaneous and visceral manifestations that result from alterations to elastic fibers. Four genetic subtypes have been described, including both autosomal recessive and dominant inheritance patterns [41]. These types have a variety of ocular, cardiovascular, and gastrointestinal manifestations.

Figure 110.11 Pseudoxanthoma elasticum. Note the chicken skin-like appearance of the axillary skin.

The cutaneous lesions consist of yellow papules and plaques that resemble chicken skin (Fig. 110.11). These lesions begin early in life and may progress to affect the buccal mucosa, neck, axillae, and other flexures. Histologically, lesions show calcification of middermal elastic fibers. Angioid streaks are the characteristic retinal finding in patients affected with pseudoxanthoma elasticum but are not specific.

Gastrointestinal involvement may present with recurrent upper or lower gastrointestinal hemorrhage (see Chapter 112). Endoscopy reveals the characteristic yellow cobblestone changes in the bowel. The pathogenesis remains unknown. The treatment is aimed at complications, but no therapy exists to alter the connective tissue abnormality. Prognosis depends on the subtype of disease.

Ehlers–Danlos syndrome

Ehlers–Danlos syndrome is a heterogeneous group of genetically inherited syndromes characterized by defective collagen. More than 10 distinct subtypes exist, with various autosomal or X-linked inheritance patterns and with diverse abnormalities of collagen production [42].

The skin may be both hyperextensible and fragile. Wound healing is delayed and may produce cigarette burn-like scars or fishmouth-like scars as well as pseudotumors over joints. Purpura caused by easy bruising and hyperextensibility of joints are prominent features of Ehlers–Danlos syndrome.

Visceral involvement is varied. Gastrointestinal perforation is prevalent in patients with type IV Ehlers–Danlos syndrome who have defective type III collagen and translucent skin with numerous ecchymoses. In addition to bowel perforation and gastrointestinal bleeding, these patients have a predisposition toward rupture of blood vessels and therefore the prognosis is particularly grave [43] (see Chapter 112).

Cutis laxa (generalized elastolysis)

Cutis laxa is a heterogeneous group of autosomal and X-linked disorders characterized primarily by abnormalities of elastic fibers [44]. The skin appears to be too large for the body. It sags and has a wrinkled aged appearance. Gastrointestinal diverticula and hernias occur [44].

Neurofibromatosis (Von Recklinghausen disease)

Neurofibromatosis is inherited in an autosomal dominant fashion. Cutaneous features such as café au lait macules, axillary freckles, and cutaneous neurofibromas are hallmarks of this disease. Neurofibromas may occur throughout the gastrointestinal tract in 25% of patients [45]. The tongue, gallbladder, stomach, and jejunum are more commonly affected than the esophagus or colon. Ulceration, bleeding, volvulus, obstruction, perforation, and intussusception may occur. Malignant transformation of neurofibromas in the gut is not common, but is well reported. Surgery is often required for symptomatic gastrointestinal involvement.

Syndromes associated with gastrointestinal polyps

Gardner syndrome (familial adenomatous polyposis)

In 1953, Gardner refined his description of a dominantly inherited triad of osteomas, epidermoid cysts, and colorectal polyposis that predisposed to colonic adenocarcinoma [46]. Gardner syndrome occurs as part of a spectrum that includes familial polyposis coli (no extracolonic lesions) and Turcot syndrome (features of Gardner syndrome plus central nervous system neoplasms) (see Chapter 64).

Patients with Gardner syndrome develop multiple epidermoid cysts in early teenage years [47]. These cysts occur in a generalized distribution, especially on the scalp, face, and extremities [48] (Fig. 110.12). Desmoid tumors, which represent locally aggressive but nonmetastasizing tumors of fibrous tissue, often affect the mesentery or the abdominal wall.

Figure 110.12 Typical epidermal inclusion cyst of Gardner syndrome. This patient had many other cystic nodules, particularly on the scalp.

Peutz–Jeghers syndrome

Peutz and, later, Jeghers described a condition with an autosomal dominant inheritance pattern characterized by small intestinal hamartomatous polyps and hyperpigmented macules of the lips [49]. Although most polyps occur in the jejunum, they also occur in the ileum, stomach, duodenum, and colon (see Chapter 64). Polyps are present in childhood and may predispose to intussusception or to gastrointestinal bleeding. The melanotic macules of Peutz–Jeghers syndrome begin in infancy. They affect the lips most commonly, but also may affect the palms, soles, digits, periorbital skin, anus, and buccal mucosa. Histologically they resemble ephelides (freckles). All except the buccal lesions fade with age [50].

Cronkhite–Canada syndrome

Cronkhite–Canada syndrome is a sporadically occurring disorder of adults defined by the tetrad of cutaneous hyperpigmentation, alopecia, onychodystrophy, and intestinal polyposis [51]. The gastrointestinal signs and symptoms (e.g., diarrhea, abdominal pain, weight loss, anorexia) often precede the onset of the hair, nail, and cutaneous manifestations by several months (see Chapter 64).

The predominant cutaneous lesions are hyperpigmented macules that coalesce to form plaques that are distributed primarily on the upper extremities but which may occur on most cutaneous sites [52]. Vitiligo may occasionally occur. Onycholysis, onychoschizia, or onychomadesis may affect all 20 nails. Widespread alopecia is nonscarring and may resemble alopecia areata [52]. The tongue may be fissured.

Cowden disease

Cowden disease, also called multiple hamartoma syndrome, is inherited in an autosomal dominant fashion [52]. Mucocutaneous markers for the syndrome include facial and oral mucosal papules that histologically represent tricholemmomas (benign hair-derived tumors). The oral lesions produce a cobblestone appearance. A scrotal tongue is often associated. Acral keratoses resemble acrokeratosis verruciformis. Patients may also have lipomas, hemangiomas, neuromas, and café au lait macules.

Hamartomatous polyps occur throughout the gastrointestinal tract, with the majority affecting the rectum and sigmoid colon. The polyps are not premalignant; however, up to one-third of patients with Cowden disease develop a malignant disease, usually of the breast or thyroid [53].

Muir–Torre syndrome

Muir and Torre each reported the association of sebaceous neoplasms and multiple visceral carcinomas [54,55]. The inheritance pattern is autosomal dominant. Cutaneous markers for the syndrome include sebaceous neoplasms (hyperplasia,

adenoma, epithelioma, and carcinoma), basal cell carcinomas, and keratoacanthomas [52].

Adenomatous colonic polyps are not a universal feature of the syndrome, but half or more of these patients do have polyps, and some develop colonic adenocarcinomas. Urogenital, hematological, breast, and other malignant diseases may occur [56]. Patients should be screened frequently for colonic polyps, colonic carcinoma, and other malignant diseases.

Acrochordons and colonic polyps

In 1982, Klein and colleagues reported an increased incidence of acrochordons (skin tags) in patients with acromegaly observed for colonic polyps [57] and suggested that patients with more than six acrochordons could reasonably be targeted for evaluation for colonic polyps [58]. Several subsequent studies confirmed the correlation between acrochordons and colonic polyps [59], although this was refuted in an autopsy study [60]. Most agree that the association is of no prognostic significance (see Chapter 63).

Cutaneous signs of gastrointestinal malignancy

Metastases and direct extension

Metastatic nodules of gastrointestinal adenocarcinoma are usually firm, pink, dermal to subcutaneous masses that most likely occur on the abdomen or pelvic area. The primary lesion has usually already been diagnosed by the time metastases develop. Biopsy of such a lesion helps to diagnose the primary site in fewer than 50% of patients [61]. An indurated nodule of the umbilicus (the Sister Mary Joseph nodule) may be the initial clinical presentation of an underlying (usually advanced) abdominal malignant disease, most commonly adenocarcinoma of the stomach or large bowel. Rarely, direct involvement of the lymphatics in the abdominal or thigh region draining a primary site can lead to extensive dermal infiltration, presenting as a sclerotic plaque. Occasionally, such a plaque can be quite erythematous and can mimic cellulitis (carcinoma erysipeloides).

Cutaneous lesions that should raise suspicion of possible gastrointestinal malignancy

Extramammary Paget disease

Extramammary Paget disease is considered to be a cutaneous adenocarcinoma, probably of apocrine gland origin [62]. It presents insidiously as an erythematous scaling or lichenified patch, often with surface erosion or crusting. Typically, the site has been treated with topical corticosteroids or antifungals without response, and the diagnosis is made by clinical suspicion and skin biopsy. If it occurs in the perianal area, it should raise suspicion of a possible underlying rectal or cloacogenic carcinoma [63] (see Chapters 65 and 66). The frequency of underlying visceral carcinoma has been reported at up to 86%, although a more recent review showed that only 25% of patients with perianal Paget disease had a concurrent carcinoma of rectal origin [63]. Treatment of Paget disease is usually by surgery (Mohs micrographic or wide excision) or radiation therapy, but the lesion frequently recurs.

Acanthosis nigricans

Acanthosis nigricans presents as a smooth, thickened, and dark appearance to the skin in body fold areas, most often in the axilla and around the neck (Fig. 110.13). If extensive, it may lead to a striking appearance, with thickening of the palms and soles and oral lesions of hyperkeratosis. Acrochordons (or skin tags) may also occur in affected sites. This clinical presentation is most often seen without malignant disease in obese patients, in certain insulin-resistant diabetes syndromes, as a familial trait, and with certain medications.

Suspicion for malignancy-associated acanthosis nigricans should arise if the condition occurs with recent onset in a nonobese patient who does not have diabetes. Biopsy of the skin is not helpful. Attention should be focused on the possibility of gastric adenocarcinoma, although other intraabdominal and pelvic sites should also be evaluated for possible malignant disease [64,65]. The malignant disease appears concomitantly in 61% of patients, but in almost 20% the acanthosis nigricans may precede the diagnosable tumor by years. In these patients, frequent surveillance is necessary. In a patient known to have had an abdominal adenocarcinoma who then develops acanthosis nigricans, a vigorous search for recurrence or metastatic disease should be undertaken. The mechanism of malignant acanthosis nigricans is thought to be related to peptide growth factors released by the tumor

Figure 110.13 Acanthosis nigricans in a nonobese adult patient.

[66]. Remission of the skin lesions occurs with removal of the tumor. There is no good dermatological or cosmetic treatment for acanthosis nigricans.

Keratoderma of the palms and soles

Keratoderma of the palms and soles (tylosis) is a nonspecific presentation of diffuse or punctate yellow hyperkeratosis of the palmar and plantar surfaces. There are multiple causes, and it is only in patients with long-standing skin lesions and a family history of cancer that the question of gastrointestinal malignant disease should be raised. The strongest association has been with esophageal squamous cell carcinoma, and in the Howel-Evans syndrome it may occur in an autosomal dominant pattern, with up to 95% of family members developing esophageal carcinoma by 65 years of age [67] (see Chapter 36). In such kindreds, regular evaluations with barium swallow and esophagoscopy are warranted [68]. Other kindreds have been described with punctate keratodermas and carcinoma of the colon or pancreas. There are individual case reports of tylosis occurring in association with esophageal or bronchial carcinoma without a family history. In most of those cases, the palmar–plantar thickening was of recent onset without any other skin disease. The diagnosis of malignant disease was usually apparent at the time of initial presentation and evaluation.

Generalized erythroderma

Generalized erythroderma is a nonspecific cutaneous reaction pattern with a large differential diagnosis of possible causes, including primary skin diseases, adverse drug reaction, and internal malignant disease (especially lymphoma). The possibility of esophageal or other occult carcinoma should be raised in an erythrodermic patient with compatible symptoms [69].

Hypertrichosis lanuginosa acquisita

Hypertrichosis lanuginosa acquisita refers to the sudden development of diffuse, fine, downy hair on the face and trunk. It is extremely rare but is strongly associated with internal malignant disease. It has been seen most often with carcinoma of the lung or colon and, less commonly, of the pancreas and gallbladder [70].

Paterson–Brown–Kelly (Plummer–Vinson) syndrome

Patients with the Paterson–Brown–Kelly (Plummer–Vinson) syndrome present with mucocutaneous findings of brittle spoon-shaped nails (koilonychia), atrophic tongue, and angular stomatitis (see Chapter 111). Dysphagia and iron deficiency complete the syndrome. Carcinoma of the postcricoid area of the esophagus occasionally occurs in long-standing cases [71].

Bazex acrokeratosis

Bazex acrokeratosis is a rare paraneoplastic manifestation of malignant epitheliomas of the upper respiratory or digestive tracts, reported for the first time by Bazex in 1965. It may appear several months before the first signs of the malignancy with erythematous, keratotic and irregular lesions symmetrically distributed in hands, feet, ears, and nose. The nails are generally early involved, becoming fragile, thin, and with the free edge raised from subungual hyperkeratosis. Skin manifestations disappear when the tumor is removed, even if the nails do not always benefit from total recovery.

Carcinoid syndrome

Flushing episodes may be the presenting sign of carcinoid syndrome, which has been seen primarily with carcinoid tumors of the small intestine with liver metastases. The flushing is a bright red color on the face and upper chest, occasionally involving the entire trunk and extremities, lasting 10–30 min. After repeated episodes, permanent rosacea-like telangiectasia and edema develop. Episodes may be provoked by food intake, alcohol, and emotional stress. The mechanism of the flushing is related to contributions by various vasoactive peptides and neuropeptides (discussed in more detail in Chapter 54). The best treatment for carcinoid flush is octreotide, which is effective in up to 90% of cases [72]. Similar flushing episodes can occur in patients with multiple endocrine neoplasia. Pellagra-like skin lesions and cutaneous metastases have rarely been reported in patients with carcinoid tumors.

Necrolytic migratory erythema

Necrolytic migratory erythema is the specific descriptive term for the cutaneous lesions of the glucagonoma syndrome, which occurs with a glucagon-secreting islet cell tumor of the pancreas (see Chapter 71). The cutaneous eruption typically affects perioral, lower abdominal, and perineal sites with a configurative erythema, erosions, and superficial necrosis and scale. Clinically, the condition resembles zinc deficiency. Patients often have angular cheilitis and a red swollen tongue. The clinical presentation consisting of glucose intolerance, weight loss, psychological changes, and anemia is more important than skin biopsy in making the diagnosis [73]. Skin lesions may respond to intravenous amino acid supplementation, to octreotide or its analog, or to treatment of the underlying tumor [74,75]. Necrolytic migratory erythema has occasionally been reported in the absence of a pancreatic tumor, but a vigorous search for a tumor is needed whenever typical skin lesions occur in a patient with other suggestive symptoms.

Bullous diseases of the skin that can directly affect the gastrointestinal tract

Epidermolysis bullosa

Epidermolysis bullosa (EB) is a spectrum of inherited mechanobullous diseases in which blisters occur spontaneously

or at sites of friction or trauma. Onset of skin lesions occurs at birth or shortly thereafter, and a dermatological diagnosis of EB has usually been made before the patient presents to a gastroenterologist. Rarely, pyloric atresia has been found in infants with junctional or recessive dystrophic EB, apparently resulting from mucosal blistering and scarring in utero. The major sites of gastrointestinal involvement, most often occurring in the recessive dystrophic form, are the oral cavity, esophagus, and anal areas [76,77] (see Chapter 37).

Esophageal lesions may become symptomatic at any time in the first three decades of life. Dysphagia is the most common symptom and may reflect the presence of esophageal bullae or web-like scarring, both of which can cause partial or total obstruction. Most such lesions occur in the cervical esophagus near the cricopharyngeal area. Anal involvement, with bullae and subsequent scarring, may lead to constipation. EB acquisita is an uncommon late-onset disease with skin blistering and scarring at trauma sites and sometimes causing extensive scarring oral and esophageal lesions [78]. There is no family history of EB in these patients, which has occurred occasionally in association with inflammatory bowel disease.

Pemphigus vulgaris

Pemphigus vulgaris is an immunological blistering disease that commonly presents with oral erosions before the onset of cutaneous lesions. Skin or mucosal biopsy findings of an acantholytic blister and evidence of IgG in the intraepidermal space on direct and indirect immunofluorescence microscopy confirm the diagnosis. Symptomatic esophageal involvement is rare (see Chapter 37) [79]. Pemphigus involving the lower gastrointestinal tract can present with hemorrhage [80].

Bullous pemphigoid

Bullous pemphigoid is another immunological blistering disease in which older patients present with tense bullae. A biopsy specimen of the lesion shows a subepidermal blister, and IgG is found in the basement membrane zone in a linear pattern on direct and indirect immunofluorescence microscopy. Mucosal involvement is less common in bullous pemphigoid than in pemphigus (see Chapter 37), occurring in the mouth in about one-third of pemphigoid patients and less often in the esophagus or anus [81]. There have been case reports of bullous pemphigoid occurring coincident with gastrointestinal malignant disease, particularly carcinoma of the colon.

Skin conditions associated with abdominal pain

Porphyrias

Variegate porphyria is the most common porphyria in which patients present with skin lesions and episodic abdominal pain. The typical skin lesions (the same as are seen in porphyria cutanea tarda; see section Cutaneous signs associated with liver disease) are noninflamed blisters and erosions at sun-exposed sites, particularly the backs of the hands. Scarring with milia formation, hyperpigmentation, facial hypertrichosis, and sclerosis may occur. Photoprotection is of minimal benefit because the patients are exquisitely sensitive to light, and avoidance of inducing drugs is important. Hereditary coproporphyria is even more rare but may also have photosensitivity as a component.

Fabry disease

The skin lesions in Fabry disease, a rare lysosomal storage disease, are punctate, 1-mm, red to blue angiokeratomas that do not blanch. They are most densely distributed from the midabdomen to the knees. Lesions have their onset from childhood to adolescence. Decreased or absent sweating may also occur. The gastrointestinal manifestations of this disease are covered in Chapter 109.

Mastocytosis

Mastocytosis is an uncommon disorder of mast cell proliferation. The most common skin lesions are urticaria pigmentosa, with childhood onset. These are usually reddish-brown macules, but solitary nodules may occur. On stroking, these lesions typically itch, and a raised wheal or vesicle occurs (the Darier sign). Much less common is a telangiectatic variant or an erythroderma that occurs in adults. Skin biopsy confirms the increased numbers of mast cells in the dermis. Cutaneous symptoms may be controlled with antihistamines. Topical cromolyn and systemic psoralen in combination with ultraviolet A irradiation (PUVA) have been reported to be helpful in some patients. The gastrointestinal manifestations of mastocytosis [82] are discussed in Chapter 109.

Herpes zoster

T7–L1 dermatomal involvement of herpes zoster may cause abdominal pain before the onset of typical grouped vesicular lesions. Involvement of sacral nerve roots can produce constipation and pain during defecation [83]. Postherpetic neuralgia can cause persistent recurrent pain in the involved dermatome.

Rosacea

Rosacea is a chronic inflammatory condition characterized by central facial flushing, telangiectasias, acneiform lesions, and possible complication of nasal thickening called rhinophyma (Fig. 110.14). Several reports have described a possible relationship between *Helicobacter pylori* infection of the gastric mucosa and rosacea; however, no large case–control studies have been performed to prove a causal relationship [84]. Rosacea is commonly treated with topical or oral antibiotics, with the highest response rate usually obtained with oral tetracycline.

Figure 110.14 Characteristic telangiectasias, acneiform papules, and rhinophyma in a patient with rosacea.

Cutaneous signs associated with liver disease

Jaundice

This yellow discoloration of the skin, mucous membranes, and sclerae occurs because of the accumulation of bilirubin and its metabolites in these areas. In liver disease, it usually results from impaired excretion of conjugated (direct) bilirubin and becomes clinically evident at blood levels greater than 2.5 mg/dL. It can occur in almost any type of liver disease [85]. Treatment of the underlying liver condition will cause the jaundice to resolve. Ultraviolet light can resolve neonatal hyperbilirubinemia.

Pruritus

Pruritus, which is often severe and debilitating, can occur in cholestasis, cirrhosis, chronic hepatitis C, primary sclerosing cholangitis, and other forms of liver failure [86]. Patients with liver disease-associated itching often have elevated bile acids, bilirubin, alkaline phosphatase, and cholesterol, but the degree of itching does not generally correlate with the degree of elevation of these parameters. In fact, as the liver disease progresses, the itch may disappear, and this sign often heralds liver failure.

Pruritus may be the only symptom of cholestasis of pregnancy, which has associated increased fetal morbidity and mortality. A study of eight women with 13 pregnancies complicated by cholestasis revealed only one normal delivery, eight stillbirths, and three cases of fetal distress, one of which resulted in fetal death. Three of these women had subsequent pregnancies, with cholestasis treated with ursodeoxycholic acid and had healthy deliveries [87].

Treatment of liver-related itch involves measures to decrease the pruritus as well as measures to target the underlying liver disease (e.g., interferon for hepatitis C or surgery for common duct stones). Topical and systemic corticosteroids, PUVA therapy, and sedating antihistamines can decrease pruritus. Opiate antagonists such as naloxone, nalmefene, and naltrexone decrease itching, suggesting that a central opioid may be involved in the mechanism of pruritus. Symptoms resembling those of opiate withdrawal may occur with use of these drugs, and naltrexone can be hepatotoxic [88].

Other forms of cholestatic itch are treated empirically, because the pathogenesis is unknown. First-line agents are the bile acid sequestering agents such as cholestyramine and colestipol, which are resins that bind bile acids in the bowel and thereby reduce blood levels. They are moderately effective in decreasing itching, but are poorly tolerated because of gastrointestinal discomfort. These agents may work by a means other than just decreasing bile acids, because they also decrease itching associated with uremia and polycythemia vera. It is typical for patients to respond initially, but many become somewhat resistant thereafter. Ursodeoxycholic acid is actually a bile acid that lowers endogenous bile acid secretion into the gut. It is the only specific therapy that causes both a biochemical and survival benefit in patients with primary biliary cirrhosis [89]. Rifampicin can decrease the pruritus of cholestasis, but it must be used with care because it can be hepatotoxic [90]. Serotonin antagonists such as ondansetron also work in some cases [91].

Polyarteritis nodosa

Polyarteritis nodosa is a reaction pattern characterized by tender palpable purpuric nodules and livedo (Fig. 110.15) most commonly on the anterior legs, often with associated fever, arthralgias, malaise, and fibrinoid necrotizing arteritis histologically. Renal insufficiency and microaneurysms may occur. Hepatic arteritis was seen in 100% of patients with polyarteritis nodosa at autopsy in one study [92]. Intrahepatic hemorrhage is also reported [93]. Polyarteritis nodosa can occur in association with hepatitis B and, less commonly, hepatitis C and infections with parvovirus B19 and HIV. It is usually treated with immunosuppressive medications such as corticosteroids, which could exacerbate the underlying infection.

Figure 110.15 Polyarteritis nodosa with characteristic livedo reticularis and tender nodules.

Figure 110.16 Cryoglobulinemia often results in acral vasculitic infarcts.

Cryoglobulinemia

Cryoglobulins are immune complexes that can form as a reaction to drugs or infections. They can deposit within blood vessels and can create palpable purpuric nodules similar those seen in polyarteritis nodosa, with similar systemic complaints. Signs and symptoms are worsened by cold exposure and may include the Raynaud phenomenon or acral skin infarcts (Fig. 110.16). Hepatitis C is probably the leading cause of essential mixed cryoglobulinemia (type II or III forms) [94]. Patients with hepatitis B infections have detectable cryoglobulins, usually of mixed type, in around 15% of cases [95]. Persistent chronic hepatitis A infection with cholestasis may result in cryoglobulinemic vasculitis [96]. Cryoglobulins resolve with treatment of the underlying liver disease.

Papular acrodermatitis of childhood

This condition, also known as Gianotti–Crosti syndrome, is associated with hepatitis B, Epstein–Barr virus infection, and other viral infections in children [97]. It is characterized by asymptomatic erythematous papules that arise on the extremities, may occur on the face, and typically spare the trunk. These lesions tend to last 2–4 weeks and resolve on their own.

Lichen planus

Lichen planus is a mucocutaneous condition characterized by pruritic, purple, polygonal papules with surmounting Wickham striae and lacy reticulate white mucosal plaques. It can occur in conjunction with hepatitis C in significantly higher prevalence than in normal controls [98]. Lichen planus can also be seen in primary biliary cirrhosis and many other liver diseases. Most often, however, there is no underlying disease. Treatments include systemic or topical corticosteroids, dapsone, PUVA therapy, and methotrexate.

Porphyria cutanea tarda

Porphyria cutanea tarda is characterized by subepidermal bullae, milia, and scarring most often on the dorsum of the hands, with hypertrichosis and hyperpigmentation of the face, photosensitivity to visible light (Soret band, 410 nm), and iron overload. It is often acquired in chronic liver diseases such as alcoholic or viral hepatitis and cirrhosis. Hepatitis C RNA has been detected in up to 91% of patients with porphyria cutanea tarda [99]. Most often, the predisposition is an inherited dysfunctional enzyme known as uroporphyrinogen decarboxylase, which is important in porphyrin metabolism, and the liver disease potentiates expression of porphyria cutanea tarda. Treatments include phlebotomy, antimalarials, deferoxamine, and thalidomide.

Hypermelanosis

There are several hypotheses to explain why patients with chronic liver disease such as cirrhosis may develop hypermelanosis, which usually manifests as a diffuse or patchy grayish mucocutaneous pigmentation. It may occur because of increased levels of adrenocorticotropic hormone or melanocyte-stimulating hormone. As a result, the melanin content of the skin may be increased, and giant melanosomes may be present. Hemosiderin may also be directly deposited in the skin in iron overload conditions such as hemochromatosis.

Vascular changes

Some of the vascular changes of liver disease are thought to occur because of altered estrogen metabolism. Spider angiomas, which are small arteriovenous malformations characterized by a central feeding vessel and radiating telangiectasias, are often seen in chronic liver disease. They are most common on the face, upper trunk, and distal upper extremities. Palmar erythema may be patchy or diffuse.

Nail abnormalities

Terry nails is an opaque whitish discoloration of the nail plate, with the distal third being pink. All nails are uniformly involved. This discoloration can be seen in cirrhosis, occurring in up to 82% of patients, but it is not specific to liver disease.

Azure lunula (blue discoloration of the half-moon distal part of the nail matrix) is seen in hepatolenticular degeneration (Wilson disease), which is the result of abnormal copper metabolism. Clubbing may also occur in liver disease.

Other cutaneous manifestations

Urticaria, urticarial vasculitis, other forms of vasculitis, erythema multiforme, erythema nodosum, and pyoderma gangrenosum (all covered in this chapter) can occur in liver disease, especially in patients with hepatitis B infection. Acute hepatitis B infection can produce a serum sickness-like reaction with fever, arthralgias, polyarthritis, urticaria, and vasculitis.

Pancreatic disease

Periumbilical purpura (Cullen sign) and left flank purpura (Grey Turner sign) are caused by dissection of blood along

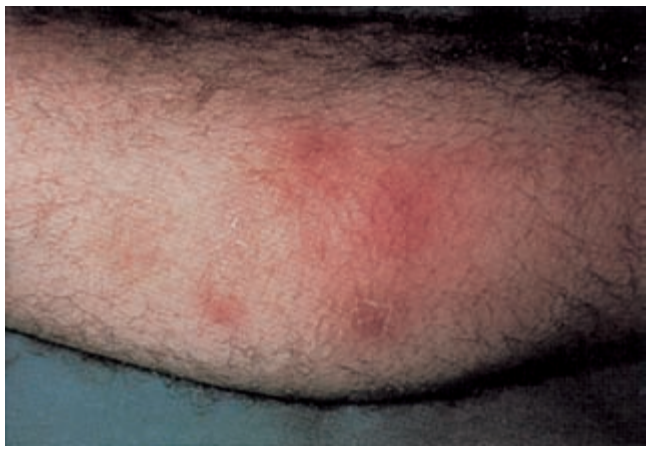

Figure 110.17 Panniculitis presenting as tender erythematous nodules in a patient with pancreatitis.

Figure 110.18 Dermatitis herpetiformis. Both elbows are involved. Note the intact vesicles and multiple crusted (i.e., excoriated) lesions.

fascial planes from retroperitoneal bleeding of acute hemorrhagic pancreatitis. Presentation of tender red subcutaneous nodules, occurring at any site but most commonly on the pretibial region of the extremities, should raise the diagnostic possibility of panniculitis (Fig. 110.17). Pancreatic fat necrosis may feel fluctuant, but lesions rarely ulcerate or discharge fluid [100]. Pancreatic fat necrosis may be the presenting sign in 22% of patients with pancreatitis or in up to 65% of patients with pancreatic carcinoma. Excisional biopsy (not punch biopsy) is indicated to confirm the diagnosis of panniculitis. The clinical differential diagnosis includes superficial migratory thrombophlebitis, which may be seen in pancreatic, gastric, or other cancers and in Behçet disease.

The eruption of multiple yellow-red papules, predominating over extensor surfaces or buttocks, suggests a diagnosis of eruptive xanthomatosis. These lesions occur in the presence of hypertriglyceridemia and type IV or V hyperlipoproteinemia and may develop in a patient with pancreatitis, particularly in the setting of diabetes mellitus.

Dermatological disorders associated with malabsorption

Dermatitis herpetiformis is an uncommon blistering disease characterized by intense pruritus and multiple grouped small vesicles distributed symmetrically over the body (Fig. 110.18). The scalp and extensor surfaces are prominently involved, and the itching and excoriation may be so severe that intact blisters are not conspicuous. Diagnosis is made by skin biopsy, which shows a subepidermal blister with a neutrophilic infiltrate of the dermal papillae. Direct immunofluorescence of perilesional skin confirms the diagnosis of dermatitis herpetiformis with the demonstration of IgA at the dermal–epidermal junction or within the dermal papillae [101,102].

Gastrointestinal manifestations may not be clinically prominent in patients with dermatitis herpetiformis who initially present to a dermatologist. Nevertheless, almost all patients have gluten sensitivity of the small intestine (see Chapter 50). Steatorrhea is observed in 20%–30% of patients, and anemia may occur secondary to malabsorption (e.g., of folate or iron). Even in the absence of gastrointestinal symptoms, strict observance of a gluten-free diet leads to improvement of the skin disease (which may take 6–24 months of careful diet restriction) and minimizes the need for medication [103,104]. Gluten challenge may cause a flare of the skin lesions in patients whose condition was previously controlled by diet.

Therapy of dermatitis herpetiformis with one of the sulfones, usually diaminodiphenylsulfone (dapsone) or with sulfapyridine, leads to prompt relief of symptoms and cessation of lesion formation (within hours to a few days). Oral dapsone is often started at a dose of 100–200 mg daily in adults and is titrated according to the clinical response and with the goal of minimizing side effects.

Malabsorption can occur with other skin diseases. Patients with extensive inflammatory skin disease, such as exfoliative erythroderma or atopic eczema, develop secondary malabsorption, termed *dermatopathic enteropathy* [105]. This is usually manifested as mild steatorrhea and is often asymptomatic; resolution is prompt with treatment of the skin disease. The mechanism is unclear, but it does not appear to result from gluten sensitivity.

Whipple disease is another cause of malabsorption that can be accompanied by diffuse pigmentation and subcutaneous nodules. This disorder generally presents with arthralgia and general malaise. The causative agent has been identified as *Tropheryma whippelii*.

Malabsorption can also occur as a result of abnormal motility or vascular compromise in systemic sclerosis and systemic

Table 110.3 Nutritional deficiencies and skin manifestations

Vitamin A	Multiple keratotic follicular papules over the extremities (phrynoderma) Generalized dry skin Sparse and fragile hairs
Vitamin B-1 (thiamin)	Glossitis Edema of the mucosae
Vitamin B-2 (riboflavin)	Seborrheic dermatitis Diffuse eczema Depapillated glossitis Hair loss, hypopigmentation, hair curling
Vitamin B-3 (niacin)	Painful erosive and pigmented scaling patches in sun-exposed areas Perianal lesions Cheilitis Red atrophic glossitis
Vitamin B-6 (pyridoxine)	Stomatitis Glossitis
Vitamin H/B-8 (biotin)	Eczema Hair loss
Vitamin B-9 (folic acid)	Lemon-yellow skin color Cheilitis Glossitis
Vitamin B-12 (cobalamin)	Generalized hyperpigmentation Vitiligo Hair loss
Vitamin C (ascorbic acid)	Follicular hyperkeratosis, perifollicular hemorrhages, perifollicular pigmentation Hair loss, corkscrew body hair Purpura
Vitamin K	Purpura and/or massive hemorrhages
Zinc	Erythematous, scaling, vesiculopustular or eroded plaques acrally distributed Stomatitis Hair loss Nail dystrophy
Iron	Cheilitis Hair loss Koilonychia
Copper	Light, sparse, brittle and kinky hair Pili torti
Proteins	
Total starvation	Dry loose skin Loss of subcutaneous fat Hair loss, hair fragility, slow hair growth rate, occasionally facial lanugo Purpura
With carbohydrate excess	Hypo-hyperpigmented scaling patches with peeling of the epidermis over edematous sites, joints and flexural areas Hair depigmentation diffuse or banded (flag sign) Purpura
Essential fatty acids	Erythematous scaling patches diffusely distributed Dry skin Intertriginous erosions Alopecia Purpura

vasculitides. Skin manifestations of chronic malabsorption are largely nonspecific and reflect altered nutritional status.

Nutritional disorders

See Table 110.3 [106–108].

Perineal skin lesions

There are several skin lesions that occur in the perianal or perineal areas that may be encountered in the course of examination or endoscopy procedure (Table 110.4) (see Chapter 66). Vesicles or erosions on an erythematous base should suggest herpetic lesions. Herpes simplex is often recurrent in this site, and in immunocompromised patients lesions may be persistent crusted erosions or ulcers. Herpes zoster usually presents acutely as dermatomal grouping of vesicles. Perianal ulcers and erosions may also occur in Crohn's disease, amebiasis, primary or secondary syphilis, or nontreponemal venereal disease. Flesh-colored pedunculated papules in the perineal area are often condylomata acuminata (venereal warts). Lesions, if they are few, usually respond well to therapy with cryosurgery, electrofulguration, surgical or laser excision, or application of topical podophyllin. Refractory lesions may respond to intralesional or systemic interferon.

Table 110.4 Perineal skin lesions (practical list of common causes)

Erythema with scale or maceration
Contact dermatitis
Seborrheic dermatitis
Psoriasis
Candidiasis
Dermatophytosis
Secondary syphilis
Extramammary Paget disease
Nutritional deficiencies
Bowen disease
Vesicles, erosions, and ulcers
Herpes simplex
Herpes zoster
Impetigo (streptococcal, staphylococcal)
Syphilis (primary or secondary)
Chancroid
Deep fungal, acid-fast bacilli, protozoal infections
Bullous pemphigoid
Pemphigus
Ecthyma
Nodules, tumors, and ulceration
Condylomata acuminata (i.e., warts)
Hidradenitis suppurativa
Squamous or basal cell carcinoma
Crohn's disease
Carcinoma: metastatic or direct extension
Kaposi sarcoma
Granulomatous herpes simplex

Erythema with scaling or maceration in the gluteal fold and perianal area raises the major considerations of candidal infection, psoriasis, seborrheic dermatitis, irritant contact dermatitis (from fecal soiling), or bacterial (streptococcal or staphylococcal) impetigo. Clinical presentation, potassium hydroxide preparation of skin scrapings, and culture are helpful in differentiating these diagnoses. If lesions do not respond to appropriate therapy for one of these diagnoses, biopsy may be indicated to rule out extramammary Paget disease. Idiopathic pruritus ani is a diagnosis that should be made only after a primary dermatosis, such as those just listed, has been excluded. It is a common complaint, particularly in middle-aged men, and psychological factors have been emphasized in some reviews [109,110]. The key to effective therapy of pruritus ani is eliminating underlying triggering factors, including infections, irritants, allergies, and anorectal disorders (e.g., rectal fissures, prolapse). Careful cleaning measures, dietary changes, and treatments ranging from topical corticosteroids to intralesional corticosteroids or cryosurgery have been used successfully. Treatment is most successful if the symptoms have been present for less than 2 years.

I MISCELLANEOUS

111 Oral manifestations of gastrointestinal diseases

John C. Rabine, Timothy T. Nostrant

Gastroesophageal reflux disease, 2774
Polyposis syndromes, 2776
Bleeding disorders, 2777
Immunodeficiency states, 2778
Nutritional deficiencies and malabsorption, 2778
Disorders of taste, 2781
Miscellaneous disorders, 2782

Many gastrointestinal disease states are associated with oral findings (Table 111.1). This chapter briefly addresses those disorders in which oropharyngeal pathology is most common.

Gastroesophageal reflux disease

The supraesophageal manifestations of gastroesophageal reflux disease (GERD), including reflux laryngitis and reflux-associated asthma, have gained increasing attention. Dental injuries, predominantly erosions, are also very common. Erosions are defined as circumscribed, punched-out, and discolored regions on the surface of a tooth, corresponding to enamel loss (Fig. 111.1), and can be differentiated from caries, which are dark defects with jagged edges [1]. Gastric acid exposure has been proposed as the mechanism of dental erosions because of its association with salivary loss [2], bulimia [3], and hiatal hernias [4]. Reflux has been documented in 83% of patients with erosions referred by their dentists for pH monitoring [5]. Parotid saliva analysis has also been proposed to be useful as GERD patients tend to have lower flow rates than control patients and have higher salivary calcium levels than bulimic patients [6].

The true incidence of dental erosions in GERD patients is unclear, but at least 20% of reflux patients have been found to have erosions [7,8] and more than 50% of patients with proven reflux by pH monitoring have been shown to have dental erosions [5]. Extrinsic acid exposure (citrus fruits, soft drinks, vinegar, chewable vitamin C tablets, etc.) is more likely to induce erosions on the labial surfaces of upper anterior teeth, whereas intrinsic acid from GERD is more likely to harm the lingual surfaces of teeth [1,9–12].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

The treatment of GERD-induced dental erosions is obviously aimed at limiting reflux and oral acid exposure. Patients should avoid acidic foods and drinks, they should allow antacids to dissolve in the mouth during symptomatic reflux events, and they should avoid brushing the teeth immediately after a reflux event. Chewing gum (sugarless) can be used to stimulate salivary flow between meals, and medications that reduce salivary flow should be avoided. In patients with xerostomia from medications, previous surgery, or previous radiation therapy, water should be consumed frequently or a saliva substitute should be used. Once the underlying reflux disorder has been addressed by the gastroenterologist, the patient should be under the care of a dentist, who can provide a polyethylene mouth guard at night to limit dental exposure to acid, topical fluoride pastes, and restorative dental procedures [13].

Laryngeal abnormalities are also very common with supraesophageal acid reflux. Symptoms that suggest reflux laryngitis include hoarseness, throat clearing, globus sensation, halitosis, or prolonged vocal cord warm-up [14]. Barium esophagraphy, upper endoscopy, and standard esophageal manometry are diagnostic in less than 25% of patients with reflux laryngitis, whereas 24-h pH monitoring is positive for distal reflux in 80% and for proximal reflux in 30%. Reflux laryngitis may be induced with minimal acid exposure. Small amounts of acid applied to the vocal cords only 3 times per week will induce significant cord edema and inflammation [15]. Therefore, microaspiration of small undetectable amounts of acid may cause laryngitis and explain both the need for strong acid suppression for effective treatment and the low number of abnormal pH studies in those patients who do respond to treatment [16,17]. Proximal acid reflux is cleared more slowly than distal acid reflux and may reflux into the oral cavity when no acid is present distally. If pH monitoring is considered in patients with supraesophageal symptoms, dual-channel monitoring should be performed.

Table 111.1 Oral lesions associated with gastrointestinal diseases

Ulceration/erosions
Crohn's disease
Ulcerative colitis
Sprue
Iron deficiency anemia
Behçet disease
Malabsorption
Acrodermatitis enteropathica
Amyloidosis
Pernicious anemia
Pyridoxine, B-6, folate deficiencies
Steroid use
Gastroesophageal reflux disease (GERD)
Lead poisoning
Graft-versus-host disease
Bulimia
Acquired immunodeficiency syndrome (AIDS)

Glossitis
Crohn's disease
Alcoholism
Sprue
Iron deficiency anemia
Pernicious anemia
Malabsorption
Carcinoid syndrome
Kwashiorkor amyloidosis
Pernicious anemia
Pyridoxine, B-6, B-2, niacin, folate deficiencies
Plummer–Vinson syndrome
Cowden disease
AIDS

Cheilitis
Crohn's disease
Alcoholism
Sprue
Iron deficiency anemia
Malabsorption
Acrodermatitis enteropathica
Plummer–Vinson syndrome
Folate, B-6, B-2 deficiencies

Vascular
Osler–Weber–Rendu syndrome

Gingivitis
Crohn's disease
Anorexia, bulimia
Sprue
Kwashiorkor

White patches
Vitamin A deficiency
Acrodermatitis enteropathica

Candidiasis
Steroid use
Kwashiorkor
Iron deficiency anemia

Tooth decay
Anorexia, bulimia
AIDS
GERD
Gardner syndrome
Collagen vascular disease (sicca complex)
Plummer–Vinson syndrome

Oral burning
Sprue
Iron deficiency anemia
Malabsorption
Niacin deficiency
Pernicious anemia
Carcinoid syndrome

In a recent study, significant differences were noted with proximal esophageal pH monitoring in patients with suspected supraesophageal reflux compared with control subjects and patients with typical GERD symptoms [18].

The gastroenterologist may be able to identify reflux laryngitis during routine upper endoscopy as the larynx is well visualized [19,20]. The posterior glottis, the posterior edges of the vocal cords and the mucosa overlying the arytenoid cartilage are seen best during inspiration when the vocal cords are abducted. The vocal cords are better examined during phonation when the cords are adducted. Classic posterior laryngitis consists of red arytenoid tissue and "piled-up" interarytenoid mucosa, but these findings are seen in the minority of reflux laryngitis patients (Fig. 111.2) [15]. Laryngeal edema is the most common finding but may easily be overlooked. Table 111.2 summarizes the laryngoscopic findings of reflux disease [19]. It is important to note that there is great controversy as to the specificity of these

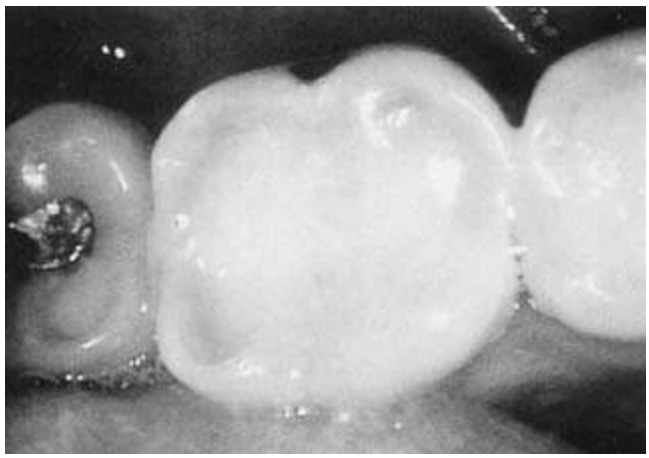

Figure 111.1 Dental erosion. Circumscribed regions correspond to exposed dentin in areas of enamel loss from repeated exposure to gastric contents in a woman with bulimia.

findings. One study suggests that many patients with presumed supraesophageal reflux based on laryngeal symptoms and findings do not respond to proton pump inhibitor (PPI) therapy or even have abnormal pH monitoring studies [21]. In another study, 52 nonsmokers with no GERD symptoms underwent laryngoscopic examinations that were independently judged by three ENT (ear, nose, and throat) specialists; approximately 50% of these patients had interarytenoid bars and medial arytenoid erythema, signs that are often attributed to supraesophageal GERD by ENT providers but appear to have questionable specificity when so common in asymptomatic patients [22].

Several studies have defined the benefits of acid suppression for reflux laryngitis. A 12-week course of omeprazole clearly improved laryngoscopic findings except for granulomas [23]. An initial response rate of 65% was seen in 22 patients treated with omeprazole 40 mg q.i.d. for 8 weeks. Relapse occurred in 38% after omeprazole was stopped. Abnormal pH studies were documented in the majority of nonresponders and there was no improvement in response with twice-daily omeprazole [24]. In another trial, 20 patients with dysphonia and laryngoscopically documented laryngitis were treated with omeprazole b.i.d. and demonstrated a 63% laryngoscopic (not clinical) response at 12 weeks [25]. Neither baseline GERD symptoms nor endoscopic findings predicted response, but pharyngeal reflux on pH monitoring (seen in only 4 patients) was predictive of response. In another study of 22 patients with idiopathic laryngitis, 50% of patients had a total symptomatic response after 3 months of lansoprazole b.i.d. therapy compared with a 10% response in the placebo group [26]. Three months of PPI therapy is considered the minimum to assess for response in supraesophageal GERD, but one study suggested that response rates improved from 48% to 70% if the PPI was continued for at least 4 months [27]. There are very limited data on the role of fundoplication for reflux laryngitis. In one study, 10 patients in whom 4 months of PPI therapy was ineffective underwent fundoplication; 80% showed improvement in laryngoscopic findings, but only 10% of patients had symptomatic improvement [28]. In short, it is reasonable to use PPI therapy empirically when reflux laryngitis is suspected, but at least 4 months of PPI therapy at b.i.d. dosing is necessary to assess response. Symptoms correlate with quality of life better than laryngoscopic findings, also supporting an empiric PPI trial [29]. The role of pH monitoring in documenting supraesophageal reflux is limited, though the longest reflux episode while supine and the fraction of supine time with pH less than 4 have been proposed to be good markers of reflux in patients with dysphonia [30].

Polyposis syndromes

Gardner syndrome

The oral manifestations of diseases associated with intestinal polyposis, such as Gardner syndrome, may be the first clue to the diagnosis.

(a) (b) (c)

Figure 111.2 **(a)** Edema and erythema of the vocal cords and posterior glottis (reflux laryngitis). **(b)** Vocal cord granuloma. **(c)** Distal reflux esophagitis in the same patient as in (a) and (b).

Multiple mutations of the adenomatous polyposis coli (APC) gene result in multiple forms of Gardner syndrome. Bone tumors, soft-tissue tumors, lipomas, desmoids, and sebaceous cysts may be seen (Fig. 111.3). Dental abnormalities including unerupted teeth, supernumary teeth, and dentigerous cysts may predispose these patients to early and profound tooth loss [31].

Peutz–Jeghers syndrome

Small intestinal hamartomatous polyps are the classic finding in Peutz–Jeghers syndrome, an autosomal dominant disease with variable penetrance. Pigmentation abnormalities with melanin deposition on mucosal surfaces are the visual hallmark. Typically appearing in the first year of life, small black or blue-gray macules form on the lips, perioral region, and buccal mucosa but may occur on any mucocutaneous surface including the fingers and toes. Perioral lesions often fade with age while those in the mouth or on the extremities may become more apparent [32]. Overall, the risk for malignancy in multiple organs can be as high as 30% and requires periodic surveillance.

Cowden disease

Multiple hamartoma syndrome, or Cowden disease, is a rare polyposis syndrome with facial trichilemmomas and oropharyngeal papillomatous growths appearing in the second decade [33,34]. Skin-colored papules, histologically neuromas, have also been described in younger patients [35]. Gastrointestinal tract malignancy is not increased but there is a higher incidence of extraintestinal malignancy, particularly breast and thyroid cancers. The overall risk for malignancy and the need for surveillance are similar to Peutz–Jeghers syndrome.

Bleeding disorders

Osler–Weber–Rendu syndrome

Hereditary hemorrhagic telangiectasias, or Osler–Weber–Rendu syndrome, is an autosomal dominant disorder characterized by widespread mucocutaneous telangiectasias of the face, ears, lips, oral cavity, nasopharynx, and hands. Oral bleeding has been reported in children, even before these vascular lesions can be seen [31]. Similar telangiectasias can be seen with scleroderma and CREST syndrome (*c*alcinosis cuti, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia), so the clinical features of these disorders can be used to differentiate them from Osler–Weber–Rendu syndrome [36]. Major bleeding sources are the nose and stomach, although colonic bleeding is recorded. Hemobilia secondary to vascular rupture can also occur. Varices are a rare source of bleeding with vascular transformation of the liver and associated cirrhosis.

Blue rubber bleb nevus syndrome

Blue rubber bleb nevus syndrome is characterized by multiple cavernous hemangiomas of the skin, oropharynx, and gastrointestinal tract. The angiomas have a blue color and smooth compliant surface, and rupture can lead to severe bleeding. The skin and gastrointestinal tract are affected more commonly than the mouth [31,37]. Histologically, these lesions consist of large, thin-walled vascular spaces with vessels lined by hyperplastic endothelium and separated by a scant network of elastin-deficient connective tissue [38].

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum is a rare form of elastic tissue degeneration producing thin vascular abnormalities in the gastrointestinal and genitourinary tracts that bleed. Yellow papules on the neck may also be seen.

Table 111.3 Immunodeficiency states (AIDS)

Type	Organism	Oral findings	Diagnosis	Treatment	Reference(s)
Fungal	*Candida albicans* Others	Whitish adherent exudates (friable)	Biopsy/brushing (yeast forms)	Topical nystatin Fluconazole or ketoconazole	41,42,45,46

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Immunodeficiency states

Acquired immunodeficiency syndrome (AIDS)

Human immunodeficiency virus (HIV)-associated oral infections are common and produce significant disability in affected patients causing anorexia, decreased oral intake, weight loss, and malnutrition. Common oral findings are given in Table 111.3.

Graft-versus-host disease

Graft-versus-host disease (GVHD) is a significant source of morbidity in bone marrow transplantation patients and generally occurs within the initial 3–4-week period after transplantation and may present as mucositis, dermatitis, enteritis, and hepatic dysfunction. Chronic GVHD often develops in patients with acute GVHD and typically presents at 3 months from the time of transplantation. Clinically, patients have symptoms suggestive of sicca complex and scleroderma. Painful oral mucositis and upper gastrointestinal dysmotility may develop, the latter resulting in gastroesophageal reflux and in bacterial overgrowth. In addition to more aggressive immunosuppression, patients with GVHD require nutritional and fluid support as well as therapy for any infectious complications.

Collagen vascular disease

Scleroderma is the classic collagen vascular disease associated with oral manifestations. Perioral skin tightening, telangiectasias of the lips and tongue, and dysgeusia are common findings. Sclerosis of the esophagus and small intestine may respectively result in the sequelae of reflux disease and in malabsorption from bacterial overgrowth. The sicca complex, characterized by decreased salivary and lacrimal gland secretion, may be seen in numerous connective tissue diseases but is classically associated with rheumatoid arthritis (Sjögren syndrome). Dental caries, tongue and buccal fissures, and swallowing difficulties may all develop. Human T-lymphocyte virus-1 (HTLV-1), has been proposed as part of the pathogenesis of Sjögren syndrome, based on the presence of serum and salivary antibodies in HTLV-1 [54]. Dermatomyositis is not commonly associated with oral manifestations, but oral ulcers, leukoplakia-like lesions, and gingival telangiectasias have been reported in association with this disorder [55].

Nutritional deficiencies and malabsorption

As summarized in Table 111.4, vitamin deficiencies may result in numerous epithelial changes in the oropharynx (Figs 111.4–111.6). Such deficiencies are usually associated with malabsorption or with inadequate intake in the setting of chronic illness. Rarely, a deficiency stems from competition for normal body stores such as with B-12 deficiency in *Diphyllobothrium latum* infestation. The malabsorptive states typically cause oropharyngeal manifestations based on the specific nutrient deficiency. A sore mouth (niacin deficiency),

Table 111.4 Vitamin/mineral/trace metal deficiencies

Type	Oral finding	Special considerations	Reference

Iron	Cheilitis, gingivitis, glossitis, ulceration, palatal pallor	Anemia	31
Zinc	Red, scaly, plaques vesicles Whitish tongue coating	Inherited (acrodermatitis enteropathica) Total parenteral nutrition, cirrhosis	31 31

Figure 111.4 Angular cheilitis. Inflammation at the angles of the mouth is commonly associated with B vitamin deficiencies such as deficiencies of riboflavin (B-2), niacin (B-3), and pyridoxine (B-6). Secondary *Candida* or staphylococci infection may develop. From Habif TP. Superficial fungal infections. In: Baxter S (ed.) Clinical Dermatology: a Color Guide to Diagnosis and Therapy, 3rd edn. St Louis: Mosby, 1996:400, with permission from Elsevier.

cheilitis and glossitis (B vitamin and folate deficiencies), stomatitis and oral ulceration (B vitamin, folate, niacin deficiencies), and bleeding (vitamin K deficiency) may all develop. White patches on the tongue reflect vitamin A deficiency. The hypermetabolism of tryptophan to serotonin with decreased niacin production can produce pellagra in patients with carcinoid syndrome.

Figure 111.5 Swollen, inflamed, bleeding gums and poor dentition may be seen in scurvy. From Briggaman R. Clinical Nutrition I Slideset. American Gastroenterological Association, 2000, with permission from Milner-Fenwick.

Inflammatory bowel states

Celiac disease

Cheilitis, gingivitis, and small vesicular ulcers of the tongue and oral mucosa are seen in celiac sprue [31]. The oral cavity may burn. Numerous but small white ulcerations can develop on the dorsum of the tongue, and swelling of the tongue can result in a "strawberry" appearance. Dental enamel loss has also been described in children [56].

Crohn's disease and ulcerative colitis

Oral lesions in inflammatory bowel disease (IBD) are extremely common with a prevalence of 4%–30%, and such lesions are more likely to be seen with Crohn's disease than with ulcerative colitis [57,58]. A prevalence of 0.5% was

Figure 111.6 Zinc deficiency may present as a scaly, erythematous rash at the angles of the mouth and the nasolabial folds in addition to stomatitis and tongue coating. From Grossman M. Figure 111.7 Aphthous ulcer. Aphthae appear as minute, shallow, white ulcers along mucous membranes. Though they may occur in healthy individuals, multiple or persistent lesions suggest an underlying diagnosis such as inflammatory bowel disease or Behçet disease. From Allison MC. Diagnostic Picture Tests in Gastroenterology. London: Mosby-Wolfe, 1991, with permission. Courtesy of Dr MC Allison.

seen in a tertiary care center specializing in oral dermatology [59]. In addition to extraintestinal inflammation in IBD, patients may develop malabsorption and subsequent malnutrition due to rapid transit, stricture formation, enterocolonic fistulas, previous severe mucosal loss, and bacterial overgrowth. Folate, iron, B-12 and fat-soluble vitamin deficiencies are most common. Trace metal deficiencies can be seen in IBD patients on total parenteral nutrition (TPN) without adequate replacement.

Crohn's disease

The oral lesions of Crohn's disease typically reflect active intestinal disease, though they may precede or follow clinically evident intestinal flares [31]. Aphthous linear labial ulcers, vestibular ulcers, pseudopolyps, and labial or buccal swelling have all been reported [31,59,60]. The various lesions frequently heal spontaneously but may also persist for several years, making it difficult to define a correlation between oral manifestations and intestinal disease activity [61,62]. Nonetheless, some have proposed that an eruption of aphthous ulcers actually predicts an impending Crohn's flare [63]. The pathogenesis of aphthous lesions is unclear, but it has been suggested that lymphocytes activated against enterobacterial toxins may release inflammatory mediators; diminished immunoglobulin A (IgA) secretion may also be involved [61–65]. Lip swelling, cheilitis, and Melkerson–Rosenthal syndrome (orofacial swelling, facial paralysis, and fissured tongue) have been described as initial presentations for Crohn's disease, particularly in children and adolescents [66,67].

Although not specific for IBD, aphthous ulcers are the most common oral manifestation of Crohn's disease and are seen in up to 20% of Crohn's patients [31]. These distinct shallow, white ulcers may be singular or widespread throughout the oral cavity (Fig. 111.7). Gingival hyperplasia and nodularity are not uncommon, and a cobblestone pattern may appear on the palate. The buccal mucosa may also show this cobblestone appearance owing to the presence of smooth nodules. Oral candidiasis has been seen in up to 5% of Crohn's patients, a finding not found in ulcerative colitis patients within the same trial [58]. One trial assessing the treatment of Crohn's oral lesions demonstrated complete remission of oral lesions with systemic steroids or with azathioprine in only 50%, whereas topical steroids induced a remission in 58% of cases [68]. Although data are limited, infliximab has also been reported as effective for oral lesions [69].

Ulcerative colitis

Apthous stomatitis and ulcers may be seen in ulcerative colitis patients, though ulcers are more typical of Crohn's disease. Cheilitis may also be seen and has been associated with scaling perioral skin and cervical adenopathy [31,57]. Pyostomatitis, also known as pyoderma vegetans, involves deep pustules that may progress to deep ulcers. This classically occurs on the lower lip but may also develop on the buccal mucosa, and peripheral eosinophilia has been reported. Like many oral manifestations of IBD, this lesion often develops during a colitis flare and resolves with aggressive IBD management; pyostomatitis may also predate a colitis flare by months or years [70]. Although not classically thought of in the oral cavity, pyoderma gangrenosa of the tongue has been reported and is characterized by deep ulceration and necrosis. It has been suggested that all of these lesions involve an immunological reaction such as circulating antigen–antibody complexes [31]. Unfortunately, many oral manifestations may persist or recur even after total colectomy. Although systemic steroids may help these lesions, topical or

locally injected steroids may lead to more rapid and profound resolution.

Behçet disease

Behçet disease is characterized by orogenital ulceration, ocular manifestations, and arthritis. Common problems include diarrhea, anorexia, bloating, and colorectal ulceration. Oral lesions consist of small or very large aphthous ulcers or of herpetiform-like ulcers. These ulcers tend to involve the palate, pharynx, and esophagus and can cause significant pain and dysphagia. In fact, recurrent oral lesions may be the only manifestation of Behçet disease for several years [71]. Based on clinical symptoms and ulcer appearance, IBD, herpes simplex virus (HSV) infection, and Reiter syndrome all need to be considered in the differential diagnosis. Periodontal disease is more common in patients with Behçet disease than in patients with ulcerative colitis or Crohn's disease and is a marker of disease activity; it is not clear if periodontal disease promotes a systemic inflammatory response that induces Behçet activity or if it is a result of the Behçet disease itself [72]. Treatment of oral Behçet lesions consists of topical steroids, nystatin, and tetracycline [31]. Thalidomide has been suggested as an alternative therapy, with an excellent response rate in one early trial [73].

Disorders of taste

There are numerous etiologies for the total loss of taste (ageusia), diminished taste (hypogeusia), and altered taste (dysgeusia). The human tongue contains approximately 10 000 taste buds, each of which contains 50–150 nerve receptors [74]. These receptors sense five primary tastes: sweet, sour, bitter, salty, and umami (taste of glutamate). It has also been proposed that there may be receptors for fatty acids as well. As summarized in Table 111.5, a variety of neurological conditions, systemic diseases, and medications are associated with altered taste. A full discussion of these processes is beyond the scope of this text [74–77]. Medications do deserve a brief mention as they impair taste by a variety of mechanisms. Some medications directly affect certain taste receptors; for example, ampicillin and pentamadine impede salty taste. Others inhibit cytochrome P450-dependent enzymes at the receptor level of the tongue, and some lead to silver sulfate deposition on the tongue. Medications can decrease turnover and regeneration of taste buds, and they may also impede taste by interfering with prostaglandin synthesis. Finally, some medications may contribute to a zinc deficiency or may alter calcium influx in taste receptors. Radiation therapy is another common cause of impaired taste, whether it be direct damage to receptors or the induction of xerostomia, which limits receptor exposure to ingested foods. Indeed, radiation therapy has a significant impact on quality of life and can cause weight loss as a result

of altered taste. It typically takes 6–12 months for taste to recover after radiation therapy, though it can take several years in some patients [75]. Treatment for taste disturbances is directed at the underlying etiology whenever possible. Though data are limited, zinc gluconate supplementation at a dose of 140 mg per day has been proposed as a reasonable approach in cases of idiopathic dysgeusia [74]. The use of vitamin A supplementation and steroids has also been reported.

Miscellaneous disorders

The oral findings and diagnostic considerations in lead poisoning, amyloidosis and Plummer–Vinson syndrome are listed in Table 111.6.

There are some features of amyloidosis that are worth mentioning. This disease may present as oral burning, jaw pain, and xerostomia [78]. Oral findings include papules, small raised ulcers, and macroglossia. Oral amyloidosis usually involves the tongue and is commonly felt to represent a paraneoplastic process, though local amyloidosis of the tongue has been reported [79]. Multiple myeloma is one condition in which oral amyloidosis can be a paraneoplastic manifestation. Hardening of the soft palate, the loss of facial expression, and difficulty in opening the mouth are other symptoms of oral amyloidosis associated with multiple myeloma [80].

Vascular lesions of the gastrointestinal tract are clinically highly relevant, and are a common cause of gastrointestinal bleeding. Among these lesions, gastrointestinal angiodysplasia is frequently encountered, whereas Dieulafoy lesion and gastric antral vascular ectasia (GAVE) are less common. An understanding of the other described lesions is important, despite their rarity, because they are frequently misdiagnosed and mistreated. For example, historically most rectal hemangiomas were misdiagnosed and mistreated as internal hemorrhoids [1].

The classification of gastrointestinal vascular lesions has been confusing because of variable classification schemes and inadequate consideration of anatomical and pathophysiological principles [2]. A simple classification based on anatomical and pathophysiological principles is illustrated in Fig. 112.1. Vascular lesions are divided into neoplastic lesions and non-neoplastic malformations, the latter including inflammatory (vasculitis) and structural malformations. Structural malformations are divided anatomically according to the most affected vascular component: arteriovenous, arterial, capillary, and venous. Neoplasms are, likewise, categorized according to the predominantly affected vessel and the cell of origin. Only the entities highlighted in color in Fig. 112.1 are discussed in this chapter. Table 112.1 summarizes the predominant clinical presentation, anatomical or histological abnormalities, endoscopic appearance, and characteristic features of the discussed lesions.

The nomenclature of these lesions has also been confusing owing to redundancy, application of erroneous pathophysiological mechanisms, use of the same name for different diseases, and inconsistent application of names to different diseases. For example, the Dieulafoy lesion has been called an exulceratio simplex, cirsoid aneurysm, caliber persistent artery, and submucosal arterial malformation; but, the Dieulafoy lesion is not an aneurysm [3]! The term phlebectasia has been used to describe both small hemangiomas or isolated venous varicosities [4]. The most commonly used name is employed in this chapter, provided the name is pathophysiologically reasonable.

Dieulafoy lesion

Pathology and pathophysiology

Although uncommon, the Dieulafoy lesion is important because it tends to bleed repeatedly and massively. Arteries normally narrow progressively in the arterial tree as successive branches approach the mucosa to terminate as submucosal end arteries. In the Dieulafoy lesion, the submucosal end artery is abnormally large; the alternative name of "caliber-persistent artery" is based on this abnormality. The lesion usually, but not always, occurs in the stomach, within 6 cm of the gastroesophageal junction and near the lesser curvature. The propensity for this location is explained by the absence of the usual submucosal arterial anastomotic gastric plexus in this region [5]. In three large clinical series, this lesion was in the proximal stomach in 75% of patients, the distal stomach in 13%, and the duodenum in 12% [6,7]. It rarely occurs in the esophagus [8].

The Dieulafoy artery is vulnerable to relatively minor mechanical trauma because it is large and superficial. Pulsations of the artery, peristaltic contractions, or passage of the food bolus may induce gastrointestinal bleeding [9]. Alternatively, the

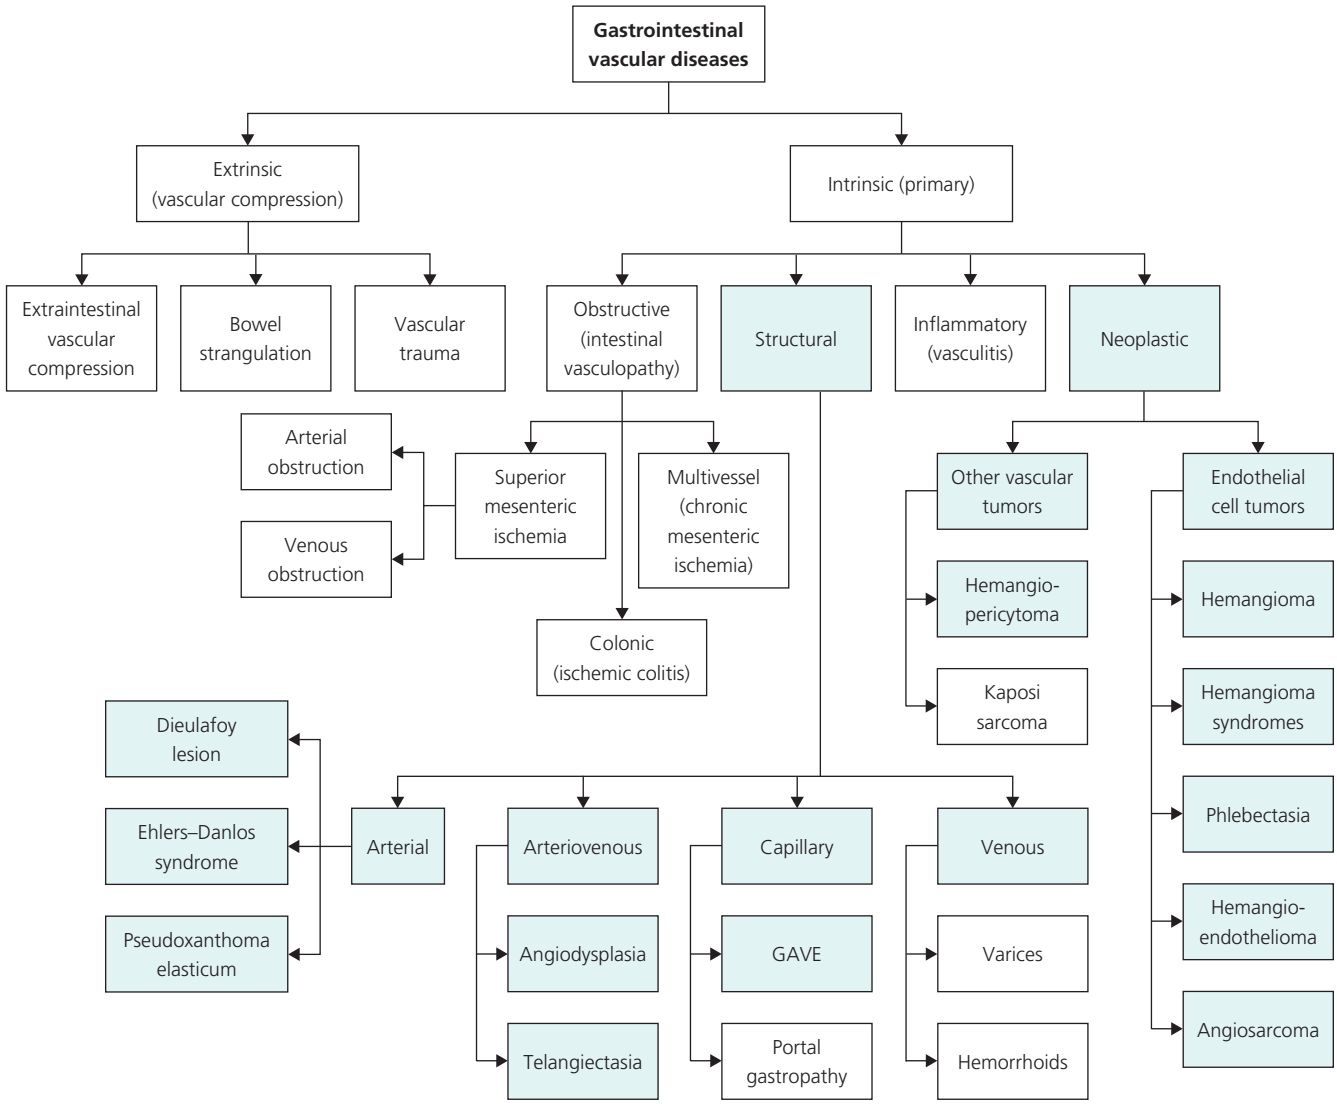

Figure 112.1 Classification of vascular gastrointestinal lesions. Diagrammatic outline of a new classification of vascular gastrointestinal lesions according to pathophysiology and according to the most affected vascular structure, whether arterial, venous, arteriovenous, or capillary. Diseases highlighted in green are discussed in this chapter. GAVE, gastric antral vascular ectasia.

large artery might cause hypoperfusion, ischemia, and erosion of overlying mucosa by shunting of blood (steal phenomenon). Both theories are compatible with the pathological findings of a thrombus attached to a large superficial artery overlying a small nonexcavated mucosal defect, with a normal vascular endothelium, without atherosclerosis, inflammation, or aneurysm [3,9,10]. Whether the lesion is congenital or acquired is unknown [3,11].

Upper gastrointestinal lesions

Epidemiology and clinical presentation

The incidence is about 1.5% among patients with upper gastrointestinal bleeding [6,12–14]. The male:female ratio is about 2:1 [7,10,14], and the mean age at diagnosis is 65 years, with a range of 1–95 years [7,10,15]. The lesion is not associated with use of alcohol, nonsteroidal antiinflammatory drugs, or tobacco, nor with the presence of peptic ulcer disease or *Helicobacter pylori* infection [7,10,16,17].

Patients present with acute, usually severe, gastrointestinal bleeding, often associated with manifestations of hemodynamic compromise such as hypotension, orthostasis, tachycardia, and prerenal azotemia. The bleeding is rarely occult and usually presents as hematemesis, melena, or hematochezia; about 50% of patients manifest both hematemesis and melena [10]. Other gastrointestinal complaints, such as abdominal pain, are atypical, and their presence should suggest another diagnosis, such as peptic ulcer or esophagitis [7].

Table 112.1 Gastrointestinal vascular malformations or neoplasms: clinical presentation, histology, endoscopic appearance, and other diagnostic features

Lesion	Predominant clinical problem	Anatomical/histological abnormality	Endoscopic appearance	Characteristic features on other tests
Arterial lesions				
Dieulafoy lesion	Severe arterial GI bleeding due to unusually large superficial artery that is vulnerable to minor trauma	Unusually large-caliber submucosal end artery, most commonly on lesser curve of proximal stomach	Pigmented, small (several millimeters wide) protuberance representing the vessel with minimal surrounding erosion and no ulceration	Angiography – extravasation of contrast from a point source in proximal stomach Endosonography – abnormally large (2–3 mm wide), high-flow, pulsatile submucosal artery
Vascular Ehlers–Danlos	GI bleeding, especially colonic, from spontaneous arterial rupture due to vascular and perivascular connective tissue weakness	Arterial wall weakness due to disordered collagen synthesis arising from mutation of *COL3A1* gene	Colonic diverticular bleeding, intramural hematomas, and other forms of arterial GI bleeding	Angiography – relatively contraindicated because of vascular fragility. MRA is the preferred test because of its greater safety
Pseudoxanthoma elasticum	GI bleeding attributed to elastin degeneration in small gastric arteries	Elastin degeneration of arterioles because of mutation of *ABCC6* gene	Bleeding from yellowish xanthomatoid papules (pseudoxanthomas) and petechiae in gastric fundus	Gastric lesions best diagnosed by EGD. Has cutaneous pseudoxanthomas, excessive skin folds, and papyraceous cutaneous scars
Arteriovenous communication or capillary lesion				
Angiodysplasia	GI bleeding from high pressure in thin-walled arteriolized veins and capillaries	Arteriovenous communications	Mucosal or submucosal, 2–8 mm wide, intensely red, dense, macular, reticular network of vessels (vascular tuft); abrupt and irregular (stellate) border	Angiography – vascular tuft, and early-filling, late-draining vein
Hereditary hemorrhagic telangiectasia	GI bleeding as a result of high pressure in thin-walled arteriolized veins and capillaries	Arteriovenous communication resulting from mutation of genes involved in blood vessel growth and repair	Endoscopic appearance identical to nonsyndromic angiodysplasia except that lesions distributed in all layers of the bowel wall	Angiography – identical to nonsyndromic angiodysplasia except for numerous lesions distributed in all layers of bowel wall
Gastric antral vascular ectasia (watermelon stomach)	Iron deficiency anemia consequent to chronic GI bleeding from dilated, tortuous, thin-walled vessels	Hypertrophied mucosa; dilated tortuous mucosal capillaries often occluded by bland fibrin thrombi; dilated tortuous submucosal veins; minimal inflammation	EGD – multiple parallel, prominent, intensely erythematous, longitudinal folds that traverse the antrum to converge on the pylorus	Endoscopic appearance with pathological analysis of endoscopic biopsy is characteristic

Table 112.1 (*cont'd*)

Lesion	Predominant clinical problem	Anatomical/histological abnormality	Endoscopic appearance	Characteristic features on other tests
Venous lesions				
Cavernous hemangiomas	GI bleeding from large, dilated, thin-walled vessels	Large, dilated, thin-walled vessels	Moderately well-circumscribed, violet-blue, sessile, compressible polypoid lesions, most commonly in distal colon or rectum	CT – large, thickened mesentery with large vacuoles next to an abnormal intestinal segment with a thickened wall that contains phleboliths
Blue rubber bleb nevus syndrome	GI bleeding from variant of GI hemangiomas with similar skin lesions	Multiple intestinal hemangiomas and similar skin lesions	Endoscopic appearance like that of cavernous hemangiomas. May have numerous and diffuse GI lesions	Capsule endoscopy is recommended if EGD and colonoscopy do not reveal the cause of GI bleeding
Klippel–Trenaunay syndrome	GI bleeding from extensive hemangiomas of the distal colon	Colonic hemangiomas; cutaneous hemangiomas; and atretic deep veins and bony hypertrophy of one lower limb	Colonoscopy – extensive infiltrative cavernous hemangioma of distal colon	CT – similar to findings with nonsyndromic colonic hemangiomas, except lesions tend to be larger and more locally invasive
Phlebectasias	Typically asymptomatic and incidental findings	Markedly dilated, tortuous vein with normal vascular wall. No portal hypertension	Colonoscopy – many dark-bluish, soft, compressible submucosal veins	Usually visualized by capsule endoscopy or colonoscopy
Neoplastic lesions				
Angiosarcomas (hemangiosarcomas)	GI bleeding, anemia, or abdominal pain. May present with diffuse metastases	Numerous interconnecting vascular channels (vasoformative structures) irregular in size and shape, atypical cells with mitosis	Hemorrhagic, ulcerated lesions	Histological markers – immunoreactive for vimentin, factor VIII-related antigen, CD34, or CD31. Immunonegative for endothelial cell markers, e.g., S-100
Hemangiopericytoma	GI bleeding from this highly vascular tumor, or constipation from a bulky GI mass	Tightly packed, spindle-shaped, neoplastic pericytes, surrounding interconnecting vascular channels	Endoscopy – solitary, circumscribed, submucosal polyp, covered by normal or ulcerated mucosa	CT – mass with multiple foci of low attenuation Angiography – richly vascular mass with a capillary blush
Hemangioendothelioma	GI bleeding from this vascular tumor, or abdominal pain, or GI obstruction	Borderline malignancy with more cellularity and mitoses than hemangiomas, but less than for angiosarcomas	Intestinal mass	Histological markers – immunoreactive for factor VIII-related antigen, CD34, or CD31

CT, computed tomography; EGD, esophagogastroduodenoscopy; GI, gastrointestinal; MRA, magnetic resonance angiography.

Figure 112.2 Endoscopic appearance of Dieulafoy lesion. Videophotograph shows a gastric cardial Dieulafoy lesion as a small, pigmented protuberance, which represents the vessel stump, with minimal surrounding erosion and no ulceration. From Lee JG, Leung JWC. Stigmata of recent hemorrhage in Dieulafoy's lesion. Gastrointest Endosc 2000;51:191, with permission.

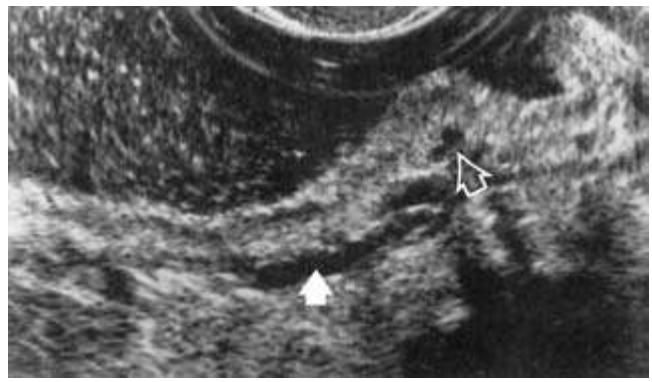

Figure 112.3 Videoendosonographic image of a Dieulafoy lesion. A relatively large gastric vessel courses outside the muscularis propria **(left**: *solid arrow***)**, penetrates the muscularis propria **(middle)**, and runs tortuously through the submucosa **(right**: *open arrow***)**. From Fockens & Tytgat [6], with permission from Gastrointest Endosc Clin North Am.

Diagnosis

The lesion is usually diagnosed by endoscopy, which reveals a pigmented protuberance, representing the vessel stump, with minimal surrounding erosion and no ulceration (Fig. 112.2). A pigmented protuberance within an ulcer represents a visible vessel in a peptic ulcer, not a Dieulafoy lesion. The Dieulafoy lesion is typically small (2–5 mm diameter); sometimes only a tiny necrotic spot is found in the proximal stomach. Stigmata of recent hemorrhage, such as an adherent clot or active bleeding, commonly occur. Active bleeding is often spurting or micropulsatile, as expected from an arterial source. The lesion should be suspected when a fresh, densely adherent clot in the proximal stomach has a narrow point of attachment to a small mucosal defect. The lesion may be missed at endoscopy because of its small size; careless gastric retroflexion; and concealment between gastric rugae, underneath blood in the gastric lake, or underneath a clot [18]. Indeed, in one large series, the lesion was detected in only 73% on the initial esophagogastroduodenoscopy (EGD) and then detected in a further 21% of cases on repeat EGD [10]. Meticulous endoscopic technique – including careful examination during gastric retroflexion, aspiration of the gastric lake, cautious irrigation of gastric clots, and adequate gastric insufflation to efface the gastric rugae – should increase the sensitivity of endoscopy. Endoscopic biopsy of the lesion is not recommended because of the risk of inducing bleeding.

Angiography is indicated for ongoing upper gastrointestinal bleeding after a nondiagnostic EGD; it was found to be diagnostic in 11 of 14 patients [10]. Angiography is suggestive of this lesion when extravasation of contrast is detected from a point source in the proximal stomach after a nondiagnostic EGD. Angiography may also demonstrate arterial tortuosity in the territory of the left gastric artery without other vascular abnormalities [19]. Angiographic findings of arteriovenous shunting, a vascular tuft, an early-filling vein, a late-draining vein, or a large draining vein are consistent with angiodysplasia, not a Dieulafoy lesion. The Dieulafoy artery is usually too small in caliber to be recognized as enlarged by angiography and, besides, is often obscured by extravasated contrast. Computed tomographic (CT) angiography or magnetic resonance angiography (MRA) may replace conventional angiography for the diagnosis [20].

Endoscopic Doppler ultrasound can confirm the diagnosis. The classic findings are an abnormally large (2–3 mm wide), high-flow, pulsating submucosal artery located along the lesser cuve near the gastroesophageal (GE) junction [21–23] (Fig. 112.3).

Therapy

Most patients require vigorous fluid resuscitation and transfusion of three or more units of packed erythrocytes for the severe bleeding. The lesion is not related to gastric acidity, and gastric acid suppression has no proven therapeutic role.

Endoscopic therapy for this point source of bleeding is particularly attractive, and fatal hemorrhage may occur without it. Endoscopic therapies include injection therapy, bipolar electrocoagulation, thermocoagulation, laser photocoagulation, endoscopic band ligation, and hemoclips [24–26]. In four large reviews, long-term hemostasis was achieved

in about 90% of patients by various endoscopic therapies [6,10,15,27]. The most experience has accumulated with endoscopic injection therapy with epinephrine (adrenaline) or polidocanol, which has been shown to achieve hemostasis in 53 of 56 patients [13,28,29]. There may be a higher risk for gastric perforation from sclerotherapy for a Dieulafoy lesion than for a gastric ulcer [30], owing to a lack of inflammation and fibrosis around a Dieulafoy lesion [6]. Endoscopic studies have reported high rates of successful hemostasis with endoscopic band ligation [31]. Two reports suggest that endoscopic hemoclips may be superior to endoscopic injection therapy [32,33]. Endoscopic epinephrine injection to reduce lesion vascularity followed by mechanical hemostasis or electrocoagulation appears to be a prudent strategy [34]. The major complication of endoscopic therapy is ulceration at the treated site.

Surgery was the treatment of choice before the development of endoscopic therapy, but surgery is now restricted to patients who fail endoscopic therapy. Surgical therapy has included electrocoagulation with vessel ligation, wedge resection, or proximal partial gastrectomy. Bleeding may recur after electrocoagulation or limited wedge resection because of the long span of the abnormal artery [35]. However, gastrectomy is theoretically unnecessary because the abnormal artery is usually restricted to the proximal stomach [36]. A wide wedge resection is a reasonable compromise between resecting too little or too much [7,16].

Therapeutic angiography with selective left gastric artery embolization before surgery for ongoing bleeding is supported by anecdotal evidence, but the hemostasis may only be transitory [37]. Although this lesion used to have a grave prognosis, the mortality decreased to about 25% with the advent of endoscopic therapy in the 1980s [7], and has since declined to about 10% [38].

Lower gastrointestinal lesions

Dieulafoy lesions of the jejunum, ileum, colon, and rectum are being increasingly reported. In one review, this lesion occurred in 0.3% of about 3000 patients with gastrointestinal bleeding [39]. About 10% of all Dieulafoy lesions are colonic. Colonic lesions also tend to bleed suddenly and severely [40–43], manifesting as bright-red blood per rectum, rather than melena, with hemodynamic instability [39].

Dieulafoy lesions of the jejunum, ileum, and colon are diagnosed preoperatively by endoscopy or angiography [44]. Lesions are more commonly detected in the colon and rectum than the jejunum and ileum, probably because of the more frequent use of colonoscopy than enteroscopy and the easier identification of lesions at colonoscopy than at enteroscopy because of a wider endoscopic field. The incidence of jejunal and ileal lesions may therefore be underestimated [45]. Videocapsule endoscopy may play an increasingly important role in diagnosing jejunoileal lesions beyond the reach of an enteroscope. The colonoscopic diagnosis is often complicated by severe lesion hemorrhage, which increases the risk and decreases the yield of colonoscopy [46]. Rectal lesions, however, are readily diagnosed by sigmoidoscopy [46,47]. The endoscopic appearance and histology of these lower gastrointestinal lesions are similar to those of gastric lesions [45].

Traditionally, surgery has been the therapy for lower gastrointestinal lesions [46,47], but colonoscopic hemostasis is being increasingly attempted, with the same modalities as are used for gastric lesions. Endoscopic therapy should be performed initially for a bleeding colonic lesion and surgery should be reserved for refractory bleeding [39,47]. The colonic Dieulafoy lesion is not a polyp and should not be removed by snare polypectomy because of risks of massive postpolypectomy hemorrhage [48].

Vascular Ehlers–Danlos syndrome

The Ehlers–Danlos syndrome is a rare heterogeneous group of six genetic disorders of collagen metabolism that cause skin hyperextensibility, articular hypermobility, and tissue fragility. Vascular Ehlers–Danlos syndrome (type IV) is the most common type associated with vascular lesions [49,50]. It results from mutation in the *COL3A1* gene that encodes for type III procollagen [51]. Patients often have a positive family history, in combination with thin transparent skin, wide thin (papyraceous) cutaneous scars overlying bony prominences, easy bruisability, and cutaneous ecchymoses from spontaneous arterial rupture as a consequence of vascular and perivascular connective tissue friability [52,53]. They have increased risks of intramural intestinal hematomas [52], colonic diverticular bleeding [52,54], other gastrointestinal bleeding [55,56], and, rarely, intestinal perforation [52,57] due to dissection or rupture of intestinal arteries. There is also increased risk of abdominal wall hernias because of connective tissue weakness [51]. About 75% of bowel complications occur in the colon [58]. The syndrome does not predispose to peptic ulcer disease, but patients with this syndrome who have coincidental peptic ulcers often bleed severely because of weakness of perivascular supportive tissue [50]. Type IV disease is diagnosed by biochemical analysis of collagen or genetic analysis [55], and leads to high mortality from repeated gastrointestinal bleeding [56]. Arteriography entails increased risks due to vascular fragility; noninvasive imaging of visceral vessels, such as MRA, is a preferred alternative. Gastrointestinal surgery produces poor results owing to tissue fragility and a bleeding diathesis; surgical anastomoses are vulnerable to disruption.

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum is a rare genetic disorder of elastin synthesis, caused by mutation of the *ABCC6* gene [59]

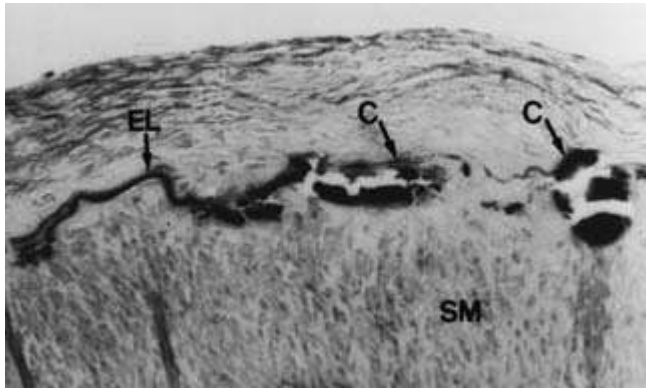

Figure 112.4 Histology of pseudoxanthoma elasticum. An elastin stain of a cross-section of the proximal stomach from a patient with pseudoxanthoma elasticum, who underwent total gastrectomy for massive refractory gastric bleeding, reveals a submucosal gastric artery with focal intimal thickening, fragmentation of the elastin lamina (EL), and intramural calcifications (C). SM, smooth muscle. From Kundrotas et al. [63], with permission from Blackwell Publishing.

and characterized by yellowish xanthomatoid papules (pseudoxanthomas) on the skin, excessive skin folds in flexural areas, angioid streaks in the ocular fundi, and intermittent claudication and weak peripheral pulses due to vascular occlusion [60]. Gastrointestinal bleeding occurs frequently; a rate of 13% has been observed in 200 patients [60]. The bleeding typically commences in young adulthood [60,61]. Most commonly, patients bleed from a characteristic lesion: numerous petechiae or erosions as well as yellowish xanthomatoid nodular lesions, that resemble the cutaneous lesions, are found predominantly in the gastric fundus [62–65]. Bleeding is attributed to elastin degeneration in small gastric arteries (Fig. 112.4) and is frequently severe and recurrent [66]. Bleeding arterioles do not vasoconstrict normally in response to hemorrhage, owing to intimal calcification and elastin degeneration, and are refractory to available pharmacological therapy [63]. Lesions may also not be amenable to endoscopic therapy because of their diffuseness. Partial or subtotal gastrectomy is the primary therapy.

Angiodysplasia

Epidemiology

Angiodysplasia is an important cause of acute and chronic gastrointestinal bleeding, particularly from the lower gastrointestinal tract. About 1% of asymptomatic healthy subjects have colonic angiodysplasia [67], whereas about 3%–6% of lower gastrointestinal bleeders have angiodysplasia [68–71]. The frequency of asymptomatic upper gastrointestinal angiodysplasia in healthy subjects is unknown, but angiodysplasia accounts for about 2%–5% of acute upper gastrointestinal bleeding [72–74]. About 3%–5% of gastrointestinal bleeding arises from the jejunum and ileum, and angiodysplasia is the most common cause of bleeding in this location [75,76]. The recognition of colonic angiodysplasia has increased markedly because of greater use of colonoscopy, causing the incidence to increase more than six-fold during the 1980s at one university hospital [77], and the recognition of small intestinal angiodysplasia has increased markedly since 2002 because of greater use of capsule endoscopy [75,78].

The incidence is unaffected by gender or race [71,77]. Angiodysplasia is not familial, but it may be confused with hereditary hemorrhagic telangiectasia (HHT), which is familial. Patients with bleeding from colonic angiodysplasia are generally elderly, with an average age of about 70 years [67,69,77,79,80], but the bleeding occasionally occurs in infants, children, and young adults [81].

Pathology

Colonic angiodysplasia occurs most commonly in the right colon, especially the cecum [82], but nearly 40% of colonic lesions occur distal to the hepatic flexure [67,83,84]. The predilection for the cecum is explained by the greater cecal mural tension owing to its larger lumenal diameter, according to the LaPlace law [85]. Upper gastrointestinal lesions occur most commonly in the stomach, sometimes in the duodenum, and rarely in the esophagus [72,77,82,86].

Angiodysplasias are often multiple [87] and tend to be clustered [80] (Fig. 112.5). Despite clustering, 15%–20% of patients with colonic angiodysplasia have upper gastrointestinal angiodysplasia, and vice versa [80,88].

Unlike the lesions of HHT, which occur in all layers of the bowel wall, angiodysplasia is restricted to the mucosa and submucosa [75]. Histologically, angiodysplasia consists of dilated, distorted, tortuous, and thin-walled vessels lined by endothelium with little or no smooth muscle and no inflammation, fibrosis, or atherosclerosis [72,79,89]. Initially, only submucosal veins are dilated, but in older lesions, mucosal veins and capillaries and even arteries become dilated [85,89] (Fig. 112.6). Congenital arteriovenous malformations, in contrast to angiodysplasia, typically have thick-walled arteries.

Associations and pathophysiology

Angiodysplasia is the most common cause of upper gastrointestinal bleeding (19%–32%) in patients with *chronic renal failure*, as compared with only about 3%–5% in the general population [90–93]. Similarly, colonic angiodysplasia is a frequent cause of lower gastrointestinal bleeding in patients with chronic renal failure [94].

The association with chronic renal failure is, however, somewhat controversial because several studies report no association [95–97]. The reported discrepancies could arise from several sources. First, the risk of angiodysplasia appears to increase with the duration and severity of renal dysfunction [90], and studies showing no association may include

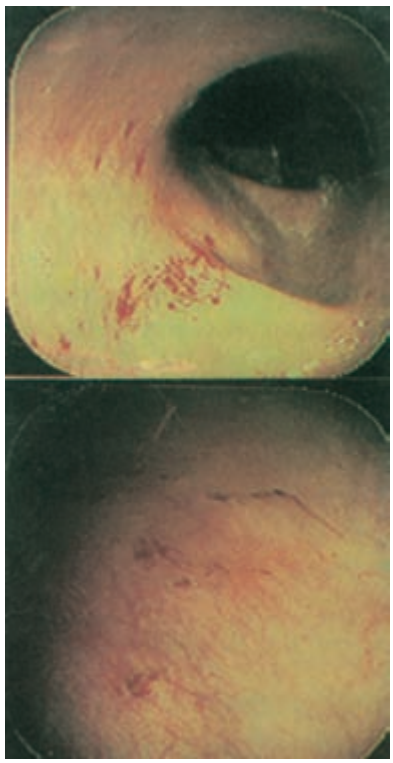

Figure 112.5 Endoscopic photo of cluster of angiodysplasia. **(a)** Colonoscopic videophotography demonstrates two adjunct clusters of angiodysplasia in the descending colon in an elderly female with iron deficiency anemia; colonoscopy revealed no other angiodysplasia in the rest of the colon. **(b)** Close-up views demonstrate the characteristic endoscopic appearance of angiodysplasia: an intensely red color, an intricate reticulonodular structure, and communication with prominent feeding or draining vessels. From Cappell [80], with permission from Springer Science and Business Media.

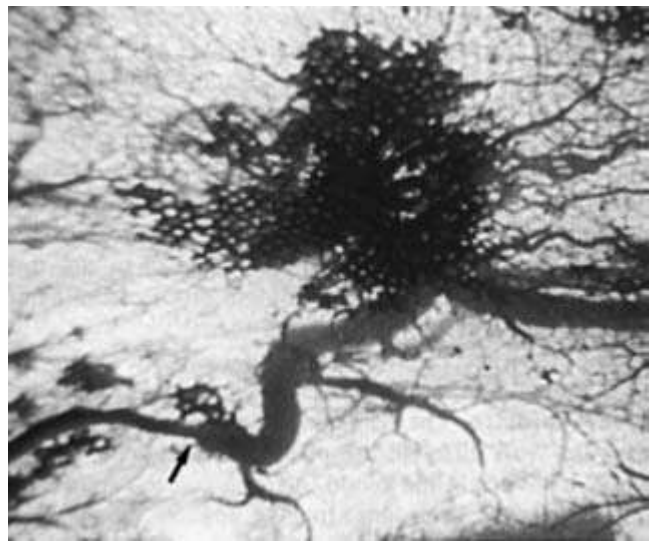

Figure 112.6 Transilluminated view of angiodysplasia. Photomicrograph through a dissecting microscope of a transilluminated, cleared colon after intravascular silicone injection reveals a mucosal ectatic vascular tangle surrounded by normal colonic crypts. The vascular tangle is drained by ectatic venules that lead to a large, distended, and tortuous underlying submucosal vein (arrow). From Boley SJ, Brandt LJ, Mitsudo SM. Vascular lesions of the colon. Adv Intern Med 1984;29:301, with permission from Elsevier.

patients with a short duration and mild severity of renal insufficiency. Second, many studies that show a lack of association were published in the early 1980s when angiodysplasia was an obscure diagnosis. Third, the presence of an association may be artifactual: platelet dysfunction with renal insufficiency may promote bleeding from and detection of otherwise clinically silent angiodysplasia [90]. In conclusion, angiodysplasia appears to be associated with chronic renal failure, but a prospective, controlled, investigator-blinded endoscopic study is needed to resolve the controversy.

The pathophysiology of this apparent association is speculative. Chronic, intermittent fluid overload in patients with renal failure may result in venous hypertension, microvascular venous dilation, and retrograde capillary dilation [92]. Older renal failure patients might have asymptomatic angiodysplasia, which could clinically manifest as a result of the bleeding diathesis associated with renal failure [93]. Hypertension and vascular disease, common in renal failure, could exacerbate bleeding from angiodysplasia [72].

After an association between *aortic stenosis* and unexplained gastrointestinal bleeding was proposed in 1958 [98], several retrospective studies showed that up to 25% of patients with angiodysplasia had aortic stenosis [82,85,87,91,99,100]. In many of these studies, aortic stenosis was diagnosed by clinical criteria without confirmation by echocardiography or cardiac catheterization [101]. An association was further strengthened by several case reports of cessation of bleeding from angiodysplasia after successful aortic valve replacement [102–104]. In two prospective endoscopic studies of 29 or 40 patients with gastrointestinal angiodysplasia, none had aortic stenosis detected by two-dimensional Doppler echocardiography [68,105]. By contrast, another study reported 32% of 73 patients with angiodysplasia had aortic stenosis on echocardiography, a much higher rate than expected [106]. Although somewhat controversial [107], the weight of evidence supports an association between aortic stenosis and gastrointestinal bleeding from angiodysplasia.

The association is likely the result of bleeding from previously clinically silent angiodysplasia caused by loss of large multimers of von Willebrand factor from high shear forces across a stenotic aortic valve. These multimers normally prevent bleeding at high-flow and high-shear-stress lesions such as angiodysplasia [108]. After successful aortic valve replacement, there is restoration of normal multimer levels and cessation of bleeding from angiodysplasia [109]. Types 2 or 3 von Willebrand disease are associated with severe bleeding

from intestinal angiodysplasia even when congenital and not associated with aortic stenosis [87,107,110].

A number of case reports have noted an association between gastrointestinal angiodysplasia and *scleroderma* or the *CREST syndrome* (calicinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) [111–114]. Although this association has not been proven in a large controlled trial, the known occurrence of cutaneous telangiectasia in scleroderma renders an association with gastrointestinal telangiectasia both credible and likely. Several cases of angiodysplasia have been reported in association with *Turner syndrome* [115,116] and *portal hypertension* [117,118]. These associations, however, are unproven.

The pathogenesis of angiodysplasia is unknown and may vary according to the associated condition and the age of onset [119]. A popular theory is that angiodysplasia is a degenerative lesion of aging caused by chronic intermittent low-grade obstruction of veins, capillaries, and arterioles that supply the mucosa [85] (Fig. 112.7). A neurovascular (or hormonal) mechanism could contribute to angiodysplasia [102]. In response to low-grade local hypoperfusion, sympathetic nerves may stimulate intestinal vascular smooth muscle relaxation to increase flow and reverse the hypoxia. With chronicity, local vascular overload, dilation, and ectasia develop pathologically [102]. This theory could explain the disappearance of angiodysplasia with intravenous meperidine injection (a problem with endoscopic diagnosis) [120] or cold water colonic irrigation [105] and the reappearance with naloxone administration. Increased expression of angiogenic factors [121] and deficient production of type IV collagen [122] have also been proposed as pathogenetic factors. Conceivably, the same genetic lesion that occurs in germ cells in HHT, as discussed later, may occur focally in somatic cells in sporadic angiodysplasia. This hypothesis, although speculative, is easily tested by molecular genetic analysis of tissue from sporadic angiodysplasia for *ENG* or *ACVRL1* mutations (see "Hereditary hemorrhagic telangiectasia" below).

Clinical presentation

Most angiodysplasias are asymptomatic and incidental. Bleeding from angiodysplasia is usually low grade and recurrent, and always painless. About 10% of patients present with acute severe hemorrhage [99]. The bleeding pattern may depend on the lesion stage, with more advanced lesions causing more frequent and more severe bleeding [79], and may depend on hemostatic parameters, with acquired von Willebrand deficiency causing severe bleeding [110]. The clinical presentation depends on the bleeding site, chronicity, and severity. Acute upper gastrointestinal bleeding most commonly manifests as melena, and occasionally as hematemesis [77]; acute jejunal and ileal bleeding as melena [75]; and acute lower gastrointestinal bleeding as hematochezia, and rarely as melena [72,77]. Chronic bleeding presents with fecal occult blood or iron deficiency anemia. Patients bleeding from angiodysplasia tend to have a longer history of gastrointestinal bleeding than other patients owing to greater difficulty in diagnosis [74,123]. Patients sometimes present with prior gastrointestinal bleeding without an endoscopic

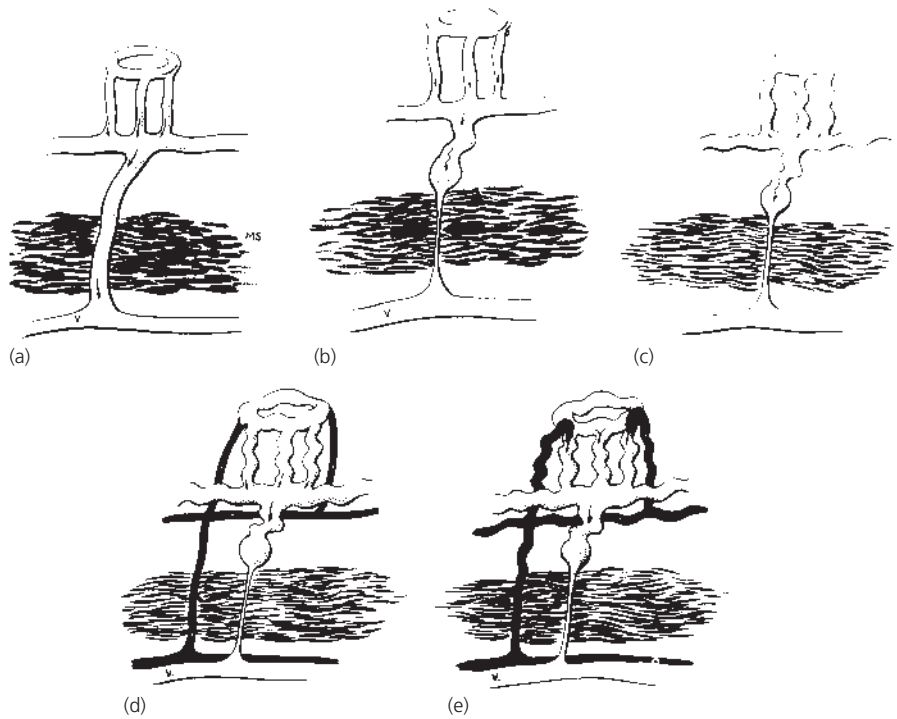

Figure 112.7 Diagrammatic illustration of a popular theory of angiodysplasia pathogenesis. **(a)** Normally patent distal veins within the muscular layer of gut drain proximal mucosal vessels, including the capillary ring. **(b)** These distal veins become partially obstructed due to muscular contractions or increased intralumenal pressure. **(c)** Chronic repeated intermittent obstruction of these distal veins results in proximal venous dilation and tortuosity. **(d)** With time, gut veins become progressively more dilated and tortuous, and the lesion propagates proximately. **(e)** Ultimately, the capillary ring becomes dilated, the precapillary sphincter becomes incompetent, and a small arteriovenous communication occurs through the ectasia. diagnosis, although this phenomenon is becoming less frequent with increasing endoscopic lesion recognition [77,119].

Physical examination is unrevealing except for signs of gastrointestinal blood loss. Although, in the past, angiodysplasia was associated with severe gastrointestinal bleeding [82], angiodysplasia is increasingly associated with mild bleeding, probably owing to earlier identification and recognition of milder cases [77].

Diagnosis

Endoscopy is the diagnostic procedure of choice [83,123]. In a study of 80 patients, colonoscopy had a sensitivity of 81% when compared with angiography and pathological examination of the resected colon [124]. Angiodysplasia may be missed behind folds, at sharp turns, or when covered by stool. True angiodysplasia can be carelessly dismissed as endoscopic erosions or fresh blood [86]. Angiodysplasia may be inconspicuous in a patient with hypotension or severe anemia and may become obscured after meperidine administration for endoscopy [120]. Although endoscopy should generally be performed after correction of hypotension or anemia with fluid resuscitation or blood transfusion, this principle is particularly important when angiodysplasia is suspected. When colonic angiodysplasia is suspected, complete colonoscopy with careful cecal examination is important. Although endoscopy is generally superior to barium studies in the evaluation of any cause of chronic gastrointestinal bleeding, this is particularly true when angiodysplasia is suspected because angiodysplasia is mucosal and macular and not visualized with barium contrast, and barium studies preclude subsequent angiography [125].

Endoscopy is a fairly specific test provided strict diagnostic criteria are applied. At endoscopy, angiodysplasia appears as a dense macular and reticular network of vessels (vascular tuft), which is typically 2–8 mm wide and is intensely red because of the high oxygen content in erythrocytes within vessels supplied by arteries without intervening capillaries (Fig. 112.8; see also Fig. 112.5). Sometimes a prominent feeding artery or draining vein is observed [68,124,126]. Some endoscopists note a pale (anemic) mucosal halo surrounding angiodysplasia due to shunting of blood (vascular steal) from surrounding tissue by the low-resistance angiodysplastic shunt [100].

It is important to assess at endoscopy whether observed angiodysplasia is the source of blood loss. In two large studies, 30%–44% of patients with angiodysplasia had other significant gastrointestinal lesions, such as colonic polyps, colon cancer, inflammatory bowel disease, or peptic ulcer disease [70,126]. Bleeding is attributed to angiodysplasia when it is actively bleeding or has an overlying clot. Otherwise, the diagnosis is made only by exclusion of other causes.

The hot biopsy technique is preferred to reduce the risk of bleeding from endoscopic biopsy, but endoscopic biopsy is generally not recommended because of the low diagnostic yield and the increased risk of provoking hemorrhage [72,87]. Pathological examination of an endoscopic biopsy supports the endoscopic diagnosis in only about 40% of cases because endoscopic biopsies are mostly mucosal, and the most consistent and characteristic histological abnormalities are submucosal.

Small intestinal angiodysplasia is the most common diagnosis (30% of cases) of capsule endoscopy performed for persistent, obscure, gastrointestinal bleeding (i.e., no etiology determined by EGD or colonoscopy), whether overt or occult [127,128]. Endoscopic stigmata of recent hemorrhage are frequently present. The endoscopic appearance and criteria for angiodyslpasia are the same at capsule endoscopy as for conventional tube endoscopy. Capsule endoscopy, however, lacks the capability for endoscopic biopsy or therapy of detected lesions.

The angiographic hallmarks of angiodysplasia are:

- a vascular tuft or tangle resulting from the local mass of irregular vessels, best visualized in the arterial phase
- an early and intensely filling vein resulting from a direct arteriovenous connection without intervening capillaries
- persistent opacification beyond the normal venous phase (slowly emptying vein), possibly resulting from venous tortuosity [129] (Fig. 112.9).

About 60%–90% of patients have each of these angiographic signs [84,129]. Angiodysplasias bleed only intermittently, and extravasation of contrast material from angiodysplasia is detected in only about 10% of angiograms [79]. The advantages of angiography are that it can detect angiodysplasia of the small intestine as well as the large intestine, and can be performed during severe hemorrhage when colonoscopy is ineffective [72]. Small intestinal angiodysplasia can, however, be missed at angiography because of misidentification as normal vascular arcades [130]. Helical CT angiography may be a relatively noninvasive alternative diagnostic test for colonic angiodysplasia, as demonstrated in a study of 26 patients [131].

Angiodysplasia is seldom detected at laparotomy by visual inspection or manual palpation of the serosal surface of gut because of its small size and mucosal location [72]. Richardson and colleagues [84] correctly identified angiodysplasia in only one of 39 laparotomies. Thus, preoperative diagnosis is critical to avoid blind bowel resection for gastrointestinal bleeding. Intraoperative enteroscopy can help localize angiodysplasia to minimize the extent of small bowel resection [132].

Differential diagnosis

At endoscopy, angiodysplasia can be differentiated from other red lesions, such as gastritis, Barrett esophagus, inflammatory bowel disease, tumor, phosphosoda enema-induced lesions, and other vascular lesions. Phlebectasia and hemangiomas are blue or wine-colored submucosal vascular masses that collapse with endoscopic air insufflation. Kaposi sarcoma

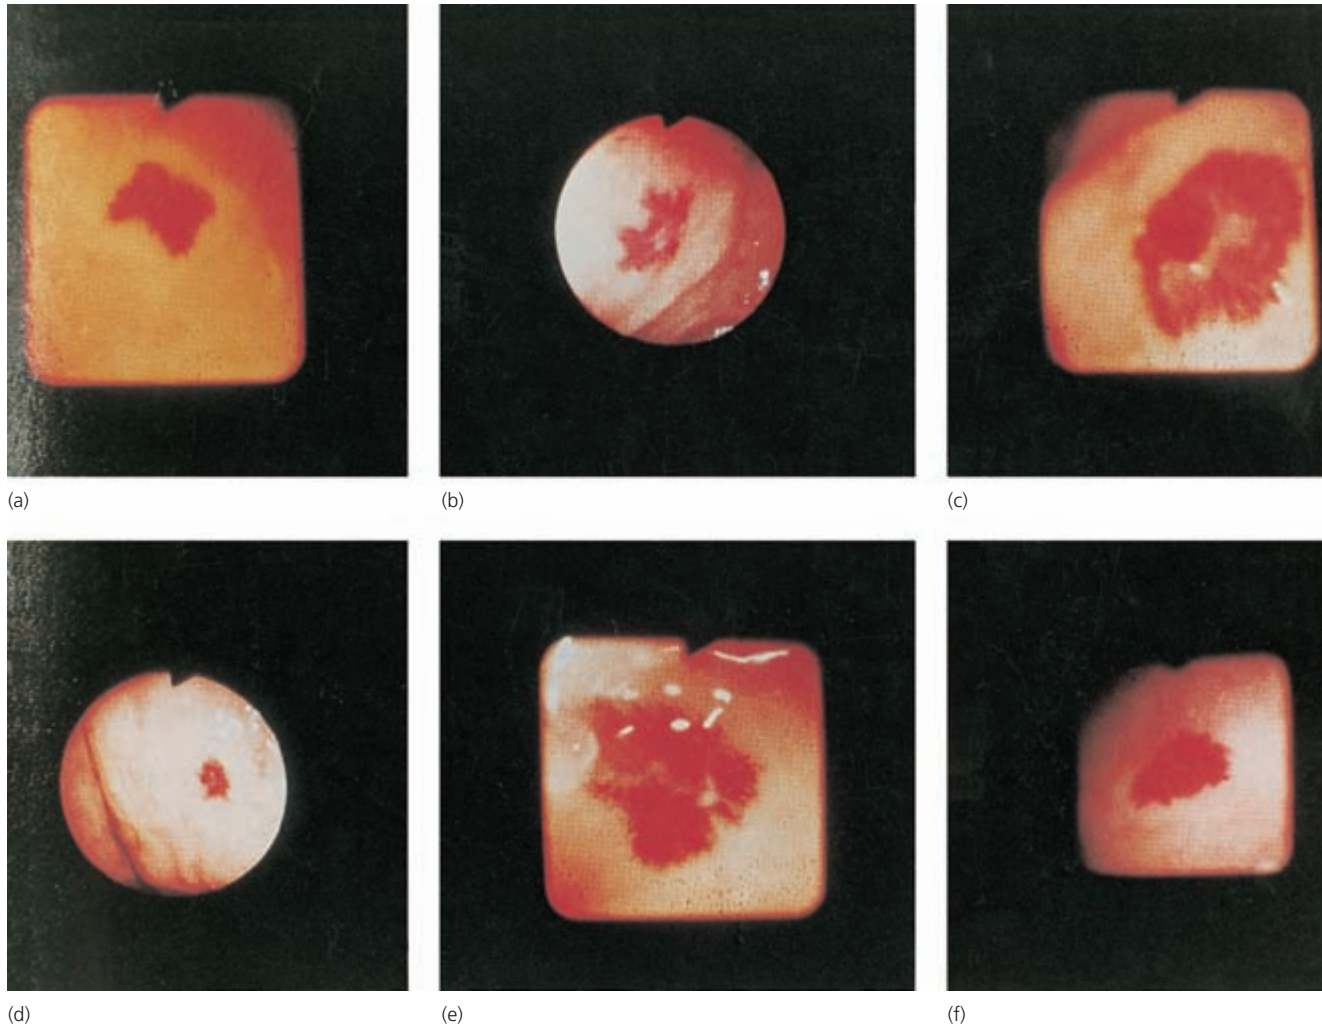

Figure 112.8 Spectrum of endoscopic appearance of upper gastrointestinal angiodysplasia. The characteristic endoscopic findings of angiodysplasia are intense erythema, well-demarcated margin, irregular stellate (star-like) margin, fine internal reticular (fern-like) structure, and macular mucosal location. Lesions range from 2 × 3 mm to 5 × 7 mm in size. All angiodysplasias are from the stomach, except for **(a)**, which is from the duodenum. From Clouse et al. [91], with permission from JAMA.

presents as a violaceous submucosal nodule or mass. A Dieulafoy lesion is typically elevated with one visible vessel. The characteristic antral location and arrangement of red lesions on longitudinal ridges distinguishes GAVE from angiodysplasia. Portal gastropathy is distinguished from angiodysplasia by a distinctive pale reticular border surrounding polygonal, intensely erythematous patches located in the proximal stomach.

The endoscopic appearance of gastrointestinal telangiectasias of HHT may be identical to that of angiodysplasia, except that the lesions of HHT tend to be greater in number, and occur in all bowel wall layers and all bowel segments. Patients with HHT may also have cutaneous telangiectasia, a positive family history, and a history of epistaxis. The diagnosis of scleroderma, CREST, or renal failure in association with angiodysplasia is based on the clinical manifestations of these conditions. The endoscopic findings in radiation colitis, aside from telangiectasia, include fibrosis, exudation, erosions, and mucosal friability, findings that are incompatible with angiodysplasia [133].

Red mucosal lesions resembling angiodysplasia when seen at endoscopy can be created iatrogenically by nasogastric aspiration or by endoscopic abrasion or suction. Lesions from nasogastric aspiration are round, colinear, equidistant, and relatively uniform in size, owing to the geometric arrangement of the nasogastric tube apertures, and are at the same stage of lesion evolution because of their simultaneous creation [134]. Lesions from endoscopic trauma are typically not seen during endoscopic intubation, but identified during endoscopic extubation. Compared with endoscopic trauma, angiodysplasia has a finely reticular (fern-like) internal structure owing to a vascular tuft, an irregular (stellate)

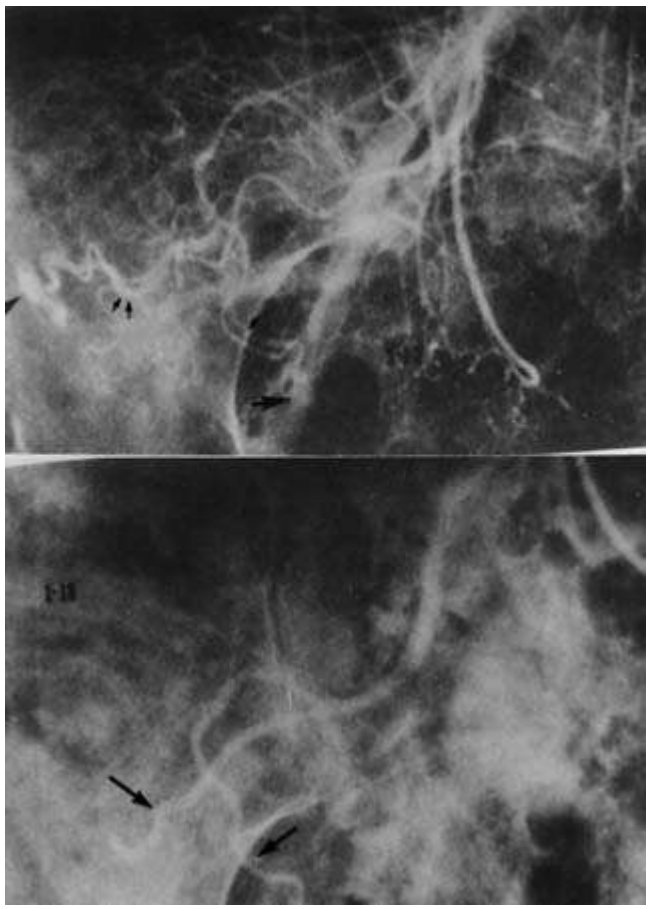

Figure 112.9 Angiographic findings in angiodysplasia. **(a)** Arterial phase shows a vascular tuft (large arrow) and two early filling veins (small arrows) that have filled with contrast before other veins. **(b)** Late phase reveals two densely opacified, dilated, and tortuous cecal veins (arrows) that still retain contrast after other veins have cleared. border as opposed to a round border with trauma, an abrupt lesion margin as opposed to an indistinct margin with trauma, and lesions lying flush (coplanar) with mucosa (see Figs 112.5 and 112.8). Thus, angiodysplasia is best diagnosed by detailed mucosal examination during endoscopic insertion with minimal use of suction [99]. The angiographic findings of angiodysplasia are occasionally mimicked by tumor or inflammatory bowel disease [72], but these other conditions are differentiated by endoscopy.

Natural history

Knowledge of the natural history of angiodysplasia provides a rational basis for deciding which angiodysplasias merit therapy based on their risk of future bleeding. Many angiodysplasias are asymptomatic and incidentally found at endoscopy, as, for example, during screening for colon cancer. Elderly patients with no history of bleeding frequently have small angiodysplasias detected in resected colonic specimens removed for unrelated colonic disease [85]. In a review of 41 patients with upper gastrointestinal angiodysplasias, 21 (51%) were incidental endoscopic findings [100]. In two series of 9 or 15 subjects with asymptomatic angiodysplasia, none experienced gastrointestinal bleeding during a mean follow-up of 2–3 years [67,126]. Thus small angiodysplasias discovered incidentaly at colonoscopy are unlikely to bleed in the near future.

Angiodysplasia is also associated with fecal occult blood, iron deficiency anemia, or gross bleeding. In a retrospective comparison of angiodysplasia and other causes of gastrointestinal bleeding, patients with angiodysplasia had a milder hospital course with fewer transfusions of packed erythrocytes, shorter hospitalizations, and lower mortality [77]. In three moderately large studies of patients with angiodysplasia presenting with bleeding or anemia, and treated conservatively by blood transfusions alone, 40%–50% rebled within 3 years [126,135,136].

Therapy

Endoscopic therapy

Therapy for angiodysplasia is stratified according to the likelihood of future bleeding as indicated by the medical history, findings on rectal examination, presence of iron deficiency anemia, and endoscopic findings. Asymptomatic angiodysplasias, incidentally found at endoscopy, are generally not endoscopically treated because of a low likelihood of subsequent bleeding [72,137]. This dictum holds particularly in the cecum and ascending colon because of the greater risks entailed by endoscopic therapy with the thinner colonic wall. Endoscopic therapy may, however, be considered when an angiodysplasia is exceptionally large or when prior bleeding from an angiodyplasia is suspected but undocumented. In other clinical situations, a graded approach to therapy is predicated on the likelihood of further bleeding from angiodysplasia. Actively bleeding angiodysplasia or angiodysplasia with recent prior bleeding, as evidenced by stigmata of recent hemorrhage, should be treated at endoscopy in the absence of contraindications, such as coagulopathy. Isolated angiodysplasias identified at endoscopy performed for recent acute bleeding that has stopped should likewise be treated if they are the suspected souce of the bleeding (e.g., no other gastrointestinal lesions identified) because of a high risk of future bleeding. Angiodysplasia associated with otherwise unexplained iron deficiency anemia may be treated at endoscopy depending on the clinical scenario. When multiple angiodysplasias are present, the endoscopist should concentrate on the largest and most accessible lesions, especially on lesions with endoscopic stigmata of recent hemorrhage.

At EGD, colonoscopy or enteroscopy, isolated, actively bleeding angiodysplasia is treated by endoscopic thermocoagulation, electrocoagulation, or photocoagulation [138]. Bleeding angiodysplasias are sometimes first injected with

alcohol or epinephrine (adrenaline) to slow the bleeding. These endoscopic therapies are relatively safe and highly successful at achieving short-term hemostasis. Gostout and colleagues [88] reported cessation of bleeding in 72 of 83 patients (87%) after laser photocoagulation during a mean follow-up period of 12 months. These therapies are also relatively effective in the long term: among 47 patients receiving laser photocoagulation, 61% had no significant gastrointestinal bleeding during 54 months of follow-up [139]. Laser therapy has a reportedly higher perforation rate of up to 4%, compared with other endoscopic therapies, because of the greater depth of tissue destruction [88,119,139]. The highest risk for perforation is in the thin-walled cecum, the most common location of angiodysplasia. Endoscopists generally prefer thermocoagulation or electrocoagulation over photocoagulation because of lower equipment costs and simpler technique, with equal efficacy.

Argon plasma coagulation (APC) is becoming the endoscopic therapy of choice because of its relatively low risks consequent to the shallow depth of tissue injury, and high efficacy given the superficial, mucosal location of angiodyslasia. Among 100 patients undergoing APC therapy of angiodysplasia for either overt gastrointestinal bleeding or iron deficiency anemia and fecal occult blood, 90 patients (90%) did not require any transfusions during a mean of 20 months of follow-up [140]. The two reported postprocedure complications were minor and without clinical sequelae. Other large studies have reported similarly high efficacy with few complications [141]. Double-balloon enteroscopy may permit APC therapy of jejunoileal lesions beyond the reach of an enteroscope [142]. Endoscopic band ligation has been reported to be effective for short-term hemostasis, but may have a higher long-term failure rate than APC [143].

Angiographic therapy

At angiography, active bleeding may be arrested by intraarterial vasopressin infusion or by transcatheter embolization. This may obviate the need for surgery or may slow bleeding enough to permit elective rather than emergent surgical resection. Vasopressin infusion has an initial success rate of about 50%–90%, with a roughly 33% chance of rebleeding [144,145]. Embolization produces a high rate of hemostasis [146,147]. Formerly, embolization had a high rate of intestinal infarction, but the frequency of this complication has decreased markedly as a result of improved catheter design and application of distal embolization. Angiography offers an alternative nonoperative therapy for jejunoileal angiodysplasia when conventional or double-balloon enteroscopy is unavailable.

Surgical therapy

Surgery is reserved for severe bleeding from well-characterized and localized lesions that are refractory to endoscopic or angiographic therapy. Endoscopy of both the upper and the lower gastrointestinal tract should be performed preoperatively, as well as capsule endoscopy, to exclude distant synchronous angiodysplasia or other lesions [80]. Right hemicolectomy is indicated for refractory bleeding from cecal angiodysplasia [99]. Even if angiodysplasia is identified only in the cecum, the entire right colon should be resected to ensure that no angiodysplasia are left behind. In right-sided angiodysplasia, none of the left colon should be removed, even if colonic diverticulosis is present, to avoid the increased morbidity and mortality of subtotal colectomy [99]. In two studies of 16 and 17 patients, this resection strategy yielded a significant but manageable long-term risk of postoperative rebleeding of 24%–37% during several years of follow-up [82,123]. Early rebleeding, which accounts for half or more of the cases, is usually the result of unappreciated lesions in the remaining colon and is usually successfully treated by subtotal colectomy [99].

Medical therapy

After reports of their use to control epistaxis from intranasal telangiectasia in HHT, estrogen and progesterone were used to control chronic recurrent bleeding from gastrointestinal angiodysplasia. These hormones are believed to promote vascular integrity [148]. Several small initial studies showed benefits from this therapy for angiodysplasia [149,150]. However, two studies of 64 [148] and 72 patients [135] reported no difference between patients treated with estrogen and progesterone versus untreated controls in the rate of bleeding cessation or in the number of units transfused.

Hormonal therapy for angiodysplasia, without HHT, is strictly reserved for patients with chronic bleeding from numerous angiodysplasias, for patients with jejunoileal angiodysplasias that are inaccessible to endoscopic therapy, and for patients who fail or cannot tolerate endoscopic or surgical therapy [148,151]. Hormonal therapy can cause feminization in male patients [152]. Other side effects include vaginal bleeding, fluid retention, thromboembolism, and congestive heart failure [153].

Hereditary hemorrhagic telangiectasia

The term telangiectasia denotes vascular ectasia, which is found as part of a systemic disease or syndrome, whereas angiodysplasia is nonsyndromic [4]. Gastrointestinal telangiectasia, which appears nearly identical to angiodysplasia, is associated with HHT, scleroderma, CREST syndrome, and possibly Turner syndrome. The latter two were mentioned above under "Angiodysplasia."

HHT is a genetic vascular disorder caused by mutation of the *ENG* (endoglin) gene (type I HHT) or of the *ACVRL1* gene (type II HHT) [154]. These mutations impair blood vessel

growth and repair, resulting in irregular, tortuous blood spaces lined by a single thin layer of endothelial cells [155]. These mutations produce a syndrome of multiple orocutaneous telangiectasias, especially on the face, lips, tongue, oral mucosa, and hands, together with multiple mucosal telangiectasias, especially in the nose and gastrointestinal tract (see Chapter 110). The cutaneous lesions are usually a minor cosmetic problem, whereas the nasal and gastrointestinal lesions frequently bleed significantly and repeatedly [156]. This bleeding tendency is explained by the thin and fragile vascular wall that lacks an elastic lamina or muscle layer, vulnerability to trauma because of vessel superficiality, and perhaps intralesional venous hypertension due to arterial shunting of blood.

The disease prevalence is about 1 per 10 000 population [157], and the gender distribution is equal [158,159]. More than 80% of patients experience epistaxis, spontaneously or after minimal trauma, which typically begins during the teenage years [157]; some 25% of patients with epistaxis require blood transfusions [153]. About 15% of patients have pulmonary arteriovenous malformations or fistulae, which can cause hypoxemia or hemoptysis [160], and about 10% have cerebrovascular malformations, which can cause a hemorrhagic stroke or brain abscess [161]. Symptomatic hepatic involvement is uncommon but important in that it can produce high-output heart failure, portal hypertension, biliary disease, or liver failure [162,163].

About 25% of patients experience clinically significant gastrointestinal bleeding, which typically begins during middle age [164,165]. This risk increases with age as patients acquire more gastrointestinal telangiectasia [166]. Chronic blood loss may result in iron deficiency anemia, whereas acute blood loss may cause hypovolemia and hypotension. Upper gastrointestinal bleeding is more common than lower gastrointestinal bleeding because upper gastrointestinal telangiectasias are more common [165]. Gastrointestinal bleeding typically manifests as melena and occasionally as hematemesis. The differential diagnosis of melena in these patients includes swallowed blood from epistaxis. The gastrointestinal bleeding is typically painless, chronic, episodic, and progressive [159]. Of 25 patients with gastrointestinal bleeding, half required blood transfusions, and one-fourth required transfusion of more than six units [164].

The diagnosis is straightforward in patients with the triad of telangiectasia, recurrent epistaxis, and a compatible family history [167]. Patients with sporadic angiodysplasia are differentiated from patients with HHT by clinical presentation in old age, a paucity of lesions, a negative family history, and exclusively gastrointestinal involvement without epistaxis. Cutaneous telangiectasias, unlike spider nevi, only partly blanch by diascopy because of vessel tortuosity. The site and source of gastrointestinal bleeding are diagnosed by endoscopy, with EGD for upper gastrointestinal bleeding, colonoscopy for lower gastrointestinal bleeding, and, increasingly, capsule endoscopy for small intestinal lesions [168]. The endoscopic appearance of telangiectasia resembles that of nonsyndromic angiodysplasia or of cutaneous telangiectasia occurring in this syndrome. Lesions tend to be widespread throughout the gastrointestinal tract. As for angiodysplasia, other causes of gastrointestinal bleeding should be excluded at endoscopy [159,165], barium contrast radiography should not be used for diagnosis [159], and angiography may be useful to diagnose the extent of bowel telangiectasia [169].

Patients generally require iron supplementation to replete iron stores. The endoscopic therapy resembles that for nonsyndromic angiodysplasia, using thermocoagulation, electrocoagulation, photocoagulation, or APC [88,139], but endoscopic therapy is complicated by lesion multiplicity, dissemination, and progression. Isolated actively bleeding telangiectasias are usually successfully treated, but patients often rebleed from other untreated gastrointestinal telangiectasias and therefore require multiple endoscopic sessions [170]. Segmental bowel resection is reserved for active, severe, and well-localized bleeding refractory to medical or endoscopic therapy because of the tendency to rebleed subsequently from telangiectasias at other sites [123,126,158]. When available, angiographic embolization can obviate the need for surgery.

In theory, systemic or generalized therapy should be better than local therapy because of the typically large number and widespread extent of the telangiectasias. A few small studies have reported a markedly decreased incidence in chronic gastrointestinal bleeding after estrogen and progesterone therapy [150,171]. Estrogen–progesterone therapy should be considered before performing gastrointestinal surgery for chronic bleeding, but decisions concerning this therapy are controversial [166].

Gastric antral vascular ectasia

Clinical presentation

This condition is relatively uncommon. It was reported in only three cases among 10 000 consecutive EGDs in 1984 [172], but is being increasingly recognized. The incidence may be as high as one per several hundred EGDs if early, but characteristic, endoscopic findings are recognized (M.S. Cappell, unpublished). The mean age at presentation is 70 years (range 50–90 years) [173–175], with a female-to-male ratio of about 4:1 [172,174–177]. Patients typically present with iron deficiency anemia from chronic occult gastrointestinal bleeding [172,175,178], but occasionally have melena from acute bleeding [173,174]. Hematemesis is unusual. The occult bleeding and anemia may be longstanding because of delayed diagnosis [174], and patients have often had multiple previous blood transfusions. The lesion is painless, but physical examination reveals pallor and fecal occult blood [175]. Patients with early endoscopic findings

tend to have less severe and less frequent symptoms and laboratory abnormalities (M.S. Cappell, unpublished).

Diagnosis

Endoscopy reveals multiple parallel prominent longitudinal folds that traverse the antrum and converge to the pyloric sphincter. The folds contain intensely erythematous linear streaks at their apices [172] (Fig. 112.10). Occasionally the streaks extend into the proximal stomach [179,180]. The term *watermelon stomach* derives from the resemblance of these erythematous linear streaks to the stripes on a watermelon rind. These lesions should not be confused with focal antral gastritis [181,182]. These erythematous lesions differ from those in antral gastritis by virtue of their location on folds radiating to the pylorus, blanching on pressure, and sharp lesion demarcation [177]. Capsule endoscopy may also reveal this gastric lesion [182]. Despite lesion vascularity, endoscopic biopsy appears safe in that it can cause slight, but not severe, bleeding [172,183]. Histological analysis of endoscopic biopsy samples taken from the apices of the longitudinal folds reveals hypertrophied mucosa, dilated and tortuous mucosal capillaries that are often occluded by bland fibrin thrombi, dilated and tortuous submucosal veins, and a lack of inflammatory infiltration [172,177,183,184]. Endosonography may demonstrate dilated ectatic vessels in antral mucosa and submucosa, whereas focal antral mural thickening may be revealed by computed tomography. Double-contrast upper gastrointestinal series may reveal prominent, scalloped antral folds radiating to the pyloric sphincter [185], and angiography may reveal mild antral hypervascularity [186]. However, these radiological procedures are seldom necessary because the endoscopic appearance and histological findings are generally diagnostic.

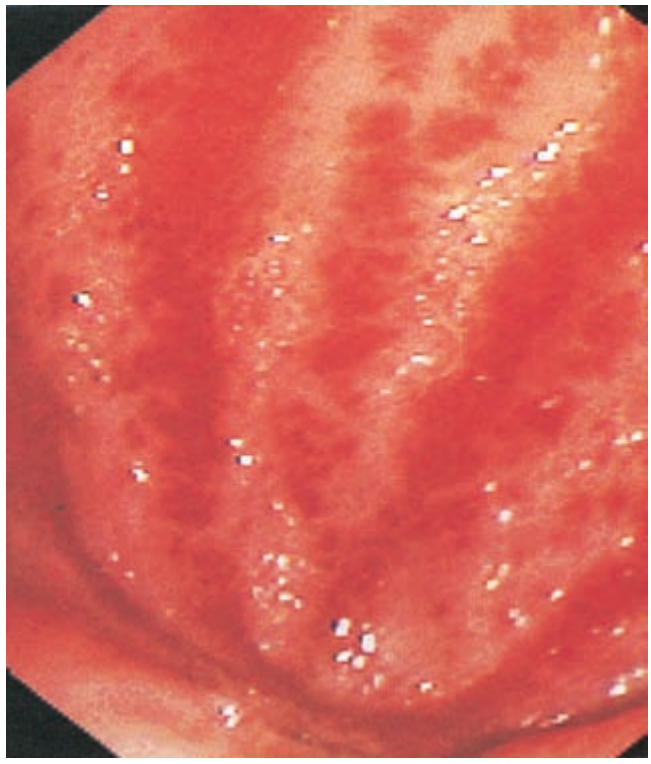

Figure 112.10 Videophotograph showing the characteristic endoscopic finding in gastric antral vascular ectasia of linear, intensely erythematous lesions at the apices of longitudinal antral folds radiating to the pylorus. The alternative lesion name of *watermelon stomach* derives from the resemblance of these erythematous linear streaks to the stripes on a watermelon rind. From Clouse RE. Vascular ectasias, tumors, and malformations. In: Yamada et al. (eds). Atlas of Gastroenterology, 2nd edn. Philadelphia: Lippincott Williams & Wilkins, 1999:550.

Etiology

The etiology is unknown. The disease is associated with atrophic gastritis [176], renal failure [187], bone marrow transplantation [188], and scleroderma [180,189]. There is also an association between GAVE and cirrhosis [190] but not portal hypertension [191–193]. These associations do not appear to provide a clue to the etiology. A trophic etiology has been proposed [194] because of the finding of elevated blood or mucosal tissue concentration of gastrin [195], prostaglandin E_2 [196], or 5-hydroxytryptamine (serotonin) [197], but these abnormalities have not been proven [190].

Alternatively, the lesion may arise from repeated antral mucosal trauma resulting from pyloric prolapse [172]. The lesion is generally restricted to the antrum, the only gastric region subject to peristaltic contractions, and generally occurs on longitudinal folds, the antral area subjected to the most trauma during peristaltic contractions [175]. Affected antral mucosa appears to be abnormally mobile and loosely attached to the underlying muscularis propria, as expected from repeated prolapse [172]. The vascular ectasia resembles that seen in other traumatic gastrointestinal lesions, such as the solitary rectal ulcer syndrome, prolapsed hemorrhoids, or intestinal intussusception [175,198,199]. Cirrhotic patients might develop the lesion as a consequence of antral dysmotility [200].

Therapy

Patients should avoid gastrotoxic or antiplatelet medications that could exacerbate the bleeding, and should receive transfusion for acute gastrointestinal bleeding, and iron replacement for chronic gastrointestinal bleeding. Patients with renal failure may require erythropoietin. Pharmacological therapy, employing variable agents, has had variable and inconsistent results [177,201]. Histamine H_2 receptor antagonists and proton pump inhibitors are ineffective because this lesion is not acid-related and patients often have hypochlorhydria from atrophic gastritis [181]. Endoscopic therapy is the initial treatment. Endoscopic ablation requires multiple endoscopic sessions because of lesion size. Lesion eradication is endoscopically recognized by complete blanching. Laser therapy

was commonly used because it requires fewer endoscopic sessions than most other modalities [174,180,202,203], but the heater probe has also been successfully used [175]. From 87% to 100% of patients have stable hematocrits without transfusions for up to 2 years after endoscopic therapy [174,180,204]. Endoscopic complications, such as perforation, stenosis, ulceration, and hemorrhage, are infrequent [173,174]. Argon plasma coagulation may become the preferred endoscopic therapy because of the diffuse nature and superficial location of the lesion. This modality entails a low risk of endoscopic complications because of the shallow depth of tissue injury [141]. Analysis of the combined results of four studies shows that 50 of 55 transfusion-dependent patients required no transfusions after APC ablation therapy, during a mean follow-up of approximately 2 years [191,205–207]. Patients should receive acid suppressive therapy after endoscopic ablation to prevent iatrogenic ulcers.

Antrectomy removes the lesion and nearly always cures the disease [172,176], but is reserved for endoscopic therapy failures because of significant surgical morbidity and a small, but significant, mortality of about 5% [177,202]. Among 45 patients undergoing surgery, only two required transfusions during a mean follow-up of 2 years; both bled from other gastrointestinal lesions [177]. Transjugular intrahepatic portosystemic shunt does not stop bleeding from GAVE in cirrhotic patients [208].

Hemangiomas

Capillary and cavernous hemangiomas

Intestinal hemangiomas are rare, with an incidence of about 1 per 15 000 patients [209]. About half of these hemangiomas are associated with cutaneous hemangiomas, most commonly in the blue rubber bleb nevus syndrome and rarely in Klippel–Trenaunay syndrome, as described later [210]. Intestinal hemangiomas are either capillary, cavernous, or mixed. *Capillary hemangiomas* consist of small (capillary-sized), thin-walled, closely packed vessels; *cavernous hemangiomas* consist of large, dilated, blood-filled, thin-walled vessels; and *mixed hemangiomas* contain both types of vascular lesions [211,212]. Capillary hemangiomas tend to be small and well circumscribed, whereas cavernous hemangiomas tend to be medium-to-large and poorly circumscribed. In both types of hemangiomas, vessels are lined by well-differentiated, flattened, and hyperplastic endothelial cells. Capillary hemangiomas tend to be located in the perianal skin, whereas cavernous hemangiomas tend to be located in the rectum and distal colon [1,213].

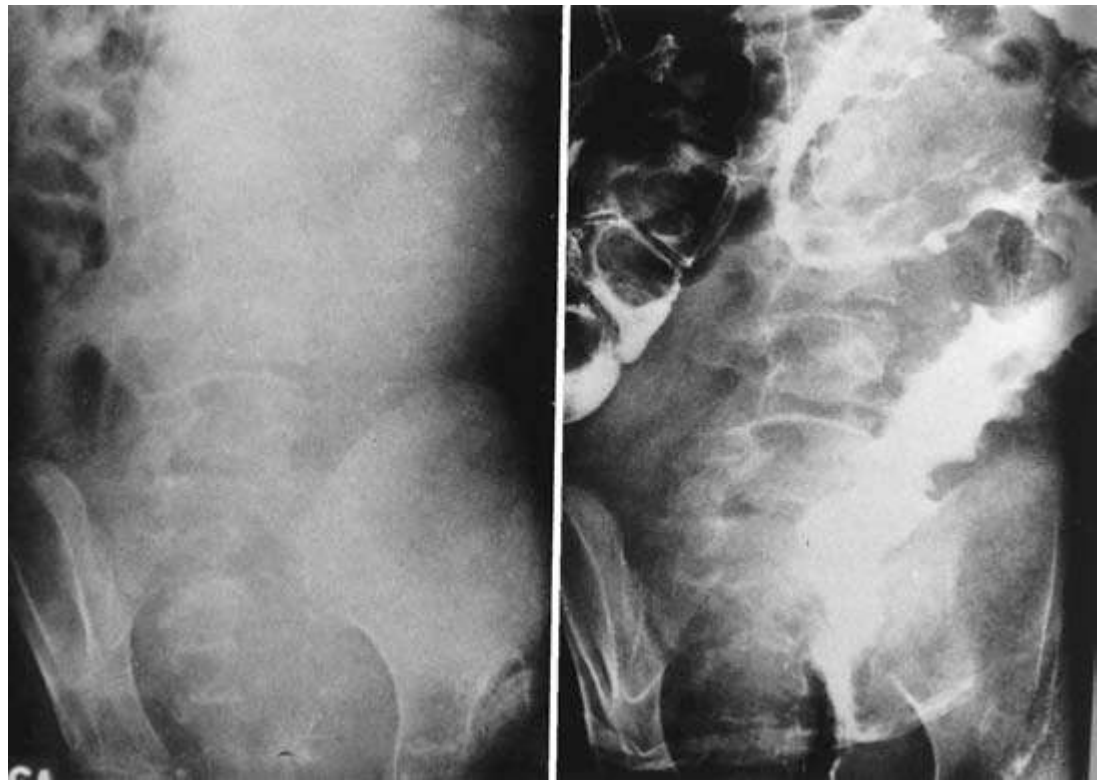
Cavernous hemangiomas are clinically more significant owing to their propensity to bleed because of their frequent large size, large blood volume, and consumption of coagulation factors and platelets [214,215]. Multiple lesions often occur within the gastrointestinal tract [216].

Colonic cavernous lesions may be asymptomatic (10%), but commonly produce acute gastrointestinal bleeding that manifests clinically as hematochezia or melena (72%) [213,217,218], or chronic gastrointestinal bleeding that manifests clinically as iron deficiency anemia [219–222]. Bleeding is typically episodic, recurrent, and progressive, and usually begins in childhood or young adulthood [223]. Bleeding lesions are generally large and cavernous. Gastrointestinal lesions can cause gastrointestinal obstruction from lumenal encroachment or intestinal intussusception [224,225]. Rectal hemangiomas may produce tenesmus and rectal urgency [212,226]. Hemangiomas occasionally extend into adjacent organs or occur simultaneously in other organs, where they clinically manifest as hematuria, epistaxis, hemoptysis, or menorrhagia, according to their location [221,223,227].

Abdominal radiographs often demonstrate phleboliths from thrombosis and calcification within hemangiomas [1,228] (Fig. 112.11a). Barium contrast studies typically reveal multiple polypoid filling defects in the stomach, small bowel, or colon, but occasionally show an annular intestinal constriction [217,227,229–231] (Fig. 112.11b). Computed tomography may demonstrate a large, thickened mesentery containing large vacuoles next to an abnormal intestinal segment with a thickened wall that contains phleboliths [1]. Magnetic resonance imaging may demonstrate intensely bright signals from these highly vascular lesions [232]. Frequently, selective angiography poorly delineates these venous lesions as a result of vascular thrombosis [233].

Esophagogastroduodenoscopy and colonoscopy have high diagnostic sensitivity in patients with upper and lower gastrointestinal lesions, respectively. Small intestinal lesions are being increasingly diagnosed by caspsule endoscopy, or even double-balloon enteroscopy [234]. The endoscopic diagnosis is straighforward in patients with the characteristic dermatological syndromes (see below), but in the absence of these the lesion can be misdiagnosed endoscopically. At endoscopy, intestinal hemangiomas appear as violet-blue, sessile, compressible, polypoid lesions [220] (Fig. 112.12a,b). It is often difficult to determine at endoscopy which lesion bled because of lesion multiplicity and multifocality [230]. Endoscopic biopsy entails a risk of profuse hemorrhage [1]. Pathological examination reveals findings typical of a capillary or cavernous hemangioma: numerous ectatic, dilated, blood-filled spaces lined by a thin layer of cuboidal endothelium and surrounded by scant fibrous stroma with occasional smooth muscle cells [221]. Lesions lack cellular atypia or dysplasia and do not undergo malignant transformation.

The differential diagnosis includes colon cancer, adenomatous polyps, hemorrhoids, and ulcerative colitis [235]. Colonic hemangiomas are distinguished from colonic polyps at endoscopy by their bluish color, typical submucosal location, compressibility, and poorly defined margins [236]. Rectal hemangiomas are distinguished from internal hemorrhoids



(a) (b)

Figure 112.11 Radiographic appearances of intestinal hemangiomas. **(a)** Abdominal radiograph of a 16-year-old white male patient with an extensive distal colonic cavernous hemangioma demonstrates a cluster of radiopaque phleboliths partly outlining the distal colonic wall. **(b)** Barium enema demonstrates irregular narrowing in the rectosigmoid and "thumbprinting" in the sigmoid and descending colon caused by intramural hemangiomatous masses. Although the rectosigmoid narrowing resembles an apple-core lesion found in colon cancer, the radiographic findings of phleboliths and intramural masses point to the diagnosis of cavernous hemangioma. From Ghahremani et al. [247], with permission from the Radiological Society of North America.

by a nodular, as opposed to serpiginous, shape; submucosal versus superficial location; and extension beyond the anorectum. Colonic hemangiomas are differentiated from pseudopolyps of ulcerative colitis by the presence of a bluish color, submucosal location, and lesion compressibility, and by the absence of mucosal granularity, blunting of the vascular pattern, and continuous involvement on colonoscopy [210]. The correct diagnosis is crucial for proper management. Polypectomy may be inadvisable because of the risk of postpolypectomy hemorrhage from a cavernous hemangioma. Hemorrhoidectomy is ineffective therapy for bleeding from rectal hemangiomas [235].

Patients typically require frequent blood transfusions for chronic gastrointestinal bleeding. Surgery for gastrointestinal bleeding is limited by the tendency for lesions to be multiple and widespread and by frequent development of new lesions [237]. Segmental resection is reserved for severe well-localized bleeding [227,229]. Endoscopic hemostasis by photocoagulation [218,238], band ligation [239], or endoscopic polypectomy [237,239] has been reported without complications.

Blue rubber bleb nevus syndrome

Although rare, this syndrome should be suspected when characteristic dermatological lesions occur in conjunction with gastrointestinal bleeding (see Chapter 110). Patients present with multiple violet-blue, slightly raised, well-circumscribed, and elastic cutaneous hemangiomas resembling a rubber nipple [240], and ranging from 0.5 to 5 cm in diameter, together with multiple gastrointestinal hemangiomas, which are commonly located from the stomach through the rectum and rarely in the esophagus or oropharynx [219,224,229] (Fig. 112.12a,b). The cutaneous lesion has a wrinkled surface and can be emptied of blood by manual pressure, leaving a wrinkled blue or white sac that slowly refills when the pressure is released [220,223]. Lesions usually begin in early childhood, and they tend to increase progressively in number and sometimes increase in size with age [227,230,239]. Most cases are sporadic, but several families have been reported with genetic transmission in an autosomal dominant pattern [227]. A candidate gene has been identified on chromosome 9 [241].

Figure 112.12 Endoscopic appearance of colonic hemangiomas. **(a)** Videophotograph of a 3-mm colonic capillary hemangioma adjacent to a mid-sigmoid diverticulum. Courtesy of T.G. Tietjen, MD, Petoskey, Michigan. **(b)** Videophotograph from the colon showing the characteristic endoscopic appearance of a cavernous hemangioma as a bluish, round, smooth, and well-circumscribed sessile polypoid lesion. From Bak et al. [239], with permission from Elsevier.

Only aspects unique to these gastrointestinal lesions are discussed here; the clinical presentation, diagnosis, and therapy were mentioned in the previous section "Capillary and cavernous hemangiomas." Significant gastrointestinal bleeding in a patient with this syndrome should be investigated by capsule endoscopy if EGD and colonoscopy are unrevealing [242]. In a clinical series of 10 patients, surgical removal by wedge resection and polypectomy of all gastrointestinal lesions was feasible and highly effective in conjunction with intraoperative enteroscopy [243]. On average, however, 137 gastrointestinal lesions were surgically resected per patient, with a mean operative time of 14 h. Nine of the 10 operated patients did not require transfusions during a mean follow-up of 5 years. Cutaneous lesions seldom require treatment because they rarely bleed and never become malignant [229].

Intestinal hemangiomas in Klippel–Trenaunay syndrome

Klippel–Trenaunay syndrome is characterized by port-wine cutaneous hemangiomas, bony and soft tissue hypertrophy, superficial varicose veins, and abnormal – atretic, hypoplastic, or occluded – deep veins, usually affecting one lower extremity but occasionally affecting both lower extremities or one or both upper extremities [244,245] (Fig. 112.13). A family history of similar lesions is usually lacking [244]. In *Parkes Weber syndrome*, patients additionally have arteriovenous fistulae.

This syndrome is associated with extensive infiltrative cavernous hemangiomas of the distal colon [246–249] and, rarely, the small intestine [250]. Patients present with chronic intermittent hematochezia and iron deficiency anemia in

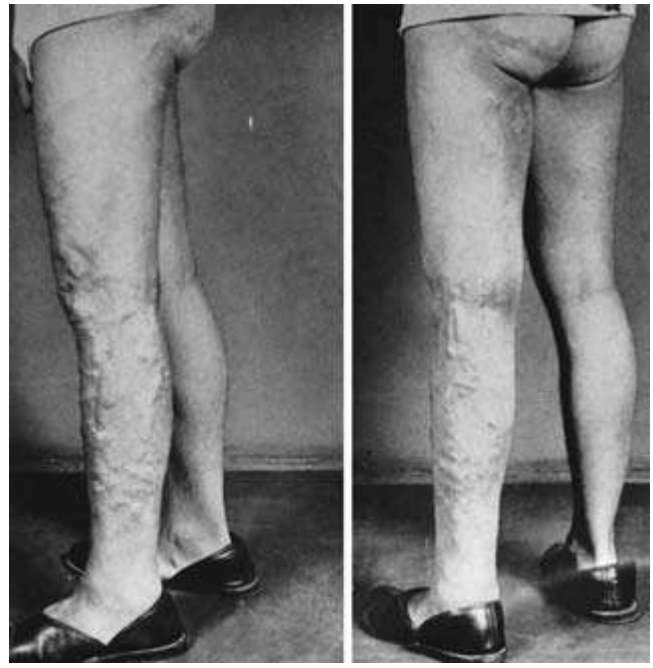

Figure 112.13 Leg lesions in Klippel–Trenaunay syndrome. A 23-year-old man has the characteristic physical findings in one lower extremity of superficial varicose veins (see left calf), an increased girth (compare size of ankles and calves in the two legs), an increased length, and a port-wine cutaneous hemangioma (see left calf). From Lindenauer [244], with permission from Lippincott Williams & Wilkins.

childhood or young adulthood [247,251]. Thrombocytopenia due to platelet sequestration and consumption may contribute to the bleeding [248], as may mesenteric venous hypertension caused by congenital obstruction of lower extremity veins and consequent overload of the internal iliac veins [249]. The rate of rectal bleeding associated with this syndrome is poorly characterized [247], but is reported as 1%–13% [249,252]. Diagnostic features found on plain abdominal radiographs, barium enema, colonoscopy, computed tomography, and selective inferior mesenteric angiography are essentially the same as those for multiple cavernous hemangiomas (see "Capillary and cavernous hemangiomas" above) [246,247,250]. Abdominoperineal resection of the colonic hemangioma is the definitive therapy. Endoscopic hemostasis may provide a nonsurgical alternative therapy in the future.

Disseminated hemangiomatosis

Rarely, patients present with more than 50 intestinal hemangiomas, which range in size from 2 to 20 mm, as part of a syndrome of disseminated hemangiomatosis involving three or more organ systems [253]. Patients present at birth with numerous cutaneous hemangiomas. Untreated infants have a 60% mortality from massive gastrointestinal bleeding, hemorrhagic stroke, or high-output cardiac failure due to arteriovenous shunting [254,255]. Corticosteroids and interferon-α have been successfully used to promote lesion regression [254,255].

Phlebectasias

Intestinal phlebectasias are venous varicosities, without portal hypertension, consisting of a markedly dilated tortuous vein, with a normal vascular wall and scant connective tissue stroma [256]. Endothelial cells within the vessel appear normal. Phlebectasias are generally classified as multiple, small hemangiomas, but this classification is controversial [212,214]. They occur primarily in elderly men [257]. Phlebectasias may also occur in the oral cavity, mostly at the base of the tongue, where they are called caviar spots (varices) or sublingual phlebectasia, and in the genitalia, where they are called Fordyce lesions or scrotal phlebectasia [256]. These orocutaneous signs are clues to the presence of intestinal lesions in elderly men with gastrointestinal bleeding.

Intestinal lesions are characteristically dark bluish-black, ranging from several millimeters to 10 mm in size, soft and compressible, blanch with pressure, are multiple, and located in the submucosa [257]. Although usually asymptomatic and incidental, they occasionally produce chronic occult or acute gross intestinal bleeding [256–258]. Because of their location, small intestinal phlebectasias are diagnosed by enteroscopy [258]. Angiography can occasionally demonstrate the site of bleeding by contrast extravasation but does not delineate these lesions [256]. Surgery is the only definitive therapy, but is reserved for severe ongoing bleeding because of the multiplicity and extent of the small bowel lesions.

Angiosarcomas

Angiosarcomas are rare, highly vascular malignancies derived from endothelial cells, representing less than 1% of sarcomas. They are divided into hemangiosarcomas and lymphangiosarcomas [259]. They commonly arise in cutaneous and subcutaneous tissue, and rarely in the gut [209]. Chronic lymphedema and prior local radiotherapy are risk factors for cutaneous angiosarcomas [260], and exposure to thorium dioxide (Thorotrast) during angiography, arsenic in insecticides, or polyvinyl chloride in manufacturing plastics are risk factors for hepatic angiosarcomas [261]. Intestinal lesions are associated with prior abdominopelvic radiotherapy [262].

Grossly, lesions appear as a hemorrhagic and often ulcerated mass. Histologically, angiosarcomas contain numerous interconnecting vascular channels (vasoformative structures), irregular in size and shape, that contain either atypical cells with sparse mitotic activity or sheets of pleomorphic cells with prominent mitotic activity. Poorly differentiated angiosarcomas are distinguished immunohistochemically from poorly differentiated adenocarcinomas by immunoreactivity for vimentin, and endothelial markers including factor VIII-related antigen, CD34, and CD31, and by immunonegativity for endothelial cell markers, such as S-100 [263,264].

Patients are generally elderly [265,266]. Lesions have been reported in the esophagus, stomach, small intestine, colon, and rectum [209,265–267]. Half of intestinal lesions are primary and half are metastatic [263]. Symptoms are similar to those with cavernous hemangiomas [266,267]. Patients commonly present with gastrointestinal bleeding, anemia, or abdominal pain, occasionally present with intestinal obstruction, and rarely present with intestinal perforation [268]. Endoscopy may demonstrate an ulcerated mass or tight asymmetrical stricture. Surgical resection is recommended. Angiosarcomas are often multifocal at diagnosis and typically biologically aggressive [265,266]. The prognosis appears to be poor as a result of early metastasis [260].

Hemangiopericytomas

Hemangiopericytomas are uncommon, richly vascular neoplasms composed of pericytes, the mesenchymal cells normally apposed to endothelial cells. The stomach is the most commonly involved gastrointestinal organ [269,270], but the small intestine [271–275], rectum [276], and even mesentery or retroperitoneum [277] can be involved. The neoplasm most commonly occurs in early middle age. Gastrointestinal tumors can present with gastrointestinal bleeding as a result of this highly vascular tumor eroding into the lumen, or with constipation as a consequence of lumenal impingement by the mural mass [278]. Other symptoms include abdominal pain, abdominal distention, and nausea and vomiting

[269,274,275]. Intestinal intussusception occasionally occurs [271–274]. An abdominal mass may be palpable because of the tumor's bulk [277]. Large tumors are rarely associated with hypoglycemia [279].

Barium studies typically reveal a smoothly contoured polypoid lesion [269,270]. Angiography demonstrates a richly vascular mass with a diffuse capillary blush [279]. Computed tomography may demonstrate multiple areas of low attenuation from necrosis, hemorrhage, or cystic degeneration within the tumor. Endoscopy may reveal a solitary, circumscribed, submucosal mass or polyp covered by normal or ulcerated mucosa. Pathological examination of endoscopic biopsy specimens reveals tightly packed, spindle-shaped, neoplastic pericytes surrounding intercommunicating vascular channels of variable caliber and shape [274,280]. The vascular channels usually resemble capillaries [281].

Most tumors are benign and slow growing [269,274,279], and many are bulky. Malignancy is characterized histologically by increased cellularity, prominent mitotic activity, hyperchromatism, cellular pleomorphism, and foci of necrosis or hemorrhage [279,282]. Wide local surgical resection is the primary therapy [282].

Hemangioendotheliomas

Hemangioendotheliomas are rare, borderline malignancies with a histological appearance between benign hemangiomas and malignant angiosarcomas. Hemangioendotheliomas display more cellularity and mitotic activity than hemangiomas, but less mitotic activity and cellular atypia than angiosarcomas. The most important subtype is epithelioid hemangioendothelioma, in which neoplastic endothelial cells focally line small extracellular vascular spaces or contain small intracellular spaces or vacuoles [283]. The tumor often arises from a vein. Immunohistochemistry shows the presence of at least one endothelial marker among factor VIII-related antigen, CD34, or CD31 [284]. This vascular tumor most commonly presents as a gastrointestinal mass with gastrointestinal bleeding, but may present with abdominal pain, intestinal obstruction, or intestinal perforation [285,286]. Hemangioendotheliomas are sometimes locally invasive but rarely metastasize. Wide local resection is the recommended therapy.

Intestinal ischemia is not rare, accounting for 0.1% of hospital admissions [1]. The increase in the incidence of these disorders in recent years is secondary to multiple factors such as heightened awareness for the diagnoses, the advanced mean age of the population, and the increasing number of critically ill patients. Despite advances in knowledge of pathophysiology, laboratory diagnosis, and imaging techniques, acute intestinal ischemia is still associated with mortality rates of more than 60% and continues to be a challenging diagnostic problem [2]. *The key to a better outcome, and the main problem in clinical practice, is early diagnosis.* The clinical setting of acute intestinal ischemia is determined by the combination of the need for rapid and aggressive diagnostic and therapeutic interventions in an often elderly and multimorbid patient, thus making clinical management a challenging task. The objectives of this chapter are to provide knowledge of the basic anatomic and pathophysiological mechanisms underlying intestinal ischemic damage, the guidelines for identification of patients who require prompt and aggressive evaluation, and delineation of the optimal diagnostic workup and type of therapy for each patient.

Anatomy of the intestinal circulation

Generally, the involved segment of ischemic intestine has a linear correspondence to the location and extent of vascular occlusion. Knowledge of the vascular anatomy is therefore crucial for the understanding of the pathophysiology, clinical presentation, and therapy of intestinal ischemia.

Celiac artery

The celiac artery arises from the abdominal aorta at about the level of the T12 or L1 vertebral body. It usually courses anteriorly and slightly inferiorly 1–2 cm before branching into the left gastric, common hepatic, and splenic arteries. The left gastric artery supplies the stomach and provides small branches to the esophagus that anastomose with aortic esophageal branches, and small branches that anastomose with the right gastric artery, a branch of the hepatic artery. The common hepatic artery divides into the hepatic artery, which supplies the liver; the right gastric artery, which supplies the stomach along the lesser curvature; and the gastroduodenal artery, which divides into right gastroepiploic and superior pancreaticoduodenal arteries to supply the antrum, duodenum, and pancreas. The splenic artery supplies the spleen and body and tail of the pancreas [3].

Superior mesenteric artery

The superior mesenteric artery (SMA) arises from the aorta approximately 1 cm below the celiac artery, usually at the level of L1. It courses inferiorly and toward the right to terminate at the level of the cecum as the ileocolic artery (Fig. 113.1a). The inferior pancreaticoduodenal artery is one of the first branches of the SMA; it supplies the pancreatic head, uncinate process, and descending duodenum, and anastomoses with the corresponding superior branches from the celiac axis. Generally there are more SMA branches to the distal small bowel than to the more proximal portions, thus providing greater potential for distal anastomotic communication. The middle colic artery arises from the proximal SMA to supply the transverse colon and communicates with branches of the IMA. The right colic artery may arise as a common trunk with the middle colic artery or have a separate origin from the SMA; it supplies the distal ascending colon and right colonic (hepatic) flexure. The ileocolic artery is the terminal branch of the SMA and supplies the distal ileum, cecum, and ascending colon.

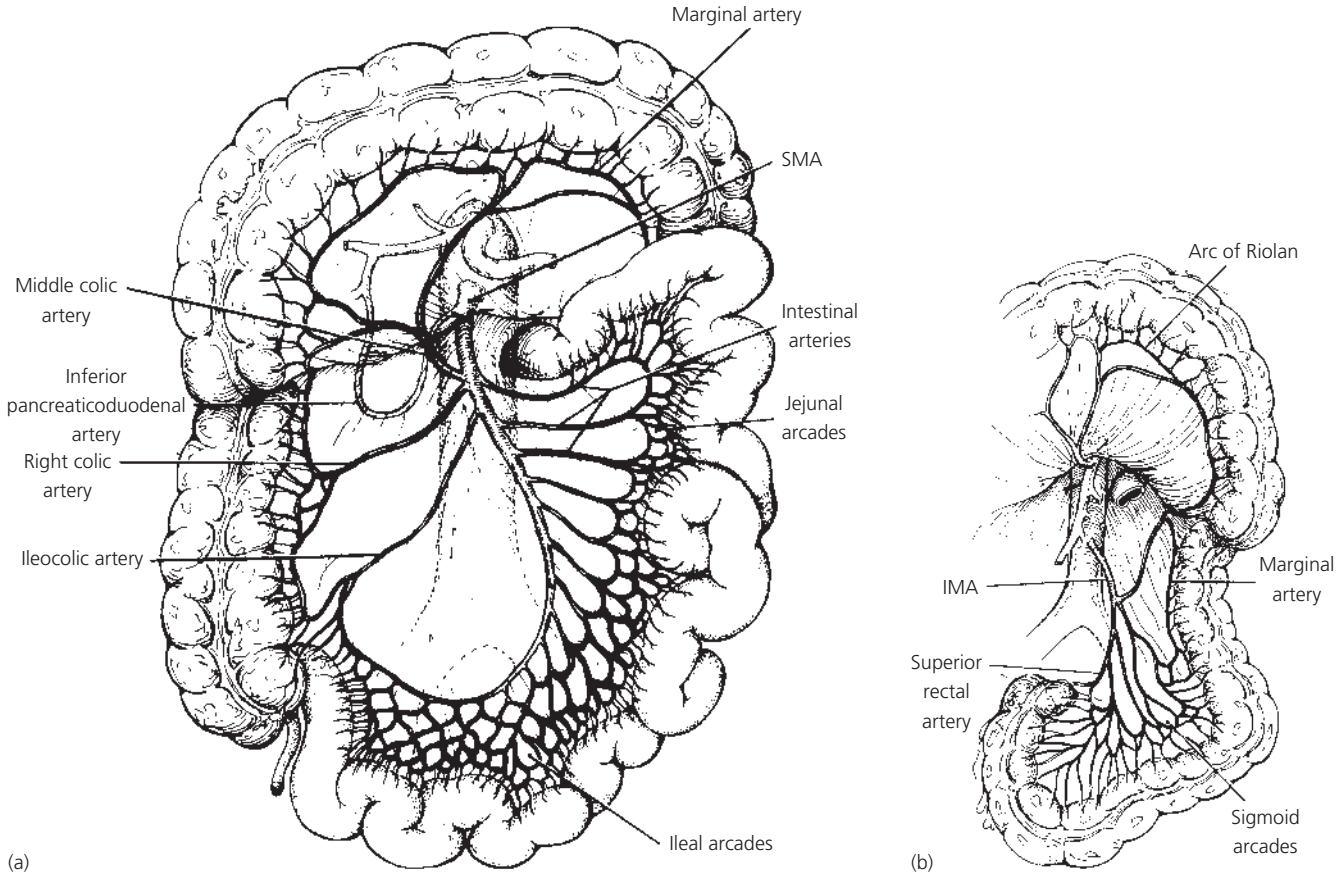

Figure 113.1 Mesenteric arterial circulation. **(a)** The superior mesenteric artery (SMA) exits the aorta 1 cm below the celiac artery. It supplies the entire small intestine except for the superior part of the duodenum, and supplies the right colon and part of the pancreas. Branches include the inferior pancreaticoduodenal artery, numerous jejunal and ileal branches, the ileocolic artery, and the middle colic artery. **(b)** The inferior mesenteric artery (IMA) arises from the aorta 3 cm proximal to the aortic bifurcation. The artery branches into the left colic, several sigmoid (inferior left colic) arteries, and the superior rectal (hemorrhoidal) artery. The arcades of the SMA and IMA interconnect at the base and border of the mesentery. The connection at the base of the mesentery provides a potential collateral channel between SMA and IMA called the "arc of Riolan." The connection along the mesenteric border provides another potential collateral channel called the marginal artery of Drummond. From Marston A, Pegington J. Macroscopic anatomy. In: Marston A, Bulkley GB, Fiddian-Green RG, Haglund UH (eds). Splanchnic Ischemia and Multiple Organ Failure. London: Edward Arnold, 1989:13, with permission from Hodder Education.

Inferior mesenteric artery

The inferior mesenteric artery (IMA) is the smallest of the mesenteric vessels and arises from the ventral aorta approximately 6–7 cm below the SMA at the level of L3 (Fig. 113.1b). The artery branches into the left colic, which supplies the left (distal) transverse colon and splenic flexure; several sigmoid (inferior left colic) arteries, which supply the sigmoid and descending colon; and the superior rectal (hemorrhoidal) artery, which supplies a large part of the rectum. The inferior rectal (hemorrhoidal) arteries derived from the internal pudendal arteries, and the small and inconstant middle rectal (hemorrhoidal) arteries, derived from the internal iliac arteries also supply the rectum.

Arterial collaterals

Extensive anastomotic and collateral circulation exists within each and between the three major intestinal vessels, as well as between the mesenteric vessels and the nonmesenteric systemic circulation. Major branches of the celiac artery interconnect in the stomach and duodenum. A series of arcades interconnect neighboring branches of the SMA [4]. A similar series of arcades interconnect neighboring branches of the IMA. The primary potential pathway of collateral flow between the celiac artery and SMA is through the gastroduodenal and pancreaticoduodenal arteries (Fig. 113.2), with the inferior pancreaticoduodenal being the most common. Additionally, omental branches of the SMA can communicate with branches of the celiac artery by the arc of Barkow [3]. An uncommon but well-described communication is the arc of Bühler, a direct communication between the celiac artery and SMA that represents a persistence of the embryonic ventral segmental arteries.

The arcades of the SMA and IMA interconnect at the base (away from the colon) and border (near the colon) of the

Figure 113.2 (a) Selective digital subtraction angiography (DSA) of the superior mesenteric artery (SMA), showing a long and high-grade stenosis of the proximal artery (arrow). **(b)** DSA injection of the celiac axis (large arrow) of the same patient demonstrating collateral filling of the distal SMA through pancreaticoduodenal collaterals (small arrow).

mesentery (Fig. 113.1b). The connection at the base of the mesentery provides a potential collateral channel between the SMA and IMA, called the meandering mesenteric artery, or arc of Riolan [4]. The connection along the mesenteric border provides another collateral channel called the marginal artery of Drummond.

Despite the presence of collateral channels, the vasculature has several points susceptible to poor perfusion (watershed areas). The middle part of the small intestine, in the middle of the area perfused by the SMA, is far away from collaterals from the celiac axis to the proximal SMA, and from collaterals from the IMA to the distal SMA. This area is the most vulnerable to develop ischemia from SMA occlusion. Narrow terminal branches of the SMA supply the splenic flexure, and the rectosigmoid junction is supplied by terminal branches of the IMA. These two watershed areas are most vulnerable to develop ischemia during systemic hypotension if the collateral anastomoses are small or tenuous [5].

Venous anatomy

The venous system generally parallels the arterial distribution. The inferior mesenteric vein (IMV) drains the rectum through the superior rectal vein, the sigmoid through the sigmoid veins, and the descending colon through the left colic vein. The superior mesenteric vein (SMV) drains the small intestine, cecum, ascending colon, and transverse colon via the jejunal, ileal, ileocolic, right colic, and middle colic veins [6]. The SMV also drains the greater omentum and distal stomach with the right gastroepiploic vein and drains part of the pancreas and duodenum via the inferior pancreaticoduodenal vein. The IMV drains into the splenic vein, which then joins the SMV to form the portal vein.

Mechanisms of ischemic injury

When blood flow to the intestine decreases below a critical point, important metabolic and structural alterations appear in a variety of intestinal cells that can eventually cause cell destruction and death. Despite the fact that restitution of blood flow is necessary to limit the progression of cellular injury associated with decreased oxygen and nutrient delivery, it has become apparent that restoration of blood flow and oxygenation to the ischemic intestine can result in a paradoxical enhancement of tissue injury, a process that has been termed "reperfusion injury." The mechanisms that are believed to participate in ischemic and reperfusion injury include the infiltration of postischemic tissues by inflammatory cells, an increased production of reactive oxygen species (ROS), alterations in vascular permeability, and inhibition of local cytoprotective mechanisms [7] (Fig. 113.3). For a detailed description of the structure and functions of intestinal microcirculation under physiological conditions the reader is directed to Chapter 22, Gastrointestinal blood flow.

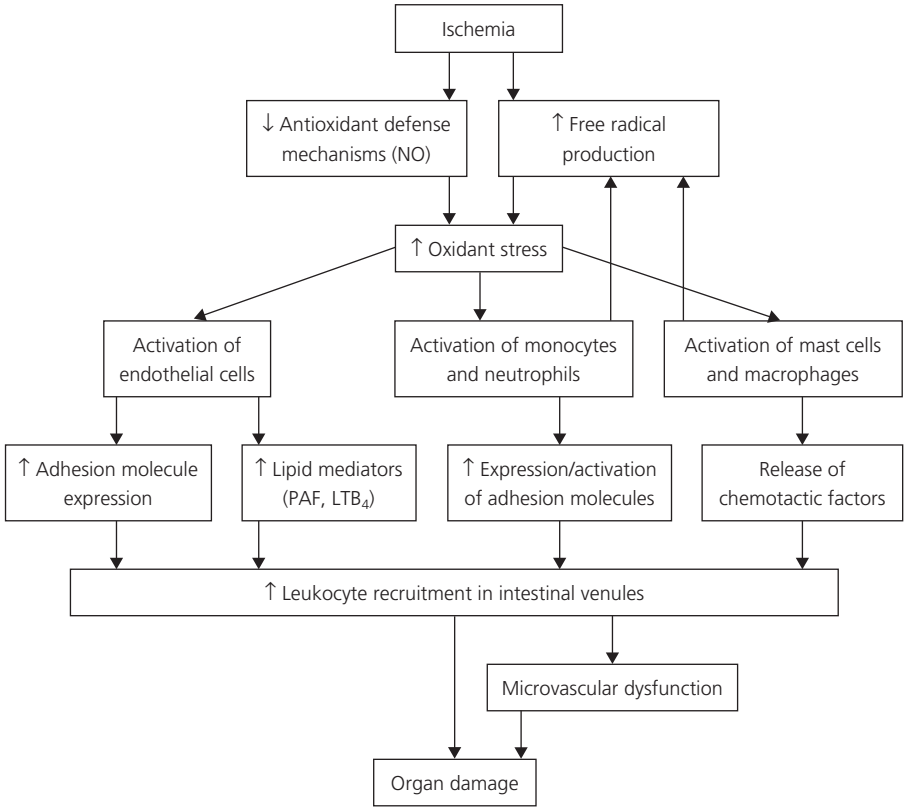

Figure 113.3 Mechanisms involved in ischemia-induced intestinal damage. Ischemia results in an increased production of oxidants, with a corresponding reduction in the synthesis of nitric oxide (NO) by endothelial NO synthase. The enhanced generation of oxidants results in the activation of endothelial cells and leukocytes. Firm adhesion of leukocytes, which is mediated by β2-integrins (CD11/CD18), is induced by engagement of activated LTB_4, and PAF with their receptors on rolling leukocytes. Sustained rolling and adhesion of leukocytes on endothelial cells are ensured by an oxidant-dependent synthesis of endothelial cell adhesion molecules, such as P-selectin and ICAM-1. The inflammatory responses to ischemia are further amplified by oxidants derived from NADPH oxidase in leukocytes, and by mediators released from mast cells and macrophages that normally reside in close proximity to postcapillary venules. ICAM-1, intercellular adhesion molecule-1; LTB_4, leukotriene B_4; PAF,

Inflammatory response

Recruitment of circulating leukocytes toward the ischemic intestine is a key event in the pathophysiology of intestinal ischemic injury. Both leukocytes and endothelial cell adhesion molecules (CAMs) participate in slowing the leukocyte as it exits the capillary and enters the postcapillary venule, which is the major site of leukocyte–endothelial cell adhesion [8]. The initial event, known as the rolling phenomenon, consists in a transient adhesive interaction and is mainly mediated by the selectin family of adhesion molecules, L-selectin, expressed on all leukocytes, P-selectin, detected on activated platelets and endothelial cells, and E-selectin, exclusively found in the latter. Several studies have reported an important upregulation of P-selectin in the intestine submitted to ischemia [9]. L-selectin has also been implicated in the process of tissue infiltration and organ failure resulting from ischemia [10].

Firm leukocyte adhesion and eventual emigration to the perivascular interstitium is mediated mainly by the intercellular adhesion molecule 1 (ICAM-1), a constitutively expressed immunoglobulin located on endothelial cells, and by its counter-receptors on neutrophils, the β_2-integrins CD11a/CD18 and CD11b/CD18. Endothelial expression of ICAM-1 has been found to increase in tissues subjected to ischemia [11] and also in distant organs, suggesting a possible role for this molecule in the pathogenesis of multiple organ failure [12]. Moreover, the administration of an antibody against ICAM-1 or against the common β_2-subunit CD18 significantly prevents leukocyte accumulation and microvascular dysfunction during reperfusion [13]. Certain conditions such as diabetes and hypercholesterolemia, which are associated with a higher risk of ischemic damage, have been shown to enhance the inflammatory response associated with ischemia and reperfusion [14–18].

Reactive oxidants

Increased production of ROS by both endothelial cells and leukocytes in postischemic tissues appears to be a key determinant of injury to the microvasculature. Ischemia promotes the conversion of the nicotinamide adenine dinucleotide (NAD)-reducing dehydrogenase form of the enzyme to the oxygen-reducing oxidase form. The accumulation of hypoxanthine during ischemia allows for a burst of superoxide and hydrogen peroxide production by the enzyme when oxygen is reintroduced into the blood vessel at the time of reperfusion. While xanthine oxidase contributes to the initial oxidant stress elicited in venules after a few minutes of reperfusion, adherent leukocytes account for the substantially greater oxidant stress that occurs thereafter [19]. This contention is supported by studies that demonstrate a diminished oxidant stress in postischemic venules of animals in which postischemic leukocyte recruitment is abrogated by

means of blocking monoclonal antibodies directed against endothelial or leukocyte adhesion molecules [20].

Imbalance of proinflammatory and protective mechanisms

There are several lines of evidence that implicate nitric oxide (NO) bioavailability as an important determinant of the inflammatory responses observed after ischemia. These include (1) a reduction in the activity of the Ca^{2+}-dependent isoform of NO synthase in postischemic tissues; (2) the ability of NO synthase inhibitors to mimic most of the microvascular alterations normally produced by ischemia, i.e., leukocyte recruitment, platelet–leukocyte aggregation, mast cell degranulation, and an increased albumin leakage; and (3) the protection against ischemia-induced leukocyte recruitment and microvascular dysfunction that is afforded by NO-releasing compounds, which replenish tissue NO levels in postischemic tissues [21,22].

Under normal conditions, the flux of NO greatly exceeds the rate of superoxide production. This allows for NO to effectively scavenge the low intracellular levels of superoxide. However, within minutes after reperfusion of ischemic tissues, the balance between NO and superoxide is tipped in favor of the latter. This imbalance results from a profound increase in the production of superoxide by endothelial cells and adherent leukocytes with a corresponding decline in the synthesis of NO from endothelial NO synthase. The relatively low levels of NO are insufficient to oppose leukocyte–endothelial cell interactions and to maintain optimal tissue blood flow.

The accumulation of superoxide that occurs in the absence of NO after ischemia allows for an enhanced generation of hydrogen peroxide. The two reactive oxygen metabolites (O_2^- and H_2O_2) can activate nuclear transcription factors such as NF-κB and AP-1, which in turn activate genes that encode adhesion molecules such as P-selectin, E-selectin, and ICAM-1 [23] (see Fig. 113.3).

Definitions of clinical syndromes

The intestinal ischemia includes a number of clinical disorders in which blood supplied to the intestine and mesentery is impaired, thus limiting tissue oxygenation and nutrient availability. This can be a consequence of reduced splanchnic or mesenteric blood flow in the overall territory or in a regional bed.

The spectrum of intestinal ischemia comprises a number of syndromes including acute mesenteric ischemia (AMI) as a result of emboli, arterial or venous thrombi, vasoconstriction secondary to low-flow states, or small bowel loop strangulation, chronic mesenteric ischemia (also named intestinal angina) due to transient, recurrent episodes of inadequate intestinal blood flow to sustain metabolic needs or to support increased metabolic demands such as that associated with digestion, and ischemic colitis, in which a circulatory insufficiency of the colon results in varying degrees of local tissue necrosis and systemic manifestation.

Acute mesenteric ischemia

Acute insufficiency of the blood supply to the intestine can result from emboli, arterial and venous thrombi, or vasoconstriction secondary to low-flow states [24,25].

Pathophysiology

Mesenteric arterial embolism

Embolization to the SMA constitutes about 5% of peripheral emboli and accounts for roughly 50% of all cases of AMI. The SMA is anatomically susceptible to embolism because it has a large caliber and arises from the aorta at a narrow angle [26]. In contrast, the IMA rarely suffers embolic occlusion because it has a small caliber, and the celiac axis rarely suffers embolic occlusion because it arises from the aorta at a right angle. Risk factors for mesenteric arterial embolism are listed in Table 113.1. The majority of mesenteric arterial emboli originate from the left side of the heart, commonly from a thrombus in the left atrium or left ventricle, or a lesion on the mitral or aortic valves [24]. Less commonly, emboli originate from an ulcerated aortic atherosclerotic plaque or a thrombosed aortic aneurysm. The most common precipitant of thrombus dislodgment and embolization is a cardiac arrhythmia, especially atrial fibrillation. Anticoagulation markedly decreases the risk of embolization from atrial fibrillation [27]. Myocardial dyskinesia, cardioversion, and cardiac catheterization are other clinical settings for embolization. The sudden occurrence of abdominal pain in these settings should prompt evaluation for SMA embolization. A substantial fraction of patients have prior emboli, and about 20% have synchronous emboli [24].

About 15% of emboli impact at the origin of the SMA, whereas the majority lodge distally 3–10 cm in the tapered segment of the SMA, past the origin of the middle colic artery [28]. Emboli tend to obstruct mesenteric flow acutely and completely and provide insufficient time to develop protective mesenteric collaterals. Intestinal ischemia due to embolic arterial occlusion can be compounded by reactive mesenteric vasoconstriction, further reducing collateral flow and worsening the ischemic insult [25].

Acute mesenteric arterial thrombosis

Arterial thrombosis accounts for about 15% of cases of acute intestinal ischemia. Thrombosis of the SMA or celiac artery is generally associated with a preexisting stenosis, usually at the origin of the arteries [29]. Typically, the SMA plaque slowly progresses to a critical stenosis over years and the residual lumen suddenly thromboses during a period of low

NOMI, nonocclusive mesenteric ischemia.

flow. Patients usually have diffuse atherosclerotic disease, with prior coronary, cerebrovascular, or peripheral arterial insufficiency (Table 113.1). About 30% of patients have histories consistent with chronic mesenteric ischemia, including postprandial pain, malabsorption, and weight loss before the acute episode [25].

Nonocclusive mesenteric ischemia (NOMI)

NOMI causes 20%–30% of acute mesenteric ischemia episodes [24,25]. Mesenteric ischemia without anatomic arterial or venous obstruction is due to mesenteric vasospasm, which can occur during periods of relatively low mesenteric flow, especially if there is underlying arterial atherosclerotic disease. Such low-flow states can result from heart failure (due to myocardial pump failure or arrhythmia), hypotension (shock, sepsis), or hypovolemia (dehydration, bleeding, treatment with diuretics) (Table 113.1). The vasoconstriction is produced by sympathetic activity, possibly mediated by vasopressin and angiotensin [30]. Moreover, mesenteric vasospasm may persist and perpetuate the ischemic injury even after correction of the precipitating event [25]. Vasoconstrictive drugs, particularly alpha-adrenergic agents, vasopressin, ergotamine, diuretics, and digitalis glycosides, can contribute to NOMI. Digitalis, even at nontoxic levels, can cause paradoxical and sustained contraction of both arterial and venous smooth muscle cells in the mesenteric circulation [31].

To make the diagnosis of NOMI, physicians must have a high index of suspicion because these patients may not present with the classic symptom complex of severe abdominal pain. Predisposing factors include myocardial infarction, congestive heart failure, pulmonary edema, aortic insufficiency, dialysis [32], and major cardiac or intraabdominal surgery [33]. The mortality of this specific subset of patients is relatively high irrespective of treatment due to the underlying medical conditions and the frequent delays in diagnosis.

Acute mesenteric venous thrombosis

Thrombosis of the SMV causes 5%–10% of the causes of AMI [34,35]. Symptomatic SMV thrombosis is about 20-fold more common than symptomatic IMV thrombosis because of the larger caliber and flow of the SMV [36]. The mean reported patient age ranges from 47 to 60 years [6], which is younger than that for superior mesenteric arteriopathy because of the association of arterial disease with atherosclerosis [37].

Although previously less than 50% of patients had a recognized cause, etiological factors are currently identified in about 80% of cases [35]. Risk factors for mesenteric venous thrombosis are listed in Table 113.2; they include hypercoagulable syndromes (protein C deficiency, protein S deficiency, factor V Leiden mutation, antithrombin III deficiency, antiphospholipid syndrome), portal hypertension, abdominal infections, perforated viscus, pancreatitis, and trauma [38]. The life-threatening complications of this syndrome are induced by the resulting bowel wall edema and increased outflow resistance secondary to venous thrombosis and increased blood viscosity, which can impede arterial inflow, leading to submucosal hemorrhage, venous capillary congestion, and bowel infarction [37].

Clinical presentations

Abdominal pain out of proportion to physical findings is a cardinal symptom in patients with AMI and is commonly manifest after embolic or thrombotic occlusion of the SMA [39]. The pain may initially be colicky but becomes constant with progression of ischemia. The pain may be localized or diffuse. The duration of pain is typically short. A history of chronic postprandial abdominal pain is present when acute arterial thrombosis is superimposed on chronic mesenteric ischemia [24]. Abdominal pain may not be appreciated in confused or critically ill patients [38].

Table 113.2 Causes of superior mesenteric venous thrombosis

Hypercoagulable states
Factor V Leiden mutation
Antithrombin III deficiency
Hyperfibrinogenemia
Antiphospholipid syndrome
Protein S deficiency
Protein C deficiency
Hormones/pregnancy
Neoplasms
Hyperviscosity syndromes
Myeloproliferative disorders
Sickle cell disease
Infection/inflammation
Pancreatitis
Appendicitis
Diverticulitis
Intraabdominal abscess
Portal hypertension
Trauma

If the clinical picture of occlusive intestinal ischemia may often be blurred and misleading, this is even truer for NOMI. Patients will often already be in intensive care for other reasons and, quite often, clinical presentation is dominated by one of the underlying diseases. Gastrointestinal symptoms may be nonspecific and present as constipation, loss of appetite, nausea, and vomiting. Abdominal pain is usually gradually increasing or discontinuous and may be colicky. Diarrhea with blood, mucus, and melena may ensue. A diagnosis of NOMI should be considered in all patients with risk factors, if the patient complains about gradually increasing abdominal discomfort with no other obvious cause, or if sedated intensive care patients develop signs of abdominal disease.

The symptoms of acute mesenteric venous thrombosis are usually less severe than those of acute arterial ischemia. Typically, these patients have a diffuse, intermittent abdominal pain of several days' or even weeks' duration.

In the absence of pain, unexplained abdominal distention and gastrointestinal bleeding may be the earliest signs of ischemia and impending intestinal infarction. Fever, diarrhea, nausea and vomiting, and diminished bowel sounds are other common but nonspecific manifestations of AMI. Diffuse or localized abdominal tenderness, rebound, and rigidity are ominous signs and usually herald transmural bowel infarction [40]. Infarction also leads to hypotension from fluid loss and septicemia, decreased urine output from hypovolemia and renal hypoperfusion, and hyperventilation from hypoxia and acidosis [38].

Diagnosis

Laboratory tests

Serum laboratory tests are not very helpful in making the diagnosis of AMI; no serum marker is sensitive or specific enough to establish or exclude the diagnosis. Moreover, elevations in the levels of serum markers most suggestive of intestinal ischemia usually occur only after transmural bowel infarction develops and, therefore, cannot be used to diagnose AMI at its early stages, when improved survival would be possible.

Leukocytosis, neutrophilia, and a shift to immature leukocytes in the leukocyte differential are common [28,41], but these laboratory findings are nonspecific markers of inflammation and infection. About 50% of patients have metabolic acidosis, an ominous finding suggestive of intestinal infarction, and 25% have hyperamylasemia [42]. Hemoconcentration may develop from fluid loss intramurally as interstitial edema, intraperitoneally as ascites, and intraluminally from fluid transudation [28]. Intestinal necrosis is associated with elevations of serum lactate, phosphate, and alkaline phosphatase levels as well as prerenal azotemia, hypoxemia, and bacteremia [26,28]. In prospective clinical studies including a reduced number of patients, increases in serum D(–)-lactate [43] or in a human homologue of intestinal fatty acid-binding protein (I-FABP) [44] have been detected. The diagnostic value of the fibrinolytic marker D-dimer, which has been studied extensively in the diagnosis of thromboembolism, has been assessed also in a clinical pilot study showing that patients suffering from mesenteric ischemia had significantly higher D-dimer levels than those with nonischemic acute abdominal events [45]. However, there are no reliable data on sensitivity and specificity of these serum markers.

Plain X-ray films of the abdomen

Plain abdominal radiography is most useful to exclude other potential causes of abdominal pain, rather than confirming the diagnosis of acute mesenteric ischemia. Completely normal plain radiographs have been reported in more than 25% of patients with mesenteric ischemia [46]. Subtle signs of AMI on plain abdominal radiographs include adynamic ileus and distended, air-filled loops of bowel, but these abnormalities are most commonly due to other causes such as pancreatitis, mechanical obstruction, or colonic pseudoobstruction. More specific radiographic findings occur in 25% of patients, usually those with advanced disease. These findings include mural thumprinting resulting from edema or hemorrhage (Fig. 113.4). In advanced stages of ischemia, pneumatosis of the bowel wall can be detected. Specifically, portal vein gas on abdominal radiography portends an extremely poor prognosis [47].

Intraluminal barium contrast evaluations are contraindicated because residual contrast can limit visualization of the

Figure 113.4 Thumbprinting. Detail of a plain abdominal radiograph showing semiopaque projections of the wall of the left colon into the lumen (arrows) resulting from submucosal edema and sometimes hemorrhage. Although thumbprinting is highly suggestive of intestinal ischemia, it occurs in relatively advanced lesion.

mesenteric vasculature during diagnostic angiography. On the rare occasion when barium studies are performed in a patient with abdominal pain not initially thought to have AMI, thumbprinting, stricture, or ulcerations can be found.

Ultrasonography

B-scan ultrasonography is widely practiced as the first diagnostic procedure in patients with acute abdominal pain. In patients with AMI, ultrasonography may reveal a thickening (> 45 mm) of bowel walls, signs of ileus with distended bowel loops, and hypoperistalsis. In severe cases, ultrasound may show intraperitoneal fluid or even air in the portal vein as a sign of massive intestinal necrosis. However, the main task of B-scan ultrasonography is to rule out other underlying abdominal pathology (e.g., aortic aneurysm).

Duplex ultrasonography may be of some benefit in visualizing flow in the SMA and celiac axis. With expert technical assistance, these tests can document proximal stenosis in the SMA or celiac axis or complete occlusion of these vessels with a high specificity (92%–100%), but relatively low sensitivity (70%–89%) [48]. Unfortunately, duplex sonography is of no value in detecting emboli beyond the proximal main vessel or in diagnosing NOMI. Moreover, identification of significant arterial stenosis does not establish the diagnosis of intestinal ischemia because total occlusion of two or even all three splanchnic vessels can be present in asymptomatic patients.

Angiography

Selective catheter angiography has long been the gold standard for diagnosis of AMI. In a review of mesenteric angiography in the diagnosis of AMI, sensitivities in five of six studies have ranged between 90% and 100%; specificity was reported in two of these studies to be 100% [2]. Although early angiography will produce a considerable number of negative results, it is essential if diagnoses are to be made early enough to improve survival [49,50]. However, prompt laparotomy should be performed in patients with suspected AMI in whom expeditious angiography is not available.

More controversial is the need for angiography in a patient with suspected AMI and signs of peritonitis. Since the latter indicate the presence of infarcted bowel, the most compelling reason for angiography, i.e., diagnosis while the effects of intestinal ischemia are still reversible, is no longer a consideration. However, angiography may still provide valuable information in these patients since it may establish a definitive diagnosis of AMI and its cause, identify all vascular lesions, which will guide revascularization procedures, and offer the possibility of administering intraarterial vasodilators in cases of NOMI. Disadvantages of traditional angiography are its limited availability and potential renal toxicity as well as its expense and time constraints.

In cases of SMA embolization, most emboli are impacted 3–10 cm from the origin of the SMA, distal to the origin of the middle colic artery. The classic meniscus sign can often be visualized at the point of occlusion, which is different from the planar defect produced by a thrombus [51]. However, when angiography is performed more than 24 h after embolization, the embolic filling defect becomes less sharp and less round because of proximal and distal clot propagation. Contrast is typically poorly visualized distal to emboli because the rapidity of embolic occlusion provides insufficient time to develop collateral flow. Other angiographic findings favoring embolus over thrombus include minimal atherosclerosis in mesenteric vessels, multiple lesions in mesenteric arterial branches, and simultaneous extramesenteric emboli [51].

Symptomatic thrombosis of the SMA is generally associated with a high-grade stenosis or occlusion of the celiac axis. The stenosis usually slowly progresses and permits reconstitution of vascular flow because of the development of collaterals (Fig. 113.2). Aortography is essential in these patients to evaluate potential inflow and outflow sites for bypass

grafts as well as to clarify the extent and location of other atherosclerotic lesions in the iliac and inferior mesenteric arteries. When the SMA distal to thrombotic occlusion fills from large collaterals, the SMA thrombus is probably chronic and not the cause of acute symptoms.

In patients suffering NOMI, angiography usually reveals multiple areas of narrowing and irregularity in major branches. The small and medium arterial branches may be decreased or absent producing a "pruned" arterial tree, and there is also impaired intramural vascular filling [50]. Acute mesenteric embolic or thrombotic obstruction may also produce mesenteric vasospasm, so NOMI is diagnosed only when acute vascular obstruction is absent. The diagnosis of NOMI is strongly favored over the diagnosis of arterial thrombosis by an absence of extramesenteric atherosclerosis and by an increase in SMA caliber after transcatheter vasodilator therapy [51].

In mesenteric venous thrombosis, selective angiograms may reveal reflux of contrast material back into the aorta due to extremely slow flow and heightened outflow resistance. A prolonged arterial phase with accumulation of contrast and thickened bowel walls is also characteristic. Extreme cases may demonstrate contrast extravasation into the bowel lumen, which may be indicative of active bleeding. The definitive diagnosis of mesenteric venous thrombosis is made during the venous phase; either a filling defect is noted within the portal vein or, in more extensive thromboses, the entire venous phase is absent [37].

Computed tomography and magnetic resonance angiography

Whereas single-detector helical computed tomography (CT) is of limited use in the diagnosis of AMI [52], except in patients suspected of having superior mesenteric vein thrombosis (Fig. 113.5) [46], the spread of spiral CT equipment has certainly increased the potential of this investigation, which now claims 92% specificity and 64% sensitivity [53]. Multidetector-row CT is the most recent evolution, which provides an even better chance of recognizing mesenteric ischemia, thanks to increased spatial resolution, the high-quality three-dimensional (3D) reconstructions (Fig. 113.6), and the shorter examination times. It has thus confirmed a fundamental role for CT in the diagnosis of AMI, achieving a sensitivity of 80%–96% and a specificity of 94%–98% [53–55], and therefore has become the test of choice in the diagnosis of AMI. Unenhanced scans can show atherosclerotic calcification and, in cases where the onset of thrombosis is of recent date, the hyperdense aspect of the vascular structure involved. In cases of advanced infarction, diagnosis can be made on the basis of the baseline scans alone, if parietal pneumatosis or air at the level of the mesenteric vessels or portal branches can be seen. In all other cases, intravenous (i.v.) injection of contrast medium is essential in order to be able to identify the characteristic causes and signs of the ischemia that have been described previously with angiography. In occlusive, embolic or thrombotic forms, CT enables the site of the vascular obstruction to be visualized, appearing as a site of defective opacification of the lumen of the vessel (Fig. 113.7). It is most easily recognized when the occlusion

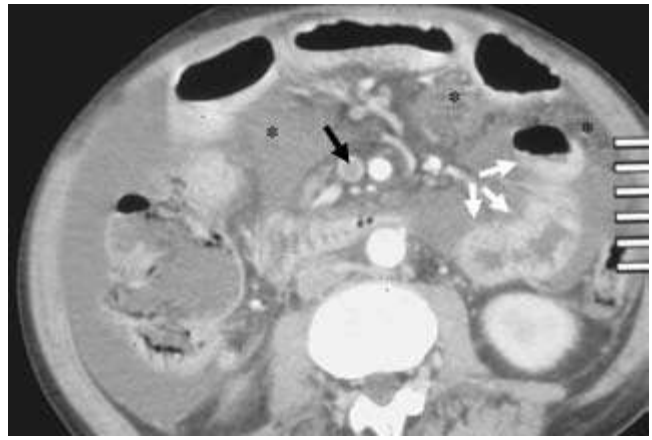

Figure 113.5 Mesenteric venous thrombosis in a patient with acute pancreatitis. Contrast-enhanced computed tomography (CT) scan shows small bowel wall thickening (thick arrows) and a hypoattenuating thrombus of the superior mesenteric vein (thin arrow). Ascites is also present (asterisks).

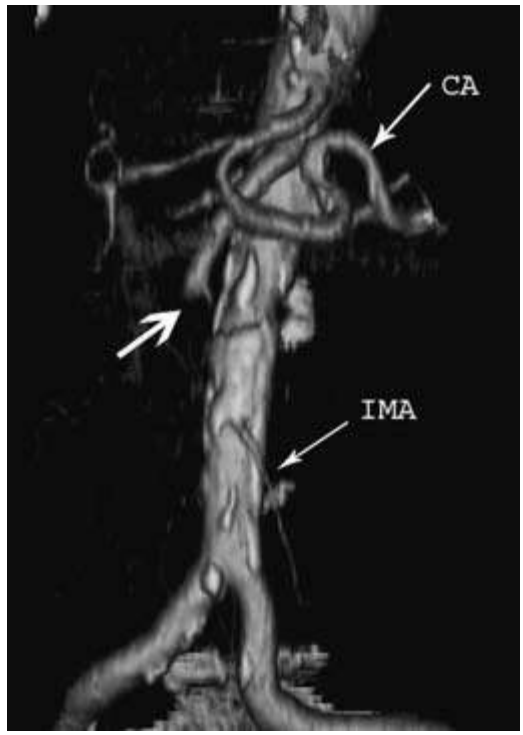

Figure 113.6 Volume-rendered three-dimensional computed tomography image of abdominal aorta in frontal projection showing occlusion of the superior mesenteric artery (SMA) (large arrow) with patency of the celiac axis (CA) and inferior mesenteric artery (IMA).

is at the level of the main trunks. Thrombosis of the main vessels can easily be seen at axial imaging, often with associated collateral vessels, depending on its chronicity. For evaluation of more distal branches of the mesenteric vessels and of narrowing or plaque at the origin of the arteries, 3D imaging offers a distinct advantage. Three-dimensional images allow better representation of complex collateral vessels [53,54]. A systematic review has demonstrated a high sensitivity of CT for ischemia in the setting of small bowel obstruction and suggests that a CT scan finding of partial bowel obstruction is likely to reflect a clinical condition that will resolve without surgical intervention [56].

Magnetic resonance imaging with angiography is another noninvasive modality that rivals conventional angiography. In mesenteric venous disease, excellent visualization of the vascular anatomy is possible in addition to assessment of portal venous patency, flow direction, splanchnic thrombosis, and changes suggestive of portal hypertension. Three-dimensional gadolinium enhanced reconstruction of vascular anatomy with a single breath hold and ultrafast scanning with digital subtraction angiography are also available [57]. High sensitivity and specificity were found for MRI in the detection of severe stenoses or occlusion of the origins of the celiac axis and SMA [58]. In patients with thrombosis of the portal or mesenteric veins, the overall sensitivity, specificity, and accuracy of MRI angiography for the detection of thrombosis have been reported to be 100%, 98%, and 99%, figures similar to those of digital subtraction angiography, suggesting that noninvasive contrast-enhanced MRI angiography has the potential to replace subtraction angiography as the standard method to assess the whole intestinal venous system [59]. However, this modality is limited in its ability to identify more peripheral occlusions and NOMI. Functional MRI angiography also has been studied: the normal increase in postprandial SMV flow compared with SMV flow in the fasting state has been shown to be less in patients with chronic mesenteric ischemia than in control subjects [60]. Additionally, the ratio of postprandial SMV flow increase to SMA flow increase is less in patients with chronic mesenteric ischemia than in control subjects [61]. While not yet routinely available, functional MRI may hold promise for the future in helping to diagnose chronic mesenteric ischemia. The major advantage of MRI over CT angiography or conventional angiography is its lack of renal toxicity.

Therapy

General measures

Initial treatment of patients suspected of having AMI is aimed at resuscitation. Fluids are aggressively administered to replace intravascular fluid lost into the interstitium as edema, into the peritoneum as ascites, or into the lumen from fluid exudation or hemorrhage. Adequate hydration and optimization of cardiac function are particularly important in NOMI because hypovolemia and hypotension exacerbate mesenteric vasoconstriction. In patients with hypotension or hypovolemia, there will always be mesenteric vasoconstriction; thus, if there is a strong suspicion of NOMI (and arterial embolus or thrombosis are considered unlikely), angiography before correction of hypovolemia or hypotension will not be of diagnostic help. Medications that cause vasoconstriction, such as vasopressin or digitalis, should be discontinued. Electrolyte abnormalities and acid–base disturbances should be corrected before surgery. Broad-spectrum antibiotics are administered intravenously because intestinal ischemia promotes bacterial translocation and sepsis. Gastrointestinal decompression via a nasogastric tube is recommended because increased intraluminal pressure may decrease mucosal perfusion. Urine volume should be monitored with a bladder catheter. In critically ill patients, pulmonary pressures and cardiac output should be monitored with a Swan–Ganz catheter to optimize fluid and drug therapy. Measurements of arterial oxygen concentration will guide the need for oxygen supplementation or mechanical ventilation.

Treatment of emboli

Various therapeutic approaches have been proposed for SMA emboli, including surgical revascularization, intraarterial perfusion of thrombolytic agents or vasodilators, and systemic anticoagulation. The therapeutic option should be chosen taking into account the presence or absence of peritoneal signs, whether arterial occlusion is partial or complete, and whether location of the embolus is above the origin of the ileocolic artery or in more distal branches.

There is uniform agreement that exploratory laparotomy is mandatory when signs of peritonitis are present and that embolectomy and resection of any infarcted bowel should be performed as necessary. When abdominal contamination

is absent, primary anastomosis is generally performed. When extensive bowel segments are questionably viable, only unambiguously necrotic bowel is resected, and a second-look operation is performed about 24 h later to permit demarcation between viable and nonviable bowel and to minimize the extent of bowel resection [62]. Anticoagulation with heparin is administered postoperatively to prevent recurrent embolization [2].

Several case reports and small series have reported successful nonoperative treatment of acute mesenteric arteriopathy using heparin [63] and thrombolytic agents including urokinase, streptokinase, and recombinant tissue plasminogen activator [64,65]. Data from that experience suggest that thrombolytic therapy is most likely to be successful when the embolus is partially occluding, or is in one of the branches of the SMA or in the main SMA distal to the origin of the ileocolic artery, and the treatment is applied within 12 h of the onset of symptoms. An important question is the long-term reocclusion rate after these therapies. Patients treated medically require close surgical observation to detect failure of medical therapy and the rapid progression to infarction. If signs of intestinal infarction develop, immediate surgery is indicated [2].

There is some controversy as to the use of vasodilators as a complementary treatment in patients with SMA embolus. There is evidence showing that vasoconstriction of both the unobstructed and the obstructed branches occurs with an SMA embolus [50]. Such vasoconstriction resolves spontaneously if the embolus is removed soon after it develops. However, if the vasoconstriction has existed long enough, it can become persistent. In these cases, intraarterial infusion of a vasodilator such as papaverine might be beneficial [2].

Treatment of arterial thrombosis

If a diagnosis of acute thrombosis of the SMA is made, emergency surgical revascularization is recommended. Simple surgical thrombectomy is unlikely to be successful in the long term, and it has to be accompanied by revascularization performed via bypass [29]. In a contaminated operative field, an autogenous aortovisceral graft is required, but polyester fluoroethylene prosthesis may be used when contamination is absent [1]. The proximal SMA should be opened through a longitudinal arteriotomy. If thrombectomy is successful, then a temporary intraarterial SMA shunt can be placed while definitive revascularization is considered. The longitudinal arteriotomy in the SMA can serve as the distal anastomotic site for an antegrade bypass originating in the supraceliac aorta or for a retrograde bypass from the infrarenal aorta or iliac vessels. As for treatment of an embolus, bowel viability is assessed after revascularization to minimize bowel resection.

Treatment of NOMI

Management of NOMI is essentially pharmacological and is readily achieved by selective infusion of vasodilators into the SMA. Splanchnic vasodilators include papaverine, tolazoline, nitroglycerin, glucagon, prostaglandin E, phenoxybenzamine, and isoproterenol [24]. The greatest clinical experience is with papaverine, which is administered as a continuous infusion into the SMA at 30–60 mg/h. This approach has resulted in a reduction in mortality rates from 70% to 90% observed through the 1980s and to 50%–55% during the last decade [25,50,62].

Subsequent management is dictated by the patient's clinical response to vasodilator therapy. Angiography may be repeated after 30 min to document the relief of vasospasm. Papaverine infusion is usually continued for approximately 24 h. A repeat angiogram should then be performed, prior to which the intraarterial infusion is changed to saline for 30 min. Depending on the clinical course and the presence or absence of vasoconstriction in the angiogram, papaverine is discontinued or maintained for another 24 h. Repeat angiograms are performed at 24-h intervals until radiographic signs of vasoconstriction have disappeared and the patient's clinical symptoms and signs have vanished. Generally, infusions can be discontinued after 24 h, but they have been maintained for as long as 5 days in some cases [25]. Certain precautions specific to the use of intraarterial papaverine are noteworthy. The patient's hemodynamic status should be carefully monitored, as significant hypotension can result if the indwelling catheter migrates into the aorta and papaverine is infused into the peripheral circulation. In this event the papaverine infusion should be replaced by with saline and the position of the catheter confirmed with plain film.

Immediate laparotomy is indicated during papaverine therapy if peritoneal signs do not rapidly remit with onset of infusion, if peritoneal signs develop during infusion, or if the patient deteriorates clinically as evidenced by increasing leukocytosis, sepsis, gastrointestinal bleeding, or unstable vital signs [25]. At surgery, gangrenous bowel is resected according to the surgical principles described for an embolus. Intraoperative peritoneal lavage with warm saline and maintenance of a warm operating room temperature moistens and warms the intestine and helps reduce mesenteric vasospasm. The SMA catheter is left in place to provide vasodilator therapy during and after surgery.

Treatment of mesenteric venous thrombosis

In asymptomatic individuals in whom the diagnosis has been made on a CT scan obtained for reasons other than abdominal pain, either no therapy or a 3- to 6-month course of anticoagulation is reasonable [2]; there are no studies to aid in this therapeutic decision. In symptomatic patients in whom an acute thrombosis of the SMV is diagnosed, by CT scan, MRI, or angiography, treatment is determined by the presence or absence of peritoneal signs. As in all patients with AMI, signs of peritonitis mandate laparotomy and resection of infarcted intestine. Successful thrombectomy of the SMV has been described [35,66]. However, it is not recommended

unless the thrombus in the proximal SMV is fresh (within 1–3 days), since most patients have diffuse venous thrombosis with distal extension, which is not suitable for thrombectomy. If the diagnosis of SMV thrombosis is established intraoperatively, anticoagulation should start immediately. Intravenous anticoagulation with heparin has been shown to prevent thrombus propagation and recurrence, and to improve survival [63–67]. In the absence of peritoneal signs, heparin should be immediately initiated, with an initial bolus of 5000 units followed by continuous infusion of 1000 units/h. Heparin dosage is then adjusted according to the prolongation of the partial thromboplastin time. Heparin is contraindicated in the presence of acute gastrointestinal bleeding from mesenteric ischemia. Heparin is administered for 7–10 days; then prolonged anticoagulation with warfarin for 3–6 months is recommended [37].

Thrombolytic therapy is rarely used for SMV thrombosis. Thrombolytic agents have been administered successfully in an antegrade fashion via the SMA [68], retrograde via the internal jugular vein [69], and transhepatically via the portal vein [70]. Nevertheless, these forms of therapy should be considered experimental for SMV thrombosis.

Prognosis

Until the early 1980s, the mortality of acute mesenteric arterial ischemia ranged from 70% to 90% [71,72]. Early diagnosis and aggressive therapy have resulted in improved survival. In a report of 21 patients with SMA embolus, intestinal viability was achieved in 100% of patients if the duration of symptoms was less than 12 h, in 56% if it was between 12 and 24 h, and in only 18% if symptoms were more than 24 h in duration before diagnosis [73]. During the last decade a 50%–60% survival has been reported in large clinical studies [73,74]. More than 90% survive when acute mesenteric arteriopathy is diagnosed early by conventional, CT scan or MRI angiography before peritoneal signs occur [28]. Variables that are independently associated with a poor prognosis include previous cardiac illness, high urea plasma levels, and small and large bowel involvement, whereas resection surgery is associated with a better prognosis [75]. Causes of death include extensive intestinal necrosis, recurrent SMA thrombus or embolus, emboli to other sites, cardiopulmonary failure, and intestinal hemorrhage.

The mortality for acute SMV thrombosis, 25%–30%, is lower than that for acute mesenteric arterial ischemia [67]. The mortality rate depends on the grade of venous occlusion, the presence of collaterals, diagnostic delays, and comorbidity [76]. In a report of 53 patients with SMV thrombosis, 55% had major postoperative complications, such as short bowel syndrome, wound infection, sepsis, and recurrent SMV thrombosis [35]. Recurrences usually involve infarction of bowel adjacent to previously resected bowel.

Chronic mesenteric ischemia

Chronic mesenteric ischemia (intestinal angina) is a clinical syndrome characterized by recurrent abdominal pain and weight loss as a result of repeated transient episodes of insufficient intestinal blood flow, usually related with the increased metabolic demand associated with digestion.

Intestinal angina is an uncommon process that occurs only when severe atherosclerotic narrowing of a major splanchnic vessel exists in association with occlusion of one or two of the remaining vessels. This is because the very efficient collateral circulatory network in the small bowel and colon can successfully overcome the single occlusion of a major vessel. In fact, intestinal angina is very uncommon despite the finding at autopsy, performed in unselected cases, of significant stenosis of any of the three major splanchnic vessel in 29% in the overall series and in 67% in those patients over 80 years of age at the time of death [77].

This ischemic syndrome is seen in middle-aged and elderly people and predominantly in women (3:2). Direct or indirect evidence of arthrosclerosis is common in these patients, with more than one-third having hypertension, coronary artery disease, peripheral arterial disease, and/or cerebrovascular disease. Patients with diabetes and smokers are at increased risk.

Clinical manifestations are related to limitations of the ability of the celiac artery or superior mesenteric artery to supply increased blood flow in response to metabolic demands after a meal, mainly because of atherosclerotic vascular lesions. Alternatively, it has been suggested that a steal phenomenon from the intestinal to the gastric circulation occurs when food reaches the stomach.

Clinical presentation

Recurrent abdominal pain and weight loss are the two primary characteristic symptoms. Abdominal pain is epigastric or periumbilical. It eventually radiates to the back and appears shortly after meals, lasting for 1–3 h. The intensity of the pain is related to the quantity of the meal or to the fat content, is crampy in nature, and has to be distinguished from pancreatic, biliary, or ulcer-related pain. As a consequence of the pain, food intake tends to diminish (sitophobia) and, with time, weight loss becomes obvious. Other unspecific symptoms such as nausea, vomiting, diarrhea and/or constipation are present in one-third of patients. Isolated cases of malabsorption associated with chronic mesenteric ischemia have been documented [78], and resolved gastroparesis has been reported after revascularization of occluded mesenteric vessels [79].

Physical findings are not specific. Weight loss with signs of malnutrition is the most common alteration, although some patients maintain their weight despite the high frequency and intensity of the pain. Abdominal tenderness without rebound may be present during an episode of severe pain.

Indirect signs of atherosclerotic vascular disease may be found, mainly diminished peripheral pulses, carotid or femoral bruits, or stigmata of past stroke.

Diagnosis

The diagnosis is mainly based on a characteristic clinical picture, the presence of an occlusive lesion in the splanchnic vessels documented by angiography, and the absence of other common causes of abdominal pain. In most cases, patients undergo an extensive workup for obscure chronic abdominal pain, including routine laboratory evaluation, plain abdominal radiographs, upper and lower GI endoscopy, small bowel barium series, and ultrasonography or abdominal CT. Laboratory abnormalities related to malnutrition, e.g., anemia, hypoalbuminemia, and hypocholesterolemia, may be present. When common causes of abdominal pain have been ruled out and suspicion of intestinal ischemia is well established from epigastric pain after meals and substantial weight loss, a CT angiographic study of the splanchnic arteries is warranted, especially in patients with risk factors. In approximately 90% of patients with intestinal angina, at least two major splanchnic vessels are found to be occluded or stenosed, and, in up to 50% of patients, blood flow in all three vessels is severely compromised [80]. In contrast, isolated occlusion of a single vessel is uncommon in documented intestinal angina.

Duplex ultrasonography can show high flow velocity and poststenotic turbulence reflected by modifications on spectral waveform and mixture of colors in the duplex image. Retrograde hepatic artery blood flow suggests stenosis of the celiac artery. In stenosis of the superior mesenteric artery greater than 50%–70%, the sensitivity of the technique is above 90%, with marginal improvement with postprandial study [81]. Sensitivity for lesions in celiac axis is slightly lower, 85%–87%. When performed by skilled operators, duplex ultrasonography may be a useful screening tool.

Treatment

For many years, surgical revascularization has been the treatment of choice for chronic mesenteric ischemia. The techniques used include antegrade and retrograde bypass grafting, transaortic mesenteric endarterectomy, and aortic reimplantation of the SMA. In the last 20 years, percutaneous transluminal mesenteric angioplasty with or without stenting has been introduced.

Patients with symptomatic chronic mesenteric ischemia should be considered for surgery with the goals to relieve symptoms, improve nutrition, and prevent mesenteric infarction. Asymptomatic patients submitted to aortic reconstruction for aortoiliac occlusive disease, in whom significant mesenteric occlusion is also present, should also be considered for bypass grafting because they have an increased risk of mesenteric infarction after surgery [82]. The indication for surgery in asymptomatic patients in the absence of a need for aortic reconstruction is not clear. It has been proposed by some authors that surgery should be considered in such patients when three-vessel ischemia is documented because of the high risk of developing ischemic symptoms or death [83]. Complete revascularization has been recommended by many surgeons, but several authors have recently proposed that bypass grafting of the superior mesenteric artery alone is an effective and durable procedure for treatment of intestinal ischemia [84]. Series published in the last 20 years have reported a wide range of outcome figures for surgical revascularization, but results of more recent publications show mortality rates from 0% to 4%, success rates (defined as relief of symptoms) over 90%, and recurrence rates under 15% [2]. Advancing age, cardiac disease, hypertension, and additional occlusive disease influence overall mortality, and concomitant aortic replacement, renal disease, and complete revascularization are associated with high postoperative morbidity rates [85]. In patients with severe weight loss, parenteral nutrition before revascularization may reduce surgical morbidity.

Chronic mesenteric ischemia has been effectively treated by the endovascular route [86]. In a series of 19 patients, successful dilation of at least one stenosed vessel was achieved in 100% of cases using balloon angioplasty, which was followed by stenting in seven cases. Significant amelioration of symptoms was observed in all cases, and three patients suffered a restenosis during a mean follow-up of 3 months [87]. A remarkable feature of this series is the success obtained by dilating only a single artery. Success and mortality rates seem not to be significantly different from those of surgical revascularization, but recurrence of symptoms has been slightly higher than after surgery in some series [88].

Based in the current information, it seems reasonable at the present time to offer surgical revascularization to low-risk patients and to perform angioplasty in those with a higher surgical risk. If it can be demonstrated that the addition of stenting to angioplasty can decrease the recurrence rate of symptoms better than angioplasty alone, then this procedure might be a valid alternative to surgery, even in low-risk patients. Surgery rather than angioplasty is indicated for suspected bowel necrosis.

In patients who survive surgical revascularization, the prognosis is excellent; 5-year survival rates approach 80%, and most patients become free from symptoms, gain weight, and resume normal eating habits [80].

Ischemic colitis

Ischemic colitis is the most common form of ischemic injury to the gut and occurs more frequently in elderly people. The true incidence in general population is not well known, but it has been estimated in the range of 4.5–44 cases per 100 000 person-years [89]. The disease can result from either

occlusive or nonocclusive events, mainly in the territory of the inferior mesenteric artery, in colonic branches of the superior mesenteric artery and in the superior and inferior mesenteric veins. Thus, ischemic colitis is predominantly seen in the left colon [90]. The splenic flexure and rectosigmoid junction, where low perfusion exists (watershed areas), are commonly affected, while the rectum is not usually compromised because of excellent collateral perfusion. Right colon ischemic colitis is rare [91], is mainly due to low-flow states, and is associated with poor prognosis [92].

Large arterial vessel occlusion may be caused by thrombi or atheromatous lesions [90]. Embolization of the inferior mesenteric artery is uncommon because most emboli are too large to enter this narrow vessel. Aortic surgery can cause ischemic colitis because of unnoticed ligation of the IMA, the occurrence intraoperative hypoperfusion in the presence of inferior mesenteric artery occlusion [93], or embolization of atheromatous debris to the hypogastric artery's tissue beds during endovascular manipulations [94]. Blood flow in the small segmental arterioles may also be compromised by small vessel disease induced by diabetes, radiation or autoimmune inflammatory arteritis, and by chronic renal failure treated by hemodialysis [95,96]. Recently, irritable bowel syndrome, constipation, and chronic obstructive pulmonary disease have also been identified to increase the risk for ischemic colitis [89,97]. Venous occlusion may occur as a consequence of hypercoagulability states (Table 113.2), pancreatitis, or portal hypertension [95]. Vessel occlusion may also be secondary to colonic obstruction from colon cancer, benign colonic strictures, adhesions, volvuli, or hernias [98]. Nonocclusive ischemia may be present in the colon due to low-flow states or vasoconstriction induced by several drugs [99,100] (Table 113.3). Ischemic colitis has been reported in long-distance runners [101].

Clinical manifestations

A wide spectrum of disorders can be seen as a consequence of colonic ischemia. These include acute, transient, self-limited ischemia (reversible colopathy characterized by mucosal and submucosal hemorrhage), acute fulminant ischemia (which is transmural and progresses to necrosis), and chronic ischemic colitis (partially reversible vascular disease usually manifested by late colonic stenosis).

Table 113.3 Drugs associated with intestinal ischemia

Estrogen–progesterone	Diuretics	Alosetron
Cocaine	Pseudoephedrine	Barbiturates
Crack	Cyclosporine	Methylsergide
Ergotamine	α-Adrenergic agonists	
Vasopressin	β-Adrenergic antagonists	
Digitalis	Psychotropic drugs	

Abdominal pain is present in more than two-thirds of patients [24]. The pain is moderately severe, crampy, mostly localized in the left lower quadrant, and sometimes associated with diarrhea. Rectal bleeding manifested by either bright-red blood in the stools or hematochezia is another common symptom. Bleeding is usually mild and does not require transfusion in most cases [102]. Abdominal distention is also frequent and can be accompanied by nausea and vomiting. Physical signs during the acute episode include abdominal distention, with mild-to-moderate tenderness, fecal occult blood, tachycardia, or moderate fever. In comparison with AMI, the majority of patients presenting with ischemic colitis have hemodynamic stability with no signs of peritonitis. However, in a small proportion of patients, massive colon necrosis may occur with obvious signs of peritonitis and shock. Hypertension and a history of cancer have been identified as independent prognostic factors of colonic necrosis in elderly people suffering an episode of ischemic colitis [103]. A minority of patients have subclinical acute ischemic disease and develop a colon stricture which can be asymptomatic or manifested by constipation, diarrhea, or recurrent abdominal pain [104].

Diagnosis

All patients, especially elderly people with any of the well-known precipitating factors, who develop abdominal pain, bloody diarrhea, and abdominal distention should be investigated for ischemic colitis.

Plain abdominal radiograms usually show nonspecific, air-filled bowel dilation. The specific finding of thumbprinting (Fig. 113.4) is found in less than 25% of cases [105]. Colonoscopy or flexible sigmoidoscopy is the method of choice for the diagnosis of ischemic colitis, as it allows direct visualization of the mucosa and tissue sampling [106]. Colonoscopy is preferable to sigmoidoscopy because 50% of the ischemic lesions are proximal to the sigmoid colon, except in the case of ischemic injury after aortic surgery, when lesions always involve the distal colon. The endoscopic examination has to be performed with caution and minimizing air insufflation in order to avoid perforation. The mucosa of the affected segment usually appears edematous, hemorrhagic, friable, and ulcerated. When bowel necrosis is present, colonoscopy reveals cyanotic, gray or black mucosa.

Biopsies often demonstrate nonspecific findings of vascular congestion, submucosal hemorrhage, interstitial edema, inflammatory infiltration, loss of superficial cells, and intravascular platelet thrombi (Fig. 113.8). Hyalinization of the lamina propria, full-thickness mucosal necrosis, the presence of atrophic microcrypts, and hemorrhage in the lamina propria are also microscopic signs suggestive of acute ischemic injury, whereas hemosiderin deposition, along with transmural fibrosis and mucosal atrophy, is a pathognomonic finding of the disease in its chronic phase [107].

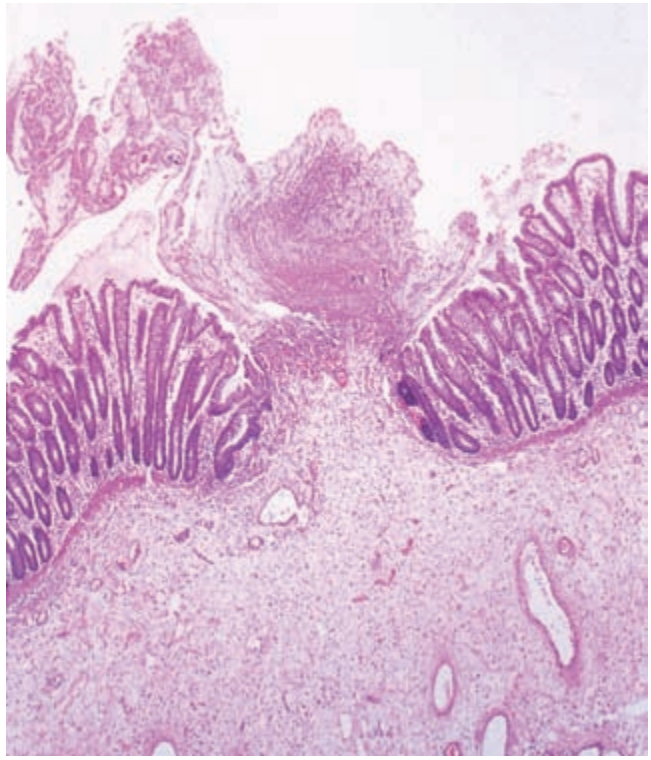

Figure 113.8 Intestinal ischemic damage. Well-delimited ulceration of the mucosa, with formation of a pseudomembrane. The remaining mucosa is normal. The submucosa has a marked edema and discrete infiltration by inflammatory cells.

Barium enema may be helpful also for the diagnosis of ischemic colitis, with a sensitivity that approaches 80% [108]. Thumbprinting is the most characteristic finding, but ulcerations, mural deformity, sacculation, and transverse ridging may also be seen. CT scan is not usually performed for diagnosis of ischemic colitis, but it can show significant alterations of the bowel wall such as circumferential, segmental wall thickening with fold enlargement, lumenal narrowing, and polypoid filling defects, and it may be helpful to exclude other diseases [109].

Angiography is not usually indicated for the evaluation of ischemic colitis because, by the time of clinical presentation, colon blood flow may be restored. However, in cases in which distinction between ischemic colitis and AMI is not clear, when only the right side of the colon is affected, and when a more generalized ischemic disorder is suspected, CT or MRI angiography must be performed. In some cases, color duplex ultrasonography is able to distinguish ischemia from inflammatory bowel disease [110], and absence of arterial flow on Doppler sonography may be a better early predictor of outcome than clinical and laboratory findings [111].

Differential diagnosis

It is not uncommon that the diagnosis of ischemic colitis is established only when repeated clinical, roentgenographic, or endoscopic studies are performed after symptoms appear. This is because the signs and symptoms of ischemic colitis overlap with those of other colonic diseases or other mesenteric vascular diseases. Infectious colitis, inflammatory bowel disease, colon cancer, radiation colitis, diverticulitis, NSAID-induced colonic lesions, and pancreatitis should be considered.

Some pathogens, such as *Escherichia coli* O157:H7 and cytomegalovirus, may cause vascular damage in the colon leading to hemorrhagic colitis, which can be easily misdiagnosed as ischemic colitis [112,113], i.e., ischemia may be a condition associated with these infections [114]. Pseudomembranous colitis caused by *Clostridium difficile* may also be mistaken for ischemic colitis [115]. Therefore, stool analysis for bacteria, ova, and parasites and the assay for *C. difficile* toxin should be performed in some cases.

The differential diagnosis between ischemic colitis and inflammatory bowel disease can be difficult in some cases [116]. Data supporting the diagnosis of ischemic colitis are age of onset, segmental distribution of injury, abrupt transition between damage and undamaged mucosa, rectal preservation (useful only for distinction from ulcerative colitis), and rapid resolution of lesions in subsequent colonoscopies [117]. In elderly people, the initial distinction between ischemic and ulcerative colitis may be more difficult. Because of its segmental involvement and rectal sparing, differentiation between ischemia and Crohn's colitis can also be difficult, although terminal ileum involvement and the presence of fistulas or colonic granulomas may help to diagnose Crohn's disease.

Radiation colitis can be easily suspected in patients with antecedents of such treatment, and colon cancer is differentiated mainly by pathological examination of colonic biopsy specimens [118]. Diverticulitis can mimic ischemic colitis, but CT is helpful to identify colon diverticula as well as mural thickening, pericolonic inflammation and eventually fistula or abscess induced by diverticulitis [119].

In the last decades, NSAID-induced colonic lesions have been identified more frequently than previously suspected. Abdominal pain and diarrhea with or without blood loss is the most common complaint of patients with such colonic lesions. Nonspecific inflammatory changes and/or erosions and diaphragm-like strictures may be seen at endoscopy, and histology may reveal findings similar to those of ischemic colitis [120].

Treatment

Patients with reversible or transient ischemic colitis manifested by mild symptoms and signs do not need specific therapy because the event usually resolves spontaneously. In patients with more severe or persistent symptoms, bowel rest and general supportive measures, including parenteral fluids, are recommended. Precipitating factors should be corrected. This includes stopping any medication with potential vasoconstrictor effects on the mesenteric vasculature or

narcotics that may worsen colonic distention. Measures should be implemented to correct low-flow states, which can be due to either hypovolemia or cardiac dysfunction. Intravenous infusion of broad-spectrum antibiotics are usually recommended [121], although no definitive clinical evidence is available of the beneficial effects of such a policy. Antibiotic use is based in the theoretical protection against bacterial translocation that occurs in severe colonic ischemia, and for early treatment of sepsis that follows massive colon gangrene [122]. In patients treated medically, endoscopy should be repeated during hospitalization to confirm diagnosis and to document recovery.

Patients showing evident signs of peritonitis require urgent surgery. Surgery is also warranted in patients in whom severe symptoms, such as abdominal tenderness or fever, or laboratory findings, such as leukocytosis or metabolic acidosis, persist or deteriorate despite medical treatment [104]. Other infrequent indications for surgery are massive bleeding, persistent ischemic lesions with protein-losing colopathy, and recurrent sepsis in a patient apparently recovered from an acute episode of ischemic colitis. In any case, segmental colectomy of the involved area should be performed and the resected specimen should be opened in the operative room to assess the extent of mucosal injury. If surgical margins are involved, an additional segment should be resected until margins appear normal. Areas of questionable viability in the colon should also be resected [90,95]. The use of intraoperative laser Doppler flowmetry has been proposed to ascertain the viability of colonic segments [123].

In patients submitted to abdominal aortic graft surgery, several strategies have been tested to improve rectocolonic microcirculation during and after surgery, hoping to prevent postoperative colonic ischemia. These include intravenous infusion of prostaglandin E_1 [124], and rectal administration of short-chain fatty acids [125].

In cases of chronic evolution of ischemic colitis, surgery is required only when colonic stenosis becomes symptomatic [126]. Segmental resection is the procedure of choice in such cases, although transendoscopic ditation may be an alternative in selected patients with symptomatic colonic stenosis in whom surgery would be high risk.

Unusual causes of mesenteric ischemia

Obstructing diseases

An uncommon and controversial cause of mesenteric ischemia is the compression of the celiac artery and eventually the superior mesenteric artery by the median arcuate ligament, especially in young, thin, female patients. It is manifested by upper abdominal pain induced by food intake and associated with weight loss. Diagnosis is made by angiography, duplex sonography, CT, or MR angiography. Surgical division of the obstructing diaphragmatic fibers and denervation of the celiac ganglion, with or without celiac artery dilatation or reconstruction, is the recommended treatment [127].

When a segment of the large bowel is obstructed, the adjacent vasculature could be compromised, thus producing regional colonic ischemia. This phenomenon, which can be manifested as an acute or chronic event, may be observed in some cases of sigmoid adenocarcinoma or small bowel carcinoid tumors, incarcerated hernia, sigmoid or cecal volvulus, intussusception, peritoneal adhesions, retroperitoneal fibrosis, neurofibromatosis, or cancer infiltrating the mesentery [90,128].

Vasculopathies

Several vasculitides may induce mesenteric ischemia. Polyarteritis nodosa (PAN) is characterized by necrosis of small or medium-sized muscular arteries with the eventual development of aneurysms. PAN may commonly involve the mesenteric circulation. In patients with PAN, gastrointestinal bleeding and bowel infarction with or without perforation are common events with very poor prognosis (mortality approximately 75%–100%). Recurrent abdominal pain and steatorrhea with weight loss are also manifestations of this syndrome. The erythrocyte sedimentation rate is usually significantly increased and diagnosis is confirmed by characteristic angiographic findings [129]. Treatment with corticosteroids and cyclophosphamide provide the best results [130]. Bowel rest, nasogastric decompression, and parenteral nutrition are often needed. Early surgery is indicated when perforation or obstruction occurs.

Unusual cases of mesenteric ischemia have been described in systemic lupus erythematosus and in the antiphospholipid syndrome [131]. Although infrequent, intestinal ischemia may be seen also in some cases of Takayasu and Buerger diseases [132,133], the latter usually presenting in young men who are heavy smokers. An increased risk of thrombotic events has been documented in Behçet and Crohn's diseases [134,135], and primary or secondary amyloidosis may be associated with intestinal ischemia [136].

Hematological disorders

Mesenteric ischemia can be associated with hypercoagulability states, mainly thrombocytosis, polycythemia, antithrombin III deficiency, antiphospholipid syndrome, proteins C or S deficiencies, 20210A prothrombin gene mutation, and factor V Leiden mutation [137–141]. The diagnosis of hypercoagulability in the presence of mesenteric ischemia is crucial to prevent further episodes by means of anticoagulation.

Drugs

Several drugs may precipitate or promote mesenteric ischemia. Estrogen–progesterone combinations used as contraceptives have been described as precipitating factors for intestinal ischemia [142]. However, the frequency and the severity of the contraceptive-related ischemic events have decreased

over time, probably because of more careful use of these drugs in patients at risk or because of a lower dose of estrogen included in the new generation of contraceptives. If mesenteric ischemia occurs in a young woman without any other risk factors, past or current use of oral contraceptives should be investigated.

During the last decade, an increased frequency of gastrointestinal events associated with cocaine use has been reported, including gastric ulcerations, intestinal ischemia, perforations, and retroperitoneal fibrosis [100]. Similar complications have also been documented in crack users (the free-base form of cocaine) [143]. The mechanism by which cocaine produces ischemia is uncertain, but it is known that it blocks the reuptake of norepinephrine and enhances the flux of calcium across the endothelial cell membrane, two pathways leading vasoconstriction [143,144]. The interval between drug ingestion and onset of symptoms varies from 1 h to 2 days, and abdominal pain, tenderness, and bloody diarrhea are the most common forms of presentation. Surgery is required in most cases to correct perforations or remove necrotic bowel segments.

Vasopressin used as a therapeutic agent for bleeding esophageal varices is associated with significant risk of systemic and regional ischemic events [145]. Indirect signs of transient intestinal ischemia are seen in some patients treated with vasopressin infusion as a consequence of its vasoconstrictor effect in the splanchnic vascular bed. This drug also reduces gastrointestinal oxygen extraction [146].

Ischemic colitis has been described associated with the treatment of irritable bowel syndrome with alosetron, a selective 5-HT3 antagonist [147]. Ischaemic jejunal vasculitis has been observed during treatment with peginterferon alfa-2b and ribavirin for hepatitis C virus [148]. Other drugs with possible effects promoting intestinal ischemia include ergotamine, digitalis, methylsergide, pseudoephedrine, barbiturates, and amphetamines [90].

114 Radiation injury in the gastrointestinal tract

Steven M. Cohn, Stephen J. Bickston

Radiation pathobiology, 2831
Pathology, 2833
Specific organ involvement, 2836

The first reports of radiation-induced injury to the gastrointestinal tract date to the early 20th century shortly after the discovery of X-rays in 1895 [1]. The use of ionizing radiation for therapy of malignancies also dates back to the early 20th century and arose out of the observations of Bergonie and Tribondeau, who suggested that "X-rays are more effective on cells which have a greater reproductive activity; the effectiveness is greater on those cells which have a larger dividing future ahead . . ." [2,3]. They went on to reason that radiation could be effective in destroying tumors while sparing many normal tissues. Although this concept may be somewhat simplistic in today's terms, it led to the expectation that side effects would occur in tissues, such as the gastrointestinal epithelium, that undergo rapid cell turnover.

The use of multimodality therapies that include radiation has become commonplace in treating many malignancies; in fact, about half of patients with cancer receive radiation therapy as a component of their treatment. Modern techniques for tomographic localization and fractionation of radiation therapy have significantly reduced short-term and long-term gastrointestinal morbidity resulting from radiation therapy. Nevertheless, most patients experience gastrointestinal symptoms associated with acute radiation therapy, such as diarrhea, abdominal pain, bloating, tenesmus, and bleeding [4]. Chest pain, dysphagia, and odynophagia may be seen when the radiation fields involve the upper gastrointestinal tract. Generally, the acute side effects of therapy can be treated with antispasmodics, antidiarrheals, and topical anesthetics. As a rule, these symptoms resolve shortly after radiation treatment ends. However, up to one-fourth of patients who receive radiation therapy also develop some form of chronic injury, defined as symptoms presenting more than 3 months after completion of therapy [4]. Symptoms are usually evident within the first 2 years after initiation of therapy; however, some patients do not develop symptoms for years or even decades [4]. Thus, it is likely that gastroenterologists will continue to encounter and treat patients with acute or chronic radiation injury in their practice.

Radiation pathobiology

High-energy photons from gamma irradiation, which is used for most types of radiation therapy, can interact with atoms in a number of ways [5]. The most prominent effect leading to radiation-induced injury is Compton scattering, first described by A.H. Compton in 1922. Compton scattering occurs when a gamma photon collides with an outer orbital electron, loses energy, and is deflected so that the energy lost by the photon is imparted to the electron, which is then ejected from the atom. These ejected Compton electrons subsequently cause many of the biological sequelae of irradiation by secondary ionizations of other atoms or through generation of other highly reactive species, such as free radicals. Such radiochemical interactions can damage a variety of cellular constituents, including DNA, proteins, and lipids. Of these, induction of single- and double-stranded breaks in DNA appears to mediate most of the lethal effects of radiation on cells. Although many cellular pathways for repairing such potentially lethal genetic damage have evolved in humans, failure to repair even a single double-stranded break in DNA may result in the death of that cell.

The amount of radiation-induced damage produced in a tissue or tumor is dependent on the energy of the gamma rays or X-rays, on the absorbed dose of radiation, and on the fractionation schedule of the administered dose of irradiation [3,5,6]. The gray (Gy) has supplanted the rad as the accepted unit of absorbed radiation dose and is defined as 1 joule of energy deposited per kilogram of absorbing material. One gray is a equivalent to a dose of 100 rad. The dose of radiation absorbed by a biological tissue is variable and related to the biochemical properties of the tissue, including tissue oxygenation, the activity of pathways that detoxify reactive

oxygen species or scavenge free radicals, and the position of cells within the cell cycle. Cells in early S phase or those undergoing mitosis appear to be most sensitive. A minority of DNA damage occurs through direct interaction with high-energy Compton electrons. However, these electrons can interact with other molecules present in the cell, including water and molecular oxygen, to generate peroxides, free radicals, and other reactive oxygen intermediates that are highly reactive with DNA and other cellular macromolecules. Unfortunately, malignant cells that are relatively hypoxic within solid tumors may be resistant to the lethal effects of photon irradiation.

Physical characteristics of the patient, previous abdominal surgeries, and concurrent medical illnesses can also influence the amount of radiation-induced damage to the alimentary tract. Predisposing factors for radiation injury have been identified: higher doses of radiation, patients whose intestines are fixed within the exposed region by adhesions from previous surgery, and those with a narrow anteroposterior diameter are at greater risk [7]. Preexisting vascular disease within the radiation field may predispose patients to increased radiation-induced vascular injury and subsequent ischemia (see "Pathology" below). Thus, patients with diabetes, hypertension, and atherosclerotic disease are all more prone to radiation enteritis [8].

Inflammation may also modify the acute response to irradiation through growth factors, cytokines, and other inflammatory mediators produced at sites of tissue injury. For example, fibroblast growth factor-2 (FGF-2), prostaglandin E_2, tumor necrosis factor-α (TNF-α), TGF-β3, interleukin-1 (IL-1), and IL-11 all decrease the sensitivity of tissues to radiation injury, suggesting that these mediators may have an adaptive function in cell survival [9–15]. Interleukin-12 has a mixed effect, protecting bone marrow-derived cells but sensitizing gut epithelial cells to radiation injury [13,16,17]. Activation of nuclear factor kappa B (NFκB), an intracellular regulator of many inflammatory responses driven by bacterial-derived macromolecules, appears to protect selectively the small intestinal epithelium against ionizing radiation-induced damage [18]. A study has suggested that the lumenal microbiota can also exacerbate radiation injury through induction of an epithelial derived protein (Fiaf) that increases sensitivity of endothelial cells and lymphocytes to radiation-induced apoptosis [19]. Thus, the interplay of the lumenal microbial environment with the mucosal immune system is complex and the effects of subsequent inflammatory responses on the biological response to therapeutic irradiation are difficult to predict.

Concurrent pharmacological therapy may also alter the response of both normal and neoplastic tissue to gamma irradiation. Tissue is more susceptible to radiation-induced injury when the radiation is administered together with chemotherapeutic agents or other pharmaceuticals that sensitize the gut. For instance, the combination of gamma irradiation with administration of chemotherapeutic agents that alter cell cycle kinetics or lead to synchronization of the replicating cell populations may potentiate damage to normal tissues or to tumor cells because the degree of radiation-induced damage varies with cell-cycle phase (see above). Therefore, the timing of irradiation in relation to administration of these chemotherapeutic agents is an important factor in determining the relative effects on tumor versus normal tissue. Halopyrimidines, such as fluorouracil, fluorodeoxyuridine, and iododeoxyuridine, may sensitize tumors both by inhibiting effective DNA repair and by increasing the amount of radiation-induced DNA damage [20,21]. Adjuvant therapy combining fluorouracil and radiation therapy for resected gastrointestinal tumors has improved survival in patients with pancreatic, rectal, and esophageal cancers [21–24]. Actinomycin D, doxorubicin, and bleomycin also sensitize cells to radiation-induced DNA damage and cell death.

Drugs with radioprotective activity are under investigation. These compounds have the potential to improve the therapeutic index for radiation therapy. For example, the prostaglandin analogues misoprostol and dimethyl-prostaglandin E_2 both decrease radiation-induced apoptosis in rapidly replicating intestinal epithelial cells and enhance epithelial stem cell survival after irradiation [9,12]. Data for aminosalicylates give mixed results [25].

A number of growth factors and cytokines, including FGF-2, HST-1 (FGF-4), keratinocyte growth factor, transforming growth factor-β3 (TGF-β3), and IL-11, also have radioprotective activity in the intestine if administered before irradiation [11,15,18,26–28]. Free radical scavengers, such as amifostine (WR-2721), have been shown to be radioprotective in both experimental systems and clinical trials [29]. Whether these radioprotective agents will find a role in routine clinical practice remains to be established.

Because DNA damage is thought to be the primary mechanism mediating the lethal effects of radiation [5,6], a number of complex intracellular systems have evolved to repair DNA damage induced by radiation as well as damage induced by chemotherapeutic agents. Some of these proteins are specifically involved in recognition and repair of DNA damage. Other enzymes, such as DNA-dependent protein kinase, are involved in DNA replication and V(D)J recombination during immunoglobulin gene rearrangement in normal lymphocytes. These enzymes also play a central role in rejoining double-stranded DNA breaks induced by radiation injury in epithelial cells in the gastrointestinal mucosa [6,30,31].

The fate of injured cells after irradiation is a complex process. Cells that cannot repair radiation-induced DNA damage adequately will eventually undergo "mitotic cell death" or mutation because of genomic instability as a consequence of the unrepaired DNA strand breaks and other DNA damage [6]. However, in rapidly replicating cell populations, DNA damage induced by relatively small doses of irradiation can also trigger apoptotic cell death, an active, genetically pro-

grammed type of cell death. In both humans and rodents, a low frequency of physiological apoptosis occurs continuously within the lower regions of the crypt epithelium of the normal small intestine and colon, and may be an inherent part of the regulatory mechanism determining stem cell numbers in the normal adult tissue [32,33]. After even relatively low doses (about 1 Gy) of ionizing radiation, many damaged cells within the rapidly dividing crypt epithelium of the small intestine and colon undergo apoptosis [32–34]. The highest rates of radiation-induced apoptosis occur in the lower two-thirds of the crypt, a region containing the epithelial stem cells and the more rapidly replicating progenitor or "transit" cell population; this apoptosis reaches a maximum 6–12 h after irradiation. Many of the remaining cells within the proliferative zone that do not undergo apoptosis arrest at checkpoints in G1 or in late G2 phases of the cell cycle [6,34,35]. These cell-cycle checkpoints are thought to provide time for repair of DNA damage and prevent cells from entering S phase or mitosis, when the presence of even a few double-stranded DNA breaks may result in death of the cell or generation of cells with chromosomal abnormalities.

The tumor suppressor gene, *p53*, plays an important role in recognition of DNA damage and coordinating the subsequent cellular response to radiation injury, leading some investigators to describe *p53* as the "guardian of the genome" [36–38]. It is normally expressed at low levels except during DNA synthesis. Following DNA damage, expression of *p53* is upregulated and the p53 protein is translocated to the nucleus, where it binds to DNA and regulates the transcription of a number of genes, including $p21^{CIP1,WAF1}$, *GADD45*, *MDM2*, and *BAX* [39–41]. These genes are involved in regulating apoptosis or cell-cycle arrest at checkpoints at the G1–S boundary or in G2/M [42–44]. Activation of *p53* occurs rapidly in the intestinal crypt epithelium following even low doses of gamma irradiation (0.5–1 Gy). This activation results in a rapid and sustained increase in the transcription of *BAX*, a proapoptotic member of the *Bcl-2* oncogene family that mediates the apoptotic response. The ultimate fate of a cell with DNA damage also depends on the expression of other counterregulatory genes that affect apoptosis. Expression of these counterregulatory genes varies along different regions of the alimentary tract and may also depend on extracellular signals. For example, antiapoptotic members of the Bcl-2 family, including BCL-2 and BCL-X_L, suppress apoptosis by formation of heterodimers with BAX. *BCL-2* appears to be expressed in the colonic crypts, but not in small intestinal crypt epithelial cells, which explains regional differences in the sensitivity of crypt epithelial cells to radiation-induced apoptosis.

Activation of *p53* in response to DNA damage causes cells to arrest at critical checkpoints [6,36,37,43], a process that is mediated by induction of $p21^{CIP1,WAF1}$, *GADD45*, and other gene products. This arrest allows time for the cell to make a decision as to its fate (repair vs cell death) before committing itself to S phase or mitosis. Entry into S phase with damaged DNA or into mitosis in the presence of single-stranded or double-stranded DNA breaks could lead to daughter cells with unstable chromosomal structure, allowing mutations or chromosomal rearrangements to occur. Other genes, such as the gene responsible for ataxia telangiectasia (*ATM*), are thought to regulate the response to DNA damage upstream of *p53*. Thus, cells from these patients have diminished activation of *p53*, decreased cell cycle arrest at the G1–S cell-cycle checkpoint, an increased sensitivity to ionizing radiation, and increased malignant transformations.

The clonogenic stem cell populations within the intestine and colon appear to be more resistant to radiation-induced cell loss than the more rapidly replicating transit cells. Furthermore, the survival of these clonogenic stem cells may be determined by a mechanism independent of *p53* function [45]. The increased survival and proliferation of the stem cells with radiation-induced DNA damage probably enhances the capacity for restitution of the epithelial function in the short term but also may contribute to the potential for secondary malignancies many years after therapeutic irradiation (see "Pathology" below).

Pathology

The histopathological changes in the alimentary tract follow a predictable time course and may be functionally divided into early and delayed clinical syndromes [46]. The early effects primarily involve the mucosa, which is lined by rapidly proliferating epithelial cells that are sensitive to the acute effects of radiation injury. Clinical symptoms include odynophagia, diarrhea, nausea, vomiting, or gastrointestinal bleeding, depending on the location of the radiation field, the dose of radiation, and the fractionation schedule. The delayed effects are more likely to be chronic diarrhea, fibrosis, ulcer formation, or bleeding and are secondary to damage to the vasculature of the organs involved. Although the histological hallmarks seen in tissue specimens are often characteristic of acute or delayed radiation injury, no histological feature is pathognomonic for radiation-induced damage [46].

The histological and pathological features of acute radiation injury in the human alimentary tract are poorly defined because the acute effects of radiation therapy are generally well tolerated and tissue samples are rarely obtained. Thus, much of what is known about the acute effects of irradiation has been derived from a few studies in humans and more extensive experiments using animal models of radiation injury [46–51]. The earliest recognizable histological features following radiation injury to the gastrointestinal tract occur within hours, and include apoptosis of lamina propria lymphocytes and epithelial cells, the cessation of epithelial cell replication, and damage to vascular endothelial cells. This results in loss of replicating cells in the squamous epithelium

of the esophagus and the columnar epithelial cells in the gastric, small intestinal, and colonic epithelium. Mature, differentiated epithelial cells continue to be lost by extrusion, and in the absence of replacement by replication of the progenitor cells, there is subsequent loss of mucosal function: attenuation and damage to the squamous epithelium in the esophagus; reduced numbers of parietal and chief cells in the gastric epithelium, which will decrease gastric secretion; and progressive loss of the small intestinal villous epithelium, which decreases absorptive surface area, and in some patients leads to transient malabsorption of fats and other macromolecules, or acute diarrhea. In the colon, there are reduced numbers of mitoses and epithelial cell atypia with loss of nuclear polarity in the columnar epithelium lining the crypts. Swelling and loss of goblet cells leads to decreased mucus production. Microabscesses composed of granulocytes and eosinophils may be present. Mucosal and submucosal edema may also be observed in both the small intestine and colon.

An increase in the replicating crypt epithelial cell population in the small intestine and colon, through proliferation of stem cells located near the base of the crypts, is observed beginning about 3 days after low doses of irradiation. This increase in crypt epithelial proliferation can compensate for the initial loss of differentiated epithelial cells [34]. However, the survival of the stem cell population is compromised at higher single doses of gamma irradiation, limiting epithelium repair. Fractionated irradiation protocols enable higher total doses to be administered by allowing repair and recovery of replicating epithelial cells and stem cells between fractions [6]. If damage to the stem cell population is severe after high doses of radiation, then epithelial integrity and barrier function are lost, leading to translocation of lumenal bacteria and eventual death from loss of fluids and serum proteins, hemorrhage, and sepsis 7–10 days after irradiation. Although rarely, if ever, seen in therapeutic applications of gamma irradiation, death from this syndrome has been observed after exposure of individuals to a single whole-body dose of 10–20 Gy as a consequence of radiation accidents or atomic warfare [46,52].

Liver biopsies are rarely obtained from patients with acute hepatic injury secondary to therapeutic irradiation for solid neoplasms. However, hepatic venoocclusive disease can be seen in bone marrow transplant recipients after cytoreductive therapy with combined chemotherapy and irradiation (see "Liver" below) [53–55], usually occurring before day 30 posttransplantation [54]. Hepatic histology shows vascular congestion (which is most prominent in centrilobular areas), subendothelial edema, endothelial destruction, sinusoidal dilation, and centrizonal hepatocyte necrosis with attenuation of the hepatocellular cords [53]. Deposition of clotting factors in the walls of hepatic venules suggests that microthrombus formation may be the primary pathogenic mechanism [56]. Occlusion of central veins by thrombus is sometimes observed. As the disease progresses, deposition of collagen in hepatic sinusoids, fibrosis of hepatic venules, and sclerosis of venular walls may be seen [53,54]. One proposed mechanism for the increased sensitivity to combined chemotherapy and irradiation in this setting involves depletion of glutathione stores in sinusoidal endothelial cells and hepatocytes [54,57–59].

The delayed effects of radiation injury most commonly occur from 6 months to 5 years after radiation therapy; however, symptoms may appear as early as 3 months or as late as 30 years after radiotherapy in a small number of patients [46,60,61]. Vascular injury and regeneration are characteristic of chronic radiation injury and are often observed in pathological specimens [46]. These findings are sometimes focal and may be missed unless multiple levels through the specimen are examined. Myointimal proliferation in medium-sized muscular arteries may lead to chronic ischemic injury because of the marked decrease in the lumenal diameter of these vessels (Fig. 114.1). Ulceration of the overlying mucosa occurs in areas of localized ischemia (Fig. 114.2). Thrombosis is sometimes seen associated with these lesions and is more frequent in vessels with fibrinoid necrosis adjacent to deep ulcerations. The presence of lipophages or foamy macrophages in the intima of small arterioles is also a characteristic finding of delayed radiation injury, although this lesion may also result from other etiologies (Fig. 114.3). Telangiectatic vessels are frequently found in the submucosa and probably account for the diffuse bleeding sometimes observed in radiation enteritis (Fig. 114.4). Sclerosis or medial fibrosis indicative of healing vasculitic lesions may also be observed.

Changes in the submucosa are frequently observed in delayed radiation injury and are thought to be secondary to the chronic vascular damage described earlier [46]. Increased collagen deposition and fibrosis are often observed with

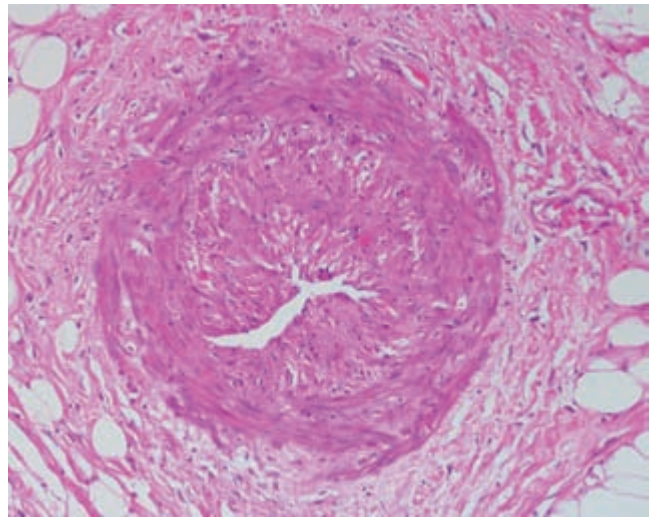

Figure 114.1 Myointimal proliferation nearly occludes the lumen of a moderate-sized mesenteric artery. This process usually occurs over several years after radiation injury and may lead to chronic ischemic injury to the intestine. (Original magnification × 100.) Courtesy of Dr Christopher Moskaluk.

(b)

Figure 114.2 Radiation-induced ulceration in the colon. **(a)** Gross appearance of a well-demarcated ulcer present in the rectum years after external radiation for an adjacent neoplasm. **(b)** Histological appearance with chronic ulceration, mucosal necrosis (solid arrow), and dense submucosal fibrosis (open arrow) similar to that seen in ischemic injury. The lesion is notable for the absence of a prominent inflammatory infiltrate. (Original magnification × 20.) Courtesy of Dr Christopher Moskaluk.

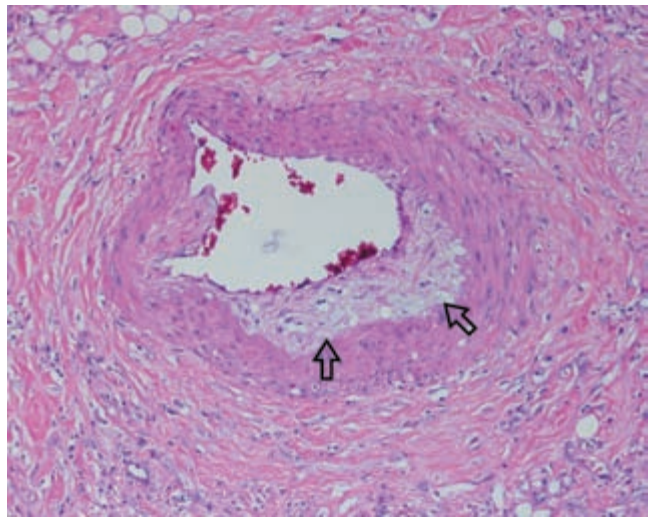

Figure 114.3 Intimal lipophage accumulation in intestinal arteriole after irradiation (arrows). These foam cells may be seen in the intima of small arteries and arterioles of the intestine several years after irradiation and may lead to lumenal narrowing of these vessels. (H & E stain; original magnification × 100.) Courtesy of Dr Christopher Moskaluk.

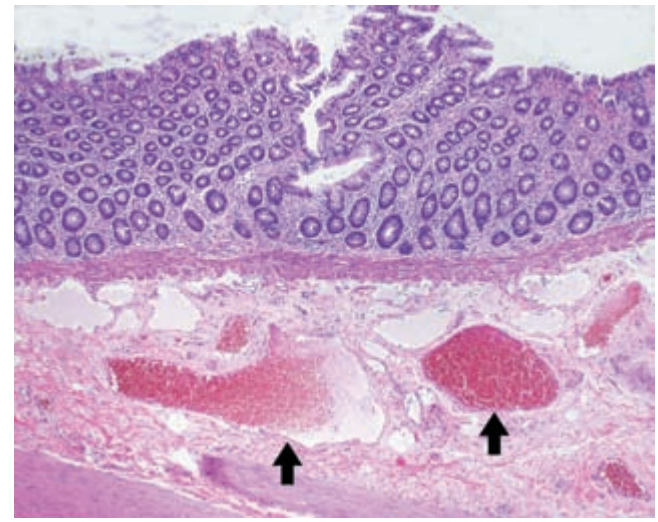

Figure 114.4 Submucosal telangiectasias (arrows) are seen in delayed radiation injury. Dilated venules and lymphatic channels are seen in the submucosa underlying relatively normal-appearing colonic epithelium. (H & E stain; original magnification × 40.) Courtesy of Dr Christopher Moskaluk.

minimal cellular inflammatory infiltrate. The fibrosis may be confined to the submucosa or may extend through the muscularis propria and account for the thickening or strictures that may occur within any irradiated region of the alimentary tract. Atypical fibroblasts with bizarre nuclei are sometimes found in areas of fibrosis (Fig. 114.5). The appearance of these fibrotic lesions in the small intestine may resemble that of Crohn's disease, both on gross inspection and on radiological examination, although fistulae and creeping fat are rarely observed.

Mucosal alterations in the small intestine include villous atrophy, flattening of epithelial cells, and fibrosis of the lamina propria [46]. These findings are often observed in patients with or without symptomatic radiation enteritis and may result in malabsorption when these changes are extensive. Superficial erosions and mucosal ulceration are common, sometimes penetrating deep into the submucosa and muscularis propria and occasionally perforating into the peritoneal cavity. Chronic changes in the mucosa of the colon are similar to those seen in the small intestine.

Colitis cystica profunda is a rare delayed complication of radiation injury [46]. The importance of this lesion is in distinguishing it from invasive adenocarcinoma. Its symptoms are similar to colitis cystica profunda secondary to other

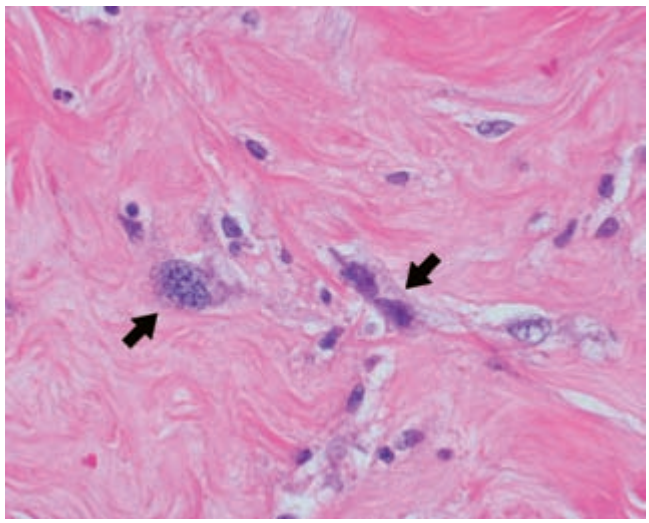

Figure 114.5 Atypical fibroblasts in radiation injury (arrows). Bizarre-appearing, pyknotic fibroblasts are frequently seen in the delayed phase of radiation injury in the alimentary tract. Although these atypical fibroblasts are frequently observed, their presence is not specific for radiation injury. (H & E stain; original magnification × 400.) Courtesy of Dr Christopher Moskaluk.

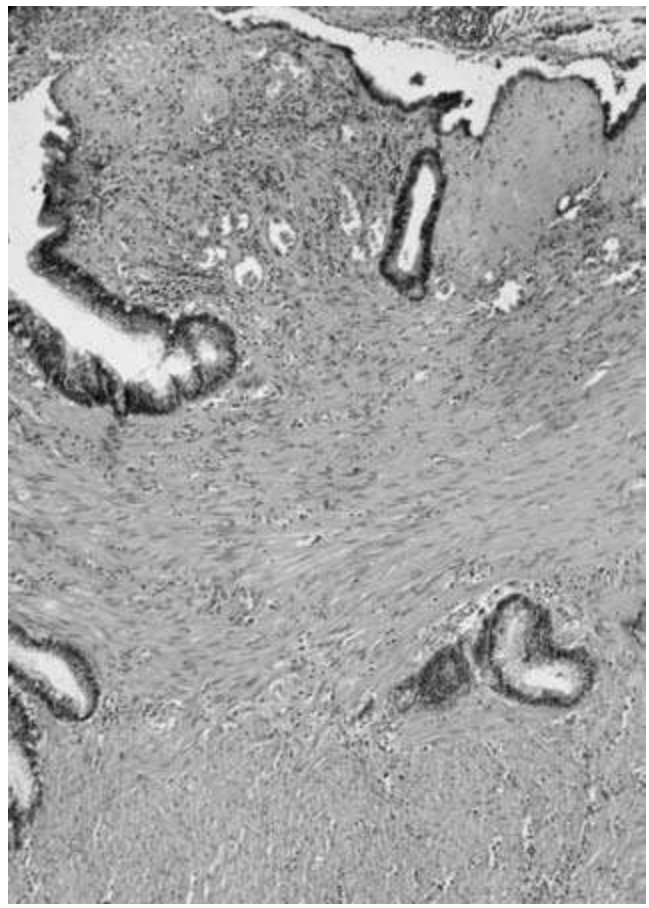

Figure 114.6 Colitis cystica profunda. Colonic glands are seen penetrating the muscularis mucosa into the submucosa and muscularis propria. This lesion is distinguishable from carcinoma by the normal cytological characteristics of the epithelium lining the penetrating glands. (Original magnification × 40.) Courtesy of Dr Christopher Moskaluk.

etiologies. However, its histological appearance may differ from colitis cystica profunda of other causes in that colonic glands extend deep into the submucosa and sometimes penetrate into the muscularis propria [46,61] (Fig. 114.6). The presence of glands lined by normal epithelium usually makes it easy to distinguish colitis cystica profunda from adenocarcinoma in pathological specimens.

The development of secondary epithelial or stromal malignancies is also a potential complication of radiation therapy [46,62–64]. However, the number of documented cases is relatively small, and most of these cases generally have occurred after lower doses of gamma irradiation (< 10 Gy). For example, the frequency of colon cancer is increased in atom bomb survivors 30 years after their exposure (relative risk of 2.4 compared with a matched control population), and an increased risk for colon cancer has been documented in a cohort of women irradiated with relatively low doses (6.25–10.5 Gy) for benign uterine bleeding [46,65–67]. Thus, whereas exposure of the colon to radiation may increase the risk for developing a secondary malignancy, the interval between therapeutic irradiation and development of secondary malignancies may be relatively long [46,65,66].

Specific organ involvement

Esophagus

Radiation therapy for thoracic tumors and hematological malignancies can result in both acute and long-term esophageal injury. The field required to treat thoracic, hematological, and some pharyngeal malignancies frequently (25% in one series [68]) exposes the esophagus to sufficient radiation to produce pathological changes, but clinical syndromes generally require doses of 60 Gy [69]. This threshold may be lower in patients whose tissue is sensitized by chemotherapeutic agents. Three major syndromes related to esophageal irradiation have been described:

- acute inflammation with odynophagia or dysphagia
- fibrosis with stricture and dysphagia
- fistula formation with aspiration into the trachea, or lethal bleeding from the aorta.

During the acute phase of radiotherapy, symptoms are usually related to mucosal injury and the inflammatory response. Patients typically present with mucositis, which causes odynophagia or dysphagia beginning after the second week of treatment. Frank bleeding is unusual [70]. Acute dysphagia may also reflect a motor disturbance. A pattern

of ineffective peristalsis at and distal to the radiation field may occur 4–8 weeks after initiation of radiation therapy.

The diagnosis of acute-phase radiation-induced esophagitis is usually evident from the patient's history and symptoms, although other conditions need to be excluded. Acute infection must be considered, particularly for those whose immune systems are impaired by the underlying disease or its treatment. Pill ulceration and reflux esophagitis are also in the differential diagnosis. Endoscopic evaluation is the test of choice, allowing characterization of the lesion and tissue sampling where appropriate. Barium swallow may offer some information in unusual circumstances when endoscopy is not clinically feasible, but these radiological studies are normal or non-diagnostic most of the time [71].

Prevention of acute radiation injury should be considered the first line of therapy. Limiting the total radiation exposure and careful selection of the radiation field are important preventive measures. Pharmacotherapy and dietary modifications have also been advocated [72]. If symptoms of odynophagia and dysphagia are sufficiently severe, temporary interruption of radiation therapy for several days to 1 week or enteral nutritional support may be necessary. Pharmacological therapy is often administered on an empirical basis and is directed at controlling symptoms; for example, topical lidocaine is generally given for odynophagia and may be compounded into a variety of "stomatitis cocktails" along with antacids, antihistamines (diphenhydramine), or antifungal (nystatin) ingredients. Antisecretory therapy is frequently used but, like these cocktails, suffers from the same lack of substantiating data [70,73].

Patients with strictures or fistulae typically present some time after radiation therapy has been completed (i.e., 6 months or later after initiation of treatment). Diagnosis and therapy of strictures and fistulae typically require a combination of radiological and endoscopic techniques. Fluoroscopic evaluation is needed to determine the site, whereas either fluoroscopic or combined endoscopic and fluoroscopic methods can be used for subsequent dilation or stent placement. The initial approach to treatment of late esophageal stenosis is careful dilation. Balloon dilation devices may be preferable to rigid dilators because they allow isolated radial expansion of the stricture with minimal axial pressure. The complication rate for the dilation of strictures induced by radiation is no greater than that for dilation of strictures with other etiologies [74]. However, stent migration of conventional plastic endoprostheses was substantially higher in the radiation group (21%) than in the nonradiation group (3%) [74].

The introduction of the self-expanding metallic stent (SEMS) has substantially changed the therapy of esophageal cancer and radiation-induced stenosis and fistula formation. Typically, a SEMS is a cylinder of wiremesh or a coil with spring memory for a particular configuration. The first was introduced in 1983 [75]; coated and uncoated varieties are available, and a variety of materials, attachments, and delivery devices are under investigation. The compromised circulation associated with radiation injury can be further worsened by the radial forces from these stents. This may account for the increased perforation rates seen in radiation strictures compared with esophageal cancers stented before or without associated radiotherapy (36% vs 2.5%), and may contribute to the increased mortality (22% vs 0%) seen in the same series [76].

The coated stent is useful for patients suffering tracheoesophageal fistulae. However, enteral nutritional support may be necessary in patients with severe acute symptoms or with difficult-to-manage chronic strictures or fistulae. In patients with uncoated SEMS, later placement of a percutaneous endoscopic gastrostomy is generally feasible because the wiremesh typically embeds securely in the esophagus. Coated SEMS may not be amenable to the same wait-and-see approach.

Stomach

Gastric damage following radiation therapy is rare, but injury can occur when the stomach lies within the radiation field of an adjacent extragastric tumor [46,77]. Gastric irradiation was used in the past as therapy for peptic ulcer disease because modest doses of radiation could significantly deplete the parietal and chief cell populations, inducing gastric atrophy [46,78,79]. In the era before effective medical therapy was available, this approach was taken for patients with refractory ulcers. A total dose of 1600–1700 cGy given in 10 divided doses resulted in atrophic gastritis with associated decreases in acid and pepsin production. However, in most, acid production returned to normal basal levels within 2 years [69,79,80].

Most patients receiving gastric irradiation are asymptomatic, although hemorrhage due to multiple gastric erosions has been reported as an early complication [46]. Gastric injury from greater exposures can present more dramatically, with stenosis, fistulae, and perforation [81]. Strictures are more common in the antrum and cardia than in the body or fundus. Delayed ulceration may also occur in this setting and is difficult to distinguish from peptic ulcer disease. Radiation-induced ulcers heal poorly because of obliterative arteriolitis within the ulcer bed. Ulceration and gastric strictures usually occur at doses exceeding 4500–5000 cGy, and about half of patients experience clinically significant gastric injury at doses greater than 5500 cGy [46].

The diagnosis is usually made on the basis of clinical presentation and patient history. Endoscopy may reveal an irregular thickened mucosa similar to the appearance of a gastric neoplasm or an appearance indistinguishable from peptic ulcer disease. Fluorographic upper gastrointestinal studies or computed tomography (CT) may be useful in demonstrating the presence of strictures. However, these studies may only show thickening of the gastric wall with an appearance similar to that seen in gastric malignancies. Data are lacking to guide therapy for this uncommon condition. In

patients exposed to less than 20 Gy, simple passage of time may suffice.

Small bowel

The small intestine is particularly susceptible to radiation injury. Significant epithelial cell death may be observed as early as 4–6 h after irradiation, even with the relatively small 1–2-Gy fractions commonly used in some radiation therapy regimens. Radiation injury to the small intestine most often occurs in the clinical setting of radiotherapy for gynecological, urological, rectal, or retroperitoneal malignancies. The degree of injury appears proportional to the radiation dosage delivered to the segment of small intestine lying within the radiation field [82,83]. The relatively fixed position of the duodenum, distal ileum, and cecum within the abdominal cavity make these regions particularly vulnerable to radiation-induced injury [6,46]. Ninety percent of patients have significant lesions at doses of more than 3000 cGy, compared with 40% at 10–30 Gy, and 20% at less than 10 Gy [84]. Previous abdominal surgery that may fix loops of bowel in place is another important risk factor [7,85,86].

Radiation injury to the small bowel can also be divided into acute injury and a chronic syndrome. Nausea, diarrhea, and abdominal discomfort are cardinal manifestations of acute injury. Although many of these symptoms are attributable to epithelial cell death and subsequent loss of mucosal function, symptoms such as nausea and vomiting occurring within a few hours of irradiation may be mediated by the production of inflammatory cytokines. Fortunately, the epithelium regenerates, and function is restored within 2 weeks, with corresponding resolution of the acute symptoms [84]. This acute syndrome may foreshadow the occurrence of chronic radiation enteritis, at least in children [87]. It is not clear whether this holds for adults, of whom about 5% develop chronic enteritis after exposure [47].

Symptoms of chronic radiation enteritis typically occur 1–2 years after exposure, but presentation 20 years after radiotherapy has been described [88–90]. The central mechanism of injury is vascular damage with progressive localized ischemia (see "Pathology" above). This leads to ulceration of the mucosa, fibrosis with stricturing, and, less frequently, fistula formation or even perforation. Radiographs of the small intestine or colon may reveal evidence of single or multiple strictures or mucosal ulceration, a pattern similar to that observed in Crohn's disease [4,91] (Fig. 114.7). The condition may also be detected with wireless capsule endoscopy, but caution is needed because of the risk of lodging the capsule in a stricture [92]. The risk of capsule lodging may be lessened by employing a capsule designed to check patency [93]. Life expectancy is poorer in patients whose enteritis is complicated by fistulae rather than bleeding [94]. Loose stools are the most common symptom and may be caused by a number of abnormalities: bile salt malabsorption in 65%, bacterial overgrowth in 45%, severe fat malabsorption in 40%, rapid intestinal transit in 35%, and lactase deficiency from villous blunting with consequent lactose intolerance in up to 20% [8,95].

Figure 114.7 Barium small bowel radiograph showing an ileal stricture (arrowheads) in a patient with diarrhea several years after radiation therapy for cervical cancer. Courtesy of Dr Hubert Schaffer.

Prostheses or mesh material may be used as a preventive measure to displace or protect the small intestine during radiation therapy [96–98]. Acute radiation injury is treated supportively and with dose adjustment [99]. Antispasmodics and medications that decrease bowel motility must be used cautiously given that many of these patients are at risk for outright obstruction from underlying tumor or surgical adhesions. Perforation may have a bland presentation in this setting; typical signs of peritonitis, such as fever and severe abdominal pain, may be absent, and adhesions may wall off free air [100,101]. The data are contradictory for the use of aminosalicylates as a preventative measure. In a prospective double-blind study of sulfasalazine (2 g/day) given to 87 patients undergoing radiation, diarrhea occurred in 55% of the sulfasalazine and 86% of the placebo groups, respectively [102]. However, in another trial, mesalazine at 4 g/day was not beneficial [103].

The treatment of chronic radiation enteritis requires patience and long-term pragmatism. Once symptomatic, this condition is persistent at best and worsens in many, even after surgical resection of diseased intestine [4]. Cholestyramine is often a good choice as both a nonspecific antidiarrheal agent and for targeted therapy of bile salt malabsorption [95]. Other antidiarrheals, such as loperamide and diphenoxylate, may also be useful. A peripheral opiate antagonist, loperamide-*N*-oxide, was used successfully in a series of 18 patients with radiation enteritis [104]. Treatment was associated with fewer bowel movements and improved bile salt absorption. Bacterial overgrowth can be treated with antibiotics, such as amoxicillin clavulanate, ciprofloxacin, or tetracycline. The immunomodulatory effects of these agents may

play a role along with their antimicrobial action, but this has not been studied in radiation enteritis.

Specialized enteral formulas, such as elemental diets, are available for treating moderate malnutrition. However, they are costly, and their superiority to standard formulas has not been established [105]. Total parenteral nutrition may be required for severe malnutrition or when enteral feeding is not feasible. Support with total parenteral nutrition allows correction of malnutrition, but recurrent symptoms are a problem in up to 47% of patients [106]. Methylprednisolone may provide additional benefit, but the long-term role of this relatively toxic agent is unknown [107].

It is prudent to avoid surgery whenever possible in chronic radiation enteritis, given the likelihood of intraoperative and postoperative difficulties. Surgery is required in about one-third of patients for management of strictures causing small bowel obstruction or for perforation. Complications are common (30%), and the mortality rate can be particularly high (> 5%) for emergency operations [108]. Outright resection of the involved small bowel segment is considered preferable to bypass because of the high incidence of complications, such as perforation, bacterial overgrowth, and fistulization [109].

Colon and rectum

Radiation proctosigmoiditis is among the most common complications of radiation injury. Many gynecological and urological tumors are treated with radiation, and the relatively fixed location of the rectum makes it more susceptible to radiation injury than the rest of the colon [110]. There is a clear dose-related incidence of injury, with acute symptoms common at doses of 30–40 Gy and with more than one-third of patients suffering injury at 60 Gy [111]. Complication rates from patient reports, rather than record abstraction, are higher still [112–115]. When a series of patients undergoing 6 weeks of radiotherapy for nongastrointestinal pelvic tumors was studied at 2-week intervals using sigmoidoscopy, biopsies, and symptom scores, histological and endoscopic abnormalities were both most pronounced after 2 weeks of therapy and improved subsequently. However, symptomatic complaints climbed consistently to the end of the 6-week observation period [116]. One-third to one-half of patients suffer acute injury with diarrhea and tenesmus during the first months of or after therapy. As a rule, these symptoms resolve over the following 6 months, but about 15% of patients continue to suffer chronic proctitis, manifested by rectal pain, diarrhea, and bleeding [114]. The degree of bleeding has some prognostic value: those patients who do not require transfusion have a high rate of spontaneous remission (70%), low rate of surgery (5%), and low mortality rate (25%); and patients who require blood transfusions or who suffer significant bowel disturbance have a low rate of spontaneous remission (< 20%), often require surgery (50%), and have substantial mortality (60%) [117].

Many medical approaches have been tried for treatment of patients with acute or chronic radiation injury involving the colon and rectum. Most attention has been paid to the unfortunate 15% of patients who suffer from chronic radiation proctitis. Unfortunately, no therapy stands out as clearly superior, and the risks of each must be weighed against possible benefits. Oral aminosalicylic acid preparations by themselves do not appear effective, although they may help if combined with steroid treatment [118]. Sucralfate enemas by themselves appear effective and well tolerated [119]. Oral sucralfate was beneficial in a series of three patients, but a larger series is needed to evaluate the oral approach [120]. Sucralfate prophylactically administered orally or rectally has not been shown to prevent radiation injury [121,122]. Short-chain fatty acids are nutrients that promote colonocyte survival and proliferation and have been advocated to accelerate healing in radiation proctitis. In one double-blind study, placebo-treated patients ultimately reached the same level of recovery at 6 months [123]. A crossover study of 20 patients showed encouraging results, but the logistics of drug preparation and the odor of short-chain fatty acids present obstacles to this therapy [124]. The potential of antioxidant therapy has also been investigated: vitamin E (400 IU three times daily) and vitamin C (500 mg three times daily) were helpful in an open-label series of 20 patients [125]. The application of formalin has been used to treat refractory bleeding from radiation proctitis through a presumed mechanism of obliteration of the telangiectatic vessels through coagulative necrosis. In one series, 50 mL of 4% formalin solution was introduced into patients under sedation and kept in contact with the mucosa for 30 s and then cleared away using saline irrigation. Five to six aliquots were used in each session. However, complications were often encountered [126]. In another series of five patients (one treated with topical application of formalin-soaked gauze), severe pain occurred in one patient and another experienced acute colitis requiring hydration and antibiotics. In another prospective study examining 11 patients treated with four 20-mL aliquots and a total of 15 minutes contact time, all patients had decreased bleeding without reported complications [127]. There is anecdotal information on outpatient instillation of dilute formalin solution using a lubricated slip-tip syringe, followed by prompt evacuation into a bedpan. Hyperbaric oxygen has been used successfully to improve the healing of ulcers in radiation proctitis [128,129].

Surgical and endoscopic treatments may be tried when bleeding from telangiectasia is the predominant manifestation of radiation injury (Fig. 114.8). It is critical to weigh potential benefit against risk in this setting. Patients who do not require transfusion generally do not require an interventional approach. Laser therapy can be associated with nonhealing ulcers and may aggravate bleeding or cause outright ulceration. Argon plasma coagulation is designed to create a more controlled level of treatment-induced injury and is

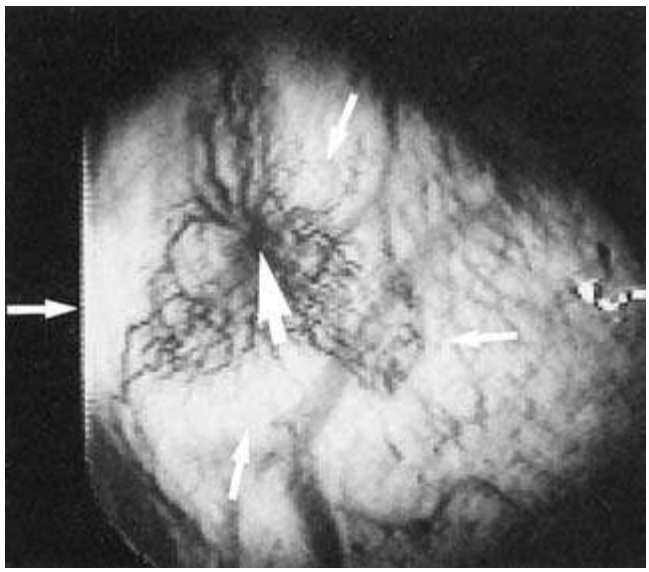

Figure 114.8 Endoscopic appearance of telangiectasia (small arrows) with prominent central arteriole (large arrow) and surrounding pallor in a patient with radiation proctitis.

used to obliterate natural gastrointestinal telangiectasias. Its introduction as an endoscopic treatment led to some enthusiasm about its use in radiation-related bleeding. Compared with treatment of classic telangiectasias from other causes, argon plasma coagulation of telangiectasias associated with radiation injury appears effective on the evidence of several small series [130–133]. Less appears to be more, as higher wattage can be associated with greater complications [134]. Settings of 25–40 W appear to work well [135,136].

Individual episodes of bowel obstruction may be treated conservatively with bowel rest, intravenous fluids, and nasogastric decompression, but recurrent obstruction or an unresponsive episode may require surgery. Surgical intervention for stricture generally consists of resection of the diseased segment, with primary anastomosis. Outcome is best if sufficient resection is performed to ensure that one margin is free from radiation injury [4,137].

Liver

Older administration techniques made liver injury common when therapeutic radiation was directed at tumors within the hepatic parenchyma. The therapeutic index using these older techniques was unfavorable, with doses of 3000–3500 cGy offering consistent injury but inadequate therapeutic effect. Thus, hepatic irradiation waned in popularity until more modern technology, such as nonaxial planes of administration and sophisticated modeling, made it possible to deliver higher doses safely [138].

Hepatic injury following irradiation typically manifests about 4–8 weeks after exposure, but may occur as early as 2 weeks or as late as 7 months. In reports from the 1960s, more than one-fourth of patients with radiation hepatitis had a clinical presentation consistent with Budd–Chiari syndrome or obstruction of suprahepatic veins [139,140]. Nonspecific symptoms, such as malaise, fatigue, and weight gain, are common. Ascites is often present but may be below the threshold for bedside detection. Right upper quadrant pain is also common, but jaundice is not, in keeping with the characteristic laboratory findings in which alkaline phosphatase levels are elevated with minimal increases in bilirubin and mild elevation of transaminases [141,142]. The acute illness is generally well tolerated and usually resolves with supportive care, but development of chronic radiation-induced hepatitis has also been described [143]. Computed tomography findings may be helpful. In one series, 23 of 31 patients (74%) showed a low-attenuation area adjacent to the hepatic tumor on tomographic scans of the targeted radiation field. A sharp, straight interface was rarely seen at the treatment margin. These findings were maximal 2–3 months after completion of therapy and persisted for up to 3 months. Atrophy in the treated segment or lobe and hypertrophy of the untreated liver were seen in several patients [144]. With proton-beam irradiation, abnormalities noted on CT scans may persist as long as 42 months [145]. Given the setting and frequency with which combined modalities of treatment are used, the differential diagnosis for this condition must always include metastatic disease and drug toxicity.

Liver injury is a particular concern with bone marrow transplantation, in which the combination of total-body irradiation and high-dose chemotherapy for initial cytoreductive therapy is commonly used. Venoocclusive disease, presenting with weight gain (fluid retention), jaundice, and tender hepatomegaly, is common, occurring in 10%–60% of patients within several weeks after transplantation [54,146,147]. Weight gain and increasing liver size with tenderness may herald the onset of venoocclusive disease and usually precede the development of hyperbilirubinemia [54]. Serum aminotransferases may also be elevated. Mortality rates from venoocclusive disease in this setting range from 0% to 67% [54]. Supportive treatment with diuretics and careful fluid and electrolyte management are usually effective in mild to moderately severe venoocclusive disease. Treatment of severe cases of venoocclusive disease has been less successful.

Chemotherapeutic regimens that potentiate hepatic injury when combined with therapeutic irradiation include mitomycin C, MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone), CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), CCNU [2-chloroethyl-3-cyclohexyl-1-nitrosurea (lomustine)], and pro-MACE (prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide) [148,149]. Injury from combined therapy is clearly more severe than that seen from radiation alone and carries an overall mortality rate of 30%–50%.

Treatment of patients with isolated radiation injury to the liver is generally supportive. Salt restriction and diuretics are often helpful. Improvement over months is the rule, with

a mortality rate of less than 20%, although those patients who become jaundiced may have a worse course [139]. With combined injury the treatment is similar, but more aggressive therapy may be required.

CAM use in liver disease, 2844
CAM use in pancreatic disease, 2848
CAM use in peptic ulcer and nonulcer dyspepsia, 2849
CAM use in irritable bowel syndrome, 2850
CAM use in inflammatory bowel disease, 2851
CAM use in diarrheal states, 2853
Safety issues, 2854
Conclusion, 2856
Future directions, 2856

One of the recent trends in health care has been the marked growth in the use of complementary and alternative medicine (CAM). Two widely used definitions of CAM are "those health care and medical practices that are not currently an integral part of conventional (Western) medicine" and "those interventions neither taught widely at U.S. medical schools nor generally available in U.S. hospitals." During the 1990s, the federal government created the National Center for Complementary and Alternative Medicine (NCCAM), as well as the Office of Dietary Supplements. Moreover, versions of *Physicians' Desk Reference* were created and are now updated for both herbal therapies and dietary supplements. The NCCAM has grouped CAM into five major areas. The greatest proportion of human as well as experimental animal and in vitro research relating CAM to gastrointestinal (GI) diseases has evaluated biologically based therapies (the major focus of this chapter). Other forms of CAM include manipulative and body-based methods, energy therapies, mind–body interventions, and alternative medical systems (Table 115. 1).

The increasing interest in CAM was highlighted in studies by Eisenberg and colleagues, demonstrating a high prevalence of CAM use and a large sum of out-of-pocket dollars spent on CAM in the United States [1,2]. Indeed, in 1997, approximately 15 million adults took prescription medicines in conjunction with herbal remedies or high-dose vitamins, and total out-of-pocket costs for CAM were estimated to be at least $27 billion. A 2001 survey found that approximately half of American adults were taking nonprescription dietary or mineral supplements [3]. Patients reported equal confidence in their CAM providers and their traditional medical doctors [2]. Of great importance, almost 40% of patients did not disclose their CAM use to their traditional physicians. In spite of this high use and cost of CAM, there are few data evaluating/supporting its cost-effectiveness [4].

CAM users tend to be highly educated, are often white (non-Hispanic), and frequently use CAM therapy for chronic diseases. Use of CAM in chronic illness may result from frustration with the lack of efficacy of conventional therapy and the fact that CAM allows patients some control over their therapy. Thus, it should not be surprising that CAM is frequently used by patients with chronic GI diseases. For example, a recent British survey found that patients with inflammatory bowel disease used CAM as often as those with functional GI disorders; both groups used CAM with greater frequency than the general population [5].

In spite of important data generated on CAM over the past 10–15 years, students in most traditional Western medicine training programs continue to receive limited education about CAM therapies, and therefore may be reluctant to use them. However, recent studies suggest that practitioners are beginning to recognize gaps in effectiveness of conventional therapies and may be more willing to accept CAM treatments for patients with chronic complaints [6]. Because of all these factors, it is important that health-care providers be knowledgeable about CAM, including both potential benefits and side effects. This chapter reviews CAM use and its role in major GI disease processes.

CAM use in liver disease

Use of CAM in liver disease appears to parallel overall widespread CAM use in the United States [7]. We will review the use of milk thistle (silymarin), glutathione prodrugs, *S*-adenosylmethionine (SAM), betaine, vitamin E, zinc, lecithin, glycyrrhizin, and herbals in liver disease.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Table 115. 1 Types and examples of complementary and alternative medicine

Type of CAM	Examples
Biologically based therapies	Herbal therapies Special diets to promote health Orthomolecular therapies (e.g., megavitamins) Biological therapies (e.g., shark cartilage)
Alternative medical systems	Oriental medicine Maintaining proper balance of Qi Traditional Indian medicine, Ayurveda Homeopathy (dilute treatments more potent)
Mind–body interventions	Meditation Prayer Mental healing Art, dance, and music therapy
Manipulative and body-based methods	Osteopathy Massage therapy Chiropractic
Energy therapies	Qigong Touch therapy to maintain body's energies and balance Bioelectromagnetically based therapies

CAM, complementary and alternative medicine.

Silymarin (milk thistle)

Silymarin is the active ingredient extracted from *Silybum marianum* (milk thistle). The plant is a member of the daisy family, and the leaves have prominent white "milky" veins [8]. This agent protects animals from multiple types of experimental liver injury induced by carbon tetrachloride, acetaminophen, iron overload, bile duct obstruction, alcohol, and, very importantly, mushroom poisoning [8–10]. Its hepatoprotective effects are highlighted by its use in the treatment of *Amanita* mushroom poisoning, with studies in several animal species documenting the efficacy of this agent both in pretreatment phases and following mushroom ingestion [8,10]. Moreover, cases have been reported in which positive results were achieved in patients up to 3 days after accidental ingestion.

In the United States, silymarin is probably the most widely used form of CAM in the treatment of liver disease. It has antioxidant activities, protects against lipid peroxidation, beneficially modulates cytokines, has antifibrotic effects, and promotes liver regeneration [8,9]. Large controlled trials of silymarin have been performed in Europe, with variable results. Ferenci and colleagues [11] evaluated 170 patients with cirrhosis in a treatment program (140 mg three times daily) that had a mean duration of 41 months. They observed a positive beneficial effect, especially in patients with alcoholic cirrhosis and in those with milder disease (Child class A). On the other hand, a study by Pares and colleagues [12] found no beneficial effects (150 mg of silymarin three times daily) in a study of 200 patients with alcoholic cirrhosis, some of whom also had hepatitis C. A recent Cochrane metaanalysis of 915 patients found modest improvement in some liver tests, but no improvements in liver-related mortality in high-quality studies [13]. In spite of these issues, silymarin is likely to remain one of the most popular forms of CAM therapy for liver disease because it has a good safety profile and has been extensively investigated in multiple forms of experimental liver injury in animals. Results of recently initiated National Institutes of Health (NIH)-funded randomized trials of Silymarin are eagerly awaited.

Glutathione and glutathione prodrugs

Glutathione is a tripeptide that is synthesized from glutamate, cysteine, and glycine. Glutathione, in its reduced form, is the main nonprotein thiol in cells and has an important role in the detoxification of electrophils and protection against reactive oxygen toxicity [14]. Glutathione cannot be taken up by hepatocytes, but a number of pharmacological agents have been devised to enhance intracellular pools. The most widely used include *N*-acetylcysteine (NAC) and 2-oxothiazolidine-4-carboxylic acid (OTZ), with NAC available as a supplement [14].

Glutathione prodrugs have been used extensively in virtually every known experimental model of hepatotoxicity with beneficial results [14]. The glutathione prodrug NAC (given

orally and now available intravenously) is the standard therapy for acetaminophen toxicity in humans [15]. Maintaining adequate hepatocyte glutathione levels has been documented to prevent acetaminophen liver injury. However, information on glutathione prodrugs in prospective randomized studies in other forms of liver disease is very limited. A recent phase I clinical trial of antioxidants, including oral and i.v. glutathione, showed improvement in liver enzymes and quality of life in hepatitis C virus (HCV) patients, but this was a nonrandomized study using multiple antioxidants [16].

Glutathione prodrugs can not only directly affect the hepatocyte, they can decrease proinflammatory cytokine production also, presumably through inhibition of the oxidative stress–sensitive transcription factor nuclear factor-κB (NF-κB) in Kupffer cells/macrophages [17]. For example, Pena and colleagues [18]. demonstrated that the glutathione prodrug procysteine increased whole-blood glutathione and inhibited monocyte tumor necrosis factor (TNF) and interleukin 8 (IL-8) production when given intravenously to patients with stable cirrhosis. Similarly, procysteine was shown to protect against alcohol-induced liver injury in the intragastric ethanol feeding model [19]. Thus, glutathione prodrugs can, in theory, decrease oxidative stress in hepatocytes and attenuate proinflammatory cytokine production in Kupffer cells to inhibit hepatotoxicity.

S-Adenosylmethionine

SAM is an obligatory intermediate in the conversion of methionine to cysteine in the hepatic trans-sulfuration pathway (Fig. 115.1). The conversion of methionine to SAM involves transfer of the adenosyl moiety of adenosine triphosphate (ATP) to the sulfur atom of methionine and is catalyzed by methionine adenosyltransferase (MAT). SAM is a precursor for the synthesis of polyamines, choline, and glutathione, and is also the major methylating agent for a vast number of molecules via specific methyltransferases [20].

Patients with many types of both acute and chronic liver disease have elevated plasma methionine levels, markedly delayed clearance of an oral methionine load, and decreased hepatic MAT activity. Subnormal hepatic SAM levels have been reported in various experimental models of liver injury, and SAM therapy in rats attenuates liver injury secondary to cholestasis, ethanol, carbon tetrachloride, fatty liver, acetaminophen, or galactosamine [20,21]. Liver-specific *MAT* (*MAT1A*) knockout mice have been generated [22]. Initially, they are highly susceptible to another "stress," such as a choline-deficient diet. Later, fatty liver and periportal inflammation develop, which may have a great relevance not only to alcoholic liver disease but also to nonalcoholic steatohepatitis (NASH). Lastly, very late in life, hepatic cancer develops in some mice. Deficiency of MAT modulates the expression of many genes, especially those involved in proliferation (growth), and normal *MAT1A* activity appears to be important for maintaining the hepatocyte in a "differentiated" state [20,22]. Studies from our laboratories have shown that SAM down-regulates production of the cytotoxic proinflammatory cytokine TNF, as well as increasing the antiinflammatory cytokine IL-10 [20]. Mato and colleagues reported that patients with alcoholic liver cirrhosis who were randomized to receive SAM (1200 mg daily orally) for 2 years had lower rates of liver mortality/liver transplantation (16% vs 30%) than a placebo-treated group [23]. SAM has also been used successfully in various types of cholestatic liver disease. Thus, substantial animal studies and emerging clinical data indicate that SAM may be useful in several forms of liver disease. Some potential beneficial effects of

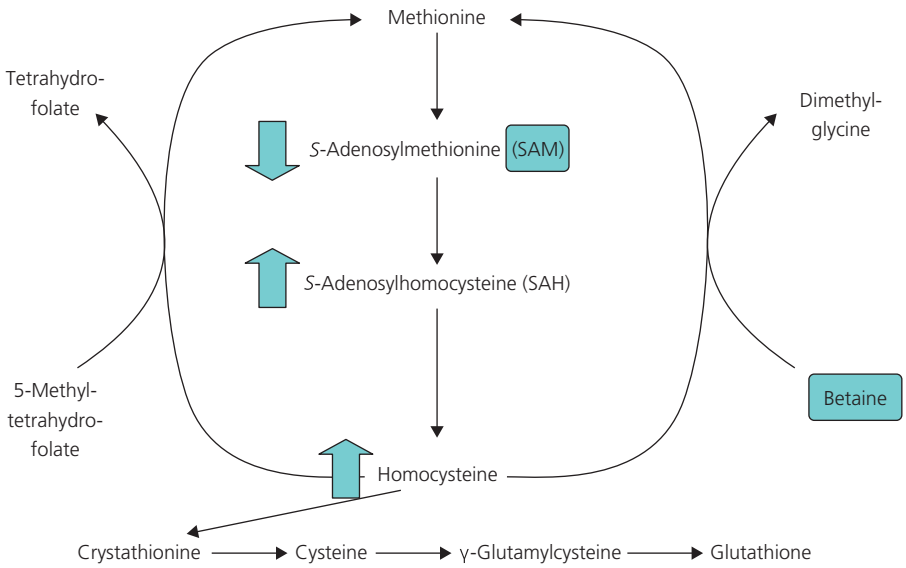

Figure 115.1 Hepatic methionine metabolism. Chronic alcohol consumption and several forms of liver disease cause *S*-adenosylmethionine (SAM) deficiency, but enhancement of homocysteine and *S*-adenosylhomocysteine (SAH). SAM can act as a therapeutic agent by replacing inadequate endogenous SAM, improving the SAM/SAH ratio and stimulating crystathionine β-synthase activity and subsequent reduced glutathione (GSH) production. Betaine can help remove SAH and homocysteine with subsequent regeneration of methionine.

SAM include increased glutathione production, improved mitochondrial function, decreased proinflammatory cytokine production, and enhanced methylation reactions [20].

Betaine

Betaine (trimethylglycine – initially discovered in the juice of sugar beets) acts as an organic osmolyte to protect cells from stress and functions as a major methyl donor in the methionine cycle (see Fig. 115.1) [24]. Thus, SAM and betaine together are involved in linked vital metabolic processes in the liver. In the transmethylation pathway, SAM is converted to *S*-adenosylhomocysteine (SAH). While SAM levels tend to be low in most forms of liver disease, SAH levels are often elevated, as are homocysteine levels [25]. SAH can sensitize hepatocytes to TNF-induced hepatotoxicity, and homocysteine is a major inducer of fatty liver [25]. Increases in SAH and/or decreased SAM to SAH ratios inhibit most transmethylation reactions. Thus, it is important to be able to remove excess levels of both SAH and homocysteine from the liver. Betaine facilitates the conversion of homocysteine back to methionine and helps remove both SAH and homocysteine (Fig. 115.1).

Betaine is known to be protective against a variety of forms of experimental hepatotoxicity such as those induced by endotoxin, carbon tetrachloride, chloroform, alcohol and others [24,26]. As noted previously, low levels of SAM are observed in most forms of liver disease and SAM is hepatoprotective. Betaine functions by removing SAH and homocysteine from the liver, as well as regenerating SAM [27].

Abnormalities in SAH and homocysteine levels are now being recognized in both experimental forms of liver injury and in human injury. Our group, Barack's laboratory, and others have documented elevated SAH levels in experimental models of liver disease, and studies by several groups document elevated homocysteine levels in animal models of liver injury [25–27]. As noted previously, the SAM/SAH ratio and SAH levels critically regulate transmethylation reactions (with increased SAH inhibiting transmethylation reactions) [25]. Studies from Ji and Kaplowitz reported that hyperhomocysteinemia induced endoplasmic reticulum stress with subsequent liver injury in alcohol-fed mice, and removal of homocysteine by betaine supplementation attenuated fatty liver and liver injury [26]. Studies from Barack and coworkers clearly indicated that betaine removes not only homocysteine but also SAH and protects against alcoholic liver injury in animals (see Fig. 115.1 – betaine facilitates methionine regeneration from homocysteine) [27]. Our findings suggest that elevated SAH levels increase sensitivity to TNF-induced hepatotoxicity, and we postulate that this is a clinically relevant cause of TNF-induced hepatotoxicity in patients with alcoholic liver disease [25]. Betaine has been used with success in a human pilot study in NASH patients, and larger trials are ongoing in NASH, with promising initial results [28].

Vitamin E

Vitamin E is a potent chain-breaking antioxidant that is widely used as a nutritional supplement. Depressed serum and hepatic levels of vitamin E have been documented in several types of liver disease [29].

Vitamin E has been used extensively with hepatoprotective effects in experimental models of liver injury, such as that induced by carbon tetrachloride or ischemia [29]. Vitamin E has been used in human liver disease with some success, with probably the most compelling data generated in children with NASH [30]. Obese children were given vitamin E (400–1200 IU) in an open-label pilot study, and all children with NASH demonstrated an improvement in liver enzymes without losing weight. Multiple subsequent studies have been performed in NASH patients, with most showing some beneficial effects of vitamin E [8]. Vitamin E has multiple potential beneficial effects, including membrane stabilization, reduced NF-κB activation and TNF production in monocytes/Kupffer cells, and decreased collagen production [17]. Vitamin E treatment has also been reported to decrease serum levels of the profibrotic cytokine transforming growth factor beta (TGF-β) in NASH patients [31]. Some of the initial enthusiasm for vitamin E use in liver disease has been tempered by a recent metaanalysis suggesting a potential for toxicity with high doses (see section on safety issues), and the results of NIH trials of vitamin E and NASH are eagerly awaited.

Polyenylphosphatidylcholine (lecithin)

Polyenylphosphatidylcholine (PPC) is a lipid extract from soybeans that has been shown to have hepatoprotective effects, especially in alcoholic liver disease [32]. PPC (specifically, dilinoleoylphosphatidylcholine, or DLPC) has been shown to prevent the development of septal fibrosis and cirrhosis in alcohol-fed baboons and has also been shown to stimulate the release of collagenase activity by cultured hepatic stellate cells. Stellate cell activation in rats has also been found to be decreased by DLPC. These animal studies of DLPC led to a large Veterans Administration cooperative study in patients with early alcoholic liver disease. No significant difference was found between the active agent and placebo; however, alcohol intake was markedly decreased in both groups and projected disease progression was improved [32].

Glycyrrhizin

Glycyrrhizin is an extract made from licorice roots that has been used in a variety of GI disease processes, ranging from peptic ulcer disease to liver disease. Glycyrrhizin has been reported to improve liver enzymes in a variety of patients with chronic hepatitis, including hepatitis C [8]. While it stimulates endogenous interferon production, it does not appear to decrease viral load in hepatitis C [8]. A retrospective study of intravenous glycyrrhizin therapy in patients with chronic hepatitis C found an approximately a 2.5-fold reduction in the risk of hepatocellular carcinoma [33].

Although glycyrrhizin has potential beneficial effects, it also has a variety of side effects, including aldosterone-like properties that predispose to electrolyte imbalance and fluid retention, and therefore we do not recommend that our patients use this drug [8,34].

Zinc

Zinc is an essential trace element, and zinc deficiency is well documented in many types of liver disease, including alcoholic liver disease [35]. Potential functional consequences of zinc deficiency of relevance to liver disease include neurosensory defects, skin lesions, hypogonadism, immune dysfunction, altered protein metabolism, and depressed wound healing [35]. Zinc deficiency has been best studied in patients with alcoholic liver disease, in whom there is not only decreased serum zinc levels but also increased urinary losses of zinc and poor zinc absorption [35]. Recent studies with experimental animals have shown that zinc supplementation markedly attenuates the development of alcohol-induced hepatotoxicity [36]. Beneficial actions of zinc include suppression of alcohol-induced oxidative stress, inhibition of hepatocyte apoptosis, maintenance of intestinal integrity, and a reduction in TNF production, to name only a few [36]. In humans, zinc supplementation has been shown to reverse or attenuate some of the functional consequences of zinc deficiency in alcoholic liver disease, such as skin lesions, immune dysfunction, and impaired night vision [35]. Zinc also has been used as adjunct therapy in hepatic encephalopathy with some success [37]. Lastly, zinc is now widely used for the treatment of Wilson disease [38]. Zinc induces intestinal metallothionein, which binds copper in the gut mucosa, preventing its absorption and resulting in its excretion in the stool. The dose of zinc used in Wilson disease is usually at least 150 mg of elemental zinc (50 mg orally three times a day) in order to effectively induce intestinal metallothionein.

Oriental herbals

Herbals are widely used to treat a variety of chronic inflammatory processes, such as rheumatoid arthritis, as well as in the chemoprevention of cancer. Green tea and green tea polyphenols down-regulate proinflammatory cytokine production (e.g., TNF) and block endotoxin lethality and endotoxin-induced hepatotoxicity in galactosamine-sensitized rats [39]. Other major polyphenols are made from grape seeds; they also have antioxidant/antiinflammatory properties and have been used to protect experimental animals from liver injury.

TJ9 is commonly used in China and Japan to treat hepatitis B and C and comes from an aqueous extract from the roots of a variety of plants. This agent has been shown to be hepatoprotective/antifibrotic in certain animal models of liver injury and to down-regulate proinflammatory cytokine production [8,40]. Compound 861 is an aqueous extract of 10 defined herbs that is reported to have very potent antifibrotic activity. It has been used extensively in China as an antifibrotic agent and has been reported actually to decrease fibrosis in sequential liver biopsy specimens from patients with hepatitis B [8,41]. It has also been shown to be effective in carbon tetrachloride-induced liver injury and to have antiproliferative effects on stellate cells in vitro. Selected other herbals used to treat liver disease include *Phyllanthus amarus*, *Picrorrhiza kurroa*, CH-100, and ginseng. One of the major problems with herbals is that they are actually a combination of agents that are poorly characterized and not highly reproducible from one lot to the next. The potential risks of herbals have recently been reviewed and are discussed in the section on safety issues [7,8].

CAM use in pancreatic disease

Currently, effective therapies for pancreatic disease, especially chronic pancreatitis, are limited. Relief of abdominal pain, malabsorption, and diabetes are the main areas of focus, with abdominal pain being the most difficult symptom to treat. Because pancreatic enzyme replacement therapy is ineffective in controlling pain [42] and large randomized studies evaluating endoscopy or surgery are lacking [43], patients and providers are actively seeking alternative therapies for chronic pancreatitis, including acupuncture, herbal therapies, and antioxidant therapy.

Acupuncture

Acupuncture has been used for decades in traditional Chinese medicine. The Chinese believe that the interaction of yin and yang creates the vital life force known as Qi (pronounced chee) and that diseases occur when the flow of Qi is disrupted (excessive or deficient). Qi flows through the body in meridians or channels and can be accessed via acupoints. Modern functional magnetic resonance imaging studies have shown reproducible, regionally specific, and quantifiable effects on relevant structures in the brain when acupoints are stimulated [44]. However, in the only randomized prospective study of 23 patients with nonalcoholic chronic pancreatitis, neither electroacupuncture nor transcutaneous electrical nerve stimulation was as effective as medical therapy [45].

Antioxidants

The increased use of antioxidants as an alternative therapy for chronic pancreatitis is based on the compelling evidence of persistent oxidative stress in patients with chronic pancreatitis [46], in addition to increased lipid peroxidation and altered glutathione metabolism [47]. Furthermore, regardless of the cause of injury, oxidative stress is felt to be pivotal in the progression to parenchymal pancreatic tissue destruction [48]. Compared with control subjects, the serum antioxidant profiles of patients with acute and chronic pancreatitis, and of those with hereditary pancreatitis, reveal lower plasma

concentrations of selenium, vitamin A, vitamin E, xanthine, β-carotene, β-cryptoxanthine, and lycopene [49,50]. Additionally, selenium deficiency in chronic pancreatitis has been well documented, with some patients experiencing relief of chronic pain after selenium supplementation [51].

The histological hallmarks of chronic pancreatitis include loss of parenchyma, fibrosis, blockage of pancreatic ducts with protein plugs that calcify, and variable degrees of inflammatory cell infiltration with a predominance of lymphocytes. Cytokines and chemokines released from these cells promote ongoing inflammation. Elevated proinflammatory cytokines have been found in the serum [52], peripheral blood monocytes [53], and more recently in the pancreatic tissue [54] and pure pancreatic juice [55] from patients with acute and chronic pancreatitis. Cytokine response predicts disease severity and outcome, supporting the rationale for the antioxidant- and cytokine-blocking therapies now under development. In a prospective trial of 10 patients with chronic and acute recurrent pancreatitis of various causes, supplementation with a complex containing vitamin E, vitamin C, and organic selenium resulted in significant pain relief and a decreased need for hospital admission during the year of treatment in comparison with the year before treatment [56]. In a 20-week, double-blinded, placebo-controlled, switch-over trial of supplementation with selenium, β-carotene, vitamin C, vitamin E, and methionine, most patients reported fewer attacks with significantly less background pain while on treatment [57]. A retrospective cross-sectional audit of 94 consecutive patients with chronic pancreatitis on antioxidant therapy followed for an average of 30 months showed a decrease in the requirements for surgical intervention, in the number and intensity of painful attacks, and in absences from work [58]. Large prospective placebo-controlled trials are needed to confirm these preliminary observations and guide practitioners on the best doses for these over-the-counter preparations.

CAM use in peptic ulcer and nonulcer dyspepsia

Peptic ulcer disease remains prevalent despite the recognition of its association with *Helicobacter pylori* infection and the availability of potent antisecretory medications. For thousands of years, alternative therapies were used to provide symptom relief and promote ulcer healing, especially in Indian and Chinese traditional medicine.

Acupuncture

Acupuncture has been used extensively in China and the former Soviet Union for the treatment of peptic ulcer. The physiological basis of acupuncture effects on acid secretion has been well studied in animals and humans [59]. In a prospective randomized study of human volunteers, electroacupuncture, but not sham acupuncture or simple acupuncture, significantly reduced vagally stimulated acid secretion [60]. Clinical trials reporting efficacy for acupuncture in humans with gastric or duodenal ulcer have been criticized for poor study design and lack of randomization.

Acupuncture may be useful for persons with nonulcer or functional dyspepsia. These patients have been shown to be hypersensitive to gastric distention, and somatic stimulation with transcutaneous electric stimulation can reduce the discomfort associated with gut distention [61]. Electroacupuncture modulates gastrointestinal motility by significantly increasing the percentage of regular gastric slow waves as measured by electrogastrography (EGG) [62], and by influencing duodenal peristalsis. Several small uncontrolled trials claim efficacy for acupuncture in subjects with nonulcer dyspepsia [63]. Future controlled randomized trials are needed to clarify whether patients with nonulcer dyspepsia or documented gastroduodenal dysmotility can benefit from acupuncture.

Probiotic/herbal therapies

Yogurt containing appropriate bacteria (probiotic therapy) has been shown to suppress *H. pylori*, and combining yogurt with antibiotics can improve *H. pylori* eradication. Moreover, recent research has shown that prior treatment with *Lactobacillus acidophilus*- and *Bifidobacterium*-containing yogurt significantly improved the efficacy of quadruple therapy in eradicating residual *H. pylori* after failed triple therapy [64].

Sangre de grado is derived from the sap of several Amazonian trees of the *Croton* genus (*C. dracanoides*, *C. planostigma*, *C. lechleri*). It is commonly used in tropical South America to treat a variety of GI illnesses, including infectious diarrhea, gastritis, and peptic ulcer, and it is also used topically for wounds, bites, and insect stings [65]. It is inexpensive and widely available, unlike many of the Western pharmaceuticals. Its mechanism of action is unknown, but its efficacy has been attributed to potent antibacterial properties. Despite the high prevalence of *H. pylori* infection in South America, no current studies have focused on sangre de grado and *H. pylori* eradication per se.

In a randomized clinical trial of 508 patients with endoscopically proven gastric or duodenal ulcers and documented *H. pylori* infection, the Chinese herb Chuanjia Weidan was compared with cimetidine. Ulcer healing rates and symptom reduction were similar, but the *H. pylori* clearance rate was 75% with Chuanjia Weidan therapy, versus 6% for the cimetidine-treated group. Ulcer recurrence rates were also higher for the cimetidine treated group [66]. A preliminary screening of more than 200 different Chinese herbal medicines revealed that 38 of the preparations had growth-inhibiting effects on *H. pylori* organisms cultured from 136 subjects with antral infection [67].

Other botanicals and herbals with reported efficacy and extensive use in the treatment of humans with peptic ulcer

include flavonoids (quercetin, silymarin, naringin, anthocyanosides, sophoradin derivatives), saponins, tannins, gum guar and mucilages (myrrh), licorice, aloe gel, goldenseal, and capsicum (chili) [68]. Proposed mechanisms of action include inhibition of prostaglandins, cytoprotection, antiinflammatory or immune modulatory effects, altered nociception, and suppression of *H. pylori*. Well-designed randomized controlled trials supporting many of these claims are lacking. For nonulcer dyspepsia, there are several randomized controlled trials that support the efficacious use of peppermint oil alone or in combination with caraway oil for symptom relief [69]. The effects of these agents are most likely due to their ability to relax smooth muscle.

CAM use in irritable bowel syndrome

Irritable bowel syndrome (IBS) is one of the functional bowel disorders characterized by chronic or recurrent abdominal pain and disturbed defecation without structural or biochemical abnormalities. Although the pathogenesis of IBS remains unknown, the documented altered bowel motility patterns and exaggerated pain perception to visceral distention (visceral hyperalgesia) suggest neurohormonal or autonomic dysfunction as a likely cause [14,70].

Treatments for IBS generally focus on symptom reduction; however, no single treatment is reliably effective. Rather, multiple regimens combining dietary and lifestyle modification, normalization of bowel habits, antispasmodics when indicated, and anxiolytics or antidepressants are used. Often, an initial approach is to increase dietary fiber; however, clinical controlled studies of fiber therapy have revealed conflicting results [71]. Because of the limited efficacy of conventional treatments for IBS, many patients seek alternative therapies. A questionnaire completed in a physician's waiting room in Britain revealed that one in five patients with IBS had used some form of alternative therapy. Also, 41% were agreeable to consultation with alternative medicine practitioners, compared with only 6% of patients with "organic" upper GI diseases. Of alternative medicines used at home, herbal remedies were most common [72]. However, most people with IBS symptoms do not seek formal medical care, and the use of alternative therapies in these individuals will remain difficult to quantify unless surveys of large cross-sections of the population are developed and administered.

Acupuncture

Acupuncture therapy may benefit patients with IBS through a variety of mechanisms, including its effects on GI motility and autonomic function. Coffin and colleagues [61] examined the effects of transcutaneous electrical nerve stimulation of the hand during balloon distention of the stomach and duodenum and found that it induced somatosensory stimulation and raised the discomfort threshold. Kunze and colleagues [73] found a greater relief of symptoms with real (31%) than with sham (17%) acupuncture in patients with IBS. Among 10 patients with IBS, Diehl and colleagues [74] reported a good response to acupuncture in four and a partial response in five, with one nonresponder. In another small study of seven patients given acupuncture for IBS, all reported an improved sense of general well-being and less abdominal bloating, but no change in abdominal discomfort or bowel patterns [75].

Commonly used herbal therapies

Essential oils are known for their carminative and antispasmodic properties, and thus have been used for various GI ailments. Peppermint oil (*Mentha* × *piperita* L.) is derived from steam distillation of the aerial parts of flowering peppermint (*Mentha* × *piperita*). Its active component is menthol, which has pharmacological properties similar to those of calcium channel antagonists [76]. Peppermint oil has been shown to relax smooth muscle from isolated human colonic cells. In a metaanalysis of eight randomized controlled trials, peppermint oil use found to be beneficial for relief of IBS symptoms; however, only one trial selected patients based on the Manning diagnostic criteria for IBS, illustrating the need for more scientifically rigorous methodology in future studies. Additionally, not all studies reported the doses used, so that practical recommendations for use cannot be reliably made [77]. Peppermint oil use may increase gastroesophageal reflux disease (GERD) owing to relaxation of the lower esophageal sphincter, but otherwise it has no known harmful effects such that patients may self-administer to seek their own dose–response needs.

Ginger root (*Zingiber rhizoma*, *Zingiber officinale*) has been used for thousands of years in Asia to treat multiple GI ailments, including nausea, dyspepsia, cholera, and diarrhea, as well as motion sickness, postoperative vomiting, and hyperemesis gravidarum. The pharmacological properties of ginger include antioxidant effects and inhibition of prostaglandins. It also increases intestinal tone and peristalsis. Ginger supplementation enhances charcoal meal transport in mice, with effects felt to be similar to or slightly weaker than those of metoclopramide and domperidone [78]. For practical uses, the dose of ginger needed to relieve symptoms would need to be self-assessed by users; ginger is believed to be nontoxic.

Licorice (*Glycyrrhiza glabra*, *Glycyrrhiza uralensis*) is used to treat functional dyspepsia, bronchitis, and peptic ulcer. It has expectorant properties and antiinflammatory and antiplatelet effects, and it increases prostaglandin levels. Overuse can result in salt and water retention, hyperkalemia, hypertension, and edema. Many drug–drug interactions are also possible.

Derived from the plant *Hypericum perforatum*, St. John's wort is the herb most commonly used worldwide to treat depression and anxiety. In clinical studies comparing St.

John's wort with various serotonin reuptake inhibitors, it was equally effective for the treatment of depression and had fewer side effects [79]. The active ingredient of St. John's wort, hypericin, acts by inhibiting the reuptake of norepinephrine, serotonin, and dopamine. Controlled trials of St. John's wort use in IBS have not been reported.

Perhaps because of their agreeable flavor and aroma, or the ceremony of making and sharing a beverage with others, the commercial use of herbal teas is increasing. The following have reported benefits for the GI tract and their use is felt to be safe, but controlled clinical trials of efficacy have not been published. Chamomile (*Matricaria camomilla*, *Chamaemelum nobile*) is felt to have GI antispasmodic, antiinflammatory, and antimicrobial activities, in addition to anxiolytic and slight sedative effects. The licorice-tasting herbs fennel (*Foeniculum vulgare*) and anise (*Pimpinella anisum*) are touted to help expel gas and aid digestion. Lemon balm (*Melissa officinalis*) has mild sedative, carminative, and antispasmodic effects, and fragrant raspberry leaf (*Rubus idaeus*, the "pregnancy tea") is reported to relieve morning sickness, nausea, and dyspepsia [80].

Chinese herbal agents

In traditional Chinese medicine, rather than single agents being used, multiple herbs are combined for their synergistic properties. In a randomized placebo-controlled trial of 176 patients with IBS according to the Rome criteria, those receiving treatment with individualized herbs ($n = 58$) or a standard formulation of Chinese herbs ($n = 63$) reported significant relief of bowel symptoms and quality of life in comparison with those receiving placebo ($n = 55$). No greater benefit for those receiving individualized herbs rather than standard herbs during the 4-month study was found. However, only the subjects who had received individualized herbs showed a sustained relief of symptoms 14 weeks after completion of the study. The authors concluded that further investigation of Chinese herbal medicine as a treatment for IBS should be undertaken [81].

Indian herbal agents

The bilva (*Aegle marmelos correa*) plant from the Indian Ayurvedic system of medicine has been used to treat chronic constipation, flatulence, diarrhea, and colic. Yadav and colleagues [82] randomized patients with IBS to one of three groups: standard treatment (clidinium bromide, chlordiazepoxide, and ispaghula), herbal therapy (bilva plus the sedative herb *Bacopa monniere* L.), or placebo. Both active treatment groups significantly improved compared with the placebo group. A subanalysis revealed that the standard therapy was most beneficial for patients with pain as a predominant symptom, whereas the Ayurvedic herbs were most beneficial for those with diarrhea. At 6-month follow-up, relapse rates did not differ between the active treatment and placebo groups.

CAM use in inflammatory bowel disease

Inflammatory bowel diseases (IBDs) exhibit a large degree of heterogeneity, both in disease expression and in response to established therapies. The toxicity and relatively low efficacy of many standard medical therapies impel up to 50% of IBD patients in some populations [5] to seek complementary or alternative therapies, including probiotics, nutritional supplements, and botanical products. Clinical evaluations of alternative therapies suggest therapeutic benefits, but definitive clinical trials demonstrating objective evidence of efficacy remain sparse.

Probiotics

Publications concerning probiotics (viable microorganisms with putative health effects) have proliferated recently, while clinical trials have not kept pace. Probiotic bacteria stimulate nonspecific host resistance to microbial pathogens, enhance humoral immune responses to pathogens, and enhance antiinflammatory cytokine profiles [83,84]. They also alter the composition of the lumenal flora by producing lactic acid, bacteriocins, and other antimicrobial peptides that are efficacious against pathogens.

Lactobacterium species, in general, perform well against pathogenic bacteria without inhibiting other probiotic organisms. Most species adherent to the small bowel belong to the *Lactobacillus* genus and perform well as potential probiotics. *Lactobacillus salivarius* competes exceptionally well against pathogenic bacteria without inhibiting other beneficial strains of lactobacilli or bifidobacteria isolated from the human ileum [85].

Many IBD patients exhibit imbalances of the intestinal microflora [86,87]. The current concept of dysbiosis, or altered balance between pathogenic and protective bowel flora, has enhanced the popularity of probiotic therapy. The most convincing evidence to date regarding the benefits of probiotic therapy comes from trials in ulcerative colitis (UC). One randomized, double-blind, placebo-controlled (RDBPC) trial demonstrated significant improvement in patients with mild to moderate UC ingesting a *Bifidobacterium*-containing fermented milk product [88]. *Escherichia coli* Nissle 1917 benefits the maintenance of 5-aminosalicylic acid (5-ASA)-induced remission [89,90]. In an open-label trial with VSL#3 (a combination of probiotic organisms), 69% of UC patients with mild to moderate activity despite 5-ASA therapy experienced remission of symptoms, and 23% responded [91]. Evidence for a probiotic benefit in Crohn's disease has been less dramatic. When used in a complementary fashion in a small RDBPC trial, *Lactobacillus rhamnosus* GG administered to patients who are tapering off remitive medications did not improve duration of remission [92]. Two other maintenance of remission trials fared better: 70% of patients in remission on corticosteroids maintained remission with *E. coli* Nissle

1917 compared with 30% receiving placebo [93], while the addition of *Saccharomyces boulardii* to mesalamine maintained remission at 6 months in 94% of patients receiving both compared with 62% in patients receiving mesalamine alone [94].

Studies in mice reveal that probiotic administration leads to the competitive displacement of intestinal pathogens and the engagement of cell membrane receptors that modulate signaling events for cytokine synthesis [95]. A variety of organisms, including *Lactobacillus* and *Bifidobacterium* species possess the ability to modulate cytokine production and immune function in an antiinflammatory fashion in several models of intestinal inflammation [95–98].

Helminthic parasites

A theory recently advanced suggests that tolerance to lumenal bacterial antigens (helper T cell type 2 [Th2] mucosal conditioning) may be conferred by exposure to helminthic parasites [99]. The decline in helminthic infestations in the United States during the past 60 years has been offered as an explanation for the rise in the incidence of Crohn's disease during the same period [99]. Antigen characteristics determine whether an antigen-presenting cell (APC) influences a naive T cell to assume either a Th1 (interferon-γ, TNF-α) or Th2 profile (IL-4, IL-5, IL-10, IL-13) [100,101]. Immune response to helminthic antigens generally elicits a strong Th2-type reaction, whereas patients with Crohn's disease mount a Th1 response to lumenal antigens. Persons harboring helminths are more apt to mount a diminished Th1 response when challenged with proinflammatory antigens [99]. Mice exposed to *Schistosoma mansoni* before trinitrobenzene sulfonic acid and ethanol were protected from the development of experimental colitis [102]. IL-10 deficient mice inoculated with the helminths *Heligmosomoides polygyrus* and *Trichuris muris* were far less susceptible to inflammation caused by bacterial exposure than were those given a sham inoculation [99]. Based on these data, researchers conducted an open-label clinical trial involving 29 Crohn's disease patients with persistent inflammation despite conventional medical therapy [103]. Patients received 2500 live *Trichuris suis* eggs every 3 weeks for 24 weeks. Seventy-nine percent of patients experienced a drop in Crohn's disease activity index (CDAI > 100), and 72% met remission criteria. An RDBPC study by the same group using *T. suis* on medically refractory mild to moderate UC demonstrated a 43% response to therapy compared with 17% response to placebo [104].

Prebiotics/short-chain fatty acids

Prebiotics, described as "nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of beneficial bacteria in the colon, thereby improving the host's health," [105] provide an additional mechanism for influencing the population dynamics of the intestinal microflora. The most beneficial prebiotics reach the cecum, where they can promote the growth of lactic acid-producing microorganisms. Recovery of a high proportion of the chicory *Fructans inulin* and its hydrolysate, oligofructose, from ileostomy outputs supports their ability to reach the cecum [106]. Prebiotics are present in significant amounts in a wide variety of fruits and vegetables and are fermented by colonic bacteria to lactic acid and short-chain carboxylic acids [107]. Other oligomers with prebiotic potential are lactulose and such sugar alcohols as mannitol and xylitol. Additionally, prebiotics such as oligofructose may function in a primary antibacterial role by augmenting the growth of beneficial probiotic strains, as seen in competition experiments between strains of *E. coli, Clostridium perfringens*, and *Bifidobacterium infantis* [106]. Colonic aerobic bacteria act to salvage energy for the host by fermenting undigested food materials to short-chain fatty acids, which in turn are absorbed by colonocytes [97]. Butyrate has been shown to inhibit the production of cytokines as well as the activation of NF-κB [108]. Initial trials of short-chain fatty acids demonstrated efficacy, but subsequent trials showed mixed results, possibly because of poor compliance. An open-label study investigated the effects of *Plantago ovata* (an alternative source of butyrate) on 12-month remission rates, either alone or in combination with standard 5-ASA therapy. Remission rates were similar for the groups [108]. A subsequent abstract evaluated butyrate yields from a variety of fibers, comparing *P. ovata* seeds, husks, and other forms of fiber. All produced significant amounts of butyrate, but butyrate production from the seeds tended toward a higher output [109]. Germinated barley foodstuff, a by-product of beer fermentation, was evaluated as first an inductive therapy in patients with mild to moderate UC not responding to standard UC therapy [110]. Patients receiving germinated barley foodstuff had significantly lower activity scores, reduced levels of C-reactive protein, and endoscopic improvement compared with subjects receiving standard medical therapy. Bacterial composition and butyrate levels changed during therapy [110]. A follow-up study determined that long-term open-label administration provided an improvement in 6 months in patients entering the trial with mild–moderate symptoms [111].

Transforming growth factor-β

Therapy with enteral nutrition has been shown to be efficacious in Crohn's disease. A specific dietary component, TGF-β, has been studied individually for its applicability as an IBD treatment. TGFs are multifunctional polypeptides found in milk. An oral polymeric diet rich in TGF-β was studied in 29 children with Crohn's disease [112]. Seventy-nine percent achieved remission within 8 weeks of therapy, with two treatment failures that required surgical intervention or steroid therapy. Laboratory indicators of inflammation decreased with therapy, and a follow-up colonoscopy revealed endoscopic improvement in about 50% of cases. Moreover,

this same TGF-β-rich enteral formula attenuated intestinal inflammation in the IL-10 knockout mouse [113].

Green tea

Green tea extracts contain high levels of antioxidants. The polyphenol fraction accounts for most of the antioxidant potential and includes the compounds (–)-epicatechin (EC), (–)-epigallocatechin (EGC), (–)-epicatechin-3-gallate (ECG), and (–)-epigallocatechin-3-gallate (EGCG) [35]. Green tea polyphenols are more potent antioxidants than either vitamins E or C and have potent antiinflammatory properties [114]. Green tea polyphenols have been shown to inhibit intestinal inflammation in the IL-2 knockout mouse model of IBD. An important potential mechanism for treating IBD, independent of antioxidant properties, relates to the effects of the green tea polyphenol (GrTP) fraction on NF-κB, a nuclear activating protein [114]. EGCG inhibits, in a dose-dependent fashion, the effects of inflammatory mediators on NF-κB by inhibiting the phosphorylation of inhibitor of κB (IκB) by IκB kinase (IKK). When bound to IκB, NF-κB cannot migrate to the nucleus and bind with cytokine promoter sequences, interrupting the proinflammatory cascade [114]. The antioxidant properties of GrTP were evaluated in a model of intestinal oxidative stress induced by dextran sodium sulfate (DSS) administered to Balb/C mice [115]. GrTP administration significantly improved the colon length and blood antioxidant levels, while lowering TNF-α and serum amyloid A (SAA) levels when compared with DSS-treated animals that had not received any antioxidant therapy.

Fish oil

Arachidonic acid metabolites, particularly leukotriene B_4 (LTB_4), are important components in the inflammatory processes associated with IBD. Arachidonic acid metabolites cause increased vascular permeability, vascular dilation, and neutrophil recruitment. Serum LTB_4 levels are increased in patients with ulcerative colitis [116]. Eicosapentaenoic acid (EPA), a component of fish oil, can reduce the formation of LTB_4 by serving as a competitive substrate for 5-lipoxygenase, thereby producing a less potent metabolite, LTB_5. Controlled trials of fish oil in patients with ulcerative colitis have demonstrated trends toward efficacy. The data of Hawthorne and colleagues [117] suggested a steroid-sparing effect from 4.5 g of EPA per day in patients with ulcerative colitis. Belluzi and colleagues [118] found that an enteric-coated preparation of 1.8 g of EPA per day maintained remission in patients with Crohn's disease. An RDBPC trial in 38 pediatric Crohn's disease patients who had achieved remission with a 2-month course of steroids demonstrated that coadministration of encapsulated ω-3 fatty acids resulted in remission being maintained for longer, and in a greater percentage of subjects at 12 months (39% vs 5%), than administration of 5-ASA alone [119].

Botanical derivatives

A specific inhibitor of 5-lipoxygenase is contained in the gum resin from *Boswellia serrata*. Indian patients with chronic colitis were treated with either *Boswellia serrata* preparation or sulfasalazine [120]. Gum therapy was associated with a higher rate of response than sulfasalazine therapy. A pilot study evaluating purified curcumin (550 mg) as an adjunct therapy in a mixed cohort of patients with UC or Crohn's disease demonstrated a clinical response to the botanical therapy in both types of IBD as well as a marked reduction in sedimentation rate [121]. The authors of both studies called for formalized testing of these products.

Nicotine

Tobacco use has a well-described dichotomous effect in IBD. Although smoking may aggravate Crohn's disease, patients with ulcerative colitis may experience disease onset or a flare of their existing disease with smoking cessation [122]. Investigators have attempted to exploit this clinical effect by administering nicotine supplements to patients with UC. In an RDBPC study of nicotine patches (average 17 g daily) for the treatment of active UC, a statistically significant response was observed in comparison with placebo [123]. Two subsequent studies with the nicotine patch as monotherapy showed no statistical improvement in remission rates [124], but a study by Sandborn and colleagues [125] did demonstrate a significant improvement in clinical parameters. Other routes of administration, including oral therapy and rectal enemas, continue to be plagued by either side effects or poor efficacy [126,127]. The use of nicotine therapy will likely benefit only a small, select population of UC patients.

CAM use in diarrheal states

Antibiotic-associated diarrhea occurs in approximately 20% of hospitalized patients receiving antibiotics, with up to 33% of cases related to *Clostridium difficile* [128,129]. The other 66% experience symptoms related to alterations in the bacterial production of short-chain fatty acids [130]. Antibiotic-associated diarrhea was reduced from 27% in a placebo group to 9% in a group taking the probiotic *Enterococcus faecium* [131]. Other organisms shown to be efficacious in antibiotic-associated diarrhea include *Lactobacillus rhamnosus* GG, *Lactobacillus acidophilus* and *Lactobacillus bulgaricus* administered in combination, and *Saccharomyces boulardii* [130]. Worldwide, infectious diarrhea remains a leading cause of morbidity and mortality in infants and children. Numerous studies have investigated the potential of many probiotic and prebiotic agents for the treatment of these conditions. Trials with *L. rhamnosus* GG and *S. boulardii* used as prophylactic therapy for diarrheal infections demonstrated small overall reductions in diarrhea in comparison with the placebo, although some study populations experienced substantial

benefit [132]. The evaluation of probiotics as abortive agents for diarrheal illnesses has been carried out mainly in children, who are at the greatest risk for serious illness and death. *E. faecium* and *S. boulardii* relieve symptoms in acute diarrheal illnesses, and *L. rhamnosus* GG decreases the rate of rotaviral diarrhea and viral shedding [133].

Traditional remedies for diarrhea include the ingestion of a variety of plant extracts. Pectin, from green bananas, serves as a source of amylase-resistant starch [134]. Pectin passes through the small intestine undigested, then undergoes fermentation in the colon into short-chain fatty acids [135]. The presence of short-chain fatty acids in the colon stimulates salt and water absorption and also has a trophic effect on colonic and small bowel mucosa [136]. When dietary pectin and green bananas were blended into a rice-based diet and used to treat children with persistent diarrhea resulting from a variety of infectious and noninfectious causes, a statistically significant reduction in stool weight and relief of symptoms were noted in the treated children in comparison with the children on control diets [134]. Many other antidiarrheals derived from plant sources are undergoing preclinical testing. Recent clinical trials have demonstrated a significant benefit from wood creosote, a derivative of seirogan (an herbal antidiarrheal) [137], and tormentil root extract, which has been used in Eastern Europe as a traditional medicine [138].

Safety issues

The safety of CAM agents is not well defined, in large part because of a lack of regulatory guidelines. In 1994, Congress passed the Dietary Supplement Health Education Act, which exempted dietary supplement producers from many Food and Drug Administration (FDA) regulations. Consequently, dietary supplements are under less government scrutiny than over-the-counter nonprescription drugs. Thus, it is critical that both consumers and health-care workers understand that the labeling of CAM products is not necessarily correct, that products may not be pure, and that the advertised dose may not be correct.

Concerns about safety relate to both product content and potential harm. Multiple studies have documented great variability in the composition of herbal products/supplements, with some products containing only a small fraction of the advertised dose [139–141]. This product variability is probably an unavoidable aspect of many Chinese herbal compounds, and traditional prospective clinical trials are difficult to design because of the inherent variability in the therapeutic agent. Toxicity induced by CAM products has been reported [140,142]. Hepatotoxicity is one of the most frequently reported side effects of CAM products (e.g., germander- and pyrrolizidine alkaloid-containing compounds), sometimes leading to liver transplantation or death [142–144]. Recently reported cases of hepatotoxicity due to kava-kava and to various weight loss agents have heightened awareness of this problem and have reinforced the need to carefully question patients with elevated liver enzymes about CAM use (see Tables 115.2 and 115.3 for examples of CAM hepatotoxicity) [8]. A recent report from one medical center highlighted the risk of fulminant hepatic failure requiring liver transplantation following CAM ingestion [145].

Some CAM products are contaminated with drugs/toxins [139]. A classical example is the report of a young woman who presented with nausea, vomiting, and an irregular heart

Table 115.2 Selected complementary and alternative medicine agents and related hepatotoxicity

Herb/supplement	Description
Aristolochia	Contains highly toxic aristolochic acid
Bajiaolian	Used in treatment of tumors and snakebites, but elevation of liver enzymes within hours of ingestion has been reported
Black cohosh	Popular herbal remedy used for treatment of menopausal symptoms, but multiple reports of hepatotoxicity
Cascara sagrada	Laxative, has caused cholestatic hepatitis
Celandine	Can cause acute hepatitis
Chapparral	Used especially for respiratory tract infections, but liver damage has been reported
Eternal life	Chinese herbal remedy has been associated with hepatotoxicity
Germander	Used for its antimicrobial and anti-inflammatory activity; can cause severe liver damage; removed from most markets
Kava-kava	Documented to have caused hundreds of cases of hepatic damage worldwide
LipoKinetix	Used for weight loss; can cause acute hepatitis and fulminant hepatic failure
Ma huang	Used in weight loss and increasing energy, can cause acute hepatitis
Pennyroyal	Has been associated with severe hepatotoxicity, including one fatality
Pyrrolizidine alkaloids	Has been reported to induce portal hypertension, venoocclusive disease, ascites, and eventual hepatic failure
Senna	A laxative, has been reported to cause toxic hepatitis after overdosing
Skullcap	Reported to cause venoocclusive disease and liver failure

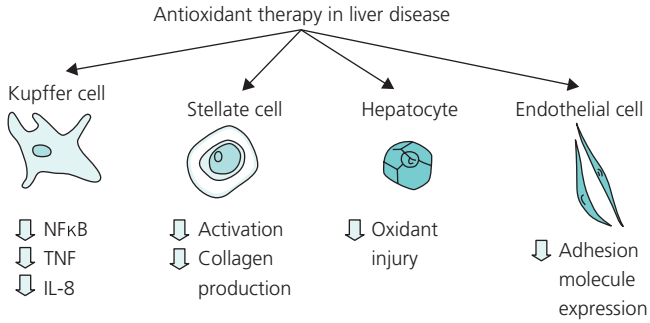

Figure 115.2 Most forms of complementary alternative medicine therapy in liver disease have antioxidant effects. These theoretically increase proinflammatory cytokine production, decrease stellate cell production and subsequent collagen production, attenuate oxidant injury in hepatocytes, and decrease endothelial cell adhesion molecule expression. IL-8, interleukin 8; NF-κB, nuclear factor κB; TNF, tumor necrosis factor.

beat after she initiated an oral regimen of dietary supplements for "internal cleaning." The patient was found to have an elevated digoxin level, and her herbal medications were contaminated with plant extracts containing a cardiac glycoside (*Digitalis lanata*) [146]. Importantly, some Chinese patent medicines purposely contain small amounts of prescription drugs (e.g., antibiotics, ephedrine, methyltestosterone) [139,147]. These drugs may also be contaminated with heavy metals (e.g., lead, arsenic, mercury) [148]. CAM agents can interact adversely with traditional medications (Fig. 115.2 and Table 115.4). An example is the potential interactions of St. John's wort with cyclosporine (cyclosporin) and indinavir [149]. This interaction was highlighted when cardiac transplant patients underwent rejection shortly after starting St. John's wort, presumably because of the induction of cytochrome P450 3A4 by the St. John's wort [150]. It is important to instruct all transplant patients (and other patients on immunosuppressive therapy) to inform their physician before starting any CAM agent. Other, more common, side effects also can be seen with relatively safe agents, such as St. John's wort, including photosensitivity, especially in virally infected patients. A variety of herb–anesthesia interactions are possible (e.g., garlic, gingko, St. John's wort), such as bleeding, and the American Society of Anesthesiologists recommends that patients discontinue all herbal medicines 2–3 weeks before elective surgery and inform their physicians about their CAM use [151]. Indeed, the public can be easily misinformed about CAM agents and inadvertently take an unintended product with a subsequent adverse outcome. On the other hand, some studies may raise

Table 115.3 Selected other adverse effects of herbal remedies on the gastrointestinal tract

Herb	Main use	Adverse effect
Aloe	Constipation, IBS	Diarrhea, abdominal cramps
Black cohosh	Joint pains, menopausal symptoms	Nausea, vomiting
Ephedra	Weight loss	Hypertension, stroke, myocardial infarction, death
Gentian	Appetite stimulant, digestive aid	Nausea, vomiting
Sassafras	General well-being	Carcinoma

IBS, irritable bowel syndrome.

Table 115.4 Clinically proven interactions of complementary alternative medicine (CAM) with conventional medicines

CAM agent	Drug interaction	Consequence
Ginger, ginko	Iron	Reduced absorption of iron
Ginseng, garlic	Warfarin	Increased warfarin levels, increased risk for bleeding
St. John's wort	Cyclosporine, indinivar	Reduced cyclosporine and indinivar serum levels
Chili/capsiacin	ACE inhibitors	Cough
Psyllium	Lithium	Reduced lithium levels
Liquorice	Spironolactone	Reduced effectiveness
	Prednisolone	Hypokalemia, salt and water retention
SAM	Serotonin reuptake inhibitors	Enhanced serotonin elevations

ACE, angiotensin-converting enzyme; SAM, *S*-adenosylmethionine.

inappropriate concerns about CAM agents. A recent meta-analysis on high-dose vitamin E reported a minimal, but significant, increase in mortality [152]. Only a select number of studies were included in this metaanalysis, and it is unclear whether the conclusions can be extrapolated to the population at large. However, many patients taking high-dose vitamin E for reasons such as NASH have discontinued therapy. This study reinforces the need for careful interpretation of the CAM literature.

Conclusion

In conclusion, CAM is already being widely used by our patients with chronic gastrointestinal symptoms and liver disease, either alone or in conjunction with conventional therapies. Today, many types of CAM therapy are based on substantial scientific rationale (e.g., SAM for liver disease, certain green tea polyphenols as antiinflammatory therapy). Some forms of CAM have yielded very positive clinical trial data (e.g., acupuncture and ginger for nausea and vomiting, peppermint oil for dyspepsia, and probiotics for diarrhea). However, because a great potential for toxicity or drug interactions also exists, both the patient and health-care provider need to be optimally educated about CAM. Clinicians may best be served by subscribing to the *PDR for Herbal Medicines* and the *PDR for Nutritional Supplements*. Most of the information in these references originates in publications of Commission E, a European scientific advisory panel with functions similar to those of the FDA, whose focus is to collect and publish information regarding herbal preparation, dosages, purity, uses, drug–drug interactions, and deleterious effects. In addition to the previously mentioned versions of *Physicians' Desk Reference*, the websites of the Cochrane Database System reviews (*http://www.cochrane.org*) and the NCCAM (*http://nccam.nih.gov*) are valuable sources for updated information.

Future directions

CAM therapies hold promise for treating a variety of gastrointestinal and liver diseases, especially those ailments with gaps in effective "traditional" therapies. Research in CAM should continue to focus on scientific rationale, and randomized controlled trials should be designed with sound methodology in order to yield practical and safe application of CAM in clinical practice. Leaders in health care education need to include CAM training in their school curricula as well as continuing medical education programs, and practice guidelines need to incorporate CAM where there is evidence of efficacy. It should be irrelevant whether therapies are categorized as traditional or complementary or alternative, but they should be effective, safe, and available to those who need them.

Essential concepts in reprocessing of endoscopes and accessories, 2868
Compliance with recommendations for endoscope reprocessing, 2870
Future trends, 2870
Summary, 2871

The risks of gastrointestinal endoscopy are generally discussed in terms of those directly related to the procedure (e.g., oversedation, bleeding after polypectomy, and perforation of the gastrointestinal wall). However, another theoretical risk of endoscopy involves the introduction of pathogens from the endoscope or accessories into patients undergoing a procedure. Because the endoscope and accessories often come into contact with potentially infectious fluids (e.g., blood) from one patient, and then are reused in subsequent patients, pathogens could be passed from patient to patient if not completely removed after each use. Nonpathogenic organisms could theoretically be transmitted to immunocompromised hosts by the same mechanism. Another potential mechanism whereby infection could be introduced via endoscopy is colonization of the endoscope or accessories by organisms in the environment after proper reprocessing, with introduction of these organisms into a subsequent patient. Although apparently rare, clinically significant infections have been documented in the literature by each of these scenarios. In most cases, a breakdown in accepted practices of endoscope and accessory reprocessing can be identified.

Endoscope and accessory reprocessing involves a series of steps that result in the generation of a patient-ready system: a system free of any organisms that might pose a risk of infection to the subsequent patient undergoing endoscopy. In keeping with the concept of universal precautions, each patient is assumed to be potentially infected with a pathogen.

Transmission of infection through endoscopy

The risk of transmission of infection from patient to patient via endoscopes and accessories appears to be quite small. An American Society for Gastrointestinal Endoscopy (ASGE) review identified 28 cases of transmission of infection via endoscopy since the implementation of standard guidelines for endoscope reprocessing. In each case the reviewers felt that some breach in endoscope reprocessing techniques occurred (although this may not be true because some cases apparently occurred in the face of accepted reprocessing techniques). They estimated that the risk of infection from endoscopy was approximately 1 in 1.8 million [1]. This estimate may be understated, in view of the many reports of infection cited in the following sections.

Hepatitis virus

Transmission of hepatitis C virus (HCV) from a carrier undergoing colonoscopy to two subsequent patients has been documented [2]. HCV genotyping and nucleotide sequencing established that all three patients were infected with the same isolate. Accepted reprocessing techniques were not performed between each procedure. Transmission of hepatitis B virus (HBV) from patient to patient has been reported [3]. Acute HBV infection developed 96 days after endoscopy and therapy for a bleeding ulcer. The endoscope was used immediately before to treat bleeding esophageal varices in a patient with HBV. In this case, however, the endoscope and accessories had been reprocessed carefully following accepted protocols. Serotyping of the HBV showed the same subtype in both patients. The patient with the bleeding ulcer did receive blood transfusions; nevertheless, the investigators (and subsequent reviewers [4–6]) feel that this case most likely represents transmission of HBV. Several clinical series indicate

that the likelihood of HBV transmission from patient to patient is extremely low [7–17]. In many of these series, the endoscope and accessories were not reprocessed following currently accepted protocols, yet no infection in subsequent patients was evident. Transmission of hepatitis virus from patient to patient via endoscopy, although possible, is exceedingly rare.

Human immunodeficiency virus

Transmission of HIV as a result of gastrointestinal endoscopy or bronchoscopy has not been reported, but the virus can be recovered from these instruments after procedures in infected patients. Sampling of the suction and the air/water channels immediately after use in patients with HIV infection revealed HIV-specific DNA by polymerase chain reaction (PCR) in 7 of 20 endoscopes [18]. In a similar study, all seven bronchoscopes tested were positive for HIV-specific DNA [19]. HIV was readily eradicated from all contaminated endoscopes and bronchoscopes using standard reprocessing techniques.

Salmonella species

Numerous reports implicate endoscopy in transmission of *Salmonella* infections [20–27]. A group of patients developed infection with *Salmonella* serotype Newport after undergoing colonoscopy subsequent to this procedure being done in a patient with acute infection [20]. Organisms identical to those recovered from the index case were identified in 8 of 48 patients who had procedures before the transmission was recognized. The apparent source of infection was not a colonoscope but the spring from a biopsy forceps. In all these series, the technique of endoscope reprocessing was less rigorous than currently recommended.

Pseudomonas aeruginosa

Pseudomonas aeruginosa is a ubiquitous organism. It can be found in tap water and can quickly colonize any damp area, including the channel of a reprocessed endoscope, water bottle, or endoscopic automated reprocessor. *Pseudomonas* species have even been identified as contaminants within hospital disinfectants, including chlorhexidine [28]. Therefore, although the cases mentioned so far involved transmission of organisms from patient to patient via a contaminated endoscope, pseudomonal infections involve the introduction of this organism from the environment into a patient.

In one clinical series seven patients had *P. aeruginosa* bacteremia after endoscopic retrograde cholangiopancreatography (ERCP) in a 1-year period, with one death related to the infection [29]. In each case the infected patient was the first case of the day in which that duodenoscope was used. In six of the seven cases, the endoscope had been reprocessed more than 48 h prior to the endoscopy. Cultures from these endoscopes after prolonged storage were positive for *P. aeruginosa*, *Escherichia coli*, and *Serratia marcescens*. Similar culture results were obtained from other devices in the endoscopy suite, including wash basins, water irrigation bottles, and irrigation syringes. Infection control measures, including alcohol flushing of endoscope channels after reprocessing prior to compressed air drying to eliminate moisture that would serve as the medium for bacterial growth, resulted in elimination of further cases. The endoscope has been identified as the source of infection in several other series as well [30–40]. Patients may become infected even when the pancreatobiliary tree is normal at the time of ERCP [35].

There may be sources of *P. aeruginosa* infection other than the operating channel of an endoscope. Struelens and colleagues noted an increase in post-ERCP bacteremia after the implementation of automated reprocessors in the endoscopy suite [41]. *Citrobacter* and *Pseudomonas* species were among the organisms identified in patients and cultured from duodenoscopes, and the reprocessor also showed evidence of bacterial contamination. Additional steps, including alcohol and air flush of the duodenoscope channels after reprocessing, and disinfection of the automated reprocessor, remedied the situation. Although the literature on transmission of *P. aeruginosa* involves primarily duodenoscopes, other endoscopes may be similarly colonized. Alvarado and colleagues noted a significant increase in the colonization rate of upper gastrointestinal endoscopes with *P. aeruginosa* after reprocessing in a recently purchased endoscopic automated reprocessor [42]. When endoscopes that had been manually reprocessed were tested, none were found to be contaminated with *P. aeruginosa*. Certain areas of the endoscopic automated reprocessors, including the water inlet hose and air vents, were not accessible to the disinfectant solution and served as a reservoir for the organism. This design flaw in the original endoscope automated reprocessor has been corrected. The problem was corrected in the endoscopy suite by implementation of additional steps to the disinfection process, including rinsing of endoscope surfaces and channels with 70% isopropyl alcohol after machine disinfection, then drying with forced air for 10–20 min [43].

Serratia marcescens

Serratia marcescens has been reported as an infectious complication of ERCP, sclerotherapy, and bronchoscopy. Two consecutive patients developed complications of ERCP related to the organism: acute hemorrhagic pancreatitis (patient died) and acute cholecystitis [44]. Cultures from the duodenoscope biopsy channel and intraoperative cultures for both patients grew *S. marcescens*. A case of with *S. marcescens* mediastinitis and empyema after variceal sclerotherapy was reported, although the organism was not recovered from the endoscope or endoscopy suite [45]. Transmission was also reported via bronchoscopy to six patients after the instrument had been used on a patient with *S. marcescens* pulmonary infection [46]. The organism was recovered from the bronchoscope on subsequent testing. Prior to this episode, the disinfection process

involved only mechanical cleaning, suctioning water and alcohol through the operating channel, wiping the scope with alcohol, and drying the operating channel by aspirating ambient air. After the consecutive infections were identified, Betadine was added to the operating channel cleaning regimen, and gas sterilization was performed. These additional steps eliminated the organism.

Helicobacter pylori

There are multiple clinical series documenting patient-to-patient transmission of *Helicobacter pylori.* In 1979, a group of volunteers undergoing studies of gastric acid secretion developed rapid hypochlorhydria [47]. Endoscopic biopsy revealed histological gastritis. Although no organism was recovered, the investigators suspected an infectious etiology. A similar report noted gastritis and hypochlorhydria in four of six volunteers undergoing gastric acid analysis for a clinical study [48]. Contaminated pH probes rather than endoscopes were the source of infection in these series, emphasizing that proper disinfection must be performed on all gastrointestinal devices (e.g., manometry catheters, pH probes). Gastritis with *H. pylori* developed in an individual with normal baseline histology who underwent serial gastric analysis and endoscopy as part of a research protocol [49]. Presumably the endoscopic procedure was the source of the infection, although no information is offered as to whether the source was the endoscope, the biopsy forceps, or other unidentified agent.

A retrospective review of patient-to-patient endoscopic transmission of *H. pylori* (with restriction enzyme analysis of bacterial DNA) suggested the rate of transmission due to endoscopy and biopsy was 1.1% over 3 years [50]. The method of endoscope disinfection involved mechanical cleaning, a 30-min wash with 2% glutaraldehyde, sterile water rinse, and hot air dry. Biopsy forceps were not always sterilized between use, but sometimes "cleaned and disinfected." All the patients infected with *H. pylori* in the series underwent mucosal biopsy, raising the possibility that the forceps was the source of infection. In a study of nine patients with recurrent infection after *H. pylori* eradication, two had recurrent infection introduced via endoscopy [51]. The investigators reported that "improved" reprocessing techniques eliminated further transmission. The source of transmission (endoscopy, forceps) was not specified.

Mycobacterium species

The contamination of a flexible endoscope with *Mycobacterium* organisms has been regarded primarily as a problem for bronchoscopists, not gastrointestinal endoscopists. However, with the possibility of transmission of atypical mycobacteria to immunocompromised hosts, a review of this literature is relevant to gastrointestinal endoscopists.

Early reports describe patient-to-patient transmission of *Mycobacterium tuberculosis* via bronchoscopy when disinfection was performed using an iodophor, a chemical disinfectant currently felt to be inadequate for endoscope reprocessing [52,53]. However, use of a bronchoscope colonized with *M. tuberculosis* does not necessarily lead to cross-infection. In one series 19 patients had bronchoscopy using a bronchoscope colonized with *M. tuberculosis*. None of the patients developed symptoms or signs of tuberculosis or positive skin tests.

Continual colonization of bronchoscopes with *Mycobacterium chelonae* led to clinically significant respiratory infection in two immunocompromised patients [54]. Glutaraldehyde disinfection of the bronchoscopes did not remedy the problem, nor did ethylene oxide sterilization. When the bronchoscopes were sent for structural analysis, punctures of the operating channels were found, with gross contamination of proteinaceous material within. The bronchoscopes were still functional despite these internal defects. Clinical experience such as this is the basis for current recommendations regarding leak testing of flexible endoscopes with each use.

Mycobacterium tuberculosis and *M. avium* were transmitted via contaminated bronchoscopes, despite use of a rigorous reprocessing protocol involving mechanical cleaning and 2% glutaraldehyde [55]. The endoscope channels were not the source of contamination, but persistent mycobacterial contamination was present on the suction valve. This contamination could not be eradicated with glutaraldehyde, but was eradicated with steam autoclaving. Persistent colonization of endoscopes and bronchoscopes with *M. chelonae* has also been linked to persistent colonization within an automated reprocessor [56]. Attempts to disinfect the reprocessor were not successful because of the formation of biofilm within a portion of the reprocessor. Addition of 70% alcohol rinsing to the endoscopes after reprocessing eliminated the problem. A similar case of *M. abscessus* transmission was traced to persistent colonization of an automated reprocessor [57].

Other organisms

Other microorganisms that have been reported to be transmitted via endoscopy or bronchoscopy include *Listeria*, *Strongyloides*, *Rhodotorula*, *Trichosporon*, *Enterobacter*, and *Citrobacter* [5,38,58–61].

Sterilization and levels of disinfection

The Association for Professionals in Infection Control and Epidemiology (APIC) has proposed definitions helpful in a discussion of endoscope reprocessing (Table 116.1) [62]. Varying levels of disinfection and sterilization may be achieved when reprocessing an endoscope and accessories. In fact, the same agent may achieve sterilization or high-level disinfection of an endoscope depending on factors such as the exposure time and the degree to which debris and organic material were removed prior to exposure to the agent. It is reasonable therefore to ask if an endoscope and accessories

Table 116.1 Definitions in endoscope reprocessing

Sterilization
Complete elimination of all forms of microbial life

Disinfection
Elimination of most or all pathogenic organisms
- High level: all microorganisms except high levels of bacterial spores are destroyed
- Intermediate level: eliminates most microorganisms, except some viruses, fungi, and bacterial spores
- Low level: eliminates most bacteria, but not more resistant organisms such as mycobacteria and spores

Cleaning
Removal of foreign material (e.g., blood, tissue) from the endoscope and accessories; includes wiping, brushing channels, enzymatic detergents, ultrasonic cleaners

should be sterilized between each use, or if a lower standard, such as high-level disinfection, is acceptable.

In 1968, Spaulding proposed a classification scheme that has been accepted and retained (with minor modifications) by experts in infection control, including the APIC [63]. A device that enters sterile tissue or the vascular system is called a critical device, and must be sterilized prior to use. Noncritical devices involve contact with intact skin, and intermediate or low-level disinfection is acceptable. A device that comes into contact with mucous membranes, but not sterile tissue or the vascular system, is called semicritical, and high-level disinfection is deemed sufficient for these items. However, this produces somewhat of a double standard for endoscopy. In many cases, endoscopes simply contact mucosal surfaces, fitting the Spaulding classification scheme nicely. However, a biopsy forceps, sclerotherapy needle, or papillotome may come in contact with the vascular system. Because these devices are passed through the operating channel of the endoscope, should the endoscope be considered a critical device? Although there is no simple answer to this question, most experts in infection control, including APIC, have recommended high-level disinfection for the endoscope, but sterilization of accessories that come into direct contact with the vascular system [6].

Problems specific to the endoscope and the endoscopy unit

The endoscope is a complex structure, with multiple channels and interior surfaces in its internal construction. Areas that cannot be accessed with a cleaning device or disinfectant/sterilant cannot be reprocessed reliably. The operating channel of the endoscope is accessible to a cleaning brush, and manual cleaning of this channel is essential in endoscope reprocessing. The operating channel may become damaged, forming a nidus of persistent colonization. This damage may not be recognizable to the operator because the endoscope may perform normally until the damage is advanced and fluid invasion of the system causes overt malfunction. The air/water channel of the endoscope is smaller and in many endoscopes cannot be brushed manually; forcing air through the channel after the procedure and use of liquid or gas disinfectants/sterilants that can insinuate themselves into these small areas are used to disinfect the air/water channel of the endoscope. The newer, totally immersible endoscopes lend themselves to this aspect of reprocessing. Some newer endoscopes do allow for mechanical cleaning of the air/water channel.

Another aspect of disinfection is the time allotted for the process. Most endoscopy suites have a limited number of endoscopes available and therefore require reasonable turnaround times. A highly effective technique for sterilizing or providing high-level disinfection that requires several hours is not practical and cannot be implemented in most endoscopy suites.

Organisms and their resistance to chemical disinfectants and sterilants

Organisms are not equal in their resistance to destruction by chemical disinfectants or sterilants. Among the most susceptible are viruses such as HBV and HIV. These viruses are readily inactivated (i.e., rendered unable to cause infection if injected into a susceptible host) by a number of chemical disinfectants and sterilants [62]. Among the agents effective in HBV inactivation are glutaraldehyde at 1% and 0.1% concentrations (5-min exposure), 80% ethyl alcohol (2-min exposure), and 98°C heat for 2 min [64]. Hanson and colleagues reported that 2% glutaraldehyde was effective in inactivating HIV in serum within 2 min, but 1% glutaraldehyde was ineffective after 15 min of exposure, and 70% ethanol did not inactivate the virus after a 10-min exposure [65]. Resnick and colleagues reported that HIV was rendered noninfective with exposure to solutions of 0.5% sodium hypochlorite (1 min), 70% alcohol (1 min), and 0.08% quaternary ammonium chloride (10 min) [66]. Van Bueren and colleagues also found inactivation of cell-free and cell-associated HIV with 10-min exposure to 70% alcohol [67].

In general, the bacteria that may lead to cholangitis or other infections from endoscopy, including *P. aeruginosa*, *S. marcescens*, and *Salmonella* species, are also destroyed by common disinfectants and sterilants [62]. There is a report of isolation of a strain of *P. aeruginosa* resistant to disinfection by gluteraldehyde [68]. Small viruses, including poliovirus and hepatitis A virus (HAV), may be more difficult to inactivate. Chemical disinfectants, including 70% ethanol, 3% and 6% hydrogen peroxide, and dilute aldehydes, are only variably effective against poliovirus [69]. Solutions of 2% glutaraldehyde and high-concentration hypochlorite are necessary to inactivate the virus reliably. Only 0.5% sodium hypochlorite, 0.3% organochlorine, 2% glutaraldehyde, and modified quaternary ammonium compounds effectively inactivated coxsackievirus, adenovirus, parainfluenza virus, and coronavirus [70]. Only 2% glutaraldehyde, quaternary ammonium compounds with high concentrations of HCl, and sodium hypochlorite were effective in HAV inactivation [71]. Among the less efficacious compounds were iodines, alcohols, acetic acids and peracetic acids, and hydrogen peroxide. Peracetic acid and 2% glutaraldehyde are among the chemical sterilants able to inactivate human rotavirus [72]. Among the less efficacious agents were 70% ethyl alcohol and sodium hypochlorite. Protozoan species are also relatively more resistant to destruction. Campbell and colleagues found that *Cryptosporidium* oocysts were resistant to many common disinfectants but were inactivated by some agents, including formol saline and ammonia compounds [73]. The commonly used agents in reprocessing endoscopes were not tested in this series.

Among the most resistant microorganisms are mycobacteria and bacterial spores. Several agents, including quaternary ammonium compounds, dilute sodium hypochlorite, 70% ethanol, povidone iodine, iodophors, and chlorhexidine, are ineffective against *M. tuberculosis*; more concentrated sodium hypochlorite, and 2% glutaraldehyde, are effective [74]. Contact times are important: 2% glutaraldehyde did not destroy the organism in 1 min but did in 10–30 min. A study with spores of *Bacillus subtilis* and *Cryptosporidium sporogenes* found that 6% hydrogen peroxide solution was extremely effective against the spores, while 2% glutaraldehyde solutions reduced the number of viable spores but did not completely eradicate all spores, even with prolonged exposure times [75]. Glutaraldehyde, peracetic acid, and 10% hydrogen peroxide were the most effective agents in a study of *B. subtilis* spores, but none totally eradicated all spores [76]. Some mycobacterial species have been reported to be resistant to even prolonged exposure to glutaraldehyde solutions [77].

Common chemical disinfectants and sterilants

A large number of chemical disinfectants and sterilants may be used in hospitals or endoscopy suites. Several factors determine the suitability of a given agent for endoscope reprocessing:

- the agent must be effective against a broad range of viruses, fungi, and bacteria, including mycobacteria
- the time of exposure necessary for this activity must not be prohibitively long
- the agent must not damage the endoscope or accessories
- the agent should not be toxic to staff or patients
- the cost must not be prohibitively high.

Gas sterilization of endoscopes has long been established as an effective method. Ujeyl and colleagues found that only a 20-min exposure rendered endoscopes free of microorganisms with no apparent damage [78]. Alfa and colleagues raised concerns about the ability of sterilizers to completely eradicate organisms from the narrow lumens of endoscope channels. Multiple bacteria, including *P. aeruginosa*, mycobacteria, and bacterial spores, were inoculated into plastic tubing 3.2 mm in diameter and sterilized with several agents, including ethylene oxide. None of the tested methods completely sterilized the narrow lumen when serum and salt were also present [79]. This result emphasizes the need for mechanical cleaning prior to disinfection and sterilization with any gas or chemical.

One commonly used agent is glutaraldehyde. In the exposure time typical for endoscopy suites, it is an effective high-level disinfectant. If allowed sufficiently long contact times, sterilization is possible. Effective killing of bacteria, tubercle bacilli, and viruses occurs within 10 min, and vegetative spores in less than 3 h [80]. Kovacs and colleagues found that 2% glutaraldehyde achieved high-level disinfection from *M. chelonae* in endoscopes with only a 10-min exposure, but only if mechanical cleaning and alcohol rinsing were also performed [81]. However, not all clinical series support effective killing of mycobacteria within 10 min. In one study, the length of exposure with 2% alkaline glutaraldehyde required to achieve 99% eradication of all mycobacterial species ranged from 10 to 40 min (10 min for *M. tuberculosis*) [82]. These data have led to differing recommendations for the exposure time necessary for 2% glutaraldehyde to achieve high-level disinfection. The US Food and Drug Administration (FDA) had required labeling of Cidex (2% glutaraldehyde; Johnson & Johnson) as effective as a high-level disinfectant only after a 45-min exposure at 25°C [83]. However, Rutala and Weber [83] and prior APIC guidelines [6] argued that this amount of exposure time was only necessary if no mechanical cleaning of the endoscope had occurred prior to glutaraldehyde treatment, and that exposure times of 20 min or more were sufficient to achieve high-level disinfection if mechanical cleaning was performed. Guidelines of several professional societies support a 20-min exposure time for high-level disinfection [84,85], as do the most recent APIC guidelines for infection prevention and control in flexible endoscopy [86]. Testing of endoscopes contaminated with *Enterococcus* or *H. pylori* confirm these recommendations [87,88].

Rhinitis, dermatitis, nausea, headache, and respiratory difficulties are among the reported adverse effects on staff of

glutaraldehyde exposure [89–93]. Epidemiological studies have suggested that spontaneous abortions are higher among staff performing sterilization with ethylene oxide but not glutaraldehyde [94]. Adequate ventilation is necessary in areas where this agent is handled, staff should wear appropriate protective equipment, and the atmosphere should be periodically tested to ensure that concentrations are within appropriate parameters.

Glutaraldehyde has been linked to episodes of colitis in patients undergoing endoscopy. In one series [95], six patients experienced low-grade fever, tenesmus, and bloody diarrhea, with symptoms lasting approximately 5 days. It was felt that the colitis was due to a gradual build-up of glutaraldehyde in the post-reprocessing rinse water, and failure of the staff to use forced air to dry the channels after reprocessing. In a similar outbreak most of the cases were in patients whose sigmoidoscope was reprocessed by a new staff member who did not flush residual glutaraldehyde from the endoscope channels after reprocessing [96].

Ortho-phthalaldehyde is a high-level disinfectant whose use decreases the time of endoscope reprocessing compared with glutaraldehyde (at least 12-min manual soak, at least 5 min in automated reprocessor). In contrast to glutaraldehyde, there appear to be no issues with odor or air handling.

Peracetic acid is an effective chemical sterilant, active against all organisms, including bacterial spores [97,98]. Bradley and colleagues evaluated the Steris System 1 Processor (0.2% peracetic acid) in the reprocessing of endoscopes contaminated with vegetative bacteria and spores. All bacteria were killed within 1 min and spores within 5 min [97]. The investigators noted that the cost per cycle was higher than for reprocessing with glutaraldehyde. Whitbourne and Preston confirmed the efficacy of the Steris process on 10 medical devices contaminated with high titers of bacterial spores (approximately 10^7 colony-forming units/mL) [99]. The process involves exposure of the medical device to the peracetic acid for 12 min, followed by several automatic rinses with water sterilized by passage through a membrane filter, for a total cycle time of approximately 25 min. Fuselier and Mason reprocessed cystoscopes for 1 year using the Steris System 1 processor, and then used the Voluntary Hospital Association Plus Glutaraldehyde HLD system the next year. They reported no "clinical differences" between the two systems, but no microbiological data were presented. Yearly operating costs for the Steris processor totaled $6037, compared with $445 for the HLD system [100].

Hydrogen peroxide is another agent active against a wide range of microorganisms. Vesley and colleagues tested the efficacy of 2% glutaraldehyde, 6% hydrogen peroxide, and ethylene oxide in endoscopes contaminated with *Pseudomonas* or *Bacillus* species [101]. Ethylene oxide was the most effective agent overall. Hydrogen peroxide was more effective than 2% glutaraldehyde against the *Bacillus* organisms. However, the exposure times for these liquid chemicals was only 10 min, not the minimum 20 min recommended by APIC for glutaraldehyde. As with glutaraldehyde, hydrogen peroxide may cause iatrogenic colitis [102].

Other FDA-cleared sterilants and high-level disinfectants include various concentrations or combinations of the above-mentioned agents, as well as hypochlorite and hypochlorous acid 650–675 ppm and active free chlorine, and glutaraldehyde in combination with phenol/phenate or isopropanol.

Essential concepts in reprocessing of endoscopes and accessories

The overriding principle in endoscope reprocessing is that each patient must be assumed to potentially possess an infectious agent that could be passed via the endoscope to a subsequent patient. It is inappropriate for an endoscopy unit to reserve an endoscope or set of endoscopes for patients identified with some known pathogen. Rather, processes must be in place where all endoscopes are reprocessed in such a way that all potential pathogens are eliminated.

Several professional societies, including the APIC, the Society of Gastroenterology Nurses and Associates (SGNA), and the ASGE have published guidelines for proper reprocessing of endoscopes and accessories [84–86]. Essential aspects of these guidelines are presented below and summarized in Table 116.2. These are not intended to be a substitute for the step-by-step detail presented in the guidelines.

Table 116.2 Some essential concepts in the reprocessing of endoscopes and accessories

Inspection for damage should be performed after each case. Leakage testing may identify internal damage not apparent from endoscope performance
Mechanical cleaning prior to exposure to the disinfectant/sterilant is essential
High-level disinfection is the current standard for endoscope reprocessing
Endoscopic accessories that may contact the vascular system must be sterilized if reused; mechanical cleaning alone or high-level disinfection is inadequate
Channels must be adequately dried after high-level disinfection to prevent colonization with microorganisms
Duration of use and monitoring of effective concentration for high-level disinfectants/sterilants must follow manufacturer's recommendations
Continuous quality improvement is essential for each endoscopy unit

Inspection for damage

Leaks, tears, and other disruptions to the external or internal integrity of the endoscope may be a nidus of continual colonization by microorganisms [54]. Internal damage to the endoscope may not be apparent to the endoscopist until it is far advanced because the endoscope may still perform well. The endoscope must be carefully inspected prior to reprocessing. Leak testing may detect internal structural damage at an early stage.

Mechanical cleaning

Removal of organic material prior to exposure to chemical disinfectants or sterilants is the most important step in endoscope reprocessing. Scrupulous cleaning of external surfaces, use of enzymatic detergents on external surfaces and internal channels, passing a brush through the operating channel, brushing or forcing air through the more narrow air/water channel, and manual or ultrasonic cleaning of detachable parts of the endoscope are all part of this process. Special attention must be given to difficult-to-access portions of the endoscope, such as elevators and elevator channels of the duodenoscope. The elevator should be mechanically cleaned and the channel flushed.

Removal of organic and foreign material is necessary to achieve high-level disinfection. Alfa and colleagues studied the suction channels of 10 bronchoscopes, duodenoscopes, and colonoscopes immediately after procedures. They identified multiple compounds and organisms, including protein, hemoglobin, carbohydrate, endotoxins, and bacteria. Mechanical cleaning eliminated a good deal of this material, but protein and some bacteria remained [103]. Lewis and Arens noted persistence of HIV and vegetative bacteria after high-level disinfection of dental devices when the organism was entrapped in commonly used lubricants [104]. The necessary exposure time of the liquid chemical sterilants to achieve high-level disinfection is decreased by prior mechanical cleaning.

Mechanical cleaning of the endoscope, without exposure to chemical sterilant, eliminated microorganisms in one study from 66 of 68 sites tested [18]. Other studies document the efficacy of mechanical cleaning in inactivation of HBV [105], HCV [106], *H pylori* [107–110], Gram-negative bacteria [111], and *Clostridium difficile*. Thorough mechanical disinfection plus use of an approved chemical disinfectant/sterilant is highly effective in eliminating bacteria and viruses from endoscopes, but is not effective when mechanical cleaning is ineffective [113].

Use of a recommended disinfectant or sterilant for high-level disinfection

Manual high-level disinfection may still be performed but, with the advent of totally submersible endoscopes, automated reprocessors have become more common. These machines lessen the amount of time staff members must devote to the overall process, and lessen exposure to glutaraldehyde, if this is the agent of choice. Vesley and colleagues showed that automated reprocessors were more effective than manual high-level disinfection in killing *B. subtilis* [101]. However, Fraser and colleagues found no difference in overall endoscope contamination rates when endoscopes disinfected manually were compared with those disinfected in automated reprocessors [114]. Automated reprocessors do have potential drawbacks. Persistent infection of the endoscope reprocessor with resultant contamination of the endoscope has been documented [42]. The endoscope must be properly positioned within the machine, with all adapters and covers correctly placed. Furthermore, with endoscopic automated reprocessors using glutaraldehyde, the effective concentration of the disinfectant will decrease with repeated use [115]. Dilute glutaraldehyde is less effective in its action against microorganisms [116,117]. A test strip or other device must be used at least daily to monitor the concentration of the liquid disinfectant, possibly more frequently depending on procedure volume. Solutions must be changed in accordance with the manufacturer's recommendations. *o*-Phthalaldehyde appears to be stable for up to 14 days of use; just as with glutaraldehyde, test strips to monitor concentration should be used routinely [118]. Again, solutions must be changed in accordance with the manufacturer's recommendations. For all high-level disinfectant/sterilant agents, the duration of use and monitoring of effective concentration should follow the manufacturer's recommendations.

Rinsing and drying

The chemical disinfectant or sterilant must be rinsed from the internal and external surfaces of the endoscope. If tap water (which may be colonized with microorganisms) is used, a rinse with 70% alcohol should be performed. Drying with compressed air (or drying cycles on some automated washers) will also decrease the likelihood of residual moisture, which can be a source of colonization. Drying of endoscopes prior to prolonged storage significantly decreases the rate of bacterial colonization [119], and forced air drying adds effectiveness to the disinfection process [120]. Alcohol rinse prior to prolonged storage may also decrease the likelihood of colonization. Endoscopes should be stored with the insertion tubes uncoiled, and in a well-ventilated cabinet to facilitate continued air drying, and with valves and buttons removed.

Reprocessing of endoscopic accessories

Because biopsy forceps and other accessories may come into contact with the vascular system, these items should be sterile prior to each use. Both disposable (single use) and reusable forceps are commercially available. Improperly reprocessed biopsy forceps may be the source of transmission of infection. Single-use disposable forceps do not expose patients to this risk. Two recent trials support the use of disposable over reusable forceps in terms of cost and function [121,122].

Most accessories for therapeutic ERCP, including papillotomes, guidewires, and extraction balloons, are labeled as single-use items. These items incur a significant cost for the endoscopy suite and are not entirely compensated by technical room reimbursements [123]. Reusable papillotomes are available. These devices function well after multiple uses and sterilizations, but cost more than single-use papillotomes [124,125]. The cost associated with endoscopic accessories has led some centers to reprocess items labeled as single use. Kozarek and colleagues found that the majority of single-use papillotomes performed well with multiple uses and sterilizations. No organisms were recovered from the devices after manual cleaning followed by ethylene oxide sterilization [126]. In a follow-up study, this group found that the "single-use" papillotomes could be used an average of 3.4 times, and such reuse saved approximately $66 000 in 1 year for their practice. No infectious complications were attributed to the reuse [127]. This group has also studied the reuse of other single-use items such as argon plasma coagulation probes, and assert that sterilization could be achieved and up to 10 uses from a single probe obtained [128]. In a 1995 survey of hospitals in Australia, 58% were reusing at least some medical devices labeled as single use [129], and a more recent survey documented reuse is common in the Asia–Pacific region [130]. There are no data to indicate how common this practice is in the USA. A recent APIC guideline states only that this practice is "controversial," and that implementation of such a program "requires a major institutional commitment, including a monitoring committee with clearly defined protocols" [86].

Continuous quality improvement

Proper reprocessing of endoscopes and accessories requires an organized plan, motivated and educated staff, and a continuous quality improvement process that monitors each step of the process. Breakdowns in reprocessing techniques can lead to clinically significant infections, and even death. The process can fail due to technical or human error. Staff and processes must be assessed and improved continually. Each unit should develop its own plan and should generate data on factors including competence of staff and results of random cultures from endoscopes, reprocessors, and accessory equipment.

Compliance with recommendations for endoscope reprocessing

One concern about endoscope reprocessing is the complexity of the process and the potential that some steps might be omitted or performed inadequately in a busy endoscopic practice. Several investigators have examined the actual practice of endoscope reprocessing, either with surveys or site visits. A 1988 survey of 74 endoscopy suites in western Europe revealed that once a procedure was completed in a patient with no known infectious disease, high-level disinfection was not performed after upper endoscopy in any center, in only 13% of centers after colonoscopy, and in only 30% of centers after ERCP [131]. In a 1989 survey only 45% of Australian hospitals responding followed a process for high-level disinfection after each case [132]. Two years later, a repeat survey indicated that high-level disinfection was satisfactorily performed by 75% of respondents [133]. A 1991 survey in 107 endoscopy units in North Carolina found that glutaraldehyde was the chemical disinfectant used in 91% of units. Only 51% exposed the endoscope to glutaraldehyde for at least 20 min (a 10-min cycle was used in most other centers), and 54% rinsed with only tap water (not sterile water or alcohol after tap water) after disinfection [134]. A US survey of SGNA members and nonmembers with an interest in endoscope reprocessing found that 93% performed chemical disinfection after each case; glutaraldehyde was the disinfectant used in 88% of respondents' practices [135].

A more sobering report came from Kaczmarek and colleagues, who directly studied endoscopic reprocessing practices in 26 endoscopy suites: 24% of endoscopes cultured after high-level disinfection were positive for bacterial growth. A lack of sterilization of all biopsy forceps was observed in 78% of units. Several other basic errors in the disinfection process were observed [136]. Variability was also observed in 18 endoscopy areas in eight Massachusetts hospitals; however, high-level disinfection was practiced in 17 of 18 endoscopy areas. Glutaraldehyde soak times varied from 10 to 45 min, and not all areas performed sterilization of biopsy forceps [137]. In a more recent survey, a significant minority of US centers did not completely conform to established society guidelines for reprocessing [138]. In a 1996 survey of 20 Japanese endoscopy suites, endoscopes in all centers were used in consecutive patients with mechanical cleaning but no high-level disinfection [139].

Future trends

Proper reprocessing of endoscopes demands time and careful attention, is not foolproof, and is associated with significant cost. Therefore, the concept of a sheathed or disposable endoscopic system is very attractive. A new endoscopic system in which the working surfaces are covered with a disposable sheath has been assessed in clinical trials [140,141]. In a prospective trial, the length of time required to perform endoscopy was slightly longer than with the conventional endoscope, while set-up and reprocessing times were far shorter [142]. Recent reports indicate promise for new techniques of endoscope reprocessing using super-oxidized or acidic electrolytic water [143–146]. A complete list of FDA-cleared sterilants and disinfectants, along with their specific attributes, can be found at the FDA website [147].

Summary

Introduction of infection into patients undergoing endoscopy is rare but may occur. Infection may be due to patient-to-patient transmission or from introduction of microorganisms from the environment into patients. Potential sources of infection include the endoscope, accessories, and automated reprocessors. High-level disinfection is recommended for reprocessing endoscopes, but sterilization is indicated for accessories that may come into contact with the vascular system. The process of high-level disinfection requires close attention to multiple steps. Several clinical series have demonstrated breakdowns in this process, with resultant morbidity and mortality. A continuous quality improvement system is essential for each endoscopy center.

Medication regimens, 2876
Procedural monitoring, 2880
Postprocedure monitoring, 2881
Complications of sedation and their management, 2881
Training for use of sedatives, 2882

Introduction

Sedation and analgesia improves patient tolerance to endoscopic procedures by alleviating anxiety and pain [1]. Adequate and comfortable sedation improves the public reputation of endoscopy, enhances adherence with colonoscopic screening, and increases the likelihood of patients returning for follow-up examinations [2]. Sedation prevents or blunts potentially harmful autonomic stress responses, e.g., hypertension and tachycardia [3,4], although some studies found that sedation did not reduce cardiac stress [5,6]. Sedation is critical to accomplish procedures in children and uncooperative adults. Patient comfort allows the endoscopist to focus on the technical performance of endoscopy.

Some patients tolerate esophagogastroduodenoscopy (EGD) and colonoscopy with little or no sedation. Tolerance of unsedated procedures is more likely with older age, lack of anxiety, male gender, absence of abdominal pain history [7–11], and higher levels of education [12]. Ultra thin endoscopes facilitate EGD without sedation [13–15]. Cultural differences in pain perception and expectations of patients and physicians produce great variation in sedation practice between countries. Very high percentages of unsedated colonoscopy have been reported from Finland [16], Turkey [17] and Northern Italy [18]. Sedation is used less in Asia and Europe compared with America [19]. However, general anesthesia with propofol is used commonly in France [20].

Sedation is associated with several cardiac and respiratory adverse events. For these reasons, it is important for endoscopists to assure effective as well as safe sedation during endoscopy. Endoscopists and their nurses, therefore, need a strong familiarity with the different levels of sedation, adverse events as well as patient resuscitation maneuvers, including reversal agents. Continuous hemodynamic monitoring, oximetry, and periodic check of the depth of sedation during the procedure are crucial.

Continuum of depth of sedation

Table 117.1 shows the levels of sedation as defined by the American Society of Anesthesiologists (ASA) [21] and Joint Commission on Accreditation of Healthcare Organizations (JCAHO) [22].

It is important to realize that sedation is a continuum and patients may slip quickly through the various stages. Continuous monitoring of depth of sedation is critical. Individuals administering moderate or deep sedation should be trained adequately to rescue patients from deep sedation and general anesthesia, respectively. A set of standards of practice specific to monitoring and sedation for gastrointestinal endoscopy by nonanesthesiologists has been issued by ASA [21] and by the American Society for Gastrointestinal Endoscopy (ASGE) [23].

Presedation preparation

Clinicians should perform a sedation-oriented history including a history of experience with previous sedation, sleep apnea, major comorbidities, drug allergies, current medications, smoking, and alcohol or substance use. A complete assessment of airway, baseline vital signs, respiratory rate and effort, and general neurological status should be done. Patients should fast for a minimum of 6 h before the procedure, though clear liquids can be consumed up to 2 h prior;

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Table 117.1 Continuum of depth of sedation

	Minimal sedation (anxiolysis)	Moderate sedation/analgesia (conscious sedation)	Deep sedation/analgesia	General anesthesia
Responsiveness	Normal response to verbal stimulation; cognition and coordination may be impaired	Depressed; purposeful response to verbal commands or light tactile stimulation	Depressed; not easily arousable; purposeful response to repeated or painful stimulation	Loss of consciousness; unarousable even by painful stimulation
Airway	Maintained	No intervention needed to maintain patent airway	Intervention may be needed to maintain patent airway	Intervention often needed to maintain patent airway
Spontaneous ventilation	Maintained	Adequate	May be inadequate	Frequently inadequate; positive pressure ventilation may be required
Cardiovascular function	Maintained	Usually maintained	Usually maintained	May be impaired

Modified from the American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-anesthesiologists, 2002 [21], with permission from Lippincott Williams & Wilkins.

this would be increased to 8 h and 4 h respectively for elderly patients [24]. In emergency situations, when fasting is not practical, either the target level of sedation should be modified or endotracheal intubation should be considered. Appropriate preprocedure counseling must be done regarding risks and benefits of, and alternatives to sedation. Intravascular access should be obtained and maintained through recovery. Routine sedation does not require the presence of an anesthesiologist, however in case of severely compromised patients or those with a difficult airway or with previous adverse reaction to sedation, such consultation may be warranted.

Medication regimens

The choice of sedatives depends on the endoscopist's preference for and familiarity with different regimens as well as the type of procedure. Brief procedures can be completed with minimal amounts of sedation in some cases, whereas therapeutic procedures may require deep sedation. For moderate sedation benzodiazepines are typically used either alone or in combination with an opiate. Propofol is an emerging agent for endoscopy. It may be used either alone for deep sedation, or it can be combined with benzodiazepines or opiates and targeted to minimal, moderate, or deep sedation. Sedatives are given intravascularly for endoscopy and must be administered slowly and titrated in small increments. Another approach is patient-controlled analgesia which allows patients to administer their own sedation [25,26]. The pharmacology of the commonly used agents is summarized in Table 117.2.

Benzodiazepines

Benzodiazepines induce relaxation, anxiolysis, and amnesia. Additional doses are given according to the desired level of sedation as well as patient tolerance. The most commonly used benzodiazepines for endoscopy are midazolam [27–29] and diazepam, both of which are comparable in efficacy [30]. Midazolam is preferred because of better efficacy and tolerability [31], shorter duration, better amnesic properties, and 2–3 times higher potency than diazepam [32]. Also, it has a decreased incidence of local pain and phlebitis compared with diazepam. It does not significantly affect the gag reflex when given in recommended doses. Midazolam crosses the placenta and also enters breast milk. Both midazolam and diazepam are pregnancy category D. However, birth defects have been associated with chronic oral use of diazepam during pregnancy [33–36]. Short-term use for endoscopic procedures during pregnancy is widely considered safe.

Benzodiazepines do not have analgesic properties and usually require coadministration of opiates for endoscopy. Dosages must be reduced in elderly or debilitated patients and in those receiving narcotics or other CNS depressants concomitantly. Underlying liver disease must also be considered as benzodiazepines are metabolized by the liver.

Adverse effects include paradoxical agitation and severe respiratory depression, which is greatly potentiated by coadministration of opioids. Inadvertent overdose can cause severe respiratory depression, hypotension, general anesthesia and apnea. Management is supportive and administration of the reversal agent flumazenil (see below).

Opiates

Meperidine and fentanyl are among the most commonly used opiates for gastrointestinal endoscopy. They have sedative as well as analgesic properties. Meperidine affects both the central and the peripheral nervous systems and its metabolites have neurotoxic potential. Renal impairment can lead to accumulation of metabolites, which may cause seizures.

Table 117.2 Pharmacology of commonly used sedatives

Sedative		Mechanism of action	Properties	Onset/peak effect	Duration of action	Side effects	Dosing
Benzodiazepines	Midazolam	Binds to benzodiazepine receptors on postsynaptic GABA neuron in CNS, including the limbic system, reticular formation and enhances the inhibitory effect of GABA on neuronal excitability	Induces sedation and amnesia. No analgesic properties	Onset 1–5 min	1–3 h	Respiratory depression (decreased tidal volume or respiratory rate); potentiated by concomitant use of opiates; respiratory arrest; apnea hypotension CNS depression; drowsiness; oversedation. Paradoxical agitation	i.v. Initial: 0.5–2 mg over 2 min; repeat doses every 2–3 min; usual total dose: 2.5–5 mg. Decrease doses in elderly and by 30% if opiates are administered concomitantly. Maintenance: 25% of dose used to reach sedative effect
	Diazepam	Same as midazolam	Less potent and amnesic than midazolam	Onset 3–10 min	2–8 h	Same as midazolam	i.v. 2.5–5 mg; incremental doses of 2.5 mg at 3–4 min intervals
Opiates	Meperidine	Binds to opiate receptors in CNS, causing inhibition of ascending pain pathways; produces generalized CNS depression	Analgesic with mild sedative properties. Slow onset and longer duration than other opioids. Used for longer procedures	Onset 1–3 min Peak 10–15 min	2–3 h	Respiratory depression, hypotension, nausea, vomiting, CNS depression	i.v. Initial: 15–50 mg; redose 25 mg at 5 min intervals as needed
	Fentanyl	Binds with receptors within CNS, increases pain threshold, alters pain reception, inhibits ascending pain pathways	Analgesic with mild sedative properties. Rapid onset and recovery; well-suited for outpatient endoscopy	Onset 30 s; peak effect 5–8 min	0.5–1 h	Respiratory depression, hypotension, bradycardia, CNS depression, nausea, vomiting	i.v. Initial: 25–100 µg; redose 25–50 µg/dose every 1–2 min as needed
Propofol		Hindered phenolic compound with i.v. general anesthetic properties	Rapid onset. Fast recovery. Smaller doses are required when used with narcotics. No analgesia, weak amnesic effect	Onset 30–60 s	3–10 min	Hypotension, apnea, injection site stinging or pain	i.v. Initial 20–40 mg slow injection. Incremental boluses of 10–20 mg every
Promethazine		Blocks postsynaptic dopaminergic receptors in the brain; alpha-adrenergic blocker; competes with histamine for the H1-receptor; reduces stimuli to the brainstem reticular system	Synergizes sedation; combats nausea	Onset 3–5 min	2–6 h	Hypertension, bradycardia, confusion, disorientation. Rapid administration may cause transient hypotension	i.v. 12.5–50 mg/dose. Infused at a maximum rate of 25 mg/min
Droperidol		Butyrophenone neuroleptic tranquilizer. Mild alpha-adrenergic inhibitory action	Exerts anti-emetic and anti-anxiety effect. Mild sedative ECG monitoring for 2–3 h after administration is suggested	Onset 3–10 min	2–4 h	Q–Tc prolongation and torsades de pointes (dose dependent). Hypotension, tachycardia, restlessness, anxiety. Extrapyramidal symptoms	i.v. Initial 2.5 mg; redose 1.25 mg to achieve desired effect; administered as a rapid IVP, over 30–60 s. Administer additional doses with caution. Maximum dose 5 mg

CNS, central nervous system; ECG, electrocardiogram; GABA, gamma-aminobutyric acid or γ-aminobutyric acid; i.v., intravenous; IVP, intravenous pyelogram; Q–Tc, Q–T interval corrected for rate (the Q–T interval is measured from the Q point to the end of the T wave on an ECG).

The dose should be reduced to 75% of normal for creatinine clearances of 10–50 mL/min and to 50% for creatinine clearances < 10 mL/min. The initial starting dose is 0.4 mg/kg; however, this should be reduced in the elderly. Titration should be done using half this dose, keeping in mind that onset of action may be 5–10 min. Fentanyl is a morphine-like compound, although much more potent. It produces profound analgesia and suppresses respiratory and cough centers. It has rapid onset and clearance and reduced incidence of nausea compared with meperidine. In high doses, it can cause chest wall rigidity and respiratory difficulty. One disadvantage of fentanyl is cumulative respiratory depression with successive doses which may result in dissociation between analgesia and respiratory depression [37]. Both meperidine and fentanyl are pregnancy category C.

All narcotics should be used cautiously in patients taking other CNS depressants. They should be avoided in patients taking monoamine oxidase inhibitors. Caution must be taken with liver disease, just as with benzodiazepines.

Propofol

Propofol is a substituted isopropyl phenol, which promotes gamma-aminobutyric acid or γ-aminobutyric acid (GABA) activity in the brain. It is a relatively new addition to sedation regimens in endoscopy. In comparison to benzodiazepines/opioids, the mean time to onset of sedation is shorter: depth of sedation is greater, with faster recovery [38] and discharge sooner. Propofol induces amnesia when titrated to deep sedation or general anesthesia [39,40]. Rapid onset of sedation and rapid recovery may improve efficiency of endoscopy units [41]. Safety and efficacy of propofol has been demonstrated for colonoscopy, EGD, EUS, and ERCP [38,42–44]. Surveys of patient satisfaction found that propofol compared with regular sedation had no significant impact on or improvement in patient satisfaction [31,42,45].

Propofol has been administered by intermittent bolus [46,47], continuous infusion [46,48], and patient-controlled analgesia [49–53]. Intermittent bolus allows faster onset of sedation and has been preferred for endoscopy [54]. Initial boluses when the drug is used as a single agent are typically 30–50 mg and are adjusted for age, weight, and comorbidities. Subsequent boluses are 10–20 mg. When used as a single agent, propofol is typically targeted to deep sedation for endoscopy. Avoidance of respiratory depression, as with most sedatives, is critically dependent on gradual titration [55,56]. Propofol, when used as a single agent for moderate sedation, often precipitates withdrawal responses with coughing occurring during upper endoscopy. Deep sedation is usually required when the drug is given alone.

Propofol has been safely administered by nonanesthesiologists for endoscopy in more than 200 000 patients without reported death and only one case requiring endotracheal intubation [57]. In a meta-analysis, propofol was less likely than narcotics and benzodiazepines to produce hypoxemia [58]. A registered nurse supervised by the endoscopist is the most common model [54,59–62]. The registered nurse must have no duties except drug administration and patient monitoring. A technician should assist the endoscopist with technical performance of the procedure. The rationale for administration by nonanesthesiologists is cost reduction. Anesthesia groups have opposed nonanesthesiologist administered propofol [63–65], citing the package insert [66,67] and safety concerns [68], but the evidence from clinical studies overwhelmingly supports the safety of nonanesthesiologist administered propofol [45,69–74].

Successful training programs for nonanesthesiologists incorporate didactic training, testing and typically 2 weeks of observation and supervised administration [69,75,76]. Nonanesthesiologists should not pursue administration of any sedative for endoscopy without appropriate training. Propofol administration by nonanesthesiologists in nonintubated patients is prohibited in 12 states by state laws or nursing practice acts [77].

Nonanesthesiologist administration of propofol as a single agent should be performed with caution in patients at increased risk of aspiration (e.g., achalasia, acute upper GI bleeding, delayed gastric emptying), increased risk of airway obstruction (e.g., sleep apnea, high risk airway assessment), and multiple comorbidities. Propofol is contraindicated with allergy to eggs or soybeans [66,67].

Coadministration of benzodiazepine or opioids enhances the sedative effect of propofol. They also block withdrawal responses and coughing and allow titration of propofol to moderate sedation [78]. Combination regimens targeted to moderate sedation would be logically expected to reduce the safety concerns of anesthesiologists. Combination therapy allows total propofol doses to be reduced by about 50% [79,80] and make propofol administration easier by prolonging the interval between doses [47,81]. Patients who are candidates are usually ASA class I to III.

The major drawback of propofol is the potential for respiratory depression, the risk of which far outweighs the risk of cardiovascular compromise [58]. Burning at the site of injection is common and lidocaine may block the effect. Monitoring patients receiving propofol is discussed below.

Antihistamines

Phenergan and diphenhydramine can be used as sedatives adjunct to opiates or benzodiazepines and to treat nausea induced by these medications. Phenergan is pregnancy category C, and diphenhydramine is B.

Droperidol

Droperidol is a neuroleptic and is used as an adjunct for complex endoscopic procedures and in patients who have paradoxical reactions to standard sedation or in whom narcotics and benzodiazepines are likely to be inadequate [82,83] (history of alcoholism, prescribed or illicit benzodiazepine or opiate

use, or prior difficulty with conscious sedation). Droperidol exerts a calming and antiemetic effect, has a mild sedative and α-adrenergic inhibitory action, and can cause prolonged postprocedure drowsiness. It does not exacerbate opioid-induced respiratory depression. Additional boluses should not be administered for agitation once the procedure has started because, by the time dosages take maximal effect, the procedure may be complete and recovery may be prolonged. Safety and efficacy have been demonstrated in several studies [84–86]. It prolongs the Q–Tc interval (Q–T interval corrected for rate) on the electrocardiogram and can induce torsades de pointes which prompted FDA to issue a black box warning. Cardiac events, some fatal, have been reported in patients without known risk factors for Q–T prolongation [87]. Droperidol is contraindicated if the Q–Tc is prolonged > 440 ms in men and > 450 ms in women. Caution must be exercised in patients with risk factors for Q–T prolongation such as congestive heart failure, bradycardia, cardiac hypertrophy, hypokalemia, hypomagnesaemia, or concomitant use of drugs that prolong Q–T interval. The heart rhythm should be monitored for 3 h after administration. Droperidol is pregnancy category C. Guidelines for its use has been suggested by ASGE [83].

Combination regimens

Combinations of benzodiazepines and opiates are often used [88] and are efficacious and well tolerated [42,45,47,49,89,90]. Combination therapy risks increased cardiorespiratory complications and the dose of each drug should be reduced. Addition of benzodiazepines to opioids enhances sedation and amnesia and addition of opioids to benzodiazepines adds analgesia. Their combination has synergistic effects. According to one study, pain experienced during colonoscopy was similar whether or not a combination was used. [91] Similar results for upper endoscopy were demonstrated in another study [92]. However, this study also showed that endoscopists preferred combinations of benzodiazepine and opiates. Ideally, each drug should be administered separately to achieve the desired effect and the dose of each should be correspondingly reduced [21]. Opiates should be administered first because of the slower onset of action of meperidine.

In situations where high doses of narcotic and benzodiazepines provide inadequate sedation, Phenergan or diphenhydramine may be used in addition to synergize sedative effects.

The combination of propofol with a benzodiazepine or an opioid enhances the sedative effects of propofol and allows propofol to be targeted to minimal or moderate sedation [78]. Propofol has variable amnesic effect, which can be improved by coadministration of a benzodiazepine. Also it has no analgesic properties, so addition of a narcotic is recommended for painful procedures targeted to moderate sedation. The quality of sedation and recovery profile were similar to those reported with standard dose propofol.

Adjuvant drugs

These drugs increase tolerance and reduce doses of sedatives required.

Pharyngeal anesthesia

Topical anesthetics subdue the gag reflex during upper endoscopy. Commonly used topical anesthetics include benzocaine, tetracaine, Cetacaine and lidocaine. They may not improve upper endoscopy in patients already getting conscious sedation [93–95]. Benzocaine has a rapid onset and short duration. One study suggested that topical anesthetics are most useful in patients undergoing EGD for the first time, who are less than 40 years of age, or who are anxious [96]. Methemoglobinemia is an important adverse effect associated with the use of topical benzocaine [97–100] as well as Cetacaine [101]. It presents with clinical cyanosis with a normal arterial Po_2 [102]. Treatment is intravenous methylene blue [2 mg/kg). Topical anesthetics may also cause an idiosyncratic anaphylactic reaction [103]. Systemic effects such as arrhythmia and seizures owing to absorption have been observed rarely [104,105]. Topical anesthetics have been implicated in the development of pneumonia after EGD [106].

Reversal agents

Reversal agents should be used when patients develop severe respiratory depression including hypoxia and decreased ventilation that does not respond to supplemental oxygen or gentle stimulation.

Flumazenil is a benzodiazepine antidote and competitively inhibits the activity at the benzodiazepine recognition site on the GABA/benzodiazepine receptor complex, resulting in reversal of central nervous system (CNS) depression without reversing the amnesia. The dosage of 0.2 mg intravenously may be repeated at 1 min intervals to a maximum dose of 3 mg. It has limited efficacy in reversing respiratory depression. For this reason, naloxone should be tried before flumazenil in patients who develop severe respiratory depression after being given a combination of opiates and benzodiazepines. Re-sedation may occur owing to the shorter half life of flumazenil compared with benzodiazepines. However, in practice this rarely is a problem unless large doses of benzodiazepines or additional agents have been used [107]. Flumazenil also may be used to treat paradoxical reactions to benzodiazepines. Flumazenil administration can precipitate acute withdrawal in patients on prolonged benzodiazepine therapy. The duration of action is 1–2 h and the drug is pregnancy category C.

Naloxone is a pure opioid antagonist that competes and displaces narcotics at opioid receptor sites. It is used to reverse sedation and respiratory depression caused by opiates and the degree and extent of reversal is dose dependent. The usual dose is 0.4–2 mg intravenously over 30 s. It may be cleared faster than meperidine, thus in patients who receive

high doses of meperidine, resedation may occur. Repeat doses may be given at 2–3-min intervals to a maximum of 10 mg. Acute withdrawal and severe pain may occur in chronic opiate users. Acute reversal may cause tachycardia, hypertension, or pulmonary edema due to release of catecholamines. Therefore, caution must be exercised in elderly patients and those with cardiovascular disease. Too rapid reversal may cause nausea, vomiting, diaphoresis and circulatory distress. The duration of action is 1–4 h and the drug is pregnancy category B.

Elective use of reversal agents for quicker recovery is not recommended at this time [21] and is only marginally supported by literature [108,109].

General anesthesia

General anesthesia may be appropriate in patients with paradoxical agitation to benzodiazepines, for difficult to sedate patients, for children [110], and for emergency therapeutic procedures that are anticipated to be long and complicated [111]. It is also an option for patients who are obtunded or have high aspiration risk, including active hematemesis.

Pregnancy and lactation

For sedation, meperidine alone is preferred with small doses of midazolam if needed. Fentanyl is preferred over meperidine for breast-feeding mothers. Breast-feeding should be delayed by at least 4 h after maternal midazolam administration and for 24 h after propofol exposure.

Procedural monitoring

Owing to the potentially dangerous cardiopulmonary complications associated with sedation, careful patient monitoring is mandatory. For moderate sedation, periodic blood pressure monitoring, continuous pulse oximetry, and pulse measurements are mandatory. For deep sedation or propofol titrated to any level of sedation, continuous electrocardiogram (EKG) is mandatory and capnography may be considered [21,76,83]. Continuous clinical monitoring of respiratory effort is essential with deep sedation. Vital signs, oxygenation and level of consciousness should be assessed before the beginning of the procedure, after administration of sedatives, at regular intervals during the procedure, during initial recovery and just before discharge. Depth of sedation is continuously monitored clinically in all patients.

Oxygen tanks, oral suction devices, oral airways, reversal agents and fully equipped code carts must be available in the endoscopy unit. Cardiac defibrillators should be immediately available for patients with cardiovascular disease undergoing moderate sedation and for all patients undergoing deep sedation. It is also recommended that an individual with advanced life support skills be within 1–5 min away for moderate sedation and within the procedure room for deep sedation.

Oximetry

Respiratory depression is a major cause of sedation associated morbidity. Hence pulse oximetry is an established standard protocol for procedural monitoring [21,112,113]. Pulse oximetry provides early warning of impending respiratory failure and hence allows intervention before clinically dangerous hypoxemia occurs. Early detection of hypoxemia decreases adverse events such as cardiopulmonary arrest and death. The pulse oximeter is a spectrophotometric device that detects and calculates the differential absorption of light by oxygenated and reduced hemoglobin to produce an estimate of oxygen saturation. Pulse oximetry does not substitute for clinical monitoring of respiratory rate and effort [114]. Supplemental oxygen has been shown to prevent or reduce desaturation when given during endoscopic procedures [115–120]. Supplemental oxygen administration will maintain normal oxygen saturations in the face of prolonged hypoventilation or apnea.

Motion may cause false alarms owing to probe dislodgement. A waveform is essential to distinguish true desaturations from motion artifact. Readings may be inaccurate with shock or vasoconstriction.

Capnography

Hypoventilation may be masked in patients who are receiving supplemental oxygen and may lead to CO_2 retention and respiratory acidosis. Capnography is the continuous measurement of inhaled and exhaled CO_2 concentration, typically displayed as a numeric value and a graphical tracing. Carbon dioxide absorbs light in the infrared region of the electromagnetic spectrum and quantification of the absorption generates a curve. Capnography provides breath-to-breath feedback and generates a respiratory rate that is measured at the airway [121] (Fig. 117.1). There is evidence that capnography may detect ventilatory compromise that would otherwise not be detected by routine monitoring [122]. It is superior to oximetry for evaluation of ventilation [123,124] and it accurately detects apnea [125]. It may be considered in all patients receiving deep sedation (or moderate sedation involving propofol) and for those receiving moderate sedation if the procedure is long, the patient is older or with comorbidities or if adequate observation of ventilatory effort cannot be ensured [126]. However, there is no evidence that routine use of capnography improves outcomes in patients undergoing sedation with propofol.

Bispectral monitoring

Bispectral monitoring (BIS) assesses brain activity and expresses it as a value on a linear scale from 100 (fully awake) to 0 (no cortical activity). Values below 60 correlate with general anesthesia. When used for benzodiazepine or opiate sedation, BIS values have been shown to track the sedative effect (parallel to OAA/S) and correlate with patient recovery and endoscopist satisfaction [127–129]. During

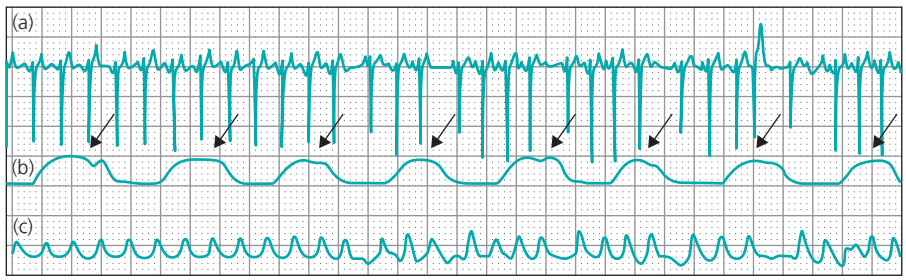

Figure 117.1 A baseline recording of the electrocardiogram **(tracing a)**, respiratory activity with capnography **(tracing b)** and pulse oximetry curve, which corresponds to the arterial pressure waveform **(tracing c)**, in a patient before receiving propofol. **Tracing b** is a normal capnography curve demonstrating a stable respiratory pattern. The peaks of the curve (arrows) represent the carbon dioxide tension at end exhalation. The rapid downstroke after the peaks represents the inhalation phase of the respiratory cycle. (Note: *y*-axis represents the partial pressure of carbon dioxide, expressed in mmHg.) Reproduced from Vargo JJ [48], with permission from Elsevier.

propofol sedation, the BIS scores lag behind the actual sedation level during both induction and recovery, but correlates fairly well with sedation level during the maintenance phase [130]. Currently, BIS is not a standard monitoring tool in routine endoscopy.

Hemodynamic monitoring

Blood pressure should be measured before and after the procedure and at 5–10 min intervals during the procedure. More frequent monitoring may be done (every 3–5 min) in patients with acute gastrointestinal bleeding and if hemodynamic disturbances are anticipated and in patients with underlying cardiopulmonary disease.

It has been recommended that EKG monitoring should be used during deep sedation [76] and in patients with significant cardiovascular or pulmonary disease undergoing moderate sedation. It is also recommended in elderly patients, those with acute gastrointestinal bleeding and those in whom prolonged procedures are anticipated [21]. However, the necessity of EKG monitoring has not been shown conclusively.

Postprocedure monitoring

Because of duration of the action of sedatives, patients are at risk for complications during recovery. Therefore, continuous monitoring is recommended until patients recover to a level of minimal sedation. The clinician should be in proximity until the patient is hemodynamically stable and arousable [76]. Patients may be discharged when their vital signs have stabilized and they are fully alert.

Sedatives may cause a prolonged period of impaired cognition, so patients are advised against driving, operating heavy machinery and making important decisions until the following day. Discharge instructions must be written because of the amnesic effects of the medicines.

Complications of sedation and their management

Morbidity and mortality owing to cardiopulmonary complications continues to be a major problem in gastrointestinal endoscopy. Risk factors for sedation related complications include older age [24,131], comorbid conditions [132] (particularly pulmonary disease), emergency and therapeutic procedures [21,23,133–135], upper GI bleeding [136–138], compromised airway [139], obesity [139], dementia, and anemia [23].

Cardiopulmonary complications constitute about 40–50% of all endoscopic complications [140,141]. The most common are aspiration, hypoventilation and airway obstruction [88,142–144]. The incidence of cardiopulmonary events with narcotics and benzodiazepines has ranged from of 2 per 1000 [106] to 5.4 per 1000 procedures [145]. However, only 0.01–0.03% cases are significant such as myocardial infarction or life-threatening arrhythmias [114,146,147]. The incidence of sedation-related mortality with narcotics and benzodiazepines has ranged from 1 per 3000 to 1 per 11 000 cases [106,145,148,149]. Seventy-three deaths were reported from over-sedation from midazolam within the first 4 years of its introduction [145]. There are no reported cases of endotracheal intubation or death from nonanesthesiologist administered propofol for endoscopy over an experience exceeding 200 000 cases [38,42,43,56,59,61,69,71,72,78,81,150–157]. Thus nonanesthesiologist administered propofol by trained personnel is as safe, if not safer than administration of narcotics or benzodiazepines by endoscopists.

Respiratory depression

Respiratory depression and airway obstruction are the primary causes of drug-induced morbidity and may manifest as hypoxemia or CO_2 retention, usually but not always together

[124,133]. Hypoventilation risk is increased in patients receiving high doses of benzodiazepines and opiates [133], not only because of their sedative effect but also depression of respiratory drive due to decreased central responsiveness to CO_2.

Hypoxia

For EGD, the physical presence of the endoscope may contribute to hypoxemia [158,159] with higher degree of desaturation occurring with large diameter endoscopes [132] and in procedures performed by inexperienced endoscopists [160]. The need for bag–mask ventilation during nonanesthesiologist administration of propofol is substantially greater during upper endoscopy compared with colonoscopy [54]. Looping during colonoscopy may cause transient desaturation [146], however it is generally mild and transient. Severe and prolonged hypoxemia, particularly if it causes respiratory arrest, is usually drug-induced [124,133]. Sustained desaturation to less than 90% may prove dangerous in elderly and those with ischemic heart disease [161]. It may lead to cardiac ischemia [162–164] and both atrial and ventricular arrhythmias [132,165]. Although risk factors exist (see above), most studies have shown that it is impossible to predict by medical illness or age which patients will become hypoxemic [124,133,166,167].

Carbon dioxide retention reflects alveolar hypoventilation and may occur during endoscopy [124,133]. Although, oxygen supplementation readily corrects hypoxemia, it does not correct underlying hypoventilation. Severe hypoventilation may go undetected by pulse oximetry once supplemental oxygen is applied.

Patients with respiratory depression and hypoxia should be given supplemental oxygen by increasing the amount of oxygen delivered or changing the delivery route from nasal cannula to face mask. If the patient is snoring and breathing is labored, tilting the head and lifting the jaw may open the airway. The oropharynx should be suctioned and an oral airway inserted if necessary. If these maneuvers do not help or if the patient is apneic or hypoventilating, breathing should be assisted with a bag–valve–mask device.

Cardiac and hemodynamic complications

Myocardial ischemia and infarction may occur during endoscopy, particularly in patients with cardiac disease [163,164]. It correlates better with periods of tachycardia than periods of hypoxemia [162]. Hemodynamic disturbances during endoscopy include vasovagal reactions and fluctuations in blood pressure and pulse. Vasovagal reactions usually manifest as diaphoresis and bradycardia and frequently are a result of overinsufflation and pain during colonoscopy. Atropine is effective in treating bradycardia. Significant increases or decreases in blood pressure occur commonly during endoscopy [146,168,169]. Hypotension may respond to fluid administration if the underlying cause is hypovolemia. Most hypotension during endoscopy is well tolerated, but prolonged or severe hypotension should lead to consideration of reversal agents and vasopressor agents such as ephedrine or dopamine in addition to fluid administration. Hypertension may be treated with giving more sedatives or analgesics if the patient is under sedated or by decreasing pain, e.g., reducing endoscope loops or by suctioning air.

Aspiration

Aspiration may result in pneumonia and adult respiratory distress syndrome as well as cardiopulmonary arrest and carries a high risk for mortality [106]. The risk is increased with obtundation, dementia, excessive esophageal or gastric fluid or food and in those with active upper gastrointestinal bleeding. Prophylactic endotracheal intubation is indicated with active hematemesis, especially from variceal bleeding [170] or those who are unstable, obtunded, or uncooperative. When excessive gastric contents are encountered, excessive insufflation should be avoided and the procedure should be terminated if the material cannot be readily cleared by suction. Elderly patients are at increased risk for aspiration as a result of an increase in the sensory stimulus threshold required for reflexive glottic closure. It is advisable to avoid topical inhibition of the gag reflex in high risk patients. A catheter for oropharyngeal suction should be by the bedside at all times.

Cardiac arrhythmias

The risk of arrhythmias increases with advanced age, underlying cardiovascular disease, arterial desaturation and, in case of EGDs, the diameter of the endoscope used [132]. The most common arrhythmia was sinus tachycardia which may occur as a result of hypoxemia or painful stimuli.

Procedure termination

Procedure termination as a result of inadequate or excessive sedation may result in morbidity owing to delayed therapy, extended hospitalization, repeat or alternative procedures such as surgery and increased cost. Diab et al. [171] found a 7% incidence of procedure termination during EGD using midazolam alone for sedation. In a prospective multicenter study, 4.1% of all endoscopic retrograde cholangiopancreatographies (ERCPs) had to be terminated prematurely owing to difficulty with sedation [124]. If difficulty is anticipated with sedation for a therapeutic procedure, general anesthesia by an anesthesiologist may be considered.

Training for use of sedatives

Several guidelines have been published regarding training for personnel administering sedatives [21,23,172,173]. Recommendations for safe administration of conscious sedation are emphasized in reviews [88,142]. Although there are no strict requirements, it is obvious that education in pharmacology

Box 117.1 Skills and training required for use of sedatives

The individual administering sedation should:

- be familiar with pharmacology and adverse effects of all sedatives to be used
- be aware of the contraindications to use of each sedative and analgesic
- be able to assess for sedation risk and airway risk
- be able to determine sedation level and recognize complications
- allow for adequate time between dosages to prevent cumulative overdose
- be familiar with antagonists if available
- be trained in rescue of patients from oversedation, including basic life support skills such as cardiopulmonary resuscitation, techniques to open airway, and bag–mask ventilation
- undergo training in sedative administration, including a period of observation of experts followed by supervised administration

of sedatives reduces risk of complications (Box 117.1). It is also recommended that an individual with advanced life support skills be within 1–5 min away for moderate sedation and within the procedure room for deep sedation.

A ENDOSCOPIC

118 Upper gastrointestinal endoscopy

William R. Brugge

History and background, 2888
Technical considerations, 2888
Videoendoscopes, 2889
Introducing the endoscope, 2890
Advanced imaging procedures, 2895
Safety of upper GI endoscopy, 2899

Upper gastrointestinal (GI) endoscopy is the basis for many of the diagnostic and therapeutic procedures offered by endoscopists and gastroenterologists. This chapter reviews the current status of endoscopic procedures performed in the esophagus, stomach, and duodenum. Diagnostic endoscopy will be reviewed in detail, including standard and advanced imaging techniques, diagnostic specimen collection, and criteria for endoscopic diagnoses. Therapies applied during upper GI endoscopy will be examined, but will not be described in detail.

The diseases that are often diagnosed and managed with upper GI endoscopy will also be reviewed, particularly those diseases that lend themselves to further understanding with a knowledge of upper GI endoscopy. This chapter will also examine the risks and contraindications for endoscopy to help the reader understand the cost–benefit analysis of a procedure compared with alternative diagnostic or therapeutic approaches (Box 118.1). The final section considers speculations about endoscopy trends in the future and improvements in diagnostic and therapeutic modalities.

History and background

The father of modern endoscopy is Rudolf Schindler [1]. He pioneered the use of gastroscopy through the use and development of a semirigid gastroscope. The first endoscopic device was introduced in 1806 by Philip Bozzini, who developed a "Lichtleiter" (light conductor) "for the examinations of the canals and cavities of the human body." However, the Vienna Medical Society disapproved of such a device, and the development stalled.

An endoscope was apparently first introduced into a human in 1853. The use of an electric light was a major step in the improvement of endoscopy; these lights were at first external. Later, smaller bulbs became available, making internal light possible. Jacobeus has been credited with early endoscopic explorations of the abdomen and the thorax with laparoscopy (1912) and thoracoscopy (1910). One of the major developmental milestones for endoscopy was the invention of a superior glass fiber for flexible endoscopes by Basil Hirschowitz. The technology not only resulted in the first useful medical endoscope, but revolutionized of endoscopic uses, and led to practical fiberoptics.

Technical considerations

Upper GI endoscopy is a highly technical procedure that requires a close cooperative arrangement between physicians and nurses. A well-organized facility will optimize patient safety and the ability to provide the appropriate techniques. With only a few exceptions, upper GI endoscopy should be performed in a hospital or a medical care facility that can reliably provide highly trained personnel and specialized equipment. In addition to a wide array of endoscopes and processors, the procedure unit should be equipped with the appropriate accessories suitably organized.

In addition to procedure rooms, it is critical to have a travel cart that will enable endoscopists to carry out endoscopic procedures at sites remote from an endoscopy unit. Well-maintained, controlled-access storage is essential for the endoscopic accessories. There must be a well-designed area for endoscope disinfection and preparation of accessories for sterilization. It is also critical to have preparation and recovery areas for the evaluation and monitoring of patients.

Electrocautery devices are critical for the performance of many endoscopic procedures. In many units, the devices are not installed in each procedure room. As these devices are frequently used, it is critical that they be readily available during procedures and properly maintained by qualified personnel.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Box 118.1 Indications and contraindications for esophagogastroduodenoscopy

EGD is generally indicated for evaluating:

- upper abdominal symptoms that persist despite an appropriate trial of therapy
- upper abdominal symptoms associated with other symptoms or signs suggesting serious organic disease (e.g., anorexia and weight loss) or in patients > 45 years old
- dysphagia or odynophagia
- esophageal reflux symptoms that are persistent or recurrent despite appropriate therapy
- persistent vomiting of unknown cause
- other diseases in which the presence of upper GI pathological conditions might modify other planned management (examples include patients who have a history of ulcer or GI bleeding who are scheduled for organ transplantation, long-term anticoagulation, or long-term nonsteroidal antiinflammatory drug therapy for arthritis, and those with cancer of the head and neck)
- familial adenomatous polyposis syndromes
- for confirmation and specific histological diagnosis of radiologically demonstrated lesions
  1 suspected neoplastic lesion
  2 gastric or esophageal ulcer
  3 upper tract stricture or obstruction
- GI bleeding
  1 in patients with active or recent bleeding
  2 for presumed chronic blood loss and for iron deficiency anemia when the clinical situation suggests an upper GI source or when colonoscopy results are negative
- when sampling of tissue or fluid is indicated
- in patients with suspected portal hypertension to document or treat esophageal varices
- to assess acute injury after caustic ingestion
- treatment of bleeding lesions, such as ulcers, tumors, vascular abnormalities (e.g., electrocoagulation, heater probe, laser photocoagulation, or injection therapy)
- banding or sclerotherapy of varices
- removal of foreign bodies
- removal of selected polypoid lesions
- placement of feeding or drainage tubes (peroral, PEG, percutaneous endoscopic jejunostomy)
- dilation of stenotic lesions (e.g., with transendoscopic balloon dilators or dilation systems using guidewires)
- management of achalasia (e.g., botulinum toxin, balloon dilation)
- palliative treatment of stenosing neoplasms (e.g., laser, multipolar electrocoagulation, stent placement)

EGD is generally not indicated for evaluating:

- symptoms that are considered functional in origin (there are exceptions in which an endoscopic examination may be done once to rule out organic disease, especially if symptoms are unresponsive to therapy)
- metastatic adenocarcinoma of unknown primary site when the results will not alter management
- radiographic findings of:
  1 asymptomatic or uncomplicated sliding hiatal hernia
  2 uncomplicated duodenal ulcer that has responded to therapy
  3 deformed duodenal bulb when symptoms are absent or respond adequately to ulcer therapy

Sequential or periodic EGD may be indicated:

- surveillance for malignancy in patients with premalignant conditions (i.e., Barrett esophagus)

Sequential or periodic EGD is generally not indicated for:

- surveillance for malignancy in patients with gastric atrophy, pernicious anemia, or prior gastric operations
- surveillance of healed benign disease such as esophagitis or gastric or duodenal ulcer
- surveillance during repeated dilations of benign strictures unless there is a change in status

EGD, esophagogastroduodenoscopy; GI, gastrointestinal; PEG, percutaneous endoscopic gastrostomy.

Videoendoscopes

Videoendoscopy, introduced in the mid-1980s, has dramatically improved and expanded the field of endoscopy. Videoendoscopy is now used almost universally. The endoscopic image is generated electronically, using a charge-coupled device (CCD) located in the tip of the endoscope [2]. Endoscope processors manage the images and display them on video monitors. Prior to videoendoscopy, fiberoptics generated the images on small hand-held eye-pieces.

The first videoendoscopes used black and white CCDs that required a color wheel. Green, red, or blue light was sequentially sent down the illumination bundle of the endoscope and activated the CCD at the tip [3]. A color image was reconstructed using the three sets of images generated by the colored lights. The videoprocessor displayed a full-color image of the GI tract lining, although with apparent image flickering during rapid movement. Most current videoendoscopes use a color CCD that obtains the image in color on the tip of the endoscope [4]. These devices provide 30 000–850 000 pixels of resolution. By incorporating high-pixel-density

charged-coupled devices, high-resolution endoscopes provide images that display vivid mucosal detail. High-resolution endoscopes are capable of discriminating objects 10–70 μm in diameter; in comparison, the naked eye is capable of discriminating objects 125–165 μm in diameter. The videoendoscope has controls for air, water, and suction and knobs for moving the tip up, down and to the right and left. The instrument channel is shared for the passage of accessories and suction. There are also buttons on the videoendoscope control handle to activate digital video recording, image capture and recording of video images.

Videoendoscopy has greatly expanded the viewing capabilities of procedures. Multiple monitors in the procedure room provide bright vivid images than enable many personnel to participate in procedures. The live video images can also be distributed remotely to sites within an institution, or to remote sites for teaching, research, and demonstration [5]. Endoscopy training has improved dramatically with the use of videoendoscopy. Documentation of procedures is provided by the saving, retrieval, and reviewing of stored digital images [6]. Stored images can be recalled from a central image storage system and sent to any location in the endoscopy service. The storage drives can be used for image processing and management, as well as enabling reliable storage of endoscopic images and information on PACS (picture archiving and communication system) [7]. Hardware and software are now available for the capture, editing, and storage of video clips. This type of material will further improve teaching and patient care [8].

Introducing the endoscope

Most small-diameter videoendoscopes can be easily passed under direct vision through the upper esophageal sphincter. The tip of the instrument is advanced in the midline into the direction of the closed cricopharyngeal sphincter. The patient is asked to swallow, and under direct vision the tip of the instrument is passed from the epiglottis and larynx into the proximal esophagus. In the past, endoscopes were passed blindly aided by the swallowing action. The direct vision technique allows an inspection of the pharynx, epiglottis, and vocal cords prior to insertion. Furthermore, direct imaging may decrease the risk of the inadvertent passage of the endoscope into a proximal esophageal diverticulum. Small-diameter videoendoscopes can also be passed transnasally and may provide the opportunity to perform unsedated endoscopy [9].

Endoscopes are designed to enable the endoscopic controls (e.g., air, water, and suction valves – tip direction wheels) to be controlled with the left hand. The right hand is used to advance the instrument and to manipulate the tip control knob. Torque of the endoscope is accomplished by rotating the instrument control handle with the right hand, which results in rotation of the entire shaft and tip of the endoscope. A central instrument channel is used for a wide variety of devices and accessories. The instrument channel is variable in diameter and some instruments have two instrument channels.

The normal upper GI endoscopic examination

The endoscopic examination of the upper GI tract begins with an examination of the upper esophagus as the endoscope is passed through the upper esophageal sphincter. Since the proximal esophagus is best examined on withdrawal, the endoscope is usually passed to the mid-esophagus, where the formal examination begins. At 40 cm lies the ora serrata, which is the junction between the pearly stratified squamous mucosa and the gastric columnar epithelium. The esophageal folds can be seen to change with air distention. It is possible to recognize extrinsic pressure on the esophagus from adjacent structures, such as the aorta and the left main stem bronchus. The impingement by the diaphragm is apparent in the upper stomach and defines the presence of a hiatal hernia.

With slight angulation to the left and anteriorly, the endoscope is passed into the stomach. Air is insufflated to distend the stomach. It is important to notice the presence of food, bile or blood in the gastric lumen. Gastric fluid in the cardia should be aspirated to improve endoscopic inspection and to reduce the likelihood of regurgitation and aspiration during the procedure. The gastric mucosa is inspected, and observations are made about the color, texture, and size of folds. The gastric folds begin in the upper portion of the stomach and extend down to the entrance into the antrum. With gentle distention of the stomach, these folds often flatten. The size, number, and depth of mucosal defects are noted. Indentation of the lumen by mural lesions, or extrinsic compression by extrinsic organs, can be observed.

A complete examination of the stomach requires a retroflexed view of the stomach. The maneuver takes place in the antrum with a 180° flexion of the endoscope in an inflated stomach. The gastroesophageal (GE) junction, cardia, and fundus can be examined by pulling the endoscope. Retroflexion also permits inspection of a hiatal hernia. Lesions in a hiatal hernia and the GE junction are best viewed in a retroflex position.

The entry into the antrum of the stomach is marked by the incisura, a fold on the lesser curve of the stomach. The antrum can be easily identified by the lack of folds and a conical shape. The antrum is the site of the initiation of peristalsis. Vigorous contractions begin in the proximal antrum and progress through the antrum at a frequency of approximately three per minute. Antral peristalsis terminates in the pylorus. The viewing of peristalsis enables the endoscopist to examine the antral mucosa in detail, particularly for infiltrating lesions. Peristalsis may be weak or absent in a heavily sedated patient, but quantification of peristalsis is not possible.

Once the examination of the body and antrum has been completed, the endoscope is advanced to the pylorus. It is sometimes necessary to create a loop along the greater cur-

vature before the tip of the endoscope can progress through the pylorus. With a small-caliber endoscope, it is possible to inspect the bulb in detail. The endoscope is passed beyond the apex of the duodenal bulb into the second descending portion of the duodenum. Passage from the tip of the bulb into the descending duodenum is readily performed with a turn of the endoscope to the right. The duodenal bulb is usually free of folds; duodenal Kerkring folds begin in the descending portion of the duodenum. A tangential view of the ampulla is usually appreciated.

After completion of the examination in the duodenum, the endoscope is withdrawn, during which time the endoscopist can examine the mucosa of the duodenum, stomach, and esophagus. If there is any suspicion of a lesion in the stomach, it is important to inflate the stomach, flattening the folds and allowing a detailed examination of the gastric mucosa for small ulcers, angioectasia, and early gastric cancer. After completion of the examination of the stomach, air is withdrawn. During the withdrawal of the endoscope through the esophagus, it is important to examine upper esophagus, the upper esophageal sphincter (UES), and the larynx because these may not have been examined in detail during the initial entry.

In transnasal esophagogastroduodenoscopy (EGD), a small-caliber endoscope is passed via the most patent side of the nasal cavity after local application of lidocaine gel and a nasal decongestant (Boxes 118.1 and 118.2) [10]. After inspection of the pharynx, the scope is introduced into the esophagus after traversing the UES under direct vision. Following evaluation of the esophagus, the stomach and duodenum are entered and evaluated.

The use of endoscopic accessories

The use of endoscopic accessories has greatly expanded the number of procedures that can be performed with endoscopy. Accessory devices are used to obtain tissue, inject agents, direct cautery, deliver diagnostic and therapeutic light, and provide additional imaging probes (Table 118.1).

Biopsy forceps

Biopsy forceps are used to retrieve mucosa specimens for histology or culture (Table 118.2). The size of the forceps, often determined by the size of the instrument channel, will determine the size of the specimen obtained. The standard forceps used in a 2.8-mm biopsy channel have a span of 8 mm and can retrieve a full-thickness biopsy of the mucosa. Large cup forceps provide larger specimens with less crush artifact. Forceps are available for single or multiple biopsies. A small central knife, an optional feature, is used to hold multiple specimens. "Hot forceps" (with cautery) should not be routinely used as they provide inferior histological specimens [11]. Reusable and disposable forceps are available [12].

Biopsy specimens are retrieved with tweezers or by flushing, but care should be taken to avoid fragmentation of the specimen. It is not necessary to orient mucosal specimens; this is usually performed in the pathology laboratory. Large biopsy forceps should be used to obtain mucosal specimens for the detection of malignancy, in order to maximize the

Box 118.2 Summary of proposed quality indicators for esophagogastroduodenoscopy

1. Accepted indication(s) is provided before performance of EGD
2. Informed consent is obtained, including specific discussion of risks associated with EGD
3. Prophylactic antibiotics are given in patients with cirrhosis with acute upper GI bleeding who undergo EGD
4. Prophylactic antibiotics are given before placement of a PEG
5. Complete examination of the esophagus, stomach, and duodenum, including retroflexion in the stomach
6. Biopsy specimens are taken of gastric ulcers
7. Barrett esophagus is measured when present, with the location of the gastroesophageal junction and squamocolumnar junction in centimeters from the incision being documented
8. Biopsy specimens are obtained in all cases of suspected Barrett esophagus
9. Type of upper GI bleeding lesion is described and location is documented. For peptic ulcers, at least one of the following stigmata is noted: active bleeding, nonbleeding, nonbleeding visible vessels (pigmented protuberance), adherent clot, flat spot, cleaned base
10. Unless contraindicated, endoscopic treatment is given to ulcers with active bleeding or with nonbleeding visible vessels
11. In cases of attempted hemostasis of upper GI bleeding lesions, whether hemostasis has been achieved is clearly documented
12. When epinephrine injection is used to treat nonvariceal upper GI bleeding or nonbleeding visible vessels, a second treatment modality is used (e.g., coagulation or clipping)
13. Variceal ligation is used for endoscopic treatment of esophageal varices
14. Written instructions, which include particular signs and symptoms to watch for after EGD, are provided to the patient on discharge
15. In patients undergoing dilation for peptic esophageal strictures, PPI therapy is recommended
16. Patients diagnosed with gastric or duodenal ulcers are instructed to take PPI medication for an H_2 antagonist
17. Patients diagnosed with gastric or duodenal ulcers have documented plans to test for the presence of *H. pylori* infection
18. Rebleeding rates after endoscopic hemostasis are measured

EGD, esophagogastroduodenoscopy; GI, gastrointestinal; PEG, percutaneous endoscopic gastrostomy; PPI, proton pump inhibitor.

Table 118.1 Methods for esophageal stenosis dilation

Type of stenosis	Maloney dilation	TTS-CRE balloons	Insight dilator	Catheter-based balloon dilator
Benign esophageal stenosis	Highly effective	Highly effective	Not well tested	Not indicated
Malignant esophageal stenosis	Transient effect	Transient effect	Not well tested	Not indicated
Achalasia	Not effective	Transient effect	Not tested	Effective
Benign pyloric channel stenosis	Not indicated	Effective	Effective	Not indicated
Malignant duodenal stenosis	Not indicated	Transient effect	Not indicated	Not indicated

TTS-CRE, through the scope controlled radial expansion.

Table 118.2 Endoscopic methods for tissue sampling

	Forceps	Brush	Needle	Cap-assisted EMR	Snare resection
Barrett with dysplasia	Large particle forceps in four quadrants	Possibly effective	Not indicated	Highly diagnostic	Not indicated
Esophageal cancer	Large particle forceps	Highly diagnostic	Not indicated	Not necessary	Not indicated
Gastric cancer	Resection biopsy	Rarely used	Not indicated	Highly diagnostic	Not indicated
Gastric lymphoma	Highly diagnostic	Highly diagnostic	Possibly	Not necessary	Not indicated
Gastric GIST	Not effective	Not effective	Method of choice for tissue acquisition	Curative for small lesions	Curative for small lesions
Duodenal polyp	Consider resection	Not indicated	Not indicated	For resection therapy	Diagnostic and curative
Ampulla adenoma	4–6 specimens	Not indicated	Not indicated	For resection therapy	Diagnostic and curative

EMR, endoscopic mucosal resection; GIST, gastrointestinal stromal cell tumor.

quality and quantity of tissue. The risk of bleeding from biopsies is negligible.

Most endoscopic forceps obtain mucosa and, occasionally, a small amount of submucosa. To sample more deeply into a lesion, such as a submucosal tumor, needle cytology may be applied, or repetitive sampling with large biopsy forceps should be made in the same area ("well biopsy") (Table 118.2). The acquisition of diagnostic material from the esophagus is more difficult than from the stomach because of the orientation of the esophagus. Angled forceps will improve the biopsy of the esophagus [13].

As an alternative to pinch biopsies, a snare may be used to obtain a large sample of tissue from abnormal mucosa (Table 118.2) [14]. The snare is placed over the fold or polypoid area, tightened, and gently pulled away from the wall. Prior injection of saline or diluted epinephrine in the submucosa may lift the mucosa to facilitate snaring and to prevent deep mural damage. As the snare is pulled through the lesion, the electrosurgical current aids in the cutting through the tissue and prevents bleeding.

The snare biopsy technique can be extended by lifting the targeted mucosa prior to snaring. In this technique, a two-channel endoscope is used with the snare in one channel and lifting forceps in the second channel [15]. The snare is opened and the forceps is directed through the snare. The tissue is grasped by the forceps and pulled up into the snare. As the snare is tightened, the tissue can be excised with electrocautery. This technique may result in unexpectedly large, deep biopsy specimens and is not recommended for the inexperienced endoscopist.

Tissue acquisition may also be achieved using techniques associated with endoscopic mucosal resection (EMR). Typically, EMR techniques are employed for the resection of a flat neoplastic lesion, such as early gastric cancer. Many EMR techniques incorporate a submucosal injection to separate the lesion from the muscularis propria. Epinephrine diluted with saline is the commonly used injectant because it provides transient hemostasis as well as separation of the wall layers. The most commonly performed method for EMR is cap-assisted EMR. In this technique, a translucent plastic cap is placed on the tip of an endoscope and the target tissue is aspirated into the cap. A small snare placed inside the rimmed cap provides the ability to resect a considerable amount of tissue. The lesion is suctioned into the cap and the snare tightened around the lesion. The snare is then advanced out of the cap to enable the extent of the captured

mucosa to be confirmed prior to transection. Newer methods for EMR use the application of a band to select and lift mucosa or lesions for resection [16]. Large surface area mucosal malignancies can be resected using endoscopic knives. This technique has been used to resect superficial gastric malignancies of the stomach in Japan and in the Western world; the technique is used to resect Barrett mucosa.

Cytology brushes

Retrieval of specimens for cytological evaluation is easier than using biopsy forceps for tissue acquisition (Table 118.2) [17]. Brushing of mucosal lesions is usually performed for the diagnosis of infectious processes in the upper GI tract. However, cytology brushing is also important in lesions that are inaccessible for biopsy, such as tight strictures in the esophagus. Cytology brushes are often protected by a plastic sheath, which aids in the retrieval of diagnostic material. After removal of the cytology brush from the endoscope biopsy channel, the specimen is placed on a glass slide and into preservative solution. For the diagnosis of *Candida* infections, a simple smear can be submitted for fungal staining.

Cytological material from the upper GI tract can also be retrieved with the use of an aspiration needle [18]. Aspiration cytology is usually performed for cystic lesions, submucosal tumors, or infiltrating malignancy in the gastric wall. A small-gauge needle is used to obtain small amounts of tissue or fluid from the lesion using suction. Needle aspiration cytology is usually performed with endoscopic ultrasonography (EUS) guidance because of the ability of EUS to direct the needle into areas rich in cytological material.

Measuring devices

Occasionally it may be important to know the actual size of an identified lesion. Endoscopic estimation of size is often inaccurate and underestimates the size of lesions. The closer the tip of the endoscope is to the target, the larger the lesion appears. Measuring methods include using open biopsy forceps with a known distance between the tips of the biopsy cups, using a spring-type measuring probe with gradations of known length, and using a projected grid [19].

Measuring mucosal blood flow

Endoscopic imaging of the upper GI mucosa is not a reliable method for the measurement of mucosal blood flow or the detection of abnormal blood vessels. The measurement of blood flow may be used in focal lesions or for a mucosal process. Doppler ultrasound probes can detect the flow in abnormal blood vessels below the mucosa, such as varices, or in an artery in the base of an ulcer [20]. Doppler devices can be used before and after endoscopic hemostatic therapy, such as injection or thermal therapy for an artery in the base of an ulcer [20,21]. It is also possible to use a laser Doppler device to measure mucosal red blood cell velocity, a parameter thought to correlate with mucosal blood flow [22]. The assessment of mucosal blood may be predictive of ulcer healing [23]. Mucosal blood flow is normally increased in the mucosa adjacent to ulcers and attenuated blood flow is predictive of slow healing. Paradoxically, it appears that blood flow is decreased in areas of portal hypertensive gastropathy [24].

Endoscopic imaging can be expanded through the use of spectroscopy probes that can be placed through the instrument channel to image the mucosa. Advances in fiberoptics, light sources, and detectors have led to the development of several novel methods for tissue evaluation in situ [25]. The term "optical biopsy" refers to methods that use the properties of light to enable the operator to make a diagnosis at endoscopy, previously possible only by using histological or cytological analysis. Promising imaging techniques include fluorescence endoscopy, optical coherence tomography, confocal microendoscopy, and molecular imaging (Table 118.3). Point detection schemes under development include light scattering and Raman spectroscopy. Such advanced diagnostic methods go beyond standard endoscopic techniques by offering improved image resolution, contrast, and tissue penetration and providing biochemical and molecular information about mucosal disease. The detection of dysplasia arising in Barrett esophagus would be an obvious goal of optical spectroscopy [26].

Endoscopic ultrasonography

One of the major advances in endoscopy is the coupling of ultrasound with endoscopy (endoscopic ultrasound or EUS). There are two approaches to this combination of technologies. In the first approach, the endoscope has an ultrasound device built into the tip of the endoscope. The ultrasound transducer can be oriented radially and provide cross-sectional images of the GI tract or in a linear orientation. In the linear orientation, fine-needle aspiration can be directed with ultrasound imaging of the GI tract and for the major organs adjacent to the esophagus, stomach, and duodenum. The alternative to using dedicated ultrasound endoscopes is to use small ultrasound probes that can be passed through the instrument channel. Probe endosonography provides high-resolution radial images of wall lesions. EUS imaging has dramatically improved tumor staging, acquisition of tissue from the pancreas, and will provide injection therapies. See Chapter 129 for more on EUS.

Chromoendoscopy

Chromoendoscopy is an in vivo technique in which the mucosa or a lesion is washed with an agent designed to enhance mucosal imaging (Table 118.3). Chromoendoscopy agents include those that enhance the mucosal detail or in which the agent is absorbed by certain cell types (vital staining). The dye agent is usually sprayed against the mucosa using a specially designed catheter passed down the biopsy channel of the endoscope. The various dyes are used for specific clinical settings and provide specific information regarding mucosal abnormalities. Before using any of these

Table 118.3 Summary of endoscopic image enhancement techniques used for detection of gastrointestinal malignancy

Endoscopic technique	Agent or device used	Mechanism	Clinical application
High-resolution endoscopy	High-resolution endoscope with high pixel density (e.g., 850 000)	Increased resolution by the CCD on the endoscope	Endoscopic identification of surface details, such as crypts, glands, and pit pattern
Magnification endoscopy	Magnification endoscope with manual (lens change) or electronic control	Magnification of the endoscopic image	Endoscopic identification of surface details enhanced with dyes
Combined high-resolution and magnification endoscopy	Magnification endoscope with manual (lens change) or electronic control	Magnification of the endoscopic image	Endoscopic identification of surface details enhanced with dyes
Chromoendoscopy	Topical agents often used in conjunction with magnification endoscopy		
	Lugol solution	Contrast dye, staining glycogen in squamous epithelium	Detection of early squamous cell carcinoma of the esophagus
	Methylene blue	Absorptive dye, staining absorptive epithelium (small intestine and colon) including Barrett	Detection of Barrett esophagus and early malignancy arising from Barrett (lack of staining)
	Indigo carmine	Contrast dye, outlining mucosal surface	Detection and mapping of gastroduodenal malignancies
	Acetic acid	Reversible intracellular protein denaturation	Detection of Barrett epithelium
Narrow band imaging	Electronic light source with narrow-band filters	Enhancement of surface capillary patterns, pits, and villi	Detection and mapping of early gastric and esophageal cancer
Fluorescence endoscopy	Image-processing module that provides real-time fluorescence images 5-Aminolevulinic acid (topical or systemic) HAL	Sensitizers accumulate selectively in malignant lesions and induce fluorescence upon illumination with light of the appropriate wavelength	Detection of early gastric and colonic adenomas and malignancies
Confocal microscopy	Dedicated combined endoscope and microscope image processing unit Acriflavine hydrochloride or fluorescein sodium	Fluorescent agents are absorbed by tissue and provide cellular and histological details	Broad applications in detection of mucosal neoplasia

CCD, coupled chip device; HAL, hexaminolevulinate.

dyes, it is necessary to wash away adherent mucus. This is often accomplished using a solution of dimethyl polysiloxane, sodium bicarbonate, and pronase. A 10% solution of *N*-acetylcysteine can also be used before spraying the dye.

Contrast chromoendoscopy

Contrast agents are used to accentuate minute alterations in mucosal architecture by accumulating in normal or abnormal mucosal structures and accentuating small lesions. This is best achieved using indigo carmine, which pools between mucosal grooves and provides a three-dimensional image of the mucosa. Similar effects have been reported with acetic acid [27]. Contrast chromoendoscopy is often used in conjunction with high-resolution endoscopy [28].

Vital staining

Vital dyes, such as methylene blue, are absorbed by epithelial cells, and the differential absorption by a mucosal process may aid in the detection of dysplasia (Table 118.3). Absorptive staining takes place over a few minutes during the application of the dye to the tissue. After staining is achieved, the solution is washed away. Lugol solution stains intracellular glycogen in nonkeratinized squamous epithelium and therefore normally stains the entire esophageal mucosa (Table 118.3). Early esophageal cancer and high-grade squamous dysplasia do not stain with Lugol solution [29]. Lugol staining is useful in looking for plaques overlying varices, evaluating high-risk patients, or to precisely map a neoplasm of the esophagus. Methylene blue dye is used to enhance the detec-

tion of dysplastic tissue arising from Barrett epithelium as the dye is not absorbed by the dysplastic tissue [30]. Biopsies are directed to areas of Barrett mucosa that lack staining.

Congo red is a reactive stain that maps the acid-producing parietal cell mucosa, staining from red to dark blue in the presence of acid secretion. Lesions associated with hereditary diffuse gastric cancer can be detected by Congo red and methylene blue staining [31].

Advanced imaging procedures

Upper GI endoscopy provides an opportunity to guide the passage of imaging instruments in close proximity to lesions or areas of interest [32]. Endoscopic ultrasound is the most commonly performed advanced imaging procedure. Small ultrasound catheters may be passed through the endoscope in order to provide high-resolution imaging of mucosal lesions. Using water as a medium, the high-frequency probe offers a detailed examination of mucosal and subepithelial lesions and their relationship to the wall structure of the GI tract. Probe endosonography may provide staging of early malignancy as well as differentiate between cystic, solid, and lipomatous lesions (Table 118.4). The disadvantages of probe endosonography include the need for water immersion and the inherent inability to provide imaging of histological structure.

Optical coherence tomography (OCT) is an infrared-based imaging technique that provides high-resolution imaging of mucosal details. Although OCT is used clinically in cardiology and ophthalmology, it is not a standard imaging technique in endoscopy. OCT is ideally equipped to differentiate between the basic epithelial structures, such as squamous and columnar epithelia [33]. Extensive testing in the setting of Barrett esophagus has demonstrated the ability to diagnose Barrett esophagus [34]. Furthermore, there is some evidence that OCT may be able to detect early changes of dysplasia and guide mucosal biopsies [35,36].

Magnification endoscopy is often used to provide higher-resolution images of the epithelium in concert with chromoendoscopy (Table 118.3). Most videoendoscopes provide optional magnified or "zoom" imaging. The most obvious application of this relatively simple technique is in the detection of duodenal villous atrophy. Using saline or contrast agents to separate the villi, high-resolution endoscopy can be used to reliably and accurately diagnose sprue (Table 118.3) [37]. Similar techniques have been applied for the diagnosis of Barrett esophagus. The finding of villi arising from the esophageal epithelium is diagnostic of intestinal metaplasia [38]. Changes in the villi morphology have enabled endoscopists to diagnose early gastric cancer [39].

Narrow band imaging (NBI) involves the use of interference filters to illuminate a target in narrowed red, green and blue (R/G/B) bands of the spectrum (Table 118.3). The imaging modality is built into commercial endoscopy processors and no catheters or probes are necessary. NBI provides imaging of the surface of epithelium, particularly of the surface vascular pattern. Many early malignancies have surface pattern changes in vascularity, such as the corkscrew pattern

Table 118.4 Radiological and endoscopic imaging used to stage gastrointestinal malignancies

Imaging modality	Device used	Agent used	Detection of malignant tissue	Availability	Clinical applications
EUS	Dedicated echoendoscope; high-frequency ultrasound probes can be used through the instrument channel; fine-needle aspiration device can be used with linear EUS	Water is used as a coupling agent. Levovist and Definity are intravenous ultrasound contrast agents rarely used in EUS	The vast majority of malignancies are relatively less echoic (hypoechoic) than normal tissue	Widely available	Frequently used to stage esophageal, gastric, pancreatic, and rectal cancer
OCT	Laser infrared light source, semiconductor optical amplifier, catheter probe	None	Changed architecture of tissue (e.g., loss of goblet cells) is used as a sign of malignancy	Not commercially available; prototypes used in research centers	Staging of superficial malignancies
CT	An X-ray beam is emitted in a fan shape as the rotating frame spins the X-ray tube and detector around the patient. Multidetector CT with computer-generated images	Intravenous and oral iodine-based contrast agents	Using ionized radiation, the vast majority of malignant tissue have a different attenuation, accentuated by the use of intravenous contrast	Helical CT is widely available. MDCT (multidetector CT) will become widely distributed	Broad applications in staging of advanced GI malignancies

CT, computed tomography; EUS, endoscopic ultrasound; GI, gastrointestinal; OCT, optical coherence tomography; MDCT, multidetector computed tomography.

seen in early gastric cancer [40]. When NBI is used in conjunction with magnification endoscopy, the diagnosis of intestinal metaplasia of the esophagus can be secured with a high degree of accuracy [41]. In comparative trials, NBI has produced results similar to high-resolution chromoendoscopy [42].

Endoscopic confocal microscopy provides the highest resolution images of the GI tract of any imaging modality (Table 118.3) [43]. The instrument is a dedicated endoscope with an independent processor and is not yet widely available. Confocal endomicroscopy uses blue laser light and is often used in conjunction with an intravenous and a topical fluorescent agent. The images obtained from this technique provide near real-time cellular details, including individual epithelial cells to a depth of 1–2 mm. The crypts of the colonic mucosa, the villi of the terminal ileum and duodenum, the gastric pits of the stomach, and the squamous epithelium of the distal esophagus can be clearly visualized. The technique has been demonstrated to improve the detection of dysplasia arising from the colonic mucosa in patients with inflammatory bowel disease [44]. The high-resolution imaging has demonstrated *Helicobacter pylori* organisms in the gastric mucosa [45].

Removal of foreign bodies

In removing a foreign body, the endoscopist should carefully evaluate the patient for any possible evidence of airway obstruction or perforation prior to the endoscopic procedure. During removal of a foreign body, an overtube provides a degree of protection of the airway by preventing dropping of the foreign body during removal, but the only way to ensure complete airway patency is to use a cuffed endotracheal tube.

The mucosa can be protected, especially in the removal of sharp objects, by using an overtube to protect the intestinal lining during removal of a sharp foreign body [46]. It is possible to remove foreign bodies with rigid and flexible endoscopes. Foreign bodies in the area of the hypopharynx and very proximal esophagus are often best removed with an open laryngoscope and grasping forceps. For other foreign bodies, flexible endoscopes are used, preferably with a large instrumentation channel (2.8–3.5 mm). The larger channel allows a variety of instruments to be used to grasp and hold the foreign body. These include baskets of the Dormia type, forceps for grasping the foreign body, and polypectomy snares. Alligator forceps with teeth are useful for grasping coins and other types of smooth objects. If an object is irregular or soft, other devices, such as baskets, snares, and graspers with three prongs, can be used. An irregular, sharp object, an object with a ragged surface, or an object that is impacted in the wall (e.g., dental plate) may require a rigid laryngoscope or esophagoscope to be passed under general anesthesia for removal of the foreign body.

If the foreign body is sharp, a plastic overtube should be used to protect the esophagus (Fig. 118.1) [34]. The endoscope can be withdrawn into the overtube while grasping the foreign body, which protects the mucosa from injury by the sharp foreign body as it is being removed. This also eliminates the possibility of dropping the foreign body in the hypopharynx, causing pulmonary aspiration of the object. The overtube is useful if the endoscope must be passed several times for removal of a foreign body, such as a piece of meat. An alternative to a plastic overtube is a simple latex protector hood fastened to the tip of the endoscope [35].

Most experienced endoscopists practice before attempting foreign body removal. A foreign body similar to that swallowed by the patient is manipulated with the type of instrument available to grasp the foreign body during endoscopy. This time spent in forethought and planning makes the foreign body removal safer and easier [36].

Endoscopic control of upper gastrointestinal bleeding

Upper GI bleeding is one of the most common indications for upper GI endoscopy. For approximately 85%–95% of these patients, a precise diagnosis of the cause of the bleeding can be obtained. For a few patients with massive hemorrhage, endoscopic control of bleeding may not be possible. In most

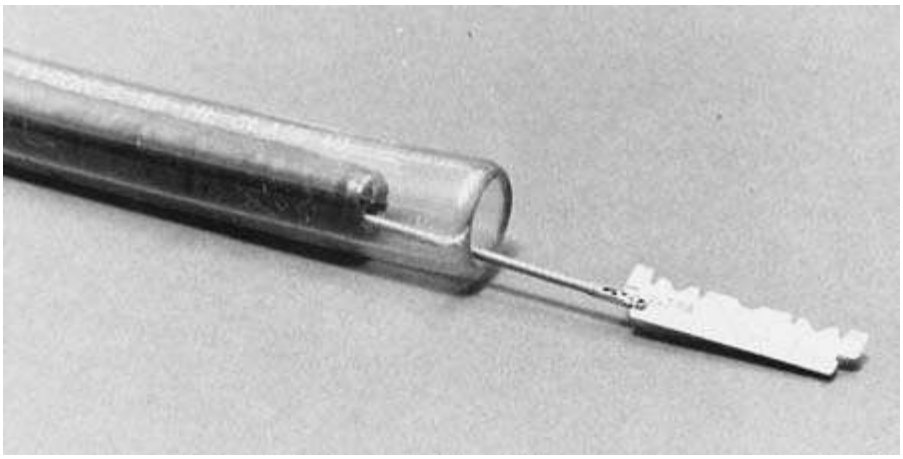

Figure 118.1 A plastic overtube around the endoscope allows safe retrieval of sharp or pointed foreign bodies.

Figure 118.2 In polypectomy, the snare loop is positioned around the sessile, adenomatous, gastric polyp.

patients with bleeding, endoscopy can be performed as soon as the patient is stabilized hemodynamically. Endoscopic treatment of nonvariceal and variceal bleeding is discussed in Chapters 123 and 124.

Polypectomy

Although polyps in the upper GI tract are relatively common, removal is not necessary in the vast majority of patients [47]. Removal of a polyp or polypoid lesion is indicated in neoplastic lesions or those lesions that cause bleeding or symptoms [48]. Polypectomy is accomplished using a wire snare placed over the polyp in a fashion similar to colonoscopy (Fig. 118.2). Snares of a variety of sizes and shapes are available, including a symmetric ellipse, a hexagon, and a slightly hooked configuration. After the handle is closed, the tip of the snare should retract at least 1 cm into the plastic overtube. As the snare is tightened on the lesion, an electrocoagulative current is applied, alone or in combination with a cutting current, during the transection of the polyp.

The complications with gastric polypectomy include hemorrhage and perforation. Because of the thickness of the gastric wall, perforation is rare, but hemorrhage may be a significant problem. The risk of bleeding is probably greater in large polyps with thick stalks. Injection of the stalk with epinephrine is recommended, but may not always prevent bleeding. Mechanical hemostatic devices, such as endoloops or clips, can prevent bleeding after polypectomy [49].

Mucosal resection

Endoscopic mucosal resection is a group of techniques designed to remove superficial malignancies of the GI tract. The lesions are most commonly located in the stomach, but an increasing number of dysplastic lesions are being discovered in Barrett esophagus. Usually, the lesion is first examined with endosonography to prove its superficial nature. In principle, the lesion should be limited to the mucosal layer, but lesions involving the submucosa can also be resected. After proper localization with chromoendoscopy or fluorescence endoscopy, the lesion is lifted after submucosal injection of an agent designed to separate the mucosa from the deep layers [50]. Thereafter, the lesion is aspirated, usually into a small translucent cap located on the end of an endoscope. The size, shape, and flexibility of the cap will determine the amount of tissue that is resected [51]. More advanced freehand techniques are being investigated for the removal of large portions of malignant gastric mucosa [52]. Transection is performed with cautery, allowing the specimen to be retrieved for histopathological examination. Although the primary purpose of EMR is resection of malignancy, the procedure also provides detailed histological evidence of the tumor stage (Table 118.2) [53]. Mucosal specimens obtained with EMR techniques provide a higher accuracy for the detection of mucosal malignancy [54]. When used for the resection of mucosal adenocarcinoma in Barrett esophagus, cap-assisted EMR provides high rates of remission {Conio, 2005 #6}.

Dilation

Esophageal stricture dilation may be performed using Maloney dilators, wire-guided dilators, or balloons (Table 118.1) [55]. Flexible endoscopy has an increasingly important role in dilating strictures through the use of through-the-scope (TTS) balloons or placement of a guidewire [56]. However, the overall need for esophageal stricture dilation has decreased with the increasing use of proton pump agents [57]. TTS or controlled radial expansion (CRE) balloon dilation of esophageal strictures is highly successful and safe [58]. The radial force provided by a CRE balloon is greater than the radial force generated by bougie dilation. Stricture dilation has been eased by the use of CRE balloons, dramatically improving patient tolerance. In a complex stricture, the balloon should be guided with a guidewire. However, in most strictures, the balloon is easily placed in the stricture and held in place during pneumatic dilation. Balloons used for CRE vary from 4 to 20 mm in diameter when fully inflated with a liquid, and many provide graduated dilation over 3 mm. The risk of perforation is low in benign strictures, but malignant strictures can be safely dilated only to 14 mm [59].

Semirigid esophageal dilating devices are guided through strictures using a guide wire placed endoscopically. The guidewire with a spring tip is passed through an instrument channel across the stricture. With the guidewire in place, the endoscope is removed. Confirmation of the positioning of the guidewire below stricture can be obtained with fluoroscopy, but is rarely needed. Increasing diameter dilators are passed over the guidewire and across the stricture. The guidewire

and the spring tip should remain below the area to be dilated throughout the procedure. Thermoplastic Savary dilators are the most commonly used wire-guided dilator [56].

Using the same principles for esophageal stricture dilation, TTS balloons can be used in the pylorus and duodenum [60]. Benign strictures of the pylorus are easily dilated with lasting effects [61]. Passage of the balloon and its inflation can be monitored with fluoroscopy to be certain that the waist of the balloon, representing the stricture, has been obliterated. Balloon dilation of benign strictures is highly effective.

Stents

Esophageal stent placement is a highly effective procedure for the palliation of malignant dysphagia. The timing of stent placement is very important in order to provide optimal benefit to the patient and avoid complications, such as stent migration. Prior to stent placement, endoscopy is used to evaluate the degree of narrowing, measure the length of the tumor narrowing, and determine the distance from the top of the tumor to the incisor teeth, an important factor in placing the prosthesis. Patients and family should be fully informed of the risks and complications of esophageal stent placement.

Prior to the placement of an esophageal stent, the esophageal lumen must be large enough to accommodate a stent. Dilation of the malignant stricture can be accomplished with CRE balloons or bougies. After the length of the stricture is determined, the stent length should be long enough to include 2.5–3 cm proximal to the narrowing and the same distance distal to the narrowing to prevent early restenosis by tumor. The proximal and distal sites of the stricture should be marked with an injection of contrast or the placement of a clip.

Expandable esophageal stents that are placed across a malignant stricture readily provide lumenal patency. Self-expanding esophageal stents are provided in a covered or a noncovered format [62]. These devices are passed over a guidewire through the malignant narrowing, within a sheath covering the compressed stent. After the constraining sheath is released, the stent is left in place and expands. The expanding stents have the advantage of producing a wide lumen through the stenosing tumor mass. However, these stents are difficult to remove. Stents covered by a silicone membrane may prevent tumor ingrowth and offer relief from symptoms associated with fistulas and leaks [63]. One variety of covered esophageal stents are designed to be used in benign strictures and be removed [64]. The long-term efficacy of the use of stents in benign strictures has not been defined.

Laser tumor ablation

An endoscope can be used to guide a neodymium-doped yttrium aluminum garnet (Nd:YAG) laser to provide long-term patency of a malignant esophageal stricture [65]. Repeated ablative sessions are required in order to eliminate sufficient malignant tissue for symptomatic relief. Long-term success, in terms of relief of dysphagia, is relatively modest, about 66% [65]. This approach has largely been replaced with the placement of self-expanding metal stents [66]. Stenting can provide rapid relief from dysphagia with only one endoscopic procedure and is associated with low risk. Endoscopic laser therapy with homogentisate oxidase (HGD) has been used in small numbers of patients with Barrett esophagus [67]. In addition, laser therapy has been used to ablate low-grade malignancies of the esophagus, such as

Table 118.5 Endoscopic methods for ablation of malignancy

	Argon plasma coagulation	Photodynamic therapy	RFA	Ethanol	Laser
Primary clinical indication	Ablation of vascular lesions	Barrett esophagus with dysplasia	Ablation of hepatocellular carcinoma	Ablation of hepatocellular carcinoma	Ablation of esophageal malignancy
Method of application	Topical application via catheter	Intravenous photosensitizer and catheter-guided light exposure	Percutaneous needle with RFA wire	Needle injection	Catheter-directed laser light
Primary oncological application	Barrett esophagus	Barrett esophagus with dysplasia	Hepatocellular carcinoma, hypernephroma	Hepatocellular carcinoma	Esophageal malignancy
Additional targets	Adenomas	Gastric malignancy	Hepatic metastases, pancreatic cancer	Pancreatic cystadenomas	Gastric malignancy
Mechanism of action	Coagulation and heat	Cell death induced by singlet oxygen	Heat	Protein denaturation	Heat

RFA, radiofrequency ablation.

granular cell tumors [68]. An alternative method of applying laser photocoagulation is to use argon plasma coagulation (APC) (Table 118.5), which is highly effective in the ablation of Barrett epithelium [69].

Photodynamic therapy

Photodynamic therapy (PDT) is an ablative therapy that can be delivered through an endoscope. An appropriate photosensitizing agent, such as a hematoporphyrin derivative, is injected intravenously and is taken up in high concentration in the area of gastric or esophageal malignancy. A standard endoscope is used to place a flexible fiber bundle to the tumor site and red laser light therapy is administered. Light activation results in singlet oxygen release and superficial tumor necrosis. PDT can be used in conjunction with EMR for the elimination of focal dysplastic lesions of the esophagus [70]. PDT may also be used for T1 malignancies of the esophagus, although the long-term success has not been determined [71]. In a prospective blinded trial, PDT eliminated high-grade dysplasia in 77% of patients [72].

Safety of upper GI endoscopy

Before endoscopy is performed, a thorough history should be obtained from the patient. The history should include previous surgery, endoscopic procedures, and anesthesia history. A list of the patient's medications should be generated. A review of active medical problems will help the endoscopist assign an ASA (anesthesia risk) score and decide whether the patient will safely tolerate conscious sedation. A history of airway or upper esophageal surgery, procedures, or of radiation, will help decrease the risk of perforation.

Knowledge of bleeding tendencies in the patient or the patient's family and any history of drug allergies should be obtained. If there is a history of bleeding abnormalities, a clotting screen with a prothrombin time, partial thromboplastin time, platelet count, and bleeding time is indicated. If there is evidence of chronic liver disease or other hematological disorder, it is important to check the degree of coagulopathy.

Diagnostic endoscopy with biopsy is usually safe in patients who are taking oral anticoagulants or aspirin. However, for a patient who is to be treated with electrocoagulation for polypectomy or hemostasis, anticoagulants should be discontinued before the endoscopic procedure and for 7–10 days after the procedure to prevent delayed bleeding. Aspirin-containing compounds and other antiplatelet agents, such as nonsteroidal antiinflammatory drugs (NSAIDs) and ticlopidine, should be avoided for an appropriate interval (i.e., aspirin for 7–10 days; NSAIDs for 2–3 days) before an endoscopic procedure that may involve removal of tissue.

Most patients begin fasting after midnight the evening before the procedure. The patient should have no liquids for 4 h before endoscopy and no solids for at least 6–8 h beforehand. Patients with gastric outlet obstruction may be kept on a clear liquid diet for 24–48 h, and lavage of the stomach with a large-bore tube may be necessary to remove retained stomach contents.

Informed consent is an important risk management technique and should be obtained by a physician prior to every procedure. The physician should provide a realistic assessment of the risk of the procedure and the consequences of the complications. A discussion of risks should include a statement of the risks of conscious sedation.

Topical anesthesia to the pharynx is often provided in order to minimize the gag reflex during endoscopy. The need for the topical anesthetic in the setting of intravenous conscious sedation is controversial [73]. Excessive amounts of topical lidocaine may result in methemoglobinemia [74]. Intravenous conscious sedation is the most commonly provided anesthesia for patients undergoing endoscopy [75].

For endoscopic procedures that are expected to be brief and in which small-caliber or pernasal endoscopes are used, no intravenous sedation may be necessary unless the patient is anxious [9]. For therapeutic procedures that involve larger-diameter instruments and longer periods, the patient is usually sedated to deeper levels of sedation [76]. In a small percentage of patients, the administration of a benzodiazepine will result in a paradoxical reaction [77]. General anesthesia may be required in patients who cannot tolerate conscious sedation when there are airway issues, such as removal of foreign bodies in small children [78,79]. Propofol anesthesia can be provided safely with properly trained personnel in the endoscopy unit [80].

Bacteremia may be associated with endoscopic procedures. In a patient with a preexisting heart condition, there may be a risk of developing infectious endocarditis, although this risk is small (Table 118.6). The efficacy of antibiotic prophylaxis for endocarditis is unproven, although prophylaxis appears to be effective in patients with prosthetic valves, surgically constructed systemic–pulmonary shunts, and hypertrophic cardiomyopathy (Table 118.6). Prophylactic antibiotics are advised for patients with known endocarditis or prosthetic cardiac valves. For gastrointestinal endoscopic procedures, the standard regimen is 2 g of ampicillin, administered intravenously or intramuscularly, plus gentamicin (1.5 mg/kg, not to exceed 80 mg), administered intravenously or intramuscularly 30 min before the procedure, followed by 1.5 g of amoxicillin taken orally 6 h after the initial medication. Alternatively, the parenteral regimen may be repeated once 8 h after the initial dose.

The most common complications of upper GI endoscopy are related to the cardiopulmonary effects of sedative drugs [78]. Benzodiazepines cause dose-related hypoxia that can be readily treated with administration of oxygen [81]. In randomized trials, propofol is a safe and well-tolerated anesthetic for upper GI endscopy [82]. Recovery after propofol

Table 118.6 Antibiotic prophylaxis for endoscopic procedures

Patient condition	Procedure	Antibiotic prophylaxis
High risk		
Prosthetic valve	Stricture dilation	Recommended
History of endocarditis	Variceal sclerotherapy	Recommended
Systemic pulmonary shunt	ERCP/obstructed biliary tree Other endoscopic procedures, including EGD and colonoscopy (with or without biopsy/ polypectomy), variceal ligation	Recommended Recommended
Synthetic vascular graft (<1 year old)		Optional
Complex cyanotic congenital heart disease		Optional
Moderate risk		
Most other congenital abnormalities	Esophageal stricture dilation	Optional
Acquired valvular dysfunction (e.g., rheumatic heart disease)	Variceal sclerotherapy	Optional
Hypertrophic cardiomyopathy	Other endoscopic procedures, including EGD and colonoscopy (with or without biopsy/polypectomy), variceal ligation	Not recommended
Mitral valve prolapse with regurgitation or thickened cordae		Not recommended
Low risk		
Other cardiac conditions (CABG), repaired septal defect or patent ductus, mitral valve prolapse without valvular regurgitation, isolated secundum atrial septal defect, physiological functional, heart murmurs, rheumatic fever without valvular dysfunction, pacemakers, implantable defibrillators)	All endoscopic procedures	Not recommended
Obstructed bile duct	ERCP	Recommended
Pancreatic cystic lesion	ERCP, EUS-FNA	Recommended
Cirrhosis, acute GI bleed	All endoscopic procedures	Recommended
Ascites, immunocompromised patient	Stricture dilation Variceal sclerotherapy Other endoscopic procedures, including EGD and colonoscopy (with or without biopsy/polypectomy), variceal ligation	No recommendation
All patients	Percutaneous endoscopic feeding tube	Recommended (parenteral placement cephalosporin or equivalent)
Patients with prosthetic joints	All endoscopic procedures	Not recommended

Cardiac prophylaxis regimens (oral 1 h before, i.m. or i.v. 30 min before procedure).
Amoxicillin by mouth or ampicillin i.v.: adult 2.0 g; child 50 mg/kg.
Penicillin-allergic patients: clindamycin (adult 600 mg; child 20 mg/kg) or cephalexin or cefadroxil (adults 2.0 g, child 50 mg/kg) or azithromycin or clarithromycin (adult 500 mg, child 15 mg/kg) or cefazolin (adult 1.0 g, children 25 mg/kg i.v. or i.m.) or vancomycin (adult 1.0 g, child 10–20 mg/kg i.v.).
CABG, coronary artery bypass graft EGD, esophagogastroduodenoscopy; ERCP, endoscopic retrograde cholangiopancreatography; EUS-FNA, endoscopic ultrasound-guided fine needle aspiration; GI, gastrointestinal.

is quicker than after standard conscious sedation. Sedation with propofol during therapeutic endoscopy provides a rapid onset of deep sedation with a desaturation rate of 15% [83].

Perforation is the most directly assignable complication of upper GI endoscopy, but this occurs in less than 0.1% and is increasingly rare. The most common cause of perforation is the passage of the blind tip of the endoscope into a malignant stricture. If these perforations are recognized early, immediate surgery and repair will provide closure with the minimum of complications. The performance of EMR and resection of a subepithelial malignancy is also associated with esophageal or gastric perforation. However, in the case of EMR, the perforations are usually small and may be managed with endoscopic clipping. The third most common cause of perforation is the performance of large-balloon dilation of a stricture or achalasia. These types of perforations are more accurately referred to as tears, and their management is much more difficult. Uncomplicated, small perforations may be managed endoscopically and with supportive care. Large tears require urgent surgical resection and/or repair.

Introduction

The small intestine has been relatively inaccessible to flexible endoscopy until recently [1]. Its length is a challenge to endoscopy. The small intestine accounts for 75% of the total length and 90% of the surface area of the gastrointestinal (GI) tract. In adults it measures about 570 cm at postmortem [2], which is substantially longer than conventional videogastroscopes. Colonoscopes and gastroscopes measure 100–180 cm. There are features about its position and anatomy that limit the endoscopist's chance of passing longer endoscopes much further than a few centimeters into it, either through the mouth and duodenum or through the ileocecal valve. The tight curve from the bulb around the head of the pancreas and its relatively fixed retroperitoneal posterior position as it crosses the spine to the ligament of Treitz, whence it passes downwards as a loosely supported much-looped structure on a mesentery, is a challenge. If a colonoscope is passed through the mouth into the jejunum and a surgeon pleats the small intestine over the endoscope by hand at laparotomy, the stiffness of the endoscope tends to stretch the mesentery, which is attached posteriorly, as the endoscope follows the loops of small intestine and increases the friction exerted by the intestine on the endoscope. Colonoscopists can usually enter the terminal ileum for a few centimeters. Either way, the distance and the curved path that a conventional endoscope has to pass to reach the small intestine mean that the force for effective forward propulsion which can be exerted on the tip of an endoscope is small. Loops tend to form and enlarge in the stomach or in the colon, which can make deep small intestinal intubation difficult.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

Recent technical developments in the design of longer flexible instruments, specifically for push enteroscopy, have made this examination much more successful.

The advent of wireless video-capsule endoscopy [3] has released the endoscopist from the requirement to exert force on a long floppy cable-type endoscope to examine relatively short segments of small intestine. This device exploits peristalsis to propel the videoendoscope through the small intestine and can usually acquire images from the whole of the small intestine, from the pylorus to the cecum.

The development of a double-balloon insertion method for push enteroscopy has substantially increased the length of small intestine that can be reached by flexible endoscopes with an accessory channel. It is now possible to examine the whole of the small intestine in a majority of patients, although this requires passing the enteroscope, overtube, and balloon apparatus into the mouth and the anus on separate occasions.

Technical advances

There has been a substantial increase in small intestinal endoscopy in the last 10 years, which has followed two technical advances (Table 119.1). The first was the development of specific endoscopes for push enteroscopy [1,4–6] (Fig. 119.1). Careful attention to the design allowed better transmission of force to the tip and shaft stiffness for use at flexible endoscopy. These instruments were longer than colonoscopes, measuring 200–240 cm (Fig. 119.2), and slimmer, usually measuring 11 mm in diameter, but with a 2.8-mm accessory channel. They were initially designed for use with an overtube to aid deep intubation, which usually needed X-ray control for safe insertion. The overtube appeared to cause some of the complications associated with push enteroscopy, for example sometimes causing esophageal trauma [7]. The addition of video imaging [4–6] to these instruments allowed very high-quality images to be obtained from the esophagus

Table 119.1 New and available video methods of small intestinal imaging

What is new?
Wireless capsule endoscopy
Double-balloon push enteroscopy
What is available?
Push enteroscopy
Pediatric/adult colonoscopes to be used for push enteroscopy
Intraoperative enteroscopy using a colonoscope
Laparoscopic assisted enteroscopy
Ileoscopy at colonoscopy
What is no longer used?
Sonde enteroscopy
New nonvideo methods for small intestinal imaging
Computed tomography enteroclysis and virtual enteroscopy
Ultrasound
Magnetic resonance enterography

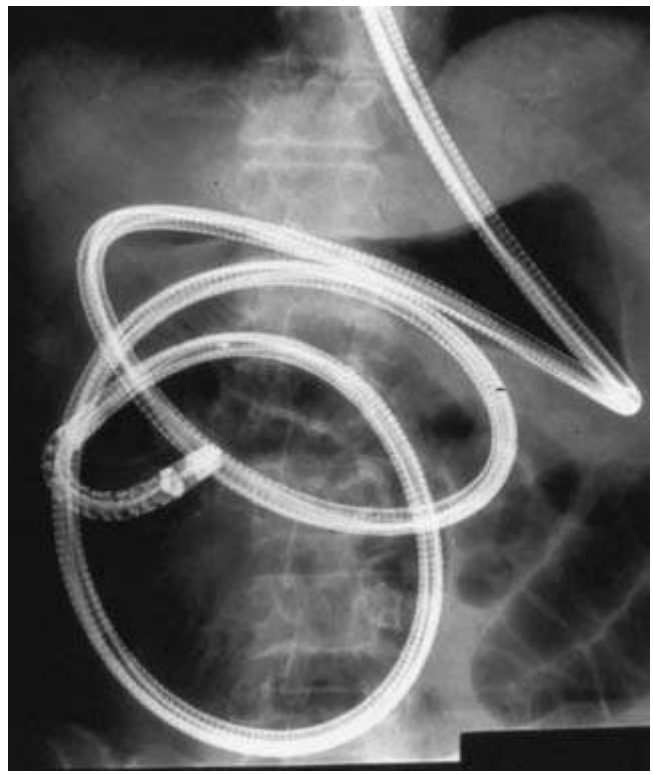

Figure 119.2 Fluoroscopic image of 240-cm-long push enteroscope, which is introduced to its maximum length into the jejunum.

to the jejunum. Despite some evidence that 240-cm enteroscopes do not reach further or find more pathology than those of 200 cm [8], some of the newer instruments are longer than the earlier enteroscopes (240–280 cm). Variable-stiffness enteroscopes have recently become available [9].

Most [9–16] endoscopists [8] found that these instruments could be used almost as well without an overtube and thus dispensed with the need to perform this procedure under X-ray control. There was evidence from two studies that the use of an overtube was associated with a significant increase in depth of insertion into the small intestine by 10–15 cm [17,18] but did not increase pathology findings in either of these studies. The whole of the duodenum and some of the jejunum can be examined by video-colonoscopes [19,20], especially with pediatric colonoscopes, which are more widely available than push enteroscopes and of the same diameter but substantially shorter (135 cm vs 200–240 cm) [21].

It is difficult to be sure how far push enteroscopes are usually advanced into the small intestine because there are no landmarks and it is easy to overestimate the distance examined. A few groups have attempted to measure the distance with or without X-rays, and obtained results that seem rather short (45, 70, or 100 cm) [11,17,18] given the length of the small intestine (about 570 cm in adults at postmortem).

Wireless capsule videoendoscopy was first used in humans in 1999 [3]. It was able to provide video images from the whole of the small intestine and received Food and Drug Administration (FDA) approval in 2002, following the demonstration of safety and efficacy as an adjunct to the investigation of patients with suspected small intestinal disease, especially obscure gastrointestinal bleeding. Although this

technology has been available for a relatively short period, it has been widely adopted and used in more than 750 000 patients. Table 119.2 compares the differences between this technology and push enteroscopy.

Over this period, another technology – Sonde-type enteroscopy – has atrophied and been largely abandoned. This method was usually carried out with a thin (5–7 mm), very long flexible transnasal endoscope with a balloon and a guide thread attached to its tip (Fig. 119.1). Once in the stomach, a conventional transoral gastroscope was used to catch the guide thread and push the Sonde enteroscope through the pylorus. The balloon was inflated and the endoscope was propelled by peristalsis through the small intestine. After about 6 h, a radiograph was taken to see how far it had passed, and the Sonde enteroscope was withdrawn, sometimes recording the image on video [21,22].

There has been another recent advance in the ability to image the small intestine – using flexible endoscopy. Yamamoto et al., in conjunction with Fujinon [23], have developed a double-balloon enteroscope system which can be advanced much further into the small intestine than other push enteroscopes. The balloons are used to pleat the small intestine on the overtube, which is cautiously advanced over the enteroscope. This technique takes much longer to perform than conventional push enteroscopy and needs X-ray screening, but it can sometimes examine even the whole of the small intestine, though usually with both anal and oral insertion on different days. The system [24,25] may well be an important advance in enteroscopy because it may allow endoscope-directed therapy, such as biopsy, snare polypectomy, and thermal treatment, of any area in the small intestine.

A side-viewing duodenoscope is occasionally helpful in viewing periampullary or duodenal abnormalities [26], which are not well seen with a forward-viewing endoscope, or for assessing whether bleeding is coming from the biliary or pancreatic duct [27].

Diagnostic laparoscopy can be especially valuable in children with suspected small intestinal bleeding [28] and probably should be used early in young males with recurrent bleeding because a Meckel diverticulum is the cause in two-thirds of male patients under 25 [29]. It is also of some value in middle-aged patients when a small intestinal tumor is suspected [30]. There has been some interest in using laparoscopy to pleat the small intestine over a push enteroscope in order to advance the enteroscope to the ileocecal valve [31,32].

Open surgical exploration with an endoscope passed through the mouth or through an enterotomy, for example in the cecum, continues to be an important last resort investigation in some patients with difficult GI bleeding [33].

Push enteroscopy

Technique

Push enteroscopes are heavier and longer than standard gastroscopes. They are slightly more difficult to handle during esophageal intubation and passage across the pylorus, but the push characteristics and increased flexibility allow for better handling in the jejunum. The bending section of push enteroscopes is longer, to allow increased angulation in all directions (Fig. 119.1).

A complete examination of the esophagus and stomach should be performed with the instrument before entering the duodenum; looping of the instrument in the stomach may produce red marks, usually on the greater curve, which may be difficult to distinguish from vascular ectasias or erosions

on pullback. Reducing air insufflation and consequent distention of the stomach, by sucking out the air in the stomach before entering the duodenum, may lead to deeper insertion of the enteroscope. The patient may feel discomfort as the instrument is advanced, distending the greater curvature of the stomach. Paradoxical or arrested tip motion occurs if the instrument loops within the fundus. By exerting pressure and clockwise torque, the endoscopist can generally push through the loop. Care should be taken not to form a loop within the stomach. Once the scope has been advanced into in the second part of the duodenum, pulling the endoscope back will produce paradoxical advancement, as is the case during endoscopic retrograde cholangiopancreatography (ERCP). The ligament of Treitz is usually encountered 85–110 cm from the incisors, and usually requires full tip deflection to find the lumen. Once around the ligament, the first jejunal loop can be identified by a straight configuration, which points in a caudal direction if seen on a radiograph.

Overtube

A variety of methods have been used to try to reduce the tendency of the enteroscope to loop in the stomach. These include the use of abdominal pressure, internal stiffening devices [11], and overtubes [11,17,18] of 60–100 cm in length. Some have two ring-shaped metal tip markers to facilitate placement under screening and to prevent the overtube tip from being compressed. Others have a more pliable Gore-Tex tip of 10 cm in length, which may limit mucosal trauma when advancing the overtube over the endoscope. The overtube is initially backloaded onto the shaft of the endoscope, and is advanced down the endoscope through the esophagus until its distal tip rests within the second portion of the duodenum or beyond the ligament of Treitz. Fluoroscopy is helpful for overtube use as prepyloric placement does little to aid deep intubation. The softer Gore-Tex-tipped overtube may buckle in the stomach and fail to provide sufficient rigidity. As the overtube is advanced, the endoscope shaft needs to be straightened by twisting the endoscope shaft clockwise while pulling it backward. Some commercially available enteroscopes are too floppy to be used without an overtube. Recently, a shape-lock overtube, which has interlocking rings that can be pulled tight with wires to lock the device into a fairly rigid conformation, and has an external and internal hydrophilic coated sheath, has been used to aid insertion of push enteroscopes deep into the small intestine.

Diagnostic applications

The main indication and pressure for improvements in enteroscopy has been obscure gastrointestinal bleeding in patients with a negative gastroscopy and colonoscopy. Push enteroscopy has been performed with published diagnostic yields of 30%–50% [1,11]. One surprise has been that in a proportion of such patients having a push enteroscopy – about 25% – the cause has been found in the esophagus, stomach or duodenum within reach of a gastroscope and was missed on a previous gastroscopy. A list of common missed causes of obscure bleeding is given in Table 119.3.

Table 119.3 Common missed causes of bleeding in the upper gastrointestinal tract that may be found during enteroscopy

Large hiatus hernia with Cameron erosions
Watermelon stomach
Dieulafoy exulceratio simplex
Varices
Ulcers
Angiodysplasia

Gastrointesinal stromal cell tumors
Neuroendocrine tumors, e.g., carcinoid, Zollinger–Ellison syndrome
Polyps
Adenomas
Hamartomatous polyps
Lipoma/angiolipoma
Neurofibromas
Duplication cysts
Adenocarcinomas
Lymphomas
Sarcomas
Metastases, e.g., melanoma, renal cell carcinoma

Push enteroscopy has helped in the diagnosis, biopsy, and management of small intestinal tumors (Table 119.4). Other indications include malabsorption including coeliac disease; assessment of Cohn's disease, nonsteroidal antiinflammatory drug (NSAID)-induced strictures and erosions, abnormalities on barium or computed tomography (CT), and worm infestation.

Therapeutic applications

Push enteroscopes include a standard 2.8-mm biopsy channel that has been used for several therapeutic functions within the proximal small intestine, as well as for directed biopsy [11]. The more the instrument becomes looped as it advances into the small bowel, the greater the difficulty in getting instruments to emerge from the biopsy channel. This particularly applies to instruments with a long rigid tip, such as a heater or bipolar probes and balloons, rather than snares and laser fibers.

Biopsy

Endoscopic forceps-type biopsy has now largely replaced the use of a suction-fired biopsy capsule as a means of taking

small bowel biopsies [34]. The advantages of the endoscopic method are speed, ease, patient comfort, and reliability. Enteroscopic biopsies can reduce the chances of proximal duodenal inflammation and shorter villi in the bulb causing confusion when examining for celiac disease. They might offer advantages in the workup of patients with diarrhea or malabsorption, particularly if focal specific mucosal abnormalities have been seen in the proximal jejunum on small bowel radiograph contrast series [14]. In countries such as the UK, where celiac disease is the most common cause of malabsorption, enteroscopic biopsy does not add much information that is not acquired by duodenal biopsies taken with a gastroscope because celiac disease mainly affects the proximal jejunum. It is more useful in assessing celiac-like syndrome patients with unresponsive sprue or celiac patients with weight loss when a lymphoma is suspected [35–37]. The cause of diarrhea in patients with chronic human immunodeficiency virus (HIV)-related diarrhea is more likely to be detected by jejunal biopsy than by duodenal biopsy [38].

Jejunal feeding tube placement

Push enteroscopy has also been used in a variety of ways to place jejunal feeding tubes. It has been used to carry a transgastric jejunal tube through a previous gastrostomy into the jejunum [39–41]. Nasojejunal feeding tubes have been placed using the Seldinger over-the-wire technique [42]. The push enteroscope is placed into the jejunum initially and then a guidewire is advanced. The endoscope is removed, leaving the guidewire in place. A feeding tube is advanced over the wire and then rerouted from the mouth through the nose. This method has been combined with a sewing method for attaching the jejunal feeding tube to the stomach to prevent displacement [11].

Direct percutaneous endoscopic jejunostomy placement

By using push enteroscopy, the pull technique for the placement of percutaneous gastrostomies has been extended to permit direct percutaneous jejunostomies [11,41,42]. This technique has also been used to place jejunal tubes for small bowel enemas [43] as well as to obtain cholangiograms in patients after Roux-en-Y hepaticojejunostomy [11,44].

Polypectomy

Polypectomy can be performed in the small intestine via the push enteroscope using snares [11,45]. Surveillance of patients with a polyposis syndrome can be performed with push enteroscopy, allowing biopsy and polypectomy of larger lesions. Removal of large jejunal hamartomatous polyps in the Peutz–Jegher syndrome has become part of the screening of this autosomal dominant condition with a malignant potential (Fig. 119.2). The more proximal lesions are relatively easy to remove, but endoscopic removal may require an enteroscope and snare used at open surgery: this technique can find and deal with polyps that cannot be identified by surgical palpation and transillumination [46].

Treatment of gastrointestinal bleeding

In addition to diagnosis, push enteroscopy allows cauterization of bleeding sites. Using bipolar cautery, Foutch was able to fulgurate angiodysplasias in 11 of 12 patients [19]. Control of bleeding was obtained in 8 of the 11 treated patients. Askin and Lewis [47] assessed the long-term effectiveness of push enteroscopic cauterization of bleeding arteriovenous malformations in 89 patients. Of these patients, 61 were cauterized and 28 were not. The group that was cauterized required significantly fewer blood transfusions than the noncauterized group. In another series of 50 patients undergoing therapeutic push enteroscopy, bleeding was terminated in all patients with isolated angiomas and reduced in more than half of the patients with multiple jejunal angioma, as well as in some malignant tumors [48]. In addition, in 9 of the 50 patients the bleeding source was found within the reach of a gastroscope [48] and successfully treated. This group had a significantly reduced transfusion requirement compared with their precauterization status. Heater probes and bipolar probes, as well as monopolar probes and laser fibers, are available in lengths to fit the newer longer push enteroscopes. Argon plasma probes are just long enough to reach beyond 240-cm enteroscopes. Power levels should be reduced for cautery of flat lesions in the small intestine, as it is thinner than the stomach and colon.

Injection of small intestinal varices

Small intestinal varices, especially in the duodenum and ileum, around anastomoses or adhesions in patients with mesenteric thrombosis are an uncommon cause of bleeding but can be misdiagnosed and biopsied and may cause torrential bleeding. Successful treatment of bleeding jejunal varices using push enteroscopy to inject a sclerosant has been described [49].

Complications

Complications are uncommon with push enteroscopy, which is probably nearly as safe as gastroscopy, and most series report that no complications occurred. Some of the complications appear to be associated with the use of a metal-tipped overtube. These include a Mallory–Weiss tear, pancreatitis most likely secondary to papillary trauma, a pharyngeal tear, and three cases in which long strips of gastric mucosa were torn off during advancement of the overtube [7,12,21]. These complications with overtubes occurred prior to the addition of a Gore-Tex tip. Duodenal perforation has been described [50] but appears less common than with ERCP or endoscopic ultrasound. Some series describe severe patient discomfort, which is usually in relation to stretching of the stomach as a loop is formed along the greater curve while trying to transmit forward pressure to advance the tip in the small bowel.

Intraoperative video-enteroscopy

Technique

The endoscope needs to be cleaned, but not sterile, because the technique involves either peroral intubation of the small intestine or placement of the endoscope into a nonsterile bowel through an enterotomy, in which case it can help to place the endoscope in a sterile plastic sheath. The endoscope is advanced into the proximal jejunum through the mouth prior to laparotomy; once the abdomen is open it may be difficult to advance the instrument around the ligament of Treitz. With oral intubation using an adult colonoscope, the endotracheal tube cuff may need to be deflated to permit passage of the wide-caliber endoscope. Once the endoscope has been positioned in the proximal jejunum, laparotomy is performed. It can be helpful to place a noncrushing clamp across the ileocecal valve to prevent distention of the colon with insufflated air, because colonic distention can lead to difficulties with subsequent abdominal closure.

The examination is carried out by an endoscopist and a surgeon; the endoscopist looks at the endoscopic image using minimal air insufflation while the surgeon holds the endoscope tip inside the small bowel so as to inspect a short segment ahead of the endoscope. The surgeon then advances the endoscope into another segment. The view is best seen by dimming the overhead lights, also allowing the surgeon to look at the transilluminated bowel, which can be helpful in finding angiodysplasia. Once examined both internally and externally, the small bowel is pleated onto the shaft of the endoscope and the next section of bowel is examined. Care has to be taken not to overstretch the mesentery on colonoscopies or push enteroscopes, which are rather stiff for this use. Active bleeding within the small bowel may diminish the effectiveness of this examination. Visual examination and interpretation has to be performed during intubation and not on pull-back because mucosal trauma occurs with pleating, causing artifact that may be confused with the appearance of angiodysplasia [51]. A technique of reverse transillumination to help differentiate trauma from vascular ectasias in this setting and to allow visualization of the feeding vessel has been described [52]. At the end of the examination, the endoscope is withdrawn and the surgeon can resect the abnormalities identified by the sutures.

An alternative technique is to perform an enterotomy through which a "sterilized" endoscope or an endoscope covered by a sterile plastic sheath is placed. The enterotomy is generally performed in the mid-small bowel, allowing both proximal and distal intestinal intubation, but it can be performed in the cecum if vascular ectasias are suspected in this area, or in the distal small bowel. Retrograde intubation of the small bowel can alternatively be performed after the cecum has been inspected. The colonoscope is advanced through the ileocecal valve by the surgeon and up the small intestine.

Diagnostic and therapeutic utility

Intraoperative endoscopy has been used for a variety of indications [46,47,52–58], but until recently was probably the endoscopic method most widely used in identifying small intestinal sites of bleeding beyond the proximal jejunum. It can be successful in identifying the site of blood loss in selected patients with reported yields of 83%–100% [53–58]. Vascular ectasias are the most common nonpalpable cause of bleeding, but radiation enteritis, ulceration, malignancies, strictures, and polyps (e.g., multiple polyps in Peutz–Jegher syndrome) may require intraoperative endoscopic identification. Hemostasis can be achieved at intraoperative enteroscopy, either by resection of the bleeding lesion or by transendoscopic ablation of the bleeding lesion, usually with a thermal endoscopic method.

Complications

Prolonged ileus, sepsis, and perforations (the surgeon should listen for a hissing sound that indicates that perforation has occurred) are common sequelae of operative enteroscopy.

Outcome studies of the value of video-enteroscopy with flexible instruments

Several studies have looked at the number of diagnoses, the influence on management, and the subsequent clinical path of patients who have enteroscopy for suspected small intestinal outcome. Recent prospective studies have suggested that management was altered in more than 50% who had push enteroscopy [57,58]. One study has shown that the costs of investigating and managing patients who bleed from the small intestine are different and substantially more expensive than the costs of patients who bleed from other gastrointestinal sites [59]. Outcome studies of the value of push enteroscopy in nonbleeding conditions suggest that it can be of value in malabsorption [14,60], Crohn's disease [61], NSAID toxicity [62], and worm infestation [63]. It can be usefully performed in nonspecialist, district general hospitals [64].

It may be helpful to have some knowledge of the clinical patterns and appearances of the many less common or rare diseases that can affect the small intestine [65]. Access to an atlas [66] and a book-length review on enteroscopy (in the *Gastrointestinal Endoscopy Clinics of North America*) [67] may help.

Wireless capsule videoendoscopy

The development of wireless capsule endoscopy [3,68–72] has changed videoendoscopy of the small intestine into a much less invasive and more complete examination [3,71,73–83]. It has been particularly successful in finding the cause of obscure gastrointestinal bleeding of suspected small intestinal origin [73–83] (Fig. 119.3).

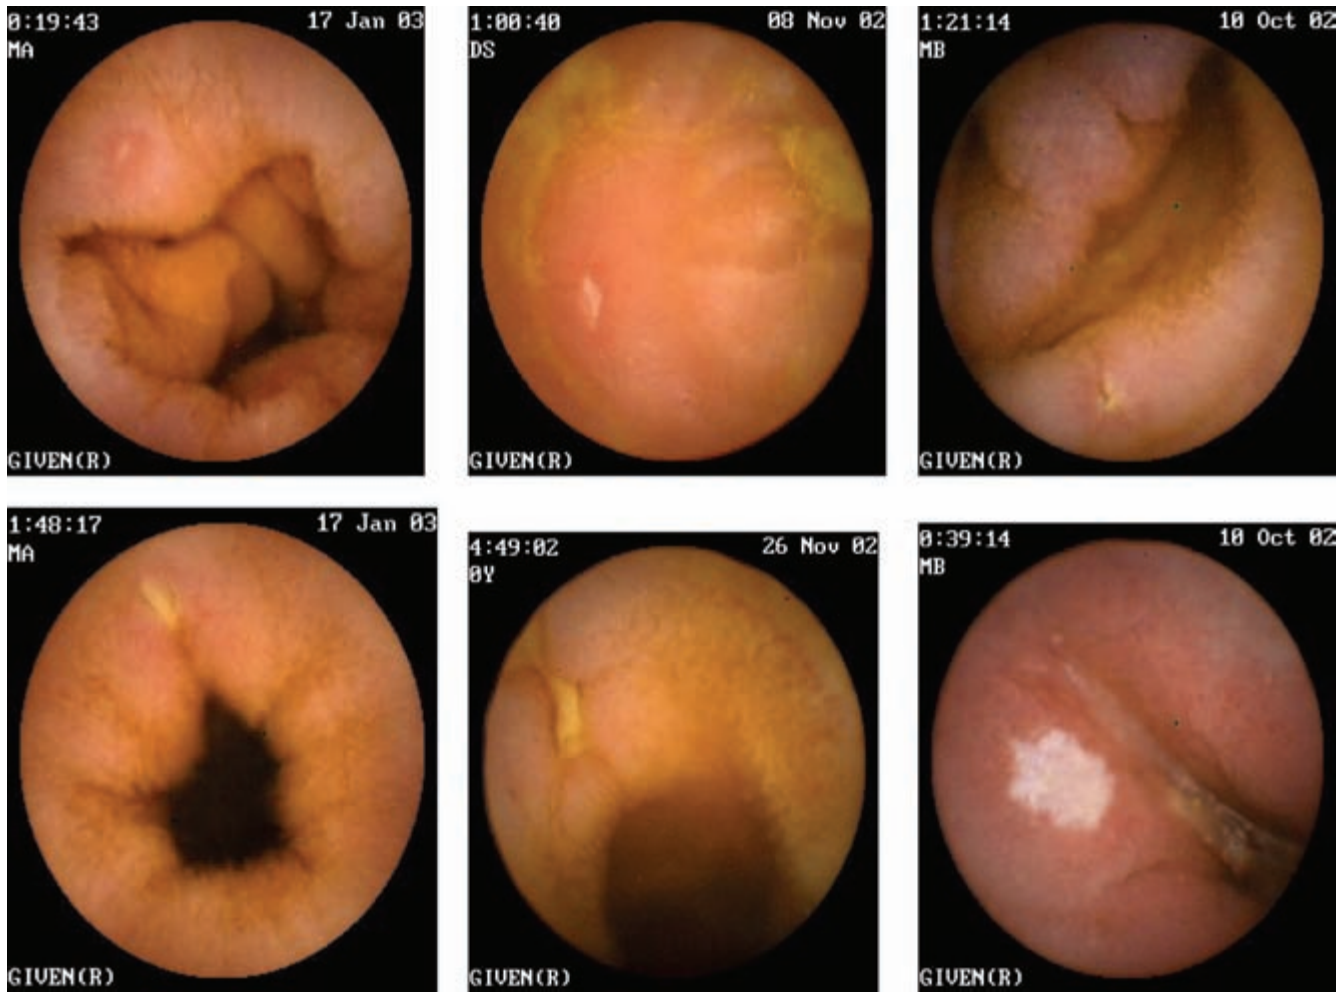

Figure 119.3 Aphthous ulceration.

Figure 119.4 Capsule endoscope with six light-emitting diodes.

The capsule endoscope (M2A, Given Imaging, Yokneam, Israel) contains a video-imager, transmitter, light source, and batteries in a rounded cylindrical plastic container measuring 11 × 26 cm [3]. There is a clear optical dome-shaped window that allows the intestine to be illuminated by an array of six (formerly four) light-emitting diodes (Fig. 119.4). The image is captured through a short focal length lens with a wide angle as the optical window of the capsule sweeps past the gut wall, without requiring air inflation of the gut lumen. The video images are transmitted using radiotelemetry (operating in an ultra high frequency (UHF) of 432 MHz) to an array of eight aerials attached to the body. They allow image capture and enable calculation and indication of the position of the capsule in the body. The capsule transmits images at a rate of two (or more recently four) frames per second for over 7 h, allowing the acquisition of over 50 000 images of the gastrointestinal tract.

These images are subsequently downloaded from the portable recorder for analysis off-line. Currently, the time needed to evaluate the video sequence takes between 45 min and

2 h and varies with the experience and concentration of the examiner as well as the number of pathological abnormalities present.

Wireless capsule endoscopy can provide about 7–8 h of continuous video imaging of the gastrointestinal tract. This usually allows image acquisition from the esophagus, stomach, small intestine and right colon. The capsule is propelled by peristalsis and is passed through the anus into the toilet, usually 1 or 2 days after ingestion. Because the gut is a hollow tube it is unimportant as to whether the capsule points forward or backward as it passes through. This form of endoscopy is painless, does not require sedation, and, in consequence, the patient is ambulant and does not need to be confined to a hospital during the examination [3,73–83].

Procedure and technique

To obtain consent, an explanation of the procedure should be provided that specifically includes the facts that the capsule may become stuck in the small intestine, requiring surgical removal; that capsule endoscopy does not always image the whole of the small intestine; that a plain abdominal radiograph may be performed if colonic images are not seen and the capsule is not seen in the toilet by the patient; and that MRI scans should not be done if the capsule is not known to have emerged. The patient should have an overnight fast or be nil by mouth for 12 h prior to ingesting the capsule. Preparation, as for colonoscopy, may improve the quality of images in the lower small intestine, but there are few data to support one regime over another. This is necessary if images of the right colon are important, for example in patients with incomplete colonoscopy.

The battery packs need to be fully charged and the patient details registered on the workstation with the recorder before starting the examination. The aerial cable should be securely attached to the recorder and placed in the belt. The patients should be shown how to manage the belt and lift it in the event of having to go to the toilet and to lay it carefully to the side while lying down in bed during the examination period. The capsule can then be removed from its packaging, which contains a magnet. This action will activate the capsule by releasing an internal magnetic switch and the capsule will start flashing. The patient can then swallow the capsule, usually with some water. Most patients can swallow it with the first gulp, but some children and a few adults find it difficult. Of these, some may be helped by asking them to place it in the mouth and then to try to swallow it while drinking out of a bottle. It is helpful to ask the patient to keep an eye on the flashing light on the recorder and the connection between the aerial and the recorder and to report back if it stops flashing over the next 2 or 3 h.

Patients should be asked not to eat for 3 h after swallowing the capsule but told that they can drink clear water. They can have a light meal after this time. The belt and aerial can be removed 8 h after swallowing the capsule, or when the recorder has stopped flashing. Patients should return the recorder, aerials, and belt but do not need to find and return the disposable capsule.

The images on the recorder need to be downloaded and processed prior to interpretation. Currently, image analysis of the 50 000 or so images acquired over the 8-h period takes about an hour or more to complete. It is probably unwise to read all the images at the fastest of the three available speeds. It is helpful to store any unusual images as well as definite abnormalities as thumbnails for more careful subsequent review. The points of entry into the stomach, duodenum, and cecum need to be marked to enable the localization software to image the passage of the capsule inside the abdomen. Abnormalities detected as blood by the blood-sensing algorithm need to be checked. Newer software places two adjacent images side by side to allow faster image analysis. The recording, with marked thumbnails, needs to be saved to the hard drive and to a CD-ROM. A typed report with an interpretation of the findings needs to be generated.

It may help to take breaks while reading the images as a loss of concentration may lead to missing important pathology, which may be seen only on a single frame. Interpretation of small intestinal images is not always easy and it may help to go backward and forward over some image sequences and to ask another endoscopist for an opinion. There is a wide range of pathologies, and numerous rarities are found that can affect the small intestine. The visual appearances are not specific, especially for the wide range of tumors found in the small intestine (Table 119.4). Benign conditions, including Crohn's disease, amyloidosis, and lymphangiectasia, have a wide range of appearances. It can be difficult to be sure when a red spot is really an angiodysplasia. In young males, it may be helpful to review the lower small intestinal images for a double-lumen suggestive of a Meckel diverticulum and to run over some of the images in the light of the patient's clinical history.

Most patients think that wireless capsule endoscopy is great and find it preferable to conventional endoscopy or colonoscopy [74,82]. It has been at least as successful as, and sometimes significantly more successful [75,82] than, push enteroscopy in finding the cause of obscure gastrointestinal bleeding (Table 119.5) in published series with yields of 55%–70% (Table 119.6). A blood-sensing algorithm may assist in alerting the physician to an area of bleeding pathology (Fig. 119.5) [84]. It has been successful in identifying small intestinal tumors (Table 119.4), even though multiple other investigations have failed [74,82,85], but may miss other tumors [86]. It has been significantly more successful than barium studies [87] in finding pathology in the small intestine, and has outperformed barium meal as well as state-of-the-art enteroclysis [88,89] and computed tomographic enteroclysis [90] in fully published recent studies.

Limitations

The images from the esophagus, stomach and colon are not as good as those acquired during conventional endoscopy, but may show pathology in these areas. The quality of images in these areas is likely to improve as specific wireless capsule devices and methods for image acquisition in these areas are developed. The images from the small intestine are somewhat poorer than enteroscopic views because the capsule cannot wash or be pulled back to re-examine a possible abnormality. At present, wireless capsule endoscopes cannot take biopsies from or provide therapy for a patient. With its current acquisition time of 7–8 h, the capsule fails to provide images from the cecum about 15% of the time. As a consequence, an uncertain length of small intestine remains unexamined. A few patients, especially children, have difficulty swallowing capsule endoscopes. Occasional patients retain it for prolonged periods in the stomach since there is a very wide range of "normal" gastric emptying times. Images may be poor in patients with morbid obesity. It can take a long time to interpret the images. Skill and experience are required. Many of the findings can be of unknown significance. Pathology may only be seen on a single frame. Because it can travel looking forward or backward, it may not look at pathology in an expected direction. Images in the lower small intestine are often rather dark. The recurring cost of the capsule as a disposable and the relatively lengthy examination times require specific funding and organizational strategies.

The main complication is that the capsule may become impacted in strictures [91] or diverticula [83]. Most commonly, capsule impaction is symptomless. Sometimes capsule impaction may be a good outcome, leading to identification of strictures, diverticula or ulcers, which can be resected. If the capsule can be reached by an endoscope, a snare with a net is the most useful retrieval tool since the capsule is more difficult to grasp with a stone basket or simple snare. Inadvertent MRI might cause complications as the capsule will respond to a magnetic field. If a capsule examination does not provide colonic images and the patient does not see the capsule in the toilet it might be sensible to take a plain abdominal radiograph to check for passage. Pacemakers are probably of no contraindication. Capsule endoscopy has been approved by the FDA for use in children over 10 years of age.

Double balloon enteroscopy

Double-balloon enteroscopy, sometimes called push-and-pull enteroscopy, is a new method that may allow complete visualization, biopsy, and treatment in the small bowel.

The double-balloon enteroscope features two balloons, one attached to the distal end of the 200-cm endoscope (9 mm in diameter) and the other attached to a transparent tube sliding over the endoscope (Fig. 119.6). The enteroscope

Figure 119.6 Double-balloon enteroscope.

is thinner and shorter than most push enteroscopes. When inflated with air, the balloons can grip sections of the small intestine and shorten the small intestine by pleating it over the endoscope. Sequential shortening of the small intestine over the endoscope onto the overtube and advancement of the endoscope allows the endoscope to be advanced further into the small intestine than push enteroscopes, and may examine up to more than half of the small intestine. If passed through the anus first, as in Japan, or through the mouth first, as in Europe, and then through the other route, usually on another day, it appears to be possible to examine the whole of the small intestine in more than two-thirds of patients.

Yamamoto, whose groups developed this method in Japan with Fujinon, reported that the double-balloon endoscopy system was used to perform 178 enteroscopies (89 by the anterograde approach and 89 by the retrograde approach) in 123 patients [92]. Insertion of the endoscope beyond the ligament of Treitz or ileocecal valve was possible in all 178 procedures. It was possible to observe approximately one-half to two-thirds of the entire small intestine by each approach, and observation of the entire small intestine was possible in 24 (86%) of 28 attempts. The source of bleeding was identified in 50 (76%) of 66 patients with GI bleeding, scrutiny of strictures was possible in 23 patients, and a tumor was examined endoscopically in 17 patients. Two complications (1.1%) occurred. Endoscopic therapies in the small intestine, including hemostasis (12 cases), polypectomy (one case), endoscopic mucosal resection (one case), balloon dilation (six cases), and stent placement (two cases), were performed successfully.

In a recent European series reported by May, 248 consecutive double-balloon enteroscopies (push-and-pull enteroscopies) were performed in a prospective study in 137 patients with suspected small bowel disease, most with chronic GI bleeding (66%) [93]. On average, 240 ± 100 cm of the small bowel was visualized by using the oral route, and 140 ± 90 cm was visualized by using the anal route. The investigation time averaged 73.5 ± 25 min. The overall diagnostic yield was 80% (109/137 patients). The main diagnosis was angiodysplasia (40/109; 37%); erosions and ulcerations of various etiologies were found in 27% (29/109). Polyps and tumors, including malignancy, were identified in 25% (27/109). No relevant pathology was found in 20%. Subsequent treatment was influenced by the results in 104 patients (76%): endoscopic therapy in 57 (41.5%), medical treatment in 23 (17%), and surgery in 24 (17.5%).

Feasibility and diagnostic/therapeutic yield in patients with suspected small bowel disease

It seems clear that double-balloon enteroscopy can reach further than push enteroscopy without balloons. It can allow a variety of therapeutic procedures to be performed as well as biopsy. The accessory channel in most of the enteroscopes used with the double-balloon technique is only 2 mm, which limits therapy, although experience is being reported with prototypes with a larger 2.8-mm channel.

A comparison between wireless capsule endoscopy and double-balloon enteroscopy in 35 patients by Hadithi et al. [94] showed that small bowel abnormalities were detected using wireless capsule endoscopy in 28 (80%) of the 35 patients with obscure gastrointestinal bleeding, compared with 21 (60%) of the 35 patients using double balloon enteroscopy ($P = 0.01$). Both examinations were well tolerated, but capsule endoscopy was more acceptable to patients. No major adverse event occurred after either examination. Biopsies ($n = 27$), argon plasma coagulation ($n = 19$), tattoo injection ($n = 8$), and polypectomy ($n = 2$) were feasible with double-balloon enteroscopy when indicated in 27 of the 35 patients (77%).

The identification of a Meckel diverticulum [95] and endoscopic resection of a duodenal carcinoma in a patient with a Roux-en-Y gastrectomy [96] suggests that this method can reach parts of the small intestine that could not be reached by more conventional endoscopes. Therapy of bleeding from some small bowel sources has been reported using this method [92–94]. Double-balloon enteroscopy has also allowed the removal of capsules caught by strictures in the small intestine [97,98], treatment of strictures [99,100], and resection of Peutz–Jeger hamartomatous polyps throughout the small intestine without laparotomy [101].

There is a price to pay for this type of enteroscopy. It is uncomfortable for patients, can cause ileus [102], and takes much longer to perform than conventional push enteroscopy. The most experienced group admit all their patients for 2 days so that they can enteroscope from the mouth and the anus on consecutive days. There is a recurring cost for the disposable double balloons. Even so, it is likely that double-balloon enteroscopy will come to replace a good deal of push enteroscopy. It seems to be complementary to capsule endoscopy, allowing detailed review of lesions found by capsule endoscopy offering biopsy and therapeutic options.

Clinical management of patients with obscure gastrointestinal bleeding

The most common causes for small bowel investigations are patients with obscure gastrointestinal bleeding and a suspected small intestinal bleeding source. It is assumed that these patients have been investigated with a negative gastroscopy and colonoscopy.

If the review of the gastroscopy and colonoscopy findings suggest that this examination was incomplete or of poor quality, it may be appropriate to repeat upper endoscopy and colonoscopy prior to any other examinations. The clinical history and any other investigations should be reviewed for hints about the possible location of the obscure bleeding. Age, location of any discomfort, length of history, color of blood seen by patient, presence of skin abnormalities, unexplained abnormal blood tests, weight loss, and previous history of malignancy (e.g., melanoma) should be used to focus the search. Investigation pathways can be constructed based on the age and symptoms of the patients.

If a male between 10 and 25 years of age presents with obscure GI bleeding, a Meckel scan should be performed. If positive, surgery should be undertaken without further imaging. Because the scans are frequently negative in such patients, and bleeding from a Meckel diverticulum accounts for bleeding in two-thirds of this group of patients, capsule examination could be the next step to look for this and other causes of bleeding, such as Crohn's disease. If the capsule examination is negative, an early laparoscopy should still be considered.

In all higher age groups, specific questioning about aspirin or NSAID use, site of abdominal pain if any, history of previous treatment for malignancy (e.g., melanoma), duration of bleeding, and time since last bleed should influence the choice and order of investigations.

If the patient is aged between 40 and 65, with a short history of recurrent anemia, continuous bleeding or transfusion requirement, or weight loss and raised inflammatory markers, a more intensive investigational algorithm should be followed with early push enteroscopy or capsule examination. If the patient is a female, consider a gynecological opinion, including pelvic ultrasound and fecal occult blood testing, prior to intensive small intestinal investigation.

If the history is short, or in the case of active bleeding, transfusion requirement, alarming symptoms, or an anxious patient, then capsule examination should be the next examination. Double-balloon enteroscopy should be considered for patients with uncertain abnormalities on capsule enteroscopy or incomplete examinations, for therapy. An algorithm of examinations in these patients is given in Box 119.1.

Conclusion

Video-enteroscopy is changing the management of patients with small intestinal disease. It is of proven value in the diagnosis of patients with obscure GI bleeding. There is a high incidence in most enteroscopic series of lesions being missed or their significance not being understood on initial gastroscopy (Table 119.3). A case could be made for a repeat gastroscopy by an experienced endoscopist before performing push enteroscopy or wireless capsule examination. There is also a well-documented miss rate [103] for colonoscopy of polyps and cancers, which may be due to failure in reaching the cecum (10%–22% in large colonoscopy series) or to incomplete examination on rapid withdrawal of the colonoscope.

In patients with documented malabsorption, push video-enteroscopy with biopsy is sometimes of value in establishing a diagnosis when duodenal biopsies are unhelpful. It is more valuable in assessing compliant patients with celiac disease who have weight loss and diarrhea, when a lymphoma is suspected, and in assessing ulcerating jejunitis.

Push enteroscopy is frequently disappointing in assessing patients with negative barium studies in whom Crohn's disease is suspected [11,14], perhaps because Crohn's disease less commonly affects the proximal jejunum. Wireless capsule endoscopy has been, perhaps surprisingly, good at finding evidence of early Crohn's disease [104–106] in patients with negative colonoscopy and barium studies, and probably is the most important advance in imaging for this disease. It has shown that negative ileoscopy does not exclude the diagnosis of Crohn's disease. The fairly common finding of one or a few aphthous ulcers in the small intestine at capsule endoscopy requires further assessment because not all of these patients have Crohn's disease nor is the ulceration likely to be the cause of chronic abdominal pain in all of them. In patients with chronic abdominal pain, the yield of wireless capsule endoscopy is low but not zero [107]. Wireless capsule studies have been able to visualize ileal tuberculosis [108] and worm infestation, and have helped in the management of small bowel transplantation [109]. It has been suggested that abnormal delays in capsule transit can indicate the presence of small intestinal pathology [110].

Video-enteroscopy has opened up a new world of diagnoses and possibilities to the gastroenterologist. It is a privilege to

Box 119.1 Algorithm for investigation of patients with obscure gastrointestinal bleeding and suspected small intestinal bleeding.[a]

- Review clinical history: If male and under 25 consider following Meckel diverticulum algorithm. Presence of liver disease, the patient's or the endoscopist's report on color of blood seen if any, specific questioning about aspirin or NSAID use, site of abdominal pain if any, history of previous treatment for malignancy (e.g., melanoma), length of patient history, and time since last bleed should influence the choice and order of investigations.
- If aged 40–65 and with a short history of recurrent anemia, or with continuous bleeding, a transfusion requirement or weight loss and raised inflammatory markers, follow more intensive investigational algorithm.
- If premenopausal females, consider gynecological opinion, pelvic ultrasound, and fecal occult blood testing prior to intensive small intestinal investigation.
- Review endoscopy and colonoscopy findings. The finding of a large hiatus hernia, blood in the stomach with no obvious cause, an examination by an inexperienced operator, the suggestion that a colonoscopy was incomplete may suggest that a repeat gastroscopy or colonoscopy by a more experienced operator should be performed prior to push or wireless capsule enteroscopy. If the patient describes bright red rectal bleeding then anoscopy and repeat colonoscopy may be helpful prior to enteroscopy.
- Review ultrasound (US), computed tomography (CT), and technetium bleeding – scanning images if any. If there is weight loss or anxiety about cancer, consider US or contrast enhanced CT. If active bleeding is seen in duodenum but no source found, consider using side-viewing endoscope and/or contrast enhanced CT.
- If blood is seen in the stomach, hiatus hernia is known or suspected, known liver disease or if first endoscopy is performed by a relatively inexperienced person, then investigate with repeat gastroscopy by an experienced endoscopist or a push enteroscopy with careful examination of esophagus and stomach prior to small intestinal examination. If negative consider capsule examination next.
- If short history, active bleeding, transfusion requirement, alarm symptoms, anxious patient then capsule examination should be the next examination.
- If male between 10 and 25 years old, a Meckel scan should be performed. If positive then laparoscopic examination and removal should be undertaken. Because the scans are frequently negative in such patients and bleeding from a Meckel diverticulum accounts for bleeding in two-thirds of this group of patients, early laparoscopy, perhaps following a capsule examination, should be considered.

a It is assumed that these patients have been investigated with a negative gastroscopy and colonoscopy.

see images of small intestinal abnormalities at videoendoscopy, such as an ulcerated Meckel diverticulum or active bleeding from a tumor in the middle of the small intestine, which were not possible until recently. The increasing use of this resource and the comfort and ease with which some of these examinations can be performed make it likely that video imaging will have a substantial impact on the management of small intestinal disease.

In the last few years, enteroscopy has been the most rapidly evolving form of endoscopic imaging, necessitating a complete rewrite of this chapter. It is likely that the pace of evolution will remain rapid in this area.

Instrumentation

Flexible fiberoptic technology began to be used for visualization of the colon several years after fiberoptic gastroscopy was introduced in 1957. The first commercially available fiber-colonoscope, the Overholt Coloscope, appeared in the early 1960s. Modern colonoscopes, whether fiberoptic or video, give a brilliant, high-resolution, color view of the mucosa through wide-angle (120–140°) optics. The 20–30-fold magnification at 5 mm distance rivals the close-up view of a dissecting microscope, but colonoscopes provide excellent distant views as well. Tip angulation in four directions to 160–180° allows angulation around most acute flexures. Retroflexion (i.e., J configuration) is possible in the proximal colon or rectum, thus minimizing the risk of missing significant lesions in capacious areas that could not be seen with older, less maneuverable instruments. The length of the instruments varies from the 65-cm flexible sigmoidoscope to the 165-cm colonoscope. The instruments range in shaft diameter from 1-cm pediatric colonoscopes to 15-mm therapeutic instruments. Combined instrumentation/suction channel sizes range from 2.8 to 3.8 mm in diameter with some therapeutic colonoscopes having two accessory/suction channels. A colonoscope is similar in design to a gastroscope, but it has a more flexible shaft to accommodate the various colonic bends encountered. Smaller-diameter pediatric colonoscopes or standard gastroscopes, which are more maneuverable in the colons of babies and small children, also have a place in examining ileostomies and fixed or strictured adult colons. Their ability to retrovert in the capacious portions of the colon can also make some difficult polypectomies easier. Zoom colonoscopes have the capability of image magnification to levels similar to a dissecting microscope (150× original). Enhanced maneuverability is possible with a variable-stiffness instrument [1]. High-resolution optical chips afford greater definition of the visual image. Several colonoscopes have an integral pressurized water jet to wash the colon surface, whereas others may be pushed through the colon by an air-lock system [2]. A shape-locking overtube has been developed to prevent excess looping in the sigmoid area [3].

A full range of endoscopic accessories is available for colonoscopes, including biopsy forceps, electrocoagulating hot-biopsy forceps, cytology brushes, washing and spraying catheters, sclerotherapy needles, various sizes of dilating balloons, and a full range of polypectomy snares and retrieving devices. Other standard techniques can be applied, such as the introduction of balloons or tubes over a guide wire and insertion of self-expanding stents for obstructing cancer. Thermal therapeutic devices such as the heater probe, bipolar electrocoagulation, argon plasma coagulator, or laser are as applicable to the lower gastrointestinal tract as they are to the upper gastrointestinal tract. Some endoscopists use an overtube as a splinting or stiffening device to control looping in the sigmoid colon or as a temporary stent to facilitate rapid withdrawal and reinsertion of the colonoscope.

Blind rectal ultrasound probes can assess invasion in tumors of the anorectal area. Direct-vision, ultrasound-bearing colonoscopes may also have a role in tumor staging. Small ultrasound probes may be passed through the instrument channel of the colonoscope to provide ultrasound as desired at any point throughout the colon [4] (e.g., before removal of sessile lesions, to check the relation of the colon wall to surrounding organs before electrocoagulation).

Fluoroscopy is rarely employed for passage of the colonoscope, but a nonradiological computer-generated image of

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

the scope position and configuration is available. This technology uses a magnetic field locator to read the force from tiny electromagnets embedded in a dedicated scope (or from a probe carrying electromagnets inserted into the accessory channel) to reconstruct an exact model on a monitor [1].

Anatomical basis of colonoscopy

The ease or difficulty of colonoscopy in a given patient is related to the degree to which the supporting mesenteries fuse to the posterior abdominal wall during fetal development. Although the descending and ascending colon become fixed retroperitoneally, in about 10%–15% of subjects they remain mobile on mesocolons that are usually tethered to the sigmoid and transverse parts of the colon. The consequence for the endoscopist is that these colons, being mobile, can move around freely and unpredictably within the abdomen, largely uncontrollable by the various straightening or rotation maneuvers that are effective with conventional colonic anatomy.

There are no fixed anatomical landmarks between the anus and the ileocecal valve, but there are geographical clues that often are helpful (but may also be misleading) to the endoscopist. At about 17 cm, the colonoscope leaves the capacious rectum and enters the narrower, extraperitoneal part of the sigmoid colon (Fig. 120.1). The sigmoid has frequent circular haustral infoldings – which may be especially exaggerated with diverticular disease – into which the instrument tip impacts if steering is not accurate.

In contrast to the zigzag path of the sigmoid colon, the descending colon is a short, tubular segment. An acute angulation of the instrument tip at the junction of the sigmoid and descending colon may afford a clear view of the tubular descending colon, but forward progress may be impeded by loops in the instrument caused by the tortuous and convoluted sigmoid colon.

The transverse colon (Fig. 120.2) frequently shows a triangular configuration as a result of its three longitudinal muscles, or taeniae coli, that act as limiting boundaries to air distention. The liver is a fairly predictable landmark with the flat, bluish-gray surface and sharply defined edges caused by the balloon-like, air-filled colon contacting the hepatic surface (Fig. 120.3).

On entering the ascending colon, the superior lip of the ileocecal valve may appear in the distance as a short, flat segment on the most proximal circular haustral fold (Fig. 120.4). The upper lip may have a notched bulge or may appear thickened by fat accumulation. Most often the opening into the ileum is slit-like on the inferior side of the fold invisible to the endoscopist advancing toward the cecum. The appendiceal orifice, a less definite landmark, is seen as a crescent-shaped slit or a circular convolution of folds at the blind saccular cecal pole (Fig. 120.5). Multiple, pale-reddish, 1–2-mm circular

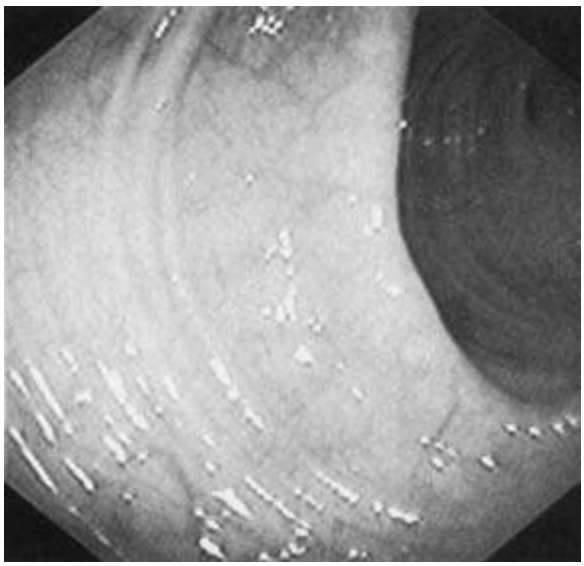

Figure 120.1 In the sigmoid colon, the circular outline with the light reflex over arcs of circular musculature clearly indicates the center of the lumen for close-up endoscopic steering purposes.

Figure 120.2 Transverse colon shows the characteristic triangular outline resulting from the relative thickness of the three longitudinal taeniae coli. The circular muscle is much thinner.

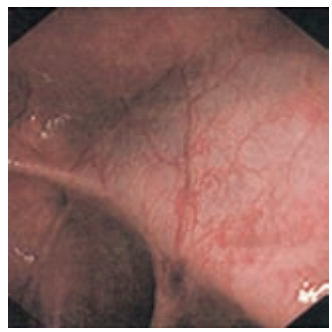

Figure 120.3 Hepatic flexure shows the dark impression of the liver. Similar discoloration can be caused by other extracolonic viscera at the splenic flexure or in the distal colon. Note the longitudinal impression of a taenia and the transverse haustral folds.

Figure 120.4 Ileocecal fold shows the characteristic notch on a flattened fold. The notch denotes the superior lip of the ileocecal valve. The opening is just proximal to and below the notch, and cannot be seen without marked angulation of the instrument tip.

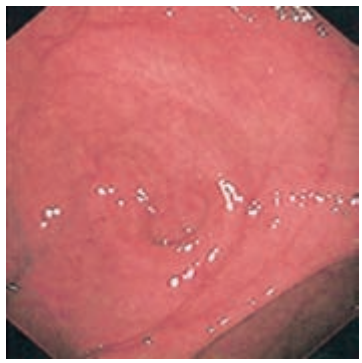

Figure 120.5 The appendix orifice is variable in configuration. Here, the orifice is round, but it may also be seen as a crescent-shaped slit. It is usually rather insignificant in appearance. The internal aspect remains the same after appendectomy.

halos are often seen in proximity to the appendix when using the videoendoscope. These represent lymphoid follicles.

The ileal mucosa has a granular appearance when the ileum is air-filled, and short frond-like villi are visible in pools of fluid. The granular appearance is caused by multiple light reflections from the individual villi. Nodules of lymphoid tissue measuring 1–3 mm, and sometimes aggregated into 10–15-mm plaques of Peyer patches, are normal in the terminal ileum, and particularly prominent in children. By contrast, the normal colorectal mucosa is smooth and shiny, although with deflation, fine transverse innominate grooves may show, especially with surface dye spray.

Throughout the colon, a fine interlacing vascular pattern is visible through the transparent overlying epithelium. When the normal vascular pattern is hidden by mucosal congestion, visible as diffuse redness of the surface, a pathological process must be considered, but biopsies are needed to differentiate between inflammatory change and traumatic or reactive hyperemia. Opacity of the surface can also be caused by

Figure 120.6 Retroversion of the endoscope in the rectum is a useful maneuver to find or remove small polyps in the distal part of the rectal ampulla. The dentate (pectinate) line is serpiginous at the junction of the squamous mucosa of the anal canal and the columnar rectal mucosa.

thickening that occurs after chronic colitis or by edema. In the rectum, the vascular pattern is more pronounced, with larger vessels. Hemorrhoidal veins may appear wide and tortuous. A U-turn (i.e., retroflexion) maneuver in the rectum should always be attempted to afford a view of the rectal ampulla, the dentate line (Fig. 120.6), and internal hemorrhoids [5], but the rigid anoscope gives a superior view of this area by dilating it maximally.

Localization during colonoscopy

The position of the colonoscope can be judged approximately by a combination of factors, principally the length of instrument inserted and the characteristic appearances of certain areas, including the sharply defined blue color of the liver, the fluid-filled splenic flexure area, and the triangular air-filled transverse colon. Most instruments are bright enough to transilluminate the abdominal wall where the bowel approximates to the surface at the splenic flexure (left midaxillary line), transverse colon, or cecum.

The transabdominal impression of the endoscopist's palpating fingers may often be seen from within. Transillumination or endoscopically visible indentation by finger palpation in the right iliac fossa, however, does not necessarily indicate that the tip of the instrument is located in the cecum, because the instrument tip may stretch almost any portion of the colon into the right lower quadrant during colonoscopic intubation. For instance, mobile portions of the bowel, such as the sigmoid or the midpoint of the transverse colon, can be pushed toward the right iliac fossa.

All localizing judgments that depend on landmarks or palpation can be mistaken. For instance, if using the length of scope inserted, in a long or mobile colon, 80 cm of shaft may be looped in the proximal sigmoid, whereas in the same patient during withdrawal, the instrument may be straightened so that the splenic flexure is 40 cm from the anus, and the hepatic flexure (or even the cecum) can be reached with

50–60 cm of instrument. The only definitive landmarks are the appendiceal orifice, the ileocecal valve, and the ileum seen through the ileocecal valve, but even this may be difficult to locate, and the valve can be effaced after severe or long-standing inflammatory disease.

Because of the absence of absolute landmarks throughout the colon, even if the endoscopist has reported success in total colonoscopy with identification of the ileocecal valve and cecal pole, there is still the possibility of being grossly mistaken about the location of the instrument tip and the anatomical localization of pathological findings. Experienced endoscopists can occasionally mistake the splenic flexure for the hepatic flexure, or the hepatic flexure for the cecum, and thereby mislead the surgeon as to the site of an obstructing tumor [6]. In spite of this, fluoroscopic guidance is rarely used, but some find it helpful in the endoscopist's learning phase and in a few difficult cases. The magnetic imager [1] is a localizing device whereby small electromagnets are inserted into the colonoscope shaft, either during manufacture or embedded in a catheter-type wand. External sensors can detect the magnetic energy and plot a computer image of the shape and location of the endoscope. There is no radiation, and the computer-generated image is similar to that obtained fluoroscopically.

Any lesion seen by colonoscopy can be marked with an intramural deposit of carbon particles using sterilized India ink or a pure carbon suspension, injected through a long, flexible, injector needle; these techniques enable subsequent surgical localization or enable the endoscopist to find the area on a subsequent examination [7]. A gray-blue submucosal stain of carbon particles permanently remains at the injection site. Vital dyes, such as methylene blue, indocyanine green, or indigo carmine, are rapidly absorbed, disappearing within hours or days. It is possible to mark a lesion or the proximal extent of tip progress with metal clips [8], but this technique is not often clinically useful.

Bowel preparation

Total colonoscopy is rarely possible in the unprepared colon. Patients with profuse watery diarrhea are sometimes mistakenly thought not to require preparation and are often found to have an opaque mucosal coating of fecal material that obscures adequate view of the surface. Even patients with a surgically defunctionalized bowel produce inspissated mucoid residue and require cleansing. A patient with massive colonic bleeding may effectively cleanse the colon of fecal material, but often a residual coating of blood obscures mucosal events during the colonoscopic examination.

Limited preparation

When it is necessary to examine only the distal colon segments, an adequate preparation can consist of one or two evacuant enemas of tapwater, saline, or, more usually, a small-volume hypertonic phosphate or other proprietary enema, given 15–60 min before the examination begins. This allows enough time for proper bowel clearance but is not so long that proximal contents move distally. Limited bowel preparation presumes normal colonic ability to empty the whole left colon rapidly by mass action. This may not happen in patients with diverticular disease or strictures, for whom even limited examination must usually be preceded by full bowel preparation. A limited preparation does not remove potentially explosive gases from the proximal colon, and distal electrosurgery should not be instituted unless these gases have been removed by purge or by air exchange.

Full preparation

A wide variety of bowel preparations are available [9]. Ideal attributes for bowel preparation include pleasant taste and avoidance of excessive volume, cramps, or the need for enemas. Certain modifications of medication and diet are necessary. Oral iron medications must be stopped 4–5 days before colonoscopy, because the formation of organic iron tannates in combination with dietary green-vegetable residue renders colon contents black, sticky, and difficult to clear. Constipating agents such as codeine or loperamide should be discontinued 12 h before colonoscopy. It has been suggested that aspirin and other antiplatelet drugs or anticoagulants be discontinued 7 days before examination to reduce the risk of immediate or delayed bleeding should polypectomy be performed, but this may not be necessary because clinical experience has not borne out any excess bleeding risk in patients on aspirin as noted in a guideline prepared by the American Society for Gastrointestinal Endoscopy [10]. No matter what the preparation regimen, colon cleansing is enhanced by a clear or full-liquid diet for 24–48 h before the examination.

Purgative regimens

Purgative regimens are still the most commonly used form of bowel preparation. Their advantage is that the colon, after a contact laxative such as senna, or bisacodyl, is stimulated to evacuate most of the bowel contents. Disadvantages are that the evacuation stimulus can cause severe cramping abdominal pain, that the cecal region is often poorly cleared, and that some solid residue often remains distally. Therefore, enemas or oral osmotic agents may be required to supplement the cleaning effect of the purgative. Contemporary bowel cleansing methods do not require enemas.

Osmotic purges can be used as an alternative to enemas, either adding to or supplementing the oral purgative with up to 2 L of an agent such as magnesium salts (e.g., citrate, sulfate) or a nonabsorbed carbohydrate (e.g., mannitol, lactulose, sorbitol). Magnesium sulfate has strong purgative and osmotic effects but also an unpleasant taste, so that the milder but citrus-flavored magnesium citrate is generally preferred. Mannitol has been the most widely used of the carbohydrate

solutions. Its sweet taste can be reduced by cooling, and the likelihood of nausea is prevented by preadministration of an oral antiemetic prokinetic agent such as domperidone or metoclopramide 30 min before administration. Five-percent mannitol is isotonic, and 2 L is drunk slowly over 1 h or more. The use of mannitol or other carbohydrate preparations risks explosion during electrosurgical procedures, because of the production of hydrogen gas by the fermentation of intestinal bacteria. This risk can be effectively eliminated by insufflation of carbon dioxide during the procedure or by meticulously aspirating gas and reinsufflating air before electrosurgery. A low-volume sodium phosphate preparation is commonly used for endoscopy preparation and has been well received by patients [9]. The evening before and 4 h before colonoscopy, 45-mL aliquots of sodium phosphate taken orally produce a vigorous catharsis. Cleansing enemas are not required. Fluid balance shifts, absorption of sodium, or hyperphosphatemia may cause deleterious effects, especially in the presence of cardiac or renal disease. The noxious taste may be circumvented by dehydrated sodium phosphate in pill form. Studies published in 2005 [11] implicated the precipitation of phosphate crystals in the renal tubules as a cause of chronic renal insufficiency. This may be related to relative dehydration from inadequate fluid intake during the preparation phase, and the water loss from the powerful cathartic effect.

Balanced electrolyte solutions based on polyethylene glycol (PEG) as an osmotic agent, administered in a volume of 4 L orally or by nasal tube; result in an acceptable bowel preparation. The salty, oily taste and required large volume cause about 10% of patients to stop drinking the solution, thereby failing to prepare their colon adequately. Newer formulations with flavoring have improved palatability and may improve patient compliance. Although package instructions advise minimal dietary restrictions, better results can be expected from a 24-h full-liquid diet. Simple saline solution (0.9% sodium chloride) is effective and arguably safe for preparation of the majority of patients, but potassium losses and electrolyte fluxes can be avoided by appropriate additional ingredients. Other cathartic regimens have been introduced that require ingestion of only 2 L of PEG solution with adequate bowel cleansing [12].

The regimen chosen for whole-colon preparation necessarily varies according to circumstance, patient preference, and clinical indication. Patients need to sleep and must be able to travel without fear of incontinence, so that the timing of preparation must also be adjusted according to the time of examination and travel arrangements. Frail, ill, and elderly patients may require modified preparation, sometimes on an inpatient basis if cooperation is uncertain. If obstruction is a possibility, oral preparations may be dangerous or at least should be spread out over a longer period. In almost all circumstances, a patient fit for total colonoscopy is fit for full-bowel preparation. Compromise in reducing the regimen may result in poor preparation and in only being able to perform a limited examination or a less accurate colonoscopy.

Whichever of the different purgative regimens is chosen, it must cause profuse, clear, fluid diarrhea. A more vigorous preparation may be required for the patient with chronic constipation or severe diverticular disease or a patient whose bowel was not properly cleansed with a previous regimen. It is desirable that patients continue to drink fluids up to a few hours before the examination.

Medication

Sedation

Sedation is unnecessary for some examinations, especially those that are limited, or in patients after sigmoid colon resection or in whom a previous procedure is known to have been easy. A great deal also depends on the patient's attitude and on local custom. Endoscopists in some countries rarely sedate, whereas those in other countries almost always do. Some routinely use general anesthesia administered by an anesthesiologist or, more rarely, by the endoscopist [13,14], although this may add to the risk of complications by removing feedback from the patient relating to pain from loops or difficult electrosurgical procedures. Using less sedation makes for easier change of position and greater safety. Using no sedation allows the patient to leave rapidly and unescorted after the procedure. Endoscopists who never use sedation may have a lower success rate in total colonoscopy [14,15].

Some stretching of peritoneal attachments, at least transiently, is inevitable during colonoscopy. This causes gnawing or acute unpleasant visceral pain. Coupled with air distention and the sensation of rectal fullness simulating the desire to defecate, this can make a slow examination difficult to bear for some patients who are mildly or not sedated, although others tolerate it easily. Pain during colonoscopy can usually be rapidly diminished or eliminated by reducing the loops responsible for stretching the mesentery, or by aspirating air, but sometimes further doses of analgesic agents are needed. Normal diet, activities, and medication can usually be resumed as soon as the mild stress of the examination and the effects of medication are over.

Antispasmodics

Antispasmodics (glucagon 0.5–1 mg i.v.; hyoscine-*N*-butyl bromide 20–40 mg i.v.) are thought by some to increase the difficulty of insertion by rendering the colon atonic and therefore more likely to stretch and loop, but they eradicate circular muscle spasm and may increase the accuracy of examinations for small lesions such as polyps or angiodysplasias [16]. Some endoscopists use antispasmodics routinely, and others not at all.

Antibiotics

A prosthetic heart valve, history of endocarditis, surgically constructed or congenital systemic–pulmonary shunt, or synthetic

vascular graft less than 1 year old places a person at high risk for infection with various procedures. Even in these persons, however, there are insufficient data strongly to justify antibiotic prophylaxis for colonoscopy with or without biopsy or polypectomy [17,18]. Antibiotics are not recommended for colonoscopy with or without biopsy, polypectomy, or esophageal variceal ligation in patients with cirrhosis and ascites unless they present with an acute bleeding episode. Nor are antibiotics recommended for immunocompromised patients, those with prosthetic joints or pacemakers, or patients with a history of rheumatic valvular dysfunction, mitral valve prolapse with insufficiency, hypertrophic cardiomyopathy, or for most congenital cardiac malfunctions. If antibiotics are deemed necessary, the recommended dose is amoxicillin 2.0 g p.o. 1 h before the procedure, or ampicillin 2.0 g i.v. or i.m. within 30 min before the procedure.

Colonoscopy procedure

Position and position changes

The left lateral position is most commonly used for flexible sigmoidoscopy and colonoscopy, mainly because it gives convenient access to the perineum for insertion. However, colonoscopic examinations can be, and in some centers are, performed in other positions, including lithotomy, knee-chest/elbow, and right lateral positions. Especially if a large-volume fluid preparation regimen has been used, position changes can modify both the configuration of the colon and of the air and fluid within it because of the effects of gravity. When forward progress can no longer be accomplished, a change in the patient's position will aid tip advancement in two-thirds of cases [19].

Insertion of the endoscope and flexible sigmoidoscope

Digital examination of the anorectum is used to lubricate the area generously and to palpate any lesion. A local anesthetic gel may reduce anal discomfort. When there is rectal stenosis, a fistula, or abnormal anal sensitivity, it may be desirable to use a small-diameter pediatric instrument or a gastroscope. The technique for flexible sigmoidoscopy is the same as for the first part of a colonoscopy, except that it is less important to avoid looping, because the proximal colon is not to be intubated. Characteristically, there is a red-out when the instrument enters the rectum, because the tip abuts on the rectal mucosa. Simultaneous air insufflation and instrument withdrawal are required to disimpact it, and angulation or rotational movements are useful to find the rectal lumen. Movements of the instrument tip should thereafter be slow and deliberate, taking care to steer toward the lumen before pushing inward, so as to avoid constantly losing the view. When the lumen cannot be seen, continuing to push the instrument shaft into the rectum stretches the sigmoid colon into unnecessary and painful loops and rarely results in tip advancement, because once impacted against a haustral fold the tip tends to remain stationary while the rest of the scope flexes into a loop with its concomitant traction on the mesentery.

Slide-by is a term describing the maneuver when the tip is against the mucosal surface, no part of the lumen can be seen, and the instrument is pushed forward causing the mucosal vessel pattern visibly to slide across the lens. This maneuver should be avoided but is permissible for short distances and only when the instrument is known to be pointing in the correct direction; if tip movement stops and the mucosa blanches, additional pressure risks perforation, and the instrument must be withdrawn to locate the lumen. Withdrawal and disimpaction of the tip is a routine procedure that should be performed every time the view is lost for more than a few seconds.

Diverticular disease is often associated with thickened rings of circular muscle or fixation of the sigmoid colon by pericolic adhesions from previous inflammatory episodes. The resulting distortion and angulations can make it difficult to locate the lumen and coax the instrument through, because the tip is not free to maneuver normally. In a few cases, the angulations are so acute that a small-diameter pediatric colonoscope or a standard gastroscope with their shorter radius of tip deflection may allow passage through diverticular disease where the standard colonoscope cannot be passed [20]. Despite the technical problems in intubation, endoscopic examination of diverticular disease can be clinically valuable, mainly because the distorted appearances seen on barium enema may make it impossible to exclude malignancy on radiological grounds. Similar bowel fixation and angulation may occur after hysterectomy as a result of postoperative adhesions between the sigmoid colon and anterior aspect of the pelvic cavity.

If any pathology is seen during flexible sigmoidoscopy, a biopsy can be easily and safely performed. However, electrosurgery for polyp removal is contraindicated after the limited bowel preparation for flexible sigmoidoscopy because of the significant hazard of explosive gas mixtures.

Total colonoscopy

The insertion technique is fundamental to rapid, relatively pain-free, and accurate total colonoscopy. Difficulty during intubation of the proximal colon or passage around the hepatic flexure is invariably related to failure to straighten the colonoscope in the distal colon before attempting the last part of the insertion. Looping in the sigmoid colon is a continual and recurrent problem throughout a colonoscopy but especially when it is necessary to push harder to transmit force around a looped colonoscope to reach the cecum.

During a colonoscopy, there are only a limited number of options available to the endoscopist. These include:

- pushing the instrument in or pulling it out
- twisting the shaft to the right or the left

- insufflation or withdrawal of air
- using tip controls to steer up, down, right, or left
- use of abdominal pressure to reduce loops
- changes of patient position.

The difference between the slow endoscopist who reaches the cecum infrequently after a traumatic examination and a fast endoscopist who examines the whole colon in over 95% of patients within an average time of 10 min is the ability to use the various options logically, quickly, and sequentially without repeating a nonproductive maneuver over and over again.

During the intubation phase, the instrument controls must be continuously manipulated while using torque to keep an adequate view of the lumen. The endoscopist must concentrate on visual detail to locate and find the direction when it is briefly lost, and back off quickly if the tip impacts into a bend or fold. The endoscopist can feel when the instrument is passing freely and can be advanced or when it is becoming snarled and should be withdrawn to straighten the shaft before pushing in again. The biggest mistake of the inexperienced endoscopist is to think that a good view of the lumen is an unqualified signal to push, especially when looped in the sigmoid with a view of the descending colon; pushing under these conditions often results in an expanding sigmoid loop with resultant pain but without tip progress.

Some sigmoid loops, such as the spiral alpha loop configuration that may form in the sigmoid colon, are favorable, because they allow the instrument to proceed into the descending colon without forming acute angulations; others, such as the N loop, which more frequently occurs in the sigmoid, put the tip into an acute angulation at the descending colon junction, making this area difficult and painful to pass through. Fluoroscopy is not necessary to ascertain the presence of a loop, because it is apparent that a loop is forming whenever the shaft is pushed in more than the tip advances. Additionally, once a loop is stretched on its mesentery, additional pushing hurts the patient. Conversely, when the colonoscope shaft is straight, with the colon shortened or pleated over it rather than stretched, only a light touch is needed on the instrument with 1:1 correspondence between shaft and tip during push–pull and rotational movements. When there are no excessive loops, tip angling using the dial controls is also easy and full. Conversely, when the tip is maximally deflected using both control knobs and the lumen is still at an acute angle, this indicates that the scope is in a loop configuration. The best maneuver is to withdraw and straighten the shaft, and if that cannot be accomplished, short in-and-out thrusts of the scope often result in forward tip movement.

Because of the multiple bends, folds, and twists of the large bowel, it is inevitable during a colonoscopy that the instrument will loop or start to loop on many occasions. After each advance, by pulling back and restraightening the shaft, the colon is effectively shortened and pleated over the instrument, which is progressively advanced on a "three-steps-forward-and-two-steps-back" basis.

It is usually not possible to keep the instrument straight or the patient completely comfortable all the time because of the unpredictability of the sigmoid colon. There may be a period of difficulty or looping before the tip reaches the fixed retroperitoneal part of the descending colon or the splenic flexure, where the shaft can be fully straightened by pulling back with clockwise rotation to only 50 cm from the anus. Unfortunately, because of the variability of the anatomy and attachments of the sigmoid and descending colon, this first part of a colonoscopy is the most difficult part of the procedure.

Passing the splenic flexure into the transverse colon is usually easy if the sigmoid has been straightened and can be held straight. After maximal shaft withdrawal, the combination of gentle shaft advancement with clockwise twist maintained, simultaneous abdominal pressure over the sigmoid, and avoidance of tip overdeflection usually allows progress into the transverse colon. Overaggressive pushing tends to reform the loop in the sigmoid, and overangulation impacts the tip into the flexure (i.e., the inverted "J" or "walking stick handle" effect). If, after several attempts, the tip does not advance, the instrument should be withdrawn and restraightened; rotating the patient into the right lateral position almost invariably causes the splenic flexure to drop downward, allowing the instrument to slide more easily around to the midtransverse colon. With the patient in the right lateral position, the midtransverse colon often sags down into a rather acute bend, providing a good point at which to withdraw and restraighten the colonoscope once again and also to rotate the patient onto the back or into the left lateral position before insertion into the proximal colon.

In the proximal transverse colon or hepatic flexure region, and thereafter in the even more capacious ascending colon, deflation is extremely helpful in advancing the instrument and shortening the distance to the ileocecal region. Aspiration of air causes the colon to deflate concentrically so that the diameter is smaller, but it also results in shortening the colon longitudinally. A few additional maneuvers may be helpful in assisting total intubation, such as rolling the patient into the prone or supine position or asking the patient to inspire to lower the diaphragm. The more difficult it is to reach up or around the hepatic flexure and down to the cecal pole, the less likely it is that aggressive forward pushing will work. The longer and more mobile the colon is, the more certain it is that force will generate loops that will absorb all the motive power applied. With attention to technique and patience, even a redundant colon often shortens to only 50–60 cm at the hepatic flexure, permitting the tip to slip down the last few centimeters with ease as air is aspirated. Advances in technology enable electromagnetic imaging devices to visualize, in real time, the three-dimensional localization of the colonoscope without radiographic involvement, which may have a significant impact on practice [1].

Ileocecal region

Even experienced endoscopists can be mistaken in thinking that a capacious hepatic flexure is the cecal pole, or that tonic contraction of the ileocecal fold represents the appendiceal orifice. The appendiceal orifice is seen often merely as a crescent-shaped slit or a circular convolution of folds. When a crescent orifice is seen, the apex of the crescent almost invariably points toward the ileocecal valve. With the tip in the cecum and the crescentic orifice clearly visible, deflection of the tip in the direction indicated by the apex of the curve will align the scope with the ileocecal valve orifice. Withdrawal of the shaft and deflection of the up/down control dial in the direction of the appendix curve when the first large fold is encountered will often result in ileal intubation. Alternatively, withdrawing the colonoscope 10 cm or so back up the ascending colon and looking for the tell-tale inward bulge of the valve on the ileocecal fold, which is the first encircling fold back from the cecal pole, is another method to permit the endoscopist to determine where to angulate and enter the ileum following reintubation of the cecum. Even so, ileal intubation can be difficult and may require several minutes and not a little skill and patience. The anatomy is variable, and both colon and colonoscope can rotate or move during attempted insertion. Some ileocecal valves show prominent pouting lips; others, however, are the merest slit on the reverse side of the ileocecal fold, which may require visualization by attempting retroversion of the bending section of the colonoscope within the cecal pole.

Terminal ileum

A skilled endoscopist can enter the terminal ileum with reasonable ease in approximately 80% of cases [21] and can almost invariably obtain a blind forceps biopsy through the valve in the remaining patients. Failures arise mainly when deformity or scarring make angulation impossible or the opening too narrow, but poor bowel preparation and loops in the instrument can be contributory problems. Endoscopic assessment of the mucosa of the terminal ileum is straightforward. Although the polypoid lymphoid follicles that are frequently present may cause the radiologist mistakenly to diagnose Crohn's disease and consider cobblestoning, these nodules and the surrounding mucosa are covered with normal pink mucosa with a granular surface in air or with small villi visible underwater.

The endoscopic view of the terminal ileum is usually limited to 5–10 cm. There is rarely a serious indication to attempt further insertion, because ileal Crohn's disease almost invariably involves the terminal part of the ileum, other lesions such as ileal angiodysplasia are exceedingly rare, and a Meckel diverticulum is not endoscopically accessible because it is located 1 m proximally. If deep ileal intubation is attempted, 30–50 cm is usually the limit of what can be seen because of the acute angulations that occur in the small bowel.

Role of the assistant

Colonoscopy must not be performed by one person alone. A properly trained and observant gastrointestinal assistant is an absolute necessity for the proper performance of colonoscopy. The assistant's functions extend beyond the confines of the endoscopic procedures itself to include:

- setting up the room before the procedure
- recording endoscopic photographs
- noting biopsy specimens
- filling out requisition forms for the histopathologist.

All equipment that may possibly be necessary for the procedure must be assembled and available before the examination. The endoscopic assistant monitors the patient and assists with accessories. If polyps are encountered, the snare and patient return-plate must be plugged into the electrocautery apparatus, which requires setting the proper diathermy levels and testing to ensure that all equipment is functioning properly. During the examination, additional lubricant, gloves, and abdominal pressure may be provided from time to time during various phases. The assistant orders and prepares the necessary preendoscopic medications and is responsible for maintenance of the emergency cart, which must include antidotes for the various medications used, cardiac drugs, resuscitation equipment such as an Ambubag, endotracheal tubes and laryngoscopes, intravenous solutions, and oxygen. The cleaning, care, and maintenance of all the endoscopy equipment is in the hands of the assistant, who is responsible for mechanical cleaning and disinfection procedures. Most colonoscopists prefer to advance and withdraw the shaft of the instrument with the right hand, while the left hand manipulates the dial controls as well as the air/water and suction buttons. However, some colonoscopists prefer a two-person technique, whereby the assistant advances the instrument while the endoscopist handles the control portion of the colonoscope.

Therapeutic procedures

Colonoscopy makes possible a range of therapeutic procedures. Polypectomy is the most obvious, but electrocoagulation, laser photocoagulation, or injection therapy of vascular lesions (e.g., telangiectasias, angiodysplasias, hemangiomas, and radiation changes) are all routine [22]. The argon plasma coagulator is a monopolar device that delivers thermal energy to the colon wall in a noncontact fashion. It is useful for arteriovenous malformations, radiation telangiectasias, and fulguration of residual adenomatous tissue at the base of piecemeal polypectomy sites [23].

Snare polypectomy of pedunculated or sessile polyps is efficient, rapid, and relatively safe. By constricting the tissue within the closed snare wire, low electrical power (often only 15–20 W) is sufficient for transection and heat sealing of

blood vessels, with localized tissue heating. Because the colon mucosa is insensitive to thermal injury, the patient should feel nothing during polypectomy or electrocoagulation unless full-thickness heating is occurring, which causes the patient to warn of peritoneal pain at an early stage, before actual damage has occurred. If small (2–5-mm) polyps are found, simultaneous biopsy and electrocoagulation with electrically insulated hot-biopsy forceps can be performed. This rapid procedure ensures that a histological specimen is obtained. An alternative technique for small, sessile polyps is cold resection, or cheese-wiring across the base by closing the snare in the absence of current [24]. Snared tissue can be retrieved for pathological analysis by aspiration through the instrument channel into a filtered suction-trap or into a gauze tissue placed at the connection of the suction tubing with the endoscopic umbilical cord. Larger polyps can be retrieved whole using the snare loop or other grasping devices, although this may necessitate several reinsertions of the endoscope for multiple polyps. A metal basket or nylon-mesh net allows retrieval of several polyps or fragments from the right colon.

Except for polyps with an extremely broad base, almost all benign-appearing polyps encountered can be removed endoscopically. Pedunculated polyps are removed with snare application around the pedicle. Pure coagulating current at low power is used by most endoscopists following snare-loop tightening, providing controlled and localized tissue heating for blood vessel obliteration [25]. Thicker stalks with increased risk of immediate or delayed bleeding can be preinjected with an epinephrine (adrenaline) solution to ensure hemostasis before snaring. Both flat and broad-stalked polyps with early invasive colon carcinoma may be successfully resected by the submucosal injection polypectomy (SIP) technique, whereby the polyp is elevated by a fluid injection (3–10 mL [but possibly up to 40 mL] of saline or diluted epinephrine solution) into the submucosa prior to transection [26]. Various solutions have been used to prolong the duration of the submucosal cushion including a viscous solution of sodium hyaluronate [27] and the proprietary "artificial tears" whose active ingredient is hydroxyl-propyl-methylcellulose. If the polyp is exceptionally large and snare placement is difficult, it may be useful to remove segments sequentially until the base can be easily visualized and complete transection can be accomplished. Even extremely large pedunculated polyps may be removed in piecemeal fashion. Polyps that usually cannot be removed endoscopically are those that cover a substantial area of the colonic surface (i.e., > 30% of the circumference), extend over two interhaustral folds, are obviously malignant, or involve the appendiceal orifice [28].

Every effort should be made to retrieve all the resected portions of each polyp and to submit them to the pathologist for histological evaluation. Because of the force of gravity, polyps have a tendency to fall into fluid pools or crevices, which hide them from view making retrieval difficult. There are various techniques for polyp retrieval. Although in clinical circumstances, only about 94% of transected colon polyps are recovered for full histopathological interpretation, those most likely to be lost are small and of little clinical significance.

Prior to the introduction of neostigmine therapy, tube decompression in patients with pseudoobstruction (Ogilvie syndrome) or postoperative ileus was accomplished by placing a tube through the colonoscope channel, sliding it over an endoscopically placed guide wire [29] or by carrying the tube up alongside the endoscope during insertion. Immediate decompression occurs, but because of the frequency of recidivism, the tube is left until it is expelled spontaneously, signaling restoration of normal propulsive contractions. Volvulus can be reduced by placing a wide-caliber tube beyond the twisted segment, provided the colon is not gangrenous – in which case surgery is mandatory. Foreign bodies can be successfully removed endoscopically from all levels of the large bowel. Balloon dilation is possible, usually with through-the-scope (TTS) balloons inserted under direct vision into a stricture, with or without prior guide wire placement [30]. The controlled radial expansion (CRE) balloons exert maximal dilating force over a range of sizes according to the degree of pressure applied. An appropriate-sized balloon gives sufficient dilation for most circumstances with minimal risk of splitting the stricture. These balloons have the advantage of allowing passage over an endoscopically positioned guide wire, with correct insertion and dilation observed either endoscopically or on fluoroscopy. Other techniques for stricture dilation include incision into the stricture with electrocoagulation by a needle-knife, the slightly protruded tip of a polypectomy snare, or a papillotome; these methods are, however, useful only for relatively thin, short strictures.

Short strictures, such as those after right hemicolectomy for Crohn's disease or when postoperative complications result in localized anastomotic narrowing, respond well to endoscopic dilation. A single dilation can be permanently effective or can last for a few weeks to many months depending on the presence of any inflammatory condition likely to cause restenosis [28]. Postoperative anastomotic stenoses may be dilated widely during the first examination, because there is usually considerable fibrosis around the anastomotic site, making the occurrence of free perforation unlikely. Primary strictures in inflammatory bowel disease unrelated to surgery, however, do not have the same surrounding cicatricial reaction, and the initial dilation should be limited to not greater than twice the diameter of the stricture to avoid perforation. Frequently, the lumenal narrowing in Crohn's disease is related to active inflammation with circular muscle spasm and so is rarely ameliorated by attempts at endoscopic dilation techniques. Self-expanding metal stents effectively dilate malignant strictures, and are usually permanently

embedded into the tissue once inserted. They may be used for decompression prior to surgery or for symptom palliation. New removable plastic stents have been developed for esophageal lesions [31], and may be adapted to benign colon strictures.

Indications

Flexible sigmoidoscopy

Flexible sigmoidoscopy should be the procedure of first choice for examination of the rectum and sigmoid colon. It is useful for evaluating complaints most probably caused by conditions affecting the lower bowel, and for population-based screening for colon and rectal cancer. It should replace rigid proctosigmoidoscopy except when the rigid instrument is used for screening examinations of the rectum on grounds of cost, expediency, and the ease of taking larger biopsy specimens. The rigid proctoscope (i.e., anoscope) is preferred for assessment of hemorrhoids and anal canal pathology, which are often poorly seen with a flexible instrument, even in retroversion.

Flexible sigmoidoscopy alone may be considered sufficient examination in patients with minor disturbance of bowel habit, obvious hemorrhoidal bleeding such as blood dripping into the toilet bowl following defecation, or localized left iliac fossa pain. With minimal discomfort and no sedation, the rectum, sigmoid colon, and often the descending colon or splenic flexure can be examined.

Colonoscopy

Colonoscopy can be performed in any patient fit for barium enema who can tolerate a full-colon preparation (Table 120.1) [32]. With the increasingly widespread availability of endoscopic skills and improvements in instrument technology, colonoscopy can often be regarded as a first-line procedure not proceeded by radiological imaging. A prior computed tomography (CT) scan or barium enema rarely helps the endoscopist, because the configuration on radiographic films gives little indication of how easy or difficult the colonoscopy will be. Most patients find radiological imaging a more unpleasant experience than colonoscopy because of the sustained inflation required in the radiological procedure [33] and perhaps also because of the sedative/analgesic medications often given for colonoscopy.

High-yield indications

Abnormal CT scan

The highest diagnostic yield of endoscopic pathology is in patients with tumor, polyps, stricture, or mucosal disease diagnosed on radiological imaging. Colonoscopy provides histological confirmation or confident exclusion of a questionable abnormality and allows immediate therapy where appropriate.

Table 120.1 Indications for colonoscopy

Evaluation of abnormality on barium enema likely to be clinically significant, such as a filling defect or a stricture
Evaluation of unexplained gastrointestinal bleeding (including occult bleeding)
Unexplained iron deficiency anemia
Screening and surveillance for colonic neoplasia
Chronic inflammatory bowel disease of the colon if more precise diagnosis or determination of the extent or activity of disease will influence immediate management
Clinically significant chronic diarrhea of unexplained origin
Intraoperative identification of a lesion not apparent at surgery (e.g., polypectomy site, location of a bleeding site)
Treatment of bleeding from such lesions as vascular malformation, ulceration, neoplasia, and polypectomy site
Foreign body removal
Excision of colonic polyp
Decompression of acute nontoxic megacolon or sigmoid volvulus
Balloon dilation of stenotic lesions (e.g., anastomotic strictures)
Palliative treatment of stenosing or bleeding neoplasms
Marking of a neoplasm for surgical localization

Modified from American Society for Gastrointestinal Endoscopy [32].

Colon polyps: benign and malignant

Nearly all polyps can be snare-resected during the procedure, and some radiologically diagnosed carcinomas prove to be benign lesions that are manageable endoscopically. Even with an apple-core lesion on radiographic films, colonoscopy can confirm the histology of the lesion and in the absence of obstruction, also rule out synchronous polyps and cancers.

Five percent of pedunculated or broad-based polyps removed endoscopically are found histologically to contain invasive carcinoma, with malignant cells traversing the muscularis mucosae into the submucosal layer. The biologically benign entity in which malignant cells are present only superficial to the muscularis mucosae should not be described as "carcinoma in situ," but rather by the more innocuous term "severe dysplasia." Surgical resection is not necessary in pedunculated polyps with invasive carcinoma if there is a sufficient margin (1–2 mm) between the limit of invasive carcinoma and the resection line on multiple sections, if the carcinoma is well or moderately well differentiated, and if there is no lymphatic or venous invasion [34]. There is controversy about whether these endoscopic and histological principles should be applied to the local removal of sessile malignant polyps or whether surgery should be recommended unless the patient is a poor operative risk. Because malignant polyps and polypoid carcinomas tend to occur in older, frail patients, and surgery rarely yields resectable lymph nodes without evidence of distant metastases, there is an increasing tendency to use conservative endoscopic

management, even in lesions failing to meet the above criteria, unless the patient is an excellent surgical risk. The use of a permanent colonic tattoo makes it possible to localize a malignant polypectomy site with accuracy in the event that surgical resection is necessary or for subsequent surveillance after an interval of a few months before entering a normal follow-up regimen.

Rectal bleeding of undetermined etiology

Rectal bleeding, especially if sustained, dark, or mixed in the stools, is frequently caused by tumor or mucosal pathology. In the subgroup of patients with visible rectal bleeding in whom a barium enema and sigmoidoscopy are normal, about 10% of referral patients have cancer, 15%–20% have polyps (Fig. 120.7), and up to 50% have some kind of a visible abnormality, including traumatized, inflamed, or ulcerated mucosa. Blood loss or anemia, particularly in elderly persons, remains the highest-yield indication for colonoscopy. Total colonoscopy should be performed rather than double contrast barium enema (DCBE) in the assessment of rectal bleeding, whether overt or occult, because of the obvious bonus of color view in seeing blood, altered blood, or bleeding points, which can be flat and totally invisible on radiographic films. It may also be possible to treat the cause of bleeding endoscopically [35].

Acute colonic bleeding

Acute colonic bleeding of overwhelming proportions may require surgery and perioperative bowel irrigation with on-table colonoscopy, but bleeding of lesser severity may stop spontaneously. Ten percent of patients admitted to an intensive care unit with a tentative diagnosis of acute colonic bleeding will have an upper gastrointestinal source [36], which must be considered in all instances. In most cases of acute bleeding, an attempt at conventional colonoscopy examination is indicated before resorting to angiography, scintigraphy, or other investigational techniques. If possible, oral or nasal tube electrolyte bowel preparation is started immediately after the patient presents, because blood coating makes localization of the bleeding site difficult without preparation or if enemas reflux blood proximally. Colonoscopy should be performed as soon as practicable, because the aim is to examine the bowel while fresh bleeding continues. Waiting even an hour or two may miss the opportunity for diagnosis and allow degradation of blood into a dark unpleasant mess. Changes of patient position during the examination, while bleeding is active, help to maintain adequate visualization. Expertise is needed in this situation, but a cause for bleeding should be apparent in more than half of cases, and treatment may be possible by polypectomy, electrocoagulation, injection therapy, or other means. Postpolypectomy hemorrhage should be managed by immediate colonoscopy without preparation, because the site of bleeding is known [37]. An algorithm for the approach to acute lower gastrointestinal (GI) bleeding has been published [38].

Figure 120.7 A smooth sessile adenoma is located in the descending colon.

Anemia

Iron deficiency anemia or a positive fecal occult blood test should be evaluated by colonoscopy rather than DCBE, because flat lesions such as angiodysplasia or minor inflammatory change cannot be diagnosed radiologically. Even if radiographs appear normal, endoscopy is known to find significant numbers of radiologically missed lesions such as cecal carcinomas. In anemic patients, gastroscopy and colonoscopy can be performed at the same visit. The object of endoscopy in anemic patients mainly is to rule out carcinoma or vascular anomalies with certainty; about 80% have negative examinations, but the endoscopic opinion of normality is considerably more certain than a negative radiographic film result.

Chronic diarrhea

Patients with long-standing diarrhea require an accurate examination with histological biopsies routinely taken and other specimens as appropriate. Rectal evaluation is adequate in many patients, but total colonoscopy and ileal examination complete the investigation and sampling process in one definitive test. Microscopic or collagenous colitis can occur despite normal endoscopic appearances; therefore, biopsy specimens must be taken in any patient with chronic diarrhea or increased bowel frequency [39]. However, the normal colonic mucosa frequently harbors inflammatory cells, and great care should be taken to avoid misinterpretation and overdiagnosis of inflammatory bowel disease when none is truly present, based on an inexperienced pathologist's report of acute or chronic inflammation on biopsy specimens. Collagenous colitis is diagnosed histologically from a thickened intraepithelial collagen layer. Ischemic colitis has a range of appearances, from slight reddening and friability, to varying degrees of ulceration, to frank gangrene; the diagnosis is often possible by combining the typical history of sudden onset of pain, bleeding, and diarrhea with endoscopic evidence of a perisplenic distribution.

Inflammatory bowel disease

Often, the mucosal appearances are sufficient to make immediate assessment of the extent and type of colitis [40]. Crohn's disease, in particular, shows a rather characteristic pattern of small aphthoid ulcers with intervening normal mucosa unlike the generalized redness of early ulcerative colitis. More advanced inflammatory diseases of any type, including ulcerative colitis, Crohn's disease, tuberculosis, or amoebic colitis, can be virtually indistinguishable from each other because of the limited range of responses of the colon to various diseases that affect the mucosal surface. Once the diagnosis of inflammatory bowel disease has been established, there are only a few indications for follow-up colonoscopy besides malignancy surveillance, unless there is a marked change in symptoms. Dye spray in the colon has been reported to increase the yield of dysplastic lesions. This technique is becoming increasingly used during surveillance colonoscopies. Methylene blue or indigo carmine are applied with a specialized spray catheter [41].

Cancer surveillance or prevention

The long period preceding cancer during which a focal adenomatous polyp is visible gives the opportunity for visualization, biopsy, and destruction of precancerous lesions, even at sizes of 1–2 mm. Accuracy is possible, because color makes it easy to distinguish which small excrescences are fecal, which are air bubbles, and which are polyps. A syndrome of flat adenomas has been described [42]; these adenomas may have a tendency to degenerate into carcinoma while still relatively small in diameter. Detecting their presence may be enhanced by zoom colonoscopy or by dye spraying or "chromoendoscopy."

The recommendations of an expert multidisciplinary panel, published in 1997 [43], included offering colonoscopy every 10 years to asymptomatic average-risk persons aged 50 years or older. In addition, the panel suggested annual fecal occult blood tests in this population, with colonoscopy as the investigation of choice if the occult blood test is positive. A flexible sigmoidoscopy is recommended every 5 years, followed by colonoscopy to remove polyps, biopsy cancers, and to examine the rest of the bowel should an adenoma or cancer be seen. Colonoscopy is indicated for any patient with a positive fecal occult blood test and in those who are at increased risk for polyp and cancer formation, including those with first-degree relatives with either colorectal cancer or an adenomatous polyp – in whom screening should begin at age 40. People with a family history of familial adenomatous polyposis whose genetic testing is positive or indeterminate should be offered flexible sigmoidoscopy every 12 months beginning at puberty. A family history of hereditary nonpolyposis colorectal cancer (HNPCC) should trigger an examination of the entire colon every 2–3 years starting between the ages of 20 and 30 years.

The interval between surveillance examinations after removal of adenomatous polyps or an operation for colorectal cancer is a matter of debate [44], but the expert panel has made the following recommendation: removal of an adenomatous polyp larger than 1 cm in diameter or of multiple polyps requires repeat colonoscopy 3 years after the initial examination, and if that is negative or reveals only a single small tubular adenoma, the surveillance interval can be increased to 5 years. In special circumstances, such as a polyp with invasive cancer, large sessile adenomas, or numerous adenomas, a shorter follow-up interval may be necessary. In patients who have had a colorectal cancer surgically resected with a curative intent, if total colonoscopy had not been performed preoperatively, a complete colon examination should be completed within 1 year of the resection. If this or the preoperative examination was normal, subsequent colonoscopy is indicated in 3 years, and if normal, every 5 years.

Surveillance examinations in extensive ulcerative colitis [45] and Crohn's colitis patients normally start 8 years after onset of disease and are repeated at 1- or 2-year intervals, with 10 or more biopsy specimens taken at representative sites around the colon. The endoscopist is alert for any nodular, indurated, or plaque-like lesions in the colon, but varying degrees of low- or high-grade dysplasia may be found in relatively normal-looking mucosa, a finding that is enhanced with chromoendoscopy.

Intraoperative colonoscopy

The most common indication for intraoperative colonoscopy is to localize the site of a previously endoscopically resected malignant polyp (not necessary when preoperative tattooing is performed) during laparoscopy [46]. The site may heal completely in 3 weeks, leaving no external sign of its location, but it can often be endoscopically identified as a scar on the mucosal surface. Another indication is to assist the surgeon in identifying which colonic segment is the source of massive lower GI hemorrhage.

Low-yield indications and circumstances when colonoscopy is not indicated

Conditions manifesting with functional symptoms such as long-standing constipation, bloating, or chronic abdominal pain, may be investigated by CT or radiographic examination if there is no occult or overt colonic bleeding (Table 120.2) [32]. However, the elderly patient may be unable to cooperate with the need to retain contrast and air, resulting in a poor radiographic examination. Bowel symptoms in patients older than 70 years of age may be better investigated by colonoscopy than radiographic examinations.

A flexible sigmoidoscopy may be the examination of choice when the patient presents with an acute diarrheal syndrome, because the view of the distal colonic mucosa often (but not always) mirrors the findings in the remainder of the colon. Excepting surveillance for malignancy, repeated colonoscopy for routine follow-up of patients with established inflammatory bowel disease provides little clinically

Table 120.2 Circumstances in which diagnostic colonoscopy is usually not indicated or has a low diagnostic yield

Chronic, stable, irritable bowel syndrome or chronic abdominal pain
Acute diarrhea
Metastatic adenocarcinoma of unknown primary site in the absence of colonic signs or symptoms when it will not influence management
Routine follow-up of inflammatory bowel disease
Upper gastrointestinal (GI) bleeding or melena with a demonstrated upper GI source

Modified from American Society for Gastrointestinal Endoscopy [32].

useful information. Colonoscopy need not be performed in the patient with overt GI bleeding in whom an active upper GI source has been demonstrated. Similarly, there is no indication for colonoscopy in the patient with an adenocarcinoma where the primary site of the tumor is unknown, unless the result of colonoscopy will influence the management of the patient.

Contraindications

Colonoscopy is a relatively stressful physiological experience and a strong vagal stimulus that can produce dysrhythmias, minor electrocardiographic disturbances, and a degree of hypotension; therefore, it is contraindicated for several weeks after myocardial infarction [47]. Both the air pressure involved in distention of the colon and the unavoidable stretching during passage around loops and bends have the potential to increase any existing risk of perforation. Because of this, colonoscopy is contraindicated in the acute or abscess phase of diverticulitis. Severe acute episodes of ulcerative, Crohn's, ischemic, or infective colitis have generally been considered a contraindication for colonoscopy, but some reports suggest that, with due expertise and care, it is safe and may be of value in therapeutic decision-making in these situation [48].

Therapeutic maneuvers increase the hazards of colonoscopy. Balloon dilation in a sick patient may justify antibiotics. Polypectomy carries a small risk of immediate primary bleeding or of delayed secondary hemorrhage for up to 29 days after the procedure. The likelihood of delayed bleeding is especially increased in patients with a coagulopathy or in those taking anticoagulants or antiplatelet therapy. When medical conditions prohibit discontinuation of Coumadin (warfarin), the patient may be admitted to the hospital for the substitution of intravenous heparin for oral anticoagulation. When the coagulation parameters have returned to normal levels, the intravenous heparin dosage should be stopped 4 h before colonoscopy with polypectomy. If a clean polypectomy has been performed without bleeding, heparin may be restarted 4 h after the procedure, and oral anticoagulants reinstituted 12–24 h later although the possibility of delayed hemorrhage will remain. The patient must remain on heparin until the international normalized ratio (INR) levels have returned to the therapeutic level. If polypectomy is associated with bleeding, an attempt should be made to withhold heparin for 8–12 h if it is considered that the patient can safely remain off anticoagulants for that period. Low molecular weight heparin has been used during periods of Coumadin discontinuation but this has not been subject to clinical investigations [10].

Polypectomy can result in perforation by cutting through the bowel wall or by applying sufficient thermal energy to burn through and necrose the full thickness of the colon, resulting in a perforation delayed for between several minutes and many days after the polypectomy. The colon wall is extremely thin – the normal mean colon wall thickness is about 2.2 mm [49]. Some features of a full-thickness thermal injury to the colon wall, including localized pain, fever, and leukocytosis, may occur 6–24 h after polypectomy. This is known as the postpolypectomy or transmural burn syndrome [26], and must be distinguished from a perforation. Transmural damage is localized and self-sealing when bowel loops, mesentery, omentum, or other adjacent peritoneal surfaces become adherent, so that conservative management with antibiotics and bed rest is usually sufficient.

When signs of frank perforation occur after colonoscopy, it is safest to advise immediate surgery. If only a small amount of free air is present on a postendoscopy radiographic film and the patient has no symptoms, it may be safe to treat the patient conservatively, with antibiotics but without surgery. In any event, a surgeon should always be involved in observation of the patient and in deciding whether or not surgery is indicated [50].

Morbidity and mortality rates for colonoscopy are unknown but reviews from the late 1980s and 1990s indicate that the perforation rate is about 1 in 2500 colonoscopies [51], with a mortality of 1 in 15 000 colonoscopies; most deaths occur after inappropriate conservative management of suspected perforation [52]. An institutional review [53] found that there may be one perforation per 1200 colonoscopies, with almost half due to mechanical trauma and the rest resulting from polypectomy or electrocautery. Most perforations occurred at the rectosigmoid junctional area. Conservative management was successful in one-fourth of those with polypectomy perforations and in 10% of cases of mechanical injury.

The bleeding rate after polypectomy varies from 0.26% to 1.5% [51], but probably can be reduced with better attention to hemostatic techniques such as the sole use of coagulating current and slow transection. The use of cutting current may be associated with a higher immediate bleeding incidence [54]. Injection or other means of endoscopic therapy for immediate control of bleeding should avoid the small number of cases in which angiographic or operative intervention was

previously necessary. Unexpected radiographic demonstration of free air in the abdominal cavity (pneumoperitoneum) of symptomless patients submitted to routine abdominal radiography after colonoscopy has been reported. Surgeons also report the existence of hematomas, serosal splits, and manifestations of local colonic trauma in patients coming for laparotomy soon after colonoscopy. These facts serve as a reminder to all endoscopists, particularly those in the learning phase, to be cautious, to be considerate to the patient, to avoid oversedation, and to be prepared to abandon a colonoscopy that appears unreasonably traumatic.

Virtual colonoscopy (CT or MR colography)

A computer reconstruction of a rapidly performed abdominal spiral CT scan provides a simulated tubular view of the intestinal lumen. Infoldings (haustra), outpouchings (diverticula), and intralumenal protuberances (polyps) can be identified. The process is noninvasive, requiring a single breath-hold while the colon is maximally air-inflated. Cancers and most polyps over 10 mm in diameter can be identified, but smaller polyps may be overlooked when compared with findings at conventional colonoscopy [55]. Retained stool may give a false-positive reading, and flat mucosal lesions are difficult to identify. Technological developments have increased the accuracy of this tool, which will take a place among the procedures for evaluating the colon. Work is in progress for a computer software system capable of finding polyps using dedicated algorithms [56]. The reader is referred to Chapter 130 for detailed information on CT colonoscopy, and to Chapter 131 for detailed information on MR colography.

Colonoscopy has become the procedure of first choice for most colonic investigations. Barium enema for radiographic evaluation of the large bowel has been supplanted by virtual colonography. It is estimated that it is unusual but possible to miss a polyp equal to or exceeding 1 cm in diameter during colonoscopy [57].

Limitations of colonoscopy

It is pertinent to mention that the endoscopist is capable of gross errors in localization and occasionally of missing large lesions. Blindspots for the endoscopist occur in certain areas, such as the rectal ampulla and flexures (especially the mobile sigmoid–descending colon junction), behind acute bends, and in regions of spastic muscle contractions. Adhesions or strictures can render the endoscope tip immobile and make a proper view for targeted biopsies impossible. Large polyps on long stalks can be missed by the endoscopist because they move around and may spring out of the field of view as the colonoscope is pulled back. Poor preparation and redundant or mobile colons also make the endoscopic examination less accurate.

Careful inspection for possible abnormalities is important during intubation as well as during the withdrawal phase of a colonoscopy, because the view of the stretched colon is different from that obtained when the bowel is shortened. Several passes may be needed to see all aspects of an angulated or convoluted area properly. There is no room for complacency by the endoscopist over the accuracy of colonoscopy, because it takes dexterity and integrity to be sure that an optimum examination has been performed. It can be assumed that 5%–10% of the mucosal surface is not seen during colonoscopy. This explains the significant pick-up of lesions up to 5–10 mm in diameter during the check colonoscopies usually performed within 1 year (or even on the same day) [58] of a previous colonoscopy and polypectomy to establish a "clean colon" that is free of adenomas. It has been estimated that 27% of adenomas in the size range 1–5 mm are missed on colonoscopy, as are 13% of adenomas in the range 6–9 mm, and 6% of those over 10 mm [58]. Colonoscopy can miss colonic cancer in the intramucosal lesions of chronic ulcerative colitis, within strictures, or where there is submucosal involvement by extrinsic neoplasm or metastases.

In addition to diagnostic difficulties, the mechanical limitations of colonoscopy are relevant. An expert manages up to 98%–99% total colonoscopy, especially if there is no stricture or stenosing lesion to prevent insertion. Less expert endoscopists or those with a smaller case load may reach the cecum [59] less than 90% of the time and are more likely to be slow, inaccurate in diagnosis and localization, and more traumatic and liable to complications. The lack of proper means of teaching colonoscopy skills limits its clinical application worldwide.

Costs

Colonoscopy is highly cost-effective. The instrumentation involved is inexpensive compared to radiography. A colonoscope should last for at least 500 examinations before major repair or replacement becomes necessary. The actual physician time involved per procedure is greater for colonoscopy than for the virtual CT scan, during which the examination may be performed by a technician. The overall cost is approximately equal if a radiography and flexible sigmoidoscopy-first schema is compared with a colonoscopy-only approach to the investigation of patients with lower GI symptoms. Many patients with an abnormal sigmoidoscopy or virtual CT scan demonstrating a lesion or probable pathology will require a subsequent colonoscopy for confirmation, polypectomy, or biopsy; whereas only a few with the colonoscopy-first approach will require a virtual CT scan [56].

Future developments

Videocolonoscopy will allow improvements in image resolution as well as potential for computer enhancement and related developments that should improve diagnostic accuracy, localization, and ease of instrument handling. Advances in bowel preparation should permit comfortable clearance in a few hours instead of the 24–48-hour preparations used at present. Developments in safe, short-lived analgesia should make insertion easily tolerated while allowing normal activities soon afterward, such as driving or return to work. Anesthesiologists and some endoscopists administer propofol for colonoscopy, during which period the patient is in a deep stage of anesthesia, but recovery is reasonably rapid. Computerized interactive teaching models will permit education in manipulative and interpretive skills without imposing an undue burden on and risk to patients during the endoscopist's early training phase [60].

Development of other diagnostic and therapeutic modalities will allow the endoscopist to apply miniaturized imaging probes to areas of interest and to ablate lesions more completely and safely than can be performed at present. For instance, ultrasound probes passed through the instrumentation channel help to determine the presence and depth of penetration of malignancy [61]. Optical coherence tomography (OCT) uses light instead of sound waves to achieve an "optical biopsy" of the mucosa and submucosa [62]. A new technology is emerging to record spectrophotometric measurements of tissue fluorescence by a sensing device passed through the accessory channel [63]. Differentiation between neoplastic and normal tissue by their inherent differences in level of tissue excitation by laser stimulation may be sufficient for diagnostic purposes or will enable directed biopsy of abnormal areas [64]. With improved photosensitizing agents and laser photocoagulation or locally injected immunotherapeutic agents, colonoscopy should be able to make further inroads into territory that is traditionally considered the domain of the surgeon.

Wireless "capsule" endoscopy [65] has been developed for small bowel exploration, where peristalsis is the propulsive force for movement, and the narrow-caliber lumen is sufficiently illuminated by the light to produce a diagnostic visual image. A capsule has been developed for the colon and studies are continuing for its assessment [66] in spite of several differences between the large and small bowel such as:

- the diameter is wide and folds may hide lesions
- peristalsis is relatively slow in the colon
- the capsule tends to tumble and its movements cannot be controlled
- there is no therapeutic capability.

Some or all of these factors can be overcome in the future, which may see the development of robotic therapeutic capsules armed with snare, forceps, scissors, and clips.

The future prospects for GI imaging seem limitless; already the colonoscope is the best imaging system for the colon, and has the additional ability to perform therapy including injection, biopsy, decompression, and polypectomy.

A ENDOSCOPIC

121 Endoscopic retrograde cholangiopancreatography, endoscopic sphincterotomy and stone removal, and endoscopic biliary and pancreatic drainage

Tony E. Yusuf, Daniel K. Mullady, David L. Carr-Locke

Ampulla of Vater (major duodenal papilla), 2933
Sphincter of Oddi dysfunction, 2934
Biliary system, 2935
Pancreas, 2945

Endoscopic retrograde cholangiopancreatography (ERCP) is an advanced endoscopic procedure that has been available for over three decades. It encompasses the use of a side-viewing endoscope and various accessories to gain access to the biliary and pancreatic ductal system under fluoroscopic guidance. First described in 1968 by McCune et al. [1], ERCP has evolved into a complex endoscopic procedure for the diagnosis and therapy of pancreatobiliary diseases with many defined indications. ERCP requires dedicated and supervised endoscopy training to acquire the different techniques, which include endoscopic papillectomy, sphincter of Oddi manometry, biliary sphincterotomy, pancreatic sphincterotomy, stone removal, tissue sampling, stenting, and drainage of peripancreatic fluid collections. ERCP has an overall complication rate of 4.95%. Complications includes pancreatitis (1.8%), hemorrhage (1.13%), cholangitis (0.57%), perforation during sphincterotomy (0.57%), others (0.57%), and death (0.12%) [2]. This chapter summarizes the clinical applications and techniques used during ERCP.

Ampulla of Vater (major duodenal papilla)

Ampullary adenoma and carcinoma

Small intestinal tumors represent 2.4% of all gastrointestinal malignancies and 55.2% of these are found in the duodenum [3,4]. Duodenal adenomas are common in patients with familial adenomatous polyposis (FAP), with 50%–100% occurring in a periampullary location [5–7]. Sporadic adenomas of the papilla are being increasingly recognized, often as an incidental finding during a routine upper endoscopy. In postmortem studies, the incidence of adenomas of the ampulla of Vater is 0.04%–0.12% [8]. The frequency of carcinoma in papillary adenomas has been reported to range from 30% to 65% [9,10].

Because histologically proven adenomas of the papilla are premalignant and follow the adenoma–carcinoma sequence similar to that seen in the colon [11], resection of these lesions is recommended. Traditionally, the approach to these lesions was wide radical resection with pancreaticoduodenectomy, as the presence of malignant foci can be missed on preoperative biopsies. This was accompanied by significant morbidity and a mortality rate as high as 30% [12,13]. Even with improvements in surgery, local resection is currently the method of choice, with lower morbidity and mortality but an association with a known recurrence rate [14–16].

Endoscopic resection of the papilla (endoscopic papillectomy or ampullectomy) is gaining popularity and wider acceptance as a less invasive treatment modality for ampullary lesions and, in particular, for those patients who are poor operative candidates. One study concluded that ampullectomy is the procedure of choice for resecting benign lesions smaller than 3 cm, small neuroendocrine tumors, and T1 carcinomas of the ampulla [17]. The technique involves gross inspection of the papilla with a side-viewing duodenoscope. The margins of the lesion can be highlighted by chromoendoscopy with spraying dye such as methylene blue or indigo carmine; however, this step is not often required as the lesion is usually protuberant (Fig. 121.1). A cholangiogram and a pancreatogram are carried out to define intraductal tumor extension and to opacify the ducts with contrast to aid in identifying the ductal orifices after the procedure is completed. One approach is to perform a small pancreatic sphincterotomy

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

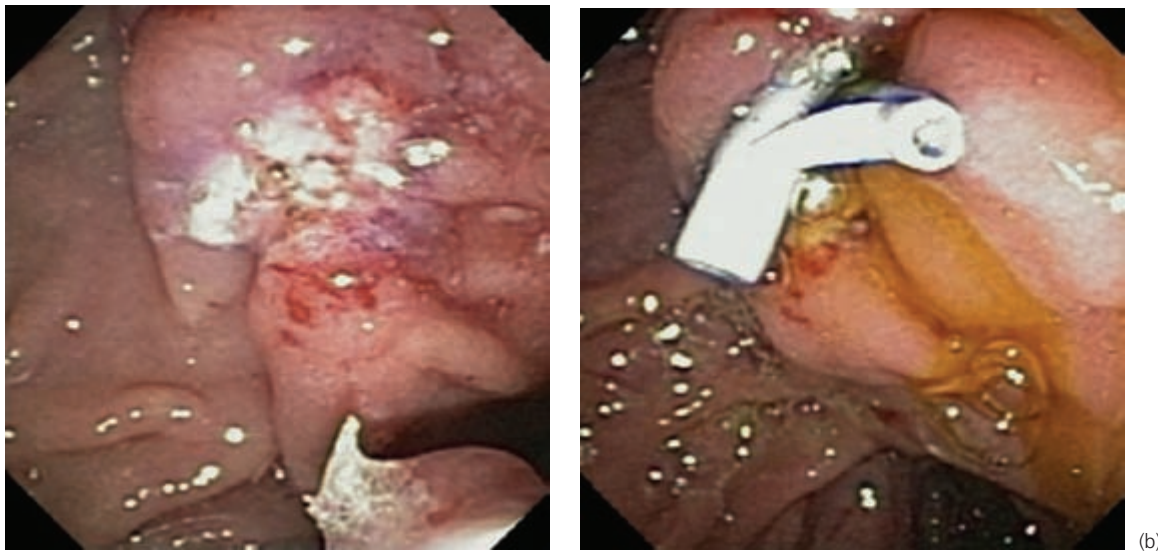
Figure 121.1 A 48-year-old man with hereditary nonpolyposis colon cancer (HNPCC) found to have ampullary adenoma on screening upper endoscopy.

and to place a small pancreatic stent prior to piecemeal snare polypectomy [18]; however, most commonly an en-bloc snare excision of the entire lesion is performed using electrosurgical current and the specimen is retrieved for histopathological examination. Residual adenomatous tissue at the margins of the resection site can be ablated with contact thermal or noncontact argon plasma coagulation. At the end of the procedure, a short polyethylene pancreatic stent is placed to minimize the risk of postprocedural pancreatitis. Occasionally, a biliary stent is also placed to optimize bile drainage (Fig. 121.2). In a prospective randomized controlled trial of endoscopic ampullectomy in 19 patients with ampullary adenoma, the risk of postprocedural pancreatitis was 0% in the stented group compared with 33% in the unstented group [19]. The stents are removed endoscopically at 1 month and the site inspected for residual adenoma. Surveillance endoscopy with a duodenoscope is carried out every 6–12 months for benign lesions to assess for recurrent adenomatous tissue.

Accurate preoperative diagnosis and staging of papillary tumors is essential in planning the therapeutic intervention. Endoscopic biopsies of papillary adenomas cannot exclude the presence of carcinoma [10,20]. Adenocarcinoma was found at surgery or follow-up in 30%–60% of patients with a primary preoperative diagnosis of papillary adenoma [10,11]. ERCP with biopsies and endoscopic ultrasound (EUS) is the current accepted approach for diagnosis and staging of ampullary tumors. EUS has been shown to be an accurate endoscopic imaging modality for local staging of ampullary tumors and assessment of lymph node status [21,22]. In one study, EUS T-staging and failure to adequately lift the ampullary lesion with a submucosal saline injection were predictive of malignancy by univariate analysis [23]. Patients with inoperable ampullary cancer causing biliary obstruction will have a self-expandable metal stent placed into the main bile duct for adequate biliary drainage. Metal stents provide long-term palliation of malignant biliary obstruction, with a median stent patency period of 8 months, and are more cost-effective than plastic stents in patients with a life expectancy of 6 months or more [24–26].

Sphincter of Oddi dysfunction

The sphincter of Oddi is a muscular structure made of smooth muscle fibers that surrounds the distal pancreatic duct, bile



(a) (b)

Figure 121.2 **(a)** The same patient as in Figure 121.1 after papillectomy. **(b)** The same patient after stenting of the bile duct and pancreatic duct.

duct, and ampulla of Vater. This sphincter mechanism lies mostly within the duodenal wall and measures 6–10 mm in length [27–32]. Functionally, the sphincter of Oddi is independent from the duodenal smooth muscle system and it serves to prevent reflux of duodenal contents into the ductal system and to control the flow of bile and pancreatic juice into the duodenum [32].

Sphincter of Oddi dysfunction, commonly known as SOD, refers to an abnormality within the sphincter, either motility related (dyskinesia, spasm) or structural (stenosis), related to chronic inflammation or fibrosis. SOD can involve the biliary sphincter, the pancreatic sphincter, or both. Patients typically present with episodic epigastric pain radiating to the back and associated with hepatic or pancreatic enzyme abnormalities. Postcholecystectomy abdominal pain similar to the preoperative pain of suspected biliary origin occurs in 10%–20% of patients [33]. In two studies, SOD was diagnosed in 9%–11% of patients during evaluation of postcholecystectomy pain [34,35].

SOD is classified into a biliary type according to the Milwaukee classification of Hogan and Geenen [36], and a pancreatic type according to Sherman et al. [37]. Each classification system has three types: biliary I patients have biliary-type pain, abnormal liver function tests (alanine aminotransferase [ALT] and aspartate aminotransferase [AST] levels > 2 × normal) documented on two or more occasions, delayed drainage of ERCP contrast of more than 45 min, and a dilated common bile duct of more than 12 mm diameter; biliary II patients have biliary-type pain but only one or two of the above criteria; and biliary III patients have only biliary-type pain and no other abnormalities. Pancreatic I patients have recurrent pancreatitis or typical pancreatic pain, elevated pancreatic enzymes 1.5–2 × the upper limit, a dilated pancreatic duct of more than 6 mm in the head and 5 mm in the body, and delayed contrast during ERCP of more than 9 min; pancreatic II patients have pancreatic pain and one or two of the above criteria; and pancreatic III patients have only pancreatic-type pain.

Sphincter function can be evaluated by invasive and noninvasive methods [38]. Noninvasive methods include the morphine–prostigmin provocative test; hepatobiliary scintigraphy, which evaluates radionuclide filling and drainage of the bile duct; and ultrasound assessment of the pancreatic duct and bile duct after secretin or cholecystokinin stimulation [39–44]. The gold standard diagnostic test for SOD is manometric assessment of basal sphincter pressure by sphincter of Oddi manometry (SOM). A baseline ERCP is usually performed to exclude pancreatobiliary diseases such as congenital anomalies, stones or malignancy. SOM involves the use of solid-state or perfusion low-compliance catheters that can measure the biliary and pancreatic sphincter pressures through ports located at the distal end [45]. Multiple station pull-throughs are performed and graphic recordings of the pressures are displayed on a dedicated computer station. Selective cannulation of the bile duct or pancreatic duct for isolated sphincter pressure measurement is guided by clinical suspicion for the origin of symptoms. The patient must be sedated for the procedure and smooth muscle relaxants are avoided as they may interfere with the sphincter mechanism and interpretation of results. A basal sphincter pressure greater than 40 mmHg above duodenal pressure is considered abnormal and sphincterotomy is the current standard treatment of choice for SOD in the appropriate clinical setting. Most of the data on the effect of endoscopic therapy of SOD refer to biliary sphincterotomy. Symptomatic patients with type I SOD benefit from sphincterotomy (90%–100%) irrespective of the manometry findings; thus, manometry is not required for this group of patients [38,46]. In type II SOD, 85%–95% of patients with an elevated basal sphincter pressure benefited from sphincterotomy and reported improvement of symptoms after 2–4 years of follow-up [47,48]. Patients with type III SOD and an elevated basal sphincter pressure on SOM may benefit from sphincter ablation in 55%–65% of cases [38].

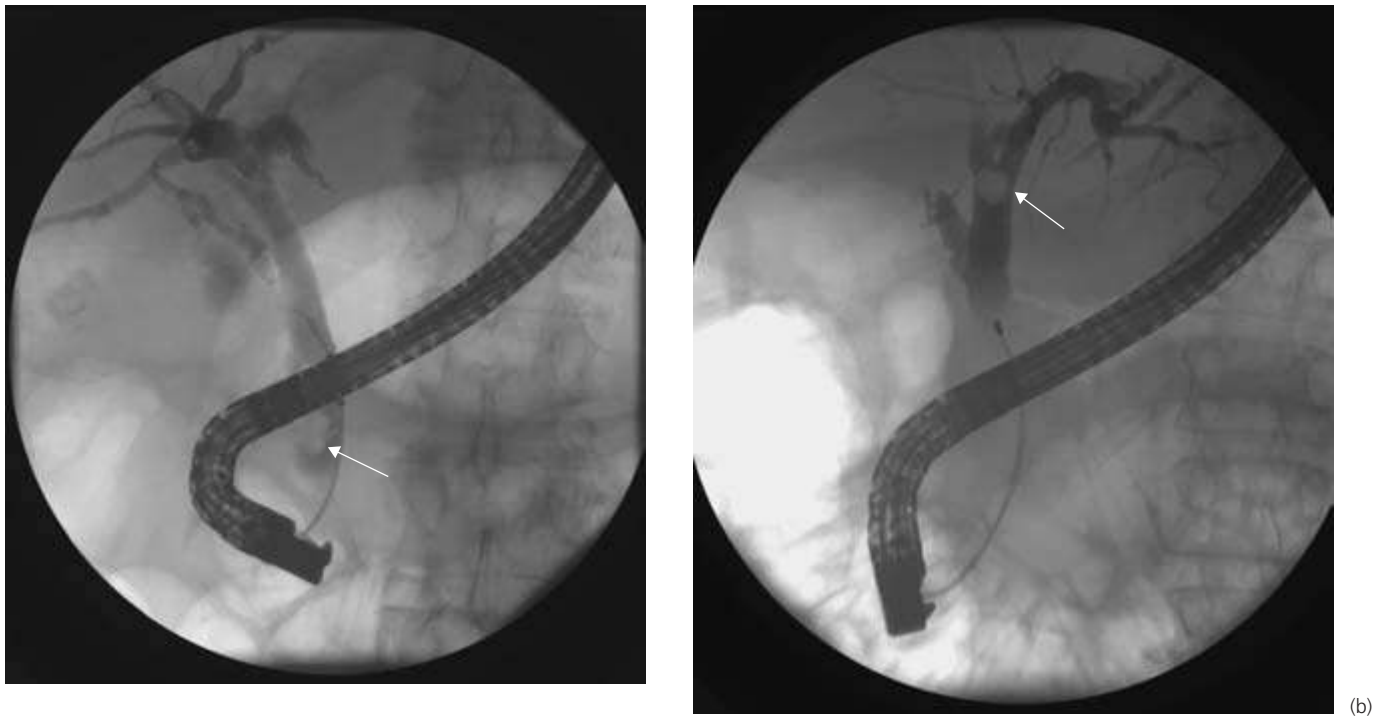
The rate of complications is high in patients undergoing endoscopic sphincterotomy for SOD and varies from 10.8% to 21.7% [49,50]. Pancreatitis is the most common complication and occurs in up to 20% of patients. The risk of pancreatitis may be minimized by stenting of the pancreatic duct. Patients with suspected pancreatitis following SOM and sphincterotomy should be admitted to hospital for observation and treatment.

Biliary system

Bile duct stones

Bile duct stones occur in 6%–15% of cases of symptomatic cholelithiasis and in 1%–2% of cholecystectomies performed for acalculous biliary disease [51–55]. Patients may present with abdominal pain of biliary origin (erroneously termed biliary colic), cholangitis, jaundice, pancreatitis, transient elevation of hepatic aminotransferases, or a filling defect with or without biliary ductal dilation on imaging studies such as transabdominal ultrasound, computed tomography (CT), and magnetic resonance cholangiopancreatography (MRCP). When choledocholithiasis is suspected clinically or on imaging studies, the ultimate therapy is extraction of the stones from the biliary tree to minimize serious complications such as severe pancreatitis, sepsis, and death. Stone extraction can be achieved endoscopically, surgically, or radiologically using the transhepatic approach.

Endoscopic removal of bile duct stones is the mainstay of treatment and first-line therapy of choice in centers that have expertise in this technique (Fig. 121.3). Since the first descriptions of endoscopic sphincterotomy by Classen and Demling [56] and Kawai et al. [57] in 1974, the role of ERCP in the management of bile duct stones has witnessed a



(a) (b)

Figure 121.3 (a) Choledocholithiasis in the distal common bile duct (arrow). **(b)** Choledocholithiasis in the proximal common hepatic duct (arrow).

tremendous growth. By using standard techniques of stone extraction (see below), up to 90% of bile duct stones can be removed after a biliary sphincterotomy [58]. The remaining 10% of cases require more advanced techniques (see below).

Patients are sedated before therapeutic ERCP performed for bile duct stone removal. In most medical centers, conscious or moderate sedation is administered. Alternatively, general anesthesia is used in selected groups of patients such as children, the elderly, the severely ill, those with serious cardiopulmonary problems or difficult airways, and those who are difficult to sedate based on previous history. In one study that retrospectively analyzed 1056 ERCPs performed on patients under conscious sedation (82%) or general anesthesia (18%), the latter was given more frequently to patients with primary sclerosing cholangitis, liver transplant recipients, and those undergoing painful dilations whereas conscious sedation was more frequently given to patients with neoplasia and choledocholithiasis. More interventions per ERCP were performed with the patient under general anesthesia than with the patient under conscious sedation ($P < 0.001$), and with conscious sedation the ERCP failure rate was double that with general anesthesia (7% vs 14%, $P = 0.012$) [59].

Access to the bile duct by deep cannulation is essential to achieve endoscopic therapy of bile duct stones. Biliary access can be difficult in some patients and there are a number of different techniques that can be used in this situation to gain entry into the bile duct. Once stones are identified on a cholangiogram, the decision should be made as to what accessory instruments need to be used. A biliary sphincterotomy (incision of the intraduodenal portion of the common bile duct sphincter muscle) is usually performed to the maximum extent of the endoscopic landmarks and under direct endoscopic guidance prior to stone removal (Fig. 121.4). This is achieved with the use of a sphincterotome catheter that has a cutting electrosurgical wire at the distal end. Sphincterotomy is associated with some complications. A retrospective analysis of complications in 535 patients who underwent endoscopic sphincterotomy found a complication rate of 5.4%, which included bleeding (2.4%), retroduodenal perforation (0.4%), pancreatitis (0.6%), cholangitis (1.3%), and cholecystitis (0.7%); 14% of these patients required an operation. Overall mortality was 0.3% [60]. A multicenter study by Freeman et al. [49] identified, in a multivariate analysis, five significant risk factors for complications occurring within 30 days of endoscopic biliary sphincterotomy. These were suspected SOD, cirrhosis, difficult bile duct cannulation, precut (access) papillotomy, and use of a combined percutaneous–endoscopic procedure. The rate of complications was highest when the indication for the procedure was suspected SOD (21.7%) and lowest when the indication was removal of bile duct stones within 30 days of laparoscopic cholecystectomy (4.9%). Compared with endoscopists who performed fewer ERCP procedures, those who performed more than one sphincterotomy per week had lower rates of all complications (8.4% vs 11.1%, $P = 0.03$) and severe complications (0.9% vs 2.3%, $P = 0.01$).

Since the first description in 1983 [61], endoscopic balloon dilation of the papillary sphincter, or balloon sphincteroplasty,

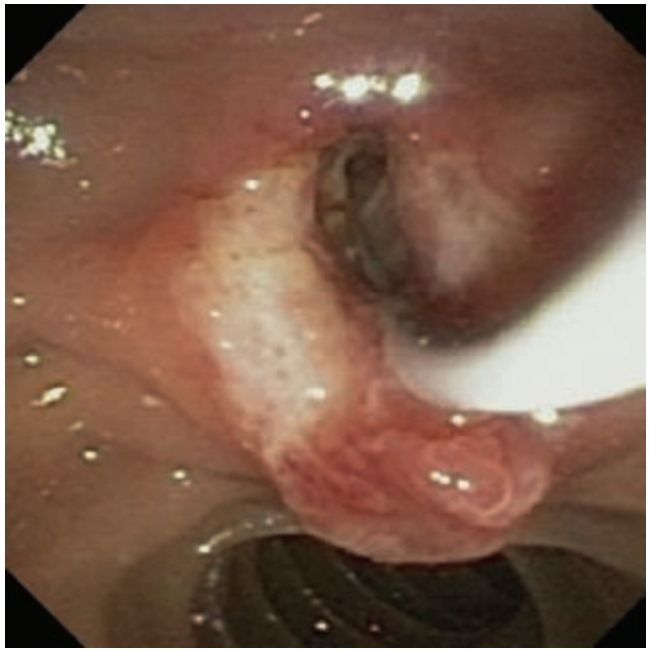


Figure 121.4 Endoscopic appearance of a widely patent biliary sphincterotomy.

has been proposed as an alternative to endoscopic sphincterotomy for the treatment of papillary stenosis and management of bile duct stones [62–66]. This involves the use of a hydrostatic balloon positioned across the papilla and inflated under high pressure while dilation is monitored fluoroscopically. The potential advantages over endoscopic sphincterotomy are preservation of the sphincter mechanism and possible minimization of short- and long-term complications.

A metaanalysis of eight prospective randomized trials comparing endoscopic balloon dilation with sphincterotomy in the treatment of bile duct stones found similar outcomes in overall complications and success rate in stone removal [67]. There was less bleeding but higher rates of postprocedural pancreatitis with balloon dilation than with sphincterotomy (0% vs 2.0% and 7.4% vs 4.3% respectively). There were no significant differences in the rates of perforation or infection. Mechanical lithotripsy was required more frequently in the group of patients who had papillary balloon dilation than in the sphincterotomy group (20.9% vs 14.8%, $P = 0.014$). The authors recommend the use of endoscopic balloon dilation of the papillary sphincter in the group of patients with coagulopathy to minimize the risk of bleeding. A multicenter study of 237 patients with bile duct stones randomized to balloon dilation and sphincterotomy found that dilation is associated with increased short-term morbidity and death secondary to pancreatitis compared with sphincterotomy [68]. As there seems to be an increased incidence of adverse events in Western populations, balloon dilation of papilla cannot be recommended as the routine first-line option in the management of bile duct stones. Balloon dilation of a previous sphincterotomy may, however, be safer than repeated sphincterotomy.

An attempt at stone extraction should be made after a biliary sphincterotomy is performed unless the patient condition mitigates in favor of drainage only. The most commonly used accessories for this purpose are balloon catheters and baskets made of metal wire. The choice between a balloon or a basket depends on the size of the stones and endoscopist preference [69]. For large and multiple stones (≥ 10 mm), a basket is preferable (Fig. 121.5). A balloon is commonly used

(a)

(b)

for smaller stones and sludge by virtue of its ability to inflate to the bile duct diameter and occlude the lumen. By this method, the stones can be swept outside the duct and into the duodenal lumen (Fig. 121.6). Stones larger than 15 mm present a challenge to the endoscopist and often require alternative and complex endoscopic techniques such as the use of a mechanical lithotripter or intraductal shock waves generated by electrohydraulic or laser techniques. A mechanical lithotripter consists of a basket similar to the standard basket used to extract stones but with an additional outer metal sheath against which stones are crushed using a manual cranking device. Shock waves used to fragment bile duct stones are delivered by a thin catheter probe introduced into the channel of a cholangioscope (ultrathin endoscope), which is in turn advanced into the bile duct lumen through the working channel of a duodenoscope (Fig. 121.7). The source of energy used to generate shock waves can be electrical (electrohydraulic) or a laser [70,71]. The procedure is performed under combined endoscopic and fluoroscopic guidance. Intermittent bolus of saline infusion into the bile duct through the cholangioscope is necessary to create a medium for shock wave transmission and to optimize visualization of the duct lumen. Newer lasers that integrate a stone detection system can be used under fluoroscopic guidance only.

In rare situations, the standard basket can become entrapped with a stone in the bile duct and this can be managed with a special lithotripter designed for this urgent condition. If this method fails a number of other techniques are available, and rarely is surgical intervention required. In addition, when complete stone removal fails, insertion of a biliary endoprosthesis or stent provides temporary biliary drainage, minimizing the risk of biliary sepsis before further endoscopic attempts at duct clearance are made [72,73]. Long-term biliary drainage, especially in old and frail patients, has now been questioned as a safe alternative to clearance [74].

Hepatolithiasis, the presence of stones in the intrahepatic biliary tree above the hepatic duct confluence, is difficult to treat and poses a major challenge to the endoscopist. A study from Japan reported the effectiveness and long-term results of peroral cholangioscopic lithotomy for hepatolithiasis in 36 patients over 11 years [75]. Large stones refractory to mechanical lithotripsy were fragmented using electrohydraulic or laser lithotripsy. Extracorporeal lithotripsy was used when the endoscopic approach was difficult. Complete stone removal was achieved in 64% of patients, of whom 78% remained symptom-free. The cumulative recurrence rate for patients who had complete stone removal was 21.7% at 164 months.

Cholelithiasis and choledocholithiasis

When patients present with the combined problem of gallstones in the gallbladder and bile duct simultaneously, there are two questions to answer: (1) what is the best method for clearing the bile duct and (2) what should be done with the gallbladder? The sequential options are: (1) laparoscopic cholecystectomy with laparoscopic bile duct exploration; (2) laparoscopic or open cholecystectomy followed by postoperative ERCP; (3) preoperative ERCP followed by cholecystectomy (laparoscopic or open); (4) open cholecystectomy with open exploration of the bile duct; (5) ERCP and no cholecys-

tectomy; and (6) in special circumstances, a range of additional and much less commonly used surgical and nonsurgical techniques such as percutaneous cholecystostomy, percutaneous access to the bile duct including percutaneous cholangioscopy, techniques for Mirizzi syndrome, management of hepatolithiasis, and approaches to recurrent stones after biliary and nonbiliary upper gastrointestinal surgery. It is unlikely that one option will be appropriate for all clinical circumstances in all centers in all countries as the variables of disease states, patient demographics and risk stratifications, available endoscopic, radiological, and surgical expertise, patient preferences, and health-care economics will all have significant influences on practice [76].

In patients with contemporaneous cholelithiasis and choledocholithiasis, it is usually the latter that dominates the acute clinical presentation and leads to intervention for pain, obstructive jaundice, cholangitis, pancreatitis, or any combination thereof. Less commonly, asymptomatic bile duct stones are discovered incidentally on noninvasive imaging for nonbiliary indications, during evaluation of symptomatic cholelithiasis, or intraoperatively during cholecystectomy. Since the universal adoption of laparoscopic cholecystectomy as the primary method for treating cholelithiasis in the early 1990s, only a minority of surgeons have mastered the techniques required for laparoscopic transcystic or direct choledochal exploration to treat choledocholithiasis, and there has been some reluctance to convert to open bile duct exploration for this indication. Since ERCP became the standard approach for acute presentations of choledocholithiasis in the 1980s and with the overall success of endoscopic bile duct clearance, the question of treating cholelithiasis surgically became a secondary issue.

Although there is evidence that elective and emergent clearance of the bile duct by ERCP had advantages over open bile duct exploration [77–79], the comparison of ERCP therapy with laparoscopic bile duct clearance is much more equivalent for most stones in the elective setting [78,80]. Unfortunately, this surgical option is not always available and the evidence is therefore tempered by local expertise. Following endoscopic bile duct clearance, the decision to leave the gallbladder in situ and follow the patient expectantly (option 5 above) compared with routine laparoscopic cholecystectomy has been studied [80,81]. In a prospective randomized multicenter trial by Boerma et al. [80], 27 out of 59 patients allocated to a "wait and see" policy had recurrent biliary symptoms, of whom 22 underwent cholecystectomy for biliary pain or acute cholecystitis. In a study of Chinese patients over the age of 60 years, Lau et al. [81] reported a 7% occurrence of biliary events (cholangitis, pain) after endoscopic bile duct clearance and laparoscopic cholecystectomy in contrast to 24% after endoscopic duct clearance and leaving the gallbladder in situ. Although their patient recruitment was not consecutive and the very-high-risk surgical patients were excluded, these observations are valuable.

Where the expertise is available, elective management of cholelithiasis and choledocholithiasis by the laparoscopic approach should be offered. The role of ERCP in the management of acute calculous bile duct disease remains central and optimal. The majority of patients after successful endoscopic bile duct clearance should undergo laparoscopic cholecystectomy as early as possible to reduce the risk of a further biliary event or to treat cholecystitis if already present. There will still be a small population of patients, however, considered at high risk for laparoscopic cholecystectomy and, in these, judicious conservative management of the in situ gallbladder is justifiable.

Mirizzi syndrome

First described by Mirizzi [82] in 1948, Mirizzi syndrome, a rare complication of gallstone disease, refers to stone impaction in the neck of the gallbladder or the cystic duct and subsequent inflammation and extrinsic compression of the main bile duct leading to obstructive jaundice and cholangitis. Mirizzi syndrome is classified into two types, type I and type II, based on cholangiographic findings [83]. Type I refers to extrinsic compression of the main bile duct secondary to a stone in the cystic duct or gallbladder and type II occurs when there is a cholecystocholedochal fistula. Type II has been further subdivided into three subtypes based on the size of the defect in the common duct [84] (Fig. 121.8).

Transabdominal ultrasound and CT are often the initial imaging studies performed in suspected cases of Mirizzi syndrome but these studies are limited by regional inflammation and bowel gas [85,86]. Direct cholangiography during ERCP or via the percutaneous transhepatic route is the diagnostic method of choice. A distended gallbladder, extrinsic compression of the main bile duct, and a dilated intrahepatic biliary tree are seen in type I Mirizzi syndrome. A fistulous tract between the gallbladder and bile duct may be seen in type II Mirizzi syndrome. A stone that is fixed in the region of the cystic duct or gallbladder should also raise the possibility of this diagnosis. MRCP is an alternative noninvasive imaging modality that can be utilized to diagnose Mirizzi syndrome [87].

Treatment of Mirizzi syndrome has traditionally been surgical. Endoscopic management consists of drainage and decompression of the bile duct and/or gallbladder [88,89]. This is essential in relieving jaundice and treating cholangitis before surgical intervention. Binmoeller et al. [90] reported the use of electrohydraulic lithotripsy in 14 patients with Mirizzi syndrome who were at high risk for surgery. Stones were impacted in the cystic duct and ranged in diameter from 1.5 cm to more than 3 cm. Insertion of the cholangioscope along with the lithotripsy probe and stone fragmentation was successful in all patients without mortality. One patient had a cystic duct leak of contrast that was attributed to pressure necrosis from an impacted stone. This resolved spontaneously with conservative management. A study of 25

Figure 121.8 Mirizzi syndrome: large stone in the neck of the gallbladder causing compression of the common bile duct.

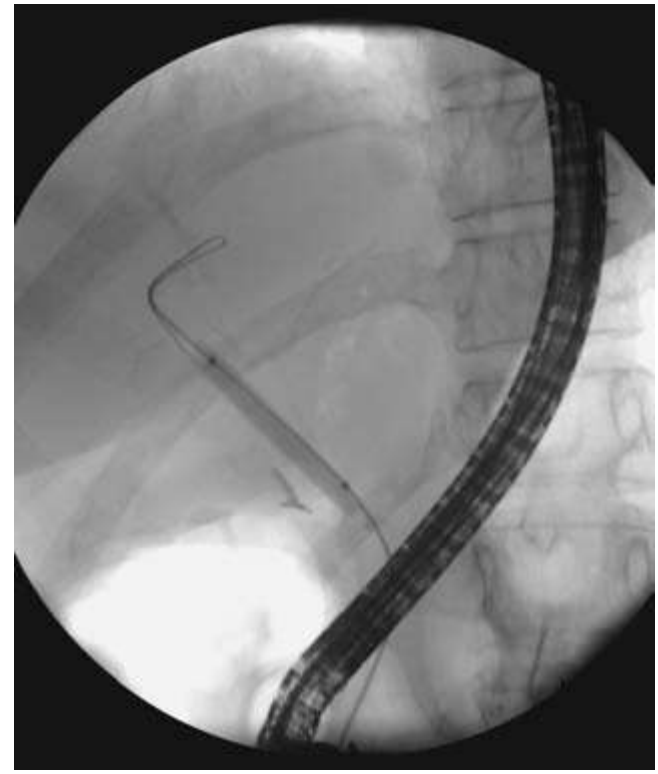
patients with Mirizzi syndrome in whom 13 were managed only by endoscopic therapy such as endoscopic sphincterotomy, bile duct stenting, mechanical lithotripsy, and extracorporeal shockwave lithotripsy achieved complete stone removal in three. Nine patients were treated with long-term biliary stenting [91]. The authors concluded that endoscopic therapy of Mirizzi syndrome is an effective temporizing intervention before surgery and can be the only therapy for patients who are poor surgical candidates. The use of extracorporeal shockwave lithotripsy to fragment stones in the cystic duct in patients with Mirizzi syndrome has also been reported [92].

Bile duct strictures

Benign biliary strictures result from many different etiologies of which the commonest include anastomotic, operative injury and chronic pancreatitis. Patients often present with cholestasis, cholangitis, or secondary biliary cirrhosis [93]. In the past surgical management was the standard approach, with associated morbidity and mortality, but currently endoscopic therapy with dilation and stenting offers a less invasive and an effective line of therapy (Fig. 121.9). The insertion of multiple biliary stents for the treatment of benign strictures has gained wide acceptance in the endoscopy community. In one study [94], 46 patients with chronic pancreatitis and distal common bile duct stricture who presented with obstructive symptoms were divided into two groups: group 1 ($n = 34$) had single stent placement exchanged at 3- to 6-month intervals and group 2 ($n = 12$) had multiple simultaneous stent placement at 3-month intervals [94]. Patients were followed up for a mean period of 4 years. At the end of the treatment period, liver function tests nearly normalized in all patients in group 2, whereas only marginal benefit was noted for patients in group 1. In total, 12% of patients in group 1 had recurrent cholangitis compared with none in group 2. Distal common bile duct stricture diameter increased from a mean of 1.0 mm to 3.0 mm in patients after treatment with multiple stent placements (group 2); no change in diameter was noted in patients treated with a single stent (group 1). Bergman et al. [95] reviewed ERCPs performed on 74 patients with postoperative bile duct stenosis over a 10-year period. The most common surgical procedure performed was cholecystectomy with and without bile duct exploration. Two 10F stents were inserted for a maximum of 12 months and exchanged every 3 months to avoid stent occlusion and risk of cholangitis. Of the 47 patients treated according to protocol, stents were eventually removed in 44 patients who were followed up for a median of 9.1 years. Restenosis occurred in nine patients (20%) at a median of 2.6 months (range 1 week–2 years) after stent removal. Patients presented with cholestasis, jaundice, and cholangitis. Of these patients, four went for surgery and five had repeated stenting. Costamagna et al. [96] reviewed the records of 45 patients with postoperative strictures treated with placement of an increasing number of stents. The maximum number of stents were placed relative to the stricture tightness and distal bile duct diameter until the stricture resolved. Previous surgery in these patients included cholecystectomy (open and laparoscopic), liver transplantation, hepatic trauma with biliary repair, and hepatic resection. The success rate for stent placement was 89% and early complications occurred in 9% (cholangitis, pancreatitis) with stent occlusion requiring early exchange in 18%. In total, 42 patients completed the protocol (mean number of stents 3.2 +/– 1.3; range 1–6) over a treatment period of 12.1 +/– 5.3 months (range 2–24 months). Among 40 patients followed up for a mean of 48.8 months (range 2–11.3 years), there was no recurrence of symptoms caused by recurrent biliary stricture. The authors concluded that this aggressive approach of biliary stenting may improve long-term results for patients with postoperative biliary strictures. The sequential insertion of an increasing number of plastic biliary stents with larger diameters was also found to be an effective therapy for distal common bile duct strictures that developed as late complications of endoscopic sphincterotomy [97]. In addition, the use of self-expandable metal stents (SEMS) in benign bile duct strictures secondary to chronic pancreatitis has been shown to provide successful and prolonged biliary drainage in a selected group of patients [98].

Biliary obstruction secondary to malignant bile duct stricture of pancreatic, biliary or metastatic origin is usually

(a)



(b)

(c)

Figure 121.9 **(a)** Benign right hepatic duct stricture after cholecystectomy. **(b)** Balloon dilation of benign right hepatic duct stricture. **(c)** Plastic stent across benign stricture after balloon dilation.

palliated by stent placement. Polyethylene plastic stents are placed into the bile ducts of patients with tumors that may be surgically resectable, and during initial evaluation when histology or cytology is not yet available. Locally advanced and metastatic tumors of biliopancreatic origin and those patients who are poor surgical candidates are suitable candidates for metal stents (Fig. 121.10). SEMS are commonly used for ease of deployment, high patency rate, and cost-effectiveness despite the high cost of individual stents [99,100]. The patency of metal stents is significantly prolonged compared with polyethylene stents, a median of 273 days vs 126 days in one study [99]. A cost-effectiveness analysis by Arguedas et al. [101] found that initial metal stent placement for palliation of obstructive jaundice in patients with pancreatic cancer was associated with a slightly lower cost per patient and slightly higher quality-adjusted life months compared with a plastic stent (US$13 466 vs US$13 879 per patient and 1.832 vs 1.799 quality-adjusted life months respectively). A prospective multicenter study of Diamond stents (one type of metal stent) in 126 patients with malignant biliary obstruction secondary to inoperable tumor had technical and clinical success rates of 96% and 98% respectively. There were no major procedure-related complications. Stent occlusion occurred in 22% and all were treated with plastic stent placement. Median stent patency was 477 days. Overall median survival was 173 days and the 30-day mortality rate was 13% [102].

Malfunction of SEMS can be attributed to tumor ingrowth or overgrowth, tissue hyperplasia at the ends of the stent, and migration. SEMS can be covered or uncovered by a thin plastic coat. Uncovered stents have a higher occlusion rate but a lower migration rate than covered ones. Some types of covered stents are potentially removable endoscopically [103]. Comparative trials are ongoing.

Tissue sampling of bile duct strictures is important in defining their nature (benign vs malignant) and can be achieved by forceps biopsy, brush cytology and needle aspiration. Biliary brush cytology is the most common method of sampling but has a low sensitivity of 30%–60% and a specificity of over 90% [104–106]. The sensitivity of brush cytology is higher for primary bile duct tumors (80%–86%) and when combined with biopsies of the stricture (63%) [104,106]. One study compared a new long cytology brush with rigid bristles oriented at 45 degrees to the standard brush and found improved cellularity with the long brush; however, cancer detection rates were not improved [107]. Additional molecular techniques such as fluorescence in situ hybridization, digital image analysis, and flow cytometry may improve accuracy [108–110].

Bile leak

Iatrogenic injury to the bile duct is a known complication of cholecystectomy. Postoperative bile leak occurs in 0.1%–0.5% of patients after open cholecystectomy and in 0.8%–1.1% of patients after laparoscopic cholecystectomy [111–114]. Injury to the cystic duct is the most common type of injury. Patients may present with abdominal pain, abdominal tenderness, fever, and continued drainage through the Jackson-Pratt drain when present. ERCP is the most accurate technique for delineating the site of the leak and can offer endoscopic therapy (Fig. 121.11) [115]. A study of 64 patients with postcholecystectomy bile leak over a 5-year period found a 1.1% leak incidence among those who had a laparoscopic approach [113]. Patients presented a mean of 5.3 ± 4.2 days (range 0–21 days) postcholecystectomy with abdominal pain (89%), abdominal tenderness (81%), fever (74%), jaundice (43%), and nausea and vomiting (43%). A biloma was detected by ultrasound in 73% of patients and by CT in 95%. The leak site was identified by hydroxyiminodiacetic acid (HIDA) scanning in 19% of patients and by ERCP in 98% of patients. Leak sites were the cystic duct (77%), accessory duct of Luschka (15%), and the common bile duct, common hepatic duct, and an aberrant intrahepatic duct (8%). Bile duct stones were found in 22% of patients. Rates of intraoperative complications and conversion to open surgery were greater among patients who developed leaks (5.2% vs 0.6% and 33% vs 6.3% respectively, $P < 0.00001$).

In addition to delineating the site of bile duct leak, ERCP can offer endoscopic therapy such as sphincterotomy alone, stent placement alone, a nasobiliary drain, or any combination of these. The purpose of endoscopic therapy is to decrease the pressure gradient between the bile duct and duodenum, allowing preferential flow of bile through the transpapillary route and sealing of the leak site. The optimal endoscopic approach is not well established but most endoscopists insert a single 10F stent across the major papilla. The stent does not have to cross the leak site unless there is a major bile duct injury. One study concluded that endoscopic placement of short transpapillary stents without sphincterotomy is a temporary, effective, and technically simple method of pressure equalization [116]. A retrospective study by Kaffes et al. [117] of 100 patients referred for ERCP for suspected postcholecystectomy bile leak evaluated the outcome of different endoscopic treatment. A total of 93 patients had ERCP therapy: stent alone ($n = 40$), endoscopic biliary sphincterotomy alone ($n = 18$), sphincterotomy and stent ($n = 31$), papillary dilation and stenting ($n = 1$), and no endoscopic therapy ($n = 3$). In the stent alone group, one patient required additional ERCP but not surgery to control the leak. In the sphincterotomy alone group, four patients required surgery and two needed repeat ERCP to control the leak. No additional intervention (endoscopic or surgical) was required for the other groups of patients. The authors concluded that the optimal endoscopic therapy for postcholecystectomy bile leak is stent placement.

Bile duct cysts

Bile duct cysts or choledochal cysts are congenital anomalies typically seen in children and young adults, although they

can be diagnosed at any age. They may affect the intrahepatic biliary tree, extrahepatic biliary tree, or both. They occur with an incidence of 1:13 000–1:2 000 000 live births and are three times more common in females than in males [118–120]. Choledochal cysts are commonly classified into five types according to Todani et al. [121], with type I the most common type and type V the least common [120,122–125]. Type I (80%–90%) involves the extrahepatic bile duct and is subclassified into IA (common type), IB (segmental dilation), and IC (diffuse dilation). Type II (2%) is a diverticulum in the main bile duct. Type III cysts (1.4%–5%) involve the intraduodenal portion of the bile duct and are also referred to as choledochocele. Type IV (13%) is the second most common type and is more frequently seen in adults. Type IV is subclassified into IVA (multiple intra- and extrahepatic cysts) and IVB (multiple extrahepatic cysts). Type V (less than 1%) or Caroli disease refers to single or multiple dilations of intrahepatic bile ducts (Fig. 121.12).

The etiology of choledochal cysts is not clear but the most accepted theory is an association with anomalous pancreatobiliary junction (APBJ) with a long common channel (> 15 mm) [126,127]. In this condition, the junction of the bile duct and pancreatic duct is located outside the duodenal wall and reflux of pancreatic juice can result in inflammation and cystic dilation of the bile duct. The risk of malignancy of the biliary tree (gallbladder and bile duct) is increased when APBJ is present, with an overall risk of 14% in patients with choledochal cysts and 50% in those without cysts [128,129]. Classic presenting symptoms and signs are jaundice, abdominal mass, and pain, which are more common in children than adults (82% vs 25% respectively) [130]. Adults often present with vague abdominal pain, cholecystitis, cholangitis, and pancreatitis [119,130,131]. Choledochal cysts are often suspected on imaging studies such as abdominal ultrasonography and CT scan carried out for nonspecific abdominal complaints. ERCP usually establishes the diagnosis, classifies bile duct cysts, and detects the presence of APBJ. MRCP is being increasingly used as a noninvasive imaging modality for various pancreaticobiliary disorders and has been shown to have an overall detection rate for choledochal cysts of 96% [132].

Surgical management of choledochal cysts (cyst excision and biliary reconstruction based on the type of cyst) is the recommended approach to avoid the risk of biliary tract malignancy. Several surgical techniques have been reported such as complete resection of affected bile ducts with Roux-en-Y reconstruction, cyst enterostomy, cyst excision and hepaticojejunostomy, cyst excision and choledochoduodenostomy, and extrahepatic cyst excision with a Roux-en-Y hepaticojejunostomy [133–135]. Management of choledochocele is controversial and endoscopic therapy by biliary sphincterotomy has been recommended [136,137]. In one study, 15 symptomatic patients with choledochocele were identified out of 1019 ERCP referrals over a 7-year period [137]. In total, 12 were treated by endoscopic sphincterotomy and 3 by surgery. Of the 14 patients who had a complete follow-up, 11 were asymptomatic and had normal liver biochemical tests at a median of 18 months (range 12–97). One patient died of a misdiagnosed ampullary carcinoma arising in the choledochocele. The authors concluded that choledochocele, when recognized, should be treated by endoscopic sphincterotomy and that an ampullary carcinoma may develop in a choledochocele.

Pancreas

Endoscopic retrograde cholangiopancreatography and gallstone pancreatitis

The goal of therapeutic ERCP in the setting of acute gallstone pancreatitis is to clear the bile duct of stones that, if left in place, may worsen the severity of pancreatitis and increase the risk of further attacks. Urgent ERCP and sphincterotomy in gallstone pancreatitis has clearly been shown to improve morbidity and mortality in patients with severe attacks but has little or no benefit in patients with mild pancreatitis as the majority of these patients pass the stones spontaneously. The most cited randomized controlled trials are from the United Kingdom, Hong Kong, Poland, and Germany [138–141]. A metaanalysis of these studies has shown that ERCP with endoscopic sphincterotomy reduces morbidity and mortality

Table 121.1 Endoscopic retrograde cholangiopancreatography (ERCP) in biliary pancreatitis for patients with predicted mild attacks

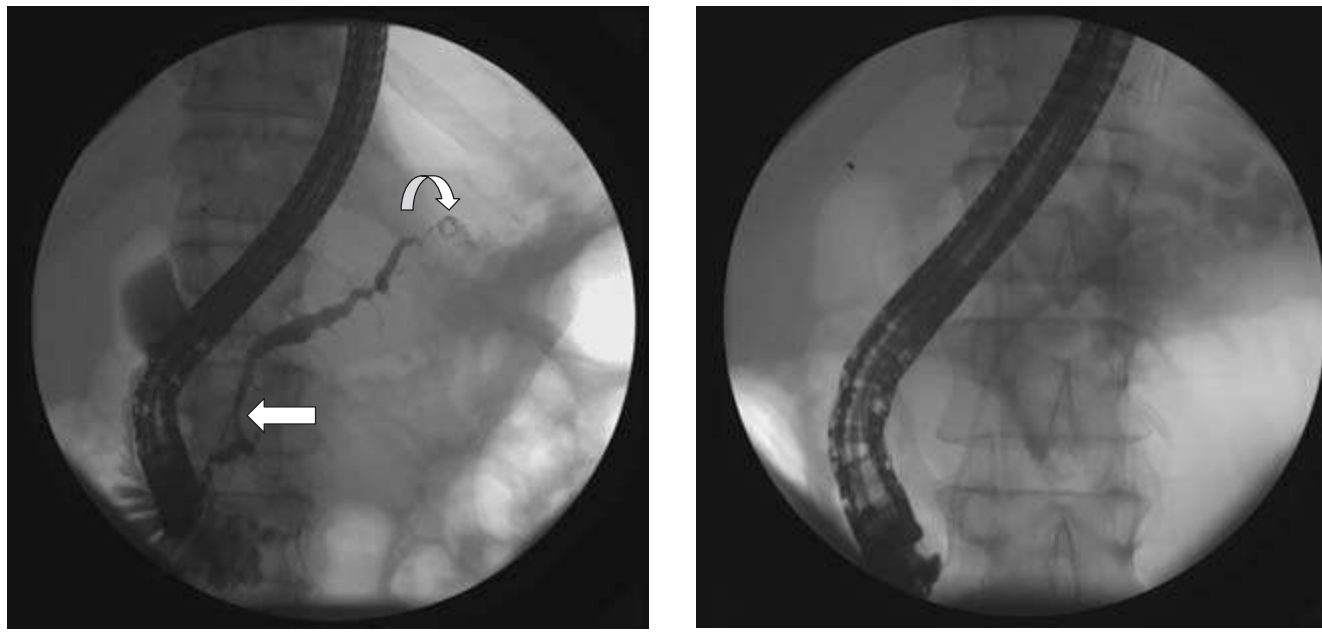
of patients with acute biliary pancreatitis, and treating 26 such patients is predicted to save one life [142]. Tables 121.1 and 121.2 summarize the results of these studies with regard to morbidity and mortality rates in patients who underwent therapeutic ERCP vs conventional treatment in the setting of predicted mild and predicted severe pancreatitis [143]. A prospective randomized controlled trial has shown decreased morbidity in patients who underwent early ductal decompression by ERCP and sphincterotomy (within 48 h) for gallstone pancreatitis compared with those who had therapy after 48 h of the onset of symptoms [144]. An algorithm has been proposed by the senior author [143] which indicates that those patients presenting and continuing with mild pancreatitis require supportive therapy and a subsequent cholecystectomy, preferably during the same admission, whereas those patients in whom evidence of biliary obstruction develops, with or without cholangitis, those deteriorating after an initial mild attack, or those presenting with severe pancreatitis from the outset should be considered for urgent ERCP and sphincterotomy for removal of bile duct stones. Cholecystectomy should be planned for the same admission, if possible, but can be delayed after sphincterotomy because there is a degree of protection from further pancreatitis in this circumstance.

Chronic pancreatitis

Chronic pancreatitis is a progressive disease with persistent inflammation, fibrosis, atrophy of the gland, and ductal abnormalities. Chronic pancreatitis causes significant morbidity related to chronic abdominal pain, loss of exocrine and endocrine function, and complications such as stone disease and pancreatic fluid collection. The severity of chronic pancreatitis is graded according to Cambridge criteria that classify the disease into equivocal, mild, moderate, and severe based on main duct and side branch abnormalities and other findings such as cystic cavities and stones [145]. The pancreatic duct pressure may be elevated secondary to strictures, stones, or outflow obstruction at the level of the major papilla (Fig. 121.13). The goal of therapeutic ERCP is to decompress the pancreatic ductal system and relieve the obstruction with the hope of minimizing attacks of recurrent pancreatitis and alleviating chronic abdominal pain.

Benign strictures and stone disease of the main pancreatic duct can result in ductal obstruction and hypertension, which may be the basis of relapsing pain and recurrent pancreatitis. The strictures are treated by balloon or catheter dilation and insertion of a plastic stent that is exchanged every 2–4 months for up to 1 year [146]. In about 75% of patients symptomatic improvement is immediate, but ERCP-related



(a) (b)

Figure 121.13 (a) Chronic pancreatitis with stricture in the head (straight arrow) and spontaneous leak in the tail (curved arrow). **(b)** Stent placement to treat tail leak.

pancreatitis and symptomatic stent occlusion are common [147,148]. Management of pancreatic duct stones in patients with symptomatic chronic pancreatitis is a challenging issue to the endoscopist. Stone extraction is technically feasible if the stones are small, few in number, located in the head of the pancreas, and not impacted [146]. A pancreatic sphincterotomy is often required and the stones are removed with a basket or balloon. Stones located in the upstream duct proximal to a stricture require stricture dilation before extraction. The use of endoscopic balloon dilation of the pancreatic sphincter before stone extraction in patients with chronic pancreatitis has been shown to be safe and effective [149]. Pancreatoscopy and electrohydraulic lithotripsy of pancreatic duct stones has been advocated as an adjunct option to conventional methods and extracorporeal shock wave lithotripsy in the treatment of refractory stones [150]. In a study of six patients with pancreatic duct stones, complete or partial stone clearance was successful in five patients, who experienced complete relief of abdominal pain for at least 6 months following the procedure [150]. No complications were reported.

In patients with recurrent abdominal pain and pancreatic ductal obstruction, the mainstay of therapy is ductal decompression to decrease the pancreatic duct hypertension and maintain outflow of pancreatic secretions. In a multicenter study of 1000 patients with painful chronic pancreatitis and pancreatic ductal obstruction secondary to strictures or stones treated endoscopically and followed up for 2–12 years, relief of pain was seen in 65% and surgical intervention was performed in 24% [151]. A prospective randomized trial of 72 patients with pancreatic ductal obstruction and pain comparing surgery (resection, drainage) and endoscopic therapy (sphincterotomy and stenting and/or stone removal) found, at the 5-year follow-up, complete absence of pain to be more frequent after surgery (37% vs 14%, respectively), with the rate of partial relief being similar (49% vs 51%, respectively) [152]. In a study of 22 patients with pain and a dilated pancreatic duct who underwent endoscopic therapy, pain disappeared and analgesics could be discontinued in all patients immediately after endotherapy. Six patients were pain-free after a mean period of 5.5 years. Four patients underwent surgery for frequent pain relapses after a mean period of 2.5 years. Six patients were lost to follow-up [153].

Pancreatic stent placement has been shown to be effective in reducing pain in two small series of patients with malignant pancreatic duct strictures [154,155].

Pancreatic duct disruption and fluid collection

Pancreatic duct disruption and subsequent fluid collection formation can be the result of acute or chronic pancreatitis. A pseudocyst is a collection of amylase-rich pancreatic juice enclosed by a wall of nonepithelialized, fibrous, or granulation tissue [156]. Symptomatic pseudocysts may be drained percutaneously (radiologically), surgically, or endoscopically [157,158]. Endoscopic drainage of pancreatic pseudocysts and pancreatic necrosis can be performed by using transpapillary or transmural (transgastric, transduodenal) placement of endoprostheses [159]. The transpapillary approach is utilized for pseudocysts communicating with the main pancreatic duct, with the tip of the stent positioned in the cyst cavity

after a pancreatic sphincterotomy [160]. Fluid collections not communicating with the pancreatic duct are often drained using the transmural approach. The goal is to establish a communication between the cyst cavity and gastric or duodenal lumen for continuous drainage of pancreatic juice. The major prerequisites for such a procedure are a distance between the cyst and gastrointestinal tract of 10 mm or less and an obvious bulge on endoscopy [160] or a window for needle puncture demonstrated on EUS. The steps for the standard procedure are summarized as follows: entry into the cyst cavity, placement of a guidewire within the cyst, dilation of the track between the cyst and gastric or duodenal lumen, and double pigtail stent placement (Fig. 121.14).

Endoscopic transmural drainage of pancreatic pseudocysts was first described more than 20 years ago [161,162]. There are a variety of entry methods into the pseudocyst cavity [163–166]. Transmural entry is obtained by entering the collection at the point of maximal endoscopically visible extrinsic compression, by using a modified papillotome, dedicated cystotome, or needle-knife with or without electrocautery, which in turn may be performed at the site of prelocalization with a sclerotherapy needle [167,168]. Other endoscopists have described both localization and entry into the collection by using a large-caliber needle without electrocautery using the Seldinger technique [166].

The use of EUS before the procedure or EUS-guided drainage has gained popularity and importance. EUS can be used before considering drainage of a pancreatic fluid collection for four reasons. First, in a patient with a pancreatic collection following a documented episode of pancreatitis, EUS allows assessment of the collection for the presence of significant solid debris, which may alter the management strategy. Second, if the endoscopist is uncertain whether the collection in question represents a true pseudocyst or other noninflammatory cystic lesion, EUS allows one to obtain a definitive diagnosis by analyzing both the ultrasonographic features and cyst contents aspirated during EUS [169]. Third, EUS can detect the presence of varices between the gastric and cyst wall and, finally, EUS can mark a site for needle puncture. Once the decision has been made to proceed with endoscopic drainage, EUS may be used to guide transmural drainage. It has been shown that endosonographic imaging of pancreatic pseudocysts before drainage provides important information, such as the intervening vessels or distance between the cyst and gut wall, and may change management in a subset of patients [170]. Although there is no definite evidence that transgastric drainage is superior to transduodenal drainage, the long-term patency of the transduodenal drainage track may reduce the recurrence rate of pancreatic pseudocysts [171].

To explore the practice of pseudocyst drainage among different endoscopists, a web-based survey was distributed by the author to endoscopists who are members of the American Society for Gastrointestinal Endoscopy (ASGE) and who

practice in the United States and abroad [172]. Of the 3054 endoscopists to whom the survey was sent, 266 (8.7%) replied; 198 performed pseudocyst drainage (103 [52%] from the United States and 95 [48%] international members). The median of the total number of drainages per physician was 15 (range 1–364). The transgastric route was the most commonly used drainage route (65%). Transmural entry was performed using a needle-knife in 53% of transmural drainages that were not EUS guided. The number of stents placed ranged from one to five and these remained in place for 2–30 weeks. CT scan was used before drainage by 95% of all respondents. EUS imaging was used before drainage by 72 of 103 (70%) US endoscopists compared with 56 of 95 (59%) international endoscopists ($P = 0.1$). EUS-guided drainage was used by 56% of the US endoscopists compared with 43% of the international endoscopists ($P = 0.06$).

Pancreas divisum

Pancreas divisum, the failure of fusion of the dorsal and ventral pancreatic ductal systems during embryogenesis, is the most common variant of pancreatic ductal anatomy and occurs in about 10% of individuals (Fig. 121.15) [173]. The relationship between pancreas divisum and pancreatitis remains controversial. In a retrospective review of ERCPs carried out in 6850 patients, pancreas divisum was found in 0.5% [174]. Acute pancreatitis was associated with 17.1% of those with pancreas divisum and chronic pancreatitis with 28.6%.

Endoscopic therapy of pancreas divisum in patients with recurrent pancreatitis and abdominal pain aims to decompress the dorsal pancreatic duct by stent insertion and minor papillotomy. In a prospective trial of patients with pancreas divisum and recurrent pancreatitis randomized to dorsal pancreatic duct stent placement ($n = 10$) or control ($n = 9$) and followed for a mean of 28.6 months and 31.5 months, respectively, statistically significant fewer hospitalizations and emergency room visits were seen in the stented group [175]. Lehman et al. [176] evaluated the outcome of minor papillotomy in 52 patients with pancreas divisum and acute recurrent pancreatitis, chronic pancreatitis, and chronic pain. The mean duration of symptoms was 5.1 years before endoscopic therapy. A short stent was placed in the dorsal duct and a sphincterotomy was performed using a needle-knife over the stent. The stent was removed after 2 weeks and patients were followed for a mean of 1.7 years. Patients with acute recurrent pancreatitis had a significant reduction in the mean symptom score and number of hospital days per month compared with the group of patients with chronic pain and chronic pancreatitis. In addition, the group of patients with acute recurrent pancreatitis had significant improvement postpapillotomy compared with those with chronic pancreatitis (76.5% vs 27.3%, $P = 0.01$) or chronic pain (76.5% vs 26.1%, $P = 0.002$). Stent-induced ductal changes were seen in 15% of patients. The authors of the study concluded that minor papillotomy should be considered for the group of patients with pancreas divisum and acute recurrent pancreatitis. A retrospective study of 53 patients with pancreas divisum treated with endoscopic minor papillotomy and followed for a median of 29 months reported an overall long-term improvement in 32.1%, more favorable for the group of patients with recurrent pancreatitis [177]. Injection of botulinum toxin into the minor papilla of five patients with pancreas divisum and idiopathic recurrent pancreatitis

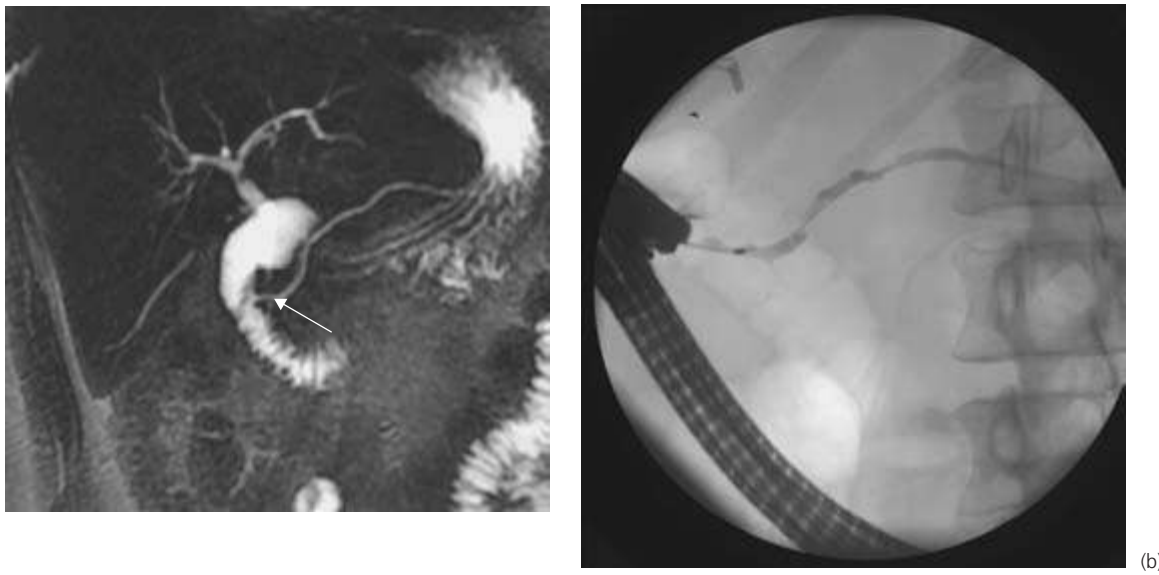

Figure 121.15 **(a)** Magnetic resonance cholangiopancreatography (MRCP) showing the dorsal pancreatic duct crossing the bile duct (arrow) characteristic of pancreas divisum. **(b)** Endoscopic retrograde cholangiopancreatography (ERCP) in pancreas divisum with contrast injected via the minor papilla and the guidewire in the dorsal pancreatic duct.

was found to be technically feasible and safe and to offer short-term relief of symptoms [178].

Autoimmune pancreatitis

With the report of a case of chronic inflammatory sclerosis of the pancreas with a possible underlying autoimmune mechanism in 1961 by Sarles et al. [179], awareness was brought to this relatively new entity, and the concept of "autoimmune pancreatitis" (AIP) was proposed by Yoshida et al. [180] in 1995. The accepted terminology for autoimmune pancreatitis is lymphoplasmacytic sclerosing pancreatitis, although the former designation is more in common usage.

The epidemiology of AIP is not well understood but a prevalence of 5% has been reported among patients with chronic pancreatitis [181]. The disease is more common in males with a mean age of incidence of 58 years. The coexistence and association of AIP with other autoimmune diseases such as primary sclerosing cholangitis, Sjogren syndrome, and diabetes mellitus have been reported [182–185]. Diagnostic criteria have been proposed by the Japan Pancreas Society [186], including: (1) pancreatic imaging studies show diffuse narrowing of the main pancreatic duct with irregular walls and diffuse enlargement of the pancreas; (2) laboratory data demonstrate abnormally elevated levels of serum gamma-globulin and/or IgG, or the presence of autoantibodies; and (3) histopathological examination of the pancreas shows fibrotic changes with lymphocyte and plasma cell infiltration. For diagnosis of AIP, criterion 1 must be present along with 2 and/or 3 (Fig. 121.16).

Several imaging modalities are utilized to assist in the diagnosis of AIP. A retrospective study of 29 patients (25 males, mean age 57.1 years) with a histopathological diagnosis of AIP reviewed findings on different imaging techniques [187]. CT scan showed focal and diffuse pancreatic enlargement. Similar findings were seen on magnetic resonance imaging (MRI), along with a rim-like enhancement in one patient. On MRCP, pancreatic duct strictures were seen in two patients and a sclerosing cholangitis-like appearance was seen in one patient. EUS demonstrated diffuse enlargement of the pancreas ($n = 13$) and a mass in the head region ($n = 6$). ERCP showed a distal common bile duct stricture ($n = 12$), irregular narrowing of intrahepatic ducts ($n = 6$), diffuse and irregular narrowing of the pancreatic duct ($n = 9$), and focal stricture in the proximal duct ($n = 6$). Follow-up CT scan performed within 6 months of steroid therapy (40 mg/day of prednisolone for 4–6 weeks) showed resolution of the common bile duct stricture and CT abnormalities in three patients. ERCP showed similar findings in three patients. One patient developed a proximal pancreatic duct stricture after 12 months and another had diffuse progression of pancreatic duct strictures within 2 months.

Multiple bile duct strictures with morphological features similar to those seen in primary sclerosing cholangitis (PSC) have been associated with AIP. This entity of atypical PSC or sclerosing pancreaticocholangitis has been shown to respond dramatically to steroids [188–192]. The cholangiographic appearance of the bile duct strictures has been proposed to allow differentiation between strictures of PSC (band-like, beaded or pruned appearance, diverticulum-like) and those strictures associated with AIP (segmental, long with prestenotic dilations, and distal common bile duct strictures) [193].

Intraductal papillary mucinous neoplasm

Intraductal papillary mucinous neoplasm or IPMN is a cystic neoplasm of the pancreas that involves the main pancreatic duct, side branches or both. It is characterized by intraductal growth of mucin-producing epithelium, segmental or diffuse ductal dilation, and gaping or fish-mouth papilla from which large amounts of mucin flow. Around 75% of IPMN arise from the main pancreatic duct in the head of the pancreas whereas the branch duct type arise from the uncinate process (most common) or tail of the pancreas [194]. The true incidence of IPMN is not known but it was found in 19% of pancreatic neoplasms in one surgical series [195]. IPMN occurs more commonly in elderly men who often present with recurrent pancreatitis. Jaundice and weight loss can be the presenting symptom in cases with malignant transformation.

A number of imaging modalities are used in clinical practice to diagnose IPMN including CT, EUS, MRI, and ERCP. A patulous and gaping papilla (major, minor) with excretion of copious amounts of mucin is the hallmark for IPMN [196,197] and is seen on endoscopic views during ERCP (Fig. 121.17). A pancreatogram is remarkable for an ecstatic and dilated pancreatic duct and intralumenal filling defects secondary to mucin or mural nodules [198]. During ERCP, pancreatic juice can be aspirated for cytology and transpapillary brushings and biopsies can be obtained from suspicious lesions seen on pancreatograms. In one study, pancreatic juice cytology had a sensitivity of 40% for malignant IPMN and it was more useful in cases with main duct disease with mucin hypersecretion and mural nodules [199]. In another study, pancreatic juice cytology had a higher sensitivity for IPMN when collected by peroral pancreatoscopy than with a catheter (62.2% and 38.2% respectively) [200].

Pancreatoscopy involves the use of an ultrathin endoscope (pancreatoscope, baby scope) that is introduced through the working channel of a duodenoscope (mother scope) and advanced into the pancreatic duct through the major papilla. The ductal epithelium can be examined and directed biopsies of suspicious mural nodules or masses can be performed. Pancreatoscopy has been increasingly used as an adjunct to other imaging modalities for diagnosis and determining the extent of IPMN. In one series of 30 patients with IPMN, the diagnosis after surgery and histological confirmation was adenocarcinoma ($n = 6$), adenoma ($n = 20$), and hyperplasia ($n = 4$) [201]. ERCP findings were enlarged papilla (63%), dilated main pancreatic duct (87%), and cystic lesion (73%). On EUS and intraductal ultrasonography (IDUS), four lesions were greater than 10 mm and all had adenocarcinoma. None

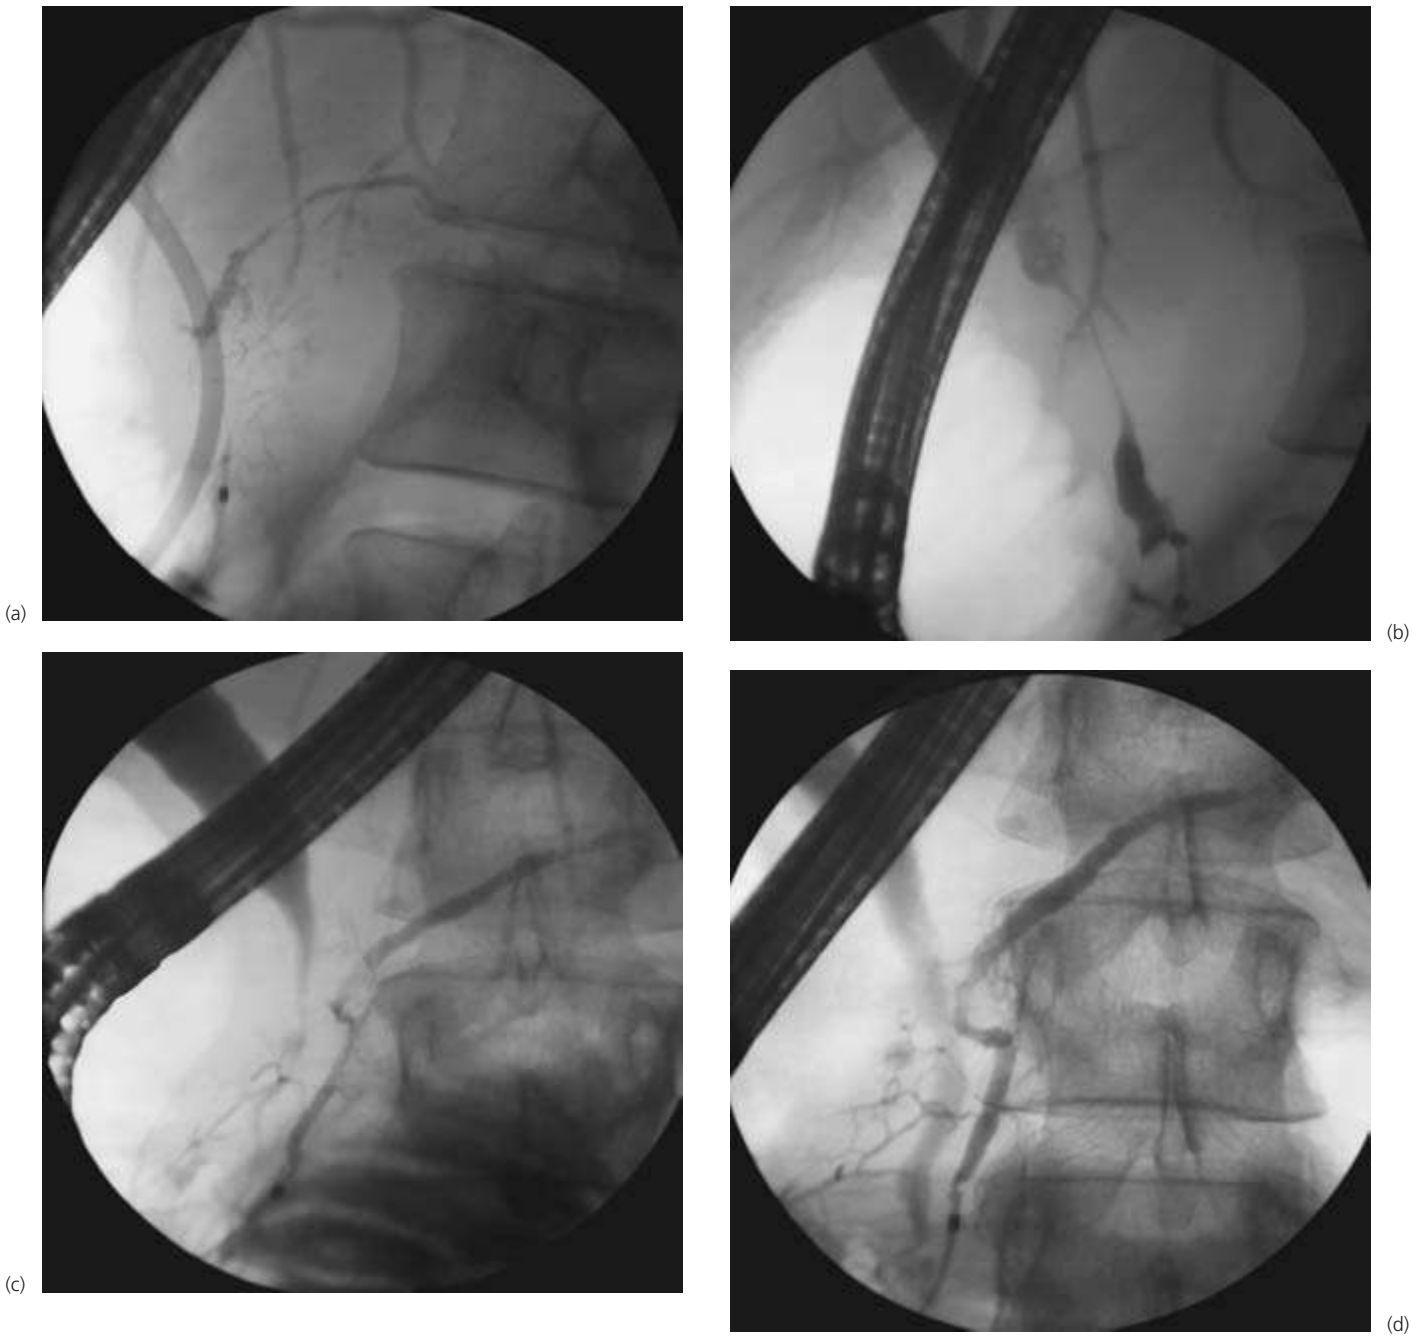

Figure 121.16 (a) A 36-year-old with jaundice and recurrent pancreatitis. The pancreatogram shows an irregular, nondilated pancreatic duct with multifocal stricturing consistent with autoimmune pancreatitis. **(b)** The same patient with a high-grade common bile duct stricture simulating malignancy. **(c)** Improvement in common bile duct stricture and pancreatogram after 1 month of steroid therapy. **(d)** Marked improvement on endoscopic retrograde cholangiopancreatography (ERCP) after 2 months of steroids.

of the lesions of less than 3 mm had cancer. Peroral pancreatoscopy was performed in 26 patients and papillary tumor was found in 100% of the cases of carcinoma and 13% of the cases of adenoma. Redness and proliferation of blood vessels were seen in 83% of carcinomas, 31% of adenomas, and not at all in hyperplasia. Fish egg-like appearance was noted in 31% and 25% of the cases of adenoma and hyperplasia respectively. The sensitivity for detecting lesions greater than 3 mm compared with histology was 67% (92% by EUS and 100% by IDUS). Biopsies through the pancreatoscope and pancreatic juice cytology were positive in 50% of adenocarcinomas. The results of this study suggest that pancreatoscopy is an adjunct to other diagnostic modalities for the diagnosis of IPMN. Therapy remains operative in good surgical candidates.

A ENDOSCOPIC

122 Gastrointestinal dilation and stent placement

James D. Lord, Richard A. Kozarek

Dilation, 2958
Stent placement, 2963
Future applications, 2970

The primary goal of treatment of any stenosis is lumenal enlargement and amelioration of obstructive symptoms. Such symptoms depend on the stricture etiology and site and may include dysphagia, nausea and vomiting, abdominal pain and obstipation, or frank bowel obstruction. This chapter compares the various technologies available for the treatment of stenoses with regard to ease and site of application, patient tolerance, cost–benefit ratio, and available safety and efficacy data.

Historically, the dilation of gastrointestinal strictures was limited to accessible anatomical areas, primarily the esophagus or anorectum. With the advent of endoscopically or radiographically placed polyethylene balloons, a variety of gastric, small bowel and colonic strictures also became amenable to dilation. Likewise, prosthetic stent placement was initially limited to the esophagus and subsequently expanded into the pancreaticobiliary tree. However, expandable metallic stent technology has allowed treatment of previously inaccessible and more central (e.g., gastric, duodenal, colorectal) stenoses.

Whereas all the current dilating systems achieve efficacy by either stricture stretch or fracture, data are sparse regarding the specific mechanism of action by which each individual dilating system works. The few existing small prospective studies comparing the efficacy and side effects of various dilating systems or techniques has failed to demonstrate consistent or significant differences in outcomes. Similarly, the few available randomized studies comparing different expandable prostheses in the esophagus have shown little difference in efficacy or safety between different stent brands. However, technological improvements incorporated into some prostheses do appear to reduce the risk of certain complications, such as stent migration or overgrowth, or gastroesophageal reflux. Data regarding central stent placement has been more limited, but existing randomized trials agree that prostheses compare favorably with surgery for malignant colorectal or gastroduodenal obstructions.

Dilation

Theoretical considerations

The basic goals of stricture dilation include safe and effective lumenal enlargement plus the prevention of restenosis [1]. Efforts to achieve the latter goal may include proton pump inhibitors after esophageal bougienage for a reflux-induced stricture [2], placement of a prosthesis after dilation of an esophageal malignancy, or elective surgical resection, plasty, or bypass of a dilated area after dilation or stent placement for an obstructing rectosigmoid malignancy.

Although the exact mechanisms by which dilation results in lumenal enlargement remain uncertain, circumferential stretch and stricture split are two likely possibilities. The former presupposes considerable elasticity in circumferential fibrous tissue, and the latter an inherent rigidity in which dilation results from one or several longitudinal tears. It is unlikely that a pylorus of 3 mm diameter can be dilated to 10 or 15 mm without significant laceration of scirrhous tissue and, potentially, of muscle. Indeed, gross longitudinal tears and histological disruption of collagen and circular muscle have been described after esophageal bougienage for fibrous stenoses and achalasia [3]. Most perforations associated with dilation, in turn, appear to be an extension of these tears.

Among the earliest dilation techniques, bougienage was first used by Fabricius d'Acquapendente, who used a wax dilator for a food impaction [4]. The term *bougienage* is derived from the Algerian town of Boujiyah, the medieval capital of the wax candle trade. Cork and woven silk dilators have also been used, the latter since at least the 16th century, when Thomas Willis used a cork-tipped whalebone to treat a probable achalasia patient.

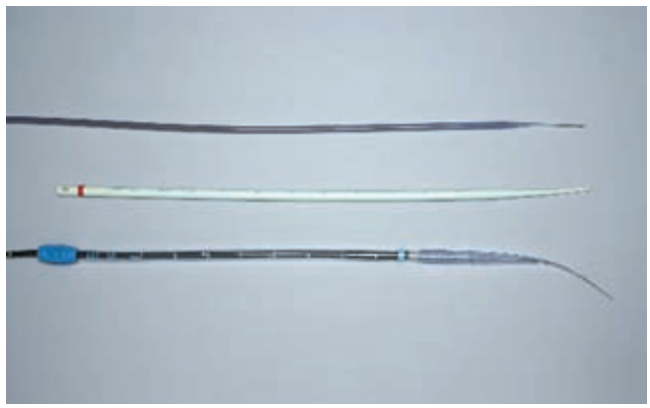

Figure 122.1 Dilating systems: Maloney **(top)**, Savary–Gilliard **(middle)**, and Optical **(bottom)** dilators. The latter two are wire-guided, with the Optical dilator also admitting an endoscope for direct visualization.

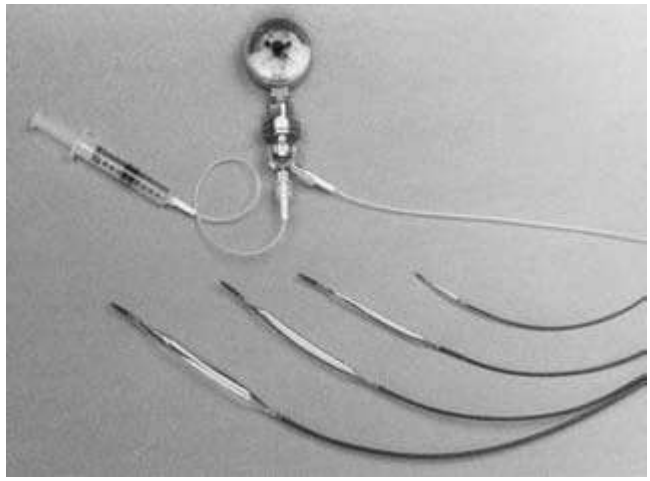

Figure 122.2 Polyethylene balloon dilating kit includes mercury manometer and injection syringe. Balloons are passed over an endoscopically or radiographically placed guidewire.

Table 122.1 Dilators for gastrointestinal stenoses

Mercury bougies
Blunt-tip (Hurst)
Tapered-tip (Maloney)
Guidewire directed
Metal olives (Jackson–Plummer, Eder–Puestow)
Hollow-core polyvinyl (Savary–Gilliard, American)
Neoplex stepped-diameter (Celestin)
Spindle-shaped (Keymed Advanced dilator)
Polyethylene balloons
Through the scope (TTS)
Guidewire facilitated
Controlled radial expansion (CRE)
Latex balloons
Brown–McCardy
Mosher
Miscellaneous
Woven silk (Jackson, Phillips)
Graded, plastic oversheath
Tapered-tip endoscope
Balloon or tape affixed to endoscope shaft
Electronic/mechanical (Starck variant)
Tapered transparent oversheath (Optical dilator)

Dilating modalities can be divided into mercury bougies, guidewire-directed dilators (Fig. 122.1), polyethylene balloons (Fig. 122.2), and miscellaneous types (Table 122.1) [1]. Mercury-filled dilators, ranging in size from 3 to 20 mm (10–60Fr), can be subdivided into the original, blunt-tipped Hurst bougies, and tapered-tip variants called Maloney bougies. Originally passed without fluoroscopic control, these dilators are now used infrequently by many practitioners.

Historically, guidewire-directed dilators have included Jackson–Plummer bougies and Eder–Puestow dilators. These include a triple olive variant, in which multiple metal olives of increasing diameter are placed on the same dilating shaft [5]. Five additional wire-guided dilating systems have subsequently been marketed: the KeyMed Advanced dilator (KeyMed Ltd, Southend-on-Sea, UK), consisting of three spindle-shaped silicone bougies on stainless steel shafts; the stepped neoplex Celestin dilator; two types of hollow-core polyvinyl systems, the Savary-Gilliard and the American; and the transparent Optical dilator. The Celestin dilating system consists of two tapered dilators that reach a maximum diameter of 12 and 18 mm respectively. The Savary-Gilliard system (Wilson-Cook Medical, Winston-Salem, NC) consists of bougies ranging in size from 5 to 18 mm (15–54Fr). The American Dilating System (CR Bard Inc., Billerica, MA) ranges in size from 7 to 20 mm (21–60Fr). In contrast to the barium-impregnated American dilators, Savary-Gilliard dilators are longer and have a more gradually tapered tip. The fifth type of tapered dilator, called the Optical dilator (Inscope, Cincinnati, OH), is a hybrid device that has only recently been marketed. Actually three separate dilators with variable diameters ranging from 14 to 20 mm, these hollow devices fit over an endoscope to allow direct visualization at the time of bougienage, and thus theoretically improve procedural safety.

After wire-guided bougies, the second major advance in dilation technology was the development of polyethylene balloons for use in the gastrointestinal tract [6,7]. Ranging in diameter from 4 to 40 mm [6], dilating balloons are fixed on 5–7Fr catheter shafts that range between 100 and 200 cm in length. They can be passed over an endoscopically or radiographically placed guidewire, or directly through the scope (TTS) to allow dilation of previously inaccessible strictures in the stomach, small bowel, and colon. A full dilation set includes balloons of variable length and diameter, 5-mL to 30-mL syringes, guidewires, and a manometer to delineate balloon pressure during inflation. A dilating gun to maintain pressure

and stopcocks to ensure a constant pressure during inflation are optional. More recent advances in balloon technology have included the development of low-profile or high-compliance balloons. The latter can withstand a dilating pressure threefold to fourfold higher than previously marketed balloons to potentially improve results in recalcitrant strictures, although balloon compliance has not been found to affect dilation success in achalasia [8,9]. A newer development is the controlled radial expansion (CRE) balloon (Boston Scientific, Natick, MA) [10]. These balloons can be passed over a guidewire and inflated with variable pressure to predictably increase balloon diameter. A single CRE balloon, depending on the pressure used to inflate it, may increase in diameter from 6–8, to 8–10, to 10–12, to 15–18, or to 18–20 mm.

Technical applications

In general, radiologically or endoscopically directed dilation should be safer and more effective than blind dilation [7,11], particularly for sharply angulated, extremely tight, or proximal esophageal stenoses, as well as more central stenoses in the stomach, duodenum and colon. These general principles must be balanced against the availability of fluoroscopy, the added cost of endoscopy or fluoroscopy, and the physician's previous experience with a particular dilating modality. Endoscopically facilitated guidewire placement and subsequent bougienage of the esophagus need not always require fluoroscopic control if copious guidewire has been placed into the stomach or a marked guidewire is used and attention is given to ensure that guidewire displacement does not occur with endoscope withdrawal [1].

Of importance technically is the degree of lumenal enlargement that can be undertaken safely in a single dilating session. There remains a maxim in esophageal bougienage that one should increase a lumenal stenosis by no more than 2 mm (6Fr) in a single dilation session [1]. Although it is based on common sense and an attempt to avoid such complications as bleeding and perforation, this adage does not necessarily hold true for most rings or webs and some pliable reflux-induced strictures. The degree of lumenal enlargement should be contingent not only on the nature of the stricture itself (i.e., membranous or fibrotic) but also on the degree of associated lumenal ulceration and the risks and benefits of alternative treatment modalities. These decisions cannot be made by a review of the scant existing literature discussing side effects of dilation, but require a great deal of common sense on the part of the physician [1,11,12].

Esophageal strictures

Most patients who present with dysphagia have had previous esophagoscopy, although a few with lower esophageal rings may have had barium studies alone. With rings, webs, and mild reflux stenosis, mercury bougienage after a 6-h fast and pharyngeal anesthesia can often be done using a single 16–18 mm (48–54Fr) Maloney dilator [13]. Such dilators can be passed in the upright or lateral decubitus position. Although ideally done under fluoroscopic control to avoid kinking or retroflexion, many esophageal dilations can be performed safely without these capabilities.

Long, angulated, or eccentric esophageal strictures, as well as severe (< 7 mm) stenoses, are best handled with a guidewire dilating system. Patients require an initial endoscopy to define the stricture's cause and characteristics, for example length, diameter, pliability, eccentricity, and associated pseudodiverticula. Because a biopsy of the entire length of the stricture can be performed after dilation, it is sometimes best to delay tissue sampling until immediately after the dilation. Polyvinyl dilators, which have supplanted Eder–Puestow metal olives in most centers, always requires guidewire placement [1,11,14]. This is usually done in conjunction with initial endoscopy, at which time a fluoroscopically monitored wire with a spring tip can be passed through the stricture and fed freely into the stomach. Alternatively, the wire can sometimes be passed radiographically without endoscopy. After baseline endoscopy and stricture sizing, a dilator approximately the size of the stricture is passed, making sure the guidewire is fixed and the patient's neck is flexed forward. This is followed by one or two additional dilators, for an increment of up to 3 or 4 mm (10–12Fr), contingent on the stricture, before repeat endoscopy and stricture biopsy. Because of their gradual taper, polyvinyl dilators can pass through most stenoses with relative ease. The hesitation felt with these systems is related more to dilator friction over the guidewire than to the stricture itself.

Moderate stenoses (7–13 mm) can be dilated using either mercury bougies under fluoroscopic control or wire-guided polyvinyl dilators. The latter systems can be used without radiographic monitoring in some, although it is imperative that the guidewire is advanced far into the stomach and not inadvertently withdrawn at the time of endoscope removal. This is best done by feeding a marked guidewire forward in conjunction with endoscope or bougie withdrawal and having an assistant fix the wire at the level of the patient's mouth [1]. In addition, polyethylene balloons have been used to dilate moderate esophageal strictures [15]. The claimed advantages of balloon dilators over other systems have included ease of passage, dilation of the stricture alone, and radial as opposed to vector force applied to a stenotic wall [1], suggesting that such balloons should be safer and more effective. However, randomized trials comparing balloons to bougienage in benign esophageal strictures have demonstrated little consistent advantage to warrant the higher cost of balloon dilation in most cases [16–20]. If fluoroscopy is used to ensure waist dilation, total costs using this technology in our institution are threefold higher than dilation with polyvinyl dilators and eightfold higher than mercury bougienage [21]. Given this and the fact that such balloons are marketed as one-time use devices, balloon technology is better limited to areas of the gut not accessible to other types

of dilators. One notable exception is achalasia, where forceful disruption of the lower esophageal sphincter is usually performed with a balloon to afford a larger diameter and avoid blindly passing a dilator through the redundant and often tortuous esophagus associated with this condition (see Chapter 31). The technique of balloon dilation is described in the next section.

Nonesophageal strictures

Most nonesophageal strictures require balloon dilation, although stenotic gastric stapling orifices and anastomotic strictures of the rectosigmoid can be enlarged with polyvinyl dilators or even electrocautery [22–24]. Although both transendoscopic and wire-guided balloons have shown comparable safety and efficacy for benign colonic anastomotic strictures, wire guidance allows the use of larger balloons, which appears to reduce the need for repeat dilations in this setting [25]. The use of TTS or CRE balloons provides certain advantages, including direct stricture visualization, improved placement control, and immediate evaluation of the dilated stenosis [6]. TTS or CRE dilators require endoscopic estimation of stricture size for selection of a balloon that is 1–2 mm (3–6Fr) larger. Both balloon and dilator shaft should be coated with silicone, and negative pressure should be applied to the balloon using a 10- or 20-mL syringe. These measures, as well as avoiding excessive angulation of the endoscopic tip, allow dilator passage until all or part of the balloon is visualized. In the case of pyloric stenosis dilation, the balloon should be centered in the stenotic pylorus under a combination of endoscopic and fluoroscopic control. The latter also helps prevent damage of the bulb apex or C loop wall related to excessive pressure of the balloon tip or extreme balloon angulation.

Although air can be used for inflation, 10%–25% contrast solution allows better visualization fluoroscopically and a more uniform balloon dilation. Placement of the endoscope tip against a transparent balloon during inflation additionally provides a transendoscopic view of the stricture from within the balloon throughout dilation. Obliteration of the balloon waist is required with pressures up to 1212 kPa (12 atmospheres). Although larger balloons may increase the risk of perforation [26]. Balloon compliance has not been found to affect dilation safety or efficacy in achalasia [8,9]. Similarly, randomized trials of balloon dilation in achalasia have not found the duration of balloon inflation or number of inflations in a session to significantly impact procedural efficacy or safety [27,28]. In the case of most strictures, 30 s of dilation, repeated a second or third time after repositioning of the balloon, usually produces good results. After dilation has occurred, the balloon must be completely evacuated and the endoscope tip must be straightened to allow balloon retrieval. Additional, larger dilating balloons can then be used, although the degree of lumenal enlargement to be attempted in a single session remains a matter of common sense and is contingent on size of the initial stenosis, presence and degree of active ulceration, and patient discomfort with initial dilation. Using pyloric dilation again as an example, the ultimate goal is to dilate to 15–18 mm and follow up with complete endoscopic inspection of the pylorus and duodenum. This goal sometimes requires two or three dilating sessions separated by an interval of several days if the obstruction is acute, or several weeks if it is chronic.

Indications and contraindications

Indications for dilation are contingent on the anatomical area involved (Table 122.2). In the esophagus, symptoms are most often dysphagia and food impaction, although atypical chest pain, aspiration, and odynophagia may also be seen [19,29–31]. Indications for pyloric dilation are usually recurrent nausea and vomiting, weight loss, abdominal pain, and severe reflux [32,33]. Small bowel and distal colonic stenoses may require dilation for intractable obstipation, progressive diminution in stool size, pain, and recurrent bowel obstruction [22–24,34]. The causes of the above and of a variety of miscellaneous stenoses are listed in Table 122.2.

The only absolute contraindication to esophageal dilation mentioned in guidelines for esophageal dilation published in 1998 by the American Society for Gastrointestinal Endoscopy (ASGE) was acute or incompletely healed esophageal perforation [11]. Common sense dictates that contraindications to dilation also include a lack of informed consent, an acute abdomen, or a deeply ulcerated stenosis for which the risks of dilation outweigh the benefits. Indeed, relative contraindications listed by the ASGE include bleeding disorders, cardiopulmonary instability, recent esophageal perforation or

IBD, inflammatory bowel disease; NSAID, nonsteroidal antiinflammatory drug.

surgery, and a large aortic aneurysm, but specifically excluded concomitant radiation therapy or forceps biopsy. For extraesophageal dilation, similar contraindications presumably apply, but there may also be lesion-specific contraindications, such as colonic stenosis associated with acute diverticulitis.

Risks and alternatives

Risks of gastrointestinal dilation include problems associated with all endoscopic procedures. The risks associated with the addition of dilation have usually been defined as an increased incidence of bleeding, perforation [35], and bacteremia [36,37], although the incidence of these complications has not been well defined for gastroduodenal and colorectal dilations. Most data on gastrointestinal dilation derive from esophageal bougienage with a combination of Puestow and mercury dilating systems in over 850 patients with benign esophageal strictures compiled from various series [7,13,38]. Reported complications in these patients included 16 perforations, five major bleeding episodes, two aspirations, and one death. This compares with perforation rates of 0.4% for mercury dilators and 0.6% for metal olives reported in an ASGE survey [7]. Such perforations are usually in the cervical esophagus and relate to improper dilator introduction or in the thoracoabdominal esophagus just proximal to the stenosis related to dilator or guidewire kinking. Less frequently, the stricture itself splits, as may be seen with achalasia (1%–5% perforation rate) [1]. Overall, the reported risk of perforation with esophageal dilation ranges from 0.1% to 0.4%, with the greatest risk associated with longer, narrower, angulated or irregular strictures [39]. While scant bleeding is not uncommon after esophageal dilation, significant hemorrhage was identified in less than 0.5% of dilations in 1976 [40] and is presumably even less common with modern techniques.

However, bacteremia is quite common, occurring after 22.8% of esophageal dilations, and more frequently than with nearly any other endoscopic procedure [41]. While this probably represents no significant infectious risk in the vast majority of patients, there is sufficient concern about endocarditis in patients with cardiovascular structural abnormalities to support the use of prophylactic antibiotics in this population. Specifically, the American Heart Association (AHA) and ASGE recommend that patients with a history of prosthetic cardiac valves, prior endocarditis, complex cyanotic congenital heart disease, a surgical systemic–pulmonary shunt, or a recent (< 12 months old) vascular graft should receive ampicillin or, if penicillin allergic, clindamycin, vancomycin, or a macrolide antibiotic 30 min prior to dilation [42,43]. The AHA also recommends gentamicin coadministration, although this may reasonably be reserved for colonic or gastroduodenal dilations. In patients with other congenital heart disease, valvular dysfunction, or hypertrophic cardiomyopathy, antibiotic prophylaxis is optional.

Long-term pharmacological implications of dilation must also be considered in any discussion of risks. Reflux-related esophageal strictures and many pyloric stenoses require long-term proton pump inhibition and possibly use of a prokinetic agent. Dilation of a stenosis from Crohn's disease usually requires adjustment of immunosuppressive medications to minimize the inflammatory response and stricture reformation [44].

The benefits and risks associated with lumenal dilation must be considered in relation to alternative treatment modalities, including other endoscopic therapies, surgery, or conservative management. Direct comparisons between dilation and these alternatives are sparse, but include several trials in which biopsy forceps or needle knife-mediated incision of Schatzki rings was at least as safe and effective as dilation [45] and possibly superior [46,47]. Furthermore, use of alternative approaches, such as electrocautery, in conjunction with dilation may enhance the latter's clinical efficacy [48]. Dilation should not be the sole treatment in individuals who require bougienage so frequently that cumulative risk and expense become prohibitive. In this setting, intralesional steroid injection may reduce the frequency with which dilation is required [49,50]. Alternatively, definitive management with surgical resection may be more appropriate.

Efficacy

Esophagus

Although dilation results in immediate symptomatic improvement in the majority of patients with benign esophageal strictures, multiple dilation sessions are often required. Strictures commonly recur, resulting in a return of dysphagia and necessitating repeat dilation. Using sequential bougies over a period of days to months, Puestow and mercury dilating systems have been associated with a 70%–100% improvement in dysphagia in a number of series [7,13,38]. Other studies have reported symptomatic improvement in excess of 90% [21,51,52].

A number of series have assessed balloon dilators for esophageal stenoses. In an early series, 93% of dilations of benign and malignant esophageal strictures in 88 patients were technically successful, with a 3% minor complication rate and 91% symptomatic improvement over a mean of 10 months [53]. Additional series and trials comparing balloon technology to Eder–Puestow or Savary dilators have demonstrated comparable efficacy between these technologies for benign esophageal stenoses [51,53–55]. Similarly, in a randomized prospective trial there was no significant difference between Eder–Puestow and Celestin dilators in long-term symptom relief of 72 patients, although the Celestin system was thought to be quicker and cause less pharyngeal trauma [56].

A number of series have reviewed experiences with hollow-core polyvinyl dilating systems [4,21,52,54,55,57]. Dumon and colleagues claimed efficacy in all 300 patients treated for benign or malignant esophageal stenosis, with only one perforation [57]. Our group successfully dilated 432

patients with 716 courses of dilation therapy; 89% were dilated with polyvinyl dilators and only 8% required fluoroscopic monitoring [21]. Approximately 80% of the dilation sessions were undertaken with a single large dilator or employed incremental dilators of 6 mm or more in a single session. There were no complications directly related to the bougienage. Additional large series have been published with polyvinyl dilators [52], but there have been no published series using the Optical dilator, so claims about improved procedural safety with this device remain to be confirmed.

Stomach

The only large series of gastric dilation are limited to polyethylene balloon dilation, and series with long-term follow-up report conflicting results. Since the initial description of successful hydrostatic dilation in a patient with pyloric stenosis and gastric outlet obstruction [58], several series have been published using this technique. McLean and colleagues radiographically dilated 94 gastrointestinal strictures in 92 patients, with a mean follow-up of 389 days in 80 patients [59]. Of these patients, 33 had various forms of gastric stenosis. Technically, 25 of the 33 were successfully dilated, and 70% were symptom free at 1 year. Perng and colleagues reviewed 42 patients with benign gastric outlet obstruction [32]. At a median follow-up of 2 years, two-thirds of patients had sustained improvement and one-third required surgery. The symptom-free rates at 1, 2, 3, and 4 years were 85%, 78%, 69%, and 69%, respectively, and the independent prognostic factor for failure was need for more than two courses of dilation for symptom relief. Lau and colleagues reviewed 45 patients who had successful gastric outlet obstruction dilation, four of whom had rapid reobstruction and were found to have malignancy [33]. At a median follow-up of 39 months, more than 50% of patients required surgery, 18 for recurrent obstruction, two for interval perforations, and one for bleeding. Nevertheless, a 60%–65% good-to-excellent symptomatic response at 1–2 years has been reported [32,33], and this should be compared with the results of drainage or resective therapy for benign gastric outlet obstruction [29]. A cost analysis comparing pyloric balloon dilation with vagotomy and pyloroplasty at our institution [73] showed balloon dilation to be cost-effective in the short term at one-tenth of the total costs of vagotomy and pyloroplasty. However, long-term acid suppression was not considered.

Small bowel

Because of the problems of access to the small intestine, there are few data regarding dilation of proximal small bowel strictures [62]. However, there are multiple series using balloon technology to dilate ileal or anastomotic ileocolonic strictures in Crohn's disease [44]. Dilation of 27 anastomotic strictures in patients with Crohn's disease led to no complications, and after 7–38 months 18 patients remained free of obstructive symptoms [63]. A prospective study of 55 patients with Crohn's disease with 59 ileocolonic strictures noted 90% technical success with complications in 11% (six perforations) [34]. Complete long-term symptom relief was noted in 34 patients (62%). Corticosteroid injections into inflamed small bowel following anastomotic balloon dilation may decrease restenosis rates further [64–66]. However, results remain anecdotal and data should be placed into the perspective of surgical resection or stricturoplasty.

Colon

Most reported colonic dilations have been used for rectal or anastomotic stenoses [22,23]. Linares and colleagues dilated 33 anorectal strictures in patients with Crohn's disease with a variety of techniques; half experienced short- or long-term symptomatic relief [67]. Pietropaolo and colleagues dilated postoperative strictures in 42 patients, using either balloons or bougies, with a 2.4% failure rate but no morbidity or mortality [68]. A combination of various types of dilators with endoscopic electrosection in 39 patients with benign anastomotic strictures resulted in no complications or symptoms in any patient at a mean follow-up of 25 months [23]. Solt and colleagues performed 133 balloon dilations over 17 years in 57 patients with benign (primarily anastomotic) strictures, with a 30% eventual reoperation rate but no procedural complications [69]. Finally, Virgilio and colleagues used a 30–40 mm achalasia dilator in 18 patients with anastomotic strictures following resection for colorectal cancer [70]. A total of 45 dilating sessions was performed in 17 of the patients. Long-term symptom relief was described in 16 patients (94%) and complications were limited to one episode of bleeding and a punctiform bowel perforation. Remaining unanswered questions include the relative efficacy of balloons as opposed to polyvinyl dilators for rectosigmoid stenoses, and the rapidity with which stenoses at various sites can be safely dilated.

Stent placement

Theoretical considerations

In contrast to dilation, stent placement attempts to reestablish permanent continuity to the lumen of the gastrointestinal tract. The fact that such prostheses are placed primarily in the setting of malignancy suggests that the technology is imperfect: gastrointestinal stents occlude, migrate, erode, and may allow reflux of potentially noxious gastrointestinal contents depending on their location [71]. Symonds is credited with the first prosthesis placement in the esophagus in 1887. Initial stents were fabricated of ivory or boxwood and held in place by a variety of external fixation devices until the development of the inverted funnel by Gootskin in the early 1900s. Since then, a variety of homemade and commercially available esophageal prostheses have been used, the latter usually constructed of latex or silicone molded over

a stainless steel core (Table 122.3 and Fig. 122.3). Inserted surgically or pushed into place using bougies, a small-caliber endoscope, or an expandable metal olive fixation device (Nottingham introducer), the design of these stents and insertion devices precluded placement across central or sharply angulated stenoses. Their application was also primarily limited to esophageal or gastroesophageal malignancies.

Expandable stents have largely supplanted rigid stents in the esophagus and have also made gastroduodenal and colorectal stenoses amenable to prostheses (Table 122.3) [72]. Although they differ in expansile force and delivery systems, all these prostheses are deployed in a compressed state, with subsequent spontaneous or balloon-assisted expansion. Uncovered stents, typically consisting of a cylindrical metal mesh tube, become embedded in the mucosa, which permanently anchors the stent in place but can allow stent occlusion from tumor ingrowth [73]. Alternatively, stents covered with a membrane reduce stent reocclusion, but may increase rates of stent migration [74]. Consequently, a wide variety of stent technologies have arisen, employing flared stent ends, partial coverage, and novel materials to simultaneously minimize both reocclusion and migration. At least three major types of metal stents are currently marketed in the USA, and variations of these stents are marketed around the world (Fig. 122.4).

The Wallstent (Boston Scientific, Natick, MA) was initially introduced as a two-layer stainless steel, double-dog bone prosthesis with an interposed layer of silicone. Uncovered or partially silicon-covered stents have subsequently been marketed that range between 18 and 25 mm in diameter and which are constrained by an 18Fr delivery system. A version of this prosthesis (Flamingo stent, Boston Scientific International) has also been marketed in Europe and has a pronounced taper to prevent distal migration when placed across esophagogastric junction tumors [75]. More recently, an uncovered nitinol mesh version, called the Wallflex stent (Boston Scientific), has been marketed; it is available with

Figure 122.4 Expandable prostheses **(left to right)**: Flamingo and covered Wallstent II, uncovered Wallstent, uncovered Ultraflex, partially covered Ultraflex, covered Z stent with and without Dua antireflux valve, small intestinal submucosa-covered Z stent (prototype device), Esophacoil, and Polyflex stent.

diameters up to 25 mm and requires only a 10Fr delivery system, thus facilitating transendoscopic deployment.

The Gianturco Z stent available in the USA (Wilson-Cook, Inc., Winston-Salem, NC) is a 20-mm diameter urethane-covered stainless steel prosthesis that flares to 22–25 mm at the ends. Ranging from 4 to 14 cm in length, the prosthesis must be back-loaded into a 28Fr compression catheter at time of placement [76]. In contrast, the Z stent marketed in Europe and Asia has a different coating and delivery system and also has small barbs on the shaft to minimize migration. The Songstent (M.I. Tech Co. Ltd, Seoul, Korea), also not available in the USA, resembles the Z stent [77] but includes a variant with a thread attached to the wire frame to facilitate retrieval [78]. Another variant of the Z stent contains an antireflux "windsock" valve (Dua Anti-Reflux Valve, Wilson-Cook) designed to minimize the regurgitation commonly associated with stent placement across the distal esophagus or gastric cardia [79]. The FerX-Ella (Radiologic, UK Medical Ltd, Sheffield, UK) and Choo (M.I. Tech Co. Ltd) stents have also been marketed with antireflux valves. The latter, marketed in Asia and Europe, can also be retrieved by a thread attached to its nitinol frame [80], much like the Songstent.

The Ultraflex prosthesis (Boston Scientific) is a 10 or 15 cm long, 18–25 mm diameter stent also made of weaved nitinol, with or without a covering, which is released by pulling a long suture used to constrain the stent on an insertion shaft. The Memotherm stent (CR Bard Inc., Billerica, MA) is also made of a nitinol weave [81], is uncovered, and is available in a version dedicated to colonic applications [82]. Niti-S stents (TaeWoong Medical, Seoul, Korea) represent a diverse array of additional nitinol mesh stents available outside the USA. Finally, the EsophaCoil (Medtronic Inc., Eden Prairie, MN) is a spiral nitinol coil, constrained on an insertion shaft by three trip wires, which is no longer available in the USA [83].

All the above differ not only in design and delivery system but also in physical characteristics. Although all are more malleable than conventional prostheses, Ultraflex and Wallflex stents can often be used for angulated stenoses. Fully covered Z stents, Song, and Choo stents can, at least in theory, be removed and may ultimately play a role in refractory benign strictures. Wallstents and Ultraflex prostheses imbed deeply into the esophageal wall and may have a role to play in patients with esophageal–airway fistulae without a tumor shelf. Each prosthesis generates a different amount of radial force (EsophaCoil > Wallstent > Z stent ≈ covered Ultraflex stent), which may help define the type of stent chosen for a given application [84].

An advantage of expandable metal prostheses over their conventional counterparts in the esophagus is their ability to be inserted under combined endoscopic and fluoroscopic control. Additionally, because expandable prostheses have a limited need for dilation for placement [72], they may be associated with less risk of bleeding or perforation during insertion. Moreover, their flexibility allows placement beyond acutely angulated malignancies, and their ability to imbed into the esophageal wall should minimize subsequent stent migrations. Their use in central stenoses offers a previously unavailable therapeutic option to patients with recurrent, metastatic, or unresectable obstructing malignancies. Examples include obstructing sigmoid cancer with widespread disease, or advanced pancreatic cancer causing gastric outlet obstruction [85–87].

In addition to the various expandable metal stents described above, a self-expanding plastic stent called the Polyflex stent (Willy Rusch GmbH, Kernen, Germany) [88] has become available. These 16–21 mm diameter, 9–15 cm long polyester mesh stents are fully covered by a silicone membrane. The inert nature of this coating appears to reduce the hyperplastic tissue reaction at the ends of the stent that is commonly seen within weeks to months of metallic stent placement, preventing removal of the latter. Initial studies thus indicate that Polyflex stents can be removed from most patients months after placement with variable ease. As such, their use has been expanded to include the treatment of benign or temporary problems, such as peptic strictures [89–91] or esophageal leaks [92–94]. Unfortunately, the large size (36–42Fr) of the insertion catheter required by these stents precludes transendoscopic placement, and thus restricts their use primarily to esophageal lesions. Additionally, their polyester mesh does not generate as much radial force as metal stents, which may limit their efficacy with tighter or stiffer stenoses, and may contribute to their documented higher rate of migration [88]. The Alimaxx-E stent (Alveolus, Charlotte, NC), available in Europe and marketed in the USA, is a nitinol mesh stent fully embedded in silicone. This prosthesis may overcome some of the limitations of the Polyflex stent while

remaining potentially removable. However, its efficacy and side-effect profile remain to be defined.

Considerable progress has been made toward increasing the safety, efficacy, and applicability of stent technology. What remains ill-defined, however, is the role this technology should play compared with conventional treatments such as surgery or percutaneous endoscopic gastrostomy/jejunostomy (PEG/J) placement. Moreover, where this technology fits into our therapeutic armamentarium of ablative therapies (Nd:YAG laser, bipolar cautery, caustic therapy, argon plasma coagulation, photodynamic therapy, and endoscopically assisted brachytherapy) requires continued evaluation [95].

Technical application

Stent placement requires stricture dilation to a size that admits a conventional prosthesis or the delivery system of an expandable stent [71]. Strictures are commonly dilated to 30–36Fr even with small (18Fr) delivery systems. This precludes stent dislodgement when the delivery system is retrieved through a partially expanded prosthesis and may avoid a need for stent dilation, which can itself result in dislodgement. Perhaps the most important technical aspects of stent placement are accurate placement and adequate measurement of the stenosis with selection of a prosthesis 4–6 cm longer than the neoplasm. While a subset of expandable prostheses can be placed either through or alongside an endoscope without radiographic control [96], most endoscopists use concomitant fluoroscopy, marking the proximal and distal stricture margins with either external markers or injections of contrast material. This allows more precise prosthesis placement and may allow repositioning of the prosthesis prior to full stent deployment.

Esophageal strictures

Esophageal prosthesis placement requires adequate dilation both to allow passage of various delivery devices and to localize and measure the length of the neoplasm [71]. Necessary dilator sizes range from 48 to 51Fr for conventional prostheses and from 24 to 36Fr for expandable prostheses. Preoperative bronchoscopy may be required, particularly for bulky extrinsic neoplasms, as stent placement may be associated with airway compression and acute respiratory distress. Tumor localization can be done by using external radiopaque markers taped to the patient's chest but is more commonly accomplished by injecting water- or lipid-soluble contrast material into the proximal or distal tumor margins [71]. Alternatively, endoscopic placement of radiopaque clips can be used.

Prosthesis placement requires fluoroscopic control, although some of the smaller delivery systems (Ultraflex, single-braid Wallstent) allow simultaneous endoscopic visualization during delivery [71]. Stents should be 4–6 cm longer than the neoplasm, contingent on local anatomy (e.g., esophagogastric junction, cricopharyngeus, contralateral gastric wall; stricture angulation). Conventional prostheses are pushed into place over a guidewire using a variety of devices to stabilize the stent (e.g., small-caliber endoscope, Savary-type dilator, Nottingham expandable olive fixation shaft) and various types of pusher tubes. These devices encounter considerable resistance at the level of the cricopharyngeus and may require neck hyperextension for passage. After conventional stents are pushed into place, the pusher tube and delivery system are retrieved and an immediate repeat endoscopy should be performed to document correct prosthesis position. Expandable prostheses have variable delivery systems (Fig. 122.5) [71]. Polyflex stents, Z stents and Wallstents are deployed by pulling back a compression catheter. Ultraflex stents are constrained by a single long suture that can be pulled off the delivery shaft. Although Z stents essentially retain their preexpansion length after deployment, there is significant foreshortening of both Wallstents and Ultraflex prostheses, making proper placement crucial.

Despite the plethora of prostheses now available, certain practices are followed after placement of all prostheses. The most important is the need for immediate endoscopy

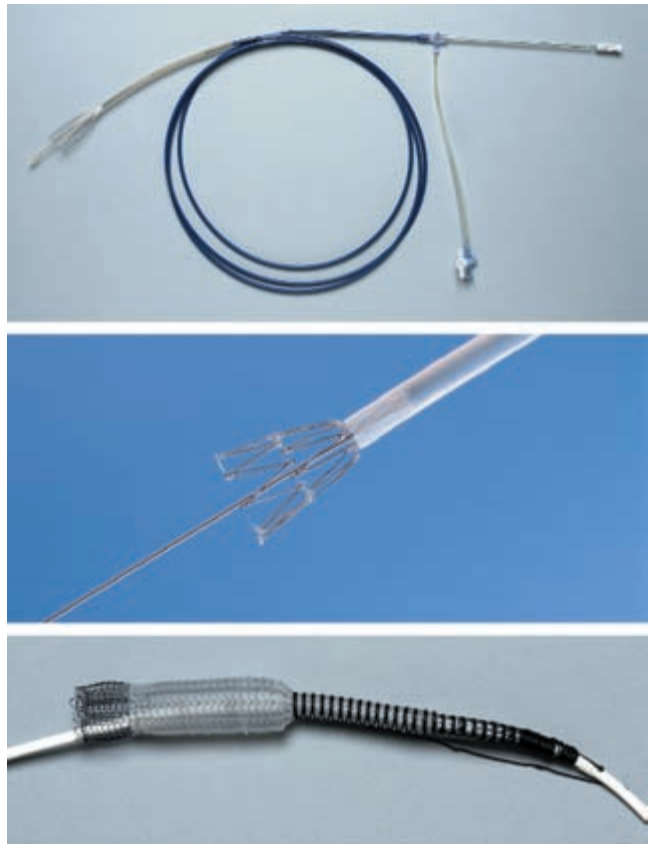

Figure 122.5 Stent deployment devices: Wallstent **(top)** and Z stent **(middle)** are deployed by withdrawing a compression catheter sleeve. Ultraflex stent **(bottom)** is released by uncoiling a suture from the proximal or distal end.

after insertion to assure that the prosthesis has accomplished the treatment goal, e.g., correct location, full expansion, or occlusion of tracheoesophageal fistula. Problems occur when the prosthesis is too long or short, abuts into the cricopharyngeus or contralateral gastric wall, or has inadequate radial force to open a tight neoplastic stricture. The latter may preclude retrieval of the delivery system. Airway compression and immediate migration at the time of placement are additional potential problems. The endoscopist has to be prepared to deal with these problems with balloon dilators, as well as additional expandable and conventional prostheses to correct problems associated with inadequate length, acute angulation, or migration. Excessive stent material extending too far beyond a stricture's margin may cause occlusion or mucosal injury, although it may be trimmed from metallic stents with an argon plasma device [97]. Once expandable stents have fully deployed, the coated Z stent and Polyflex stent are the only prostheses available in the USA with the potential to be repositioned. The uncovered Ultraflex prosthesis, in turn, can be completely removed, at least in theory, up to several weeks after placement.

Nonesophageal strictures

Expandable prostheses can be placed in the proximal stomach and distal colorectum using conventional delivery systems and techniques similar to those described for the esophagus. Stents approved in the USA specifically for colonic application, including the colonic Z stent (Wilson-Cook), Enteral Wallstent (Boston Scientific) and colonic Memotherm stent (CR Bard), share a wider diameter of 20–30 mm to reduce the risk of obstruction. However, strictures in the more proximal colon, as well as those in the duodenum or proximal jejunum, require either a longer insertion system or a stent mounted on a 3–4 mm shaft that can be placed through a large channel endoscope [95]. A variety of stents have been developed for transendoscopic enteral placement, including the Enteral Wallstent and Wallflex stents (Boston Scientific), the Hanaro enteral stent (M.I. Tech), the Niti-S duodenal and pyloric stents (TaeWoong Medical), and the EnterElla duodenal stent (Radiologic). These stents require balloon dilation of the malignant stenosis, delineation of stricture length, localization with contrast injection at the tumor margins, and concomitant endoscopic and fluoroscopic control to ascertain proper placement and prosthesis expansion. If biliary and duodenal stents are both required, as may be the case in locally advanced pancreatic cancer, the permanent biliary stent should be placed first whenever possible, as it is technically very challenging to cannulate the biliary system through the fenestration of a duodenal stent.

Indications and contraindications

For the most part, conventional and metal expandable prostheses are difficult or dangerous to remove once placed, and thus should be reserved for obstructing or fistulizing neoplasms that cannot be cured by resection, or in potentially curable patients with prohibitive operative risk (Table 122.4) [71,72]. The most experience has accrued in the proximal gut for malignant dysphagia or esophago-airway fistulae. The latter can be a consequence of primary esophageal carcinoma, lung cancer, or mediastinal metastases. Gastric outlet obstruction from widespread pancreatic cancer has traditionally been treated by gastrojejunostomy or PEG/J in infirm patients, but the latter might be ideal candidates for stent insertion into the C loop [86,98]. Likewise, patients who present with malignant colon obstruction usually have far advanced disease (stage III [40%] or IV [60%]) [87]. Traditionally treated with palliative resection or bypass, colorectal prosthesis placement appears to be a useful alternative, both to allow adequate preoperative bowel preparation in surgical candidates [99,100] and as long-term palliation in a subset of patients with malignant ascites or liver metastases, and thus a higher operative risk [101–103].

While removable stents, such as the plastic Polyflex stent, can also be used for malignant stenoses [88,91,104], their ability to be removed months after deployment expands the indications for prostheses to include benign conditions as well. In the esophagus, temporary placement of a Polyflex stent for 6 weeks to 13 months has been successfully used

Table 122.4 Indications for prostheses

Conventional stents
Esophagus
Malignant dysphagia (esophagus, esophagogastric junction, lung, mediastinal tumor)
Esophago-airway fistula
± Benign disease, e.g. caustic ingestion/anastomotic stricture or leak
Expandable stents
Permanent prostheses
Esophageal
Malignant dysphagia
Esophago-airway fistula
Gastroduodenal (high surgical risk)
Malignant pyloric/C-loop obstruction
Gastric/pancreatic/biliary tumor
Colorectal (high surgical risk)
Obstructing/malignant stenosis
? Benign strictures: radiation, Crohn's disease
Removable prostheses
Esophageal
Refractory peptic stricture or ring
Anastomotic leak
Gastroduodenal/colorectal (theoretical)
? Anastomotic stricture
? Radiation or Crohn's stricture

to provide durable relief from a variety of benign causes of esophageal stenosis, including peptic, caustic, anastomotic and radiation-induced strictures [89,90]. Additionally, this covered stent allows temporary occlusion of nonmalignant esophageal perforation [92], particularly postsurgical anastomotic leaks [93,94]. Although minimal literature exists on the extraesophageal application of removable stents, these prostheses may soon become indicated for benign strictures of the colorectum, stomach, or even small bowel in the near future.

With this notable exception of removable stents, prostheses are generally contraindicated in the low-risk and potentially curable patient [71,95], as permanent stents have a long-term potential for erosion, occlusion, and migration. Conventional prostheses should not be placed in the setting of a tracheoesophageal fistula unless there is an adequate shelf to seat the stent. Esophageal stents should not be used if placement of a dilator approximating the stent diameter results in significant airway compression by a bulky neoplasm. Stents may be contraindicated if placement cannot be undertaken without impingement on the cricopharyngeus muscle or anal sphincter, or if the opening of a placed stent would abut a contralateral lumenal wall, thus occluding it. An absolute contraindication for prosthesis placement is an inability to endoscopically or radiographically define both the proximal and distal stricture margin.

Risks and alternatives

Esophageal strictures

Complications with the early rigid esophageal stents were not uncommon, and so provide a paradigm for possible omplications with more modern stents. Acute procedure-related complications included perforation, bleeding, tracheal compression, and tube malposition. Total complications with these conventional stents have approximated 20%, with a mean procedure-related mortality of 8.6% [71]. Subacute complications include erosion with bleeding or fistula development, stent migration, food bolus impaction, and tumor overgrowth. Variable degrees of reflux are inevitable if the esophagogastric junction has been stented, and florid regurgitation or aspiration may be noted in patients who have delayed gastric emptying as a consequence of vagal denervation or gastric infiltration by tumor.

Complications of expandable prostheses are variable and contingent on prosthesis design and endoscopist experience, but are generally similar to those of conventional prostheses, except less common [105–108]. For example, a Swedish nationwide review of 152 recipients of expandable metal esophageal stents revealed such complications as transient chest and pharyngeal discomfort (in nearly all patients), stent migration (in 5% of cases), bleeding (in 1%), incomplete stent expansion (in 1%), perforation (in 1%), and stent occlusion (in 10%) from food impaction or tumor overgrowth or ingrowth [109]. The latter is a complication unique to expandable stents, and can be reduced with covered stents, although this increases the risk of stent migration [110–112]. As with conventional stents, gastroesophageal reflux can complicate expandable stents placed across the lower esophageal sphincter, prompting some manufacturers to incorporate valves or sleeves into versions of their prostheses. While some of these modifications have appeared ineffective in randomized trials [113], others have demonstrated as much as an eightfold lower rate of subjective [114] or objective reflux [79,115] than unmodified prostheses, with rare cases of potentially fatal reflux aspiration pneumonia seen only with the valveless stents in these studies. The ability to place expandable esophageal stents more proximally than conventional prostheses [116] has also associated them with rare complications such as cervical discitis [117] and stent perforation into the common carotid artery [118].

The risk of life-threatening complications from both conventional and expandable stents may be increased in esophageal cancer patients with prior chemotherapy and radiation. Multiple series have reported increased rates of bleeding, perforation, sepsis, or tracheoesophageal fistula formation in such patients [107,119–122]. However, a number of reports have also found no significant association between these complications and chemoradiation therapy [123–125], raising the question of whether these patients are particularly sensitive to variations in stent design, physician technique, or institutional experience.

Tumor ablative technologies have also been studied as alternatives to stent placement. In randomized trials, endoscopic laser therapy by itself was less effective than covered or uncovered expandable stents at relieving dysphagia [110], although it increased median survival and quality of life, as well as treatment cost, in one study [126]. However, the cost and survival with laser therapy were found to be comparable, and the quality of life actually worse, relative to stents in a Greek case series [127]. The addition of external beam radiotherapy to laser increased serious complications, hospitalization time, and cost, but did not result in more long-term efficacy than stents [128]. A major limitation of laser therapy is the need for repeated endoscopic treatments.

In contrast, single-dose esophageal brachytherapy has compared favorably with partly covered Ultraflex stent placement in a randomized trial of 209 patients [129]. Although stents resulted in more immediate relief of dysphagia, these symptoms were better in brachytherapy recipients after about 5 months. Cost, survival, and quality of life were not significantly different between the two groups. Similar results have also been reported with multiple sessions of endolumenal brachytherapy relative to Ultraflex stent placement [130].

Nonesophageal strictures

Although few randomized trials have been conducted with extraesophageal stents, a plethora of case series have been summarized by metaanalyses concerning gastroduodenal

[131] and colorectal [132,133] malignancies. According to these analyses, stent migration and occlusion are among the most common complications, each occurring in 5%–17% of placements. While occlusion is usually from tumor ingrowth or overgrowth, 10%–25% of colonic stent obstructions can also be from fecal impaction. Life-threatening complications, namely perforation or severe bleeding, are rare, with each occurring in less than 1% of gastroduodenal stent placements. However, the rate of perforation is higher (up to 5%) with colorectal stent placement, particularly if balloon predilation was employed, and it constitutes the major etiology of the 0.5%–1% mortality observed with this procedure. Unique to gastroduodenal prostheses, biliary obstruction, with jaundice or cholangitis, complicates 1.3% of placements. Pain is less commonly a complication with extraesophageal stent placements than with esophageal stents, being reported in only 2.5%–5% of cases, and usually as transient or minor pain.

Surgery is the principal alternative to stent placement for extraesophageal obstructions, and has historically been indicated for emergency colorectal obstructions, even in patients for whom a surgical cure is not possible. Recent randomized trials and case series have concurred that while stents and surgery for malignant colorectal obstruction have comparable morbidity and mortality, colectomy is associated with longer hospitalization and usually necessitates colostomy [99,100,102,103,134]. Similarly, surgical treatment of malignant gastric outlet obstruction is comparable to stent placement in terms of morbidity, mortality, and ultimate clinical efficacy, but takes longer to achieve that efficacy and results in longer hospitalization [102]. Thus, reports have suggested that prostheses represent a more attractive approach to malignant extraesophageal obstructions than their surgical alternatives. There are few data that compare prostheses to less invasive palliative alternatives such as a jejunal feeding tube or a diverting cecostomy.

Efficacy

Esophagus

Conventional stents can be successfully placed in approximately 90%–95% of patients with malignant esophageal obstructions, with mean patient survival of 2–4 months [71]. Terminal events frequently include tumor cachexia or subacute stent-related problems such as aspiration or stent erosion into major vessels.

Numerous series defining long-term results of expandable stent placement for malignant dysphagia have been published, revealing technical and clinical success rates comparable to conventional stents [71,75,135–137]. As noted above, these results are contingent, in part, on both stent design and initial successful palliation of dysphagia, but usually reveal fewer complications and shorter hospitalization with expandable stents. Nevertheless, in most series, survival appears identical to that following conventional prosthesis insertion [71], underscoring the degree to which mortality is dictated more by the underlying malignancy than the complications of these palliative prostheses. Our study comparing 85 patients in whom conventional versus expandable prostheses were placed for malignant dysphagia documented comparable levels of post-stent dysphagia (0.4 vs 0.9), fistula occlusion (13/15 vs 13/14), and survival (87 vs 90 days) [123]. Comparable palliation and complication rates have been noted in studies comparing Z, Ultraflex and Flamingo prostheses for malignant dysphagia [138,139].

Benign esophageal strictures have been successfully treated with temporary Polyflex stents, with 80% of recipients remaining symptom-free many months after stent removal [89,90]. These stents have also successfully occluded 78%–89% of esophageal anastomotic leaks in some small series [92], with less mortality and shorter hospitalization than surgical or conservative management [93]. Furthermore, placement of a Polyflex stent inside a previously placed, and normally permanent, metal stent has been reported to facilitate the removal of the latter, presumably through local tissue ischemia [90].

Nonesophageal strictures

Numerous series relating to stent placement in malignant stenoses of the stomach, small bowel, and colon have been summarized in the aforementioned metaanalyses [131–133]. Technically successful stent deployment was reported in 97% of gastroduodenal and about 93% of colorectal placements, with most failures due to inability to cannulate a very high grade obstruction with a guidewire. Curiously, the technical success rate was not increased in colorectal strictures when predilation was performed to facilitate guidewire passage [133], suggesting that the increased risk of colonic perforation these analyses associated with predilation [132,133] may not be warranted. Factors that predict a lower likelihood of technical success with colorectal prostheses include lesions proximal to the rectosigmoid, where only about 85% of placements were successful [132]. Extrinsic colorectal compression from noncolorectal primary malignancies were also less amenable to stent placement, with only 78% of these cases achieving technical success [132].

About 88% of extraesophageal prostheses achieved clinical success, namely improved oral intake for gastroduodenal stents [131] and colonic decompression for colorectal stents [132,133]. The majority (61%) of gastroduodenal stent failures were due to disease progression, with most of the remainder reflecting stent migration (20%) or incorrect deployment (15%) [131]. Although stent malposition or migration also caused about half the clinical failures of colorectal prostheses, perforation was another significant limitation, accounting for 15%–30% of failures in this group [132,133]. In a subset of patients who received a colorectal prosthesis as a bridge to surgery, 72% were able to undergo a single-stage colectomy and thus avoid colostomy [132].

Future applications

The future of gastrointestinal dilation is contingent on further experience with the newer dilating systems, such as CRE balloons, in comparison to polyvinyl dilators. Both expanded experience and controlled clinical trials should allow improved definition of the indications, benefits, procedure costs, and risks for individual dilating systems, and for specific stenotic lesions. New technologies, such as the transparent over-the-scope Optical dilator, may facilitate endoscopic guidance and visualization during dilation to improve the safety of dilation, and extend the applicability of solid dilators beyond esophageal and anorectal stenoses. If the latter proves true, solid dilators could ultimately provide a more cost-effective alternative to balloons for central stenoses. The future of gastrointestinal dilation may also include the development of dilators that can detect a fall in wall tension or resistance within a tissue during dilation, as an indication that the dilation is adequate. By thus identifying a point beyond which further lumenal enlargement may be unnecessary or hazardous, devices such as these should improve safety.

There are also likely to be additional technological combinations using dilators and various thermal modalities for malignant stenoses. Just as bipolar tumor probes have conjoined Eder–Puestow dilators with multipolar electrocautery to treat concentric esophageal or rectal neoplasms, similar electrodes have been implanted on balloons or polyvinyl dilators. A new approach is to take a quartz laser fiber and surround the tip with a balloon so that the balloon keeps the fiber tip in the center of the lumen. These catheters may ultimately allow treatment of nonresectable biliary, gastroesophageal, or rectal neoplasms by transmission of laser energy. Photodynamic therapy, in turn, may play an increasing role in the treatment of malignant stenoses, while argon plasma coagulation or endoscopic cryotherapy may be used in lieu of Nd:YAG laser to open a lesion or facilitate stent placement.

Finally, as noted already, dilation will be increasingly used in conjunction with expandable stent technology. Permanent expandable stents, undergoing refinement both in the endoprostheses themselves and in their delivery systems, hold at least the potential of prolonged stricture patency and decreased stent migration. A Niti-S esophageal stent impregnated with a β-emitting radionuclide has been tested in dogs in an effort to combine the benefits of brachytherapy and stent technology in a single device [140]. Z stents covered with small intestinal submucosa have facilitated reepithelialization of vascular and airway stents in animal models [141,142] and may hold similar potential in the alimentary canal. At the same time, as the technology improves for removable prostheses, their role in the treatment of benign conditions may expand to obviate repeated dilation sessions, and potentially provide a novel future treatment for benign central stenoses and leaks.

A ENDOSCOPIC

123 Percutaneous endoscopic gastrostomy

Brian J. Dunkin, Jeffrey L. Ponsky

Methods, 2974

Feeding, 2983
Endoscopic jejunostomy, 2983
Removal and replacement of PEG tubes, 2984
Conclusion, 2984

Percutaneous endoscopic gastrostomy (PEG) was introduced in 1980 as an alternative to operative gastrostomy for those patients requiring long-term intubation of the stomach [1]. It was devised as a safe and effective nonoperative means of providing enteral nutrition. The method has become widely practiced, with approximately 230 000 PEGs placed in patients in the USA annually [2].

The concept of a surgically created fistula between the stomach and abdominal wall was first conceived by Egeberg in 1837 and attempted by Sellidot in 1849. A variety of surgical approaches were developed, culminating in the more popular Janeway and Stamm methods [3]. Both were effective in creating a gastrocutaneous fistula, but use of these techniques was somewhat limited because the patients were frequently poor surgical candidates and these procedures required a laparotomy, often with general anesthesia.

Thus, delivery of enteral nutrition was most often by means of nasoenteric tubes. This was effective but associated with numerous frustrations and complications. These tubes were frequently large in caliber and constructed of stiff rubber or plastic, making them uncomfortable. Frequent plugging of the tubes necessitated replacement, and it was not unusual for them to become dislodged, accounting for up to 60% of tube removals [4,5]. Esophagitis also developed from irritation of the esophageal mucosa by the tube, and gastroesophageal reflux was common because the tube rendered the esophagogastric junction incompetent [6,7]. This reflux frequently led to the development of aspiration pneumonia. Long-term use of nasoenteric tubes also caused parotitis and erosion of the nasal cartilage.

In 1980, the technique of PEG was introduced. This method allowed the formation of a tube gastrostomy without laparotomy or general anesthesia. Safety of the procedure was ensured by endoscopic visualization of tube insertion, and placement directly into the stomach reduced the risk of complications encountered with the nasoenteric tube. The original method described by Ponsky and Gauderer has been called the pull technique [8]. Two modifications of the original method have been introduced and have gained some popularity. These are referred to as the push or Sacks–Vine technique and the introducer or Russell technique [9,10]. All these methods have been shown to be safe and effective.

Complications of percutaneous gastrostomy, although not frequent, are known to occur and are well documented. Careful attention to patient selection and the details of the method may help to reduce the incidence of undesirable outcomes. The increasing ease by which enteral access is established with percutaneous gastrostomy has led to tremendous growth in the application and use of this procedure. Moral and ethical dilemmas arise as the technique is applied to an increasingly debilitated population of patients. Further study of the technique and its long-term outcome has provided answers to some of these problems.

Methods

Patient preparation

Proper preparation can help avoid complications. The patient should not be fed for 6 h prior to the procedure. If an antibiotic with good Gram-positive coverage is not already being administered, then a single intravenous dose should be given [11]. The most common organisms cultured from PEG site infections are *Staphylococcus aureus* and β-hemolytic streptococci. Cefazolin is very good at covering these and other commonly encountered organisms [12]. The patient should be positioned supine with the head elevated to reduce the risk of aspiration. Many practitioners forgo the use of topical anesthetic to the oropharynx in these supine patients because it may increase the risk of aspiration and has not been shown to improve patient tolerance of upper endoscopy [13]. Because

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

it can be difficult to intubate the esophagus in this position, it is sometimes preferable to start the endoscopy in the left lateral decubitus position and then reposition the patient supine. Suction should be available to manage oropharyngeal secretions, and the patient should be maintained on supplemental oxygen. In addition, blood pressure and pulse oximetry should be monitored by a nurse in attendance throughout the procedure. A full endoscopic survey, including inspection of the duodenum, should be conducted prior to PEG placement. Such a survey has led to a change in patient management in 4%–36% of patients [14,15].

Standard techniques

Pull (Ponsky–Gauderer) technique

Once positioned, the patient is given intravenous sedation and the abdomen is washed and draped in a sterile fashion. The room lights are dimmed as the gastroscope is passed into the stomach. Transillumination of the abdominal wall by the light of the scope is an indication that intervening structures have been displaced and that the stomach lies in contact with the abdominal wall. The site selected for placement of the gastrostomy should be one at which transillumination is well seen. Finger pressure by the assistant at this point produces a clear indentation of the gastric wall as seen by the endoscopist (Fig. 123.1). This indentation should be covered by an open polypectomy snare passed through the endoscope. To enhance the safety and accuracy of PEG placement, use of the *safe tract technique* described by Foutch is very helpful. The technique begins with identification of the best site of finger indentation or transillumination. A syringe with local anesthetic is advanced only a small distance beneath the skin. Suction is applied to the syringe barrel as it is advanced more deeply. The appearance of air in the syringe barrel and visualization of the needle tip in the stomach by the endoscopist should occur simultaneously. Should air appear in the syringe barrel before the needle tip appears in the stomach, an alternative site should be selected as this usually indicates that an intervening air-containing viscus, such as colon or small bowel, has been punctured.

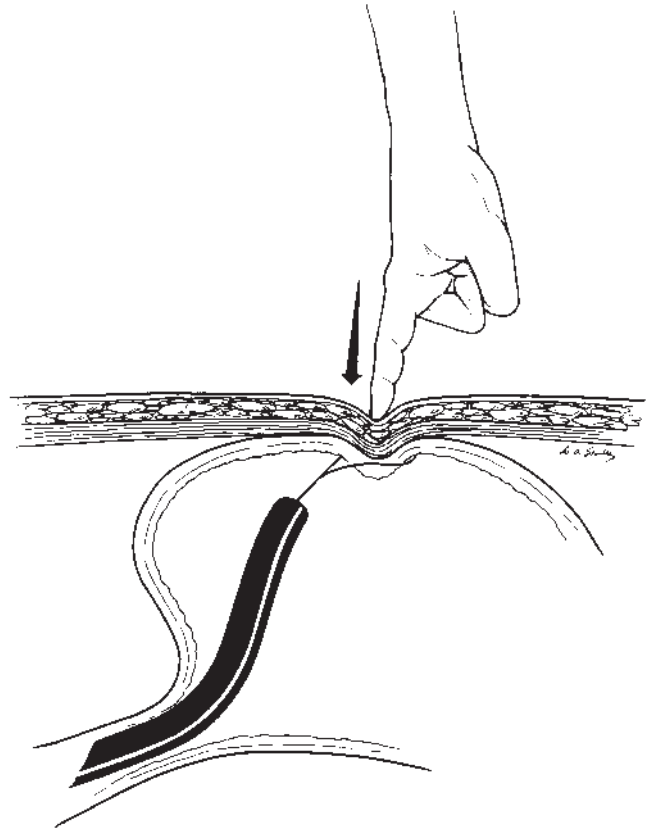

Figure 123.1 The endoscopist observes a distinct indentation of the gastric wall as the assistant applies finger pressure to the abdominal wall at the proposed site of puncture.

Local anesthetic is injected into the abdominal wall at the proposed area of puncture, and a 1-cm incision is made in the skin. An intravenous cannula is thrust through the incision and into the gastric lumen. If the polypectomy snare is correctly positioned, the thrusting needle will enter the center of its loop. If not, the snare is quickly looped around the cannula and tightened near the point where the cannula exits the gastric mucosa (Fig. 123.2). A long stout suture or wire is

Figure 123.2 The snare is looped around the cannula and tightened near the point where the cannula exits the gastric mucosa.

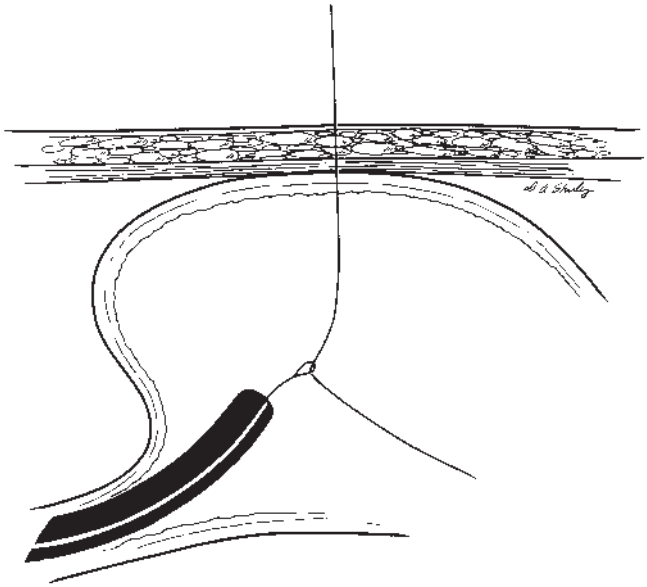

Figure 123.3 The snare is tightened around the suture and pulled out of the patient's mouth using the gastroscope.

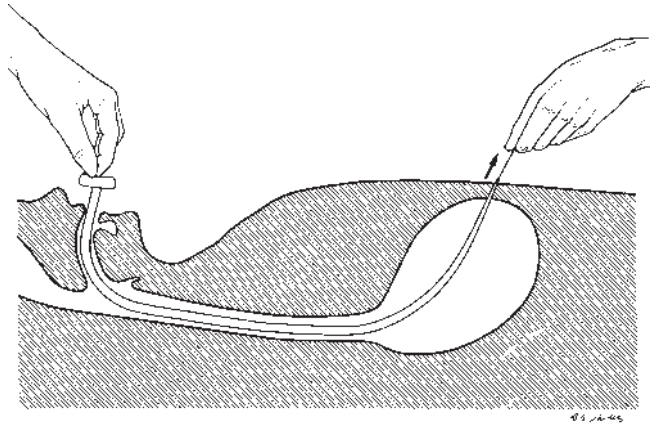

Figure 123.5 The assistant pulls on the abdominal end of the suture, and the gastrostomy tube proceeds down through the esophagus and stomach to exit the abdominal wall.

passed through the needle into the gastric lumen, and the snare is moved from around the cannula to tighten around the suture itself (Fig. 123.3). The suture is pulled with the endoscope from the stomach and out of the mouth. The drainage end of the gastrostomy tube is affixed to the suture at the patient's mouth (Fig. 123.4). The tube is well lubricated, and pull is begun on the abdominal end of the long suture so that the gastrostomy tube moves down the esophagus and exits the abdominal wall (Fig. 123.5). An outer bolster is applied, which holds the gastric and abdominal walls in close contact. Many endoscopists reinsert the gastroscope at this point to check the position of the head of the tube and adjust the external bumper to avoid excessive tension on the head of the catheter. If there is no suspicion of a technical problem, however, this step may be omitted at the discretion of the endoscopist [17].

Push (Sacks–Vine) technique

This method differs little from the pull technique. The patient is prepared, the puncture performed, and a guidewire grasped and pulled from the patient's mouth in the same manner (Fig. 123.6). In this procedure, however, a special gastrostomy tube with a long tapered dilator end is pushed over the guidewire. Both ends of the wire must be held under tension as the tube is pushed down the esophagus and exits the abdominal wall (Fig. 123.7). Once the tube emerges from the abdominal wall, it may be grasped and pulled the rest of the way into its final position. The gastroscope is reinserted (at the discretion of the endoscopist as described above) to ensure that the head of the catheter lies in contact with the gastric mucosa. An outer crossbar or faceplate is added to fix the abdominal and gastric walls together.

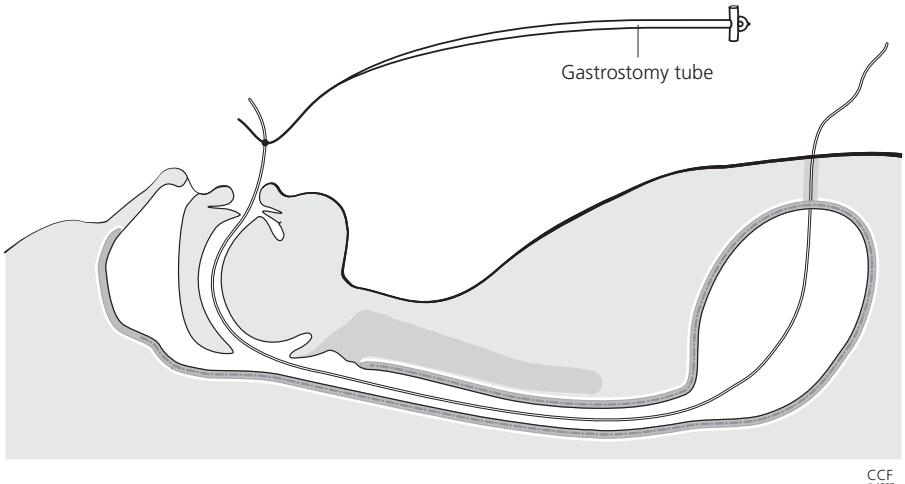

Figure 123.4 The gastrostomy tube is affixed to the suture at the patient's mouth.

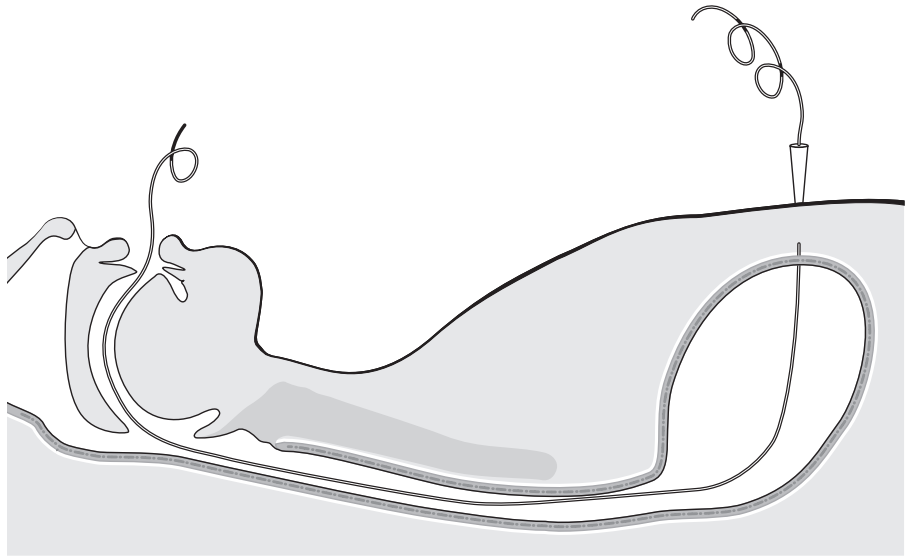

Figure 123.6 As in the pull technique, the cannula is inserted into the stomach, a guidewire is passed through it, and the wire is grasped and pulled out of the mouth using the gastroscope.

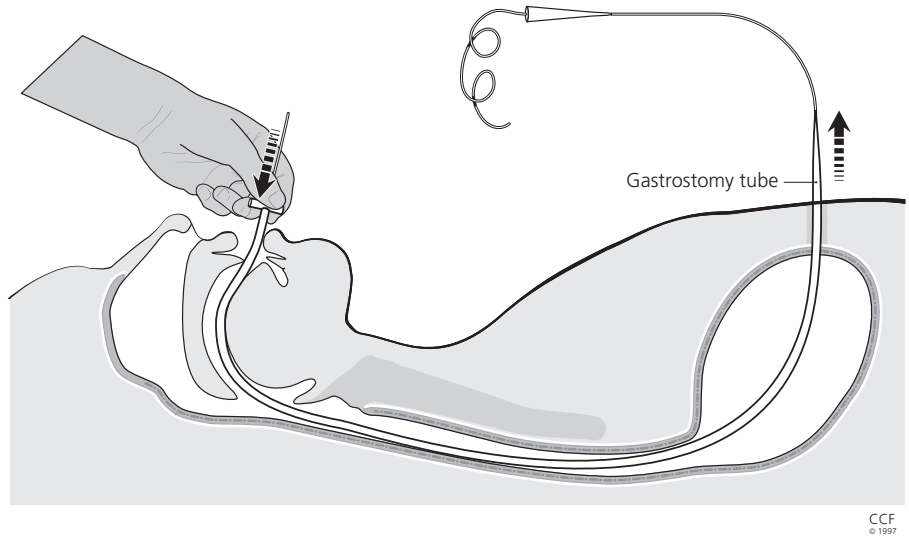

Figure 123.7 Both ends of the wire are held under tension while the gastrostomy tube is pushed down the esophagus and out the abdominal wall. Once the tube emerges from the abdominal wall, it is grasped and guided into position.

Introducer (Russell) technique

The percutaneous method for insertion of a central venous catheter as described by Seldinger has been adapted to the performance of gastrostomy placement in the introducer method. Developed by Russell and colleagues [10], this method allows percutaneous placement of a gastrostomy tube without passing the tube through the oropharynx and with only a single insertion of the endoscope. The gastroscope is passed into the stomach, and the room lights are dimmed. Transillumination of the abdominal wall and finger pressure at the point of best transillumination are used to identify the proper site for puncture. Once the site for insertion has been established, the skin is anesthetized and a small incision is made. A needle is introduced into the gastric lumen, and a guidewire is passed through the needle. The needle is removed, and an introducer with an outer peel-away sheath is passed over the guidewire into the stomach (Fig. 123.8). The wire and introducer are removed, leaving only the sheath in the stomach. A balloon catheter is introduced through the sheath and inflated (Fig. 123.9). The sheath is removed, and the balloon of the catheter is pulled up to the gastric mucosa. The catheter is either sutured to the skin, or an outer faceplate is applied to hold the gastric and abdominal walls in approximation.

Comparison of standard methods

All these techniques for the performance of percutaneous gastrostomy have been widely used and found effective. Each provides benefits that should be considered in choosing a method for a particular patient [18].

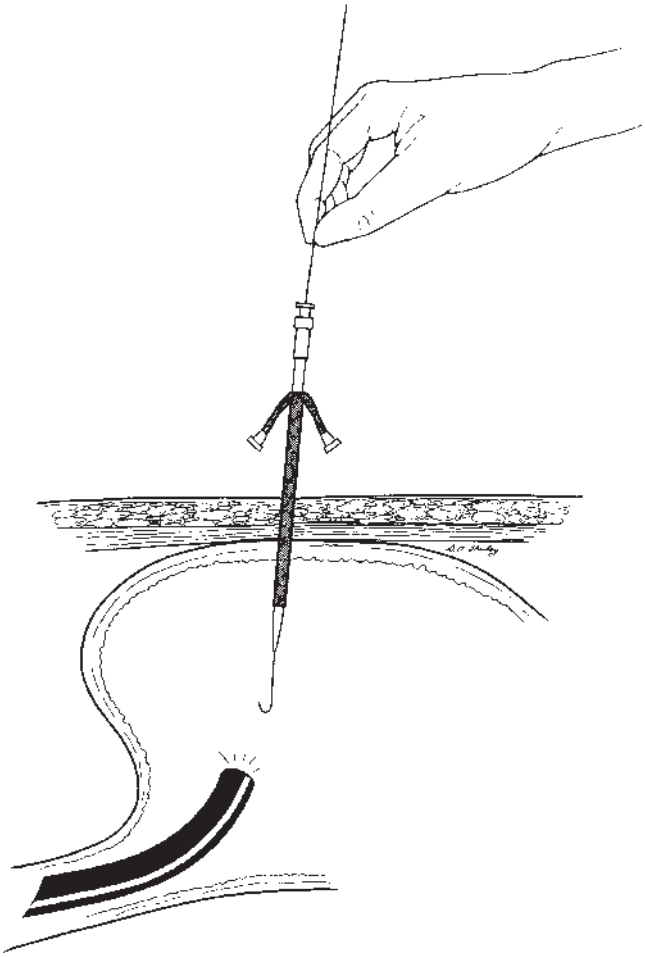

Figure 123.8 The introducer and its outer sheath are passed over the guidewire into the gastric lumen.

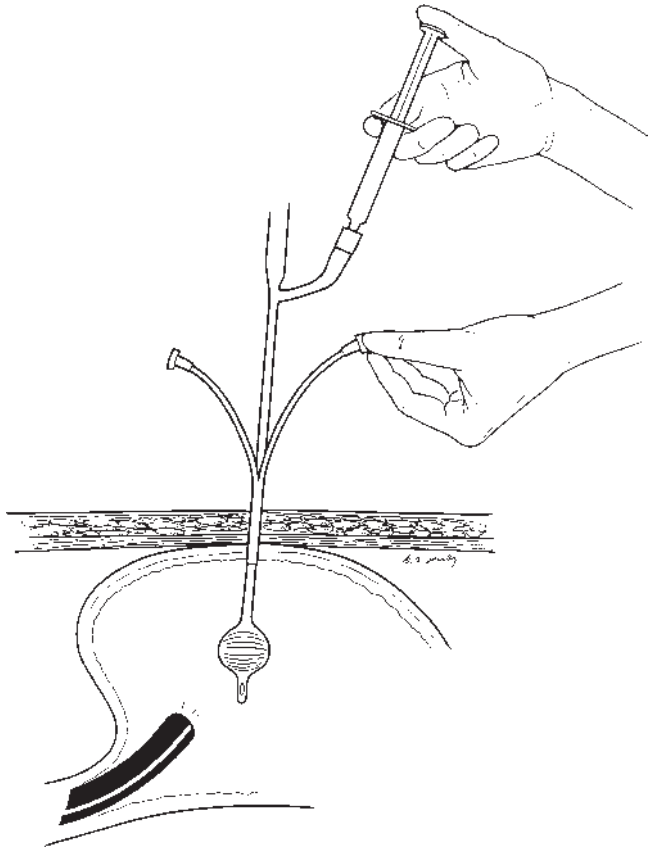

Figure 123.9 The introducer and guidewire are removed, and the balloon catheter is inserted through the sheath. The balloon is inflated and the sheath is peeled away.

The pull technique provides the physician with a great deal of control. The puncturing needle is stabilized with the surrounding snare, ensuring that loss of air from the gastric lumen does not result in loss of the puncturing needle. The gastrostomy tube is pulled down the esophagus and out of the abdominal wall in a direction that apposes the gastric and abdominal walls. This should minimize leakage around the puncture site. The soft button of the pull PEG trailing free behind the tube may be more deformable than that of the push PEG, thus allowing it to traverse a narrowed esophagus more readily. The push method adds the stability of a guidewire to act as a trolley on which the tube can ride as it passes through the alimentary tract. Both these methods have the potential of introducing oral bacteria or tumor cells from a lesion in the oropharynx or esophagus into the tissues of the abdominal wall. Thus, infection and metastasis of carcinoma are potential complications with these techniques.

The introducer method enjoys the advantage of direct puncture insertion of the tube. This avoids the potential risk of infection from oral flora and possibly reduces the risk of cancer seeding to the abdominal wall. The method permits insertion of a gastrostomy in patients with narrow lesions of the esophagus without fear of disrupting such lesions while the catheter is positioned. In the introducer technique, the endoscope serves only an observatory function. However, the forces of insertion with the introducer method push the stomach away from the abdominal wall and may lead to the creation of a submucosal tunnel in the stomach without puncture of the mucosa. Loss of control of the punctured stomach and leakage of gastric contents is also more likely to occur. Finally, the tubes used for this procedure are of small diameter and suffer from premature extrusion secondary to deflation of the balloon catheter.

In practice, each of these methods has been demonstrated to be effective and to have a low rate of complications. Experienced endoscopists are familiar with all these techniques and select the one with which they are most comfortable and that best suits the needs of the patient.

Alternative techniques

Incision omission PEG

The traditional method of pull PEG placement includes making a skin incision large enough to permit bacterial egress. It was thought that this technique would reduce stoma site

infections. Sedlack and colleagues have called into question the validity of this step of the procedure and advocate simply pulling the tapered end of the PEG tube directly through the skin without the creation of an incision [19]. The force required to pull the tube into position is 47% greater when compared with standard pull PEG (some tube tips pulled off during the process), but stoma infection rates were lower and patient comfort after the procedure was similar. The authors state that there may be additional advantages of eliminating the scalpel from the PEG kit such as improved safety for the procedure team, lower cost of the kits, and less creation of hazardous waste.

SLiC technique

This is a modification of the introducer technique and is named after the describing authors Sabnis, Liu, and Chand [20]. Endoscopic access to the stomach is gained in the usual fashion and the site for PEG placement chosen. However, in place of the introducer and outer peel-away sheath, a 7–8 mm radially expanding Step trocar (United States Surgical, Inc., Norwalk, CT) is used to traverse the abdominal wall and gain access to the lumen of the stomach. The PEG tube is placed through this trocar which is then removed to allow securing of the tube in the usual fashion. The advantage of the trocar is that it maintains a secure airtight access and allows placement of a large 20Fr Malecot tube. Such a tube is more resistant to plugging or inadvertent removal. Other advantages of the procedure include minimizing the chance for tumor seeding to the PEG site and the ability to place large-bore tubes even in patients with lesions of the oropharynx or esophagus since the tube is not pulled through these areas.

Percutaneous transesophageal gastrostomy tube

Percutaneous transesophageal gastrostomy tube (PTEG) was developed in Japan as an alternative route of access into the gastrointestinal tract [21]. It is placed via the cervical esophagus thus avoiding traversal of the abdominal cavity and gastric wall. This has potential advantages in those patients who have a contraindication to standard PEG placement such as ascites, carcinomatosis, or obstructed oropharynx. The procedure is usually performed under conscious sedation in the endoscopy unit. The patient is in semirecumbent position. A guidewire is inserted through the nose and into the esophagus and its position confirmed by fluoroscopy. A rupture-free balloon (RFB) is passed over this guidewire distal to the cricopharyngeus and inflated with dilute contrast material. The RFB can be punctured with a needle without collapse or rupture. Traction is maintained on the RFB to keep it in the cervical esophagus. Ultrasound is used to locate the inflated RFB and confirm that it has displaced the carotid artery and jugular vein medially and the thyroid medially and superiorly. Color Doppler is a useful addition to the visualization. Once the puncture site has been chosen, the area is anesthetized with a local anesthetic and, under ultrasound guidance, a straight needle with an outer sheath is advanced through the left side of the neck until the tip enters the RFB. Needle placement is confirmed by aspiration of contrast from the balloon. The inner needle is then removed and a second guidewire is inserted through the sheath and into the RFB. The sheath is removed, the wire secured at skin level, and the RFB deflated and advanced distally in the esophagus. This allows the cervical guidewire to fall out of the lumen of the balloon but remain within the esophagus. The RFB and nasal guidewire are then removed. An incision is made over the guidewire in the neck and a 16Fr dilator with outer peel-away sheath is inserted under fluoroscopic guidance over the wire and into the esophageal lumen. The dilator and wire are removed and the PTEG balloon catheter advanced via the sheath into the proximal stomach. The balloon is inflated and pulled upward so that the tip of the catheter rests just below the esophagogastric junction. Its position is confirmed by the injection of contrast under fluoroscopy. The peel-away sheath is then removed and the catheter secured at skin level.

PTEG has been placed most often in patients with malignant obstruction of the gastrointestinal tract and massive malignant ascites [22]. It avoids the complication of peritonitis in these patients and provides more comfortable and complete decompression of the stomach than a nasogastric tube or standard PEG.

Radiologically placed gastrostomy

Gastrostomy tubes may be placed under radiological guidance without endoscopy using a Seldinger technique like that described for the introducer method. A number of studies have examined these methods and found them to compare favorably with endoscopically guided insertion [23]. Common indications for radiologically placed gastrostomy (RPG) tubes are esophageal stenosis due to malignant or benign stricture or any situation in which endoscopy is contraindicated for the patient. Some have argued that patients with oropharyngeal cancer should have RPG tubes as well to avoid seeding cancer to the abdominal wall. A more recent common indication is to access the remnant stomach after Roux-en-Y gastric bypass surgery for morbid obesity [24]. Gastric bypass patients have a small gastric pouch completely separated from the majority of the remnant stomach and directly connected to the jejunum. Post-bypass access to the gastric remnant for decompression, imaging, or to serve as a conduit for endoscopy have all been described using RPG tubes [25]. Interestingly, a common method of initial access is to percutaneously pass a needle through the left lobe of the liver and into the lumen of the remnant stomach which is then filled with air and contrast. This route of access avoids traversing an intervening loop of bowel. Once the stomach is maximally inflated and visualized with contrast, a more direct anterior abdominal wall approach is used for placement of the gastrostomy tube. One disadvantage of the RPG tube is its small caliber, which makes it prone to clogging.

This can be avoided by sequentially up-sizing the tube over time after the access tract has matured.

Mini-laparoscopically guided percutaneous gastrostomy

In some patients PEG tube placement is complicated by inability to transilluminate, absence of a stomach after prior resection, or failure of radiological placement. In these situations mini-laparoscopy has been used to assist in placement of the gastrostomy tube [26]. Using conscious sedation and local anesthesia, a 2.3-mm diameter Veres needle (Richard Wolf GmbH, Knittlingen, Germany) is percutaneously passed into the intraperitoneal space and used to instill 1.5 L of nitrous oxide. The Veres needle is then exchanged for a 1.9-mm diameter laparoscope (Richard Wolf GmbH). Upper endoscopy is performed and the appropriate insertion point of the stomach or jejunum is chosen using direct laparoscopic visualization. The standard pull technique is then used to place the gastrostomy or jejunostomy tube. The pneumoperitoneum is subsequently evacuated and the laparoscope withdrawn leaving only a small 1.9-mm diameter incision on the abdominal wall.

Indications

PEG was first conceived as a means of providing long-term enteral nutrition to those patients unable to ingest food by mouth but who have a functioning gastrointestinal tract. Nutritional support should be initiated in all patients anticipated to be without nutrient intake for two or more weeks. If the patient has a functional gastrointestinal tract and is expected to require enteric feeding for less than 30 days, then a nasogastric or nasoenteric tube should be used. If it is anticipated that enteric feeds will be required for more than 30 days, however, then a tube gastrostomy or enterostomy should be considered. Such patients may have severe neurological or developmental disorders, obstruction of the oropharynx from trauma or tumor, or a critical illness requiring prolonged endotracheal intubation.

As the safety and efficacy of PEG has been demonstrated, the population of patients benefiting from it has expanded. PEG tubes have been placed in burn patients (even through burned skin) to facilitate enteric feeding of high caloric density formulas [27]. They have also been placed in patients about to receive neoadjuvant therapy for esophageal cancer [28] and head and neck carcinoma [29,30]. Victims of severe maxillofacial injury have benefited from PEG tube placement as well [31].

Non-alimentation-related applications have also been described. These include decompression of the stomach for gastric atony, uncorrectable obstruction, carcinomatosis, and gas bloat following Nissen fundoplication [18,32,33]. The method has also been used for the administration of unpalatable medications to children [34] and the refeeding of bile to patients with external biliary fistula [35]. Multiple PEG tubes have been placed in patients with paraesophageal gastric herniation and gastric volvulus as a method of gastropexy [36]. Finally, RPG tubes have been used to gain access to the remnant stomach in Roux-en-Y gastric bypass patients for decompression or to allow for gastroscopy or endoscopic retrograde cholangiopancreatography via the PEG tract [25].

Despite the excellent overall safety profile of PEG tube placement, careful consideration should be given prior to insertion. Controversy exists as to whether PEG tubes should be placed in patients with advanced dementia or incurable metastatic cancer [37]. Some have even questioned whether PEG tubes decrease the risk of aspiration when compared with use of a nasogastric tube, although more recent data show that patients with a nasogastric tube have a significantly greater risk of aspiration than patients with PEG tubes (40.7% vs 20.3%) [38]. The endoscopist must act as more than a technician and provide reasonable expectations to the patient, the patient's family, and the referring provider when making a decision about PEG tube placement.

Contraindications

As experience has grown with PEG tube placement the number of absolute contraindications to placement has become few. Uncorrectable coagulopathy, peritonitis, or any process that precludes endoscopic access to the gastrointestinal tract are the only absolute contraindications to standard PEG tube placement.

Other disease processes raise concern about PEG tube placement and must be managed cautiously. Massive ascites is one such process. Patients with massive ascites are at major risk for complication from PEG tube placement. However, successful placements have been described using preprocedure treatment with β-blockade, diuresis, nitrate administration, and paracentesis [39,40]. Avoiding access via the peritoneal cavity with PTEG has also been successfully used in these difficult patients (see Methods). Patients on peritoneal dialysis, with gastric varices, or on immunosuppression were also once considered not to be candidates for PEG. However, successful placement has been accomplished in all these patients with careful preparation and rigorous adherence to excellent technique.

Inability to transilluminate the abdominal wall, usually because of morbid obesity or the presence of an intervening structure between the stomach and the abdominal wall, is another scenario that requires caution. Endoscopic and transabdominal ultrasound have been used to ensure that no intervening structures are present and to guide the passage of a spinal needle through a thick abdominal wall [41]. Alternatively, a cut-down through the skin and subcutaneous tissue under local anesthesia has been used in an obese

patient so that fascia could be visualized and a PEG tube safely placed [42]. The safe tract technique described by Foutch has been advocated as more important to the safe placement of a PEG tube than transillumination, especially with modern endoscopes that use lower levels of light intensity for visualization [43]. Without these additional maneuvers, however, the inability to transilluminate the abdominal wall is a contraindication to PEG tube placement.

Other situations where PEG tube placement should be performed with caution include prior surgery, distended loops of small bowel, presence of a ventriculoperitoneal shunt, or severe cardiac disease. Previous abdominal surgery is not a contraindication to PEG tube placement if there is meticulous adherence to the details of the procedure, including transillumination of the abdominal wall [44]. As described above, a safe tract should be identified in these patients by looking for aspiration of air from only the stomach during passage of the angiocatheter [45]. These same principles apply when treating a patient who has distended loops of small bowel. The presence of a ventriculoperitoneal shunt is not a contraindication to PEG tube placement as long as care is taken to avoid the catheter [46]. A preprocedure abdominal radiograph can be helpful. Severe underlying heart disease increases the risk of major complication in PEG tube placement, possibly related to use of intravenous sedation [47]. However, Cappell and Iacovone have shown that a PEG tube can be safely placed within 1 month following myocardial infarction if it is considered essential and the patient is otherwise stable [48]. Severe malnutrition has been identified as a risk factor for complications from PEG tube placement [49]. A serum albumin of less than 3 g/dL is an independent risk factor for 30-day mortality in hospitalized patients. Although these data have not resulted in the use of minimum serum albumin level as a selection criterion for PEG candidates in most institutions, it does warrant careful counseling of the patient and referring physician as to the potential for complications following PEG tube placement in severely malnourished patients.

Complications

Large cumulative retrospective studies have reported that 10%–16% of both adult and pediatric patients have at least one complication following PEG tube placement [50]. The overall mortality rate is 1%, with a major complication rate of 3% and a minor complication rate of 13% [51]. This section reviews the most commonly encountered complications.

Wound infections

Wound infections account for up to 30% of all minor complications. These are caused by multiple organisms, but most commonly by *S. aureus* and β-hemolytic streptococci. Gossner and colleagues [12] have shown that a single prophylactic dose of cefazolin covers 72% of the organisms encountered in PEG infections and will reduce the rate of infection following PEG placement from 28.6% to 7.4%. In contrast, cefoxitin is only effective against 33% of the organisms encountered. Infection usually becomes evident as erythema around the gastrostomy tube site several days after the procedure, with local tenderness and slight edema of the skin. The patient often demonstrates a low-grade fever and leukocytosis. Early recognition and incision and drainage of the area under local anesthesia frequently resolves the problem. Failure to identify and treat this problem at an early stage can result in necrotizing infections of the abdominal wall and death. Necrosis of the tissue of the abdominal wall that is interposed between the head of the tube and the outer bolster may play a major role in the occurrence of infection at a PEG site. Excessive tension applied to the bolster acts as a tourniquet, producing ischemia of the underlying tissue. Loose contact is all that is required between the outer bolster and skin. If a dressing is required, it should be placed over the bolster, not under it, for the same reason. It is a good idea to begin systemic antibiotics for all infections around the tube and to continue them until the infection is resolved. Also, an adequate skin incision in the abdominal wall has been advocated to allow room around the gastrostomy tube for the egress of bacteria. However, experience with incision omission PEG has called into question the validity of this tenet for reducing PEG site infections (see Methods).

Buried bumper syndrome

Extrusion of the head of the tube from the gastric lumen into the subcutaneous tissue (the buried bumper syndrome) has been encountered. This is almost certainly caused by excessive tension applied to the tube. To prevent leakage of gastric contents and ensure adhesion of the stomach to the abdominal wall, the physician may pull up on the gastrostomy tube and push downward on the outer bolster. Although this fixes the stomach to the abdominal wall, it also produces ischemia of the intervening abdominal wall tissue, with subsequent necrosis. This can be avoided by ensuring that no tension is present when the head of the catheter is placed in contact with the gastric mucosa and that the outer bolster only loosely approximates the skin. Such approximation of the gastric and abdominal walls results in satisfactory adhesion without tissue necrosis.

Leakage or inadvertent early removal

Leakage of feedings into the peritoneal cavity may occur after percutaneous gastrostomy. This is usually the result of separation of the gastric and abdominal walls and is often due to necrosis of the abdominal wall tissue caused by excessive tension on the catheter. Patients who develop abdominal tenderness, fever, or leukocytosis should be evaluated for leakage and the resultant peritonitis. This may be done by instilling water-soluble contrast material into the gastrostomy

tube under fluoroscopic guidance. Intraperitoneal extravasation indicates that something has gone awry. If the contrast study results indicate that the head of the tube remains in the stomach and that the extravasation is around the tube, the clinician may pull up on the tube, providing a bit more tension to seal the leak, and place the tube to drainage; intravenous fluids and antibiotics should be administered. If the contrast study results reveal complete separation of the gastric and abdominal walls with dislodgement of the tube from the stomach, the tube should be pulled from the abdominal wall, a nasogastric tube inserted to effect gastric drainage, and intravenous fluids and antibiotics begun. A patient whose PEG tube has been pulled out inadvertently less than 2 weeks from the time of insertion should be treated similarly. If at any time the patient's condition begins to deteriorate or signs of peritonitis worsen, exploratory laparotomy or laparoscopy with operative repair should be performed.

Gastrocolic fistula

Gastrocolic fistula has rarely been known to occur after percutaneous gastrostomy. This type of fistula may be caused by puncture of the colon at the time of gastrostomy or pinching of the colon between the gastric and abdominal walls with subsequent necrosis of the colonic wall and fistula formation. This complication usually becomes apparent after several weeks, with the development of severe diarrhea following feedings. It may be documented with an upper gastrointestinal series or barium enema. In nearly all cases, the condition may be treated by removing the gastrostomy tube. The fistula closes rapidly once the tube is removed.

Progressive enlargement of gastrostomy stoma

Progressive enlargement of the gastrostomy stoma around the gastrostomy tube may occur in some patients. Although this, too, may be the result of excessive tension on the tube, it is also occasionally seen in patients in whom the gastrostomy tract is well established. Poor nutritional status may play a part in the development of this problem, as may excessive movement of the tube at the skin level. The temptation in addressing this problem is to remove the gastrostomy tube and replace it with a larger one that fills the hole. This solves the problem for a short time, but the tract soon enlarges again. A better solution is to remove the tube entirely and allow the tract to close. After it has closed a bit, a new smaller tube may be inserted. Also, minimizing movement at the skin by securing the tube properly or placing it through a baby bottle nipple or a similar stabilizing device is effective.

Pneumoperitoneum

Pneumoperitoneum is a frequent occurrence after percutaneous gastrostomy. This may be the result of air escaping around the puncturing needle. Routine radiographs of the abdomen are unwarranted. Air in the abdominal cavity has been shown to last for up to 5 weeks after PEG tube placement. Patients found to have pneumoperitoneum after gastrostomy must be clinically evaluated. In the absence of abdominal tenderness, leukocytosis, or fever, there is no need for further evaluation. However, the patient who demonstrates any of these should be evaluated with a water-soluble contrast study through the gastrostomy tube for signs of separation or intraperitoneal extravasation. One case was reported of tension pneumoperitoneum during PEG tube placement causing hemodynamic compromise, but this is exceedingly rare [52].

Neoplastic seeding to the abdominal wall

Neoplastic seeding to the skin from both oropharyngeal and esophageal cancers has been reported following PEG tube placement [53]. If the gastrostomy is being placed for palliation, this may not be an issue. However, if placement is part of the patient's therapy, as in preparation for neoadjuvant radiation therapy for esophageal carcinoma, then this must be considered. The mode of tumor spread to the abdominal wall remains controversial, but direct inoculation from disruption of the tumor by instrumentation at the time of PEG tube placement seems most likely. This hypothesis is supported by the observation that metastasis of head and neck cancer to the skin rarely occurs spontaneously and that abdominal wall metastasis following PEG tube placement has only been observed using the pull technique [54]. The incidence of such metastasis is low (< 1%), but ominous since the average survival after development is 7 months and the 1-year survival is zero [55]. Given this fact there may be advantages to using an introducer technique in this setting.

Aspiration

Aspiration with the development of pneumonitis or pneumonia is a potentially major complication of PEG tube placement, occurring either at the time of insertion or afterward during feeding. It is associated with a very high mortality. In an effort to minimize this risk, some have advocated placing feeding tubes further down the gastrointestinal tract either via the PEG tube (percutaneous endoscopic gastrojejunostomy, PEG/J) or directly as a percutaneous endoscopic jejunostomy (direct PEJ). There has been controversy regarding the efficacy of this technique, but prospective data have shown that the incidence of gastroesophageal reflux and aspiration significantly reduces as the level of infusion descends from the stomach down through the first, second, and third portions of the duodenum [56]. Heyland and colleagues also showed in a metaanalysis of seven studies that shifting the level of infusion of tube feeds from the stomach to the small bowel was associated with a 24% reduction in aspiration pneumonia [57].

Stoma problems

Good skin care is important after gastrostomy. It is common to see a foreign body reaction around the tube with some

exudate or granulation tissue. This is usually easy to treat. The exudate is merely swabbed away with hydrogen peroxide. The site should be left open to the air. Granulation tissue may be cauterized with silver nitrate. Occlusive dressings should be avoided because they lead to maceration of the underlying skin.

Feeding

Once the PEG tube has been placed without complication, the next issue is how to feed through it. Intermittent feeding is preferred because it is easy to administer (no pump required), well tolerated, and physiological. The formula is allowed to flow in by gravity over a period of 30–60 min. Rapid bolus feeds should be avoided because they decrease lower esophageal sphincter pressure to incompetent levels and are associated with free gastroesophageal reflux. Patients should be placed in a semirecumbent position to reduce the risk of aspiration. Most endoscopy units start feeding 24 h after PEG tube placement with the initiation of a continuous infusion of water at 50 mL/h. Once this has been tolerated for 4 h, the infusion of a full-strength polymeric formula is begun at 50 mL/h and advanced by 25 mL/h every 12 h as tolerated until the goal rate is reached. This method is anecdotal, however, and some clinicians have demonstrated that a continuous infusion of full-strength formula at 30 mL/h can be safely initiated only 3 h after PEG tube placement [58]. The choice of formula is based on the patient's caloric needs, tolerance, and associated medical conditions. Residual volumes are often checked on a regular basis until tolerance of the regimen has been demonstrated. This practice is controversial, however, and McClave and colleagues have shown a poor correlation between gastric residual volume and risk of aspiration even at volumes greater than 400 mL [38]. In addition, tubes smaller than 10Fr in size have been shown to be unreliable for the determination of residual volume [59].

Endoscopic jejunostomy

Endoscopic jejunostomy is a modification of PEG intended to accomplish feeding into the jejunum. There are two methods. The first places the jejunal feeding tube through the gastrostomy tube (PEG/J). This method is similar to that of PEG, with the gastric tube acting to anchor the apparatus and decompress the stomach while a longer enteric tube is passed through the PEG and positioned in the distal duodenum or proximal jejunum [60]. The advantage of this system is that use of the PEG to gain access to the gastrointestinal tract minimizes the risk of traversing another loop of intestine during placement as well as leakage from around the tube or inadvertent displacement of the tube tip from within the jejunal lumen. The disadvantage of this system is that correct placement of these tubes has proved difficult. Traditionally, a suture is attached to the tip of a jejunal tube prior to passing it through the PEG and into the stomach. The suture is grasped with a biopsy forceps loaded through the endoscope and dragged under direct vision into the duodenum. Deep passage is often impossible, however, and the tube frequently drags back into the proximal duodenum or stomach during removal of the endoscope. A pediatric colonoscope or enteroscope may be used to ensure passage of the jejunal tube into the distal duodenum or proximal jejunum. More recently, various guidewire techniques have been described to assist in placement. Duckworth and colleagues [61,62] have described passing a guidewire through a 24Fr PEG tube and grasping it with a biopsy forceps passed through the endoscope. The wire is dragged under direct vision into the distal duodenum or proximal jejunum. While still holding it with the forceps, tension is applied to the free end of the wire to straighten it. A 12Fr jejunal feeding tube is then passed over the wire. The endoscope is removed by a rocking motion followed by removal of the guidewire. Tube placement is confirmed by abdominal radiograph. An initial placement success rate of 100% has been reported, but there is a 20% long-term tube failure rate due to malpositioning or occlusion. Chaurasia and Chang have described passing a pediatric bronchoscope through the PEG and into the distal duodenum to gain access to the bowel [63]. A wire is passed through the scope and guided beyond the ligament of Treitz using fluoroscopy. The jejunal feeding tube is then passed over the wire and into position. Finally, Leichus and colleagues [64] have described passing the endoscope into the stomach and through an open polypectomy snare that has been passed into the stomach via the PEG. The tip of the endoscope is placed in the distal duodenum and a guidewire passed through it and beyond the ligament of Treitz. The wire is kept in position while the endoscope is withdrawn, leaving the peroral wire to be grasped at the intragastric segment by the trans-PEG polypectomy snare. The snare is pulled so that the oral end of the wire is retrieved from the PEG. A jejunostomy tube is then passed over the wire and into position confirmed by fluoroscopy.

To overcome some of the placement difficulty with PEG and PEG/J systems, Shike and colleagues [65] described placing a feeding tube directly into the jejunum using a similar technique to that of PEG (direct PEJ). This was initially used only in patients with partial or total gastrectomy but has subsequently been used in patients without gastric resection. Such placement may require use of a push enteroscope or pediatric colonoscope, and fluoroscopic guidance is useful. When successful, this procedure obviates the problem of tube migration and ensures placement beyond the ligament of Treitz. It is also easier to place larger-caliber tubes that are less likely to fail from occlusion. When used in combination with a PEG, better decompression of the stomach can be obtained

because the PEG tube is not partially occluded by the PEG/J system. There is a greater potential for complications, however. The mobility of the jejunum and the higher likelihood for intervening structures between it and the abdominal wall make strict adherence to technique mandatory. The thin wall of the jejunum is also more likely to allow leakage of enteric contents around the tube. Finally, the direct PEJ tube can act as a "maypole" around which the small bowel can twist and obstruct.

The proposed advantage of jejunal feeding is a decrease in the risk of aspiration. Whether this is a true benefit is controversial, with early studies failing to demonstrate an advantage over PEG. Many of these studies were small and the tip of the jejunal tubes were often only in the proximal duodenum. Later studies have confirmed placement of the tube into the distal duodenum or proximal jejunum using an over-the-wire technique and have demonstrated virtual elimination of aspiration associated with feeding [61].

The indications for PEG/J or direct PEJ are tracheal aspiration, reflux esophagitis, gastroparesis, insufficient stomach from previous resection to perform PEG placement or to tolerate gavage feeding, or enteral access in patients with partially obstructing lesions from gastric or pancreatic carcinoma.

Removal and replacement of PEG tubes

PEG tubes may require replacement when the tube has become frayed, obstructed, or develops a leak. Additionally, in some patients, an enlarging stoma may be the result of excessive tube motion at the skin level. In such cases, removal and replacement with a skin-level device may be advantageous. Elective tube removal should not be performed until a secure tract has formed, usually at least 10 days to 2 weeks from the time of insertion.

When PEG tubes are inadvertently removed prematurely, peritonitis is a threat. If discovered immediately, such patients can often be treated with nasogastric suction and intravenous administration of antibiotics. With close observation and steady improvement, the PEG may be repeated in about 1 week. Should the patient demonstrate signs of peritonitis or sepsis, urgent laparotomy is indicated.

All currently manufactured PEG tubes have deformable or partially deflatable internal bolsters that allow for removal by means of external traction without the need for endoscopy [66]. Some have advocated cutting the tube at skin level and letting the internal bumper pass spontaneously. In adults this is associated with a relatively low risk of complication [67], but in children there is a particularly high risk of small bowel obstruction, retained internal components, or perforation and the internal bumper should be removed with the endoscope [68].

Although PEG tubes may be replaced with balloon tip catheters, the balloons generally last only a short time and these tubes have been known to migrate and obstruct the pyloric channel. Use of a mushroom-tip catheter or a skin-level device is preferable. Gauderer and colleagues developed the concept of a skin-level gastrostomy device [69]. This device has an antireflux valve that permits a cosmetic solution to gastrostomy feedings. It may be placed after removal of a previous gastrostomy tube or at the time of the creation of the initial PEG. A standard tube is often preferable to the skin-level device in patients who require custodial care because it is more easily accessed by nursing personnel.

Conclusion

Percutaneous gastrostomy is a simple procedure with significant advantages over open gastrostomy and few severe complications. Proper patient selection, close attention to detail during placement, and rapid assessment of potential problems minimizes unsatisfactory outcomes.

Gastroesophageal variceal bleeding is an unpredictable complication of portal hypertension with an associated mortality of 20%–40% with each bleeding episode in patients with cirrhosis [1,2]. About one-third of all deaths in patients with cirrhosis can be directly attributed to acute variceal bleeding. The mortality can be minimized by effective primary prophylaxis in high-risk subjects, optimal management of acute bleeding, and universal secondary prophylaxis after the index bleed. This chapter will briefly discuss the anatomy of the portal venous system and pathophysiology of portal hypertension, and discuss in more detail the prevention and management of upper gastrointestinal bleeding secondary to portal hypertension.

Portal venous anatomy and physiology, and causes of portal hypertension

The anatomy of the portal venous system is shown in Fig. 124.1. The portal vein (PV) is about 5 cm long and formed behind the neck of the pancreas by the confluence of the splenic vein (SV) and superior mesenteric vein (SMV). The inferior mesenteric vein drains into the SV before the confluence of SV and SMV. The left gastric vein (also known as the left coronary vein) and right gastric vein (the smaller of the two) usually drain into the PV immediately after the confluence of the SV and SMV, but they may also drain at the confluence or into the SV. The short gastric vein, which drains the fundus of the stomach, enters the spleen above the origin of the SV. Usually remnants of the umbilical vein drain

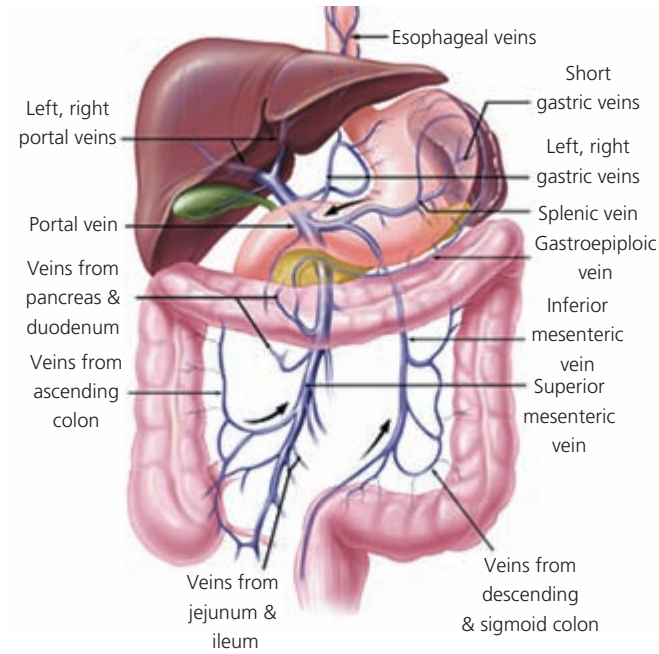

Figure 124.1 Anatomy of the portal venous system.

into the left portal vein and cystic vein from the gall bladder communicate with the right portal vein. About 70% of blood flow into the liver is through the portal vein and the rest comes from the hepatic artery. Three hepatic veins drain blood away from the liver into the inferior vena cava (IVC), but the caudate lobe drains directly into the IVC. The blood vessels near the cardia of the stomach are drained by the azygos vein. Normal azygos blood flow is between 150 and 200 mL/min, but this increases significantly in the presence of portal hypertension.

Normal PV pressure is 5–10 mmHg, and the gradient between PV and IVC is 1–5 mmHg. Under physiological

conditions, hepatic sinusoids have tremendous compliance and will maintain the pressure within these ranges even when the blood flow increases significantly. Portal hypertension is diagnosed when the portal venous pressure gradient (difference between PV and IVC pressure) is elevated above 5 mmHg. However, complications of portal hypertension usually do not occur until the pressure gradient is above 10 mmHg.

Portal hypertension occurs for a variety of reasons, but the most common cause is cirrhosis. In the majority of patients with cirrhosis, the resistance to flow is at the sinusoidal level. Portal hypertension may also occur due to portal vein occlusion or compression (presinusoidal) or due to obstruction in hepatic veins or the suprahepatic IVC (postsinusoidal). The common causes of portal hypertension are shown in Table 124.1. In primary biliary cirrhosis and schistosomiasis, the resistance is predominantly at presinusoidal level. Worldwide, schistosomiasis is a common cause of presinusoidal portal hypertension. This is caused by a granulomatous inflammation in response to the eggs laid by *Schistosoma mansoni* or *S. japonicum* in the presinusoidal portal venules. Idiopathic portal hypertension, common in Asia, is also presinusoidal. It is important to note that presinusoidal portal hypertension cannot be assessed indirectly by measuring the hepatic venous wedge pressure gradient (HVWPG). Rare causes of portal hypertension include nodular regenerative hyperplasia, congenital hepatic fibrosis, hereditary hemorrhagic telangiectasia (Fig. 124.2), and splanchnic arteriovenous fistula.

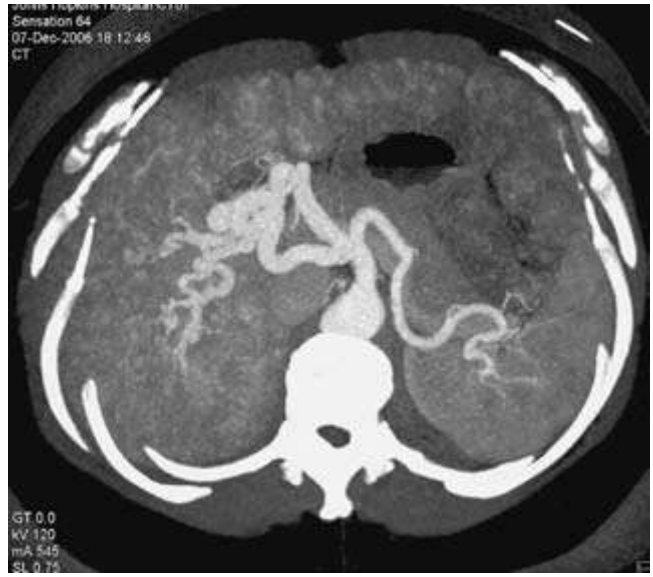

Figure 124.2 3D CT scan of a patient with hereditary hemorrhagic telangiectasia.

Portal venous imaging and measurement of portal pressure

The portal vein can be imaged in many ways, including ultrasound with Doppler, three-dimensional computed tomography (3D-CT) scan (Fig. 124.3), magnetic resonance imaging (MRI), endoscopic ultrasound (EUS), and angiogram. Of these, ultrasound with Doppler is commonly used to assess PV and hepatic vein patency. However, this investigation is decidedly operator dependent. A CT scan along with 3-D construction is a valuable test to assess liver parenchyma, liver masses, PV patency, splenic size, and to some degree the severity of collaterals. A magnetic resonance venogram (MRV) or angiograms are performed only when a firm assessment cannot be made by other methods.

Measurement of portal pressure is not performed routinely in clinical practice. However, it is an extremely valuable test to assess the risk of variceal bleeding. Portal pressure can be measured by direct puncture (transhepatic) or by a trans-

Figure 124.3 3D CT scan is a sensitive and reliable way to assess portal venous anatomy.

jugular intrahepatic route. Direct measurement is preferred only when presinusoidal portal hypertension (PHTN) or portal vein stenosis is suspected. In clinical practice, portal pressure is assessed indirectly by measuring hepatic venous wedge pressure (HVWP), where a balloon catheter (it can also be done by wedging a catheter into a hepatic vein) is passed into the hepatic vein and the balloon inflated to create a stationary and continuous column of fluid between the hepatic vein and the sinusoids. Total occlusion is confirmed by injection of contrast into the occluded hepatic vein. Free hepatic venous pressure (FHVP) is then measured by deflating the balloon. The difference (HVWPG) between HVWP and FHVP (HVWPG = HVWP – FHVP) is equal to the portal venous pressure gradient (portal pressure minus intraabdominal IVC pressure).

Studies have consistently shown that the risk of variceal bleeding is low (rarely gastric varices may be an exception) when HVWPG is less than 12 mmHg. Reduction of HVWPG below 12 mmHg or a 25% reduction from baseline significantly reduces the risk of variceal bleeding [3,4].

Pathophysiology of portal hypertension

The pathophysiology of portal hypertension is complex and incompletely understood despite the advances in our knowledge at the molecular level. Portal pressure is dependent on portal blood flow and resistance to portal venous flow (Ohm's law). In addition to the fixed defect caused by cirrhosis, the reversible contractile component in the hepatic vascular bed and the hyperdynamic splanchnic circulation, induced mainly by nitric oxide and to some extent by other local and systemic neurohumoral mechanisms, aggravate the portal hypertension and lead to complications including gastroesophageal variceal bleeding, ascites, hyponatremia, and hepatorenal syndrome [5–14]. A detailed discussion of the pathophysiology of portal hypertension and its complications is beyond the scope of this chapter, but important aspects are illustrated in Fig. 124.4 and briefly discussed here. Increased resistance to blood flow in the liver and increased splanchnic blood flow are two critical components of advanced portal hypertension.

The increased resistance in the liver in cirrhosis is due to "fixed" defects in the liver (including collagen deposition in the space of Disse, "capillarization" of sinusoids, thrombosis of portal venules, and compression of portal vein by large cirrhotic nodules), and increased, but potentially reversible, contractility of smooth muscle and hepatic stellate cells. The early event in the development of portal hypertension is chiefly mechanical obstruction caused by the "fixed" defects. The reversible contractile component in the hepatic vascular bed is important because this aspect may be amenable to pharmacological therapy. An imbalance between vasoconstrictors (endothelin-1, angiotensin, leukotrienes, norepinephrine [noradrenaline]) and vasodilators (nitric oxide, carbon monoxide, prostaglandins) may partly determine the resistance to portal venous flow within the liver by the effect of that imbalance on hepatic vasoregulation [6].

Although the collateral circulation decompresses the portal system in the early stages, it becomes inadequate with disease progression because of increased portal blood flow caused by changes in the splanchnic bed and the development of resistance in the collateral circulation. A hyperdynamic circulation, characterized by an increased cardiac output, markedly reduced systemic vascular resistance, and reduced mean arterial pressure, is a common cardiovascular manifestation of patients with cirrhosis and advanced portal hypertension [5,6,11]. The marked reduction in vascular resistance predominantly involves the splanchnic arterioles [5]. Local paracrine and autocrine vasodilators, including nitric oxide (perhaps most important), prostacyclin, and carbon monoxide, play a role in the pathogenesis of splanchnic vasodilation. It seems that nitric oxide (NO) is the most important mediator of splanchnic vasodilation [5,6,8–14]. Unlike in the hepatic circulation, NO is upregulated in the splanchnic bed. The precise events that lead to increased NO production remain unclear. Moreover, it is unclear whether increased NO production precedes or develops as a consequence of the hyperdynamic circulation. The activation of nitric oxide synthase (eNOS) in the endothelial cells is multifactorial and may include mechanical stimuli such as "shear stress" and other stimuli, including vascular endothelial growth factors, endotoxemia, or inflammatory cytokines including tumor necrosis factor-α (TNF-α). These stimuli may result in increased NO production through pathways that include eNOS phosphorylation and interaction with other proteins. Although our understanding of these pathways is incomplete, the

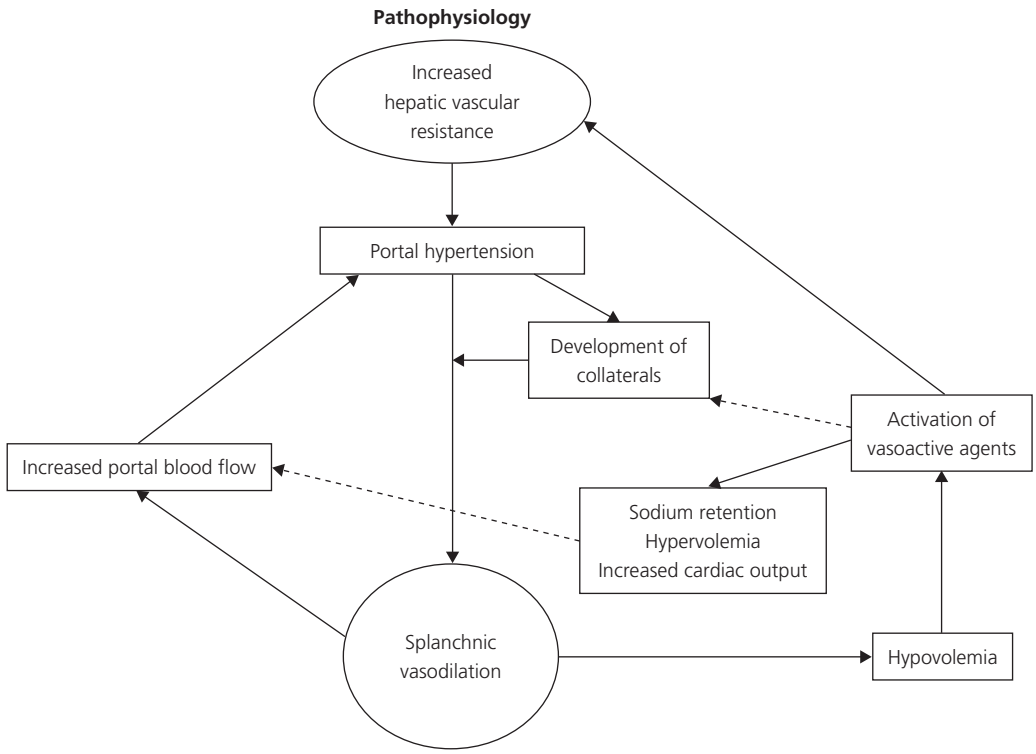

Figure 124.4 Pathophysiology of portal hypertension.

accumulating circumstantial evidence favors a key role for NO in the pathogenesis of splanchnic vasodilation in patients with advanced cirrhosis and portal hypertension [8–13,15,16]. Other alleged factors that contribute to the splanchnic vasodilation include increased levels of circulating vasodilators such as prostacyclin (prostaglandin I-2, PGI-2), vasoactive intestinal peptide (VIP), anandamide (an endogenous vasodilatory cannabinoid), substance P, platelet-activating factor, and glucagon [17–19]. Endogenous vasodilators, PGI-2 and PGE-2, counterbalance the vasoconstrictor effects of angiotensin-II, norepinephrine, vasopressin, and the augmented sympathetic tone to maintain renal blood flow and glomerular filtration rate (GFR). Increased vascular synthesis of prostacyclins contributes to increased circulating levels of prostacyclin; however, the vasodilating effect of prostacyclin is probably localized to the vascular bed where it is synthesized. Endotoxemia may be a causative factor for increased prostacyclin levels [18]. In contrast to increased systemic prostacyclin, renal prostaglandin synthesis decreases with advanced liver disease, which may contribute to the marked renal vasoconstriction found in the hepatorenal syndrome. For this reason, use of nonsteroidal antiinflammatory drugs (NSAIDs) is discouraged in patients with cirrhosis.

Experimental evidence has shown that when one of the vasoactive mediators, such as NO or prostacyclin, is inhibited, other vasoactive pathways are upregulated thereby preventing the correction of the splanchnic vasodilation. The complex relationship among these vasoactive systems implies that no one factor is likely to be solely responsible for the splanchnic vasodilation seen in patients with portal hypertension. Despite our increased understanding of the pathogenesis of portal hypertension, we have not been able to develop effective pharmacological agents to manage portal hypertension and its complications because of the complex relationship of the vasoactive system, as discussed above. However, this understanding has helped us to explore various pharmacological options, and hopefully we will see significant progress in this field in the coming decade. Drugs used for the management of portal hypertension include nonselective β-blockers, isosorbide mononitrate (ISMN), somatostatin (and its analogue octreotide), and vasopressin (and its analogue Glypressin). Drugs undergoing evaluation include angiotensin receptor blockers. Isosorbide mononitrate (which acts as a NO donor) and potentially angiotensin receptor blockers reduce intrahepatic resistance, whereas other drugs mainly reduce portal inflow. Somatostatin may also act by inhibiting endothelin-1-dependent hepatic stellate cell contraction. Octreotide and β-blockers may constrict collateral vessels. The mechanism of action of these drugs is discussed in more detail later in this chapter. The remainder of this chapter will focus on the management of gastrointestinal bleeding secondary to portal hypertension.

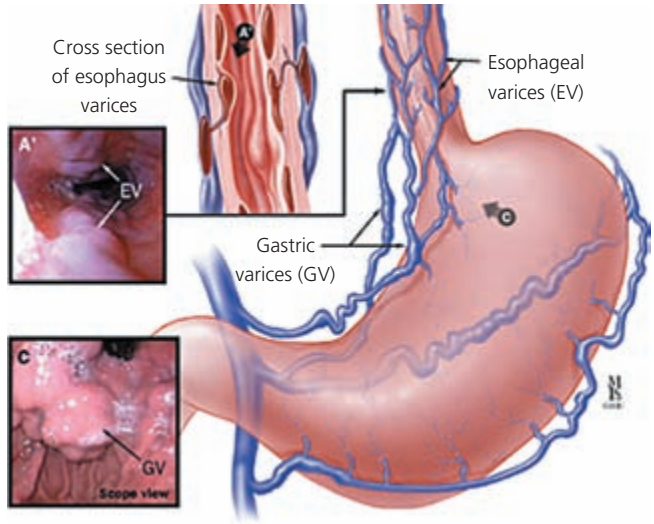

Figure 124.5 Collateral circulation in portal hypertension.

Figure 124.6 MRI showing large fundal varices.

Gastroesophageal varices

Varices are seen mainly at the gastroesophageal junction (GEJ) largely because of the unique anatomy [20]. Four zones (gastric, palisade, perforating, and truncal) of venous drainage are identified at the gastroesophageal junction. The *gastric zone* is 2–3 cm distal to the GEJ, and here longitudinal submucosal and lamina propria veins drain into short gastric and coronary veins. Most of the collateral circulation is seen between left and right gastric veins, and these collaterals appear as esophageal or gastric varices in continuation with esophageal varices (Fig. 124.5). Above this zone is the *palisade zone*, where veins appear more superficial with no communications between these veins and periesophageal veins that run parallel but outside the lumen. This zone extends for 2–3 cm and is the most common site for bleeding. Above this zone is the *perforating zone*, where there is an excellent venous plexus between submucosal and periesophageal veins. Bleeding is less common here, but these perforating veins continue to feed submucosal veins, which may explain why varices recur after band ligation or sclerotherapy. The *truncal zone* extends for another 10 cm as longitudinal veins with excellent venous connections with periesophageal veins. The endoscopic treatment of varices is mainly aimed at obliterating the varices in the palisade zone and to some extent the perforating zone.

In addition to gastroesophageal varices, large varices can also be seen in the retroperitoneum, rectum (collaterals between the IMV and pudendal vein), around the umbilicus (collateral between the remnant of the umbilical vein and left portal vein), and around the ileostomy stoma (as in patients with primary sclerosing cholangitis). Rarely, varices are seen in the colon, small intestine, and duodenum.

In cross-sectional studies, gastroesophageal varices were seen in only one-third of patients with cirrhosis, with a higher prevalence in those with decompensated cirrhosis. In a longitudinal surveillance study, only 31% (83/265) patients with primary biliary cirrhosis developed varices during a median follow-up of 5.6 years [21]. In this study, serum bilirubin and histological staging were independent predictors for the development of varices, and among those who developed varices, 1-year and 3-year bleeding rates were 33% and 41%, respectively.

Gastric varices

The prevalence of gastric varices in published reports varies from 6% to 16%, and the incidence appears to increase after esophageal variceal obliteration. Gastric varices are usually seen in association with esophageal varices or, rarely, in isolation as in splenic vein thrombosis (segmental portal hypertension). The gastric varices may be seen as a continuation of esophageal varices along the lesser curve or in the fundus, or as isolated varices in the fundus or antrum. Lesser curve varices are formed by the deep submucosal veins that arise from the left gastric vein. Fundal varices develop from the short gastric or posterior gastric veins; direct anastomotic veins between gastric and retroperitoneal veins also may be involved. These varices can be readily seen on 3D-CT scan or MRI as large collaterals (Fig. 124.6).

Ectopic varices

Ectopic varices other than rectal varices are rare, and generally occur in the duodenum, ileostomy stoma, small intestine, colon, or rectum. Duodenal and stomal varices are more often seen in portal vein thrombosis. Rectal varices are commonly seen in patients with cirrhosis, but bleeding is uncommon. Rectal varices are dilated superior and middle hemorrhoidal veins (Fig. 124.7).

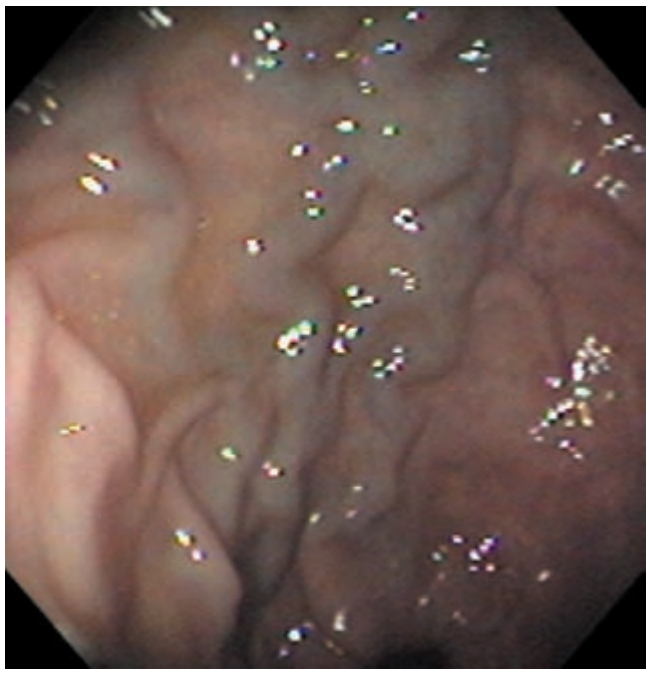

Figure 124.7 Rectal varices.

Risk of variceal bleeding and associated mortality

The evidence suggests that approximately one-third of patients with documented esophageal varices bleed within 2 years of the time of diagnosis. Bleeding from varices is an unpredictable complication of cirrhosis, with an associated mortality of 20%–40% with each bleeding episode [23–26]. A study has shown that in-hospital mortality of acute variceal bleeding has remained at around 20% since the mid-1990s despite advances in the management of acute variceal bleeding [2]. Many patients who survive the immediate post-bleeding period subsequently die from the complications of bleeding including sepsis, bacterial peritonitis, or renal failure. The mortality of variceal bleeding is directly related to the severity of liver disease, with a relatively low mortality in Child A patients (~ 10%–20%) and high mortality (~ 70%) in Child C patients [22–25] (Table 124.2). It is important to note that only one-third of all deaths in patients with cirrhosis can be directly attributed to variceal bleeding. This is an important consideration when the results of clinical trials are analyzed. Unfortunately many interventional studies have lacked the adequate sample size needed to show a difference in overall mortality or bleeding-related mortality. Nevertheless, these studies have helped us to define the management of these patients in a more objective manner.

The risk of bleeding from gastric varices is not well characterized, but the overall mortality from bleeding gastric varices exceeds 50%. In one study, 74 of 293 patients who presented to a center were found to have bleeding from gastric varices [26]. In other studies, the reported bleeding rates from gastric varices range from 14% to 36%. In one prospective study of fundal varices, 15/132 had previous variceal bleeding at the time of enrollment [27]. During follow-up, the cumulative risk of bleeding at 1, 3, and 5 years was 16%, 36%, and 44%, respectively. Large varices, red signs, and advanced liver disease were independent predictors of bleeding on multivariate analysis.

Bleeding from nongastroesophageal sites varies from 1.6% to 5% in the large reported series. The common ectopic sites, usually seen in association with esophageal varices, are

duodenum, colon, anorectum, and enterostomy. Rarely, these varices may be localized, especially in the colon, and result from superior or inferior vein thrombosis, tumor infiltration, adhesions, or congenital malformation.

Primary prophylaxis

The rationale for primary prophylaxis (prevention of first bleeding episode) is based on the high mortality associated with each variceal bleeding episode. The aim of primary prophylaxis is to treat high-risk patients with minimal complications. The treatment should be relatively cheap and effective, and should reduce bleeding-associated mortality and improve overall survival. In this section, we will discuss the risk factors for the first variceal bleed, the optimal treatment and its efficacy, and the cost-effectiveness of primary prophylaxis [28].

Endoscopic screening

It is difficult to show any benefit with primary prophylaxis in unselected patients with cirrhosis because of the low bleeding rates in patients without the risk factors for bleeding. Although β-blockers are considered effective in preventing the first bleed, studies in unselected patients with cirrhosis have failed to demonstrate any significant benefit with β-blockers. In a study where 319 "unselected" (not selected based on risk factors) patients with chronic liver disease were randomized to either propranolol or placebo, the overall incidence of bleeding within the first year was only 3.5% (11/319), with a similar incidence of bleeding in both groups [29]. The findings of this study emphasize the importance of endoscopic screening and staging of esophageal varices before primary prophylaxis because prophylaxis is likely to benefit only those with risk factors.

Independent risk factors that have been reported to predict the presence of esophageal varices include:

- elevated prothrombin time
- low platelet count
- splenomegaly
- portal vein (PV) diameter greater than 13 mm by ultrasound [30–33].

Based on these findings, it has been suggested that screening might be restricted to cirrhotic patients with a prothrombin activity less than 70%, a platelet count less than 100×10^9/L, splenomegaly, or ultrasonographic PV diameter greater than 13 mm [30–32]. However, the existing recommendation is screening for esophageal varices by endoscopy in all patients with cirrhosis because of the high mortality associated with variceal bleeding. The cost-effectiveness of such a strategy will be discussed later in this section. Patients who are unlikely to benefit from prophylactic therapies and those with low life expectancy may be excluded from screening [33]. When no varices or small varices without stigmata (low-risk varices) are found on initial screening endoscopy, repeat endoscopy is recommended every 2 years. A new development in this field is the use of capsule endoscopy for screening. Although small preliminary studies are encouraging, larger studies that are in progress will determine the sensitivity and specificity of this technique to diagnose and stage esophageal and gastric varices.

Staging of esophageal varices

Because only 30%–40% of patients with varices bleed in the first 2 years after the diagnosis of esophageal varices, it is important to identify the subgroup (those with risk factors) that is most likely to bleed and offer the most effective treatment to those patients [34]. Reproducible staging of varices is important for many reasons, including accurate description (common terminology), surveillance (reproducibility), treatment, and research (identify high-risk subjects) purposes. However, there are too many classifications described in the literature and many of them are subjective with significant intra- and inter-observer variation [34–37]. Based on the author's own experience, a minor modification of the Japanese Research Society for Portal Hypertension classification for staging varices is recommended for routine clinical purposes [35,38]. In this classification, esophageal varices are described by:

- the extent (distance from GE junction in cm)
- size (F0 – no varices; F1 – small and nontortuous; F2 – tortuous, but less than 50% radius; F3 – large and tortuous)
- color (blue or white)
- presence of red signs (red wale markings, cherry-red spots, hematocystic spots) (Fig. 124.8a,b).

Staging of gastric varices

Gastric varices are described by their location (cardia or fundus) and size (small and large) as well as whether they are in continuation with esophageal varices (Fig. 124.9). The most commonly used classification, described by Sarin et al. [39], divides gastric varices into four groups:

- GOV1 – when esophageal varices extend into the lesser curvature
- GOV2 – when esophageal varices extend into the fundus
- IGV1 – isolated fundic varices without esophageal varices
- IGV2 – isolated antral varices (Fig. 124.10).

Predictors of first variceal bleeding

Many risk factors have been identified as predictors of first bleeding in patients with esophageal varices. There is a general consensus that patients with advanced cirrhosis (Child B and C), large varices, varices with red signs (red spots, wale sign, hematocystic spot), and those with high portal pressure (HVWPG ≥ 12 mmHg) are more likely to bleed [34,35,40–42]. It has been shown that the risk of bleeding is higher with:

- proximal extension of varices (63% with the proximal third vs 26%% when seen only in the distal third)
- larger varices (F1, 15%; F2, 32%; F3, 68%)

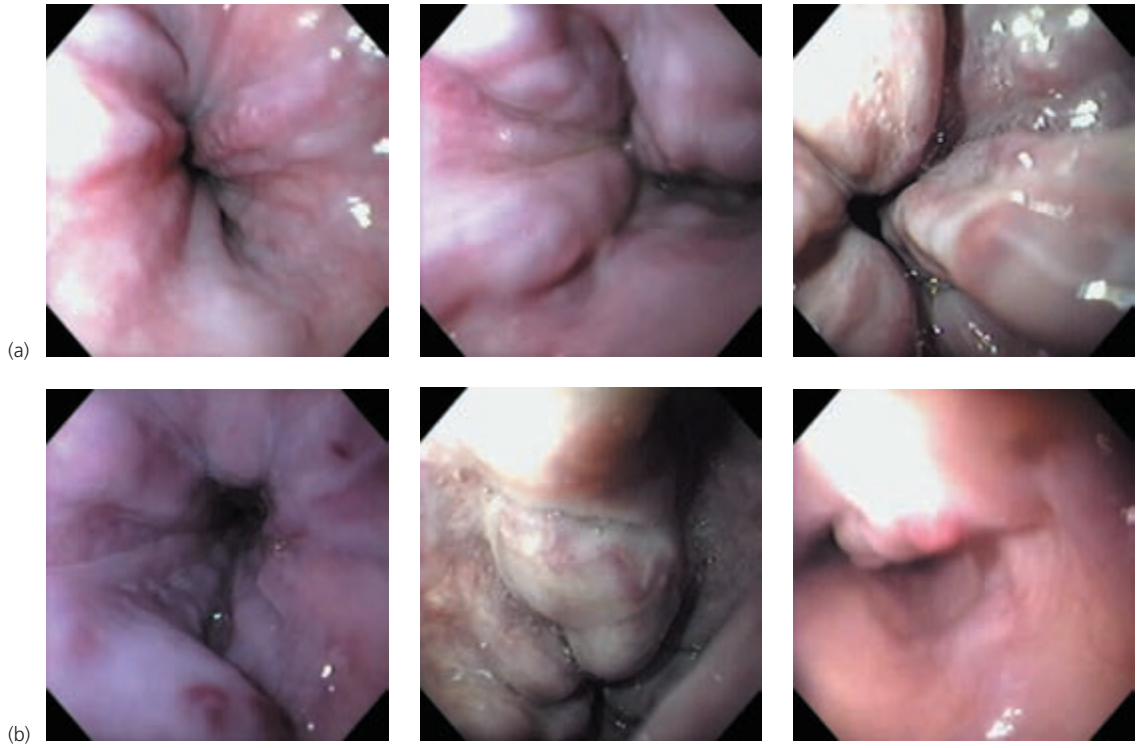

Figure 124.8 **(a)** Grading of esophageal varices based on their size. **(b)** "Red signs" of esophageal varices.

Figure 124.9 Small and large gastric varices.

- blue varices (80% vs 45% with white)
- red signs (76% vs 17% without)
- hematocystic spots (100% vs 49% when absent) [35].

Many studies have confirmed that HVWPG is directly related to the risk of bleeding [41–44]. It has been consistently shown that patients do not bleed if the HVWPG is less than 12 mmHg [41,43]. Pharmacological intervention studies have confirmed that the risk of bleeding is absent or markedly diminished (bleeding risk reduced by 80%) if the HVWPG is reduced below 12 mmHg or more than 25% below the baseline pressure respectively [1,3,42]. Other risk factors for variceal bleeding include continued alcohol use and hepatocellular carcinoma [34,45].

Therapeutic options for primary prophylaxis

In the 1960s, before the endoscopic era, a number of randomized, controlled surgical shunt trials were conducted for primary prophylaxis of variceal bleeding. Although these trials consistently showed a significant reduction in variceal and gastric mucosal bleeding in patients who had shunts, the

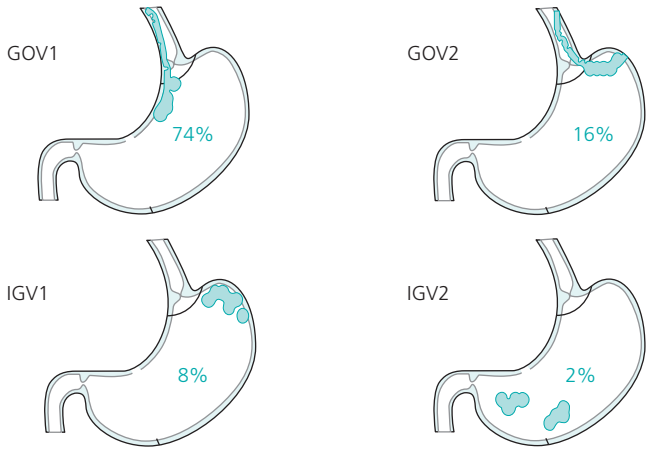

Figure 124.10 Sarin's classification of gastric varices.

mortality and the incidence of chronic hepatic encephalopathy were significantly higher in the shunted patients compared with the control group [46]. These poor results and the advent of endoscopy led to the abandonment of shunt surgery for primary prophylaxis. Esophageal transection with devascularization has been tried for primary prophylaxis. There is no convincing evidence to recommend this form of surgery for primary prophylaxis, and such surgery may make future liver transplantation technically more difficult. Transjugular intrahepatic portosystemic shunt (TIPS) has not been studied for primary prophylaxis, but based on secondary prevention trials; it is unlikely to be beneficial and may be even be detrimental [47]. On the basis of the evidence, there is no role for shunt, nonshunting surgery, or TIPS for the primary prophylaxis of variceal bleeding.

Sclerotherapy

Prophylactic sclerotherapy has been the subject of many small and large randomized controlled studies. Early reports claimed a reduced bleeding rate and improved survival in patients who had sclerotherapy compared with controls, but subsequent studies have not confirmed these results. A large multicenter trial ($n = 281$) involving men with moderate to severe alcoholic liver disease was terminated prematurely (after 22.5 months) because of higher mortality in the sclerotherapy arm compared with the sham therapy arm (32.2% vs 17.4%, $P = 0.004$) [48]. It has been argued that inclusion of patients with a lower risk of bleeding in these trials may have masked the benefits for patients who had a higher risk of bleeding. To test this hypothesis, a number of trials were conducted where only those patients with high risk of bleeding were enrolled. These studies also failed to show a consistent improvement in survival in the treated group compared with the control group. A metaanalysis of eight controlled studies showed that prophylactic sclerotherapy may reduce mortality by 11% (95% confidence interval [CI] 4%–19%) [49]. The results of this metaanalysis should be interpreted with caution because the difference was only marginal and the analysis included pooled data from heterogeneous studies [49,50]. The evidence suggests that, even in high-risk patients, the benefits from prophylactic sclerotherapy may be marginal and the procedure is not cost-effective.

β-Blockers

Nonselective β-blockers reduce portal pressure by reducing cardiac output, and by reducing portal inflow through antagonism of the β_2 receptors on the splanchnic vessels. β-Blockers also may increase portocollateral resistance and hence reduce collateral blood flow. Many trials have assessed the efficacy of nonselective β-blockers such as propranolol or nadolol for primary prophylaxis. Although some earlier studies did not show significant differences in bleeding rates in patients treated with propranolol [29,51,52], a majority of studies have shown that nonselective β-blockers reduced the risk of first bleeding by about 50% in patients with large varices [52,53]. Metaanalyses of these trials have also confirmed a benefit in the treated group with regard to bleeding (about 50% reduction) and mortality (25%–45% reduction) [46,53,54].

Patients with varices are unlikely to bleed if the HVWPG is maintained below 12 mmHg [42]. Unfortunately, with the available drugs this can be achieved only in a small group of patients. Unless a reliable noninvasive method is developed, it is difficult to justify repeated HVWPG measurements to determine whether or not a drug therapy is effective. So for all practices, the end point of treatment is to achieve a resting heart rate of less than 60 beats/min or a 25% reduction from the baseline heart rate. The major disadvantage of β-blockers is poor tolerance and compliance. Despite these limitations, the use of nonselective β-blockers is cost-effective and should be the treatment of choice for primary prophylaxis for patients with advanced liver disease and large gastroesophageal varices. Use of long-acting preparations, gradual increments in dose, and better patient education may improve the compliance. In patients with cirrhosis the practice is to continue administration of β-blockers indefinitely or until liver transplantation. Although there are no convincing data to support this strategy, a small study seems to indicate that the risk of bleeding returns to that expected in the untreated population when propranolol is discontinued [55].

It has been suggested that the hemodynamic response to β-blockers may predict the risk of subsequent bleeding. Merkel et al. measured the HVWPG before and 1–3 months after treatment with nadolol or nadolol plus ISMN in 49 patients with large varices and no previous variceal bleeding [56]. A good response – defined as a reduction in HVWPG to ≤ 12 mmHg ($n = 12$), or a reduction in HVWPG by more than 20% from baseline ($n = 18$) – was seen in 30 (61%) patients. During a follow-up of 5 years, seven (7/19) "poor-responders" and two (2/30) "good-responders" had variceal bleeding. The probability of bleeding at 3 years was 41% in

poor-responders and 7% in good-responders ($P < 0.001$). As in many previous studies, none of the 12 patients who had a reduction in HVWPG to ≤ 12 mmHg had variceal bleeding. Although this is perhaps the "optimal" treatment strategy and the best predictor of bleeding, the costs may be prohibitive for routine clinical care. In addition, the invasive nature of the process (twice in the same patient) may increase the risks and reduce the compliance.

An alternative strategy was tested in another study where HVWPG was measured before and 90 min after a single dose of 80 mg of propranolol in 33 patients [57]. Of the 22 patients who had a reduction in HVWPG equal to or greater than 20%, only one had variceal bleeding during a follow-up of 9–38 months, and none of the patients whose HVWPG was reduced below 12 mmHg had bleeding. Although this was a small study, if these results are reproduced in larger studies, a similar strategy could be recommended, provided cost is not an issue, to all patients with large varices before initiating primary prophylaxis with β-blockers. Those who do not show a reduction in HVWPG could then be offered alternative treatments.

The cost-effectiveness of measuring HVWPG has been examined in many studies using hypothetical models. Hicken et al. examined the role of HVWPG in patients with varices at risk for bleeding [58]. The authors compared three protocols:

- β-blocker therapy without measurement of HVWPG
- a single measurement 4 weeks after the initiation of treatment
- two measurements (one before and another 4 weeks after initiation of treatment).

Compared with the standard practice (no measurement of HVWPG), the incremental cost with one HVWPG measurement was $108 185 per bleeding prevented and $355 200 per death averted. The corresponding figures for two measurements of HVWPG were $202 796 and $719 300, respectively. Although these costs may not be a true reflection of real costs, nevertheless HVWPG may be prohibitive for routine use. Cheaper and less invasive techniques need to be developed to measure portal pressure for "optimal" and effective primary prophylaxis.

Nitrates

About one-third of patients with cirrhosis do not tolerate β-blockers because of side effects including hypotension and severe fatigue. Of the other vasodilators that also been studied for primary prophylaxis, nitrates have been the most promising. Although not clearly understood, it is thought that nitrates may reduce intrahepatic resistance by acting as a NO donor, and thereby relaxing the actively contracting hepatic stellate cells [59]. However, there is evidence to suggest that the response of stellate cells to NO may be impaired in cirrhosis [60]. Another study suggested that ISMN may act "by means of reflex splanchnic arterial vasoconstriction in response to vasodilatation in other vascular beds" [61].

Isosorbide mononitrate has been tried in patients for primary prophylaxis and the results have been mixed. In a double-blind, randomized, controlled trial, Garcia-Pagan et al. compared ISMN ($n = 67$) and placebo ($n = 66$) in 113 consecutive cirrhotic patients with varices who could not tolerate or had contraindications for β-blockers [62]. The variceal bleeding rate was similar at 1 year and 2 years in both groups. In multivariate analysis, presence of the variceal red sign was the only independent predictor of bleeding (relative risk 3.4, $P < 0.01$). Based on this study, the authors concluded that ISMN does not have any role for primary prophylaxis. Another study comparing ISMN with placebo found an increased mortality in patients above 50 years of age [63]. In addition, a tendency for ascites to increase in patients treated with nitrate monotherapy has been reported.

Endoscopic variceal band ligation

Primary prophylactic sclerotherapy failed to show any distinct advantage over no treatment because the benefits of sclerotherapy were negated by the local complications of sclerotherapy. Banding, with fewer local complications, was a logical alternative to sclerotherapy [64] (Table 124.3) (Fig. 124.11). Many studies have determined the role of endoscopic variceal ligation (EVL) for primary prophylaxis [65–72].

In a small study, Sarin et al. randomized 35 patients to banding and 33 to no treatment and found a lower bleeding rate in the banding group (3/35, 8.6%) compared with the no treatment group (13/33, 39.4%, $P < 0.01$) during mean follow-up of 14 months [65]. Although overall mortality was similar (11.4% vs 24.2%), there was a trend toward lower bleeding-related mortality in the banding group (2.9% vs 15.2%, $P = 0.08$). Another prospective, randomized trial comparing prophylactic EVL with no treatment found that EVL was associated with a significantly decreased risk of variceal hemorrhage and overall mortality [66]. In this study, EVL was more effective in Child A patients compared with those with decompensated disease (Child B and C). A prospective, randomized trial conducted in Taiwan found that patients with Child–Pugh class B cirrhosis and high-risk varices (F2 or F3 with red color signs) had a significantly lower risk of variceal bleeding than untreated patients [67]. In addition, a trend toward reduced mortality and less blood transfusion requirements was seen in patients undergoing banding. Apart from the small sample size, the major concern of these studies was the "no-treatment" arm because the standard of care for primary prophylaxis during the study period was β-blocker therapy, and one may consider that it was unethical to have a "no treatment arm" for such studies.

Band ligation has also been compared with sclerotherapy for primary prophylaxis of variceal bleeding; no difference in efficacy was found [68]. As in secondary prevention trials, band ligation required fewer sessions to eradicate varices in patients, but the recurrence rate of varices was higher in those treated with ligation.

Table 124.3 Complications of endoscopic treatment

Treatment	Common complications	Uncommon complications
Sclerotherapy	Retrosternal chest pain Ulcers Bleeding from ulcers Mediastinitis Transient dysphagia Stricture[b]	Esophageal perforation Bacterial peritonitis/sepsis[a] Motility disorder Portal/mesenteric vein thrombosis Aspiration pneumonia[a] Pleural effusion
Band ligation	Retrosternal chest pain Ulcers Transient dysphagia	Stricture Perforation Aspiration pneumonia[a] Bacterial peritonitis/sepsis[a] Bleeding from ulcers

a More common in acute variceal bleeding.
b Late complication.

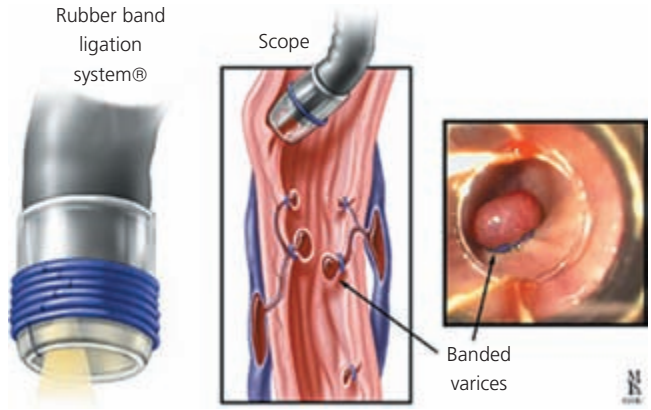

Figure 124.11 A cartoon showing esophageal variceal banding.

Because the "best available" treatment for primary prophylaxis was nonselective β-blockers, any new treatment modalities needed to be tested against that treatment. Sarin et al. addressed this by comparing banding to propranolol in a study (high-risk patients with large varices and red signs) where 44 patients were randomized to propranolol and 45 to endoscopic banding [69]. During a mean follow-up of approximately 14 months, 12 patients in the propranolol group and 4 in the ligation group had variceal bleeding, with an actuarial probability of bleeding of 43% in the propranolol group and 15% in the ligation group ($P = 0.04$). Three of four patients in the banding group experienced their first bleeding before varices were completely obliterated. The overall mortality and bleeding-related mortality were similar in both groups. In this study, 7 of 89 patients had noncirrhotic portal hypertension. Moreover, the study has been criticized for inadequate dosage of propranolol (mean propranolol dose was 70 mg vs 123 mg in other studies [46,52–54]). The higher bleeding rate in the propranolol group (43% vs 22% in other trials) may have been due to inadequate β-blocker dosage. Despite some of the criticisms and the small sample size, it was an important and provocative study that stimulated further research into the role of variceal banding for primary prophylaxis.

In a three-arm study, Lui et al. compared endoscopic banding ($n = 44$), propranolol ($n = 66$), and ISMN ($n = 62$) in 172 patients with grade II to III varices over a 6-year period [70]. During a mean follow-up of 20 months, by intention-to treat analysis, variceal bleeding occurred in 7% in the banding group, 14% in the propranolol group, and 23% in ISMN group. The 2-year actuarial risk of first bleeding was 6.2%, 19.4%, and 27.5%, respectively. The incidence of side effects was significantly greater in the propranolol (45%) and ISMN (42%) groups compared with the banding group (2%, $P < 0.001$), and this resulted in withdrawal of treatment for 30% of patients in the propranolol group and for 21% in the ISMN group. When patients were analyzed based on the treatment received, the actuarial bleeding rate was significantly different only between the banding and ISMN groups (7.5% vs 33%, log rank test $P = 0.03$), and there was no difference between the banding and propranolol groups [70]. A trial comparing band ligation and β-blockers in patients with large varices and a HVWPG greater than 12 mmHg was abandoned when investigators realized that they would require 424 patients in each arm to show a difference in bleeding rates between the groups [71]. Subsequently, a small study suggested that propranolol-treated patients had higher bleeding rates compared with those who were treated by banding [72]. Because the difference in bleeding rates between endoscopic therapy and β-blocker therapy for the prevention of first variceal bleeding is small, a large multicenter trial with an estimated sample size of 500 patients in each arm will be

required to demonstrate a statistically significant difference between these two treatment options [71].

A metaanalysis of 601 patients from five randomized controlled trials comparing banding with "no treatment" confirmed that banding reduced first variceal bleeding (relative risk [RR] 0.36, CI 0.26–0.5), bleeding-related mortality (RR 0.20, CI 0.11–0.39), and overall mortality (RR 0.55, CI 0.43–0.71) [73]. However, when banding was compared with β-blockers in 283 patients from four randomized trials, the only benefit with variceal banding was in the reduction of first variceal bleeding (RR 0.48, CI 0.24–0.96). Bleeding-related mortality and overall mortality were similar with banding and propranolol, suggesting that the role of variceal banding may be in patients who cannot tolerate β-blockers because of side effects, hypotension, or noncompliance.

If noninvasive, reliable methods for measuring portal pressure are identified, it will be appropriate to offer banding to those who fail to show significant reduction (< 25% reduction from baseline) in portal pressure with pharmacological therapy. However, methods of measuring HVWPG are not applicable or cost-effective for the majority of patients with large esophageal varices.

Combination treatment

Sclerotherapy plus β-blocker

Combination treatment with endoscopic sclerotherapy and β-blockers has not shown any advantage over β-blockers alone for primary prophylaxis. In one study, 86 patients with high intravariceal pressure (> 18 mmHg) were randomized to either propranolol alone ($n = 42$) or propranolol plus sclerotherapy ($n = 44$) [74]. There was a trend toward a higher bleeding rate (23%) in the combination group compared with those who received only propranolol (14%, P = not significant [NS]) during a median follow-up of approximately 24 months. There was a significantly higher complication rate in the combination group (52% vs 19%, $P = 0.002$), but mortality rates were similar (14% vs 18%, P = NS). Predictably, this study showed that there is no role for sclerotherapy in combination with β-blockers for primary prophylaxis.

β-Blocker plus isosorbide mononitrate (ISMN)

Although β-blockers reduced the risk of bleeding in patients with large varices, about 50% of patients who were on β-blockers experienced variceal bleeding. This was perhaps the result of a combination of factors including poor compliance, intolerance to maximal treatment, and, more importantly, inadequate reduction in portal pressure. Because it is not practical or cost-effective to monitor HVWPG before and after treatment with β-blockers to assess the treatment response, many investigators have studied the effect of a combination of β-blockers and ISMN. The combination treatment of nitrates with β-blockers has produced conflicting data.

In one study, Merkel et al. compared nadolol alone ($n = 74$) and nadolol plus ISMN ($n = 72$) in 146 patients with large esophageal varices [75]. Nadolol was started at 40 mg daily and increased every second day to achieve a 20%–25% reduction in resting heart rate. In the combination group, ISMN was started with nadolol, and the dose of ISMN was increased from 10 mg twice daily to 20 mg twice daily if patients could tolerate it. During a median follow-up of 30 months, 11 (11/74) from the nadolol-alone group and 4 (4/72) in the combination group had their first episode of variceal bleeding ($P = 0.03$ by Kaplan–Meier analysis). The cumulative risk of bleeding was 18% for the nadolol-alone group and 7.5% for the combination group. The mortality was not statistically significantly different (14/74 vs 8/72) between the groups, but there was a trend favoring the combination group. As a sequel to this study, the authors reported the long-term results (up to 7 years of follow-up) of the same cohort [76]. During the study period 16 patients in the nadolol group and 8 in the combination group had variceal bleeding ($P = 0.02$), with a cumulative bleeding risk of 29% and 12%, respectively. However, the mortality remained similar in both groups. By contrast, a multicenter, prospective, double-blind, randomized controlled trial ($n = 349$) comparing propranolol plus placebo ($n = 174$) to propranolol plus ISMN ($n = 175$) found no significant difference in the risk of first variceal bleed at 1 year (8.3% vs 5%) and 2 years (10.6% vs 12.5%) [77]. Moreover, there were significantly more frequent adverse side effects in the combination group secondary to a higher incidence of headache. These observations suggest that combination treatment of β-blockers plus ISMN is a reasonable option for primary prophylaxis if patients cannot tolerate maximal β-blockers. There is no role for routine combination treatment of β-blockers and ISMN for primary prophylaxis.

Nadolol plus spironolactone

Other drugs, including spironolactone, have been tried for primary prophylaxis. In one such study, combination therapy using nadolol plus spironolactone for primary prophylaxis of variceal hemorrhage did not show any additive effect [78].

Cost-effectiveness of screening and primary prophylaxis

There is overwhelming evidence to suggest that primary prophylaxis with β-blockers is beneficial in patients with cirrhosis and large varices with stigmata of imminent bleeding (Table 124.4). However, screening is not routinely performed in the majority of patients with advanced cirrhosis. In one study, only 46% of patients referred for liver transplantation to a tertiary center had either endoscopy or barium studies to assess the presence of esophageal varices [79]. We are unlikely to make a major reduction in the incidence of first bleeding without better use of screening and prophylaxis among the community of gastroenterologists. Although there are no rigid criteria, it has been suggested that all patients

with cirrhosis should have a screening endoscopy. If there are large varices, they should be offered prophylactic therapy. If varices are absent, they should have surveillance endoscopy every 2 years. If the varices are small, they should have repeat endoscopy every 1–2 years based on the severity of liver disease.

Many studies have examined the cost-effectiveness of primary prophylaxis for variceal bleeding. Using a Markov model, Teran et al. compared the cost-effectiveness of propranolol, sclerotherapy, and shunt surgery after stratifying patients by their risk of bleeding [80]. Whereas sclerotherapy had no advantage for quality of life, shunt surgery was associated with decreased quality of life. Propranolol was most cost-effective (cost saving $450–14 600 over a 5-year period) followed by sclerotherapy and shunt surgery.

In another study, using Markov modeling, Spiegel et al. examined whether it was cost-effective to treat all patients with cirrhosis without screening endoscopy [81]. The authors compared six different strategies:

- strategy 1: universal screening followed by β-blockers if there are varices
- strategy 2: screening followed by banding
- strategy 3: selective screening only in high-risk patients followed by β-blockers if varices are present
- strategy 4: selective screening followed by banding
- strategy 5: empirical β-blocker therapy in all patients
- strategy 6: no prophylactic therapy.

Cost estimates were from a third-party payer perspective and the outcome measure was the cost of first variceal bleeding prevented by the above six strategies. As expected, strategy 6 was the least expensive and, in comparison, the cost of strategy 5 was $12 408 per additional variceal bleeding prevented. Strategies 2 and 3 were most expensive ($175 000 per additional bleed prevented), whereas the costs of strategies 4 and 5 were in between. Based on this mathematical modeling, the authors recommended universal β-blocker therapy for all patients with cirrhosis. Another strategy that was not examined in this study is the use of screening endoscopy in only those who do not tolerate β-blockers.

Other investigators have also addressed the cost-effectiveness of screening and no prophylaxis or prophylaxis with either β-blockers or banding using Markov models [82,83]. Saab et al. recommended universal prophylaxis with β-blockers because it was associated with lower costs ($34 100) and higher quality-adjusted life years (6.5) [82]. By contrast, costs and quality adjusted life-years were $36 600 and 4.84 for "no prophylaxis" and $37 300 and 5.72 for screening and β-blockers for those with large varices. In another study, a Markov simulation model was created in two cohorts of 50-year-old patients with compensated or decompensated cirrhosis [83]. Four strategies were examined in this study:

- no screening or prophylaxis
- screening followed by β-blockers
- screening followed by banding
- universal prophylaxis with β-blockers.

In compensated cirrhosis, screening followed by β-blockers was cost-effective ($3605 per year of life saved), and in decompensated cirrhosis universal β-blockers was cost-effective ($1154 per year of life saved).

The results based on Markov models are sensitive to the prevalence of esophageal varices, risk of bleeding, and cost of endoscopy and primary prophylaxis. In the absence of clinical trials, I believe that it is premature to abandon screening or surveillance endoscopy before starting prophylactic β-blockers because of the high incidence of side effects associated with such therapy and the low risk of bleeding in patients with small varices [29]. Moreover, the awareness of the presence of large esophageal varices may improve compliance among the patients. In addition, the physician may offer alternative treatment (variceal banding) to the high-risk subjects who do not tolerate β-blockers. In future, less invasive tools such as capsule endoscopy may be used for screening if ongoing studies corroborate the excellent sensitivity and specificity shown in small preliminary studies.
