Ductal adenocarcinoma of the pancreas

Nonendocrine tumors of the pancreas cover a wide spectrum of pathologies, including solid tumors (adenocarcinoma, acinar cell carcinoma) and cystic tumors (serous cystadenoma, mucinous cystadenoma/adenocarcinoma, intraductal papillary mucinous tumor of the pancreas). However, by far the most common is pancreatic ductal adenocarcinoma, and consequently this will be the focus of this chapter.

It is estimated that 213 000 men and women die of pancreatic cancer worldwide each year. It is the fourth leading cause of cancer death in the United States (33 000 cases annually) and the sixth leading cause in Europe (30 000 cases annually) [1]. Most patients present late, have only a few months to live, and will die from the disease. Worldwide, the 1-year and 5-year survival rates are 25% and 5%, respectively. The mortality rate is nearly identical to the incidence rate. Survival is improved when disease is confined to the pancreas, although this only occurs in 15%–20% of cases.

Potentially beneficial developments continue to occur in the field of pancreatic cancer research. They include a rapid growth in the characterization of the genetic abnormalities associated with the disease, the appearance of new diagnostic techniques that have improved our ability rapidly to diagnose and stage it, and effective new therapeutic modalities, which allow nonsurgical palliation in many patients. Curative surgery is performed with operative mortality rates of only 1%–2%, compared with 10 times that in the 1980s. A number of new operations exist, which hold the promise of more effective treatment with less morbidity. In this chapter, we discuss these advances and present a broad overview of the diagnosis and management of patients with pancreatic neoplasms.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Epidemiology and risk factors

Although the peak incidence of pancreatic carcinoma occurs in the seventh decade of life, 10% of patients develop pancreatic cancer at or before the age of 50 years [2]. There is a slight male predominance [3]. In general, high rates are found in developed industrialized countries (8.5 per 100 000 males; 5 per 100 000 females); lower rates occur in developing regions of the world (2.4 per 100 000 males; 1.6 per 100 000 females) [4]. The overall incidence of the disease is 30%–40% higher in the African-American population than in Caucasians in the United States (10.2 per 100 000 vs 6.6 per 100 000).

Smoking

The risk factor most strongly linked to pancreatic cancer is cigarette smoking, which may account for 25%–30% of cases [5,6]. It approximately doubles the chance of developing the disease. The relation between number of pack years of smoking and the risk of pancreatic cancer is not as strong as it is with lung (10–15-fold increased risk) or oropharyngeal cancers, but it is generally true that the risk is greater with more cigarettes smoked [7]. The risk of pancreatic cancer rapidly decreases when individuals discontinue cigarette use. The relative risk falls to about 1 only 10–15 years after quitting [8]. The smoking of cigars and other forms of tobacco probably does not increase risk.

Chronic pancreatitis

A case–control study for the United States Veterans Administration compared the occurrence of chronic pancreatitis in

2639 pancreatic cancer patients with a matched control group of 7774 subjects. A history of chronic pancreatitis increases the risk of developing pancreatic cancer anywhere from 2-fold to 15-fold in case–control studies [9–12]. In all types of chronic pancreatitis, the risk of pancreatic cancer is elevated. For example, patients with idiopathic or alcoholic pancreatitis have a 15-fold increased risk of pancreatic cancer [10]. For those with hereditary pancreatitis, the lifetime risk of pancreatic cancer is approximately 30%–40% [11,13]. For those patients with tropical pancreatitis (a type of chronic pancreatitis occurring in persons living in the southern regions of India or Africa), the risk of pancreatic cancer is also high [14]. This suggests that the etiology of the pancreatitis is not a factor, but that the changes associated with chronic inflammation and fibrosis in the pancreas are more important. A large number of epidemiological studies in both the United States and Europe have failed to find any consistent etiological association between alcohol consumption (in nonalcoholic patients) and the development of pancreatic cancer [5,6].

Coffee

In an Italian multicenter study, consumption of more than three cups of coffee per day increased the risk for pancreatic cancer even when the data were controlled for potential confounding factors such as cigarette smoking or alcohol use, and when the analysis was restricted to nonsmoking coffee drinkers [15]. However, a case–control study in Japan and a metaanalysis of data published between 1981 and 1993 did not support the notion that either caffeinated or decaffeinated coffee or tea were risk factors for pancreatic cancer [16].

Aspirin use

The role of aspirin use in preventing pancreatic cancer development is not clear. Whereas several case–control studies report no association between aspirin use or NSAID use or the duration of use and the risk of pancreatic cancer [17–19], other studies have variously shown both an inverse relationship and a positive correlation between aspirin use and pancreatic cancer [20–23].

Diet

In general, a high total energy intake correlates with an increased risk of pancreatic cancer [24,25]. Meats and foods of animal origin increase the risk [26,27]. Protein and fat consumption have been shown to be promoters of pancreatic carcinogenesis in experimental animals [3]. Clinical studies showed a correlation between meat consumption and pancreatic cancer [28,29]. The dietary nitrite content has been linked to pancreatic cancer, possibly through the formation of nitrosamines, which are potent carcinogens [30].

In an experimental model, caloric restriction has reduced the frequency of preneoplastic pancreatic lesions, but similar evidence in humans is not yet available [31]. Products of plant origin and dietary fiber, in particular, appear to be protective [32]. Supplemental intake of antioxidants (α-tocopherol or β-carotene) did not reduce the risk of pancreatic cancer over a follow-up period of 5–8 years [33]. There are conflicting data about the protective role of folic acid in pancreatic cancer [34–36].

Obesity

Prospective cohort studies including 46 648 men (ages 40–75) and 117 041 women (ages 30–55) showed that a body mass index (BMI) of at least 30 kg/m^2 was associated with an increased risk for pancreatic cancer [37]. In addition, total physical activity was shown to be inversely related to pancreatic cancer risk for those with a BMI of 25 or greater [37]. The increased risk associated with obesity is thought to be related to abnormal glucose metabolism, insulin resistance, and hyperinsulinemia commonly seen in obese individuals.

Diabetes mellitus

The diabetes–pancreatic cancer relationship has been confusing because some patients with pancreatic cancer develop diabetes as a manifestation of their underlying pancreatic tumor. The diabetes sometimes appears as an early manifestation of pancreatic cancer, occurring many months before the tumor becomes evident. Of the two types of diabetes, type II is the most frequently observed in adults; it is related to obesity and sedentary lifestyle and is the form linked to pancreatic cancer. In a metaanalysis of 20 studies with data on the duration of diabetes prior to pancreatic cancer, individuals with diabetic histories of 5 or more years had a two-fold elevation in pancreatic cancer risk compared with those without a history of diabetes, or diabetes of less than 5 years duration (relative risk, 95% confidence interval [CI] 1.2–3.2) [38]. A population-based study of over 2000 patients with diabetes suggests that approximately 1% of diabetes subjects over the age of 50 years will be diagnosed with pancreatic cancer within 3 years of first meeting criteria for diabetes [39].

Genetic factors

It is estimated that familial factors and genetic susceptibility play significant roles in the development of around 10% of pancreatic cancer cases [40]. In a prospective study of familial pancreatic cancer (FPC) kindreds, defined as kindreds having at least one pair of first-degree relatives with pancreatic cancer, and sporadic pancreatic cancer (SPC) kindreds, defined as families without such an affected pair, the observed-to-expected rate of pancreatic cancer was significantly elevated in members of FPC kindreds (9.0; 95% CI 4.5–16.1), but not in the SPC kindreds (1.8; 95% CI 0.22–6.4). This risk in FPC kindreds was elevated in individuals with three (32.0; 95% CI 10.2–74.7), two (6.4; CI 1.8–16.4), or one (4.6; CI 0.5–16.4) first-degree relative(s) with pancreatic cancer. Risk was greater in smokers than in nonsmokers [41]. The possibility of genetic anticipation in familial pancreatic cancer with the

presentation of cancer occurring earlier with more recent generations, has been suggested [42].

No single pancreatic cancer gene has been identified, but several inherited syndromes with an excess of pancreatic cancer cases have been described. These syndromes include familial breast cancer (*BRCA2* mutations), familial atypical multiple melanoma syndrome (FAMMM), hereditary pancreatitis, hereditary nonpolyposis colorectal carcinoma (HNPCC), Peutz–Jeghers syndrome, familial adenomatosis polyposis, Gardner syndrome, and von Hippel–Lindau syndrome [11,40,43–49]. It is also possible that polymorphic genes (e.g., single nucleotide polymorphisms) play a role in inherited and sporadic cancer. Because smoking is a strong risk factor for pancreatic cancer, it seems reasonable that the polymorphisms in genes that detoxify carcinogens in tobacco smoke could be important (e.g., cytochrome P450 system, *N*-acetyltransferases, glutathione-*S*-transferases) [50–52].

Pathogenesis and molecular pathology

Pancreatic cancer precursors lesions, also known as pancreatic intraepithelial neoplasia (PanIN), are seen more commonly in patients with pancreatic cancer compared with those who do not have the disease (Fig. 70.1) [53,54]. Pancreatic intraepithelial neoplasia (PanIN) precursor lesions can be graded from PanIN-1A (flat mucinous epithelium) to PanIN-2 (columnar epithelium with nuclear atypia) to PanIN-3 (in situ carcinoma) [54]. This histological- and cytological-based model of pancreatic precursor lesions is supported by molecular analyses (mutational analysis, immunohistochemical analysis, and loss of heterozygosity studies), which have identified most of the molecular changes seen in invasive ductal adenocarcinoma in PanIN lesions, with the prevalence of these genetic alterations increasing with increasing degrees of cytological and architectural atypia in the duct lesions in PanIN.

Oncogenes

Oncogene mutations – through point mutations, amplification, or chromosomal translocation – confer on the pancreatic cancer cell a "gain of function," usually manifested as a constitutively active and unrestrained growth-promoting protein, point mutations in the *KRAS* oncogene (most commonly in codon 12, but also codons 13 or 61), and overexpression of ERBB2 are the earliest genetic alterations occurring in pancreatic ducts with minimal cytological and architectural atypia (PanIN-1A and PanIN-1B) [55–61].

Tumor suppressor genes

Inactivation of tumor suppressor genes that have an important role in pancreatic oncogenesis, such as *p53*, *DPC4* (deleted in pancreatic carcinoma locus 4), and *BRCA2*, occurs in later stage precursor lesions. The *p53* gene product is inactivated by mutation in 50%–75% of infiltrating ductal carcinomas [62–65]. The p53 protein is a nuclear binding protein that regulates the transcription of factors important in cellular processes such as cell-cycle modulation, DNA surveillance and repair, differentiation, and apoptosis. The tumor suppressor gene *SMAD4* (small mothers against decapentaplegic 4; also called *DPC4* – deleted in pancreatic carcinoma 4) is a member of the transforming growth factor-β (TGF-β) family. Its protein product is a cytoplasmic protein that, in response to transforming growth factor binding to its receptor, translocates to the nucleus, binds the Smad-binding element of DNA, and regulates transcription. Inactivation of SMAD4 (DPC4) is present in approximately 55% of invasive pancreatic adenocarcinomas [66].

The *p16* tumor suppressor gene function is affected in virtually all infiltrating ductal adenocarcinomas by homozygous deletion or a combination of loss of heterozygosity (LOH) and point mutations or methylation of the promoter region [67]. The *p16* gene encodes a protein that serves as a cyclin-dependent kinase (inhibitor). Its interaction with cyclin C-complexes effectively arrests cells in the G1 phase.

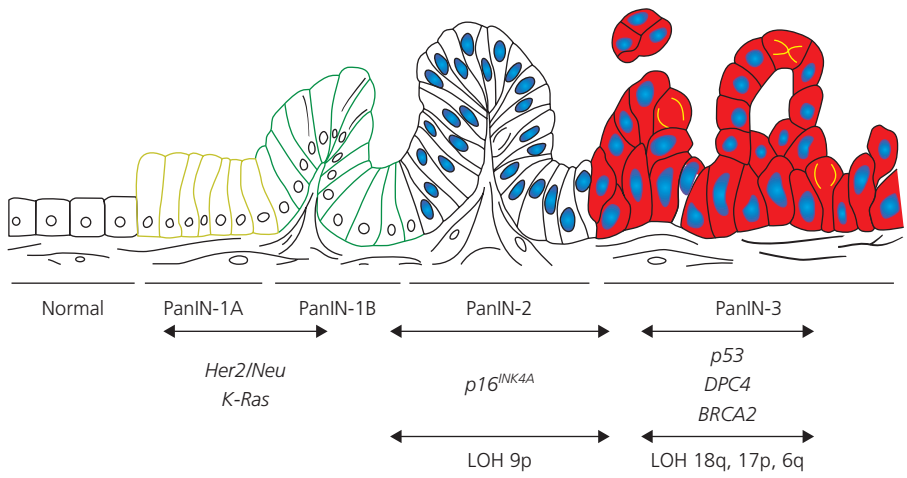

Figure 70.1 Pancreatic carcinogenesis: progression of pancreatic intraepithelial lesions (PanIN) from normal to invasive cancer. LOH, loss of heterozygosity. Adapted from Maitra et al. [62].

Inactivation results in loss of its restrictive action on cell growth.

Cell cycle regulators

Overexpression of cyclin D1 protein, a positive regulator of the cell cycle, has been documented immunohistochemically in 60%–85% of invasive pancreatic adenocarcinomas [68,69]. Cyclin D1 overexpression in pancreatic cancer has been associated with a poor prognosis and decreased survival [68,70], whereas decreased expression of cyclin D1 in pancreatic cancer has been associated with increased chemosensitivity and decreased expression of multiple chemoresistance genes [71].

Epithelial mucins

The apomucins MUC1, MUC2, and MUC5 are frequently overexpressed in epithelial cancers. The principal pancreatic mucin is MUC1, which is expressed in normal pancreatic ducts and acini [72]. The transfection of MUC1-expressing constructs into MUC1-negative tumor cell lines results in increased tumorigenicity and invasiveness in vivo; functional studies have shown MUC1 to be upstream of the oncogenic GRB2–SOS–RAS signaling pathway [73–75]. Expression of MUC1 is commonly (up to 100%) observed in invasive pancreatic adenocarcinomas at both the transcript and protein level. The gastric foveolar mucin, MUC5, is normally expressed in the gastric epithelium but is downregulated in the course of intestinal metaplasia. Unlike MUC1, it is not expressed in normal pancreatic ducts, but like MUC1, it is expressed in the majority of invasive pancreatic ductal carcinomas [62,76].

In addition to these gene mutations, there is also evidence that various growth factor receptors (e.g., epidermal growth factor [EGF] receptor, ERBB2, ERBB3, TGF-β receptors 1–3), growth factors (e.g., EGF, TGF-α TGF-β receptors 1–3, fibroblast growth factors [αFGF and βFGF]), and intercellular and endothelial-leukocyte adhesion molecules (e.g., intercellular adhesion molecule-1, endothelial leukocyte adhesion molecule-1) are upregulated in human pancreatic adenocarcinomas [77,78]. These changes may stimulate further tumor growth and enhance the metastatic behavior of pancreatic cancer cells, thus possibly contributing to shorter postoperative survival following tumor resection [77,79–81]. Vascular endothelial growth factor (VEGF) receptors and ligands promote endothelial cell growth and survival, enhancing angiogenesis. Expression of VEGF occurs in 90% of pancreatic cancers; it correlates with microvessel density and, at moderate–high levels, with reduced survival [82–84].

Developmental signaling and cancer stem cells

The Notch pathway plays an important role in directing decisions about the fate of cells in the developing pancreas and in pancreatic cancer initiation and invasion [85,86]. Upregulation of a number of Notch target genes is seen in preneoplastic lesions and in invasive pancreatic cancer [87]. Hedgehog signaling, which is crucial for the development of the gastrointestinal tract, has a major role in the initiation and growth of pancreatic cancer [88–90]. Cancer stem cells have a great potential for self-renewal and production of differentiated progeny. A $CD44^+CD24^+ESA^+$ phenotype (0.2%–0.8%) isolated from primary pancreatic cancer cells with a 100-fold increased tumorigenic potential has been described [91].

Pathology

Ductal adenocarcinoma and its variants make up more than 90% of all malignant exocrine pancreatic tumors. Others include acinar cell carcinomas, sarcomas, and malignant lymphomas. About two-thirds of ductal adenocarcinomas occur in the head of the gland; the rest occur in the body or tail, or diffusely throughout the pancreas. They are characterized by an intense desmoplastic reaction in which duct-like structures of varying degrees of differentiation are seen. The desmoplastic reaction comprises an extracellular matrix, together with a number of different host cell types, including fibroblasts, small endothelial-lined vessels, residual normal epithelia, and a variety of inflammatory cells, which are both locally derived and recruited from the circulation [92]. The interplay between all these cell types and the pancreatic cancer cells influences new blood vessel formation, invasion, metastasis, and evasion of the host immune system [93]. Because of their proximity to the intrapancreatic portion of the common bile duct, tumors in the head usually produce jaundice because they compress and obstruct the bile duct as they grow. They often obstruct the pancreatic duct as well, and although steatorrhea may result, there may not be any obvious symptoms. Tumors of the head of the pancreas are usually at least 2 cm in diameter when they are first diagnosed. Tumors of the body and tail commonly are larger (5–7 cm) and more advanced when they are discovered because they produce symptoms relatively later than head tumors. The symptoms from tumors in the body and tail are usually caused by malignant infiltration of the retroperitoneal structures and nerves, which produces pain. By the time the diagnosis is made, almost all are unresectable. Nevertheless, there is evidence that resectable body tumors have a similar prognosis to resectable tumors in the head of the gland. Approximately 70%–80% of adenocarcinomas of the head of the pancreas have metastasized to regional lymph nodes by the time they are discovered, which worsens the prognosis but does not preclude cure. These tumors also commonly invade lymphatic channels and perineural spaces. The prognosis is also influenced by the degree of tumor differentiation and by the presence of invasion of the retroperitoneal tissues adjacent to the cancer. Distant metastases (e.g., lung) may occur, but pancreatic cancer typically infiltrates locally into the adjacent structures (e.g., stomach, duodenum, colon,

Table 70.1 Staging of carcinoma of the pancreas

TNM classification	
T0	No evidence of primary tumor
Tis	In situ tumor
Tl	Tumor limited to the pancreas, < 2 cm in greatest dimension
T2	Tumor limited to the pancreas, > 2 cm in greatest dimension
T3	Tumor extends directly into duodenum, bile duct, or peripancreatic tissues
T4	Tumor extends directly into stomach, spleen, colon, or celiac axis vessels
N0	Regional lymph nodes not involved
N1	Regional lymph nodes involved
PN1a	Metastasis in a single regional lymph node
PN1b	Metastases in multiple regional lymph nodes
M0	No distant metastases
M1	Distant metastases present
American Joint Committee on Cancer (AJCC) stage	
IA	T1, N0, M0
IB	T2, N0, M0
II	T3, N0, M0
III	T1, N1, M0; T2, N1, M0; T3, N1, M0
IVA	T4, any N or M
IVB	any T, any N, M1

transverse mesocolon, portal and superior mesenteric veins, superior mesenteric artery). The liver is the most common site of intraabdominal metastasis, and peritoneal seeding of the tumor is also seen. In patients without distant spread, vascular invasion by tumor is the most common reason for unresectability (Table 70.1).

Clinical manifestations

The most common symptoms in patients with cancers in the head of the pancreas are jaundice and abdominal pain, usually with some degree of weight loss. In those with tumors of the pancreatic body, jaundice is unusual. Abdominal pain and back pain are common, and weight loss may be profound.

Pain

The cause of the abdominal and back pain associated with cancer in the head of the pancreas may be gallbladder and bile-duct distention associated with biliary obstruction, pancreatic duct distention associated with pancreatic duct obstruction, and invasion of retroperitoneal or somatic nerves. Abdominal pain associated with pancreatic cancer may also be as a result of acute pancreatitis, which may be the clinical presentation in 5% of pancreatic cancer patients. In the absence of another recognized etiology for an attack of pancreatitis, the possibility of an underlying carcinoma should be considered [94].

Jaundice

Jaundice, accompanied by pain, is the presenting symptom in 80%–90% of patients with cancer of the head of the pancreas. Painless jaundice is uncommon. Rarely, pancreatic malignancy can present with ascending cholangitis.

Weight loss

By the time the diagnosis is made, weight loss of more than 10% of ideal bodyweight is common. There are several possible explanations for such weight loss. The pain associated with the tumor produces anorexia in almost all patients, so decreased food intake is the most common cause. Malabsorption also may occur, especially in patients with pancreatic duct obstruction in the head of the pancreas, as digestive enzyme output from the pancreas may be prevented from entering the duodenum. It is less likely in those with pancreatic duct obstruction from body tumors, because enzymes from the pancreatic head drain normally, and are enough to maintain normal fat and protein absorption. Finally, there is the suggestion that a humoral substance secreted by the tumor increases catabolic activity [95].

Diabetes mellitus

Diabetes sometimes appears as an early manifestation of pancreatic cancer, occurring many months before the tumor becomes evident. Some 5% of patients with pancreatic cancer will have developed diabetes mellitus within the previous 2 years, and recent-onset diabetes may therefore serve as a warning sign [96].

Other clinical features

Light-colored stools and dark urine are characteristic of obstructive jaundice. Other symptoms include pruritus, nausea, vomiting, and weakness. Vomiting may result from duodenal or gastric outlet obstruction caused by tumor invasion. In some cases, when there is no apparent obstruction, it may be caused by abnormal gastric motility for as yet obscure reasons. Less common findings include superficial thrombophlebitis and gastrointestinal bleeding. In advanced stages, gastrointestinal bleeding may occur from direct invasion of the tumor into the duodenum, stomach, or colon.

Physical findings

Physical examination may reveal hepatomegaly, a palpable abdominal mass, or ascites. In the past, a distended palpable gallbladder (Courvoisier sign) was thought to be pathognomonic for bile-duct obstruction caused by a tumor. When gallstones caused the bile-duct obstruction, gallbladder distention was thought to be less likely because chronic inflammation of the gallbladder wall caused scarring and contracture of the viscus. However, the gallbladder is palpable only in about one-half of jaundiced patients with pancreatic cancer,

so the Courvoisier sign is of no practical diagnostic value. In those patients with pruritus, persistent scratching produces excoriation and lichenification of the skin. Rarely, an abdominal bruit can be heard if the tumor compresses the aorta or splenic artery.

Diagnostic investigations

Routine clinical tests

In patients with biliary obstruction, the total serum bilirubin and alkaline phosphatase concentrations are elevated. The total bilirubin level tends to be greater with malignant obstruction than obstruction from benign causes (> 15 vs 5 mg/dL). Serum amylase elevation is seen in only 5% of patients with pancreatic cancer.

Tumor markers

A variety of tumor-associated antigens have been studied as possible markers for pancreatic cancer. The most sensitive (80%) and specific (90%) is cancer antigen (CA) 19-9, but it still falls short of the ideal because it is almost never positive with small tumors (< 1 cm). Values of CA 19-9 also may be abnormal with other cancers (gastric, colorectal cancer) and with some benign conditions (cholangitis). Determination of serum CA 19-9 levels may be useful to provide some assurance that the tumor has been resected in its entirety, to signal the presence of recurrent disease after resection, and to determine the response to adjuvant therapy [97,98].

Rationale of the workup in patients with suspected pancreatic cancer

There are two main goals of the diagnostic workup in patients who are thought to have a pancreatic malignancy. The first is to establish the diagnosis with a high degree of certainty. In patients who are candidates for surgery, this usually does not require histological proof of malignancy. The second is to decide whether the patient should undergo an operation in an effort to either resect or palliate the disease. Because patients with unresectable pancreatic cancer have a median survival of no more than 1 year (Table 70.2), it is particularly important to avoid the morbidity (and cost) of an operation if it will not help [99].

Noninvasive techniques

Transabdominal ultrasound (US) may be useful as a first-line investigation in patients with jaundice to distinguish between intrahepatic and extrahepatic causes. Extrahepatic obstruction from a pancreatic (or any periampullary) cancer would be expected to show dilated intrahepatic and extrahepatic biliary radicles (Fig. 70.2). Transabdominal US can also identify gallstones that may be the cause of obstruction.

Table 70.2 Published survival after pancreaticoduodenectomy with tumor involving surgical margins (R1, R2)

Study	*n*	Survival
Neoptolemos [135]	101	11 months median
Sohn [136]	184	12 months median
Nishimura [137]	70	6 months median
Yeo [139]	58	10 months median
Nitecki [139]	28	6.8% 5-year survival
Willett [140]	37	12 months median

R1, positive margins by microscopy; R2, macroscopic tumor at surgical margin.

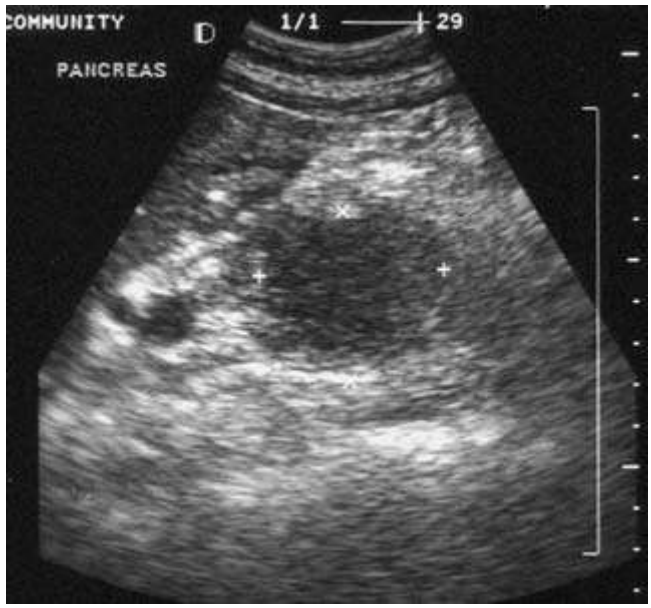

Figure 70.2 Transabdominal ultrasound in a patient showing a hypoechoic mass in the head of the pancreas.

Although transabdominal US provides some information about the relationship of the tumor to surrounding structures, computed tomography (CT) is much better in this regard. Transabdominal US is a relatively inexpensive test, with a sensitivity of 70% and a specificity of more than 90% for the diagnosis of pancreatic cancer [100–102].

Multidetector helical CT with high-quality thin sections is the best overall option for diagnosis, as well as the preoperative staging of pancreatic cancer. It provides information about the nature and site of the lesion (e.g., pancreatic versus other periampullary tumors, hilar bile-duct tumors), its resectability (e.g., presence of hepatic metastases, vascular invasion), and vascular anatomy. It is important to stress that helical CT is the state-of-the-art procedure. When helical CT is compared with the conventional technique, and especially when imaging of both the pancreas and liver is done

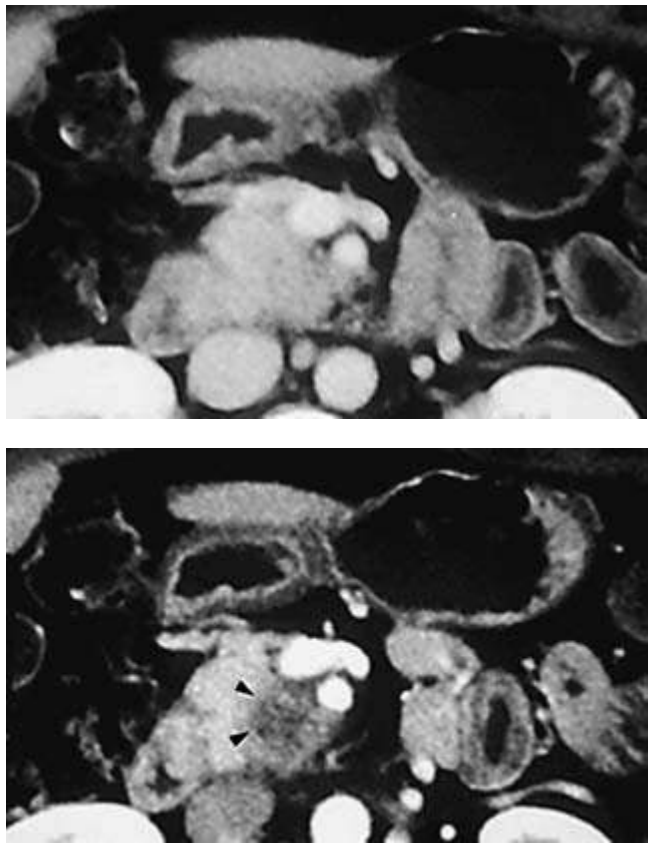

Figure 70.3 **(a)** On a conventional computed tomography (CT) scan, the primary tumor in the uncinate process of the pancreas is not seen. **(b)** The helical (spiral) CT scan performed 4 days later reveals the tumor (arrowheads). Courtesy of David Lu, UCLA Department of Radiology, Los Angeles.

separately according to published protocols, the differences in the sensitivity and specificity of the two approaches are dramatic [103] (Fig. 70.3). Extraordinary detail is provided about vascular anatomy and vascular invasion by the tumor (Fig. 70.4) [99,104]. A CT scan can detect tumors measuring about 2 cm or greater in diameter; these appear as lucent areas because they are less well perfused with blood than the adjacent pancreatic tissue. The technique has a false-positive rate of less than 10%, which is usually caused by focal pancreatitis, or variations in normal pancreatic anatomy that are mistaken for tumor.

Magnetic resonance imaging (MRI) may provide slightly better pancreatic tissue contrast than CT, but spatial resolution is inferior. Magnetic resonance cholangiopancreatography (MRCP) provides detailed ductal images without the risk of ERCP-induced pancreatitis [105]. It was hoped that MRI would be superior to CT in outlining the blood vessels, but such an advantage has not been demonstrated [106]. Consequently, MRI for pancreatic cancer staging is generally limited to instances in which patients cannot receive CT contrast (e.g., allergy to the dye, impaired renal function).

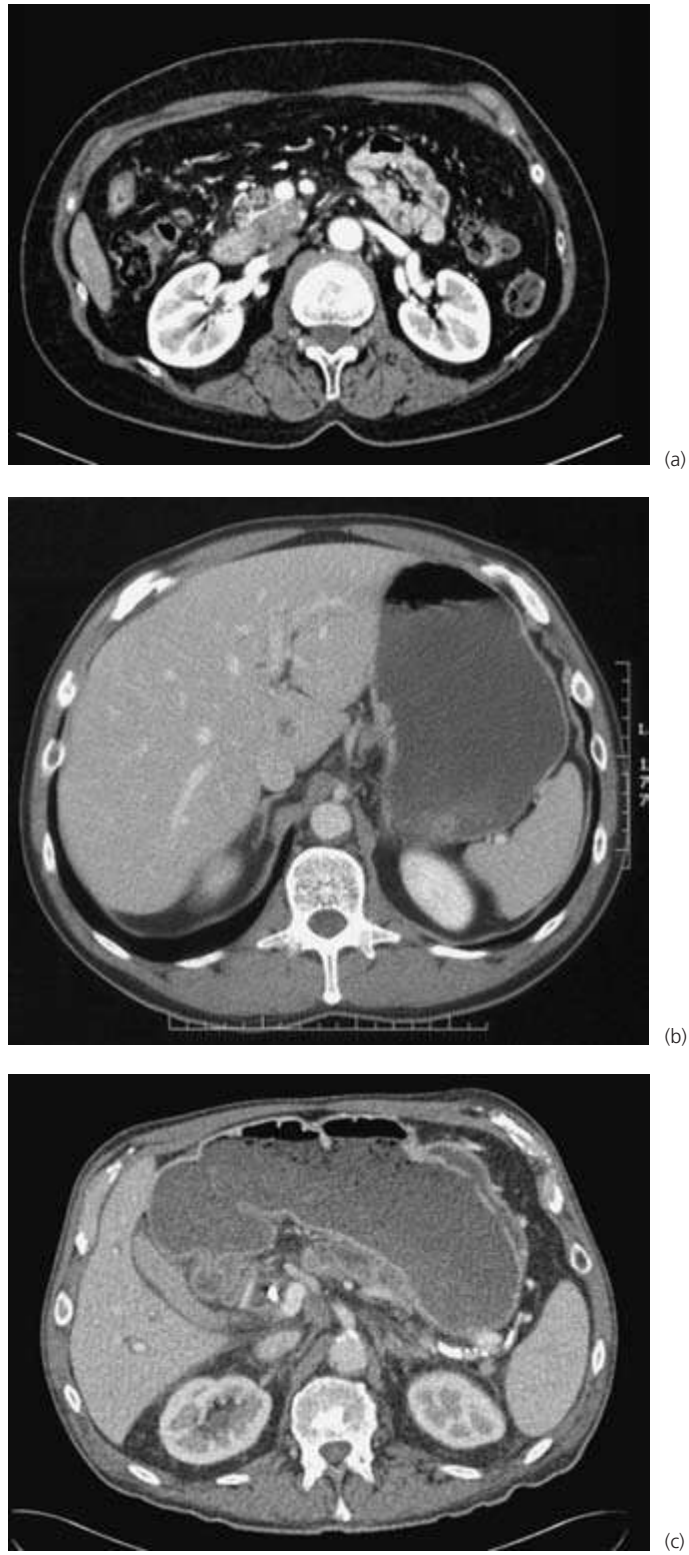

Figure 70.4 Computed tomography evidence of surgical unresectability. **(a)** Pancreatic head mass with superior mesenteric vein involvement. **(b)** Hypointense liver lesion suggestive of metastasis. **(c)** Celiac lymph node metastasis.

The value of positron emission tomography (PET) for the diagnosis of pancreatic malignancy is unclear. According to published studies, PET can identify pancreatic cancer and differentiate it from chronic pancreatitis with a sensitivity of 85%–98% and a specificity of 53%–93% [107,108]. Moreover, PET may be able to clarify diagnoses that are uncertain and to document metastatic disease where CT findings are equivocal [108]. However, it is still unclear how PET will fit into the overall pancreatic cancer staging algorithm [109,110].

Invasive techniques

Endoscopic retrograde cholangiopancreatography (ERCP) has a sensitivity of 95% and a specificity of 85% for the diagnosis of pancreatic cancer [111]. The classic finding that suggests pancreatic cancer is obstruction of both the bile and pancreatic ducts in the head of the pancreas, the so-called double-duct sign. In tumors of the body or tail of the pancreas, only the pancreatic duct is abnormal. At the time of ERCP, brushings for cytology may be obtained from the pancreatic duct, which has sensitivity of about 60% in proving the diagnosis of malignancy. Also at the time that the ERCP is done, a stent can be placed into the obstructed common bile duct; this has an important role in the palliation of patients who do not require surgery.

In spite of its value, diagnostic ERCP is not required in most patients with pancreatic cancer. Its role is confined to palliation of obstructive jaundice, particularly in patients who are not candidates for surgery. If a patient has a history typical for pancreatic cancer (e.g., pain, jaundice, weight loss) with a mass in the head of the pancreas evident on CT scan, then an ERCP is unnecessary for the diagnosis and will add nothing to the workup.

When tumors are small or poorly visualized on CT scan, endoscopic ultrasonography (EUS) provides a minimally invasive, accurate method of defining the extent of the primary tumor–vessel relationships and evaluating surrounding lymph nodes (Fig. 70.5). With surgical pathology as the gold standard, studies have shown that EUS accuracy in tumor staging and estimation of lymph node involvement ranges from 69% to 85% and 54% to 75%, respectively [106,112,113]. Lymph nodes infiltrated by carcinoma usually appear as round, hypoechoic masses more than 1 cm in diameter. Endoscopic ultrasonography can provide information about whether the tumor invades the portal, splenic, or superior mesenteric veins, the celiac axis, or superior mesenteric arteries. Common EUS criteria for vascular involvement include abnormal vessel contour, loss of vessel–parenchymal interface, tumor visible within the vessel lumen, and the presence of dilated peripancreatic venous collaterals [114]. When results are compared with surgical findings, EUS accuracy ranges from 69% to 93% [113–116], and its ability to predict tumor resectability ranges from 72% to 93% [113,116]. Endoscopic ultrasound can detect tumors smaller than those detectable by CT scanning techniques (< 2.0 cm in diameter), with sensitivity and specificity for tumor detection as high as 99% and 100%, respectively [114,117,118].

Figure 70.5 Endoscopic ultrasonogram showing a hypoechoic pancreatic head mass involving the portal vein.

Endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) is the method of choice for obtaining a pathological diagnosis of malignancy (Fig. 70.6). Pretreatment confirmation of malignancy is critical for patients with locally advanced or metastatic disease who will be treated nonoperatively. Nearby lymph nodes and liver lesions can also be sampled using EUS-FNA to aid in local staging, with a low complication rate of 1%–2% [114]. However, for patients presenting with a low-density solid mass in the pancreas, who have resectable disease by CT criteria, a histological diagnosis of malignancy is unnecessary. In a patient with a negative CT scan but a history that suggests pancreatic cancer, EUS is useful because it is the most sensitive method for detecting a small tumor that has escaped detection by CT. Likewise, EUS may be useful to estimate the resectability of the tumor because of vascular involvement if the CT scan does not resolve that issue.

Percutaneous transhepatic cholangiography (PTC) is useful in patients with proximal bile-duct obstruction (e.g., from a tumor at the hepatic duct bifurcation) to delineate the bile duct anatomy on the hepatic side of the obstruction. However, MRCP may be the preferred technique in most of these patients. Endoscopic placement of a biliary stent is associated with a lower morbidity and procedure-related mortality rate than the percutaneous transhepatic route, because it minimizes the risk of bile leak and bleeding [119]. If an endoscopic approach is not possible, a combined approach involving the insertion of a transhepatic catheter and guidewire, which can be retrieved by the endoscopist, may be

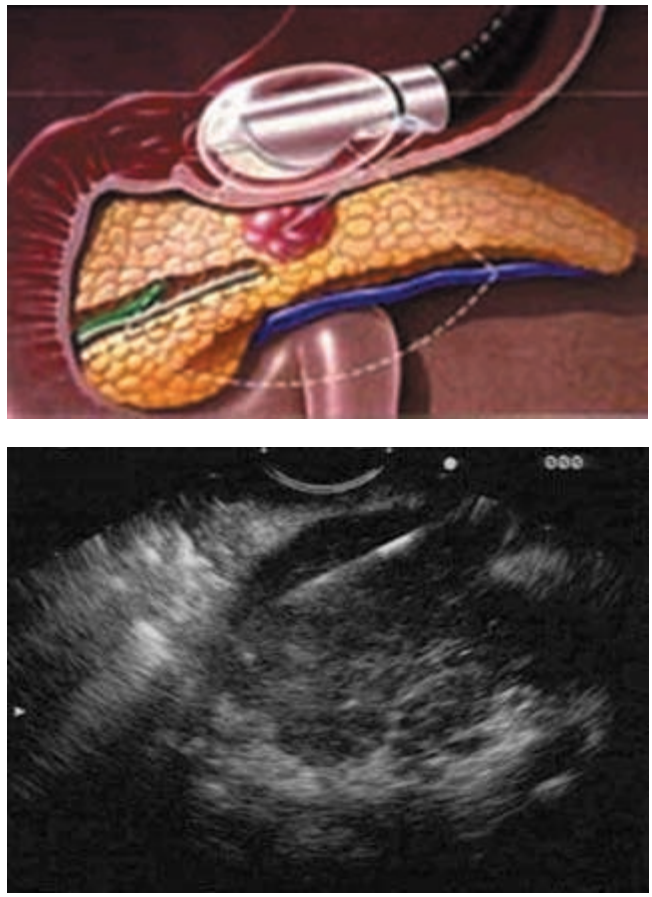

Figure 70.6 **(a)** Endoscopic ultrasound and fine-needle aspiration (FNA), demonstrating a linear echoendoscope biopsying the pancreas transgastrically. **(b)** Endoscopic ultrasound and FNA of a 2.5-cm localized hypoechoic mass in the head of the pancreas. The FNA needle is seen in the top right-hand corner. Cytological analysis of the aspirated specimen revealed adenocarcinoma.

used. This allows successful stent placement in a group of patients for whom endoscopic stenting alone is unsuccessful [120,121].

Computed tomography remains suboptimal for detecting small-volume peritoneal metastases and hepatic metastases measuring less than 1 cm. For this reason, laparoscopy, often combined with laparoscopic ultrasound, may be useful. Staging laparoscopy prior to laparotomy can provide tissue for the diagnosis of metastatic disease, which may avoid laparotomy in some patients [122]. There is debate about whether it should be used in all patients or confined to a selected group. We favor the latter, and often begin with staging laparoscopy when the preoperative CA 19-9 level exceeds 1000 U/mL, when imaging suggests advanced disease that cannot be confirmed by other techniques, or in many patients with cancers in the body or tail of the pancreas.

Tissue diagnosis

Preoperative FNA for cytology can be obtained percutaneously using a fine-gauge needle under CT or US guidance, or endoscopically by endoscopic ultrasound (EUS) or ERCP (Fig. 70.6). Complications include hemorrhage, pancreatitis, pancreatic fistula, and seeding of the needle tract with cancer cells, all of which are uncommon. Fine-needle aspiration should not be done routinely in the workup of patients with suspected pancreatic cancer, but it is indicated in situations where the cytological proof of malignancy will alter management (e.g., in a patient with an unresectable pancreatic tumor). A negative FNA does not rule out the possibility of malignancy, however.

Experienced pancreatic surgeons do not require histological proof of malignancy before proceeding with resection. Resection is performed on the basis of the patient's history, the information from preoperative tests, and the gross findings at operation. With this approach, experienced surgeons err less than 10% of the time (i.e., a resection is performed for what turns out to be benign disease) [123]. This is acceptable because the mortality rate of resection is low (1%–2%), and the majority of patients who undergo resection for benign disease have chronic pancreatitis for which resection is also appropriate.

Treatment: surgery

Preoperative management

As in all patients about to undergo major surgery, it is important to optimize cardiac, pulmonary, and renal function preoperatively. Although these patients have often lost weight, most are still nourished adequately to undergo the operation safely. However, if the serum albumin is less than 3 g/dL, or if surgery must be delayed for more than several weeks after the diagnosis is established, supplemental nutrition is often appropriate.

Preoperative biliary drainage

Because obstructive jaundice can cause defects in hepatic, renal, and immune function, it was hoped that preoperative relief of the jaundice would correct these defects, and decrease postoperative morbidity and mortality rates. Unfortunately, several randomized controlled studies have proven that routine preoperative bile duct stenting does not help [124–133] (Table 70.3). However, if the operation must be delayed several weeks (including in the setting of neoadjuvant therapy), or if cholangitis or pruritus occur, a plastic biliary stent (at least 10 French, if possible) should be placed endoscopically in jaundiced patients. The use of permanent metal biliary stents is discouraged in patients who are candidates for resection. These stents incite a severe inflammatory reaction and eventually may be incorporated into the bile-duct wall. This can complicate or even prevent the resection.

Table 70.3 Studies of preoperative biliary stenting in pancreatic cancer: infectious complications (%)

Study	*n*	Stented	Unstented

Hochwald [131]	71	66	38
Heslin [132]	74	46	11
Pisters [130]	265	37	11
Hodul [133]	212	28	20

Operative management: resection

The first successful resection for a periampullary cancer was performed as a two-stage operation by the German surgeon Kausch in 1909. In 1935, Whipple performed a similar procedure for an ampullary carcinoma, which by 1942 he had refined into a one-stage resection [134]. That operation has been called a pancreaticoduodenectomy, or Whipple resection, and it is similar to the one performed today (Fig. 70.7). The principal goal of the operation is the removal of all gross and microscopic disease within the pancreas and draining lymph nodes, a so-called margin-negative or R0 resection [135–140]. In the hands of experienced pancreatic surgeons around the world, the operative mortality rate of this procedure is 2% or less.

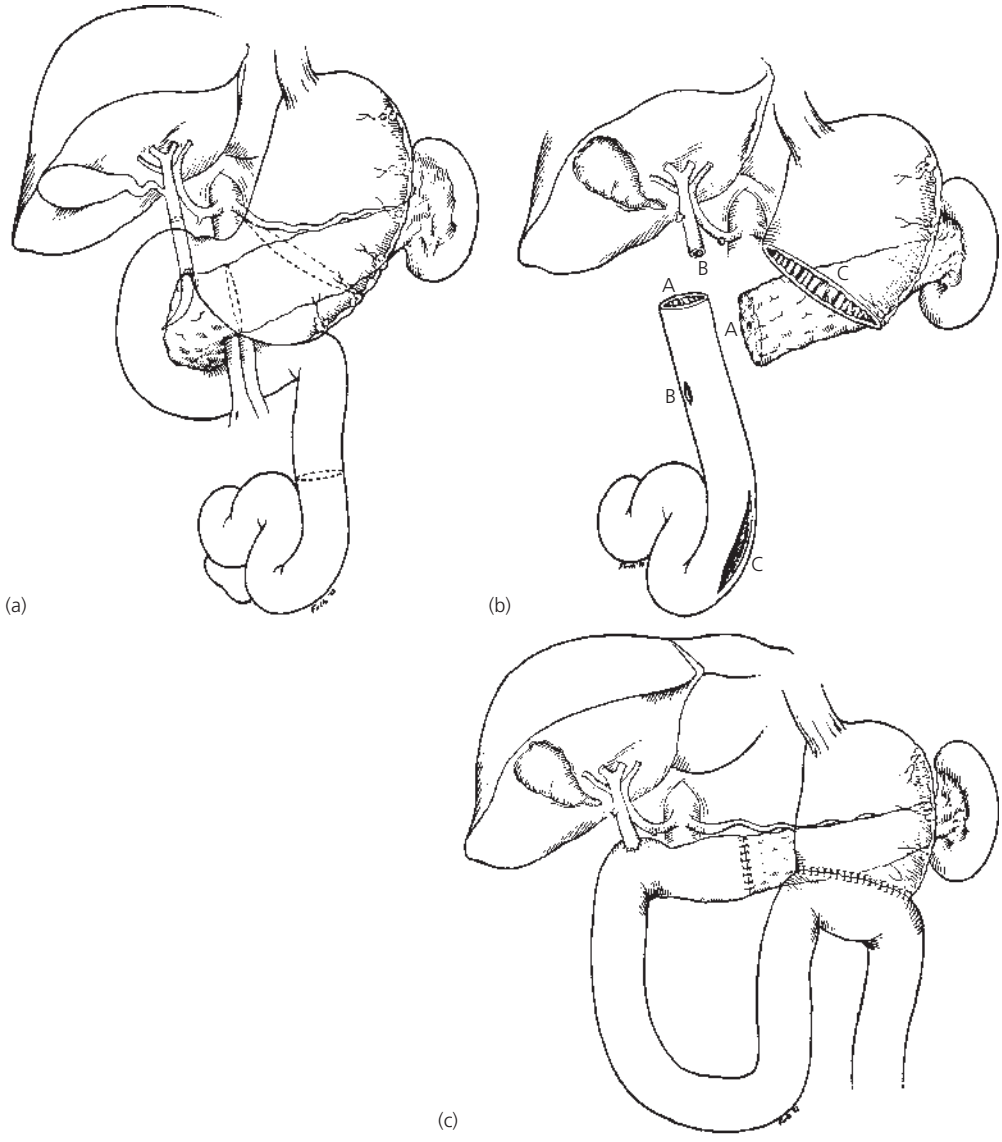

Figure 70.7 The standard Whipple pancreaticoduodenectomy. **(a)** Dashed lines indicate the resection margins in the typical operation for a tumor in the head of the pancreas. **(b)** The specimen has been resected. A, B, and C represent the sites for subsequent anastomoses between the bowel and the pancreas, bile duct, and stomach. **(c)** The completed anastomoses are shown.

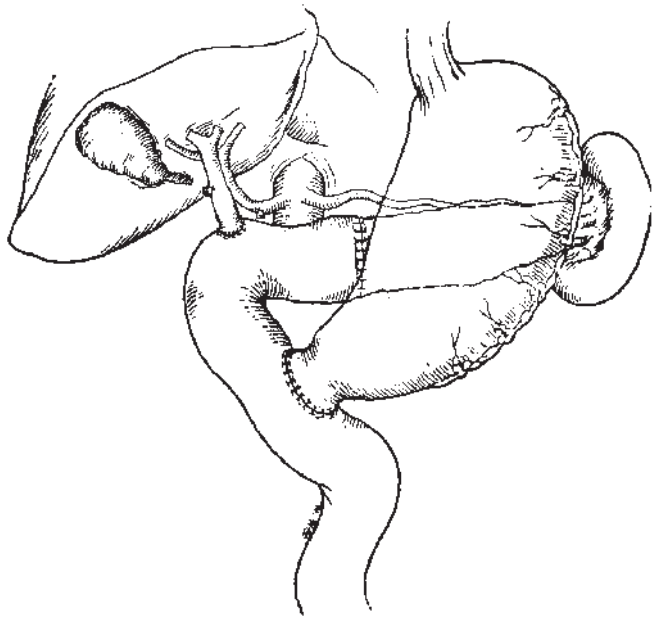

Figure 70.8 The pylorus-preserving modification of the standard Whipple pancreaticoduodenectomy is shown. The entire stomach, the pylorus, and several centimeters of duodenum are retained.

Resectable tumors in the body or tail of the pancreas require a distal pancreatectomy and splenectomy. The head of the pancreas, gallbladder, bile duct, stomach, and duodenum can usually be preserved because the tumor and its lymphatic drainage do not involve these structures. Mortality and morbidity rates are lower than after a Whipple resection. Because of the late presentation of symptoms, most patients with adenocarcinoma of the pancreatic body and tail present with locally advanced disease or distant metastases (or both), which precludes resection [141]. Central pancreatectomy, which may be used to resect benign tumors of the neck and mid-body of the pancreas, should not be used for pancreatic cancer. Nor should laparoscopic pancreatic resections be done for known malignant pancreatic disease.

Modifications of pancreaticoduodenectomy

Pylorus-preserving Whipple resection

Because of concern that the standard Whipple resection is associated with excessive weight loss and nutritional disturbances, many surgeons adopted this modification in which the stomach, pylorus, and first 2–3 cm of duodenum are preserved (Fig. 70.8). The operation was first described in 1944, but it did not become popular until the 1970s, when it was described for patients with chronic pancreatitis; later it was adopted for patients with pancreatic cancer as well [142]. The modified operation does not compromise the chance for cure of the cancer, and is associated with complication, morbidity, and mortality rates similar to the standard operation (Table 70.4) [143–149]. Most surgeons perform the two procedures interchangeably, reserving the standard Whipple for patients with larger, more extensive tumors.

Radical (extended) Whipple resection

Some surgeons have advocated the use of a more radical pancreatic resection to improve cure rates [150]. The standard Whipple (in which peripancreatic and subpyloric lymph nodes are generally removed) is modified by removal of more peripancreatic soft tissue and lymph nodes, often with resection of segments of the superior mesenteric and portal veins, when they appear to be involved by tumor. Although some of the uncontrolled studies reported improved survival, several prospective randomized trials have not [151–153]. Most surgeons in the United States are skeptical that the radical operation cures more patients, and it is rarely done in this country [154,155].

Vascular resection

Tumor involvement of the superior mesenteric or portal vein has generally been considered a contraindication to resection, although it is technically possible to remove limited segments of these vessels and reconnect the two ends. Retrospective data suggest that patients treated by pancreaticoduodenectomy combined with venous resection have a life expectancy similar to those treated with a Whipple resection

Table 70.4 Comparison of outcomes for standard pancreaticoduodenectomy and pylorus-preserving pancreaticoduodenectomy

Study	*n*	Outcomes
Lin [143]	31	Increased delayed gastric emptying in pylorus-preserving pancreaticoduodenectomy ($P = 0.08$)
Seiler [144]	77	Longer operative time in standard pancreaticoduodenctomy No statistically significant difference in the other parameters measured (operative blood loss, surgical morbidity, delayed gastric emptying, mortality, length of hospitalization), disease recurrence, and overall survival
Zerbi [145]	72	No significant differences
Tran [146]	170	No differences in median blood loss, duration of operation, postoperative delayed gastric emptying, positive margins of resection, median disease-free survival, overall survival

without venous involvement, but that none are cured by the operation. Thus, although such locally advanced disease can be safely removed by extending the resection to include a segment of the vein, this should be viewed as an effort at palliation. However, involvement of the celiac axis, or hepatic or superior mesenteric arteries is an absolute contraindication to resection of the cancer (Table 70.5) [156–164].

Surgical outcomes

Surgical resection offers the only chance for cure. Nevertheless, according to the National Cancer Database, between 1985 and 1995 only 9% of more than 100 000 patients had their pancreatic cancer resected. The 5-year survival rates were between 13% and 17% for resection alone, and 23% for patients who had resection followed by adjuvant therapy. Selected series of patients who have undergone a curative (R0) resection have survival rates of 25%–35% after 5 years; however, up to one-half of the patients who survive 5 years still die from recurrent disease due to micrometastases unrecognized at the time of resection. Thus, adjuvant therapy is widely accepted as an important adjunct to management and the best hope for better long-term results.

Operative mortality and regionalization

Significant improvements in mortality, morbidity, and length of hospital stay have come as a result of improved operative techniques, anesthesia, and perioperative care [165–167]. As a result, mortality rates at most high-volume centers are less than 5%, and numerous centers report rates of under 2%. In specialist centers, resectability rates (the fraction of patients operated on who actually undergo resection) are around 80%, reflecting referral practices and case selection [165,168–170]. The overall 3-year survival is higher for patients treated at high-volume centers (37%) than at medium (29%) and low-volume (26%) centers [171]. Even after adjusting for perioperative deaths and case mix, patients treated at high-volume centers are less likely to experience late mortality [111,172–176]. The more frequently surgeons performed pancreaticoduodenectomy, the lower the in-hospital mortality rate, the length of stay, and hospital charges.

Palliation

Surgical palliation

During exploration, when resection of the primary tumor is not possible, the surgeon must decide whether any palliative procedures should be done. Because most patients with cancer in the head of the pancreas are jaundiced at the time of operation, a bypass to relieve the biliary obstruction is the most common procedure. An anastomosis between the gallbladder and the jejunum (cholecystojejunostomy) or common bile duct (choledochojejunostomy) are both effective bypass techniques (Fig. 70.9) [177,178].

At the time of the initial exploration, it is unusual that patients have duodenal obstruction from the tumor, but up to 15% develop it sometime before they die [178]. Thus, most surgeons perform a prophylactic gastrojejunostomy at the same time that a biliary bypass is done (Fig. 70.10). This is not associated with increased morbidity or mortality rates [179,180]. Occasionally, patients complain of vomiting preoperatively, and no objective evidence can be found for duodenal obstruction. In these patients, a gastrojejunostomy usually does not relieve the symptom, and the patient may still be unable to eat. The problem is probably caused by abnormal gastric motility, perhaps because of tumor infiltration of the nerve plexuses. Although prokinetic agents may help, the symptom is often refractory to all forms of treatment.

Nonsurgical palliation of biliary and duodenal obstruction

Endoscopic stenting of biliary obstruction represents an alternative to surgery in individuals with unresectable pancreatic cancer, which may avoid operation altogether. The

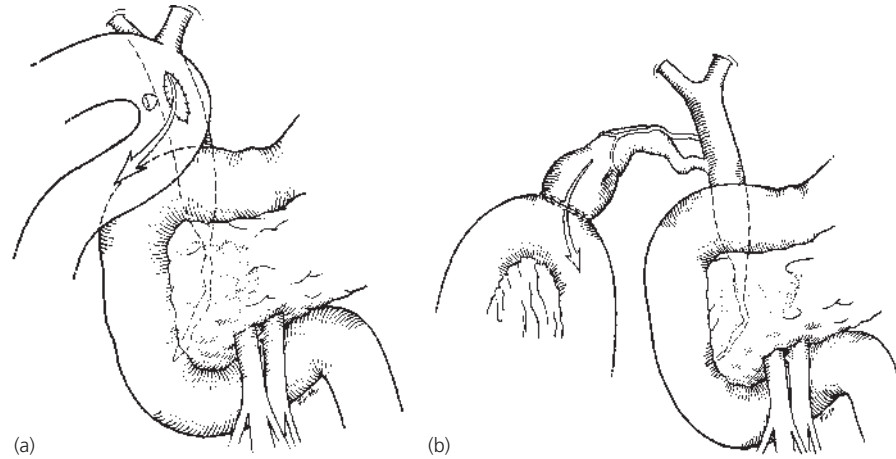

Figure 70.9 (a) Choledochojejunostomy and **(b)** cholecystojejunostomy. Each of these operations effectively relieves biliary obstruction by diverting the bile into the small intestine proximal to the tumor.

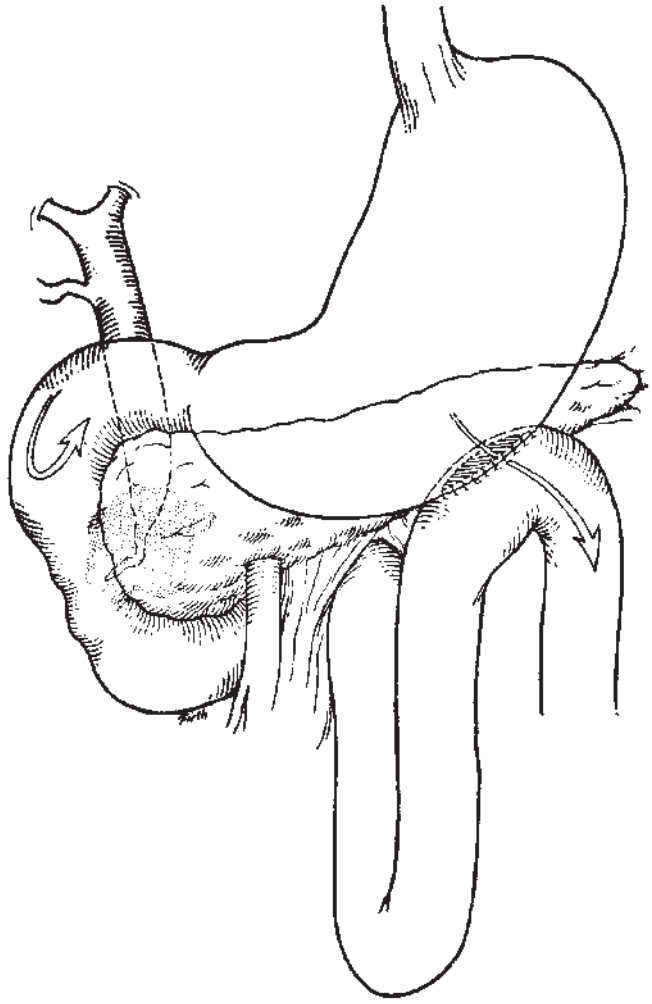

Figure 70.10 Gastrojejunostomy. The stomach can empty into the small intestine directly when the tumor obstructs the duodenum.

advantages and problems associated with both surgical and endoscopic approaches have been defined in several prospective randomized studies that compared the two [181–187]. In general, operative biliary bypass is more expensive, because of charges associated with the surgical procedure itself, and the hospitalization required for recovery. However, surgical bypass is more likely to provide permanent relief of the jaundice than are the endoscopically placed stents. Endoscopic stenting is associated with a lower procedure-related complication rate and mortality when compared with surgery [187]. It seems reasonable to reserve surgery for patients with both good performance status and small tumors, who are likely to survive longer than average, and to place a stent in patient with advanced tumors who are unlikely to survive longer than the usual patency of the stent.

Self-expanding metallic stents are larger (10 mm) than the 10–11-French plastic stents in common use, and they are less likely to become obstructed. As the lumen of this type of stent is so large, biliary drainage is superior to that seen with plastic stents and they rarely block due to debris. However, tumor ingrowth through the mesh of the self-expanding metal stents can occur. The use of thin membranes to cover self-expanding stents may minimize this problem.

To date there has been no randomized comparison between expanding metal stents and biliary bypass surgery. Laparoscopic techniques for both biliary bypass and gastrojejunostomy may decrease the cost and discomfort of the surgical approach, and permit more rapid hospital discharge [188,189]. On occasion, duodenal obstruction can be effectively treated with duodenal stents [190–192].

Malabsorption

Some patients with unresectable pancreatic cancer experience fat malabsorption because the tumor obstructs the pancreatic duct, and insufficient amounts of pancreatic enzymes

enter the duodenum. The result is diarrhea and steatorrhea, which interfere with the ability to gain weight and adversely affect quality of life. About 25% of patients who undergo pancreaticoduodenectomy also may suffer from malabsorption, which requires treatment. Although fat absorption itself cannot be restored to normal, the goal should be to stop the diarrhea, restore adequate nutrition, and maintain body weight. The principles of treatment require that about 30 000–40 000 U of lipase be supplied with each of four to five meals spread throughout the day.

Pain

Conventional treatment of the pain associated with pancreatic cancer includes both opioid and nonopioid analgesics as well as nonsteroidal antiinflammatory drugs, tricyclic antidepressants, and antineoplastic agents [193]. However, pain from advanced pancreatic cancer is often difficult to control, and narcotics may be ineffective. If this occurs, visceral pain may be managed by celiac plexus block, either at the time of surgery or later by a percutaneous or endosonographic approach (Fig. 70.11). Pain is relieved in up to 90% of patients, and significant complications are uncommon [194,195]. Other approaches to pain control in locally advanced or metastatic pancreatic malignancy include pancreatic ductal decompression (endoscopic or surgical), external beam radiation, or chemoradiation [178,196–198].

Figure 70.11 Endoscopic ultrasound-guided celiac nerve block for palliation of pain.

Systemic therapy

Adjuvant therapy

Patients with no detectable evidence of residual disease at the time of resection are likely to harbor microscopic tumor deposits that, if left untreated, will lead to tumor recurrence and death. These patients may benefit from adjuvant therapy after the tumor has been removed surgically. Randomized phase III trials studying the role of chemotherapy (5-fluorouracil, 5-FU) and chemoradiation therapy in the adjuvant setting, suggest that postoperative adjuvant therapy improves survival in patients with resected adenocarcinoma; consequently, this has become the standard of care. Unfortunately, median survival is less than 2 years, and long-term survival is under 20% in most phase III trials. Results from two large randomized trials show that adjuvant systemic chemotherapy increases the 5-year survival from 9%–12% with resection alone to 21%–29% and 23% with either 5-FU and folinic acid or gemcitabine, respectively [199,200]. The role of radiation therapy in this setting has been brought into question by the ESPAC 1 study, which concluded that patients who had radiation alone or in combination with chemotherapy fared worse than those who had chemotherapy alone [135, 199]. However, the mode of radiation therapy delivery, the use of bolus injections of 5-FU, and the lack of quality control for the radiation therapy has raised questions about that conclusion, and the role of radiation remains unsettled. An American Intergroup trial (RTOG 9704) studying adjuvant chemoradiotherapy has reported median and 3-year survival rates. This study used background 5-FU-based chemoradiotherapy together with pre- and post-chemoradiation systemic chemotherapy comprising either 5-FU or gemcitabine. The results show no difference in median survival or 3-year survival across all patients. There was, however, a significant improvement in survival with the gemcitabine-based treatment in patients who had tumors of the pancreatic head [201].

Locally advanced disease

Treatment of locally advanced disease (tumor extension into adjacent major blood vessels or organs, preventing complete surgical resection with negative margins) in the United States has been defined by three randomized trials: two early Gastrointestinal Tumor Study Group (GITSG) trials and an Eastern Cooperative Oncology Group (ECOG) trial [202–204]. The treatment includes continuous infusion 5-FU and gemcitabine in combination with radiation therapy. Based on the results of the available randomized trials, it is unclear if radiation therapy is an essential element of treatment of patients with locally advanced pancreatic cancer.

Metastatic disease

Metastatic pancreatic cancer tends to be a rapidly progressing disease, often accompanied by a constellation of debilitating

symptoms. An important phase III randomized trial compared weekly gemcitabine ($n = 63$) with weekly bolus 5-FU ($n = 63$). Overall survival in patients treated with gemcitabine was significantly improved compared with patients treated with 5-FU (median survival 5.7 vs 4.4 months, respectively; $P = 0.0025$). The 1-year survival rates were 18% for patients treated with gemcitabine vs 2% in patients treated with 5-FU. Clinical benefit response was experienced by 24% of the patients treated with gemcitabine compared with only 5% of the patients treated with 5-FU ($P = 0.0022$) [205]. Most studies have shown no benefit in adding an additional agent to gemcitabine, compared with gemcitabine alone, in the management of metastatic pancreatic cancer. However, a randomized phase III trial has demonstrated statistically significant improved survival in advanced pancreatic cancer by adding erlotinib – an oral HER1 (epidermal growth factor receptor, EGFR) tyrosine kinase inhibitor – to gemcitabine in the management of locally advanced and metastatic pancreatic cancer [206].

Neoadjuvant therapy for locally advanced disease

Neoadjuvant therapy in patients with locally advanced disease may downstage the tumor and allow resection with clean surgical margins. There are several theoretical benefits to this approach where the treatment is given *prior* to surgery. Candidates for neoadjuvant therapy include not only patients with lesions of borderline resectability (e.g., those with CT or EUS evidence of vascular involvement), but also the larger group with radiographically resectable pancreatic cancer. However, for this latter group, no trial has ever shown an improvement in either resectability rate or survival when comparing preoperative with the more common adjuvant therapy. Therefore, neoadjuvant therapy has not been used widely and still must be considered experimental.

Prognosis

Surgical resection provides the only chance for cure, but the median survival after resection is only 18–20 months, and the overall 5-year survival is 20%. However, if the tumor is removed with clear surgical margins and no lymph node metastases are found, the 5-year survival may be as high as 50%. Various prognostic indicators for survival after resection for pancreatic cancer have been evaluated. One of the strongest factors is negative lymph node status. In one center, a median survival of more than 4.5 years was seen in patients with negative nodes, vs 11 months when nodes were involved. Unfortunately, even small tumors have metastasized to nodes in up to 80% of cases. Poorly differentiated tumors are associated with a worse prognosis than well-differentiated ones (10% vs 50% 5-year survival). Patients with smaller tumors (< 2 cm in diameter) tend to have a better prognosis than patients with larger tumors. Another important prognostic factor is whether the resection margins of the resection specimen are involved with tumor.

Less common exocrine pancreatic tumors

Mucinous cystadenoma and cystadenocarcinoma

Mucinous cystic neoplasms are large (often > 5 cm), bulky, unilobular, or multilobulated macrocysts containing mucin (Fig. 70.12). The cysts are lined with mucinous columnar epithelium that forms papillary projections, which may contain varying degrees of dysplasia ranging from benign to borderline to invasive cancer. They are associated with "ovarian stroma," which is pathognomonic of the process. Because mucinous cystadenomas are premalignant, they should be resected in most patients. Ninety percent of these tumors occur in the body/tail region of the pancreas, and the appropriate treatment is distal pancreatectomy. These neoplasms comprise 2%–5% of exocrine tumors and are more common in women (female-to-male ratio 9:1). The peak age of occurrence is 40–60 years [207]. They appear to have a better prognosis than ductal pancreatic cancers; the 5-year survival after a curative resection of a mucinous cystadenocarcinorna is at least 30%.

Serous cystadenoma and cystadenocarcinoma

These lesions are typically large, well-demarcated, multiloculated microcystic tumors. They usually have a characteristic honeycomb appearance, and the individual cysts are 1 cm or less in diameter, which is smaller than the individual cysts in mucinous cystic neoplasms (Fig. 70.13). They account for about 1% of neoplastic pancreatic lesions and usually occur in older adult women in the sixth and seventh decades of life.

Figure 70.12 Computed tomography scan of a patient with a malignant mucinous cystadenocarcinoma, which was resected.

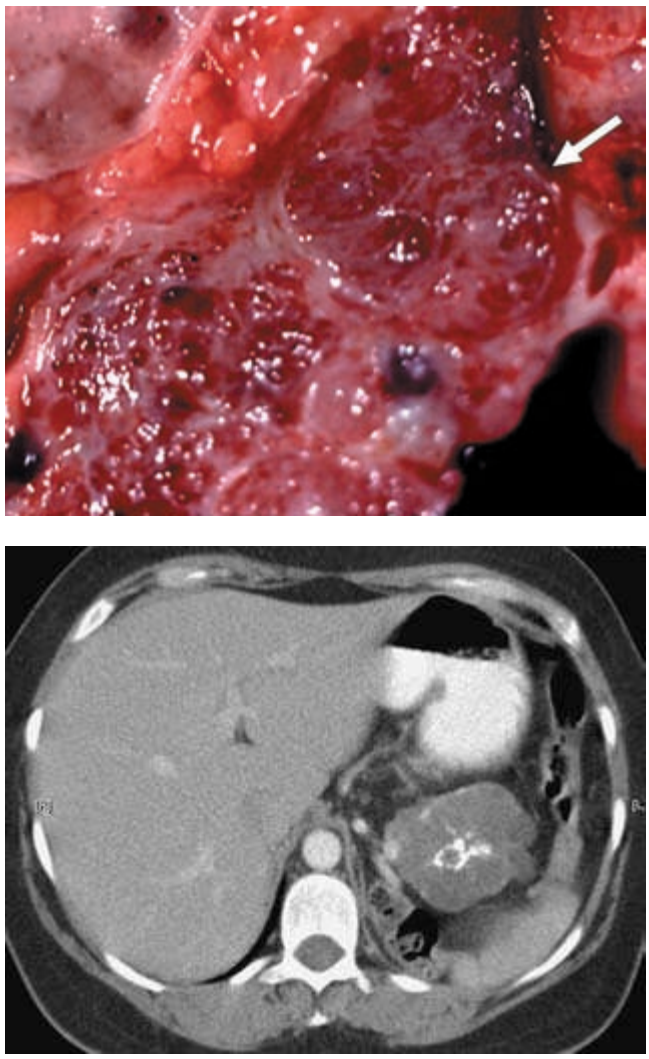

Figure 70.13 **(a)** Surgical resection of a serous cystadenoma (arrow) with the honeycomb appearance. **(b)** Computed tomography scan of patient with benign serous cystadenoma with the characteristic central calcification.

These so-called microcystic adenomas are usually asymptomatic and are found incidentally when a US or CT scan is done for some other reason. One-third of the tumors occur in the head of the pancreas [208,209]. Malignant transformation of serous lesions is rare. Although surgical resection offers a definitive diagnosis, because of the low risk of malignancy, surveillance is also an option for the management of these tumors. These neoplasms, as well as the mucinous cystic tumors previously discussed, should not be confused with pseudocysts, where internal or external drainage procedures are acceptable forms of treatment.

Solid and papillary epithelial neoplasm

Solid and papillary epithelial neoplasms appear to be increasing in frequency [210,211]. They are most common in adolescent girls and young women, and have a characteristic appearance on CT scan. The tumors are often large and may produce vague abdominal discomfort, which leads to their discovery. They have a favorable prognosis, and most patients are cured by resection. Nevertheless, some of these tumors may recur locally and there is one report of liver metastasis. The majority of these tumors occur in the body or tail of the pancreas, where they are treated with distal pancreatectomy. When they occur in the head, pancreaticoduodenectomy is required.

Intraductal papillary mucinous neoplasm

Patients with intraductal papillary mucinous neoplasm (IPMN) often present with repeated episodes of inflammation from underlying chronic pancreatitis [212]. In fact, these patients are likely to present with abdominal pain as the principal complaint. The pancreatitis is caused by obstruction of the pancreatic duct by intraductal tumor growth and inspissated mucus, which these tumors secrete (Fig. 70.14a). A dilated

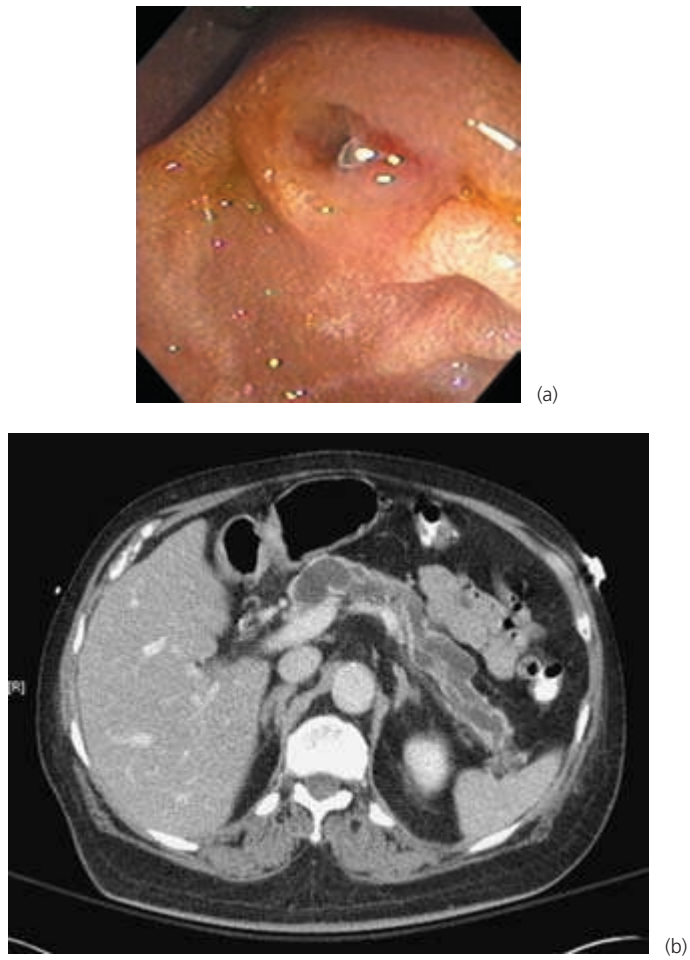

Figure 70.14 Main-duct intraductal papillary mucinous neoplasm (IPMN). **(a)** Endoscopic image of mucin extruding from ampulla in a main-duct IPMN. **(b)** Computed tomography imaging revealing a diffusely dilated main pancreatic duct in main-duct IPMN.

pancreatic duct is revealed by CT scans (Fig. 70.14b). The ductal dilation is confirmed by ERCP, which often shows intraductal mucus appearing as filling detects. A glob of mucus emanating from the gaping orifice of the ampulla of Vater is characteristically seen at the time of ERCP (Fig. 70.14a). Based on the origin of the disease, IPMN is classified into main duct type variant and a branch duct type (Fig. 70.15). Approximately half the lesions show papillary malignant changes, but even these tumors have a better prognosis than the usual ductal adenocarcinoma. A review of a single center's experience with 60 resected IPMNs revealed that these tumors are being recognized more frequently [213]. In this series, 37% of the resected IPMNs were associated with an adjacent invasive adenocarcinoma, and the 5-year survival for those patients undergoing IPMT resection was 57% [213]. Branch-duct-type IPMNs are considered to have less malignant potential compared with main-branch-type. Treatment is required both to remove any premalignant or malignant disease that may be present and also to relieve the episodes of pancreatitis. This may require total pancreatectomy because the entire pancreatic duct can be affected. Because of the lower risk of malignancy, surveillance has been advocated in patients with side branch IPMT [212].

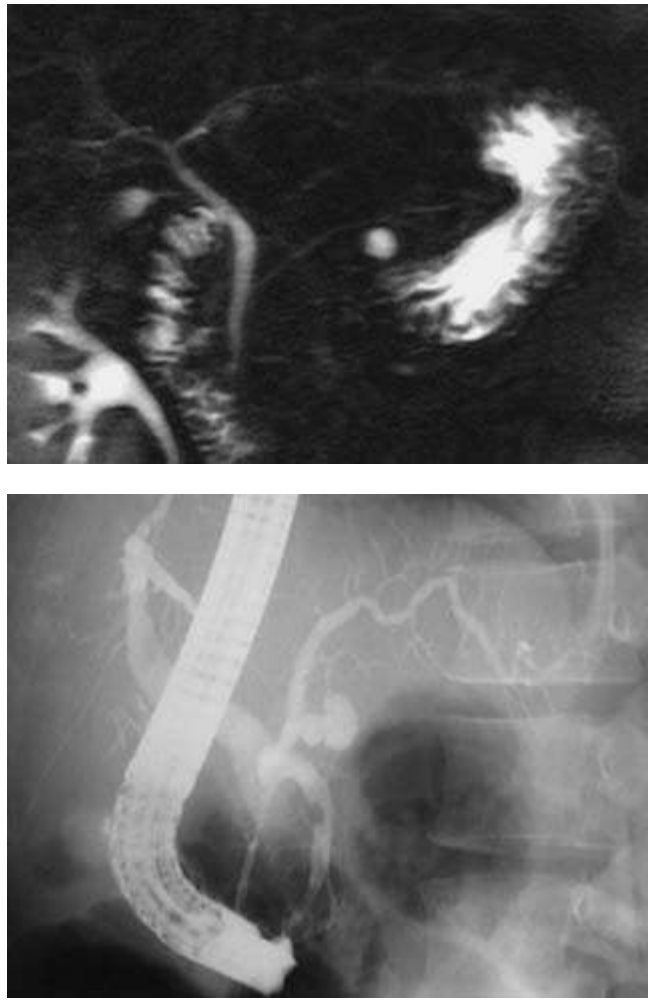

Figure 70.15 Branch-duct intraductal papillary mucinous neoplasm. **(a)** Magnetic resonance cholangiopancreatogram showing a normal pancreatic duct with an associated pancreatic body cyst. **(b)** Endoscopic retrograde cholangiopancreatogram showing opacification of a side-branch cyst.

Acinar cell tumor

Acinar cell carcinomas are uncommon and characterized by an acinar arrangement of cells supported by minimal fibrous stoma [214]. Zymogen granules are present, which may be identified by electron microscopy. Patients may have elevated serum lipase levels and associated nonsuppurative panniculitis of the extremities and bone marrow, and manifest subcutaneous nodules and polyarthritis. These tumors usually occur in adults in their sixth to eighth decades of life [215].

71 Endocrine neoplasms of the pancreas

Robert T. Jensen

Epidemiology, 1875
Pathology and tumor biology, 1876
Clinical features and diagnosis, 1879
Tumor localization, 1890
Treatment, 1897

Endocrine tumors of the pancreas are classified according to the type of clinical syndrome present (Table 71.1). In general they share a number of common features including various aspects of pathology, natural history, considerations in treatment, localization studies, and treatment of metastatic tumors. In each case, except for nonfunctioning pancreatic endocrine tumors (PETs), the principal clinical manifestations of the endocrine tumor are due to the extensive release of hormones by the tumor into the circulation. Each of the various hormones released in the different syndromes occurs naturally and is important in mediating various physiological processes (see Chapter 41). However, in the PET syndromes these hormones are not under normal physiological regulation and are released autonomously by the tumor. Pancreatic endocrine tumors are classified as either functional or nonfunctional (Table 71.1) depending on whether a clinical syndrome caused by an ectopically released hormone is present. Nonfunctional PETs frequently ectopically release hormones and peptides – pancreatic polypeptide (PP), chromogranin, neurotensin, or neuron-specific enolase; however, these cause no distinct clinical syndromes [1–6]. The term "nonfunctional PET" is commonly used and will be retained here to mean any PET not secreting products that cause a distinct syndrome although some actually release peptides and are, strictly speaking, functioning. The term "pancreatic endocrine tumor" (PET) is also retained in this chapter to indicate the tumors listed in Table 71.1, although it is also a misnomer in that a number of these tumors also occur outside the pancreas – i.e., gastrinomas, VIPomas (vasoactive intestinal polypeptide), somatostatinomas, GRFomas (growth hormone-releasing factor), and ACTHomas (adrenocorticotrophic hormone) (Table 71.1). These tumors are also frequently called islet cell tumors; however, it is unproven that they originate from pancreatic islets [7,8]. It is important to realize that although these tumors are usually slow growing in many cases, some are aggressive [2,9,10], therefore effective therapy will require treatment of the autonomous hormone overproduction and treatment directed at the tumor itself. In this chapter the common features of these tumors will be dealt with together and the distinctive features separately. Gastrinoma was discussed in Chapter 4 and will, in general, not be dealt with.

Epidemiology

In general, PETs are uncommon, having a prevalence of less than 10 per million population [2,11–13]. In some older series insulinomas were reported to be the most common PET, with an incidence in various series of 0.8–0.9 per million population per year, whereas gastrinomas were reported to occur in 0.1–0.4 per million per year [14]. However, in subsequent studies [11,14], gastrinomas were as common as insulinomas (1–3 new cases/year/million population). The remaining symptomatic PETs each occur in fewer than 0.5 per million per year [11,12]. Approximately 400 cases of glucagonoma have been reported worldwide [15–18], 250 cases of VIPomas [19–21], and 201 cases of somatostatinomas [22–26]; the number of cases of GRFomas is unclear. The relative frequency of these tumors is insulinomas, nonfunctional PETs, and gastrinomas occurring approximately with equal frequency, 2–8 times more commonly than VIPomas, and 17–30 times more commonly than glucagonomas [2,11,12]. Somatostatinomas were equal in frequency to glucagonomas in some studies, but less common in others [2,11,12]. In various series PETs had an incidence equal to [12], or half that [27] of carcinoid tumors. In autopsy studies, PETs occur in 0.5%–1.5% of cases [4,9,12]; however, in less than 1 in 1000 cases was a functioning PET thought to occur [9,12]. In surgical studies nonfunctioning PETs are reported to comprise 15%–33% of all PETs removed [1,28–30], and in a large pathology series they accounted for 36% of all PETs [4]. In addition to the established PETs listed in Table 71.1, it has been proposed [31] that PETs secreting calcitonin cause

Table 71.1 Endocrine tumors of the pancreas

Name of tumor	Name of syndrome	Signs or symptoms	Primary location	Hormone causing syndrome
Gastrinoma	Zollinger–Ellison syndrome	Abdominal pain Diarrhea Esophageal symptoms	Pancreas 60% Duodenum 30% Other 10%	Gastrin
Insulinoma	Insulinoma	Hypoglycemic symptoms	Pancreas 99–100%	Insulin
Glucagonoma	Glucagonoma	Rash, anemia Diabetes/glucose intolerance Weight loss Thromboembolic disease	Pancreas 99–100%	Glucagon
VIPoma	Verner–Morrison Pancreatic cholera WDHA	Severe watery diarrhea Hypokalemia	Pancreas 90% Other 10% (neural, adrenal, periganglionic tissue)	VIP
Somatostatinoma syndrome	Somatostatinoma	Diabetes mellitus Cholelithiases Diarrhea Steatorrhea	Pancreas 56% Duodenum/jejunum 44%	Somatostatin
GRFoma	GRFoma	Acromegaly	Pancreas 30% Lung 54% Jejunum 7% Other 13% (adrenal, foregut, retroperitoneum)	GRF
ACTHoma	ACTHoma	Cushing syndrome	Pancreas 4–16% all ectopic Cushing	ACTH
PET causing carcinoid syndrome	–	Diarrhea Flushing	Pancreas 100%	Serotonin, tachykinins, prostaglandins
PET causing hypercalcemia	–	Symptoms due to increased calcium	Pancreas 100%	PTHrP
Nonfunctioning	PPoma Nonfunctional	Weight loss Abdominal mass Occasionally asymptomatic hepatomegaly	Pancreas 100%	None (PP or chromogranin released but no symptoms due to hypersecretion)

ACTH, adrenocorticotrophic hormone; GRF, growth hormone-releasing factor; PET, pancreatic endocrine tumor; PP, pancreatic polypeptide; PTHrP, parathormone-related peptide; VIP, vasoactive intestinal polypeptide; WDHA, watery diarrhea, hypokalemia, achlorhydria.

a distinct syndrome with diarrhea; however, too few have been described to establish them as constituting a distinct syndrome. In addition, rare cases have been described of PETs secreting renin and causing hypertension [32]; secreting erythropoietin to cause erythrocytosis and polycythemia [33]; secreting luteinizing-hormone and causing masculinization [34,35], and ovarian tumors secreting peptide YY (PYY) causing constipation [36–38].

Pathology and tumor biology

Pancreatic endocrine tumors share a number of pathological features [8,39]. These tumors frequently contain ductular structures and produce hormones not normally produced in the adult pancreas. Therefore they are thought by some to originate from an immature stem cell [4]. Because endocrine cells bud off from ductules during ontogenesis of the pancreas and ductular structures are present in these tumors, it has been suggested these cells may originate from ducts. A study in patients with multiple endocrine neoplasia type I (MEN-I), 80%–100% of whom develop PETs, provided evidence that the PETs originate from ducts [40], whereas a second study concluded they developed from islets [41]. The tumors are thought to originate from cells that are part of the diffuse neuroendocrine cell system [8,42]. These cells share cytochemical properties, and these tumors, together with carcinoid tumors, medullary carcinoma of the thyroid,

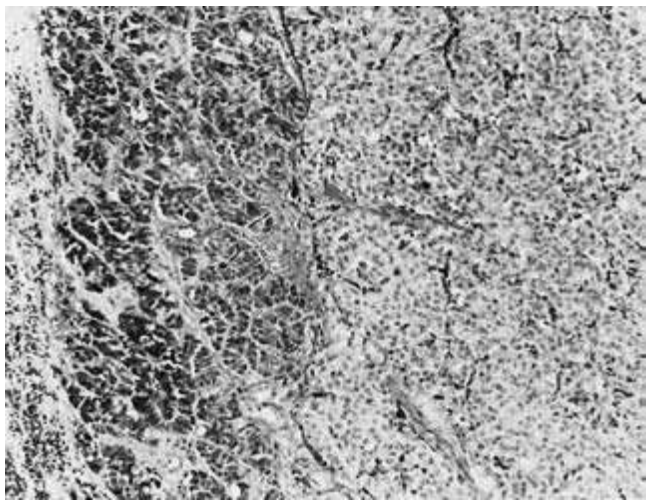

Figure 71.1 Photomicrograph of an insulinoma. This insulinoma (right) demonstrates a typical histological pattern seen with pancreatic endocrine tumors, with monotonous sheets of small, round cells with uniform nuclei and cytoplasm. The tumor is well marginated and interfaces with the normal pancreas (left) by a distinct margin. (H & E stain; original magnification × 100.)

melanomas, and pheochromocytomas, have been called APUDomas (amine precursor uptake and decarboxylation) [2,8,42,43]. The tumors are composed of monotonous sheets of small round cells with uniform nuclei and cytoplasm (Fig. 71.1). Mitotic figures are uncommon. Ultrastructurally, the tumors demonstrate electron-dense granules that contain various peptides, amines, neuron-specific enolase, synaptophysin, and chromogranin A and C [2,8,39,43]. Frequently PETs are multihormonal when examined by immunocytochemical techniques [4,8,14,28,44,45]. In various series over 50% of all PETs contain more than one hormone as determined by immunocytochemistry [14,44–46]. In insulinomas, for example, glucagon has been identified by immunocytochemical methods in 0%–44%, somatostatin in 0%–18%, gastrin in 3%–11%, PP in 18%–39%, and ACTH-like immunoreactivity in 11% [28,43]. Particularly common are PP cells, which have been identified in 22%–39% of insulinomas, 0%–67% of glucagonomas, and 50%–75% of VIPomas [28]. In some cases numerous hormones are released into the circulation whereas in others only one peptide may be detectable [28,44,45]. It is not apparent why patients with a given PET syndrome present only with a syndrome characteristic of hypersecretion of only one of these peptides; although the tumor contains multiple peptides [47].

In addition to producing and frequently releasing multiple gastrointestinal peptides, PETs produce a number of products that are characteristic of neuroendocrine differentiation and are used to identify these tumors [8,39]. These general markers are neuron-specific enolase, chromogranins A, B, and C, synaptophysin, epitope Leu-7, protein gene product (PGP)-9.5, and the alpha or beta subunit of human chorionic gonadotropin (α- or β-HCG) [3,12,48–52]. Chromogranins are acidic glycoproteins that are present in almost all endocrine or neuronal tissue [3]. Chromogranin is released into the plasma in patients with PETs or carcinoid tumors [27,48,53,54], and elevated plasma levels of chromogranin A, B, or C are reported in more than 90% of such patients [3,4,27,48,49,54]. Increased plasma levels of α-HCG and β-HCG also occur in PETs and have been reported by some to be suggestive of malignancy; however, this remains controversial [2,3,14,28,48,55]. Neuron-specific enolase (NSE), the γ-γ dimer of the glycolytic enzyme enolase, occurs in the cytoplasm of most neuroendocrine cells, is present in most PETs as well as carcinoids and other APUDomas [3,42,51], and is frequently released into the plasma and can be used as a tumor marker [48,56]. Synaptophysin is a calcium-binding vesicle membrane glycoprotein that is synthesized independently of the other neuroendocrine proteins [12]. The presence of chromogranin immunoreactivity in the tumor is the most generally used marker to identify a pancreatic tumor as endocrine in origin [8,39].

Because patients with PETs are living longer as a result of increasingly effective therapy, the development of a secondary symptomatic PET syndrome may become more common [44,45]. One study suggests that a secondary symptomatic PET syndrome is common, occurring in 7.5% of patients with a mean follow-up of 19 months [44], whereas another study suggests it is uncommon, occurring in only 2% of patients with gastrinoma followed for a mean duration of 11 years [45]. Because of the frequent presence of multiple peptides in the PET as shown by immunocytochemistry, it has become increasingly difficult, if not impossible in most cases, to determine immunocytochemically which of the hormones found in the tumor are clinically important in that patient [14,43]. Therefore, a functional PET syndrome should only be diagnosed if the clinical symptoms are present and plasma elevations are documented, and not on the basis of immunohistochemical results only.

A WHO classification has been proposed for PETs, as well as carcinoids and other gastrointestinal (GI) neuroendocrine tumors, assigning the tumors to one of three categories (well-differentiated tumor, well-differentiated carcinoma, poorly differentiated carcinomas) based on their size and histology, including measures of proliferation (mitoses, proliferative antigen Ki-67) [8,39]. Furthermore, for the first time a consensus conference has proposed a TNM staging classification of PETs and other foregut neuroendocrine tumors, and also proposed a working formulation for the grading of these tumors based on mitotic index and the Ki-67 index [57]. This classification system is meant to help clinicians in the stratification, treatment, and follow-up of these patients [57]. In general, histological classification of PETs has failed to predict the growth pattern of the tumor or determine whether it is malignant [8,14,43,58]. Furthermore, there is no definite

correlation between the histological pattern and the type of clinical syndrome the tumor is associated with [14,43,59]. Therefore, at present malignancy can only be unequivocally established in those patients who are demonstrated to have metastatic tumor spread either to lymph nodes or the liver, gross invasion or infiltration into adjacent organs, or clear blood vessel invasion [14,43]. Because of this it is not fully established what percentage of PETs are malignant. The benign nature can only be established by long-term follow-up. In general, 5%–10% of insulinomas are reported as malignant, whereas in various series 50%–90% of the other tumors are reported as malignant [2,9,14,18,19,22,25,43,59,60].

The size of the tumor is usually not related to the severity of the hormonally induced symptoms; however, in general, there is a correlation between size and the occurrence of malignancy [9,10,46,57,59,61]. Whereas insulinomas, like gastrinomas, are generally small (< 2 cm), glucagonomas and the other PETs are larger at the time of detection (frequently > 5 cm) [14,18,19,22,25,59,60]. The majority of the primary PETs are solitary and encapsulated when not associated with MEN-I (see below) [8,39]. When metastatic spread occurs it is usually to regional lymph nodes first and later to the liver. Late in the course of the disease, metastases to bone may also occur [10,62].

Pancreatic endocrine tumors may occur either in a nonfamilial form (sporadic) or be associated with an inherited syndrome [7,8,63–66]. Inherited syndromes associated with PETs include MEN1 and three phacomatoses (von Recklinghausen disease, von Hippel–Lindau disease, and tuberous sclerosis) [12,63,65]. Multiple endocrine neoplasia type I (or Wermer syndrome) is an autosomal dominant disorder characterized by tumors or hyperplasia of multiple endocrine organs. Hypercalcemia due to hyperparathyroidism is the most common abnormality (i.e., occurring in 97% of patients) [63,65,67], whereas nonfunctional PETs are the second most frequent abnormality, occurring in 80%–100%. Functional PETs occur in 40%–80% of patients with MEN-I. The incidence of gastrinomas, insulinomas, glucagonomas, and VIPomas in MEN-I is 54%, 21%, 2%–3%, and 1%–3%, respectively [4,68]. Pituitary and adrenal cortical adenomas also occur but are less common [4,67]. The chromosomal defect in MEN-I maps to chromosome 11q13, and a study [69] using positional cloning identified the *MEN1* gene in this region; the gene is proposed to function as a tumor suppressor gene [68]. The *MEN1* gene contains 10 exons and encodes a unique ubiquitously expressed 610-amino acid protein, called menin, a nuclear protein that binds to numerous transcription factors [65]; however, its exact function remains unclear. Studies [70,71] suggest a similar double acquired loss of the *MEN1* gene may be important in sporadic (noninherited) PETs because 32%–38% of these have loss of heterozygosity at the 11q13 locus [65,71]. Furthermore, 27%–39% of sporadic PETs have mutations in the *MEN1* gene, suggesting that some sporadic PETs have a pathogenesis similar to PETs in patients with MEN-I [71]. The exact percentage of patients with PETs who have MEN-I varies in different series and with different tumors, from less than 5% to 25% [14,72]. Multiple endocrine neoplasia type I is present in 20%–25% of patients with gastrinomas [14,73], in 4%–6% with insulinomas [60], in 13%–17% with glucagonomas [17,18], in 6%–11% of patients with VIPomas [19,74], in 7% with somatostatinomas [25], and in 33% with GRFomas [22]. The recognition that the PET can be part of the MEN-I syndrome is important because multiple PETs are frequently present [14]. Furthermore, screening of family members for various features of the syndrome is indicated [14].

Almost all insulinomas either occur in the pancreas (Table 71.1) or are attached to it [60,75–78] although rarely an aberrant insulinoma may be found in carcinoid tumors in the duodenum, ileum, lung, or mesentery [60,75]. Multiple insulinomas occur in only 10%–13% of cases, and in these patients the presence of MEN-I should be suspected [59,60]. Glucagonomas occur almost entirely within the pancreas, usually in the pancreatic body and tail [16–18,59,79,80]. In contrast to insulinomas or gastrinomas, the majority of glucagonomas are usually large (3–10 cm) at the time of diagnosis [16–18,59,79,80]. Almost all VIPomas in adults are pancreatic in location (i.e., > 90%); however, occasionally the VIPoma syndrome is reported in association with a pheochromocytoma or carcinoid tumor of the intestine [19–21]. In children, the VIPoma syndrome is often caused by a ganglioneuroma or ganglioneuroblastoma [21,81,82]. VIPomas are usually large tumors [19,21,80]. Somatostatinomas, similar to gastrinomas, frequently are found in extrapancreatic locations (Table 71.1) [14,22,23,25]. In various reviews [22,25], 47%–56% of somatostatinomas are in the pancreas, usually in the pancreatic head, and 44%–52% are extrapancreatic, usually in the small intestine (duodenum or jejunum). Similar to glucagonomas or VIPomas, somatostatinomas tend to be large (mean size 5 cm) [23,25,83]. Nonfunctioning PETs and PPomas occur in the pancreas, and are usually greater than 5 cm in diameter [1,30]. Other less common functioning PETs such as those associated with acromegaly (GRFomas) [23,84], carcinoid syndrome [85], paraneoplastic hypercalcemia [28,86,87], or Cushing syndrome [28,88–90] are usually large tumors within the pancreas.

In addition to the MEN-I syndrome, there are reports of PETs in patients with von Recklinghausen disease [24,66,91–93], von Hippel–Lindau disease [66,94], and tuberous sclerosis [66]. In a number of patients with von Recklinghausen disease duodenal somatostatinomas are reported [24,25,66,92,93] as well as, rarely, Zollinger–Ellison syndrome [91]. In von Hippel–Lindau syndrome, 10%–17% of the patients have a PET, which is usually nonfunctional, but occasional insulinomas and VIPomas are described [4,66]. Somatostatinomas have also been reported in von Hippel–

Lindau disease [95]. Among patients with tuberous sclerosis, three were reported with insulinomas and one with a nonfunctioning PET [4,66].

For a time the molecular pathogenesis of PETs was largely unknown [7,64,65]. In contrast to most common nonendocrine tumors (e.g., pancreatic, colonic, gastric adenocarcinomas), alterations in neither common tumor suppressor genes (retinoblastoma gene, p53 gene) nor common oncogenes (e.g., *JUN*, *SRC*, *RAS*, *FOS*, *MYC*) are generally present in PETs or the closely related carcinoid tumor [7,63–65], suggesting they are not generally important in their molecular pathogenesis. However, studies suggest alterations in the *MEN1* gene (as discussed above), the *p16/MTS1* tumor suppressor gene, and in the *DPC64/SMAD4* gene; amplification of the *HER-2/neu* (ERBB2) protooncogene; and loss of an unknown tumor suppressor gene on chromosome 1 or 3p, which could also be important [7,9,63–65]. Comparative genomic hybridization and genome-wide allelotyping studies show that both chromosomal losses (especially 1p, 3p, 3q, 6p, and 22q) and gains (especially 7q, 17q, 17p, and 20q) are common events, and that the frequency of these changes differs between PETs and carcinoids, suggesting that they have a different pathogenesis [64,65]. There are mutations in the *MEN1* gene in one-third of sporadic PETs [71], and alterations in the *p16/MTS1* gene in 50%–92% of PETs, suggesting that these are particularly important. Whether the presence of these alterations carries a worse prognosis is unclear.

Clinical features and diagnosis

In each PET syndrome, except with nonfunctioning tumors, early symptoms are caused by the excessive hormone release, whereas late symptoms (e.g., cachexia, pain, bleeding) are primarily due to the metastatic spread of the tumor per se.

Insulinoma

Insulinomas are endocrine tumors that originate in the pancreas, secrete excessive amounts of insulin, and cause a distinct syndrome characterized by symptoms caused by hypoglycemia.

Insulinomas rarely occur in adolescence. The average age at presentation in most series is between 40 and 50 years, with 60% of the insulinomas occurring in females [4,59,60,76,76,77,96].

The clinical manifestations of insulinomas are due to the hypoglycemia secondary to the excess unregulated insulin secretion by the tumor. The symptoms are typically associated with fasting, that is, the attacks characteristically occur before breakfast, when a meal is delayed, or hours postprandially. The majority of patients have symptoms of central nervous system dysfunction secondary to hypoglycemia (neuroglycopenic symptoms), which include headaches, confusion, lightheadedness, visual disturbances, irrational behavior, drowsiness, or even confusion resulting in coma. Patients with insulinomas misdiagnosed as psychiatric or neurological problems have been reported [12]. The majority of patients also have symptoms due to catecholamine excess secondary to the hypoglycemia, such as sweating, tremor, palpitations, and irritability [59]. The average time from onset of symptoms to diagnosis is 3 years, although some studies suggest this to be decreasing [4,97].

The presence of an insulinoma should be suspected in all patients with hypoglycemia, especially patients with a history of fasting hypoglycemia or with a family history of MEN-I. Fasting hypoglycemia can result from a number of different conditions (Table 71.2) [59,76,98–100]. It should be remembered that insulinoma is only one cause of fasting hypoglycemia, and other causes should also be suspected such as inadvertent or deliberate administration of insulin, ingestion of oral hypoglycemia agents, alcoholism with severe liver disease or malnutrition, or other extrapancreatic tumors (Table 71.2). The diagnosis of insulinoma requires the demonstration of hypoglycemia combined with an inappropriate elevation of plasma insulin concentration and ultimately a PET. Insulinomas characteristically cause hypoglycemia during fasting, in contrast to postprandial hypoglycemia, which is seen in a number of conditions such as after gastric bypass surgery for obesity [100–102].

The key to establishing the diagnosis is suspecting the symptoms could be due to hypoglycemia; the Whipple triad [103], described in 1938, was long used to diagnose insulinomas. It consisted of: presence of hypoglycemic symptoms; detection of hypoglycemia (< 50 mg/dL); and relief of symptoms with glucose ingestion. Unfortunately the symptoms are not specific for insulinoma [104]; in a large review of 1085 cases they were present in only 43% of cases of insulinomas [60]. Consequently, a fast with monitoring of plasma insulin, glucose, C-peptide, and proinsulin values is the study usually used to establish the diagnosis of insulinoma [76–78,99]. A 72-hour fast in the hospital (with free access to water) is usually undertaken [59,99]. The above mentioned blood studies should be monitored at regular intervals (2–4 h) and more frequently if the blood sugar level decreases to less than 50 mg/dL. If at any point the patient becomes symptomatic, repeat serum levels of the studies listed above should be obtained before administering glucose. The test is terminated for neuroglycopenic symptoms or for persistent glucose levels of less than 40 mg/dL. Over 90% of insulinomas reported have been detected in this fashion, and 70%–80% of patients will develop hypoglycemia during the first 24 h of fasting, and 90%–98% by 48 h [59,76]. In normal nonobese subjects, serum insulin concentrations decrease to less than 6 μU/mL (i.e., assessed by the standard insulin radioimmunoassay [RIA]) when blood glucose decreases to 40 mg/dL or less, and the ratio of serum insulin to glucose remains less than 0.3 (in mg/dL) [59,98,99]. An insulinoma is considered present if serum insulin concentrations remain

Table 71.2 Causes of fasting hypoglycemia

Category	Cause or agent
Mediated by endogenous insulin or insulin-like factors	Pancreatic islet disease (insulinoma, hyperplasia, nesidioblastosis) Spontaneous autoimmune antiinsulin antibody syndrome Autoantibodies to insulin receptor Noninsulin tumor-associated hypoglycemia
Reduced hepatic glucose output	Deficient gluconeogenesis or glycogen storage Hormonal deficiencies (e.g., adrenal insufficiency) Enzymatic defects (e.g., glucose-6-phosphatase deficiency) Ethanol consumption and poor nutrition Severe liver disease
Drugs or other pharmacological causes	Sulfonylureas or biguanides Insulin administration Ingestion of ackee fruits (hypoglycin) Other drugs (aspirin, pentamidine, haloperidol, quinine)

Modified from Jensen [4]; Boden [59]; Grant [76]; Comi et al. [99].

constant or increase during hypoglycemia. One set of proposed criteria are:

- documented glucose levels near or below 40 mg/dL (2.2 mM)
- concomitant insulin levels ≥ 6 μU/mL (43 pmol/L)
- elevated C-peptide levels (≥ 0.2 nmol/mL in a patient without elevated sulfonylureas in the plasma) [76].

Some add a requirement for a serum proinsulin greater than or equal to 5 pmol/L [77,105] or an insulin:glucose ratio greater than 0.3 [59,99]. In one study all 114 patients with insulinoma operated on between 1980 and 1995 had a positive fast [76], whereas in another review all 132 patients with insulinomas fulfilled the biochemical criteria, but 4 of 132 patients (3%) did not become symptomatic [106]. In the small percentage of patients with a negative test (i.e., serum insulin concentration decreases to < 6 μU/mL with hypoglycemia) but in whom insulinoma is still suspected, additional tests such as various provocative tests may have to be used [28,59,76,98,99,106]. Plasma insulin is being increasingly measured by insulin-specific immunoradiometric assay or immunochemoluminescent assays, which have no cross-reactivity with proinsulin, as do many of the standard insulin RIAs, and thus give lower insulin levels; resulting in 30%–60% of patients with insulinomas having plasma insulin levels below 6 μU/mL [107,108]. Using insulin-, proinsulin-, and C-peptide-specific assays a study involving 33 insulinoma patients and 67 controls [108] demonstrated that the most sensitive criterion for diagnosing insulinoma was the combination of an elevated proinsulin level with a fasting glucose level below 45 mg% [108].

The diagnosis of insulinoma can be difficult because an inappropriately elevated serum insulin concentration associated with hypoglycemia can be observed in a number of different conditions (Table 71.2) [100]. Besides insulinomas, β-cell hyperplasia (or nesidioblastosis), factitious or inadvertent administration of excessive insulin or oral hypoglycemia agents, and autoantibodies against insulin or the insulin receptor can also cause these findings (Table 71.2) [59,99,100]. β-Cell hyperplasia, or nesidioblastosis, consisting of a proliferation of insulin-producing cells, is a leading cause of hyperinsulinism in newborns and has also occasionally been reported in adults [99,109]. Of these varying causes of hypoglycemia and hyperinsulinemia (Table 71.2), surreptitious use of insulin or sulfonylureas is the most difficult to distinguish from an insulinoma [98–100,105,110]. To differentiate these conditions determinations of serum concentrations of proinsulin, C-peptide, antibodies to insulin, and sulfonylurea need to be done [76,98–100,105,110].

Insulin is synthesized as proinsulin, which consists of a single-chain molecule containing both a 21-amino-acid α-chain and a 30-amino-acid β-chain connected by a 33-amino-acid connecting peptide (C-peptide) [111,112]. Insulin and C-peptide are liberated in equimolar amounts, and because proinsulin or its intermediate are also found in granules it is also detected in small quantities in the serum with insulin [99,111,112]. Normal subjects have less than 25% of the serum insulin as proinsulin. Serum proinsulin has been reported to be elevated in at least 80%–90% of patients with insulinoma [98,99,108,112]. Because high proinsulin values are not found in other hypoglycemic disorders (elevated levels can occur in cirrhotics and patients with type 2 diabetes), an elevated value is helpful in the diagnosis of insulinoma. In insulinoma the characteristic findings are either a normal or elevated serum concentration of C-peptide, absence of antibodies to insulin, and lack of detectable sulfonylurea in the blood [76,98,100,108]. In a typical patient with surreptitious use of insulin the C-peptide level is decreased, proinsulin is

normal or decreased, antibodies to insulin may be present, and serum sulfonylurea determinations are negative [98,99]. In patients who surreptitiously use sulfonylureas, the serum concentration of proinsulin is usually normal, antibodies to insulin are not present, and sulfonylurea is detected in the serum or the urine [98,99].

VIPoma

The VIPoma syndrome is due to an endocrine tumor, usually located in the pancreas, that secretes excessive amounts of vasoactive intestinal peptide (VIP), which causes a distinct syndrome characterized by fasting, large-volume diarrhea, hypokalemia, and hypochlorhydria (Table 71.3).

The VIPoma syndrome is also called the Verner–Morrison syndrome because of its original description by these two authors in two patients with profuse watery diarrhea, hypokalemia, and dehydration with a non-β-cell pancreatic islet cell tumor [113]. It has also been termed pancreatic cholera, and the WDHA syndrome (for the watery diarrhea, hypokalemia, and achlorhydria that some patients develop) [20,21,82]. Although early in the presentation the diarrhea may be episodic or intermittent, characteristically the diarrhea is large in volume (> 1 L/day), secretory in nature, and persists during fasting (Table 71.3) [4,20,21,28,114–116]. The diarrhea fluid frequently is described as having the appearance of weak tea. An increased net secretion of sodium and chloride into the small intestine has been demonstrated in these patients [117,118]. The sum of fecal sodium and potassium concentrations multiplied by two will equal the osmolality, thus there is no osmotic gap [21]. In general these patients are reported not to develop steatorrhea [21,116] – in only 16% in one study [21] – nor have abdominal cramping pain, but some studies suggest pain may be more common than reported previously [21,28,74]. Studies assessing malabsorption are usually normal, with a normal fecal fat excretion in 84%, normal D-xylose in 94%, and a normal Schilling test in 87% [21]. The increased fecal loss frequently leads to dehydration (Table 71.3) [21,74]. Hypokalemia is present in most patients (Table 71.3) [19–21,74,114,119,120] and is the result of the large losses of potassium in the diarrhea fluid. Hypochlorhydria rather than achlorhydria is found in 28%–76% of patients with VIPoma syndrome (Table 71.3) [20,74,119]. This has been attributed to the inhibitory effect of VIP on gastric acid secretion [20,28]. Flushing is seen in 13%–28% of patients with the VIPoma syndrome [19,20,74,121] and has been attributed to the vasodilatory effects of VIP (Table 71.3) [20,122]. The fact that prolonged infusion with VIP in humans results in a gradual decrease in the flushing suggests the development of tachyphylaxis [12]. This phenomenon has been used to explain why only a minority of patients develop flushing [20]. Hyperglycemia is noted in 20%–50% of patients with VIPomas [21,74], and it has been attributed [20] to the glycogenolytic effect of VIP on the liver (Table 71.3) [123]. Hypercalcemia also is reported in 25%–76% of patients with VIPoma [20,21,28,74]. At present the mechanism of hypercalcemia in most cases is not established; however, it seems to be related to the tumor itself because it is relieved by complete tumor removal [21]. Only 6%–11% of patients with VIPomas have a history of MEN-I, and only 1%–3% of all MEN-I patients develop VIPomas, and therefore this is rarely the cause of the hypercalcemia [19,21,68,72,74].

Table 71.3 Clinical features of the VIPoma syndrome

Sign/symptom	Frequency (%)
Secretory diarrhea	89–100
Hypokalemia	67–100
Weight loss	33–72
Dehydration	44–95
Hypochlorhydria	34–76
Hyperglycemia	20–50
Hypercalcemia	25–50
Flushing	13–28
Dilated, atonic gallbladder	Unknown

Data from Jensen [4]; Soga and Yakuwa [19]; Matuchansky and Rambaud [21]; Smith et al. [114]; Verner and Morrison [119,136].

Beside VIP a number of substances [20,124], including secretin [12], gastric inhibitory polypeptide [125], pancreatic polypeptide [126], and prostaglandins [127], are reported to cause diarrheogenic secretion in some patients. Controversy arose in early studies about whether or not VIP was the sole cause of the diarrhea in WDHA, because VIP was not found to be elevated in all patients by different investigators, and exogenous VIP infusions for 1 or 2 h did not cause diarrhea in humans [128]. However, in subsequent studies only VIP has been found to be elevated consistently in patients with the WDHA syndrome [20,81,114,120,124,129,130]. Furthermore, continuous infusion of VIP for 10 h in normal subjects to achieve plasma VIP concentrations similar to those seen in patients with WDHA produced profuse watery diarrhea by 6–7 h [129,131]. The diarrhea produced in these patients is similar to that seen in patients with WDHA. The ability of VIP to cause intestinal secretion is consistent with its known mechanism of action. Vasoactive intestinal peptide has been shown to cause net chloride secretion associated with increased short circuit current, to bind to specific receptors on intestinal epithelial cells, and to activate adenylate cyclase and increase cyclic AMP levels in intestinal cells [28,132]. Occasional patients with the WDHA syndrome have normal plasma concentrations of VIP [20]. Another VIP-related peptide, peptide histidine isoleucine (PHI), is reported to be elevated in the plasma of patients with WDHA [21,28,133,134]. Tumor tissue obtained from patients with the WDHA syndrome also demonstrated PHI-like immunoreactivity, which was produced by the same cells as VIP [21,28,133,134].

Furthermore, analysis of a WDHA tumor demonstrated that VIP and PHI sequences are in the same gene [132,134]. Infusions of PHI also caused intestinal secretion although PHI was 32 times less potent than VIP [135]; therefore, although PHI was reported to coexist in 22 of 24 VIPomas [133], because of its low potency it remains to be proven whether PHI is contributing to the diarrheal state [21].

The definite diagnosis of VIPoma requires the establishment of a secretory diarrhea, demonstration of elevated serum concentrations of VIP and identification of a PET. The possibility that VIPoma and not some other cause is responsible for the diarrhea may be suggested by measuring the stool volume [20,21,28,116]. In 70%–80% of patients with VIPomas the stool output is greater than 3 L/day [21,136]; in 100% of 52 patients it was greater than 1 L/day [21]; and when the stool output is less than 700 mL/day the diagnosis of VIPoma is excluded [20]. In addition the diarrhea persists during fasting [20,21,114] and the sum of the concentration of stool sodium and potassium multiplied by two equals the isotonicity [21].

A number of diseases can give chronic secretory diarrheas with similar volumes and need to be differentiated from VIPomas [116]. The diarrheas due to midgut carcinoids in the carcinoid syndrome or medullary thyroid carcinoma are primarily due to motility disturbances and rarely reach the volume typical of VIPoma syndrome [21,116]. However, high-volume fasting diarrhea occurs in patients with Zollinger–Ellison syndrome [14,73,116], diffuse islet-cell hyperplasia [21], patients who surreptitiously use laxatives or diuretics, the pseudopancreatic cholera syndrome [21,81,137], and patients with other disorders such as AIDS [138,139] or, occasionally, sprue [140,141]. The serum gastrin concentration is elevated in patients with Zollinger–Ellison syndrome but not in patients with VIPoma. Furthermore, effective treatment of the gastric hypersecretion stops the diarrhea in patients with Zollinger–Ellison syndrome [14,73,116,142].

To differentiate patients with VIPoma from those with pseudopancreatic cholera syndrome or laxative abuse a reliable VIP radioimmunoassay is required [20,21,81]. The normal fasting plasma VIP concentration measured in a number of laboratories ranges from 0 to 190 pg/mL [20,81,124]. The fasting plasma VIP concentration is best determined at the time when diarrhea is present because between diarrheal periods in an occasional patient with VIPoma, VIP levels may be normal [20]. The mean concentration of plasma VIP in one series of 29 patients with the VIPoma syndrome was 956 pg/mL, with a range of 225–1850 pg/mL [20,28]. In another series [82] of 52 VIPomas the mean value was 702 pg/mL, with a range from 159 to 2530 pg/mL. In several reviews [19,74,114,115], 94%–100% of patients with VIPomas had elevated plasma VIP levels. Normal plasma VIP levels are reported to occur in 12% of cases with a pancreatic tumor and in 82% of cases with pancreatic islet cell hyperplasia [21]. In most studies plasma VIP levels are not elevated in patients with laxative abuse [20,21,81,124,125]. Patients with chronic secretory diarrhea due to chronic laxative abuse can be difficult to detect, but this should be suspected if plasma VIP levels are normal or a laxative screen is positive [143]. Because of the difficulty in diagnosing laxative or diuretic abuse, a laxative screen should be performed in any patient with unexplained chronic diarrhea [144]. Even using a standard laxative screen, laxative abusers may be difficult to detect without sophisticated methods such as using gas-liquid chromatography–mass spectroscopy to assess specimens [145,146].

Elevated plasma VIP levels should not be the sole basis for the diagnosis of a VIPoma [20,147]. Other conditions including prolonged fasting, inflammatory bowel disease, small bowel resection, radiation enteritis, and chronic renal failure can occasionally elevate plasma VIP levels [20,147]. In one study [147] of 193 patients with chronic diarrhea, eight different gastrointestinal hormones (motilin, PP, neurotensin, somatostatin, substance P, VIP, gastrin-releasing peptide, and calcitonin) were assessed, and 45% of the patients had one or more elevated levels; however, no patient had a PET. This study showed that false-positive elevations of plasma levels for those hormones reported to cause diarrhea, including VIP, are not uncommon; therefore, such determinations need to ordered selectively and carefully interpreted in light of other clinical and laboratory findings to establish the correct diagnosis [147].

Glucagonoma

Glucagonomas are endocrine tumors of the pancreas that secrete excessive amounts of glucagon and cause a distinct syndrome characterized by dermatitis, glucose intolerance, weight loss, and anemia (Table 71.4).

The first description of what we know as the glucagonoma syndrome was reported in 1942 [148] in a patient with a skin rash associated with pancreatic cancer. M^{c}Garvan and

Table 71.4 Clinical features of the glucagonoma syndrome

Sign/symptom	Frequency (%)
Dermatitis (migratory necrolytic erythema)	64–90
Hypoaminoacidemia	41–100
Glucose intolerance or diabetes mellitus	38–90
Weight loss	56–96
Anemia	33–85
Diarrhea	14–29
Thromboembolism	12–35
Glossitis, cheilitis	14–40
Psychiatric disturbance	0–17

Data from Jensen [4]; Guillausseau et al. [15]; Wermers et al. [16,170]; Frankton and Bloom [17]; Soga and Yakuwa [18]; Guillausseau and Guillausseau-Scholer [79]; Leichter [153]; Stacpoole [154].

colleagues, in 1966, reported the first well-described case of a patient with the glucagonoma syndrome [4,149]. The patient had elevated immunoreactive glucagon in plasma, diabetes mellitus, a skin rash, and a PET. In 1973, Wilkinson [150] introduced the term "necrolytic migratory erythema" for the skin rash associated with PETs. Mallinson and colleagues in 1974 [151] specifically established the association of glucagonomas with the skin rash when they reported nine cases with the clinical glucagonoma syndrome consisting of dermatitis, diabetes mellitus, unexplained weight loss, hypoaminoacidemia, anemia, and a glucagon-producing tumor of the pancreas.

The peak incidence for the glucagonoma syndrome is in the age range 45–70 years, and the syndrome has not been described in children [15–18,59,79,152]. The characteristic skin rash associated with the glucagonoma syndrome, called necrolytic migratory erythema, is present in the vast majority of cases (Table 71.4) [16–18,79,152–156]. The skin lesion starts as an annular erythema at intertriginous and periorificial sites. It is normally found on the buttock, groin, perineum, and thighs. The erythema subsequently becomes raised and the central parts form superficial bullae. The top of the bulbous lesion frequently detaches, leaving eroded areas that become crusted (Fig. 71.2). Lesions frequently become confluent. The extent and the severity of the lesions may wax and wane [155,156]. Healing in 2 or 3 weeks results in hyperpigmentation (Fig. 71.2). Histologically, early skin lesions demonstrate a superficial spongiosis and necrosis and subcutaneous blister formation [153,154]. The pathogenic mechanism by which the glucagonoma syndrome produces this characteristic skin rash is unclear [155,157]. A number of studies report that the skin rash can be caused by prolonged hyperglucagonemia because it developed in patients who were given glucagon for long periods [158–160]. Glucagon-induced hypoaminoacidemia may be one mechanism because correction of the hypoaminoacidemia has been shown to correct the dermatitis without changing plasma glucagon concentrations [161,162]. The resemblance of the lesions to those seen with zinc deficiency has resulted in trials of zinc therapy, with some responses [17]. However, resolution of the rash has been reported following simple hydration with glucose and saline [163]; therefore, it is not known that either hypoaminoacidemia or zinc deficiency are necessarily causative in all patients. A number of other clinical features are also characteristic of the glucagonoma syndrome (Table 71.4). Angular cheilitis (Fig. 71.2) is a common feature as is nail dystrophy and thinning of the hair [16,17]. Some patients develop a painful glossitis (Table 71.4).

Hypoaminoacidemia occurs in most patients and, as originally pointed out by Mallinson, the levels of amino acids may vary with the intensity of the disease [18,155,164]. The hypoaminoacidemia is thought to be secondary to the hyperglucagonemia because glucagon infusions have been demonstrated to have a controlling influence on amino acid metabolism by altering gluconeogenesis [165]. It has been demonstrated in human subjects that glucagon deficiency caused by either suppression with somatostatin or total pancreatectomy increases plasma amino acid concentrations [28,166,167]. Conversely, the administration of glucagon decreases plasma amino acid concentrations [167]. Metabolic studies [168,169] in patients show an increase in amino acid catabolism, a 15% increase in whole-body lipolysis, and a 15% increase in hepatic glucose production; the energy expenditure, as well as the rate of protein breakdown, were normal.

Diabetes mellitus and glucose intolerance occur frequently in patients with the glucagonoma syndrome (Table 71.4) [18,138,154,155,170]. However, in one study [16], diabetes was present in only 38% at presentation and developed in an additional 38% as the glucagonoma progressed. The relationship of the hyperglucagonemia to the diabetes mellitus or glucose intolerance remains unclear. Glucagon levels in

Figure 71.2 Migratory necrolytic erythema involving the face in a patient with metastatic glucagonoma. These typical skin lesions usually start on the extremities or at intertriginous or periorificial sites. The lesions initially are erythematous and scaly, later become raised and bullous, and finally become crusty, as is evident in this patient. Healing results in hyperpigmentation. Angular cheilitis, a common feature in patients with glucagonoma, is also present in a mild form in this patient. The patient also demonstrates loss of the buccal fat pad and temporal muscle wasting indicative of the generalized wasting these patients characteristically develop.

patients with glucagonomas do not correlate well with the degree of glucose intolerance [153,154,170]. Furthermore, various treatments have resulted in definite changes in plasma glucagon concentrations but have not produced correlated changes in blood glucose. For example, tumor resection and normalization of blood glucose may not result in the correction of the glucose intolerance [79]. The somatostatin analogue, octreotide, may depress plasma glucagon levels, but frequently does not improve the diabetes [12,16,17,171]. In some patients, however, removal of the glucagon-producing tumor has improved glucose tolerance [164]. Whether or not glucagon causes glucose intolerance appears to depend to a large degree on the patient's insulin reserve. If it is intact, hyperglucagonemia is present without glucose intolerance [16,59,170].

Weight loss is a common feature of patients with the glucagonoma syndrome and it may be profound (Table 71.4; Fig. 71.2) [15–18,79,138,153–155]. A number of observations suggest weight loss is a specific feature of the glucagonoma syndrome. Weight loss is prominent in patients with small tumors as well as those with metastatic tumor and is not seen early in other PETs unless malabsorption is present, suggesting the cachexia is an intrinsic feature of the glucagonoma syndrome. The weight loss has been attributed to the catabolic effects of glucagon [169]. However, in one study in which glucagonomas from a pluripotent rat islet tumor were transplanted into normal animals, severe anorexia and adipsia developed. Studies show that bilateral vagotomy had no effect on the development of anorexia, that the satiety peptides, cocaine- and amphetamine-regulated transcript (CART) or leptin, are unlikely to be the mediators, and that the unknown mediator can override the potent appetite-stimulatory effect of neuropeptide Y (NPY) [172,173]. These results suggest that the glucagonoma's anorectic effects are caused by the production of a novel substance by the glucagonoma and not due to glucagon per se because other transplanted glucagonomas producing similar levels of plasma glucagon elevation do not cause anorexia.

Thromboembolic phenomena are more common in patients with the glucagonoma syndrome (Table 71.4) [15–17,79,153,154]. Both deep-vein thrombosis and pulmonary emboli have been reported to occur in a significant number of cases and have been the cause of death in some patients [15,153,154]. Glucagon is not known to affect coagulation parameters, and the pathophysiology of the thromboembolic events in glucagonoma has not been systematically studied. A normochromic, normocytic anemia is also reported to be a frequent finding in patients with glucagonomas (Table 71.4) [16–18,59,79,138,153]. Serum iron, serum vitamin B-12, and serum folate concentrations are usually normal, and the anemia does not respond to therapy with any of these agents. It does, however, respond to resection of the tumor [174–176]. Further evidence that the anemia may be due to glucagon excess is that prolonged therapy with a long-acting glucagon preparation decreased erythropoiesis in rats and mice [176]. Psychiatric disturbances, particularly depression, have been reported in a number of patients with the glucagonoma syndrome; however, the exact frequency or even whether they are more common in patients with glucagonoma has not been established (Table 71.4) [16,17,79,148].

Glucagonoma is usually suspected in patients with chronic unexplained and therapy-resistant dermatitis and elevated erythrocyte sedimentation rates, and is associated with glucose intolerance, thromboembolic phenomena, or the MEN-I syndrome (Table 71.4) [12,17,153–156,170,177]. Necrolytic migratory erythema is the presenting feature in 70% of patients [155,178], occurring from 1 month to 3 years (mean 12 months) before the diagnosis of the pancreatic tumor [156]; in some patients no other extracutaneous symptom is present [179]. Unfortunately, not only is necrolytic migratory erythema frequently misdiagnosed, but a number of other conditions besides glucagonomas can cause this rash, including hepatitis B infections [180], myelodysplastic disorders [181], short bowel syndrome [182], malnutrition [183], cirrhosis, celiac sprue, other malignancies, inflammatory bowel disease, malabsorptive syndromes, and specific nutritional deficiencies [157]. Diagnosis of glucagonoma rests on demonstrating a pathological elevation of the plasma glucagon concentration. In almost all patients with glucagonoma the plasma glucagon concentration is elevated (> 150 pg/mL) [18,153,156,170]. In one study of 23 patients with proven glucagonoma the plasma glucagon concentration had a mean value of 2110 pg/mL (± 1 standard error of the mean [SEM]) whereas the highest value in a patient without glucagonoma was 409 ± 29 pg/mL. In a review of 58 published cases of glucagonoma, plasma glucagon levels exceeded 1000 pg/mL in 90%, were between 500 and 1000 pg/mL in 7%, and were less than 500 pg/mL in 3% [15,79]. In a study of 21 cases from the Mayo Clinic [16], 48% of patients had values greater than 1000 pg/mL, and 86% exceeded 500 pg/mL. It has been suggested that a plasma glucagon concentration of more than 1000 pg/mL is diagnostic of glucagonoma, because other causes of elevated plasma glucagon levels do not produce this degree of elevation [4]. However, in some studies [16,156] plasma glucagon levels below 500 pg/mL have been reported in a subset of patients (< 15%) and therefore a high degree of suspicion for the disease should be maintained, especially in patients with small tumors or MEN-I [17]. Other conditions that are associated with increased plasma glucagon concentrations include renal insufficiency, acute pancreatitis, hyperadrenal corticalism, hepatic insufficiency, severe stress (trauma, exercise, bacteremia, diabetic ketoacidosis), prolonged fasting, familial hyperglucagonemia, or other PETs [17,18,59,79,153,170,177,184,185]. In two studies [18,170], one involving 71 patients with fasting hyperglucagonemia at least twice the upper limit of normal (i.e., > 120) [170], and the other [18] comprising 407 cases of glucagonoma from the literature, only 21% and 57%,

respectively, of the patients included had a clinical glucagonoma syndrome. Therefore, hyperglucagonemia without the glucagonoma syndrome is not necessarily uncommon. In one series [170] the hyperglucagonemia occurred with polyfunctional PETs in 69% of the cases, especially with patients with Zollinger–Ellison syndrome, insulinomas, and carcinoid tumors; in almost all cases the hyperglucagonemia was not associated with the glucagonoma syndrome. In general, in these nonglucagonoma conditions causing hyperglucagonemia, the plasma glucagon is not elevated above 500 pg/mL except in patients with cirrhosis [59,79,153]. For the occasional glucagonoma patient with a fasting plasma glucagon concentration less than 1000 pg/mL that may overlap with other conditions, there is no proven provocative test that will clearly distinguish these conditions [59,79]. Usually, however, these nonglucagonoma conditions can be excluded on clinical grounds. One to three percent of MEN-I patients develop glucagonomas [68], and in various series from 0% to 20% of all patients with glucagonomas had MEN-I [15–17,153,154]; these patients can be difficult to diagnose because they have minimal symptoms early in their disease course [17].

Somatostatinomas

Somatostatinomas are endocrine tumors of the pancreas or intestine that secrete excessive amounts of somatostatin, which cause a distinct syndrome characterized by diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea (Table 71.5).

In 1977 the first two cases of somatostatinomas were independently reported [186,187]. On the basis of these reports and the known actions of somatostatin, it was proposed that the clinical somatostatinoma syndrome consisted of mild diabetes mellitus, gallbladder disease, weight loss, and anemia [4]. Diarrhea, steatorrhea, and hypochlorhydria became additional features as other cases have been described (Table 71.5) [83,188,189].

Table 71.5 Clinical features of the somatostatinoma syndrome

	Frequency (%) in cases of somatostatinoma[a]		
Sign/symptom	**Pancreatic**	**Intestinal**	**Somatostatinoma syndrome[a]**
Diabetes mellitus	90–95	21	95
Gallbladder disease	90–94	43	68
Diarrhea	60–97	10–40	37
Steatorrhea	83	12	47
Hypochlorhydria	86	17	26
Weight loss	30–90	20–45	68

a Somatostatinoma refers to a pancreatic endocrine tumor that shows somatostatin-like immunoreactivity and may occur without (89%) or with (11%) the somatostatinoma syndrome, which is due to somatostatin secretion by the tumor [25,90].
Modified from Jensen [4]; Vinik et al. [22]; Sassolas and Chayvialle [23]; Soga and Yakuwa [25].

There is no general agreement on the definition of a somatostatinoma. In the literature this term is generally used to indicate a PET possessing somatostatin-like immunoreactivity and it may (11%–45%), or may not (55%–89%) be associated with clinical symptoms due to ectopic release of somatostatin [23–25]. In this chapter the term "somatostatinoma syndrome" will be used to indicate a somatostatin-producing PET associated with clinical features due to ectopic somatostatin release (Table 71.5), and the term "somatostatinoma" to include a PET containing somatostatin immunoreactivity.

Somatostatin is a tetradecapeptide originally isolated and purified from ovine hypothalamic tissue [4]. It inhibits the release of almost all other hormones, and has direct effects on a number of gastrointestinal functions, including potent inhibition of basal and pentagastrin- or meal-stimulated acid secretion, cholecystokinin-stimulated pancreatic enzyme secretion, and intestinal absorption of amino acids [190,191]. A number of studies have suggested that somatostatin has a paracrine effect on antral gastrin release. Somatostatin also has marked effects on gut motility and transit time [190,191].

Somatostatinomas primarily occur in the pancreas (41%–75%) or in the upper small intestine (25%–54%) [22,23,25,26,192]. In the pancreas 56%–78% of the somatostatinomas occur in the pancreatic head [22,25,26]. Tumors not in the pancreas occur in the duodenum (43%–96%), ampullary area (48%), jejunum (5%), or cystic duct area [22,25,26]. Most somatostatinomas (> 96%) are solitary and vary from less than 1 cm to 10 cm in diameter, with a mean of 4–5 cm [25]. Pancreatic tumors are larger than duodenal tumors (5 cm vs 2 cm) ($P < 0.0001$) [25], and in one study [22] were found to be more malignant than intestinal tumors (92% vs 6%), but not in another study [25] (i.e., both 50%). With duodenal somatostatinoma the occurrence of lymph node metastases correlates with primary tumor size [193]. Electron microscopic studies show typical D-cell secretory granules in 52%–89% of the tumors [22,25,193].

The mean age of patients with pancreatic somatostatinomas or intestinal somatostatinomas is 45–50 years, with a range of 30–84 years [22,192]. In one series [22], patients with pancreatic somatostatinomas show a 2 to 1 female predominance, whereas in those with intestinal somatostatinoma 60% of the patients are males [22]; however, in another review somatostatinomas occurred with equal frequency in both genders [25].

In assessing the symptoms/signs due to somatostatinomas it is important to differentiate between those due to the PET per se, which are similar to any PET (i.e., pain, icterus, weight loss, hepatomegaly, abdominal tumor), from those that are due to the increased somatostatin secreted by the PET. In one large literature review of 173 cases of somatostatinomas [25], only 18 cases (11%) were associated with the

somatostatinoma syndrome (Table 71.5). In the same study [25], of all patients with somatostatinomas, 93% initially had symptoms or signs, with the most frequent being abdominal pain (40%), weight loss (26%), icterus (23%), abdominal tumor (12%), diarrhea (18%), nausea/vomiting (16%), and hepatomegaly (10%). Diabetes mellitus or glucose intolerance occurs in 63%–90% of patients with somatostatinomas [22,23,83]. However, the diabetes mellitus occurred in 90%–95% of the patients with pancreatic somatostatinomas but in only 21% of those with intestinal somatostatinomas (Table 71.5) [22]. The diabetes is usually mild, and severe hypoglycemia or ketosis, although reported, are uncommon [23,28,189]. The development of diabetes mellitus or glucose intolerance is secondary to the ability of somatostatin to inhibit insulin and glucagon release [22,23] and the replacement of functional islet tissue by tumor [83]. This latter factor may explain why diabetes mellitus is more common in patients with pancreatic than with intestinal somatostatinomas (Table 71.5) [22]. In patients with the somatostatinoma syndrome, 95% had diabetes mellitus (Table 71.5) [25].

Gallbladder disease (cholelithiasis) is reported in 65%–90% of patients with somatostatinomas [22,23,83], and in 90%–94% of patients with pancreatic and 43% of patients with intestinal somatostatinomas (Table 71.5) [22]. Cholelithiasis was present in 68% of patients with the somatostatinoma syndrome (Table 71.5) [25]. The high incidence of gallbladder disease in patients with somatostatinomas and the lack of low incidence in patients with other PETs suggests a causative association between the gallbladder disease and somatostatinoma. This conclusion is supported by studies demonstrating that somatostatin analogues inhibit gallbladder emptying, alter the motility of the sphincter of Oddi, alter hepatic bile secretion, and affect the bile composition [23,190,194]; and by studies of patients with acromegaly or PETs treated long term with octreotide [190,195,196]. Two of the latter studies [190,196] demonstrated that 13%–66% of patients treated long term with octreotide develop gallbladder sludge or gallstones.

Diarrhea and steatorrhea were reported in 36%–90% of patients in various studies [22,23,25,83]. The diarrhea characteristically consists of 3–10 foul-smelling stools per day, and the steatorrhea varies from 20 to 76 g/day [22]. Diarrhea and steatorrhea are much less common in patients with intestinal (10%–40%) rather than pancreatic somatostatinomas (60%–97%) (Table 71.5) [22,25]. In some, but not all cases the severity of the diarrhea and steatorrhea correlates with the size and degree of metastatic spread of the tumor and improves with tumor resection [83]. Somatostatin has been shown to inhibit pancreatic enzyme and fluid secretion as well as gallbladder motility [190]. In addition, somatostatin also inhibits intestinal absorption of lipid, D-xylose, vitamin B-12, and folate [4]. These biological actions of somatostatin may be responsible for the maldigestion, steatorrhea, and diarrhea observed in these patients [83]. The fact that patients with intestinal somatostatinomas have less diarrhea or steatorrhea has been attributed to their lower plasma somatostatin levels or the lack of local effects of the somatostatinoma within the pancreas (Table 71.5) [22]. Diarrhea is present in 37% and steatorrhea in 47% of patients with the somatostatinoma syndrome (Table 71.5) [25].

Hypochlorhydria was found in 33% of patients in one study [83], in 53% of patients in a second study [22], and in 70% in a third study [25]. Hypochlorhydria occurred in 86% of patients with pancreatic and 17% of patients with intestinal somatostatinomas [22], and was present in 26% of patients with the somatostatinoma syndrome (Table 71.5) [25]. Infusion of somatostatin has been shown to inhibit gastric secretion in normal human subjects as well as basal and food-stimulated gastrin release [4]. As with the glucagonoma syndrome, weight loss is common in patients with somatostatinomas [23], being reported in 32%–90% of patients with pancreatic tumors and in 20%–45% of patients with intestinal tumors [25,83] (Table 71.5), with weight loss ranging from 9 to 21 kg. Weight loss was reported in 68% of patients with somatostatinoma syndrome (Table 71.5) [25]. The weight loss may be secondary to the diarrhea and malabsorption. Other less common features reported in patients with somatostatinoma include mild to moderate anemia in 15%–67% of patients with somatostatinomas [25], and in 21% of patients with the somatostatin syndrome [25]. Also, the occurrence of various associated endocrine disorders is reported in patients with somatostatinomas [83]. In one study, four patients were reported to have hypoglycemic episodes with normal or elevated plasma insulin concentrations and were diagnosed as having insulinomas [83].

The diagnosis of somatostatinoma has been applied to numerous PETs in the literature based only on immunohistochemical results; in most cases (55%–89%) this is not associated with the somatostatinoma syndrome due to ectopic somatostatin release [23–25,92,93]. The diagnosis of the somatostatinoma syndrome requires the demonstration of increased plasma concentrations of somatostatin-like immunoreactivity (SLI) in the resected tumor and at least some features of the appropriate clinical syndrome (Table 71.5). The establishment of SLI only in a resected tumor is not sufficient for the diagnosis of the somatostatinoma syndrome. Minimal increases in plasma SLI levels need to be interpreted with caution because they can occur in nonendocrine disorders [23]. Furthermore, whereas plasma SLI levels are frequently elevated with pancreatic tumors, in small intestinal somatostatinomas the SLI levels are frequently normal [23,24]. Frequently SLI is detected as a subpopulation of cells in a variety of PETs, especially nonfunctional tumors [23]. High plasma SLI levels have been reported with endocrine tumors outside the pancreas or intestine, as with small cell lung cancer, bronchial oat cell carcinoma, medullary thyroid carcinoma, pheochromocytomas, and other catecholamine-producing extraabdominal paragangliomas [23]. It is likely in the future that the syndrome will be diagnosed earlier

because of the increased clinical awareness of the somatostatinoma syndrome (Table 71.5) and the greater availability of reliable assays for the determination of SLI in blood. As yet these assays are complicated by the need for extraction of the plasma and are not widely available.

The diagnosis of somatostatinoma at a time when plasma SLI concentrations are only marginally elevated and the tumor has not yet metastasized will require the development of reliable provocative tests. Tolbutamide and arginine have been reported to stimulate plasma SLI increases [83,197]; however, arginine is a well-established stimulant for normal D-cells and thus is unlikely to differentiate normal from supernormal secretion [83]. Furthermore, although tolbutamide stimulates SLI increases in animals [197], it is reported not to cause changes in plasma SLI concentrations in normal human volunteers [198]. Until an adequate provocative test is developed, if somatostatinoma is to be diagnosed earlier, it may be necessary to determine plasma SLI concentrations in all patients with diabetes mellitus without a family history and with any other clinical features of the somatostatinoma syndrome, or in all patients with unexplained diarrhea [188].

In most studies somatostatinomas have been found more or less by accident [83]. Because most somatostatinomas (i.e., 89% [25]) do not produce the somatostatinoma syndrome and the most common presenting symptoms are nonspecific (abdominal pain, weight loss, icterus, diarrhea, nausea/vomiting) [25], the correct diagnosis is rarely suspected prior to the discovery of a PET at laparotomy for cholecystectomy, during imaging studies for nonspecific complaints, or after a biopsy for metastatic liver disease discovered during a workup for nonspecific GI symptoms [22,23,25]. In particular, the presence of psammoma bodies in a duodenal tumor should raise the suspicion that the tumor could be a somatostatinoma [23,25,192,199]. These lesions are found in approximately one-half of duodenal somatostatinomas [23–25], but are uncommonly found (i.e., 2%–5%) in pancreatic somatostatinomas or in other types of duodenal carcinoids or duodenal gastrinomas [23,192,199]. Duodenal somatostatinomas are increasingly associated with von Recklinghausen disease [23,24,92,93,200,201]. Duodenal somatostatinomas in patients with von Recklinghausen disease are similar to sporadic duodenal somatostatinomas in that they are rarely (i.e., 2%) associated with symptoms of the somatostatinoma syndrome, infrequently cause elevated plasma SLI levels, frequently contain psammoma bodies (37%–66%) [24,25], and are less frequently malignant (30% duodenal vs 70% pancreatic) [24,25]. Somatostatinomas are uncommon in MEN-I patients, occurring in 0.65% of patients in one study involving 580 MEN-I patients [68].

GRFomas

GRFomas are endocrine tumors that frequently originate in the pancreas but also occur in other extrapancreatic sites and secrete excessive amounts of growth hormone-releasing factor (GRF), which causes acromegaly. Tumors releasing GRF (GRFomas) were described in 1982 [202,203]. Growth hormone-releasing factor, a 44-amino-acid peptide originally isolated from human PETs causing acromegaly, is structurally similar to VIP [23,202], and GRF-like immunoreactivity (GRF-IR) is present in neurons in the hypothalamus as well as in multiple extrapituitary tissues [204]. The true frequency of this syndrome is still not established but a review in 1997 included 40 cases [84]. In one immunocytochemical study [205] of PETs, four of nine (44%) contained GRF-IR, although only one patient had acromegaly. In another study [206] 6 of 24 (25%) PETs – of which 16 were associated with various clinical syndromes (8 insulinomas, 5 gastrinomas, 2 VIPomas, and 1 Cushing syndrome) – were found to have GRF-IR material but no patient had clinical acromegaly. GRFomas occur in the pancreas in 29%–30% of cases; 47%–70% occur in lung tumors, with the majority in the right lung; 8%–10% occur in the small intestine; and up to 13% are found in other sites including adrenal gland, foregut, and retroperitonium (Table 71.1) [23,84,204,207,208]. The patients were 15–66 years old, with an average age of 38–39 years [84,207,208]. A female predominance (78%) is seen with pancreatic GRFomas, and indeed with all GRFomas (73%) [84,207,208]. The clinical features can be divided into three categories:

- acromegalic features due to ectopically released GRF causing excess growth hormone secretion
- clinical features due to hormones other than GRF coreleased, such as gastrin causing Zollinger–Ellison syndrome, or ACTH causing Cushing syndrome
- local symptoms due to the mass effect of the hormone [23,207,208].

The mean duration from symptom onset to diagnosis is 5–6 years [207,208]. The acromegalic features of GRFomas are indistinguishable from those of classical acromegaly [23,204,207,208]. Patients usually have a large pancreatic tumor (> 6 cm; range 1–25 cm), and in 33%–39% of cases the tumor is metastatic at the time of diagnosis [84,207]. The majority of pancreatic GRFomas occur in the pancreatic tail [84,204,208]. In one series [207] metastatic disease was present in 30% of the patients with pancreatic GRFomas and in two of the three patients with intestinal GRFomas [208]. No relationship between the presence or absence of metastases, tumor size, or plasma GRF level was found [208]. Multiple pancreatic GRFomas occurred in 30% in one series [208], usually in patients with MEN-I [23]. Forty percent of the patients with pancreatic GRFomas had associated Zollinger–Ellison syndrome, Cushing syndrome was present in 40%, and one-third of the patients had associated MEN-I syndrome [28,208–210].

GRFomas are usually suspected in a patient with acromegaly and an elevated growth hormone level with hepatic metastases or with abdominal complaints [23,202,203,207,208].

Pancreatic GRFomas are often associated with a gastrinoma and Zollinger–Ellison syndrome or Cushing syndrome. Therefore, any patient with Cushing syndrome or peptic ulcer symptoms, diarrhea, a pancreatic mass, or with symptoms suggestive of chronic esophageal reflux who presents with acromegalic features should be suspected of having a GRFoma. Furthermore, pancreatic GRFomas have occurred in a number of patients with the MEN-I syndrome [209,210]. Any patient with acromegaly with hyperparathyroidism or a family history of MEN-I should also be suspected of having a GRFoma. The diagnosis should be suspected in any patient with acromegaly without a pituitary adenoma; with acromegaly associated with hyperprolactinemia, which is seen in 70% of GRFomas; with paradoxical growth hormone response to thyroid-stimulating hormone (TSH) or during an oral glucose tolerance test [23,84,207,208]. A GRFoma is a rare cause of acromegaly, occurring in 0 of 177 unselected patients with acromegaly in one study [211]. The diagnosis is confirmed by performing a plasma assay for growth hormone-releasing factor and for growth hormone [23,84,207,208]. Elevated plasma levels of growth hormone (usually > 5 μg/L in men and 10 μg/L in women) and an elevated plasma GRF confirm the diagnosis, whereas GRF levels are normal to low in patients with pituitary acromegaly [204]. One review proposes an empirical diagnostic threshold value for GRFomas of 300 pg/mL for the plasma GRF level [23]. Healthy subjects have GRF levels less than 50–100 pg/mL [84] and patients with pituitary adenomas causing acromegaly have plasma GRF levels of less than 200 pg/mL [23,211]. In addition to elevated levels of growth hormone and GRF, patients with GRFomas also have raised plasma levels of insulin-like growth factor 1 (IGF-1), similar to patients with acromegaly due to a pituitary adenoma [207].

Nonfunctioning pancreatic endocrine tumors

Nonfunctioning PETs (NFPETs) are endocrine tumors that originate in the pancreas and either secrete no peptides or their secreted products do not cause clinical symptoms. Unlike functional PETs, the symptoms that occur are due to the effects of the tumor per se and not to the secreted products [1,22,29,30]. Frequently NFPETs release peptides that cause no clinical symptoms, including chromogranin A (69%–100%), chromogranin B (100%), PP (50%–100%), α-human chorionic gonadotropin (α-HCG; 40%), β-HCG (20%), synaptophysin, neuron-specific enolase, and (in some) neurotensin [1,3,22,47,48,56]. Immunocytochemically these tumors often contain multiple peptides [1,43]. In one study of 30 such tumors [43], 50% had immunoreactivity for insulin, 30% for glucagon, 40%–75% for PP, 13% for somatostatin, and 13% for none of these. Usually NFPETs are solitary, large tumors (72% > 5 cm in one study [212]) and occur primarily in the pancreatic head (ratio of 14:2:3 in the head, body, and tail, respectively, in one study [212]), except in patients with MEN-I, who frequently have multiple NFPETs detected, often less than 2 cm in diameter and histologically invariably have multiple, microscopic tumors [213–215]. Frequently NFPETs are diagnosed after the patient presents with symptoms or signs of metastatic tumor in the liver (cachexia, abdominal pain, hepatomegaly) and a liver biopsy is performed that reveals metastatic endocrine tumor [1,22,29,30,216]. Infusions of PP into animals have been shown to have numerous effects including inhibition of pancreatic secretion, relaxation of the gallbladder, weak inhibition of pentagastrin-stimulated acid secretion, and various stimulating effects on gastrointestinal motility [217]. It is unclear why patients with PETs and high plasma concentrations of PP do not have symptoms cuased by the increased level of PP per se. Typically the patient with a NFPET is 40–60 years of age [1,6,22,29,30,218]. Some series demonstrate a male predominance for NFPETs [29,219], whereas in others there is a female predominance [6,218]. Patients with NFPETs frequently present with abdominal pain (in 36%–56%), jaundice (28%–40%), weight loss (24%–46%), or abdominal masses (8%–40%), and in 16% of the patients tumors were found incidentally at surgery in asymptomatic patients [30,212]. In a large series [6] the NFPET was discovered incidentally by ultrasound in 35% of the patients; these patients were asymptomatic and the tumors were smaller than in patients with NFPETs with symptomatic presentations. In most series [1,5,29,30,216,219], but not all [6,220,221], more than 60% (range 64%–92%) of patients with NFPETs have metastatic disease at the time of diagnosis [1,22,30,212]. The median delay in time from first symptoms to diagnosis varies from 0.5 to 2.7 years [1].

Usually NFPETs are not differentiated from any other malignant tumor of the pancreas prior to histological studies [1,22]. In one series the diagnosis of a NFPET was not made in a single patient prior to surgery [29]. Furthermore, 20% of the patients were asymptomatic and the tumors were found incidentally during other operative procedures [29]. Any patient with a long survival (> 5 years), previously diagnosed as having metastatic pancreatic adenocarcinoma, should be suspected of possibly actually having a NFPET. An elevated plasma level of chromogranin A or B (69%–100%), PP (50%–100%), α-HCG (40%), β-HCG (20%), neuron-specific enolase (31%), or positive somatostatin receptor scintigraphy (SRS) is strong evidence to suggest that a pancreatic mass is a PET [1,3,22,48,56,222]. In 53 patients with adenocarcinoma of the pancreas, none had elevated plasma levels of PP [22]. However, elevated levels of PP do not establish the diagnosis of a PPoma even when a pancreatic mass is present because plasma PP levels are increased in 22%–71% of patients with functional PETs [1,45,223,224] as well as in nonpancreatic carcinoid tumors. In one study [224] plasma PP levels were over 1000 pg/mL in 32% of patients with gastrinomas, in 21% with insulinomas, in 57% with glucagonomas, in 74% with VIPomas, in 33% with somatostatinomas, and in 45% with carcinoid tumors. Furthermore, plasma PP

elevations can occur with renal failure, old age, post-bowel resection, alcohol abuse, certain infections or inflammatory conditions, acute diarrhea, diabetes, pancreatitis, or with eating [224]. To improve the specificity an atropine suppression test has been proposed [224]. In a study of 48 patients with elevated plasma PP levels, atropine (1 mg i.m.) did not suppress the levels in any of 18 patients with PETs, but did suppress it in all patients without PETs. In one study [222] none of 28 pancreatic ductular cancers was positive with SRS whereas 65% of proven PETs were positive. Furthermore, 42% of long-term survivors of pancreatic adenocarcinoma (> 3 years) were positive by SRS, suggesting they were really PETs misdiagnosed [222]. In a study of 61 NFPETs [221], 56 (91%) were well differentiated, 5 (9%) poorly differentiated, and 56% of patients demonstrated metastases. Factors that correlated with malignancy included: the presence of vascular or perineural invasion; a Ki-67 proliferative index greater than 2%; a mitotic rate greater than or equal to 2; tumor size greater than or equal to 4 cm; capsular penetration; nuclear atypia; lack of progesterone receptors; and presence of calcitonin [221]. These factors had prognostic significance for survival [5,221]. As yet there are no data to suggest that NFPETs producing PP or other peptides differ in biological behavior from tumors not producing these peptides [219].

Other tumors

Cushing syndrome associated with a PET (ACTHoma) is usually [88,187,225–227] recognized in patients with another symptomatic PET. The ectopic Cushing syndrome is usually due to release of ACTH by the tumor and occasionally to release of corticotropin-releasing hormone by the tumor [228–230]. In various studies 4%–16% of all cases of ectopic Cushing syndrome are due to PETs secreting ACTH [89]. Cushing syndrome occurs in 19% of patients with MEN-I with Zollinger–Ellison syndrome, and is due to pituitary production of ACTH; the disease in these patients is usually mild [88]. Cushing syndrome occurs in 4%–5% of patients with sporadic Zollinger–Ellison syndrome [10,88,225–227]. In patients with the sporadic form of Zollinger–Ellison syndrome, the symptoms of Cushing syndrome are severe, usually occur in patients with metastatic disease, and the Cushing syndrome is due to ectopic production of ACTH [88,226,227]. In one study [226] each patient with ectopic Cushing syndrome resulting from a PET had metastatic disease in the liver, although in other studies rare patients with nonmetastatic disease with Zollinger–Ellison syndrome and Cushing syndrome due to ACTH release by the gastrinoma are reported [90]. These patients with metastatic disease usually respond poorly to chemotherapy [88]; in one prospective study [10] the development of Cushing syndrome in patients with gastrinomas was an independent predictor of poor survival, with patients surviving for a mean of only 1.7 years after onset of the syndrome [88]. The occurrence of Cushing syndrome only as a clinical manifestation of a PET is uncommon [231,232].

Paraneoplastic hypercalcemia due to a PET releasing parathormone-related peptide (PTH-RP), a PTH-like immunoreactive material, PTH, or an unknown hypercalcemic substance has been reported rarely [86,87,233–235]. In most [86,233], but not all [86,122] cases describing paraneoplastic hypercalcemia with a PET [233] the tumors are large and are metastatic to the liver at the time of diagnosis. In a review [86] of 23 cases of PETs associated with hypercalcemia, 30% occurred in patients with VIPomas. The tumors were generally large (7–18 cm) and in seven of eight patients PTH-RP was demonstrated immunohistochemically [86].

It has been proposed that there is a *neurotensinoma syndrome* associated with PETs [22,28,47,236]. Neurotensin is a 13-amino-acid peptide first extracted from bovine brain and subsequently also isolated from human gastrointestinal tract [237]. Neurotensin has a number of pharmacological effects including causing hypotension, tachycardia, and cyanosis, stimulating pancreatic protein and bicarbonate secretion, affecting intestinal motility, and stimulating jejunal and ileal fluid and electrolyte secretion [237]. The clinical features of the patients described with neurotensinomas with PET include diarrhea with hypokalemia, weight loss, and in some cases diabetes, cyanosis, hypotension, and flushing [22]. In the six cases included in one review [22], one-half were cured by tumor resection and the remainder responded to streptozotocin treatment [22,28,236]. Other authors [45,236] have raised the question of whether a specific neurotensinoma syndrome actually exists. In one study [236] of 180 patients with functional PETs an elevated plasma neurotensin level was found in six patients with VIPomas and the clinical symptoms of those patients did not differ from those without an elevated plasma neurotensin level. In a second study [45], 19% of patients with Zollinger–Ellison syndrome were found to have an elevated plasma neurotensin level and their symptoms did not differ from those without an elevated plasma neurotensin level, suggesting that a distinct neurotensinoma syndrome does not exist.

The *carcinoid syndrome* can be caused by PETs [4,85]. These tumors are characteristically malignant (65%–88%) and large [4,85]. Pancreatic PETs [27] are foregut carcinoids that may lack DOPA decarboxylase, the enzyme that converts 5-hydroxytryptophan to serotonin (5-hydroxytryptamine) [27]; however, 84% of patients with pancreatic PETs associated with the carcinoid syndrome have increased urinary 5-hydroxyindoleacetic acid (5-HIAA) levels, which can be used for the detection of the PETs [4].

A small number of patients have been described with PETs or other abdominal neuroendocrine tumors secreting biologically active peptides, which are associated with various clinical symptoms and thus may be new clinical syndromes, although in almost all cases too few patients have been described to establish this latter point. Rare cases are described of PETs secreting erythropoietin causing polycythemia and erythrocytosis [33]; secreting luteinizing hormone

causing masculinization [34,35]; secreting renin and causing hypertension [32], and ovarian tumors secreting peptide YY (PYY) causing constipation [36–38].

Tumor localization

The techniques used for tumor localization and the rationale for using various localization methods are similar for all PETs. Once the particular type of PET is established by the proper radioimmunoassay and functional studies, tumor localization studies need to be undertaken for a number of reasons. For appropriate management of the patient the tumor's location and extent must be established [238–242]. The only possible long-term cure of these syndromes is by surgical excision of the tumor. To establish whether the tumor is potentially resectable, tumor localization studies are essential. In all cases except insulinoma, the majority, if not all of these tumors, if followed long enough, may be malignant, and therefore if metastatic spread is not present at the time of diagnosis an attempt should be made surgically to cure these patients. Gastrinomas and insulinomas frequently present as small tumors [46,60,78,93,243,244]. Up to 50% of PETs that occur frequently extrapancreatically, such as gastrinomas [14,46,93,243,244], and 10%–20% of PETs that occur almost entirely within the pancreas, such as insulinomas [59], are not found at surgery. Therefore, detailed localization studies may help the surgeon in finding the tumor. Furthermore, except for insulinoma, the other PETs are frequently diagnosed only after metastatic spread to the liver has occurred [5,14,18,19,22,25,59]. To determine whether treatment should be started for the metastatic disease and to assess the results of such treatment, tumor localization is essential [2,5,14,245,246].

Techniques reported to be useful for localizing PETs include:

- abdominal ultrasound [2,14,238,240,247–250]
- computerized axial tomography (CT scan) (Figs 71.3 and 71.4; see also Figs 71.7 and 71.8) [2,4,14,234,238,240,247–253]
- selective abdominal angiography (Figs 71.5 and 71.6) [2,4,14,238,250,252,254,255]
- magnetic resonance imaging (MRI; Fig. 71.7; see also Fig.71.4) [2,238,242,247,248,256]
- radiolabeled somatostatin receptor scanning (SRS) (Fig. 71.8; see also Figs 71.7 and 71.12) [247,257–262]
- endoscopic ultrasound (Fig. 71.9) [241,247,251,263–266]
- selective venous sampling for hormones from portal venous tributaries using a transhepatic approach (i.e., portal venous sampling, PVS) (Fig. 71.10) [14,151,255,267–269]
- hepatic venous sampling for hormones after intraarterial injection of secretin (gastrinomas) or calcium (insulinomas) (Fig. 71.10) [255,269,270]
- intraoperative ultrasonography (Fig. 71.11) [248,271,272].

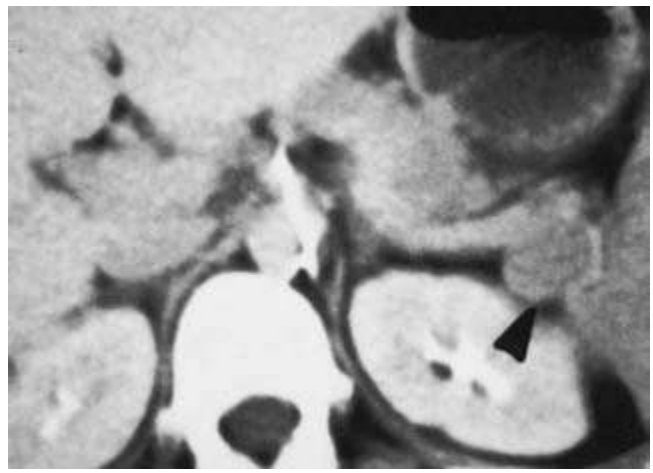

Figure 71.3 Computed tomographic (CT) scan in a patient with an insulinoma in the pancreatic tail, indicated by the arrowhead. The splenic vein courses around the tumor. The CT scan with intravenous contrast will localize 17%–40% of insulinomas. (Courtesy of Dr Jeffrey A. Norton, UCSF, San Francisco.)

Small PETs (< 2 cm) have been the most difficult to localize. The ability of conventional imaging studies (ultrasound, CT scanning, MRI scanning, and selective angiography) to image a PET has been shown to be dependent on the size of the tumor [253,254,256]. For example, using any of the imaging modalities (ultrasound, CT scanning, selective angiography, or MRI) less than 10% of tumors smaller than 1 cm, 30%–40% of tumors 1–3 cm, and 70%–80% of tumors greater than 3 cm were detected [14,273]. Therefore most VIPomas, glucagonomas, and somatostatinomas, which are usually clinically suspected, will only be detected when the tumor is large (frequently > 4 cm). One study demonstrated that small PETs (gastrinomas < 1 cm) also were less frequently detected than large tumors by SRS [258]. Table 71.6 summarizes the results of studies of the ability of the various modalities to localize insulinomas, which are characteristically small (< 2 cm), as are most duodenal gastrinomas at the time of clinical presentation, compared with other PETs [17–20,25,76,223]. The results with insulinomas are presented separately, not only because of their smaller size at presentation, but also because they are found almost exclusively within the pancreas, whereas gastrinomas, VIPomas (in children), and somatostatinomas can frequently be extrapancreatic [18,19,25,60,75,258]. Ultrasound, CT scanning (Fig. 71.3), and MRI (10%–30%) are relatively insensitive, whereas selective abdominal angiography (60%; Figs 71.5 and 71.6), selective portal venous sampling for insulin (80%; Fig. 71.10), intraoperative ultrasound (89%; Fig. 71.11), endoscopic ultrasound (82%; Fig. 71.9), and hepatic venous sampling for insulin after calcium injection (94%; Fig. 71.10) are sensitive methods to localize insulinomas. Insulinomas differ from other PETs in possessing a low density of somatostatin receptors that bind octreotide with high affinity

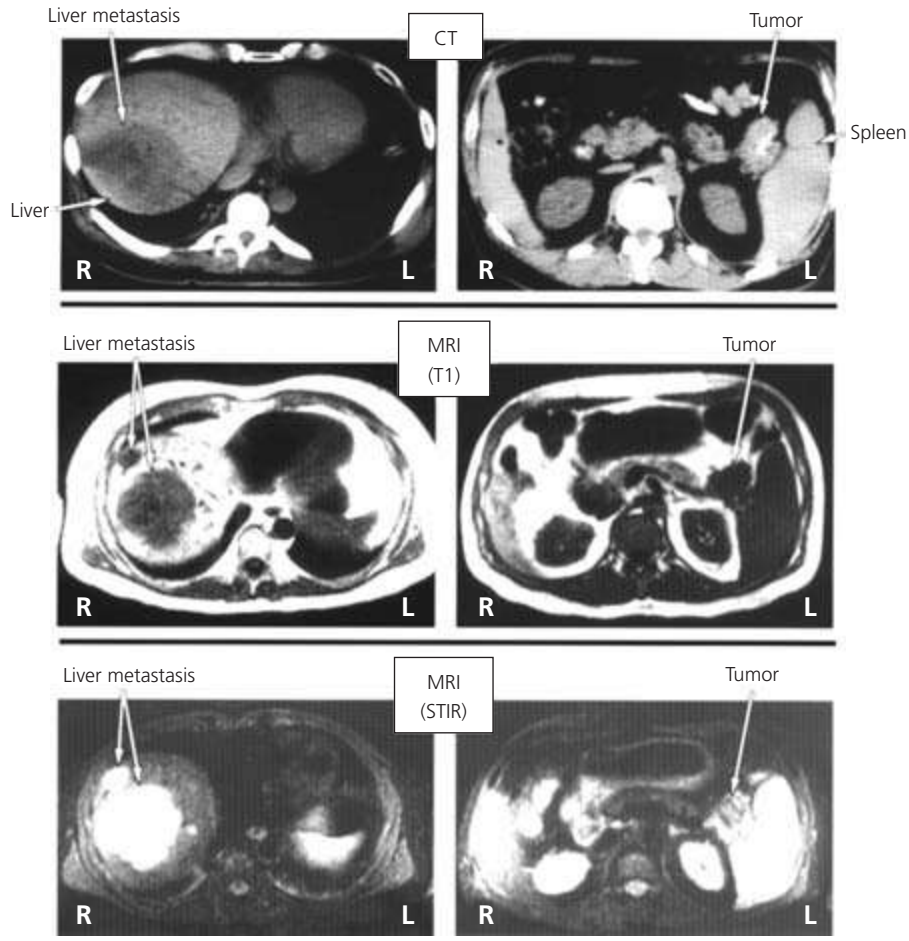

Figure 71.4 Computed tomographic (CT) scan **(top panels)**, magnetic resonance imaging (MRI) T1-weighted image **(middle panels)**, and an STIR (short inversion time inversion recovery) MRI **(bottom panels)** in a patient with a pancreatic endocrine tumor (PET) metastatic to the liver producing parathormone-related peptide causing hypercalcemia. In the left panels the CT scan (top) demonstrates a solitary large metastasis in the right lobe of the liver (arrow), which is not well outlined, whereas on the T1 (middle) and the STIR (bottom) MR images two metastases are clearly seen (arrows) in the right lobe of the liver. In the right panels more caudal views show the primary tumor in the pancreatic tail. The CT scan (top, right) demonstrates clearly the 4-cm pancreatic tail tumor with central calcification, whereas it is less well seen on the MRI T1 (middle) and STIR images (right). This figure demonstrates that metastases from PETs are often much more easily identified on MR images, especially the STIR images, because the tumor has a characteristically bright appearance [14,399]. In contrast the primary tumor is frequently seen better on the CT scan.

(subtypes 2 and 5: sst_2 and sst_5) and therefore SRS is much less sensitive in localizing insulinomas (i.e., 25%, Table 71.6) [259,260]. Results for localization of other PETs except insulinomas are listed in Table 71.6 and compared with the values for insulinomas. These results are primarily based on studies of gastrinomas because the other PETs are uncommon, and frequently the patients with these tumors present with advanced metastatic disease so that routine surgical exploration is not performed. Similar localization data involving large numbers of patients are not available with other PETs within the pancreas. However, because VIPomas, GRFomas, and glucagonomas are almost entirely intrapancreatic it is likely that results similar to those for insulinomas of similar size will be obtained except for the SRS, which will be higher in these tumors. For somatostatinomas, which are frequently extrapancreatic, it is likely that results similar to those obtained with gastrinomas will be found. Ultrasound and MRI are relatively insensitive at localizing noninsulinoma PET primaries (24%–25%); however, CT localizes 50%, angiography finds 68% [14,238,254], selective venous sampling for gastrin reveals 70% [238,267,269], intraoperative ultrasound demonstrates 91% [238,248,271], endoscopic ultrasound finds 70% [238,263], and SRS also localizes 70% [247,257,261,262,274,275]. All PETs are hypervascular and therefore angiography is frequently the most sensitive conventional imaging modality [238,254,255,257]. Figures 71.5 and 71.6 show the typical hypervascular appearance of a primary PET (insulinoma; Fig. 71.5) and hepatic metastases from a malignant insulinoma (Fig. 71.6).

Two newer localization methods that are being increasingly used in patients with PETs are SRS and endoscopic ultrasonography (Table 71.6). Pancreatic endocrine tumors, in addition to a number of other neuroendocrine tumors (carcinoids, medullary thyroid cancer, pituitary adenomas, small cell lung cancer, paragangliomas) and other nonendocrine tumors – lymphomas (Hodgkin disease, non-Hodgkin lymphoma), central nervous system tumors (meningiomas, astrocytomas), breast cancer, prostate cancer – and granulomatous diseases (sarcoidosis, tuberculosis, Wegener granulomatosis), frequently possess high densities of somatostatin receptors, which can be used for localization studies with radiolabeled somatostatin analogues [190,259–261]. For SRS,

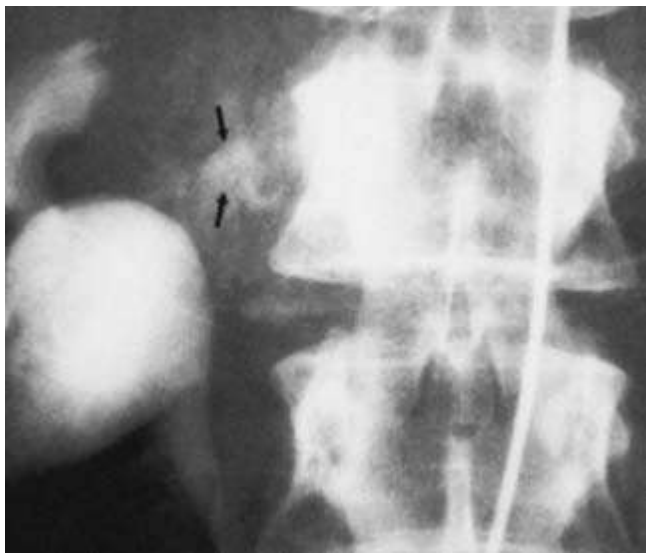

Figure 71.5 Selective angiographic localization of the pancreatic endocrine tumor (PET) in a patient with insulinoma. The insulinoma (1 cm, arrows) is localized in the pancreatic head by a selective celiac artery injection. Insulinomas, as other PETs, are characteristically hypervascular, as demonstrated in the insulinoma in this patient. Because of this hypervascularity even small pancreatic primary lesions are frequently only seen on angiography. Angiography localizes 60% of insulinomas and 68% of the primary tumors in other PET syndromes.

Figure 71.6 Selective common hepatic artery injection in a patient with metastatic insulinoma. The primary insulinoma is demonstrated by the large arrows in the pancreatic head and two hepatic metastases are located in the liver (small arrows). In only 10%–15% of patients with insulinomas are the tumors malignant, whereas in other pancreatic endocrine tumors the majority are malignant. Of the conventional localization methods – ultrasound, computed tomography (CT) scan, magnetic resonance imaging (MRI), angiography – angiography and MRI are the most sensitive modalities for localizing liver metastases (see Table 71.6). Courtesy of Dr Jeffrey A. Norton, UCSF, San Francisco, CA.

in the United States, the radiolabeled octreotide analogue [^{111}In]DTPA-DPhe^{1}octreotide is used [190,260] for tumor localization studies. In vitro autoradiographic studies demonstrate that 100% of gastrinomas, glucagonomas, nonfunctional PETs, 61%–67% of insulinomas, and 88%–96% of carcinoids bind radiolabeled octreotide but 0% of pancreatic adenocarcinomas [257,259,260]. Cloning studies demonstrate that there are five subtypes of somatostatin receptors and that radiolabeled octreotide binds with high affinity to receptor subtypes 2 and 5, with intermediate affinity to subtype 3, and with low affinity to subtypes 1 and 4 [4,190,191]. The overexpression of somatostatin receptors seen on autoradiography in PETs is consistent with the results of SRS in various studies. Tumor is visualized with SRS in 87%–96% of patients with a carcinoid tumor, 73%–100% with a gastrinoma, 46%–61% with an insulinoma, 82%–89% with a nonfunctional PET, 100% with a glucagonoma, and 50%–80% with a VIPoma in two reviews consisting of 477 patients [259,260]. In a comparative study [257] of conventional modalities and SRS in 80 patients with gastrinomas, SRS identified a possible primary tumor in 58% and was superior ($P < 0.001$) to angiography (28%), MRI (30%), CT scan (31%), or ultrasound (9%); moreover, SRS was equal to the combination of all conventional imaging studies combined (48%). Furthermore, SRS [257] alone identified a primary tumor in 20% of patients. Another study [258] confirmed the greater sensitivity of SRS over conventional imaging studies, but demonstrated that SRS can also frequently miss (> 50%) PETs measuring less than 1 cm in diameter. The former study [257] concluded that SRS was the imaging study of choice to localize noninsulinoma PETs. Figure 71.7 demonstrates the increased sensitivity of SRS over the CT scan or MRI in detecting tumor recurrence in a lymph node in a patient with a malignant PET. A number of additional studies have compared the ability of SRS and other imaging studies to localize tumors in some patients with insulinomas [247,251,261] and most patients with other PETs [247,257,276]. In these studies SRS localized an insulinoma in 10% and a gastrinoma in 71%–81% of patients, whereas CT scan, ultrasound, or MRI detected 20% of insulinomas and a primary tumor in 38% of patients with other PETs.

Numerous studies [275,277–281] have examined the ability of SRS to alter clinical management in patients with PETs, which is the most important test of its potential utility. In these studies SRS altered clinical management in a mean of

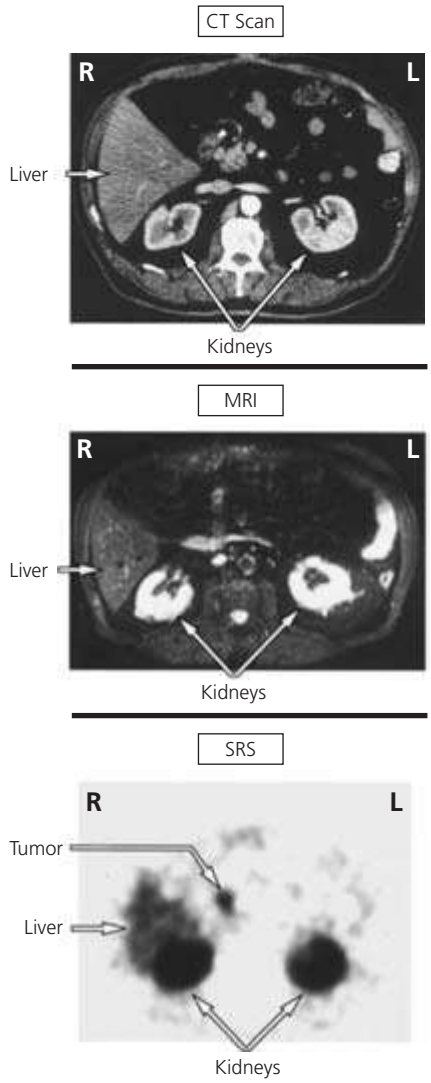

Figure 71.7 Comparison of the ability of computed tomography (CT) scan, magnetic resonance imaging (MRI), and somatostatin receptor scintigraphy (SRS) to localize a pancreatic endocrine tumor (PET). This patient previously had undergone resection of a duodenal PET secreting chromogranin A and gastrin, and underwent reexamination when the serum chromogranin A level increased 1 year postresection. Neither the CT scan **(top)** nor the MRI **(middle)** demonstrated a lesion, whereas the SRS demonstrated a tumor in the pancreatic head area. At surgery a 1.5-cm pancreatic head lymph node containing tumor was found and resected. This study demonstrates the greater sensitivity of SRS for localizing all noninsulinoma PETs [190,257–260] and why it is the initial imaging study of choice in these patients.

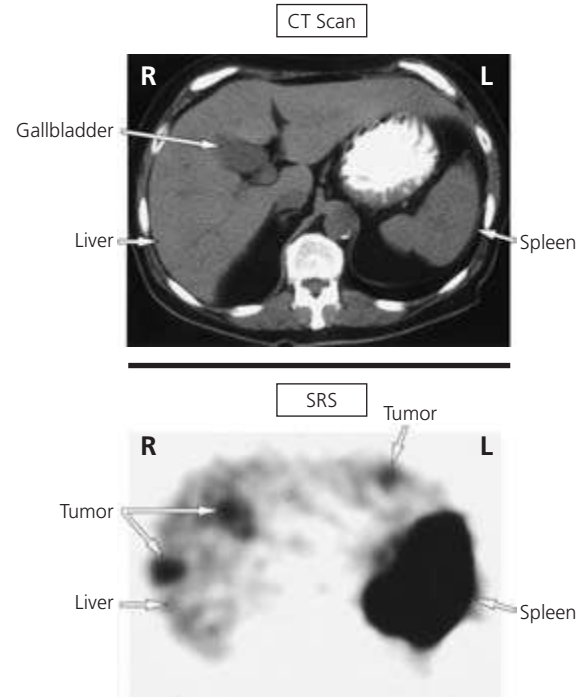

Figure 71.8 Comparison of the ability of computed tomography (CT) and somatostatin receptor scintigraphy (SRS) to localize metastatic pancreatic endocrine tumors (PETs). This patient had right upper quadrant pain with an elevated serum chromogranin level and gastrin level. The CT scan **(top)**, magnetic resonance imaging, ultrasound and angiography were negative; however, the SRS **(bottom)** showed three liver metastases. A percutaneous biopsy demonstrated metastatic PET. This study demonstrates the greater sensitivity of SRS for detecting metastatic disease, both in the liver and at other distal sites, in patients with malignant PETs [4,190,257–260,275,277,282].

30% of the patients (range 12.5%–53%). Management was altered by SRS primarily by clarifying equivocal lesions seen on conventional imaging studies, particularly by identifying liver metastases, a primary tumor, or distant metastases [275,277,278]. One particularly important category of clarifying lesions concerned small hemangiomas of the liver (< 2 cm) [282]. These have a prevalence of 7.3%–15% in autopsy studies, appear indistinguishable from small liver metastases of PETs on MRI or angiography, and cannot be distinguished easily by red blood cell (RBC) scanning or any imaging modality [282]. In one study [282], SRS was positive in 93% of patients with small liver metastases (mean diameter 1.3 cm) of PETs and negative in all small hepatic hemangiomas (mean diameter 1.3 cm). Somatostatin receptor scintigraphy had a significantly better sensitivity, accuracy, and positive and negative predictive value than any other modality for identifying the liver metastases (Fig. 71.8).

Numerous studies demonstrate that endoscopic ultrasound (EUS) is a sensitive method to detect PETs, especially if the PET is intrapancreatic (Fig. 71.9) [241,247,251,264–266,283]. In ten different studies, EUS localized an insulinoma in 57%–92% of patients [241,247,251,263,265,266], and was almost equally sensitive as calcium provocative testing (i.e., 88%) [265], whereas CT scan only localized a tumor in 0%–20%, and SRS in 12%–14%. Similarly, EUS localized a gastrinoma overall in 40%–100% of patients [265], a pancreatic gastrinoma in 75%–100% of cases in four studies

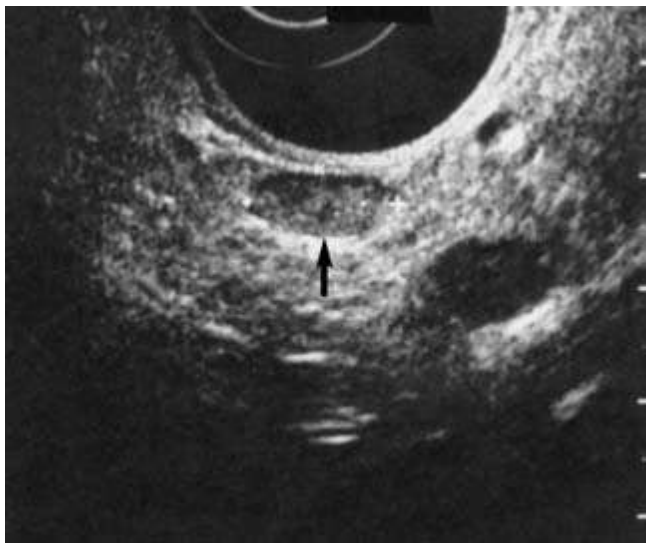

Figure 71.9 Endoscopic ultrasound of a patient with an insulinoma. This image of the head of the pancreas was taken using a 12-MHz probe at the level of the duodenal bulb. It shows a 1.3 × 0.7-cm sharply demarcated, relatively hypoechoic nodule (arrow), which was an insulinoma that was later enucleated at surgery. The splenic vein is seen below the tumor in the 5 o'clock position. The patient was a 29-year-old woman with clinical history and laboratory values diagnostic of insulinoma, but with negative dynamic computed tomography and selective angiography studies. This result shows the sensitivity of endoscopic ultrasound for localizing even small, intrapancreatic endocrine tumors. The author wishes to thank Dr Charles J. Lightdale, Director of Clinical Gastroenterology, Columbia-Presbyterian Medical Center, New York, for providing this picture.

[247,251,264], and a duodenal gastrinoma in 0%–67% in five studies [4,241,247,264]. Therefore, EUS was particularly sensitive for localizing PETs within the pancreas and with insulinomas is more sensitive than SRS, whereas with other PETs in the pancreas it is at least equal in sensitivity to SRS [247,265]. Figure 71.9 shows the ability of endoscopic ultrasound to localize an insulinoma in a patient. To obtain optimum results with EUS requires considerable expertise, whereas SRS can be performed in most radiology departments. However, to obtain optimum results with SRS, SPECT (single photon emission computed tomographic) scanning is needed [259]. Neither EUS nor SRS localizes many small extrapancreatic PETs, especially duodenal gastrinomas [243,258], but SRS has the advantage over EUS of allowing total body assessment at one time; therefore it is especially useful for identifying distant metastases. With both EUS and SRS false-positive results can be obtained; however, the exact rate is not well defined. Somatostatin receptor scintigraphy can be positive in thyroid disorders, breast disease, lymphomas, granulomatous diseases (e.g., sarcoid, tuberculosis), gallbladder filling, wound infections, accessory spleen, various arthritides, and other non-PET neuroendocrine tumors, such as gastric carcinoids [190,260,284,285]. In one prospective study [285], SRS had a false-positive rate of 12% for localizing a gastrinoma; however, when the clinical context was carefully considered, the proportion of cases in which false-positive SRS results altered clinical management was only 3%. There are no comparable studies on the false-positive rate of EUS for small PETs, especially when extrapancreatic.

For metastatic disease to the liver, SRS is more sensitive than conventional imaging studies (Table 71.6) [190,257,275,277,282]. This is shown in Figure 71.8 for a patient presenting with right upper quadrant pain with an elevated serum chromogranin level but normal CT scan and other conventional imaging (MRI, angiography, ultrasound). The SRS demonstrated three liver metastases, which were proven to be metastatic PET. In a comparative study [257] of 24 patients with proven hepatic metastases in patients with gastrinomas, SRS was positive in 92% of the patients, which was significantly better than ultrasound (46%), CT scanning (42%), angiography (62%), and was equal to MRI (71%). The combination of all conventional imaging studies was equal to SRS alone (83% vs 92%, respectively).

Functional localization by venous sampling for hormonal gradients from various portal venous sites or peripheral veins has been used for both insulinomas and other PETs (Fig. 71.10) [14,151,267–269]. This procedure requires considerable expertise and was associated with complications in 20% of the patients in one large study [268]. A simplified method has been developed that has replaced direct venous sampling from portal venous tributaries and does not require transhepatic catheterization. Studies demonstrated that gastrinomas can be functionally localized by measuring hepatic venous samples for gastrin gradients after selective intraarterial injection of secretin, and that this method was more sensitive than PVS, required less expertise, and had lower morbidity [243,286]. A similar procedure has been developed for localizing insulinomas [270,287] using calcium gluconate (0.01–0.025 mEq Ca^{2+}/kg) and is frequently used when the other imaging studies are negative [288,289]. In one comparative study [270] in patients with insulinomas the intraarterial study with selective hepatic venous sampling for insulin levels was positive in 88% of the patients, compared with only 9% for ultrasound, 17% for CT scan, 43% for MRI, 36% for angiography, and 67% for PVS. Calcium infusions may also stimulate the release of hormones from other PETs, so this approach may be useful in these tumors [4]. A typical result is shown in Fig. 71.10 where a much larger increase in insulin concentration in the hepatic vein was seen after the splenic arterial injection; at surgery insulinomas were found in the pancreatic tail in the area supplied by this artery.

Intraoperative ultrasound can be a valuable aid in localizing PETs at the time of surgery (Fig. 71.11) [248,271]. Intraoperative ultrasound is particularly useful for localizing small intrapancreatic PETs, but is less sensitive for extrapancreatic

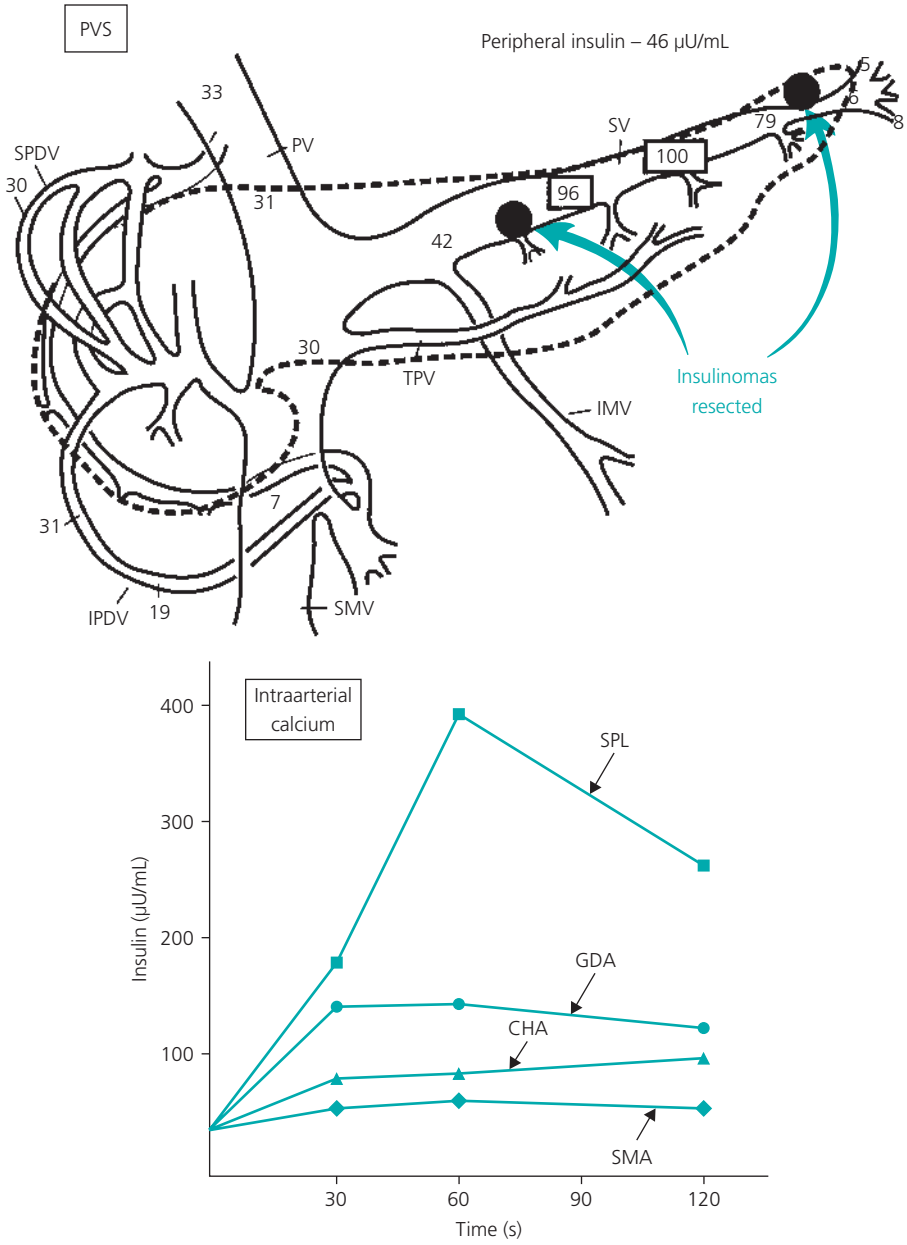

Figure 71.10 Functional location of an insulinoma by selective venous sampling for insulin concentrations in portal venous tributaries (top) or by selective hepatic venous sampling for insulin concentrations after selective intraarterial calcium injections (bottom) in a patient with multiple insulinomas in the setting of multiple endocrine neoplasia type I (MEN-I). **Top panel:** a sampling catheter was passed across the liver and venous samples obtained from the indicated locations; simultaneous peripheral venous samples were obtained and assayed for insulin concentration. The step up to 100 μU/mL is seen in the mid-splenic vein, suggesting a tumor in the pancreatic body or tail. IMV, inferior mesenteric vein; IPDV, inferior pancreaticoduodenal vein; PV, portal vein; SMV, superior mesenteric vein; SPDV, superior pancreaticoduodenal vein; SV, splenic vein. TPV, transverse pancreatic vein; **Bottom panel:** calcium gluconate (0.01 mEq Ca^{2+}/kg) [270] was selectively injected into the indicated arteries and hepatic venous samples obtained prior to injection and at 30 s, 60 s, and 120 s postinjection and analyzed for insulin concentration. There was a marked increase after the splenic artery injection (SPL), whereas after injection into the gastroduodenal artery (GDA), common hepatic artery (CHA), and superior mesenteric artery (SMA) there was a much smaller increase. Two insulinomas were found at surgery (see location by arrows in top panel) in the pancreatic body and tail, which is in the area localized by the PVS sampling as well as the area supplied by the splenic artery. The intraarterial calcium method is more sensitive than portal venous sampling [269,270], requires less expertise, and can be done at the time of angiography thereby avoiding a separate procedure. In some studies [270] the intraarterial calcium is the most sensitive modality for localizing small insulinomas.

tumor [248,271]. Intraoperative ultrasound may also suggest whether the PET is malignant, define the proximity of a PET to the pancreatic duct, and further define the anatomy of a nodule palpated at surgery [248,271]. Intraoperative ultrasound is essential when laparoscopic tumor resection is attempted [290–293]. The use of intraoperative ultrasound at surgery will be discussed further below (see "Surgical treatment").

Bone metastases have been described in patients with advanced PETs [62]. In one study [62] of 115 patients with gastrinomas, bone scanning, MRI of the spine, and SRS were compared for their ability to identify bone metastases. Eight patients (7%) were shown to have bone metastases, and SRS and MRI had the highest sensitivity and specificity [62]. Bone scanning had a low specificity and was less sensitive than SRS or MRI of the spine. Bone metastases occurred in 31% of the patients with liver metastases, were confined to patients with liver metastases, were usually in the axial skeleton initially, and their detection changed management in all cases [62]. Figure 71.12 shows an example of the ability of SRS to image the entire skeleton at once and localize bone metastases in a patient with a malignant PET. In this patient SRS detected more spinal metastases than MRI, demonstrating its high sensitivity.

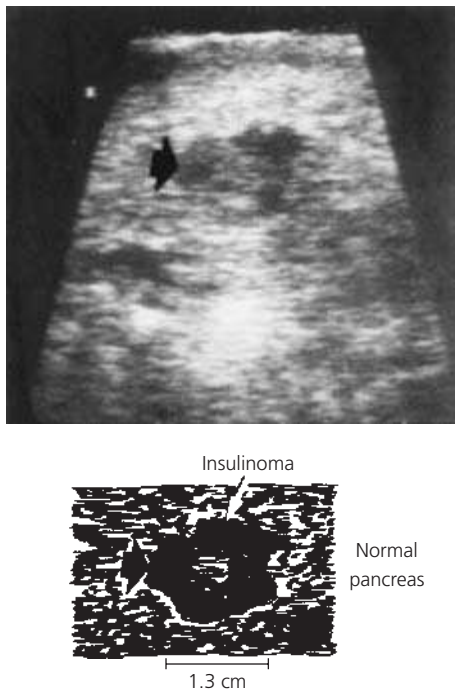

Figure 71.11 Intraoperative ultrasound localization of an insulinoma. **Top:** intraoperative ultrasound image of an insulinoma (arrow). The image was taken with a 10-MHz transducer. **Bottom:** drawing of the ultrasound image with the arrow indicating the tumor. A 1.3-cm, nonpalpable insulinoma was found at surgery in the pancreatic head. Studies [248] demonstrate that intraoperative ultrasound will localize 88% of insulinomas. In this patient the use of intraoperative ultrasound guided the successful enucleation of this tumor, which could not be identified at surgery by any other means. Courtesy of Dr Jeffrey A. Norton, UCSF, San Francisco, CA.

Figure 71.13 summarizes the recommended approach to a patient with a PET that is not an insulinoma. In such a patient both the location of the primary tumor and possible occurrence of liver or distant metastases need to be assessed. Because of its increased sensitivity and ability to image the entire body in one study, SRS is recommended as the initial study with SPECT imaging. If the SRS scan is positive for liver metastases, the extent and number of lobes need to be established to determine whether surgical resection of all imageable tumors is possible, as discussed below under "Treatment". If diffuse metastases are present, a CT- or ultrasound-guided percutaneous liver biopsy should be done (Fig. 71.13). Because it is difficult to evaluate increases in tumor size by SRS, an MRI or CT scan should be performed to evaluate changes in the size of liver metastases over time [245]. If no metastases are present and no primary tumor is seen, endoscopic ultrasound should be performed by an experienced endoscopist. If a primary tumor is still not seen, a selective angiogram should be performed and the use of intraarterial calcium with determination of hepatic venous hormonal gradients considered (Figs 71.10 and 71.13).

Studies from Europe provide evidence that positron emission tomographic scanning using [^{11}C]5-hydroxytryptophan or gallium 68-labeled somatostatin analogues may have greater sensitivity than SRS or other conventional imaging modalities [261,294–296] and therefore be clinically useful in a subset of patients. In a study [294] using a gallium-68-radiolabeled octreotide analogue (^{68}Ga-DOTA-Tyr^3-octreotate) involving 84 patients with gastrointestinal neuroendocrine tumors, positron emission tomography had greater sensitivity (97% vs 55%) and accuracy (96% vs 58%, $P < 0.01$) with equal specificity (92%) to SRS. This technique is not approved for use in the United States.

Table 71.6 Studies assessing the ability of various modalities to localize insulinomas and other pancreatic endocrine tumors

	Mean percentage localized (range)		
		Other pancreatic endocrine tumors	
Localizing modality	**Insulinomas**	**Primary**	**Liver metastases**
Ultrasound	27 (0–64)	24 (6–70)	40 (14–76)
Computed tomography scan	30 (16–61)	50 (33–100)	70 (35–100)
Magnetic resonance imaging	10 (0–25)	25 (21–100)	80 (43–100)
Selective angiography	60 (41–90)	68 (35–100)	69 (33–86)
Selective portal venous hormone sampling	80 (63–96)	71 (46–94)	N/A
Hepatic venous sampling for insulin after intraarterial calcium	94 (88–100)	N/A	N/A
Intraoperative ultrasound	89 (80–100)	91 (80–100)	N/A
Endoscopic ultrasound	82 (57–93)	70 (40–100)	N/A
Radiolabeled somatostatin receptor scintigraphy	50 (12–56)	70 (56–100)	94 (88–100)

Data from Jensen [4,190]; Jensen and Norton [12,28,47,190]; Orbuch et al. [238]; Norton and Jensen [241]; Norton et al. [243]; Zimmer et al. [247]; Norton [248]; London et al. [249]; Rosch et al. [251]; Krenning et al. [259]; Strader et al. [269]; Gibril et al. [474].

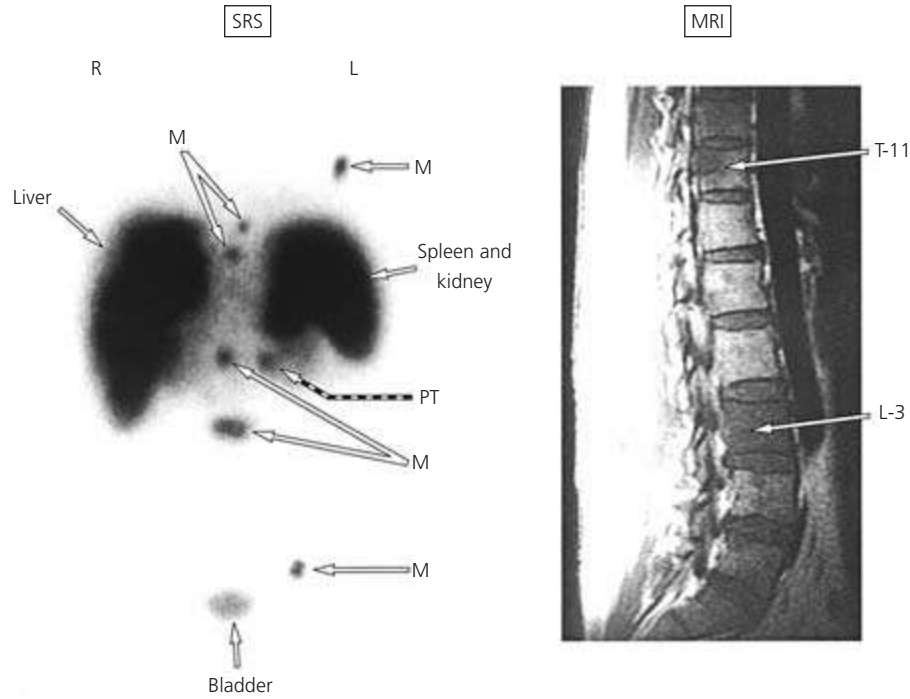

Figure 71.12 Comparison of the ability of somatostatin receptor scintigraphy (SRS) and magnetic resonance imaging (MRI) to localize bone metastases in a patient with a malignant pancreatic endocrine tumor (PET) secreting glucagon and gastrin and located in the pancreatic tail. In this patient with back pain, MRI demonstrated T11 and L3 metastases (**right panel**, arrows) whereas SRS **(left panel)** demonstrated numerous metastases (labeled M) in the thoracic and lumbar spine, ribs, and right pelvis. The broad dotted arrow on the SRS shows the primary tumor (labeled PT). This patient's results show the high sensitivity of SRS for localizing bone metastases and the ability of SRS to allow a complete body scan at one time.

Treatment

General

All patients with functioning PETs have two problems that are interrelated but often have to be dealt with separately. Acutely, the symptoms due to the state of excessive hormone must be controlled, and ultimately the tumor itself must be dealt with. Although excision of the PET would solve both clinical problems, this is frequently not possible because of several possible factors: there is unresectable metastatic disease at time of diagnosis; the primary PET cannot be found at surgery; or curative resection is not achieved. Furthermore, the clinical condition of the patient may have deteriorated because of complications of the hormone excess state necessitating treatment prior to surgery [2].

Even with the increased ability to control the symptoms of the hormone excess state with various medical therapies, a number of factors suggest that all patients with PETs should be considered for surgical resection of the tumor. First, although only 5%–15% of insulinomas are reported as malignant, with the other PETs at least 50% are malignant, and in many reports this percentage of patients or more have metastases at the time of diagnosis [2,297]. For example, in various studies up to 90% of all gastrinomas [14,46,244], up to 90%–100% of nonfunctional PETs [1,5,29,298,299], 82% of glucagonomas [15], and 50%–60% of VIPomas [20,21] were malignant. Furthermore, although in some studies large tumors were more likely to be malignant [9,10,59,61,300–304], metastases occasionally occur with small tumors; therefore, the absence of tumor on the initial imaging studies or small tumor size do not rule out metastatic disease. Although a number of patients with metastatic glucagonomas [59,79], gastrinomas [9,10,14,61], and somatostatinomas [23,305] have been reported to have long-term survivals, detailed studies of PETs, such as gastrinoma, in which there has been effective therapy for the gastric hypersecretion since the late 1980s, suggest that for patients with advanced disease the long-term prognosis is worse than originally thought [9,10,14,79,300,306,307]. Results from studying primarily patients with gastrinomas have provided insights into prognostic factors and determinants of survival in these patients, insights that are likely also important with other less common PETs because of their similar biological behavior, histopathology, growth patterns, and metastatic pattern (Table 71.7) [9,10,46,61,245,300]. These studies demonstrate that various PETs in different patients frequently grow at markedly different rates [9,10,19,61,245,300,308]. In approximately 75% of patients with gastrinomas the tumor demonstrated either no growth or indolent growth, whereas in 25% it demonstrated aggressive growth [10,61]. Furthermore, even in patients with liver metastases, aggressive growth occurred in less than one-half; however, all the deaths occurred in this subgroup of patients [245]. The presence or absence of liver metastases initially, or the development of liver metastases during follow-up, is the single most important prognostic factor (Fig. 71.14) [9,10,19,61,300,303,304,309]. For example, in one study [10]

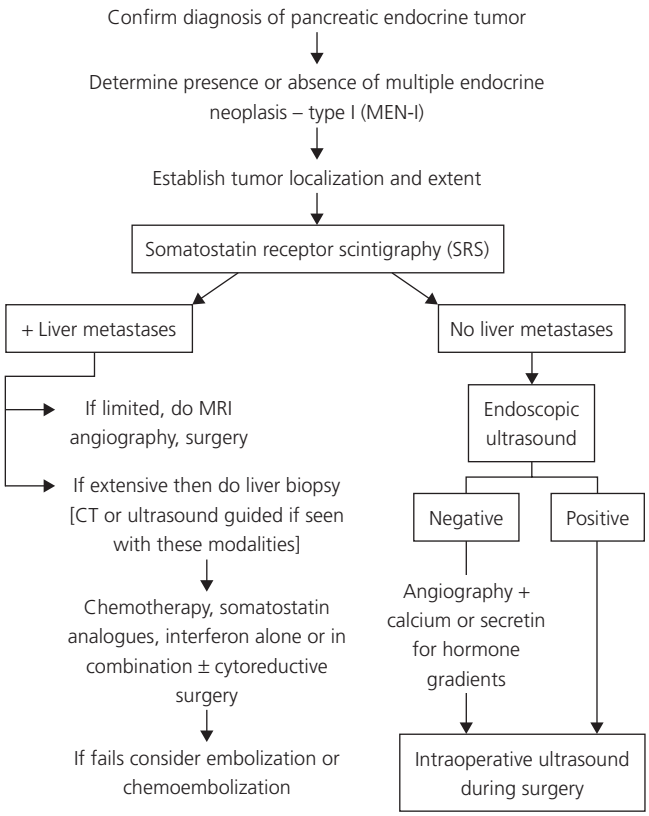

Figure 71.13 Algorithm summarizing the approach to tumor localization in a patient with a pancreatic endocrine tumor that is not an insulinoma. Because of its increased sensitivity for detecting the primary and metastatic disease both in the liver and at distal sites [190,257,260,275,277] and its ability to cover all body areas in one study, somatostatin receptor scintigraphy (SRS) with single photon emission computed tomographic imaging is the initial localization method of choice. SRS will localize more than 90% of patients with liver metastases [4,190,257,260,275,277]. If no liver metastases are seen, endoscopic ultrasound (EUS) is the most sensitive method for localizing the pancreatic primary [263,474]. If the EUS is negative, selective angiography with intraarterial injection of calcium (insulinoma, somatostatinoma, glucagonoma) and sampling of hormonal levels in hepatic venous samples should be done. At surgery intraoperative ultrasound should always be used because it will identify lesions not seen by other methods [248]. Up to 15% of patients with metastatic disease in the liver may have resectable disease and should be considered for surgery [4,246,306,316]. CT, computed tomography; MRI, magnetic resonance imaging.

the 15-year survival in patients with liver metastases that were present during initial assessment was 26%, whereas in patients without liver metastases it was 96%. The extent of liver metastases (one lobe, two lobes, diffuse) (Fig. 71.14), presence of lymph node metastases, bone metastases, a large primary tumor size, primary location (pancreatic worse prognosis than duodenal gastrinoma), various histological features, tumor marker levels (chromogranin A, specific hormone level, such as gastrin), flow cytometric features, and proliferative indices (Ki-67, mitotic index), have all been shown to be

Table 71.7 Prognostic factors in pancreatic endocrine tumors (PETs) for decreased survival

Category	Prognostic factor
Clinical features	Female gender Absence of multiple endocrine neoplasis–type 1 (MEN-I) syndrome
Laboratory features	Increased chromogranin A in some studies Increased gastrin level in gastrinomas Lack of progesterone receptors
Tumor extent/size	Presence of liver metastases Increased extent of liver metastases Presence of lymph node metastases Presence of bone metastases Primary tumor site Primary tumor size (> 2–3 cm = worse prognosis)
Tumor behavior	Growth of liver metastases Incomplete tumor resection Nonfunctional tumor Development of ectopic Cushing syndrome Increased depth of tumor invasion
Histological features	Necrosis High nuclear atypia Poor tumor differentiation High growth indices (high Ki67 index [> 2%], PCNA expression, mitotic rate) Capsular invasion Vascular or perineural invasion Low vessel density
Other	Flow cytometric features (i.e., aneuploidy) *RAS* oncogene or *p53* overexpression

Data from Jensen [4,9,190]; Yu et al. [10]; Weber et al. [61]; La Rosa et al. [221]; Madeira et al. [300]; Hochwald et al. [302]; Panzuto et al. [304]; Metz et al. [310]; Marion-Audibert et al. [475].

important prognostic factors in various studies of PETs (Table 71.7, Fig. 71.14) [2,9,10,57,61,190,221,300,302,304,310]. Studies have shown that survival is directly related to tumor extent. In patients with primary tumors so small that no tumor was found at the time of surgery, the 5- or 10-year survival was 90%–100% [14,79,306]. In patients with complete tumor resection the 5- or 10-year survival was also 90%–100%. But in patients whose tumors were incompletely resected or who developed a recurrence postoperatively, the 5-year survival varied from 14% to 76%, and 10-year survival was 20%. In some studies [311,312], but not others [302,304,313], survival was better with functional than with NFPETs. In patients with unresectable PETs, such as gastrinomas metastatic to the liver, the 5-year survival varied from 20% to 75%, and the 10-year survival in one study was 30% (Fig. 71.14) [14,79,306]. These data suggest that once metastatic disease occurs the prognosis is signific-

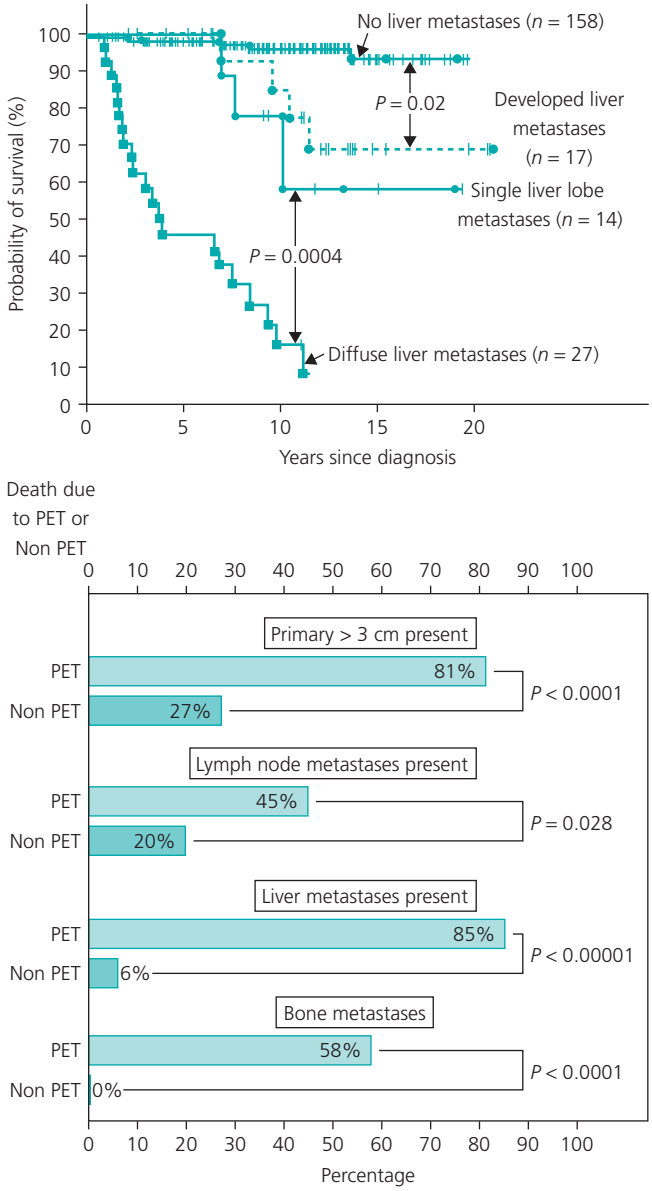

Figure 71.14 Effect of the development or extent of liver metastases from a pancreatic endocrine tumor (PET) **(top panel)**, presence or absence of lymph node or bone metastases, or PET primary size on disease-related survival. Data are from 158 patients and are modified from Yu et al. [10] **(top)** and Jensen [46] **(bottom)**. These results demonstrate that the presence of liver, bone, or lymph node metastases, a large primary PET size, and increased extent of liver metastases are all important predictors of a tumor-related death.

antly worsened. Two important studies [314,315] demonstrate for the first time that resection of the primary PET significantly decreases the rate of development of liver metastases or improves survival (or both). The improvement in survival [315] by surgery was due to resection of the primary PET, because only tumor-related death rates were altered by the surgical resection. Furthermore, because therapy for advanced disease is in many cases only partially effective [2,14,246,304] it is important to attempt to resect the PET while it is still localized. Unlike gastrinoma, the long-term medical therapy of the other various PETs is not well established and it is not known what percentage of patients will be refractory to medical treatment. Therefore, in functional PET syndromes not including gastrinomas, cytoreductive surgery may be helpful because it may improve symptom control [246,316,317]. Lastly, the long-term toxicity of most medical therapies, except those for gastrinomas, is not well established.

Treatment of nonmetastatic disease

Medical treatment

General treatment considerations

The initial management of patients with insulinomas, and the long-term management of those patients with insulinomas who are not surgically cured, is directed at controlling the hypoglycemia. The simplest form of nonsurgical control is dietary management. Frequent small meals may alleviate symptoms [76,99]. In severe cases intravenous glucose combined with various drug therapies may be required. In general, 10% dextrose should be avoided because of the electrolyte imbalances generated by the combination of elevated serum concentrations of glucose and hyperinsulinemia [99]. Some investigators have used slowly absorbed nutrients to maintain normal blood sugars prior to surgery. This may be preferable to diazoxide because of reports of sudden hypotension in some patients receiving diazoxide prior to surgery [318]. However, diazoxide (150–800 mg/day) has been used successfully to manage patients with insulinoma prior to surgery as well as in long-term treatment [76,78,99,319]. Diazoxide is a benzothiadiazide that has a plasma half-life of 28 hs and a peak hyperglycemic effect 12 h after an oral dose or 4 h after an intravenous dose. Its hyperglycemic action is attributed to direct inhibition of insulin release by adrenergic stimulation and by enhancing glycogenolysis [59,76]. The main side effects of diazoxide are sodium retention (47%), gastrointestinal symptoms such as nausea, and occasionally hirsutism [59,76,78,99,319]. Sodium retention can be minimized by administration of diazoxide with a diuretic and restricting sodium intake. The gastrointestinal side effects can be decreased by taking the drug with meals [59,99]. Diazoxide is primarily excreted by the kidneys and is known to displace various protein-bound drugs and increase their free concentrations in the serum [99]. Diazoxide therapy should be initiated with low doses and increased to a maximum of 600–800 mg/day in two or three divided doses as tolerated or until symptoms are controlled. In general approximately 50%–60% of patients will respond [59,76,78,99,319,320]. Patients have been treated for up to 22 years with diazoxide [319], demonstrating that it can be effective in the long term. The calcium channel blocker verapamil [76,78,321,322] and diphenylhydantoin [323] have also been used to control hypoglycemia, with some

success in some patients when diazoxide has failed. The long-acting somatostatin analogue, octreotide (Sandostatin, Novartis), has been shown to be effective in 36% of patients for the acute and long-term control of hypoglycemia in patients with insulinoma [28,121,171,190] and this will be discussed further in the next section.

In the initial management of patients with VIPomas the most important issue is to replace the large volumes of fluid and electrolytes lost, and correct the hypokalemia and acidosis [20,21,114]. This is particularly important because acutely a common cause of death in these patients is renal failure associated with hypokalemia and hypokalemic nephropathy [20]. Formerly, drug therapy included the use of high doses of prednisone (60–100 mg/day) [20], which decreases diarrhea in 40%–50% of patients [20,20], and the use of clonidine [324], angiotensin II [325], norepinephrine (noradrenaline) [325,326], indometacin (indomethacin) [327,328], lithium carbonate [329], phenothiazines [330,331], propranolol [28], metoclopramide [332], lidamidine [333], and loperamide [333], all of which decreased the diarrhea in a small number of patients. These agents primarily enhanced sodium absorption in the proximal small intestine or inhibited intestinal secretion [20]. Subsequent studies demonstrated that the long-acting somatostatin analogue, octreotide controls diarrhea in 87% of all patients with VIPomas [28,114,190], and this has become the drug of choice. It will be considered in detail below (see "Octreotide").

In patients with glucagonoma the rash – migratory necrolytic erythema – may be severe. Some studies suggest that correction of the hypoaminoacidemia with parenteral amino acids and normalization of the plasma amino acid levels will improve the rash [79,161,162]. However, another study noted disappearance of the rash after surgical resection of the glucagonoma but not dietary normalization of the plasma amino acids [163]. Octreotide [121,171,190] improves symptoms in 84% of patients with glucagonomas and its use will be discussed in detail below.

Octreotide

As pointed out earlier, somatostatin has been shown to inhibit the release of a number of hormones in both animals and in human volunteers, and to have direct actions on a number of target organs including inhibition of gastric and pancreatic secretion, intestinal absorption, and gastrointestinal motility [190,191]. Administration of natural somatostatin by continuous infusion to a number of patients with functioning PETs demonstrated symptomatic improvement in patients with VIPomas, insulinomas, gastrinomas, and glucagonomas [28,47,121,190]. However, natural somatostatin has a short half-life ($t_{0.5}$ 2–3 min) [12,190] and therefore has limited therapeutic efficacy because it has to be given by continuous intravenous infusion.

The synthetic octapeptide analogue of somatostatin, octreotide acetate (Sandostatin), has a half-life ($t_{0.5}$ 100 min.) 33 times longer than somatostatin and thus can be administered two to four times a day [121,190,334,335]. In the rat, compared with native somatostatin, it was 70-fold more potent at inhibiting growth hormone release, 3-fold more potent at inhibiting insulin release, 23-fold more potent at inhibiting glucagon release, and 80-fold more potent at inhibiting acid secretion [190,334,335]. Octreotide is usually started at a dose of 50–150 μg b.i.d to t.i.d. subcutaneously given by self-administration, the dose being increased if not effective. Doses of up to 750 μg t.i.d have been used in patients with the carcinoid syndrome and PETs [121,171,190]. There have been reports in small numbers of cases where intermittent subcutaneous administration of octreotide was ineffective or only partially effective and the continuous infusion of octreotide was more effective [190,336]. One long-term study [337] reported on seven patients with various PETs treated for a median period of 20 months (range 13–54 months) in which octreotide was initially effective in all. Worsening of symptoms and rising plasma hormone concentrations occurred over a median period of 5 months after starting therapy; these parameters were initially reversed by increasing the octreotide dose, but after a median of 13 months (range 5–34 months) the symptoms returned and were no longer responsive to higher doses of octreotide.

In one review of 55 patients with insulinoma [190], octreotide improved some symptoms in 31% and plasma insulin concentrations decreased in 41%. However, 65% of the patients received octreotide for less than 1 week because most went to curative surgery. In a second series of 17 patients with insulinoma [338], octreotide controlled symptoms of hypoglycemia in 58%. Octreotide also decreases growth hormone secretion and plasma glucagon levels and thus it may worsen the hypoglycemia. A reduction in hypoglycemia attacks has been noted only occasionally [339]. Octreotide was given for over 1 month in 10 patients [190]. In short-term studies octreotide appears to benefit 36% of patients with insulinoma, but the true percentage of patients with insulinomas who continue to respond to octreotide is not clear [171]. Of the five subtypes of somatostatin receptors, octreotide has high affinity for sst_2 and sst_5, intermediate affinity for sst_3, and low affinity for sst_1 and sst_4 [190,191]. The response rate of insulinomas to octreotide is likely lower than other PETs because insulinomas frequently possess low densities of somatostatin receptors or lack somatostatin receptor subtypes 2 and or 5 (sst_2 and sst_5), which have high affinity for octreotide/lanreotide analogues, whereas 80%–90% of the other PETs possess high densities of high-affinity sst_2 and sst_5 receptors [190,259,340]. This finding may also explain why insulinomas appear to be less responsive than glucagonomas, VIPomas, gastrinomas, or GRFomas to octreotide and are imaged less frequently by SRS [190,259,259,260]. This proposal is supported by a study [338] that correlated sst receptor expression in insulinomas and the functional responses to octreotide administration as

well as the ability of radiolabeled somatostatin analogues to image the tumor. In the 50% of insulinomas not responding to octreotide, sst_2 receptors were not found but sst_5 receptors were present, leading to the conclusion that the presence or absence of sst_2 receptors on the insulinoma partially explains the variable responses of insulinomas to octreotide and to imaging with SRS [338].

Octreotide improved diarrhea in 27 (87%) of 31 patients with VIPomas in one review [190], and plasma VIP concentrations decreased in 87% of the patients, which is similar to the 78%–90% response rate in other reports [19,21,114,121,171,190]. In the same review [190], tumor size was evaluated in 18 patients with VIPomas and a decrease in size occurred in 4 patients. All patients demonstrated a decrease in diarrhea within the first 24 h but in three patients the effect lasted only a few days [121]. Octreotide was given for more than 1 month in 90% of the patients and remained effective for over 6 months in 50% of all patients. However, some patients developed decreased responsiveness to octreotide with time, and the dose had to be increased. In 87% of patients there was a decrease in the VIP plasma level with octreotide treatment although in many cases it did not return to the normal range [190,341,342]. In up to 25% of patients the diarrhea may respond without a decrease in plasma VIP levels [171]. The apparent discrepancy in response and plasma hormone levels may be partially explained by the fact that multiple forms of VIP occur in the plasma and after octreotide treatment only the native peptide may disappear; this may represent a small fraction of the total VIP immunoreactivity and, therefore, no change in plasma VIP is detected [342]. An example of such a patient is shown in Fig. 71.15. This patient [341] had severe secretory diarrhea of 5816 ± 185 g/day with daily losses of 616 mmol of sodium and 348 mmol of potassium; the patient required 3 L/day of fluid with 462 mmol of sodium and 400 mmol of potassium to maintain serum potassium at 3.4 mmol/L and bicarbonate at 15–24 mmol/L (Fig. 71.15). Octreotide 100 µg twice a day was started and stool output fell to 292 ± 55 g/day, with daily fecal loss of 5 mmol sodium and 25 mmol of potassium and rising serum potassium and bicarbonate levels. This VIPoma was secreting VIP, motilin, PP, and neurotensin, which with octreotide treatment decreased the plasma levels by 94% for PP, 76% for VIP, 88% for neurotensin, and 70% for motilin (Fig. 71.15) [341]. This patient's diarrhea was controlled for 3 months, at which time she died of respiratory failure [341]. The cost-effectiveness of long-term octreotide treatment in patients with VIPomas has been studied [343]. It was concluded that long-term octreotide treatment decreases medical costs for a VIPoma patient by 50% [343].

In 33 patients with glucagonoma, octreotide improved the skin rash in 24 patients and reduced plasma glucagon concentrations in 78% of patients [16,17,28,47,79,121,171,174, 190,344]. Weight loss, pain, and diarrhea improved in patients with these symptoms, but octreotide may not improve

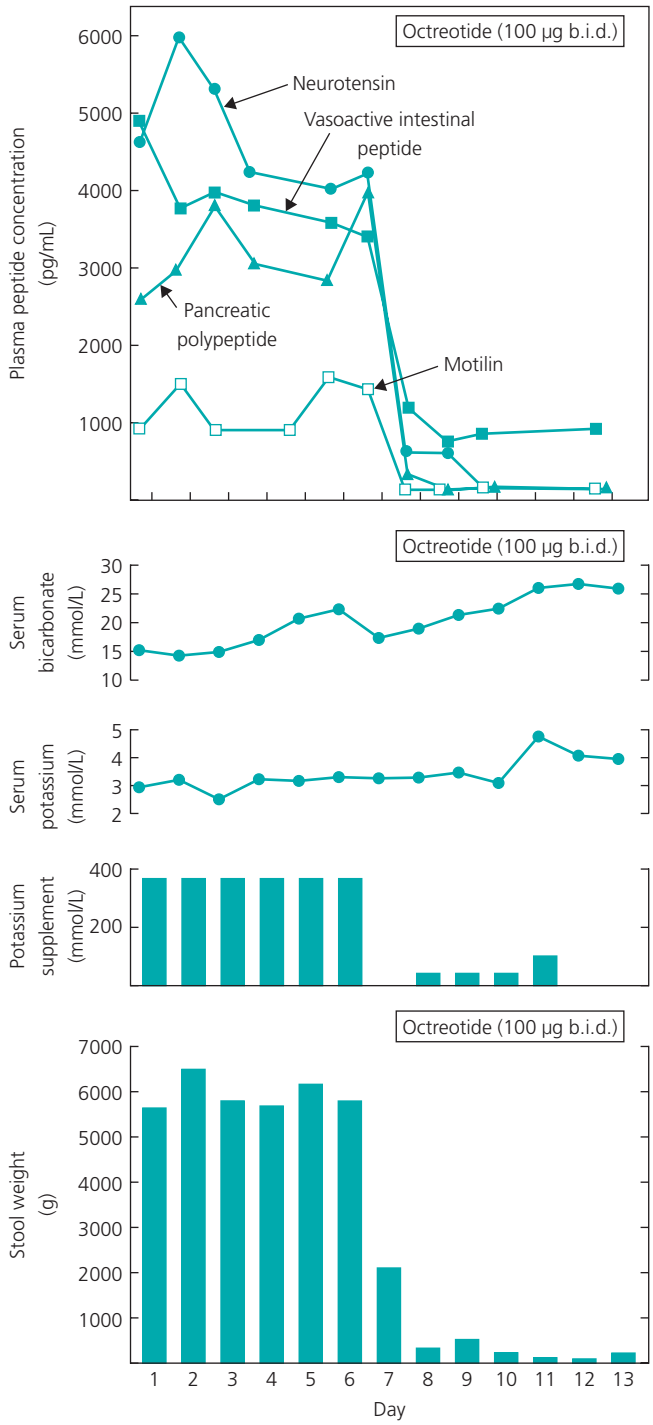

Figure 71.15 Effect of octreotide treatment on hormonal levels, stool weight, serum electrolytes, and potassium replacement in a patient with a metastatic VIPoma. This patient [341,342] had a VIPoma secreting vasoactive intestinal polypeptide (VIP), neurotensin, pancreatic polypeptide (PP), and motilin. Shown are values for the different parameters for 6 days prior to, and 7 days after, receiving octreotide 100 µg b.i.d. subcutaneously. The hormone levels all decreased by more than 70%, serum bicarbonate increased, and potassium intake was decreased by 94%, and stool weight decreased by over 95% (5816 ± 185 g/day to 292 ± 55 g/day). The patient was maintained for 3 months on octreotide, remaining asymptomatic until death of unrelated causes.

the diabetes mellitus [16,79,174]. Octreotide usually does not affect tumor size, decreasing the tumor size in only 8% of cases in one study [16] and in only 4% of cases in the literature [16,190]. Decreases in plasma glucagon concentration occur in 80%–90% of patients but do not always parallel the improvements in the rash [79,121,171]. Octreotide was administered for more than 1 month in 94% of patients and remained effective for over 6 months in 75% of all patients. In one study [16] the duration of treatment ranged from 2 months to 3.5 years.

Bromocriptine, a dopamine agonist, is effective in patients with classical acromegaly; however, it only reduces GRF levels in 25% of patients with GRFomas [84]. Octreotide has become the agent of choice for GRFomas [23,84,190,204,207,209]. Octreotide reduces symptoms of both growth hormone excess and elevated GRF plasma concentrations in patients with GRFomas [23,84,171,190,345]. In most patients reported with GRFomas, octreotide improved symptoms and reduced the GRF levels in all patients [23,84,190,207], although in one study [346] continuous infusion was required. Eight of the nine patients received treatment with octreotide for more than 6 months [171,190,345]. Pituitary shrinkage occurred with octreotide treatment in some studies [207]. In GRFomas, the suppression of growth hormone secretion is mainly due to a suppressive effect at the pituitary level because plasma GRF levels do not become undetectable [84].

A small number of patients with somatostatinomas were treated with octreotide [171,347]. In three of four treated patients plasma somatostatin-like immunoreactivity levels decreased, and in two patients symptoms due to the somatostatinoma syndrome (diarrhea and diabetes) were improved [347].

Long-term treatment with octreotide has a number of unresolved issues. Many patients require increasing doses of octreotide over time, and some patients require high doses [171,190,348]. In a small number of patients when the octreotide was stopped and restarted, the symptoms were controlled at a lower dose of octreotide [171], whereas other patients did not respond. Furthermore, it is unclear why in some cases intermittent subcutaneous (s.c.) injections are not effective, whereas continuous low-dose s.c. infusions are effective. It is also unclear whether the sustained-release preparations (octreotide-LAR, lanreotide-SR, lanreotide-autogel) [349] will be effective in cases where intermittent s.c. octreotide injections prove ineffective. Octreotide, in addition to reducing the ectopic release of hormone, also decreases growth rate in a significant proportion of PETs and decreases tumor size in a small percentage of patients [2,171,190,308]. This will be discussed in a later section (see "Somatostatin analogues") but it is not established that the dose of octreotide is the same for both effects.

Side effects have been recorded in approximately 50% of patients undergoing short-term octreotide treatment, but these have rarely been serious enough to stop therapy [121,171,190]. Most patients only experience some pain or discomfort at the subcutaneous injection site (9%) [121]. The other most common side effects are gastrointestinal, including nausea (15%), vomiting (1%), constipation, crampy abdominal pain, and diarrhea (13%), which may improve with time [171]. Steatorrhea can occur with octreotide [190]: at low doses the steatorrhea is usually mild and transient, but at high doses gross steatorrhea can occur [350]. Dunne and colleagues [121] reported that 13% of patients developed diarrhea, 6% had fatty stools, and 8% experienced loose stools; elevated fecal fat levels were demonstrated in nine patients. Rarely does octreotide have to be stopped because of steatorrhea; and occasionally it may impair glucose tolerance and unmask diabetes mellitus. Occasional postprandial hyperglycemia has been reported [171]. Reactions were graded as mild in 48%, moderate in 38%, and severe in 15% [121]. Most of the side effects were short-lived and did not result in stoppage of octreotide treatment. A number of studies have assessed the safety and adverse effects of octreotide during long-term treatment, especially on gallstone formation and gallbladder function, particularly in patients with acromegaly [190,195,196,351]. In one study [195] of 103 acromegalic patients treated with octreotide (s.c.) for a mean of 30 months, 66% of patients experienced an adverse event in the first year and 46% in the second. Most were related to the GI tract, including diarrhea (58%), abdominal discomfort (44%), loose stools (36%), nausea (30%), flatulence (13%), and constipation (9%). With continued treatment the adverse events usually disappeared, and only 5% of patients discontinued treatment because of adverse events. In a detailed review of octreotide-LAR, 30% of patients developed GI side effects, which were mild in most cases and did not require drug discontinuation [349]. Various studies in acromegalic patients have shown the incidence of gallstones to range from 1% to 80%, with a mean of 29% [4,190,195,349,351]; however, it is reported that only 1% develop symptomatic gallbladder disease [349]. In one study [196] of 33 patients with carcinoid syndrome or PETs treated long-term with octreotide, the overall incidence of cholelithiases or gallbladder sludge was 52%. Seven percent of the patients had symptomatic disease and required an emergency cholecystectomy. The incidence of cholelithiases varied with octreotide dose [196], being 35% in patients on a low dose (150 μg t.i.d.) and 61% with a high dose (500 μg t.i.d.). The incidence of acute cholecystitis was 12% in the low-dose group and 5% in the high-dose group [196]. Eleven percent of patients underwent elective cholecystectomy. Long-term treatment can also alter glucose tolerance significantly in some patients; therefore, glucose levels should be monitored [190].

Long-term treatment with synthetic somatostatin analogues has been greatly simplified by the availability of sustained-released forms [190,349,349,352]. Both a long-acting octreotide formulation (Sandostatin LAR, 30 mg i.m.

every month; available in the United States and Europe) and a slow-release lanreotide (lanreotide SR, 30 mg i.m. every 10–24 days; available in Europe) or sustained-release formulation of lanreotide in gel form (lanreotide autogel) (60, 90, or 120 mg/month i.m.; available in Europe) are being used for the treatment of acromegaly, carcinoid syndrome, and PETs [4,190,349,349,352–354]. Following a 30 mg i.m. injection of octreotide-LAR, a plasma level of 1 mg/mL is achieved and maintained for more than 25 days and therefore this formulation can be administered monthly [349]. The principal side effects of octreotide-LAR are similar to those discussed in the previous paragraph for the shorter-acting formulation, and include pain at the injection site and GI symptoms (usually mild and frequently transient – pain, cramping, diarrhea) [4,349,349,352–356]. Octreotide-LAR and lanreotide SR impair gallbladder emptying [4,194,349,353,354], and octreotide-LAR has been shown to inhibit cholecystokinin (CCK) release [194]. Studies of long-term octreotide treatment have variously reported no increase in the incidence of gallstones (at 12 months), the development of asymptomatic biliary sludge in 15% of patients, and the development of symptomatic gallstones in 1% [4,349,353,354]. Lanreotide SR is reported to cause new gallstones in 10%–26% of patients [352,357]. Other side effects reported with octreotide-LAR or lanreotide autogel with long-term use in patients with acromegaly include hypoglycemia (2%) and hyperglycemia (15%) but they are symptomatic in only a small percentage of patients [4,349,353,354].

Surgical treatment

All patients with PETs should undergo exploratory laparotomy for possible cure [2,243,248,317,358]. Exceptions are patients with unresectable metastatic disease or the occasional patient whose symptoms are well controlled by medical management but who also has a concurrent medical problem that makes the risks of surgery prohibitive. It is particularly important that the surgery is performed only by a surgeon with experience in operating on patients with PETs [14,78,99,244,359]. Even experienced general surgeons and many endocrine surgeons have little experience with these rare tumors and therefore will frequently miss small tumors, perform unnecessary major resections, or fail to perform the appropriate resection to palliate symptoms.

As outlined above (Fig. 71.13), prior to surgery all patients should undergo localization studies and if the tumor localization or extent is still unclear, then functional localization studies (selective hormone sampling of portal venous tributaries) or calcium infusion with hepatic venous sampling (insulinomas, somatostatinomas, VIPomas) should be considered. Even if localization studies are negative, provided metastatic disease or a prohibitive concurrent illness are not present, the patient should undergo exploratory laparotomy [2,5,14,78,80,92,243,244,248,258,317,360].

The surgical approach has been reviewed [78,92,243,252, 317,360], and is guided by the tumor location. At exploration the liver should be carefully explored for evidence of metastatic disease. In the case of PETs that are frequently extrapancreatic in location the entire abdomen, especially the proximal small intestine, should be carefully explored to locate extrapancreatic tumors [243,252]. An extended Kocker maneuver should be performed to allow thorough examination of the pancreatic head area. The entire pancreas must be carefully explored, even if one PET is found, because there may be multiple tumors [99]. A detailed exploration for multiple endocrine tumors is particularly important in those patients with MEN-I [4,14,359,361,362]. Isolated small insulinomas should be removed by enucleation because they are rarely malignant. Isolated noninsulinoma PETs in the pancreatic body or tail should be removed either by enucleation or en bloc by distal pancreatectomy because they may be malignant [243,248,252]. Pancreatic head and proximal pancreatic body tumors require enucleation with careful dissection to avoid damage to the main pancreatic duct and its attendant morbidity. If at surgery an isolated hepatic metastasis is found and can be removed without increased risk, then it should be excised with negative margins [2,252]. Aggressive surgery, such as a proximal cephalic pancreaticoduodenectomy (Whipple operation), is indicated only in selected patients with widespread involvement in the pancreatic head region or with tumors that cannot be enucleated, because it has not been established that the potential benefit outweighs the increased risk of morbidity in most patients [2,14,243,360]. Pneumococcal vaccine (Pneumovax) should be administered preoperatively to lower the risk of postsplenectomy sepsis.

At the time of surgery the use of intraoperative ultrasound may be helpful and is recommended [14,76,248,322,323,360]. Studies show this technique will identify a certain number of PETs that would otherwise not be identified and therefore should be used routinely (Fig. 71.11) [2,14,248,271,363]. In seven studies [248], intraoperative ultrasound localized 89 of 101 (88%) insulinomas. Intraoperative ultrasound changed operative management in 10% of all cases of gastrinomas [271], either by localizing additional tumors or by determining that a tumor was malignant. Intraoperative ultrasound is particularly helpful for intrapancreatic lesions [248]. In one study [271] intraoperative ultrasound localized 96% (22 of 23) of pancreatic gastrinomas, and in a review of four studies [248] it localized 91% of 34 pancreatic gastrinomas. However, it is less sensitive for localizing duodenal tumors, finding only 30% of duodenal gastrinomas in two studies [271]. In 12 consecutive patients with occult insulinomas not visualized by any conventional imaging study, intraoperative ultrasound identified 10 of 11 (91%) of the insulinomas that were correctly identified including five pancreatic head insulinomas not identified by palpation. The use of intraoperative ultrasound not only localizes primary tumors not

detected by other modalities, but also reduces complications like fistulae, pancreatitis, and pseudocysts by allowing better definition of the anatomy prior to a procedure [248].

At the time of surgery in patients with insulinomas there have been occasional reports of hypoglycemia during manipulation of the tumor. Use of the artificial pancreas (Biostator) has documented an increased glucose requirement during resection of the insulinoma [364]. A number of centers document successful tumor removal by demonstrating rebound hyperglycemia. However, a study has shown that rebound hyperglycemia did not occur in 23% patients with successful tumor excision [365], and therefore its use is not recommended.

In most studies, 75%–98% of patients with insulinomas were cured by surgery [59,60,76,78,99,106,250,252,317, 360,363,366]. With glucagonomas there have been a number of reports of successful excision of the tumor [4,12,47,79,80,177,367,368], and in many cases follow-up has been sufficiently long enough to suggest cure. However, at least 50%–95% of the patients with glucagonomas have metastases at the time of diagnosis, with a significant additional percentage at the time of surgery [16,18,79,368]. A number of cases of glucagonomas have shown recurrence during long-term follow-up, despite apparently complete resection of all tumors initially. Therefore, the true long-term cure rate is not established. With VIPomas, somatostatinomas, GRFomas, and PPomas, many patients present with metastatic disease and, although curative resections do occur, the exact percentage of patients cured by surgical excision of the tumor has not been adequately studied [30,74,317].

If the patient is found to have more extensive disease with either local invasion or metastases at time of surgery, or metastatic disease prior to surgery, then the question of debulking or cytoreductive surgery often arises, especially if the patient has a functional PET syndrome [4,246,306,316, 317,360,369,370]. This will be dealt with more extensively in the following section.

Treatment of metastatic disease

Metastatic PETs have traditionally been characterized as slow growing [9,12], albeit based on few data about the rate of growth of untreated metastatic disease, because many patients require antitumor therapy to control symptoms. However, some insights into the natural history of metastatic disease have been gained [9,10,245,307,308]. In one study [245] of 19 patients with proven metastatic gastrinoma in the liver, the tumor demonstrated no growth over a 29-month period in 26% of patients, 32% had slow growth (1%–50% volume increase/month), and 42% had rapid growth (> 50% volume increase/month). These results agree with another study [308], which found that 78% of patients with metastatic neuroendocrine tumor to the liver demonstrated progressive disease over a 6-month period. A third study [10] demonstrated that 50% of patients with gastrinomas die from tumor-related causes, with the extent of metastatic disease and presence of bone metastases being important prognostic factors. These studies demonstrate that in most patients metastatic PETs continue to increase in size, and in approximately 50% the growth is rapid [245]. Survival studies also support these findings [10,245]. In one study [245], 62% of patients with rapidly growing liver metastases died and 0% of the patients with liver metastases showed either no tumor growth or slow growth over a mean follow-up period of 5.5 years. No clinical or laboratory parameter correlated with growth rate; however, the growth rate was highly predictive of death from the tumor [245]. In one large study [367] involving 85 patients with various functional PETs, none of the patients without metastatic disease died (follow-up 3–18 years, median 8 years). However, for the 41 patients with metastatic disease, 66% died from tumor progression, with overall 5- and 10-year survival rates of 54% and 28%, respectively. In patients with metastatic disease not to the liver (primarily lymph nodes) [367], the 5-year survival was significantly better (90%; $P < 0.001$) than those with hepatic metastases at diagnosis (23%). The 5- and 10-year survival rates [367] for patients with malignant insulinomas are 50%–88% and 50%–75%, for gastrinomas 47%–53% and 18%–30%, for glucagonomas 60% and 52%, and for VIPomas 20%–88% and 25%, respectively [18,19,60,74,367]. The natural history of metastatic VIPomas, glucagonomas, somatostatinomas, or insulinomas is not clear because effective therapy for the hormone excess state did not exist in most cases and patients frequently died of complications resulting from the hormone hypersecretion. However, with the availability of the long-acting somatostatin analogue, octreotide, this may change in the future. Excellent long-term survival data are available for patients with gastrinomas, for which effective therapy has existed for over 20 years (Fig. 71.14) [10,14,61,243]. Overall 5- and 10-year survival rates are 74% and 60%, respectively, in six series [14,61], whereas for patients with a tumor completely resected they are 100% and 90% [61]; with a primary tumor so small that no tumor was found at surgery they are 95% and 84% [14,61]; for patients in whom the tumor was resected but who were not cured or had a recurrence they are 75% and 56% [61]; and in patients with unresectable tumors they are 44% and 33%, respectively. These findings are in agreement with studies of patients with PETs without metastases, for whom 5-year survival rates were found to be 80%–90% [303,304,371], with rates of 40%–51% for those with metastases [303,304,371]. These data clearly demonstrate that overall survival correlates with the extent of the disease. Furthermore, two large studies [10,61] of 185 patients demonstrate that the single most important determinant of long-term survival in patients with gastrinoma is the presence of liver metastases. Moreover, of patients with metastatic disease who subsequently died, 50%–70% of the deaths were due to tumor progression [10,14]. There are no data to suggest that the

other metastatic PETs will differ from gastrinoma in their natural history, and in fact the study of survival of patients with other PETs [367] reviewed above suggests a similar natural history. This conclusion is further supported by the fact that similar percentages of patients with the various noninsulinoma PETs have metastatic or malignant disease, suggesting that their malignant potential and growth patterns are similar [20,22,59]. Therefore, most authorities would agree that treatment directed at the metastatic disease is indicated [2,4,5,372–377].

Disagreement occurs over the type, efficacy, and timing of therapy. Chemotherapy [4,14,299,373,375,378–388], tumor cytoreduction by surgical resection or radiofrequency ablation [4,14,246,306,316,370,389–394], hepatic arterial embolization (for functional tumors metastatic to the liver with or without chemotherapy [chemoembolization]) [4,373,374,395–397], interferon [4,398–402], the use of the long-acting somatostatin analogues [4,171,308,401,403–407], liver transplantation [4,408–412], and somatostatin receptor-mediated radiotherapy [4,413,413,414] have all been reported to have positive effects on metastatic PET growth. Each will be considered below.

Chemotherapy

A number of different chemotherapeutic regimens have been evaluated in patients with metastatic PETs [4,14,299,373,375,382,384,388,395,413,413–416]. In most studies, because of the rare occurrence of PETs, chemotherapy for PETs has been considered together as a group or in other cases included in series with metastatic carcinoid tumors [2,4,14,299,382,387]. Although some studies [4,299,382] reported no difference between different types of PETs in their responsiveness to chemotherapeutic agents, it has been pointed out that the sample size of the various tumors included in these studies was too small to establish whether each type of PET responds equally to chemotherapy [14,381]. In fact, some clinical observations suggest there may be significant differences in their responsiveness. For example, in some studies up to 90% of metastatic VIPomas are reported to respond to streptozotocin, frequently with a complete response [20]. In contrast, only 5%–40% of patients with metastatic gastrinomas increasing in size prior to treatment responded to streptozotocin plus 5-fluorouracil with or without doxorubicin, and in no case was there a complete response [4,381]. Furthermore, a high proportion of metastatic glucagonomas are reported to respond to dacarbazine (DTIC), with several complete remissions in some studies [2,4,175,379,417–419], whereas in other PETs DTIC has a low response rate (i.e., 6%) [4].

In almost all studies, streptozotocin is used either alone or in combination with one or both of 5-fluorouracil and doxorubicin [2]. Streptozotocin is a nitrourea antibiotic originally isolated from a streptomycete [420,421]. In early studies it was observed to induce diabetes mellitus [422]. The first report of clinical effectiveness of streptozotocin in a PET was in 1968 [423]. Since then it has been generally used in the treatment of PETs either alone or in combination with other agents [4]. In various series streptozotocin alone is reported to cause objective remissions in 34%–62% of PETs whereas other single-agent therapies have been relatively ineffective, with 5-fluorouracil, etoposide, doxorubicin, carboplatin, methyl-CCNU (1-[2-chloroethyl]-3[4-methylcyclohexyl]-1-nitrosourea), tubercidin, and DTIC giving objective responses in 0%–33% [4,367,373,375,388,395]. Synthesis of chlorozotocin (CZT), a chloroethyl analogue of streptozotocin, was reported in 1975 [423]. Compared with streptozotocin, CZT was reported to have only mild to moderate gastrointestinal toxicity, but myelosuppression was the dose-limiting side effect [4,424], Furthermore, it had the practical advantage of only having to be administered in a single intravenous dose during each course of chemotherapy. In two studies chlorozotocin alone had a response rate of 30%–53%, which is similar to streptozotocin alone [4,382,425]. Streptozotocin with one or both of 5-fluorouracil and doxorubicin has been reported to cause objective responses in 5%–80% of patients, with mean response rate of 43% in the different reports [4,299,379,382,395,426]. The chemotherapeutic agents of choice for metastatic PETs are streptozotocin and doxorubicin in combination [382]. This recommendation is based on an Eastern Cooperative Oncology Group (ECOG) comparative study [382] of streptozotocin and doxorubicin vs streptozotocin plus 5-fluorouracil or CZT in 105 patients with metastatic PETs. Streptozotocin plus doxorubicin had a 69% response rate, which was significantly higher than the 45% response rate achieved with streptozotocin plus 5-fluorouracil, or the 30% response rate with CZT alone. Furthermore, streptozotocin [382] plus doxorubicin had a significant advantage in terms of survival ($P = 0.0004$). A previous prospective study [299] done by the ECOG had also demonstrated the superiority of double-agent therapy over streptozotocin alone, with streptozotocin plus 5-fluorouracil having a higher response rate of 63% compared with 40% with streptozotocin alone in patients with metastatic PETs. In four subsequent prospective studies examining streptozotocin and 5-fluorouracil with or without doxorubicin in patients with liver metastases derived from gastrinomas or PETs, response rates of 5%, 16%, and 40% were reported [4,381,426]. In no study were there any complete responders, and in one study there was no difference in survival between responders and nonresponders [381]. In a study involving 61 patients with malignant PETs [426], the response rate to streptozotocin, 5-fluorouracil, and doxorubicin was 39%; however, none of the 11 patients with gastrinomas responded, suggesting that response rates may differ for different PETs. It is not clear whether this difference in response rates from those previously reported with PETs is due to differences in the tumors themselves, to differences in the extent of metastatic disease, or to differences in assessing tumor response in the different studies.

The use of both streptozotocin and CTZ is associated with significant side effects. In prospective studies 74%–100% of patients experienced nausea/vomiting and 20%–40% developed renal toxicity with increased serum creatinine, proteinuria, or both. The nausea and vomiting are frequently severe but can be controlled in almost every patient with 5-hydroxytryptamine (5-HT) receptor antagonists such as ondansetron [2,427]. In most cases these side effects are reversible, including the early renal effects; however, in the 1992 ECOG study [382], nine patients developed chronic renal failure and seven patients required dialysis. Serum creatinine and urine protein must be assessed prior to each cycle of chemotherapy [299,381].

Various triple-drug combinations with or without streptozotocin have been tried in small numbers of patients, with variable response rates; these include streptozotocin with 5-fluorouracil plus doxorubicin [4,367,381] or with tubercidin, 5-fluorouracil, doxorubicin, and cisplatin, and 5-fluorouracil with DTIC and epirubicin [4,428,429].

Poorly differentiated PETs have a poor prognosis [430]. In one study the combination of etoposide and cisplatin [383] was used in 13 patients with metastatic carcinoid tumors, in 14 patients with metastatic PETs, and in 18 patients with anaplastic tumors. Zero percent of the carcinoid tumors, 14% of the PETs, and 67% of the anaplastic neuroendocrine tumors demonstrated a partial to complete regression [383]. Two subsequent studies [4,431] confirmed the effectiveness of this combination in undifferentiated or poorly differentiated carcinoids or PETs, with response rates of 54% and 42%. It is therefore recommended that platinum-based chemotherapy regimens be used for the treatment of patients with poorly differentiated PETs [373,375,390,432].

Most experts agree that chemotherapy, chemoembolization, hormonal therapy, or interferon are only indicated in patients with extensive metastatic disease (usually to the liver) [2,4,14,246,373,375,376,379,388,396] and are not indicated for treatment of the primary tumor when surgery is not curative. There is no agreement, however, about when to commence chemotherapy, chemoembolization, hormonal therapy, or interferon [2,4,14]. Some groups recommend treatment only when the patient develops symptoms due to the PET [4,299], whereas others recommend it only when the tumor is demonstrated to be increasing in size [2,4,14,381,391].

Other treatments of metastatic disease

Interferon

Because of the toxicity and relatively poor response rates of chemotherapy in patients with extensive metastatic PETs, other approaches have been investigated. Interferon (human leukocyte α-interferon, IFN-α) is reported to be effective in controlling symptoms in a number of patients with PETs and carcinoid tumors [4,376,386,398,400,433,434]. One review [435] analyzed results in 383 patients from 13 studies of various neuroendocrine tumors (carcinoid tumors, PETs) treated with interferon (recombinant IFN-α2a, recombinant IFN-α2b, recombinant IFN-α2c, natural leukocyte IFN-α). A biochemical response (decreased tumor plasma or serum marker) occurred in 44%, there was a decrease in tumor size in 11% [435], and tumor stabilization in 35%. Of the 58 patients with PETs in another review of 322 patients [398], 51% had a biochemical response and in 12% a decrease in tumor size occurred with a mean duration of treatment of 20 months (range 2–96 months) [398]. Patients with VIPomas had a higher response rate (83%, 10 of 12) than those with other PETs [4]. Twenty-eight of the 58 patients had received chemotherapy prior to treatment with interferon, but their biochemical response rate was no different from those without previous chemotherapy (55% vs 44%) [398]. Disease stabilization occurred in 14 of 58 (24%) of patients, with a mean duration of 16 months. A number of studies showed that IFN-α treatment rarely decreases the size of either a malignant PET or carcinoid tumor (0%–12%), but it can inhibit further tumor growth – in 24%–80% of patients with metastatic neuroendocrine tumors [4,398,434,435]. In a review [401] of 274 patients with malignant GI neuroendocrine tumors (NETs: carcinoids, PETs) no patients had a complete response, 11% had a partial tumor response, 70% had tumor stabilization, and 23% had progressive disease with interferon treatment. These studies suggest that IFN-α is minimally effective as a primary tumoricidal agent, but it does have tumoristatic activity in a significant percentage of patients [4,398–401]. Studies of human NETs demonstrate that IFN-α activates the STAT (signal transducer and activator of transcription) cascade, reduces cyclin B levels resulting in inhibition of cyclin-dependent kinase 2 activity, which causes delayed progression from the S to the G2 phase of the cell cycle and inhibition of anchorage-dependent and independent cell growth [402]. Also transactivation of the vascular endothelial growth factor (VEGF) gene is inhibited due to Sp1/Sp3-dependent inhibition of the VEGF promoter resulting in inhibition of angiogenesis [402]. Interferon has also been used in combination with a number of agents such as 5-fluorouracil [4,386], but it is not clear that this enhances its antitumor effect. Interferon is increasingly being used in combination with somatostatin analogues, which will be discussed in the next section [4,400,401,434,436–438].

Somatostatin analogues

A number of studies in animals and in vitro studies in various tumor cell lines have demonstrated that somatostatin analogues can inhibit the growth of various tumors under differing experimental conditions [190,401,406]. The effects of somatostatin analogues are mediated through interaction with five classes of G protein-coupled somatostain receptors, sst_1–sst_5 [191,406]. Somatostatin receptor activation can inhibit growth by blockade of autocrine/paracrine-mediated growth, inhibition of growth factor production, inhibition

of mitogenic signals, induction of apoptosis, and inhibition of angiogenesis [406]. Studies demonstrate that except for insulinomas, more than 90% of PETs possess somatostatin receptors [259,260,401,439–441]. Hormonal therapy with the long-acting somatostatin analogue, octreotide, is reported to cause a decrease in tumor size in 12% of patients with NETs in one review of cases reported up to 1988 [403], and in 0%–8% of patients in various studies [4,308,355,401,404,407,442,443]. However, disease stabilization is reported in 25%–88% of patients with metastatic neuroendocrine tumors treated with somatostatin analogues [4,355,356,401,407,442,443]. The mean duration of stabilization is 18–26 months. Predictors of the antiproliferative response (i.e., stabilization, tumor decrease in a PET progressive prior to treatment) to octreotide have been studied in well-differentiated metastatic PETs [405,443]. In one study [405] a rapid growth rate prior to treatment predicted a poor response rate to somatostatin analogues, whereas in a second study [443] a pancreatic primary (i.e., a PET rather than a malignant carcinoid tumor), no previous tumor surgery, and the presence of distant extrahepatic metastases predicted a poor response. In this latter study responders had a significantly better survival at 3 years than nonresponders (100% vs 53%, $P = 0.004$). These results demonstrate that octreotide alone, similar to interferon, has minimal tumoricidal activity against PETs. However, in a significant number of patients it stabilizes the disease, preventing further progression, but because of a lack of randomized studies it remains unclear whether octreotide causes stabilization for periods of time sufficient to increase survival. The combination of somatostatin (either subcutaneouly or in long-acting forms) with IFN-α is reported to cause disease stabilization in 57%–89% of patients with malignant NETs, some of whom did not previously respond to either agent alone [4]. However, three prospective studies have not shown that the combination of IFN-α and a somatostatin analogue (lanreotide or octreotide) is better than either alone [436–438]. These findings remain controversial and each of these studies has been criticized on various methodological points [434].

Hepatic artery embolization/chemoembolization

Hepatic artery embolization with or without postocclusion chemotherapy (streptozotocin, doxorubicin, 5-fluorouracil, or DTIC) has been used successfully in patients with various PETs [2,4,374,395–397,444–450]. Because the liver derives only 20%–25% of its blood supply from the hepatic artery and 75%–80% from the portal vein, and because most PETs are vascular with an arterial supply, hepatic artery embolization can be used to treat metastatic disease to the liver if the portal vein is patent. In some studies, 55%–100% of patients with metastatic NETs have symptomatic improvement, and 33%–80% have an objective response [4,12,374,397,445,447–449,451]. Chemoembolization with doxorubicin in iodized acid combined with gelatin or sponge particles, or with streptozotocin, 5-FU, cisplatin, or mitomycin C, is reported to improve symptoms in 67%–100% of patients and to decrease tumor size or hormone levels in 33%–100% of patients [4,374,397,446–449,451–453]. The mean duration of objective responses is 6–42 months [4,374,397,447,449–451]. An analysis [448] of 123 patients with metastatic PETs found a reduced response rate in patients with malignant PETs involving more than 75% of the liver and with extrahepatic metastases.

This procedure is not without significant side effects. In the literature [444] the overall mortality for this procedure is less than 3% of cases, but pain develops in 50%–100%, nausea or vomiting in 50%–90%, and fever and leukocytosis are seen in 30%–60% of patients; moreover, 5%–15% are reported to have severe complications including hepatic failure, bleeding, infection, or acute renal failure [4,94,374,396,447,452]. In almost all patients some degree of abdominal pain, nausea, vomiting, and fever occurs, which lasts for up to 10 days [453]. Furthermore, in patients with metastatic PETs and in up to 31% of patients with gastrinoma metastatic to the liver, metastases to bone can occur [62], suggesting that procedures, such as embolization, directed at the liver may be of limited value to control metastatic spread in patients with extensive disease. However, in a patient with a hormonal syndrome that cannot be controlled by other therapies, this procedure may be helpful [2,27,374,397,447].

Hepatic artery embolization has been combined with IFN-α treatment [12,27,454] in patients with metastatic carcinoid tumors, which closely resemble PETs in responsiveness and histology. One year after the treatment, five of seven patients (71%) continued to demonstrate a decrease in the metastatic disease in the liver, whereas with interferon alone ($n = 10$) only 10% demonstrated a decrease. In another study [454] involving 36 patients with metastatic carcinoid tumors, interferon alone resulted in a 24% response rate (decrease in 5-HIAA secretion) and survival rate was 40% after 5 years. With interferon and hepatic artery embolization, in contrast, the response rate was 60% and 5-year survival rate 75%.

Cytoreductive surgery and radiofrequency ablation (RFA)

The systematic removal of all resectable tumor (i.e., cytoreductive or debulking surgery) may prolong the life of some patients with functional PETs [2,4,12,14,30,246,306,316,317,358,370,389,394,455–458]. Systematic removal of all resectable disease has been reported to help control symptoms in patients with malignant insulinomas [4,76,78,317,367], glucagonomas [4,21,59,317,449], VIPomas [4,20,21,80,317], GRFomas [4,23], somatostatinomas [317], and nonfunctional PETs [1,4,5,30] and has led to the suggestion that resection should be performed when possible in cases where extensive tumor is identified at the time of surgery and resection does not entail increased risk. There are no studies in which cytoreductive surgery has been evaluated in a controlled, prospective manner. It is important to distinguish

between the possible benefits of such surgery for patients who are asymptomatic (nonfunctional tumors) or have symptoms well controlled (gastrinomas, effective medical control of other tumors), and for patients in whom symptoms are not controlled. In the former group such surgery is performed to extend survival, although no controlled studies have established this. In the latter case there are numerous examples cited above with each of the symptomatic PETs where cytoreductive surgery improved symptoms. A number of studies [4,316,369,449,455,457,458] and reviews [246,246,394,456] have provided data using this approach. It is important to remember that surgical removal of all visible tumors is only possible in a small proportion (5%–15%) of all patients who have PETs with metastatic disease [4,246,306,370,455,456]. In one study, the tumor was completely excised in 80% of cases with metastatic disease in which surgical excision was initially deemed possible; survival was 79% at 5 years with a mean follow-up of 3 years. In another study [316] 36 extended hepatectomies or hepatic lobectomies and 38 nonanatomical liver resections were performed in patients with advanced disease due to malignant NETs. Perioperative mortality was 2.7%, morbidity 24%, and 4-year survival was 73%, with 90% of patients having symptomatic improvement [316]. In a retrospective comparison of results [449] with cytoreduction or embolization in 120 patients with malignant NETs (33 PETs, 87 carcinoids), the patients treated with cytoreductive surgery had a longer survival with equally effective control of symptoms. In another review [246] of different surgical series, 63 patients were analyzed from five different series of patients with malignant PETs who underwent resection of liver metastases. Operative mortality was 0%–6%, symptom control was achieved in most patients (at least 85%), and 5-year survival was 60%–80%. The authors concluded from this review [246], like the authors of numerous other studies, that cytoreductive surgery should be performed whenever it is possible to resect at least 90% of the malignant PET [4,246,370,449,455,456,458].

However, it is important to remember that this approach is only possible in less than 15% of patients, it has not been systematically evaluated, and it remains unclear whether patients identified with metastatic disease by localization studies prior to surgery and with symptoms well controlled by medical management will have long-term benefit from debulking surgery. In fact a review [389] injects a note of caution about the use of aggressive cytoreductive surgery, pointing out that this surgery can be associated with a high complication rate and that many of these patients survive for a prolonged period of time even with advanced disease. The authors recommend that cytoreductive surgery be performed in patients with metastatic PETs only if the PET is potentially fully resectable; if it is not fully resectable they recommend refraining from performing a partial resection.

Radiofrequency ablation (RFA) is increasingly used for patients with malignant PETs with hepatic metastases, either alone or in combination with other antitumor treatments [115,374,397,459–462]. It can be performed laparoscopically or at the time of surgery, causes tumor destruction by converting radiofrequency waves into heat, and is performed with an RFA catheter with an electrode tip from which current passes into the tissue [459–462]. Both tumor size and the number of lesions are rate limiting (RFA is usually used if there are less than five lesions under 3.5 cm in diameter), although larger tumors have been successfully treated [374,462]. Morbidity is generally low (5%) with occasional cases of abscess formation or hemorrhage [374,459,460]. Response rates of 85%–96% are reported, with responses lasting up to 35 months, including control of symptoms in patients with functional tumors [115,374,459,460]. Although the use of RFA has not been shown to extend survival, its ability to reduce tumor mass and assist in controlling symptoms due to the tumor per se or to uncontrolled hormone secretion makes it an increasingly used procedure for small metastases or limited numbers of metastases, especially in patients with functional malignant tumors [115,374,459–461].

Liver transplantation

Liver transplantation continues to be used used in selected patients with metastatic NETs (PETs and carcinoid tumors) [4,12,408–412,463,464]. The use of hepatic transplantation for many metastatic tumors such as colorectal carcinoma, cholangiocarcinoma, or metastatic sarcomas, has been largely abandoned because of early recurrence. However, because of their more indolent biological behavior of metastatic NETs, patients with these are considered more likely to benefit from liver transplantation [4,412,463,464]. The reports are generally confined to small numbers of patients with limited follow-up [4,408,409,412,463,464]. In a review [463] of reports of liver transplantation in patients with malignant NETs ($n = 103$) (48 PETs, 43 carcinoids), the 5-year survival rate was 45%, and occasional long-term cures are reported [463]. In a series of 15 patients with malignant NETs (10 PETs, 5 carcinoids) treated with liver transplantation, the transplant was found to provide good relief of symptoms and the 5-year survival was 90%. Reviews [412,463] suggest that liver transplantation should be considered in younger patients (< 50 years old) with malignant NETs in whom disease is confined to the liver with an absence of concurrent extensive surgery.

Somatostatin receptor-mediated radiotherapy

The presence of high densities of somatostatin receptors on almost all NETs (PETs and carcinoids) [4,190,259,260], which is widely used to localize these tumors [4,190,259–261,274], is being investigated as a means of possible antitumor treatment using radiolabeled analogues [4,274,413–415,465,466]. Agents reported to have antitumor effects in humans include: [^{111}In]DTPA-octreotide, which emits conversion and auger electrons; and somatostatin analogues, usually coupled by a

DOTA group (1,4,7,10,-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) to yttrium 90, which strongly emits β-particles, or to lutetium 177, which is a beta and gamma emitter [4,274,413–415,465,466]. In 52 patients with malignant NETs (carcinoids, PETs) treated with [^{111}In]DTPA-octreotide in two studies, a complete tumor response, partial tumor response, or stable tumor-related disease occurred in 0%, 0%–8%, and 42%–81% of patients, respectively [415]. In four series involving 229 patients treated with [^{90}Y-DOTA,Tyr^3]octreotide, [^{90}Y-DOTA]lanreotide, or [^{90}Y-DOTA,Tyr^3]octreotate, complete tumor responses, partial responses, and stable disease occurred in 0%–3%, 6%–37%, and 44%–80% of the patients, respectively [413,415]. One series [413,467] reported results from 129 patients with malignant NETs treated with [^{177}Lu-DOTA^0,Tyr^3]octreotate; 2% had a complete tumor response, 32% had a partial tumor response, and 34% developed stable disease.

Generally, somatostatin receptor-mediated radiotherapy has been safe and severe side effects uncommon [413–415,466]. Approximately 30% of treated patients develop acute side effects at the time of the injection or within a few days (i.e., nausea, vomiting, increased tumor pain); these are usually mild and can be controlled by symptomatic treatment. Hematological toxicity occurred in a maximum of 15% in different series, and was generally transient, although 0.3% of treated patients developed a myelodysplastic syndrome [413]. Renal toxicity can also occur, but it can be limited by coadministration of amino acids, especially arginine and lysine, and is reported almost entirely in patients receiving yttrium 90-labeled somatostatin analogues [413,415,466]. The above results suggest this form of treatment holds considerable promise for the treatment of patients with advanced disease. As yet, no controlled study has demonstrated that it can extend life, and it is not a licensed therapy in the United States although it is undergoing evaluation in a number of centers.

Newer antitumor therapies

Studies involving usually small numbers of patients with metastatic progressive GI neuroendocrine tumors (both PETs and carcinoids) have reported the effects of various agents, including:

- angiogenesis inhibitors – endostatin, VEGF-A inhibitor, bevacizumab, sunitinib (SU11248)-tyrosine kinase inhibitor active against VEGFR, c-kit, platelet-derived growth factor receptor (PDGFR); VEGF tyrosine kinase inhibitors, sunitinib, vatalanib, sorafenib
- growth factor inhibitors – VEGF, IGF-1, transforming growth factor-α (TGF-α), PDGF, epidermal growth factor (EGF) – or growth factor receptor inhibitors (imatinib: PDGFR inhibitor; gefitinib: EGFR inhibitor)
- inhibitors of the mammalian target of rapamycin (mTor) (everolimus, temsirolimus)
- the DTIC analogue, temozolomide with thalidomide [388,468–473].

Studies with bevacizumab, everolimus, temozolomide, and thalidomide have shown sufficient promise such that phase III studies, either alone or in combination with other agents, are either planned or likely [468,469].

72 Hereditary diseases of the pancreas

Jonathan A. Cohn

Cystic fibrosis, 1921
Hereditary pancreatitis, 1930
Rare inherited diseases of the exocrine pancreas, 1933
Hereditary aspects of idiopathic chronic pancreatitis, 1934

The two most common hereditary diseases of the exocrine pancreas in adults are cystic fibrosis (CF) and hereditary pancreatitis (HP). In the United States the prevalence of CF at this time is 30 000, and HP is probably 10–20 times less common. Both conditions are monogenic diseases and show mendelian inheritance. Although most individuals with CF or HP are diagnosed during childhood, nearly all individuals with these conditions survive well into adulthood. Both CF and HP cause potentially serious gastrointestinal problems and often require specialized care from gastroenterologists.

Discoveries made since the late 1980s have largely defined the genetic, molecular, and cellular basis of CF and HP. The main goal of this chapter is to summarize this information and to explain how it has implications for pathogenesis and for clinical practice. The exocrine pancreas is also affected by many less common monogenic diseases and clinical information about these rare conditions will be briefly summarized. Finally, this chapter will review emerging information about how genetic factors influence individual susceptibility to common nonhereditary forms of pancreatic disease.

Cystic fibrosis

Cystic fibrosis (Online Mendelian Inheritance in Man [OMIM] number #219700) is an autosomal recessive disease of the exocrine glands. The main clinical features of CF are recurrent lung infections leading to progressive pulmonary insufficiency, partial or complete pancreatic insufficiency, and abnormal sweat gland function. The first comprehensive description of CF was published in 1938 [1], and the genetic basis of CF was determined in 1989 [2,3].

Cystic fibrosis is the most common life-threatening genetic disease in Caucasians. It occurs in 1 in 3000 live births in the United States. The incidence of CF is similar in many European Caucasian populations, it is lower in African-Americans (1/15 000), and CF is extremely rare in other populations (e.g., 1/350 000 in Japan) [4,5]. Genotypically, CF is caused by two loss-of-function mutations in the gene encoding CFTR, the CF transmembrane conductance regulator protein. Carriers of CF have one loss-of-function *CFTR* mutation plus one normal *CFTR* allele and represent 3%–4% of the general population in the United States.

The epidemiology of CF in the United States has changed markedly since the late 1980s [6]. The median predicted survival was 16.0 years in 1970, 25.5 years in 1985, and 36.5 years in 2005; over 90% of individuals with CF survive into adulthood (past age 18) [7]. This improvement in survival corresponds to a 12-fold increase in the population of CF adults since the late 1970s [8]. Gastrointestinal complications are an increasingly important clinical challenge in this population.

Genetic and molecular basis

In 1989, CF was one of the first human disease genes to be identified by positional cloning [2,3]. The CF gene contains 27 exons, spans approximately 250 kb of DNA on chromosome 7q31.2, and encodes the CFTR protein. The latter is an integral membrane protein of 1480 amino acids that is expressed in many types of epithelial cells. Each CFTR molecule contains 12 transmembrane sequences, which embed the protein in the plasma membrane and form a channel through which anions (chloride or bicarbonate) can passively flow into or out from the cell interior. Each CFTR molecule also contains three cytoplasmic domains, which control ion transport by CFTR.

Identification of the CF gene was crucial for understanding the pathogenesis of CF at the molecular level. Before the CF gene was identified, epithelial cells from many CF-affected tissues were known to exhibit defective cyclic adenosine monophosphate (cAMP)-regulated anion secretion [9,10]. Once the *CFTR* gene was identified, antibodies to CFTR epitopes were developed for studying the biochemical properties,

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

distribution, and role of the protein in human tissues and cells [11]. These studies showed that CFTR can be phosphorylated by cAMP-dependent protein kinase [12] and that the protein occurs at sites in many epithelial tissues where CF is known to cause abnormal ion transport [13,14].

The CF gene was also used to produce recombinant CFTR for directly studying the protein's function. When CFTR was purified and inserted into lipid bilayers, the intrinsic anion channel function of CFTR was shown to be stimulated when cAMP-dependent protein kinase phosphorylated regulatory sites on CFTR [15]. In further studies, CFTR was unexpectedly found to function as a regulator of other ion transport proteins including certain sodium channels [16], chloride channels [17], and anion exchangers [18]. Finally, somatic gene transfer was used to show that the CF anion transport defect could be corrected in epithelial cells by expressing functional CFTR protein; when combined with clinical and genetic data, this indicated that CFTR function is necessary and sufficient for correcting the ion transport defect in CF cells and it suggested that CF might eventually be amenable to gene therapy [19,20].

The intrinsic properties of CFTR also help to explain the pathogenesis of organ dysfunction in CF. In most gastrointestinal tissues affected by CF, CFTR occurs at the apical plasma membrane of the cells lining the duct or crypt epithelium [13,14]. At this site, the net flow of anions and water into the duct or crypt lumen is normally subject to tight control by neurohumoral agents acting through cAMP-dependent protein kinase. Depending on the tissue, the predominant secreted anion may be chloride or bicarbonate and the main neurohumoral regulators also are tissue-specific. However, the general pattern is that CFTR functions at the apical plasma membrane of these cells as a cAMP-regulated anion channel and thereby promotes the regulated secretion of fluid (and often also of bicarbonate) into the lumen.

In humans with CF and also in affected tissues of mice lacking CFTR, CFTR function is reduced at the epithelial cell apical plasma membrane and this causes inadequate anion and fluid secretion. In many ductal epithelial tissues (exocrine pancreas, intestine, hepatobiliary tract, and male reproductive tract), this causes plugging or obstruction of the lumen with inspissated secretions, and this can cause injury upstream from the obstructed lumen [13]. In other tissues (e.g., airway), sodium hyperabsorption accompanies anion hyposecretion, and the combined impact of these two defects is to cause an even greater reduction in net fluid secretion into the lumen. At these sites, sodium hyperabsorption in CF is attributed to inadequate regulation of sodium channels due to the loss of CFTR function [16].

CFTR mutations

Over 1500 different *CFTR* mutations have been detected in individuals with CF or related conditions [21]. Annotated information about these mutations is compiled in a database developed by the Cystic Fibrosis Genetic Analysis Consortium and is available online as the Cystic Fibrosis Mutations Database (http://www.genet.sickkids.on.ca/cftr).

Mutations of CFTR have been divided into five categories based on their molecular mechanism [21,22]:

- class I mutations prevent the production of full length CFTR
- class II mutations cause defective intracellular trafficking of newly synthesized CFTR
- class III mutations cause defective regulation of CFTR
- class IV mutations cause abnormal ion channel function
- class V mutations cause partial reductions in the abundance of functional protein.

Class I mutations include stop (nonsense) mutations, frameshift mutations, and some mutations at conserved splice sites. The most common class II and III mutations are small deletions or missense mutations located in one of CFTR's cytoplasmic domains. Class IV mutations are missense mutations in one of the protein's channel-forming transmembrane sequences. Class V mutations are often splice variants causing reduced splicing efficiency or creation of a new splice donor site. Residual CFTR function is usually low in individuals with genotypes consisting of two alleles with class I, II, or III mutations, whereas residual CFTR function tends to be higher in individuals who have a class IV or V mutation [23,24].

One mutation, ΔF508, accounts for most CF-causing alleles [3]. Transcripts of *CFTR* containing ΔF508 produce a mutant protein lacking the phenylalanine normally found at position 508. Although this phenylalanine residue (F508) occurs in a CFTR domain required for ATP-dependent regulation [25,26], the main effect of this mutation is to cause CFTR to misfold, to mislocalize, and to undergo accelerated degradation in CF cell lines [27–29] and in tissues from CF patients [30,31]. Thus, ΔF508 is a class II mutation.

About half of CF patients in the United States are ΔF508 homozygotes, and another 40% are compound heterozygotes who have one ΔF508 allele plus one less common CF-causing allele. Patients who are ΔF508 homozygotes have low residual CFTR function (< 2% of normal) and typically have pancreatic insufficiency. By contrast, pancreatic sufficiency occurs in CF patients who have genotypes causing less severe loss-of-function (e.g., with 5% residual CFTR function) [21,32,33]. The amount of residual CFTR function correlates closely with the clinical features, as summarized in Table 72.1 [34].

This CFTR genotype–phenotype correlation was later extended to genotypes producing higher residual CFTR function (~ 10% of normal). These genotypes often occur in infertile males who have normal pulmonary, pancreatic, and sweat gland function [35–37]. In these cases, infertility is caused by congenital bilateral absence of the vas deferens (CBAVD, OMIM #277180), a condition similar to the cause of male infertility in CF. Although CBAVD patients often have *CFTR* genotypes consisting of two abnormal alleles, they are

Table 72.1 Clinical diagnoses and *CFTR* genotypes correlate with residual function of cystic fibrosis transmembrane conductance regulator (CFTR) protein

	PI-CF	PS-CF	CBAVD, ICP	CF carrier
CFTR mutations	Severe + severe	Severe + milder	Severe + mild–variable	Severe + wild-type
Residual CFTR function[a]	0%–2%	2%–5%	5%–25%	50%
Pancreatic insufficiency	Present[b]	Absent[b]	Absent	Absent
Abnormal sweat test	Present	Present	Variable	Absent
CF lung disease	Present	Present	Absent	Absent
Male infertility	Present	Present	< 30% of cases[c]	Absent
Pancreatitis	Absent	10%–15% of cases[c]	< 30% of cases[c]	Absent

CBAVD, congenital bilateral absence of the vas deferens (male infertility); CF, cystic fibrosis; ICP, idiopathic chronic pancreatitis. PI, pancreatic insufficiency; PS, pancreatic sufficiency.

a Residual CFTR function is expressed as % of normal.

b Present or absent features show mendelian inheritance based on the *CFTR* genotype; these features are present (or absent) in over 95% of individuals (or in under 5%) depending on the *CFTR* genotype.

c These three conditions show complex inheritance (not mendelian); the *CFTR* genotype is predisposing (it increases disease risk markedly) but it is not sufficient to cause the disease.

From Cohn et al. [34].

protected from CF lung disease because one of their mutant alleles causes only partial loss-of-function [36,38,39].

Congenital bilateral absence of the vas deferens can be viewed as a mild, single-organ, nonpulmonary variant of CF. It is associated with *CFTR* genotypes consisting of one severe mutation (CF^{sev}) plus one mild-variable mutation ($CF^{m\text{-}v}$). With CF^{sev} mutations, nearly all CFTR function from that copy of the gene are eliminated; such mutations are generally class I, II, or III mutations. Individuals with CF^{sev}/CF^{sev} genotypes consistently develop CF lung disease [38]. By contrast, $CF^{m\text{-}v}$ mutations are generally class IV or V mutations that reduce CFTR function by 50%–90% and are associated with variable clinical features [38]. Thus, residual CFTR function is roughly 10% of normal in individuals with $CF^{sev}/CF^{m\text{-}v}$ genotypes. In CBAVD, the most common CF^{sev} mutation is ΔF508 (as in CF); the most common $CF^{m\text{-}v}$ mutation in CBAVD is an intron 8 variant consisting of a short polythymidine tract (5T instead of 7T or 9T). The 5T allele reduces the efficiency of splicing at this site, such that about 80% of the resulting CFTR protein molecules are nonfunctional because they lack exon 9 [36,40,41].

Vas deferens disease related to CFTR can show either monogenic (mendelian) or complex (nonmendelian) inheritance depending on the level of residual CFTR function. In individuals with low residual CFTR function (e.g., under 5% of normal), CBAVD shows autosomal recessive mendelian inheritance: CBAVD occurs in nearly every male who has a *CFTR* genotype causing this degree of CFTR malfunction. By contrast, in individuals with higher residual CFTR function (e.g., 5%–20% of normal), the abnormal *CFTR* genotype increases the risk of CBAVD but the genotype is not sufficient to cause the condition; most men who have $CF^{sev}/CF^{m\text{-}v}$ genotypes do not develop CBAVD [42]. Susceptibility to CBAVD is increased in $CF^{sev}/CF^{m\text{-}v}$ genotypes but the effect is not large or consistent enough for the condition to show mendelian inheritance in these cases. Thus, in individuals with $CF^{sev}/CF^{m\text{-}v}$ genotypes, the occurrence of the clinical phenotype (CBAVD) must be influenced by genes other than *CFTR* or by nongenetic factors.

Pancreatic disease related to CFTR also can show either monogenic or complex inheritance depending on the level of residual CFTR function caused by an individual's *CFTR* genotype. If residual CFTR function is low (e.g., 0%–2% of normal), then pancreatic insufficiency occurs consistently along with CF lung disease and other CF manifestations in a condition showing autosomal recessive inheritance for each feature [43]; these individuals do not develop pancreatitis [32]. If residual CFTR function is roughly 5% of normal, then CF lung disease occurs consistently but pancreatic insufficiency is absent; in this group, the pancreatic phenotype is variable in that 10%–15% of these individuals develop recurrent or chronic pancreatitis [32]. Finally, for individuals with even higher levels of residual CFTR function (roughly 10%–20% of normal), CF lung disease is absent but there continues to be an elevated risk of pancreatitis [44]. Thus, CFTR-related pancreatic insufficiency shows monogenic inheritance whereas CFTR-related pancreatitis shows complex inheritance, as summarized in Table 72.1 [34].

Diagnostic criteria

Most CF patients are diagnosed by one year of age. The diagnosis is usually suggested by respiratory symptoms (in 46% of individuals diagnosed in 2000), malnutrition or failure to thrive (29%), steatorrhea or abnormal stools (23%),

meconium ileus or intestinal obstruction (18%), or a family history of CF (15%). Less common presenting features include neonatal screening (8%), nasal polps or sinus disease (4%), rectal prolapse (3%), prenatal diagnoses (3%), electrolyte imbalance related to salt loss (2%), and liver disease (1%). Prenatal and neonatal diagnoses are increasingly common [45].

Two types of criteria must be met for a diagnosis of CF [46]. First, the individual must have clinical evidence consisting of either a positive newborn screening test result or a history of CF in a sibling or at least one phenotypic feature consistent with CF. Many phenotypic features can fulfill this criterion. About half of patients have respiratory symptoms such as persistent sinopulmonary colonization with CF-associated pathogens (e.g., *Pseudomonas aeruginosa*), chronic productive cough, persistently abnormal chest radiographs (e.g., bronchiectasis or lobar atelectasis), airway obstruction, nasal polyps, sinus disease, and digital clubbing. In cases where respiratory symptoms are initially absent, the diagnosis is often supported by gastrointestinal findings such as intestinal obstruction (meconium ileus or distal intestinal obstruction syndrome), rectal prolapse, pancreatic insufficiency, recurrent pancreatitis (especially in adolescents), and focal biliary cirrhosis or multilobular cirrhosis. In other cases, the diagnosis is supported by evidence of protein–calorie malnutrition, malabsorption of fat-soluble vitamins, salt loss syndromes (typically with chronic metabolic alkalosis), or male infertility due to CBAVD.

In addition to meeting one of these clinical criteria, a diagnosis of CF also requires unequivocal functional or genetic evidence of CF. To meet this criterion, the individual needs to have either an abnormal sweat chloride value, or two CF-causing *CFTR* mutations detected by DNA testing, or abnormal CFTR-mediated ion transport detected by measuring nasal potential difference responses. The first option, namely the quantitative pilocarpine iontophoresis sweat test, is usually the most informative laboratory test in adults when CF is suspected. This test uses standardized protocols and is reliably performed at over 100 CF Foundation-accredited care centers throughout the United States [47]. Sweat chloride values below 40 mM are normal, values above 60 mM are abnormal, and intermediate values are borderline; abnormal values should be confirmed by testing on a second day.

If an adult's clinical presentation suggests CF but sweat testing is normal, *CFTR* DNA testing is usually done next. If this identifies two CF-causing *CFTR* mutations, then the DNA testing establishes the diagnosis of CF (assuming that the individual's clinical features also support the diagnosis). It should be emphasized that a mutation is classified as CF-causing only if it consistently causes CF (e.g., in practically all individuals who have the mutation on one allele plus ΔF508 on the other allele). Apart from ΔF508, few *CFTR* mutations are known to consistently cause CF. If DNA testing detects at least one nondiagnostic *CFTR* allele (any of the hundreds of mutations causing an unpredictable phenotype), then the DNA testing is inconclusive. To diagnose CF in these cases, nasal potential difference measurements can be used to test for defective CFTR-mediated ion transport. Reliable testing by this method requires standardized procedures and is performed at a limited number of CF care centers [48].

Common manifestations and complications

Lung disease and abnormal sweat test results occur in over 95% of individuals with CF. For males with CF, the prevalence of infertility due to CBAVD is also over 95%. Most mortality in CF results from lung disease (78%) or complications after lung transplantation (12%) [45].

Table 72.2 compares the frequency of common complications of CF in children and adults. The number of CF adults is increasing rapidly and this predicts that the frequency of certain complications will also increase. Many of these complications result from conditions primarily affecting gastrointestinal organs. One example is diabetes: roughly half of older CF patients have CF-related diabetes as a late complication of their CF pancreatic disease. About half of these individuals require insulin to treat what is typically a brittle form of diabetes. A second example is osteoporosis: this condition also is increasing rapidly in prevalence due to improved survival of adults with CF. Incompletely treated pancreatic insufficiency is one factor promoting osteoporosis in CF individuals. A third example is gastrointestinal cancer. Although cancer occurs rarely in CF patients, the risk of certain gastrointestinal cancers is unexpectedly high. For example, the age-adjusted risk of cancers of the colon, of the small intestine, and of the biliary tract is increased approximately

Table 72.2 Complications occurring during one year in children and adults with cystic fibrosis (% of patients)

Complication	0–18 years	18 + years
Acute GI bleeding	0.2	0.3
Cirrhosis with portal hypertension	0.8	1.6
Gallbladder disease requiring surgery	0.1	0.8

20-fold in CF adults [49,50]. This information should be considered when deciding how to evaluate CF patients who have symptoms consistent with these diagnoses. The frequency of these cancers may rise markedly as the number of older CF adults continues to increase.

Pancreatic disease

Pancreatic insufficiency occurs in 85% of CF patients and is usually evident by the age of 5 years [51]. In most cases, pancreatic injury begins in utero with early obstruction of intrapancreatic ductules by inspissated eosinophilic plugs. Fatty infiltration of the exocrine tissue is often prominent, as the pancreas gradually shrinks and becomes fibrotic with cystic changes (Fig. 72.1) [52]. These histopathological changes correlate with findings seen by computed tomography (CT) imaging. Lipomatosis and atrophy are the dominant findings on pancreatic imaging in most CF patients, whereas cystic changes and a grossly normal pancreas are each observed in about one-tenth of cases [53].

Most CF patients with pancreatic insufficiency (PI) have genotypes causing nearly complete loss-of-function for CFTR-mediated ion transport [43]. This applies to all ΔF508 homozygotes and to individuals who have ΔF508 on one *CFTR* allele plus a second mutation causing severe loss-of-function on their second allele. Apart from ΔF508, the G542X, G551D, W1282X, N1303K, and R553X mutations are the most common causes of PI. Affected individuals predictably develop steatorrhea due to severe pancreatic insufficiency, which generally has an early onset and can be anticipated based on the genotype. These individuals need pancreatic enzyme replacement.

Individuals with *CFTR* genotypes producing small amounts of residual CFTR function (about 5% of normal) usually have subclinical defects in pancreatic electrolyte secretion [54]; these individuals are classified as pancreatic sufficient because they do not have steatorrhea [32,54]. In the United States, many of these individuals have genotypes including at least one of the following mutations: G551S, R117H, R347H, P574H, R334W, R352Q, or T338I. Although these and other mutations are associated with pancreatic sufficiency in CF, DNA testing is usually not helpful for predicting pancreatic function in individual cases. First, this group of mutations is only found in a minority of CF individuals who have pancreatic sufficiency. Second, the pancreatic phenotype in individuals with genotypes causing 5% residual CFTR function is less predictable than with genotypes causing nearly complete loss-of-function. One complication is the fact that 10%–15% of pancreatic-sufficient CF patients develop recurrent or chronic pancreatitis [55]. Some of these individuals later develop a secondary form of pancreatic insufficiency (often as young adults) despite having *CFTR* genotypes that would otherwise be associated with pancreatic sufficiency [54]. Although these individuals do not have fat malabsorption as children, they often need pancreatic enzyme supplements as adults.

Pathogenesis

The localization of CFTR protein in normal human pancreas helps to explain the role of CFTR during pancreatic exocrine secretion. The protein occurs in the cuboidal epithelial cells lining smaller intrapancreatic ductules (Fig. 72.2). At this location, CFTR plays a critical role. The pancreatic juice is initially secreted as a concentrated, protein-rich fluid produced by acinar cells (Fig. 72.3). This fluid then flows through narrow pancreatic ductules, which are lined by epithelial cells that secrete bicarbonate into the ductal lumen and thereby modify the composition of the pancreatic juice. Alkalinization and dilution at this site reduces the viscosity of the pancreatic

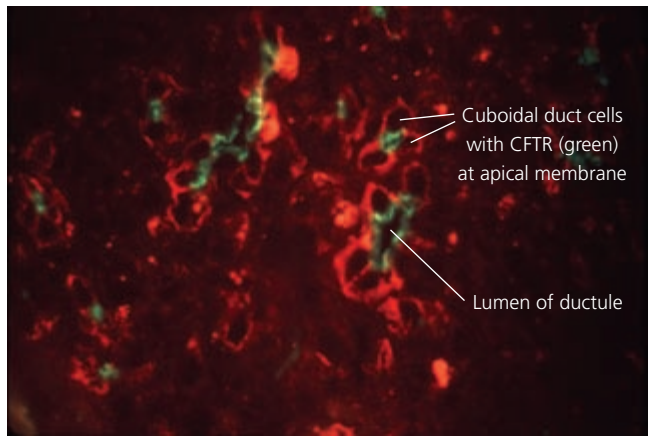

Figure 72.2 Localization of the cystic fibrosis transmembrane conductance regulator protein (CFTR) in normal human pancreas. From Marino et al. [13], with permission from the American Society for Clinical Investigation.

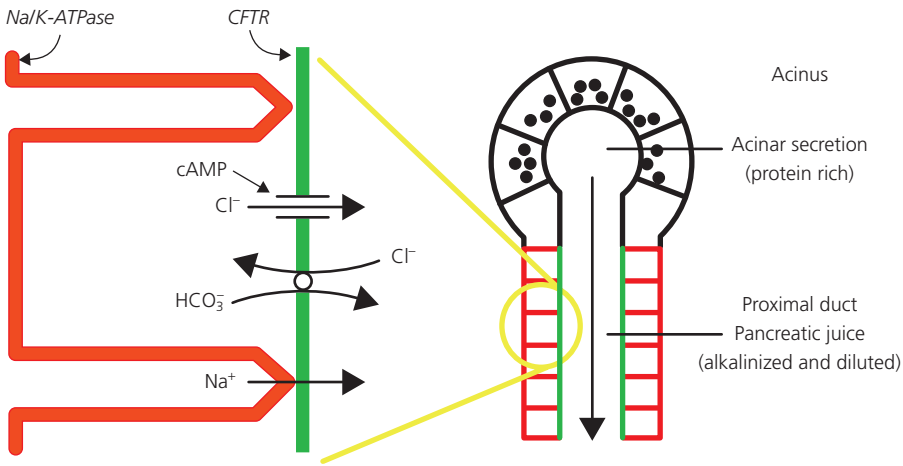

Figure 72.3 A model showing the proposed role of the cystic fibrosis transmembrane conductance regulator (CFTR) protein during pancreatic exocrine secretion. Modified from Marino et al. [13], with permission from the American Society for Clinical Investigation.

juice and promotes the solubility of many protein constituents. Within the pancreatic duct cells, CFTR occurs at the apical plasma membrane where the CFTR protein promotes cAMP-regulated bicarbonate and fluid secretion by functioning as an anion channel and probably also as a regulator of anion exchange [13,18]

Early features of CF pancreatic disease include plugging of the smaller pancreatic ducts [52] and defective bicarbonate secretion [56,57]. These features agree well with what is known about the intrinsic function of CFTR [15] and about the localization of CFTR protein in human pancreas [13]. Taken together, this evidence suggests that CFTR contributes to normal pancreatic secretion by diluting and alkalinizing the pancreatic juice to prevent obstruction of the smaller pancreatic ducts with proteinaceous plugs.

Evaluation

Pancreatic enzyme replacement therapy in CF patients is often started based on symptoms of steatorrhea without formal testing to document malabsorption. This approach is appropriate for most ΔF508 homozygotes and for others with genotypes known consistently to cause severe loss of CFTR function, as long as these individuals will be treated for pancreatic insufficiency. However, when this approach is used with individuals who have less predictive *CFTR* genotypes, it can cause misclassification with respect to pancreatic insufficiency. One report indicates that this type of misclassification is common: when 1215 CF patients were tested for pancreatic insufficiency, roughly 12% had unequivocally normal fecal elastase 1 levels; this agreed well with the known frequency of genotypes causing pancreatic sufficiency in CF. A surprising finding in this study was that most of these pancreas-sufficient CF individuals had been receiving enzyme supplements (67/127 cases, after excluding cases with pancreatitis) until they were tested for research purposes; this study also identified some individuals (24/1074 cases) who needed enzyme supplements but who were previously misclassified as having pancreatic sufficiency [58]. Because CF usually causes profound pancreatic insufficiency, nearly all CF patients in the study had elastase 1 values that unequivocally were either normal (> 200 μg/g stool) or abnormal (< 100 μg/g). These data suggest that many groups of CF patients will benefit from fecal elastase 1 testing. This testing will be especially important for individuals in whom the *CFTR* genotype is not predictive regarding pancreatic insufficiency.

In CF patients, it is also common to assess pancreatic function indirectly by evaluating nutritional status, malabsorption symptoms, and blood levels of fat-soluble vitamins. Secretin testing and quantitative stool fat studies are not widely used in most CF care centers. However, quantitative fat analysis can be helpful when malabsorption is suspected in individuals who have a normal elastase 1 level (> 200 μg/g stool) or who are responding poorly to enzyme supplements. Formal testing for malabsorption also is important for the rare CF patient who has a genotype predicting pancreatic insufficiency but who has clinical findings that suggest pancreatic sufficiency. Finally, pancreatic function can change over time in CF patients who have pancreatitis. Guidelines do not exist for monitoring pancreatic function in this group of CF patients; borderline fecal elastase 1 values may be more common in this group than in others with CF.

Treatment

Pancreatic enzyme supplements are used to treat CF patients with pancreatic insufficiency. For adults, enzyme supplements are usually administered as capsules containing enteric-coated enzymes formulated as microspheres or microtablets. These enzyme products contain multiple pancreatic enzymes and they significantly improve malabsorption of fat and protein in CF children and adults [59,60]. For adults starting on enzyme supplements, the initial dose per meal is typically 500 U lipase per kilogram bodyweight; for snacks, half this dose is used. Traditionally, dose adjustments are guided by

symptoms or other evidence of ongoing malabsorption (e.g., quantitative fecal fat testing). Dose adjustments aim for the minimum effective dose and sometimes require gradual increases in enzyme dose up to a maximum of 2500 U lipase per kilogram bodyweight per meal. Higher enzyme doses are avoided due to the risk of fibrosing colonopathy [61].

Significant but incomplete correction of steatorrhea is expected in most CF patients [59,60]. Persistent steatorrhea can limit nutritional status, and this correlates closely with prognosis in CF [62,63]. Many factors can limit the effectiveness of enzyme therapy in CF patients: one frequent limitation is poor patient adherence to pancreatic enzyme replacement therapy recommendations [64]. Generic or nonproprietary substitution of enzyme products can raise questions about enzyme potency and stability [65]; optimal enzyme delivery to the duodenum depends on when capsules are ingested [66] and can be reduced by gastric dysmotility [67]. Acid suppression is widely used in CF patients and can promote enzyme efficacy by multiple mechanisms [64]. Finally, CF patients develop unrelated conditions causing malabsorption; treatable possibilities should be considered, including celiac disease [68] and giardiasis [69]. More generally, inadequate responses to enzyme replacement in CF may also be due to extrapancreatic consequences of reduced CFTR function. For example, postlipolytic defects contribute to fat malabsorption in CF patients and in murine models of CF [70,71]. Cystic fibrosis has been associated with intestinal pH dysregulation, abnormalities of the unstirred water layer, and abnormalities in bile acid pools; the importance of these and other extrapancreatic events in humans with CF is uncertain [72].

Nutritional aspects

Nutritional status has a major impact on survival in CF. Until the late 1980s, the approach to nutritional support varied widely from one CF care center to another. At that time, many US CF care centers prescribed a carbohydrate-rich, low-fat diet with supplemental medium-chain triglycerides and protein hydrolysates, aiming to minimize steatorrhea symptoms and encourage appetite. By contrast, a limited number of centers (mainly in Canada) prescribed a caloric-dense, high-fat diet that was more palatable but required higher doses of pancreatic enzymes. When clinical outcomes were compared at two such centers in 1988, median survival for CF patients was 9 years longer at the center where the caloric-dense diet was prescribed [62]. Factors other than differences in dietary management did not seem to explain the survival difference and these data led most US CF care centers rapidly to adopt the caloric-dense approach to nutritional support [73]. As anticipated, this change in clinical practice led to a gradual narrowing of the gap in nutritional status between CF patients in Canada and those in the United States over the subsequent decade [74]. Nutritional status is therefore recognized as a powerful predictor of prognosis in CF [63,75], and consensus guidelines strongly recommend using a caloric-dense dietary approach in CF children [76] and adults [8].

In the United States, most CF patients receive their care at CF care centers where nutritional support is emphasized. Trained personnel assist with evaluating nutritional status to assure that malnourished patients are identified promptly and treated aggressively. For adults, nutritional status is mainly evaluated by comparison with ideal bodyweight (IBW) tables or by calculating body mass index (BMI). For IBW, %IBW is calculated based on published data for small-frame individuals [77]. Adults with CF having a %IBW below 90% are classified as having malnutrition and are candidates for more intensive monitoring and nutritional support.

A report indicates that %IBW values underestimate the severity of malnutrition in many individuals, especially children with short stature [78]. For this reason, US CF care centers are modifying their nutritional assessment approach to emphasize BMI as the preferred measurement. Body mass index is calculated as the weight (in kilograms) divided by the square of the height (in meters). For CF adults, when BMI values drop below the normal range of 20–25 kg/m^2, there is a dramatic decrease in lung function (Fig. 72.4) [7]. To prevent this, BMI and weight are followed closely. Small declines in either parameter lead to aggressive and early intervention. Target values for BMI in male and female CF adults are 23 and 22 kg/m^2, respectively. Those CF adults who have BMI values below 19 kg/m^2 are classified as having malnutrition; CF adults who have intermediate BMI values (above 19 but below 22–23 kg/m^2) are treated as having a high risk of developing malnutrition [79].

It is difficult to achieve target %IBW or BMI values in CF patients. Daily caloric intake in CF should be 20%–50%

Figure 72.4 Relationship between lung function and body mass index (BMI) in adults with cystic fibrosis. FEV_1, forced respiratory volume in 1 s. Data from Cystic Fibrosis Foundation Patient Registry 2005 Annual Data Report [7], with permission from the Cystic Fibrosis Foundation.

above that in non-CF individuals [76]. This is based, in part, on the fact that resting energy expenditure is increased at early stages of CF prior to the development of clinically significant lung injury or infection [80,81]; resting energy expenditure is further increased during pulmonary exacerbations due to the impact of infection and airway obstruction on the work of breathing [82,83]. However, caloric intake is often compromised by problems with appetite and absorption.

To maintain adequate caloric intake, CF patients are encouraged to select high-fat foods and snacks because these choices are energy-dense and appetizing. Malabsorption of fat-soluble vitamins is common with pancreatic insufficiency and is managed using supplements specifically formulated for the CF population. Monitoring for vitamin K and vitamin D deficiency is particularly important due to the frequent use of antibiotics and to the increasing prevalence of osteoporosis in older CF patients. Vitamin E deficiency also is common. Appetite stimulants can help some CF patients achieve adequate caloric intake. Small clinical trials have tested megestrol acetate [84,85] and cyproheptadine [86] in CF patients; the available data favor cyproheptadine with respect to effectiveness and safety. Gastroesophageal reflux causes significant symptoms in about half of CF adults; this is a potentially correctable cause of poor appetite and it is treated aggressively. When CF patients develop moderate or severe malnutrition during their clinical course, placement of a gastrostomy or jejunostomy tube should be considered [87,88].

Diabetes

Diabetes occurs in many older pancreatic-insufficient CF adults as a late complication of their CF pancreatic disease. The occurrence of diabetes in CF is signficant because it accelerates the progression of CF lung disease and it shortens survival [63]. In CF children with pancreatic insufficiency, diabetes is rare and pancreatic histopathology characteristically shows sparing of the islets [52]. By contrast, the adult CF pancreas exhibits sclerotic disruption of the islet architecture [89].

Cystic fibrosis-related diabetes differs from both common forms of diabetes (type 1 and type 2) in its clinical features. Diabetics with CF resemble type 1 diabetics (and differ from type 2 diabetics) in having low fasting insulin levels, normal (or high) insulin responsiveness, and a low BMI; however, CF-related diabetes differs from type 1 diabetes with respect to the absence of ketoacidosis, the insidious onset, and the absence of anti-islet antibodies. More importantly, both common forms of diabetes are associated with high glucagon levels, whereas glucagon levels are low in CF-related diabetes; this correlates with an overall loss of islet cells in CF-related diabetes and explains why diabetes tends to be especially brittle in CF patients [90].

Screening for CF-related diabetes depends on annual random blood sugar determinations. If the random blood sugar level is abnormal (> 126 mg/dL), further testing includes measuring the fasting blood glucose or performing an oral glucose tolerance test. Testing for glycohemoglobin is not sensitive enough to reliably identify diabetics in the CF population [90].

The treatment of CF-related diabetes differs from the treatment of other forms of diabetes. In most diabetics, caloric restriction is used for glycemic control, whereas this approach can be dangerous in CF because it is so difficult for CF patients to ingest enough calories to meet their elevated levels of energy expenditure. Fat intake in most diabetics is usually limited to 30% of total calories and sugar intake is strictly restricted; by contrast, a high-fat diet (40% of total calories as fat) with relatively little sugar restriction is advised for diabetics with CF. For most diabetics, salt intake is restricted, whereas this would be contraindicated for many CF patients. Finally, snacks and unstructured meals are discouraged for most diabetics, whereas they are encouraged for most CF patients [8,90].

Intestinal disease

The most common intestinal findings in CF are meconium ileus (MI) and distal intestinal obstruction syndrome (DIOS). Approximately 15%–20% of CF patients present with MI and 4%–20% of CF adults develop DIOS [45,91]. Both conditions result from blockage of the terminal ileum with impacted fecal material. Distal intestinal obstruction syndrome should be distinguished from constipation, a more common problem in CF patients in which intestinal blockage begins in the rectum.

The pathogenesis of MI and DIOS is incompletely understood and probably results mainly from anion hyposecretion caused by the absence of functional CFTR at the apical membrane of enterocytes [14]. The best characterized role of CFTR in enterocytes is to function as the rate-limiting apical chloride channel for cAMP-activated fluid secretion into the colonic crypt lumen [92]. Excessive ion transport by CFTR at this site causes secretory diarrhea; CFTR plays a critical role in this response because the intestinal secretory response to cAMP-dependent agonists (e.g., cholera toxin) is blocked in humans with CF, in transgenic mice lacking functional CFTR, and in animals treated with CFTR inhibitors [93,94]. cAMP-mediated anion secretion has also been linked with CFTR function in the small intestine, although other roles of CFTR may also be important at this site [95–98].

Most CF individuals with MI or DIOS have pancreatic insufficiency [91,99]. In the past, DIOS was attributed to inadequate doses of pancreatic enzyme therapy. However, it has been established that pancreatic insufficiency is associated with the subset of *CFTR* genotypes causing more severe ion transport abnormalities in many CF-affected tissues; it therefore seems likely that the risk of intestinal obstruction is higher in these CF patients because they have lower residual CFTR function in their enterocytes. The risk of MI is highly heritable; concordance rates for this complication in

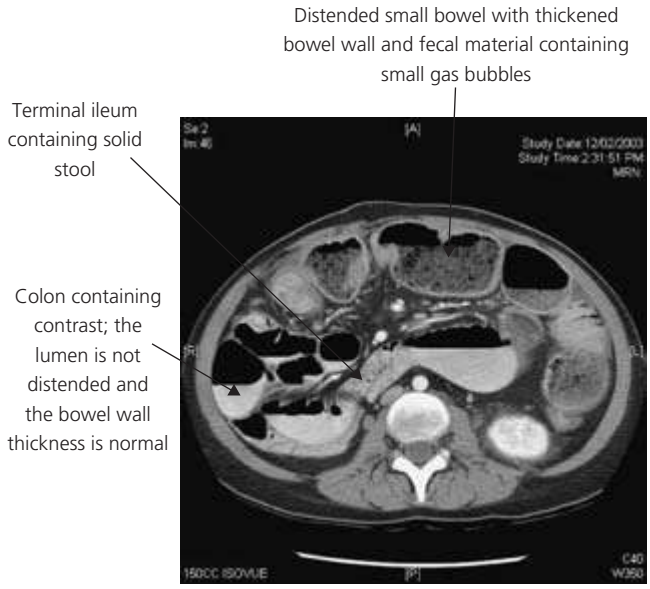

Figure 72.5 Abdominal computed tomography scan of an adult cystic fibrosis patient with distal intestinal obstruction syndrome. The terminal ileum is filled with solid stool. Proximal to this obstruction, the small bowel is distended (note thickened bowel wall and gas bubbles in fecal material). Distal to the transition point, the colon contains contrast and is not distended. Courtesy of Dr Carlos Micames, Duke University Medical Center.

monozygotic twins with CF are higher than in dizygotic twins, and ongoing studies aim to identify the modifier gene(s) responsible for this [99,100]. By contrast, twin studies in individuals with DIOS did not show heritability [99].

MI and DIOS are potentially dangerous complications of CF. Both conditions are characterized by partial or complete bowel obstruction caused by inspissated fecal material in the terminal ileum or cecum. Usually MI occurs within 2 days of birth and does not occur in adults. For DIOS, the mean age when an initial episode occurs is 20 years and recurrence is common [91]. The diagnosis is suggested by abdominal pain with a right lower quadrant mass. Abdominal radiographs usually show impacted stool in the ileum or cecum and this often appears granular or bubbly (Fig. 72.5). Because DIOS can lead to intussusception, volvulus, or ischemia, early recognition and intervention is important. Initial evaluation should include imaging studies to exclude appendicitis (e.g., by CT or sonography). Management includes correction of dehydration and electrolyte abnormalities, nasogastric decompression, and enemas (often using gastrografin with Tween-80) followed by intestinal lavage using polyethylene glycol electrolyte solutions (Golytely). Powdered polyethylene glycol (MiraLax) is effective for constipation in CF and regular use may also reduce the frequency of DIOS episodes. Some patients supplement this by intermittently using Golytely.

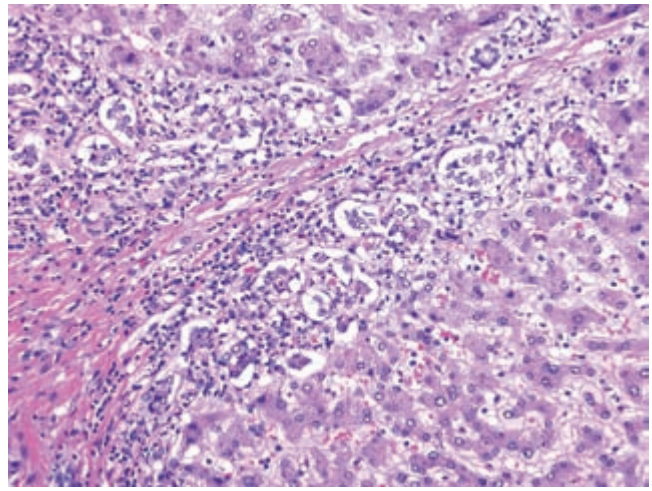

Figure 72.6 Photomicrograph of the liver from a patient with cirrhosis due to cystic fibrosis. Courtesy of Dr Victor Roggli, Duke University Medical Center.

Liver disease

The most important form of liver disease in CF is cirrhosis with portal hypertension (Fig. 72.6). Approximately 2% of CF adults have clinically significant portal hypertension, and liver disease accounts for approximately 2% of mortality in CF [45]. The prevalence of milder forms of liver disease in CF adults is uncertain and cholestasis probably occurs in 20%–30% of individuals [101]. Cholestasis is usually asymptomatic and biochemical markers do not reliably detect progression to focal or multilobular biliary cirrhosis. In one series of closely monitored patients who progressed to cirrhosis, the mean age at onset of cirrhosis was 10 years [102].

Liver histopathology varies widely in individuals with CF. Approximately half of CF patients have periportal steatosis. The most distinctive early feature of CF liver disease is plugging of the intrahepatic bile ducts with eosinophilic concretions [52]. The term *focal biliary cirrhosis* is used to describe a patchy and uneven form of bridging fibrosis often found in CF; the frequency and natural history of bridging fibrosis in CF has not been precisely defined.

The term *multilobular biliary cirrhosis* describes the form of biliary cirrhosis found in more advanced CF liver disease. This condition also tends to be patchy such that one lobe or segment can have normal histopathology whereas another lobe or nearby segment can be cirrhotic. For this reason, there is a high risk of sampling error when using percutaneous or transjugular liver biopsy to evaluate the severity of CF liver disease. Serum markers (e.g., liver function tests) are also unhelpful for monitoring early cirrhosis because they are often abnormal in CF individuals who do not have cirrhosis. Many individuals with multilobular cirrhosis are asymptomatic until developing portal hypertension. The risk of CF liver disease is increased in individuals who have pancreatic insufficiency and in males; some data suggest a further increment in risk in individuals who have had MI [102,103].

The primary defect in CF liver disease resembles that in CF pancreatic disease. The CFTR protein mainly occurs in the apical membrane of the epithelial cells lining the intrahepatic bile ducts. In individuals with CF, reduced CFTR function in the duct cell probably leads to inadequate alkalinization and dilution of the bile as it flows through the ducts, thereby leading to ductal plugging and cholestasis [104]. Ductal obstruction leads to hepatic fibrosis and injury resembling that occurring in other forms of biliary cirrhosis such as primary biliary cirrhosis and primary sclerosing cholangitis. Based largely on the effectiveness of ursodeoxycholic acid for primary biliary cirrhosis [105], ursodeoxycholic acid (10 μg/kg, twice daily) is used at some centers to treat CF patients who have persistently abnormal liver function tests (cholestasis) to try to prevent cirrhosis [106]. In CF, ursodeoxycholic acid can improve clinical and biochemical status [107]. However, this treatment has not been shown to affect mortality or liver fibrogenesis in CF.

The clinical management of portal hypertension and decompensated cirrhosis in CF is similar to that in non-CF individuals. Some patients develop advanced liver disease despite having relatively mild lung disease and these individuals can be favorable candidates for liver transplantation. Liver transplantation was performed on a total of 29 CF patients in the United States during 2004 and 2005; for comparison, lung transplantation was performed on 314 CF patients during the same period [7].

Patients with cystic fibrosis also develop other forms of hepatobiliary liver disease. Approximately half of CF patients have hepatic steatosis. This tends to be periportal and it may partly explain the frequent occurrence of abnormal liver function tests in asymptomatic CF individuals. Inflammation (steatohepatitis) is usually not prominent and it is uncertain whether steatosis plays a significant role in promoting fibrosis in these CF individuals [108]. In the past, profound hepatic steatosis was often found in newly diagnosed patients with severe malnutrition; steatosis in these cases improved with treatment of malnutrition. In other cases, hepatic congestion can occur in the setting of cor pulmonale due to advanced lung disease.

The most common biliary tract finding in CF is the occurrence of a nonfunctional and small gallbladder (microgallbladder) by ultrasonography. This finding occurs in one-fourth of CF individuals and it agrees well with information about the distribution and function of CFTR in the gallbladder. Normally CFTR occurs as an apical protein in the gallbladder epithelium [109]; reduced expression of CFTR at this site correlates with reduced cAMP-dependent anion and fluid secretion [110,111]. Symptomatic gallstones occur in fewer than 1% of CF adults per year [45].

Individuals with CF also develop a sclerosing cholangiopathy. In some patients (fewer than 10%), this leads to bile duct stenosis and the cholangiographic features can resemble primary sclerosing cholangitis. Based on histopathology, the secondary form of sclerosing cholangitis in CF does not exhibit the distinctive features of primary sclerosing cholangitis (e.g., prominent inflammation and concentric rings of periductal fibrosis). The evaluation and management of biliary disease in CF is similar to that in non-CF individuals [112].

Hereditary pancreatitis

Hereditary pancreatitis (HP, OMIM #167800) is an autosomal dominant disease of the exocrine pancreas characterized by recurrent attacks of acute pancreatitis leading to chronic pancreatitis. It was first described in 1952 [113] and the genetic basis for most cases was discovered in 1996 [114].

Families with HP have been identified throughout the United States and Europe, and to date approximately 700 cases have been reported with confirmatory DNA testing [115]. The prevalence of HP is unknown. In regions where there are multiple large HP families, this diagnosis can account for up to 10% of chronic pancreatitis in children evaluated at tertiary referral centers [44]; in other regions, the diagnosis is probably much less common.

Genetics and molecular basis

In 1996, the gene responsible for most cases of HP was mapped to chromosome 7q35 and shown to encode the protein cationic trypsinogen [114]. Cationic trypsinogen is produced by the *PRSS1* gene. It is one of three trypsinogen isozymes and normally represents 60%–70% of the trypsinogen in pancreatic juice. Pancreatic juice also contains anionic trypsinogen produced by the *PRSS2* gene (comprising 30% of trypsinogen) and mesotrypsinogen produced by the *PRSS3* gene (comprising 5%–10%) [116].

Each isozyme is produced as an inactive preproenzyme consisting of a signal peptide, a trypsinogen activation peptide, and a proteolytically active trypsin moiety. The signal peptides each contain 15 amino acids and are removed before trypsinogen is delivered to the zymogen granule. The trypsinogen activation peptides each contain eight amino acids and are removed when trypsinogen is activated, an event normally occurring after exocrine secretion of trypsinogen from the acinar cell. Trypsinogen activation within the acinar cell is ordinarily blocked by a reversible trypsin inhibitor protein located in zymogen granules with trypsinogen. This inhibitor is a 56-amino-acid protein and is encoded by the pancreatic secretory trypsin inhibitor (*PSTI*, also known as *SPINK1*) gene located on chromosome 5q32 [117,118].

Trypsinogen is normally cleaved by enterokinase to produce active trypsin in the duodenal lumen. Once activated, trypsin acts on many proenzyme substrates including other trypsinogen molecules. Because one trypsin molecule can activate many trypsinogen molecules, a rapidly escalating chain reaction can occur if trypsin activation occurs at a site

where trypsinogen is abundant. If such a chain reaction is initiated in the pancreatic parenchyma, this can be dangerous because the resulting protease activity can digest the pancreas and thereby expose additional trypsinogen molecules to produce increasing levels of proteolysis and tissue injury.

Several protective mechanisms normally prevent large amounts of activated trypsin from accumulating in the pancreas. For example, intracellular trypsinogen is normally sequestered in zymogen granules, where it is physically separated from intracellular proteases capable of activating the proenzyme (e.g., in lysosomes). For preventing a potentially catastrophic uncontrolled chain reaction, two protective mechanisms are especially important. First, acinar cells produce the PSTI protein that functions in zymogen granules to reversibly inhibit proteolysis by blocking the active site of trypsin [117]. Second, active trypsin molecules are unstable and become cleaved at a specific site (R122 in trypsin) to produce enzymatically inactive fragments [115].

Autoactivation refers to the ability of trypsin to digest and thereby activate other trypsinogen molecules; autodegradation refers to the ability of one trypsin molecule to digest and inactivate other trypsin molecules. Excessive intrapancreatic trypsin activation with pancreatic injury could result from defects causing enhanced autocatalytic production of active trypsin from trypsinogen (autoactivation) or it could result from defects causing prolonged survival of active trypsin due to reduced autodegradation. Trypsin autodegradation depends sensitively on the trypsin concentration (because autodegradation is a bimolecular reaction) and also on the calcium concentration. At higher calcium levels, calcium binds to trypsin and leads to a conformational change causing R122 to become inaccessible. Thus, high calcium levels can reduce tryptic autodegradation and thereby encourage the accumulation of larger amounts of active trypsin during pancreatitis [115].

The first gene identified as a cause of HP was *PRSS1*. Two mutations have been shown to cause HP as an autosomal dominant disease, R122H and N29I [114,119]. Together, these mutations account for most cases of HP in the United States and Europe [120]. A third *PRSS1* mutation, A16V, has been detected in over a dozen unrelated cases of pancreatitis; this mutation occurs at the signal peptide cleavage site in cationic trypsinogen and it is mainly associated with sporadic cases of chronic pancreatitis in children [115,121]. Dozens of additional *PRSS1* mutations have also been detected in rare or unique families with pancreatitis, but the clinical significance of these mutations is unknown [115].

The impact of the R122H and N29I mutations on cationic trypsinogen was defined by comparing the biochemical properties of recombinant proteins produced with or without disease-causing mutations. When compared with normal (wild-type) trypsinogen, each mutant form of trypsinogen exhibits a biochemical defect, explaining how the mutation causes pancreatitis. The R122H mutation causes trypsinogen to undergo both increased autoactivation and reduced autodegradation, whereas the N29I mutation causes increased autoactivation without affecting autodegradation [122]. Thus, both *PRSS1* mutations change the intrinsic biochemical properties of cationic trypsinogen to shift the balance between trypsin autodegradation and trypsin autoactivation in favor of increased trypsin activation [115].

The discovery that the *PRSS1* R122H mutation causes hereditary pancreatitis was important because it provided new insight into the pathogenesis of pancreatitis [114]. It showed that excessive activation of trypsin is sufficient to cause recurrent attacks of acute pancreatitis in humans. It also showed that recurrent acute pancreatitis can progress to chronic pancreatitis. Although both mechanisms of pathogenesis had been widely discussed before this (e.g., Chiari had suggested that pancreatitis resulted from autodigestion of the gland a century earlier), the clinical, genetic, and molecular characterization of HP and of the *PRSS1* R122H mutation provided compelling evidence that these mechanisms play a crucial role in the pathogenesis of some cases of pancreatitis.

Once *PRSS1* was identified as the gene causing most HP, additional studies of monogenic forms of pancreatitis further explored the link between excessive trypsin activation and pancreatitis. Three findings particularly support this link:

- *PSTI* loss-of-function mutations were identified as the cause of autosomal dominant HP in some families where *PRSS1* mutations are absent [123,124]. The *PSTI* mutations detected in some families (L14R or L14P) produce unstable mutant proteins whereas other cases were caused by deletion of 1336 bp (exon 1) of the *PSTI* gene; either mechanism would produce low levels of functional PSTI protein and thereby predispose to excessive intrapancreatic trypsin activation.
- Some cases of HP were shown to be caused by a large (605 kb) triplication including both *PRSS1* and *PRSS2* [125]. In these cases, high levels of these trypsinogen isozymes would be caused by a gene dosage effect due to increased copy number.
- In murine models of pancreatitis, transgenic over- or under-expression of *PSTI* [126,127]and transgenic expression of the R122H variant of *PRSS1* [128] each caused changes in pancreatic injury consistent with the concept that excessive trypsin activation plays a central role in pancreatitis.

Common manifestations and complications

The initial clinical features of HP are identical to those of non-hereditary forms of pancreatitis. Some individuals have minimal symptoms or only a single attack of acute pancreatitis. The more typical clinical course consists of recurrent attacks of acute pancreatitis leading to chronic pancreatitis over decades. Symptoms usually start in childhood (median age at onset is 13 years) and 90% of patients become symptomatic by age 30. When comparing groups of HP patients who have the R122H vs the N29I *PRSS1* mutations, the R122H

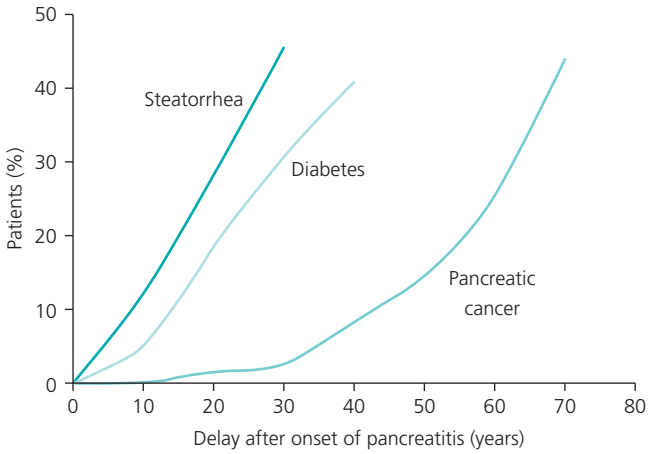

Figure 72.7 Complications of chronic pancreatitis occur gradually in patients with hereditary pancreatitis. Based on data in Howes et al. [120] and Lowenfels et al. [129].

mutation is associated with an earlier age at onset (10 years vs 14 years) [119,120].

Generally, HP patients survive for more than 50 years after the onset of their pancreatitis. Over time, most HP patients gradually develop exocrine and endocrine pancreatic insufficiency. For both complications, there is a usually a delay of decades between the onset of pancreatitis symptoms and the onset of exocrine or endocrine pancreatic failure (Fig. 72.7). The cumulative lifetime risk is over 60% for each complication. When diabetes mellitus occurs in HP patients, the condition tends to be brittle and is distinct from type 1 or type 2 diabetes. Chronic or recurrent abdominal pain can dominate the clinical picture and requires pancreatic resection or a drainage procedure in one-fifth of cases [120].

The most serious complication of HP is pancreatic cancer. Cancer is rare during the first two decades after the onset of HP symptoms. The cumulative risk of pancreatic cancer gradually rises and it exceeds 40% after seven decades [129]. The age-adjusted risk of pancreatic cancer is increased by about 60-fold by HP [130] and is not influenced by mutation status, gender, or maternal vs paternal mode of inheritance [120]. On average, pancreatic cancer occurs 15–20 years earlier in HP patients who smoke cigarettes than in nonsmokers [120,130]; preliminary findings suggest that when HP patients use either tobacco or alcohol, the risk of pancreatic cancer may be increased approximately two-fold [130].

Diagnostic studies

In the pregenomic era, the autosomal dominant nature of HP was emphasized to distinguish this condition from other familial forms of pancreatitis. Dominant inheritance is supported by identifying multiple affected individuals (at least two first-degree or at least three second-degree relatives) in at least two generations. Criteria like this are still used in research studies designed to exclude individuals in whom the inheritance pattern is equivocal or uncertain. However, in clinical practice it is unhelpful to use such stringent criteria because family history information is often incomplete.

With the availability of *PRSS1* mutation testing for clinical use, DNA testing is commonly used to make a new clinical diagnosis of HP. In the United States, *PRSS1* mutation testing is licensed to Ambry Genetics, Irvine, CA. If an individual has a clinical history of recurrent acute pancreatitis (RAP) or chronic pancreatitis (CP) and if *PRSS1* DNA testing detects either of the known HP-causing mutations (R122H or N29I), then this establishes the diagnosis of HP. This can help patients by preventing further testing, which might otherwise be performed to exclude rare causes of pancreatitis. If *PRSS1* DNA testing detects an uncommon mutation, then information about the detected mutation may be available through a database established to collect and distribute clinical and genetic data related to *PRSS1* mutations – the University of Leipzig Database of Genetic Variants in Patients with Chronic Pancreatitis (http://www.uni-leipzig.de/pancreasmutation). Interpretation of *PRSS1* DNA testing can be complicated by the absence of a detected *PRSS1* mutation in many HP families. Patients should understand the limitations and potential risks (e.g., of discrimination) of DNA testing for HP before being asked to provide informed consent for this testing.

In clinical practice, individuals with unexplained RAP or CP are often tested for *PRSS1* mutations regardless of their family history. It is common for individuals to be diagnosed with HP even when their initial family history data seem to be negative for HP [131]. Because the age of onset for HP is much earlier than for other forms of CP or RAP, *PRSS1* DNA testing should particularly be considered in individuals in whom pancreatitis begins at a younger age (e.g., under 20–30 years). For both common HP-causing *PRSS1* mutations (R122H and N29I), the penetrance of HP is approximately 80% [114,119,120]. This predicts that a fraction of HP patients (20%) will have no affected parent in spite of the autosomal dominant inheritance pattern. Outside of research studies, *PRSS1* gene testing should generally not be offered to asymptomatic relatives of HP individuals.

Complications of HP are evaluated using the same approach as in other forms of chronic pancreatitis. Due to the high lifetime risk of pancreatic cancer in HP, there is a particular need to develop screening methods for early cancer detection in individuals with HP. Several approaches to screening have been considered [132], but none has been prospectively tested in this population. In other familial forms of pancreatic cancer, endoscopic ultrasound (EUS) and CT can be useful for screening high-risk individuals [133]. However, these approaches may be less useful for screening individuals with HP due to the pancreatic structural changes commonly found in longstanding HP. A related point is that many abnormalities found by EUS will prove to be benign or low-grade neoplastic lesions. Thus, there is no consensus about the best approach to screening for malignancy in HP [134].

Treatment

Hereditary pancreatitis resembles CP with respect to most aspects of therapy. One general goal is to try to prevent acute attacks of pancreatitis. Patients with HP are often advised to limit their intake of alcohol and fatty foods based on early data associating these exposures with painful attacks in HP [135]. A small pilot study suggested that antioxidants and vitamins may also help prevent acute attacks of pancreatitis [136]. Finally, cigarette use is strongly discouraged based on the impact of smoking on the risk of pancreatic cancer in HP [130].

One distinctive feature of HP is that the lifetime risk of pancreatic cancer is much higher in HP than in other forms of CP. This has implications for the surgical management of HP patients: if an older HP patient is a candidate for pancreatic resection (e.g., for pain control or to remove a suspicious lesion detected by a screening procedure), then total pancreatectomy should be considered [134].

Rare inherited diseases of the exocrine pancreas

Shwachman–Diamond syndrome

Shwachman–Diamond syndrome (SDS; OMIM #260400) is an autosomal recessive condition characterized by pancreatic exocrine insufficiency, bone marrow failure, and skeletal abnormalities [137–139]. At least 250 families have been identified and the frequency of SDS is thought to be approximately 1 in 80 000 [140].

The syndrome is caused by mutations of the *SBDS* gene (Shwachman–Bodian–Diamond), a gene located on chromosome 7 (at 7q11) and predicted to encode a 250-amino-acid protein [141]. This protein occurs in the nucleolus where it apparently participates in RNA processing [142]. Approximately 90% of SDS families have mutations of the *SBDS* gene. Most detected mutations are gene conversions in which part of the *SBDS* gene is exchanged with a closely related but nonfunctional pseudogene located near the *SBDS* gene. The two most common *SBDS* splicing mutations in this condition are 183-184TA→CT and 258+2T→C; half of SDS patients are compound heterozygotes who have one copy of each of these two mutations [141].

Common manifestations

Most SDS patients present with findings related to pancreatic insufficiency such as failure to thrive and steatorrhea. In approximately 90% of cases, this is clinically evident within one year of birth. Pancreatic insufficiency in SDS is caused by defective development of the pancreatic acini. Histopathology shows fatty replacement of the acinar tissue with preservation of the pancreatic ducts and islets. Thus, pancreatic lipomatosis is typical in patients who undergo CT or ultrasound imaging [138]. The histopathological findings in SDS (acinar hypoplasia with ductal preservation) correlate with the pattern of abnormal pancreatic exocrine function observed when SDS patients undergo secretin testing: SDS causes relatively severe impairment of pancreatic enzyme secretion while causing relatively mild effects on bicarbonate secretion [54].

The second characteristic feature of SDS is bone marrow dysfunction. Nearly all SDS patients have persistent or cyclic neutropenia, and approximately half of SDS patients also have anemia or thrombocytopenia [138]. Recurrent bacterial and viral infections occur in most SDS patients and result from multiple mechanisms including neutropenia, defective immune function, and impaired neutrophil chemotaxis [143]. Typical infections include sinusitis, pneumonia, osteomyelitis, urinary tract infection, septicemia, and abscess. Up to one-third of SDS patients eventually develop myelodysplastic syndromes, and roughly half of these individuals develop acute myelogenous leukemia [139].

Growth and skeletal abnormalities also are typical features of SDS. Half of patients develop metaphyseal chondrodysplasia involving the femoral head. A second common finding is shortening or flaring of the ribs with costochondral thickening. Delayed growth is typical and many SDS patients remain below the fifth percentile for height and weight despite treatment of their pancreatic insufficiency.

Clinical evaluation and management

When young children present with steatorrhea or other evidence of pancreatic insufficiency, sweat testing is usually the first diagnostic procedure because CF is much more common than SDS. If sweat testing is normal, then SDS becomes the most likely possibility. In such children, the diagnosis of SDS is often supported by abnormalities in the blood count (e.g., persistent neutropenia). DNA testing is available as a clinical assay and this is the definitive method for confirming a diagnosis of SDS. This test is performed by the Molecular Genetics Laboratory, Hospital for Sick Children, Toronto, Canada. DNA testing is also used to screen siblings of SDS patients. In families where SDS is caused by identified mutations of the *SBDS* gene, DNA testing is sensitive and specific. Rare SDS patients will have no known SBDS mutation when tested; in these cases, the diagnosis of SDS depends on laboratory data showing unequivocal evidence of pancreatic and bone marrow dysfunction.

Pancreatic insufficiency in SDS is treated with pancreatic enzyme replacement therapy starting with enzyme doses similar to those used in CF. This therapy tends to be more effective than in other forms of childhood pancreatic insufficiency (e.g., CF) in which multiple defects contribute to steatorrhea including problems with bicarbonate secretion and postlipolytic absorptive mechanisms. In SDS, pancreatic insufficiency often becomes less severe over time.

The bone marrow disease of SDS requires specialized care by a hematologist. Neutropenic infections can be life-

threatening and are often treated using granulocyte colony-stimulating factor (GCSF) with antibiotics. Due to the high risk of developing myelodysplastic syndromes or acute leukemia, surveillance bone marrow studies are used to try to identify candidates for bone marrow transplantation [139]. The skeletal disease of SDS is usually asymptomatic but occasionally requires orthopedic referral [144].

Other rare diseases of the exocrine pancreas

Johanson–Blizzard syndrome (OMIM #243800) is an autosomal recessive condition consisting of pancreatic exocrine insufficiency with nasal alar hypoplasia or agenesis of the nasal cartilage [145]. This syndrome is also often associated with hypothyroidism, deafness, imperforate anus, scalp defects, and mental retardation [146]. The estimated frequency is 1/250 000 [147]. When detailed family history data can be obtained, consanguinity is often evident [146].

Johanson–Blizzard syndrome is caused by loss-of-function mutations of the *UBR1* gene [146]. This gene encodes a ubiquitin ligase that apparently is required for maintaining normal pancreatic acinar cell function in utero in mice and humans. Johanson–Blizzard syndrome resembles SDS with respect to its effects on pancreatic histopathology and on exocrine function: both conditions cause fatty replacement of the acini with relative sparing of other pancreatic structures and also cause severe impairment of pancreatic enzyme secretion with relative preservation of bicarbonate secretion [148]. However, the two conditions differ in that the development of pancreatic acini seems to be normal in Johanson–Blizzard syndrome whereas it is abnormal in SDS; also, Johanson–Blizzard syndrome does not cause the hematological or skeletal defects seen in SDS [148]. The treatment of pancreatic insufficiency in both conditions is similar.

Pearson syndrome (OMIM #55700) is a rare autosomal dominant condition consisting of refractory sideroblastic anemia and pancreatic insufficiency in young infants [149]. Most cases are caused by large deletions or duplications of mitochondrial DNA [150,151]. The initial clinical presentation is usually dominated by severe macrocytic anemia, with bone marrow studies showing severe hemosiderosis, ring sideroblasts, and prominent vacuolization of erythroid and myeloid cells [152]. Pancreatic findings at autopsy include fibrosis rather than fatty replacement; pancreatic function testing shows abnormalities in both acinar and ductular secretions [149,153].

Pancreatic agenesis (OMIM #260370) is a rare condition causing persistent and severe exocrine and endocrine pancreatic insufficiency in early infancy. Individual cases have been associated with mutations of different genes required for pancreatic development such as *PDX1* and *PTF1A* [154]. By contrast, *agenesis of the dorsal pancreas* (OMIM #167755) can cause diabetes without significant exocrine insufficiency [155]. An unrelated and rare pancreatic cause of steatorrhea is *congenital lipase deficiency* (OMIM #246600) [156].

When exocrine and endocrine pancreatic insufficiencies occur together in older individuals, this can result from maturity-onset diabetes of the young (MODY, type VIII) with exocrine dysfunction (OMIM #609812), an autosomal dominant condition caused by mutations of carboxyl-ester lipase [157]. Early findings in this condition include steatorrhea, reduced serum levels of fat-soluble vitamins and low-density lipoprotein (LDL) cholesterol, and pancreatic fatty infiltration, whereas diabetes occurs as a later finding with a mean age at diagnosis of 34 years. Pancreatic lipomatosis occurs before pancreatic atrophy, fibrosis, and endocrine insufficiency. This condition illustrates how a primary defect affecting an acinar cell protein can produce exocrine insufficiency leading to a monogenic form of diabetes [158].

Hereditary aspects of idiopathic chronic pancreatitis

Idiopathic chronic pancreatitis (ICP) accounts for most nonalcoholic cases of chronic pancreatitis in the United States and Western Europe. The prevalence of chronic pancreatitis is approximately 1.3 per 1000, with ICP accounting for 20%–30% of these cases [159]. Plugging of the smaller pancreatic ducts is a frequent early finding in ICP [160–162]. In this respect, the histopathology of ICP resembles that of CF pancreatic disease [52]. Idiopathic chronic pancreatitis also resembles CF in that it is associated with abnormal sweat tests [163,164]. These considerations were deemed suggestive that some cases of ICP might result from inadequate ductal fluid and bicarbonate secretion and that *CFTR* mutations might thereby predispose to ICP.

This hypothesis was supported by two reports in 1998 [165,166] and confirmed in further studies in which many ICP patients were comprehensively tested for *CFTR* mutations [44,167–170]. By combining the data in these European and US studies the following conclusions emerge. When *CFTR* DNA testing is performed on ICP patients, CF-causing mutations (CF^{sev} using nomenclature explained above under "Cystic fibrosis") are found in approximately 20% of cases. This is roughly five times the frequency of these mutations in the general population and indicates that ICP risk is increased five-fold in CF carriers on average [171]. Roughly 10% of ICP patients are *CFTR* compound heterozygotes who have one CF^{sev} mutation plus one $CF^{m\text{-}v}$ (mild-variable) mutation. These $CF^{sev}/CF^{m\text{-}v}$ genotypes are rare in the general population and they increase the risk of ICP over 50-fold [171].

The inheritance pattern for CFTR-related ICP is complex. In individuals who have $CF^{sev}/CF^{m\text{-}v}$ gentoypes, the risk of ICP is markedly increased. Nonetheless, most $CF^{sev}/CF^{m\text{-}v}$ individuals do not develop ICP. This is analogous to the occurrence of pancreatitis in 10%–15% of individuals who have pancreatic-sufficient CF lung disease [32,55]. In both cases, the *CFTR* genotype is predisposing, but not sufficient,

to cause pancreatitis (see Table 72.1). Thus, genetic or environmental factors other than the *CFTR* genotype must be important in determining whether ICP develops in any particular CF^{sev}/CF^{m-v} individual.

Patients with ICP who have CF^{sev}/CF^{m-v} *CFTR* genotypes differ from healthy individuals and from others with ICP. Residual CFTR function in the CF^{sev}/CF^{m-v} ICP cases is reduced to roughly 5%–25% of normal by the *CFTR* genotype (see Table 72.1), and this is associated with abnormal or borderline sweat chloride values and also with abnormal nasal bioelectric responses in most cases [44,170]. Many of these ICP patients also have extrapancreatic manifestations of reduced CFTR function, including male infertility, chronic bronchitis with CF-associated pathogens (e.g., *Pseudomonas aeruginosa*) and severe sinopulmonary disease [44,171].

Since 1998, many other candidate genes have been tested to explore whether they might influence an individual's risk of developing ICP. So far, two modifier genes for ICP risk have been identified, *PSTI/SPINK1* and *PRSS2*. For *PSTI*, the N34S variant occurs in roughly 2% of healthy individuals and at seven times this frequency in ICP [44,172–175]. N34S occurs with multiple intronic polymorphisms, and indirect evidence suggests that one or more of these polymorphisms is required for the trypsin inhibitor function of *PSTI* to be affected [176]. The proteins produced by the *PSTI* and *CFTR* genes occur at different sites in the pancreas and these genes probably have independent and additive impact on ICP risk [44]. The *PSTI* N34S variant has also been associated with tropical calcific pancreatitis (OMIM #608189) [177,178] and with alcoholic pancreatitis [179,180].

For *PRSS2*, the G191R variant occurs in 3% of healthy individuals and in 1% of individuals with ICP or alcoholic pancreatitis [181]. Thus, individuals with a G191R allele are protected from pancreatitis. This mutation modifies anionic trypsinogen (the *PRSS2* protein) by creating a new cleavage site where the protein is rapidly digested and degraded, to shift the balance between trypsin activation and inactivation in the acinar cell. The *PRSS1* A16V mutation is a second example of a trypsinogen mutation known to influence ICP risk; as discussed above under "Hereditary pancreatitis," this mutation has been detected in many children who have ICP [121].

Genetic testing and ICP

Testing for the *PRSS1* gene should be considered in younger patients who have ICP (see "Hereditary pancreatitis" above). In a mixed population including sporadic and familial cases of pancreatitis, an HP-causing mutation (R122H or N29I) or an ICP-associated mutation (A16V) was detected in 4% of tested individuals [182].

The role of *CFTR* gene testing in ICP patients is not established. Potential benefits of CF gene testing in ICP include helping patients to understand their disease, promoting early detection of extrapancreatic CFTR-related conditions (e.g., CBAVD), identifying CF carriers for genetic counseling, and identifying rare CF patients in whom ICP occurs before the onset of lung disease. The finding of *CFTR* mutations in an ICP patient may improve medical care and patient satisfaction in cases where physicians might otherwise suspect undisclosed alcohol use.

CFTR mutation testing is more likely to be positive in younger ICP patients and in those who have extrapancreatic evidence of reduced CFTR function (e.g., borderline sweat testing). When ICP patients are tested using CF carrier screening assays, false-negative results are common because many ICP-associated alleles are not represented in the mutation panels used in these assays [44,170,182]; this consideration also limits the use of carrier screening assays to test non-Caucasian ICP patients [183]. Comprehensive DNA testing improves assay sensitivity [169,182], but it can cause misunderstandings when it detects an uncharacterized mutation.

Cystic fibrosis gene testing has major limitations in ICP. Although CF gene testing can identify individuals who have a high ICP risk, it does not predict who will develop ICP because pancreatitis never occurs in most individuals with high-risk genotypes (e.g., *CFTR* compound heterozygotes). For individuals already known to have ICP, the results of gene testing do not affect patient care and guidelines do not exist for genetic counseling in this setting.

When CF is suspected in individual ICP cases, early referral to a CF care center is advised to ensure that the diagnostic evaluation is properly performed, interpreted, and explained. Individuals should not undergo DNA testing until they understand the limitations and risks of this testing. When ICP patients do undergo *CFTR* gene testing, the results should be interpreted cautiously [171]. In one-third of cases, comprehensive CF gene testing will detect at least one abnormal *CFTR* allele [182]; in most of these cases, special expertise will be required to interpret the detected genotype and to explain the test result clearly to the patient. DNA testing should not be used to make a diagnosis of CF except in rare cases where the genotype contains two CF-causing mutations [46]. Although many ICP patients have *CFTR* genotypes containing two mutations, it should be emphasized that few ICP patients have genotypes in which both mutations are known consistently to cause CF. When individuals are incorrectly classified as having CF, this misdiagnosis can cause harm in many ways including effects on employability and insurability [184,185]. CFTR gene-testing data can be difficult to interpret in adults who undergo this testing for nonpulmonary indications. Before explaining the results of this testing to individual patients, published consensus guidelines should be considered [46,186].

Gallbladder and biliary tract: anatomy and structural anomalies

Theodore H. Welling, Diane M. Simeone

Embryological development, 1940
Anatomy of the gallbladder, 1940
Anatomy of the extrahepatic biliary ducts, 1944
Congenital variations and malformations, 1948

The extrahepatic biliary tract has a great number of variations, with a wide range of these variations also seen in the vasculature surrounding the extrahepatic biliary tree. Increasing use of diagnostic and interventional radiology as well as therapeutic endoscopy has made it essential for a wide variety of physicians to become familiar with the anatomy of the extrahepatic biliary tract. This review of anatomy and anomalies of the extrahepatic biliary tree will assist surgeons, gastroenterologists, and radiologists in understanding and recognizing the variations they may encounter.

Embryological development

The biliary tract develops from the primitive gastrointestinal tract, in the distal foregut, as a ventral sacculation; it is first apparent at week 5 of gestation when the embryo is 3 mm long (Fig. 73.1a). This sacculation grows and extends into the ventral mesentery, dividing into two buds: the cranial bud develops into the liver and intrahepatic bile ducts and the caudal bud develops into the gallbladder and cystic duct (Fig. 73.1b). The base of the diverticulum ultimately becomes the common bile duct. Another small bud develops from the proximal aspect of the caudal bud and grows inferiorly, ultimately developing into the ventral pancreas (see Fig. 73.1a,b).

The cranial bud divides into two smaller buds that grow upward toward the septum transversum (future diaphragm). These eventually become the right and left lobes of the liver. The caudal bud is carried superiorly by the growth of the cranial bud and stops at the undersurface of the cranial bud to become the gallbladder and cystic duct (Fig. 73.1c). Rarely, continued advancement of the caudal bud too far superiorly will result in an intrahepatic gallbladder, which is almost always embedded within the right lobe of the liver.

As the cranial and caudal buds are advancing, the ventral pancreatic bud rotates through 180 degrees from right to left, allowing it to fuse with the dorsal pancreatic bud to form the complete pancreas. Fusion of the two parts of the pancreas occurs during week 7 of gestation. Because the lower end of the common bile duct is attached to the ventral pancreatic bud, the rotation results in fusion of the junction of the common bile duct and the duodenum on the posteromedial duodenal wall, posterior to the dorsal pancreatic duct (Fig. 73.1d).

The ventral sacculation from which the biliary tract arises is originally composed of a solid cord of endodermal cells and contains no lumen. Beginning at week 7 of gestation, vacuolization begins to occur and a completely open lumen is formed in the gallbladder, cystic duct, hepatic ducts, and common bile duct within 1 week. By the third month of gestation, bile flow is demonstrable through the canalized biliary tract into the duodenum [1].

Anatomy of the gallbladder

Gross anatomy

The gallbladder is a pear-shaped sac that is located along the inferior surface of the liver in line with the division of the anatomic left and right lobes; it lies in a depression known as the gallbladder fossa (Fig. 73.2). The adult gland is typically 7 cm to 10 cm in length and has an average capacity of 30 mL. The gallbladder is intimately attached to the liver by loose connective tissue, which contains small veins and lymphatics that connect between the gallbladder and liver. Occasionally, one or more small accessory ducts from the liver traverse this connective tissue to enter the gallbladder directly. Inadequate ligation of an accessory duct may account for the occasional bile leak that occurs after cholecystectomy.

The remainder of the gallbladder not in direct contact with liver is covered by peritoneum reflected from the liver. The

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

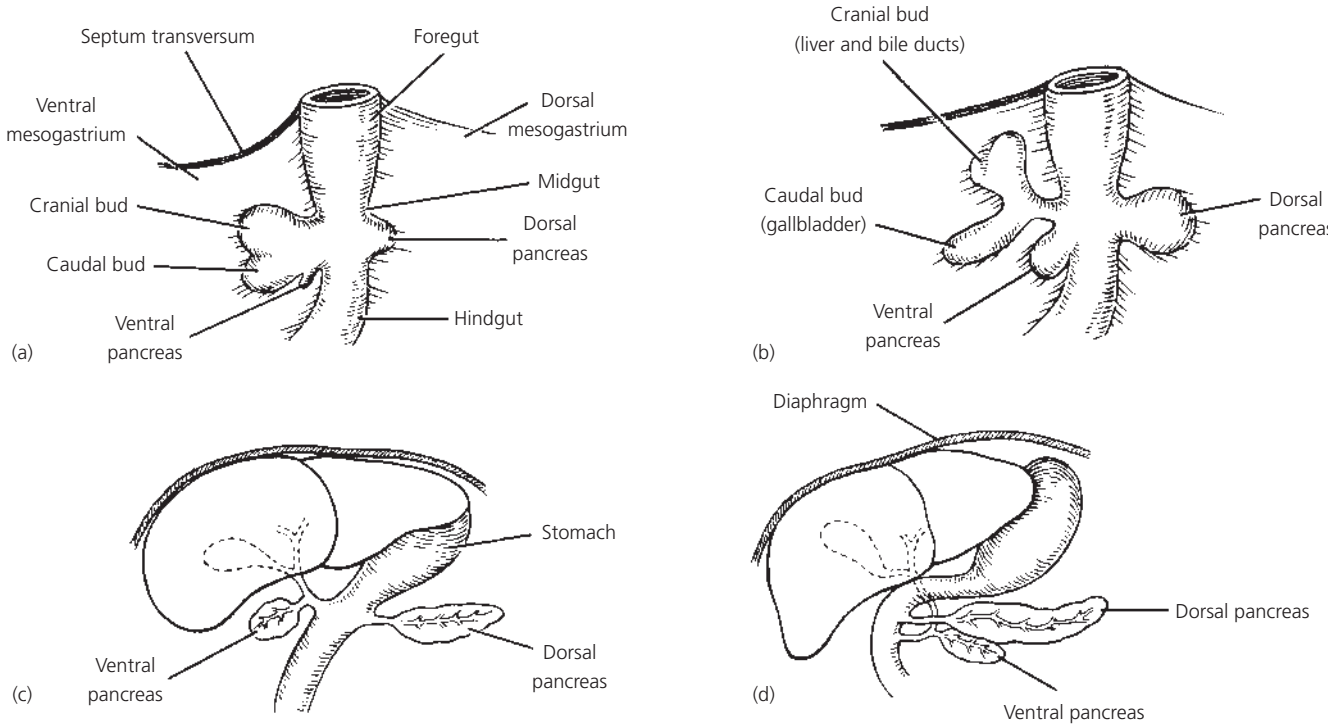

Figure 73.1 Embryology of the developing biliary tract. **(a)** At the 3-mm stage of the embryo, the ventral bud enters the mesogastrium and soon divides into a cranial and a caudal bud. A smaller caudad bud represents the origin of the ventral pancreas. **(b)** As the embryo reaches 5 mm, the cranial bud, which will form the liver and intrahepatic biliary tract, moves toward the septum transversum, pulling the caudal bud, which will form the gallbladder and extrahepatic bile ducts. **(c)** When the embryo reaches 7 mm, the right and left lobe of the liver occupy the position under the septum transversum. The ventral pancreas and the extrahepatic biliary tract are visible. As the ventral pancreas rotates to reach the dorsal pancreas, it pulls the lower end of the common bile duct with it. **(d)** At the 12-mm embryonic stage, the ventral pancreas has rotated, and the anatomic relations between the bile ducts and the gastrointestinal tract have assumed their mature forms.

gallbladder is divided into four anatomical areas: fundus, body, infundibulum, and neck. The fundus is the rounded end of the gallbladder that normally extends 0.5 cm to 1 cm beyond the liver margin and is covered with peritoneum. The fundus rests on the duodenum and hepatic flexure of the colon (see Fig. 73.2) and is in direct contact with the anterior abdominal wall, usually near the lateral border of the right rectus abdominus muscle at approximately the level of the ninth costal cartilage; however, its position may vary. The fundus may occasionally possess a kink, known as a phrygian cap deformity, which has no pathological significance.

The fundus merges imperceptibly into the body, the largest part of the gallbladder, and is the segment that is closely attached to the liver on one side. This intimate contact is responsible for early direct spread of gallbladder carcinoma into the liver. The infundibulum represents a transitional region between the body and neck. It is notable because occasionally a shallow diverticulum may be present on the inferior surface of the infundibulum, referred to as a Hartmann pouch. Gallstones may become impacted within the Hartmann pouch, causing cystic duct obstruction and thus acute cholecystitis.

The neck is a short (usually 5–7 mm) region that tapers into the cystic duct. The neck occupies the deepest part of the gallbladder fossa and lies in the free border of the hepatoduodenal ligament.

Arterial blood supply

The blood supply to the gallbladder is usually from a single cystic artery that arises from the right hepatic artery, traverses the triangle of Calot, and divides into two branches close to the gallbladder wall [2] (Fig. 73.3a). One branch runs along the peritoneal surface of the gallbladder and the other branch runs in the gallbladder fossa between the gallbladder and liver. When the cystic artery arises from the right hepatic artery, its course is often parallel and medial to the cystic duct. Double or accessory cystic arteries have been reported in up to 20% of people. Variations in the site of origin and course of the cystic artery are common. The cystic artery typically arises from the right hepatic artery (95%), but also may arise from the left hepatic artery, the common hepatic artery, an aberrant right hepatic artery that arises from the superior mesenteric artery, the gastroduodenal artery, the superior mesenteric artery, or the celiac axis directly (see Fig. 73.3).

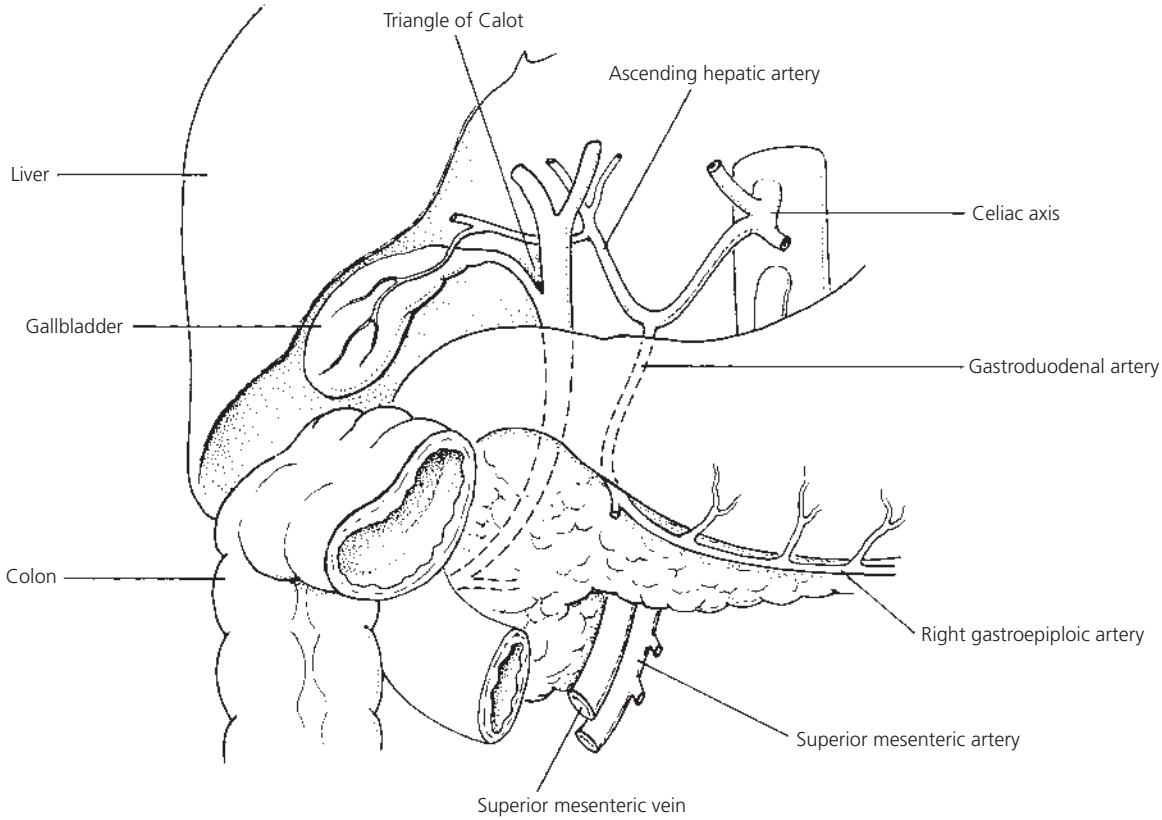

Figure 73.2 Relation of the gallbladder and the extrahepatic biliary tract to the liver, duodenum, colon, and pancreas.

The cystic artery may be short or long, and may pass either behind the hepatic duct (84%) or may cross the hepatic duct anteriorly.

The cystic artery, when it originates from the right hepatic artery, may closely parallel the right hepatic artery for a distance before reaching the gallbladder. In 5%–10% of cases, the cystic artery does not arise from the right hepatic artery until just before it enters the right lobe of the liver, thus creating a short (only a few millimeters) cystic artery. Failure to recognize this may lead to inadvertent ligation of the right hepatic artery during cholecystectomy.

Venous and lymphatic drainage

The gallbladder lacks a major cystic vein but rather drains through a network of small veins. These veins run either from the hepatic surface of the gallbladder directly to the liver or run toward the cystic duct and join venous collaterals from the common bile duct before ultimately draining into the portal vein.

The lymphatic drainage of the gallbladder parallels the venous drainage pattern. Lymph flows directly from the gallbladder to the liver or may drain toward the cystic duct into a single node or group of nodes. From these lymph nodes, lymph may ultimately drain into several nodes along the surface of the portal vein and common bile duct.

Nerve supply

The gallbladder is innervated by branches of both the sympathetic and parasympathetic nervous systems, which pass through the celiac plexus. Preganglionic sympathetic nerves arise from the T8 and T9 levels. Postganglionic sympathetic nerves originate at the celiac plexus and travel along the hepatic artery and portal vein to the gallbladder. Parasympathetic nerves arise from branches of the vagal trunks. Unlike the branches of the posterior vagal trunk, which pass through the celiac plexus, the branches of the anterior vagal trunk reach the gallbladder by way of the gastrohepatic ligament (Fig. 73.4). Visceral pain caused by gallbladder wall distention or inflammation is conducted through afferent sympathetic fibers and is referred to the epigastric, right subcostal, or right scapular regions. The nerve supply to the common bile duct is the same as for the gallbladder.

Although gallbladder contractility is primarily mediated by cholecystokinin (CCK), innervation of the gallbladder also modulates gallbladder contractility. Vagal activity contributes to normal gallbladder tone and enhances the ability of sub-

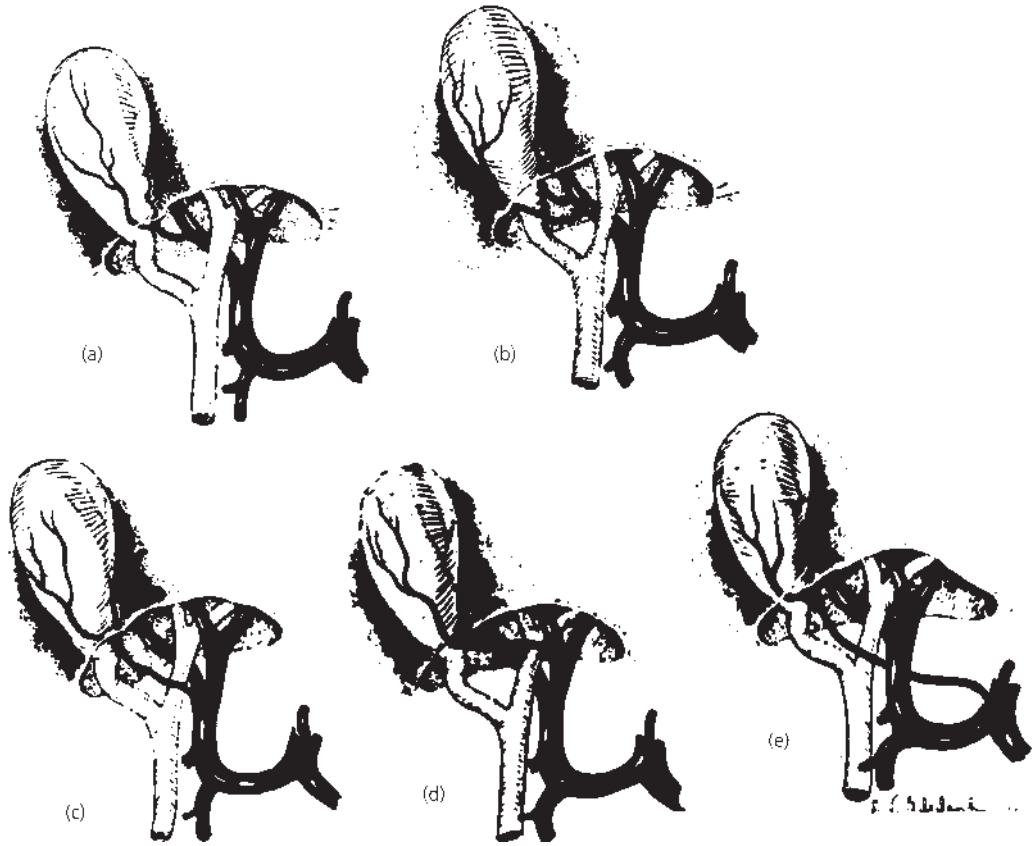

Figure 73.3 Common variations in the origin of the cystic artery. **(a)** It originates most commonly from the right hepatic artery; it traverses the triangle of Calot, and, on reaching the gallbladder, it divides into two main branches. **(b)** Occasionally the two branches come off the right hepatic artery independently. The cystic artery may cross the hepatic duct anteriorly **(c)**, come off the left hepatic artery **(d)**, or, more rarely, come directly from the celiac axis **(e)**. From Lindner [1] with permission from Elsevier.

threshold doses of CCK to promote gallbladder mobility [3]. Sympathetic fibers enhance gallbladder relaxation. In addition to the classic parasympathetic and sympathetic nervous systems, a large number of peptide-containing neurons exist within the gallbladder. The peptides identified thus far by immunocytochemical techniques include CCK [4], vasoactive intestinal polypeptide [4], gastrin-releasing peptide [5], neuropeptide Y [6], pituitary adenylate cyclase-activating polypeptide [7], calcitonin gene-related peptide [7], and substance P [7]. The physiological functions of these peptidergic nerves within the gallbladder remain to be elucidated.

Histology and ultrastructure

The gallbladder has five layers: epithelium, lamina propria, muscularis, perimuscular connective tissue layer, and serosa. The mucosa, lined with a simple columnar epithelium, consists of many folds that increase the efficiency of the gallbladder in concentrating bile. The apical surface of the epithelium is covered with abundant microvilli. The basal surface of the epithelium is in contact with the lamina propria, which is rich in loose connective tissue, elastic fibers, blood vessels, and lymphatics. The muscularis is an arrangement of circular, longitudinal, and oblique fibers without any well-developed layers. Ganglia may be found between the muscle fibers of the muscularis. The subserosa contains loosely arranged collagen and elastic fibers, as well as larger blood vessels and lymphatics. This thick subserosal layer attaches the gallbladder to the liver. Dissection during cholecystectomy usually takes place between the subserosa and serosa, which in normal circumstances is an avascular plane. The serosa is absent from the surface of the gallbladder that is in direct contact with the liver. Mucus is secreted into the gallbladder from tubular alveolar glands found in the mucosa lining the infundibulum and neck of the gallbladder.

At the ultrastructural level, the gallbladder epithelium is well suited for its physiological role of concentrating bile. The columnar epithelial cells have basally located nuclei and apices covered with numerous microvilli that protrude into the gallbladder lumen. Numerous mitochondria are present within the epithelial cells, which facilitate the active process of bile concentration. Epithelial cells are tightly joined together along their lateral membranes by tight junctions, which separate the gallbladder lumen from the intercellular spaces. During active bile concentration, the intercellular

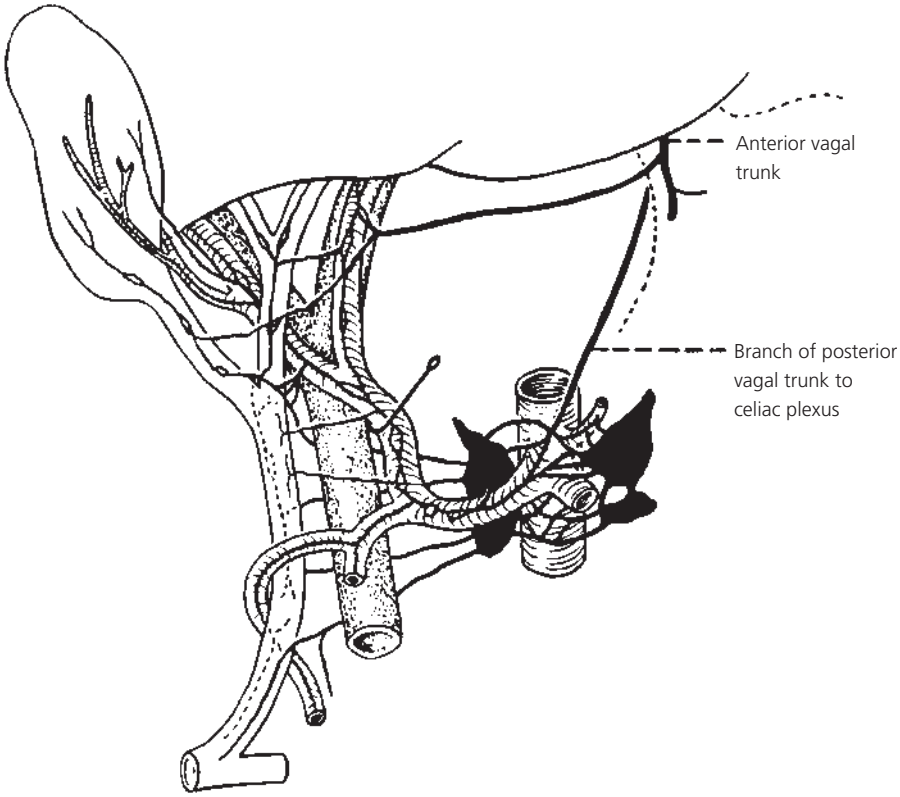

Figure 73.4 Schematic representation of the innervation of the gallbladder and extrahepatic biliary tract. The nerves originate from both vagi and from the celiac axis. They reach the biliary tract, traveling along the walls of the hepatic artery, except for the direct vagal branches of the anterior vagus, which cross through the gastrohepatic ligament.

spaces become distended with water and electrolytes. Water extracted during this process passes into a rich capillary network in the lamina propria.

Anatomy of the extrahepatic biliary ducts

Hepatic ducts

The common hepatic duct is formed by the union of the right and left hepatic ducts. In 95% of cases, this union takes place outside the liver, just below the level of the porta hepatis. In 5% of cases, the left and right hepatic ducts join within the substance of the liver. The lengths of the right and left hepatic ducts vary from 0.5 cm to 2.5 cm in length, with the left hepatic duct usually longer than the right. The ducts may join at a wide or acute angle, depending on their extrahepatic length; however, they usually join about 1 cm below the porta hepatis to form the common hepatic duct. The confluence of the right and left hepatic ducts lies anterior to the portal venous bifurcation, usually overlying the origin of the right branch of the portal vein. An accessory right hepatic duct is present in 10% of people.

Anatomic variations of the hepatic duct confluence most commonly involve the right hepatic duct, with the right anterior and right posterior branches often taking a variable course. The right anterior and posterior branches join to form a common right hepatic duct 60%–65% of the time, whereas the right anterior and posterior duct branches join at the confluence approximately 12% of the time. About 20% of the time, the right anterior duct will join separately onto the common hepatic duct with the right posterior and left hepatic duct joining first to form the common hepatic duct. The common hepatic duct passes downward in the superior portion of the hepatoduodenal ligament and lies anterior to the portal vein and to the right of the hepatic artery (Fig. 73.5). In cases when the cystic duct inserts on the right hepatic duct or at the junction of the union of the right and left hepatic ducts, there is no common hepatic duct. The length of the common hepatic duct varies from 2 cm to 6.5 cm. It joins the cystic duct to form the common bile duct.

The course of the right hepatic artery is variable in relation to the right hepatic duct and common hepatic duct. Usually the right hepatic artery passes posterior to the common hepatic duct near the junction of the right and left hepatic ducts (64%). In 24% of people, the right hepatic artery or the cystic artery may pass anterior to the common hepatic duct. In the remaining patients (12%), the right hepatic artery arises from the superior mesenteric artery and runs parallel and to the right of the common bile duct and posterior to the cystic duct. Because of the inconstant location of the right hepatic artery and its close proximity to the cystic artery, the right hepatic artery may be mistaken for the cystic artery and is particularly vulnerable to injury during biliary tract surgery.

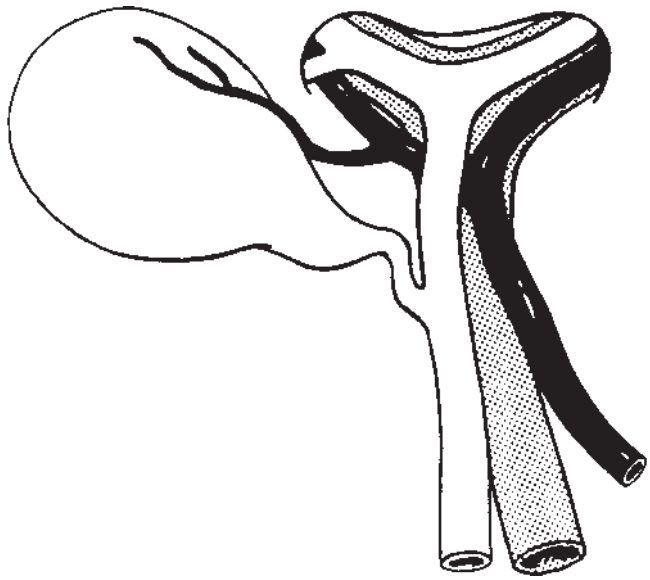

Figure 73.5 Schematic representation of the hilum of the liver. The right anterior and posterior hepatic ducts join to form the right hepatic duct. This duct and the left duct join outside the liver capsule to form the common hepatic duct. The left duct is usually longer and more superficial than the right. The triangle of Calot, with the right hepatic artery and the cystic artery, is also clearly displayed. From Lindner [1] with permission from Elsevier.

The triangle of Calot, originally described in 1891, is bounded superiorly by the hilum of the liver, on the right by the cystic duct, and on the left by the common hepatic duct [8] (see Fig. 73.5). Dissection of the triangle of Calot during cholecystectomy must be carried out with care because many important structures run through this triangle: the right hepatic artery, the cystic artery, 90% of accessory hepatic ducts, and 95% of aberrant right hepatic arteries. In cases when there is a replaced right hepatic artery originating from the superior mesenteric artery, the vessel travels toward the liver in a position posterolateral to the common bile duct and just behind the cystic duct. Here it is vulnerable to injury. Complete dissection of the triangle of Calot, with separation of the base of the gallbladder from the liver bed, allowing identification of the only two structures that should be emanating from the gallbladder, the cystic duct and cystic artery, is critical to avoid injury during cholecystectomy.

Cystic duct

The cystic duct arises from the neck of the gallbladder and joins the common hepatic duct. Its lumen usually measures 1 mm to 3 mm, but it may occasionally be as large as 10 mm, allowing larger gallstones to enter the common bile duct. Whereas the cystic duct typically joins the common hepatic duct directly (70%), the site of the cystic duct junction with the extrahepatic biliary tree may vary from the right hepatic duct down to the level of the ampulla (Figs 73.6 and 73.7). The length of the cystic duct may vary from 0.5 cm to 8 cm.

Figure 73.6 Endoscopic retrograde cholangiopancreatogram demonstrating an anomalous junction of the cystic duct with an accessory right hepatic duct.

The cystic duct may join the right hepatic duct, may run parallel to the common hepatic duct for a distance with connective tissue ensheathing both ducts, and, in some instances, may not enter the common hepatic duct until passing behind the duodenum. Additionally, the cystic duct may spiral around the common hepatic duct, passing either dorsal or ventral to the common hepatic duct before joining it. These anatomic variations may lead to bile duct injury during cholecystectomy, especially if dissection is carried out to clearly define the union of the cystic duct and common bile duct, a practice that is unnecessary during cholecystectomy.

Within the cystic duct, the mucosa forms a series of 5–10 crescent-shaped folds, known as the spiral valves of Heister. They span the length of the cystic duct and project into the cystic duct lumen. These valves serve to prevent excessive distention or collapse of the gallbladder with changes in cystic duct pressure and may function to block the passage of gallstones into the common bile duct. They may make catheterization during intraoperative cholangiogram difficult.

Common bile duct

The union of the cystic duct and common hepatic duct forms the common bile duct. Its length is approximately 7.5 cm, but

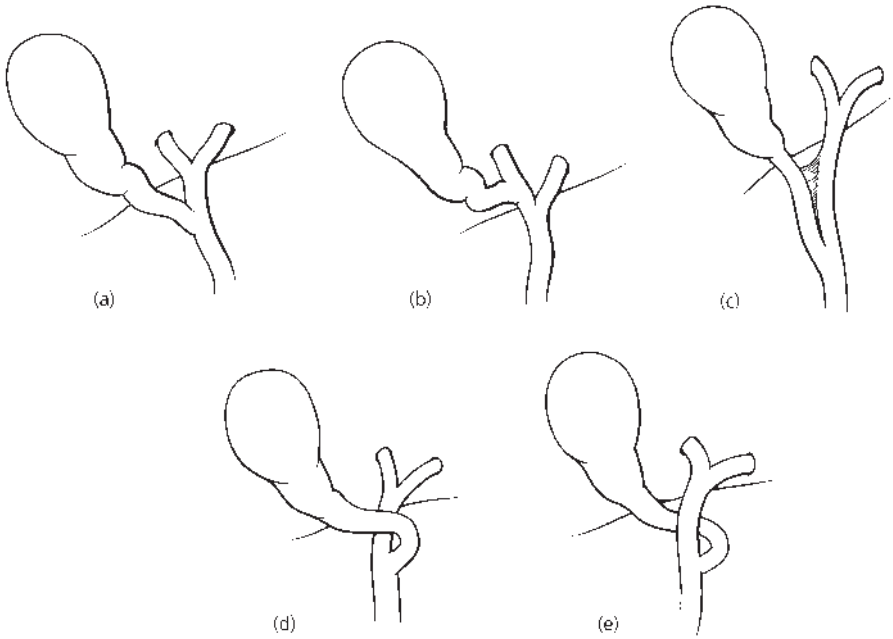

Figure 73.7 Variations in cystic duct anatomy. **(a)** Cystic duct joins common hepatic duct directly (most common). **(b)** Cystic duct joins the right hepatic duct. **(c)** Low junction of cystic duct with common hepatic duct. **(d)** Anterior spiral of cystic duct before joining common hepatic duct. **(e)** Posterior spiral of cystic duct before joining common hepatic duct.

this can vary depending on the relative lengths of the cystic and common hepatic ducts. The mean diameter of the common bile duct is about 6 mm, but it may dilate significantly in the face of distal obstruction. The common bile duct is divided into four anatomic segments: supraduodenal, retroduodenal, pancreatic, and intraduodenal. The supraduodenal segment is usually 2.5 cm in length and is located in the right border of the hepatoduodenal ligament. It lies anterior to the portal vein and to the right of the ascending common hepatic artery. This anatomic relationship allows the surgeon to compress these three structures between an index finger inserted through the foramen of Winslow into the lesser sac and a thumb placed anteriorly across the hepatoduodenal ligament. This maneuver is referred to as the Pringle maneuver and allows rapid occlusion of the blood supply to the liver, which is useful for controlling major liver hemorrhage.

The retroduodenal segment lies posterior to the first part of the duodenum and is about 2.5 cm to 4 cm long. As it runs to the inferior surface of the duodenum, it moves right to left, lying just to the right of the gastroduodenal artery. The retroduodenal common bile duct is loosely attached to the duodenum by a thin layer of areolar tissue. The close relationship of this portion of the common bile duct and the duodenal bulb means that it may occasionally be involved in the inflammatory process of a posterior penetrating duodenal ulcer and may be inadvertently injured during antrectomy.

The pancreatic segment of the common bile duct extends from the lower border of the first part of the duodenum to the posteromedial wall of the second portion of the duodenum where the duct penetrates the duodenal wall. It may be entirely retropancreatic, or it may lie within the substance of the head of the pancreas. Obstruction of this segment of the common bile duct is common with cancers of the pancreatic head, which often initially present with painless jaundice.

The common bile duct then turns 90 degrees to the right to enter the posteromedial wall of the descending duodenum. The final, or intraduodenal, segment of the common bile duct is about 2 cm long and travels obliquely through the duodenal wall with the main pancreatic duct. The common bile duct may join the main pancreatic duct outside the duodenum, or the ducts may form a common channel as they traverse through the duodenal wall, in both of these cases opening through a single ostium on the major ampulla of Vater. This site is typically 7 cm to 10 cm from the pylorus. From the inside of the duodenal lumen, the termination of the ampulla appears as a small, protruding, nipple-like structure marked by a longitudinal duodenal fold. In 29% of cases, a septum persists between the two ducts, and the ducts empty on the papilla as separate ostia.

Ampulla of Vater

Union of the common bile duct and the main pancreatic duct forms the ampulla of Vater. The length of the ampulla is variable, and if there is no junction of the common bile duct and main pancreatic duct, there is no true ampulla of Vater. Rienhoff and Pickrell [9] studied the pancreatic duct system in 250 autopsy specimens. They found an ampulla longer than 2 mm in 46% of cases (range from 3 mm to 14 mm), an ampulla less than 2 mm in 32% of cases, and no junction of the pancreatic and bile ducts in 29% of cases.

The common bile duct narrows significantly as it passes through the wall of the duodenum, and the ampulla narrows before it enters the duodenal lumen. These narrowings

are frequent sites for stones to lodge and cause either biliary or pancreatic obstruction. Additionally, these are potential sites of injury when instrumented during common bile duct exploration.

Sphincter of Oddi

The intraduodenal segment of the common bile duct and the ampulla is surrounded by a sheath of smooth muscle fibers referred to collectively as the sphincter of Oddi. The sphincter of Oddi is a unique group of muscle fibers that arise from the bile duct wall and manometric studies have verified that the sphincter acts independently of the duodenal musculature. The resting pressure of the sphincter of Oddi is approximately 13 mmHg above duodenal pressure [10]. Regulation of bile flow is primarily controlled by the sphincter of Oddi. Relaxation of the sphincter occurs with CCK stimulation and is facilitated by parasympathetic stimulation. Sympathetic stimulation causes increased sphincter tone.

The preampullary portion of the common bile duct is invested in a sheath of circular muscle referred to as the sphincter choledochus (sphincter of Boyden) (Fig. 73.8). The distal main pancreatic duct may have a short sphincter called the sphincter pancreaticus. If present, the sphincter pancreaticus and sphincter choledochus may intertwine in a figure-of-eight manner. The smooth muscle sheath surrounding the ampulla is called the sphincter of the ampulla; if there is no ampulla, the distal sphincter is simply called the sphincter of the papilla. During endoscopic sphincterotomy, the sphincter of Oddi is divided using electrocautery to relieve common bile duct obstruction from a common duct stone.

Arterial blood supply

The arterial blood supply to the extrahepatic bile ducts is segmental; because of the segmental nature of the blood supply, extensive mobilization of the extrahepatic bile ducts may lead to ischemic injury and development of postoperative biliary stricture and should therefore be avoided [11]. The hepatic ducts and the supraduodenal portion of the common bile duct are nourished by small arterial branches from the cystic artery (Fig. 73.9). The retroduodenal portion of the common bile duct is supplied by branches of the retroduodenal and posterior superior pancreaticoduodenal arteries. The

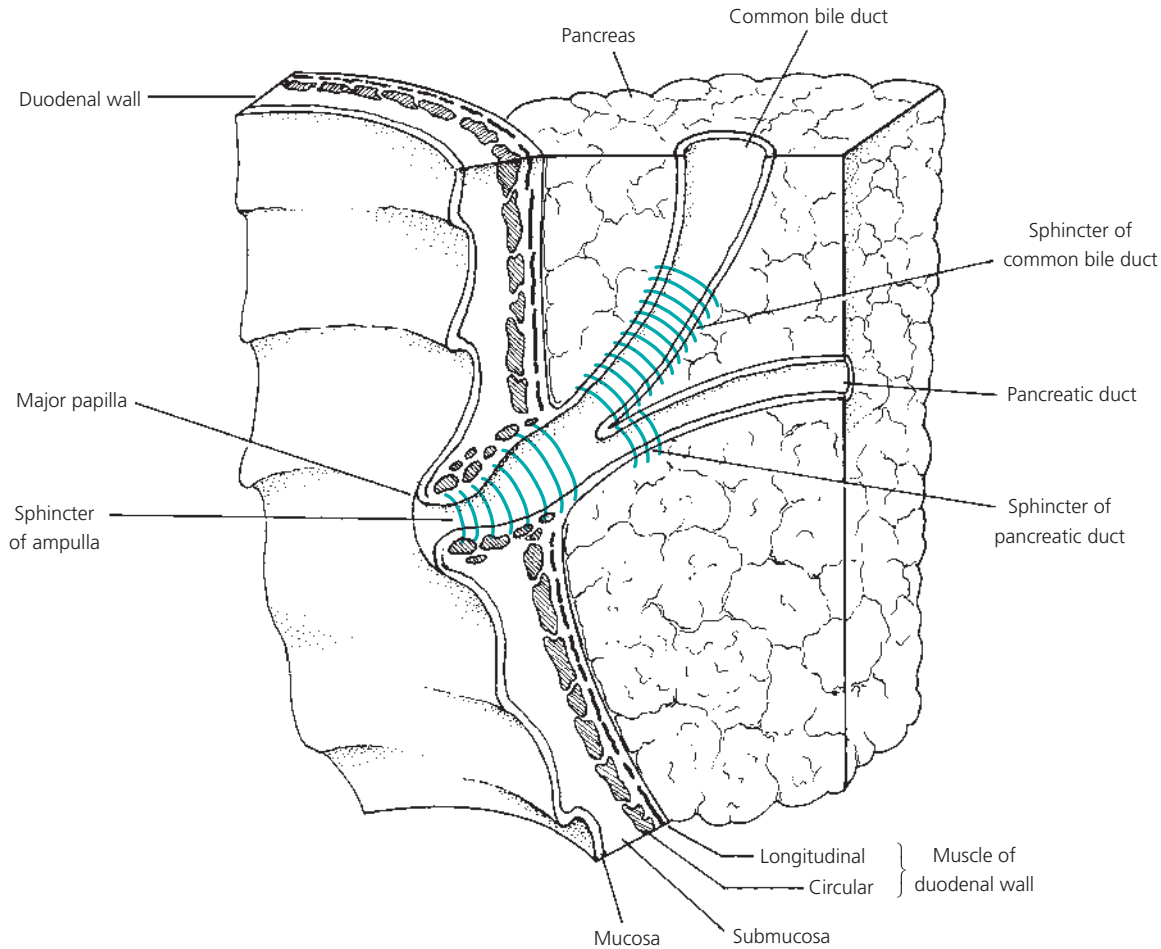

Figure 73.8 The muscular apparatus at the terminal end of the common bile duct. The bile duct is closely associated with the pancreatic duct, and they both enter the medial wall of the duodenum tangentially. Each duct has its own sphincter, which is poorly developed in the pancreatic duct.

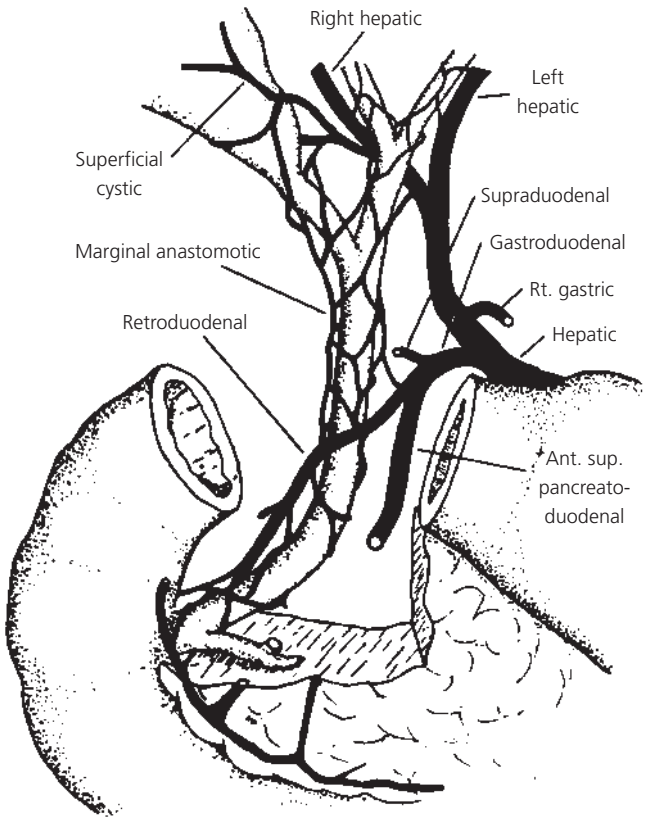

Figure 73.9 The extrahepatic biliary tract is supplied by a rich vascular net of vessels from the hepatic and gastroduodenal arteries. The relationship between the hepatic arteries and the extrahepatic biliary tree is evident.

pancreatic and intraduodenal segments of the common bile duct are supplied by both the anterior and posterior superior pancreaticoduodenal arteries.

Venous and lymphatic drainage

The veins of the hepatic ducts and proximal common bile duct, like those from the gallbladder and cystic duct, enter the liver directly. Veins from the lower portion of the common bile duct drain into the portal vein. The lymphatic drainage from the hepatic ducts and upper common bile duct flows superiorly along the course of the common bile duct to lymph nodes in the porta hepatis. Some lymphatic drainage arising from the inferior portion of the common bile duct may reach the deep pancreatic nodes near the origin of the superior mesenteric artery. All lymphatic drainage ultimately reaches the celiac lymph nodes.

Histology and ultrastructure

The mucosa of the extrahepatic bile ducts contains columnar epithelium surrounded by a layer of connective tissue. The epithelium contains many mucous glands. Muscle fibers in the hepatic ducts and proximal common bile duct are relatively few and discontinuous, and may be arranged in either a longitudinal or a circular direction. As the common bile duct approaches the duodenum, it begins to develop a more substantial muscle layer, which merges into the sphincter of Oddi complex, where distinct bundles of muscle fibers are evident.

Congenital variations and malformations

Gallbladder and cystic duct

Congenital anomalies of the gallbladder may be classified into three different categories: anomalies of number, anomalies of form, and anomalies of position. Duplication of the gallbladder is thought to occur in approximately one of every 4000 human gallbladders [12]. With complete duplication, the gallbladders are separate, and the cystic ducts may join one another before entering the common duct or each cystic duct may enter separately. Partial duplications can result in bilobed gallbladders (Fig. 73.10a), in which the two gallbladder cavities are separate at the fundus but joined at the neck and drain through a common cystic duct. Gallbladders may also be septate (divided by a partial or complete septum) with septa present in either a longitudinal or transverse direction, the latter referred to as an hourglass gallbladder (Fig. 73.10b). Septate gallbladders are thought to be a result of incomplete vacuolization of the solid endodermal cord during development. None of these abnormalities of the gallbladder by themselves have clinical significance unless they are involved in a pathological process.

Lack of development of the gallbladder bud results in agenesis of the gallbladder. Most cases are associated with extrahepatic biliary atresia [13]. In the absence of associated biliary atresia, an intrahepatic gallbladder or left-sided gallbladder must be ruled out before the diagnosis is made.

Abnormal migration of the caudal bud (future gallbladder and cystic duct) of the ventral diverticulum during development may cause an anomalous gallbladder position. If the caudal bud advances beyond the cranial bud (future liver), it may become buried in the liver substance, creating an intrahepatic gallbladder. These are usually identified by ultrasonography before cholecystectomy and may make cholecystectomy slightly more difficult. If the caudal bud lags behind the cranial bud, a floating gallbladder is created. A floating gallbladder is a gallbladder that is completely covered with peritoneum; it is usually suspended from the liver by a mesentery. A floating gallbladder is at a higher risk for torsion. Left-sided gallbladders are rare, but they have been described in the setting of situs inversus (all abdominal viscera are reversed right for left) or in the setting in which the gallbladder alone is transposed [12]. The gallbladder has also been found in other unusual locations such as the falciform ligament [14], the abdominal wall [15], and the retroperitoneum [16]. Regardless of the anomalous position of the gallbladder, it is important to realize that in almost all cases

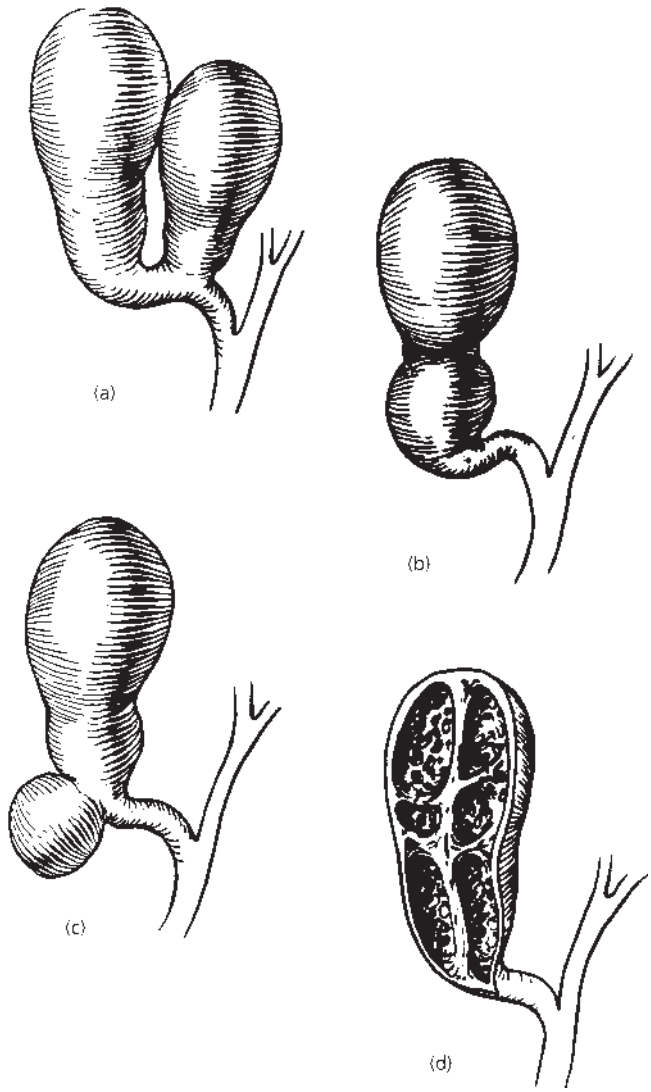

Figure 73.10 Two gallbladders **(a)**, a bilobed gallbladder **(b)**, a diverticulum at the neck **(c)**, and a septated gallbladder **(d)** are all anatomic variations that relate to the embryological development of the biliary tract. From Lindner [1] with permission from Elsevier.

the cystic duct will inevitably join the common bile duct in a relatively normal position.

Abnormal development of the gallbladder bud may also cause anomalies in the cystic duct. Double cystic ducts may drain a single, nonseptate gallbladder and join the biliary system at the common bile duct or right hepatic duct. There may be absence of the cystic duct, and, in this case, the neck of the gallbladder drains directly into the common bile duct. Failure to recognize this anomaly has resulted in excision of a segment of the common bile duct during cholecystectomy in which the common bile duct has been mistakenly identified as the cystic duct. Liberal use of intraoperative cholangiography has been emphasized when intraoperative anatomy is confusing or anomalies are present.

Hepatic ducts and common bile duct

True accessory hepatic ducts result from the development of an extra bud from the biliary anlage during development. Accessory ducts are much more common on the right than the left. They may drain directly into the gallbladder, the right or left hepatic ducts, the cystic duct, or the common bile duct. Accessory hepatic ducts are present in about 10% of individuals. Cystohepatic ducts that drain bile directly from the liver to the gallbladder are rare. Aberrant hepatic ducts, unlike true accessory ducts, result from an extrahepatic course of a duct that is normally contained within the liver parenchyma. Accessory ducts provide a second drainage route from a region of the liver, in contrast to an aberrant duct, which represents the only drainage to a particular region of the liver, but lies in an unusual location. Almost all aberrant hepatic ducts represent the right anterior segmental duct, which joins the right posterior segmental duct outside the liver. This extrahepatic union occurs in about 10% of cases and may result in mistaken identification of the right anterior segment duct as the cystic duct during cholecystectomy, with inadvertent ligation [17]. Both aberrant and true accessory hepatic ducts are at equal risk for injury during cholecystectomy.

Anomalies in the common bile duct do exist but are uncommon. The common bile duct may contain two lumens but appears to be single externally. The common bile duct may be completely duplicated, with one duct draining the right lobe of the liver and one duct draining the left lobe. Duplicated ducts usually empty separately into the duodenum [18,19]. Rarely, the common bile duct may open into the gastrointestinal tract at an ectopic site. The common bile duct has been reported to drain into the stomach [20] and the duodenal bulb [21], as well as the distal duodenum [22,23].

Biliary atresia

Biliary atresia is defined as the obliteration of the extrahepatic or intrahepatic bile ducts, with many different variations described (Fig. 73.11). The incidence of biliary atresia is 1 per 15 000 births. Between 10% and 15% of patients with biliary atresia have associated anomalies of the inferior vena cava (absence), portal vein (preduodenal portal vein), intestine (intestinal malrotation), and spleen (polysplenia) [24]. Most patients have a form of biliary atresia with complete obstruction of the gallbladder and extrahepatic bile ducts, whereas 10%–15% of patients have obstruction of the proximal hepatic ducts with patency of the gallbladder and distal common bile duct. Only 1%–2% of patients have proximal hepatic duct patency.

In biliary atresia, the bile ducts are replaced by dense fibrotic tissue containing evidence of both an acute and chronic inflammatory process [25]. Typically, there is obliteration of the entire extrahepatic biliary tract, including the gallbladder. Extrahepatic biliary atresia frequently extends into the intrahepatic bile ducts, probably as an end result of a

Figure 73.11 The different forms of biliary atresia. Biliary atresia may be partial, affecting the intrahepatic or extrahepatic portions of the biliary tract, or it may be a complete process **(d)**. From Lindner [1] with permission from Elsevier.

destructive process leading to fibrosis and obliteration of the biliary tree, with development of secondary biliary cirrhosis [26]. If left untreated, the typical course is one of progressive hepatic insufficiency, with an average survival of 12–19 months [27].

The pathogenesis of biliary atresia is not known. Existing data seem to contradict the theory that failure of recanalization of the bile ducts during development is the cause. Data accumulated from the surgical experience using portoenterostomy have provided some insight into the disease process. Early establishment of bile drainage, typically before 60 days, can reverse the liver injury and is associated with long-term survival, whereas delay in establishing bile drainage until after 120 days is often associated with progression of cirrhosis and a poor outcome. In addition, infants who develop biliary atresia are rarely jaundiced at birth and frequently have bile-stained meconium; biliary atresia has rarely been demonstrated in autopsy studies of fetuses [28]. These observations suggest that biliary atresia is a dynamic process targeting the extrahepatic bile ducts, with progressive destruction rather than a static process. The best available data suggest that 80% of cases are secondary to infection with a cholangiotropic virus such as cytomegalovirus, reovirus, or rotavirus, followed by an exuberant immune response destructive to the ductal epithelium that may persist even after eradication of the offending agent [29–32].

The clinical presentation of biliary atresia is progressive neonatal jaundice with an onset in the first few weeks of life. Jaundice usually becomes visible in the first 2–4 weeks of life. Biliary atresia must be differentiated from neonatal physiologcial jaundice, as well as from congenital infectious causes, such as cytomegalovirus and rubella, and genetic diseases, including α_1-antitrypsin deficiency.

Technetium 99m-iminoacetic acid (^{99m}Tc-IDA) hepatobiliary scanning is the imaging test of choice for biliary atresia, especially when preceded by a 5-day to 7-day course of phenobarbital to increase bilirubin conjugation and excretion. The sensitivity of the test for biliary atresia is 100%, with a specificity of 94% [33]. An abdominal ultrasound should also be performed as a standard part of the evaluation of the jaundiced infant and is helpful to evaluate the possibility of other sources of biliary obstruction. Liver biopsy is nondiagnostic in up to 25% of patients and is often unnecessary to make a diagnosis.

Mortality associated with medical management of biliary atresia is close to 100% so surgical therapy has become the treatment of choice. The standard operation, hepatic portoenterostomy, termed the Kasai procedure, was first described by Kasai and Suzuki in 1959 [34] following their original observation of residual microscopic bile channels in the fibrous tissue of the porta hepatis in patients with biliary atresia. The Kasai procedure consists of exploratory laparo-

tomy with excision of the occluded extrahepatic biliary system and a Roux-en-Y enteric anastomosis to the transected fibrotic cord at that level of the porta hepatis where microscopic bile ducts have been documented by frozen section. Primary hepatic transplantation is reserved for patients with a delayed diagnosis and advanced cirrhosis at presentation or patients with failed Kasai procedures [35].

Most series report a 40%–60% 5-year survival rate following portoenterostomy [36,37]. In general, one-third have good long-term results with minimal or no liver dysfunction and normal growth and development, one-third do poorly and are dependent on immediate liver transplantation for survival, and one-third have slow, progressive liver dysfunction over a period of months to years and subsequently need liver transplantation. Although the failure rate is fairly high, the fact that one-third of patients will do well and never require transplantation and another subset will experience normal growth for a period of years before potentially requiring transplantation, in addition to the shortage of transplantable organs, has prompted centers to use the Kasai procedure as first-line therapy for biliary atresia [38–40].

Choledochal cyst

Autopsy studies of Egyptian and Chinese mummies have shown that gallbladder stones have existed for more than 35 centuries. Today, over 20 million Americans have gallstones, and more than 700 000 cholecystectomies are performed annually in the United States. Gallstone-related symptoms and complications are among the most common gastroenterological disorders requiring hospitalization, at an estimated annual cost of almost $6.5 billion. This chapter summarizes the epidemiology, pathogenesis, clinical manifestations, and evolving treatment of gallstones.

Epidemiology

This disease is nonfatal and often asymptomatic so the diagnosis of gallstones is not always made before death. Clinicopathological studies suggest that approximately two-thirds of the population with gallstones are asymptomatic [1]. Methods most commonly used to determine gallstone prevalence include autopsy studies, determination of cholecystectomy rates, and ultrasonography. Gallstones are generally classified as cholesterol stones, pigment stones, and mixed stones. In most Western countries, more than 75% of gallstones are the cholesterol type.

Gallstone prevalence increases with age, and gallstones are more prevalent in females of any age group [2]. The prevalence of gallstones varies widely in different countries and among different ethnic groups in the same country. The wide scatter in gallstone prevalence among different nations and ethnic groups is strong evidence that genetic factors are involved in gallstone formation. Those with the highest prevalence of gallstones are the Pima Indians of North America, Chileans, and Caucasians in the United States [1,3,4]. Next are the populations of Sweden, Germany, and Austria, followed by New Zealand, Great Britain, Norway, Ireland, and Greece [5–9]. The Asian populations in Singapore and Thailand have the lowest prevalence of gallstones [10,11]. Animal models have been developed that may help in the identification of genetic factors for gallstones [12–14].

The type of gallstone also varies among cultures. In developed countries, cholesterol gallstones are most common and usually occur in the gallbladder. In Africa and Asia, where the prevalence of gallstones is low, pigment gallstones are most common, and stones also can be found in the bile ducts.

Progressive increases in the prevalence of gallstones support a role for environmental factors in their pathogenesis. Cholecystectomy rates partly reflect the provision of medical services, and the prevalence of gallstones at autopsy may vary even within a country during a given time period. Nevertheless, several studies have shown increases in the prevalence of gallstones over time [8,15–17]. The Westernization of Japan since World War II is one example. Since the late 1940s, the prevalence of gallstones in Tokyo has more than doubled, and there has been a change from pigment to cholesterol gallstones [16]. In Saudi Arabia over a 10-year period, the frequency of cholecystectomy increased sharply, a rise not matched by the increase in population, use of medical services, or number of other surgical procedures. A shift to a more Western diet has been suggested as a possible explanation [18].

Recent studies have shown significant effects of lifestyle and behavioral factors, including obesity, physical activity, diet, and medications, in predisposing to both symptomatic and asymptomatic gallstones. For example, the risk of asymptomatic or symptomatic gallstones increases with increasing body mass index [19,20], with central obesity appearing to be more significant than peripheral obesity [21,22]. Both men and women who have low levels of recreational physical activity are at higher risk for cholecystectomy [23,24]. Diets high in carbohydrates and especially simple sugars, low in vegetable proteins, and low in fiber have also been

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

associated with symptomatic gallstones [25–28]. Medications including thiazide diuretics and estrogen replacement therapy may increase the risk of symptomatic gallstones [29,30].

Etiology

Pathogenesis of cholesterol gallstones

The total body pool of cholesterol is supplied by de novo synthesis from acylcoenzyme A (acyl-CoA) and dietary absorption [31,32]. Approximately 20% of biliary cholesterol comes from new hepatic synthesis [33,34]. The remainder originates from a preformed pool within the liver [35,36]. Important contributors into the hepatic pool include hydrolysis of cholesteryl ester stores, dietary sources as chylomicrons, and direct hepatic and extrahepatic synthesis of the lipoproteins high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL). Total hepatic cholesterol is tightly regulated within a narrow range [37,38]. Cholesterol can be eliminated from the body by biliary excretion or by conversion to bile acids (Fig. 74.1). The association of gallstones with serum cholesterol levels is not straightforward; although gallstones may be linked to decreased serum HDL cholesterol and increased serum triglyceride levels, no such association has been found for total serum cholesterol levels [39,40].

Various defective metabolic states can disrupt this regulatory balance, resulting in absolute biliary cholesterol hypersecretion or relative bile acid hyposecretion and predisposing to gallstone formation. Both defects can coexist, as in the case of the Pima Indians [41].

Several mechanisms may be operative in biliary cholesterol hypersecretion [42–46]. Clinical situations associated with excessive secretion of biliary cholesterol include obesity, aging, drug effects, and hormonal therapy [47]. Nonobese patients with gallstones may have higher intracellular levels of total and free cholesterol, suggesting enhanced intracellular cholesterol transport [48]. Table 74.1 summarizes some of these examples and the proposed underlying pathogenesis. Animal studies have shown that there are specific genes that determine susceptibility to cholesterol stone formation in mice [12,14]. Further work has identified the bile salt export pump as a candidate protein for the *Lith1* gene [49]. Other candidate genes associated with gallstones in mice include those for hydroxy-methyl-glutaryl-CoA (HMG-CoA) reductase, canalicular multispecific organic anion transporter (Cmoat), intracellular lipid transporters (Pctp and Fabp6), lipoprotein lipase, and lecithin-cholesterol acyltransferase [14]. The human homologues to these animal genes are still being identified. Recent studies in humans have shown that dysfunction of the MDR3 protein, a phosphatidylcholine transporter found in the biliary canalicular membrane, predisposes to

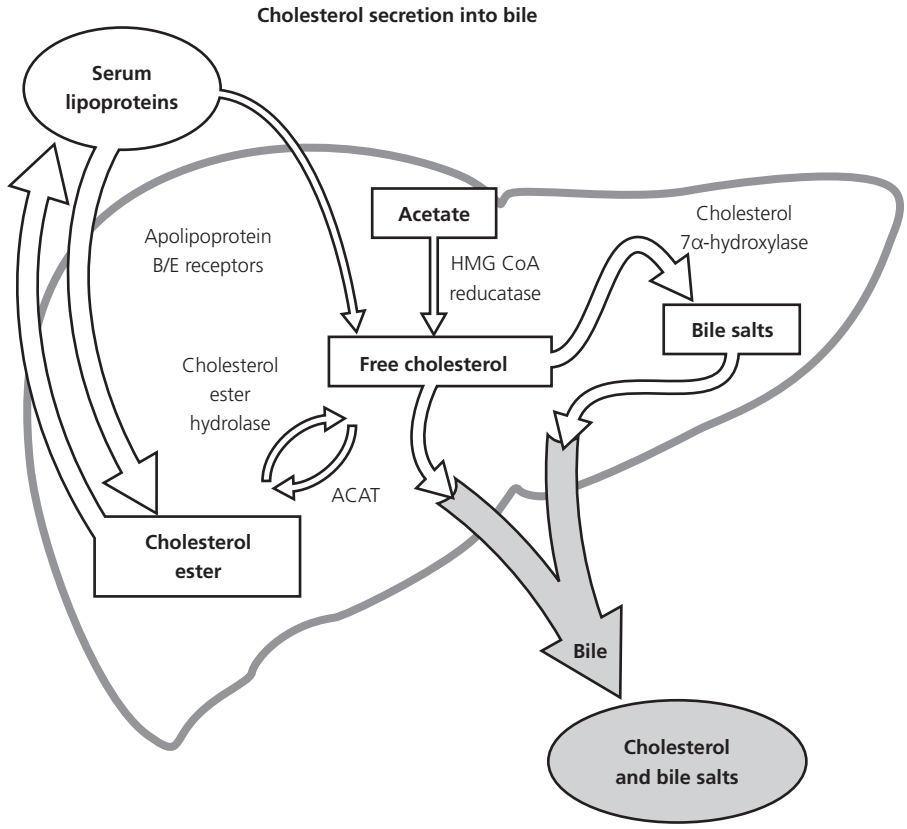

Figure 74.1 Schematic representation of cholesterol and bile acid metabolism in the liver. The liver is the major site for cholesterol synthesis and metabolism in the liver. The free pool of cholesterol in the liver is derived from de novo cholesterol synthesis or uptake from plasma lipoproteins. Cholesterol synthesis from acetate is regulated by hydroxy-methyl-glutaryl-coenzyme A (HMG-CoA) reductase. Cholesterol may be esterified by acyl:cholesterol:lecithin transferase (ACAT) for storage in the cholesterol ester pool in the body. Cholesterol may be eliminated from the body by secretion into bile or by transformation into bile acids through the rate-limiting enzyme 7α-hydroxylase.

Table 74.1 Risk factors associated with cholesterol hypersecretion in bile

Clinical examples	Pathogenesis
Obesity, hyperlipoproteinemia	Increased hydroxymethylglutaryl-coenzyme A activity leading to increased mevalonic acid and cholesterol synthesis
Progesterone, oral contraceptives, clofibrate	Inhibition of hepatic acyl-coenzyme A cholesterol acyltransferase activity leading to decreased conversion of cholesterol to cholesteryl ester stores
Estrogens	Increased lipoprotein receptors B and E leading to increased hepatic cholesterol uptake; inhibition of 12α-hydroxylase leading to decreased synthesis of chenodeoxycholic acid
Selected nonobese Japanese	Increased hepatic intracellular transport of cholesterol
Selected nonobese Caucasians	Reduced activity of 7α-hydroxylase leading to a defect in conversion of cholesterol to bile acids; increased enterohepatic cycling of bile acids, leading to increased biliary deoxycholate levels
Age	Age-related decrease (?) in 7α-hydroxylase activity
Marked weight reduction	Mobilization of tissue cholesterol

formation of intrahepatic and gallbladder cholesterol stones [50–53]. In addition, the *ApoE4* genotype has been linked to an increased prevalence of cholesterol gallstones in humans [54–56]. Apolipoprotein E (ApoE), a lipid transfer protein, is reported to be associated with stones with high cholesterol content [55], faster dissolution when treated with ursodeoxycholic acid, and higher recurrence rates after lithotripsy [56]. ApoE may have a role in the regulation of biliary cholesterol secretion [57]. The role of genetic factors and their interactions with other environmental factors deserves further study in humans.

More recent data have shown a role for serum leptin in regulating biliary cholesterol secretion. Leptin is a hormone produced by adipocytes, and its levels correlate strongly with body mass index. Studies of leptin-deficient and leptin-resistant mice have shown that higher leptin levels may mediate biliary cholesterol saturation and gallbladder motility [58–62], therefore providing a possible molecular link between body mass index, cholesterol supersaturation of bile, and ultimately cholesterol gallstone formation.

Alternatively, relative bile acid hyposecretion may lead to biliary cholesterol supersaturation (Table 74.2) [63–65]. A diminished bile acid pool and secretion rate may result from excessive intestinal losses or decreased production. In nonobese patients with cholesterol gallstones, cholic acid and chenodeoxycholic acid pools are reduced, and deoxycholic acid is often increased in bile [65]. Conversion of cholic acid to deoxycholic acid, possibly in the small intestine or by colonic bacteria, may account for these changes [66,67]. Deoxycholic acid concentrations in bile are increased with prolonged transit time, potentially linking intestinal transit to gallstone formation [67,68]. With an expanded deoxycholate pool in bile, biliary cholesterol secretion rises [69].

Cholesterol solubilization

Free cholesterol is virtually insoluble in aqueous solution. Bile acids, because of their unique amphipathic properties, are able to solubilize cholesterol and phospholipids in mixed micelles [70,71]. Phase equilibrium diagrams can be constructed to characterize cholesterol solubility in a defined

Table 74.2 Risk factors associated with relative bile acid hyposecretion

Clinical examples	Pathogenesis
Ileal disease, bypass, or resection	Impaired bile acid absorption or excessive losses
Cerebrotendinous xanthomatosis	Inherited 26-hydroxylase deficiency leading to incomplete oxidation of the cholesterol side chain and decreased bile acid production
Congenital 12-hydroxylase deficiency	Decreased cholate and deoxycholate synthesis
Selected nonobese Caucasians	Excessive feedback suppression of bile acid synthesis leading to a decreased pool, hepatic return, and secretion
Primary biliary cirrhosis, chronic cholestasis	Decreased bile acid secretion

milieu of various lipid concentrations. Using these data, the cholesterol saturation index can be calculated [72]; this is the ratio of the actual amount of cholesterol in a given bile sample to the maximal cholesterol carrying capacity of that sample determined in vitro. Bile that has a cholesterol saturation index greater than 1 is considered supersaturated. Supersaturated bile that does not form cholesterol crystals is called metastable.

In addition to classic micelle packaging, cholesterol can be solubilized with phospholipid (principally phosphatidylcholine) as unilamellar vesicles ranging in size from 40 nm to 100 nm [73–76]. Vesicles consist of a bilayer of phospholipid interdigitated with cholesterol, without associated bile acids. These vesicles are thought to be assembled within the hepatocyte and then transported to the biliary canaliculus [77]. Vesicles comprise a separate and distinct carriage system that probably represents the major mode of cholesterol transport from the hepatocyte.

Bile acid secretion is the primary driving force behind the biliary secretion of cholesterol and phospholipid [78–79]. As bile acids are actively secreted against a gradient into the canaliculus, they induce the subsequent secretion of cholesterol–phospholipid vesicles into bile. Hydrophobic bile acids are more effective in provoking lipid secretion, although the maximum rate of biliary lipid secretion is similar for all bile acids [80]. Within the canaliculus, the bile acid concentration increases, reaching a micellar concentration that allows conversion to mixed micellar carriers. This interchange continues in a dynamic fashion within the ductules, ducts, and gallbladder [81]. The relative percentage of cholesterol transported in the micellar fraction can vary dramatically, depending on the physiological conditions. For example, at low bile acid secretion rates, as with fasting, the predominant form of cholesterol carriage in hepatic bile is vesicular [73,74]. Conversely, the higher bile acid concentration in the gallbladder favors a shift toward micelle formation (Fig. 74.2 and Fig. 74.3) [73,74].

The cholesterol present in gallstones consists of oxidized species (oxysterols) [82]. The presence of oxysterols also correlates with the presence of bacterial DNA, suggesting that they might be products of biliary cholesterol oxidation as a result of bacterial–leukocyte interactions and generation of reactive oxygen species [83]. The presence of these oxysterols may also affect mucin secretion. Whether these oxysterols contribute to gallstone formation, chronic inflammation or cancer development is unknown.

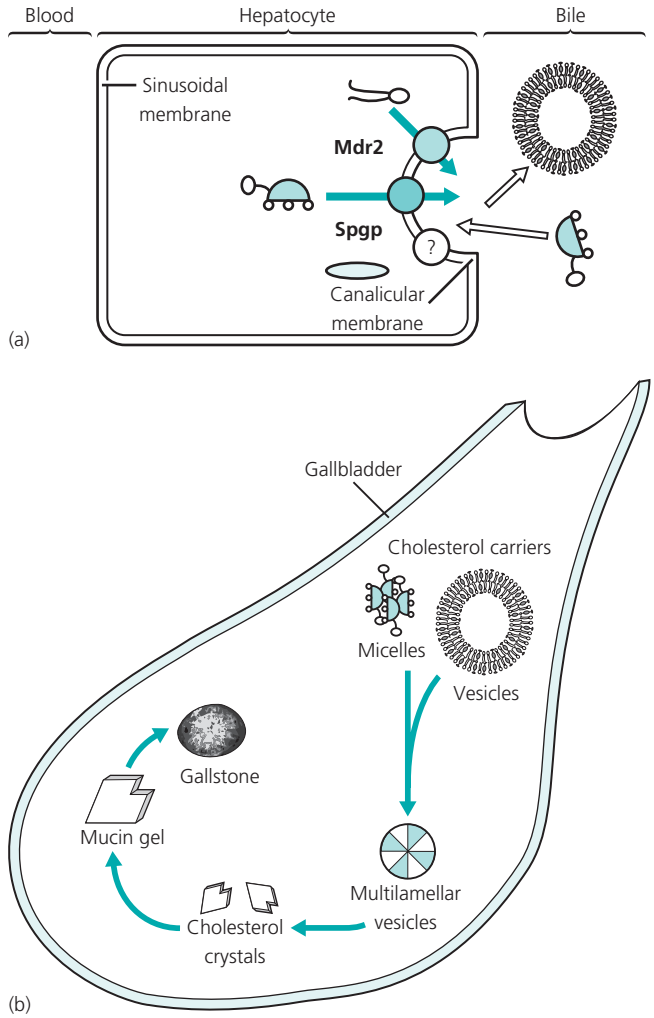

Figure 74.2 Schematic representation of biliary lipid secretion. At the biliary canalicular membrane of the hepatocyte, vesicles of cholesterol and phospholipids are secreted. Bile salts are also secreted by the bile salt export pump **(a)**. Inside the canaliculus, mixed micelles of bile salts, cholesterol, and phospholipids are formed when bile salts reach a critical micellar concentration. As bile is further concentrated in the gallbladder, more vesicles are converted to mixed micelles. Mixed micelles transfer more phospholipid than cholesterol in solubilizing biliary lipids. Vesicles in the gallbladder are relatively depleted in phospholipid and enriched in cholesterol. These vesicles are more unstable and prone to nucleation **(b)**.

Nucleation of cholesterol crystals

An early and indispensable step in cholesterol gallstone formation is nucleation, the initial precipitation of solid cholesterol crystals in saturated bile (Fig. 74.3). Fusion and aggregation of cholesterol-carrying vesicles may be crucial for crystal generation. Under video-enhanced microscopy, crystals appeared to originate from aggregated vesicles [84–86]. Nucleation of crystals results in decreases in vesicular cholesterol without changes in micellar cholesterol [73] so cholesterol in vesicles may be more unstable and prone to precipitate than cholesterol in mixed micelles.

Vesicles in bile are heterogeneous. Gallbladder bile vesicles are likely to participate in nucleation; the vesicles in hepatic bile are much more resistant to nucleation. This discrepant behavior is partly caused by the difference in their relative cholesterol-to-phospholipid contents. Vesicles that have increased ratios of cholesterol to phospholipid aggregate, fuse,

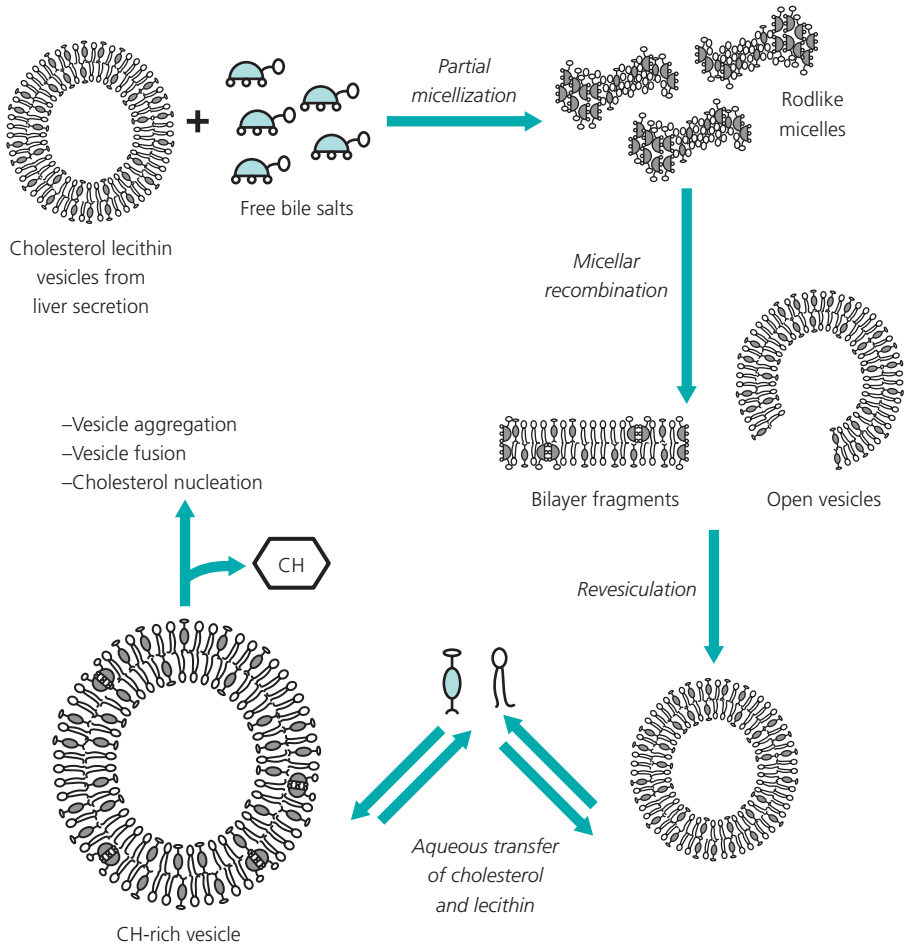

Figure 74.3 Schematic representation of cholesterol nucleation. In bile, cholesterol exists in two soluble forms, vesicles and mixed micelles. These forms are in dynamic equilibrium depending on the total bile salt and lipid concentration. With concentration, vesicles are depleted of phospholipid and enriched in cholesterol, resulting in a tendency for vesicles to aggregate and fuse. Pronucleators may also cause vesicular fusion. The fused vesicles lead to formation of multilamellar liposomes or liquid crystals. Cholesterol separates from the liquid to the solid crystalline form during nucleation. Whether vesicles can nucleate into solid cholesterol crystals is unclear. CH, cholesterol.

and nucleate more readily [86]. The concentrated bile acids within the gallbladder may preferentially remove vesicular phospholipid over cholesterol during the dynamic shift to the micellar phase. The remaining vesicles are relatively cholesterol enriched and nucleation prone. Conversely, hepatic vesicles have lower cholesterol-to-phospholipid contents and are therefore more stable.

Many people secrete supersaturated bile without developing gallstones [87]. Gallbladder bile taken from patients with cholesterol stones nucleates more rapidly than equally saturated bile from controls, suggesting that factors in addition to cholesterol supersaturation must be involved. Considerable efforts have been made to identify specific factors enhancing nucleation. Biliary proteins have generated the most attention, as total biliary protein content is increased in bile with cholesterol crystals compared with samples without crystals [88,89].

Burnstein and colleagues provided the first major evidence for a potent pronucleating agent in bile [90]. Glycoproteins and other proteins or peptides isolated from bile may associate with vesicles, regulate calcium salts, and influence cholesterol precipitation in bile [90–95]. Putative pronucleators include α_1-acid glycoprotein, aminopeptidase N, immunoglobulins G and M, haptoglobin, fibronectin, and α_1-antichymotrypsin [96–103]. However, the role of these proteins in vivo remains controversial [104–106]. In contrast, other biliary protein fractions, such as apolipoproteins AI and AII, a biliary glycoprotein heterodimer, and immunoglobulin A inhibit nucleation during in vitro assays [107–110].

Gallbladder mucin appears to be an important pronucleating factor. Mucin, a high-molecular-weight glycoprotein that is the major organic constituent of gallbladder mucus, consists of a polypeptide core with multiple oligosaccharide side chains. These peptide cores also contain hydrophobic domains that bind pigment, cholesterol, and phospholipid, entrapping vesicles and micelles in their binding sites [111,112]. With this close contact, membrane fusion and mixing can occur with the formation of multilamellar vesicles. Addition of mucin to supersaturated bile greatly accelerates cholesterol crystal nucleation [106,113]. Mucin may become incorporated into the core of the growing gallstone, providing an architectural framework for crystal growth and stone formation [114]. Mucin can therefore act as a pronucleator [115]. Mucus hypersecretion before stone formation appears to be

a universal antecedent in a number of animal models of lithogenesis [116,117]. The stimulus for mucin hypersecretion is not clear, although prostaglandins may play a role. For example, the hypersecretory response can be inhibited by the administration of large doses of oral aspirin in the human gallbladder [118], and aspirin ingestion can completely abolish the subsequent formation of cholesterol crystals and gallstones [119]. However, inhibition of prostaglandin synthesis with indomethacin does not prevent mucin hypersecretion in a prairie dog model [120,121]. Although prostaglandin activity may play a role in the pathogenesis of mucin hypersecretion, the role of other factors such as lithogenic bile or hydrophobic bile salts awaits study [122–124].

Calcium complexes are present in the central matrices of many, if not all, cholesterol stones, where they may serve as potential niduses for cholesterol crystallization [125–128]. Calcium has been shown to bind to mixed micelles, simple micelles, and simple vesicles in vitro, potentially explaining its role in cholesterol crystal nucleation [129]. Calcium may also regulate gallbladder secretion of electrolytes and glycoproteins [130,131]. Nevertheless, various studies have found conflicting data about biliary calcium levels in gallstone patients [132–134].

Role of the gallbladder

The importance of the gallbladder in cholesterol gallstone pathogenesis must be emphasized. Cholecystectomy essentially cures the patient of recurrent de novo cholesterol stone formation. Both gallbladder mucosal function and motility are important. The gallbladder can absorb excess water and electrolytes, concentrating bile [135]. Sodium and chloride ion fluxes are altered in an animal model of lithogenesis [136]. The gallbladder also normally secretes hydrogen ions and mucin.

Alterations of lipid metabolism in gallbladder epithelium that might increase cholesterol content have also been found. HMG-CoA reductase activity, governing cholesterol synthesis, is lower in the gallbladder mucosa than in hepatic tissue, and acyl:cholesterol:lecithin transferase (ACAT) activity, catalyzing the esterification of cholesterol, is several times higher than in the liver [137]. Normal human gallbladders can absorb phospholipids and cholesterol from bile in vitro, resulting in less lithogenic bile [138]. In contrast, gallbladders from patients with cholesterol stones are less able to absorb cholesterol and phospholipids, resulting in potentially more lithogenic bile.

In addition to epithelial cell function, gallbladder motility is of vital importance. Gallbladder stasis is a risk factor for lithogenesis, as mucin gels accumulate with prolonged bile storage. The viscosity of these gels may interfere with mechanical emptying. Increased cholesterol nucleation and crystal growth as well as enzymatic and nonenzymatic hydrolysis of bilirubin conjugates occur with prolonged stasis. The resulting unconjugated bilirubin may precipitate with calcium.

Altered gallbladder contractility before cholesterol stone formation has been shown in a lithogenic animal model [139]. In humans, prolonged total parenteral nutrition (TPN) induces gallbladder hypomotility and profound stasis, predisposing to subsequent biliary sludge and possible stone development [140]. High spinal cord injury is linked to gallbladder stasis and gallstone formation [141,142]. Pregnancy, oral contraceptives, obesity, diabetes mellitus, and octreotide therapy are also associated with impaired emptying and cholelithiasis [143–145].

Biliary sludge

Precipitates in bile have been called by many names – biliary sludge, microlithiasis, and pseudolithiasis. Sludge is best diagnosed by microscopic examination of a fresh sample of gallbladder bile [146]. Sludge also can be seen ultrasonographically as low-amplitude echoes without postacoustic shadow that layer with gravity [147,148] (Fig. 74.4). In certain clinical conditions, sludge may evolve into cholelithiasis.

Biochemically, sludge is composed of calcium bilirubinate granules and cholesterol monohydrate crystals embedded in a mucus gel. Ceftriaxone may precipitate as a calcium salt that appears ultrasonographically as sludge [149]. These calcium precipitates, with cholesterol crystals 50 μm or more in diameter, produce the characteristic ultrasonic echoes in sludge. The deformable mucin gel accounts for its unique layering and flow characteristics [148].

In a prospective study of patients receiving prolonged TPN, 6% of the patients developed sludge during the initial 3 weeks. By 4–6 weeks, 50% of the patients had sludge, and after 6 weeks, its appearance was universal [150]. Stones developed in 43% during follow-up. Significantly, sludge resolved in all

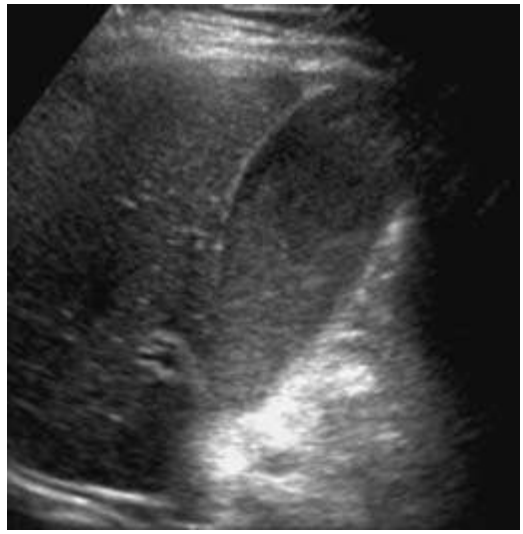

Figure 74.4 Ultrasound scan showing gallbladder sludge. Sludge appears as low-amplitude echoes without postacoustic shadowing that shift with positioning.

the patients within 4 weeks after reinstitution of oral feedings. Although stasis was undoubtedly the major factor in sludge formation, these patients represented a medically ill population with complicating metabolic derangements.

Gallbladder sludge may also appear spontaneously in selected individuals. The clinical outcome of patients who presented with upper abdominal pain and sludge on initial ultrasound examination was examined [148]. In approximately 18%, the sludge resolved over a 2-year period. It had a disappearing and reappearing course in about 60%, and gallstones also developed in 14%. Another retrospective study demonstrated similar findings, with sludge disappearing spontaneously after 2 months in most [151]. Complications including stones or acute acalculous cholecystitis developed in 19.6%. Patients with sludge may represent de novo cholesterol stone formers who have been detected at an early stage. In the absence of distal obstruction, sludge can be associated with abdominal pain (i.e., biliary colic), acute cholecystitis, or pancreatitis and should be regarded as part of the spectrum of gallstone disease [147,148].

In summary, cholesterol lithogenesis begins with altered hepatic secretion of biliary lipids, resulting in cholesterol supersaturation of bile. Gallbladder mucin hypersecretion and stasis develop, perhaps through the action of chemical mediators. As the bile is progressively concentrated, the vesicular fraction becomes relatively cholesterol enriched. These vesicles aggregate and fuse. When the balance of the opposing promoting and inhibitory factors favors nucleation, biliary sludge or microlithiasis forms. The crystals formed are retained within the gallbladder, where they grow and conglomerate with mucin glycoprotein and other constituents such as calcium and bilirubin. Continued stasis and impaired emptying of cholesterol precipitates lead to macroscopic stone formation.

Pathogenesis of pigment gallstones

Chemical composition and clinical associations

Pigment gallstones are subclassified into two types, brown and black, which differ in morphology, pathogenesis, and clinical correlations (Table 74.3). In contrast to cholesterol gallstones, race and ethnicity are not important determinants of pigment gallstones. Black pigment stones can occur in persons with no predisposing factors. In the United States, black pigment gallstones are found in the gallbladder and are not associated with bacterial infection.

Factors associated with the formation of black pigment stones include chronic hemolysis (e.g., sickle cell disease), thalassemia, prosthetic heart valves, advancing age, long-term TPN, and cirrhosis [152–155]. Black pigment stones seldom coexist with cholesterol stones in the same gallbladder. A

Table 74.3 Clinical associations and compositions of black and brown pigment gallstones

Characteristics	Black	Brown
Color	Black	Brown, orange, yellow
Size	0.3 cm to 0.6 cm	0.5 cm to 2 cm
Consistency	Amorphous, powdery, solid	Soft, laminated, muddy
Anatomic location	Gallbladder	Gallbladder and bile ducts
Geography	West and Asia	Mostly Asia
Diet	High-protein diet	Low-protein diet
Disease associations	Hemolysis, cirrhosis, "healthy" persons	Cholangitis, ova, parasites, sutures
Bile cultures	Usually sterile	Infected (*Escherichia coli*, *Bacteroides* sp., ova, parasites)
Recurrent stones	Uncommon	Frequent
Radiological calcification	Diffuse (up to 70% of stones radiopaque)	Usually radiolucent, slightly calcified
Principal components	Pigment polymer, calcium phosphate, calcium carbonate	Calcium bilirubinate, calcium soaps of fatty acids, cholesterol
Etiology	Increased excretion or hydrolysis of conjugated bilirubin	Bacterial hydrolysis of conjugated to unconjugated bilirubin
Bile pigment – total major form	40 (10–90)[a] Insoluble polymer	50 (28–79)[a] Calcium bilirubinate
Calcium	15 (3–40)[a]	5 (3–9)[a]
Calcium salts		
Carbonate	13 (0–65)[a]	None
Phosphate	5 (0–32)[a]	< 1[a]
Palmitate + stearate	1 (0–3)[a]	23 (11–67)[a]
Cholesterol (unesterified)	3 (1–13)[a]	10 (2–28)[a]
Organic matrix (glycoproteins, mucins, carbohydrates)	24 (10–73)[a]	12 (0–30)[a]

a Values are given as a percentage of dry weight of the stone and are means, with ranges in parentheses.
Adapted from Ostrow [327] and Leuschner et al. [328].

calcium-regulatory protein that may mediate calcium precipitation has been isolated from black pigment stones [156].

In Asia, brown pigment stones are often found in the bile ducts and are strongly associated with bacterial infection [157]. There is a high incidence of infection with *Escherichia coli*, with the bacterial presence within stones easily demonstrated [158–160]. Biliary secretory immunoglobulin A is decreased [161]. Infected bile exhibits high bacterial β-glucuronidase activity, often associated with a juxtapapillary duodenal diverticulum [162,163]. Molecular studies have shown that bacterial DNA can be recovered from most gallstones, except for those with very high cholesterol content [164–166], confirming a role for bacteria in pigment gallstone pathogenesis.

Deconjugation of bilirubin

Bilirubin, a tetrapyrrol-like cholesterol, is insoluble in water. After glucuronidation, bilirubin is secreted, mostly as the water-soluble diglucuronide (75%–80%) or monoglucuronide (20%) forms, with a small amount of unconjugated bilirubin (3%). Both the black and brown pigment stones contain calcium-bilirubin salts so the pathogenesis of pigment stones involves the deconjugation and precipitation of bilirubin.

In patients with chronic hemolysis, there is a 10-fold increase in the excretion of conjugated bilirubin in hepatic bile [167]. In an animal model of ileal resection, bilirubin circulates enterohepatically during the early postsurgical period, with increases in biliary levels of this molecule [168]. In patients with Crohn's ileitis or who had undergone ileal resection, concentrations of conjugated and unconjugated bilirubin were increased compared to patients with Crohn's or ulcerative colitis. In these studies, it has been hypothesized that unconjugated bilirubin is absorbed from the colon in the presence of ileal disease. These findings may help explain the increased incidence of pigment stones in patients with ileal disease.

The role of biliary β-glucuronidase in the pathogenesis of pigment gallstones has been controversial. Studies employing molecular genetic techniques have implicated bacterial infection in producing brown pigment stones, with bacterial β-glucuronidase hydrolysis of conjugated bilirubin to form insoluble bilirubin [165,166]. However, this hypothesis does not seem to be relevant to black pigment gallstones [169]. β-Glucuronidase activity in uninfected bile has been demonstrated, suggesting that this enzyme may also originate in the epithelium [170–172]. However, another risk factor, gallbladder stasis, must be present for precipitates of calcium bilirubinate to form. Stasis, similar to the scenario described for cholesterol nucleation, can provide an opportunity for nonenzymatic hydrolysis of bilirubin diglucuronide and its subsequent precipitation [173,174]. Prolonged TPN, with attendant gallbladder stasis, can result in the formation of gallbladder sludge and black pigment stones [150,175].

The gallbladder may contribute to pigment gallstone formation in other ways. Calcium homeostasis is intimately linked to black and brown pigment gallstones, because both kinds contain predominantly calcium bilirubinate. Hepatic bile is supersaturated with calcium carbonate. The gallbladder epithelium can acidify bile, increasing the solubility of calcium carbonate. Impaired acidification of bile in an inflamed gallbladder may contribute to pigment gallstone formation. Gallbladder epithelium secretes a matrix of mucous glycoprotein into bile that binds to bilirubin and other hydrophobic lipids and is contained in black and brown pigment gallstones [111].

In summary, pigment gallstones begin with increased hepatic bilirubin excretion. Gallbladder stasis or bile infection allows the hydrolysis of bilirubin diglucuronide to less soluble forms. Impaired acidification of bile by the gallbladder perturbs calcium and bilirubin solubility, and mucus secreted by the gallbladder epithelium buffers hydrogen ions, enabling calcium carbonate, phosphate, and bilirubin to precipitate. For reasons that are poorly understood, the calcium bilirubinate in brown pigment stones remains in the monomeric form, but undergoes significant cross-linking to become polymeric and crystalline in black pigment stones.

Clinical manifestations

Biliary colic

Approximately one-third of patients with gallstones are symptomatic. Biliary colic as the result of transient obstruction of the cystic duct by sludge or stones is the main complaint in 70%–80% of symptomatic patients. Implicit in the term biliary colic is the fact that the gallbladder mucosa does not show features of acute inflammation. The pain of biliary colic is thought to be caused by functional spasms around an obstructed cystic duct; the pain of acute cholecystitis is caused by gallbladder wall inflammation.

Although it may be variable, biliary pain often has specific characteristics. The pain is episodic and severe, and it is located in the epigastrium or less frequently in the right upper quadrant, left upper quadrant, the precordium, and the lower abdomen [176,177]. The pain may be precipitated by eating a large meal, but often no single food is the lone culprit. Pain may develop without any precipitating events.

Typically, the pain has a sudden onset and rises steeply in intensity over a 15-min interval to a steady plateau lasting as long as 3 h. Resolution of pain is slower. Pain lasting more than 6 h should raise the suspicion of cholecystitis. The pain may radiate to the interscapular region or, rarely, to the right shoulder. Vomiting and diaphoresis are not uncommon. The patient is usually restless and unable to find a comfortable position. Residual tenderness in the upper abdomen may persist after an attack. The interval between attacks is unpredictable and may be weeks, months, or years. True biliary colic should be differentiated from nonspecific dyspepsia.

Flatulence, pyrosis, aerophagia, vague abdominal discomfort, and fatty food intolerance are common complaints of many patients, whether or not they have cholelithiasis [178].

The ability to differentiate true biliary pain from nonspecific abdominal symptoms significantly impacts the success of treating gallstone disease. For example, a cholecystectomy performed for gallstone-induced biliary colic is usually curative, but symptoms often persist if it is performed for patients with nonspecific dyspepsia and cholelithiasis [179,180]. It is worthwhile to clarify prevalent misunderstandings about biliary pain. First, biliary colic is a misnomer, because the pain is steady, not intermittent or fluctuating. Second, the pain is primarily epigastric. It is inappropriate to interpret pain not located in the right upper quadrant as atypical of gallstone symptoms. Third, fat intolerance is not a feature of biliary colic. Fourth, despite the availability of many imaging techniques to demonstrate the presence of gallstones, the diagnosis of biliary colic is ultimately based on clinical judgment.

Acute cholecystitis

The most common cause of acute cholecystitis is obstruction of the cystic duct by gallstones, resulting in acute inflammation of the gallbladder. Approximately 90% of cases are associated with cholelithiasis. Obstruction likely damages the gallbladder mucosa, initiating an inflammatory reaction involving prostaglandins and other chemical mediators [181,182]. Although bacteria are commonly found in the gallbladder bile of patients with acute cholecystitis, this is probably a secondary event [183,184]. Secondary bacterial infection can progress to empyema.

Most patients with acute cholecystitis have had previous attacks of biliary pain. The pain of acute cholecystitis typically lasts longer than 3 h and shifts from the epigastrium to the right upper quadrant with the emergence of localized tenderness and associated vomiting. With time, the intensity of pain may diminish, but tenderness increases. Fever is common, but is rarely over 38.3°C (101°F). The sequence of clinical features represents visceral pain of ductal impaction by stones, proceeding to gallbladder inflammation with parietal pain.

In elderly patients, presenting signs and symptoms may be especially mild. On physical examination, Murphy's sign, an abrupt arrest in inspiration secondary to pain during direct palpation of the right upper quadrant, may be present. In 30% to 40% of patients, a palpable mass may be present. Jaundice is present in 15% of patients with acute cholecystitis, even without choledocholithiasis and obstruction. The pathogenesis may involve edema and compression around the inflamed cystic duct. The differential diagnosis of cholecystitis includes choledocholithiasis, acute cholangitis, and pyogenic or amebic liver abscesses.

Chronic cholecystitis

Patients with chronic cholecystitis usually have gallstones and have had repeated attacks of biliary pain or acute cholecystitis. This results in a thickened and fibrotic gallbladder, which shows evaginated mucosal pouches (Rokitansky–Aschoff sinuses) on histological examination. It is uncommon for the gallbladder to be palpable during an attack of pain. The patient may have fewer symptoms referable to the gallbladder but may present with associated gallstone complications such as recurrent pancreatitis, choledocholithiasis, and cholangitis.

Choledocholithiasis and cholangitis

Small gallstones passing into the common bile duct from the gallbladder may eventually proceed to the duodenum. They may also remain in the common bile duct and give rise to complications. The majority of stones in the common duct have the same composition as those in the gallbladder. However, some are softer and more brown in color because of deposits of calcium bilirubinate and other calcium salts, including fatty acid complexes [153]. Common duct stones are frequently associated with infected bile, which may or may not be clinically apparent.

Choledocholithiasis is one of many causes of obstructive or "surgical" jaundice, which must be differentiated from hepatocellular or "medical" jaundice. Obstruction of the passage of bile results in jaundice and pruritus. The pathogenesis of pruritus is unclear, although retention of bile salts with irritation of sensory nerve endings and retention of endogenous opiate agonists have been proposed as mechanisms. Sometimes pruritus can be the predominant or incapacitating symptom. With biliary obstruction, the feces may be hypocholic or acholic. Light-colored or clay-colored stools are uncommon in bile duct obstruction resulting from gallstones because the obstruction is rarely complete, but are more commonly observed with malignant strictures of the common bile duct.

Unlike with malignant obstruction of the common bile duct, a palpable and nontender gallbladder because of cholelithiasis (Courvoisier law) is uncommon. The biliary obstruction is usually incomplete, and the gallbladder itself is likely to be fibrotic, scarred, and nondistensible secondary to chronic cholecystitis. However, the exceptions to this rule are substantial, with frequent false-positive and false-negative results.

Obstruction of the common bile duct also causes increased intraductal pressure, inhibiting bile flow and causing the reflux of bile from the canaliculus into the sinusoids. The normal pressure in the common bile duct is 10 cmH_2O to 15 cmH_2O. With obstruction, the pressure can rise to above 40 cmH_2O, causing biliary duct dilation [185,186]. Therefore, dilation of the extrahepatic and intrahepatic bile ducts is a valuable sign of common bile duct obstruction and is best seen using ultrasonography or a computed tomography (CT) scan. Clinically, the only manifestations may be mild hepatomegaly or right upper quadrant tenderness.

Prolonged biliary obstruction induces fibrogenesis in the liver, potentially leading to secondary biliary cirrhosis. The

propensity for developing cirrhosis varies with the completeness and duration of obstruction. On average, choledocholithiasis will lead to secondary biliary cirrhosis after about 5 years [187]. Patients with incomplete obstruction more commonly present with portal hypertension, and those with complete obstruction present with hepatic failure [188]. Even if the patient has cirrhosis, every effort should be made to relieve the obstruction, because reversal of portal hypertension and secondary biliary cirrhosis has been reported [189].

A common complication of choledocholithiasis is cholangitis. For bacterial infection to occur, biliary obstruction or bile stasis is always present, although obstruction is not always associated with overt bacterial infection. For example, cholangitis is extremely common in choledocholithiasis, not uncommon in sclerosing cholangitis, and relatively uncommon (10%–15%) in malignant bile duct strictures.

The typical clinical picture, occurring in 70% of cases, consists of biliary pain, jaundice, and chills and rigors (Charcot triad). Pain, usually characteristic of biliary colic, occurs in 90% of patients. Bacteremia with chills and fever occurs in 95%, and clinical jaundice in 80%. Clinical signs are nonspecific, with mild hepatomegaly, tenderness, and occasionally rebound tenderness [190]. For many patients, cholangitis is a short and self-limited illness complicating choledocholithiasis or sclerosing cholangitis. However, shock, multiple liver abscesses, or multiorgan failure may result. Blood cultures are often positive and reflect the organisms infecting the bile ducts. The most commonly found organisms are *E. coli*, *Klebsiella* sp., *Pseudomonas* sp., and enterococci. Coinfection with anaerobes occurs in 15% [191–193].

Acute pancreatitis may be precipitated by the passage of stones or sludge in the common bile duct, and sludge or microscopic stones may account for a significant proportion of cases of idiopathic pancreatitis [146,194].

Differential diagnosis

Clinical signs and symptoms

The clinical symptoms and signs of biliary tract disorders are not highly specific. The patient's history, physical findings, and laboratory data should be carefully examined. A clinical impression of biliary colic should be confirmed by imaging studies. Gallstones are found commonly and may coexist with other disorders so the finding of gallstones does not exclude other diseases contributing to or complicating the patient's clinical picture. Disorders of other visceral organs, including the upper gastrointestinal tract, colon, kidneys, and pancreas, should be excluded by appropriate diagnostic tests. Extraabdominal disorders that may produce a similar clinical picture include angina pectoris, dissecting aortic aneurysm, spinal neuralgia, pleuritis, pericarditis, and uncommon metabolic disorders such as hereditary angioedema (C1 esterase inhibitor deficiency) and acute intermittent porphyria.

In addition to pain, patients with acute cholecystitis usually present with symptoms and signs of local inflammation (e.g., right upper quadrant mass, tenderness) and systemic toxicity (e.g., fever, leukocytosis). The differential diagnosis includes other causes of intraabdominal inflammation or infection. Acute appendicitis can cause a difficult diagnostic problem. The periumbilical pain shifting to the right lower quadrant with an inflamed mass may be confused with biliary colic with an inflamed gallbladder. A gallbladder can be low lying or an appendix can be subhepatic. Fever and leukocytosis are features of both. Ultrasonography or hepatobiliary scintigraphy may be helpful.

It may be difficult to differentiate acute pancreatitis from cholecystitis because the two conditions produce tenderness in an overlapping area. Gallstones may cause acute pancreatitis, and cholecystitis and pancreatitis therefore may coexist. Acute cholecystitis alone can be associated with hyperamylasemia, but pancreatitis often has higher enzyme levels. Biliary scintigraphy and imaging techniques such as ultrasound and CT scans are helpful diagnostically.

Perforated peptic ulcer usually produces more dramatic pain and peritoneal signs. Plain abdominal radiographs or CT scans often show free intraabdominal air. If free air cannot be seen and ulcer perforation is still suspected, an urgent radiographic study with water-soluble contrast should demonstrate the perforation.

Diagnostic studies

Laboratory tests

In uncomplicated biliary colic, the results of hematological and biochemical tests are normal. In acute cholecystitis, leukocytosis with a "left shift" is usually seen, but this does not differentiate it from other intraabdominal infections. Edema and inflammation of the gallbladder can partially obstruct the common bile duct, causing mild elevation of the serum aminotransferases and alkaline phosphatase. Elevation of serum bilirubin can also be associated with the enzyme level changes, especially if the common hepatic duct or common bile duct is involved in the inflammatory reaction. Bilirubin elevation is proportional to the degree of obstruction. Alkaline phosphatase, however, is produced by bile canalicular and ductular cells, and its elevation does not depend on the magnitude or cause of obstruction.

Abdominal pain, fever, and jaundice are often the presenting features of choledocholithiasis. In such cases, the bilirubin level is usually between 2 mg/dL and 10 mg/dL, and the alkaline phosphatase is less than five times normal. If the level of bilirubin is above 15 mg/dL, a neoplastic obstruction should be strongly suspected. If ductal dilatation is documented by ultrasonography or CT scans, a cholangiogram should be obtained to define the cause and level of obstruction.

Radiological studies

Plain abdominal films are rarely useful in uncomplicated biliary colic, because only 13%–17% of gallstones contain sufficient calcium to be radiopaque. In acute cholecystitis, radiographs are obtained to exclude other intraabdominal causes of abdominal pain, fever, and leukocytosis, such as perforated ulcer or intestinal obstruction. Occasionally, when emphysematous cholecystitis is present, intramural gas outlining the gallbladder can be seen, but this is better shown using ultrasonography.

Ultrasonography has high specificity and sensitivity for the diagnosis of biliary sludge or gallstones and should be a routine examination in the evaluation for gallstone disease. Stones appear as high-amplitude echoes with postacoustic shadowing (Fig. 74.5). Biliary sludge appears as low-amplitude echoes without postacoustic shadowing that shift with positioning (Fig. 74.4). Other potential findings include thickening of the gallbladder wall (> 2 mm), intramural gas, and a pericholecystic collection of fluid; these last two suggest active gallbladder inflammation or infection. Dilatation of intrahepatic or extrahepatic bile ducts suggests distal obstruction. However, the sensitivity of ultrasonography for choledocholithiasis is only 40%–50%, and therefore a normal ultrasound does not rule out this diagnosis [195].

Hepatobiliary scintigraphy can confirm or exclude the diagnosis of acute cholecystitis with a high degree of sensitivity and specificity. After a 2-h to 4-h fast, the patient is given an intravenous injection of a technetium 99 m-labeled iminodiacetic acid derivative (^{99m}TC-IDA agent), which is excreted into the bile ducts, and is sequentially imaged under a gamma camera. Several ^{99m}Tc-IDA compounds have been developed and differ with respect to their degree of hepatic uptake and time to reach a peak concentration in bile.

In a normal study, images of the gallbladder, common bile duct, and small bowel appear within 30–45 min. A normal ^{99m}Tc-IDA scan virtually rules out the diagnosis of acute cholecystitis in a patient who presents with abdominal pain. Failure to visualize the gallbladder by 90 min despite adequate views of the liver, common bile duct, and small bowel strongly suggests acute obstructive disease. False positives can result from non-fasting states, prolonged fasting states, or chronic cholecystitis. Delayed repeat scanning after 4 or more hours decreases the false-positive rate and provides sensitivity and specificity of approximately 97% and 90%, respectively. Morphine causes contraction of the sphincter of Oddi, increasing common bile duct pressure and enhancing filling of the cystic duct. Administration of low-dose morphine at 1 h may obviate the need for delayed repeat scans. Hepatobiliary scintigraphy cannot provide anatomic information and cannot directly identify gallstones.

Oral cholecystography is seldom employed as a primary diagnostic test for the detection of gallstones or acute cholecystitis. The study involves the administration of oral contrast tablets such as iopanoic acid the night before. The contrast is absorbed from the small bowel, conjugated and excreted by the liver, and concentrated within the gallbladder. The following morning, abdominal radiographs are obtained. Extrabiliary conditions such as small bowel disease, hepatic dysfunction, or prolonged fasting can all lead to gallbladder nonvisualization [196,197]. Inadequate gallbladder visualization can occur in 15%–50% of patients after a single dose. The chief advantage of oral cholecystography over ultrasound is its ability to assess the patency of the cystic duct and gallbladder function, which may be useful if medical therapy of gallstones is being considered. Moreover, the size, number, and degree of calcification of stones can be accurately determined.

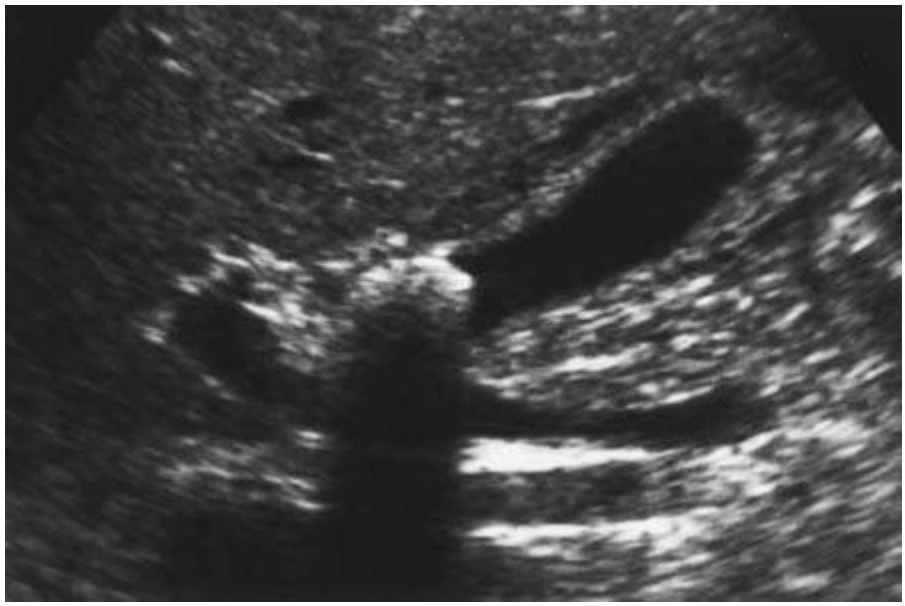

Figure 74.5 Ultrasound scan showing gallstones. The stones generate high-amplitude echoes and are large enough and dense enough to constitute substantial acoustic impedance in the path of the ultrasound beam. Hence, there is a void behind the stone, known as the postacoustic shadow. Some edema of the gallbladder wall is also seen, suggesting acute cholecystitis.

CT can also be used in the detection of cholelithiasis. Although superior to ultrasound in other clinical situations, CT is not as reliable in diagnosing gallbladder stones. However, CT is useful in demonstrating dilated bile ducts and mass lesions and can be considered the test of choice if clinical suspicion of a tumor (e.g., pancreatic cancer) obstructing the common bile duct is strong.

When a more definitive view of the biliary system is needed, cholangiography should be performed by a retrograde endoscopic route (i.e., endoscopic retrograde cholangiopancreatography [ERCP]) or through a percutaneous transhepatic cholangiography (PTC) (Fig. 74.6). The selection of either approach depends on the expertise at a particular institution and on the level and nature of the suspected lesion. In general, ERCP is used to demonstrate the lower limit of an obstruction and has the advantage of the ability to sample tissue. PTC demonstrates the upper limit of an obstructive lesion or a proximal obstruction better. Both tests have a risk of introducing infection in the presence of obstruction.

Other options for less invasive diagnosis of bile duct stones include magnetic resonance cholangiopancreatography (MRCP), helical CT, and endoscopic ultrasound. MRCP has been shown to be over 90% sensitive and specific for the diagnosis of bile duct stones, when compared to ERCP [198–201]. It also has the advantage of being noninvasive and potentially allowing diagnostic imaging without the risks of PTC or ERCP. Helical CT has also been studied, and found to have sensitivity and specificity of 80%–85% [202,203]. The addition of an oral contrast agent for CT cholangiography may provide sensitivities and specificities comparable to MRCP [204]. Endoscopic ultrasound can detect bile duct stones and biliary sludge with high sensitivity, without the morbidity associated with ERCP [205–208]. With the availability of many tests, the choice of diagnostic test should be based on local availability and expertise.

Clinical course and complications

Natural history of asymptomatic gallstones

The rate with which gallstones develop varies. In patients on TPN or in obese persons with rapid weight loss, the interval can be weeks. In Pima Indians, the progression from cholesterol-supersaturated bile to formation of gallstones takes 5–10 years [209]. When gallstones do form, the risk factors for developing symptoms are unknown. It is estimated that 60%–80% of all gallstones are asymptomatic at a given time [210–212]. However, the rate at which stones give rise to symptoms and complications is relatively small. In contrast, once gallstones start to cause biliary-specific symptoms, the risk of continuing problems is relatively high.

Studies by Wenckert and Robertson [213] and Lund [214] followed a total of 1307 patients with gallstones for up to 20 years and concluded that 50% of patients remained asymptomatic, 30% had biliary colic, and 20% had complications. Some have cited such data as indicating prophylactic cholecystectomy for all patients with gallstones, regardless of the severity of symptoms. However, the patients in these studies, although asymptomatic at the time of entry to the follow-up study, had previously been hospitalized for symptoms related to gallbladder disease.

Gracie and Ransohoff followed a cohort of 123 asymptomatic persons with gallstones that were found by oral cholecystography [215]. These 110 men and 13 women (average age 54 years) were followed for 11–24 years. New-onset biliary colic developed at a rate of 2% per year for the first 5 years, but the cumulative incidence over time plateaued, such that the total incidence was 15% at 10 years and 18% at 15 and 20 years. Three patients (2%) developed complications, all preceded by repeated attacks of biliary colic, and all had uneventful cholecystectomies. No deaths related to gallbladder disease occurred in this cohort.

The GREPCO study has reported follow-up of 161 initially asymptomatic patients with gallstones [216]. Biliary colic developed in 11.9% at 2 years, 16.5% at 4 years, and 25.8% at 10 years. The subjects were also followed for development of complications of gallstones, including cholecystitis, pancreatitis,

and biliary obstruction. After 10 years, 3% of those who were initially asymptomatic developed complications, including one person who developed gallbladder adenocarcinoma.

A 20-year population-based survey of mortality in Pima Indians showed that the overall age- and sex-adjusted death rate was higher in those with a history of gallstones, with a ratio of 1.9 [217]. The death rate attributed to malignancies was 6.6 times higher in those with gallstones. Of the 20 fatal malignancies in patients with gallstones, 11 were cancers of the gastrointestinal tract, with 6 cancers of the gallbladder or bile ducts.

These studies highlight the question of whether a link between gallstones, cholecystectomy, and malignancies exists. A modest increase in the risk of colon cancer, but not of rectal cancer, has been found after cholecystectomy [218–220]. Increased rates of gallbladder carcinoma or carcinoma of the extrahepatic bile ducts in patients with gallstones have been found in an autopsy series and in a case–control study [221,222]. The mechanisms for the increased risk of malignancy have not been clarified.

Natural history of symptomatic gallstones

Once an episode of biliary colic has occurred, there is a high risk of repeated attacks of pain. Cohort studies following symptomatic gallstone patients indicate that 58%–72% of patients have ongoing symptoms and complications [214,223]. More than 90% of complications, such as cholecystitis, cholangitis, and pancreatitis, are preceded by attacks of pain. The most serious complications are gangrene and perforation of the gallbladder, occurring in about 10% of cases of acute cholecystitis.

When the gallbladder perforates, the outcome depends on the anatomic relation with the neighboring structures. The perforation can localize to form an abscess; it can be a free perforation with peritonitis; or it can communicate with another hollow viscus as a fistula. A localized perforation with a pericholecystic abscess is most common. This should be suspected when acute cholecystitis is slow to resolve, especially with a second episode of fever, right-sided abdominal pain, or the appearance of a right upper abdominal mass. Ultrasonography and CT may show the pericholecystic abscess, but this is not dependable. If the degree of clinical suspicion is high, the diagnosis should be confirmed at surgery. This is especially so in elderly patients or patients on long-term steroid treatment in whom fever and the inflammatory response may be minimal.

In 1%–2% of perforations, especially in the fundus of the gallbladder, free perforation occurs and carries a mortality rate of at least 30%. Bile and purulent peritonitis are almost always associated with persistent or progressive abdominal pain. When the diagnosis is suspected, no test can establish the diagnosis without further delaying intervention and causing additional tissue injury. Antibiotics should be given and emergency surgery performed.

When the gallbladder perforates into the adjacent intestine, an attack of acute cholecystitis often subsides as the inflamed organ is decompressed. Cholecystoenteric fistulae are most common in the duodenum, followed by the hepatic flexure of the colon, stomach, and jejunum. If the gallstones are completely discharged and are small enough to pass rectally, an uncomplicated cholecystoenteric fistula results. However, if stones are still present in the gallbladder or in the common bile duct, chronic symptoms may arise.

Bowel obstruction may result when a fistula develops and the gallstone is too large to traverse the intestine (gallstone ileus). The diameter of the stone is usually greater than 2.5 cm and the site of obstruction is commonly in the small intestine, most often at the ileocecal valve. Although patients with gallstone ileus sometimes have a previous history of acute cholecystitis, stones usually erode slowly through the gallbladder, and the symptoms may be minimal. Gallstone ileus should always be considered in older patients with intestinal obstruction [224,225]. Plain abdominal radiographs may show air in the biliary tree or the presence of a calcified gallstone, and contrast studies often reveal the site of communication. Ultrasound scans can detect air in the biliary tree but not the site of the fistula. CT scans are less useful in detecting gallstones and fistulae, although they also may show air in the biliary tree.

Treatment

Because gallstones are common and often asymptomatic, the treatment of gallstones should consider the patient's clinical presentation (Fig. 74.7). For asymptomatic gallstones, before active treatment is instituted, the following questions should be considered. What is the rate at which new-onset symptoms emerge? If symptoms develop, what is the risk of these evolving to complications, and what is the risk of morbidity and mortality from such complications? What is the risk of prophylactic treatment? What are the short-term and long-term costs of prophylactic treatment compared with no treatment or delayed treatment?

The fractional and cumulative risk of developing symptoms is not great (2%–5% per year). Complications generally develop after the emergence of symptoms. Risk–benefit analyses of elective cholecystectomy have shown no advantage to aggressive prophylactic cholecystectomy for patients with asymptomatic gallstones. Once symptoms or complications develop, gallstones should be treated. Options include surgery, dissolution, or fragmentation of symptomatic gallstones (Table 74.4). Cholecystectomy is a safe procedure with a mortality rate of 0.1%–0.2% for either open or laparoscopic procedures [226–228]. The surgical mortality rate of 0.9%–1.8% is higher for patients older than 60 years of age [229,230]. With common bile duct exploration, the mortality rate is approximately two to three times higher.

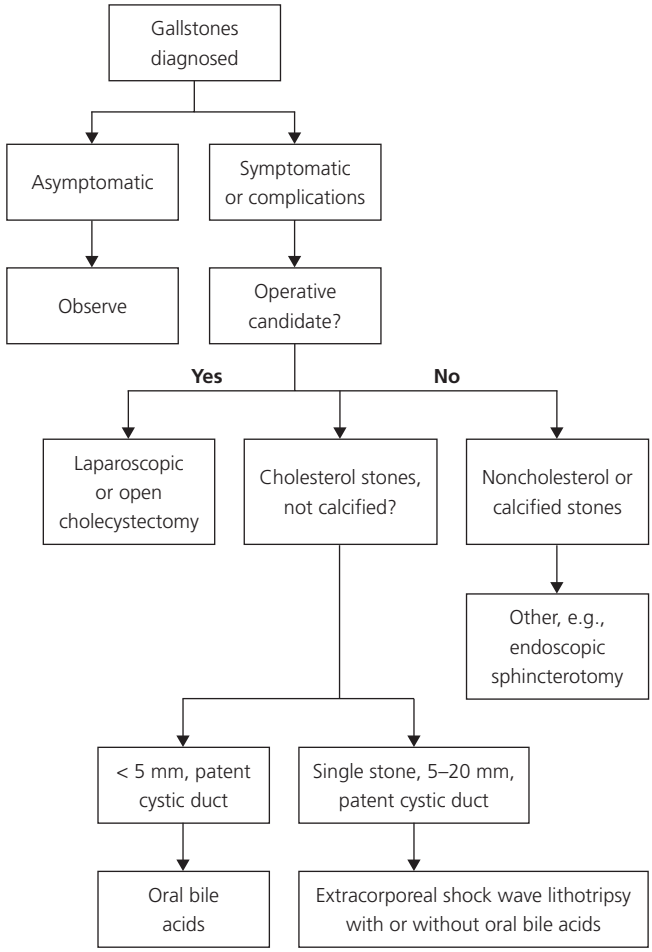

Figure 74.7 Algorithm for management of biliary sludge and gallstones.

Generally, the indications for cholecystectomy should not change, and asymptomatic patients should not undergo surgery despite the widespread availability of laparoscopic cholecystectomy. However, in certain subsets of patients, it may be prudent to make exceptions and proceed with a prophylactic cholecystectomy. These groups include children, patients with porcelain gallbladder, and the morbidly obese [231,232]. A calcified or "porcelain" gallbladder is associated with a higher risk of cancer [233]. In the obese, a cholecystectomy is recommended if the patient undergoes bariatric surgery [234]. Patients who are immunosuppressed on a long-term basis may represent another group, as signs of acute cholecystitis may be "masked." It is also agreed that patients with choledocholithiasis, even if asymptomatic, should have the bile duct stones removed and undergo cholecystectomy. This is reinforced by postmortem studies, which showed that ductal stones contributed significantly to death even in asymptomatic patients [235,236]. Patients with diabetes mellitus are a controversial group. It has been stated that diabetics have a higher risk of complications, morbidity, and mortality from gallstones. However, they may have an increased operative risk with elective and emergency cholecystectomy, largely because of concomitant cardiovascular disease [237,238].

Surgical treatment

Cholecystectomy is the only definitive treatment. Elective cholecystectomy is usually simple, safe, and curative; is indicated for most patients with symptoms; and is the first choice when complications ensue. Nonsurgical modalities of treatment are less favored with the advent of laparoscopic cholecystectomy.

Laparoscopic cholecystectomy

Laparoscopic cholecystectomy was first performed in France in 1987 [239]. The procedure has since become the standard of care for the treatment of symptomatic cholelithiasis and acute or chronic cholecystitis. In fact, the overall rate of cholecystectomy increased rapidly with the introduction of the laparoscopic approach, possibly because of wider patient and physician acceptance of this method of treating

Table 74.4 Therapeutic options for symptomatic gallbladder stones

Therapy	Candidates	Stone clearance (%)	Mortality (%)	Disadvantages
Laparoscopic cholecystectomy	No previous abdominal surgery, normal gallbladder wall	100	< 1	Invasive, requires general anesthesia, possible bile duct injury
Oral bile acids	Patent cystic duct, functioning gallbladder, floating radiolucent stones, < 5 mm in diameter	80–90	0	Delayed stone clearance, possible stone recurrence
Extracorporeal shock-wave lithotripsy with oral bile acids	Patent cystic duct, functioning gallbladder, solitary radiolucent stones up to 20 mm in diameter	70–90	< 0.1	Delayed stone clearance, possible stone recurrence
Contact dissolution with methyl tert-butyl ether	Radiolucent stones, gallbladder attached to liver, patent cystic duct	50–90	Limited experience	Invasive, bile leakage (5%), stone recurrence

gallstones [240]. There is also some evidence that the indications for cholecystectomy have broadened since introduction of the laparoscopic approach [241]. Due in part to the rapid acceptance of the procedure by patients and physicians, there have been few randomized, controlled trials comparing laparoscopic with open cholecystectomy [242,243]. However, publications compiling results for more than 5000 patients have documented its safety and efficacy [244]. Retrospective comparative studies have shown that laparoscopic cholecystectomy produced fewer complications, shorter hospital stays, more rapid returns to normal activities, and minimal use of postoperative analgesia [245–247]. Additionally, overall mortality appears to be lower [248].

The technique involves general anesthesia with endotracheal intubation. A pneumoperitoneum is established, and the laparoscope with video camera attached is inserted through an umbilical incision. Accessory trocars and cannulas are inserted through separate sites. The gallbladder, cystic duct, and cystic artery are identified. An intraoperative cholangiogram can be performed by cannulation of the cystic duct, allowing the detection of common bile duct stones and delineation of the ductal anatomy. The blood supply to the gallbladder is identified and controlled, and then the cystic duct is ligated. The gallbladder is dissected from the underlying liver bed, using electrocautery or laser energy. The gallbladder is removed through the incision site. Stones may need to be mechanically crushed within the gallbladder before removal. Stones spilled into the peritoneal cavity are retrieved [249].

The primary indication for laparoscopic cholecystectomy is identical to that for open cholecystectomy: symptomatic cholelithiasis. Absolute contraindications include an inability to tolerate general anesthesia and uncontrolled coagulopathy. Relative contraindications include scarring or inflammation, precluding access to the gallbladder using the transperitoneal approach, and diffuse peritonitis. As surgeons have accumulated more experience, the technique has been applied to a variety of patients. The procedure has been successfully performed in anticoagulated patients, obese patients, children, and pregnant women prior to the third trimester [250–253].

Examination of the results of large series illustrates the pertinent aspects of the procedure. An early analysis of 1518 laparoscopic cholecystectomies performed at academic and private hospitals was published [254]. In 4.7% of the patients, the procedure was converted to open cholecystectomy, most often because of difficulties in identifying anatomy as the result of inflammation or bile duct injury. Of the 1518 patients in this series, 96.5% had ultrasound examinations before surgery to document cholelithiasis, and preoperative cholangiography was performed in 4.2% of patients. Intraoperative cholangiography was used routinely by some surgeons and selectively or not at all by others. Intraoperative cholangiograms were obtained in 29.3% of patients, with a failure rate of 23.3%.

Complications, including delayed discharge, undesired change in therapy, readmission, biliary injury or leakage, infection, hemorrhage, or conversion to open cholecystectomy, occurred in 5.1% of cases. Superficial wound infection was the most common complication. Injuries to the common bile duct or the hepatic duct occurred in 0.5%. Similar to other groups, the rate of bile duct injury was higher early in a given surgeon's experience with the procedure, illustrating the steep learning curve associated with the procedure. The mean hospital stay was 1.2 days, with a range of 6 h to 30 days. One patient died [228,244].

There is some debate about the appropriate use of intraoperative cholangiography at the time of laparoscopic cholecystectomy. Some argue for routine operative cholangiography to look for unsuspected common bile duct stones and to identify ductal anatomy, anomalies, and injuries. Intraoperative cholangiography is usually safe and successful, and appears to reduce the risk of bile duct injury [255,256]. Others argue for a more selective approach, using preoperative clinical, and ultrasonographic assessment to predict the likelihood of common duct stones. A history of jaundice or pancreatitis, dilated common bile ducts on ultrasound, and elevated levels of bilirubin, aminotransferases or alkaline phosphatase can be used as an indication for preoperative ERCP with possible sphincterotomy or intraoperative cholangiogram [245,257]. Preoperative ERCP and sphincterotomy does not interfere with laparoscopic cholecystectomy or increase the operative complication rate [258]. Statistical models to predict which patients have choledocholithiasis, and therefore might benefit from preoperative ERCP or intraoperative cholangiogram, have been developed [259,260].

If choledocholithiasis is discovered intraoperatively, several options are available. The surgeon may perform a common bile duct exploration with either laparoscopic or open access with transcystic duct retrieval of stones. Bile duct exploration can also be carried out using laparoscopic or endoscopic techniques [261]. In experienced hands, laparoscopic bile duct exploration appears to have high success rates (75%–91%) [262,263]. It also has the potential advantages of using only one procedure for treatment of these patients and avoiding the delay inherent in postoperative ERCP. For those patients in whom the procedure is not successful, postoperative ERCP with sphincterotomy remains an option. The modalities of therapy in this area are evolving rapidly, and the perioperative approach to common bile duct stones should depend on local availability and expertise.

A serious direct complication of laparoscopic cholecystectomy is injury to the common bile or hepatic ducts. This may result from misidentification of the common duct for the cystic duct, resection of part of the common and hepatic ducts, or associated right hepatic arterial injury. The estimated incidence of bile duct injury varies from 0.3%–2.7% [264]. In contrast, biliary tract injuries are estimated to occur in 0.25%–0.5% of open cholecystectomies [265]. A major

risk factor for bile duct injury is the experience of the surgeon. Bile duct injuries appear to be much more common early in a surgeon's experience with the technique. Other risk factors appear to be the presence of aberrant biliary tree anatomy and the presence of local acute or chronic inflammation [264]. Intraoperative cholangiography may reduce the risk of bile duct injuries [256]. Bile leaks may also develop as the result of displacement of the operative clips on the cystic duct.

Bile duct injury leads to two clinical manifestations: bile leakage into the peritoneum, with resulting abdominal pain and bile peritonitis, or biliary obstruction as the result of partial or complete hepatic or common duct obstruction from ductal ligation or stricture. Patients can present 3–7 days after surgery with fever, abdominal pain, anorexia, ileus, ascites, nausea, or jaundice. Patients with late-onset stricture may present months later with jaundice. Biliary scintigraphy using ^{99m}Tc-IDA can be used to diagnose bile leakage [266]. ERCP with stent placement or sphincterotomy can be used both diagnostically and therapeutically. ERCP appears to be the treatment of choice for less severe lesions, such as minor lacerations of the common bile duct [264, 267]. It may also be used to treat bile leakage because of displaced cystic duct clips. Lesions in the proximal biliary tree may be more amenable to percutaneous transhepatic approaches [268]. Surgical repair may be necessary in some patients, such as those with transected common bile ducts [264,268–270]. Intraabdominal bile collections may need to be drained percutaneously.

Certain clinical scenarios remain controversial, such as the management of patients with acute cholecystitis; in particular, the timing and route of cholecystectomy. Although laparoscopic cholecystectomy has been performed successfully in acute cholecystitis, this group of patients has a higher incidence of common bile duct stones, and the procedure may be technically more difficult and last longer [271]. In this setting, intraoperative cholangiograms may be more difficult to obtain and bile duct injuries more common. Randomized trials comparing early surgery (< 3 days) with delayed surgery (4–6 weeks) for acute cholecystitis show no benefit to delaying surgery [272–274]. Patients in the early surgery group had longer operating times, but they had similar rates of conversion to open cholecystectomy and shorter hospital stays. Laparoscopic cholecystectomy appears to provide similar outcomes compared to open cholecystectomy in this setting [275]. Early cholecystectomy for acute cholecystitis, initially using a laparoscopic route, may therefore be appropriate.

Conversion to an open cholecystectomy should be undertaken if the operative field is not adequately visualized or variant anatomy is encountered. Conversion to an open procedure should not be considered a complication. In most series, conversion rates are higher with emergency operations. Reported rates range from 1.5%–15%, with most reporting rates around 5% [228]. With experience, the operative conversion rate appears to fall.

Many studies suggest that the indications for cholecystectomy are broader with the availability of laparoscopy [241]. Cholecystectomy may be performed in some patients whose symptoms are not clearly biliary in origin. In contrast, some patients with symptomatic gallstones may not receive surgery in a timely fashion. Glasgow and colleagues found that 1.3 per 1000 people underwent cholecystectomy for symptomatic gallstone disease in California in 1996 [276]. Of these, 56% had biliary colic, and the remainder had more severe complications such as acute cholecystitis, gallstone pancreatitis, or cholangitis. Patients presenting with biliary colic were more likely to undergo laparoscopic surgery electively, while those with the more severe complications were more likely to require an emergency or open procedure. In many patients, surgery was significantly delayed after the development of initial symptoms. Patients being treated for complicated gallstone disease had significantly longer hospital stay and costs. There is evidence for both underuse and overuse of laparoscopic cholecystectomy. Clarifying the appropriate indications for surgery and ensuring timely recognition and treatment of gallstone symptoms remain as priorities to improve clinical care of these patients.

Endoscopic treatment

Stones may be removed from the common bile duct by means of ERCP with sphincterotomy. Larger stones may require mechanical lithotripsy. In the postoperative period, endoscopic and radiographic techniques may be used to extract stones through a T-tube tract. Stones may be extracted or fragmented with the help of a choledochoscope. In all of these modalities, the gallbladder is left in situ, allowing the possibility of recurrent stone formation. Patients undergoing sphincterotomy alone for treatment of their gallstone disease have a much higher rate of future biliary complications than patients who also undergo cholecystectomy [277,278]. Therefore, cholecystectomy should be considered in all patients who have common bile duct stones even if a sphincterotomy is performed.

Medical dissolution

With the advent of laparoscopic cholecystectomy, medical therapy for gallstone disease has fallen out of favor. These therapies are limited to patients who are not operative candidates.

Oral bile acid litholysis

Two bile acids, chenodeoxycholic acid [3α,7α-dihydroxycholanoic acid (CDCA)] and ursodeoxycholic acid [3α,7β-dihydroxycholanoic acid (UDCA)], have been used for gallstone dissolution [279–284]. These two bile acids induce the secretion of undersaturated hepatic bile and do not increase the absolute amount of bile acids secreted. The

biological effects of administration of CDCA and UDCA include suppression of de novo hepatic cholesterol synthesis by inhibiting HMG-CoA reductase and enhancement of the activity of 7α-hydroxylase, leading to an increase in bile acid synthesis [285,286]. Intestinal absorption or reabsorption of cholesterol is down-regulated [287].

CDCA has more associated side effects and a lower success rate in dissolving gallstones so UDCA, the major bile acid of the Himalayan black bear, is the bile acid of choice for gallstone dissolution. UDCA is a remarkably safe compound. The usual dose is 8 mg/kg per day to 12 mg/kg per day. The proper selection of patients is a major factor affecting the success of bile acid therapy. The selection criteria include gallstones predominantly consisting of cholesterol; pigment stones or calcified stones are excluded. Small stones that are buoyant in an oral cholecystogram examination have a 90% chance of dissolution. Stones should have a large surface area in relation to their mass, and those with a diameter larger than 1.5 cm are not suitable. Patency of the cystic duct should be documented by oral cholecystogram or hepatobiliary scanning.

Extracorporeal shock-wave lithotripsy

Energy generated externally can be directed to fragment gallstones. This method of treatment combines two approaches: oral bile acid therapy and fragmentation of gallstones. Extracorporeal shock-wave lithotripsy (ESWL) requires accurate localization of the gallstones within the gallbladder, which is usually achieved by three-dimensional ultrasonography. The source of energy varies with different methods. Fragmentation of a gallstone into small fragments (< 3 mm) results from successful ESWL. Depending on the type of lithotriptor, one to several sessions of ESWL may be needed before optimal fragmentation can be achieved. The remaining gallstone fragments can pass into the duodenum spontaneously or can be rapidly dissolved by the oral bile acids. UDCA, usually given before and concurrently with ESWL, is continued for several months until the stones have completely disappeared [288].

If patients are properly selected, ESWL is effective and safe [289]. Selection criteria of patients for ESWL are similar to those listed for oral bile acid therapy. Single, small cholesterol stones can be successfully fragmented in more than 90% [290–292]. However, patients with larger or multiple stones have a lower success rate of 34%–71% [293].

About 20% of patients develop biliary colic for several weeks after ESWL (25% of these patients require cholecystectomy), and 1% develop pancreatitis [290,291,293]. Other side effects include local discomfort, petechiae or bruising, transient gallbladder dysmotility, and microscopic hematuria. ESWL is used in the United States mostly for problematic common bile duct stones that are not cleared by ERCP with sphincterotomy [294].

Contact solvents

When gallstones can be accessed by a catheter, solvents can be delivered directly to dissolve the stones. The most commonly used agent is methyl tetrabutyl ether (MTBE). To dissolve gallstones, a catheter is introduced into the gallbladder by a percutaneous transhepatic approach, and MTBE is introduced and withdrawn from the catheter [295,296]. Dissolution can be achieved within a few hours [297]. In well-selected patients in specialized centers, this method is 90% successful and safe. Complications include those caused by the percutaneous puncture procedure and side effects if the MTBE drains into the duodenum (e.g., hemolytic anemia, erosive or hemorrhagic duodenitis, aspiration pneumonia, somnolence). Small cholesterol gallstones without a thick calcified rim are suitable for this therapy. Calcified or pigment gallstones, cirrhosis of the liver with portal hypertension, and coagulopathy are contraindications.

Rational approach to treating symptomatic gallstones

Surgery remains the definitive curative method of gallstone treatment. The advent of laparoscopic cholecystectomy and its widespread acceptance has revolutionized surgical treatment of gallstones. Laparoscopic cholecystectomy is regarded as the treatment of choice for symptomatic gallstones. For patients unable or unwilling to pursue this route, nonsurgical methods such as oral bile acid therapy or lithotripsy are available (Fig. 74.7).

When stones are removed but the gallbladder is left behind, stones may recur. With oral bile acid therapy, the cumulative recurrence rate is about 15% in 2 years and 50% in 10 years [298, 299]. Patients with multiple stones have higher recurrence rates than those who have solitary stones. The long-term recurrence rate after ESWL is also high, 15% at 1 year and 60% at 5.5 years [56]. It is not generally agreed whether long-term, low-dose UDCA can protect against recurrence.

To our knowledge, no formal cost comparison has been made between surgical and nonsurgical treatment. Surgery has a high immediate cost and low long-term cost. Nonsurgical means of treatment may have a low immediate cost but they have high long-term cost because of recurrent or persistent disease. In selecting patients for nonsurgical treatment, a diagnosis of gallstones by ultrasonography is insufficient. The physician must also determine gallstone composition and gallbladder function. Regular monitoring by ultrasonography during nonsurgical treatment may be necessary. These additional tests increase cost.

In approaching a patient with symptomatic gallstones, an elective cholecystectomy remains the gold standard. ERCP may be required to remove common bile duct stones or for management of complications after cholecystectomy. For patients who cannot or will not have surgery, the preferred form of medical treatment is oral bile acid dissolution in appropriate candidates.

Acalculous cholecystitis

Acute cholecystitis can present as an acalculous disorder in 5%–10% [300,301]. This entity is distinct from gallstone-related disease in that it usually occurs in the setting of major surgery, critical illness, trauma, or burn-related injury. The patients tend to be predominantly male and older than 50 years of age. Many of them are on TPN, and bile inspissation or sludge formation may occur. Hypotension and sympathetic vasoconstriction may contribute, predisposing the patient to ischemic injury. Extensive small vessel occlusion has been shown in cholecystectomy specimens from these patients [302]. Another postulated risk factor is mechanical ventilation with positive end-expiratory pressure [300]. The positive end-expiratory pressure may decrease portal perfusion and increase resistance in the common bile duct, with subsequent stasis [303,304]. The pathogenesis of acalculous cholecystitis probably involves some combination of bile stasis, chemical inflammation, and mucosal ischemia. Gallbladder ischemia may be the only predisposing factor found in many cases. Bacterial infection, usually by gram-negative bacteria and anaerobes, appears to be a secondary phenomenon.

In acalculous cholecystitis, complications such as gallbladder gangrene and perforation, emphysematous cholecystitis, or empyema, may develop more rapidly than in calculous cholecystitis [300]. One retrospective study revealed that 70% of patients had gangrene, empyema, or perforation of the gallbladder evident at the time of surgical exploration [305]. This increased complication rate that occurs in the setting of advanced age and other illnesses contributes to the higher mortality rate associated with this disorder. For these reasons, it is important to suspect and pursue an early diagnosis. It should be suspected in patients who are critically ill with signs of sepsis such as fever or leukocytosis, but with no obvious source. Findings on physical examination and laboratory studies are not necessarily helpful. Potential diagnostic modalities include ultrasonography, CT, hepatobiliary scintigraphy, and laparoscopy.

Ultrasonography is usually the initial modality chosen. Criteria for acalculous cholecystitis include a thickened gallbladder wall (> 4 mm), pericholecystic fluid, subserosal edema without ascites, intramural gas, sloughed mucosal membranes, or a sonographic Murphy sign. Reported sensitivity ranges from 67%–92%, with specificity over 90% [306]. Experience with CT is also favorable. Diagnostic criteria are similar to ultrasonography. The sensitivity and specificity of CT for acalculous cholecystitis are over 95% [306]. Another advantage of CT is the ability to look for other intraabdominal pathology. Results with hepatobiliary scintigraphy are variable, with reported sensitivity rates ranging from 68%–91% and frequent false-positive results. Adjunctive use of morphine to enhance gallbladder filling may improve the accuracy of this test [307]. Patients in whom the diagnosis is uncertain or with generalized peritonitis may benefit from diagnostic laparoscopy or exploratory laparotomy. In small series of patients, diagnostic laparoscopy appears to be accurate and safe [308,309]. Some suggest empiric percutaneous cholecystostomy if the diagnosis is suspected but cannot be confirmed with other modalities [310].

Rare causes of acute cholecystitis include specific infections, such as *Salmonella* or *Candida* [311,312]. Cytomegalovirus and cryptosporidia can infect the biliary system and produce cholecystitis and cholangitis in severely immunocompromised patients, such as those with acquired immunodeficiency virus (AIDS) or after bone marrow transplantation [313,134]. In patients with AIDS, infection with microsporidia such as *Enterocytozoon bieneusi*, *Pneumocystis carinii*, and *Isospora belli* have been documented [315]. However, acute calculous cholecystitis may also occur in these patients. No specific symptoms can differentiate these two, and patients may have coexisting gallstones and opportunistic infection. In these patients, acalculous cholecystitis probably represents part of the spectrum of AIDS-related cholangiopathy.

Once a diagnosis of acalculous cholecystitis is made, the gallbladder must be drained or removed. Choosing the treatment modality may be difficult as patients often have severe comorbid conditions. Options include percutaneous or surgical cholecystostomy, surgical cholecystectomy, or endoscopic transpapillary biliary drainage [310,316–318]. Percutaneous cholecystostomy has been gaining favor. Its advantages include the use of local anesthesia and the ability to be performed at the bedside. Also, percutaneous cholecystostomy can be the definitive therapy in acalculous cholecystitis. The overall success rate is 63%–94% with a low complication rate of approximately 10% [319]. Complications include liver laceration, hemorrhage, infection, hemobilia, bile leak, bile peritonitis, and catheter dislodgment. Other disadvantages of cholecystostomy include a limited ability to look for other causes of sepsis and potentially inadequate drainage in cases of pericholecystic abscess, gangrene, or gallbladder perforation. Surgical cholecystostomy or cholecystectomy is the traditional therapy, but patients may be poor operative candidates. Endoscopic transpapillary drainage has been reported in small series and has not gained widespread acceptance [316].

Recurrent pyogenic cholangitis

Recurrent pyogenic cholangitis, also known as Oriental cholangiohepatitis or hepatolithiasis, is a syndrome seen primarily in southeast Asia including Taiwan, China, Japan, and Korea. Patients present clinically with recurrent attacks of abdominal pain, fever, and jaundice. Recurrent pyogenic cholangitis was once among the leading causes of acute abdominal emergencies in Hong Kong [320]. However, the

prevalence of intrahepatic stones is likely decreasing in many parts of Asia [321].

Primary intrahepatic stones are generally calcium bilirubinate or mixed stones. Intrahepatic calcium bilirubinate stones contain less bilirubin and more cholesterol than pigment stones in the extrahepatic bile ducts [322]. The pathogenesis of these stones is complex, and likely involves a combination of bile infection, malnutrition or dietary factors, biliary stasis, and possibly parasitic infestation. It is generally believed that bacterially mediated hydrolysis of bilirubin by β-glucuronidase is crucial to the formation of pigment stones. This leads to the formation of unconjugated bilirubin, which may precipitate as calcium bilirubinate. The β-glucuronidase enzyme often originates from *E. coli* or other bacteria in the biliary tree. There has been a debate about whether bacterial infection precedes or is a sequel of stone formation. However, in at least some patients with bilirubinate stones, bile infection precedes stone formation [162]. β-Glucuronidase can be inhibited by glucarolactone, whose levels are decreased in patients with a low protein and low fat diet [323]. It has therefore been suggested that dietary factors contribute to the formation of intrahepatic stones. The role of infection by parasites such as *Ascaris lumbricoides* or *Clonorchis sinensis* has been controversial. The parasites or their ova have been found as niduses for intrahepatic stones in earlier studies [322]. However, infection with these parasites is widespread, but recurrent pyogenic cholangitis is uncommon outside southeast Asia. Even within endemic countries, there is not a direct correlation between the prevalence of parasitic infection and the occurrence of this syndrome. These lines of evidence suggest that factors in addition to parasites are important for the development of these stones.

Recurrent pyogenic cholangitis frequently presents in patients less than 50 years of age. Men and women are affected equally. It is more common with lower socioeconomic status and malnutrition. Symptoms occur when the stones cause partial or complete biliary obstruction, either with or without associated infection. Many patients will present with epigastric or right upper quadrant pain or discomfort. Acute cholangitis, with fever, right upper quadrant pain, and jaundice, is also common. Physical examination may show right upper quadrant tenderness, hepatomegaly, or an enlarged gallbladder. Laboratory results are generally consistent with the degree of biliary obstruction and infection. In advanced cases, biliary cirrhosis and its sequelae may develop.

Recurrent pyogenic cholangitis is often diagnosed clinically in endemic areas. Delineating the extent and location of stones and strictures is essential to planning further treatment. Abdominal plain films are rarely useful as the stones are usually radiolucent. CT scan may be useful to assess ductal dilation. Percutaneous or endoscopic retrograde cholangiography provides the most accurate information. The left intrahepatic duct is preferentially involved. Frequent findings on cholangiography include stones, biliary strictures, and ductal dilation. The intrahepatic ducts may also appear "pruned" with decreased arborization [324]. Histologically, increased fibrous tissue around the portal tracts may be found with bile ductular proliferation.

Surgery is the primary method of treatment for this syndrome. The role of endoscopic treatment is relatively limited because of the difficulty in treating intrahepatic strictures and stones. Surgery should aim to remove as many stones as possible and to achieve adequate drainage of obstructed ducts [324]. In rare cases, hepatic resection can be undertaken if the stones and strictures are localized. If strictures cannot be managed operatively, many surgeons will create a Roux-en-Y choledochojejunostomy with the end of the loop left in the subcutaneous abdominal wall tissue [325]. This allows easier access for later endoscopic or interventional radiological treatment.

Interventional radiology techniques are also important in the management of recurrent pyogenic cholangitis. If percutaneous transhepatic drainage can be established, cholangioscopy can be used to direct attempts at electrohydraulic or laser lithotripsy, stricture dilation, and stone clearance [326]. Solvents such as MTBE are ineffective, because the stones are not cholesterol stones. Many patients will require a combined surgical and interventional radiological approach to achieve adequate drainage and stone clearance.

Primary sclerosing cholangitis, 1978
Variant primary sclerosing cholangitis syndromes, 1992

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts. Histological characteristics include the presence of portal tract inflammation, periductal fibrosis, and loss of small bile ducts. Disease progression is almost universal among subjects, resulting in biliary cirrhosis, hepatic failure, and possibly cholangiocarcinoma. Immunological and genetic alterations have been cited as factors in its pathogenesis [1,2]. Understanding the natural history of PSC has become important because of the success of liver transplantation as an effective therapeutic modality.

Epidemiology

With the increasing availability of endoscopic retrograde cholangiopancreatography (ERCP), a growing body of knowledge about the clinicopathological features of PSC has emerged. Fifty to seventy percent of affected individuals are male with an average age at diagnosis of 40 years [3–10]. The male predominance seen in PSC has not been observed in inflammatory bowel disease (IBD) or similar autoimmune liver diseases such as primary biliary cirrhosis (PBC) and autoimmune hepatitis (AIH). However, a significant proportion of female subjects have been reported among select cohorts [8,9]. The suggestion of a reduced survival outcome from PSC in female subjects, however, has yet to be confirmed [9].

The close association between PSC and IBD, however, is well established. Among northern Europeans, 70%–80% of PSC patients have chronic ulcerative colitis (UC) [11–14]. Lower prevalence rates of IBD in PSC, however, have been noted elsewhere [15,16]. These wide variations appear to be related to influences that are not explained by clinical practice. The use of surveillance colonoscopy with mucosal biopsy assessment, while improving the detection of subclinical IBD, is nonetheless required if accurate prevalence estimates for IBD in PSC are to be determined. No meaningful difference in PSC-related survival, however, has been observed among patients with or without IBD [9]. Ulcerative pancolitis or colonic involvement alone by Crohn's disease imparts the greatest risk for PSC [10,11]. Conversely, about 2.4%–4% of patients with UC [10,12–14] and 1.4%–3.4% of patients with Crohn's disease [11,14] either have PSC or develop PSC. From descriptions in the general population there is an estimated prevalence rate of 13–140 cases of PSC per 1 million persons [10]. Population-based epidemiological investigations of PSC have revealed annual incidence and cross-sectional prevalence rates of 0.9–1.3 and 8.5–20 per 100 000 population, respectively [17–19]. However, PSC has been reported at lower rates in geographic areas outside northern Europe and the United States, using less well-defined methods [20,21]. The accuracy of prevalence data is limited by several factors including the failure to identify asymptomatic patients, those with fluctuations in liver biochemical parameters such as serum bilirubin, and those without coexisting IBD. From an estimated prevalence rate of 40–225 cases per 100 000 US population for UC, the prevalence of PSC is estimated to be between 2 and 11 cases per 100 000 persons [10].

A Swedish investigation into the familial occurrence of PSC revealed a prevalence of 0.7%, which represents a 100-fold increased risk of developing PSC in first-degree relatives of patients with PSC. Ongoing investigations into the genetic factors are discussed later in this chapter [22]. An English study found an increased prevalence of PSC in patients with underlying celiac disease compared to the normal population [23]. Whereas a negative relationship between smoking history and UC activity is well established [24], similar investigations

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

have also been conducted in PSC. By comparing patients with UC with age-matched and gender-matched controls, a lower prevalence rate of PSC (4.9%) was observed among individuals who smoked compared with nonsmoking controls (26.1%) [25].

Pathogenesis

Progress in understanding the pathophysiology has been slowed by the lack of an animal model for PSC. Several potential animal models exist that exhibit similar immunological and genetic susceptibility to PSC, but none fully represents the human form of the disease. Genetic and immunological alterations as well as nonimmunological features have been cited as factors in the pathogenesis of PSC as well as in disease progression.

Genetics

As previously mentioned, PSC is 100-fold more common in first-degree relatives [22], suggesting genetic inheritance, but it does not follow classic genetic (mendelian) inheritance patterns. To date, no specific autoantigen has been elucidated.

Normal biliary cells express human leukocyte antigen (HLA) class I (A, B, and Cw) but not class II (DR, DQ, and DP) molecules, but class II molecules appear to be aberrantly expressed on the biliary cells of PSC patients [26,27]. An increased prevalence of HLA-A1, HLA-B8, and HLA-DR3 alleles in PSC has been described but remains nonspecific given the occurrence of these alleles in other organ-specific autoimmune diseases [26]. Greater than expected frequencies of the HLA-DRw52a antigen and HLA-DRB3*0101 were initially reported among 100% of patients undergoing liver transplantation at a US center [28]. Subsequent investigations have not supported the DRw52a allele as an important susceptibility marker for disease development [29]. HLA-DRB3*0101 appears to be the most common susceptibility locus in 55%–65% of PSC patients [30] and may be universal in end-stage liver disease from PSC [13]. In Scandinavia, however, the HLA alleles DRB1*0301 and DRB1*1301 have been reported as the primary susceptibility loci in PSC [31]. Of potential significance is the reported association between DRB3*0101 and reduced survival among subjects with PSC [29]. Rapid disease progression has also been suggested with the existence of HLA-DR4 where a protective effect was once previously proposed [32]. A multicenter investigation found the HLA-DR3,DQ2 heterozygous genotype associated with more rapid disease progression in PSC whereas a protective effect was linked to HLA-DQ6 [33]. Overall these genetic associations with PSC are complex and poorly understood.

A number of non-major histocompatibility class candidate genes may also be related to the immune dysregulation in PSC. Serum cytokines including interleukin-1 (IL-1) and IL-10 have been examined as inflammatory response mediators in PSC. No association between IL-1 and IL-10 gene polymorphisms with susceptibility or resistance to PSC has been observed [34,35]. Major histocompatibility class I chain A (MICA) and chain B (MICB) genes have also been studied in PSC. MICA5.1 (90% vs 74%) and MICB24 (58% vs 29%) were significantly increased among PSC patients compared with controls [36]. The frequency of PSC patients carrying all four alleles was also significantly greater than controls (49% vs 18%). Between two independent PSC populations [37], the MICA*008 allele was more common in PSC than in controls (66% vs 48%) whereas the MICA*002 allele had a protective effect from PSC. A chemokine receptor (CCR5) is expressed on T cells and macrophages. A 32-basepair deletion in the chemokine receptor 5 gene (CCR5-Delta32) leads to a nonfunctional receptor. Conflicting evidence exists whether this deletion is associated with PSC. Although one study [38] notes a higher rate of this defect in PSC and a relation to severity of disease, the most evidence suggests that there is no association [39,40]. Matrix metalloproteinases (MMPs) regulate fibrosis production. A common polymorphism in the promoter sequence of stromelysin (MMP-3) results in increased transcription. The influence of a matrix metalloproteinase-3 (MMP-3) functional polymorphism may influence susceptibility and disease progression in PSC as demonstrated in one study [10], but not confirmed in another [41]. Intercellular adhesion molecule-1 (CD54) gene polymorphisms have been implicated in the susceptibility to a range of inflammatory diseases, including IBD, but have not been clearly associated with PSC [42,43].

Immune-mediated

Evidence that PSC may be immune mediated is circumstantial, and largely because of disease associations with other autoimmune processes [44]. Cellular immune abnormalities have been described focusing primarily on the significance of lymphocyte function in PSC. CD4 T-lymphocyte recognition of antigens found on biliary epithelia is hypothesized to initiate the immune-mediated histological damage seen in PSC [30,45]. T-cell reactivity studies have demonstrated the activation of both suppressor and cytotoxic lymphocyte populations with exposure to major histocompatibility antigens in vitro [45]. A recent study using freshly isolated liver-derived T cells from PSC patients showed that cell proliferation and the function of these T lymphocytes are impaired in PSC patients compared with normal controls and other patients with autoimmune liver diseases [46]. The study demonstrated an inability to detect any normal cytotoxic activity among liver-derived T cells and natural killer cells from these patients, which was thought to be a consequence of exposure (maybe even chronic) to high levels of tumor necrosis factor-α (TNF-α) in vivo. The study also showed that these liver-derived lymphocytes from PSC patients showed increased expression of intracellular TNF-α. Interestingly, the addition of anti-TNF antibodies restored the diminished proliferative responses of the T cells in vitro [46]. Bernal and colleagues [47] studied the association of TNF polymorphism with PSC and concluded

that genetic susceptibility to PSC may be determined by polymorphism within the TNF genes, particularly with the TNF2 allele. The increased numbers of hepatic B-cell lymphocytes reported among PSC patients with advanced histological disease are not found with earlier stages of disease, suggesting that cellular infiltration may be a secondary phenomenon related to chronicity [48]. In a Swedish study, anti-biliary epithelial cell antibodies were demonstrated in 63% of PSC patients; in 90% of these patients the autoantibodies reacted only with cytokine-stimulated target cells. Interestingly, the antibody-positive PSC patients had either the HLA-DRB1*0301 or HLA-DR2 allele (see below) compared with those without ($P = 0.007$) [49]. These studies suggest a coordinated inflammatory response that implicates both the cellular and humoral arms of the immune response in the pathogenesis of PSC. Several potential animal models exist that exhibit similar immunological and genetic susceptibility to PSC, but none fully represents the human form of the disease.

A number of clinical investigations have also confirmed the presence of numerous humoral immune markers in the sera of patients with PSC. Non-organ-specific markers such as immunoglobulins G and M, antinuclear antibody, and anti-smooth muscle antibody are often found at low but detectable titers [2,50]. Their relevance in the pathogenesis of PSC may occur among patients displaying clinical features of AIH and PSC. Elevated levels of circulating immune complex molecules have also been reported in up to 80% of PSC patients and other HLA-B8-DR3-associated immune-mediated diseases [50,51]. Selected cross-reactive antibody species among patients with UC and PSC are not seen in patients with PSC alone, suggesting a shared mechanism for immune-mediated damage [52]. Perinuclear antineutrophil cytoplasmic antibody (pANCA) has been reported in 26%–85% of patients with PSC and in 70% of UC patients without PSC [53–55]. These are "atypical" pANCAs and are distinct from the pANCA of microscopic polyangiitis, with the target antigen possibly a neutrophil nuclear envelope protein. In fact, because it is not a cytoplasmic protein, the term peripheral antineutrophilic nuclear antibody (pANNA) has been suggested [56]. The antigenic and subsequent potential pathogenic role of pANCA, however, is unknown [57]. Seropositivity for pANCA in PSC has been reported with extensive involvement of the biliary tree, hepatic dysfunction, and severe cholestasis; titers tend to remain unchanged after liver transplantation [58]. Antibodies to *Saccharomyces cerevisiae* have been observed in PSC, but they appear to be of limited clinical value [59]. Little progress has been made in elucidating the immunological mechanisms of this disease.

Nonimmune-mediated

The primary target of immune-mediated injury in PSC is the biliary epithelium. Increased expression of class II major histocompatibility complex molecules on biliary epithelial cells in PSC in support of their role as antigen-presenting cells remains controversial.

The strong association between PSC and IBD suggests that an infectious etiology may be present in specific individuals [60]. Alterations in the mucosa of diseased bowel facilitating portal bacteremia may be responsible. Increased levels of TNF have been found in animal models linked to portal bacteremia and the resulting activated hepatic Kupffer cells [61]. Clinical evidence in humans, however, is noted for the relative lack of significant colonic inflammation in both patients with PSC and patients after total proctocolectomy for refractory UC [62]. Eksteen and colleagues have shown that T cells activated in the gut are recruited to the liver by aberrant expression of gut-specific chemokines, and that these lymphocytes can persist for years potentially explaining the delayed onset of PSC despite colectomy in some patients [63]. Bjornsson et al. were unable to demonstrate a role for small bowel bacterial overgrowth and increased intestinal permeability in the pathogenesis of PSC [64]. As with primary biliary cirrhosis, the role of *Helicobacter* sp. infection in developing PSC has been examined. The significance of an increased rate of *Helicobacter* sp. DNA in patients with PSC (especially those with UC) compared to those with non-cholestatic liver disease requires further study [65]. An increased rate of α-hemolytic streptococci from explanted liver tissue [66] and bile [67] has been demonstrated in PSC. Among PSC patients with or without previous ERCP, α-hemolytic streptococci were the most frequent isolates despite similar positive culture rates. The impact of α-hemolytic streptococci on etiopathogenesis or disease progression in PSC remains unknown. Infections with viruses such as cytomegalovirus among immunocompromised hosts can result in PSC-like changes [68].

Hepatic histological features of cystic fibrosis can resemble PSC, but gene analysis (*CFTR* gene) did not demonstrate higher gene carriage rates in patients with PSC [69]. Immunodeficiency syndromes have been identified with cholangiographic changes suggestive of PSC including, familial immunodeficiency syndrome, X-linked inmunodeficiency, angioimmunoblastic lymphadenopathy, acquired immunodeficiency syndrome (AIDS) without known explanation [70].

Bile acid metabolite hepatotoxicity has been observed in animal models after chenodeoxycholic acid breakdown to lithocholic acid by bacterial 7-α-dehydroxylation in the colon. No major bile acid abnormalities have been identified among human subjects with PSC [71]. A possible role of biliary lipotoxicity, in the sense of deranged and consequently toxic bile composition, has been suggested as a trigger for the development of cholangitis, but it requires further investigation [72]. Biliary tree injury resulting from hepatic artery chemoembolization with fluorodeoxyuridine, 5-fluorouracil, and mitomycin can yield cholangiographic features compatible with PSC [73]. Direct toxicity or ischemia to bile ducts is hypothesized.

Table 75.1 Symptoms and signs at initial presentation in primary sclerosing cholangitis

Finding	Prevalence (%)
Symptom	
Fatigue	75
Pruritus	70
Jaundice	65
Weight loss	40
Fever	35
Asymptomatic	10
Sign	
Hepatomegaly	55
Jaundice	50
Splenomegaly	30
Hyperpigmentation	25
Xanthelasma	4

Clinical manifestations

Asymptomatic elevations in serum liver biochemistries or the development of symptoms such as fatigue (75%) and pruritus (70%) are often observed with the diagnosis of PSC (Table 75.1). Jaundice (65%) and weight loss (40%) are less common and should raise the suspicion of advanced disease or a complication related to PSC [1,2,4,8]. The average duration of symptoms prior to diagnosis is 2 years. Fever and abdominal pain in a patient with PSC is highly suggestive of bacterial cholangitis, which can manifest at initial presentation [74]. A previous history of IBD and elevated serum liver biochemistries often prompts investigations to exclude PSC. Among patients with refractory UC requiring total proctocolectomy, it has been shown that PSC may still develop among these individuals [62].

Asymptomatic primary sclerosing cholangitis

Whereas symptomatic PSC is commonly associated with jaundice or pruritus, an increasing number of asymptomatic cases are being identified. Asymptomatic patients have represented between 15% and 25% of most reported observational cohorts examined [4–6,9,19,75]. Recent reports, however, have observed prevalence rates of greater than 40% for asymptomatic PSC [8,19,76].

Progression of liver disease can also occur among asymptomatic patients but existing data are conflicting. Over a 6-year period, the evidence for advancing liver disease was noted among 34 of 45 (76%) asymptomatic subjects with a 31% rate of liver transplantation or death [75]. Minimal histological abnormalities (stage I–II) on liver biopsy with no cases of cirrhosis were found in the majority of subjects at study entry. Estimated median survival for asymptomatic patients without liver failure was 65%–75% at 7–10 years compared with 96% for comparable age-matched and sex-matched healthy individuals [19,75]. Helzberg and colleagues [4] reported that 11 of 13 asymptomatic individuals remained symptom free for a mean duration of 37 months, resulting in an overall survival rate of 75% at 9 years. Independently, no significant decompensation over a 4.4-year period among 27 asymptomatic subjects has also been described [3].

Despite a silent or subclinical presentation at diagnosis, there is evidence to support that asymptomatic PSC becomes symptomatic. Fatigue, pruritus, jaundice, or abdominal discomfort develops in 60% of patients [4–6,8]. The similar frequencies in clinical deterioration among asymptomatic and symptomatic patients, however, emphasize the lack of predictive ability associated with subjective complaints at diagnosis [4,6]. Differences in criteria for defining the asymptomatic state may explain the discrepancy in published results. Fatigue and weight loss have been reported in up to 30% and 24% of asymptomatic subjects, respectively. In addition, advanced histological features have been demonstrated in 30% to 43% of subjects considered asymptomatic at diagnosis [3,75].

Symptomatic primary sclerosing cholangitis

The majority of subjects in reported investigations have been described as symptomatic based on findings at diagnosis [3–9]. Helzberg and colleagues [4] first reported an 18% mortality rate among patients with PSC over a mean follow-up period of 56 months. All deaths occurred in symptomatic individuals. A similar mortality rate of 14% over 51 months has been observed with a reduced median survival for symptomatic individuals as well (112 months compared with 144 for the entire cohort) [8]. Two larger series have provided evidence to suggest a more aggressive disease course for symptomatic PSC. Among 174 patients with PSC who were followed at the Mayo Clinic [5], a 41% combined rate for liver failure, cholangiocarcinoma, and need for transplantation was observed over 6.25 years of follow-up. Median survival for the entire cohort was 11.9 years. For symptomatic patients with PSC, the median survival was reduced to between 8 and 9 years. Similar results were reported from Kings College [6], where a median survival of 12 years was observed among 126 subjects over a 6.9-year period.

Biochemical features

Serum hepatic biochemical parameters usually reflect a cholestatic profile. Alkaline phosphatase values often predominate with elevations up to three times the upper limit of normal in nearly 95% of patients [1–9]. Serum alanine aminotransferase and aspartate aminotransferase levels can also be found between two and three times higher than the upper limit of normal [3,4,8,9,74]. Serum total bilirubin is normal in 60% of individuals [1,2,74]. Levels of total bilirubin, which often fluctuate in PSC, are of concern for

advanced disease when persistent elevations occur. No significant differences in serum liver biochemistry profiles have been seen among asymptomatic and symptomatic individuals at diagnosis [75]. Normal serum albumin measurements and prothrombin times, which reflect hepatic synthetic function, are found in the majority of patients at diagnosis [3–9].

Serological features

Serum immunoglobulin levels and autoantibodies are associated with PSC. Elevations in immunoglobulin G and immunoglobulin M in up to 40% and 60% of individuals, respectively, are observed [2,7]. Antinuclear antibody and smooth muscle antibody (SMA) can also be detected but are at lower titers compared to those found in AIH [2,7,77]. Antimitochondrial antibodies (AMA) are exceedingly rare in PSC [5,77]. Atypical pANCAs (see Immune-mediated section) are detected in the serum of PSC patients at rates between 30% and 80% [53,54] but they lack specificity because they are also observed in PBC, AIH, and UC [54,78]. Angulo and colleagues [79] have observed a greater rate of seropositivity for antinuclear antibody, anticardiolipin, antithyroperoxidase, ANCA, and rheumatoid factor among patients with PSC compared to control subjects. Ninety-seven percent of PSC patients were found to have one or more autoantibodies whereas 81% were found with three or more. The presence or absence of IBD was not significantly associated with autoantibody history.

Figure 75.1 Cholangiographic features in primary sclerosing cholangitis. Multifocal strictures with intervening saccular dilation ("beads-on-a-string" appearance) of both intrahepatic and extrahepatic bile ducts are shown.

Radiographic features

Cholangiography

The diagnosis of PSC is made by cholangiography. Both ERCP and percutaneous transhepatic cholangiography (PTC) have been employed in a nonoperative setting, but they are invasive. Magnetic resonance cholangiopancreatography (MRCP) is increasingly being used for diagnostic purposes and ERCP and PTC are saved for difficult diagnoses or therapeutic uses. PSC commonly affects the entire biliary tree in a heterogeneous manner. Intrahepatic duct involvement is almost universal among patients with PSC [80]. Only 15%–20% of patients will have hilar duct involvement with sparing of the remaining extrahepatic duct. Segmental fibrosis of both intrahepatic and extrahepatic ducts with subsequent saccular dilation of normal intervening areas results in the characteristic "beads-on-a-string" appearance seen with cholangiography in PSC (Fig. 75.1). Bile duct strictures are of varying lengths but can be up to several centimeters. The serrated appearance of bile duct walls and occasional diverticula are also identified in extrahepatic portions of the biliary tree in 25% of patients [81].

The initial use of MRCP for suspected PSC has been increasingly recognized [82,83]. Among 23 of 73 patients identified with PSC [82], an overall diagnostic accuracy of 90% for MRCP compared to 97% for invasive cholangiography was reported. Comparable diagnostic accuracy has been demonstrated for MRCP compared with ERCP [84] but some still argue that better diagnostic accuracy for extrahepatic strictures is obtained with ERCP [85]. Advantages for MRCP over invasive cholangiography include the visualization of bile ducts proximal to obstructed areas and hepatic parenchymal assessment for features of cirrhosis and portal hypertension or lobar atrophy. The inclusion of subjects with advanced PSC and overestimation of stricture length by MRCP have been observed as potential biases for both investigations.

Cross-sectional imaging

Computed tomography (CT) [86–88] and magnetic resonance imaging (MRI) [88–90] have been used in the evaluation of PSC. Radiological features of PSC detected by cross-sectional imaging include segmental dilation of intrahepatic bile ducts and a paucity of increasing dilation toward the hilum [86]. Gallstones have been identified in up to 25% of patients with PSC and asymmetric thickening of the gallbladder wall independent of cholelithiasis may also be observed [87]. Marked hypertrophy of the right and caudate hepatic lobes and simultaneous atrophy in the remaining liver are often seen in cirrhotic-stage PSC [88]. As observed for other etiologies of cirrhosis, the presence of confluent hepatic fibrosis and resulting regenerative nodule formation may

be confused for hepatocellular carcinoma. With MRI, the presence of abnormal T2-weighted signal intensity from periportal areas is common and correlates with fibrosis [89]. Enlarged areas (greater than 1.5 cm) of abnormal T2 signal within portal areas are considered suspicious for cholangiocarcinoma [90].

New diagnostic procedures being investigated include the use of dynamic three-dimensional biliary scintigraphy (technetium 99 m hepatobiliary iminodiacetic acid single-photon emission CT [HIDA SPECT]) for differentiating between parenchymal and ductal contributions to deranged liver function [91]. Duodenal endoscopic ultrasound may be able to provide additional diagnostic proof for extrahepatic disease, but its clinical utility is uncertain [92]. Although limited by lack of availability, transpapillary cholangioscopy appears to increase the ability to distinguish between malignant and benign dominant bile duct stenoses in patients with PSC [93]. In addition, cholangioscopy detects stones missed by cholangiography in more than 30% of PSC patients referred for dominant strictures or stones [94].

Histological features

Liver biopsy is required for staging disease severity and determining prognosis in PSC. Periductal fibrosis with inflammation, bile duct proliferation alternating with obliteration, and ductopenia constitute the main histological findings [95]. Fibroobliterative cholangiopathy, which is considered the most diagnostic finding for PSC on liver biopsy, is present in only 10% of patients [96]. However, similar findings may occur in varying stages of other conditions such as PBC, AIH, or chronic extrahepatic bile duct obstruction. The histological abnormalities in PSC are classified into four stages. Stage I (portal stage) is associated with a nonspecific inflammation confined to the limiting plate, which surrounds the portal tract; fibrosis is usually not seen at this stage. Stage II (periportal stage) is associated with inflammation extending beyond the limiting plate with expansion of the portal tracts; fibrosis is seen involving the portal and periportal areas. Stage III (septal stage) is characterized by septal or bridging fibrosis spanning the portal tracts in conjunction with bridging necrosis (Fig. 75.2). Stage IV, or cirrhosis, is when complete septal fibrosis in association with evidence for nodular regeneration is present [95].

Differential diagnosis

Table 75.2 lists the differential diagnoses for PSC. The identification of serum hepatic biochemical elevations consistent with cholestasis in a male patient with concurrent IBD is strongly suggestive of PSC. Excluding structural causes for biliary obstruction, including choledocholithiasis, by ultrasonography or cross-sectional imaging is also required. Cholangiography by direct or imaging methods, which reveals the typical features of PSC, is considered the gold standard for diagnosis. Although liver biopsy is not mandatory to confirm the diagnosis of PSC, its performance is helpful for staging and excluding other causes of chronic cholestasis.

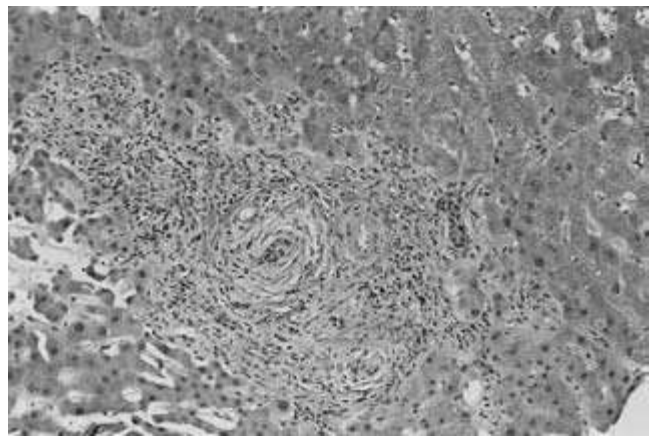

Figure 75.2 Histological features of primary sclerosing cholangitis. Portal tract expansion with chronic nonspecific inflammation, edema, and periportal fibrosis consistent with stage II disease is shown.

Table 75.2 Differential diagnosis of primary sclerosing cholangitis

Extrahepatic biliary tract obstruction
Choledocholithiasis
Strictures
Malignancy
Primary biliary cirrhosis
Autoimmune hepatitis
Autoimmune pancreatitis
Pyogenic hepatic abscesses
Fungal cholangitis
Acquired immunodeficiency syndrome cholangiopathy
Choledochal cyst
Cystic fibrosis
Cirrhosis
Intrahepatic hepatocellular carcinoma
Cholangitis glandularis proliferans
Eosinophilic cholangitis

PBC more commonly affects women than men (with a 9 : 1 ratio) and is rarely associated with IBD. The diagnosis is confirmed by elevated serum titers of AMA. Early histological involvement is characterized by lymphoplasmacytic portal infiltration or granulomatous inflammation ("florid duct lesion") [97]. AMA-negative PBC or autoimmune cholangitis is clinically similar to PSC in the absence of cholangiography. With normal biliary tree visualization, a liver biopsy is required to distinguish this condition from small-duct PSC where involvement with ductular fibrosis is more prominent [98].

AIH is distinguished from PSC by

- predominant elevations in serum aminotransferase levels compared to alkaline phosphatase and bilirubin
- the presence of elevated serum antinuclear antibody or anti-smooth muscle antibody titers

• extensive interface or lobular lymphoplasmacytic inflammation
• normal cholangiography [99].

In children, the initial presentation of PSC often resembles AIH so cholangiography is necessary for accurate diagnosis [100]. Overlapping syndromes between AIH and PSC among pediatric and adult populations have been recognized in 2%–20% of patients based on various definitions [77,101,102]. Cholangiography in these patients, however, must demonstrate features of PSC before consideration of an overlap state is made. There may be potential benefit from corticosteroid therapy for selected individuals.

Autoimmune pancreatitis (AIP) is a disease entity that frequently involves the bile ducts (causing a sclerosing cholangitis, i.e., AIP-SC) creating similar radiographic and histological features to PSC. AIP-SC generally causes stenosis of the distal ducts, but both intrahepatic and extrahepatic changes have been described in up to 50% of patients. Liver biopsy specimens of AIP-SC were indistinguishable the biopsy specimens of patients with PSC. However, AIP is responsive to steroids, whereas PSC is not, which portends a better overall prognosis [103,104].

The development of pyogenic hepatic abscesses with invasion of adjacent bile ducts can result in irregularities that suggest PSC [105]. Frequent attacks of ascending cholangitis in natives of southeast Asia are consistent with a diagnosis of recurrent pyogenic cholangitis (oriental cholangiohepatitis). Cholangiography will show dilation of intrahepatic and extrahepatic ducts, decreased arborization with tapering of peripheral ducts ("arrowhead sign"), and straightening of the intrahepatic ducts from periductal fibrosis [106]. Systemic fungal infection may colonize or invade the biliary tree resulting in the cholangiographic features of PSC [107]. AIDS cholangiopathy presents with striking elevations in serum alkaline phosphatase with or without symptoms of jaundice and abdominal pain. Extrahepatic bile duct dilation and papillary stenosis are most commonly observed. Thickened bile duct walls rather than saccular dilations in AIDS cholangiopathy distinguish this entity from PSC [108].

Choledochal cyst involvement of intrahepatic bile ducts can also resemble PSC. Ultrasonography usually shows marked areas of ductal dilation, and cholangiography is almost invariably diagnostic [109]. Cystic fibrosis, which involves intrahepatic bile duct cystic dilation, can produce a cholangiogram typical of PSC [110].

Diffuse abnormalities of the biliary tree without discrete extrahepatic stricturing may also be observed with conditions such as cirrhosis and intrahepatic hepatocellular carcinoma. In cirrhosis, the presence of distal duct tapering is noted when cholangiography is performed. Cross-sectional imaging and liver biopsy (if indicated) will confirm the presence of cirrhosis or hepatic neoplasia when suspected [111].

Cholangitis glandularis proliferans [112] – a rare disorder similar to adenomyomatosis of the gallbladder – and eosinophilic cholangitis [113] can present with nonstricturing intrahepatic duct dilation resembling sclerosing cholangitis.

Table 75.3 Selected extrahepatic autoimmune diseases associated with primary sclerosing cholangitis

Disease	Prevalence (%)
Ulcerative colitis	70–80
Crohn's colitis	5–8
Pancreatitis	10–25
Diabetes mellitus	5–15
Autoimmune thyroid disease	3–5

Associated conditions

An increased prevalence for concurrent autoimmune disorders has been recognized in PSC but remains less common than in PBC (Table 75.3). UC remains the most commonly associated autoimmune disorder in PSC (70%–80%) [2,5–8,10–14] with colonic involvement from Crohn's disease occurring in 5%–8% of patients with PSC [11,14]. Other diseases include pancreatitis (10%–25%) [114,115], diabetes mellitus (5%–15%) [116], and autoimmune thyroid disease (3%–5%) [116]. Rare associations include Sicca syndrome [115], immune thrombocytopenic purpura [117], mediastinal or retroperitoneal fibrosis [118,119], pseudotumor of the orbit [119], Peyronie disease [120], rheumatoid arthritis [121], ankylosing spondylitis [122], Hodgkin disease [123], membranous nephropathy [124], glomerulonephritis [125], autoimmune hemolytic anemia [126], celiac disease [127,128], histiocytosis X [129], hypereosinophilia [113], focal nodular hyperplasia [130], and Down syndrome [131].

Disease-related complications

Fatigue

The frequency of reported fatigue by individuals affected by PSC is between 60% and 70% [89,74]. Its level of intensity appears to be independent of histological and cholangiographic disease severity [1–8]. Reported fatigue has been associated with reductions in health-related quality of life in PSC [132]. Knowledge of the exact mechanism responsible for fatigue in PSC remains unknown.

Pruritus

In PSC, the prevalence of pruritus ranges from 40% to 60% in reported observational cohort studies [1–8]. Proposed mechanisms of action have included bile salt retention with skin deposition [133] and the accumulation of endogenous opioid ligands and receptors within the central nervous system [134]. As with fatigue, the severity of pruritus in PSC appears to be independent of histological stage, although extrahepatic stricturing can influence symptom intensity [1–8].

A number of medical therapies have been evaluated for symptom relief from pruritus. Initial therapy with antihistamines is often associated with residual sedation and only limited success [97]. Cholestyramine (a bile-acid-binding resin) may decrease the intensity of pruritus but rarely provides complete symptom resolution [135]. Among subjects with intact gallbladders, the use of 4 g before or after breakfast is thought to maximize bile acid sequestration resulting in symptom alleviation. Divided doses over 24 h in subjects postcholecystectomy are more effective than once or twice daily dosing. Administration of cholestyramine several hours apart from other medications is recommended to prevent its elimination without gastrointestinal absorption.

Hepatic enzyme inducers including phenobarbital [136] and rifampin (rifampicin) [137–139] have been associated with improvements in bile acid flow experimentally and used in the treatment of pruritus. Excessive sedation at higher doses has limited the clinical utility of phenobarbital [136]. Rifampin at dosages of 300–600 mg/day is associated with a rapid onset of action and symptom relief in PSC [137]. Although well-tolerated, this medication is also associated with cholestatic liver injury and bone marrow aplasia in up to 10% of patients [138]. Ursodeoxycholic acid (UDCA) at dosages of 13–15 mg/kg/day has not been shown to be effective in the treatment of pruritus [139]. Other therapeutic options used for pruritus in PSC including oral naltrexone [140], activated charcoal hemoperfusion [141], and plasmapheresis [142] have been sporadically applied with good results. Among patients with intractable pruritus that is refractory to medical therapy, liver transplantation is the only existing therapeutic option [97].

Metabolic bone disease

Metabolic bone disease in PSC is related to osteopenia rather than osteomalacia (defective bone mineralization) among North American patients [143]. Decreased bone formation (osteoporosis) [144] and some degree of increased resorption [145] are felt to be important mechanisms in the pathogenesis of bone disease. Calcium and vitamin D metabolism is usually abnormal among anicteric patients with PSC [146]. The recognition of improved bone mineral density approximately 6 months after liver transplantation also suggests the presence of an unidentified substance creating osteopenia [147]. Approximately 50% of patients with PSC have osteopenia (i.e., a Z score less than − 1.0 by lumbar spine bone mineral densitometry) whereas osteoporosis (i.e., a Z score less than − 2.5) is less common in PSC than in PBC (10% compared with 35%) [148,149]. Reasons for this difference include a greater proportion of male patients with PSC with higher baseline bone mass and a slower rate of bone loss compared to women. Only 23% of patients with advanced cholestatic liver disease have normal bone density at the time of transplantation [150]. Up to 50% of liver transplant recipients have bone mineral densities below the fracture threshold. Risk factors for osteoporosis in PSC are low body mass index, older age, postmenopausal status, muscle wasting, high alkaline phosphatase, low serum albumin, and a long duration of IBD [148–150], but bone density is not clearly related to the severity of the hepatic disease [151].

Ensuring adequate intake of calcium (1000–1200 mg daily) with weight-bearing activity is recommended as an initial treatment for all individuals. Measurement of serum vitamin D levels is also an essential part of the preventative management in PSC. The presence of vitamin D deficiency is variable among patients with metabolic bone disease. Oral replacement therapy is indicated if measured serum levels are reduced compared to local normal values. The 25-hydroxylation of vitamin D is intact among PSC patients; therefore, the use of vitamin D rather than 1,25-dihydroxyvitamin D or 25-hydroxyvitamin D can be used. Dosage is generally between 25 000 and 50 000 IU two to three times per week. The efficacy of bisphosphonate therapy in PSC remains unknown. No benefit from calcitonin was observed compared with placebo among PSC patients after liver transplantation [147].

Steatorrhea

Impairment in bile acid delivery resulting in insufficient critical micellar concentrations in the small intestine is the most common cause of steatorrhea with advanced hepatic disease caused by PSC [1]. The coexistence of celiac disease with PSC has been reported in an increasing number of PSC patients [127,128]. Exocrine pancreatic insufficiency has also been observed as a cause of steatorrhea related to overall glandular dysfunction, which may be associated with chronic pancreatitis [114,115]. Determining the exact cause is important because specific therapeutic options can be employed for symptom relief. In patients with decreased bile acid concentrations, the oral replacement of medium-chain triglycerides for long-chain compounds is usually of benefit. Adherence to a gluten-free diet and pancreatic enzyme replacement therapy are recommended for patients affected by celiac disease and pancreatic insufficiency, respectively.

Micronutrient deficiency

Malabsorption of fat-soluble vitamins is common with advanced hepatic disease caused by PSC. Intrahepatic cholestasis and impaired bile acid delivery to the small intestine are putative causes. Vitamin A deficiency observed in 20%–50% of patients is often clinically asymptomatic. When symptomatic, the presence of night blindness is observed and should be corrected by oral replacement therapy with 25 000–50 000 IU two to three times a week. As discussed previously, vitamin D deficiency can occur and is the next most common fat-soluble vitamin deficiency in 15%–50% of patients [146].

Vitamin E deficiency is a rare occurrence in PSC. When present, it may be associated with ataxia from neuropathic

involvement of the posterior vertebral columns of the spinal cord. Oral replacement therapy is indicated in asymptomatic patients [152].

Vitamin K deficiency is most commonly related to severe cholestasis, cholestyramine treatment for pruritus, or significant hepatic dysfunction from end-stage PSC. The initiation of water-soluble oral vitamin K at 5 mg daily with repeat measurement of prothrombin time is effective in determining the extent of malabsorption. If correction of prothrombin time is encountered, daily oral doses between 5 mg/day and 10 mg/day may be initiated.

Biliary calculi

Biliary calculi have been reported in up to 40% of patients with PSC [1,2,74,87]. Cholelithiasis is common and often requires cholecystectomy when symptomatic biliary colic occurs in nonadvanced hepatic disease [87]. Choledocholithiasis is reported at frequencies between 5% and 15% and more commonly among symptomatic individuals with biliary strictures. The most calculi are pigmented in nature and involve both central and peripheral bile ducts [153]. The development of symptoms, including intractable abdominal pain or recurrent bacterial cholangitis, has been successfully treated by endoscopic [154,155] or percutaneous [156] methods to provide biliary decompression and stone extraction. Biliary surgery, including stone extraction and bilioenteric anastomosis [156,157], may be required only in patients that are refractory to endoscopic and percutaneous approaches.

Dominant stricture

Dominant strictures or stenoses occur in 15%–20% of patients with PSC [158]. Clinical manifestations include a sudden increase in serum alkaline phosphatase or bilirubin in the asymptomatic patient, progressive jaundice, and bacterial cholangitis [1,2,74]. Cholangiography is required to determine the nature and extent of existing strictures [158]. Balloon dilation of identified stenoses by endoscopic [154] or radiological [158] approaches often provides significant clinical improvement. For patients with an incomplete response to balloon dilation alone, the use of endoscopic stents for 3–6 months to prevent recurrent stricture formation has been advocated [159,160]. Reports of infectious complications, however, have raised questions about the efficacy of this approach [161]. Cytological brushings with pinch biopsies of all dominant strictures is required to help exclude the presence of cholangiocarcinoma [162]. Cholangioscopic evaluation may be better able to predict benign vs malignant dominant strictures, but access to this procedure is limited [163].

Bacterial cholangitis

Bacterial cholangitis in PSC is most commonly associated with a previous history of biliary tract surgery [74], bile duct calculi [153], or ductal obstruction from a dominant stricture [158]. Once suspected, empiric broad-spectrum intravenous antibiotic therapy should be initiated. Cholangiography (with ERCP if possible) should then be considered to exclude biliary obstruction and to provide biliary decompression. The use of prophylactic antibiotic therapy (oral fluoroquinolone, trimethoprim-sulfamethoxazole) especially in the setting of short-term biliary stent placement may reduce the risk for recurrent cholangitis. Recurrent episodes of bacterial cholangitis in PSC can be an indication for liver transplantation [74].

Cholangiocarcinoma

A measurable proportion of subjects with PSC will develop cholangiocarcinoma as a complication of disease. Prevalence rates appear to vary between 7% and 13% in most reported series [3,5–9,164]. Between 30% and 45% of individuals with PSC will be diagnosed with cholangiocarcinoma at the time of liver transplantation [165–171] or autopsy [3,172,173]. PSC may be simultaneously present in 30%–50% of patients of diagnosed cholangiocarcinoma. The anatomic distribution of cholangiocarcinoma in PSC primarily involves the hilum (75% of patients), intrahepatic ducts (16%), and gallbladder (8%) [174].

Risk factors for cholangiocarcinoma in PSC include inflammatory bowel disease, chronic liver disease, cirrhosis, alcohol use, smoking, human immunodeficiency virus (HIV) infection, and diabetes [175]. No association with the stage of hepatic disease in PSC is observed, with coexisting cirrhosis affecting only 20% of patients with cholangiocarcinoma [174,176]. Advanced age and longer duration of IBD [173] have also been cited. Previous or current cigarette smoking has been suggested to be associated with cholangiocarcinoma in some but not all studies [177]. The presence of colorectal dysplasia/carcinoma in patients with PSC and UC has been noted as a possible risk factor for cholangiocarcinoma [172].

The presence of oncogenic mutations, inactivation of tumor suppressor genes, and apoptosis have been postulated as mechanisms for the development of cholangiocarcinoma in PSC. Mutations in K-*ras* found in the biliary secretions of PSC patients have been associated with cholangiocarcinoma [179,180] but this remains a nonspecific finding. Aberrations of the p53 tumor suppressor gene occur in 30%–80% of patients with PSC whose disease is complicated by cholangiocarcinoma [181] but are often seen as a late finding. Chromosomal loss of 9p21 and p16 tumor suppressor gene inactivation have also been reported [182]. The recognition of biliary dysplasia as a precursor to cholangiocarcinoma has been inconsistently suggested [183,184]. A detailed review of this topic is given in Chapter 77.

The diagnosis of cholangiocarcinoma in PSC remains challenging despite recent technological advances. Using the Mayo PSC model among 48 subjects undergoing liver transplantation, the incidence of biliary tract malignancy was significantly associated with model risk scores greater than 4.4 independent of clinical status [185]. Subsequent investigations to confirm this observation have not been performed.

Marked bile duct dilation in association with a polypoid mass-like structure larger than 1 cm in diameter on cholangiography has been reported in association with cholangiocarcinoma. The distinction between benign and malignant biliary strictures from less prominent findings, however, remains difficult. Comparisons between ultrasound, CT, and MRI have demonstrated an inadequate ability to distinguish between PSC patients with and without cholangiocarcinoma [186]. Emerging techniques such as positron emission testing that show initial promise will require further examination [187].

Serum tumor markers including carbohydrate antigen 19-9 (CA 19-9) and carcinoembryonic antigen (CEA) have been employed for the early detection and diagnosis of cholangiocarcinoma. CA 19-9 levels over 100 U were found to have a sensitivity of 52%–89% and specificity of 76%–86% for detecting cholangiocarcinoma in PSC [188,189]. The combination of both markers (CA 19-9 + CEA × 40) exceeding values of 400 U was reported to have an 86% diagnostic accuracy despite a sensitivity of only 67% [189]. Similar results using this formula were reported in an independent study [190]. The prospective evaluation of four tumor markers (CA 19-9, CEA, CA 50, and CA 242) among 75 patients over 3 years failed to achieve high test performance characteristics for predicting cholangiocarcinoma [178].

The performance of endoscopic biopsy and cytological brushing for the diagnosis of cholangiocarcinoma is noted for good specificity (90%–100%) but poor sensitivity (4%–20%) [162,191]. False-positivity with cellular atypia from chronic inflammation may occur [191]. Detection of DNA aneuploidy by flow cytometry has been reported in 80% of individuals with cholangiocarcinoma compared with only 12% of patients with benign strictures [192]. Digital imaging analysis and fluorescence in situ hybridization are new techniques to detect malignancy in cytological specimens that are otherwise negative for malignant cells [193]. These techniques in addition to cytological examination improve the overall sensitivity to 35%–60% while maintaining the high specificity.

Therapeutic options for cholangiocarcinoma in the setting of PSC are limited. For extrahepatic biliary resection, operative complication and mortality rates exceed 30% and 6%, respectively, in the absence of bile duct cancer [194]. Highly selected patients, however, may derive benefits from surgical resection [195]. Curative attempts with liver transplantation to date have resulted in poor outcomes from residual tumor at surgical margins and local hepatic lymph node involvement [167,170]. The presence of cholangiocarcinoma in situ of less than 1 cm found incidentally at liver transplantation has been associated with similar long-term survival rates as individuals with PSC alone in two studies [169,196] but long-term prognosis remains poor in another study [197].

To improve outcomes in liver transplantation, the implementation of preoperative radiation and chemotherapy in 65 highly selected patients with unresectable cholangiocarcinoma and PSC yielded a 76% 5-year survival after liver transplant at the Mayo Clinic [198]. This protocol appears to provide an acceptable option for patients fitting the strict criteria for inclusion. Use of these protocols should be limited to centers with experience and prospective research involvement.

Portal hypertension

Progressive PSC can result in the typical complications of portal hypertension with or without the development of cirrhosis. These complications include ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, esophagogastric variceal bleeding, portal hypertensive gastropathy, hepatorenal syndrome, and hepatopulmonary syndrome. Patients with a platelet count below 200/mm^3, an albumin level less than 40 g/L, and a bilirubin level above 20 μ/L (1.2 mg/dL) were shown to have an increased likelihood of varices so screening those patients has been suggested [199]. A unique complication is peristomal variceal bleeding which occurs among subjects with IBD who have undergone proctocolectomy with ileostomy formation [200]. Newer surgical techniques including ileal pouch–anal anastomosis at the time of proctocolectomy are indicated among patients in whom PSC has been identified to prevent this complication [201]. Pharmacological (β-blocker) and endoscopic (sclerotherapy) therapies are without long-term efficacy [200]. Transjugular intrahepatic portosystemic shunt placement has been shown to be effective in treating uncontrolled bleeding and preventing further episodes [202].

Colonic dysplasia/carcinoma

The association between an increased risk of colonic dysplasia/carcinoma and PSC in the setting of UC is interesting but remains controversial. Decreased bile acid secretion and increases in secondary bile acid exposure of the colonic mucosa are considered potential mechanisms [203]. In addition, a greater proportion of right-sided colon neoplasia has been observed in UC patients with PSC compared with patients with UC alone [204–206]. Absolute cumulative risks for colorectal dysplasia/carcinoma of 5% (at 10 years), 31% (at 20 years), and 50% (at 25 years) have been observed in patients with PSC and UC compared with risks of 2%, 5%, and 10%, respectively for patients with UC alone [172]. Other studies, however, have failed to confirm a significant risk from PSC in developing colorectal dysplasia/carcinoma [207,208]. A metaanalysis of 11 studies confirmed a significantly increased risk of colorectal neoplasia in patients with UC with and without PSC [209]. The cumulative risk of developing colorectal carcinoma is further increased post-transplantation in PSC patients. In patients with an intact colon and IBD at the time of transplant, the risk was 14% after 5 years and 17% after 10 years [210]. Patients who have had pancolitis for longer than 10 years are at highest risk. Given the potential association between bile acid exposure and colorectal neoplasia, the use of UDCA was strongly

associated with a decreased risk for colonic dysplasia among 59 PSC patients undergoing colonoscopic surveillance for UC. This association remained after adjustment for duration and severity of PSC. A younger age of IBD onset, however, was also associated with an increased dysplasia risk [211]. These findings were confirmed in a controlled trial [212]. Surveillance colonoscopy with biopsy is recommended in patients with PSC and UC, especially after liver transplantation among patients with UC in the absence of proctocolectomy [166,213–215].

Pregnancy

Women with PSC tend to be of childbearing age. A study involving 13 pregnancies in 10 patients with PSC (4 with cirrhosis) showed that in patients with PSC, pregnancy does not seem to have a negative effect on the disease process, nor did mothers or babies show any ill effects from the PSC [216].

Disease-modifying therapies

Liver transplantation is the only effective treatment for end-stage hepatic disease resulting from PSC. As a result of the variable nature of disease progression, the development of randomized clinical trials for the assessment of therapies has been difficult. As a result, no effective medical therapy has been identified for the treatment of PSC (Table 75.4).

Medical therapy

D-Penicillamine

An increase in hepatic copper found among patients with chronic cholestatic liver disease including PSC provided the rationale for examining D-penicillamine. Among 70 patients randomized to active drug or placebo, there was no reported benefit in terms of biochemical improvement, histological stabilization, or survival free of liver transplantation after 3 years of follow-up. Major toxicities including renal disease resulted in drug discontinuation in 20% of subjects [217].

Colchicine

A randomized controlled trial of 84 subjects with PSC (44 given colchicine 1 g/day, 40 given placebo) revealed no differences in biochemical measures, histological results, or survival between groups after 36 months of follow-up [218]. Combination therapy with prednisolone and colchicine has been associated only with initial biochemical improvement after 24 months of treatment [219].

Corticosteroids

The report of beneficial results from corticosteroid use has only been demonstrated in uncontrolled trials. Patients with early-stage histological disease may have symptomatic and biochemical improvement [220]. The use of oral budesonide,

Table 75.4 Medical therapies evaluated in primary sclerosing cholangitis

Medication	Primary action	Therapeutic benefit
Controlled trials		
D-Penicillamine	Cupuretic	None
Colchicine	Antifibrotic	None
Cyclosporine	Immunosuppressive	None
Methotrexate	Immunosuppressive	Biochemical, histological (?)
UDCA	Immunomodulatory	Biochemical, histological (?)
Uncontrolled trials		
Corticosteroids	Immunosuppressive	Clinical, biochemical, histological
Azathioprine	Immunosuppressive	None
Mycophenolate mofetil	Immunosuppressive	None
Tacrolimus	Immunosuppressive	Biochemical
Pentoxifylline	TNF inhibition	None
Etanercept	TNF inhibitor	None (? Effect on pruritus)
Nicotine	Immunomodulatory	None
Silymarin	Antifibrotic	None
Budesonide	Immunosuppressive	Biochemical but osteopenia
Combination therapy	**Compared with**	
UDCA + methotrexate	UDCA monotherapy	Similar to UDCA alone
Corticosteroids + colchicine	Historical controls	Biochemical
UDCA + mycophenolate mofetil	UDCA monotherapy	Similar to UDCA alone
UDCA + metronidazole	UDCA monotherapy	Biochemical, clinical

TNF, tumor necrosis factor; UDCA, ursodeoxycholic acid.

a systemic corticosteroid with significant first-pass hepatic metabolism and reduced toxicity, in 21 patients with PSC was associated with improved hepatic biochemistry results at the expense of worsening osteopenia in a pilot investigation [221]. The use of prednisone or budesonide in combination with UDCA was not associated with significant clinical or biochemical improvement in a double-blinded, randomized controlled trial [222]. A combination of prednisone, azathioprine, and UDCA in 15 patients was noted for significant biochemical and histological improvements. These results were also observed among individuals with partial biochemical responses to UDCA [223]. Case reports detailing beneficial effects from topical corticosteroid therapy administered endoscopically through a nasobiliary drain were complicated by an increased rate of bacterial cholangitis [224,225]. If significant improvement occurs with corticosteroids, the patient is more likely to have had secondary sclerosing cholangitis as a result of autoimmune pancreatitis, because this is highly responsive to steroid treatment [226].

Azathioprine

No randomized controlled trial for azathioprine monotherapy has been reported. Open-label pilot studies are noted for their mixed results for efficacy using biochemical parameter responses [227,228].

Cyclosporine

A single randomized controlled trial of cyclosporine (ciclosporin [rINN]) among 34 patients [229] was noted for the absence of significant symptomatic, biochemical, or histological improvement (but no deterioration throughout the 2-year follow-up). Toxicity from cyclosporine, including hypertension and renal insufficiency, was minimal. Tacrolimus (FK506), a calcineurin-based inhibitor with pharmacological properties similar to cyclosporine, has been associated with significant improvements in biochemical profiles among all 10 subjects in an open-label pilot trial. Mean serum aminotransferase levels among these patients, however, were up to fivefold greater than normal values, which is not seen in patients with typical PSC. No effect on histology was observed based on limited follow-up [230].

Mycophenolate mofetil

No clinical benefit has been demonstrated when mycophenolate mofetil is used either alone or in combination with ursodiol (13–15 mg/kg) [231,232]. Both trials included patients with fairly advanced disease, so the effect of the drug earlier in the disease process is unknown.

Methotrexate

Data from a double-blind, randomized controlled trial comparing oral pulse methotrexate (15 mg/week) with placebo among 24 patients [233] is noted only for reductions in serum alkaline phosphatase. No improvements in total bilirubin histology, or survival were observed. Early-stage histological disease was associated with possible improvements in both symptoms and biochemical parameters [234]. Combination therapy with methotrexate and UDCA in 19 patients was associated with toxicity (from methotrexate) without biochemical improvement when compared to UDCA alone in 9 patients [235].

Ursodeoxycholic acid

The mechanism of action attributed to ursodeoxycholic acid (UDCA) in the treatment of chronic cholestatic liver disease is multifaceted. In addition to suppressing cytotoxic endogenous bile acid secretion [236], there is evidence to suggest that UDCA is associated with membrane stabilization [237] and reduced aberrant HLA type I expression on hepatocytes [238]. Mitochondrial dysfunction induced by hydrophobic bile acids, decreased cytokine production, and inhibition of apoptosis have also been identified in association with UDCA [239].

Early investigations suggested a beneficial effect from UDCA on PSC [240,241]. Three randomized, controlled trials comparing UDCA with placebo, however, did not show significant improvements in histology or survival despite a change in biochemical parameters [242–424]. Two recent investigations of high-dose UDCA (25–30 mg/kg/day) reported additional improvements in biochemical [245,246], cholangiographic, and histological parameters [246] when compared to standard doses. A recent study confirmed a lack of effect with intermediate dose UDCA (17–23 mg/kg/day) [247]. Results from placebo-controlled studies examining high-dose UDCA in PSC continue are awaited.

Novel therapies

Pilot investigations of oral nicotine [248] and pirfenidone [249] have failed to demonstrate improvements in serum hepatic biochemistries or Mayo PSC risk score. Despite properties of anti-TNF attenuation, the use of oral pentoxifylline was not associated with clinical or biochemical improvement among 20 patients with PSC [250]. A pilot study of subcutaneous etanercept (25 mg biweekly) showed no biochemical or radiographic benefit, but did have an effect in reducing pruritus in two of five patients [251]. The nucleoside analogue cladibrine has been associated with progression of histological fibrosis despite improvements in periportal inflammation among four patients with PSC after 24 months of follow-up [252]. A placebo controlled trial of metronidazole (600–800 mg/day) in addition to UDCA (15 mg/kg/day) suggested biochemical benefit to combination therapy as well as a trend toward radiographic improvement [253].

Endoscopic therapy

Endoscopic therapy in PSC has been successful in alleviating cholestasis aggrevated by mechanical biliary obstruction. Controversy remains, however, regarding the safety and efficacy of ERCP based on the limited numbers of patients reported and

variety of endoscopic methods utilized. Among PSC patients undergoing diagnostic ERCP, a 2% complication rate has been reported compared to 14% among patients with jaundice or cholangitis [254]. With advances in technology and endoscopic development, a number of options for therapeutic intervention are possible including endoscopic sphincterotomy, hydrostatic balloon dilation, nasobiliary tube drainage, and biliary stent placement. The current use of endoscopic dilation with sphincterotomy or stenting is associated with clinical response rates from 70% to 90% [156,255].

Among 53 patients requiring ERCP for the evaluation of biliary obstruction [155], a technical performance success rate of 88% was observed with 15 (28%) subjects experiencing procedure-related complications. Twenty-eight patients (56%) reported symptomatic improvement following ERCP for a median of 31 months. No change in cholangiographic findings, however, was seen in over 50% of cases. In the largest series reported to date of 106 patients with PSC [256], dominant stenoses were observed in 43 instances over a median follow-up of 5 years. The majority of these stenoses were treated using balloon dilation. Complications included pancreatitis (5.2%), cholangitis (3.3%), and bile duct perforation (0.5%). Survival after balloon dilation of the first recognized stenosis was significantly better when compared to predicted survival using the Mayo multicenter prognostic model.

Nasobiliary tube placement for drainage and saline irrigation has been employed to prevent recurrent biliary obstruction [224,225]. Among 12 asymptomatic patients with high-grade strictures treated initially by hydrostatic balloon dilation followed by nasobiliary tube irrigation [257], an improvement in clinical, biochemical, and cholangiographic features was documented in 75% of cases over 23 months. One patient had no change in clinical status from unresponsive disease. Progressive disease in three subjects required treatment by liver transplantation. Further use of nasobiliary tube irrigation among symptomatic patients has not been reported.

A retrospective examination of 25 symptomatic patients treated by biliary stent placement is noted for an endoscopic success rate of 84% [159]. Clinical and biochemical improvement in all cases was noted after 6 months. Additional procedures for stent exchange were associated with a complication rate of 14% over a 29-month period. During follow-up, only 12 patients (57%) remained asymptomatic with normal hepatic biochemistries. The use of short-term stenting (mean 11 days) of dominant strictures among 32 patients has been associated with an 83% improvement rate from symptomatic cholestasis (fatigue, pruritus) and biochemical improvement over 4 years [160]. Reintervention rates at 1 year (80%) and 3 years (60%) were observed. An investigation advocating the use of aggressive stricture dilation or stenting combined with UDCA therapy in PSC was based on results in an uncontrolled trial setting [258].

Biliary reconstructive surgery

Among precirrhotic individuals with extrahepatic biliary strictures refractory to endoscopic/percutaneous therapy, the use of intraoperative resection has been performed successfully [194,259–261]. Common sites of involvement in this setting include the common bile duct and perihilar regions. Early reports involving 17 of 22 patients undergoing choledochoenteric anastomosis was noted for good to excellent results in 13 patients (76%) [259]. Transhepatic stenting was employed in six patients. An overall survival rate of 82% at 52 months following surgery was observed. Among 31 patients undergoing extrahepatic bile duct resection and long-term stenting [260,261], excellent results among 26 precirrhotic individuals were reported. A 20% survival rate over 5 years, however, was noted in patients with cirrhosis.

Comparisons between operative and nonoperative therapies have been reported involving 104 patients treated surgically ($n = 54$) or using endoscopic balloon dilation ($n = 35$) and percutaneous stenting ($n = 19$) [194]. In this retrospective investigation, no differences in procedure-related morbidity and mortality were recorded. Improvements in serum bilirubin up to 3 years following resection were significantly better compared to those in nonoperative therapies. Among 40 patients with cirrhosis at surgical resection, overall 5-year survival rates of 85% (including liver transplantation in 21 patients) were noted. Transplant-free survival, however, was 78% at 5 years among subjects without decompensated cirrhosis undergoing resection. A 59% overall and 46% transplant-free 5-year survival, respectively, was observed among medically treated individuals. Cholangiocarcinoma in 9% of medically treated patients was reported in contrast to no cases among surgical patients.

Concerns regarding operative bile duct resection complicating the performance of liver transplantation have been raised [165,167,170,171]. The association between previous bile duct surgery and poor outcomes including decreased survival, however, has not been conclusively determined [166–169]. Among selected individuals with PSC, a history of previous surgery has been associated with longer operative procedure times [165,166,194] greater intraoperative blood loss [165–167], and increased risks for biliary complications after transplantation [165,166,168].

Liver transplantation

Among patients with end-stage liver disease as a result of PSC, the current treatment of choice is liver transplantation. PSC is the fourth most common indication for liver transplantation in the United States, accounting for 5%–10% of all procedures. Indications for liver transplantation are similar to other hepatic diseases including complications from portal hypertension (ascites, variceal bleeding, encephalopathy). Significant impairments in health-related quality of life from fatigue, pruritus, and painful osseous fractures may also be considerations for liver transplantation. Unusual

Table 75.6 Etiology of biliary strictures or cholangiopathy after liver transplantation

Early (< 6 months)	Late (> 6 months)
Hepatic artery thrombosis	Chronic rejection (intrahepatic)
Preservation injury (warm/cold ischemia)	Biliary tract infection (including bacterial, cytomegaloviral)
ABO blood group incompatibility	Recurrent primary sclerosing cholangitis
Anastomotic stricture	Cholangiocarcinoma
Bile leak	Cholelithiasis

circumstances prompting referral for liver transplantation in patients with PSC include recurrent cholangitis despite medical therapy, severe extrahepatic biliary obstruction among individuals with advanced hepatic disease precluding operative repair, and uncontrolled peristomal variceal bleeding. Reports from single centers performing liver transplantation in PSC are noted for patient survival rates between 90% and 97% at 1 year and 83% and 88% at 5 years (Table 75.5). Improvements in operative technique and immunosuppression have greatly contributed to improvements in patient survival. Long-term graft survival, however, has been affected by a higher incidence of rejection (acute cellular and chronic ductopenic) and hepatic artery thrombosis, in addition to recurrence of PSC [262].

Among patients with coexistent UC undergoing liver transplantation, it has been recognized that gastrointestinal symptoms may improve with the initiation of immunosuppressive therapy. Exacerbations of UC, however, are reported in up to 30%–50% of patients with some individuals requiring proctocolectomy for disease control [263,264]. An increased prevalence of pouchitis among PSC patients after liver transplantation compared to UC patients transplanted for other hepatic disease states has also been reported [265]. Patients with intact colons appear to be at increased risk for colorectal neoplasia after liver transplantation [166,213–215]. The risk has been shown to be 14% 5 years posttransplant and 17% 10 years posttransplant [210]. A duration of IBD greater 10 years is the highest risk. The cumulative risk for colorectal cancer among individuals transplanted for PSC at the Mayo Clinic [213] was calculated at 1% per year. The cumulative incidence for colonic dysplasia, however, was increased at 15% over 5 years and 21% at 8 years.

Recurrent PSC is thought to occur by 5 years in 9%–20% of patients with underlying PSC who are transplanted [266–269]. A combination of cholangiographic findings of intrahepatic or extrahepatic strictures and beading along with histological findings including biliary fibrosis/cirrhosis, fibroobliterative lesions, and cholangitis with or without ductopenia are required for accurate diagnosis of recurrent PSC [269]. Risk factors for recurrent disease have not been clearly delineated. A metaanalysis of 18 published studies showed that underlying IBD was not a risk factor for recurrence [266]. Chronic rejection is difficult to discern from recurrent PSC and it is not clear that the two entities are mutually exclusive [267]. Kugelmas and colleagues [270] have suggested that patients who received maintenance corticosteroids or orthoclone (OKT3) posttransplant appeared to be at higher risk of recurrent PSC but recurrence was not related to other immunosuppressants. PSC is a risk factor for cholangiocarcinoma but the risk in recurrent PSC, although reported, is unknown [271]. The diagnosis of recurrent PSC requires the exclusion of known causes of stricturing including ABO incompatibility, chronic ductopenic rejection, early and late hepatic artery thrombosis, prolonged cold ischemic time, and infectious causes (Table 75.6). Differentiating recurrent intrahepatic (small duct) PSC from chronic ductopenic rejection is fraught with difficulty and requires experienced pathologists and supporting clinical and radiographic evidence. Differentiating recurrent disease from other biliary complications is dependent on the clinical picture and the timing and location of the biliary strictures. See Liver transplantation section within Post-transplantation cholangiopathies section for further transplant-related issues.

Natural history and prognosis

The majority of published investigations support the contention that PSC is a progressive disease that can ultimately lead to liver failure or death. A median survival of 9–12 years in the absence of liver transplantation appears to be independent of geographic and environmental influences [3–6,9,10]. Subsets of patients with PSC, however, appear to follow different patterns of disease progression. Patients can be categorized as small duct vs large duct disease, symptomatic vs asymptomatic or with or without coexistent IBD. Symptomatic patients may do poorly compared with asymptomatic patients, but this may also reflect lead-time bias. Patients with small duct disease may have less rapidly progressive disease [272,273]. This significant variation in natural history means

that the use of mathematical prognostic models has allowed for improvements in estimating risks for disease progression and PSC-related survival independent of liver transplantation.

Subject age, serum total bilirubin, hemoglobin, a history of inflammatory bowel disease, and histological stage on liver biopsy were observed as independent predictors of death among PSC patients at the Mayo Clinic [5]. A similar prognostic index including subject age, hepatomegaly, splenomegaly, elevated serum alkaline phosphatase, and advanced histological stage has also been reported [6]. To address variations in independent populations, a multicenter prognostic model was developed using 426 patients from five centers [274]. Subject age, serum bilirubin, splenomegaly, and histological stage emerged as independent predictors of death in PSC. A revised version of the original Mayo PSC model has eliminated histological stage in favor of variceal bleeding history, avoiding the need for invasive liver biopsy for estimating prognosis [275].

Examination of the Child–Turcotte–Pugh (CTP) classification as a prognostic model in PSC has yielded mixed results [276,277]. Significant differences in 7-year survival have been demonstrated between CTP class A (89.8%), class B (68%), and class C (24.9%) patients with PSC [276]. Subject age and CTP classification were independent predictors of mortality. A subsequent investigation of 147 patients [277], however, was noted for limitations in predicting survival in CTP class B and C patients. CTP classification was not observed as an independent predictor of death in this cohort in contrast to the Mayo PSC risk score. Once a patient develops decompensated disease the model for end-stage liver disease (MELD) score more accurately predicts survival and is used when listing for liver transplantation [278].

Attempts at defining the optimal timing for liver transplantation in PSC have examined the application of existing prognostic models. Among 216 patients with PSC who underwent liver transplantation between 1981 and 1990 [170], a dramatic survival benefit was observed compared to predicted survival using the Mayo PSC model (73% vs 28% at 5 years, $P < 0.001$). Long-term survival between subjects grouped by risk score, however, was similar. The occurrence of cholangiocarcinoma, however, was associated with a significant decline in survival independent of pretransplant Mayo risk score. The presence of ascites, previous upper abdominal surgery, elevated serum creatinine, IBD, and a history of biliary tree malignancy have also been described as predictors of reduced posttransplant survival [279].

Additional investigations surrounding outcomes after liver transplantation in PSC have focused on outcomes such as health-related quality of life and resource utilization [280–282]. Among 436 patients with cholestatic liver disease including PSC ($n = 208$), the independent predictors of postoperative morbidity were subject age, renal failure (defined as serum creatinine > 2 mg/dL), Child–Pugh classification, and United Network for Organ Sharing (UNOS) status [280]. Increased resource utilization based on hospital charges has been associated with a Karnofsky score greater than 40, poor nutritional status, and renal failure [281]. A subsequent multicenter investigation, however, demonstrated that the CTP classification is a significantly better predictor of clinical and economic outcomes than the Mayo risk score [282].

Variant primary sclerosing cholangitis syndromes

Small duct primary sclerosing cholangitis

A subset of patients with typical features of PSC may have intrahepatic and extrahepatic bile ducts that appear normal by cholangiography [272,273,283–285]. The diagnosis of small duct PSC is based on

- serum biochemical profile consistent with cholestatic liver disease
- the presence of inflammatory bowel disease
- normal cholangiogram
- appropriate findings on liver histology.

Characteristic features described by liver histology assessment include mild portal mononuclear inflammation, ductular proliferation, and nonsuppurative fibrous obliterative cholangitis [284]. Fibrous-obliterative cholangitis, while considered pathognomic for PSC, occurs in only 10%–40% of cases [95]. Granulomatous cholangitis (more commonly seen in primary biliary cirrhosis) is seen in 8% of cases [1]. Disease progression is characterized by periportal fibrosis, ductopenia, and eventual biliary cirrhosis [95] or progression to large duct involvement. Previously termed "pericholangitis," the prevalence of small duct PSC is estimated to be between 6% and 35% among adults with UC [272,283,284]. As many as 33% of patients with large duct PSC are identified from normal cholangiograms during the course of their disease despite histological evidence for PSC. Isolated small duct involvement at diagnosis with eventual recognition of large duct PSC occurs in 12%–40% of cases [272,273,283,285]. Although uncommon, the progression to end-stage liver disease requiring hepatic transplantation has been associated with small duct PSC [170,272,285]. Specific reference to small duct PSC in terms of medical therapy has not been widespread given its rare occurrence. The natural history of small duct PSC appears to portend a better prognosis than large duct disease [272,273,285]. Cholangiocarcinoma has rarely been observed among patients with small duct PSC [272,283,285].

Autoimmune hepatitis–primary sclerosing cholangitis overlap syndrome

Patients with PSC and clinical features reminiscent of AIH are classified as having an "overlap syndrome" between the two conditions [286–289]. Greater than expected serum aminotransferase elevations (5–10 times) and increased titers of

serum autoantibodies, including antinuclear antibody, anti-smooth muscle antibody, and pANCA, are observed in most cases [287–289]. The presence of typical biliary stricturing and dilation seen with PSC is often accompanied by increased lymphoplasmacytic portal or periportal infiltrates on liver biopsy consistent with AIH. In PSC, the presence of overlap with AIH was previously thought to range between 35% and 54% using the original International Autoimmune Hepatitis Group (IAHG) scoring system criteria (11–12) [286]. Using the revised IAHG scoring system, a decrease in prevalence of AIH–PSC overlap between 1.4% and 11% has been reported [287,288]. In contrast, van Buuren and colleagues [289] observed similar prevalence rates of AIH–PSC overlap based on either conventional diagnostic criteria (23%) or the revised IAHG scoring system (19.5%). Empiric immunosuppressive therapy for potential benefit among patients with AIH–PSC overlap has been recommended [286,290].

Idiopathic adulthood ductopenia

Idiopathic adulthood ductopenia is a syndrome described by:

- the presence of biochemical parameters consistent with cholestasis
- the presence of histological evidence of ductopenia involving more than 50% of the bile ducts
- the presence of no evidence for the diagnoses of PSC and IBD
- the exclusion of other known etiologies for cholestasis including PBC and drug-induced hepatotoxicity [291].

Variation in the extent of bile duct loss likely reflects a spectrum in natural history [284]. Other diagnostic possibilities include an unidentified chronic viral cholangitis, small-duct PSC in the absence of IBD after colonoscopic investigation, or advanced AMA-negative PBC with resulting ductopenia [291].

Among 29 reported cases of idiopathic adulthood ductopenia [284,291] there is a median age of 27 years (range 15–67 years) at diagnosis. Male to female gender distribution is estimated at 2 : 1. Jaundice and pruritus are seen at initial presentation in 33% of cases. Disease progression reported among 10 patients occurred over a median duration of 4 years (range 5 months to 15 years). Seven of 23 (30%) patients with follow-up longer than 6.5 years died from liver disease while 4 patients required liver transplantation. Corticosteroid or UDCA therapy was associated with clinical improvement in 3 of 4 cases. Among subjects with features similar to idiopathic adulthood ductopenia despite more than 50% bile duct loss [292], a benign course was reported in 3 of 24 individuals using sequential liver biopsies over 12 years. Four of 5 patients treated with UDCA had normalization of serum liver biochemical parameters.

Other cholangiopathies

AIDS cholangiopathy

Epidemiology

Biliary tract disease in AIDS (AIDS cholangiopathy) was first described soon after the identification of HIV [293]. AIDS cholangiopathy describes a syndrome that resembles sclerosing cholangitis associated with papillary stenosis [294,295]. Pathogens involved with the development of AIDS cholangiopathy do not appear to affect patients who are immunocompromised for other reasons. The mean age of affected patients is reported to be 36.5 years with a preexisting diagnosis of AIDS from 1 to 2 years before symptomatic biliary tract involvement [295,296]. With the advent of highly active antiretroviral therapy (HAART), this entity has become rare and generally only occurs when the CD4 T-cell counts drop below 50 per mm^3. Previously, this diagnosis was known to be associated with significant mortality within 1 year of infection [296]. Since the introduction of HAART in general, as well as specific therapy for cholangiopathy, not only has the incidence of the disease declined, but the survival after developing cholangiopathy has improved to 80% at 24 months from the diagnosis [297].

Pathogenesis

Infection of the biliary or duodenal epithelium is the primary cause for ductal abnormalities in AIDS cholangiopathy. Among pathogens identified, *Cryptosporidium* is the most common and is often found without coexistent infection [294–297]. Among 82 HIV-infected patients exposed to *Cryptosporidium* in a water-borne outbreak [298], the development of abdominal pain associated with biliary tract disease occurred in 24 cases, which were confirmed by cholangiography in only 40%. Simultaneous bouts of new-onset diarrhea as a result of *Cryptosporidium* were also reported [299]. Concurrent active HIV replication and associated *Cryptosprodium parvum* infection act synergistically to increase cholangiocyte apoptosis and thus jointly contribute to AIDS-related cholangiopathies [300]. If undetected by blood or stool cultures, the next most common organism is *Microsporidium* [301,302]. Other recognized infections include cytomegalovirus (CMV) [303], *Enterocytozoon bieneusi* [304], *Septata intestinalis* [305,306], *Mycobacterium avium-intracellulare* [307], *Isospora belli* [308], and possibly HIV infection itself [309]. Hepatic CMV inclusions have been observed in 5%–44% of patients at autopsy. An estimated 33% of patients with AIDS and CMV have cholestatic liver disease, and as many as one-third of these individuals have overt bile duct abnormalities [303]. Ultimately, as many as 50% of patients with AIDS cholangiopathy have no identifiable opportunistic infection [295,301,303,305]. Malignancy such as lymphoma [309] and Kaposi sarcoma [309] has been associated with cholangitis but it rarely presents as a cholangiopathy. Histological findings in AIDS cholangiopathy observed on bile duct and liver biopsy include moderate to severe inflammation and fibrosis [310].

Clinical manifestations

The most common presentation is epigastric or right upper quadrant abdominal pain (64%–88%) with fever (20%–65%).

Jaundice, however, is distinctly uncommon. Diarrhea is also present in most cases, related to small intestinal involvement with the characteristic pathogens. Superimposed bacterial cholangitis is a rare complication [295,296,311]. Serum liver biochemistries are noted for elevations in alkaline phosphatase more than three or five times the upper limit of normal in over 75% of cases. Milder increases in serum aminotransferases (less than threefold) are also noted. Normal biochemical parameters have also been observed in 20% of instances with cholangiographic abnormalities [295,296,301,312]. Ultrasonography or CT imaging can detect biliary duct dilation (intrahepatic or extrahepatic) in most instances [313–315]. Cholangiography is required for the diagnosis of AIDS cholangiopathy. Left-sided biliary duct system involvement is observed with an increase in intrahepatic duct involvement with saccular dilations, debris, and pruning. Irregular structuring of the entire common bile duct with wall thickening in the absence of dilation is common [295,311,314]. The most common characteristic biliary tree manifestation is papillary stenosis with intrahepatic sclerosing cholangitis, which is found in 50% of cases. Other variations include intrahepatic and extrahepatic sclerosing cholangitis without papillary stenosis, papillary stenosis alone, intrahepatic sclerosing cholangitis alone, or long (> 1 cm) extrahepatic strictures [295,311,312,316,317]. Among individuals with severe pain and associated cholangitis, the identification of papillary stenosis is almost universal [295,312,318]. The presence of isolated common bile duct strictures should raise the suspicion for primary lymphoma [309] or pancreatic disease [311].

Differential diagnosis

The differential diagnosis includes choledocholithiasis, acalculous cholecystitis, periampullary tumors including pancreatic and bile duct cancer, and PSC. Choledocolithiasis will also produce intrahepatic duct dilation above the level of obstruction where biliary duct dilation is distinctly uncommon in AIDS cholangiopathy. Bile duct wall thickening appears most often. The presence of elongated stricturing with intrahepatic and peripheral bile duct dilation is more often observed with periampullary carcinoma but can resemble findings when papillary stenosis alone is present. Direct visualization and biopsy of the ampulla are required to exclude carcinoma. Global duct narrowing, diffuse stricturing, and intrahepatic stone formation characterize PSC. The finding of concomitant inflammatory bowel disease also suggests PSC even in subjects with AIDS.

Treatment

The presence of opportunistic infections and a very low CD4 count is a marker of advanced disease, and the emphasis should be on the HIV disorder, not on the AIDS cholangiopathy. Therapy of both is directed (and outcomes improved) by elevation of the CD4 count and depression of viral loads, which can only be obtained by HAART [319]. Additional treatment can be directed at identified pathogens as well as biliary tree abnormalities. Antimicrobial therapy against *Cryptosporidium* sp. with trimethoprim-sulfamethoxazole is indicated, especially among patients with coexistent diarrheal symptoms [299]. Effective treatment against *Microsporidium* sp. remains elusive [302]. Ganciclovir for CMV [303,316] and multidrug regimens against *Mycobacterium avium-intracellulare* [307] should also be provided. Albendazole for *Septata intestinalis* infection has been shown to result in symptom improvement when present [305]. Successful therapy for malignancy-related cholangiopathy with reversal of biliary tract abnormalities has been reported with B-cell non-Hodgkin lymphoma in anecdotal instances [309]. There is no indication for prophylactic treatment in patients unaffected by AIDS cholangiopathy.

Symptomatic patients with a high degree of suspicion for biliary tract disease require cholangiography by ERCP [294,295,311]. For patients with papillary stenosis alone, endoscopic sphincterotomy has been associated with improvement in abdominal symptoms, but not survival [296,316,318,319]. Often, there is little to no change in serum hepatic biochemical parameters in most cases [311]. A continued rise in serum alkaline phosphatase levels, however, suggests the presence of intrahepatic duct involvement as well [296,311]. The performance of balloon dilation or stent placement in cases of papillary stenosis is without dramatic benefit over sphincterotomy [311]. UDCA therapy for symptomatic disease is not highly efficacious [320]. A diagnosis of acalculous cholecystitis requires cholecystectomy [321].

Posttransplantation cholangiopathies

Bone marrow transplantation

Epidemiology

The most frequent etiologies of cholangiopathy within the first 80 days of bone marrow transplantation include acute graft-versus-host disease (GVHD), sinusoidal obstruction syndrome (SOS), cholangitis lenta, and drug-induced cholestasis [322,323]. Chronic GVHD is the most common cause beyond 80 days [323]. Risk factors for developing cholestatic-mediated injury after bone marrow transplantation have been identified. The use of conditioning therapies before the transplant, including combinations of irradiation or immunosuppressive agents, has most often been associated with hepatic venoocclusive disease, which is referred to as SOS [324–326]. Allogeneic donor stem cell recipients are considered to be at increased risk for acute and chronic GVHD [323]. Related sibling donors with identical HLA typing impart the lowest risk of acute or chronic GVHD among all donor source types [327]. The use of immunosuppressive agents for acute GVHD prophylaxis is also associated with an increased risk for cholestatic injury [322,328]. Antimicrobial prophylaxis against viral and fungal infections in the posttransplant period [322,329] while reducing the risk for

hepatobiliary infections may also contribute associated toxicities resulting in liver injury.

Pathogenesis

A number of pathophysiological mechanisms have been implicated in bone marrow transplant-related cholangiopathies. In cholangitis lenta, the release of bacterial cell wall components [330] as well as proinflammatory cytokines including IL-1, IL-6, and TNF-α results in bile flow impairment [331]. Biliary epithelial cells, zone 1 hepatocytes, and periductular glands have been recognized as intrahepatic targets for donor-derived lymphoid cells in acute GVHD [332]. Cell death mediated by apoptosis has also been observed but exact mechanisms for this process are not well understood [333]. Abnormalities in cellular and humoral immunity have been implicated in chronic GVHD [322]. Impaired bile salt and bilirubin transport is associated with hepatotoxicity from cyclosporine [334]. Bile canaliculus injury, hepatocyte necrosis, and elevated serum hepatic biochemistries are observed with supratherapeutic blood levels of cyclosporine [322,335]. Intrahepatic thromboses of terminal venules and central veins are observed in conjunction with clinical manifestations of SOS [324].

Clinical manifestations

Acute GVHD occurs among recipients of allogenic bone marrow and stem cell infusions. The development of a skin rash, evidence for gastrointestinal dysfunction (including nausea and diarrhea), and elevated serum hepatic enzymes are typical manifestations. Hepatic GVHD may also occur independently of skin and gut manifestations but is uncommon. Average time to onset is approximately 15–21 days after the bone marrow transplant. A delay in time to onset for acute GVHD has been reported with the use of immunosuppressive prophylaxis and nonHLA mismatched grafts. Increases in serum aminotransferase and alkaline phosphatase levels (2- to 10-fold each) with hyperbilirubinemia are characteristic. Decompensated liver disease (ascites, coagulopathy) is uncommon in the early stages of acute GVHD. A rapid increase in hyperbilirubinemia may suggest concomitant sepsis, cholangitis lenta, or SOS [322]. Liver biopsy performance is often required in this setting for diagnosis. Histological findings of acute GVHD include bile duct epithelial cell necrosis and apoptosis, mild to moderate hepatocyte necrosis, and cholestasis. Ductopenia has been reported in severe cases [336]. A recent study showed that a high level of lobular inflammation and a low level of hepatocyte ballooning were independent favorable prognostic factors for patients with GVHD [337]. The probability of developing chronic GVHD from acute GVHD is estimated at 50% or more. Progressive hepatic GVHD has been reported as an independent predictor of mortality after bone marrow transplantation. Clinical evidence for portal hypertension is often noted in the absence of histological cirrhosis when present [322].

Cholangitis lenta is associated with fever and mild hyperbilirubinemia in the early posttransplant phase and with the use of immunosuppressive treatment for acute GVHD. The time interval for preceding infection may be days to weeks. Elevations in serum alkaline phosphatase may be observed but isolated hyperbilirubinemia is the most common biochemical finding. Total bilirubin levels can reach values, as high as 15 mg/dL, but hepatic synthetic function is generally intact. Liver histology is noted for cholestasis within pericentral canaliculi and periportal areas in the absence of significant portal inflammation from immunosuppression [322,330]. The use of prophylactic antibiotics and antifungal medications has reduced the incidence of infections and sepsis and so of cholangitis lenta.

Drug-induced cholestasis can occur by idiosyncratic (cyclosporine) [338] or dose-dependent (methotrexate) [322] mechanisms. Among 38 patients receiving cyclosporine at 3 mg/kg/day [339], an increase in serum bilirubin levels was reported compared to patients given 1.5 mg/kg/day despite serum trough levels of cyclosporine in the therapeutic range (< 400 ng/ml) in the high dose group. In dosages up to 20 mg/kg/day, a majority of patients treated for acute leukemia developed jaundice and hyperbilirubinemia, which resolved after drug cessation in 2–5 days [340]. Azathioprine [341] and fluconazole [342] may be associated with hepatocyte necrosis yet more commonly result in asymptomatic serum aminotransferase elevations. Antibiotics including amoxicillin–clavulanic acid [343], flucloxacillin [344], and trimethoprim-sulfamethoxazole [345] have been reported in association with cholestatic hepatitis and chronic liver disease in rare instances. Ceftriaxone has been implicated in the pathogenesis of cholelithiasis [346]. Cholestasis is also observed after chronic total parenteral nutrition. Elevated serum liver biochemistries including total bilirubin, serum aminotransferases, and alkaline phosphatase can be attributed to total parenteral nutrition. Association between prolonged total parenteral nutrition and liver failure, however, remains rare. Reversal of liver biochemical abnormalities often occurs after discontinuation of total parenteral nutrition and resumption of oral intake. Other associated complications in the presence or absence of chronic total parenteral nutrition administration include biliary sludge, cholelithiasis, and acalculous cholecystitis [347].

Chronic GVHD of the liver has been associated with the rapid onset of bile duct destruction or subacute development of intrahepatic cholestasis. It may occur de novo or result from previous acute GVHD. Chronic GVHD generally occurs after 100 days post-bone-marrow-transplant. Hepatic involvement occurs in up to 80% of cases. Biochemical features typically include progressive elevations in serum alkaline phosphatase (as high as 15 times normal) and hyperbilirubinemia. Rapid onset chronic GVHD may present with elevated serum aminotransferases during tapering of immunosuppressive medications [322,323]. Histological features on liver biopsy include ductopenia, lymphoplasmacytic portal

inflammation, periportal fibrosis, and cholestasis. In select cases, a paucity of bile ducts may be observed (vanishing bile duct syndrome) [322,336].

The development of jaundice, hepatomegaly, and weight gain over 5% of ideal body weight is consistent with a diagnosis of SOS. The average time of onset after bone marrow transplant is between 15 and 30 days. Persistent jaundice after an episode of acute GVHD can also be from SOS in the setting of fluid retention. Biochemical features include isolated hyperbilirubinemia as the most common presentation [322,324,348]. Ultrasonography is commonly negative for biliary tract obstruction or hepatic vein thrombosis. Most patients with SOS have mild involvement and eventual spontaneous resolution. Progressive SOS, to include the hepatic venules (and thus venoocclusive disease) is associated with liver failure in select cases [348].

Treatment

Prevention of acute GVHD is the most important aspect of treatment because eventual multiple organ involvement is often fatal [349,350]. Conventional strategies have included combination pharmacological therapy with corticosteroids [322,326,351], cyclosporine [322,326], methotrexate [322,326,328], tacrolimus [328], or antilymphocyte antibodies [328]. Depletion of donor T lymphocytes by elution or monoclonal antibodies is associated with reductions in the incidence and severity of acute GVHD [352]. Reports of Epstein–Barr virus-associated lymphoproliferative disorder from depletion/elution techniques, however, have also been noted [353]. Systemic corticosteroid therapy (prednisone at 2 mg/kg/day) is the treatment of choice in acute GVHD with hepatic involvement [349]. Treatment failures (defined as persistent skin and gut symptoms) are managed with increasing corticosteroid dosages (4–8 mg/kg/day) [350] and the addition of tacrolimus [351] or antithymocyte globulin [352]. Empiric treatment of cholestasis-associated pruritus with UDCA may be of benefit in selected cases [354].

No specific therapy exists for cholangitis lenta. Treatment of the underlying infection often results in a reduction in hepatic biochemical elevations and improvement in bile flow [330].

Discontinuation of potential offending agents is the initial step in treating drug-induced cholestasis. Improvements in cholestasis and serum hepatic biochemistries occur within 5–7 days of cyclosporine discontinuation [322,340]. Dose reduction of cyclosporine or substitution with other anti-T-lymphocyte agents is recommended in the presence of acute GVHD to minimize worsening bile duct injury [322].

The use of immunosuppressive therapy including prednisone and cyclosporine is required for the treatment of chronic GVHD. Salvage therapy options include tacrolimus, thalidomide, or sirolimus [322,323]. Empiric UDCA to modulate symptoms from intrahepatic cholestasis may result in serum hepatic biochemical improvement [354].

Mild to moderate cases of SOS are treated with supportive measures. Diuretic therapy may be useful in patents with symptomatic fluid overload [322,324,348]. For severe cases of SOS, the use of thrombolytic therapy has been shown to improve hyperbilirubinemia in up to 30% of patients. The risk of significant hemorrhage among patients with preexisting thrombocytopenia including a fatality rate approaching 15% is associated with thrombolytic therapy [348,355]. Defibrotide, which has anti-thrombotic and anti-fibrinolytic properties, has been shown to improve survival in severe cases to 35%, with these patients showing complete resolution of the sinusoidal obstruction, with no adverse bleeding events [356]. The addition of antithrombin III infusion to high-dose defibrotide resulted in a complete response to therapy and 100-day survival in 93% of children with varying severity of SOS. This same study showed that the use of preemptive antithrombin III infusion did not prevent SOS development [357]. Transjugular intrahepatic portosystemic shunt placement to improve sinusoidal portal hypertension has been associated with an increased mortality in patients with severe SOS [358].

Liver transplantation

Cholangiopathies associated with liver transplantation can involve either intrahepatic or extrahepatic bile ducts with different entities tending to occur early (< 6 months) or late (> 6 months) in the posttransplant course (Table 75.6). The two most common forms of surgical biliary anastomoses performed in liver transplantation are choledochocholedochostomy (C-C) and choledochojejunostomy (C-J). Factors involved in choosing one type of anastomosis over another include underlying hepatic disease and size match between recipient and donor organ.

Epidemiology

Intrahepatic cholangiopathies after liver transplantation primarily involve the biliary epithelium. Cold ischemic injury and, possibly more importantly, reperfusion injury occur in bile duct epithelial cells [359]. Mild cases resolve spontaneously, but more severe cases may have residual damage (intrahepatic or extrahepatic) or result in primary nonfunction [360]. Blood-group-related antigens (ABH) are expressed on the epithelial cells of large bile ducts, and periductular hepatocytes, thus transplantation of ABO mismatch livers results in complications such as biliary stricturing, hepatic artery thrombosis, and cellular rejection [361]. Chronic "ductopenic" rejection occurs in 2%–5% of transplant patients and generally presents within the 6 weeks to 12 months after transplantation, but has been noted as early as 2–3 weeks postoperation. It is characterized by progressive loss of intrahepatic interlobular and septal bile ducts (ductopenia) with lipid-laden vasculopathy; more than 50% of the portal triads must be involved for it to be termed "ductopenic" [362]. As discussed previously, recurrent PSC

occurs in up to 20% of cases where strict criteria are applied to exclude other potential causes of intrahepatic biliary disease [267–269].

Extrahepatic cholangiopathies following liver transplantation include anastomotic strictures, hilar strictures, ischaemic-type bile duct stricturing, bile leaks, choledocholithiasis, and sphincter of Oddi dysfunction. The overall incidence of biliary complications ranges from 9% to 40% and complications usually develop 2–6 months after liver transplantation. Anastomotic strictures occur in 3%–7% of cases and may be early or late [363,364]. Hilar strictures after liver transplantation are associated with local ischaemia or hepatic artery thrombosis. Prolonged cold ischemia time and ABO incompatibility have also been reported as risk factors [365]. Bile leaks occur in up to 25% of transplant recipients [363,364]. Sites of injury include the biliary anastomosis, T-tube insertion site, reduced size parenchymal graft cut edge, or unrecognized collateral bile duct [363]. T-tube removal in association with C-C anastomosis is reported to comprise over 50% of all bile leaks [363,364]. The finding of choledocholithiasis after transplantation is generally associated with a biliary stricture [363]. Sphincter of Oddi dysfunction has been recognized after C-C reconstruction. Cholangiography is noted for a dilated common bile duct tapering to its origin [363,364].

Clinical manifestations

Patients with intrahepatic or extrahepatic cholangiopathies after liver transplantation often present with asymptomatic elevations in serum alkaline phosphatase or total bilirubin. Mild elevations in serum aminotransferases can occur as well. Alternatively, the presence of fever or right upper quadrant abdominal pain may be consistent with bacterial cholangitis [363,364]. Jaundice and pruritus are uncommon but can be associated with chronic ductopenic rejection [362]. Imaging studies with ultrasound or CT scanning are sensitive for the detection of intrahepatic duct dilation. Examination of hepatic arterial blood flow by Doppler ultrasonography is mandatory in the setting of biliary stricture to exclude thrombosis or stenosis [365]. If a T-tube is present, cholangiography is performed to determine the location and extent of biliary strictures when suspected [363,364]. ERCP has developed into the initial method of cholangiography in transplant patients for diagnostic and therapeutic interventions [366]. The use of PTC is indicated when distal bile duct dilation is not significant or evidence for a proximal biliary obstruction above the bifurcation is observed by imaging studies, as well as cases that cannot be accessed by ERCP (long Roux limbs etc) [363,367]. Histological examination of the allograft by liver biopsy is warranted if cholangiography is unremarkable.

Treatment

Ensuring adequate immunosuppression in the presence of chronic ductopenic rejection is mandatory. Conversion from cyclosporine to tacrolimus (FK506) is often recommended as resulting bile flow impairment reduces effective gastrointestinal absorption of cyclosporine. Treatment options for recurrent PSC deal primarily with stricture dilation with or without long-term biliary tube stenting [269]. Hepatic retransplantation in this population is the only available definitive solution if allograft failure ensues [269,367].

Surgical conversion to a Roux-en-Y choledocojejunostomy for biliary strictures associated with the C-C anastomosis was previously considered the treatment of choice after liver transplantation [363,364,368]. Recent advances in endoscopic and radiological techniques have demonstrated satisfactory results from balloon dilation or stenting. Balloon dilation of anastomotic strictures is successful in most cases. The use of stents significantly reduces the recurrence of stricturing [369]. Endoscopic management also appears more successful in the early strictures (< 6 months) as compared with late strictures (> 6 months) [370]. Patients who fail to respond after these nonoperative measures may then be considered candidates for biliary anastomosis reconstruction. Focal areas of stricturing in association with indwelling T-tubes, often related to postoperative edema, usually resolve with observation [363].

Hepatic artery thrombosis is described in 3%–9% of transplants, with another 3% of patients experiencing nonthrombotic hepatic artery complications, such as hepatic artery stenosis, redundancy, and pseudoaneurysm [371]. As the main blood supply to the biliary system stems from the hepatic artery, later complications tend to be biliary, including bile duct stricturing with subsequent cholangitis, liver biloma, or abscess or biliary necrosis with bile leak. Either the early or late presentation can progress to severe liver dysfunction and failure, however, severe graft dysfunction is observed more frequently in patients with early hepatic artery thrombosis. Retransplantation rates of 50%–80% and mortality rates of up to 50%–70% have been described in patients with hepatic artery thrombosis [372,373]. The correction of aberrant hepatic artery flow (by angioplasty or surgical revision if required) may be beneficial to prevent further bile duct injury and diffuse stricturing in the early postoperative period.

Hilar strictures are difficult to manage by operative intervention based on previous manipulation of the porta hepatis. Interventions with balloon dilation and percutaneous indwelling stent placement are often required. Problems with recurrent biliary obstruction from debris and mucosal sloughing (especially when ischemic cholangiopathy is present) require frequent tube manipulations and changes [368]. The effect of bilateral endoscopically placed stents (polyurethane and expandable metal) compared to percutaneous drainage is unknown.

Diffuse biliary stricturing can initially be managed with nonoperative methods including balloon dilation followed by stenting of dominant strictures [363,368]. Similar to hilar

strictures, the occurrence of stent occlusion has limited the long-term success of this strategy [368]. No benefit with UDCA or prophylactic antibiotic therapy for the prevention of biliary stricturing has been shown. Hepatic retransplantation in eligible candidates is often required for definitive therapy [367].

The management of choledocholithiasis is similar to non-liver-transplantation scenarios with the use of balloon dilation and stone removal by ERCP or PTC. Endoscopic sphincterotomy may or may not be required [363,366]. Sphincter of Oddi dysfunction, when confirmed using accepted criteria, is also treated by endoscopic sphincterotomy despite the absence of abnormal manometric findings [363].

Iatrogenic cholangiopathies

Operative bile duct injury

Epidemiology

Operative bile duct injury is most commonly associated with cholecystectomy (90% of instances). The incidence of bile duct injury with open cholecystectomy is estimated to be between 0.1%–0.2%, which includes minor duct (of Luschka) injuries [374]. Initial reports of bile duct injury from laparoscopic cholecystectomy between 1% and 2% have been reduced to 0.4%–0.6% [375]. Risk factors for bile duct injury include limited operative experience, acute or chronic inflammation involving the biliary tree and gallbladder fossa, and aberrant anatomy [376].

A classification system for bile duct injuries has been proposed by Strasberg and colleagues [377]. Type A injuries affect the minor ducts without the loss of biliary tree continuity, including the cystic duct and gallbladder fossa. Type B and C injuries involve aberrant right hepatic duct injuries. Occlusion of the cystic duct in this scenario is termed a type B injury whereas complete cystic duct transection is termed a type C lesion. Type D injuries involve incomplete lacerations of the primary bile ducts (common bile, common hepatic, left and right hepatic). Evolution of these lesions to type E injuries can occur. Type E injuries include five variations with lesions located between the common hepatic duct and above the bifurcation. Type A, D, and E bile duct injuries are most often reported.

Clinical manifestations

The timing and extent of injury often determines clinical presentation. Bile duct injuries are often not recognized at the time of surgery. The median time to symptoms is between 5 and 7 days but may be weeks. Fever, abdominal pain, or wound drainage can be observed. Jaundice may represent distal common bile duct occlusion or transection. A small proportion of patients will be asymptomatic at presentation. Imaging studies such as nuclear scintigraphy (HIDA scan) can document the existence of bile leakage in 90%–95% of cases. Identification and localization of bile duct injuries by cholangiography is required before repair [375,376]. Late complications including biloma formation and biliary stricture may occur [377].

Treatment

Endoscopic or percutaneous methods have been successfully employed to treat bile duct injuries. These measures are effective in the treatment of active bile leaks as well as benign postoperative strictures. Endoscopic sphincterotomy with or without nasobiliary tube or stent placement are equally effective for bile leak closure. Removal of stents in 3–4 months with repeat cholangiography to document bile leak closure is recommended. A disconnection between distal and proximal bile duct systems requires PTC for diagnosis and therapy [378].

Injuries noted at surgery require conversion to an open procedure with immediate repair. Techniques include suturing of linear lacerations, end-to-end anastomosis, and Roux-en-Y biliary reconstruction. Damage involving the common hepatic duct bifurcation is treated with biliary–enteric reconstructive techniques. Facilitation of surgical repair can be provided by preoperative stent placement. Continued stent placement after operative repair up to 3–6 months is advised [375,377]. Long-term results from surgical bile duct repair are good and are associated with the nature and extent of injury, the type of surgical reconstruction performed, and the level of experience at the treatment center [375,377].

Secondary sclerosing cholangitis

The development of cholangiographic changes similar to PSC has been reported as a secondary phenomenon resulting from complications of therapeutic interventions. The best-known causes of secondary sclerosing cholangitis are related to traumatic ischemic injuries to the vascular and subsequent biliary system [366] and hepatic artery infusion with floxuridine (FUDR) [73]. Prevalence rates for FUDR-associated secondary sclerosing cholangitis remain unchanged between 17% and 56%. Involvement of the common hepatic duct bifurcation with sparing of the common bile duct is characteristic. The arterial supply of extrahepatic bile ducts is derived primarily from the gastroduodenal arcade, which is often excluded from hepatic artery infusion. Ischaemia rather than direct FUDR toxicity to biliary epithelium appears to be the underlying mechanism of action [73]. Whereas injury appears to be contained within the biliary system, liver failure associated with FUDR-induced secondary sclerosing cholangitis is related to coexistent obstructive vasculopathy [73]. The injection of 20% formaldehyde with sodium chloride or ethanol for the treatment of hydatid disease has also been associated with secondary sclerosing cholangitis [379]. Direct sclerosant-type effects on biliary epithelia are the proposed mechanism of action.

Rare entities that have been described as etiologies of secondary sclerosing cholangitis include hepatic inflammatory pseudotumor, portal biliopathy (collective bile duct and gallbladder wall anomalies as a result of extrinsic compression

seen in patients with portal hypertension) and eosinophilic cholangitis [380].

Biliary stricture from chronic pancreatitis

Epidemiology

Biliary strictures from pancreatic disease occur based on anatomic proximity between the distal common bile duct and posterior pancreas. The presence of fixed structures including pancreatic cysts and masses are associated with extrinsic common bile duct compression. Biliary stenosis associated with the inflammation of acute and chronic pancreatitis is usually transient. Chronic biliary obstruction is noted among 4%–10% of patients with alcoholic pancreatitis. Biliary stricture following operative therapy for chronic pancreatitis is observed between 60% and 70% of cases [380,382].

Clinical manifestations

In chronic pancreatitis, there are no specific clinical features that suggest the presence of biliary obstruction. Serum hepatic biochemistries are noted for elevations in alkaline phosphatase without similar degrees of hyperbilirubinemia. Mild aminotransferase (78%) and amylase (47%) elevations can also occur. Among patients with postoperative bile duct strictures as many as 80% of cases are identified within the first postoperative year. Late manifestations may occur years after initial surgery [380,382]. Among 987 patients with benign postoperative biliary strictures followed over 25 years, the most common symptoms at presentation were fever (64%), abdominal pain (49%), and jaundice (44%). Elevations in serum alkaline phosphatase and bilirubin occurred in one-half of cases [382].

Diagnosis

Ultrasonography and cross-sectional imaging techniques are useful for documenting biliary dilation or biloma formation in select cases. Cholangiography (ERCP or PTC) can define both location and extent of stricture involvement [380,382]. A smooth, long stricture of the distal common bile duct between 2 and 4 cm is most characteristic. Hepatic histology can also identify biliary obstruction in 80% of cases involving chronic alcoholic pancreatitis with cirrhosis present in 29% of patients [380].

Course and complications

Complications associated with biliary stricture from chronic pancreatitis include cholangitis, choledocholithiasis, and secondary biliary cirrhosis. As many as 20% of reported patients have developed biliary cirrhosis or liver failure after biliary stricture formation from operative injury [380].

Treatment

In cases of biliary stricturing from chronic pancreatitis, the optimal management has yet to be defined. Surgical decompression is employed for high-grade obstruction complicated by jaundice or cholangitis [382]. Endoscopic approaches with stricture dilation and stenting have been performed with good results and minimal morbidity [383,384]. Symptomatic patients appear to benefit more from stenting with multiple stents compared to single stents [384]. Among patients with abnormal serum hepatic biochemistries and no symptoms, the pursuit of decompression is controversial. Liver biopsy features of progressive biliary fibrosis favor surgical decompression.

Biliary fistulae

Spontaneous enteric biliary fistula

Epidemiology

Prevalence rates between 0.5% and 5% after biliary tract operations have been reported. Gallstones are responsible for 90% of cases followed by peptic ulcer disease (6%) and trauma (4%). Cholecystoduodenal (75%), cholecystocolonic (15%), and cholecystogastric (6%) fistulae are the most frequent sites of tract formation. Cholecystoduodenal fistulae from gallstones almost exclusively involve the periampullary area. Fistulae may be obstructive or nonobstructive. The female to male ratio for both types is between 2 : 1 and 3 : 1. Gallbladder carcinoma has been associated with enteric biliary fistulae in 15% of cases [385–387].

Clinical manifestations

Nonobstructive fistulae are often diagnosed as incidental findings at cholecystectomy or cholangiography. Consequences of these fistulae include ascending cholangitis, weight loss, and bleeding. Obstructive fistulae present with symptoms that are reminiscent of bowel obstruction, which may be complete or partial [386]. Gallstone ileus can present with acute small bowel obstruction from gallstones of diameters greater than 25 mm. The ileocecal area is the most common site of obstruction (75%) followed by the jejunum (20%). Abdominal radiograph findings of pneumobilia are observed in only 30% of enteric biliary fistulae. Biliary reflux of oral contrast is more suggestive of biliary fistula [386].

Treatment

The treatment of choice when possible is operative. For gallstone ileus, the performance of cholecystectomy, fistula excision, and operative cholangiography to exclude choledocholithiasis is recommended. Mortality rates approaching 20% in previous reports have been reduced below 5% [385].

Operative biliary fistula

Most commonly observed in association with bile duct injury after cholecystectomy. The development of a cutaneous or internal bilioperitoneal fistula occurs in 33% of postoperative cases. Hepatobiliary scintigraphy (i.e., HIDA scan) can detect bile leaks and fistulae with greater than 90% sensitivity. Cholangiography may ultimately be required for diagnosis

confirmation. Endoscopic therapy with nasobiliary tube placement or stents have been successful in selected cases. Treatment failures require surgery or interventional radiology [387,388].

Bronchobiliary fistula

Overall prevalence rates are unknown but range between 4% and 10.5% among patients with hepatic and subphrenic abscesses, respectively. Other etiologies responsible for bronchobiliary formation include blunt abdominal trauma, bile duct stenosis, choledocholithiasis, and congenital causes. Clinical manifestations include bilioptysis, jaundice, and cholangitis. Diagnosis has been made by cholangiography and biliary scintigraphy. The therapy of choice is surgical [389].

Miscellaneous biliary fistula

Vascular fistulae with the biliary tree may occur and include both arterial and venous systems. Causes include trauma, infection, or iatrogenic factors (operative, transjugular intrahepatic portosystemic shunt). Hemobilia is the most common sign at presentation. Biliobiliary fistulae involving the gallbladder, cystic duct, or secondary biliary radicle with the main biliary tree can also occur. Compression by stone impaction in the cystic duct or gallbladder neck (Mirizzi syndrome) may result in erosion through the common bile duct resulting in fistula formation [390].

76 Cystic diseases of the liver and biliary tract

Jung W. Suh, Albert J. Chang, Shelly C. Lu

Introduction, 2009
Cystic diseases of the biliary tract, 2009
Polycystic liver disease, 2017

Introduction

Cystic dilations occur throughout the liver and biliary system. They most commonly affect the common bile duct (CBD) (i.e., choledochal cyst), but cystic dilations involving the intrahepatic ducts alone or in combination with other cystic abnormalities of the extrahepatic ducts are increasingly recognized. The terminology and classification are tremendously confused. The term choledochal cyst has commonly referred to all cystic abnormalities of the biliary tree; however, this term is best restricted to only cystic abnormalities of the CBD. Despite the many variations of these cystic abnormalities, some underlying features unify them. Biliary cysts are distinct from polycystic liver disease (PCLD), which is a rare hepatobiliary fibropolycystic disorder that is characterized by the progressive development of fluid-filled biliary epithelial cysts in the liver. This chapter reviews current understanding of cystic diseases of the biliary tract and PCLD.

Cystic diseases of the biliary tract

Epidemiology

Biliary cysts are rare, with the highest incidence in Japan, where one-half to two-thirds of all reported cases have originated [1–3]. The Japanese incidence (1 in 13 000 births) is significantly higher than in the West (1 in 150 000 births) [3,4]. The incidence is much higher among women, with a female to male ratio of 3 : 1 or 4 : 1. Between 40% and 60% of patients are diagnosed before 10 years of age, 52%–76% before 20 years of age, and 83%–90% before 30 years of age [1–3,5]. This is mainly a disease of children and young adults, although more recent series indicate that the incidence in adults is much higher than previously thought [6].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Classification

Choledochal cysts were first described by Vater and Ezler in 1723. Alonzo-Lej and colleagues classified cysts into three types [7]. Later, Todani and associates proposed the most complete and practical classification that recognizes five types of bile ducts cysts (Fig. 76.1) [8].

- Type I cysts include choledochal cysts in a narrow sense; segmental choledochal dilations; and diffuse or cylindrical dilations. Between 75% and 85% of cases are type I.
- Type II or diverticulum cysts are found anywhere in the extrahepatic ducts and make up 2%–3% of reported cases.
- Type III or choledochocele cysts, also rare, represent 1.4%–5.6% of reported cases. These are cystic dilations involving only the intraduodenal portions of the CBD. In 1989, Sarris and Tsang reviewed 48 cases in the English-language literature and proposed a further anatomic classification of choledochoceles [9]. In type A, the ampulla opens into the choledochocele, which communicates with the duodenum through another small opening. Type A choledochoceles can be further subclassified into A1, in which the pancreatic duct and CBD share a common opening into the cyst (33% of cases); A2, in which the openings are distinct (4% of cases); and A3, in which the choledochocele is small and entirely intramural (25% of cases). In type B, the ampulla opens directly into the duodenum, with the choledochocele communicating only with the distal CBD (21% of cases). This scheme is useful because of important therapeutic implications.
- Type IV cysts are also subclassified. In type IVA, multiple cysts in the intrahepatic and extrahepatic ducts account for 10%–15% of reported cases [3,10]. In type IVB, multiple cysts occur only in the extrahepatic duct and are much less common.
- Type V intrahepatic bile duct cysts (single or multiple) are also rare. They probably represent Caroli disease as originally described.

Serena and colleagues proposed a type VI biliary cyst, which is cystic dilation of the cystic duct with otherwise normal intrahepatic and extrahepatic ductal systems [11]. Three cases of type VI cysts had been described in the literature up to 1999 [12].

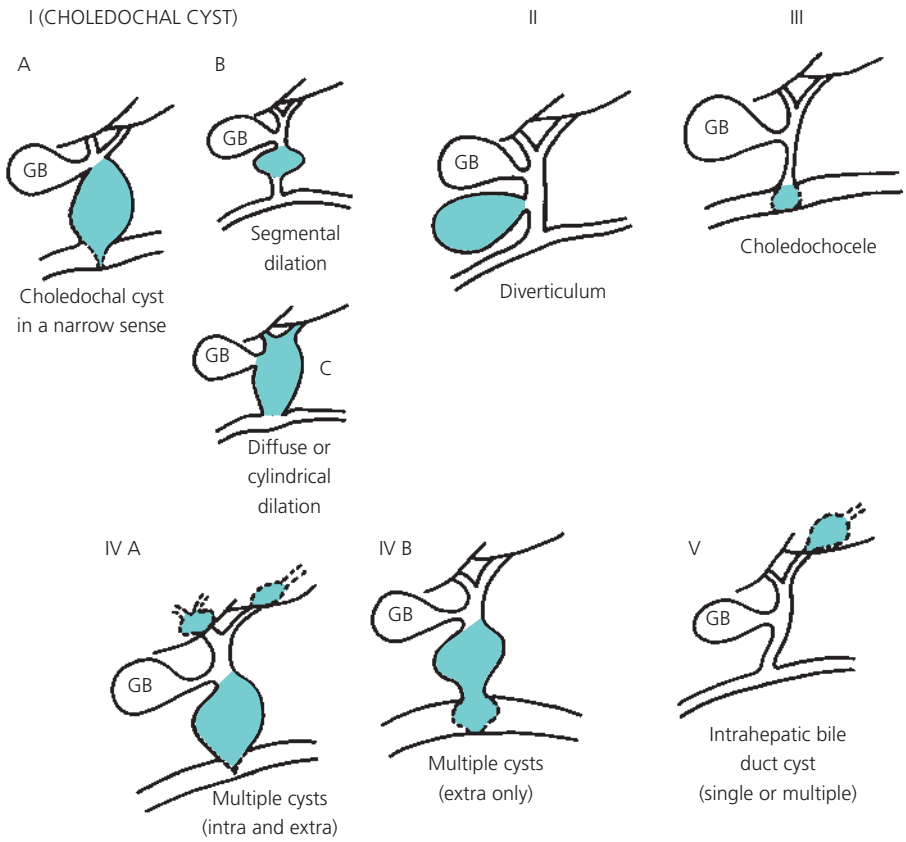

Figure 76.1 Todani's classification of biliary cysts based on location. Hatched areas represent cystic dilations.

Forme fruste choledochal cyst is a variant of choledochal cyst that has little to no cystic dilation but is associated with anomalous pancreaticobiliary ductal union (APBDU) [13]. In one series, 17 of 281 choledochal cysts were of this variant [13].

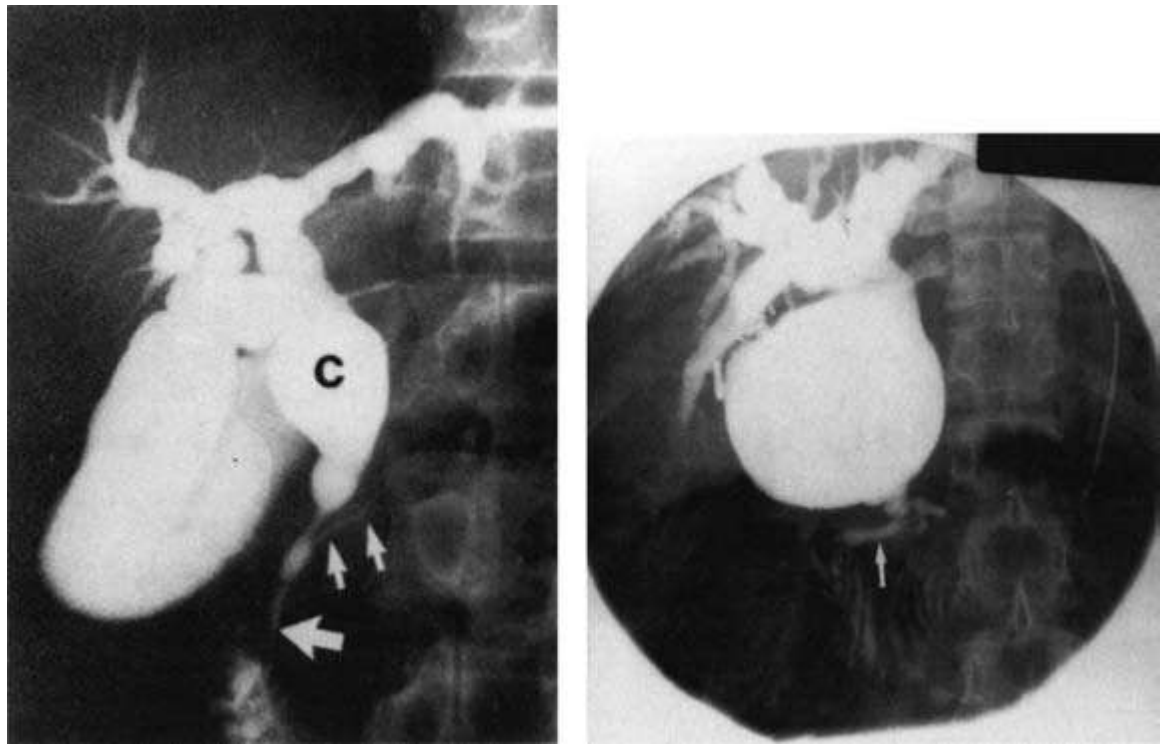
Anatomically based classification is of great practical importance in planning surgical management. Other classifications emphasize clinical presentation rather than ductal anatomy.

Pathogenesis

The cause of biliary cysts has been disputed. The major debate concerns whether cysts are congenital or acquired. Genetic factors may also be involved because the disease is more common in Japanese and familial occurrence has been reported. However, a study of a pair of monozygotic twins showed discordance for both anomalous pancreaticobiliary junction and biliary cyst [14], which is not compatible with single gene control.

Many early investigators favored the congenital malformation theory [15]. Several observations support this. First, biliary cysts appear in all age groups, and antenatal diagnosis has been reported as early as 15 weeks' gestation, making a congenital origin likely. There are also many associated anomalies of the biliary system, such as double common bile duct, double gallbladder, multiseptate gallbladder, biliary atresia, congenital hepatic fibrosis, and annular pancreas [16]. In addition, many cysts fail to shrink after decompressive surgery, suggesting inherently abnormal ductal wall development [2].

Of the theories proposing acquired cysts that of Babbitt and associates has received the most attention [17]. They proposed that choledochal cysts develop because of an anomalous arrangement of the distal pancreaticobiliary tree. In all seven of their patients with choledochal cysts, they found the CBD entered the pancreatic duct at a right angle at an abnormally long distance (> 2 cm) from the ampulla of Vater (Fig. 76.2). This abnormal anatomy impaired normal sphincteric function at the pancreaticobiliary junction. Because the maximal secretory pressure of the pancreas is 30 cmH_2O to 50 cmH_2O and that of the liver is 25 cmH_2O to 30 cmH_2O, pancreatic juice flows into the bile duct in the absence of a sphincter mechanism. This anomaly is associated with recurrent cholangitis, edema, fibrosis, obstruction of the bile ducts, and carcinoma. These complications are believed to result from chronic reflux of pancreatic juice and subsequent activation in bile of various pancreatic proteinases and lipases. In support of this are the high levels of amylase that are frequently found in the cyst fluid and the demonstration that pancreatic juice in the CBDs of animals with an anomalous arrangement can cause cystic dilation of the CBD [5,18]. Although amylase has been found in the cyst fluid, this enzyme probably does not play a pathogenic role. Amylase is not detectable in the duodenal fluid of newborns and infants,



(a) (b)

Figure 76.2 Choledochal cyst–anomalous ductal relationship. **(a)** Cystic enlargement of the common bile duct (C) with associated dilation of the common hepatic and intrahepatic ducts. The abnormal junction of pancreatic (small arrows) and common bile ducts and long common channel (large arrow) is displayed. **(b)** A large cyst involves the common hepatic and common bile ducts accompanied by intrahepatic ductal dilation. A long common channel (arrow) results from the abnormally high junction with the pancreatic duct.

but trypsin activity is the same in newborns and older children [19]. Another substance that is markedly increased in the bile of patients with APBDU (most also had biliary cyst) is lysophosphatidylcholine [20]. This was the result of increased hydrolysis of phosphatidylcholine, a normal component of bile, by increased activity of phospholipase A_2. Lysophosphatidylcholine is cytotoxic so it may play a role in the pathogenesis of biliary cysts by adversely affecting an already weakened bile duct wall and in the later development of malignant degeneration [20]. However, this theory does not explain the cause of intrahepatic cysts because of their distance from the anomalous union [21].

APBDU occurs in 65%–80% of patients with choledochal cysts [15]. APBDU is not unique to patients with biliary cysts, it is also associated with biliary malignancies (especially gallbladder carcinoma) and abnormal pancreatic ducts [22]. In a large study of 1325 patients who were examined with direct cholangiography for symptoms suggestive of hepatobiliary and pancreatic disease, 29 patients had the anomaly (2.2%), of which 21 had associated choledochal cyst. Surprisingly the frequencies of gallbladder carcinoma in patients with the anomaly were 50% and 5% in the absence or presence of associated choledochal cyst, respectively. None of the patients with gallbladder carcinoma had gallstones. The overall frequency of carcinoma of the biliary tract was 14% in patients with choledochal cyst and 50% in those without. This striking difference led the authors to recommend prophylactic cholecystectomy in patients with an APBDU [23]. Similar findings and recommendations have been reported by Sugiyama and Atomi [24].

Many investigators emphasized that cystic dilation results from a combination of two factors: segmental weakness of the duct wall and distal obstruction [25]. The weakness of the wall and the distal obstruction may be congenital or acquired. Several animal experiments support the importance of distal obstruction [2,26]. Ligation of the distal CBD in adult rabbits, rats, and dogs gives rise to diffuse dilation of the intrahepatic and extrahepatic ducts. This also occurs in neonatal lambs [26]. After CBD ligation, all six lambs in the study developed choledochal cysts, and all four adult sheep developed isolated dilation of the gallbladder. However, whether these animal experiments are applicable to humans remain unclear because not all choledochal cysts have demonstrable distal obstruction.

The infantile form of choledochal cysts appears in some cases to result from an obliterative process similar to that producing biliary atresia. Twenty-four (13%) of 188 patients with biliary cysts were also found to have biliary atresia [27]. However, well-documented cases of acquired biliary cysts in adults have appeared, including seven attributed to recurrent

attacks of pancreatitis [28]. More recent studies suggest that many other factors may also be involved, including abnormal sphincter of Oddi pressure [29], viral infection, and genetic mutations [30–32]. Tyler and colleagues found reovirus in 13 of 23 tissues from patients with extrahepatic biliary atresia and 7 of 9 tissues from patients with choledochal cysts, prevalences that were much higher than in patients with other hepatobiliary diseases (21%) or in autopsy cases (12%) [30]. This is intriguing because reoviruses can produce a disease in weanling mice with similar pathological features to human choledochal cysts [30]. However, the number of patients with choledochal cysts examined was small and causality remains to be established. Two cases of choledochal cysts in association with rare genetic syndromes have been described [31,32]. One was in association with familial adenomatous polyposis syndrome [31] and the other was in association with Simpson–Golabi–Behmel syndrome [32]. These investigators raised the possibility that mutations in their respective genes may have contributed to the development of the choledochal cyst.

Two recent studies advanced our understanding of the pathogenesis of Caroli syndrome (type V biliary cysts in association with congenital hepatic fibrosis – see Clinical presentations). First is the identification of impaired protein N-glycosylation because of phosphomannose isomerase deficiency as a cause of congenital hepatic fibrosis, a disorder of ductal plate malformation often associated with type V cysts [33,34]. These patients often present with protein-losing enteropathy, which responds to D-mannose treatment [34]. Whether the hepatobiliary abnormalities will improve is unknown. These recent findings also suggest that normal protein glycosylation is important in the formation of ductal plates. Another advance is the development of a novel animal model with features of autosomal recessive polycystic kidney disease, multiple intrahepatic bile duct dilations, and congenital hepatic fibrosis [35]. These animals exhibit increased proliferative activity and decreased apoptotic activity in the biliary epithelial cells during development compared to controls, suggesting that the remodeling defect in immature bile ducts associated with the imbalance of cell kinetics play a role in the development of the hepatobiliary abnormalities [35]. One study in rats with autosomal recessive polycystic kidney disease suggested that overexpression of the mitogen-activated protein kinase signaling pathway may be involved in biliary dysgenesis because interference with this pathway demonstrated a decrease in the proliferation activity of biliary epithelial cells [36].

It is clear that many factors are important in the pathogenesis of biliary cysts, which encompass a wide spectrum of lesions.

Clinical presentations

Type I or choledochal cysts

Patients with choledochal cysts present with two typical clinical constellations, which are determined mostly by the patient's age at presentation [2]. In infancy, jaundice with or without acholic stools is the most common finding, occurring in as many as 80% of patients [2]. The presentation is often indistinguishable from that of biliary atresia, which is sometimes associated with choledochal cysts [27]. Pain may or may not be a factor, but vomiting and failure to thrive have been reported in as many as 50% of patients [2]. Hepatomegaly is often found, and 30%–60% of patients have a palpable abdominal mass [2]. The mass is usually in the right hypochondrium, soft, elastic, round, mobile laterally, and may follow the movements of the diaphragm [8]. The classic clinical triad of pain, jaundice, and a palpable abdominal mass has been found only in 11%–63% of large series [2]. Frequently, biliary cirrhosis and portal hypertension complicate the management [27].

The noninfantile form (in patients older than 2 years) covers a wide age range, with the oldest patient reported being in the eighth decade. Asymptomatic patients have been described [37]. Chronic and intermittent pain appears to be the most common presenting symptom, reported in 50%–96% of patients [38]. Intermittent jaundice and recurrent cholangitis are also common, reported in 34%–55%. Abdominal mass is much less common; it occurs in about 10%–20% of patients. The classic triad of pain, jaundice, and a palpable mass has been reported in 3%–13% of patients [38]. Cirrhosis and portal hypertension are less often encountered. Pancreatitis may be a presenting symptom in up to 33% of the patients in the noninfantile form, possibly as a result of immature pancreatic exocrine function in infants less than 1 year old [39]. However, whether or not there is actual pancreatic inflammation is debatable [40]. When these patients present with painful attacks, they often show slight elevation of serum bilirubin levels and an increase in the degree of the choledochal dilation, possibly caused by biliary obstruction. The terms fictitious pancreatitis and pseudopancreatitis have been applied to these patients [40].

The other presentation that has been reported only in patients older than 10 years of age is that of carcinoma associated with choledochal cysts [41].

Type II or diverticulum cysts

More than 50 cases of type II or diverticulum cysts have been reported in the world literature, representing 2%–3% of large series [39,42]. Presenting symptoms generally reflect the compression of nearby structures by the cyst.

Type III or choledochocele cysts

About 125 cases of choledochocele have been reported [39,43–45]. More than 73% of reported patients were older than 20 years of age, unlike type I cysts, which are found in 60% of the patients with biliary cysts younger than 10 years of age [44]. There is also less female preponderance, with a female to male ratio of 1.4 : 1 [44]. Common presenting symptoms include intermittent episodes of abdominal pain

and obstructive jaundice. An abdominal mass is not found. Pancreatitis is much more common in choledochocele than in any other type of biliary cyst and is reported in 30%–70% of these patients, presumably caused by reflux of bile or obstruction [45]. Stones in the cele or the CBD are also much more common, reported in 25%–35% of these patients, in contrast to only 8% in type I cysts [39,45]. Rarely, intestinal (duodenojejunal) intussusception may be the presenting feature of choledochocele [43].

Type IV and V cysts or Caroli disease

Caroli and colleagues originally described this disease as a congenital malformation of the intrahepatic bile ducts, characterized by segmental cystic dilation of the intrahepatic ducts; increased incidence of biliary lithiasis, cholangitis, and liver abscesses; absence of cirrhosis and portal hypertension; and association of renal tubular ectasia or similar renal cystic disease [46].

After the first report, Caroli recognized that two distinct disease entities are associated with intrahepatic duct cysts: the simple type, which was his original description, and the periportal fibrosis type [47]. The simple type is associated with medullary sponge kidney in 60%–80% of cases. The periportal fibrosis type is also known as Caroli syndrome. In addition to intrahepatic cystic dilation, congenital hepatic fibrosis, cirrhosis, portal hypertension, and esophageal varices are frequently seen. Hepatic function is usually well preserved in the periportal fibrosis type; the major clinical manifestations are recurrent cholangitis, liver abscess formation, and portal hypertension. It is often associated with the renal abnormalities of autosomal recessive polycystic kidney disease [33].

It is apparent that Caroli disease, including the simple and periportal fibrosis types, represents only part of the spectrum of cystic disease of the intrahepatic ducts. In an excellent review by Barros and associates of 46 well-documented cases with hepatic histopathology and biliary tree studies available, only 13% of patients had the simple type [48]. Thirty-five percent had the periportal fibrosis type, 22% had intrahepatic and extrahepatic cystic dilation (i.e., type IVA of Todani's classification), and 30% had all three abnormalities: cystic dilation of the intrahepatic and extrahepatic bile ducts, and congenital hepatic fibrosis.

Congenital hepatic fibrosis refers to a unique congenital liver histology characterized by bland portal fibrosis, hyperproliferation of interlobular bile ducts within the portal areas with variable shapes and sizes of bile ducts, and preservation of normal lobular architecture [48]. The prevalence of biliary cysts in patients with congenital hepatic fibrosis has probably been underestimated, because most patients did not have cholangiographic studies performed.

The aforementioned forms of intrahepatic biliary cystic disease should be differentiated from PCLD (see Polycystic liver disease) because of significant dissimilarities. PCLD is an autosomal dominant genetic defect, but the manner of inheritance of Caroli disease remains poorly defined [33]. Polycystic liver cysts are large, contain serous fluid, and do not communicate with the biliary tree. Caroli disease cysts communicate with the biliary tree. Portal hypertension is rare in PCLD. The prognosis for PCLD patients is determined by the effect of cystic disease on the kidneys and not the liver [49]. The incidence of malignant transformation in the intrahepatic parenchymal cysts of PCLD is 1.3%, compared with 7% in Caroli disease [50].

Caroli disease is rare, and males and females are equally involved [50]. Symptoms usually appear in early adult life, with recurrent episodes of fever, chills, and abdominal pain as the result of cholangitis. More than 80% of patients present before the age of 30 years. Biliary lithiasis is found in 34% of these patients, which may predispose to recurrent cholangitis [48]. Occasionally, the disease is diagnosed later in life, with the sequelae of portal hypertension, most commonly bleeding esophageal varices [47,50].

Diagnosis

Diagnosis of biliary cysts requires a high index of suspicion. Biliary cyst should be included in the differential diagnosis of recurrent abdominal pain, pancreatitis, obstructive jaundice, or cholangitis. Most patients do not present with the classic triad of pain, jaundice, and abdominal mass. Biochemical tests only reflect the degree of biliary obstruction and infection. Correct diagnosis depends on the use of imaging studies.

Ultrasonography is the best screening method for type I, II, IV, and V, but not type III, biliary cysts [1,2,51]. Ultrasonography has allowed the antenatal diagnosis of choledochal cyst in at least 17 cases [52]. When a choledochal cyst is suspected on prenatal ultrasonography, repeat ultrasonography is indicated immediately after birth so that expeditious treatment can be provided. The major drawback to ultrasonography is that it provides little anatomical or functional information. Furthermore, choledochal cysts can be confused with other cystic lesions, such as hepatic cysts, pancreatic pseudocysts, enteric duplication cysts, hepatic artery aneurysms, and hydatid cysts [53].

Hepatobiliary scintigraphy has been advocated as a sensitive, noninvasive tool for the diagnosis of choledochal cyst. The characteristic findings are biliary tract dilation and tracer retention after 24 h [54]. It provides information about excretory patterns and has therefore been recommended by many for postoperative patient follow-up. This technique is useful for all except type III cysts, because it may fail to demonstrate tracer accumulation in a small choledochocele [51,54].

Ultrasonography and scintigraphy are complementary and provide a sound basis for preoperative diagnosis in patients younger than 2 years of age. For older patients, computed tomography (CT) has been advocated by some to be superior to ultrasound [54,55]. Percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography

(ERCP) have been regarded as providing the best detailed examinations. PTC is especially useful in defining complex anatomic cysts of the intrahepatic ducts, but ERCP provides the best visualization of the distal portion of the biliary tree, especially the relation of the biliary and pancreatic ducts [2]. This notion has been challenged in recent years by improvements made in magnetic resonance imaging [56,57]. Several studies showed that magnetic resonance cholangiopancreatography (MRCP) is as good as ERCP in the evaluation of biliary cysts, especially in adults [56,57]. However, MRCP can overlook small choledochoceles, may be inadequate for visualizing the terminal CBD or APBDU, and have lower concordance with ERCP for type I and type IVA cysts [58]. Nevertheless, because MRCP is noninvasive and is not operator-dependent, it is likely to replace ERCP and PTC as the imaging study of choice in patients with biliary cysts.

ERCP remains useful in the diagnosis of choledochoceles. The typical features are the "clubbed" appearance of the distal CBD and a round, cyst-like, contrast-filled structure in the terminal CBD, which often protrudes into the duodenal lumen. Emptying of contrast material is often delayed. Choledochoceles are easily differentiated from duodenal diverticula and duodenal duplication cysts by filling during cholangiography but not during upper gastrointestinal contrast studies (Fig. 76.3). Duodenal diverticula fill on upper gastrointestinal series but not on cholangiography. Duplication cysts do not fill with either method [59].

Endoscopic ultrasound has also been used as an additional modality with which to visualize extrahepatic biliary cysts and provide detailed images of the cyst wall and APBDU [60].

The definitive diagnosis of biliary cyst and its classification is secured by intraoperative cholangiography at the time of operative intervention. Delineation of the precise anatomy is critical in preventing injury, especially to the pancreatic duct because of the high frequency of the anomalous union, and in providing the best operative management possible [2].

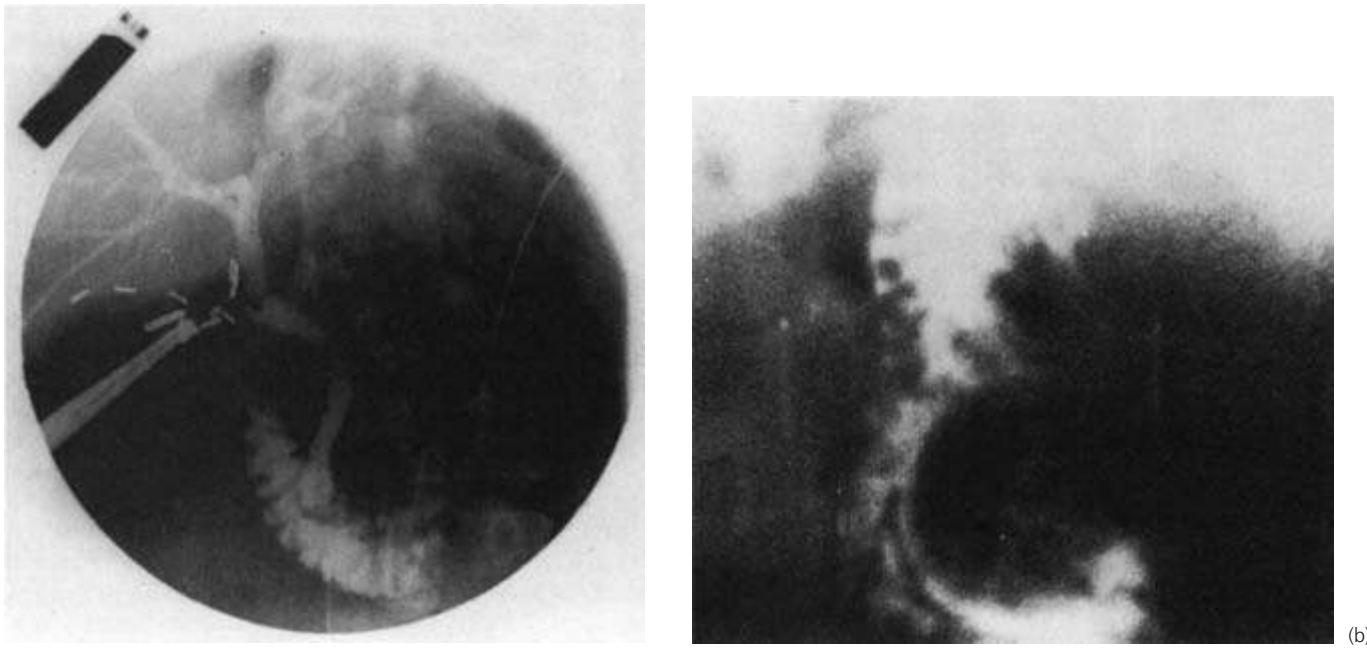
Pathology

The wall of the cyst is usually thickened because of productive fibrosis and inflammation. Histologically, dense connective tissue, fibrocollagenous and sometimes with smooth muscle and elastic elements, is seen. There is no epithelial lining, but islets of cylindrical or columnar epithelium may be preserved. A case of biliary papillomatosis arising in a choledochal cyst wall was reported [61]. Duodenal mucosa covers choledochoceles externally but the internal surface of choledochoceles is variably lined by duodenal mucosa (63% of cases), bile duct mucosa (21% of cases), or unclassified glandular epithelium (13%) [62].

Liver biopsy is abnormal in 60% of patients with biliary cysts, demonstrating biliary cirrhosis, portal fibrosis, or evidence of biliary atresia. Other abnormal findings include liver abscesses, especially in cases of Caroli disease and sludge or stones in the CBD. In newborn patients with biliary cysts, the histology is usually normal or shows mild bile duct proliferation consistent with biliary obstruction [15].

Treatment

Biliary cyst treatment is surgical with primary cyst excision as the procedure of choice [8]. Internal drainage procedures,



(a) (b)

Figure 76.3 Choledochocele type III cyst. **(a)** Cholangiography reveals a club-shaped enlargement of the distal common bile duct bulging into the duodenum. **(b)** Upper gastrointestinal series reveals a smoothly rounded filling defect in the second portion of the duodenum.

such as choledochoduodenostomy and Roux-en-Y choledochojejunostomy, are not recommended because of the high morbidity rates, the need for reoperation, and the risk of malignant degeneration [2,27]. Morbidity rate can be up to 88% with internal drainage procedures, compared with 2%–8% with cyst excision [27]. In large series, 13%–70% of patients have required reoperations after internal drainage, but a 0%–10% reoperation rate was reported after cyst excision [27,63]. Most importantly, the risk of malignant transformation is not diminished after an internal drainage procedure (see Clinical course and complications). Patients who develop biliary carcinoma after the excision of choledochal cyst are extremely rare; only three had been reported up to 1984 [64]. The fundamental reason for poor outcome after internal drainage is that diseased tissue remains and is used for biliary reconstruction. The cyst wall is inherently inflamed and fibrous, precluding normal healing. Biliary stasis persists and predisposes to recurrent cholangitis, and stone and stricture formation.

The aforementioned techniques are applicable for choledochal cysts (i.e., type I and IV cysts involving the CBD). Type II cysts should be excised. Treatment for type III cysts depends on the anatomy (see Fig. 76.1). Sarris and Tsang recommend excision of the duodenal luminal portion of the cyst, leaving the medial portion containing the ampulla intact as the preferred treatment in most cases of type IIIA cysts (i.e., A1 and A2) [9]. Transduodenal sphincteroplasty and ERCP with papillotomy have been advocated as treatment for type IIIA3 cysts. Type IIIB cysts should be treated by excision and sphincteroplasty. The malignant potential of choledochocele appears to be very low [44,45]. However, Schimple and colleagues pointed out that carcinoma has only been reported in choledochoceles that are lined by biliary or undifferentiated epithelium internally (up to 20% in some reports). They advocate complete excision of the choledochocele by separation and reinsertion of the CBD and pancreatic duct into the duodenal wall if the choledochocele is lined by biliary or undifferentiated epithelium, whereas sphincteroplasty should be reserved only for those lined by duodenal epithelium [65].

Intrahepatic cyst (i.e., type IVA, V) treatment depends on the degree of involvement. When segmental cystic disease is confined to one lobe (more often the left lobe), then lobectomy is usually curative [50,66]. If both lobes are involved, some have advocated establishing a permanent-access hepaticojejunostomy after partial hepatectomy to allow easy biliary tree access when necessary [66]. If extrahepatic cysts coexist with intrahepatic cysts (type IVA), they should be excised as previously described. Chronic antibiotic therapy in multilobar Caroli disease may have some benefit. Ultimately, if attacks of cholangitis are frequent and quality of life is poor, hepatic transplantation may be a therapeutic option. A summary of the recommended surgical treatment is given in Table 76.1.

In a long-term study of children with forme fruste choledochal cysts who underwent extrahepatic duct excision followed by Roux-en-Y hepaticojejunostomy, there were significant bile duct changes, including inflammatory cell infiltration, mucosal ulceration, and fibrosis, despite minimal cystic dilation [13]. These pathological changes are similar

Table 76.1 Suggested treatment for biliary cysts

Type of biliary cyst	Suggested treatment
Type IA	Cyst excision with Roux-en-Y hepaticojejunostomy or jejunal
Type IB	Interposition hepaticoduodenostomy
Type IC	Choledochojejunostomy or sphincteroplasty if excision is impossible
Type II	Excision if possible
Type IIIA1	Excision
Type IIIA2	Excision
Type IIIA3[a]	Sphincteroplasty or endoscopic retrograde cholangiopanctreatography with papillotomy
Type IIIB	Excision and sphincteroplasty
Type IVA	Extrahepatic cyst excision with biliary reconstruction as in IA and IB. Lobectomy if intrahepatic cyst is confined to one lobe or permanent access hepatocojejunostomy if intrahepatic cysts are diffuse Transplantation in selected cases
Type IVB	Cyst excision as in IA, IB
Type V	Hepatic resection for localized disease or permanent access hepaticojejunostomy for diffuse disease Transplantation may be an option

a Complete excision of the choledochocele by separation and reinsertion of the common bile duct and pancreatic duct into the duodenal wall if the choledochocele is lined by biliary or undifferentiated epithelium.

to those found in choledochal cysts and may place these children at high risk of malignancy. Shimotakahara and colleagues recommended extrahepatic duct excision followed by Roux-en-Y hepaticojejunostomy for all children with forme fruste choledochal cysts. However, the management of this variant in adults is still controversial [13].

Laparoscopic cyst resections and external anastomosis of choledochojejunostomy for Type I, II, and IV cysts have been reported [67,68].

Cholecystectomy should be performed at the time of cyst excision because continuous free bile flow minimizes the risk of reflux and cholangitis and because the gallbladder has shown clinical and histological evidence of cholecystitis in patients in whom secondary operations have been necessary. Furthermore, the gallbladder is predisposed to malignant change in patients with biliary cysts [69].

If the definitive surgical procedure is successful, the prognosis is generally excellent. Reversal of cirrhosis has even been reported [70].

Clinical course and complications

Complications of biliary cysts include recurrent cholangitis before treatment and after internal drainage procedures, stone formation, stenosis and stricture, pancreatitis, biliary cirrhosis, portal hypertension as the result of cirrhosis or portal vein thrombosis, liver abscess, especially in Caroli disease, and cyst rupture [9,27,71]. Gallstones may be present in approximately 25% of patients [51]. Stones can be trapped within the choledochal cysts, causing cholestasis, cholangitis, and cholecystitis [51]. Pregnancy can precipitate or aggravate symptoms of choledochal cyst, specifically cyst rupture. Twenty-six cases have been reported to rupture during pregnancy or labor [72]. Pregnant women with symptomatic choledochal cyst should avoid labor by having cesarean sections as soon as the fetus is mature.

After surgical intervention of choledochal cysts, early complications include bile leak and cholangitis [73]. Late complications depend on the type of surgery, but often include cholangitis or pancreatitis [73]. Regardless of the type of surgical reconstruction, the incidence of postoperative cholangitis is approximately 20% [74]. After Roux-en-Y hepaticojejunostomy, patients may develop diarrhea, fat malabsorption, and malnutrition.

The most feared complication is malignancy [9,75]. Carcinoma afflicts predominantly adults. The youngest patient found to have carcinoma during initial choledochal cyst surgery was 10 years of age [75]. The mean age for detecting carcinoma after enteric drainage was 35 years, with a mean interval of 10 years after the enteric drainage procedure [75]. The mean age for detecting carcinoma at the initial surgery for biliary cysts was 50 years; this is two decades earlier than the mean age for bile duct carcinoma in the general population [75]. Even though the overall incidence of biliary carcinoma in association with biliary cysts is 2.5%, it is actually 14%–18% in adult patients (thos older than 20 years) and is 50% by 50 years [2,41,75]. In contrast, the overall incidence of biliary carcinoma is 0.012%–0.48% in the general population [76]. The female to male ratio is 2.5 : 1, slightly less than that seen in choledochal cyst.

Carcinomas occur not only in the cyst wall; the remainder of the hepatobiliary and pancreatic tree can be affected. Of 154 cases of carcinoma in cases of biliary cysts, only 58% were actually in the cyst wall, 40% were gallbladder, 1.3% were pancreatic, and 0.6% were intrahepatic carcinomas [75].

The pathogenesis of malignant change in biliary cysts is unknown. Stones are not thought to be important because they are found in only 13.8% of patients with malignant change in the biliary cyst (Fig. 76.4) [75]. Adenocarcinoma is the most common type, constituting 70%–84% of all types. Other histological types are squamous (4%–9%) and undifferentiated or anaplastic (7%–21%), and one case of small cell carcinoma was reported [75]. Numerous studies have found that APBDU is a risk factor for biliary tract carcinoma

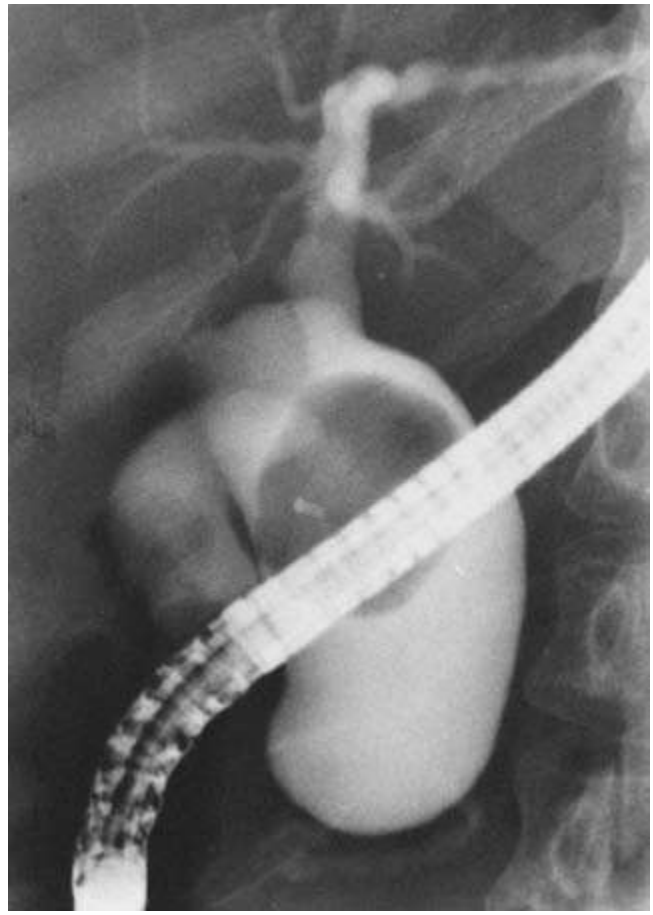


Figure 76.4 Choledochal cyst type IA. Endoscopic retrograde cholangiogram shows cystic dilation of the common bile duct with a very large filling defect as the result of a calculus. Stones are uncommon complications of biliary cysts, only reported in 13.8% of cases. Courtesy of Dr Hartley Cohen, USC School of Medicine.

[78]. This may involve mutational events involving Deleted in Pancreatic Cancer, locus 4 (*DPC-4*), *K-ras*, and *p53* genes [78,79].

Isolated intrahepatic cysts (i.e., Caroli disease) are also associated with a higher incidence of carcinoma. Overall, 7% of patients with Caroli disease were found to have cholangiocarcinoma, with no female predominance [80]. The average age at the time of diagnosis of carcinoma was 51 years [80].

MRCP may be a good diagnostic modality in the surveillance of cholangiocarcinoma, both intraluminal and periductal, but a surveillance protocol has not yet been established [58].

The prognosis of carcinoma related to biliary cysts is dismal. Almost all patients die soon after diagnosis [75,80]. One preventive therapy is total cyst excision during the initial operation. However, cyst excision does not completely eliminate the future risk of carcinoma, because the rest of the pancreaticobiliary tree appears to also be predisposed to malignant change.

Polycystic liver disease

Epidemiology

The prevalence of PCLD in autopsy studies is 0.05%–0.13% [81,82]. The most common form of PCLD coexists with autosomal dominant polycystic kidney disease (ADPKD); however, PCLD can occur without renal involvement [81,83]. Regardless of the etiology of the PCLD, the natural history is similar [84]. Gabow and colleagues observed that the hepatic cysts lag behind renal disease in ADPKD patients [85]. The hepatic cysts are rarely detected before puberty, but approximately 80% of the patients with renal cysts have liver cysts by the fifth decade of life. The liver cysts are more prevalent and prominent in women, and increase dramatically in number and size through the childbearing years [85]. A similar female preponderance is observed in isolated PCLD [84].

Pathogenesis

PCLD that coexists with ADPKD is associated with mutations of the *PKD1* (polycystic kidney disease 1) or *PKD2* [85–88] genes. Liver cysts are believed to arise from progressive dilation of abnormal biliary ducts, particularly the small intrahepatic ducts, which have lost their connection with the biliary tree [89]. The majority of the patients with ADPKD have *PKD1* gene mutations, accounting for 85%–90% of cases, whereas the remaining patients have mutations in the *PKD2* gene [90]. Interestingly, patients with mutations in *PKD2* have later onset of disease [91]. The *PKD1* gene, which encodes an integral membrane protein, polycystin 1, has been localized to the short arm of chromosome 16p13.3-p13.12 [92]. The *PKD2* gene encodes an integral membrane protein, polycystin 2, which has been linked to chromosome 4q21–q23 [93]. Although some studies have suggested that the type and position of mutations may predict phenotypic renal and extrarenal disease, no studies have analyzed the effects on hepatic cystic disease [84]. Studies in animal models demonstrate that autosomal polycystic disease may require a second somatic mutation to lead to cyst formation [94]. It is believed that loss of function of polycystin 1 and 2 leads to clonal expansion of mutated cells. Liver cysts arise from intrahepatic bile duct epithelial cells and detach from the intrahepatic bile duct as they expand and compress the surrounding parenchyma. Histological evaluation of cysts shows variable numbers of biliary microhamartomas, known as von Meyenburg complexes, which are characterized by clusters of dilated bile ducts lined by a layer of cuboidal cells surrounded by a fibrous stoma [95]. Everson and colleagues have suggested that the secretion of fluid within the cyst is triggered by hormonal signaling, primarily secretin [96].

Autosomal dominant PCLD is an entity that is distinct from ADPKD [81]. Reynolds and colleagues localized the mutation to chromosome 19p13.2–13.1 [97]. It has been further linked to a mutation in the protein kinase C substrate *80K-H* gene, which encodes a protein called hepatocystin [98–101]. So far, nine different mutations in hepatocystin have been found in patients with PCLD. All of the mutations lead to premature chain termination. Hepatocystin is a protein kinase substrate that functions as a β-subunit of endoplasmic reticulum glucosidase II [98–101]. Truncation of hepatocystin leads to failure of interaction of hepatocystin and the α-subunits, causing decreased levels of both subunits. This may compromise the processing of N-linked oligosaccharide chains of newly synthesized glycoproteins.

Clinical presentation

Most patients with PCLD are asymptomatic [84]. The cysts range in size from less than 1 mm to more than 10 cm and they may be diffuse or involve only one lobe [102]. The most common presenting symptom is abdominal pain, with or without distention [103,104]. Other symptoms, such as dyspnea and restricted mobility, are related to mass effect from massive hepatomegaly [105]. Complications of PCLD include hepatic cyst hemorrhage, rupture, or infection [105]. Rarely, patients can develop advanced liver disease with portal hypertension [105]. PCLD has been associated with other medical conditions including mitral valve prolapse, diverticulosis, inguinal hernias, and cerebral aneurysms [106].

Diagnosis

Most patients have preserved hepatic function; some have slightly elevated levels of serum alkaline phosphatase and total bilirubin and lower levels of total cholesterol and triglycerides [107]. Conventional radiological imaging, such as abdominal ultrasound and CT scans, is excellent in the detection of hepatic cysts (Fig. 76.5), and frequently, hepatic cysts are found incidentally on routine imaging [105]. Earlier studies using CT quantification have shown that hepatic parenchymal volume is preserved in PCLD, even in patients

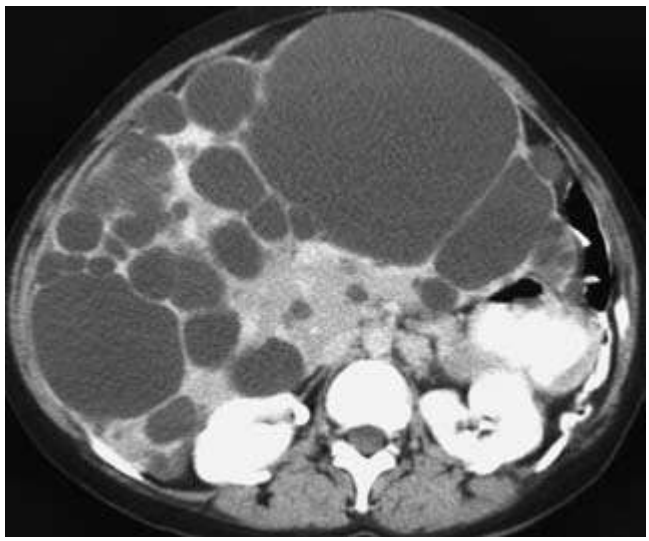

Figure 76.5 Polycystic liver disease. Small and large cysts fill the liver of a patient without polycystic kidneys.

with massive cysts [108]. MRCP can also be a useful modality for better visualizing intrahepatic ductal dilations and distinguishing PCLD from other lesions such as biliary hamartomas and Caroli disease [109].

Treatment

There is no effective medical therapy for PCLD [84]. Interestingly, an observation by Sherstha and colleagues that hepatic cystic disease worsened under the influence of pregnancy or exogenous female steroids but that renal cystic disease did not suggested that women with PCLD should avoid estrogen replacement [110].

A number of techniques are available for the treatment of symptomatic hepatic cysts. Most patients with PCLD have too many cysts or cysts of insufficient size to undergo ultrasound or CT-guided aspiration or sclerosis with ethanol [84]. Bistritz and colleagues reported the success rate of obliterating symptomatic cysts as 50%–67%, but others have reported success rates as high as 70%–90% [105,111,112]. Surgical fenestration of hepatic cysts, involving the deroofing of as many cysts as possible starting superficially and then proceeding more deeply, can be performed through open laparotomy or by laparoscopy. The optimal candidates for laparoscopic fenestration include those with a limited number (< 10) of large (> 10 cm) cysts, rather than those with diffuse involvement and smaller cysts [113,114]. Recent series, however, have reported that laparoscopic fenestration can be associated with perioperative morbidity as high as 50%, and 50% of the patients develop recurrence of cysts, requiring multiple procedures [115–117]. The most common complications following fenestration include hemorrhage, particularly from puncture of the right hepatic vein, and injury to the biliary system, which is distorted in PCLD [113]. Intraoperative ultrasound has been utilized to assess the location and position of the cysts and biliary and vascular structures [118]. Series of patients who underwent fenestration combined with partial hepatic resection demonstrated that nearly all patients experienced long-term symptom relief; however, this procedure was associated with significant perioperative morbidity, including ascites and pleural effusions [83,119].

Patients with severely symptomatic PCLD and significant comorbid conditions or diffuse liver involvement by small cysts may benefit from orthotopic liver transplantation [120]. Everson and colleagues reported that patients with PCLD who undergo liver transplant or combined liver–kidney transplant have relatively good outcomes. Based on data from the US Scientific Registry of Transplant Recipients from 1987 to 2003, survival rates for 1, 3, and 5 years for isolated hepatic transplantation were 78.1%, 71.7%, and 68.7%, respectively. Survival rates for 1, 3, and 5 years for combined liver–kidney transplantation were 79.5%, 75.5%, and 75.5%, respectively [84]. There has also been growing experience with living-donor liver transplantation for severely ill patients with PCLD [121].

F GALLBLADDER AND BILIARY TRACT

77 Tumors of the biliary tract

Christopher J. Smolock, Jeffrey A. Drebin

Cholangiocarcinoma, 2022
Benign bile duct tumors, 2033
Carcinoma of the gallbladder, 2033
Benign tumors of the gallbladder, 2038

Cholangiocarcinoma

Cholangiocarcinoma is cancer arising from the biliary epithelium. It may arise from intrahepatic or extrahepatic bile ducts. Sporadic cholangiocarcinoma is relatively uncommon, but cholangiocarcinoma has a high incidence in the presence of certain benign conditions. Information on cholangiocarcinoma is mostly derived from small case series gathered over many years and therefore tends to be descriptive. Consequently, claims for the best form of investigation or treatment must be interpreted cautiously.

Classifications

There are several suggested classifications. Clinically, intrahepatic and extrahepatic cholangiocarcinomas are distinct entities (Table 77.1) but they are linked by cell of origin and etiological factors. Intrahepatic cholangiocarcinoma arises from small ducts or ductules and presents as an intrahepatic mass. The differential diagnosis of such a mass includes other intrahepatic tumors such as hepatomas or metastatic lesions. Extrahepatic cholangiocarcinoma arises from large ducts and usually presents as biliary tract obstruction. The extrahepatic tumors may be further subdivided into upper duct tumors (also called perihilar, hilar, or Klatskin tumors) and lower duct tumors [1]. The division into upper and lower duct cholangiocarcinomas is based on staging and treatment considerations. Lower duct tumors are similar to other periampullary tumors, such as adenocarcinomas of the head of the pancreas, in terms of diagnosis and treatment.

Extrahepatic cholangiocarcinoma has been classified, for staging purposes, by a classification introduced and modified by Bismuth and colleagues [2] into four types based on the level of ductal involvement (Fig. 77.1). Cholangiocarcinomas are also classified by the TNM (tumor/node/metastases) system [3], which groups intrahepatic cholangiocarcinomas with other intrahepatic malignancies and considers extrahepatic cholangiocarcinomas as a separate group (Table 77.2). A potentially useful modification of the staging system for intrahepatic cholangiocarcinomas has been proposed [4].

Incidence, etiology, and pathogenesis

The true incidence of bile duct carcinoma is difficult to determine because reports of incidence and survival statistics from these cancers are often included with liver and gallbladder cancers or pancreatic carcinomas. Recent reports suggest that rates of intrahepatic cholangiocarcinoma may be increasing in Great Britain [5] and the United States [6]. The incidence peaks at about 65 years of age and the tumor is more common in men than women.

Sporadic cholangiocarcinoma is uncommon. The tumor usually arises in association with an underlying condition. Underlying conditions are of two types: those that have a high frequency in localized populations, such as parasitic infestation with *Opisthorchis viverrini* in northeast Thailand, and those that have a much lower frequency but a more global distribution, such as primary sclerosing cholangitis (PSC) (Table 77.3). In Thailand, liver fluke-associated cholangiocarcinoma is a leading cause of death [7,8], whereas in the United States, cholangiocarcinoma accounts for less than 1% of malignancies. The diverse predisposing causes of cholangiocarcinoma in many cases share a common pathophysiology – chronic inflammation of the biliary tract.

Opisthorchis species-related and *Chlonorchis* species-related cholangiocarcinoma are caused by eating raw fish [7,8] containing the larval stage of flukes. Eating raw fish is more common among men in the affected populations so liver fluke-associated cholangiocarcinoma is more common in the male population. Infestation is associated with increased nitrate levels in body fluids, which is reversible on treatment with praziquantel [9]. There is evidence from human [9] and animal [10] studies that *N*-nitroso compounds may be the

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Table 77.1 Classification of cholangiocarcinoma

Name	Synonyms
Intrahepatic	Small duct, intraparenchymal, peripheral[a]
Extrahepatic – upper duct	Hilar cholangicarcinoma, perihilar cholangiocarcinoma, Klatskin tumor, proximal[a] bile duct cancer
Extrahepatic – lower duct	Distal[a] bile duct cancer

Note: The classification is the authors'. Intrahepatic and extrahepatic are the main divisions in the classification per the TNM (tumor/node/metastasis) system. Extrahepatic tumors are divided into two rather than three anatomic zones following Nakeeb et al. [1].
a These terms are undesirable, particularly "proximal" and "distal." Distal means away from the center of the body and proximal means near. Note that in pancreatic terminology, distal refers to the part of the duct farthest away from the termination in the duodenum, whereas in biliary terminology, the opposite is true. The terms are properly applied to limbs, and their use in biliary–pancreatic terminology should be abandoned.

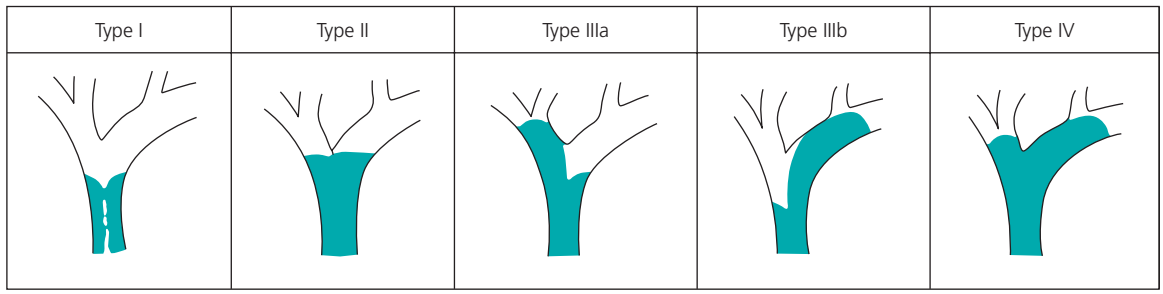

Figure 77.1 Bismuth–Corlette classification of hilar cholangiocarcinomas. Shading indicates level of ductal involvement.

Table 77.2 Tumor/node/metastasis (TNM) classification for cholangiocarcinoma and gallbladder carcinoma

A. Definition of TNM for intrahepatic cholangiocarcinoma

Primary tumor (T)			
T1	Solitary tumor 2 cm or less in greatest dimension without vascular invasion		
T2	Solitary tumor 2 cm or less in greatest dimension with vascular invasion; or multiple tumors limited to one lobe, none more than 2 cm in greatest dimension without vascular invasion; or a solitary tumor more than 2 cm in greatest dimension without vascular invasion		
T3	Solitary tumor more than 2 cm in greatest dimension with vascular invasion; or multiple tumors limited to one lobe, none more than 2 cm in greatest dimension, with vascular invasion; or multiple tumors limited to one lobe, any more than 2 cm in greatest dimension, with or without vascular invasion		
T4	Multiple tumors in more than one lobe, or tumor(s) involving a major branch of the portal or hepatic vein(s)		
Regional lymph nodes (N)			
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
Distant metastasis (M)[a]			
M0	No distant metastasis		
M1	Distant metastasis		
Stage grouping			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1	N1	M0
	T2	N1	M0
	T3	N0	M0
	T3	N1	M0
Stage IVA	T4	Any N	M0
Stage IVB	Any	T	M1

Table 77.2 (*cont'd*)

B. Definition of TNM for extrahepatic cholangiocarcinoma

Primary tumor (TN)			
Tis	Carcinoma in situ		
T1	Tumor invades the mucosa or muscle layer		
T1a	Tumor invades the mucosa		
T1b	Tumor invades the muscle layer		
T2	Tumor invades the perimuscular connective tissue		
T3	Tumor invades adjacent structures: liver, pancreas, duodenum, gallbladder, colon, stomach		
Regional lymph nodes (N)			
N1	Metastasis in the cystic duct, pericholedochal or hilar lymph nodes (i.e., in the hepatoduodenal ligament)		
N2	Metastasis in the peripancreatic (head only), periduodenal, periportal, celiac, superior mesenteric, or posterior pancreaticoduodenal lymph nodes

a This part of the classification is the same for the other two tumors listed in this table.

Table 77.3 Predisposing causes of cholangiocarcinoma

Predisposing causes with a high incidence in localized areas of the world
Infestation with *Opisthorchis viverrin* in northeast Thailand
Infestation with *Chlonorchis sinensis* in China
Intrahepatic stones
Predisposing causes with a low but more global incidence
Primary sclerosing cholangitis
Choledochal cysts
Thorotrast[a]
Ulcerative colitis

a A number of other agents have been claimed to be associated with cholangiocarcinoma, but the evidence is weak.

carcinogens involved. Liver fluke infestation is also associated with development of intrahepatic stones, which themselves are associated with an increased risk for cholangiocarcinoma [11]. Cholangiocarcinoma may develop even after stone removal, if bile duct fibrosis induced by the stone disease leads to stasis and infection [11].

Cholangiocarcinoma occurs in about 10% of patients with PSC [12] with associated biliary dysplasia a suggested precursor [13]. Also, cholangiocarcinoma occurs 10 times more frequently in patients with chronic ulcerative colitis than in the general population [14]. PSC and ulcerative colitis often coexist; in such patients, as might be expected, the incidence of cholangiocarcinoma is even higher [15]. Up to 80% of patients with PSC have inflammatory bowel disease [16]. Cholangiocarcinoma also occurs in about 10% of patients with untreated choledochal cyst disease [16,17]. Malignancy of the bile ducts and gallbladder in patients with choledochal cysts may be related to the presence of an anomalously high pancreatic duct–bile duct junction (see Carcinoma of the gallbladder). Thorotrast-related cholangiocarcinoma, resulting from exposure to high levels of α-particle radiation, is largely a disease of the past [18]. The agent has not been used since 1940.

Molecular genetics

Cancer results from the accumulation of multiple genetic abnormalities in a single cell [19]. This process of multistep carcinogenesis involves genes that control cell cycle progression and apoptotic cell death. Many of the specific genetic events responsible for neoplastic transformation in colon and pancreatic malignancies have been identified [19,20]. Relatively less is known about the events responsible for neoplastic transformation in the biliary tract.

The *erbB2* oncogene (also called the *HER2* oncogene or the *neu* oncogene) encodes a cell surface protein that interacts with several distinct cellular receptors, including the receptor for epidermal growth factor [21,22]. Overexpression of *erbB2* has been identified in tumors of the breast, ovary, stomach, pancreas, lung, and prostate. Several studies have examined expression of *erbB2* in cholangiocarcinomas [23–25]. Although an early report suggested that expression of *erbB2* was present in less than 10% of cholangiocarcinomas [23], studies from several other laboratories have identified *erbB2* expression in 67%–73% of cholangiocarcinomas [24,25]. Overexpression of the epidermal growth factor receptor as well as of cyclooxygenase-2 has also been identified in some cholangiocarcinomas [26,27]. Immunoreactivity for cyclooxygenase-2 is also increased in the surrounding hepatocytes of livers in patients with PSC and hepatolithiasis compared with those of normal adult livers [27]. There are reports that combined targeting of *erbB2* and cyclooxygenase-2 in cholangiocarcinoma cells results in a synergistic effect on suppression of cell growth as well as induction of caspase-3 activation [27,28].

The *ras* genes constitute a distinct family of oncogenes that transduce proliferative signals from cellular receptors to the cell interior [29]. One member of this family, termed K-*ras*, has been shown to be mutated in a significant fraction of colon, pancreas, and lung carcinomas. Several studies have demonstrated K-*ras* expression in cholangiocarcinomas [26,30–32]. Point mutations involving this gene may occur in more than half of all cholangiocarcinomas [31,32].

Several other genes, including the *myc* gene [33] and the *p53* gene [34], have been studied in cholangiocarcinomas. These genes encode proteins that reside in the cell nucleus and control transcription of growth regulatory genes. Expression of the *myc* gene appears to be an almost universal feature of cholangiocarcinomas [31], whereas *p53* expression, suggesting the presence of a mutant *p53* gene, has been identified in 50%–80% of cholangiocarcinomas [34–37].

The studies cited here have just begun to characterize the genetic events responsible for the development of cholangiocarcinoma. It is interesting that the genes that have been linked to cholangiocarcinoma so far, particularly *erbB2*, K-*ras* and *p53*, also appear to be involved in a high percentage of pancreatic carcinomas [28]. It is possible that this reflects exposure to common carcinogens in the biliary and pancreatic epithelium.

Pathology

Malignant tumors of the bile ducts are almost exclusively epithelial tumors (carcinomas). Tompkins and associates [38] reported that the distribution of extrahepatic bile duct cancers is 49% in the upper third, 25% in the middle third, and 19% in the lower third of the duct; 7% of these cancers were diffuse. The Johns Hopkins group reported a distribution of 6% intrahepatic; 67% extrahepatic, upper duct ("perihilar"); and 27% extrahepatic, lower duct ("distal") [1]. It must be stressed that all such figures arising from surgical case series are heavily influenced by referral patterns and may not be representative of the disease generally.

Grossly, extrahepatic bile duct cancers can be divided into three types: polypoid or nodular masses, sclerosing, and diffusely infiltrating. Some cancers may present as only a thickening of the bile duct wall, which appears to be involved in dense fibrous scar. Polypoid or papillary cancers have the best prognosis.

Histological variants of adenocarcinomas of the bile duct include well-differentiated, pleomorphic, giant cell, adenosquamous, oat cell, and colloid carcinoma. Bile duct cancers have a tendency to spread along the bile duct. The longitudinal extent of cancers along the bile duct is often difficult to determine by gross examination. Shimada and colleagues [39] performed a histological examination on 29 patients after resection and found that the mean distance of microscopic invasion beyond the gross margin was 16.8 mm toward the liver and 6.5 mm toward the duodenum. A retrospective review of 253 cases by Ebata and colleagues [40] recommended a 10-mm ductal resection margin in both directions for eradication of invasive carcinoma cells. However, a 20-mm margin was recommended to eliminate noninvasive carcinoma cells [40].

Histological diagnosis of malignant bile duct cancers may be difficult at times. Well-differentiated cancers with little invasion are difficult to differentiate from the bile duct involved in scar formation or PSC. Cancers arising in the upper duct tend to be better differentiated with more sclerotic stroma that contains chronic inflammatory cells [41]. Perineural invasion (i.e., malignant cells within nerve sheaths), a prominent feature of bile duct cancers, is not present in PSC and is the single most important diagnostic criterion of malignancy. Other problems in differential diagnosis occur with cancers of the lower bile duct that involve the ampulla, duodenum, and pancreas. All of these sites may give rise to malignant tumors with similar characteristics so it may be difficult to determine the site of origin conclusively. An important point is that bile duct cancers, compared to pancreatic adenocarcinomas, are less likely to metastasize early. As a result, surgical resection of bile duct tumors is associated with a somewhat more favorable outcome.

Hilar tumors often arise in one of the main bile ducts and produce asymptomatic obstruction of that duct before progressing to obstruct the other main duct, which leads to jaundice. Unilateral obstruction results in atrophy of the affected side of the liver and hypertrophy of the other side. This phenomenon will also occur if there is unilateral portal vein occlusion. The clinical importance of atrophy has been emphasized by Blumgart and Stain [42]. Atrophy may result in axial rotation of structures in the hepatoduodenal ligament. For instance, with atrophy of the left hemiliver and hypertrophy of the right, the structures rotate in a clockwise direction when viewed from below, which hides the hepatic artery, rotates the bile duct to the left, and exposes the portal vein on the right side of the hepatoduodenal ligament in the usual position of the bile duct. The effect of atrophy must be taken into account when adding liver resection to extrahepatic duct resections for cholangiocarcinoma [43].

Cholangiocarcinomas must also be differentiated from benign inflammatory tumors [44], also called *hepatic inflammatory pseudotumors* and *benign fibrosing disease* [45]. These inflammatory masses mimic extrahepatic and intrahepatic cholangiocarcinomas but consist of chronic inflammatory cells and fibrosis. Benign inflammatory tumors appear to occur most frequently in extrahepatic upper ducts but also occur intrahepatically [46], and less commonly in lower ducts. In a recent series of patients undergoing resection for hilar strictures, 15% were benign tumors by histopathology [45]. Failure to appreciate this diagnosis may lead to inappropriate therapies, such as long-term stenting or hepatic resection.

Bile duct cancers usually spread by direct extension to involve adjacent organs and tissues. Upper duct cancers may directly invade the liver. Cancers in the common bile duct or cystic duct may directly invade the gallbladder. Regional lymph node metastases are common, liver metastases distant from the primary occur frequently, but distant metastases are unusual.

It may be difficult to distinguish between a liver metastasis of colonic or pulmonary origin and an intrahepatic cholangiocarcinoma. Grossly, intrahepatic cholangiocarcinomas may be well or poorly demarcated, single or multiple. However, mucin production, fibrosis between acini of tumor tissue, and a more overtly glandular pattern are the main characteristics that differentiate cholangiocarcinoma from hepatoma. Immunohistochemical staining for specific cytokeratins may also be helpful. Also unlike hepatomas, some cholangiocarcinomas stain positively for cancer antigen 19-9 (CA 19-9) or carcinoembryonic antigen (CEA). CA 19-9 may be an especially helpful test in interpreting biliary brush cytology in PSC [47].

Clinical presentation

Extrahepatic upper duct and extrahepatic lower duct tumors cannot usually be separated on the basis of presenting symptoms. Most patients present with painless jaundice and its clinical constellation of dark urine, light stool, and pruritus. Nonspecific gastrointestinal symptoms such as anorexia and nausea, as well as mild weight loss and fatigue, are not unusual. Mild abdominal pain without jaundice may be the sole presenting symptom in upper duct cholangiocarcinoma; many patients with upper duct cholangiocarcinoma have had recent cholecystectomy, presumably because it was believed that gallstones were the source of these symptoms. Cholangitis is uncommon unless the biliary tree is instrumented. On examination, patients are usually jaundiced and, in the case of tumors arising below the insertion of the cystic duct, the gallbladder may be palpable.

Laboratory tests suggest extrahepatic biliary obstruction. Characteristically, the bilirubin rises over several weeks to a level of 20 mg/dL or greater if the jaundice is unrelieved and

the direct reacting fraction accounts for more than 50% of the total bilirubin. Marked elevation of serum alkaline phosphatase and γ-glutamyltransferase levels and mild elevation of aminotransferase levels are also usual.

Cholangiocarcinoma in patients with PSC is often associated with deterioration in clinical status and liver function tests. However, these signs are unreliable and late markers of cholangiocarcinoma. Cholangiocarcinoma may be present without any change in traditional liver function tests [48]. Furthermore, screening of patients at risk, such as those with PSC, using computed tomography (CT) scanning, ultrasound, and even endoscopic retrograde cholangiopancreatography (ERCP) is typically ineffective [49]. However, with the continuing advances in CT technology, there is a recent report that suggests multiphasic helical CT is improving the ability to distinguish malignant from benign common bile duct strictures [50].

CA 19-9 is emerging as a useful diagnostic marker. The Mayo group has reported that a cutoff of 100 IU was 89% sensitive and 86% specific for cholangiocarcinoma in PSC [51]. The King's College group recommend the use of an index that incorporates both CEA and CA 19-9 values and that has attained similar sensitivities for cholangiocarcinoma in PSC [50]. More recently, Levy and colleagues reported that only advanced cases of cholangiocarcinomas were detected by serum CA 19-9 in PSC patients [52]. Bile CEA levels are reportedly elevated in cholangiocarcinoma, but not in benign diseases, other than intrahepatic stones [53].

Intrahepatic cholangiocarcinomas characteristically present with nonspecific right upper quadrant pain. Other symptoms include weight loss and nausea. An intrahepatic cholangiocarcinoma may occasionally be critically situated in the central area of the liver and, as a result, may cause jaundice owing to obstruction of the main ducts by external pressure.

Diagnosis and staging

Extrahepatic, lower duct tumors

The most common cause of painless jaundice or jaundice with mild pain in the cancer age group is pancreatic carcinoma. Consequently, both lower and upper duct cholangiocarcinomas are often initially suspected to be pancreatic carcinoma. The question of which is the best initial investigation of painless jaundice is controversial. Ultrasound, ERCP, and CT scan have all been advocated. Ultrasound has the advantages of low cost and lack of invasiveness and it is the best test for detection of choledocholithiasis and cholecystolithiasis. In young patients with any pain or in older patients with pain that has characteristics of biliary colic, ultrasound is probably still the best first examination. Conversely, in the typical patient with painless jaundice, CT scan may be the best initial investigation. This is because in most instances, when a periampullary mass is detected without evidence of metastatic spread, CT scan is the only investigation needed before proceeding to surgery or staging laparoscopy with ultrasound. When no mass is present on CT scan, a diagnostic ERCP is performed to determine the site and type of biliary obstruction. Magnetic resonance cholangiopancreatography (MRCP) is another imaging modality in the diagnostic repertoire. A recent report lists comparable sensitivities, specificities, and accuracies between ERCP and MRCP in the differentiation of malignant and benign causes of biliary stricture [54].

Staging laparoscopy with ultrasound

Preoperative staging of the tumor is also of great importance. Ideally, staging locates and sizes all tumors in the body. The immediate goal of staging for the surgeon is to determine whether the tumor has spread beyond the limits of operative resection; this may be because of distant metastases or the local extent of the tumor. For staging purposes in lower duct cholangiocarcinoma, *local extent* refers to the macroscopic limits of the tumor in relation to the portal vein and superior mesenteric artery. The value of staging laparoscopy with ultrasound in hepatobiliary–pancreatic malignancies has become evident. The importance of laparoscopy in staging hepatobiliary–pancreatic malignancy was demonstrated by Warshaw's group [55], by John and associates [56], and by Weber and colleagues [57]. Additional staging information, proving that resection for cure was not possible, was obtained by Warshaw's technique in 22 of 50 patients with hepatobiliary–pancreatic malignancies who had been completely evaluated by conventional studies [58]. Of the remaining 28 patients, 26 had disease that was resectable for cure at the time of surgery. Staging laparoscopy permits evaluation of the peritoneal surfaces without laparotomy, and subsequent biopsy if metastatic implants are found. Laparoscopic ultrasound can detect vascular and distant nodal invasion, criteria which generally make the tumor inoperable [58] (Fig. 77.2). Others have found endoscopic ultrasonography [59] useful in determining the extent of tumor involvement and intraductal ultrasound during ERCP [60] valuable in distinguishing malignant from benign strictures. Fine-needle aspiration may also be performed during endoscopic ultrasonography as a diagnostic test when other tests are inconclusive [61]. The role of positron emission tomographic scanning in staging cholangiocarcinoma is still under investigation and its reliability is questionable [62–64].

Extrahepatic upper duct tumors

Altemeier and colleagues [65] and Klatskin [66] wrote classic papers on perihilar cholangiocarcinoma in an era when the biliary tree was inaccessible to preoperative imaging. Consequently, both stressed the difficulty of diagnosing this tumor. Today, there are many imaging techniques that can display the tumor or its effects on adjacent vessels. Examples include transabdominal ultrasound, CT scan, CT with angioportography, magnetic resonance imaging (MRI), percutaneous transhepatic cholangiography (PTC), ERCP, positron emission

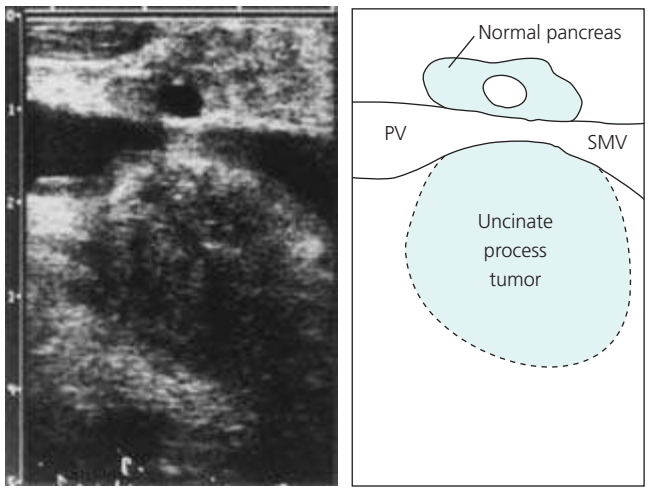

Figure 77.2 High-resolution laparoscopic ultrasound image demonstrating a 2.5-cm to 3-cm inhomogeneous hypoechoic mass in the uncinate process consistent with a pancreatic cancer. The tumor abuts the superior mesenteric vein (SMV) and portal vein (PV) posteriorly behind the neck of the pancreas, which itself appears to be normal. No evidence of actual vascular invasion is seen. At laparotomy, this adenocarcinoma was resected. From Callery et al. [58].

tomography, angiography, endoscopy with ultrasound, and laparoscopy with laparoscopic ultrasound. Diagnosis is usually based on history and imaging characteristics. Any patient who has a perihilar stricture, without evidence of ductal disease elsewhere in the biliary tree suggestive of PSC, and who has not had previous biliary surgery that might have resulted in stricture, is considered to have upper duct cholangiocarcinoma. Inflammatory pseudotumor is not ruled out by these considerations and a confident diagnosis depends on pathological examination of tissue obtained at surgery or cytological brushings obtained by ERCP or PTC. In one report covering 74 patients with biliary and pancreatic strictures, the sensitivity and specificity of brush cytology were 56% and 100% and the positive predictive value was 100% [67]. Therefore, brush cytology is diagnostic and useful when positive but of little value when negative. Perihilar tumors are less accessible than lower duct or pancreatic neoplasms so it is unlikely that a sensitivity of 50% is being achieved in these tumors. Mucobilia on ERCP is an uncommon finding but is highly suggestive of a papillary cholangiocarcinoma, which may be intrahepatic or extrahepatic [68]. Fine-needle aspiration is also useful if the mass can be seen on ultrasound examination or on CT scan. Another technique that we have used with success is to direct the biopsy needle at a stent placed through the site of duct narrowing.

Staging is also of great importance in upper duct tumors. For staging purposes, *local extent* means the macroscopic limits of the tumor in relation to the biliary tree, especially the upper level of the stricture. It also refers to whether and to what degree invasion of adjacent vessels has occurred. The upper level of the stricture provides the information for the Bismuth stage. Blumgart and Stain [42] have described the indicators of unresectable bile duct cancers: bilateral intrahepatic bile duct spread, involvement of the main trunk of the portal vein, involvement of both branches of the portal vein or bilateral involvement of the hepatic artery and portal vein, or a combination of vascular involvement on one side of the liver with extensive bile duct involvement on the other. With vascular replacement, it may be possible to resect some cholangiocarcinomas that were previously considered unresectable.

The local extent of the disease along the biliary tree has usually been determined by direct cholangiography – either ERCP or PTC (Fig. 77.3). It is the upper margin of disease that is of most interest in these tumors so PTC has been generally favored over ERCP. However, ERCP has progressed to the point that a complete picture of the biliary tree can often be obtained even when the obstruction is nearly complete. MRCP is a newer, less invasive method of evaluation of the biliary extent of perihilar cholangiocarcinoma. Although promising, it has not been determined whether it will routinely provide the detail regarding disease extent obtained by direct cholangiography (Fig. 77.4).

Vascular invasion has been assessed by angiography, color-flow Doppler ultrasound, and MRI. Angiography is the gold standard for assessing vascular involvement but is also the most invasive technique. Our preference is for color-flow Doppler ultrasound because the tumor and its extravascular extent, as well as its effect on vessels, are seen in real time and multiple detailed views of the tumor and its relationships may be obtained. Vascular deviation without narrowing is not evidence of unresectability. Color-flow Doppler ultrasound is dependent on the skill of the ultrasonographer and on the available equipment. It has been claimed that Doppler ultrasound is effective in evaluating portal vein involvement (Fig. 77.5) but less so in examining the hepatic artery [69].

Additional information on local extent of disease in or around the biliary tree can be obtained by laparoscopy with laparoscopic ultrasound. However, cytology from peritoneal washings obtained during laparoscopy has not been shown to be predictive of occult peritoneal disease in patients with hilar cholangiocarcinoma [70,71].

Laparoscopic ultrasound permits close contact between the ultrasound probe and the tumor [57,58]. The best position for the probe is often the anterior surface of the liver, looking through a 2-cm to 4-cm thickness of liver into the porta hepatis. Using this method, we have been able to identify tumor extending along the intrahepatic ducts above the level that was evident by the upper level of the biliary stricture identified on direct cholangiography. Vascular encasement and lymph node involvement may be detected (Fig. 77.6). Bilateral biliary involvement to the point that all four sectional ducts [57] are involved precludes curative resection.

Several factors preclude dogmatic statements regarding selection and order of investigation in extrahepatic upper

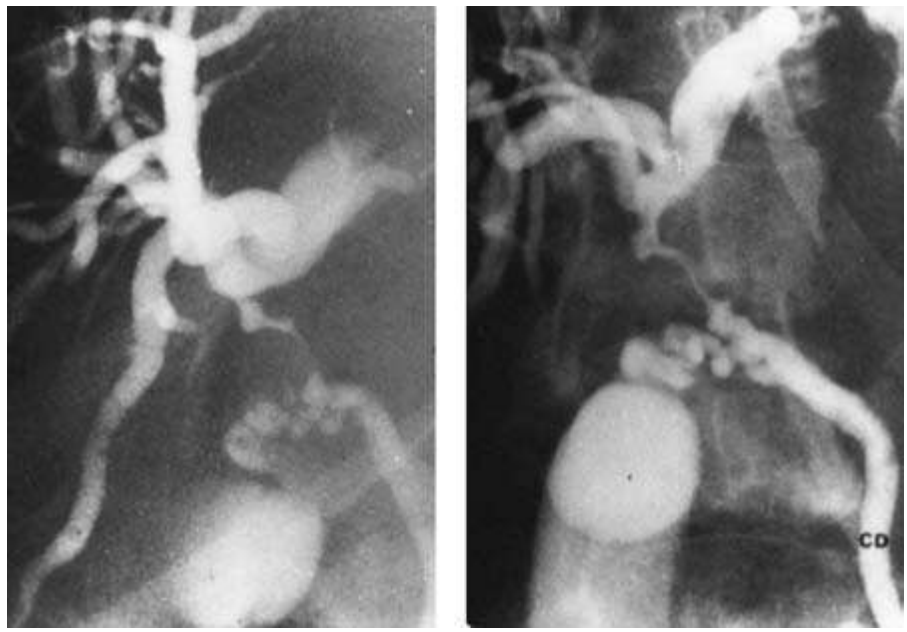

Figure 77.3 Cholangiogram shows a Klatskin tumor. The intrahepatic bile ducts are dilated and the size of the common bile duct (CD) is normal.

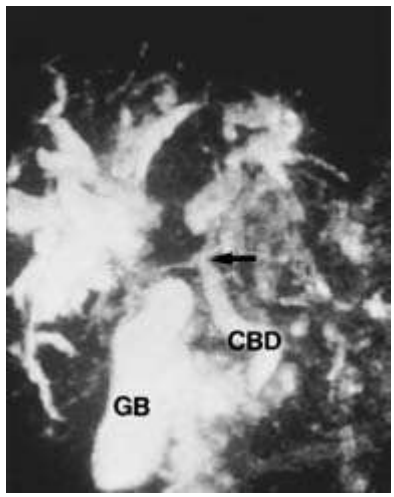

Figure 77.4 Magnetic resonance cholangiogram showing extrahepatic and intrahepatic biliary tract. Narrowing of bile duct produced by a hilar tumor is shown (arrow). CBD, common bile duct; GB, gallbladder. Courtesy of Dr Joseph T. Ferrucci, Department of Radiology, Boston University School of Medicine.

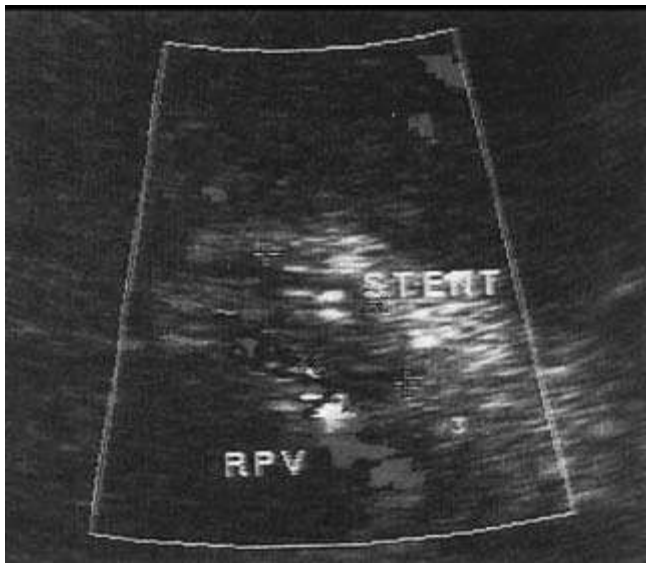
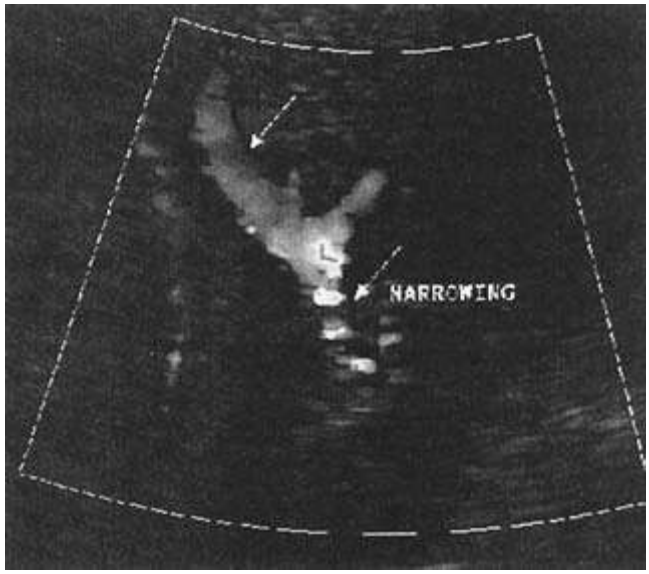
duct cholangiocarcinoma. There are no good comparative studies examining this issue; there are so many potentially valuable investigations, and further developments in imaging are occurring so rapidly, that it is unlikely that good data will be realized. Equipment and expertise vary from center to center; patients are often referred with several studies already completed; at presentation upper duct cholangiocarcinoma is often not distinguishable from lower duct cholangiocarcinoma or other malignancies causing complete obstruction of the lower duct. Consequently, initial investigation cannot be directed specifically to the perihilar region. The important considerations are that a combination of investigations must be used to achieve the goals of staging – evaluating the local extent of disease and whether it is metastatic – and that clinicians have a variety of algorithms to choose from to achieve staging. Our approach is given below.

Summary of our present algorithm for staging in extrahepatic cholangiocarcinoma

In the typical case of painless jaundice, a CT scan is obtained first. If there is a periampullary mass, the next step is staging laparoscopy with ultrasound unless therapeutic decompression of the biliary tree by ERCP or percutaneous stenting is indicated (see later). If no mass is seen, ERCP with brushings is performed when ductal dilation extends into the lower bile duct or when there is no ductal dilation. Either ERCP or PTC with brushings is performed when only the intrahepatic ducts are dilated, suggesting an upper ductal lesion. In the case of lower duct lesions, detection of a single stricture by ERCP is taken as evidence of a periampullary cancer, possibly cholangiocarcinoma, and the next investigation is staging laparoscopy with ultrasound. In the case of upper duct strictures compatible with hilar cholangiocarcinoma, the next step is to evaluate vascular involvement by color-flow Doppler ultrasound or MRI; fine-needle aspiration may be performed at the time of ultrasound. Staging laparoscopy with ultrasound then follows for those patients whose disease is still potentially resectable. The utility of staging laparoscopy in the operative assessment of extrahepatic cholangiocarcinomas has been validated in a large series from the Memorial Sloan Kettering Cancer Center [71].





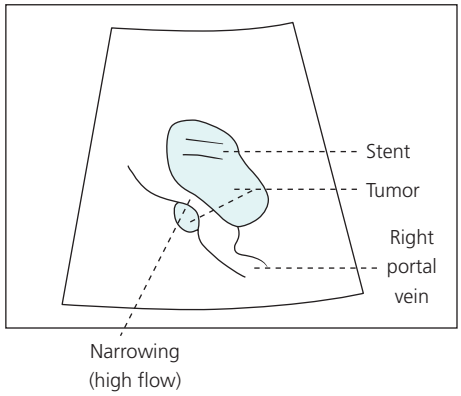


Figure 77.5 Flow Doppler ultrasonograms showing encasement of right portal vein (RPV) by tumor. A stent that had been placed through the tumor can also be seen. Note that in the area of vein encasement higher-velocity flows occur in the compressed area, compared with low-velocity flows in the non-compressed areas.

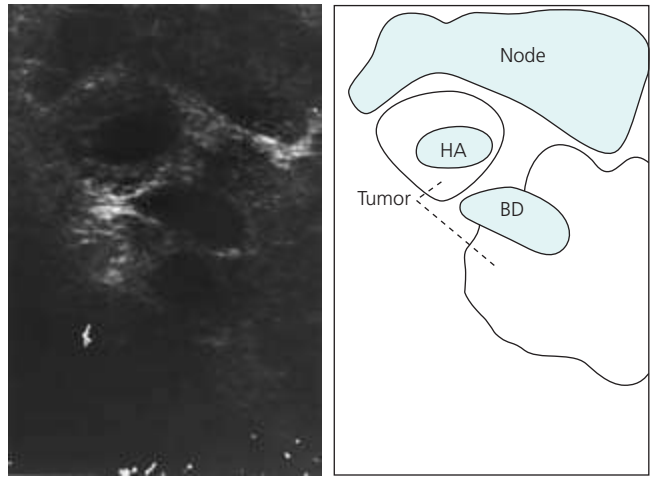

Figure 77.6 Laparoscopic ultrasonogram showing encasement of the hepatic artery (HA) and bile duct (BD). An enlarged lymph node that contains tumor is also seen.

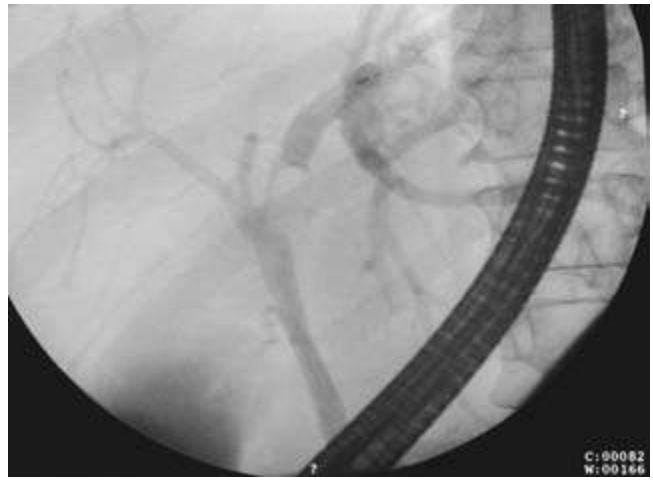

Figure 77.7 Endoscopic retrograde cholangiogram showing a bullet-shaped filling defect in the left hepatic duct. At surgery, this was found to be a tumor embolus from an intrahepatic cholangiocarcinoma. This patient presented with pancreatitis, presumably caused by such an embolus.

Intrahepatic tumors

Intrahepatic cholangiocarcinoma is in the differential diagnosis of the intrahepatic mass. Except for events such as mucobilia or tumor embolizing into the extrahepatic bile ducts, an event that may cause pain, jaundice, or even pancreatitis [72] (Fig. 77.7), intrahepatic cholangiocarcinoma does not produce highly characteristic findings. On axial imaging, the tumor may be single or multiple. Neither CT nor MRI appears superior in characterizing these rare lesions but there may be a diagnostic benefit from using both modalities, with or without ultrasound, because small nodules missed with one test

were often seen with another [73,74]. Fluorodeoxyglucose positron emission tomography scan is not sensitive in the detection of intrahepatic cholangiocarcinoma [74]. On CT scan, the lesion is usually irregular or unencapsulated and of low attenuation with only mild enhancement seen with contrast [73]. The tumors are low attenuation on CT angioportography [75]. On T1-weighted MRI the intrahepatic cholangiocarcinoma is usually of low intensity but on T2-weighted images they are of high intensity [74,76]. Local vascular invasion is often seen by CT, MRI [76] or angiography [77], and ductal dilation is often present peripheral to the tumor. Centripetal filling after gadolinium administration has been noted [76]. Liver biopsy is useful when focal nodular hyperplasia is in the differential diagnosis on the basis of imaging studies or if the tumor is inoperable because of metastatic spread or extent in the liver. Otherwise, in potentially resectable cases, the next investigation after axial imaging by either CT or MRI is staging laparoscopy with ultrasound, followed by surgical exploration and resection as for other hepatic masses [62,63].

Preoperative decompression of the biliary tract in jaundiced patients

Three randomized studies have shown that jaundiced patients do not benefit from preoperative decompression of the biliary tree [78–80]. However, these studies were performed in an era in which the most common surgical procedure performed after preoperative decompression was palliative surgical bypass of the biliary tree – a relatively short procedure associated with limited morbidity. No study has examined the potential benefit of preoperative decompression when the following operative procedure is either pancreaticoduodenectomy or liver resection. One study found that operative morbidity was greater in patients with hilar cholangiocarcinoma who had an aspartate aminotransferase level of more than 90 IU than in patients with lower levels [81]. Until definitive studies are available, preoperative decompression is still an option to be considered. In our opinion, it should be performed if hemihepatectomy for cholangiocarcinoma is planned in a jaundiced patient and may be performed if a pancreaticoduodenectomy is to be performed in a patient with longstanding or severe jaundice. Other preoperative preparations include correction of vitamin K deficiency and bowel preparation.

Treatment

Lower duct tumors

Lower duct cholangiocarcinoma is one of the four types of periampullary tumors treated by pancreaticoduodenectomy, the others being pancreatic, ampullary, and duodenal cancers. The extent of the procedure is the same as that used for pancreatic carcinoma and will not be described in detail in this chapter. The procedure has reached a "near-zero" mortality rate in expert hands at tertiary-care centers specializing in hepatobiliary–pancreatic surgery [82,83]. Often, the tissue of origin of the tumor, whether pancreatic, ampullary, or bile duct in origin, is uncertain until after the specimen has been examined pathologically and even then, doubt can remain. The main complication of this procedure is a fistula from the pancreatic–jejunal anastomosis, which occurs in 5%–10% of patients [82]. Biliary fistulae occur in about 2% of patients. Today, patients rarely die from these complications because of improvements in diagnostic and interventional radiology, intensive care, and treatment of infection [82]. Resection of part of the stomach is no longer required for lower duct cholangiocarcinoma, although there is little or no difference in short-term outcome or quality of life [84] between the pylorus-preserving and standard types of pancreaticoduodenectomy [85]. Many patients require pancreatic enzyme replacement after this procedure, but few become diabetic.

Palliative treatment of unresectable lower duct tumors is by stenting and a combination of chemotherapy and radiation. The only randomized trial of surgical bypass versus endoscopic intubation favored the latter [86]. When unresectability is determined at open exploration, a double bypass is performed to decompress the biliary tree and bypass the duodenum, which may become obstructed. Palliative resection of periampullary tumors may be unavoidable because the full extent of the tumor may not be detectable until the procedure is nearing completion. However, compared with upper duct tumors, this is an uncommon problem. Palliative resections for visceral cancers is an accepted procedure, for example, for colonic and gastric cancers, but has been avoided for periampullary tumors because of the risk of the procedure. However, an argument has been made in favor of palliative resection because the procedure can be performed with relatively little risk [87].

Upper duct tumors

The goals of surgical resection are to remove the tumor with negative resection margins. This may be accomplished with or without an associated hepatic resection depending on the extent of the tumor. In some cases, it will be known preoperatively or by intraoperative staging with ultrasound that a liver resection will be required because the disease will have spread into the liver on one side. At other times, the need for a liver resection becomes apparent only intraoperatively, after exploration, or after the extrahepatic bile ducts are resected and microscopic disease is discovered on one side at the highest possible point of extrahepatic resection. Unfortunately, it is also at this point in the operation when discovery of bilateral microscopic involvement makes it clear that a curative resection has not been accomplished and is not possible. The same considerations apply to the discovery of microscopic involvement of vessels. Operative management is further complicated by the fact that frozen-section diagnosis of the presence or absence of tumor at the resection margin may be difficult in these fibrotic cancers.

A description of the operative technique is beyond the purposes of this text; however, the principal steps in the operation are as follows. The bile duct is divided at the level of the pancreas and a negative margin is confirmed by frozen section. The bile duct and gallbladder are dissected off and away from the portal vein and hepatic arteries, leaving the latter structures bare; that is, all nodes and soft tissue are taken with the specimen. The bile ducts and surrounding tissue are freed to above the bifurcation where the tumor is situated until macroscopically normal ductal tissue is encountered in the right and left bile ducts. These ducts are divided and frozen sections are obtained. Coring out of liver tissue in the porta may permit excision to the level of the first branches of the right and left bile ducts. If the tumor has grown too far up one side to perform an extrahepatic resection, the bile duct is divided on the side to be retained, and the liver, bile ducts, and vascular structures are removed on the other side. Reconstruction is by a Roux-en-Y limb approximately 60 cm in length to avoid reflux of intestinal contents into the biliary tree. Cholangiocarcinoma commonly invades caudate bile ducts, and caudate resection is routinely performed by some surgeons for upper duct cholangiocarcinoma. This area must be carefully evaluated at surgery and caudate resection must be performed if there is any question of caudate invasion.

The important trends in surgery for upper duct cholangiocarcinoma are that a higher percentage of upper duct tumors are being resected [88], largely owing to the more common use of liver resection [89], vascular resection and reconstruction are becoming more common, and surgical morbidity and mortality are decreasing. Mortality has remained at 5% or less for more than a decade [90–93]. Liver resection combined with hilar duct resection is performed for more advanced disease so comparisons between local resection and local resection plus liver resection for outcomes, such as percentage of procedures obtaining negative margins and survival, are meaningless. The results of surgical resection depend highly on whether negative resection margins are achieved [84,93–98]. There are few 5-year survivors when resection margins are positive [84,93,98,99]. Other negative prognostic variables are tumor stage [97], nodal disease [73,97], tumor grade [54,99], bilirubin concentration [54,99], and absence of mucobilia [73]. When negative margins are obtained, the 5-year survival rate varies from 11% to 43% in recent series [1,84,93,97–99]. Again, it must be stressed that these results are in small numbers of highly selected patients. The median survival of patients with tumor-free margin is 3–3.4 years, compared with a median survival of 1–1.2 years for patients with disease at the resection margins.

Palliation of unresectable upper duct tumors may be by percutaneous [100] or endoscopic intubation or by surgical bypass. There have been no randomized trials. Metallic stents have extended the functional life of stents. Plastic stents typically clog at 3–4 months, whereas metal stents last 8–10 months or even longer [101–104]. Surgical treatment is by biliary enteric bypass, usually employing the duct to segment III, the so-called Bismuth–Corlette procedure [105]. Bypass to right-sided ducts is more difficult and less successful. Surgical implantation of large-bore tubes through the tumor has been used in the past but is now rarely employed [106,107]. Both surgical bypass and internal stenting have their proponents [91,99,108]. Stenting has the advantage of initial low morbidity and the disadvantages of occasional failure to clear jaundice, bouts of cholangitis, and the need for repeated procedures to deal with stent obstruction. With improvement in techniques of stenting, one may expect resolution of jaundice in 80% of patients, with a 10% major morbidity rate, a 30-day mortality rate of about 5%, and a median survival of 8 months [109]. Surgical bypass requires a major open surgical procedure and has corresponding early morbidity [91] but the complete clearance of jaundice is usual, and cholangitis is uncommon. There are many nonrandomized comparisons of these techniques, but all are contaminated by patient selection and consequently are of little value in determining which technique is superior. For instance, greater success in clearing jaundice by surgical bypass may partly reflect an earlier stage of disease in these patients. Patient selection is probably appropriate in this disease. Younger, healthier patients, in whom bypass to segment III will decompress 40%–50% of the liver, probably should undergo surgical decompression; whereas older patients, especially those with intercurrent disease or in whom decompression will provide biliary drainage from less than 40% of the liver mass, should be treated by nonsurgical means [110].

Radiation therapy has been used alone or in combination with other techniques. Its value is unclear because most series are small and no randomized comparisons exist. External-beam irradiation was successful in clearing jaundice in 10 of 11 patients in a report where no other decompressive measures were used [111]. Brachytherapy has been applied through percutaneous tubes, with a median survival of 23 months [112]. The combination of surgery and radiotherapy was reported to provide a median survival of 14 months in unresectable or recurrent disease [113]. Another series reported no benefit of radiation [114].

Intrahepatic tumors

The principles of treatment are the same as for other malignant intrahepatic hepatic lesions [115]. The tumor must be resected with a margin of normal tissue to obtain microscopically free resection margins (a 1-cm tumor-free resection margin is the goal) yet leave enough normally functioning liver tissue behind for the patient to have adequate liver function in the postoperative period. The size of the resection may vary from a single segment or less to resection of three of the four hepatic sections [116]. Like upper duct tumors, results depend on whether negative resection margins are achieved. There are few case series that separate these uncommon tumors from other cholangiocarcinomas. One recent series

obtained a 5-year survival rate of 44% [1] in 18 patients, whereas another reported a 32% 2-year survival rate in 19 patients [117].

Liver transplantation has been performed for intrahepatic and upper duct cholangiocarcinoma. Initially the results were disappointing. Goldstein and colleagues reported that only 3 of 14 patients (21%) lived for more than 28 months after the procedure [118], whereas in a study by Shimoda and associates 25 patients reported a 3-year survival of 32% [119]. However, two reports by Heimbach and colleagues at the Mayo Clinic show a series of 28 patients with localized, regional lymph-node-negative, hilar cholangiocarcinoma undergoing neoadjuvant therapy and liver transplantation having an actuarial patient survival of 82% at 5 years [120,121]. Liver transplantation for neoplasms must still be evaluated with the knowledge that many patients with end-stage chronic liver disease are dying while on a waiting list for liver transplantation and the comparative survival rate in this group of patients would be expected to be about 90%.

Benign bile duct tumors

Benign tumors are uncommon. Most information comes from case reports. The clinical presentation is similar to that of choledocholithiasis: pain, jaundice, and less commonly, cholangitis or pancreatitis. Adenomas are the most common benign tumors of the bile ducts. They may be single, multiple, tubular, papillary, or mixed. Multicentricity has been reported but is uncommon. Cystadenoma and granular cell tumors are rare benign tumors of the extrahepatic bile ducts. Cystadenomas are similar to and may coexist with cystadenomas of the liver and pancreas [122]. Granular cell tumors are unusual, occur most commonly in women of African heritage, and may be associated with granular cell tumors at other sites [123,124]. The malignant potential of these lesions is unknown. Reported benign mesenchymal tumors include fibromas, lipomas, leiomyomas, and neurilemomas.

Papillomatosis is a rare condition in which multiple papillary lesions involving a large amount of the bile duct mucosa may be encountered. Malignant transformation or progression to invasive carcinoma has been reported so papillomatosis of the bile duct mucosa should be considered a premalignant lesion [125,126]. This lesion should be treated by complete excision if possible; if not, regrowth is common.

Carcinoma of the gallbladder

Carcinoma of the gallbladder is the fifth most common malignancy of the gastrointestinal tract [127]. As with studies on cholangiocarcinoma, studies of gallbladder cancer tend to be small case series covering many years, and claims for the best form of investigation or treatment must be cautiously interpreted. Cancers arising from the gallbladder mucosa appear to behave in a fashion similar to other adenocarcinomas of the gastrointestinal tract; premalignant to invasive malignant changes can be found, metastatic spread occurs by lymphatic and vascular routes, diagnosis is often delayed, and survival is related to stage. Interestingly, at the population level, mortality is also inversely related to cholecystectomy rates [128].

Incidence

The highest incidence of gallbladder cancer occurs in Chileans and Bolivians [129]. Gallbladder cancer is the fourth leading cause of all cancer deaths in Chile; mortality from gallbladder cancer (5.2%) in Chile is the highest in the world [130]. Other commonly affected population groups include Native Americans, Hispanic American women, Latin American women, Japanese women in Japan, African Zimbabwean women, European immigrant women in Israel, and northern Europeans [131,132]. In contrast to the general population of the United States, in whom the incidence is low at about 3 per 100 000, gallbladder cancer is the most common gastrointestinal malignancy in Native Americans. Low rates of gallbladder cancer occur among Nigerians, New Zealand Maoris, and Chinese natives and immigrants [131].

Cancer of the gallbladder in the United States is a disease of elderly people, with the greatest incidence occurring after 65 years of age. It is three times more common in women than in men, and it is more common in whites than in African Americans. Genetic differences are exceedingly important. In North America, the highest incidence of gallbladder cancer occurs among Native Americans and Mexican Americans. In North and South America, gallbladder cancer is related to Native American rather than Spanish heritage because the incidence of gallbladder cancer in Spain, Cuba, and Puerto Rico is low. In Mexico, *mestizos* (people of mixed ancestry) have the highest incidence, whereas in Bolivia, there appears to be a difference based on tribal origin [133].

Etiology

Etiological factors that appear to be, or have been claimed to be, important for the development of gallbladder cancer include genetic characteristics, gallstone disease, bile composition, calcification of the gallbladder wall, anomalous junction of the biliary and pancreatic ducts, congenital biliary cysts, some infections [134], environmental carcinogens, and drugs. Geographic differences may reflect racial and genetic differences, although cultural differences possibly play a role. A progression from dysplasia to early cancer to metastatic cancer has been observed [135], the progression from dysplasia to cancer taking about 15 years.

Gallstone disease is associated with gallbladder cancer, but the mechanism is unknown. Most reports of the relationship between gallstones and gallbladder cancer have come from operative or autopsy studies; however, a prospective cohort

study of patients with gallstones found that gallstones did increase the risk for gallbladder cancer, but the actual incidence was very low (9 per 10 000 per person-years), and the absolute number of cases of gallbladder cancer (5 of 2583 people) in this population was low [136]. The incidence of gallbladder cancer in patients with cholecystolithiasis ranges between 0.5% and 3% [137]. Cholecystolithiasis is present in 70%–90% of patients with gallbladder cancer. Duration of gallstones, patient age, size of gallstones [138], and possible carcinogenic effects of gallstones, such as from the chemical composition [139] or from bacteria within the stones, may be important [140], although in certain studies, patients with cancers did not have larger stones, nor did their stones have higher cholesterol content [136].

Duration of cholecystolithiasis appears to be a crucial factor for the development of cancer. Patients who have had cholecystolithiasis for longer than 40 years have a significantly higher incidence of gallbladder cancer than those who have had gallstones for a shorter time. Glenn and Hays [141] suggested that 1% of patients older than 65 years of age with gallstones would develop gallbladder cancer. This more likely reflects the duration of stone disease than an effect of age. However, the possibility of cancer is not an indication for cholecystectomy in a patient with asymptomatic stones. In many countries, gallbladder cancer is unknown, which is probably related to the rate of cholecystectomies performed for asymptomatic gallstones or early in the course of patients with symptomatic stones.

Little is known about the pathophysiology of gallbladder cancer in patients with cholecystolithiasis. Chronic irritation of the gallbladder mucosa by stones, followed by repeated episodes of epithelial repair over a period of years, may lead to malignant transformation. The chemical composition of stones or bile may be related to development of gallbladder cancer. Indeed, because bile from high endemic areas is more mutagenic than that from low endemic areas [142], there is probably some factor excreted by the liver into bile that contributes to malignant transformation. Cholesterol stones are the most common type associated with gallbladder cancer. Bile acids can act as cocarcinogens, and there is a structural similarity to the known carcinogen, methylcholanthrene. In the most comprehensive analysis yet, Strom and colleagues [136] performed a case–control study in Mexico and Bolivia that compared patients with gallbladder cancer, patients with gallstones, and patients with no biliary tract disease. Their prior hypotheses, that patients with tumor would have increased levels of lithocholate, was not confirmed, but bile glycoursodeoxycholate levels were unexpectedly elevated in the patients with cancer. This paper must be read to appreciate the difficulty of performing and interpreting such a combined epidemiological and biochemical study. For instance, the authors were unsure at the end of their study whether their unexpected findings in bile acid composition were a cause or effect of the tumor. There are no conclusive data linking bile composition of bile acids to carcinoma of the gallbladder and because bile is the main route of excretion of dietary or chemical metabolites with molecular weight of more than 500, there are a large number of potentially carcinogenic compounds.

A number of recent studies from Japan have linked anomalous pancreatic–biliary duct junction (APBJ) to gallbladder and extrahepatic bile duct cancer [143–145]. There is a much higher incidence of biliary tract cancer in patients with APBJ. About 2% of Japanese patients examined had APBJ; about 75% of these cases were associated with a choledochal cyst and the rest had normal-caliber bile ducts. In those associated with choledochal cyst, cancer may arise in the extrahepatic duct or gallbladder, whereas in those without ductal dilation, the cancer seems almost always to occur in the gallbladder [143,144]. Cancer of intrahepatic ducts does not appear to be associated with APBJ. Patients with APBJ get cancer at a younger age than patients with sporadic gallbladder cancer [144]. Pediatric patients with APBJ frequently have epithelial hyperplasia of the gallbladder [146,147]. The nonmalignant areas of the gallbladder of patients with APBJ-associated gallbladder cancer show increased hyperplastic changes in the gallbladder mucosa compared with patients with sporadic gallbladder cancer [148,149]. In a cat model, side-to-side biliary–pancreatic anastomosis produced hyperplastic changes in the gallbladder within 6 months [150].

Another factor that has been associated with gallbladder cancer is partial or complete calcification of the gallbladder wall (porcelain gallbladder). Although an incidence of coexistent gallbladder malignancy of up to 25% has been claimed in patients with porcelain gallbladder, recent data suggest that this is less common [151]. Others have questioned whether porcelain gallbladder is linked to gallbladder carcinoma at all [152]. *Salmonella typhi* carriage; exposure to toxic environmental factors in the automotive, rubber, textile, and metal industries [38,135,153]; previous gastric operations [154]; and elevated body mass index [138] have been associated with gallbladder cancer.

Molecular genetics

There are relatively few studies examining the molecular events in carcinoma of the gallbladder. As in cholangiocarcinomas, the *erbB2* oncoprotein is expressed in a significant fraction of gallbladder cancers [155]. Furthermore, transgenic mice that express *erbB2* in the gallbladder epithelium develop gallbladder carcinomas [156]. Data regarding the expression of *ras* and *myc* genes in gallbladder cancer are conflicting [155,157,158] but it appears that the expression of these genes is substantially less than in cholangiocarcinomas. Similarly, point mutations involving the K-*ras* gene appear to be less common in gallbladder cancer than in cholangiocarcinomas [158]. Several studies have identified *p53* expression in gallbladder cancers; about two-thirds of

such tumors express *p53* [37,159]. Such overexpression is not seen in adenomas.

Pathology

As noted, there is a progression from dysplasia to carcinoma in situ to invasive cancer in the gallbladder epithelium that appears to take about 15 years [135]. Premalignant lesions are associated with gallbladder cancer, and it is thought that chronic inflammation may play a role in the development of premalignant lesions [41,160]. Two types of metaplasia, intestinal and squamous, have been found in patients with gallbladder cancer. The relation of intestinal metaplasia to subsequent development of gallbladder cancer has not been determined. Squamous metaplasia, squamous epithelium replacing normal gallbladder epithelium, is a rare premalignant lesion that has been found with squamous cell cancer of the gallbladder. Cholecystitis follicularis, a rare type of inflammation, has been reported in a few cases of gallbladder cancer, but its premalignant potential is unclear [41].

The classification of malignant lesions of the gallbladder is shown in Table 77.4. Sixty percent of cancers of the gallbladder are found in the fundus, 30% in the body, and 10% in the neck. They may be isolated or involve the entire gallbladder through intramural spread, analogous to linitis plastica of the stomach.

Most malignant neoplasms of the gallbladder are adenocarcinomas, which behave in a manner similar to adenocarcinomas arising from other epithelial tissues. They originate as mucosal lesions, and as growth progresses, they invade the wall of the gallbladder. The anatomy of the gallbladder wall partly explains the advanced stage of disease at which most patients with gallbladder cancer present. The lack of a well-defined muscularis leads to early entry of invasive gallbladder cancer into the perimuscular connective tissue. Lymphatic, neural, and hematogenous invasion occurs earlier with gallbladder cancer than with cancers of the gut.

Table 77.4 Malignant neoplasms of the gallbladder

Malignant epithelial tumors

Carcinoid
Lymphoma
Melanoma
Others

Gallbladder cancer frequently extends beyond the gallbladder to involve the liver and the extrahepatic biliary tree. Most patients with liver involvement have direct extension of the disease; fewer than 10% of patients have liver metastasis without full-thickness invasion of the gallbladder wall. The routes of lymphatic drainage of the gallbladder have been studied in an attempt to rationalize aggressive surgery for cancer of the gallbladder. Uesaka and colleagues [161] injected a carbon particle suspension into the primary drainage nodes – the cystic and pericholedochal nodes. The main route of drainage was on the right side of the bile duct to the superior retropancreatic node and from there directly to the paraaortic nodes or indirectly to the paraaortic nodes through the posterior pancreatic nodes. Drainage to the left side of the bile duct to the celiac nodes and drainage upward to the hilar nodes and into segment IV of the liver were much less common modes of drainage. Lymph node metastasis to the cystic, pericholedochal, peripancreatic, and celiac nodes occurs early; more than 50% of patients are found to have lymph node metastases at the time of diagnosis. Direct invasion of the duodenum and the colon also occurs. Intraperitoneal spread, Krukenberg tumors (i.e., ovarian metastases), and hematogenous dissemination occur.

A uniform staging system for gallbladder cancer has not been widely applied. Nevin and colleagues [162] developed the first clinically useful staging system. The TNM system, described by the American Joint Committee on Cancer, is the preferred staging system [3]. Survival of patients with gallbladder cancer is related to stage and histological type of cancer. Lymph node involvement is rare in stage T1 tumors [162,163]; that is, lymph node involvement almost never occurs until the muscularis has been penetrated. After that, lymph node involvement is common, occurring in about 50% of stage II patients and in 70%–80% of patients in stage III and IV [162,163]. There is a close correlation between lymph node involvement and prognosis [164–166]. Most long-term survivors are patients with well-differentiated tumors that were minimally invasive. These are usually found incidentally at or immediately after cholecystectomy (Fig. 77.8).

Clinical presentation

Signs and symptoms of gallbladder cancer are nonspecific. This explains the delay in diagnosis in most patients with gallbladder cancer. In TNM stages I and II, symptoms often mimic those of cholelithiasis and cholecystitis [167]. Indeed, in the early stages, the cause of symptoms may be the associated cholelithiasis. Pain is the most common initial complaint; it may be dull and aching, colicky, sharp, constant, or intermittent, and it may or may not radiate to the back. Other symptoms include nausea, vomiting, and anorexia. In later TNM stages, weight loss, jaundice, hepatomegaly, a

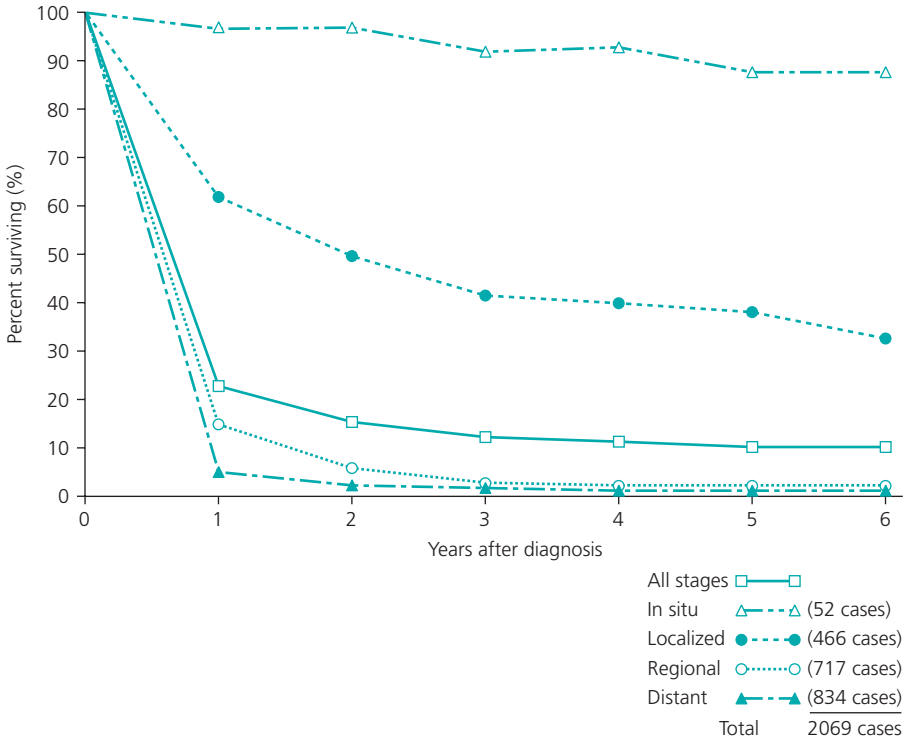

Figure 77.8 Gallbladder cancer survival rates by stage in all races and genders from 1973 to 1981. From Albores-Saavedra & Henson [41], with permission from the American Registry of Pathology.

palpable mass, or ascites may develop. Jaundice develops in 30%–60% of patients and is a poor prognostic sign because it is caused by extension of the tumor beyond the gallbladder, with obstruction of the extrahepatic bile ducts; 85% of patients with jaundice have unresectable tumors [137]. The patients may also have obstruction of the duodenum or colon. Malignant cholecystoenteric fistula may be the first indication of gallbladder cancer.

Diagnosis and staging

In most cases, the diagnosis is not made preoperatively [137]; this is true even in recent series [168]. Laboratory findings are not diagnostic but are related to abnormalities associated with bile duct obstruction. Patients frequently have increased alkaline phosphatase and bilirubin levels. Blood levels of CEA or CA 19-9, another tumor marker, may also be elevated. These findings are not diagnostic because they may have other causes.

Diagnostic techniques include oral cholecystography, ultrasonography, CT scanning, and possibly MRI. The most widely employed diagnostic study for biliary tract disease is ultrasound. Findings on ultrasonography that are suggestive, but not diagnostic, of gallbladder cancer include thickening of the wall, a mass projecting into the lumen, calcification of the gallbladder, multiple masses or a fixed mass in the gallbladder, a mass extending into the liver, or an extracholecystic mass. In a comparison of patients with unsuspected gallbladder cancer and patients with benign gallbladder disease, it was found that solitary stone, displaced stone, intralumenal mass, and invasive mass were more commonly associated with cancer [169]. A report of mucosal thickening should also be viewed with suspicion. CT scanning may help in the diagnosis but is of limited help in staging the disease except in estimating the extent of hepatic invasion [170] (Fig. 77.9).

Gallbladder polyps may be malignant but are rarely so when less than 1 cm in diameter. In a recent series of 103 patients with gallbladder polyps, no polyp was malignant if less than 1 cm in diameter, but 23% of polyps larger than

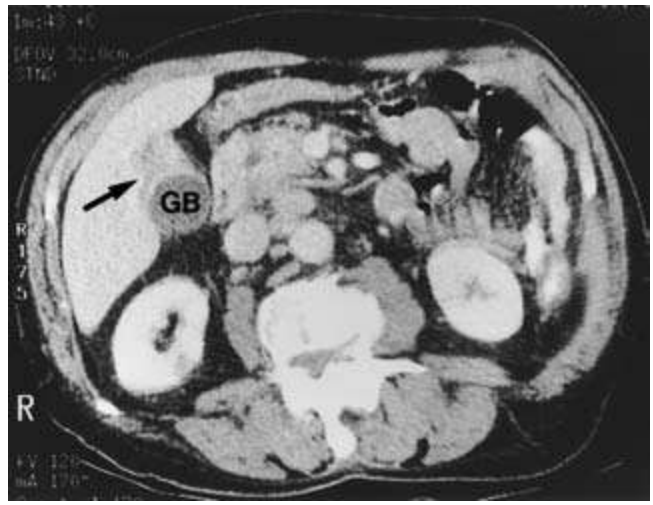

Figure 77.9 Computed tomography scan of patient with carcinoma of the gallbladder (GB) showing invasion of hepatic parenchyma (arrow).

1 cm were malignant [171]. In another series, 88% of polyps larger than 1 cm in diameter were malignant, and polyps larger than 1.8 cm were more likely to contain a more advanced stage of cancer [172]. Fine-needle aspiration appears to be an accurate way of distinguishing between polyps caused by cholesterolosis and neoplastic polyps [173], especially when the polyps are larger than 1 cm in diameter [174]; however, it is much less accurate in determining whether a neoplastic polyp is an adenoma or carcinoma [174]. Duplex Doppler ultrasound imaging of blood flow within a neoplastic polyp may also be useful in distinguishing these lesions from cholesterol polyps.

Many of the staging considerations are similar to those discussed under cholangiocarcinoma. Staging laparoscopy with ultrasound appears to have many of the same advantages for staging of gallbladder cancer that it has for other hepatobiliary malignancies [56,58,175].

Treatment

Both treatment and prognosis of gallbladder cancer depend on stage of disease [162]. Unfortunately, most cancers are diagnosed when symptomatic, and at that time, the stage of disease is usually TNM stage III or IV [165,176]. In most patients with disease that is in advanced stages, their disease is not resectable so the stage distribution at the time of open surgery has been more heavily weighted to later stages than the stage distribution of patients actually resected for cure. For instance, in a German series of 81 operated patients, the TNM stage distribution (I to IV, respectively) was 7%, 12%, 15%, and 66% [165] whereas the stage distribution of 106 radically resected cases in a Japanese series was 14%, 43%, 24%, and 19% [163]. It is to be hoped that staging laparoscopy with ultrasound will alleviate this disparity and reduce the number of patients undergoing open exploration without resection. Of the 106 patients in the Japanese series, curative resection was achieved in 74. Most of the noncurative resections were in patients with stage IVb cancer [163]. In a recent American series containing 149 patients, 58 cancers were explored, and of those, 23 were resected for cure [165]. As previously noted, these figures may not be representative of the broad population of patients contracting the disease.

There are no established principles of treatment because no definite trials establishing these exist. Most studies of treatment regimens are small, not randomized and retrospective [177]. At best, there are rational guidelines based on the facts that T1 lesions have rarely metastasized to the lymph nodes but T2 to T4 lesions have usually done so [162,163] and that radical surgery achieving negative tumor margins has resulted in acceptable results in more advanced disease [178]. There are several levels of resection. In increasing order of magnitude they are

- extraserosal cholecystectomy or cholecystectomy with wedge resection of the liver
- extraserosal cholecystectomy combined with portal lymph node dissection and sometimes extrahepatic bile duct resection
- liver resection with cholecystectomy and lymph node dissection and sometimes extrahepatic bile duct resection
- liver resection with cholecystectomy and lymph node dissection combined with pancreaticoduodenectomy (the most radical).

Beginning with the earliest stages, the recommendation for treatment may be summarized as follows. When gallbladder cancer is suspected, an open procedure should be performed. If there is no evidence of spread outside the gallbladder, an extraserosal cholecystectomy should be performed. An extraserosal cholecystectomy excises the gallbladder on a deeper plane than a standard cholecystectomy, so that the gallbladder and all connective tissue down to actual liver tissue are removed. This can be performed laparoscopically; however, it is our opinion that this should not be attempted because gallbladder perforation and bile spillage are more common in the laparoscopic technique. The negative consequences of tumor implantation or incomplete excision far outweigh any benefit of minimally invasive surgery. The excised specimen should be inked. If resection margins are negative and if the tumor has not penetrated the muscularis (T1 lesion), the procedure is considered to be complete. If margins are positive or if the muscularis has been penetrated, then resection of segments 4b and 5 and a lymph node dissection are performed. If the cystic duct resection margin is positive, then, in addition, the extrahepatic bile duct is excised to clear margins [179].

When there is obvious penetration to the serosal layer on the deep surface of the gallbladder, found with intraoperative ultrasound or palpation, then resection of the gallbladder with segments 4b and 5 and a lymph node dissection with or without extrahepatic bile duct resection is the recommended procedure. Sometimes, because of the local depth of penetration into the liver, a more extensive liver resection is required [180]. Stated otherwise, a cholecystectomy is usually sufficient for T1 lesions and usually results in cure. For T2 to T4 lesions, the extent of resection depends on the route of direct extension, whether into the liver or bile duct; a lymph node dissection is always performed.

Results in recent case series [163,165,178,181,182] appear to show marked improvement over classic reports. Mortality is infrequent, even for major resections, but there is a complication rate of about 25%, including minor complications. Exact comparisons among series are not possible because different operations have often been carried out for the same disease stage. For long-term survival, a curative resection with negative margins must be obtained. If negative resection margins are achieved, 5-year survival rates according to stage are about as follows: stage I, 90%; stage II, 80%; stage III, 40%; and stage IV, 15%. Prognosis in stage IV appears to be best when the tumor is placed in this category because of local hepatic invasion, rather than because of lymph node

involvement [165]. Lymph node involvement is an ominous sign [165], although 5-year survivors have been reported in some series [163,182]. Based on the pattern of lymph node drainage, a pancreaticoduodenectomy has been performed for T2 to T4 disease [183]. However, the results have still been poor in patients with advanced stage disease.

Palliation of gallbladder cancer mainly requires treatment of obstructive jaundice. The considerations are the same as for cholangiocarcinoma, except that percutaneous or endoscopic means of decompression are preferable in this rapidly progressive state. Chemotherapy is experimental and of no proven benefit [184]. Although some gallbladder cancers may be radiosensitive [185], radiation therapy provides little survival benefit because of the extent of tumor at the time of diagnosis. Palliation of jaundice has been reported, and intraoperative irradiation may be beneficial [186,187]. Although these types of treatments should be considered, their role has not been defined.

Incidental gallbladder cancer at laparoscopic cholecystectomy

Gallbladder cancer may be an incidental finding at laparoscopic cholecystectomy, as it was at open cholecystectomy in the past; the incidence ranges from 0.3% to 1%. The difference with laparoscopy is that port-site implantation may occur [188,189]. Port-site implantation may simply be the result of contact between the malignancy and the tissues at the perimeter of the port site at the time of gallbladder extraction. It is reported to occur in 17% of cases [190]. However, positive-pressure pneumoperitoneum appears to be another factor [191]. Preoperative suspicion should be raised by the ultrasonographic findings listed previously. Extraction of the gallbladder in a plastic bag is prudent when these signs exist or when there is evidence of gallbladder wall thickening at surgery. Every gallbladder should be inspected at the time of extraction and questionable areas should be resected for biopsy.

If a cancer is discovered, it should be treated at that time using the principles stated previously. The tissue surrounding the trocar ports should also be excised as part of the treatment because seeding may have occurred. Early reoperation is the approach of choice when the tumor is discovered on later pathological examination, when surgery at the time of the initial procedure could not proceed because of uncertainty of diagnosis or degree of penetration of the tumor, or when the surgeon believes that the proposed procedure must be discussed with the patient. Stage I gallbladder carcinomas that have clear resection margins probably require no further surgical treatment. Overall, the widespread adoption of laparoscopic cholecystectomy did not worsen the survival of patients with gallbladder cancer and patients with serendipitously treated gallbladder cancers did not have a worse survival after laparoscopic manipulation than after a standard open cholecystectomy [192].

Benign tumors of the gallbladder

Benign tumors of the gallbladder are uncommon and infrequently symptomatic. Benign epithelial tumors include adenomas and mixed tumors. Adenomas may be tubular, papillary, or mixed. One-third are multiple, and fewer than 50% are associated with stones. Benign tumors may be symptomatic, causing biliary colic, presumably as a result of shedding of tumor, which temporarily obstructs the cystic duct. Treatment is laparoscopic cholecystectomy when the mass is symptomatic and less than 1 cm in diameter. Cholecystectomy is performed for either symptomatic or asymptomatic tumors when the mass is larger than 1 cm in diameter because of the possibility of malignancy and for the same reason the procedure is performed as open surgery. Fine-needle aspiration may permit the diagnosis of cholesterolosis, in which case surgery is necessary only if symptomatic and laparoscopic surgery may be performed.

Other problems with which benign tumors of the gallbladder are confused are much more common than benign tumors of the gallbladder. These include cholesterolosis and adenomyomatosis. The former is a disease of unknown etiology in which cholesterol accumulates focally, segmentally, or diffusely in the gallbladder. Focal cholesterolosis may present as a polyp and be confused with a tumor. Adenomyomatosis goes by a variety of other names as well. It is a condition in which there is nonneoplastic ingrowth of gallbladder glands into the wall of the gallbladder and even penetration of the wall. The cause is unknown. It may be focal or diffuse. When focal, the site is usually in the fundus, producing the characteristic fundal adenomyoma. When diffuse, it produces wall thickening. Both types may be confused with malignancy. There are characteristic changes on ultrasound and contrast cholangiography, which help differentiate the process from cancer. Benign mesenchymal tumors are rare and include leiomyoma, hemangioma, and lipoma.

Introduction

The sphincter of Oddi (SO) was first described by a 23-year-old Italian medical student named Ruggero Oddi in the late 19th century (1887) after extensive research on the physiology of dogs and detailed histological examination of many species, including humans. Following this, Oddi was promoted to the Chair of Physiology at the University of Genoa but then sank into a world of depression, narcotic abuse, and homeopathic medicine before dying anonymously and mysteriously in Tunisia in 1913 [1]. Like Oddi himself, the sphincter he described has remained an item of intrigue, mystery, and controversy. A recent editorial referred to sphincter of Oddi dysfunction (SOD) as the "most misunderstood and abused diagnosis in gastroenterology" [2]. This chapter aims to clarify (as much as possible) what is known concerning nomenclature, diagnosis, and treatment of SOD.

Definitions

SOD refers to a benign, noncalculous obstruction to bile or pancreatic exocrine secretions through the SO [3]. This may be secondary to a fixed structural lesion, referred to as SO stenosis, or secondary to a motility disorder or spasm, with resultant SO dyskinesia. Other terms used to describe SOD include papillary stenosis, sclerosing papillitis, biliary spasm, biliary dyskinesia, and postcholecystectomy syndrome. It is often difficult (or impossible) to completely distinguish between stenosis and dyskinesia so the term SOD is used to incorporate both groups of patients.

Anatomy

The SO is a complex muscular sheath consisting of circular and longitudinal muscle fibers that surround the distal common bile duct, the main pancreatic duct of Wirsung, and the common channel (ampulla of Vater) before emptying into the second portion of the duodenum. It is divided anatomically into four distinct components:

- the biliary sphincter (*sphincter choledochus*), which consists of circular muscle fibers surrounding the distal common bile duct proximal to its junction with the pancreatic duct
- the pancreatic sphincter (*sphincter pancreaticus*), which consists of the short annular muscle surrounding the distal intraduodenal segment of the main pancreatic duct (of note, this is located in only 30% of the population)
- *sphincter ampullae*, which consists of a thick sheath of longitudinal muscle fibers overlying thinner circular muscle surrounding the ampulla of Vater; and
- *fasciculi longitudinales*, which consists of short muscle fibers connecting the distal end of the joined ducts [4,5].

The intramural length of the SO is 7–22 mm; the common distal segment (which may not exist in 15% of individuals) is 1–9 mm, and the extramural length of the sphincter is about 5 mm [6]. The high-pressure zone is typically 4–10 mm in length. The embryological, anatomical, and physiological features of this musculature are separate from that of the surrounding duodenal musculature (Fig. 78.1).

Physiology

The exact role of the SO remains unclear. Some investigators propose an active role of the SO in propelling bile into the duodenum whereas others suggest that the SO functions only as a regulated resistor of bile flow. The available evidence suggests a role for the SO in the following three areas:

- regulating bile flow and maintaining a low intraductal pressure
- diverting the hepatic bile into the gallbladder during the interdigestive period
- preventing reflux of duodenal contents into the biliary tree [4].

Two types of motor activity have been detailed in association with SO: baseline tonic pressure (approximately 5–15 mmHg above the common bile duct pressure and 10–33 mmHg above duodenal pressure), and superimposed phasic contractions (occurring every 8–15 s and lasting 4–5 s) [7,8].

Sphincter regulation is under both neural and hormonal control although the exact mechanisms of that control are not clearly elucidated. Three regulatory systems have been described in relation to SO activity:

- synchrony with gastric and duodenal motor activity during the interdigestive period (reflex regulation)
- hormonal control, with cholecystokinin (CCK) in particular believed to play a major role
- neural control primarily through cholinergic parasympathetic fibers.

The maximal contractive activity of the SO occurs during phase III of the migrating motor complex [9–11]. Both intraduodenal acidity and food content have been shown to affect SO activity. In some animals, gastric distention has been shown to cause an increase in SO activity; however, in humans that does not appear to be the case [12]. CCK reduces the baseline pressure and decreases the phasic contractile activity of the SO in humans; however, in other species (opossum and prairie dog), CCK increases the phasic activity of the SO without affecting the baseline pressure [4]. In general, the following hormones are believed to have a stimulatory effect on SO motility: gastrin, secretin, motilin, bombesin, galanin, neuropeptide Y, peptide YY, pancreatic polypeptide, and substance P; whereas the following hormones are believed to be inhibitory: cholecystokinin, glucagon, secretin, calcitonin gene-related peptide, nitric oxide, and cerulin [4]. In addition, numerous pharmacological agents appear to have varied effects on SO motility. Morphine, fentanyl, pentazocin, ethyl alcohol, bethanechol, and physostigmine have stimulatory function; atropine, nitroglycerin, nifedipine, amyl nitrate, and barbiturates are inhibitory. The regulation of SO motility is complex and not completely understood [4].

Diagnosis and classification

The diagnosis of SOD rests on the presence of typical clinical symptoms in the setting of associated radiographic and laboratory abnormalities.

Milwaukee Biliary Group Classification

Several classification schemes have been proposed; however, the classic ("Milwaukee Biliary Group Classification") criteria proposed by Hogan and Geenen in 1988 remain the best studied [13]. Under this system, three groups of patients with pain suggestive of biliary etiology are recognized. These patients are divided as follows:

- type I patients fulfill the following three criteria:
  - pain associated with abnormal serum aminotransferases (alanine aminotransferase and aspartate aminotransferase more than twice the normal value on at least two occasions)
  - a common bile duct dilated more than 10 mm on ultrasound or 12 mm on endoscopic retrograde cholangiopancreatography (ERCP)
  - delayed drainage of contrast from the common bile duct after more than 45 min in the supine position
- type II patients have typical biliary-type pain and, in addition, fulfill one or two of the above criteria
- type III patients have typical biliary-type pain but fulfill none of the above criteria [13].

When manometry is considered to be the gold standard, the predictability of SOD varies among these three groups with the following values: type I, 65%– 95%; type II, 50%–63%; type III, 12%– 28% [14]. Given the logistical difficulties

in assessing delayed drainage times, this criterion is often excluded in clinical practice and research studies, resulting in the modified Hogan–Geenen classification scheme [15]:

In addition, three classification groups have also been developed for pancreatic SOD. These are as follows:

- type I patients fulfill the following two criteria:
  - abnormal pancreatic enzymes on two occasions
  - pancreatic duct dilated more than 6 mm
  - delayed drainage of pancreatic duct after ERCP by more than 8 min
- type II patients present with typical pancreatic-type pain and, in addition, fulfill one or two of the above criteria
- type III patients present with typical pancreatic pain but do not fulfill any of the above objective criteria [13,16].

Rome III criteria

In 2006, the Rome III Committee established three gallbladder and biliary sphincter disorders; referred to as functional gallbladder disorder, functional biliary SO disorder and functional pancreatic SO disorder. The hallmark of all three disorders is episodic pain located in the epigastrium or right upper quadrant and all of the following:

- episodes lasting 30 min or longer
- recurrent symptoms occurring at different intervals (not daily)
- the pain builds up to a steady level
- the pain is moderate to severe enough to interrupt the patient's daily activities or lead to an emergency department visit
- the pain is not relieved by bowel movements
- the pain is not relieved by postural change
- the pain is not relieved by antacids
- exclusion of other structural disease that would explain the symptoms.

Supportive criteria are: associated nausea and vomiting, radiation of pain to the back or right subscapular region, and awakening from sleep in the middle of the night.

Functional gallbladder disorder was defined as the above symptoms in the context of an intact gallbladder and normal liver enzymes, conjugated bilirubin, and amylase/lipase. Functional biliary SO disorder was defined as typical pain (meeting all the features detailed above) in conjunction with normal amylase and lipase measurements. Elevated serum aminotransferases, alkaline phosphatase, or conjugated bilirubin temporally related to at least two pain episodes was considered to be a supportive criterion. Functional pancreatic SO disorder was defined as typical pain in conjunction with elevated amylase/lipase [17].

Clinical presentation and demographics

SOD is estimated to affect approximately 13% of patients with unexplained right upper quadrant pain following cholecystectomy and 0.9% of all individuals undergoing cholecystectomy [18,19]. Although SOD may occur in patients of any age, the classical presentation is typically a middle-aged woman [20].

In terms of clinical presentation, abdominal pain is the sine qua non of this disorder. The pain is typically located in the epigastrium or right upper quadrant, lasts for from 30 min to several hours, and may be disabling. In some patients the pain is continuous with intermittent exacerbations. It may radiate to the back or shoulder. Associated nausea and vomiting may be present. The pain may begin following a cholecystectomy; however, this is not required and patients may also present with biliary-type pain that is not relieved with cholecystectomy. Jaundice, fevers, and chills are not typically observed and should prompt consideration of an alternative diagnosis [21]. Physical examination is characterized by the absence of objective abnormalities with the most common finding being nonspecific abdominal tenderness on palpation.

Following the initial history and physical examination, initial diagnostic evaluation should focus on etiologies typical of pancreatobiliary symptomatology. Initial evaluation should include standard liver chemistries, serum amylase or lipase, and abdominal ultrasonography or computed tomography (CT) scan. If possible, laboratory evaluation should be obtained during bouts of pain. Mild elevations in aminotransferases (less than twice the upper limits of normal) are frequently observed in SOD; however, significantly greater abnormalities are more suggestive of other etiologies, such as tumors, stones, and parenchymal liver disease. CT scans can often be normal in SOD, although mild ductal dilation is not uncommonly observed and is supportive of a diagnosis of SOD. More common gastrointestinal disorders such as gastroesophageal reflux and peptic ulcer disease should also be evaluated and treated concurrently. In the presence of typical biliary-type pain and the absence of improvement with treatment of more common disorders, further work-up for possible SOD is warranted.

Diagnosis using noninvasive imaging

Sphincter of Oddi manometry (SOM) is considered to be the gold standard for diagnosis of SOM and stratification of therapy. However, this procedure is not without risk and most series suggest an increased rate of post-ERCP pancreatitis in this patient population with values ranging from 17% to 31% [22,23]. Given this, most centers would recommend that the diagnostic evaluation begin with noninvasive imaging unless the clinical, laboratory, and radiographic evidence clearly suggests SOD. This point is particularly emphasized in the Rome III guidelines published in 2006 [17]. After initial laboratory analysis and ductal imaging, consideration should be given to the tests listed below.

Morphine–prostigmin provocation test (Nardi test)

The Nardi test represents historical precedent more than established clinical care. Morphine has been shown to cause SO contraction (measured manometrically). Prostigmin (neostigmine) is a cholinergic secretory stimulant. Given together, morphine (10 mg) and prostigmin (1 mg) should theoretically induce increased biliary and pancreatic flow in tandem with SO contraction. A positive test has been defined as reproduction of the patient's typical pain in tandem with a fourfold increase in aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, amylase, or lipase levels [24,25]. However, the clinical utility of this test is questioned given that specificity and sensitivity have been poor when the Nardi test has been compared to results of biliary manometry or outcome after endoscopic sphincterotomy. This test has been largely replaced by the subsequent studies listed later in this chapter [26].

Secretory imaging studies

Ductal diameter is felt to be a significant predictor of SOD and is listed as one of the classic "Milwaukee" criteria. Provocatory imaging tests have been postulated as a noninvasive means of increasing specificity for the diagnosis of SOD. The theory behind this is as follows: following a lipid-laden meal or CCK injection, the gallbladder contracts, hepatocyte-induced biliary flow increases, and the SO relaxes; similarly, after a lipid-laden meal or secretin administration, pancreatic exocrine output increases and the SO relaxes. Therefore, if there is SOD, increased ductal dilation may be more preferentially seen after increased secretory output. In normal subjects, the bile duct diameter should remain constant or decrease with stimulation. Normative values are not clearly established but most studies define an increase of more than 1 mm to be abnormal and suggestive of possible SOD [27,28]. Studies have included patients with and without intact gallbladders. Provocatory ductal diameter has been measured using several different imaging modalities: transcutaneous ultrasound, endoscopic ultrasound, and magnetic resonance cholangiopancreatography (MRCP).

Transcutaneous ultrasound has been studied in several small studies with variable correlation when compared with SOM [29–33]. Endoscopic ultrasound with secretin stimulation has also been compared to ERCP with SOM with results suggesting "excellent negative and positive predictive values but poor overall sensitivity" [34]. Dynamic MRCP with secretin administration has been examined for noninvasive diagnosis [27,35–38]. Initial results have been encouraging with concordance between dynamic MRCP and ERCP reported to be 86% in one study; however, long-term data with larger patient populations and multiple centers are needed before this test can enter the clinical arena as anything other than a supportive research tool. Given these factors, dynamic imaging with transcutaneous ultrasound, endoscopic ultrasound, and MRCP are possibly useful clinical adjuncts to diagnosis but data do not support their use as an exclusive means of diagnosis.

Hepatobiliary scintigraphy

Quantitative hepatobiliary scintigraphy assesses bile flow through the biliary tract using radionucleotide imaging (Fig. 78.2). Functional or structural obstruction results in impaired radionucleotide flow and can support a diagnosis of SOD. However, the precise criteria used to define an abnormal study remain controversial with commonly measured variables including: the time taken to the maximal count over the biliary tree (T_{MAX}), the time taken for 50% of the tracer to accumulate over the biliary tree ($T_{1/2}$), the duodenal appearance time (DAT), the hilum-to-duodenum transit time (HDTT), and prolonged excretion of tracer from the biliary tree. Among these measurements, the most common criteria for diagnosis consist of a DAT longer than 20 min and an HDTT greater than 10 min [39–48]. Results of clinical studies have been mixed; some studies have reported sensitivities and specificities of 100% [49] while others have reported poor concordance between scintigraphic results and subsequent manometric studies [48]. Although scintigraphy has enormous appeal as an adjunct to diagnosis, its status in the management of SOD remains unclear.

ERCP with SOM

ERCP with SOM is the gold standard for diagnosis of SOD and the only means to directly measure SO motor activity [44]; however, because of the technical challenges and risk of complications inherent to this procedure, the decision to perform ERCP with manometry is not made lightly. In general, ERCP with SOM should not be considered as a pure diagnostic test unless the severity of the symptoms is such that sphincterotomy would be performed if the results of manometry were abnormal.

Technique

SOM is typically performed at the same time as ERCP. A side-viewing duodenoscope is inserted and advanced to the papilla at which time retrograde cannulation of the sphincter is achieved with a pressure-transducing manometry catheter. All medications that inhibit (anticholinergics, nitrates, calcium-channel blockers, glucagon) or stimulate (narcotics, cholinergics) the sphincter should be avoided for 8–12 h before manometry. Benzodiazepines are not thought to affect SO pressure in humans and are felt to be acceptable for sedation. Likewise, current evidence suggests that meperidine does not affect basal sphincter pressure (although it does affect phasic contraction) if used at a dose less than or equal to 1 mg per kg body weight [50]. Given that basal sphincter pressure is typically the only parameter used to guide SOD therapy, meperidine has been used frequently for conscious

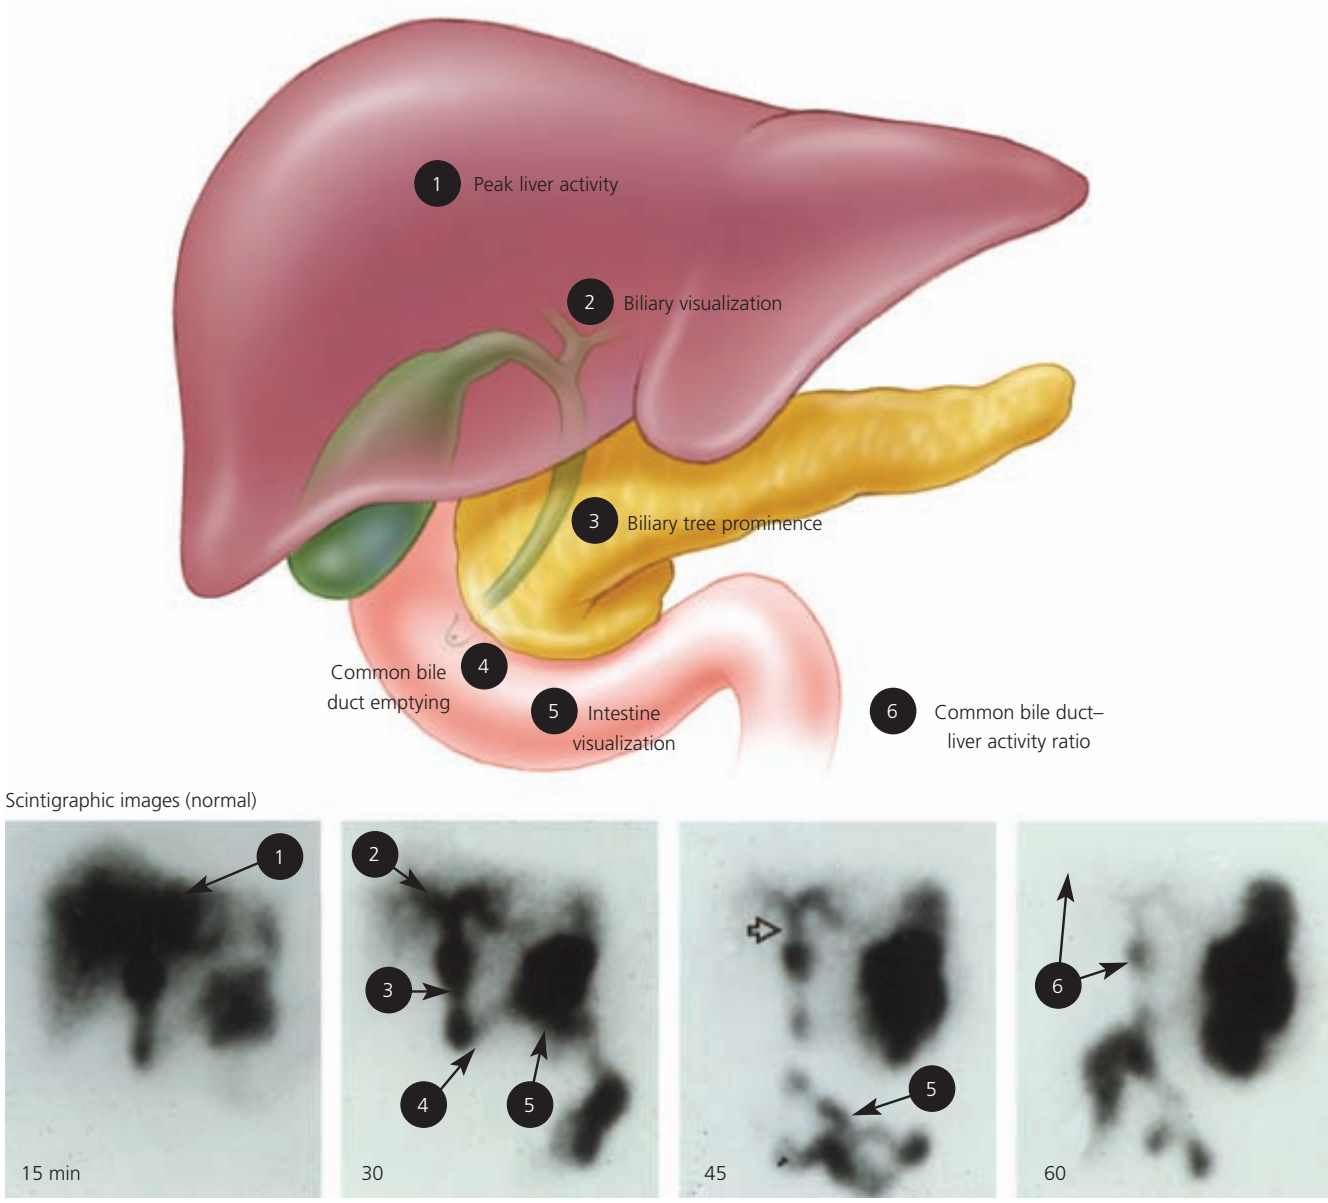

Figure 78.2 Technique of biliary scintigraphy for diagnosis of sphincter of Oddi dysfunction.

sedation at the dosing detailed above. Propofol has also been used for SOM. Although the data showing that propofol does not affect basal sphincter pressure in vivo are limited [51], there are in vitro data showing that propofol has less manometric effect than meperidine [52] – making it "standard of care" for SOM at our institution. If glucagon is needed for cannulation, at least an 8–10 min waiting period is required to allow the basal sphincter pressure to return to baseline before the manometry.

A 5-French, triple-lumen manometry catheter should be used because most standard parameters have been based on this catheter size. Aspiration catheters in which one port is sacrificed to permit end-hole and side-hole aspiration of intraductal fluid and perfusate are recommended because of the decreased risk of associated pancreatitis [23]. A minimally compliant pneumohydraulic capillary infusion system is used to perfuse the catheters. The usual rate of perfusion is 0.25 ml/channel; however, lower rates are used at some centers. Typically, a lower rate will convey an accurate basal sphincter pressure; however, the phasic wave information may not be as accurate. Distilled water is generally the perfusate of choice because saline has been known to crystallize in the capillary tubing and requires frequent flushing.

Selective cannulation of the common bile duct and pancreatic duct is required for accurate manometry. It is possible to distinguish reliably between the two ducts by gently aspirating: yellow-colored fluid signifies entry into the common bile duct; clear liquid signifies entry into the pancreatic duct. On achieving selective cannulation, the next step is to obtain a cholangiogram and pancreatogram before performing SOM

because this may provide additional information obviating the need for manometry. It has been demonstrated that obtaining a cholangiogram before manometry does not significantly alter the manometry results [53]. However, no such data are available for pancreatography.

Following selective cannulation, the manometry catheter is withdrawn across the sphincter at 1-mm to 2-mm intervals by a standard station pull-through technique. If possible, manometry should be studied in both the pancreatic duct and common bile duct because there are data that suggest that abnormal pressure may be detected on only one side in approximately 35%– 64% of patients [15,54–58]. According to at least one report, the manometric abnormality is more likely to be in the pancreatic sphincter in patients with recurrent pancreatitis and is more likely to involve the biliary sphincter in patients with biliary-type pain and elevated liver function tests [55] (Fig. 78.3).

Before performing manometry, it is necessary to either "zero" the catheter in the duodenum or to record continuous intraduodenal pressure with a separate manometry catheter attached to the outside of the endoscope. After this baseline has been established, at least two separate station pull-throughs should be obtained from both sphincters – although, for practical purposes it is often possible to use one pull-through if these results are felt to be of good manometric quality. The highest basal pressure that is sustained for 30 s should be identified. At that point, the four lowest amplitude points in that zone are identified. The mean of these four recordings is labeled as the basal sphincter pressure for that particular lead. The average of the basal sphincter pressures for all interpretable leads is then calculated as the final basal sphincter pressure. Once the basal sphincter pressure is calculated, the amplitude of phasic wave contractions is measured. This consists of the pressure increase from the basal pressure to the peak of the contraction wave. Four sample waves are taken from each lead with the mean pressure representing the phasic amplitude. The duration of phasic waves and frequency per minute can also be computed. However, most authorities rely solely on the basal sphincter pressure for diagnosis of sphincter of Oddi dysfunction as this measurement is more stable over time [16], has stronger interobserver reliability [59], is more reproducible with repeat testing [60], and is associated with response to therapy [16,61]. In addition, there is some evidence to suggest that basal sphincter pressure correlates with biliary pressure (which is markedly easier to calculate); however, this evidence needs to be substantiated in larger trials before it can enter into the realm of standard clinical care [62].

Data establishing normal values for SOM are limited. Perhaps the best data come from Guelrud and associates [63], who evaluated 50 asymptomatic patients for the purposes of measuring intraductal pressure, basal sphincter pressure, and phasic wave parameters. Manometry was then repeated on 10 subjects to establish reproducibility. However, because of the risks inherent with SOM, this study is unlikely to be repeated in a larger sample. At the present time, most authorities use a value of 35 mmHg or 40 mmHg as the upper limit of normal for mean basal sphincter pressure. As stated above, most authorities rely solely on basal sphincter pressure for the diagnosis of SOD.

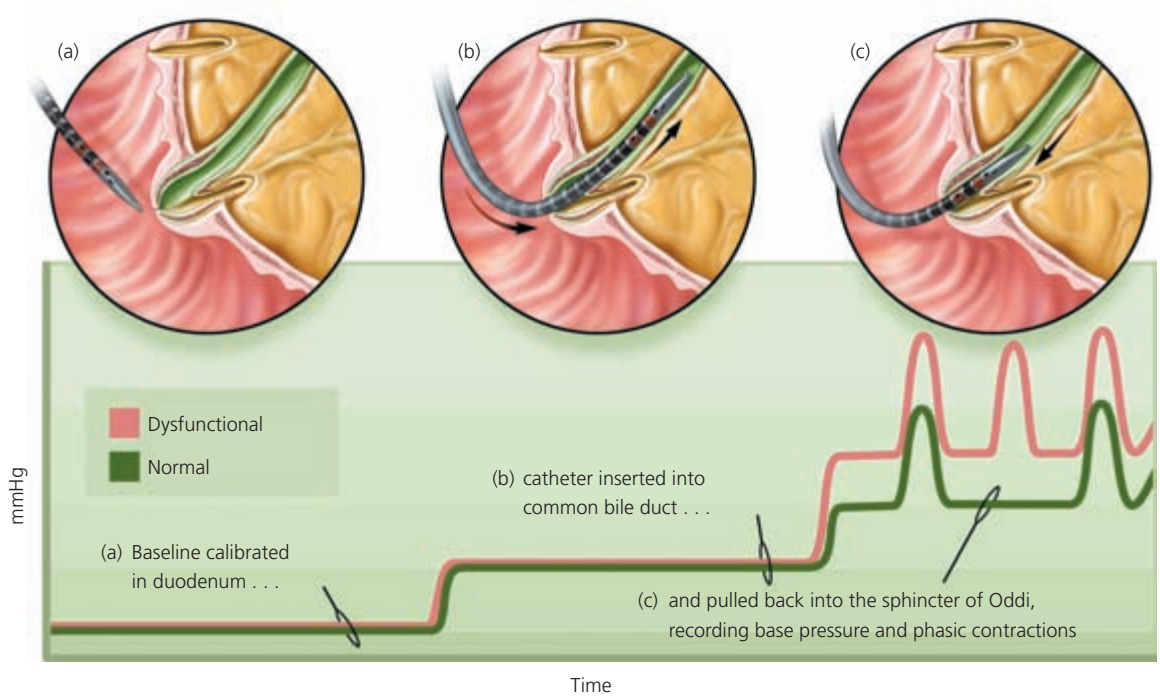

Figure 78.3 Technique of biliary manometry.

Therapy

The goal of therapy in SOD is to improve the impaired flow of biliary or pancreatic secretions into the duodenum. This can be accomplished by pharmacological, endoscopic, and surgical means. The success of therapy rests on the strength of clinical diagnosis. The various treatment options available will be discussed below.

Pharmacological therapy

Medical therapy for SOD has received little focused attention. Given that SOD is felt to result from increased sphincter pressure, theoretical consideration has been given to muscle-relaxing agents such as calcium-channel blockers and nitrates. Nifedipine has been shown to reduce basal SO pressure in volunteers and patients with SOD [64,65]. In a single small placebo-controlled crossover trial, nifedipine was associated with statistically significant decreases in the severity and frequency of pain along with emergency room visits and narcotic usage [66]. However, in vivo studies in the opossum model have shown that nifedipine has greater effects on blood pressure than SO pressure at low doses [67]. A subsequent study showed that nifedipine use was statistically associated with vascular side effects and was no more efficacious than placebo [68].

Nitrates have been shown to decrease SO tone in animal models and in humans [69]. A potential role for nitrates as therapy for SOD was suggested by one case report in which recurrent pain was relieved with nitrate administration; in this particular case, pain resolution was associated with a decrease in both basal and phasic SO activity [70]. To date, there have been no controlled trials of nitrate therapy for SOD.

Acupuncture

Intriguing data from a single pilot study suggests that electroacupuncture may be of therapeutic benefit in relaxing the SO. With selective stimulation of GB34 (*Yanglingquan*), a specific electroacupuncture site located on the lateral surface of the right leg below the head of the fibula, known in Oriental medicine to be a specific acupoint that affects the hepatobiliary system, it was possible to significantly decrease the SO basal pressure as well as the amplitude, frequency, and duration of phasic wave contractions. Moreover, this decrease correlated with an increase in CCK plasma levels. These changes were noted to be partially reversible on discontinuation of acupuncture. However, the study only examined SO pressure for 10 min after the acupoint stimulation, raising questions as to the long-term benefit and clinical relevance of these findings [71]. No long-term studies using acupuncture as therapy for SOD have been published.

Surgery

Surgical therapy for SOD is possible and was historically the mainstay of therapy. The traditional surgical approach includes a transduodenal biliary sphincteroplasty with a transampullary septoplasty (pancreatic septoplasty). There are two theoretical benefits to this approach over endoscopic therapy. First, surgery may reduce the chance of recurrent stenosis due to scarring. Second, a surgical approach may be more effective at relieving pancreatic duct stenosis because of the endoscopic difficulty of severing the transampullary septum without risking duodenal perforation [72,73]. Reported data suggest that between 50% and 60% of patients with biliary-type pain or recurrent pancreatitis treated with surgical sphincterotomy experienced clinical benefit [74–82]. However, there has been some suggestion that patients with pancreatitis may do worse than patients with recurrent biliary-type pain [79].

Despite these benefits, surgical therapy has largely been replaced by endoscopic therapy for numerous reasons: similar clinical outcomes, decreased morbidity, decreased mortality, cosmetic benefits, and increasing endoscopic expertise. Surgical therapy has been reserved for patients with restenosis following endoscopic sphincterotomy and when endoscopic evaluation is not technically feasible [44]. Nevertheless, in many centers, operative therapy continues to be the standard of care because of local expertise [14,83].

Endoscopy

Endoscopic sphincterotomy is the standard of care for patients with sphincter of Oddi dysfunction. Sphincterotomy has been extensively evaluated for different subsets of patients based on the Milwaukee classification and sphincter subset (biliary versus pancreatic). These categories will be addressed below.

Biliary sphincter of Oddi dysfunction

Consensus opinion holds that endoscopic sphincterotomy without sphincter of Oddi manometry is the standard of care for type I SOD. This argument is based on the supposition that type I SOD implies a fixed stenosis in the sphincter; hence explaining the ductal dilatation, prolonged drainage, and abnormal laboratory parameters in the context of symptomatology. In addition, because of the possibility of small tumors in the intrapapillary region leading to a fixed stenotic defect, sphincterotomy is recommended to ensure adequate visualization and suitable biopsy specimens. Nevertheless, this opinion is based on relatively scant clinical evidence and there are no randomized or controlled trials specifically evaluating therapy for type I SOD. In a small retrospective study evaluating 31 patients with type I SOD treated with sphincterotomy, Thatcher and colleagues noted clinical improvement in 87% of patients at a 3-month interval [84]. Boender and colleagues evaluated empiric endoscopic sphincterotomy without manometry in 11 patients with type I SOD and found clinical improvement in 100% of patients at a 2-year follow-up [85]. Rolny and associates described 17 patients with classic type I SOD who underwent manometry followed

by sphincterotomy (although 2 of the 17 patients underwent surgical rather than endoscopic sphincterotomy) [86]. Although all had significant clinical improvement, manometry was normal in 35%. Finally, Cicala and colleagues prospectively evaluated 30 patients with type I or type II SOD using manometry and scintigraphy [47]. Of the 8 patients with type I SOD, 6 accepted endoscopic sphincterotomy and all were clinically improved at follow-up of at least 10 months. Interestingly, when performed in the setting of type I SOD, manometry is normal in a sizeable percentage of cases (ranging from 13% to 65%) and does not appear to correlate with clinical outcome to sphincterotomy [86–89]. Therefore, at the present time, the available evidence for type I SOD indicates that sphincterotomy should be performed empirically because manometry data do not appear to impact clinical outcome and may even falsely exclude patients who would otherwise benefit clinically from therapy.

The data for optimal management in biliary type II SOD patients are not as clear. Theoretically, whereas the etiology for type I SOD patients can be viewed as a fixed stenotic process, type II SOD patients likely represent more of a transient, dyskinetic picture with less convincing evidence (based on radiographic and laboratory data) for SO obstruction. Three randomized controlled trials have been published on type II SOM management (although one only in abstract form). In a landmark study by Geenen and colleagues [16], 47 patients with type II SOD were randomized to sham sphincterotomy or endoscopic sphincterotomy. At 1-year follow-up, clinical improvement was noted in 65% of patients who underwent sphincterotomy compared with only 30% of patients who had undergone a sham procedure. An abnormal basal sphincter pressure was found to be the strongest predictor of benefit and when patients were stratified based on a basal pressure cutoff of 40 mmHg, 91% of patients with abnormal basal pressures experienced clinical improvement with sphincterotomy as opposed to only 25% with normal sphincter pressures. After a cross-over period, 17 of 18 patients with elevated pressures at study entry treated with sphincterotomy were clinically improved after a follow-up of 4 years. Toouli and associates [61] evaluated clinical outcomes to sphincterotomy versus sham sphincterotomy in 81 patients with primarily type II SOD. Sphincterotomy resulted in clinical improvement at 2 years in 11 of 13 (85%) patients with elevated basal sphincter pressures as opposed to only 5 of 13 (38%) patients who underwent a sham procedure; sphincter hypertension was the only statistically significant predictor of improvement. In an abstract, Sherman and colleagues evaluated 23 patients with manometrically documented type II SOD [90]; their data show clinical improvement in 5 of 6 (83%) patients treated with endoscopic sphincterotomy and 8 of 10 (80%) patients treated with surgical sphincteroplasty as opposed to only 1 of 7 (14%) patients treated with sham sphincterotomy. However, data from smaller non-randomized clinical series have been less definitive for patients with type II SOD with several studies showing less impressive results to manometrically guided sphincterotomy [91,92], no significant correlation between manometry and clinical outcome [84,93], or clinical improvement to empiric sphincterotomy without manometry [85,94,95]. Given the discordance in data, there is considerable debate as to whether patients with type II SOD should undergo manometrically guided therapy versus empiric sphincterotomy [96]. It is hoped that additional long-term prospective studies will further address this issue.

Type III SOD by definition consists of pain in the absence of abnormal objective measurements. It is unclear if this truly represents dysfunction of the sphincter itself as opposed to generalized intestinal dysmotility, visceral hyperalgesia, somatization disorders, or other functional abnormalities. Data in this subset are scarce [97]; however, available data support clinical improvement in approximately 30%–60% of patients with manometrically documented sphincter hypertension [90,91,98]. In addition, the complication rates appear to be significant in this population and more prospective information is needed to help guide management in this category.

Recurrent pancreatitis

The differential diagnosis of acute recurrent pancreatitis is broad and includes gallstones, microlithiasis, subclinical chronic pancreatitis, alcohol, structural lesions, tumor, drugs, pancreas divisum, and hypertriglyceridemia. Once these entities have been appropriately excluded, the possibility of SOD becomes significantly more likely. Studies by Coyle and colleagues [99], Sherman and cooleagues [100], and Geenen and Nash [101] demonstrated SOD in 31%, 33%, and 31% of cases of idiopathic acute recurrent pancreatitis, respectively. Toouli and associates identified manometric abnormalities in 25 of 28 patients with idiopathic acute recurrent pancreatitis after an extensive evaluation which was otherwise unrevealing [102].

Data regarding sphincter ablation for pancreatic SOD are largely limited to retrospective case series. However, these data indicate a response rate to sphincterotomy of approximately 50%–80%. Guelrud and colleagues evaluated 16 patients with type II pancreatic SOD [103]. After biliary endoscopic sphincterotomy and 6-month follow-up, 9 of the 16 patients (56%) were asymptomatic. Stone and colleagues evaluated 30 patients treated with sphincter ablation (endoscopic or surgical) for idiopathic acute pancreatitis [104]. In patients with documented sphincter hypertension, clinical improvement was seen in 15 of 18 patients (83%) whereas improvement was only seen in 4 of 12 patients (33%) without documented manometric abnormalities. The groups of Catalano [105] and Sherman [100] reported clinical improvement in 70% and 75% of patients with acute idiopathic pancreatitis and documented sphincteric hypertension treated with sphincter ablation, respectively. Guelrud and colleagues

reported clinical improvement in only 5 of 18 patients (28%) with documented type II pancreatic SOD treated with biliary sphincterotomy alone whereas dual sphincterotomy of both the biliary and pancreatic sphincter (either in one session or two) resulted in improvement in 86% and 77% of patients, respectively [106]. Wehrman and associates reported improvement in 8 of 9 patients (89%) treated with dual sphincterotomy for idiopathic recurrent pancreatitis and documented sphincter hypertension [98]. Coyle and colleagues reported improvement in 20 of 21 patients at 6-month follow-up [99]. However, the studies mentioned above have all been small case-series (most of which were published only in abstract form) and there are no randomized controlled trials evaluating pancreatic SOD. Based on the information above, the current standard of care is to perform manometry and subsequent sphincterotomy if the manometric values are abnormal. However, further studies are needed to guide therapy in this complicated area.

Chronic pancreatitis

Data evaluating pancreatic duct pressure and SOM in patients with chronic pancreatitis have been conflicting. Sphincter pressure has been reported to be normal [107,108], abnormal [54,109], or abnormal only in response to dynamic testing [110]. Moreover, there are data indicating that pancreatic juice viscosity may have a more direct impact on pancreatic duct pressure than sphincteric pressure [110,111]. The relationship between SOD and chronic pancreatitis was explored by Tarnasky and associates [112]. One hundred and four patients with presumptive biliary SOD (of whom 68 had confirmed sphincteric hypertension) underwent evaluation with endoscopic ultrasonography, pancreatography, and secretin stimulation intraductal function testing. Chronic pancreatitis was demonstrated in 29% of patients with confirmed sphincter hypertension as opposed to only 7% of those without SOD. At the present time, it is unclear if SOD directly leads to chronic pancreatitis or if changes associated with subtle chronic pancreatitis may induce alteration of the sphincteric pressure. It is hoped that this relationship will be clarified in subsequent studies. There is no clearly defined role for SOM in the setting of chronic pancreatitis.

Stenting, balloon dilatation, and botulinum toxin injection

Balloon dilatation of the SO was postulated to be of benefit in treating SOD under the supposition that it would be less invasive than sphincterotomy and may preserve anatomical function. However, the complication rate with this procedure was shown to be unacceptably high and there is no role for balloon dilatation in the management of sphincter of Oddi dysfunction [113]. Likewise, biliary stent placement has been evaluated for symptom relief in this disorder with similarly unacceptable complication rates [114]. Neither balloon dilatation nor stent placement (as an alternative to sphincterotomy) can be supported for the treatment of SOD.

Botulinum toxin (Botox) is a potent inhibitor of acetylcholine release that has been studied extensively in various motility disorders in the gastrointestinal tract including achalasia and gastroparesis. In a pilot study, botulinum toxin injection into the SO resulted in a significant decrease in basal sphincter pressure and improved biliary flow [115]. In a subsequent study, response to botulinum toxin in type III SOD was used as a variable to predict response to sphincterotomy [116]. In this study, 22 patients with manometrically documented type III SOD underwent botulinum toxin injection into the intraduodenal sphincter segment. Of the patients with a clinical response to botulinum toxin injection, 11 of the 12 patients later benefited from endoscopic sphincterotomy. Of the 10 patients who did not experience clinical improvement with botulinum toxin injection, only 2 of the 10 had clinical improvement with subsequent sphincterotomy. Botulinum has also been explored as a means to decrease post-ERCP pancreatitis following sphincterotomy. In a randomized controlled study of 26 patients who underwent SOM with sphincterotomy, postsphincterotomy injection of botulinum toxin resulted in a trend towards decreased postERCP pancreatitis [117]. However, this did not reach clinical significance and the rate of post-ERCP pancreatitis in this study appears to be higher than generally reported, raising questions as to the applicability of these results. More clinical data are needed before botulinum toxin can enter into the armamentarium of treatment for SOM and its use remains experimental within the context of clinical trials.

Complications

Pancreatitis is the most common major complication following SOM with reported rates as high as 31% with use of a standard perfusion catheter [22,23,118]. These numbers emphasize the risk associated with manometry and they have limited the widespread application of this diagnostic modality. Several methods have been proposed to decrease the incidence of postmanometry pancreatitis, including the use of an aspiration catheter, gravity drainage of the pancreatic duct after manometry, decrease of the perfusion rate to 0.05–0.10 ml/lumen/min, limitation of pancreatic duct manometry time to less than 2 min, and use of a nonperfused manometry system [119–121]. Moreover, if manometry is abnormal and sphincterotomy is performed, routine temporary stenting of the pancreatic duct has been shown to decrease resultant pancreatitis [122]. As has been detailed above, botulinum toxin has also been studied in this context. Using an aspiration catheter (allowing aspiration of the perfused fluid from end and side holes while simultaneously recording pressure from the two remaining side-ports), Sherman and associates were able to decrease the risk of manometry-induced pancreatitis from 31% to 4% in a series of 76 patients [23]. Using many of the above modifications

and careful patient selection criteria, more recent quotations of post-ERCP pancreatitis for patients with SOD undergoing manometry and sphincterotomy have been in the realm of 8% [123].

Approaches to treatment failure

There are several potential explanations for an apparent failure for adequate biliary sphincterotomy in a patient with well-documented SOD. First, the pain may not be of pancreatobiliary etiology. There are increasing data linking type III SOD with altered gastrointestinal motility, functional bowel disorders, hyperalgesia, somatization, depression, and anxiety as compared to control subjects [124–128]. Second, the biliary sphincterotomy may have either been inadequate or the site may have restenosed. Data on the incidence of restenosis are extremely limited; however, the one study to examine this issue reported a rate of 4.7% over a follow-up period of 7 years [129]. In these cases, the standard of care is to repeat sphincter ablation; however, there are no data available concerning the symptoms of these patients compared to control patients without restenosis.

A third possibility is pancreatic sphincter hypertension in cases where a dual sphincterotomy was not performed. Eversman and associates reported abnormal pancreatic sphincter pressure in 90% of patients with pancreatitis or persistent pain after biliary sphincterotomy [130]. Likewise, Soffer and Johlin reported abnormal pancreatic sphincter pressure in 25 of 26 patients with SOD who failed to respond to biliary sphincterotomy [131]. Finally, Elton and colleagues performed pancreatic sphincterotomy on 43 patients with type I or type II SOD who failed to respond to biliary sphincterotomy alone [132]. Following this procedure, 72% of the patients were asymptomatic. These studies have led many experts to recommend dual sphincterotomies rather than biliary sphincterotomy alone. Research into this issue is ongoing.

A fourth possibility is that certain patients with presumed SOD may in fact have subtle hitherto-undiagnosed chronic pancreatitis. Chronic pancreatitis is clearly associated with SOD and this may either cloud the diagnosis of SOD or explain an apparent lack of response to seemingly appropriate therapy. Tarnasky and colleagues demonstrated the presence of chronic pancreatitis in 20 of 69 patients with confirmed sphincter hypertension [112]. Moreover, patients with chronic pancreatitis have been shown to have a significantly decreased clinical response compared to control patients with SOD and to have no evidence of chronic pancreatitis. This was illustrated by Okolo and associates in a retrospective case series in which a significantly higher rate of recurrent pain was seen in patients with SOD and chronic pancreatitis (42%) when compared with patients with SOD but no evidence of chronic pancreatitis (27%) [133].

A final possibility is the presence of an obstructing lesion not previously identified such as a tumor, stricture, or stone either leading to an initial misdiagnosis or developing since the initial work-up. Given this possibility, a reevaluation of the sphincter with contrast is always recommended in this scenario.

Controversies

Although it has been approximately 30 years since the advent of biliary manometry [134] there is still much that remains unknown with regards to the appropriate diagnosis, treatment, natural history, and outcome of SOD. Whereas consensus is reasonably clear with regard to type I SOD, considerable debate exists regarding the optimal management of the remaining categories. Should patients with type II SOD undergo mandatory manometry before sphincterotomy? Is there a way to better define patients with type III SOD to lessen the risk of pancreatitis in this population and optimize which patients will benefit from sphincterotomy? When therapy is offered, should the initial therapy of choice be a dual sphincterotomy, biliary sphincterotomy, or selective sphincterotomy depending on the nature of the presenting symptoms? Given that manometry is abnormal in approximately one-third of patients with type I SOD, how reliable is manometry using a single time-point in the remaining, less objectively defined categories? Is there a way to increase the diagnostic yield of manometry either at a single temporal interval or through the development of a safe ambulatory technique to optimize the diagnostic yield? Is there a way to better predict which patients will respond to invasive therapy before subjecting those patients to the risks of manometry and sphincterotomy? How reliable are noninvasive diagnostic studies and is there a way to optimize these modalities? Should evaluation for this disorder even be considered in patients with an intact gallbladder?

These questions need to be addressed through randomized controlled studies. With this information, it is hoped that a universal standard of care can be developed to better guide management of this difficult disorder.

Conclusion

SOD is a complicated disorder that is challenging to diagnose and treat. At the present time, although numerous questions remain, the following general conclusions can be offered. Patients should be stratified according to the Milwaukee criteria after more common causes of recurrent postprandial abdominal discomfort have been eliminated. Patients with type I SOD should be offered sphincterotomy. There is debate regarding the necessity of manometry in type II SOD patients but we believe that manometry should be offered before therapy given the results of randomized controlled trials. Manometry is mandatory before sphincterotomy for patients with type III SOD. Given the high rate of post-ERCP

pancreatitis in this population, all efforts should be made to exclude other diagnoses before considering SOM and the procedure should only be performed by a practitioner who is skilled in the technical aspects of this disorder.

G LIVER

79 Liver: anatomy, microscopic structure, and cell types

Gary C. Kanel

Embryology, 2057
Gross anatomy, 2059
Microanatomy, 2061
Functional components: liver cell heterogeneity, 2070
Stem cells, 2070

The liver is a unique organ with a wide range of both structural and physiological functions. Understanding the arrangements of all the individual components of the liver on both gross and light microscopic examination assisted by electron microscopic and immunoenzymatic features allows a better understanding of liver histopathology and pathophysiology. Study of the embryological evolution of the hepatic and hepatobiliary elements also assists in understanding many of the key concepts in developmental abnormalities seen in a wide variety of pediatric and adult liver diseases. This chapter outlines the gross and microscopic characteristics of the liver and briefly addresses liver function, with an introductory presentation of embryological development.

Embryology

The hepatic primordium anlage first appears toward the end of the third week of gestation and is seen as a hollow midline outgrowth stalk (hepatic diverticulum) of the endodermal epithelium at the distal aspect of the foregut (future duodenal loop) [1–7]. By the fourth week, the diverticulum enlarges by way of proliferation of the endodermal cell strands (hepatoblasts) and projects cranially into the mesoderm of the septum transversum (the mesodermal plate between the pericardial cavity and the yolk sac stalk), eventually giving rise to the hepatic parenchyma and intrahepatic duct structures (Fig. 79.1). The cephalic end ultimately develops into the right and left hepatic lobes. The stalk between the diverticulum and foregut narrows, forming the extrahepatic biliary system and gallbladder. The proliferating endodermal cells initially form solid cords, which then anastomose and form isolated vesicles and cribriform tubules with centrally located lumenal structures (biliary canaliculi). The cords eventually become confluent and form channels that subdivide the cords by small capillaries, which co-mingle with the developing vitelline and umbilical veins. These channels ultimately form the hepatic sinusoids. The individual hepatoblasts are progenitor cells that develop into the mature hepatocyte, with those cells immediately adjacent to the portal mesenchyme becoming the ductal plates [8]. The rapid growth rate of the hepatic cords allows sheets several cells thick, termed *muralium multiplex*, to develop; these persist until birth, after which the cell sheets narrow to two cells (*muralium duplex*) and eventually evolve into a one cell thick trabecular cord (*muralium simplex*) by 5 years of age [9,10].

The mesoderm of the septum transversum initially surrounds the liver and is in continuity with the lesser curvature of the stomach, duodenum, and ventral body wall. The mesoderm becomes stretched between the liver and lesser curvature, forming the lesser omentum, and between the diaphragm and ventral abdominal wall, forming the falciform, coronary, and triangular ligaments. A portion also develops into the hepatic (Glisson) capsule. The developing hepatic artery and vagus nerve branches follow the mesoderm along and adjacent to the portal vein. The mesoderm on the liver surface is also in continuity with the peritoneum, whereas that portion in contact with the future diaphragm remains uncovered (*bare area*). The mesoderm is the main focus for the development of hematopoiesis, which begins at about 6 weeks and becomes most active during the sixth and seventh months, then rapidly regresses owing to developing bone marrow activity. Hematopoiesis is responsible for the prominent liver size in the fetus (up to 10% body weight by week 10, with the liver occupying most of the abdominal cavity) but regresses at birth so that only a few islands of hematopoietic cells are noted. The liver then weighs about 5% of body weight. Hematopoiesis is usually absent by 4 weeks of age. Initially, the enlarged fetal liver has symmetric right

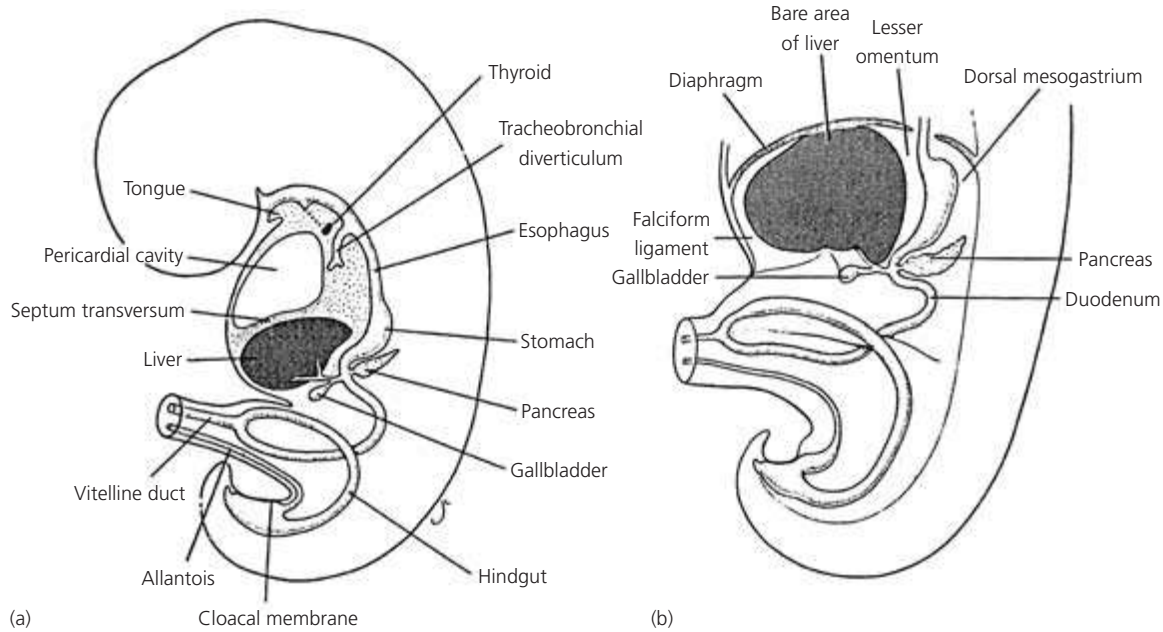

Figure 79.1 Developing embryo. **(a)** The drawing represents a 9-mm embryo, estimated at about 36 days' gestation. The liver is derived from the hepatic diverticulum (midline outgrowth stalk of the distal foregut) and projects cranially into the septum transversum and caudally into the abdominal wall. **(b)** The drawing represents an embryo that is slightly older, with the falciform ligament noted between the hepatic parenchyma and the anterior abdominal wall. From Langman [5] with permission from Lippincott, Williams & Wilkins.

and left lobes; with time, however, the growth rate diminishes but affects the left lobe more than the right, causing the size difference seen at birth. The caudate and quadrate lobes develop as subdivisions of the right lobe.

The vascular network is originally derived from the development of both the vitelline and umbilical veins and occurs at the same time as proliferation of the hepatoblasts. The cords and vessels anastomose, forming the hepatic sinusoids. The sinusoidal plexus initially receives blood through the vitelline vein and is drained into the sinus venosus, but by the fifth week the right and left umbilical veins also supply blood to the sinusoidal plexus. By the fifth week, most of the major vessels are identified and include the right and left umbilical vein, the transverse portal sinus, and the ductus venosus, which shunts blood directly from the umbilical vein into the inferior vena cava. At this time, the left umbilical vein becomes the main source of blood flow, with the right umbilical vein becoming atrophic by the fifth week. The portal vein develops from the vitelline vein and then subdivides into the right and left branches. The hepatic and portal vein branches divide the parenchyma into lobules and acini. The left umbilical vein blood flow has three major branching routes: through the sinusoidal plexus of the left half of the liver; through the sinusoidal plexus of the right half of the liver by retrograde flow from connections with the left branch of the portal vein; and through the ductus venosus. At birth, a sphincter mechanism closes the ductus venosus, causing cessation of blood flow through the umbilical vein, with the liver now receiving blood from the left branch of the portal vein. The resultant closed segment of the umbilical vein then becomes the umbilicus, and the fibrotic ductus venosus becomes the ligamentum venosum.

The biliary apparatus develops from membranous infolding occurring between the junctional complexes between individual hepatoblasts and appears initially as intercellular spaces with no distinct wall. The biliary canaliculi are first seen at week 6, with bile synthesis occurring by week 9 and bile secretion by week 12. The hepatoblasts immediately adjacent to the mesenchyme of the portal tracts form the ductal plate, which is two-layered; by 3 months, a lumen is seen within the ductal plate, with formation of double-layered tubular structures. Invasion of these cells into the portal mesenchyme occurs, forming an anastomosing network of portal duct structures. These ducts are not fully developed at term [11], after which remodeling forms the true interlobular bile ducts that assume their major role as a link between the canalicular biliary apparatus and the extrahepatic biliary tree. This biliary network is fed by a hypervascular complex of arterioles and capillaries formed from the peribiliary plexus. The immature structures at birth may persist for up to 1 month. The extrahepatic biliary tree develops from the stalk of the original hepatic outgrowth.

Individual cell functions become apparent at different but early times in embryological development [9,12,13]. α-Fetoprotein, which is found in high amounts at birth, initially is present by 1 month gestation. Glycogen may be seen

by 2 months, with glycogen synthesis becoming most apparent by 3 months; at birth, the amount of glycogen rapidly diminishes owing to rapid and active glycogenolysis. Fatty change within the hepatocyte parallels that of glycogenesis. Hemosiderin is usually visible in early stages and becomes most marked as intrahepatic hematopoiesis decreases; it then gradually decreases but may still be seen at birth in the periportal hepatocytes. The perisinusoidal cells and Kupffer cells appear by 3 months' gestation.

Gross anatomy

The liver takes up the majority of the right upper abdominal cavity and extends from the right lateral aspect of the abdomen 15–20 cm transversely toward the xiphoid [1,2,14–16]. The weight of the adult liver varies from 1200 to 1800 g, dependent on overall body size, and constitutes about 1.8%–3.1% of total body weight; however, at birth, the liver is larger compared with adjacent thoracic and abdominal viscera and constitutes about 5%–6% of body weight [1,17,18]. Anatomically, the liver has four lobes: right, left, caudate, and quadrate. The right lobe accounts for half to two-thirds of total liver volume; however, functionally, the right and left lobes are of about equal size and are divided by a line extending from the inferior vena cava superiorly to the middle of the gallbladder fossa inferiorly. A total of eight functional segments are present, each demarcated by the vascular and biliary drainage [1,2,9,14,19–21] (Fig. 79.2): the lateral (segments VI and VII) and medial (segments V and VIII) divisions of the right lobe, the medial (segment IV) and lateral (segments II and III) divisions of the left lobe, and the caudate lobe (segment I), the latter a watershed area of the right and left lobe vasculature.

The hepatoduodenal ligament connects the liver to the superior aspect of the duodenum and supports the hilar vessels and duct structures. The transverse fissure separates anteriorly the right lobe from the caudate lobe, whereas the umbilical fissure is located to the left of the quadrate lobe, which itself is bordered on the right by the gallbladder. The peritoneal layers forming the falciform ligament, which extends between the liver and the anterior abdominal wall, separate to form the superior layer of the coronary ligament and the left triangular ligament. The ligamentum teres is located along the lower edge of the falciform ligament and contains the obliterated umbilical vein remnant. The total surface area of the liver is structured by direct continuity with the surrounding abdominal organs, ligaments, and fascia.

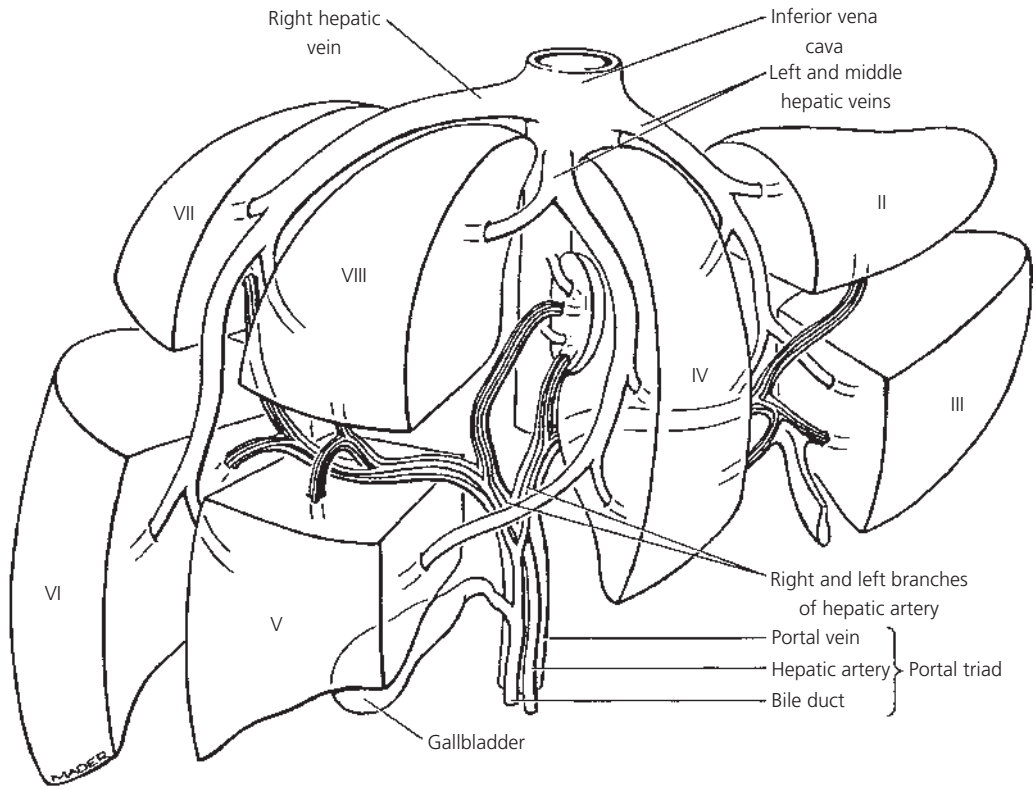

Figure 79.2 Anatomical and functional subdivisions. The liver is divided into eight functional anatomical segments, each having its own vascular flow and biliary drainage. These include the right lateral (segments VI and VII) and medial (segments V and VIII) divisions, the left medial (segment IV) and lateral (segments II and III) divisions, and the caudate lobe (segment I). From Moore KL, Dalley AF II. Clinically Oriented Anatomy, 4th edn. Philadelphia: Lippincott, Williams & Wilkins, 1999.

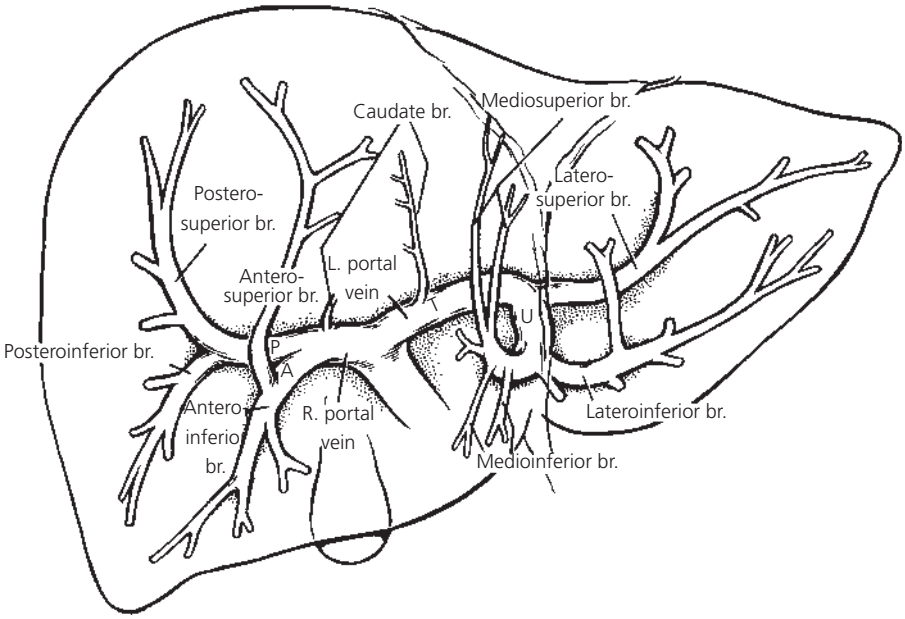

Figure 79.3 Intrahepatic branches of the portal vein. A, anterior segment; br., branch; L., left; P, posterior segment; R., right; T, pars transversus; U, embryonic ductus venosus. From Skandalakis LJ, Colborn GL, Gray SW, et al. Surgical anatomy of the liver and extrahepatic biliary tract. In: Nyhus LM, Baker RJ (eds). Mastery of Surgery, 2nd edn. Boston: Little, Brown, 1992.

The portal vein is the main route of vascular drainage of the gastrointestinal tract and is formed by merger of the superior mesenteric and splenic veins. It also receives blood from the coronary and cystic veins. The portal vein is located along the hepatoduodenal ligament posterior to the hepatic artery and common bile duct and ends at the porta hepatis at the main lobar fissure, dividing into the right and left main branches. The right branch divides early into anterior and posterior segments, whereas the left branch divides into two segments: the pars transversus, which extends to the left in the porta hepatis, and the pars umbilicus, which descends into the umbilical fossa in line with the left segmental fissure. The caudate lobe veins arise from both the right and left main portal vein branches (Fig. 79.3).

The hepatic vein is composed of three major tributaries (right, middle, left), each having intrahepatic branches. The middle and left hepatic veins often converge to form a single outflow vessel before draining into the inferior vena cava, whereas the right hepatic vein opens through a separate ostium. The caudate lobe drains directly into the inferior vena cava.

The hepatic artery is a branch of the celiac artery and ascends along the hepatoduodenal ligament and eventually divides into the right and left main branches. The right hepatic artery is usually seen behind the common hepatic duct after giving rise to the cystic artery, and eventually divides into the anterior and posterior segmental branches. The left hepatic artery passes obliquely upward and to the left in the porta hepatis, eventually dividing into the medial and lateral segmental branches. The quadrate lobe is fed by a middle hepatic artery branch, whereas the caudate lobe is fed by both right and left hepatic artery branches.

The biliary system originally arises from the bile canaliculi and can be grossly demonstrated in the larger interlobular branches. The biliary drainage of the right lobe is derived from anterior and posterior segmental branches that merge to form the right hepatic duct. Lateral and medial segmental branches merge to form the left hepatic duct that drains the left lobe. The caudate lobe is drained from three duct branches directly into the right and left hepatic ducts (Fig. 79.4). The smaller ducts do not have a distinct wall, but the larger septal branches demonstrate a thin wall secondary to periductal collagen fibers and can easily be demonstrated on gross inspection. The bile duct structures are directly fed by the hepatic artery and its branches, which parallel the ducts as they course through the various hepatic segments.

The lymphatic channels provide both sympathetic and parasympathetic innervation and are divided into deep and superficial branches. The deep lymphatic branch parallels the portal and hepatic vein branches, whereas the superficial lymphatic structures arise from the capsule of Glisson and drain through the adjacent falciform ligament, diaphragm, esophagus, and hilar lymph nodes [1,2,22].

The nerve supply parallels the main hepatic artery and portal vein and is divided into parasympathetic and sympathetic fibers. The former are preganglionic and derived from the vagus nerve, whereas the latter are postganglionic and receive their nerve supply from T7 through T10. The nerve supply enters the hepatic hilum through both anterior and posterior routes and feeds the arteries and bile ducts through sympathetic innervation. The nerve fibers branch through the main portal tracts, with smaller unmyelinated branches feeding the periportal hepatocytes. In addition, many of the nerve fibers terminate on endothelial cells lining the smallest

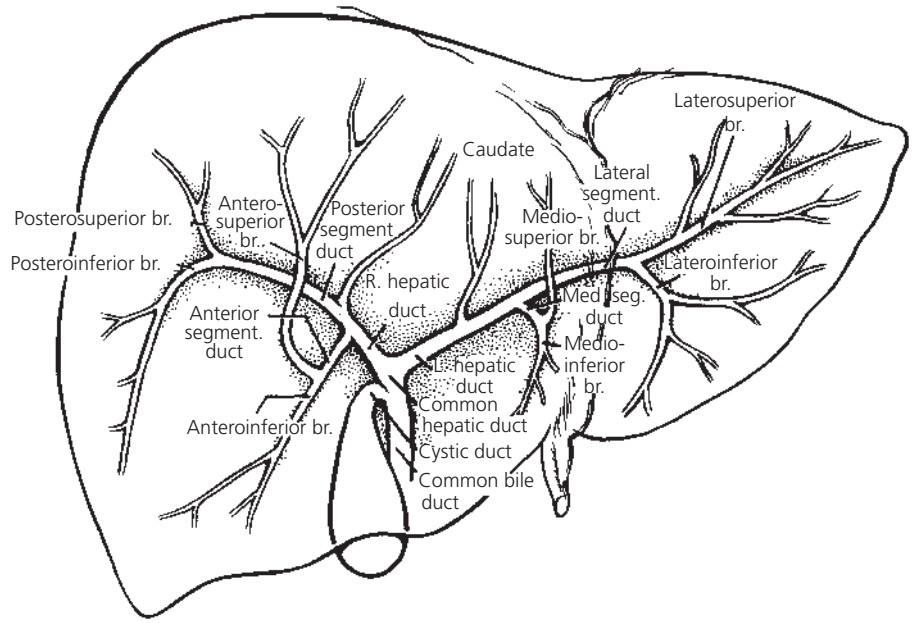

Figure 79.4 Branching segments of the intrahepatic bile ducts. br., branch; L., left; R., right. From Skandalakis LJ, Colborn GL, Gray SW, et al. Surgical anatomy of the liver and extrahepatic biliary tract. In: Nyhus LM, Baker RJ (eds). Mastery of Surgery, 2nd edn. Boston: Little, Brown, 1992.

arterioles and along Kupffer cells, stellate (fat-storing) cells, and hepatocytes [23].

Microanatomy

Normal histology

Architecture

The basic microanatomical structure of the liver can best be appreciated on a three-dimensional drawing of the portal tracts, parenchyma, and vascular flow (Fig. 79.5). This architectural arrangement is evenly spaced throughout all lobes of the liver and is best assessed under low- and medium-power microscopy [24,25]. Although the portal inflammatory and cellular components and the size of the liver cell plates vary, dependent on the developmental stage of the liver, the architectural framework can be seen in fetal liver as well. Although the architecture may at times be difficult to assess when acute liver injury is present, on recovery the arrangements universally return to normal; on the other hand, the distortion of the architecture seen in advanced chronic liver disease is for the most part irreversible.

Portal tracts

The portal tracts (Fig. 79.6) are often referred to as *portal triads*; this term is misleading in that more than three components are present. The interlobular bile ducts number from one to two per portal structure, although in infants the ducts appear early on to be slightly less frequent. The ducts are usually seen immediately adjacent to the hepatic arterioles, which are responsible for their blood supply. The hepatic arterioles are usually present singly. The portal venules similarly are a single structure, although transverse cuts of the portal tracts in biopsy material can mistakenly appear as if two or more ducts and vessels are present. True increase in portal venules and lymphatics are characteristic of portal hypertension and are usually seen in conjunction with portal fibrosis or cirrhosis. The fibrous tissue that supports the major portal components varies in amount, depending on the distance of the portal tract from the hepatic hilum, and can mistakenly be described as *fibrotic* when the biopsy specimen is taken toward the hilum. The infiltrating cellular inflammatory components within the fibrous tissue consist of scattered lymphocytes, which are scanty but often present to some degree even in normal liver.

Parenchyma

In adults, the hepatic lobules constitute about 80% of the total hepatic volume and are composed predominantly of liver cell cords one cell thick made up of polyhedral hepatocytes. The adjacent sinusoids are lined by both endothelial cells and Kupffer cells. The perisinusoidal space is located between the endothelial cells and hepatocytes. Stellate cells and collagen fibers are also present along the perisinusoidal space, but on routine hematoxylin and eosin staining of normal liver tissue, these structures are usually inconspicuous. The sinusoids drain from the portal venule and hepatic arterioles into the terminal hepatic venules (Fig. 79.7).

Parenchymal cellular components

Hepatocyte

The hepatocyte comprises about two-thirds of the total number of cells within the liver and about four-fifths of total liver volume [1–3,26–28]. Hepatocytes generally measure

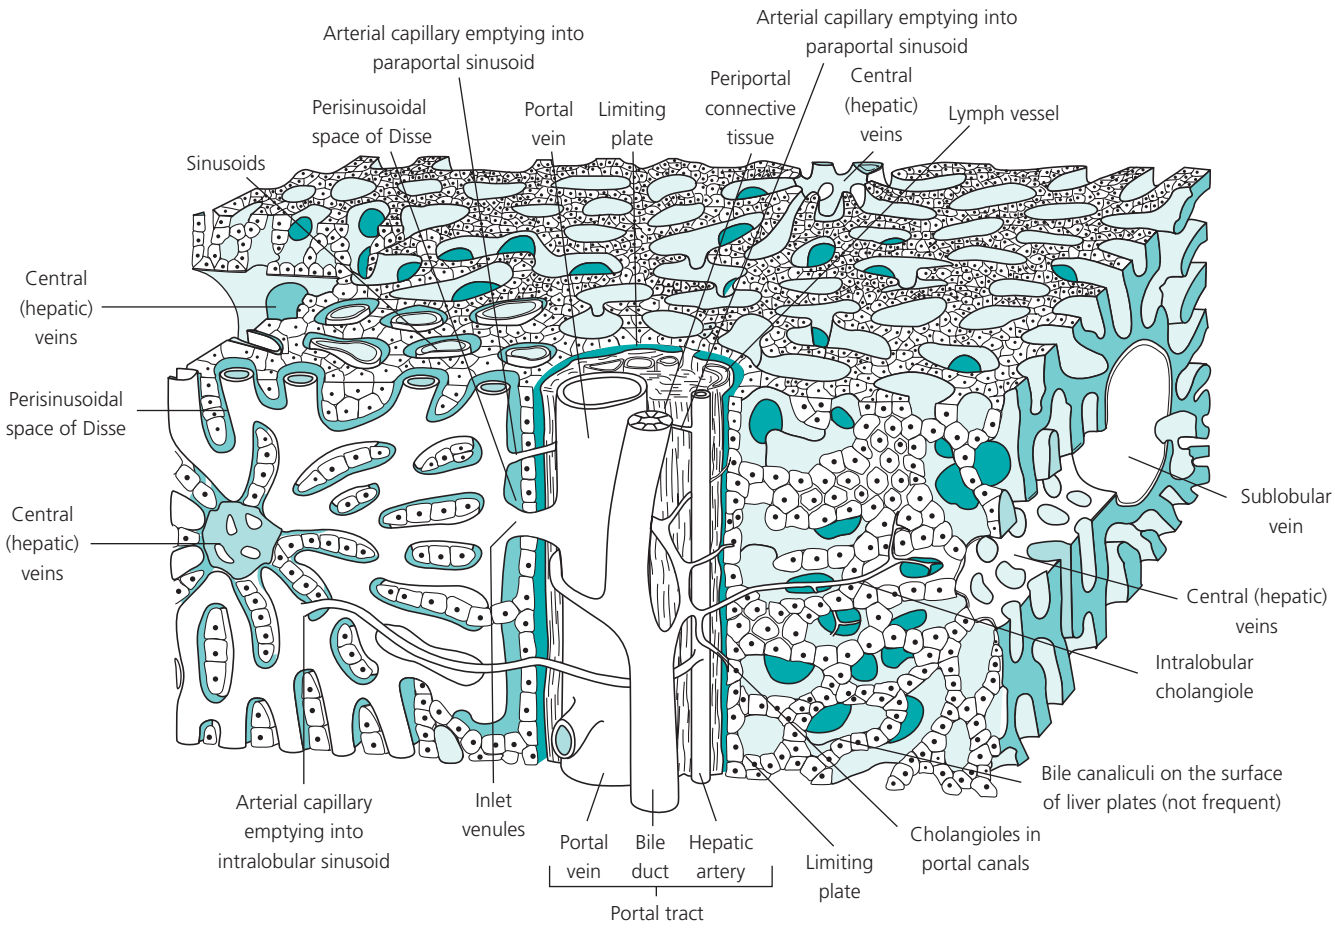

Figure 79.5 Structure of the normal liver. From Sherlock & Dooley [2], with permission from Blackwell Publishing.

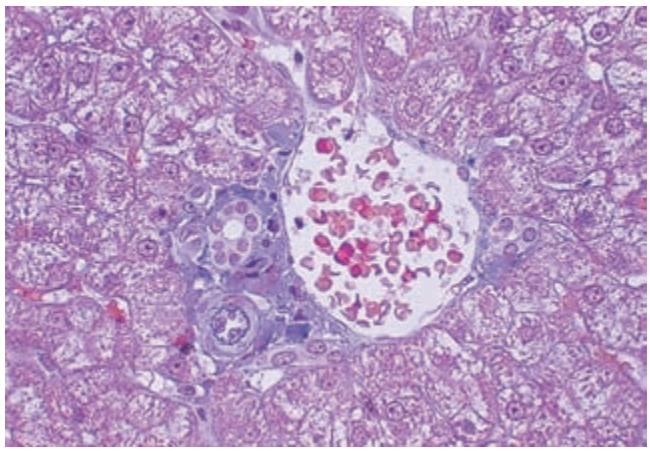

Figure 79.6 Portal tract (Masson trichrome). The major components include the hepatic arteriole, portal venule (large vessel), and bile ductule (cuboidal epithelium). There is a normal amount of collagen seen in this portal tract.

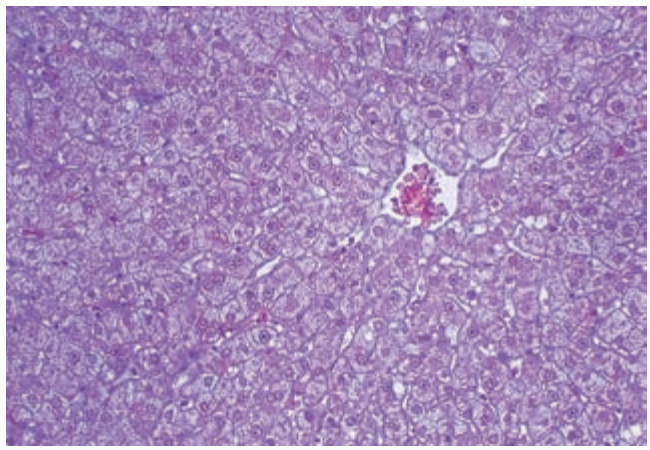

Figure 79.7 Parenchyma. The liver cell plates are one cell thick and are composed of polyhedral hepatocytes with centrally placed nuclei. These cells are bordered by sinusoids lined by both Kupffer and endothelial cells. The sinusoids drain directly into the terminal hepatic (central) venules.

25–40 μm in diameter, depending on their zonal location and patient age, and are polyhedral and multifaceted. The cells in the adult are arranged in cords that are one cell thick and have three distinct cell boundaries: sinusoidal, lateral (intercellular), and canalicular membranes [9,26]. The sinusoidal or basolateral surface area constitutes about 60%–70% of the total surface area. Microvilli measuring about 0.5 μm in length can be seen along the surface extending into

the perisinusoidal spaces. The lateral membranes lie between adjacent hepatocytes and constitute about 15% of the surface area. They are divided into a number of junctional subunits [1,26]. Gap junctions represent two adjacent membranes with a distinct 2- to 4-μm gap, whereby communication between cells for transport of metabolites occurs by way of projected particles (*bobbins*) directed from each cellular membrane. No microvilli are seen. Desmosomes are attached to the intermediate filaments and play a role in the resilience of the cell membrane. Intermediate junctions are attached to various cytokeratin filaments that also aid in cellular resilience. Tight junctions are zones of contacted membranes and represent a permeability barrier to macromolecules [29].

The canalicular membranes constitute about 15% of membrane surface area, lie toward the center of the intercellular junction, and represent the origin of biliary drainage (Figs 79.8 and 79.9). They are lined by microvilli and measure in diameter from 0.5 μm in the perivenular zone (zone 3 of Rappaport) to 2.5 μm in the periportal zone (zone 1).

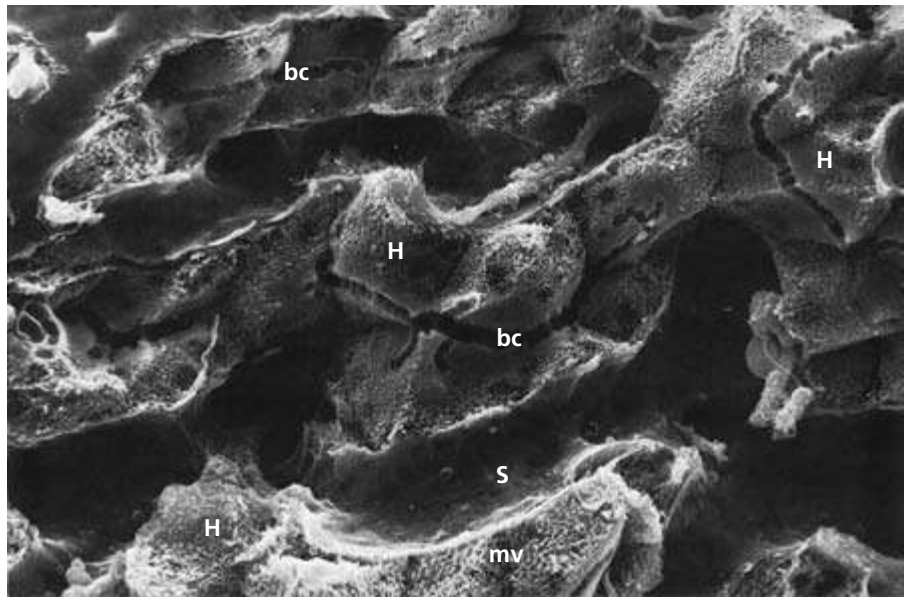

Figure 79.8 Biliary canaliculi. Using scanning electron microscopy, the liver cell plates and adjacent sinusoids (S) are seen with the bile canalicular (bc) network located between the adjacent hepatocytes (H). Microvilli (mv) are also present. From Phillips et al. [26].

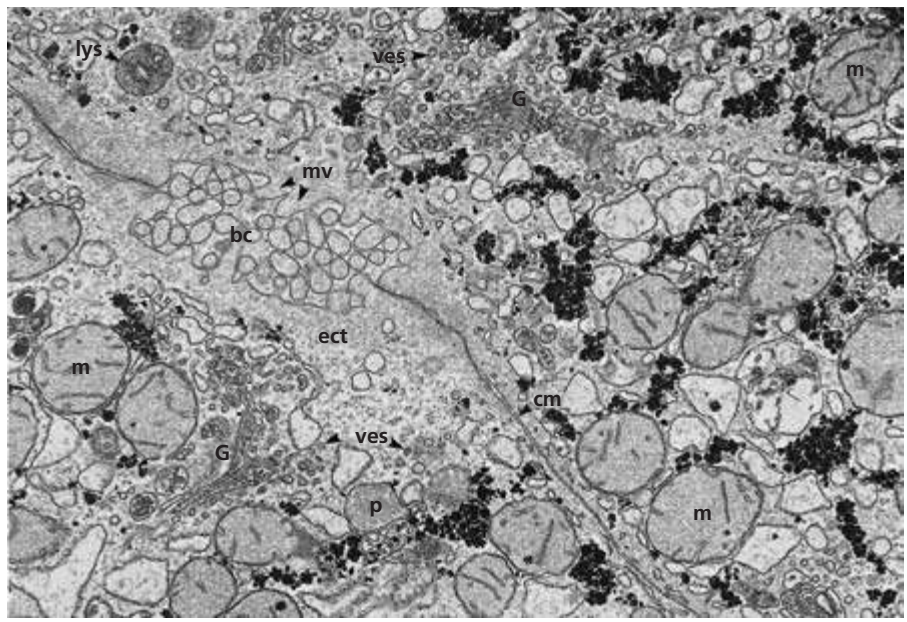

Figure 79.9 Biliary pole. Using electron microscopy, the bile canaliculi (bc) can be seen to the left of the field, surrounded by microvilli (mv) and pericanalicular ectoplasm (ect). Golgi complexes (G), vesicles (ves), mitochrondria (m), peroxisomes (p), and lysosomes (lys) can also be seen in the adjacent liver cell cytoplasm. cm, liver cell membrane. From Phillips et al. [26].

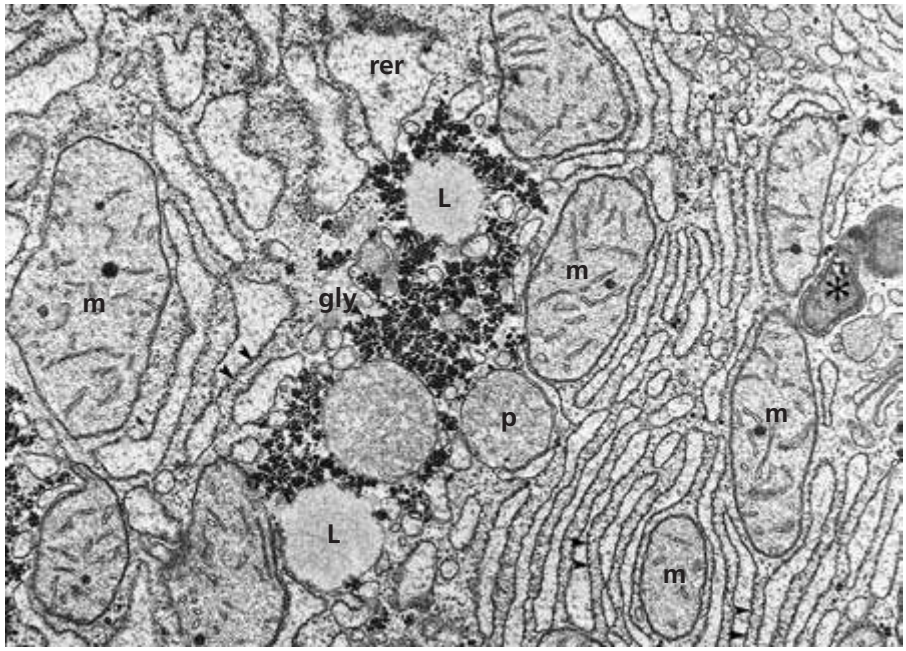

Figure 79.10 Liver cell cytoplasm. Using electron microscopy, the cytoplasm is composed of rough endoplasmic reticulum (rer), mitochondria (m), glycogen (gly), lipid droplets (L), peroxisomes (p), and secondary lysosomes (*). From Phillips et al. [26].

Nucleus

The liver cell nucleus is centrally located within the hepatocyte, measures about 10 µm in diameter, and contains clumped chromatin and nucleoli [26,30]. The nuclear membrane is composed of two envelopes separated by a narrow zone. These membranes have numerous apertures or pores that provide cytoplasm–nuclear communication. The outer membrane is often lined by ribosomes, which are in direct communication with adjacent rough endoplasmic reticulum fibers. The intranuclear chromatin fibers are composed of heterochromatin, which is round to irregular dense metabolically inactive granules, and euchromatin, which actively transcribes RNA [26]. Anywhere from one to six nucleoli can be seen, their number and size in direct proportion to their degree of activity (ribosomal RNA function). The hepatocyte usually contains one nucleus, although bilobed forms may also be seen that are more often identified in the elderly population. Mitotic figures are infrequent but may be prominent in instances of active liver cell regeneration (e.g., resolving acute viral hepatitis). Various nuclear inclusions may be identified [26,31,32] and include glycogen (frequently seen in diabetic patients), lipid, and cytoplasmic invaginations (pseudoinclusions, or nuclear membrane irregularities).

Cytoplasm

The cytoplasm constitutes about 90% of the volume of the hepatocyte and contains numerous functionally important organelles (Fig. 79.10). The cytoplasm and intracellular components vary in size, ultrastructure, and function depending on the zonal location of the hepatocytes (see Functional components: liver cell heterogeneity; see also Tables 79.1 and 79.2). The superstructure is maintained by the cytoskeleton

Table 79.1 Liver cell structural zonal variations

Zone 3 (perivenular)
Mitochondria: round; less numerous and smaller; fewer inner membranes
Peroxisomes prominent
Lysosomes numerous
Bile canaliculi with fewer microvilli, smaller in diameter
Surface area of smooth endoplasmic reticulum larger
Sinusoids form parallel vessels that open into terminal hepatic venules, are wider (30 µm), fewer in number
Endothelial cells more numerous but smaller; increase in number of fenestrations and porosity
Larger nuclear volumes
Increase in number of microbodies
Slight increase in stellate (Ito) cells[a]
Predominant collagen types I, III, VI
Zone 1 (periportal)
Mitochondria: oval and oblong; larger diameter, volume and number; greater cristae area
Rough endoplasmic reticulum more abundant
Bile canaliculi with numerous microvilli, larger in diameter
Kupffer cells more numerous
Sinusoids form interconnecting polygonal network, are smaller (6 µm), more tortuous, more numerous in number
Abundant Golgi-rich volume
Endothelial cells larger; endothelial fenestrations larger but less numerous
Numerous large granular lymphocytes (pit cells)
Predominant collagen types IV, V

a Zone distribution varies considerably depending on the nutritional state.

Table 79.2 Liver cell functional zonal variations

Zone 3 (perivenular)
Glycolysis
Glycogen synthesis from glucose
Lipogenesis
Removal of ammonia from blood by glutamine
Detoxification, biotransformation of the majority of drugs and toxins (P450 enzymes)[a]
Ketogenesis
Bile acid synthesis
Bile salt-independent fraction of bile formation; bile acid uptake (sodium independent)
Glucuronidation
Mixed function oxidase
Increase in Kupffer cell phagocytic activity
Zone 1 (periportal)
Gluconeogenesis
Glycogen synthesis from lactate
β-Oxidation of fatty acids
Amino acid catabolism
Urea synthesis
Cholesterol synthesis
Bile acid secretion
Bile salt-dependent fraction of bile formation; bile acid uptake (sodium dependent)

a Note that certain drugs and toxins (e.g., allyl formate, phosphorus) are metabolized and may cause liver cell injury in zone 1 because of different pathophysiological mechanisms.

of the hepatocyte and includes three major subdivisions: microfilaments, microtubules, and intermediate filaments [9,26,33–35].

The mitochondria are one of the most prominent intracellular organelles [9,26], averaging up to 2200 per hepatocyte. They have numerous critical functions that include oxidative phosphorylation and fatty acid oxidation and contain components essential for the urea and citric acid cycles. They are larger in the perivenular zone but more numerous in the periportal zone and generally maintain a constant volume within each hepatocyte. They are oval to oblong in shape, and measure 0.4–3.5 μm in diameter. They may be divided into outer and inner membranes separated by a gap.

The endoplasmic reticulum [26,36] is composed of a convoluted network of cisternae, saccules, tubules, and vesicles that are distributed throughout the liver cell cytoplasm and constitute about 15% of cytoplasmic volume. It is divided into two components, the rough endoplasmic reticulum and smooth endoplasmic reticulum. The rough endoplasmic reticulum is seen predominantly surrounding the nucleus and biliary channels, whereas the smooth endoplasmic reticulum forms a meshwork of small tubules that are devoid of ribosomes and often communicate with the Golgi apparatus.

The Golgi apparatus [9,26,36,37] is composed of highly polarized, parallel, flattened, dilated saccules or vesicles, is about 1 μm in diameter, and is most often present adjacent to the liver cell nucleus and biliary canaliculi. Anywhere from 40 to 60 Golgi can be seen within the cytoplasm. Golgi function includes production of secretory vacuoles for transportation and excretion of synthesized proteins into the sinusoids, bile secretion, incorporation of carbohydrates into proteins, and membrane synthesis and repair.

Lysosomes [9,26,38,39] appear as electron-dense, pleomorphic, single-membrane-bound vesicles containing enzymes such as acid phosphatase, esterases, proteases, and lipases; they are most frequently identified adjacent to the canalicular membrane. They are divided into primary and secondary lysosomes, which are actively involved in phagocytosis and eventual degradation of various cellular components.

Peroxisomes are single-membrane intracellular organelles, also termed *microbodies*, that vary in size from 0.2 to 1.3 μm [9,26,40,41]. They are round to oval, exhibit a finely granular homogeneous matrix, contain various oxidases and catalases, and primarily function in the oxidation and degradation of numerous substrates with formation of hydrogen peroxides. They are also involved in oxidation of long-chain fatty acids.

There are various intracellular components readily seen by light microscopy that contribute to the function and appearance of the liver cell [24,25]. Lipochrome pigment appears as fine to coarse brown granules and is derived from increase in lysosomal activity and intracellular condensation of various cellular remnants. Two other intracellular pigments that can resemble lipochrome include bile and hemosiderin. Bile is present as clumped green to green-yellow globules that stain positively with the Hall stain for bilirubin. Usually, the presence of intracellular bile is also accompanied by intracanalicular bile. Hemosiderin pigment is coarsely granular and golden brown, is best highlighted by the Perl iron stain, and represents red blood cell degradation remnants. Intracellular lipids appear as clear, distinct, rounded vacuoles and are composed predominantly of neutral triglycerides. The size of the fat droplets varies, with the extremely small variants (termed *microvesicular* or *foamy*) often difficult to assess on routine light microscopy unless thin 1-μm sections are prepared or fat stains (Oil red O) on frozen sections are performed. Intracellular glycogen is distributed throughout the cytoplasm but is more frequently seen adjacent to the smooth endoplasmic reticulum. Glycogen is easily demonstrated by periodic acid–Schiff (PAS) stain on frozen-section material. Nuclear glycogen, when abundant, gives the nucleus a clear appearance and may be seen in a number of liver diseases, including diabetes and Wilson disease.

Kupffer cell

Kupffer cells are sinusoid lining cells that function as tissue macrophages. They represent more than 75% of fixed macrophages throughout the body and take up about one-third of

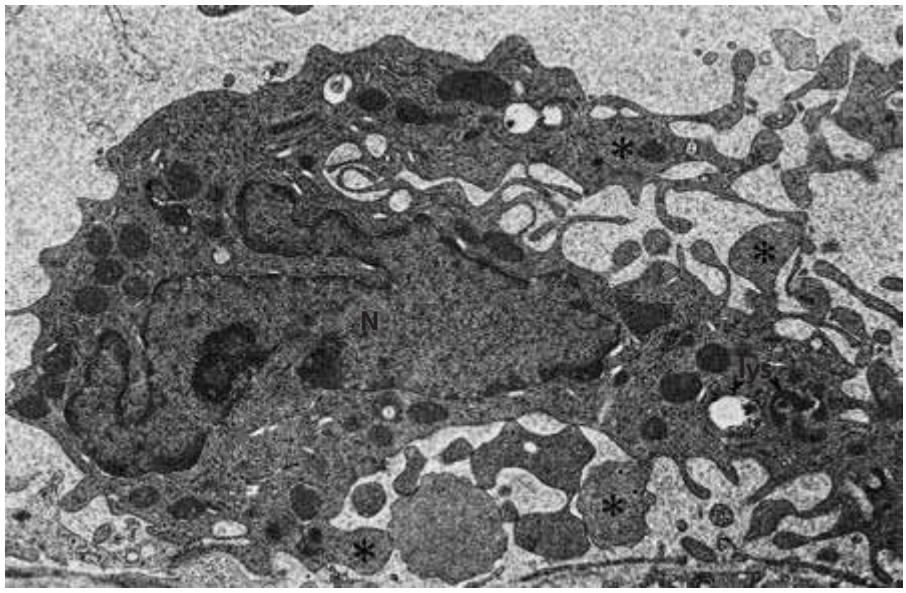

Figure 79.11 Kupffer cell. Using electron microscopy, the Kupffer cell exhibits a cleft nucleus (N), pseudopodia (*), and numerous lysosomes (lys). From Phillips et al. [26].

the hepatic sinusoidal cell volume [9,26,42–46]. Although originally derived from the circulation, they eventually rest along the sinusoidal borders and maintain the ability to divide. Kupffer cells have oval to elongated nuclei, abundant pyramidal stellate cytoplasm that contains numerous lysosomes, and measure up to 9 μm in length (Fig. 79.11). They overlie but do not form junctional complexes with the smaller endothelial cells. However, Kupffer cells may be identified in gaps between adjacent endothelial cells, with cytoplasmic processes extending through endothelial fenestrations. Their primary functions relate to phagocytosis and eventual clearance of particulate material, clearance of endotoxins and degenerating cellular components, synthesis and catabolism of lipids, clearance of senescent erythrocytes, sequestration of antigens, and clearance of immune complexes.

Endothelial cell

The endothelial cells are flattened elongated sinusoidal cells that range in size from 50 to 80 nm and represent almost half of the sinusoidal cell volume [26,42,45,47–50] (Fig. 79.12). Numerous cytoplasmic projections and clustered fenestrae or gaps that range in size from 0.1 to 0.2 μm are present (Fig. 79.13). These fenestrae function as a filtration barrier. The individual cells are loosely attached. A main function of the endothelial cell involves filtering of various macromolecules from the sinusoidal blood by receptormediated endocytosis, enabling substances such as glycoproteins and polysaccharides direct contact with the hepatocyte, but excluding and protecting the liver cell from numerous larger cellular components and various soluble compounds by receptor-mediated endocytosis (ligand binding to coated pits on the cell surface), pinocytosis (trapping of extracellular fluid droplets), and phagocytosis (plasma membrane encircling and internalizing particles) [51].

Stellate (perisinusoidal) cell

Also termed *fat-storing cells* and *Ito cells*, the stellate cells are located within the perisinusoidal liver cell recesses along the space of Disse [26,42,45,52–56] (Fig. 79.14) and constitute about one-fifth of the sinusoidal cell volume. These cells

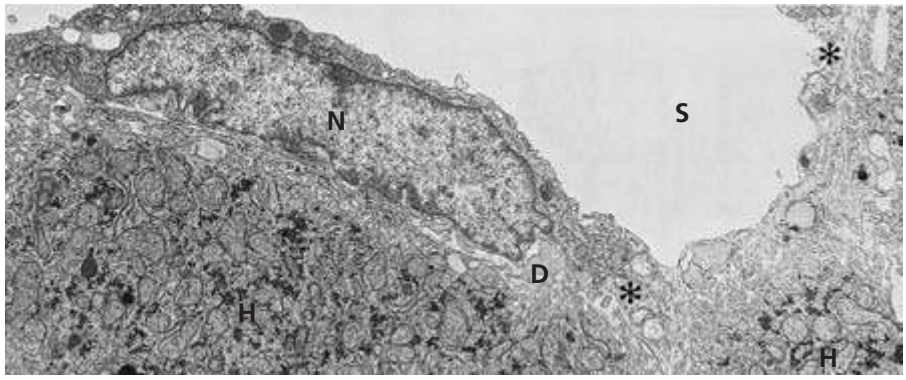

Figure 79.12 Endothelial cell. Electron microscopy of a sinusoid (S) shows an endothelial cell with an elongated nucleus (N) and scanty cytoplasm (*). The space of Disse (D) and adjacent cytoplasm of two hepatocytes (H) are noted. From Phillips et al. [26].

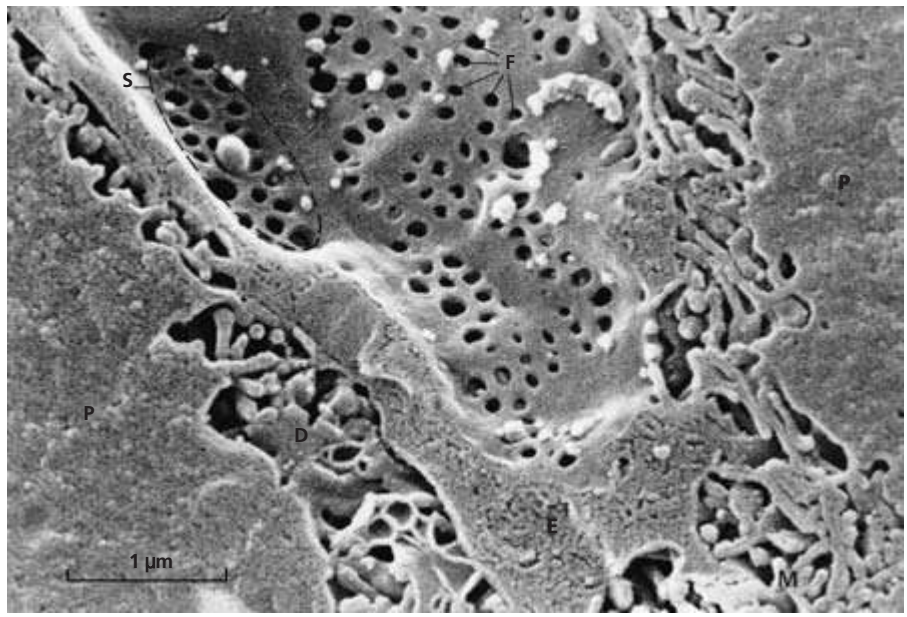

Figure 79.13 Scanning electron micrograph of the hepatic sinusoid. Numerous fenestrae (F) grouped into sieve plates (S) are demononstrated. D, space of Disse; E, endothelial cell; M, microvilli; P, parenchymal cell. From Sherlock & Dooley [2], with permission from Blackwell Publishing.

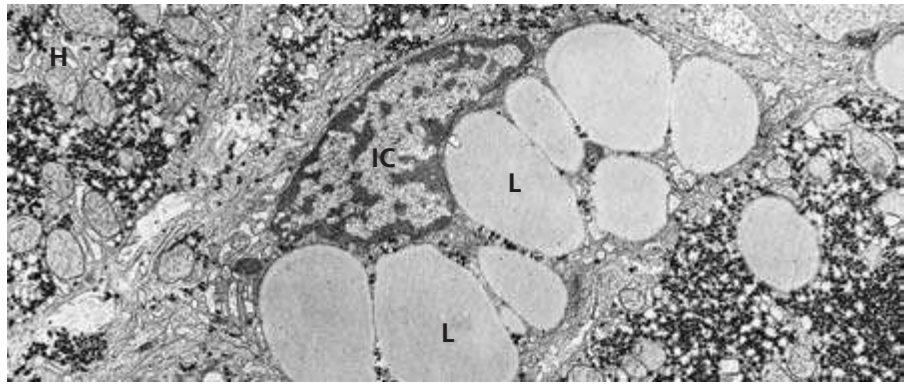

Figure 79.14 Stellate (perisinusoidal) cell. These cells, also termed Ito cells (IC), are seen by electron microscopy along the perisinusoidal recesses and characteristically demonstrate cytoplasmic lipid droplets (L) containing vitamin A. Adjacent hepatocytes (H) are noted. From Phillips et al. [26].

range in diameter from 2 to 10 µm and contain small star-shaped nuclei without prominent nucleoli. The cytoplasm often contains variably sized lipid droplets having a high concentration of vitamin A (retinoyl palmitate) that can easily be demonstrated on frozen sections as intensely green, rapidly fading fluorescence when excited at a wavelength of 328 nm [51]. Besides being the major source of vitamin A storage, the cells synthesize extracellular matrix by way of cytokine activation and resultant transformation to myofibroblasts in response to liver injury, with enhancement of protein and collagen synthesis [57,58].

Pit cell

Also termed *liver-associated lymphocytes* and *large granular lymphocytes*, pit cells are nonparenchymal T cells distributed within the sinusoidal lumen in loose contact with the endothelial or Kupffer cells. They can occasionally be seen within portal tracts [50,51,59–62]. These cells function as natural lymphocyte-activated killer (NK) cells, and contain multivesicular body-related dense granules and rod-cored vesicles [63]. They are often called pit cells because of the resemblance of these cytoplasmic granules to grape seeds [1,64]. These cells are often seen in direct contact with the endothelium in response to various immunological mechanisms and can be targeted in viral hepatitis, acute posttransplantation cellular rejection, and various primary and metastatic neoplastic processes [9,51].

Stroma (extracellular matrix)

The stroma constitutes about 10% of liver volume and overall supports the basic hepatic architectural arrangement, produces intercellular cohesion and communication, and effects cellular differentiation. The capsule of Glisson, composed of dense hypocellular collagen, encapsulates the liver and extends at the hilum into the hepatic parenchyma, forming the tensile structure of the portal tracts. Extension within the sinusoids into the space of Disse as reticulin fibers maintains the intralobular framework. Five basic types of

collagen are seen, with types I and III representing more than 95% of total collagen. Type I represents mature collagen strands, whereas type III represents new collagen (reticulin fibers). Type IV is present in the basal lamina (membrane) around small vascular structures and ducts and represents about 1% of total hepatic collagen. The noncollagenous proteins are numerous matrix glycoproteins and include laminin, the major glycoprotein component within the basement membranes; fibronectin, synthesized by perisinusoidal cells and responsible for collagen adhesion; and elastin, which stabilizes blood vessel walls. Collagen deposition is often triggered by activation of stellate cells in certain instances of liver cell necrosis and impaired or delayed regeneration of hepatocytes.

Biliary network

The main function of the biliary tract is to transport bile synthesized in the hepatocyte into the gastrointestinal tract by way of the extrahepatic biliary network. In addition, the transport proteins synthesized by biliary epithelium and located within the microvilli aid in both the secretion of bicarbonate-rich fluid and the reabsorption of various fluids and solutes that generally enhance bile flow [65]. The biliary tract can be divided into its structural components [66], the smallest of which are the biliary canaliculi. These are located along the intercellular spaces between hepatocytes, range in diameter from 0.5 to 1 μm, and are lined by microvilli. The canaliculi have numerous anastomotic connections and may undergo contractions secondary to actin, myosin, and tropomyosin [67], enabling and enhancing forward bile flow.

The canaliculi that enter the portal tracts are called the terminal ductules, periportal cholangioles, or canals of Hering. These duct structures are derived from hepatocytes located at the limiting plate and provide communication with the interlobular bile ducts. The ducts at this point develop a basement membrane and have both liver cell and ductal ultrastructural and histochemical features. Although in the normal liver these ducts are usually inconspicuous on routine light microscopy, their prominent proliferation (duct transformation, duct metaplasia) is most apparent in instances of severe liver cell necrosis that extends to and involves the periportal hepatocytes.

The interlobular bile ducts range in diameter from 15 to 20 μm, are located within the smaller portal structures, and are lined by a single layer of cuboidal cells with discrete round nuclei, usually inconspicuous nucleoli, and scanty eosinophilic cytoplasm. The duct cytoplasm contains sparse as well as relatively small mitochondria, free ribosomes, scanty endoplasmic reticulum, and abundant intermediate cytokeratin filaments (cytokeratins 7, 19) [3]. The lumenal surface contains numerous pinocytotic vacuoles. Adjoining duct epithelium shows complex interdigitations. The lumenal surface also contains microvilli. A basement membrane is apparent and easily demonstrated on PAS stain. Although the smaller ducts have no apparent wall, the larger interlobular ducts, which measure up to 100 μm in diameter, develop a small periductal fibrous sheath. Anastomoses of the smaller interlobular ducts is frequent. The main blood supply is the smaller branches of the hepatic artery and the peribiliary plexus, which run in parallel with the duct structures. These ducts express class I major histocompatibility antigens, with cytokine-mediated class II expression in instances of liver allograft rejection and certain chronic biliary tract diseases that attack ducts, such as primary biliary cirrhosis.

The larger interlobar and septal ducts measure more than 100 μm in diameter, have a fibrous wall, and are lined by a single layer of cuboidal to columnar epithelium with nuclei located toward the basement membrane. Some degree of periductal fibrous tissue is common but should not be confused with the distinct periductal concentric collagenosis seen in instances of long-term bile duct obstruction.

The interlobar and septal ducts lead into the segmental ducts that measure up to 800 μm in diameter, which eventually form the major hilar ducts that measure up to 1.5 mm in diameter. The hilar ducts ultimately branch into the main right and left hepatic ducts. The hilar ducts are lined by columnar mucus-secreting epithelium, have a distinct fibromuscular wall, and are associated with both intramural and extramural seromucinous peribiliary glands, which communicate with the bile duct lumen. The same type of peribiliary glands are also demonstrated around the intrahepatic large bile ducts [68].

Vascular network

The major blood vessels that supply the liver are the portal vein and hepatic artery. The portal vein sequentially develops interlobar, segmental, interlobular veins and preterminal branches, with the terminal portal venules measuring about 20–30 μm in diameter and seen in the smaller triangular portal tracts. The vascular inflow from the portal veins is controlled by various sphincters. The hepatic artery branches accompany the portal vein and divide within the smaller portal tracts into two segments: the periportal plexus, which branches around the portal vein and drains into the sinusoids; and the peribiliary plexus, which provides blood supply to the accompanying interlobular bile ducts by way of small capillaries that are layered around the ducts. Various connections are seen between the small arterioles and the sinusoids that are most prominent in the periportal zone (zone 1 of Rappaport). The arterial flow depends on both sphincters and contractile mechanisms that define the degree of arterial versus portal venous blood flow, with the arterial flow varying inversely with the portal venous circulation.

There are a number of organizational approaches in assessing the structure as well as function of the liver lobule [69–71]. On the basis of vascular injection studies, Rappaport and colleagues [72] described the concept of the *liver acinus*, with a stratified order of simple acini, complex acini, and acinar

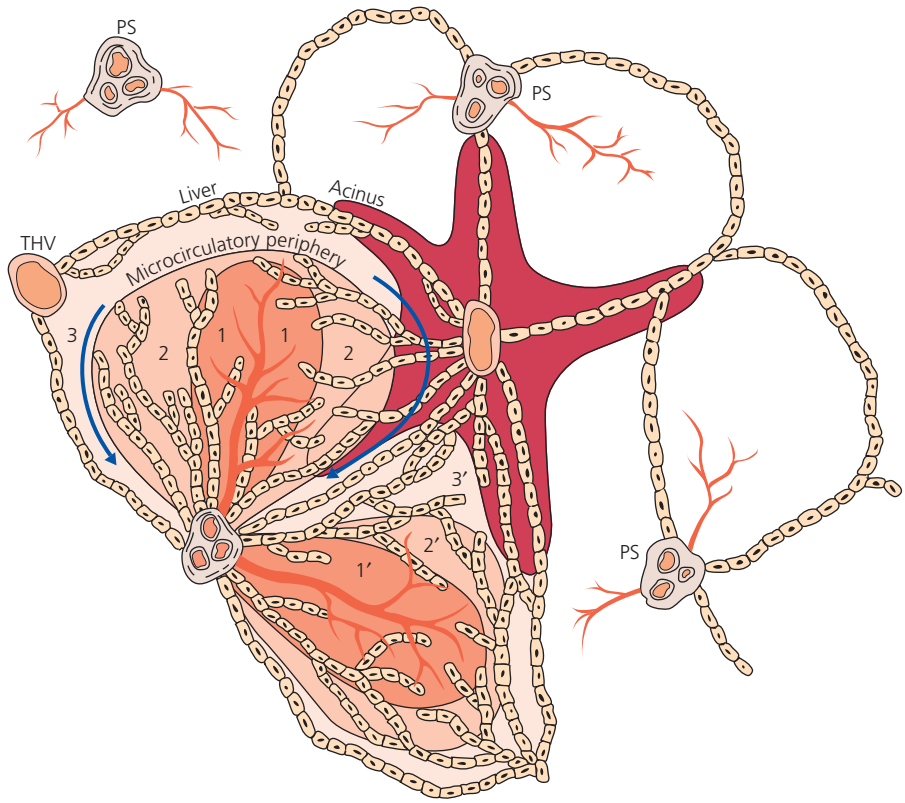

Figure 79.15 Hepatic acinus. The simple liver acinus demonstrates the three hepatic zones and their relationship to the microcirculatory blood supply. PS, portal structures; THV, terminal hepatic venule. From Sherlock & Dooley [2], with permission from Blackwell Publishing.

agglomerates. This approach is a most useful tool in assessing lobular microstructure. The simple acinus is the smallest functional parenchymal unit and centers around the preterminal portal venules, hepatic arteriole, and terminal bile ductules (Fig. 79.15). The acinus is divided into three zones (zones of Rappaport): periportal (zone 1), which includes the limiting plate; midzone (zone 2); and perivenular (zone 3), with the terminal hepatic venule at its outer lateral margin. There is no discrete demarcation separating these zones from one another. The watershed areas occur at the periphery of the acini where blood can be derived from the smallest arteriolar branches and portal venules from adjacent acini. Biliary drainage runs parallel to the vascular sinusoidal circulation. The complex acinus is derived from three adjacent simple acini fed by a preterminal portal vein and arterial branches. A small aggregate or sleeve of liver cells (acinuli) directly surrounds the preterminal branch. The acinar agglomerate is composed of about four complex acini and is fed by a portal venous branch measuring 300–1200 μm in diameter. The concept of modular microarchitectural arrangement of the hepatic parenchyma has also been introduced using a metabolic marker (alkaline phosphatase activity and its presence within endothelial cells) instead of morphology alone, and demonstrated both primary and secondary modules. The primary modules are composed of portal tracts with vascular septa drained by a common central venular network, this approach emphasizing the three-dimensional rather than two-dimensional arrangement of the liver [73].

The space of Disse lies between the hepatocyte and the endothelial cells, measures 0.2–1.0 μm in width, and forms a space that is not appreciated on routine light microscopy of biopsy material but which can sometimes be seen in autopsy livers secondary to liver cell shrinkage from autolysis. Numerous microvilli can be seen projecting from the liver cell membrane into the space of Disse. The discontinuity of the adjacent endothelial cells enables plasma to have easy access to the liver cell membranes. The space of Disse contains reticulin fibers, which can best be appreciated on special reticulin stains and which are easily seen on electron microscopy. The stellate or perisinusoidal cells (Ito cells) also protrude into this space. The sinusoids eventually drain into the terminal hepatic venules, which have no fibrous wall. These vessels then drain into the terminal hepatic and sublobular intercalated veins, and then exit the liver from the three main hepatic vein branches into the inferior vena cava.

Most hepatic lymph is derived from the space of Disse, whereas about 10% comes from capillary leakage from the peribiliary plexus. Its main function is to drain excess proteinaceous fluid from the interstitial hepatic spaces [1,74]. The hepatic lymph drainage within the space of Disse travels into the smallest lymphatic vessels within the portal tracts by way of *endothelial massaging* by circulating erythrocytes

and leukocytes within the sinusoids. The terminal branches form plexuses lined by endothelial cells and are accentuated around the hepatic arterioles in the smaller portal structures, although lymphatics are also seen adjacent to portal veins and bile duct tributaries in larger portal tracts. Small branches can also be seen along the hepatic venous outflow vessels. A lymphatic plexus is also identified within the capsule of Glisson and communicates with the intrahepatic lymphatics through anastomotic channels. Most lymphatics leave the liver at the porta hepatis, although lymphatic drainage is prominent through the capsule of Glisson in instances when the hepatic venous drainage is impaired (e.g., acute and chronic hepatic venous outflow obstruction, cirrhosis). The larger lymphatic channels have an identifiable wall and are valved.

Neural network

The nerve fibers are composed of both parasympathetic and sympathetic branches and release neurotransmitters from intrasinusoidal fibers that contribute to modulation of liver cell function. Small nerve segments can be seen within the larger portal tracts, but smaller unmyelinated fibers can be discerned by way of electron microscopy and immunohistochemical studies within the space of Disse.

Functional components: liver cell heterogeneity

The hepatocytes within the various parenchymal zones have many different specialized physiological functions that often parallel the light microscopy, ultrastructural features, and enzyme distribution patterns [1–3,23,75–81] (Tables 79.1 and 79.2). This functional heterogeneity applies not only to liver cells but also to the sinusoidal and perisinusoidal spaces, Kupffer and endothelial cells, the extracellular matrix, and even bile duct epithelial cells [82–84]. These functions are manifestations of:

- nutrient and hormonal gradients delivered to the various zones
- sinusoidal vascular perfusion and oxygen concentration gradients
- availability of innumerable substrates and cofactors
- expression of various enzyme activities through gene expression and local (zonal) genetic variations.

As a consequence, functional and morphological zonal liver cell changes and injury are end-stage manifestations of modifications, alterations, and impairment of many of these critical and complex parameters.

Stem cells

The bile duct epithelial cells harbor a subdivision of stem cells that are located near the canals of Hering [3,85]. The importance of these cells is that they have the potential to differentiate along either liver or biliary cell lines and have a critical potential in liver cell regeneration and repair [86,87]. Although the hepatocyte has been shown in several animal models to have more than adequate ability to repopulate the liver in the transplant setting [88] and shows striking regenerative activity after partial hepatectomy for tumor or in partial livers after living-related transplantation, the ability of stem cells to regenerate in instances where viable hepatocytes are not present (i.e., fulminant hepatitis with massive hepatic necrosis) shows their critical potential. The morphology in these cases, for example, shows that at the border of the portal tracts and parenchyma there is a striking proliferation of bile ductular-type cells that potentially develop from these stem cells. These cells have also been shown by immunological techniques to have parathyroid hormone-type activity that can further influence liver cell differentiation and cell division [3]. Progenitor cells isolated from normal adult liver have also been shown to express mesenchymal stem cell markers and have the ability to differentiate into mature hepatocytes when cultured in the presence of hepatocyte and fibroblast growth factors [89]. In addition, hepatic stellate cells, which normally play an important role in hepatic fibrogenesis, also have precursor potential in the developement of both endothelial cells and hepatocytes [90].

Studies have also suggested that some of these stem cells in the liver have the potential to differentiate into hematopoietic precursors [91]. Furthermore, stem cells located within the bone marrow have shown an ability to mobilize and migrate into the liver [92], with differentiation into hepatocytes and duct epithelial cells [93–96], supporting the view that these stem cells have multipotential abilities; however, it is not certain that the bone marrow-derived cells play a significant physiological function in replacing epithelial cells in the setting of hepatic injury [93].

Five viral agents have been associated with acute hepatitis. These viruses were denominated A, B, C, D, and E in order of their discovery. They are a genetically diverse group of viruses linked by their tropism for the liver, their primary site of replication. They all cause an acute hepatitis, which can range in clinical severity from an asymptomatic illness to fulminant hepatitis. Hepatitis B, C, and D viruses have the propensity to progress to chronic hepatitis. These hepatotrophic viruses account for 90%–95% of all cases of acute viral hepatitis in the United States [1]. Data from the Centers for Disease Control and Prevention (CDC) Sentinel Counties Study of acute viral hepatitis indicated that hepatitis A virus (HAV) was the cause of almost half the reported cases, hepatitis B virus (HBV) caused a third, hepatitis C virus (HCV) caused 15%, and the remaining cases were caused by non-A, non-C viruses [2]. In the United States, acute viral hepatitis has a low case fatality rate, 1%–2%, but is associated with substantial morbidity. Death from end-stage liver disease, a long-term consequence of acute viral hepatitis, ranks in the top 10 of all causes of mortality in the United States.

Other viruses from the families Arenaviridae (e.g., Lassa fever virus), Bunyaviridae (e.g., Rift Valley fever and Hanta viruses), Flaviviridae (e.g., yellow fever and dengue viruses), Filoviridae (e.g., Marburg and Ebola viruses), and Herpesviridae may cause hepatitis as part of a systemic illness but are not considered primary hepatotrophic viruses.

Epidemiology

Overview

The hepatotrophic viruses are found worldwide, and there are distinct geographic regions where each virus is highly endemic. The global distribution of each virus is closely linked to its mode of transmission. Enterically transmitted viruses, HAV and hepatitis E virus (HEV), are more common in regions of the world that lack proper sanitation and have limited access to fresh water. In contrast, the parenterally transmitted viruses, HBV, HCV, and hepatitis D virus (HDV), predominate in areas of the world where social or customary practices facilitate their transmission, explaining the high rate of HCV infection in injection drug users in the United States and HDV in the South American Indians of the Amazon basin. Despite the institution of public health measures to educate the general public on transmission risks, the number of cases of acute viral hepatitis has not declined substantially in recent years. This may be partly because risk factors for acute viral hepatitis have not been identified in 30%–40% of cases [1]. If elimination of infection is the ultimate goal, further studies on the various modes of transmission are necessary.

Hepatitis A virus

Prevalence

HAV infection occurs worldwide. The prevalence of antibody to hepatitis A (anti-HAV) correlates inversely with the socioeconomic status and the prevailing standard of hygiene of a region. In highly endemic areas, the prevalence of anti-HAV is almost universal by 5 years of age, whereas in industrialized nations, it is generally less than 5% for all age groups sampled. This finding has important public-health implications. Outbreaks of HAV infection are more common in low-prevalence areas because of a susceptible population and they are rare in endemic areas because of natural herd immunity. This explains the cyclic epidemics observed every 10–15 years in areas of intermediate prevalence, such as the United States. Additionally, a paradoxical increase in the number of cases of clinical hepatitis is observed in low- and intermediate-prevalence areas owing to a greater number of adult infections.

About one-third of the US population has serological evidence of past HAV infection. Prevalence was found to increase

with age, being born outside the US, and being of Mexican American ethnicity, according to data obtained from the Third National Health and Nutrition Examination Survey (NHANES-III, 1988–1994) [3]. The relationship with age can be explained by infections that occurred during childhood when sanitary conditions were poorer than present-day standards and by travel to endemic regions by adults. The age-adjusted prevalence of anti-HAV was highest in Mexican Americans (70%) and lowest in non-Hispanic whites (23%). This difference is probably related to socioeconomic factors rather than racial susceptibility to infection. The incidence of acute HAV infection in the United States has remained fairly constant over the past several decades. However, since the introduction of vaccination, there has been a dramatic decline in the incidence of HAV infection. Between the periods 1990–1997 (when there was no vaccination) and 2003 (vaccination) the rate of hepatitis A declined by 76% from a low of 9.1 cases per 100 000 (in 1991) to 2.6 cases per 100 000 persons [4]. Greater declines were observed in high-risk states that adopted vaccination strategies. Rates declined by 88% to 2.5 per 100 000 persons in states with vaccination programs compared to a 53% decrease elsewhere to 2.7 per 100 000 persons [4].

Transmission

HAV is transmitted primarily by the fecal–oral route through person-to-person contact or through ingestion of contaminated food or water. Viral titers are highest in stool and can reach 10^8 virions/mL [5]. This is because HAV lacks a lipid envelope and is readily secreted by hepatocytes into bile and the intestinal tract [6]. The virus is detected in stool during the incubation period, and the viral titer peaks 2 weeks before the onset of symptoms [7]. Therefore, the highest period of infectivity is before the onset of symptoms. In most cases, viremia becomes undetectable after the peak of the alanine aminotransferase (ALT) level [8]. However, experimental transmission studies performed in human volunteers and chimpanzees revealed that viremia may persist for long periods during the convalescent phase of the illness [7–9]. This suggests that blood obtained during the convalescent phase may be potentially infectious. Furthermore, the virus could be demonstrated in convalescent stool by reverse transcription polymerase chain reaction (PCR) and may be a source of infection in sporadic cases.

Viral titers in serum are about twofold less than those in stool; therefore, parenteral spread is not a significant route of transmission. Transmission has been reported occasionally in blood transfusion recipients, patients who require clotting factors, and injection drug users who share needles [10–12].

HAV is shed in the saliva during an acute illness. However, transmission has not been associated with saliva, semen, or urine [5]. Sexual transmission of hepatitis is reported in both heterosexuals and homosexuals. Outbreaks in homosexual men seem to be related to oral–anal contact during the sexual encounter [13,14]. Nosocomial spread from undiagnosed cases has been reported [15].

In the United States, the highest rates of spread are reported in household contacts, in the intimate contacts of an index case, and in child day-care centers (person-to-person spread) [16]. Data from the Viral Hepatitis Surveillance Program at the CDC in 1995 showed that contact with another person with hepatitis A was overall the most frequently identified risk factor. Attendees or employees of day-care centers accounted for 10%–15% of cases. However, nearly 50% of cases in both 1994 and 1995 reported no known risk factor [16]. It has been suggested that transmission from an asymptomatic infant or child may account for most of the adult cases of HAV infection [17]. Outbreaks of HAV have been associated with ingestion of shellfish [18,19], raw onions [20,21], salads [22], and frozen strawberries [23], but these account for a small number of cases overall.

Hepatitis B virus

Prevalence

Hepatitis B occurs worldwide; the areas of highest prevalence are China, southeast Asia, subSaharan Africa, and Alaska. Almost 50% of the world's population live in these regions, where the prevalence of hepatitis B surface antigen (HBsAg), a serological marker of chronic infection, can exceed 8% [24]. Another 40% of the world's population lives in areas with intermediate prevalence, 3%–5%, such as Japan and India. In low-prevalence areas, such as the United States, Western Europe, and Australia, the rate of HBsAg positivity is 0.1%–2%. In endemic areas, most infections occur in children, whereas in areas of low seroprevalence, most infections occur in adults.

The prevalence of HBsAg was found to increase with age in the US population and is highest in people aged 20–29 years, probably reflecting transmission through injection drug use or sexual exposure [25]. Certain US populations, such as Eskimos, have higher rates of HBsAg positivity [26]. The incidence of acute HBV infection has declined dramatically in the United States, primarily as a result of the use of the hepatitis B vaccine in high-risk groups, behavioral changes in response to the human immunodeficiency virus (HIV) epidemic, and federal regulations introduced to limit nosocomial spread.

Transmission

HBV is transmitted primarily by the percutaneous and sexual routes including exposure of the mucous membrane to bodily fluids. Not surprisingly, the highest titers of virus are seen in serum and blood; intermediate titers are seen in semen, vaginal fluid, and saliva; and lowest titers are observed in tears, urine, feces, and breast milk. The infectivity of other body fluids is 100-fold to 1000-fold less compared with blood.

Transfusion of blood products used to be the major route of transmission before the introduction of blood screening in 1985. Studies of multitransfused patients with hemophilia

before 1985 indicated that 40%–50% had markers of previous or active HBV infection [27]. Transfusion-related HBV infection has been virtually eliminated by screening of blood donors.

The transmission of HBV varies in endemic and nonendemic regions. In the United States and Western Europe, areas of low endemicity, injection drug use, and sexual exposure to an acute case or chronic carrier are the major modes of transmission. Data from the CDC Viral Hepatitis Surveillance Program showed that sexual exposure was the predominant risk factor in the United States; 26% of cases reported sexual contact with a person known to have HBV. Injection drug use was the next most common risk factor (13%). The risk for sexual transmission was directly related to number of lifetime sexual partners, use of paid sex, and previous history of sexually transmitted diseases. The risk for transmission appears to be greater from men to women.

In contrast, in endemic regions, perinatal spread (vertical transmission) and person-to-person spread (horizontal transmission) are more common modes of spread. Perinatal spread is responsible for the high rate of infection seen in China and southeast Asia [28]. Perinatal spread is more efficient if the mother is positive for HBe antigen (HBeAg). Fetal exposure to blood during passage through the birth canal is thought to be the cause of infection rather than transplacental spread. In subSaharan Africa, another highly endemic area, the major route of spread is horizontal transmission, occurring in young children between the ages of 4 and 6 years, presumably through close physical contact or intrafamilial spread. The reason for the lower rate of vertical transmission in the African population may be the low prevalence of HBeAg in the serum of females of childbearing potential [29].

Health-care workers were at major risk for exposure in the 1980s; however, widespread use of the hepatitis B vaccine has reduced the incidence of acute hepatitis markedly, from 9% in 1985 to 0.8% in 1994/1995 [30]. Nosocomial infection continues to remain a source of infection, and transmission has been reported from physician to patient, from contaminated multiuse vials and medical instruments, in hemodialysis units, and through organ transplantation, especially in the case of antibody to hepatitis B core antigen (anti-HBcAg)-positive donors after orthotopic liver transplantation (OLT).

Hepatitis C virus

Prevalence

HCV infection occurs worldwide, and it is estimated that 3% of the world's population is infected based on blood donor studies [31,32]. The geographic prevalence of antibody to HCV (anti-HCV) is fairly consistent throughout the world, ranging from 0.5% to 2%. However, the prevalence of HCV is disproportionately high in Egypt and Japan. In Egypt, this has been explained by the use of mass parenteral therapy for schistosomiasis with reusable glass syringes during the period between 1961 and 1985 and in Japan it is explained by the use of blood transfusions during World War II [33–35].

Data from the NHANES-IV study found a prevalence of anti-HCV of 1.6% in the general US population [36]. Prevalence was highest in injection drug users and in African Americans. Overall, the rate of anti-HCV was twice as high in African Americans as in whites. Groups with higher prevalence than the general population included patients with hemophilia, injection drug users, patients receiving hemodialysis, and people attending sexually transmitted disease clinics. Injection drug users are at the highest risk for acute HCV infection. Since 1989, the incidence of acute HCV infection has been on the decline, primarily as a result of screening of the blood supply and a decrease in injection drug use.

Transmission

HCV is transmitted by percutaneous, sexual, and perinatal routes. The highest viral titers are seen in blood and serum. Before the introduction of blood-screening procedures (anti-HBc and ALT levels were used as surrogate markers for non-A, non-B hepatitis beginning in 1985 until they were replaced by anti-HCV testing in 1991), transfusion of blood or blood products was a major source of infection, accounting for up to 20% of cases of infection. HCV is efficiently transmitted by blood. Between 60% and 95% of patients with hemophilia who received clotting factor before 1985 tested positive for anti-HCV [37,38]. With the introduction of screening measures, the risk for acquiring hepatitis C through blood transfusion in the United States is estimated to be 1 in 400 000 [39]. Transmission of HCV through the blood supply still occurs in countries where testing for HCV is not routinely performed. Injection drug use is a highly efficient means of transmission and is the major route of transmission of HCV in the United States. The prevalence of anti-HCV in active injection drug users who share needles is 70% after 1 year and more than 90% after 8 years. Prevalence of anti-HCV in this group has been shown to be associated with duration of injection drug use and sharing needles with a long-time drug user. Intranasal cocaine use has been suggested as a mode of transmission [40]. A cross-sectional study of volunteer blood donors in the United States reported that a history of intranasal cocaine use was independently associated with anti-HCV positivity [40].

HCV can be transmitted sexually but not efficiently. Epidemiological case–control and cross-sectional studies report independent associations between HCV infection and exposure to an infected sex partner, increasing number of sex partners, failure to use a condom, and sexual activities involving trauma [41,42]. The presence of other sexually transmitted diseases (e.g., herpes and syphilis) has been shown to facilitate the transmission of HCV. The rate of sexual transmission from an infected case to a partner is low in monogamous relationships, 1.5%, but increases with

duration of the partnership and averages 3%–5% [43,44]. The risk of transmission is higher in those with multiple sexual partners [45]. The rate of sexual transmission is the same for heterosexual and homosexual relationships. Overall, sexual transmission accounts for a relatively small percentage of acute cases, less than 10%.

Perinatal transmission of HCV occurs but the rate is low and is significantly lower compared with HBV. The rate of transmission is estimated to be 3%–5% for mothers not infected with HIV-1 and increases to 12%–14% in HIV-1-positive women [46,47]. Risk factors for perinatal transmission include high maternal viral load, HIV/HCV coinfection, and vaginal delivery [47–49]. It was suggested that cesarean section may be associated with a lower rate of perinatal transmission [50]. Transmission of HCV through breastfeeding has not been reported [51]. Mother-to-child transmission occurs but is uncommon [47,52].

Nosocomial transmission of HCV occurs but is not a major cause of new infections [53,54]. Transmission through contaminated multidose vials, through endoscopes, from physician to patient, from unsafe therapeutic injections, organ transplantation, and through surgical procedures was identified as potential sources of infection [55–58]. Needle-stick injury is a risk factor for health-care workers (see later).

Hepatitis D virus

Prevalence

HDV, the infectious agent of delta hepatitis, is found throughout the world. Its prevalence mimics that of HBsAg because it is dependent on HBV for its life cycle [59]. It is estimated that 5% of HBsAg carriers are coinfected with HDV [60]. However, there are areas where there is discordance between the prevalence of HDV and HBV, such as in China, where the rate of HBV infection is high but that of HDV is low. The reason for this is unknown. HDV is endemic in the southern Mediterranean, Amazon Basin, and tropical and subtropical Africa. Prevalence of HDV is low in the United States [61]. Recent studies indicate that the seroprevalence of HDV in southern Europe is declining. Studies in Italy confirmed a decrease in incidence of acute cases from 3.1 per 100 000 population in 1987 to 1.2 per 100 000 population in 1992 [62,63]. This decline was attributed to the introduction of hepatitis B vaccination programs and to a decrease in injection drug use [62].

Transmission

HDV is transmitted in a similar fashion to HBV. The single most important factor influencing transmission of HDV is the HBsAg status of an individual. HDV cannot be transmitted in the absence of HBsAg. Exposure to blood and blood products used to be the major route of transmission, but this has been virtually eliminated by the screening of blood for HBV [59]. In developed countries, injection drug use and sexual transmission are the major routes of spread. The mode of spread in populations from Africa and the Amazon Basin is not well understood, but tribal practices that expose individuals to blood or sexual exposure may play a role. Perinatal transmission is rare.

Hepatitis E virus

Prevalence

HEV is the major causative agent of enteric non-A, non-B hepatitis and the primary cause of sporadic hepatitis in the developing world [64,65]. HEV is found worldwide, and the highest prevalence is found in areas of the world where there is inadequate sanitation. It is endemic in southeast and central Asia. Epidemics of HEV infection, usually involving many thousands of people, occur in endemic areas. In endemic areas, the prevalence of antibody appears to increase with age; about 5% of children younger than 10 years old have antibody to HEV, but 10%–40% of adults are seropositive [66,67]. This suggests that HEV infection does not occur frequently in children in endemic areas. This discrepancy may be in part the result of the sensitivity of the test used for serological testing. The prevalence of anti-HEV in the United States is low.

Transmission

HEV is transmitted by the fecal–oral route. Highest attack rates are seen in individuals aged 15–40 years [67]. In endemic areas, consumption of contaminated water accounts for most new cases of HEV. Person-to-person spread is rare, and secondary attack rates appear to be distinctly uncommon, occurring in 0.7%–2.2% of household contacts of hepatitis E, compared with rates of 50%–75% in susceptible household contacts of hepatitis A [67]. There is no evidence for parenteral or sexual transmission. Vertical transmission is known to occur but accounts for only a small number of cases [68]. HEV is responsible for sporadic outbreaks of hepatitis. However, the reservoir of HEV during sporadic outbreaks is unclear. Recent data based on the detection of HEV in the feces of domestic swine in Nepal and the United States and anti-HEV in the sera of pigs, cattle, sheep, and rodents suggest that HEV may be a zoonosis [69–71]. Cases of HEV infection in the United States are rare and usually associated with a history of travel to an endemic area. Infection has been reported without a history of travel, lending support to the zoonosis theory.

Virology

The five known hepatitis viruses, A to E, belong to completely different virus families. Although all of them can cause acute hepatitis, only HBV, HCV, and HDV infection can lead to chronic infection. The virological characteristics of each virus are summarized in Table 80.1 and are described in detail in this section.

Table 80.1 Human hepatitis viruses

Virus	Genome	Genome size (kb)	Envelope	Classification Family	Genus
HAV	RNA positive sense, single-stranded, linear	7.5	–	Picornaviridae	Hepatovirus
HBV	DNA partially double-stranded, circular	3.2	+	Hepadnaviridae	
HCV	RNA positive sense, single-stranded, linear	9.6	+	Flaviviridae	Hepacivirus
HDV	RNA positive sense, single-stranded, linear	1.7	+	Unclassified (viroid)	Deltavirus
HEV	RNA positive sense, single-stranded, linear	7.5	–	Unclassified	Togavirus-like and alphavirus-like

Hepatitis A virus

HAV is classified in the *Hepatovirus* genus in the Picornaviridae family. It has one serotype but multiple genotypes. The virus is nonenveloped and stable to both acid and heat treatment. The HAV has a linear, positive-sense, single-stranded RNA genome of about 7.5 kilobases (kb). The genome has a protein covalently attached to its 5′ end and a poly A tail at the 3′ end [72]. The genome is organized similarly to other picornaviruses in that it codes for a single polyprotein of about 2235 amino acids [73] (Fig. 80.1). The polyprotein is divided into three main functional domains from the 5′ end, P1, P2, and P3. Individual proteins are cleaved from the functional domains, with P1 encoding the viral capsid proteins, whereas P2 and P3 encode the nonstructural proteins. The 5′ untranslated region (UTR) is the most conserved segment of the genome [74] and contains an internal ribosomal entry site that functions to initiate protein synthesis from two in-frame AUG codons [75]. Mutations in this region appear to enhance the adaptation of virus growth in cell culture but do not appear to affect in vivo virulence [76].

Cleavage within the P1, P2, and P3 domains of the polyprotein gives rise to the individual viral proteins. Four capsid proteins, designated 1A to 1D, are encoded in P1, with the P2 and P3 regions encoding proteins 2A to 2C and 3A to 3D, respectively. The 3B protein covalently attaches to the 5′ terminus of the genome and serves as the primer for replication [72]. The functions of 2A, 2B, and 3A are unclear. The 3C is probably a serine proteinase [77] involved in cleavage of the polyprotein. 3D is the putative viral RNA polymerase [78].

The replication process of HAV has been inferred from studies of other picornaviruses [79]. Entry of the virus into the host is mediated by a cell surface receptor, which has been proposed to be a mucin-like class 1 integral membrane glycoprotein [80]. Viral entry is followed by uncoating and initiation of viral protein synthesis [81]. Viral RNA synthesis proceeds from negative to plus strand and occurs in the cytoplasm. Viral assembly follows a sequence similar to that of picornaviruses in a cellular membrane compartment [82].

Hepatitis B virus

HBV has been classified into seven genotypes, A to G, based on sequence divergence [83,84]. Three types of viral particles are visualized in infectious sera using electron microscopy. Two of the viral particles are smaller spherical structures with a diameter of 20 nm and filaments of variable length with a width of 20 nm, both of which vastly outnumber the Dane

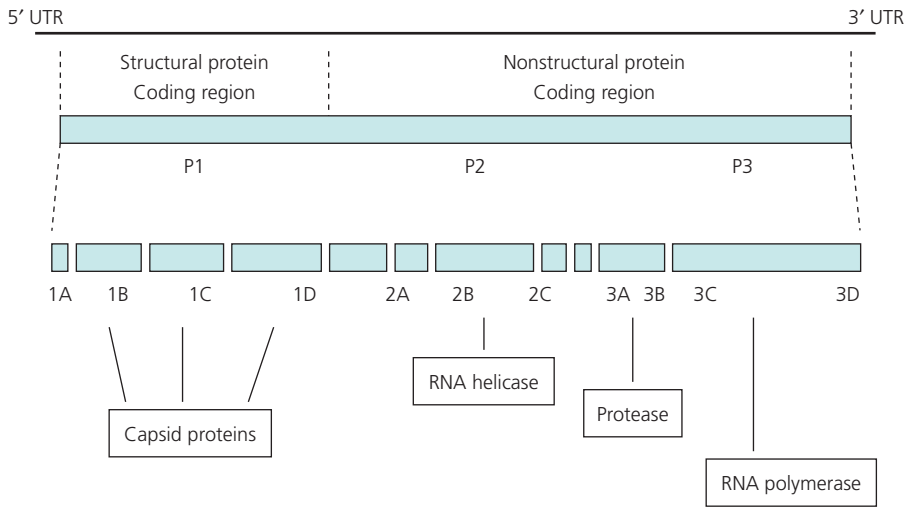

Figure 80.1 Structure of the hepatitis A virus and genetic organization. The *top line* represents the hepatitis A virus RNA genome. Translation of the genome yields the polyprotein; the *lower diagram* illustrates the three regions of the polyprotein and the individual protein products. UTR, untranslated region.

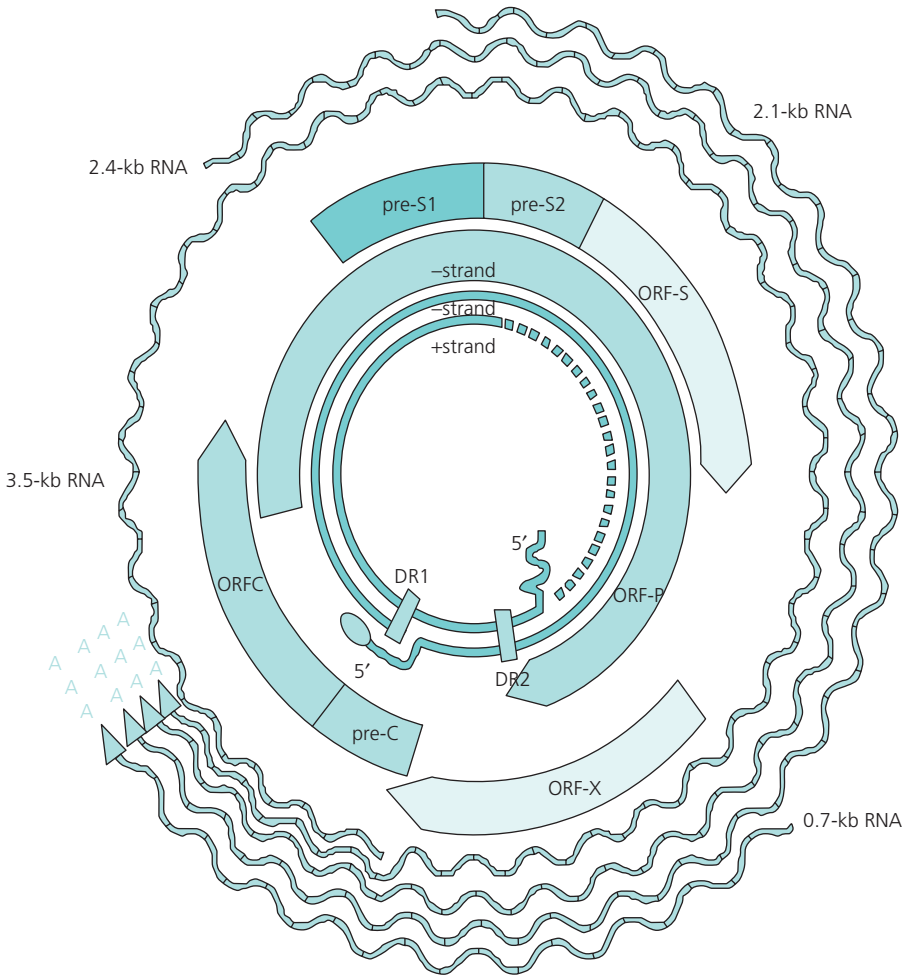

Figure 80.2 Genome structure and organization of hepatitis B virus. The hepatitis B virus open reading frames (ORFs): pre-C and C (precore and core proteins), P (polymerase protein), pre-S1, pre-S2, and S (L, M, and S surface envelope proteins), and X protein are shown. The viral genome structure is composed of the full length (–)-DNA strand and variable length (+)-DNA strand (*solid* followed by *dashed line*). The pol protein is covalently attached to the 5′ of the (–) strand and a capped oligoribonucleotide (*angulated line*) to the (+) strand. Direct repeats (DRs) 1 and 2 (*small rectangular boxes*) are shown on the genome. The *outer lines* represent the four transcripts, all terminating at a common polyadenylation site.

particles in infectious serum [85]. The spheres and filaments are composed of HBsAg and host-derived lipids and are noninfectious because they lack a nucleic acid [86]. The infectious HBV virion (the Dane particle) has a 42-nm spherical, double-shelled structure, consisting of a lipid envelope containing HBsAg that surrounds an inner nucleocapsid. The HBcAg forms a complex with viral-encoded polymerase and viral DNA genome to form the nucleocapsid [87]. The genome of HBV is a partially double-stranded circular DNA of about 3.2 kb pairs. The viral polymerase is covalently attached to the 5′ end of the minus strand [88].

The viral genome encodes four overlapping open reading frames (ORFs) (Fig. 80.2). The S ORF encodes the viral surface envelope proteins, the HBsAg, and comprises the pre-S1, pre-S2, and S regions. The core gene consists of precore and core regions. Multiple in-frame translation initiation codons are a feature of the *S* and *C* genes, which give rise to functionally distinct proteins. HBeAg and the viral nucleocapsid HBcAg are translated from initiation at the precore and core regions, respectively (Fig. 80.3). The core protein has the intrinsic property to self-assemble into a capsid-like structure and contains a highly basic cluster of amino acids at its C terminus with RNA-binding activity [89]. The precore ORF codes for a signal peptide that directs the translation product to the endoplasmic reticulum, where the protein is further processed to form the secreted HBeAg. The role that HBeAg serves is still unknown because mutations inactivating the precore region do not appear to affect viral replication [90]. One speculative role for HBeAg is as an immune tolerogen, whose function is to promote persistent infection [91]. The polymerase (pol) is a large protein (about 800 amino acids) and is functionally divided into three domains: the terminal protein domain (TP), which is involved in encapsidation and initiation of minus-strand synthesis; the reverse transcriptase domain, which catalyzes genome synthesis; and the RNase H domain, which degrades pregenomic RNA and facilitates replication. The HBX is a 16.5-kDa protein and has been attributed with multiple functions, including signal transduction, direct transcriptional activation, DNA repair, and inhibition of protein degradation [92–94]. The mechanism of this activity and the biological function of HBX in the viral life cycle remain largely unknown. However, it is well

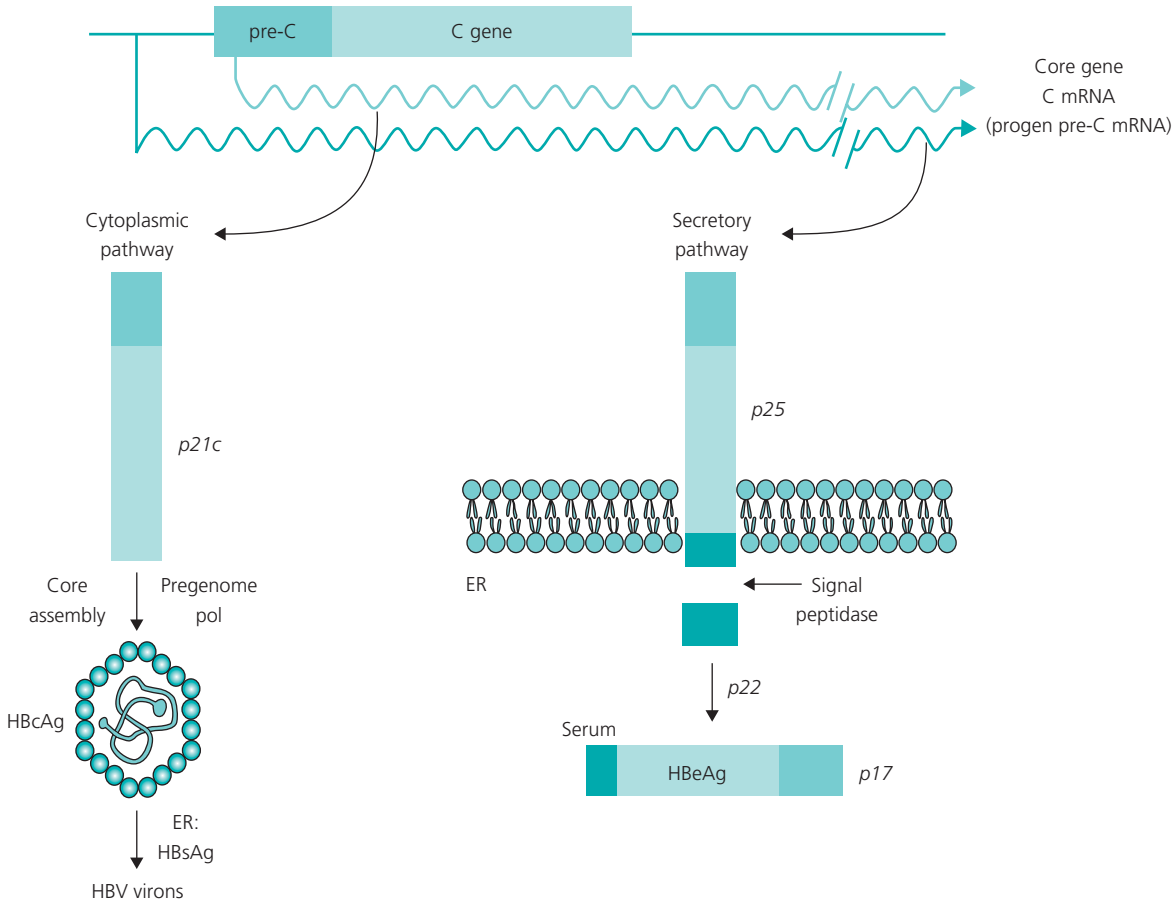

Figure 80.3 Two distinct processing pathways of *HBV* core gene. Two species of core RNAs are transcribed from the core gene. One starts before the pre-C and the other in the middle of the pre-C region. The former codes for the pre-C/C protein and is directed to the secretory pathway through the signal peptide sequence in the pre-C. After further proteolytic cleavage in the endoplasmic reticulum (ER), hepatitis Be antigen (HBeAg) is formed and secreted. The latter RNA codes for the core protein, which is involved in the nucleocapsid assembly.

established that HBX plays an essential role in HBV infection in vivo [95,96] and may contribute to the oncogenic potential of HBV [97].

Other functionally important elements within the HBV genome include two direct repeats (DR1 and DR2) in the 5′ ends of the minus and plus strands, which are required for strand-specific synthesis during replication [98]. Two enhancer elements, designated as En I and En II, confer liver-specific expression of viral gene products [99]. A glucocorticoid-responsive sequence within the S domain [100], a polyadenylation signal within the core gene [101], and a posttranscriptional regulatory element overlapping En I and part of HBX ORF have been described [102].

The HBV replication pathway has been studied in great detail and is summarized in Fig. 80.4. The initial phase of HBV infection involves the attachment of mature virions onto host cell membranes, likely involving the preS domain of the surface protein [103]. Various cellular factors have been proposed to be the viral receptors, but only the carboxypeptidase D has been shown to play an essential role in viral entry for the duck HBV [104]. Mechanisms of viral disassembly and intracellular transport of viral genome into the nucleus are not well understood and probably involve modification of nucleocapsid core protein [105]. After entry of viral genome into the nucleus, the single-stranded gap region in the viral genome is repaired by the viral pol protein, and the viral DNA is circularized to the covalently closed circular form [105]. This form of HBV DNA serves as the template for transcription of several genomic and subgenomic RNAs. Structurally, the transcripts are unspliced, polyadenylated, and possess a 5′ cap structure. The 3.5-kb genomic transcripts consist of two species with different 5′ ends: the pregenomic and the precore RNAs. The pregenomic RNA serves as the template for reverse transcription and the messenger RNA as template for core and polymerase; the precore RNA directs the translation of the precore gene product [106]. The polymerase is initiated at the pol start codon of the pregenomic RNA, probably as a result of a ribosomal scanning mechanism [107]. The large HBsAg (LHBsAg) protein is translated from the 2.4-kb subgenomic RNA, the middle (M) and small HBsAg (SHBsAg) proteins from the 2.1-kb RNA, and the HBX protein from the 0.7-kb RNA.

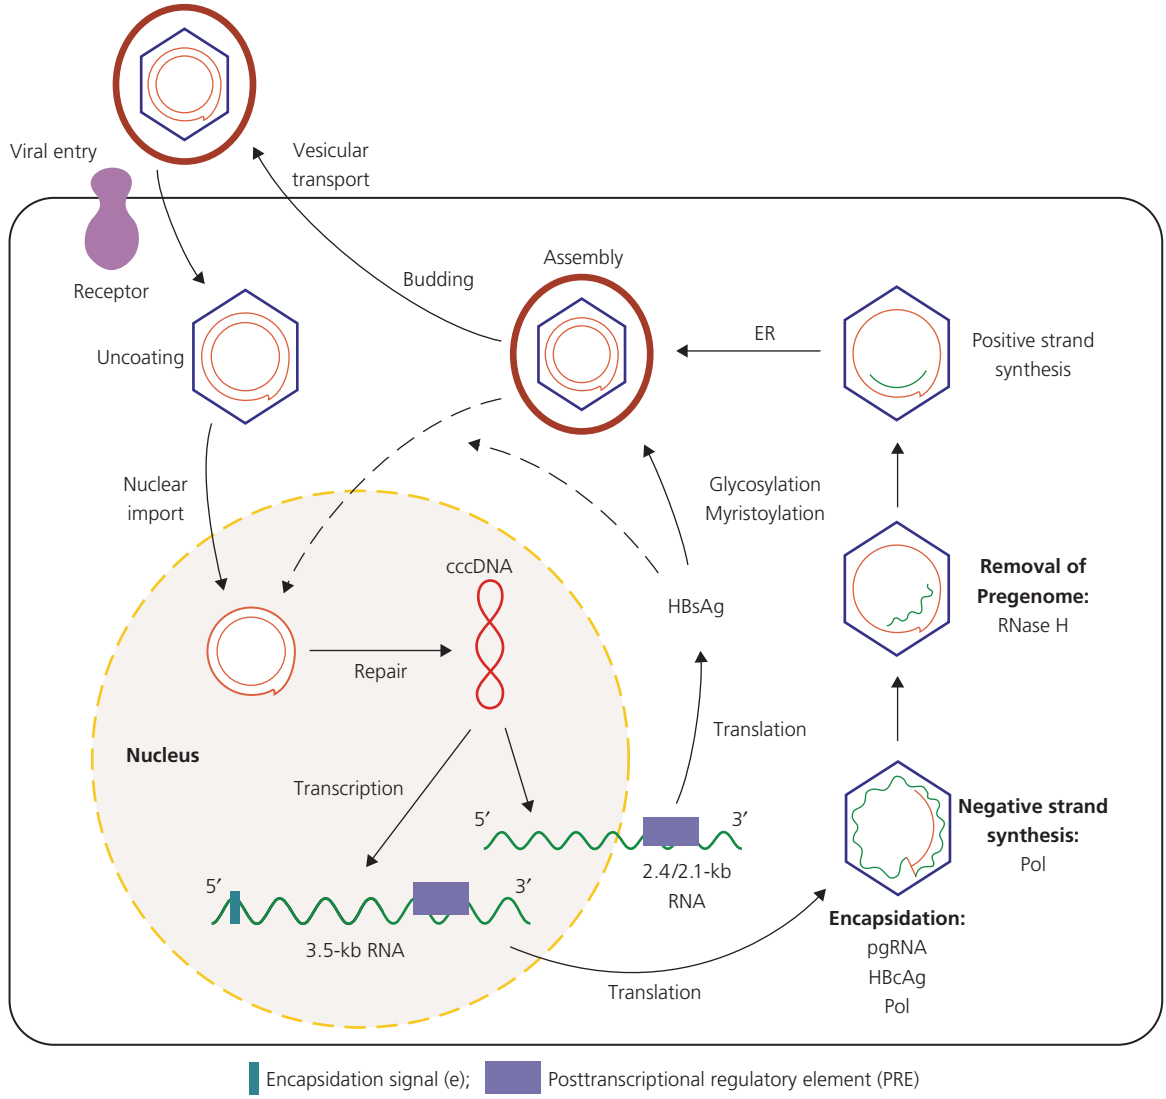

Figure 80.4 Replication of hepatitis B virus. Infectious virions probably attach to hepatocytes through the pre-S1 domain of the L protein. On entering, the nucleocapsid is delivered to the nucleus, and the viral genome is repaired to the covalently closed circular form (cccDNA). Viral transcripts are translated in the cytoplasm, and the core and polymerase proteins interact with the genomic length RNA to form the nucleocapsids. Reverse transcription occurs, and the mature virions are assembled in the endoplasmic reticulum (ER), where they acquire the surface proteins. The virion is then secreted through vesicular transport. The encapsidation signal (dark box) and posttranscriptional regulatory element (light box) on the *HBV* transcripts are shown as *rectangular boxes*.

The S protein accounts for most *S* gene products, with the L protein constituting 1%–2% and the M protein 5%–15%. Each surface protein has a glycosylation site in the S domain. Additional modifications of the M and L proteins occur at the pre-S2 domain with an N-linked oligosaccharide and a myristic acid at the N-terminal glycine residue of the pre-S1 domain [108]. The distribution of the three envelope glycoproteins varies among the types of viral particles, with little M and L protein in the 20-nm particles but relatively more L protein in the Dane particles.

Assembly of HBV begins with encapsidation of the genome. The packaging signal is a *cis*-acting element referred to as epsilon, which contains a stem-loop structure [109]. The terminal protein of the pol interacts with the epsilon and in concert with the core protein forms the nucleocapsid [110]. After encapsidation, the pol mediates the reverse transcription of the pregenomic RNA to minus-strand DNA and subsequent positive-strand synthesis. The circular form of the DNA is completed through several complicated steps of strand transfer [111]. The nucleocapsid then interacts with the envelope proteins in the endoplasmic reticulum to assemble into mature virions.

Hepatitis C virus

HCV is an enveloped virus and has been classified into six genotypes, 1–6. The virus circulates predominantly in complex

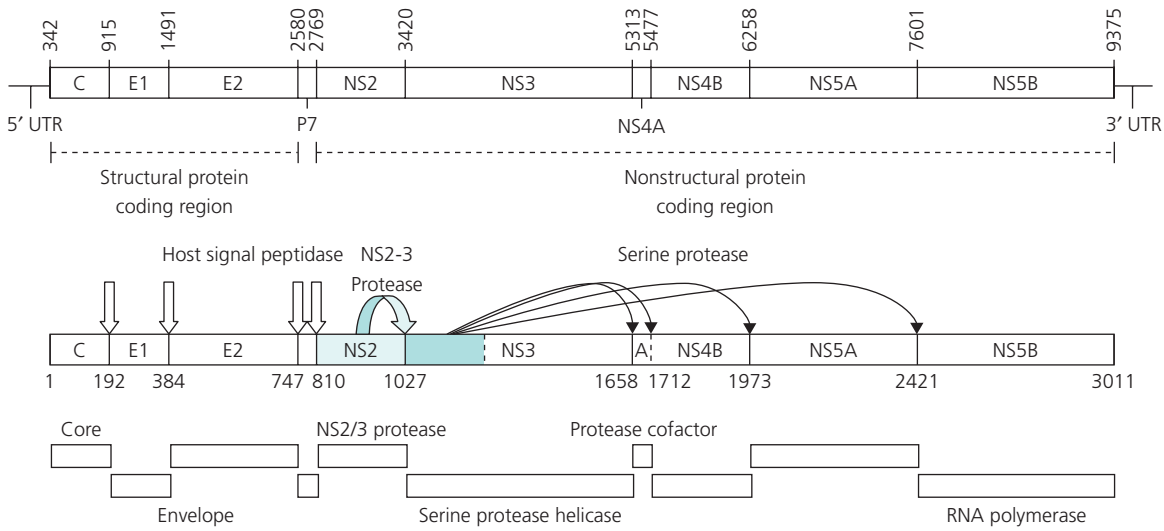

Figure 80.5 Genome organization of hepatitis C virus (HCV). The 5′ and 3′ untranslated regions (UTR) flanking a polyprotein open reading frame are shown at the *top*. Numbering refers to nucleotide positions of genes, based on the sequence of an *HCV* genotype 1a infectious clone. The middle panel shows HCV polyprotein processing with cleavage sites of host signal peptidase (*open arrows*), NS2-3 protease (*gray arrow*), and NS3 serine protease (*thin arrows*). Numbering denotes amino acid position upstream of cleavage sites. The processed HCV proteins are shown at the bottom.

with immunoglobulins and lipoproteins [112,113]. It is a member of the Flaviviridae family and has a positive-sense, single-stranded RNA genome about 9.6 kb in length with a single large ORF and highly conserved UTRs at the 5′ and 3′ ends [114–116] (Fig. 80.5). The 5′ UTR contains an internal ribosomal entry site that mediates translation. The 3′ UTR has a variable length with a 5′ to 3′ sequence followed by a polypyrimidine tract and finally by a highly conserved 98-nucleotide sequence [116]. The 3′ UTR is also predicted to have extensive secondary structures that probably play a role in viral replication. In the large ORF, the structural genes for core and two envelope glycoproteins, E1 and E2, are located at the N-terminal end and the nonstructural genes for NS2, NS3, NS4A, NS4B, NS5A, and NS5B are at the C-terminal end.

The HCV polyprotein of about 3000 amino acids is processed co- and posttranslationally by cellular and viral proteases to produce the individual gene products [117,118]. Cellular proteases in the endoplasmic reticulum catalyze the cleavage of the structural proteins, whereas viral encoded proteases cleave the nonstructural proteins [119].

The highly conserved core protein is the putative viral nucleocapsid and encompasses the first 191 amino acids of the polyprotein. The E1 and E2 are envelope glycoproteins with C-terminal hydrophobic transmembrane domains [120]. The 27 N-terminal amino acids of E2 have been designated the hypervariable region 1, owing to significant amino acid variations among all isolates [121]. Studies have suggested that sequence variations of the hypervariable region 1 result from immune pressure as a mechanism to evade host immune response.

The NS2 region encodes a metalloproteinase that requires cell membrane and N-terminal NS3 for efficient function [122]. The NS2-3 protease mediates autocatalytic cleavage between the NS2 and NS3 (Fig. 80.5). The NS3 region encodes a multifunctional protein with an N-terminal serine protease and a C-terminal RNA helicase and nucleotide triphosphatase (NTPase) [123]. The NS3 protease, distinct from NS2-3 protease activity, is involved in processing the downstream polyprotein [124]. The NS4A interacts with and acts as a cofactor for the NS3 protease [125]. The crystal structure of NS3 protease has a trypsin-like structure but becomes more chymotrypsin-like when cocrystallized with NS4A [126]. NS4B is thought to function in the formation of replicative complex in a membranous compartment [127]. The NS5A may play a role in sensitivity to interferon [128]. The NS5B is the RNA-dependent RNA polymerase that mediates viral replication. Similar to replication of other members of the family Flaviviridae, HCV replicates in the cytoplasm, presumably in a membrane-associated compartment (Fig. 80.6). The NS5B recognizes a structure in the 3′ UTR and initiates minus-strand RNA synthesis in a primer-independent template-specific process [129]. The synthesis of plus strand is presumably carried out by NS5B in a similar manner. HCV replication in vivo probably occurs in the context of multiple viral nonstructural proteins. The process of viral assembly is poorly understood and probably requires the interactions among viral genome, core, and E1 and E2 proteins.

Hepatitis D virus

HDV requires coinfection with HBV for replication [130]. Delta antigen is the inner ribonucleoprotein component of a subviral particle that is enveloped by HBsAg. HDV has many features in common with viroids, the subviral agents of plants [131]. The ribonucleoprotein complex consists

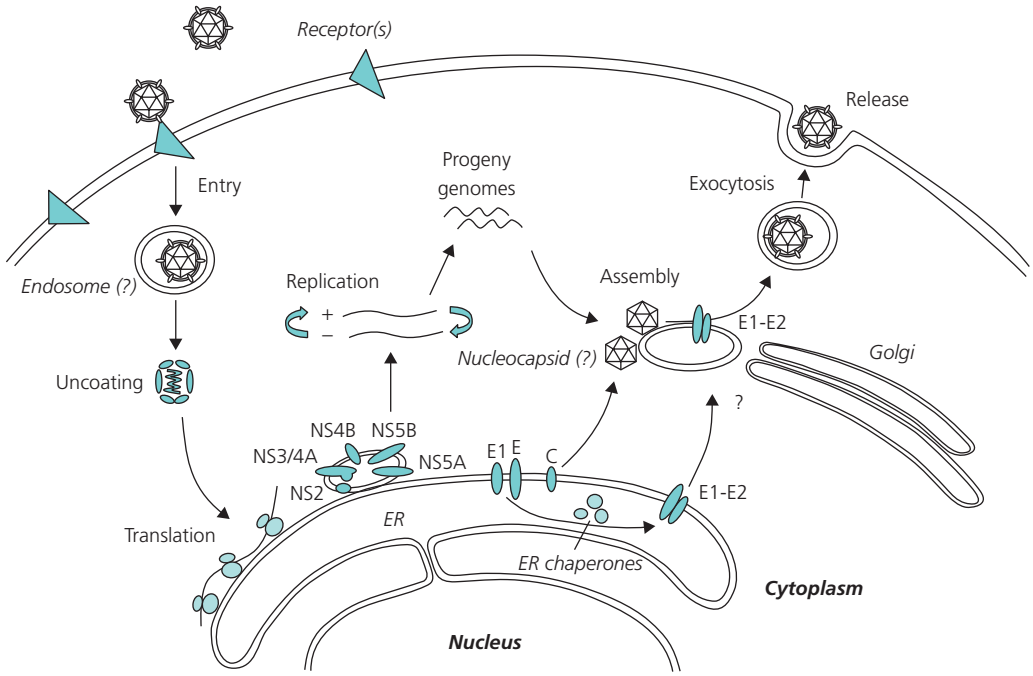

Figure 80.6 Replication of hepatitis C virus (HCV). The virion attaches and enters the susceptible cell through pathways that are not yet completely defined. The viral genome is then directed to a membranous component in the perinuclear endoplasmic reticulum (ER) region and serves as template for HCV protein synthesis. The nonstructural proteins form a replication complex with the genomic RNA and direct RNA replication (to negative and then plus strands). The structural proteins, which are retained in the endoplasmic reticulum, interact with the progeny genomes and assemble into virions. The virions are then secreted through an unknown exocytotic pathway, probably not passing through the Golgi compartment.

of small (SHDAg) and large (LHDAg) delta antigens and a single-stranded circular RNA genome 1.7 kb in length that has extensive self-complementation to form a rodlike structure (Fig. 80.7). HDV attachment to the host cell is mediated by HBsAg [132]. The HDV genome uses host RNA polymerase II to carry out RNA-directed RNA synthesis that is dependent on the small delta antigen [133,134]. Both genomic and antigenomic RNAs possess ribozyme activities that catalyze RNA self-cleavage and self-ligation. Similar to plant viroids, transcription and replication are integrated into a single process using a double rolling-circle mechanism [131]. After entry into cells, the HDV genome serves as a template for replication, resulting in the production of multimeric antigenomes. Nascent antigenomes, through their intrinsic ribozyme activities, form circular monomeric RNAs that, in turn, serve as templates for the production of HDV genomes. Alternatively, the elongating product can be cleaved and released as polyadenylated messenger RNAs, which then direct delta antigen synthesis [135].

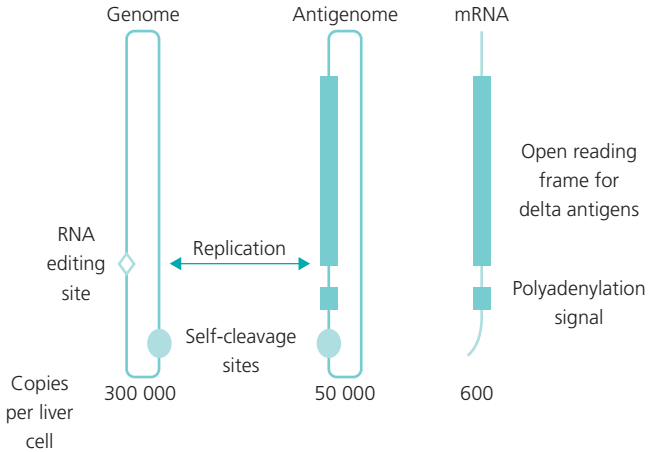

Figure 80.7 Genomic organization of hepatitis D virus (HDV). The RNA genome has a rod-like structure and contains an RNA editing and a self-cleavage site (*circle*). The antigenome is synthesized from the genomic RNA and is the template for HDV messenger RNA encoding the delta antigens. The antigenome also serves as the template for genome synthesis. The estimated copy numbers of the RNA species in the infected liver are shown *below*.

Translation of HDV messenger RNA yields the small and large delta antigens, which differ by the addition of 19 amino acids in the C-terminal end of LHDAg [136]. The small and large delta antigens have distinct functions during HDV replication. The additional C-terminal amino acids of the LHDAg contain an isoprenylation signal that appears to be important for interaction with HBsAg during viral assembly [137]. The RNA editing process results in two mRNA species coding for the two forms of HDAg and involves the double-stranded RNA-activated adenosine deaminase [138]. This RNA editing activity results in the C-terminal extension of the LHDAg [139].

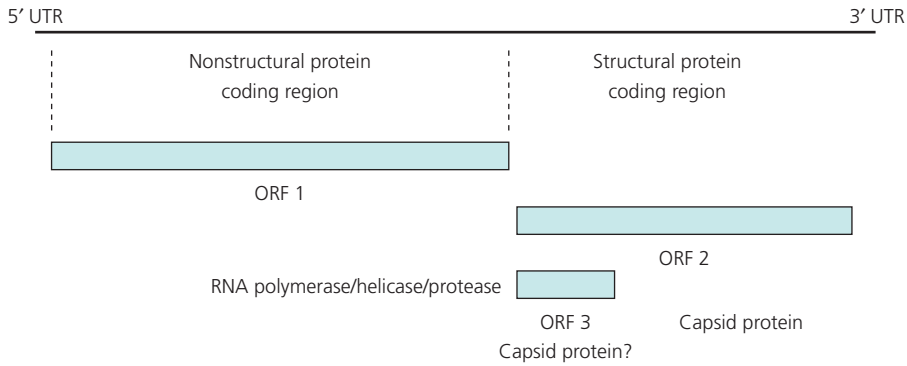

Figure 80.8 Genomic organization of hepatitis E virus. The open reading frames (ORF) are flanked by 5′ and 3′ noncoding regions and a 3′ polyadenylation. Within ORF1: MT (methyl transferase), X and Y (unknown functions), Pro (protease), Hel (helicase), H (proline-rich hinge region), Pol (RNA-dependent RNA polymerase). ORF2 codes for the capsid, and ORF3 codes for a protein of unknown function.

HDV assembly begins with the association of the delta antigens with the newly synthesized genome to yield a ribonucleoprotein complex [140]. The ribonucleoprotein complex is transported from nucleus to cytoplasm, presumably mediated by the nucleocytoplasmic shuttling function of delta antigens. The LHDAg of the ribonucleoprotein interacts with HBsAg to facilitate assembly. Large delta antigen is required for particle assembly, whereas small delta antigen is copackaged but not required for particle formation [141].

Hepatitis E virus

HEV is a nonenveloped virus and is unclassified but it is similar to togavirus and alphavirus. The viral genome is a single-stranded, positive-sense RNA genome of about 7.5 kb. It is polyadenylated and has a capped 5′ end [142]. The genome is organized into three overlapping ORFs flanked by noncoding regions (Fig. 80.8). ORF1 appears to encode the nonstructural gene products, ORF2 encodes the capsid protein, and ORF3 encodes a protein with possible nucleocapsid function [143]. Based on sequence analysis and comparison with other viral genomes, ORF1 contains several functional domains: methyl transferase, papain-like cysteine protease, helicase, and an RNA-dependent RNA polymerase [144]. ORF2 begins 38 nucleotides downstream from the 3′ terminus of ORF1 and contains arginine-rich regions believed to be involved in genome encapsidation. ORF3 overlaps one 3′ nucleotide of ORF1 and extends into ORF2.

Replication of HEV has not been characterized because of a lack of similarity to other viruses and efficient cell culture systems. The mechanisms of viral attachment, entry, and uncoating are unknown. The released genome likely uses the host translation machinery to synthesize viral gene products. Processing of the ORF1 polyprotein is carried out by either cellular proteases or a viral papain-like proteinase encoded by ORF1. The viral encoded polymerase mediates synthesis of plus- and minus-strand genomes as well as subgenomic RNA species, which serve as templates for the translation of viral antigens. The mechanism of viral assembly is unknown but probably involves the capsid function of ORF2 and ORF3.

Pathogenesis

Acute infection with hepatitis viruses is associated with a spectrum of liver diseases and systemic manifestations, ranging from asymptomatic infection, through self-limited hepatitis, to fulminant hepatitis. In addition, three of the viruses (B, C, and D) are associated with persistent infection and chronic hepatitis, the clinical manifestations of which are variable. The outcome, extent, and severity of acute viral hepatitis depend on a variety of viral and host factors. Although host responses play a major role in viral clearance and disease pathogenesis, the outcome of infection is often predicated on a variety of viral adaptive mechanisms. The pathogenesis of acute viral hepatitis involves a complicated set of virus–host interactions and is likely a result of diverse host immunological responses to the viral infection. In this section, the pathogenesis of acute viral hepatitis is discussed in the general context of viral infection and host responses and with respect to relevant issues specific to each of the viruses. Among the hepatitis viruses, the pathogenetic mechanisms have been much better studied in HBV and HCV than in the other viruses; therefore, we focus more on HBV and HCV. Furthermore, the pathogenesis of acute hepatitis is often inferred from the various studies during chronic infection (for B, C, and D), and we attempt to highlight these issues during the course of discussion in this section.

Primary infection

After gaining entry into a susceptible host, the hepatitis viruses are carried by the blood to the liver, which is the major site of viral tropism. For HAV and HEV, the viruses enter through the gastrointestinal epithelium, and the uptake mechanisms remain largely unknown. It is possible that a round of local replication may occur at the site of entry before the virus is further spread to the liver through the portal circulation. HBV, HDV, and HCV have all been reported to infect nonhepatocytes so the existence of an intermediate compartment of replication before infection of the liver has also been proposed but remains controversial [145,146].

Many initial events of viral infection have been characterized in the animal models for each virus. HBV and probably HCV replicate in a noncytopathic manner without causing injury to hepatocytes, whereas the cytopathicity of other viruses is unknown.

Immune responses

During primary infection, the initial pathway of antiviral immune response is largely unknown. Initial viral infection is associated with activation of innate immunity in the liver. Recognition of infected hepatocytes by resident natural killer or natural killer T cells leads to the activation of these cells and the induction of antiviral cytokines, including interferons [147,148]. This phase of innate immunity leads to the initial control of viral replication. This antiviral response is likely associated with a noncytopathic mechanism so little or no hepatocellular injury is evident. The innate immunity also plays a critical role in the activation of the adaptive immunity, including humoral and cellular responses. Induction of humoral immune response with the production of neutralizing antibodies prevents viral spread and leads to subsequent elimination of circulating viruses [149]. This mechanism is particularly relevant for HAV and HBV infections because of the high level of viral replication and viremia. Neutralizing antibodies against the capsid (for HAV and HEV) or envelope (for HBV) can be induced and lead to viral clearance and protection from subsequent exposure [150–152]. This constitutes the basis for the successful formulation of HAV (probably HEV as well) and HBV vaccines based on the capsid and envelope proteins, respectively. In HAV, HBV, HDV, and HEV, the immunoglobulin M (IgM) class of antibodies is detected first and serves as a useful marker for acute infection. The IgA class of antibodies has been detected in HAV and HEV infections, but the implication of its presence in viral clearance and protective immunity remains unknown [150]. On the other hand, neutralizing antibodies probably play little or no role in viral clearance during acute HCV infection [153]. A clearly defined anti-HCV IgM response has not been identified, and the antibody response [154], especially against the envelope proteins, tends to occur much later than in other hepatitis viral infections [155].

For HBV, the antibody response to the envelope proteins is a T-cell-dependent process [156]. A minority of patients infected with HBV fail to produce antienvelope antibodies, therefore contributing to the establishment of persistent infection. This deficiency resides at the level of T-cell nonresponsiveness, probably as a result of tolerance or anergy induction toward the HBV proteins [157]. The molecular mechanisms underlying this deficiency, however, are largely undefined. For HAV infection, whether the relapsing or prolonged phase is secondary to transient failure of the humoral immune response is unknown. On the other hand, antiviral antibodies may play a role in viral pathogenesis. Cell surface forms of viral antigens on infected hepatocytes could be potential targets for antibody-directed cell cytotoxicity [158,159]. However, this mechanism has not been shown to be operative in hepatocellular injury associated with any of the viral infections. In contrast, immune complex diseases with complement fixation, including glomerulonephritis, vasculitis, and cryoglobulinemia, which are major extrahepatic manifestations of HBV and HCV infections, can result from an abnormally activated antibody response to viral antigens.

The other limb of the immune response, the cell-mediated immunity, is critical for the long-term control of viral infections, including the hepatitis viruses. Although this aspect has only been studied in great detail for HBV and HCV, it is not unreasonable to suspect that cell-mediated immunity may play a role in viral clearance and pathogenesis for HAV, HDV, and HEV. Much of the information for hepatitis B has been gleaned from studies in mouse models, chimpanzees, and infected humans [157,160]. Nonprimate animal models that are susceptible to hepadnaviral infection (woodchucks, ground squirrels, ducks) have also proved useful in this avenue of research. In acute HBV infection, individuals can mount a vigorous, multispecific, and polyclonal cellular immune response to HBV. In contrast, chronically infected patients have a weak or barely detectable anti-HBV response [157]. This is true for both CD4 and CD8 responses. During acute hepatitis B, a vigorous human leukocyte antigen (HLA) class II-restricted, CD4+, helper T-cell response to multiple epitopes of HBc/eAg predominates in virtually all patients. Such a response to HBV envelope antigens, however, is much less evident. The class II-restricted, CD4+ T cells specific for nucleocapsid play an important immunoregulatory role in the control of viral infection [157,161]. By helping B cells produce neutralizing antienvelope antibodies and activating HBV-specific cytotoxic T lymphocytes (CTL), this CD4+ helper T-cell population may direct the initial antiviral response. During chronic HBV infection, the once strong nucleocapsid-specific CD4+ T-cell response becomes barely detectable, presumably as the result of a switch to T-cell exhaustion or nonresponsiveness. During exacerbation or successful treatment of chronic hepatitis B, these nucleocapsid-specific T-cell responses could reemerge [162,163].

In most viral infections, the activation of virus-specific CD8+ CTLs is critical for viral clearance. These cells can detect and eliminate or cure virus-infected cells through recognition of viral peptides in the context of HLA class I molecules. Using short synthetic peptides that mimic processed viral antigens and cells that are genetically engineered to express viral proteins, CTL responses to HBV in humans have been studied extensively [157]. These studies indicate that patients acutely infected with HBV develop a strong, polyclonal, HLA class I-restricted CTL response that is directed against multiple epitopes in all viral proteins. Similar to the class II-restricted CD4 responses in a minority of infected people, the class I-restricted CTL responses disappear and are barely detectable during the chronic phase of HBV infection [161,164].

Studies of immune responses in HCV revealed that both CD4 and CD8 responses can be detected against various viral proteins during acute infection, but the vigor and character of these responses appear to be directly correlated with the outcome of the viral infection [153]. A vigorous and multispecific CD4 and CD8 response is associated with viral clearance in both human and experimental chimpanzee infections [165,166]. On the other hand, antibodies against the envelope proteins, presumably containing neutralizing activities, arise much later in the infection and appear not to play a major role in viral clearance [167]. During acute HCV infection, those who progress to chronic infection appear to exhibit weaker cell-mediated immunity than those who recover. Several recent studies have pointed to a defect in dendritic cells in antigen presentation, presumably as a result of infection of these cells by HCV [168]. However, other studies did not confirm any defects in dendritic cell functions. Other mechanisms, such as the immunomodulatory effects of HCV core protein and the interferon inhibitory property of the NS5a protein, may also contribute to an overall weak immunity to this viral infection [169,170].

In chronic HBV and HCV infections, the detection of virus-specific CD4 and CD8 cells, albeit with low frequency and weak activities, in the peripheral blood and liver of chronically infected individuals suggests a pathogenic relationship between the indolent cellular immune response and necroinflammatory liver disease associated with chronic hepatitis [157]. Therefore, the cell-mediated immunity is a double-edged sword: vigorous response leads to viral clearance, whereas ineffective response results in chronic hepatocellular injury.

For HBV infection, the molecular and cellular mechanisms of viral clearance and hepatocellular injury have been elucidated in animal models, including both transgenic mice and chimpanzees [157,160] (Fig. 80.9). Adoptive transfer of murine CD8+, class I-restricted HBsAg-specific CTLs into syngeneic transgenic mice expressing HBV envelope protein in the liver leads to acute hepatitis [171,172]. The CTLs first target the liver through interaction between the HBV-specific T-cell receptors and the antigen-presenting HLA class I molecules on the hepatocytes and cause scattered apoptosis of hepatocytes. By secreting cytokines, including interferons, the CTLs recruit a variety of antigen-nonspecific inflammatory cells into the liver, resulting in more extensive necroinflammatory injury of the liver that resembles acute hepatitis B in humans. The predominant infiltrating effector cells are the macrophages, which probably mediate most of the hepatocellular

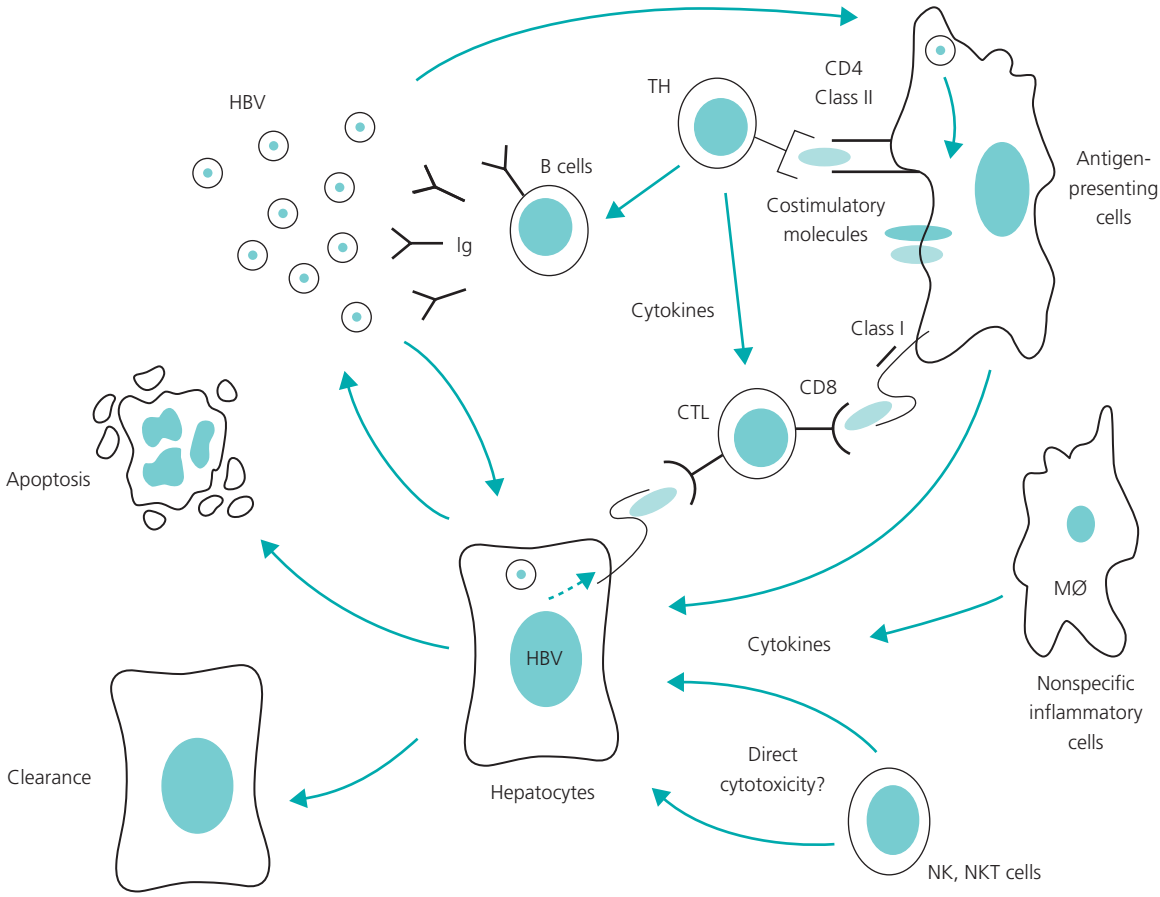

Figure 80.9 The immunopathogenesis of hepatitis B. See text for details. CTL, cytotoxic T lymphocyte; HBV, hepatitis B virus; NK, natural killer cell; NKT, natural killer T cell; TH, thymocyte.

injury in this model [173]. The CTLs, although not primarily responsible for most of the hepatocellular injury, initiate the cascade of immunological events leading to hepatitis in this model. A major consequence of these immunological events is the marked inhibition of hepatocellular *HBV* gene expression and viral replication [174]. Although the CTLs may contribute to a proportion of inhibition by direct cytolysis of *HBV*-expressing hepatocytes, a noncytolytic mechanism likely plays a substantial role in this effect [174]. Interferon-α and tumor necrosis factor-α produced by activated CTLs and other effector cells are the key cytokines involved in this mechanism [174]. A recent study in chimpanzees [160] also provided support for the noncytopathic mechanism as the major antiviral mechanism responsible for viral clearance during acute hepatitis. The resident natural killer or natural killer T cells, as discussed previously, provide the first line of defense; the CTLs, together with other inflammatory cells and production of antiviral cytokines, likely constitute the final assault on the virus. The CTL response appears to be long-lived because patients recovered from acute HBV infection harbor HBV-specific CTLs many years after viral clearance [164]. The CTLs have been postulated to persist as a result of continuous stimulation by low-level viral replication and in the meantime keep the infection in check. It is not clear how prevalent is this occult HBV infection, but low-level HBV virus can be frequently detected in patients with serological evidence of recovery [175–177]. Furthermore, active HBV infection can be reactivated in these patients on immunosuppressive therapy, and their serum or organs are capable of transmitting HBV infection [178–180].

In HCV infection, long-term persistence of virus-specific T cells has also been demonstrated despite evidence of recovery [181]. However, low-level viral infection is probably not the reason for this persistence. It is possible that these virus-specific memory T cells have unusual longevity in vivo and can be rapidly activated on viral antigen stimulation years after infection. Whether these virus-specific T cells can offer protective immunity to subsequent viral infection is unknown. The observation that chimpanzees can be reinfected despite recovery from previous infection [182,183] suggests that protective immunity may not persist after viral clearance. On the other hand, partial protective immunity has been demonstrated in both humans and chimpanzees after repeated exposure to HCV [184–186].

The cellular immune responses to HAV, HDV, and HEV are largely unknown. Although HAV-specific CD8 CTLs have been detected in liver biopsies during acute hepatitis A, their roles in viral clearance and pathogenesis remains undefined [187,188].

Clinical manifestations

General

Symptoms related to acute viral hepatitis are variable and nonspecific. It is impossible to distinguish one form of viral hepatitis from the other based solely on clinical features. The clinical course of hepatitis varies widely from an asymptomatic phase recognized only by elevation in aminotransferase levels to fulminant hepatitis with frank jaundice and hepatic coma [189–191]. About 20% of cases of acute hepatitis present with jaundice. There is a variable incubation period for each virus, ranging from 1 week to 6 months. The initial presentation is dependent on age at exposure, integrity of the host immune system, presence or absence of underlying liver disease, and the level of viral inoculum. Overall mortality is low. An overview of the clinical features of each of the five hepatotrophic viruses is given in Table 80.2.

Table 80.2 Clinical overview of the five viral hepatidides

Virus	A	B	C	D	E
Source	Stool	Blood	Blood	Blood	Stool
Transmission	Enteric	Percutaneous/ permucosal	Percutaneous/ permucosal	Percutaneous/ permucosal	Enteric
Epidemics	Yes	No	No	Yes	Yes
Incubation period (days)	15–45, mean 25	30–180, mean 75	15–160, mean 50	30–180, mean 35	14–60, mean 40
Acute hepatitis	Yes	Yes	Yes	Yes	Yes

Before the onset of symptoms, there is a prodromal phase that can last from 1 day to 2 weeks and averages 5–7 days, during which there are nonspecific constitutional symptoms. By far the most common symptom reported is loss of appetite. Patients report a distinct aversion for food that may worsen as the day progresses [192]. They may also lose the taste for tobacco and alcohol. Fatigue and weakness are common symptoms reported by 90% of patients and may be severe enough to confine them to bed. Before the onset of jaundice, two-thirds to three-quarters of patients complain of low-grade fever and flu-like symptoms. Mild headache is reported by 50%–70% of patients. Vomiting and nausea are experienced by some patients but are not predominant features of acute viral hepatitis, and their continued presence should alert one to consider alternative diagnoses. Diarrhea is not a common feature of acute hepatitis and occurs in less than 25% of cases of HAV infection. Patients often complain of a dull ache under the right rib cage or even frank pain. Closer to the onset of jaundice, the urine may begin to darken.

The prodromal phase is followed by the icteric phase. The onset of jaundice usually coincides with the peak of the serum ALT. The duration of jaundice is variable, ranging from 4 days to several months, but averages 2–3 weeks. Patients initially notice a yellow discoloration of the mucous membranes and sclerae, followed later by a sallow discoloration of the skin. The urine becomes intensely dark owing to the release of conjugated bilirubin from necrosed hepatocytes, and stools become pale as the result of an inability of the hepatocytes to conjugate bilirubin to its secretory form. During this phase, half of patients may experience itching, which is usually mild and transient. Weight loss of 2–10 kg is not uncommon. A minority of patients experience depression.

During the convalescent phase, most symptoms resolve. Jaundice disappears, with a return of normal skin, urine, and stool color. The return of appetite and gain in weight are favorable signs indicating recovery. Fatigue may persist for up to 2–6 months.

The physical examination during acute viral hepatitis may be normal, but almost all patients have some degree of hepatic tenderness. Most patients have mild hepatomegaly (12–14 cm), and the liver edge should feel soft and smooth. On occasion, it may feel firm to the examining hand, but it should never feel hard or nodular. If these findings are elicited, underlying cirrhosis should be suspected and an acute on chronic hepatitis should be considered. Splenomegaly and spider angiomas are features not commonly observed with acute hepatitis, but they may occur rarely. Jaundice is present in icteric cases, involving the mucous membranes, sclerae, and skin. The total bilirubin level usually has to be greater than 2.5 mg/dL before jaundice is clinically evident.

Extrahepatic manifestations

Extrahepatic manifestations may occur in patients with acute viral hepatitis and result from direct infection of another organ or as an immune-mediated phenomenon. A serum-sickness-like syndrome may be present in 5%–15% of patients with acute HBV infection and in fewer patients with HCV infection. It presents as a low-grade fever, rash, arthralgias, and angioneurotic edema [193,194]. The rash is usually urticarial but may be maculopapular. The arthralgias tend to involve the large joints, such as the elbows, wrists, knees, and ankles. Symptoms are thought to be immune complex mediated and resolve with onset of hepatitis.

Polyarteritis nodosa is well described in association with HBV infection. In one series, polyarteritis nodosa occurred in almost one-third of newly diagnosed cases of HBV [195]. Polyarteritis nodosa is thought to result from the deposition of antigen–antibody complexes in the intima of the vessel wall; HBsAg is the suspected antigen [196,197]. Symptoms include arthralgias, fever, abdominal pain, renal disease, mononeuritis, and skin rash. Polyarteritis nodosa occurs more often with chronic HBV infection [198]. The mortality rate ranges from 30% to 50%.

Essential mixed cryoglobulinemia (EMC) is a systemic vasculitis characterized by palpable purpura, arthralgias, and weakness. It has been linked to hepatitis A, B, and C based on the high prevalence of liver disease in patients with EMC and on the detection of viral antigens, antibody, and virus in the cryoprecipitate and the vascular lesions [199–201]. The association of EMC and viral hepatitis is strongest with HCV infection [202]. The prevalence of HCV in EMC ranges from 80% to 98% [202,203]. Cryoglobulins are serum proteins that precipitate at temperatures below 37°C [204,205]. They usually consist of polyclonal IgG complexed with monoclonal IgM with cross-reactivity against rheumatoid factor [206]. The prevalence of cryoglobulins in unselected patients with hepatitis C is unknown. Studies from referral centers report a prevalence ranging from 29% to 54% [199,207]. Most cases of HCV-related EMC are associated with chronic infection and do not correlate with viremia or genotype but appear to be related to the duration of infection and to more advanced stages of liver disease.

Renal disease is often seen in patients with acute viral hepatitis, and specific pathology is best characterized for HBV and HCV. Manifestations of renal involvement range from mild proteinuria and abnormal urinary sediment, including red blood cell and hyaline casts, to frank glomerulonephritis with renal failure. The renal lesion is thought to result from the deposition of immune complexes in the glomerular basement membrane. HBsAg, HBeAg, and HCV antigen have been demonstrated in the immune complexes from the glomerular basement membrane [208–210]. The most common renal lesions seen in HBV infection were membranous [211] and membranoproliferative glomerulonephritis [212]. Membranous glomerulonephritis occurs mainly in children from endemic regions. The natural history of membranous glomerulonephritis is not well defined [213]. Nephrotic syndrome and proteinuria are the most common presentations.

Children are more likely to be asymptomatic and to have spontaneous resolution of the nephrotic syndrome [211]. Progressive renal failure usually develops in adults. Most patients with glomerulonephritis have evidence of active viral replication, but the severity of the renal disease does not correlate with the activity of the liver disease or the viral level in serum. Membranoproliferative glomerulonephritis is the most common renal lesion seen in HCV infection, usually in association with EMC [214]. In the presence of cryoglobulins, 98%–100% of patients with membranoproliferative glomerulonephritis have detectable anti-HCV. In the absence of cryoglobulinemia, patients with chronic HCV infection may have a variety of renal lesions suggestive of primary glomerular disease including nephrotic syndrome and nonnephrotic proteinuria.

Papular acrodermatitis (Gianotti syndrome) has been described in children with acute hepatitis B [215,216]. The syndrome is most commonly seen in young children aged 1–6 years. It is characterized by erythematous papules on the arms, legs, and face with truncal sparing and lymphadenopathy. The mucous membranes are spared. It is not related to the infecting subtype of HBV. It usually runs a benign course, improving with the onset of hepatitis.

Other organ systems affected during viral hepatitis, although rarely, include the heart and gastrointestinal and nervous systems. Cases of myocarditis, pericarditis and bradycardia, and pericardial and pleural effusions have been described. Pancreatitis is commonly reported, especially in children [217] and may be the result of direct infection of the gland in the case of HAV infection. Neurological manifestations have included encephalitis, meningoencephalitis, mononeuritis multiplex, transverse myelitis, and Guillain–Barré syndrome [218–220]. A variety of hematological disorders may follow viral hepatitis, including pure red cell aplasia, pancytopenia, aplastic anemia, and hemolytic anemia.

Diagnosis and differential diagnosis

The diagnosis of acute hepatitis is based on the constellation of clinical, biochemical, histological, and serological findings. The CDC case definition of acute viral hepatitis is an illness with a discrete date of onset, accompanied by jaundice or elevated serum aminotransferase levels more than 2.5 times the upper limit of normal. The clinical symptoms associated with viral hepatitis were described in the previous section and are nonspecific for etiology. As the clinical features are similar for all the hepatotrophic viruses, specific diagnosis depends on the results of serological testing. The sensitivity of current serological assays should allow the etiology of acute viral hepatitis to be established in almost all cases by the time patients become symptomatic. In instances in which there may be a late or weak antibody response, sensitive RNA and DNA assays may be helpful in the diagnosis.

Serology

In the setting of a known exposure and appropriate symptoms with elevated serum aminotransferases, acute hepatitis A is diagnosed by the detection of IgM antibody to HAV (anti-HAV IgM) and the absence of other viral markers in serum [221,222]. Anti-HAV IgM is usually present in serum 5–10 days into the incubation period and remains detectable for up to 6 months after infection, when IgG-type antibody rises to a high titer and persists for life [223] (Fig. 80.10). Commercial assays for total anti-HAV measure both IgG and IgM, and thus a positive test result is not helpful in distinguishing acute from chronic infection. A past history of HAV infection is diagnosed by the detection of anti-HAV IgG. HAV RNA can also be detected in serum and stool during the incubation phase but this is primarily a research tool and is not used for diagnostic purposes. These molecular techniques are particularly helpful in characterizing the epidemiology of HAV infection and in identifying sources of outbreaks.

A number of viral antigens and their respective antibodies can be detected in serum after infection with HBV, and their interpretation is often the source of great confusion to physicians and patients alike. HBsAg and HBeAg are the first two viral proteins detected in serum [152] (Fig. 80.11). HBsAg may be detected as early as 1–2 weeks or as late as 11–12 weeks after infection, and its persistence is a marker of chronicity. HBeAg is considered a marker of HBV replication and infectivity. It is more important for assessing risk for transmission in chronic HBV infection [224]. HBcAg in serum is usually too scarce to detect but it can be visualized by immunostaining of liver tissue. A cytoplasmic distribution of HBcAg in hepatocytes was shown to correlate with disease activity.

Antibodies to three of the viral proteins (HBsAg, HBeAg, and HBcAg) can be detected in convalescent sera. Anti-HBc IgM class is the first to appear, followed by antibody to HBeAg (anti-HBe) and finally antibody to HBsAg (anti-HBs),

which is the marker of recovery. Anti-HBc IgG type persists after recovery and is a useful marker for prevalence studies of past exposure to HBV [225]. It should not be used to diagnose acute or chronic infection. HBsAg and anti-HBc IgM are the most frequent markers present during the symptomatic phase of the illness [152,226]. Rarely during acute HBV infection, HBsAg is rapidly cleared from serum, and anti-HBc IgM may be the only marker detectable; this particular scenario is referred to as the "window" period. This situation may also be seen during the convalescent phase of the illness when HBsAg and aminotransferase levels are declining and anti-HBs is not yet detectable. Given the sensitivity of current assays for HBsAg, this window period is rarely observed in clinical practice. Diagnosis of acute hepatitis B rests on the demonstration of anti-HBV IgM and HBsAg and negative tests for anti-HAV and anti-HCV. HBV DNA is present during the incubation and symptomatic phases of infection. Like HBeAg, it correlates with disease activity and infectivity. Current PCR-based assays have a cutoff of 100 virions/mL blood, but routine testing for HBV DNA is not recommended unless the patient is immunocompromised [227]. Persistently high levels of HBV DNA following resolution of hepatitis may be indicative of a failure to control the infection and risk for chronic infection.

Acute hepatitis C infection is difficult to recognize because fewer than 20% of cases present with jaundice [228]. Anti-HCV can be detected as early as 4 weeks after acute infection and in the majority of cases remains detectable lifelong [229,230] (Fig. 80.12). The diagnosis of acute hepatitis C infection should be based on a history of exposure, absence of previous liver disease, negative tests for other hepatitis viruses, and a positive test for anti-HCV and HCV RNA [231]. HCV RNA is detectable within 2 weeks of established infection and is also used to confirm acute infection [232]. However, routine HCV RNA testing for screening is not advocated because there is no standardization of the test. It is recommended in the investigation of immunocompromised patients who may have a low or absent antibody response.

Acute delta hepatitis may occur in two settings: simultaneously with HBV (coinfection) or after infection of a chronic hepatitis B carrier (superinfection). The serological pattern differs in each case. During coinfection, markers of HBV are usually detected first, followed later by markers for HDV. The presence of anti-HBc IgM is an important finding of HDV coinfection and a discriminating marker for distinguishing HDV coinfection from superinfection. Early in the course of coinfection, HDAg is not detectable unless the hepatitis is severe, but within 1–2 weeks, antibody to hepatitis D (anti-HDV) IgM should be detectable (Fig. 80.13). Anti-HDV IgG is usually delayed for several weeks after the onset and in some cases is present only transiently during the convalescent phase. The late and poor antibody response in acute delta coinfection makes the diagnosis difficult. It is advisable to perform repeat testing for anti-HDV IgM to confirm the HDV coinfection. HDV RNA can be detected early in the course of coinfection, but commercial assays are not available. The diagnosis of acute delta coinfection depends on the detection of anti-HDV IgM, HBsAg, and anti-HBc IgM.

Acute delta superinfection occurs in the setting of chronic hepatitis B. HDAg and HDV RNA can be detected early in the course of infection by experimental assays. In contrast to HDV coinfection, anti-HDV IgM and IgG are both present early during the symptomatic phase of acute delta superinfection (Fig. 80.14). Anti-HBc IgM is usually absent or present in low titers. Diagnosis of acute delta superinfection thus rests on the detection of anti-HDV and HBsAg and absence of anti-HBc IgM.

Diagnostic tests for antibody to HEV (anti-HEV) are available although none are approved by the US Food and Drug

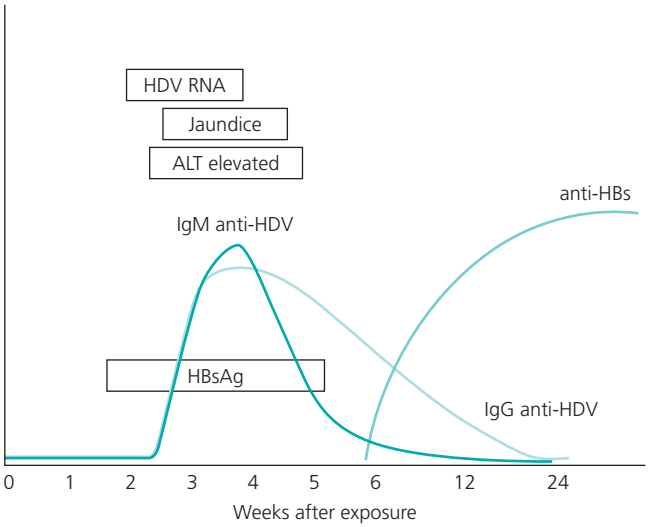

Figure 80.13 Typical serological course of acute hepatitis D virus (HDV) coinfection. ALT, alanine aminotransferase; HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M.

Administration. These tests have performed well in detecting anti-HEV in sera that are known to be positive. However, when used in panels of blood donor sera, these tests provide discordant results making them unreliable for clinical use [233]. In outbreak settings caused by HEV, anti-HEV IgM is detectable in more than 90% of patients' sera during the symptomatic phase and remains detectable for a period of 2 months after the onset of illness (Fig. 80.15). Anti-HEV IgG persists after recovery and appears to be protective against reinfection, at least in the short-term. In the appropriate setting, diagnosis of acute hepatitis E is confirmed by the demonstration of anti-HEV IgM.

Laboratory features

The laboratory hallmark of acute viral hepatitis is an elevation in the serum aminotransferase levels [234,235]. The serum ALT level is more specific for hepatocyte necrosis and is usually higher than the serum aspartate aminotransferase level. During an acute hepatitis, levels range from 10 times the upper limit of normal to more than 20 times the upper limit of normal and they peak with the onset of jaundice. The height of the ALT or aspartate aminotransferase elevation usually correlates with the degree of hepatocyte destruction but not with clinical outcome. The serum alkaline phosphatase level, a marker of biliary epithelial cell damage, may rise to two to three times the upper limit of normal but in most cases remains in the normal range. The conjugated and unconjugated serum bilirubin fractions are usually elevated. The level is dependent on the extent of hepatocyte damage but typically ranges from 85 to 340 µmol/L (5–20 mg/dL). In fulminant cases, laboratory markers of hepatic function become markedly abnormal: the prothrombin time prolongs, serum albumin falls, and higher bilirubin levels are seen. These are ominous signs that indicate impending hepatic failure and should prompt early patient referral to a liver transplantation center. During the acute phase of the illness, leukopenia with neutropenia and lymphopenia may be observed. Rarely, aplastic anemia may complicate acute viral hepatitis.

Histology

A liver biopsy can distinguish acute from chronic hepatitis and viral from nonviral causes but is rarely necessary to establish the diagnosis. Regardless of the etiology, acute viral hepatitis has certain characteristic findings.

There is an acute inflammatory response involving the entire liver [236,237]. Hepatocyte damage is greatest near the

terminal hepatic venules (zone 3). Here, the classic histological features of acute hepatitis are observed. The hepatocytes appear swollen (ballooning change). Ballooned hepatocytes have a granular, pale-staining cytoplasm with enlarged nuclei and are occasionally multinucleated. Numerous perivenular hepatocytes undergo acidophil change as a result of apoptosis. Their cell cytoplasm becomes densely stained and irregular in shape with pyknotic nuclei. These cells are thought to be the precursor of the acidophil body (Councilman body). The acidophil body is not specific for viral hepatitis but is a characteristic feature when present in abundance. The remaining hepatocytes show regenerative hyperplasia. The combination of cell swelling, cell shrinkage, apoptotic body formation, and cell loss gives rise to disruption of the liver cell plate pattern or lobular disarray [238]. When only a few hepatocytes are involved, the damage is designated *focal necrosis*. When groups of adjacent hepatocytes are involved, it is termed *confluent necrosis*.

Inflammatory cells are present within the hepatic lobule, among the damaged cells. Lymphocytes and macrophages are the major cell types. Plasma cells, neutrophils, and eosinophils are present to varying extent. Kupffer cell hyperplasia is recognizable. The mononuclear cell infiltrate also involves the portal tract. The inflammatory infiltrate may spill out of the portal tract, but this should not be confused with piecemeal or interface necrosis, a feature of chronic viral hepatitis. Surprisingly, despite the extensive destruction of liver tissue, the reticulin framework of the liver remains remarkably preserved. Cholestasis may or may not be present. Bile ductular proliferation may be seen but is not a prominent feature. Mild fatty change is seen more frequently with HCV infection. Liver fibrosis is generally absent but may be seen if the biopsy is performed late in the course of the illness.

In some cases, the confluent necrosis is severe enough to involve the entire central zone of the acinus. The necrotic cells are replaced by the condensed reticulin framework and inflammatory cells, predominantly macrophages forming central-to-portal bridging necrosis. This entity may be the precursor to fulminant hepatitis, and in one series, its presence was associated with a poorer outcome [239]. In extreme cases, there may be involvement of all zones of the acinus, referred to as *massive necrosis* with total loss of hepatocytes. The parenchyma is replaced by the collapsed reticulin framework and inflammatory cells. This is a manifestation of severe hepatitis seen in the clinical setting of fulminant hepatitis and coma.

The histological changes associated with acute viral hepatitis persist for several weeks after onset so a nearly normal liver biopsy 2–3 weeks after an episode of jaundice effectively rules out acute hepatitis. Late biopsy findings include a decrease in the degenerative changes, macrophages that stain intensely with periodic acid-Schiff stain, and numerous mitotic figures.

Staining the liver tissue with antibodies for hepatitis B surface and core antigens in the case of hepatitis B and delta antigen for delta hepatitis can help with the identification of the etiological agent of the hepatitis. Staining for hepatitis C antigen in liver tissue is not reliable [240,241].

Differential diagnosis

An array of diseases may mimic acute viral hepatitis and should always be considered in the differential diagnosis while awaiting the results of serological testing. As with any acute medical illnesses, more rapid diagnosis permits the prompt institution of specific therapy that may prevent an adverse outcome. The differential diagnosis of acute viral hepatitis is summarized in Table 80.3.

The prevalence of drug-induced liver disease is probably underestimated in clinical practice. Drug-induced liver disease should be considered in every case of acute hepatitis until the cause is firmly established. A wide variety of over-the-counter drugs are associated with hepatic toxicity, which may result in a clinical picture indistinguishable from acute viral hepatitis. Therefore, it is mandatory to obtain a detailed drug history from every patient who presents with acute hepatitis. Clinical clues to the etiology of the acute hepatitis are the timing of the rise in serum aminotransferase in relation to the onset of jaundice and presence of a serum eosinophilia. In drug-induced hepatitis, the jaundice tends to lag behind the rise in aminotransferases, whereas in viral hepatitis, the serum aminotransferase level tends to peak with the onset of jaundice. The concomitant finding of a serum eosinophilia may be suggestive of a drug-induced hepatitis.

Autoimmune hepatitis may present as an acute hepatitis in up to 30% of cases [242,243]. The typical presentation is that of a young woman with a high titer of antinuclear antibody and smooth muscle antibody or anti-LKM (liver/kidney/microsome antibody) and other clinical evidence of autoimmune disorders such as arthralgias and autoimmune hemolytic anemia. The globulin level may not be elevated during an acute presentation. Testing for the HLA markers A1, B8, and DR3 may provide substantiating evidence for confirming the diagnosis of autoimmune hepatitis.

Wilson disease is "the great imitator" and has diverse presentations, including that of acute hepatitis [244]. The diagnosis is difficult to confirm during an acute presentation and requires a high index of suspicion. It is important to establish the diagnosis early because of an extremely high mortality rate. In a recent series of fulminant hepatitis, no patients with Wilson disease referred to a transplantation center survived despite undergoing OLT [245]. The usual diagnostic criteria may be normal during an acute presentation. Ceruloplasmin level may be normal because of widespread release from necrosed hepatocytes, and urinary copper excretion may be low owing to altered renal clearance. Diagnostic clues may be the young age of the patient, a low alkaline phosphatase level, and the presence of a hemolytic anemia.

The liver may be an innocent bystander in infections that have multisystem involvement. Yellow fever, malaria, and Q

Table 80.3 Acute viral hepatitis: differential diagnosis, diagnostic testing and specific therapy

Condition	Diagnostic clue or test	Specific treatment
Drug toxicity, e.g., isoniazid, acetaminophen, phenelzine, halothane	Complete drug history including over-the-counter and complementary alternative medications. Acetaminophen level > 10 mg/dL	Withdraw offending agent. *N*-Acetylcysteine for acetaminophen toxicity[a]
Autoimmune hepatitis	ANA, SMA	Prednisone 60 mg/day
Wilson disease	Serum ceruloplasmin, 24-h urinary copper	D-Penicillamine (if diagnosed early)
Ischemic liver injury	Clinical evidence of hypotension	Correct hypotension
Toxic injury, e.g., *Amanita phalloides* poisoning	History of mushroom ingestion	None
Infections (non-A–E hepatitis), e.g., Q fever, yellow fever, malaria	Culture and serology, history of travel to endemic area	Treat specific infection
Choledocholithiasis	Ultrasound, cholestatic laboratory features	Antibiotics and drainage
Special hosts		
Bone marrow transplant recipients		
Acute graft-versus-host disease	Liver biopsy	Prednisone
Venoocclusive disease	Liver biopsy	None
Adenovirus, CMV, HSV, EBV	Serology and culture	Acyclovir for HSV and EBV; gangcyclovir for CMV; cidofivir for adenovirus
Pregnancy		
Acute fatty liver	Third trimester	Delivery
HELLP syndrome	Evidence of preeclampsia, thrombocytopenia, hemolysis	Delivery

a *N*-Acetylcysteine is administered orally in a loading dose of 140 mg/kg followed by 70 mg/kg every 4 h for 15–20 doses.
ANA, antinuclear antibody; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HELLP, *h*emolysis, elevated *l*iver enzymes, and *l*ow *p*latelets; HSV, herpes simplex virus; SMA, smooth muscle antibody.

fever may involve the liver and cause a hepatitis-like picture. Epstein–Barr virus (EBV), cytomegalovirus (CMV), herpesviruses, and adenoviruses may cause severe hepatitis in immunocompromised patients and in patients at the extremes of age. These agents should be suspected when routine serological testing is negative in an immunocompromised patient or when a history of recent travel to an endemic area is obtained from the patient.

Acute cardiovascular failure with hypotension from pump failure or sepsis can result in ischemic injury to the liver, so-called shock liver. In this setting, there can be massive hepatocyte destruction with serum aminotransferase levels more than 20 times the upper limit of normal, mimicking the presentation of an acute viral hepatitis. Bilirubin levels usually are only mildly elevated despite the degree of aminotransferase elevation. The history of hypotension and aminotransferase levels that rapidly normalize should establish the diagnosis.

Given the vast number of metabolic functions carried out by the hepatocyte, it is surprising that toxic injury is not seen more commonly. Mushroom poisoning from ingestion of *Amanita phalloides* and exposure to carbon tetrachloride are the best examples of toxic injury leading to markedly elevated aminotransferase levels. The diagnosis depends on a careful medical history indicating ingestion or exposure.

Rarely, biliary tract obstruction (choledocholithiasis or acute cholecystitis) can be confused with acute hepatitis [246]. Usually, other clinical features are present to suggest the diagnosis, such as an elevated serum alkaline phosphatase level and more intense right upper quadrant pain.

Finally, in special populations, such as bone marrow transplant recipients, unique diseases should be considered during the investigation of an acute rise in serum aminotransferase levels. These include acute graft-versus-host disease, which typically occurs within the first 28 days after bone marrow transplantation, and venoocclusive disease, which occurs within the first 2–3 weeks [247–249]. In pregnancy, acute fatty liver and the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) should be considered [250,251].

Course and complications

Course

Most cases of acute hepatitis are uncomplicated and resolve without sequelae. This is the expected outcome after infection with HAV and HEV in 99% of instances. Between 1% and 2% of cases are complicated by a fulminant course associated with a high mortality rate. Infection with HBV, HCV, and HDV may progress to a chronic hepatitis in 10%–90% of cases depending on the infecting virus, age at exposure, and immune status of the host. Chronic hepatitis is defined as persistent elevation in the aminotransferase levels 6 months

after the onset of infection and detection of specific serological or virological markers. It is best assessed by liver biopsy. Occasionally, acute hepatitis may have a prolonged course over 4 months or even up to 1 year, the best example of which is the prolonged course of HAV infection. This variant presentation needs to be differentiated from chronic hepatitis, and the most appropriate means of doing so is watchful waiting until the aminotransferase levels return to normal.

The prolonged form of HAV infection is characterized by pruritus, fever, diarrhea, and weight loss with serum bilirubin levels greater than 10 mg/dL and a clinical course lasting a minimum of 12 weeks [252,253]. It is seen more commonly in males and older individuals. Importantly, all patients recover without lasting sequelae. Some patients with this variant of hepatitis A may benefit from corticosteroid therapy [253].

In addition to the prolonged variant of HAV infection, a relapsing form is seen in up to 20% of HAV cases, distinguishable from the protracted form by its biphasic presentation [254]. Patients initially present with an acute hepatitis followed by apparent recovery only to have a recrudescence of hepatitis 5–10 weeks later. The second phase tends to be associated with higher bilirubin levels and to have a more prolonged course compared with the first phase [255]. Steroid therapy during the early phase of the illness and alcohol consumption have been identified as potential risk factors for relapsing HAV infection [254].

Despite these complications, complete resolution is the rule. Serological evidence of HAV IgM in serum during recrudescence of the illness and detection of HAV in stool during relapse are helpful tests for excluding other cause of hepatitis. The pathophysiology of these atypical presentations is unknown. A recent study in children reported an association between the protracted form of hepatitis A and HLA-DRB1*1301, a marker for pediatric autoimmune hepatitis [256]. Case reports have noted that acute hepatitis A infection may trigger the onset of autoimmune hepatitis in adults [257,258].

Other atypical courses of viral hepatitis have been described, which sometimes lead to diagnostic confusion. A biphasic pattern of hepatitis may also be observed after hepatitis D coinfection, although cholestasis is not a feature. The first peak is related to HBV infection and the second to HDV infection. On occasion, HBsAg-negative delta hepatitis is encountered during acute infection as the result of suppression of HBV replication by HDV [259]. This presentation can be perplexing for the clinician, and repeat testing for anti-HBc IgM and markers of HDV infection is recommended in suspected cases. Flares of chronic hepatitis B or reactivation are well recognized in association with chemotherapy or immunosuppression. It is important to distinguish reactivation from acute infection or nonviral causes of hepatitis because the management is different. The diagnosis of reactivation can be tricky. In most cases, the clinical picture is recognizable by elevated aminotransferase levels with detectable HBsAg and absent anti-HBV IgM in serum. However, anti-HBV IgM may be detectable in 25% of cases of reactivation, leading to confusion with acute hepatitis B. The only way to resolve this dilemma is to obtain a history from the patient of previous HBV infection or to perform a liver biopsy, which should demonstrate changes of both acute and chronic hepatitis in the case of reactivation.

Complications

Fulminant hepatitis is a complication of acute hepatitis characterized by a rapid progression to hepatic failure with associated hepatic encephalopathy. Only 1%–2% of all cases of acute viral hepatitis result in fulminant hepatitis. Fulminant hepatitis has been reported with all of the hepatotrophic viruses [260–263]. It has an extremely high mortality rate; fortunately survival has improved with improved intensive care units and with the widespread availability of OLT [264].

Risk factors for fulminant hepatitis A include older age at infection and underlying chronic hepatitis C [265,266]. The risk of fulminant hepatitis A with underlying chronic hepatitis C has not been substantiated by other studies [267,268].

Epidemics of fulminant hepatitis B have been reported with variant strains of the virus. The precore mutant, which is defective in HBeAg synthesis, has been reported to cause outbreaks of fulminant hepatitis [269–272]. However, other studies did not report a causal relationship of this mutation with fulminant hepatitis B [273–275]. This mutation was also found to arise de novo in patients with chronic HBV infection who did not develop fulminant hepatitis B, suggesting that other factors probably play a role in this multifactorial process [276]. Fulminant hepatitis B has also been reported with emergence of the antiviral drug-resistant virus, for example the rtM204V/I variant under lamivudine therapy [277,278].

Fulminant hepatitis may occur more frequently with HDV coinfection [279,280]. In addition, periodic epidemics of a severe fulminant form of delta hepatitis have been described in the Amazon Basin, referred to locally as LaBrea hepatitis [281]. This finding may be related to the particular genotype of HDV, genotype 3 [282].

Fulminant hepatitis E occurs at surprisingly high rates of 15%–25% in pregnant women during the third trimester [283,284]. The reason for this is unknown. Survival is poor.

A hepatitis-associated aplastic anemia and pure red cell aplasia may complicate acute hepatitis and is associated with a high mortality rate [285–287]. It appears to be more common in the Far East and in adolescent boys and young men [288].

Chronic hepatitis is a complication seen only with HBV, HCV, and HDV. Rates of chronic infection depend on immune status of the host and age at time of infection and vary from 10% to 90%. The causes of chronicity are unknown but undoubtedly involve a failure of the cellular immune response.

Other long-term complications of acute viral hepatitis include hepatocellular carcinoma, especially in the case of HBV and HCV infection, and lymphoma associated with HCV infection.

Prevention and immunoprophylaxis

Hepatitis A virus

Infection with HAV can be prevented by three strategies: active immunization through vaccination, which has the advantage of lifelong immunity; passive immunization through the administration of antibody made from pooled human sera processed by cold ethanol fractionation; or a combination of the two strategies.

Passive immunization

Immunoglobulin provides protection against HAV infection by the passive transfer of antibody. It can be used to provide immunity before and after exposure. The recommended dose is 0.02 mL/kg of immunoglobulin administered intramuscularly for both preexposure and postexposure prophylaxis. If used for preexposure prophylaxis, a dose of 0.02 mL/kg provides protection for less than 3 months. A higher dose of 0.06 mL/kg will provide protection for about 5 months. For postexposure prophylaxis, administering immunoglobulin within 2 weeks of the exposure is more than 85% effective [289]. Later administration is ineffective in preventing infection but will attenuate the course of disease [290]. Serious adverse events are rare after administration of immunoglobulin, but anaphylaxis has been reported after repeat administration to patients with known IgA deficiency [291]. It is safe to administer during pregnancy or breastfeeding and can be coadministered with inactivated vaccines, oral polio vaccine, and yellow fever vaccine [292]. Immunoglobulin can interfere with the immune response to other live attenuated vaccines, and these vaccines should be postponed for about 2 weeks [292].

Active immunization

Two commercially inactivated hepatitis A vaccines are available in the United States: HAVRIX and VAQTA. Both vaccines are highly immunogenic in adults, adolescents, and children, with 94%–100% achieving protective levels of antibody 1 month after a single dose of vaccine [293]. The lower limit of antibody required to prevent HAV infection is unknown, but in vitro studies indicate that levels of less than 20 mIU/mL can be neutralizing [293,294].

The efficacy of both vaccines was demonstrated in clinical trials. HAVRIX was shown in a large double-blind randomized controlled trial to have an efficacy of 94% after two doses 1 month apart [295]. Similarly, VAQTA was evaluated in a double-blind, placebo-controlled, randomized trial and had an efficacy of 100% after one dose of vaccine [296]. The vaccine has not been evaluated in the postexposure setting. A small randomized trial showed that hepatitis A vaccine was 79% efficacious in preventing HAV IgM positivity after household exposure to hepatitis A compared with no treatment [297]. Hepatitis A vaccine has not been directly compared to immunoglobulin in postexposure prophylaxis.

Table 80.4 People for whom hepatitis A vaccine is recommended

People traveling to or working in countries that have high or intermediate endemicity of infection
Men who have sex with men
Illegal drug users
People who have occupational risk factors for infection
People who have clotting factor disorders

In studies, the vaccine appears to confer long-term protection against infection, with follow-up ranging from 6 to 7 years [298,299]. Hepatitis A vaccination provides preexposure protection against HAV infection, and it is recommended for people who are at increased risk and for anyone wishing to obtain immunity. Individuals who are at increased risk for hepatitis A infection and who should be routinely vaccinated are summarized in Table 80.4. Both vaccines appear to be safe. In Europe, Asia, and the United States, about 8 million doses of hepatitis A vaccine have been administered, and serious events, anaphylaxis, Guillain–Barré syndrome, brachial plexus neuropathy, transverse myelitis, multiple sclerosis, encephalopathy, and erythema multiforme, although rare, have been reported [295].

The hepatitis A vaccine can be safely coadministered with the hepatitis B vaccine without affecting the immunogenicity of either vaccine or increasing the frequency of side effects [300]. Safety has not been evaluated in pregnancy, but because the vaccine is inactivated, the risk to the fetus is expected to be low. Similarly, no special precautions are required when vaccinating immunocompromised patients [301]. The vaccine is safe and effective when administered to patients with chronic liver disease [302,303]. Response to HAV vaccination in HIV-positive men is variable but appears to be reduced in those with low CD4 counts compared to HIV-negative men. Rates of anti-HAV range from 47% to 88% in HIV-positive individuals [304]. Antibody titers were also noted to be lower in those with HIV infection [305]. Prevaccination serological testing for susceptibility is not recommended because of the additional costs and because vaccination poses no risk to a person with a history of hepatitis A infection. Postvaccination testing is not recommended because of the high rate of response. A combined hepatitis A and B vaccine (HEPAB, Twinrix) is commercially available and appears to be safe and effective [306].

Hepatitis B virus

The goals of vaccination against hepatitis B are similar to those for hepatitis A: to prevent infection in susceptible individuals and to prevent spread of infection and chronic liver disease. Additionally, vaccination against hepatitis B can prevent infection with delta virus and prevent hepatocellular carcinoma related to HBV infection. HBV infection can be prevented by passive or active immunization or a combination of the two.

Passive immunization

Hepatitis B immunoglobulin (HBIG) is prepared from plasma that contains high-titer anti-HBs. In the United States, HBIG has an antibody titer of more than 100 000 IU/mL by radioimmunoassay. HBIG is used in conjunction with hepatitis B vaccination for postexposure prophylaxis to prevent transmission of HBV from an HBsAg-positive mother to her child or alone to prevent recurrence of HBV infection after OLT.

Active immunization

Two yeast-derived recombinant hepatitis B vaccines are available in the United States. A plasma-derived vaccine that was licensed for use in the United States in 1982 is no longer available. The vaccine is part of the routine immunization program in many countries and is effective in reducing the incidence of HBV infection in endemic areas of the world.

The recommended schedule is a series of three intramuscular doses of hepatitis B vaccine into the deltoid muscle of adults and anterolateral thigh of neonates and infants. The recommended dosing schedule induces an antibody response (anti-HBs titer higher than 10 mIU/mL) in more than 90% of adults and more than 95% of children and adolescents [307,308]. Increasing the interval between the first and second doses of HBV vaccination has little effect on immunogenicity or final antibody titer. The third dose confers optimal protection. Longer intervals between the second and third doses result in higher final titers of anti-HBs [309]. Administration of hepatitis B vaccine does not interfere with the antibody response to other vaccines [310]. The immune response is comparable to a standard course of vaccination if the product of one manufacturer is used with that of another. Hemodialysis patients usually require a higher dose or a greater number of vaccinations to achieve an adequate immune response [311,312]. Response rates among HIV-positive individuals were reported to be lower when compared to HIV-negative individuals; rates ranged from 33% to 56% and were related to CD4 count [304]. In one study, doubling the dose of HBV vaccine increased the response rate from 34% to 47% but this strategy was only effective in those with CD4 counts greater than 300 cells/mm^3 [313]. This probably also applies to immunocompromised individuals but has not been confirmed.

Clinical trials in the United States and other countries have shown that the hepatitis B vaccine is 80%–95% effective in preventing HBV infection in susceptible people [308,314–316]. If a protective antibody response is elicited, then the vaccine is 100% effective. Factors associated with nonresponse are a genetic predisposition, immunosuppression and certain chronic illnesses, age over 30 years, HIV infection, obesity, alcoholism, and male sex [317]. Studies suggest that even patients who fail to develop an adequate immune response to the vaccine (anti-HBs titer less than 10 mIU/mL) are probably protected against infection. Likewise, individuals who lose detectable antibody are probably protected because of lasting immunological memory. The vaccine appears to afford long-term protection. Studies in which the plasma-derived vaccine was used indicate that 13%–60% of patients may lose antibody after 9 years of follow-up [318–320]. A recent study from Taiwan reported a decrease in anti-HBs titers to below 10 mIU/ml in 29% of children vaccinated with the plasma-derived vaccine 15 years earlier [321]. Surprisingly anti-HBc was detected in 33% of these children but HBsAg, the marker of chronic infection, was found in only one child. In a similar long-term follow-up study from Alaska, 1578 native Alaskans vaccinated with three doses of the plasma-derived vaccine were tested after 15 years or longer [322]. The geometric mean concentration of anti-HBs decreased from 822 IU/L (measured 6 months after the third dose) to 27 IU/l after 15 years. Sixteen asymptomatic breakthroughs and eight possible breakthroughs were observed. Factors associated with higher titers of anti-HBs after 15 years included high initial serum anti-HBs level, male sex and vaccination at an older age [322].

The efficacy of the hepatitis B vaccine to prevent transmission of HBV was shown in several studies after the introduction of vaccine programs in endemic regions. Before vaccination, the carrier rate of HBV infection in Taiwan was estimated to be 15%–20%. A program of universal vaccination was initiated in 1984. This program was highly effective in reducing the rate of chronic HBV infection. Over the next decade, the rate of chronic HBV infection fell from 10.5% to 1.7% in children aged 6 years, and the annual incidence of hepatocellular carcinoma fell from 0.7 per 100 000 to 0.36 per 100 000 [323–325]. These findings were confirmed by other studies from other endemic regions [326].

Vaccination is not contraindicated in pregnant women or in those who are breast-feeding. Postvaccination testing is not recommended after routine vaccination of children or adolescents. Testing for immunity is advised only for people whose subsequent management depends on their immune status, such as infants born to HBsAg-positive mothers, dialysis patients and staff, and patients with HIV infection [320]. Booster doses are not recommended for vaccinated individuals, nor is routine serological testing recommended to determine immune status, unless a person was exposed to

the virus. Revaccination of nonresponders to a primary course of vaccine should be considered because 15%–25% develop an adequate antibody response after one dose and 30%–50% after three doses of vaccine [318]. For patients undergoing hemodialysis, vaccine-induced immunity may wane, and patients should probably undergo testing for antibody levels annually and receive a booster dose if anti-HBs levels fall below 10 mIU/mL [320].

Pain and fever are the most common side effects associated with HBV vaccination; however, in placebo-controlled trials, these side effects occurred no more frequently than with placebo [307,308,314,316]. Over 1 billion doses have been administered worldwide, and serious adverse events occur rarely [24]. A possible association between the plasma-derived vaccine and Guillain–Barré syndrome and demyelinating diseases has been reported [327]. Two recent studies failed to confirm such an association between hepatitis B vaccine and multiple sclerosis [328,329]. In addition, there are large differences in the geographic prevalence of HBV and the incidence of multiple sclerosis. Furthermore, analysis of postmarketing studies in the United States showed no increase in multiple sclerosis after hepatitis B vaccination, and reanalysis of the French data by the Viral Hepatitis Prevention Board and World Health Organization concluded that there was no association between hepatitis B vaccination and multiple sclerosis [330].

Variant viruses, with "escape mutations" in the immunodominant "a" determinant region of the HBsAg gene after vaccination, have been described. These variants have been reported worldwide. Therefore, a theoretical concern of hepatitis B vaccination is the replacement of wild-type virus by the variant strain to which vaccinated individuals in the community will be susceptible. A report from the Taiwan vaccination program described an increased prevalence of vaccine escape variants from 8% to 28% over a 10-year period, lending credence to this concern [331]. However, this finding has not been confirmed in other studies [332,333]. Furthermore, chimpanzees vaccinated with commercial hepatitis B vaccines were protected from infection after challenge with an infectious strain of the variant virus [334].

Hepatitis B vaccination is recommended for the prevention of perinatal HBV infection, for infants born to HBsAg-positive mothers, and as part of the universal vaccination of all preschool-aged children [320]. Individuals who are at high risk for acquiring HBV infection should receive hepatitis B vaccination and are listed in Table 80.5. The recommendations for use of the hepatitis B vaccine in the postexposure setting are outlined in Table 80.6. These recommendations have been updated. The major changes were to improve prevention of perinatal and early childhood HBV transmission and to improve vaccine coverage of children and adolescents who were not primarily vaccinated. Readers are referred to the following reference for a complete list of all the updated recommendations [335].

Table 80.5 People for whom hepatitis B vaccine is recommended

People with occupational risk
Clients and staff of institutions for the developmentally disabled
Hemodialysis patients
Recipients of clotting factor concentrates
Household contacts and sex partners of HBV carriers
Adoptees from countries where HBV infection is endemic
International travelers
Injection drug users
Sexually active men and women
Inmates of long-term correctional facilities

HBV, hepatitis B virus.

Table 80.6 Recommendations for postexposure immunoprophylaxis for hepatitis B

Exposure	Recommendation
Perinatal	Vaccination + HBIG
Sexual (acute case)	HBIG +/– vaccination
Sexual (chronic carrier)	Vaccination
Household (acute case)	None
Household (acute case, known exposure)	HBIG +/– vaccination
Household contact (chronic carrier)	Vaccination
Inadvertent percutaneous/permucosal	Vaccination +/– HBIG

HBIG, hepatitis B immunoglobulin.

Hepatitis C virus

No effective vaccine is available to prevent infection with HCV. This is primarily the result of a lack of neutralizing antibody, the high mutation rate of the viral genome, existence of viral quasispecies, and a lack of knowledge about protective immunity. Protection against infection after challenge with a homologous strain has been demonstrated in chimpanzees using hyperimmune serum against region 1 of the E2 protein but not against heterologous strains [336–338]. Studies in chimpanzees using a DNA vaccine encoding the E2 protein failed to protect against infection with a homologous strain of virus but may have attenuated the course of infection and prevented chronicity [339]. The recent discovery of natural immunity to HCV and the results of several vaccine studies in chimpanzees hold promise for the development of an HCV vaccine. Current strategies have been more successful in preventing acute infection from progressing to chronic infection rather than preventing acute infection. However, a recent study reported that a recombinant DNA vaccine encoding the nonstructural region of HCV in an adenovirus vector was able to elicit effective immunity against heterologous virus challenge in chimpanzees [340]. Four of five chimpanzees inoculated with 100 chimpanzee 50% infec-

tious doses (CID_{50}) were protected against acute hepatitis after infection with a heterologous virus which differed from the vaccine sequence by more than 13% at the amino acid level compared to none of five control chimpanzees inoculated with a control adenovirus and plasmid DNA vector encoding the HIV gag antigen [340].

Studies in the late 1970s showed that use of immunoglobulin failed to prevent non-A, non-B hepatitis (HCV) [341,342]. Intravenous infusions of immunoglobulin may attenuate the severity of non-A, non-B hepatitis (HCV) [343,344]. It was demonstrated that neutralizing antibodies to HCV are present in immunoglobulins derived from anti-HCV positive plasma [345]. Enrichment of such plasma containing broadly reactive neutralizing antibodies may provide a strategy for preventing HCV infection. Until further studies are carried out, use of immunoglobulin as postexposure prophylaxis for HCV infection cannot be recommended.

Hepatitis D virus

The dependence of HDV replication on HBV means that the same preventative and postexposure measures used to prevent HBV infection can be employed to prevent hepatitis D coinfection. Risk behavior modification is the only current measure to prevent HDV superinfection.

Hepatitis E virus

A recombinant vaccine for HEV is being evaluated in Nepal. Immunoglobulin has not been evaluated for postexposure prophylaxis.

Needlestick injury

Transmission of bloodborne pathogens through needlestick injury is an important issue for health-care workers. It is a significant contributor to job-related injuries and emotional stress for health-care workers. Each year, about 600 000–800 000 needlestick injuries occur in the United States. Infection with HBV, HCV, or HIV constitutes the major risk for the health-care worker after needlestick injury.

The risk for HBV infection is primarily related to the degree of contact with blood in the work environment and to the HBeAg status of the source. In studies of nosocomial transmission of HBV through needlestick injury, the risk for clinical hepatitis if the source was positive for both HBsAg and HBeAg was 22%–31%; the risk for serological evidence of HBV infection was 37%–62%. In contrast, the risk for developing clinical hepatitis from a contaminated needle from an HBsAg-positive, HBeAg-negative individual was 1%–6%, and the risk for HBV seroconversion was 23%–37% [346]. Although percutaneous exposure is an efficient mode of transmission of HBV, it accounts for a relatively small number of nosocomial infections because of increased hepatitis B vaccine use in health-care workers.

HCV is not transmitted efficiently by needlestick injury. The rate of seroconversion to anti-HCV after needlestick injury averages 1.8% per injury and ranges from 0% to 7% [347,348]. About 2.4% of new cases of HCV infection are the result of needlestick injury. A deep injury, use of a hollow-bore needle, and visible blood on the needle have been identified as risk factors for transmission of HCV [347].

Exposure prevention is the primary strategy to reduce HBV and HCV transmission by needlestick injury. Health-care workers should be educated concerning the risk for and prevention of bloodborne infections, including use of personal protective equipment and vaccination against HBV. Health-care workers were required to adopt universal precautions under regulations that were introduced in 1987 [349]. Despite these recommendations, needlestick injuries continue to occur. Regulations to prevent needlestick injury should be enforced in the workplace.

General management after a needlestick injury involves washing the wound with soap and water for a minimum of 15 min. Postexposure management should include prompt reporting, evaluation, counseling, treatment as necessary, and follow-up. The person whose blood was the source of exposure should be evaluated for evidence of HBV, HCV, and HIV infection. No special precautions are necessary to prevent secondary transmission during the follow-up period. However, exposed people should refrain from donating blood, plasma, organs, tissue, and semen. The exposed person does not need to modify sexual practices or to avoid becoming pregnant. Employers should follow all federal and state requirements for recording and reporting occupational injuries and exposures [350,351].

Specific recommendations for postexposure management are outlined by the US Public Health Service [352]. Any unvaccinated person who sustains a needlestick injury should receive the hepatitis B vaccine series. The recommendations for management of exposure based on HBsAg status of the source and vaccine status of the exposed individual are shown in Table 80.7. Both HBIG and hepatitis B vaccine can be administered simultaneously.

No specific therapy is available for prevention of HCV infection after needlestick injury. Recommendations for postexposure management are intended to achieve early identification of chronic cases and, if present, to refer to a specialist for treatment options. The source of exposure should be tested to determine anti-HCV status. Baseline anti-HCV and ALT testing should be performed on the exposed individual and repeated in 4–6 months. Testing should be extended to 12 months for HIV–HCV coinfected sources. If desired, HCV RNA testing can be performed after 4–6 weeks. All positive tests should be confirmed by testing for HCV RNA. Immunoglobulin administration is not recommended because of the absence of neutralizing antibody and the failure of immunoglobulin to prevent transmission of HCV [341,344]. Antiviral agents are not recommended for post-exposure management. Counseling should be provided to exposed people.

Table 80.7 Recommendations for postexposure prophylaxis for health-care workers following exposure to hepatitis B virus

Vaccination and antibody status of exposed health-care worker	Source and treatment		
	HBsAg-positive	**HBsAg-negative**	**Unknown/Not available for testing**
Unvaccinated	HBIG[a] × 1 and initiate hepatitis B vaccine series	Initiate hepatitis B vaccine series	Initiate hepatitis B vaccine series
Previously vaccinated			
Known responder	No treatment	No treatment	No treatment
Known nonresponder	HBIG × 1 and initiate hepatitis B vaccine series or HBIG × 2	No treatment	No treatment
Antibody response unknown	Test exposed person for anti-HBs If titer > 10 mIU/mL, no treatment is necessary If inadequate, administer HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBs If titer > 10 mIU/mL, no treatment is necessary If inadequate, administer vaccine booster and recheck titer in 1–2 weeks

a Dose of HBIG is 0.06 mL/kg intramuscularly.
HBIG, hepatitis B immunoglobulin; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

Treatment

Treatment of acute viral hepatitis is largely supportive and directed to ensuring adequate nutrition and hydration and to monitoring patients for the development of fulminant hepatitis. Drug therapy is rarely indicated for acute viral hepatitis A and E because 90%–95% of patients are expected to recover without sequelae. Therapy of acute hepatitis B has not been well studied; however, given the high recovery rate of 90%–95% in adult cases, therapy is not recommended. Based on the high response rate to interferon therapy, it may be reasonable to treat patients with clearly documented acute HCV [353].

General recommendations

Most patients with acute hepatitis can be managed outside the hospital setting as long as they can maintain adequate hydration and intake of calories. The old recommendation of bed rest is no longer advocated unless the patient experiences severe fatigue [354]. No specific dietary measure or supplement has been shown to be effective. Protein should be restricted only in patients exhibiting clinical signs of hepatic encephalopathy. During the convalescent phase, a high-protein diet may be necessary to aid in recovery. Alcohol should be avoided, and use of medications should be kept to a minimum. Drugs that are metabolized by the liver, such as benzodiazepines, should be avoided or the dose reduced if they are absolutely essential. Patients should be assessed weekly during the early phase of the illness and followed through recovery. They should be monitored for symptoms and signs of encephalopthy, such as increased somnolence, drowsiness, and asterixis and, if any of these are present, the patient should be assessed with serial trail tests. Monitoring of the serum prothrombin time is a useful marker for assessing hepatic decompensation and for deciding when to refer to a liver transplantation unit. The monitoring of serum aminotransferase levels is not helpful for assessing hepatic function because levels may return to normal in fulminant hepatic failure after massive destruction of hepatocytes. Antiemetics can be used to improve symptoms of nausea. Patients who exhibit clinical features of fulminant hepatitis should be rapidly referred to a liver transplantation unit for management. OLT may be a lifesaving procedure for patients who decompensate after acute hepatitis (see Chapter XX on fulminant hepatitis). It is not necessary to isolate patients with acute hepatitis. People caring for patients with acute HAV and HEV infection should wash their hands with soap and water. Close contacts of people with acute HBV infection should receive hepatitis B vaccine.

Specific therapy

The rationale for antiviral therapy in acute viral hepatitis is to prevent fulminant hepatitis, to ameliorate symptoms, and to prevent progression to chronic hepatitis. The indications for antiviral therapy in acute hepatitis B have not been clearly delineated. Interferon-α was compared with placebo in retrospective fashion for the treatment of acute hepatitis B. A higher rate of clearance of HBsAg and HBeAg and loss of HBV DNA were observed in the group that received interferon-α, 80% vs 54%. Therapy was well tolerated, but the concern remains that interferon therapy may worsen the hepatitis. To date, there have been no randomized, prospective trials evaluating interferon therapy for acute hepatitis B and use of this agent should be on a case-by-case basis using sound clinical judgment.

Lamivudine, a nucleoside analogue, was shown to be effective in the treatment of chronic HBV infection and may hold promise as a therapeutic agent for acute fulminant infection. This is based on the benefit determined from a few case reports in the setting of subfulminant or fulminant hepatitis B, and reports of success in treating reactivation of hepatitis B after chemotherapy and acute hepatitis B after OLT [355–358]. In one uncontrolled study 15 patients with clinically severe acute hepatitis B were treated with lamivudine 100 mg daily [359]. Lamivudine resulted in a marked improvement in clinical status in 13 patients within a mean period of 2 weeks. Encephalopathy and coagulopathy improved rapidly within 1 week and all patients were HBV-DNA-negative by PCR-based assay by 2 weeks [359]. Two patients required OLT, of whom one died. A report from Germany looking at lamivudine use before OLT in patients presenting with severe acute or fulminant hepatitis B showed similar findings with 14 of 17 patients surviving, without the need for liver transplantation, all of whom cleared HBsAg within 6 months [360]. Two patients required OLT and one patient died. Based on these uncontrolled studies it might be appropriate to consider lamivudine therapy for cases of acute hepatitis B presenting with a fulminant picture [360]. Lamivudine cannot be recommended for all cases of acute hepatitis B until more data are obtained. Studies on therapy of acute delta hepatitis are not available. Until further data are available, specific antiviral therapy is not recommended for acute HBV or HDV infection. Lamivudine should be used to prevent reactivation in patients receiving chemotherapy or high-dose immunosuppressive therapy [361,362].

Therapy for acute hepatitis C is controversial. The rationale for treatment of acute hepatitis C includes a high rate of chronicity ranging from 50% to 85%, and the relatively low response rate of 54%–56% when treatment is initiated in the chronic phase [363–365]. However, the decision to institute therapy early must be weighed against spontaneous viral clearance and the risks of therapy. Small published studies indicate that treatment of acute hepatitis C using interferon monotherapy reduces the severity of the acute hepatitis and reduces the rate of chronic infection [366–369]. The sustained loss of HCV RNA ranged from 39% to 64%, compared with 0%–20% in untreated controls. A metaanalysis of 12 controlled trials, which included 414 patients, assessed the efficacy of interferon vs no therapy for posttransfusion or sporadic acute hepatitis C [370]. The overall rate of chronicity in untreated subjects was high, ranging from 65% to 75%. Using a sustained virological response (SVR), defined as the outcome of undetectable HCV RNA 6 months after stopping therapy, interferon therapy significantly increased the SVR with a risk difference of 49% in comparison to no treatment [370]. Delaying treatment by 8–12 weeks after the onset of disease did not compromise the SVR rate. An uncontrolled study of interferon-α2b 5 MU daily for 4 weeks followed by 5 MU thrice weekly for 20 weeks was associated with a SVR in 43 of 44 patients (98%) when treatment was initiated within a mean of 89 days from the onset of infection, suggesting that early therapy was highly effective at clearing virus [353]. The argument against early treatment of acute hepatitis C is based on the fact that a substantial proportion of acute cases, 25%–30%, resolve spontaneously and that treatment during the acute phase is problematic. Two studies from Germany highlight these issues. In one study, 24 of 46 patients (52%) presenting with symptomatic, acute hepatitis C spontaneously cleared virus usually within 12 weeks after the onset of symptoms [371]. All asymptomatic patients ($n = 9$) progressed to chronic hepatitis C. It was noteworthy that delaying the start of treatment beyond 3 months did not markedly impact on SVR with a reported rate of 80% [371]. The second study treated 89 patients with acute hepatitis C using pegylated interferon-α2b 1.5 μg/kg/week for 24 weeks [372]. The SVR rate was only 71%, much lower than other studies had previously reported. Adherence to therapy was suboptimal because only 73% of patients received 80% of the dose for 80% of the prescribed duration. Psychiatric side effects were common, 27%, and one patient committed suicide [372].

Delaying therapy beyond 1 year appears to be detrimental based on the results of a Japanese study that compared early treatment within 8 weeks of onset of acute hepatitis vs delaying therapy by 1 year [373]. Delaying therapy decreased the SVR rate from 87% to 53% [373]. However, it remains to be proved whether antiviral therapy initiated during the acute stage is superior to treatment started shortly after the infection becomes chronic. Additionally, the best regimen is yet to be determined. Based on available data, a reasonable approach would be to monitor patients for a period of 8–12 weeks after the onset of hepatitis to identify those patients who will clear virus spontaneously. If patients fail to clear virus, treatment should be discussed with the patient and probably should not be delayed beyond 24 weeks after presentation. Although the optimal therapy has not been determined, it is reasonable to use monotherapy either with standard interferon 5 MU daily for 4 weeks followed by thrice weekly for 20 weeks, or pegylated interferon for 24 weeks. Long-term efficacy is not available from any of the published series.

Other viruses

Other nonhepatotrophic viruses can cause hepatitis as part of a generalized systemic infection. Members of the Herpesviridae family are covered here because of their worldwide prevalence and their special role in bone marrow transplant recipients, patients receiving chemotherapy, and post-OLT patients. The identification of other putative hepatotrophic viruses and their role in acute hepatitis are briefly discussed.

Herpes simplex virus types 1 and 2

Infection with herpes simplex virus (HSV) occurs worldwide and affects people of all ages [374]. The clinical manifestations of primary disease depend on the age and immune status of the individual. Primary infection in children tends to be a mild and subclinical illness in almost all cases. Severe infections occur more frequently in infants and immunocompromised patients. HSV-1 classically causes infection above the waist and HSV-2 below the waist. The clinical manifestations of primary disease include vesicular and ulcerative gingivostomatitis and anogenital ulceration [374]. Hepatitis caused by HSV-1 and HSV-2 infections tends to occur in the setting of generalized primary infection or reactivation. HSV hepatitis is not a major cause of non-A to non-E hepatitis [375]. Rates of fulminant hepatitis and mortality are high in infants, patients receiving chemotherapy, bone marrow transplant recipients, and women during the third trimester of pregnancy [376–378]. HSV superinfection in patients with chronic liver disease has been reported to cause fulminant hepatitis [379].

Fever and abdominal pain are the major symptoms of hepatic involvement, and patients frequently appear ill. The characteristic mucocutaneous lesions usually seen in primary infection are present in less than one-third of cases; therefore, a high index of suspicion is required to make the diagnosis. Herpes simplex should be considered in cases of fulminant hepatitis presenting in immunocompromised and sexually active individuals. Hepatomegaly may be present on clinical examination. There is often discordance between the aminotransferase levels and serum bilirubin level, with marked elevations in aminotransferases but minimal jaundice. There may be an associated leukopenia, thrombocytopenia, and coagulopathy. Liver biopsy shows nonspecific hepatocellular necrosis and a mild, scattered inflammatory infiltrate. Multinucleated hepatocytes and nuclear inclusion bodies are specific for the disease.

The diagnosis depends on positive viral cultures from body fluids and PCR detection of viral DNA from serum. Serology is not helpful because the prevalence of antibody is high in the general population. A fourfold rise in IgG titer between acute and convalescent titers is diagnostic but is not practical in acutely ill patients. Immunostaining or PCR analysis of liver tissue is rapid and specific for the diagnosis. When the diagnosis is suspected in acutely ill patients, liver biopsy for culture and immunostaining is recommended for rapid diagnosis [380]. The recently developed real-time PCR may lead to diagnosis in 3 h [381].

There have been no clinical trials evaluating therapy for acute HSV hepatitis. Acyclovir, 5–10 mg/kg, is the treatment of choice based on its success in numerous case reports [382]. Therapy should be initiated promptly while awaiting diagnostic tests because of the high mortality rate. Successful resolution has been reported with vidaribine, and it may be used as an alternative agent to acyclovir. OLT may be a lifesaving procedure [383].

Epstein–Barr virus

EBV occurs worldwide. Most cases in childhood are asymptomatic, whereas in adults, the typical symptoms of infectious mononucleosis are present: fever, malaise, headache, and cervical and axillary lymphadenopathy. The virus is lymphotrophic, and after initial infection and replication in epithelial cells of the pharynx, infects B lymphocytes. The liver is frequently involved in primary infection, but in contrast to HSV- 1 and HSV-2 infections, the hepatitis is usually mild and subclinical. Severe hepatitis has been described in immunosuppressed individuals but is uncommon. Most severe cases are the result of reactivation of latent infection.

The clinical features of EBV-related hepatitis in adolescents and adults include fever, malaise, pharyngitis, abdominal pain, and mild adenopathy. The aminotransferase level is mildly elevated and peaks during the second to fourth week of infection [384]. No pattern is specific for EBV. Occasionally, the serum alkaline phosphatase level may be markedly elevated, more than 15 times the upper limit of normal. A dissociation between the serum alkaline phosphatase and bilirubin, with an elevated alkaline phosphatase and normal serum bilirubin, has been observed. Jaundice is present in about 10% of cases and is usually mild (bilirubin less than 5 mg/dL). The coexistence of a hemolytic anemia may lead to higher than usual bilirubin levels. Most cases resolve in a few weeks, but aminotransferase levels may remain elevated for several months. Splenomegaly is frequently detected in primary infection (50%) and hepatosplenomegaly in 25% of cases. In children, a common presentation is fever, hepatomegaly, and disseminated intravascular coagulation. EBV hepatitis has been described after OLT but is infrequent and not a major cause of graft loss [385]. It may be associated with use of antilymphocyte preparations in the OLT setting. Chronic EBV hepatitis has not been reported. Cases of fulminant hepatitis occur but are rare [386].

For practical reasons, the virus is not cultured in diagnostic laboratories, and primary infection is diagnosed by demonstration of nonspecific heterophile antibody using Paul–Bunnell or slide agglutination reactions (monospot test). Heterophile antibodies may only be detected after the second week of infection and may be present for only a short time. This test has been replaced by the monospot test, which is specific and sensitive for EBV. If more specific and sensitive tests are required, immunofluorescent tests for the detection of specific antibodies to EBV proteins are available. Antiviral capsid antigen IgM and IgG antibodies are usually present at the time of onset of clinical symptoms. EBV DNA can be detected in blood but is primarily a research tool. The liver biopsy shows a mononuclear cell infiltrate involving the portal area and sinusoids with minimal hepatocyte necrosis and Kupffer cell proliferation. The liver biopsy findings may be nonspecific. To aid histological diagnosis, liver tissue can be stained for EBV nuclear antigen 1 or probed for EBV-encoded small nuclear RNA by in situ hybridization [387,388].

No controlled trials have been performed to assess treatment of EBV hepatitis because of its mild nature. Successful outcome in severe cases has been reported with acyclovir. Based on these case reports, acyclovir should be tried in severe cases of EBV hepatitis. OLT can be lifesaving when medical management fails. In the post-OLT setting, EBV hepatitis should be managed with reduction of immunosuppressive medication and judicious use of intravenous immunoglobulin [389].

Cytomegalovirus

CMV infection occurs worldwide. In cross-sectional studies, more than 50% of the population exhibited past evidence of infection with CMV [390]. Most infections are asymptomatic, especially in children. Routes of transmission are intrauterine, perinatal, and sexual through contact with blood, genital fluid, or saliva.

In infants, CMV infection can cause a neonatal hepatitis syndrome characterized by jaundice, hepatomegaly, hemolytic anemia, and thrombocytopenic purpura with mild elevations in aminotransferase level. The diagnosis may sometimes be confused with extrahepatic biliary atresia, and indeed CMV infection has been proposed as a causative agent [391]. Most cases resolve without long-term sequelae.

Primary infection in adults presents with symptoms similar to those of infectious mononucleosis. The liver is commonly involved in primary infection, but the hepatitis tends to be mild; jaundice is rarely present [392]. Patients at risk for severe hepatitis include neonates, bone marrow and liver transplant recipients, and those receiving chemotherapy. In severe cases, the level of aminotransferases may mimic acute hepatitis. Distinguishing features are prolonged fever and atypical mononuclear cells on peripheral blood smears. Fibrosing cholestatic hepatitis has been reported to occur with CMV infection [393].

The liver biopsy usually shows multinucleated giant cells in neonatal hepatitis. Intranuclear inclusions are observed in hepatocytes, Kupffer cells, and biliary epithelial cells. Hepatic lobular microabscesses are reported in liver transplant recipients [394].

The presence of atypical mononuclear cells on peripheral blood smears may suggest the diagnosis. More definitive diagnosis rests on recovering the virus from infected body fluids. The shell vial assay, which uses a combination of virus culture and immunological detection of immediate to early gene expression, is the test of choice. IgM is sensitive for the detection of CMV macroglobulins but does not reliably indicate acute infection. The presence of IgG antibody is not specific for acute infection. A fourfold rise in IgG antibody between acute and convalescent sera is diagnostic but is seen in less than 50% of cases. Liver tissue can be stained with monoclonal antibody against CMV early and late antigen, and PCR techniques can yield a faster diagnosis than routine culture [395,396].

There are no controlled trials of therapy for CMV hepatitis. There are several case reports citing the benefits of gancyclovir for severe hepatitis. Patients with normal immunity generally have a mild course and do not require treatment. Treatment should be reserved for immunocompromised patients because of associated toxicity.

Recently discovered viruses

Studies indicate that in 10% of cases of transfusion-related hepatitis, 50% of cases of fulminant hepatitis, and 20% of community hepatitis, no cause can be identified [397]. This has led to the search for other hepatotrophic viruses. Using molecular techniques, three candidate viruses have been discovered. Hepatitis G virus (HGV) or GB virus C (GBV-C), basically the same virus, was the first described, TT virus (TTV) (named after the initials of the patient from whom it was discovered) was the second, and SEN virus (SENV) the third.

Hepatitis G virus

HGV is a member of the Flaviviridae family and is distantly related to HCV. Based on blood donor studies, the virus appears to have worldwide prevalence, with a rate of viremia of 1%–2%. It can be transmitted by blood transfusion, and other modes of transmission, such as the percutaneous route, may be possible. It appears to have a high rate of persistence (91%). Initial studies suggested that this was a causative agent of non-A to non-E hepatitis, but this has not been substantiated in other studies [398,399]. Rates of HGV infection appear to be similar in transfusion recipients who developed hepatitis and in those in whom hepatitis was not seen [398]. Additionally, most cases were not associated with a rise in aminotransferases. HGV may not even be hepatotrophic because inoculation studies in a chimpanzee failed to demonstrate liver disease. Based on these studies, it has been concluded that HGV is not a cause of acute or chronic hepatitis.

TT virus

TTV was initially discovered in 1997 from the serum of a patient with non-A to non-G hepatitis [400]. TTV is a single-stranded DNA virus belonging to the Circovirus family. Studies of multitransfused individuals and blood donors suggest a worldwide prevalence, with rates of viremia ranging from 5% to 90% [400–402]. Initial studies from Japan indicated that the virus was related to hepatitis in three of five patients after blood transfusion, suggesting that it was the cause for non-A to non-E hepatitis [400]. However, a study of blood donors and prospectively followed transfusion recipients with and without hepatitis indicated a similar rate of newly acquired TTV infection in patients with (23%) and without (22%) hepatitis [402]. Transmission using serum and stool from two infants with acute TTV infection was observed in chimpanzees, but clinical and histological evidence of hepatitis was not demonstrated [403]. These data support the conclusion that TTV is not a hepatotrophic virus.

SEN virus

SENV is the most recently identified candidate virus as a potential cause for non-A to non-E hepatitis. SENV is a single-stranded DNA virus probably belonging to the Circovirus family and distantly related to TTV. Five strains have been identified (A, B, H, D, and E), but only strains SENV-D and SENV-H had low enough rates in donor populations and high rates in transfusion-related hepatitis to qualify as potential agents of acute hepatitis. Preliminary data supporting SENV as an infectious hepatitis agent included a high prevalence of SENV in injection drug users and multitransfused patients, and the prevalence of SENV was high in cases of non-A to non-E hepatitis but low in control populations [404]. In a prospective study of transfusion-related hepatitis, there was a strong association between SENV with transfusion-associated non-A to non-E hepatitis (92%), compared with transfused controls who did not develop hepatitis (24%) [405]. Persistent viremia was demonstrated for up to 12 years, and chronic elevation of aminotransferases was observed, but chronic hepatitis was not documented by liver biopsy. However, most patients with SENV infection did not have hepatitis, and replication within the liver has not been established [405]. These data appear to indicate that SENV-D and SENV-H may have a causative role in non-A to non-E hepatitis.

Summary

In summary, HGV and TTV are not causative agents of non-A to non-E hepatitis. They can be transmitted by blood transfusion, but it is debatable whether they cause liver disease after infection or are hepatotrophic at all. It is possible that they may cause liver disease in certain settings, as in immunocompromised patients infected with CMV and EBV, but this remains to be proved. They do not appear to worsen underlying viral or nonviral liver disease. SENV, another transfusion-transmitted virus, may lead to persistent infection, but more definitive studies are awaited before it can be added to the hepatitis alphabet.

Management of special populations, 2133

There are estimated to be over 400 million carriers of hepatitis B virus (HBV) worldwide [1]. The prevalence of chronic HBV varies depending on the geographical region. In the Western world, HBV is usually an adult-acquired disease with a prevalence ranging from 0.2% to 1% of the population, and is responsible for less than 10% of chronic liver disease. In Asia, Africa, and the Middle East, chronic hepatitis B (CH-B) is acquired at birth or early in life, has a prevalence of 5%–20%, and is among the leading causes of death in those regions. At least 20%–30% of those carriers will die of complications of chronic liver disease, including cirrhosis and hepatocellular carcinoma (HCC) [2,3]. The World Health Organization (WHO) places CH-B in the top 10 causes of death worldwide [4]. The estimated viral burden in the United States is at least 1.25–2 million people, with the disease concentrated in ethnic subgroups and populations with high-risk behavior [5]. With statistics based on immigration over the last 10 years and the known prevalence in those populations, the US prevalence could be as high as 2 million [6–10]. The costs of managing CH-B in the United States exceeds 350 million dollars per year [11]. Although the United States is considered an area of low prevalence for hepatitis B infection, the incidence of new cases, the prevalence of chronic infection, and the burden of acute and chronic disease maintains hepatitis B among the important communicable diseases.

The incidence of acute HBV disease fell markedly (by 67%) in the United States and Canada between 1990 and 2002 [12], compared with a marked increase during the 1980s [13]. In the 1980s, the estimated number of new (acute) cases of hepatitis B disease in the United States was more than 430 000 per year; by 1997 the estimate was only 185 000 new cases per year [14]; and in the mid-2000s, the estimate was just 78 000 cases per year [15]. These acute infections lead to 27 000–42 000 chronic infections, 17 000 hospitalizations, and ultimately 4000–5500 deaths per year from cirrhosis and HCC, as well as to the morbidity and cost of liver transplantation in about 350 patients per year [16–18].

The risk of developing chronic HBV infection after acute exposure ranges from 1% to 5% for adults, and is greater than 90% for infants born to infected mothers who are positive for hepatitis B e antigen (HBeAg), a secreted protein that is normally detectable in the bloodstream when wild-type hepatitis B virus is actively replicating. Persistent and stable HBV DNA levels detected over the first 1–4 weeks following acute hepatitis B disease indicate a strong likelihood of not clearing HBV infection; in such cases, consideration should be given to intervention with antiviral therapy [19].

Understanding of the prevalence and pattern of HBV infection, which patients are at risk, the clinical presentation, serological (Table 81.1) and molecular tests, as well as the current standards of monitoring and treatment are all essential parts of practice for clinical physicians. Advances in molecular biology and virology as well as developments in antiviral research have led to a much greater understanding of this virus, allowing implementation of new therapies and more appropriate and targeted testing, the combination of which results in improved patient outcomes. Sharing of knowledge between investigators and clinicians worldwide will continue to advance our understanding of this global public health problem.

The serious consequences of end-stage liver disease and HCC confront patients and physicians throughout the world. The combined risk of liver cancer and cirrhosis with its inherent complications of death or transplant for patients with CH-B is 25%–30% [20–24]. Communicating the high rate of severe consequences of this disease is essential to encourage patients to participate in monitoring and follow-up. Testing patients at risk for HBV infection, interpreting the serological

Table 81.1 Significance of a positive test for hepatitis B virus

Positive test parameter	Clinical significance
HBsAg	Infected and infectious
Anti-HBs	Immune (in the absence of HBV DNA)
Anti-HBc	Exposed
IgM	Recent or acute infection
IgG	Historical exposure (with possible current infection)
	or false positive
	or low-level carrier
HBeAg	High replication
Anti-HBe	May indicate low replication or presence of precore/BCP mutant
HBV DNA qualitative	Presence of HBV DNA, sensitive
HBV DNA quantitative	Presence of HBV DNA and level of replication
Anti-HD	Recent or current infection with delta hepatitis
Delta antigen/HDV RNA	Replication of delta hepatitis

BCP, basal core promoter; HBc, hepatitis B core (antigen); HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HDV, hepatitis delta virus; IgG, immunoglobulin G; IgM, immunoglobulin M.

tests available, disseminating patient education, and implementing regular follow-up are all important steps in the management of infected patients. Vaccination, the key step in eliminating this global scourge (Fig. 81.1), must be applied to all infants [25], household contacts of HBV-infected individuals, health-care workers, and adolescents and individuals who are sexually active with more than one sexual partner or use nonprescribed injectable drugs [26–28]. Vaccination of all newborns has been calculated to be cost-effective in developed countries [29,30], and may become cost-effective

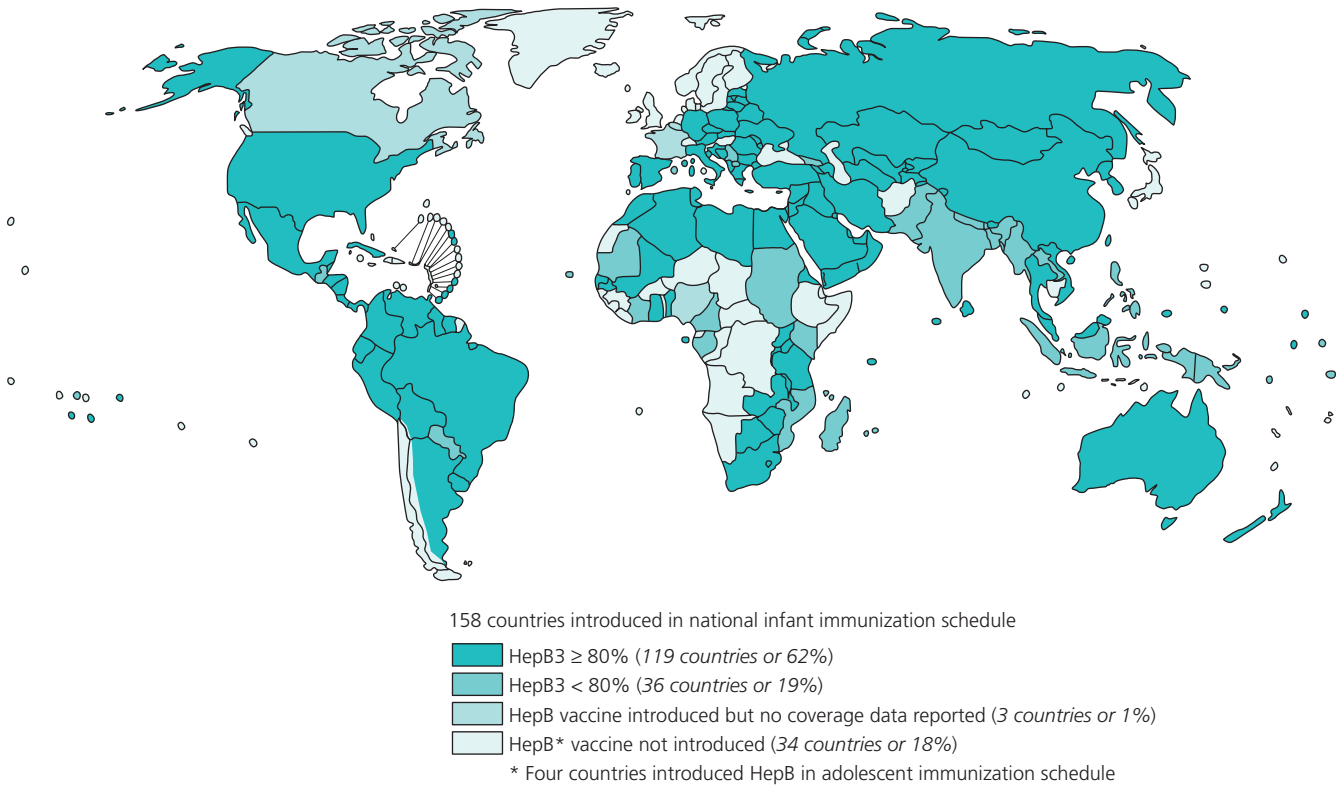

Figure 81.1 Global status of hepatitis B immunization policy. Modified from World Health Organization website, www.who.int/immunization_monitoring/diseases/HepB_map_schedule.JPG

in developing countries depending on the cost of vaccine and methods of administration. Regularly evaluating patients and counseling them about the monitoring process is important because of the ongoing revolution in antiviral therapy and its potential benefits for patients who are infected with HBV [31].

Terminology and testing for HBV have confounded many students of medicine since the discovery of the hepatitis B surface antigen (HBsAg) [29,30,32,33] because of confusing and misleading nomenclature. Inconsistent and inaccurate terms such as the oxymoron "healthy carrier" must be removed from our terminology as well as discouraging the use of the term "silent carrier." These outdated terms, often used to reassure patients or physicians, do not represent the true clinical outcome for any patient group and cannot be confidently applied to any individual patient.

The liver biopsy has a declining role in evaluating patients with CH-B and is not required for all patients. Fortunately, the outpatient liver biopsy is safe, with a risk of serious complications being less than 1:2000, and the risk of death being less than 1:12 000 [34,35]. The liver biopsy determines the *stage* of disease (fibrosis) and the extent or level of inflammation (*grade*), and evaluates for other important and treatable diseases such as fatty liver or iron overload (see Chapter 97). The liver biopsy allows the patient and physician to decide on the necessity and urgency of treatment, the presence of or risk of progression to cirrhosis, and the need and frequency of liver cancer screening as well as monitoring of viral replication and liver panels. In the future, serum tests for fibrosis and percutaneous sound-wave devices that test elasticity may further obviate the need for liver biopsy. Most importantly, levels of HBV DNA aid in the determination of a patient's risk for liver cancer, cirrhosis, and death, and are eliminating the need for liver biopsy in many patients [36–39] (Figs 81.2 and 81.3).

From the first use of the oral antiviral medication lamivudine, to inhibit HBV replication directly, increasing rates of resistance to medications have been observed over time.

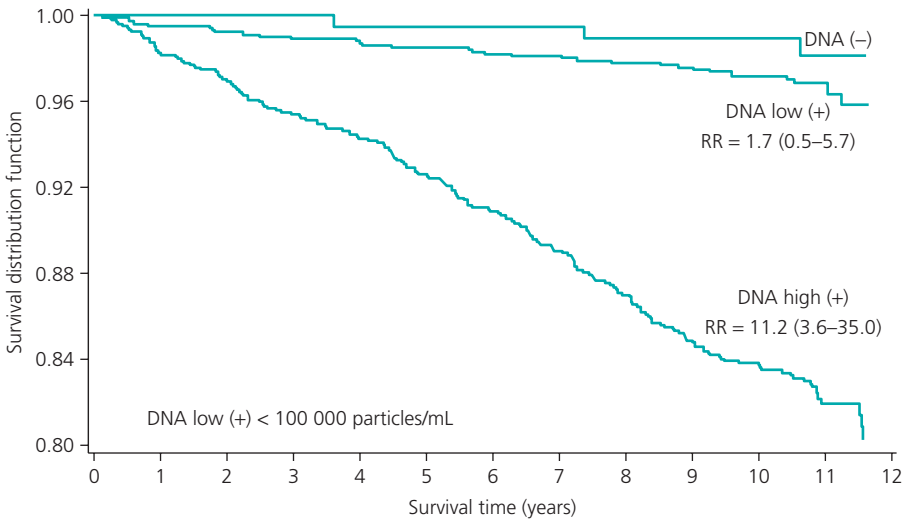

Figure 81.2 HCC mortality curves by viral load category at study entry. From Chen G, Lin W, Shen F, et al. Past HBV viral load as predictor of mortality and morbidity from HCC and chronic liver disease in a prospective study. Am J Gastroenterol 2006;101:1797.

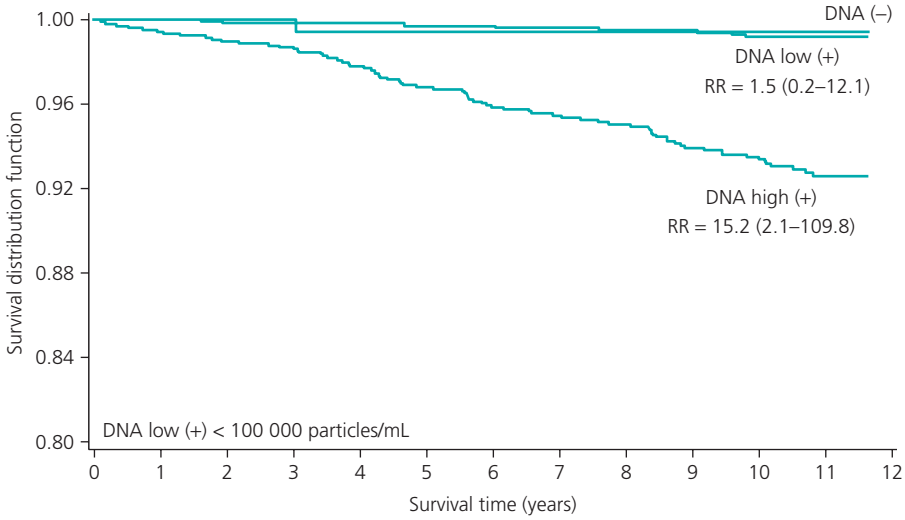

Figure 81.3 Chronic liver disease mortality curves by viral load category at study entry. From Chen G, Lin W, Shen F, et al. Past HBV viral load as predictor of mortality and morbidity from HCC and chronic liver disease in a prospective study. Am J Gastroenterol 2006;101:1797.

The clinical significance of these medication-resistant viruses will be discussed below. Fortunately, with the advent of telbivudine, adefovir, and entecavir, there has been a continued decline in the rate of resistance. This has encouraged practitioners toward earlier intervention for patients with CHB. Of greatest importance are those patients with advanced liver disease and impending liver failure because they require immediate treatment with the most effective available therapy. The most rapid suppression of virus occurs with entecavir and telbivudine, and the lowest rate of resistance with entecavir. Combination therapy with a nucleoside (e.g., lamivudine, telbivudine, or entecavir) and nucleotide (e.g., adefovir or tenofovir) is important if there is preexisting resistance to antiviral medications.

Chronic hepatitis B

Chronic hepatitis B disease is defined as hepatic necroinflammation resulting from the persistent presence of HBV infection. These patients are positive both for HBsAg and for HBV DNA, with serum levels of HBV greater than 2000–20 000 IU/mL or the presence of hepatitis B core antigen (HBcAg) staining in the liver. Liver enzyme levels are either persistently elevated or intermittently elevated over periods of 6 months or longer. The WHO case definition of CH-B requires the detection in serum of HBsAg on two occasions over a 6-month period. Liver biopsy is an important component in defining the severity of liver disease in these patients. Abnormal liver enzyme levels are defined as an alanine aminotransferase (ALT) of more than 17–20 IU/mL in women and 25–30 IU/mL in men when individuals have a normal body mass index [40–42].

The hepatitis B e antigen (HBeAg) is a secreted protein that is normally detectable in the bloodstream when wild-type virus is actively replicating; however, mutant strains of HBV can be easily selected out that replicate without producing HBeAg. Thus, patients with CH-B can be divided into two subgroups, HBeAg-positive (wild-type) and negative (basal core promoter and precore mutants), which will be discussed further under "Hepatitis B virus variants and mutants" below. Patients with normal ALT levels but high levels of HBV DNA and necroinflammation on liver biopsy are also included in the group with CH-B because of the similarity in natural history [20,22–24]. "Flares" of hepatitis B occur in some patients and are defined as intermittent elevations of serum aminotransferase levels to more than twice baseline and 10 times the upper limit of normal (ULN) [43]. These events occur in 10%–15% of patients each year and may be asymptomatic and undetected.

There are four phases of CH-B infection, although not all patients go through all phases. These are the immunotolerant phase, the immunoelimination phase (also referred to as immune clearance or immune active), the nonreplicative phase (also referred to as inactive carrier state), and the reactivation phase.

Immunotolerant phase

Individuals who are HBeAg-positive with high levels of virus in their blood (HBV DNA greater than 20 000 IU/mL) but persistently normal liver enzymes are termed "immunotolerant" and typically have normal liver histology. These individuals are typically in their second or third decades of life, develop elevated liver enzymes later in life, and can go on to cirrhosis or can undergo spontaneous seroconversion of either their HBeAg and subsequently HBsAg to the respective antibody, although this is a rare event. If HBV DNA levels remain elevated and ALT levels rise above the upper limits of normal as defined in the previous section in this chapter, consideration of a liver biopsy should be discussed [44], as well as the possibility of initiating therapy. This phase is generally seen in patients with perinatally acquired infection; it is rarely observed in those with childhood- or adult-acquired infection.

Immunoelimination phase

Individuals in the immunoelimination phase are HBeAg-positive with initially high serum levels of HBV DNA and elevated ALT with moderate or severe necroinflammation on liver biopsy. In patients with perinatally acquired HBV, the transition from the immunotolerant phase to the immunoelimination phase commonly takes place during the second to fourth decades. Most patients with childhood- or adult-acquired infection are in this immunoelimination phase at presentation. During this phase, the immune response to HBV is more active, with resulting reductions in serum HBV DNA levels. In some patients, immune control of HBV will result in substantial drops in HBV DNA with HBeAg seroconversion.

Nonreplicative phase

Individuals in the nonreplicative phase (also referred to as the inactive carrier state) are identified by the presence of HBsAg in serum, no detectable HBeAg, low levels of HBV DNA (< 2000–20 000 IU/mL), and persistently normal ALT levels for periods of longer than 6 months. A liver biopsy can be performed in such patients, but is not a usual practice, unless the ALT becomes elevated or serum HBV DNA remains persistently positive [44]. The liver disease activity index is typically less than 3 on a 1–22 scale (see Chapter 97 on liver biopsy and histology scoring systems). The clinical course of patients in this phase will be affected by the level of liver damage prior to HBeAg seroconversion, and the durability of the phase. These patients are at risk for relapse to active liver disease and replication of virus as well as HBV DNA integration into the hepatocyte nuclear DNA with the attendant risk of developing HCC later in life. They should be monitored at least every 6 months with serum tests for HBV replication, serology, liver enzymes, and synthetic tests.

Reactivation phase

Individuals in the reactivation phase are HBeAg-negative and anti-HBe-positive. Reactivation of hepatitis B disease occurs when a person is in the nonreplicative phase and develops an elevation of liver enzyme levels and a significant rise in HBV DNA levels (≥ 1.0 log IU/mL). Levels of ALT may be persistently elevated and stable, elevated but fluctuating, or only intermittently elevated. Levels of HBV DNA can also vary from high to undetectable, making serial tests necessary to identify accurately patients in the reactivation phase. The HBeAg can become positive in some patients. The liver biopsy typically has a hepatic activity index (HAI) score of 4 or greater [45]. Reactivation can occur naturally or with the use of immunosuppressive therapy. Individuals in this phase tend to be older and to have more advanced liver disease with a higher likelihood of adverse clinical outcomes.

Resolved infection

Resolved hepatitis B infection is defined by serological tests showing negative for both HBsAg and HBV DNA in a person with a history of acute or chronic HBV infection and currently normal levels of liver enzymes. These patients may remain anti-HBc positive for 5–10 years or longer and are at risk of transmitting disease on rare occasions (such as the donation of solid organ tissue). With supersensitive testing, HBV DNA may be found in the blood in a substantial number of patients. In addition, those patients who appear to have resolved HBV infection may develop active liver disease if they are treated with immunosuppressive medications such as prednisone, methotrexate, or chemotherapy. The standard is to treat these patients during chemotherapy with a nucleoside or nucleotide analogue, as discussed below.

Coinfection definition

Coinfection with hepatitis delta virus (HDV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) is defined as the presence of active viral replication with one or more of the above defined viruses determined by molecular assays, or in the case of HIV, HIV-positivity confirmed by the standard enzyme-linked immunosorbent assay (ELISA)/Western blot tests. These infectious problems will be discussed in detail below.

Serological and molecular diagnosis

As a general principle of laboratory-based investigation for a virological cause of chronic liver disease, testing should include all the major etiological agents (HBV, HBV plus HDV, and HCV) [46]. These are common infections in immigrants, and in high-risk groups such as injecting drug-users, the multiply transfused, and those who are sexually active with multiple partners. The principal screening assay for acute hepatitis B (AH-B) and CH-B, as well as for the screening of blood and organ donors, is detection of the HBsAg in serum [47], although molecular testing with more advanced nucleic acid tests such as polymerase chain reaction (PCR) and transcription-mediated amplification (TMA) are being instituted in the United States and considered worldwide.

The typical serological profiles found in active or past HBV infection are shown in Table 81.1. Hepatitis B core-specific IgG antibodies (IgG anti-HBc) are almost always present in the serum of patients with CH-B and may play a role in fetal and neonatal immunological responses to HBV where there is mother-to-child transmission (MCT). These antigens and antibodies cross the placenta in utero and thus the newly infected neonate has high titers of maternal IgG anti-HBc at birth (indicating a strong T-helper cell type 2, or Th2, response), partly contributing to its "tolerized" state to the HBV. These antibodies are not neutralizing and do not appear to influence viral replication. The detection of IgM anti-HBc is generally diagnostic of acute HBV infection [48]. Most patients with underlying inflammatory activity in the liver will show evidence of viral infection with one or more of the available tests. Typically, HBV DNA is detected and measurable by molecular techniques [49,50]. Although historically levels of HBV DNA have been measured in terms of copies per unit volume (i.e., per mL), the WHO has recommended that laboratories convert to international units (IU/mL) (Table 81.2). Relative levels of HBV DNA often correlate inversely with the degree of necroinflammatory activity in the liver, reflecting attempts by the host's immune response to control and eliminate the virus. The serum level of HBV DNA can be used for prognosis [36–39] (Figs 81.2 and 81.3).

Prevalence

The WHO has identified regions of high, intermediate, and low endemicity. High levels of endemicity (positive HBsAg

Table 81.2 Viral load testing: conversion to international units

Assay	Conversion factor
Digene Hybrid-Capture II (Digene Corp.)	No CE (European Conformity) mark
Versant HBV DNA 3.0 (bDNA) (Bayer Diagnostics)	1 IU/mL = 5.2 copies/mL

Cobas Taqman 48 HBV (Roche Molecular Systems)	1 IU/mL = 5.8 copies/mL

Conversion factors given by manufacturers.

with ≥ 8% of population infected) affect more than 45% of the world's population; intermediate rates of infection (2–7%) affect another 43% of the population; and low prevalence (< 2%) occurs in the final 12%. As assessed by a combination of serological assays, 5% of the US population has evidence of present active or past infection with HBV. About 1 out of 200 people in the United States is infected with HBV, and some ethnic subgroups have prevalence rates of 7%–20%, which closely approximate rates in their country of origin.

Transmission

Modes of transmission vary depending on the country of origin; ethnic background; local, traditional, and Western medicine practices; and, most importantly in developed countries, risk behavior. Understanding of risk factors and intervention aimed at each of the major routes of transmission is the key for preventing HBV transmission. The combination of education, prevention strategies, and vaccination could lead to eradication of the disease [51], a focus of the US Centers for Disease Control and Prevention (CDC). In populations that acquired HBV as adults, heterosexual contact (42%), men having sex with men (15%), and injecting drug use (21%) represent the most common modes of acute transmission and may represent the most common causes of chronic disease.

Perinatal transmission is considered to be the leading cause of HBV spread worldwide. However, other modes of transmission involving iatrogenic routes and the application of folk medicine in young populations are important [52]. Even taking these newly identified risks into account, perinatal transmission probably accounts for more than 60% of all childhood-acquired disease.

Nosocomial/occupational exposure and transmission is also an important issue. Health-care workers exposed to patients with CH-B and patients exposed to chronically infected medical practitioners are both at risk [53,54]. Renal dialysis patients are, historically, considered a high-risk group for acquiring or transmitting HBV because many have had extensive blood exposure in the dialysis setting [53–55]. Some US states legally require practitioners to remove themselves from practice if they perceive that they pose a risk (in this case an infectious risk) to their patients. Health-care workers who are exposed or potentially exposed to needlestick injuries or blood splash exposure are also at risk of acquiring HBV [56]. The most important steps are preventive vaccination before risk exposure, immediate testing for immunity to hepatitis B if exposure takes place, and application of hepatitis B immune globulin (HBIG) and HBV vaccine if a nonimmune health-care worker is exposed to blood or contaminated sharps [53,54,57]. Hepatitis B vaccination is strongly advised for all individuals who work in a health-care setting that may expose them to blood or body fluids. Elimination in developing countries of the practice of reusing needles may lead to a marked reduction in childhood, adolescent, and adult-acquired HBV infections [58].

Household transmission has been clearly identified as a means of acquiring HBV [16]. The route of exposure is not clear but HBV is a DNA virus that can exist outside the body for prolonged periods on fomites. Recommendations state that the sharing of household utensils that may carry blood, such as toothbrushes and razor blades, must be avoided. The transmission of HBV by means of common kitchen items and food sharing has not been described. All household members living with an individual who is positive for HBsAg or known to have CH-B should be tested for evidence of HBV infection and vaccinated if not immune. Studies have even suggested that bed bugs can be a source of HBV transmission [59,60].

Hepatitis B is also a sexually transmitted disease [16,61,62]. Individuals attending clinics treating sexually transmitted diseases commonly have evidence of exposure to HBV as indicated by the presence of anti-HBs and anti-HBc; in a subset of these patients, there will also be HBsAg in serum. Many of these patients have asymptomatic infection although some patients will present with acute HBV with jaundice and elevated liver tests following a high-risk sexual exposure.

Blood transfusion is an unlikely source of HBV in developed countries where effective screening of blood takes place. Screening of all blood units for HBV as well as predonation screening for risk behavior should become a standard practice throughout the world. The risk of acquiring HBV through a blood transfusion in the United States is less than 1 in 400 000 units. The best test to screen blood for HBV infection is determination of HBV DNA by nucleic acid testing (NAT), also termed "molecular testing," coupled with improved HBsAg and anti-HBc assays [63–66]. The risk from blood products arises because some patients donate blood before the onset of an immune response to HBV infection or appearance of clinical evidence of hepatitis. Nucleic acid testing looks set to make the blood supply even safer [64]. A number of developing countries do not screen blood or blood products for HBV, posing a major risk to patients who may undergo blood product transfusion in those countries.

Approximately 20%–35% of individuals with adult-acquired HBV infection in the United States have no known risk factor or easily identifiable risk factor [16]. Possible transmission through sexual contact, medical or dental treatment, injection drug use (IDU), sharing household utensils, or blood exposure in an occupational setting must all be considered.

Coinfection: risk groups

In patients who are infected with HBV, coinfection with HCV [67] or HIV exists in certain risk groups, especially those with adult high-risk behavior. All patients with HBV infection must be tested for HCV infection; if a history of risky sexual

exposure or IDU is discovered, HIV infection testing is also necessary. Infection with HIV clearly influences the response to HBV vaccine and treatment as well as risk of progression. Hepatitis delta virus coinfection is also an important medical issue because this RNA virus, when superimposed on HBV, results in a higher rate of chronic disease, cirrhosis, and HCC. Infection with HDV is specific also to populations in certain regions, such as Amerindians in South America, as well as high-risk populations in the Mediterranean area and the Pacific islands.

Prevention

Vaccination is the only medical intervention to date that can markedly change the incidence and prevalence of this disease. The list of HBV vaccine products available worldwide is extensive and individuals should review local product availability in their own country. All products appear to be similar in terms of immune response and level of anti-HBs titer after a series of vaccinations. Worldwide vaccination for HBV has finally come of age, with most countries utilizing or planning a broad-based HBV vaccine program (Fig. 81.1) [17,68–70]. Vaccination has already resulted in a marked decline in childhood prevalence of HBV disease in Taiwan, and more importantly has yielded a major fall in HCC even in this young age group [71–73]. This is the ultimate in cancer treatment: prevention through vaccination. The following groups of people should all be vaccinated against HBV infection:

- individuals who are exposed to blood or blood products
- those who plan to travel to developing countries
- people who live in a household with or have intimate contact with a chronically infected individual
- those who work in a health-care setting with patient contact
- children born to HBsAg-positive mothers
- patients with chronic liver disease.

Safe sexual practices, needle and syringe exchange programs or nonreusable needles, thorough blood screening, and medical instrument sterilization are all essential components of a prevention program.

For children born to HBV-infected mothers, prevention of perinatal and early horizontal transmission with injection of HBIG combined with vaccine, or vaccine alone, is recommended or considered the standard of care in most parts of the world [74]. Because of the expense, HBIG administration to the infant at the time of birth (in combination with vaccination) is only available for use in countries with higher per capita health-care expenditures. Without HBIG, vaccination appears to protect more than 80%–90% of infants when administered at birth; it must be followed by two additional doses at 1 and 6 months. Intramuscular injection of HBIG (0.5 mL) combined with HBV vaccine has an even higher efficacy, protecting more than 98% of infants. Some special populations have a low or exceedingly low response to conventional vaccines, which has led to the development of more immunologically active vaccines or adjuvants to promote an increased response rate. Examples of such populations include older patients, organ transplant patients, renal dialysis patients, and immunosuppressed populations, including patients coinfected with HIV. Hepatitis A vaccination of patients with CH-B is emerging as the standard of care in many countries because of the high mortality rate for acute hepatitis A virus (HAV) superinfection, as demonstrated in outbreaks such as the Shanghai epidemic [75].

Postvaccination testing is only required for those individuals who need to know their HBV immune status for their medical management or for potential occupational exposure risks. Revaccination results in an antibody response in more than 30% of all persons who do not respond to a primary vaccination series [76]. Postvaccination anti-HBs levels remain above the value regarded as protective (10 IU/mL) in about 50% of patients for up to 15 years. It is also clear that patients who do not have measurable antibodies can mount an amnestic response and be protected from HBV infection [77–79]. There is no evidence that HBV vaccine is associated with any form of arthritis or neurological sequelae [80–82]. Vaccination has no role in the treatment of the patient with CHB.

Based on the epidemiological picture described above, the populations to screen for evidence of HBV infection and to vaccinate if not infected with HBV are:

- patients who are born to parents from endemic regions of the world
- patients with a history of high-risk sexual activity or more than 50 lifetime sexual partners
- men who have sex with men (MSM)
- any person with a history of injecting drug use
- individuals who have or have had sexually transmitted diseases
- household contacts or sexual contacts of individuals who are positive for HBsAg
- persons who have had medical care or injections in a developing country
- any person with acutely or chronically elevated liver enzymes
- individuals with HIV or HCV infection.

Children are a special subgroup of patients who need to be considered at risk of chronic infection if they are born to a mother who is HBsAg-positive and do not receive HBV vaccination (with or without HBIG) at birth. Also, all children who originate from orphanages in developing countries should be tested for HBsAg. Moreover, all immigrants from developing countries where there is a significant prevalence of HBV need to be screened for HBsAg, as well. Both pediatric and adult travelers to developing countries are at risk for HBV infection and need to be tested if evidence of liver disease is present.

Hepatitis B virus variants and mutants

Although HBV is a DNA virus, replication is through an RNA intermediate requiring an active viral reverse transcriptase/polymerase enzyme. The polymerase (reverse transcriptase) of HBV lacks a conventional proofreading function as is found in other higher-order DNA polymerases. Therefore, HBV exhibits a mutation rate more than 10-fold higher than other DNA viruses, more closely resembling retroviruses such as HIV. The prevalence or number of nucleotide substitutions found in the viral genome varies depending on the duration and stage of liver disease. The natural evolutionary rate for the HBV genome in CH-B is approximately $1.4–3.2 \times 10^{-5}$ substitutions per site per year. In the liver transplant setting, this increases by up to 100-fold as a result of increased viral replication that results in an average increase of 1–2 $\log_{10}$ IU/mL in HBV viral load. This higher substitution rate may be a result of the immunosuppression regimen associated with transplantation, especially the use of steroids, and the positive enhancing effect on the HBV glucocorticoid response element (GRE) located in the viral genome. Mutant viruses are defined as subpopulations of HBV that emerge when there is either immune or medication selection pressure that allows particular populations or quasispecies to emerge.

Mutants affecting HBeAg production

The pre-C/C open reading frame (composite ORF) encodes the core protein (p21) and the precore (p25) protein/HBeAg (p14–17). The core protein is the major polypeptide of the nucleocapsid and is expressed as the HBcAg. The C ORF is preceded by a short, upstream in-phase ORF known as the precore region from which the soluble HBeAg is synthesized. Both HBcAg and HBeAg proteins are targets for immune-mediated viral clearance mechanisms. The two major groups of mutations that affect HBeAg synthesis are precore region mutations (nucleotide G1896A), which block translation, and mutations in the basal core promoter (BCP), which reduce transcription, usually at nucleotides 1762 and 1764, all resulting in diminished production of HBeAg, usually as a consequence of increased host immune pressure. Precore mutations frequently occur temporally related to core gene mutations/deletions. Patients with precore mutations typically have about 1–2 log lower levels of serum HBV DNA compared with those patients with "wild-type" HBeAg-positive CH-B. Mutations in the BCP are likely to increase viral replication and enhance disease activity, especially in genotype C HBV-infected patients [83].

X gene mutants

The X protein is a nonstructural protein, encoded by the X gene, that can transactivate a variety of cellular and viral promoters by activating signaling pathways [84]. X has been reported to interact with a number of nuclear proteins involved in cell-cycle regulation, DNA repair, and transcription. Persistently high levels of the HBx expression have been associated with the development of liver tumors in transgenic mice. The X protein can transform nontumorigenic cell lines in vitro.

Pre-S/S gene mutants

The S envelope gene contains three in-frame start codons that divide the gene into the three surface proteins of HBV: The pre-S1 region, the pre-S2 region, and the S region. Three corresponding mRNAs serve for the synthesis of these proteins. The pre-S1 promoter (SPI) is located upstream of the S gene, whereas transcription of the pre-S2 and S mRNAs is directed by the S promoter (SPII), which is located within the pre-S1 region. Surface mutations have obvious clinical relevance in the prevention of HBV because of their impact on prophylactic vaccination as well as laboratory-based diagnosis [29,85,86]. Several large HBV vaccination programs in endemic regions have revealed a 2%–3% incidence of vaccine escape mutants resulting from alterations in the HBsAg protein. Generally, the amino acid substitution Gly145Arg of the S protein makes this epitope unlikely to bind to anti-HBs generated to wild-type HBsAg. The "a" determinant of the HBsAg is a peptide sequence located between amino acids 99 and 170 of the S protein, which represents the major immune target of anti-HBs. This antibody reactivity is directed mainly against the second loop of this determinant, comprising amino acids 139–147. In patients infected with HBV exhibiting surface mutations affecting the "a" determinant, the mutant HBsAg may not be detectable by commonly used HBsAg assays, especially if based on monoclonal antibody "capture" reagents. As a result, these mutants do represent a potential public health problem because patients harboring HBV with these surface mutants remain infectious but do not exhibit readily detectable HBsAg and hence may escape diagnosis [14,87–90]. Viral HBsAg escape mutants have been described in the liver transplant setting where hepatitis B immune globulin exerts pressure on the virus. Subsequent changes in HBsAg have been documented with resultant fulminant hepatic failure in a few patients.

Polymerase gene mutations

The polymerase ORF is the longest within the HBV genome, covering almost 80% of the whole genome and overlapping the other three ORFs. The HBV polymerase protein mediates encapsidation of the pregenomic RNA into the core particle and synthesizes the HBV DNA genome therein. It has four enzymatic activities: DNA synthesis priming activity; RNA-dependent reverse transcriptase (RT) activity; DNA-dependent DNA polymerase activity; and RNaseH (RNA degradation) activity. Hepatitis B virus quasispecies with mutations in the

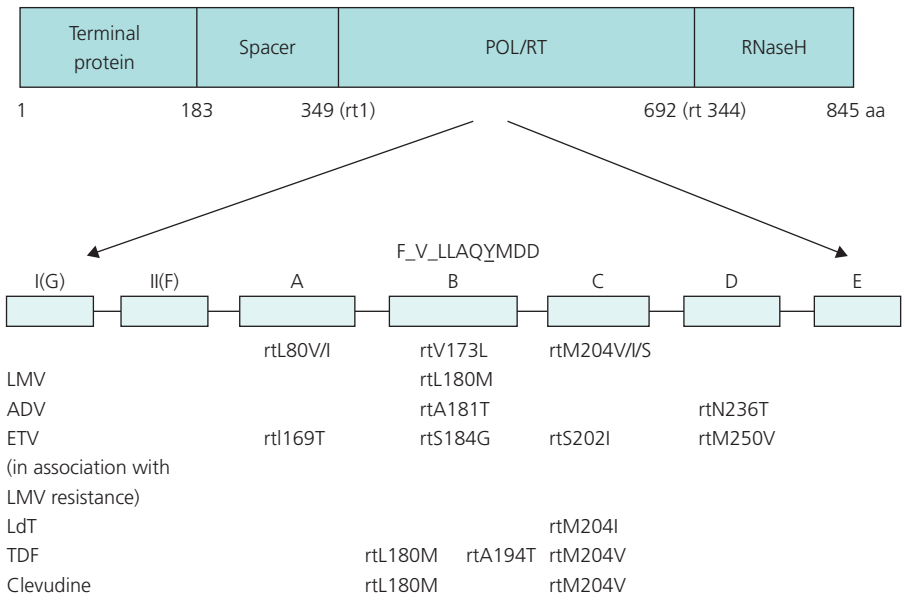

Figure 81.4 Mutation locations associated with antivirals. Adapted from Locarnini S. Molecular virology of hepatitis B virus. Semin Liver Dis 2004;24(Suppl. 1):3.

polymerase gene have been detected in patients undergoing oral antiviral therapy. The locations of the major mutations associated with the antivirals lamivudine, adefovir, entecavir, telbivudine, and tenofovir have been determined (Fig. 81.4). These mutations significantly decrease the in vitro and in vivo sensitivity of the polymerase to nucleoside/nucleotide analogues [91].

Genotypes and serotypes

Hepatitis B virus has a number of genetic variants described as serotypes (adw, ayw, and adr) and genotypes (A, B, C, D, E, F, G, and H). Our understanding of the clinical significance of HBV genotypes is evolving (Table 81.3). For example, genotyping can be used to determine who is the best candidate for interferon therapy (genotype A), who may be at higher risk for liver cancer (genotype C), and who may have an increased risk of resistance to medications (genotype D for adefovir resistance). Genotype assessment and nucleic acid sequence analysis may allow epidemiologists to track the transmission and movement of HBV strains through the world or regions of the world, to establish other epidemiological behavior of HBV infection, including the investigation of common source outbreaks [92], and to establish clinical behaviors specific to each subgroup.

Genotyping is accomplished by sequencing the HBV genome, using a line probe assay (capture hybridization), or by using serologically based antibody testing. Routine genotype testing before initiation of antiviral therapy has been advised [44].

Depending on the predominant HBV genotype in the particular geographical setting, patients infected with genotypes other than A (such as B, C, D, and E) often present to the liver clinic seropositive for anti-HBe rather than HBeAg.

Table 81.3 Hepatitis B virus genotypes and associations

Genotype	Associations
Ae	Spontaneous sAg seroconversion Interferon response
B	Spontaneous eAg seroconversions Better response to lamivudine
C	Increased rate of HCC Increased rate of perinatal transmission
D	High rate of adefovir resistance
E	
F	Unstable HBeAg seroconversions High HCC rate Fulminant hepatic failure
G	Unable to secrete HBeAg
H	

eAg, e antigen; HBeAg, hepatitis B e antigen; HCC, hepatocellular carcinoma; sAg, surface antigen.

These patients are infected with the precore G1896 stop codon precore mutation ("precore mutant") or basal core promoter mutants A1762T+G1764A. Genotype A HBV-infected patients still tend to present to the clinic seropositive for HBeAg.

Clinical manifestations and laboratory tests

Clinical manifestations of chronic HBV infection range from no signs or symptoms of disease (the majority of patients) to the warning signs of end-stage liver disease [93]. The clinical

manifestations of end-stage liver disease are the same as those seen in patients with other causes of liver failure. Some patients with HBV develop extrahepatic manifestations of infection including periarteritis nodosa and leukocytoclastic vasculitis with the increased likelihood of major damage of target organs (including peripheral nerves, kidneys, brain, and gut) caused by immune complex deposition [94,95]. Examination of the creatinine level in each patient with HBV infection and assessment for proteinuria is important. All of the medications used for the treatment of chronic HBV need to be dose adjusted if there is a decrement in renal function. Peripheral skin rashes can be assessed by punch biopsy to look for signs of vasculitis. Some patients will need a visceral and renal angiogram to identify angiographic signs of vasculitis in those organs due to periarteritis nodosa.

Cirrhosis may manifest early and subtly with changes in sensorium, memory loss, and day–night reversal. The signs of sequential liver synthetic test result abnormalities (including low albumin, elevated bilirubin, prolonged international normalized ratio [INR], low cholesterol, and high ammonia) and progression to marked signs of portal hypertension are not peculiar to HBV infection (see Chapters 90 and 91). The presence of portal hypertension is manifested by splenomegaly, ascites, varices, thrombocytopenia, leukopenia, and coagulopathy, as seen in patients with cirrhosis of other causes. Acute flares of disease in patients with HBV with cirrhosis are more common than in conditions such as HCV infection or autoimmune diseases in which the inflammatory process is often "burned out."

Laboratory tests are an integral part of evaluating patients with both AH-B and CH-B. It is important to differentiate liver enzymes from liver function tests, although these two terms are often confused or, unfortunately, combined. Liver enzymes are markers of liver inflammation and do not reflect liver function. The ALT, aspartate aminotransferase (AST), alkaline phosphatase, and γ-glutamyltransferase (GGT) enzyme determinations are useful markers for liver inflammatory activity only. Normal ranges for ALT are being fully reassessed and practitioners need to examine closely how their local laboratory sets a "normal" range and whether this is truly a "healthy" ALT. Normal "healthy" ALT is estimated to be < 19 IU/mL for women and < 30 IU/mL for men [44]. These tests, if showing elevated values, should lead a clinician to a full laboratory evaluation for HBV infection as well as investigating other causes of liver disease such as fatty liver, herbal medications, and alcohol-induced liver disease [56,96], over-the-counter and prescription medications, HCV infection, hemochromatosis, autoimmune disease, and Wilson disease. An elevated liver enzyme level in a patient who is HBsAg-positive provides a compelling indication for liver biopsy or consideration of treatment without a biopsy.

Liver function tests commonly include cholesterol, albumin, INR, bilirubin, and ammonia. When the results of liver function tests become abnormal, there is usually severe liver injury present, which could indicate end-stage liver disease or a flare of hepatitis superimposed on chronic liver disease. A flare, or marked rise, in liver enzyme levels, and a decline in liver function co-occur with an increased immune response directed at the HBV-infected hepatocyte. Such a flare of disease activity can also represent superimposed infection such as HCV or HDV, worsening HIV disease (if HIV infection is present), and potential progression to end-stage liver disease. When results of liver synthetic tests become abnormal in a patient with CH-B, a clinician should strongly consider consulting with a transplant center if the patient has no contraindications for transplantation. There should also be a strong consideration of immediate initiation of antiviral therapy with a nucleoside/nucleotide analogue. In the setting of liver synthetic abnormalities, interferon is relatively contraindicated, unless used by expert hands, typically in a tertiary referral center.

Laboratory surrogates to assess for the severity of liver disease include signs of hypersplenism, such as a low platelet or low white blood cell (WBC) count. Platelet counts below 100 000–150 000/mL should elicit strong suspicion of advanced fibrosis. An elevated α-fetoprotein (AFP) is usually associated with inflammation and ongoing liver injury; however, AFP is a poor parameter for the presence or absence of hepatocellular carcinoma and is no longer a first-line test for HCC screening [97]. The degree of AFP elevation informs about the risk of HCC in the future and occasionally is associated with the presence of hepatocellular carcinoma. A high ferritin and iron saturation could arouse suspicion of hemochromatosis although abnormalities in biochemical markers of iron overload are also common in patients with marked fibrosis or cirrhosis. A "reversed" AST/ALT ratio, where the AST is higher than the ALT, also supports advanced fibrosis or cirrhosis.

Patients with CH-B may have a moderately reduced quality of life compared with those without persistent HBV infection. Patients with end-stage liver disease will have a markedly reduced quality of life, although this is true for all patients with advanced liver disease and is not specific to HBV infection. Patients who undergo treatment with interferon often have a reduced quality of life during treatment but most tolerate full doses and a full course of treatment. If the patient clears HBV infection, his or her quality of life may improve after treatment to regain a normal level; hence, treatment may be not only cost-effective but also cost-saving [98,99].

Hepatocellular carcinoma is a serious risk for all individuals who are persistently HBsAg-positive (see Chapter 93). The estimated lifetime risk for HCC in patients who are chronically HBsAg-positive is estimated to be about 20%. This risk is markedly increased in patients with lifelong HBV infection, cirrhosis, active liver disease as demonstrated by biopsy, elevated liver enzyme levels, elevated HBV DNA level (Fig. 81.2), a history of alcohol abuse, chronic infection lasting more

than 30–50 years, dietary exposure to aflatoxins, a family history of HCC, an elevated AFP, or coinfection with HCV, HIV, or HDV [100–103]. Issues such as prevention of HCC by vaccine are covered in other sections, and prevention of HCC by use of interferon and antiviral therapies will be discussed under "Treatment" below. Patients with CH-B need to be informed of the risk of HCC and should be considered for HCC screening, depending on resources and available treatments. The initiation and frequency of screening depend on the relative risk of HCC in special groups of patients with HBV and, most importantly, in patients with cirrhosis.

Differential diagnosis

All patients with elevated levels of liver enzymes (see discussion above for what are considered normal and elevated liver enzymes) need to be screened for fatty liver, medication toxicity, elevated iron (blood and tissue concentrations), HBV and HCV infection, and alcohol abuse. The differential diagnosis of chronic HBV infection includes considering acute HBV infection, which usually can be differentiated by the presence of anti-HBc IgM (Table 81.1). Patients with elevated liver test results and detectable presence of anti-HCV in serum can be evaluated by the use of molecular testing. If HBV DNA is not measurable and HCV RNA is found to be elevated, HCV is considered the dominant disease and therapy should focus on the HCV infection. Autoimmune disease rarely occurs concomitantly with HBV disease and is also rarely caused by HBV. One must rule out biliary obstruction if the GGT or alkaline phosphatase concentration is higher than the AST or ALT serum levels. A baseline ultrasound is considered standard of care in all patients with elevated levels of liver enzymes to rule out other diseases, assess for fatty liver, assess spleen size, evaluate for varices, and look for space-occupying lesions as well as to reassure the patient about the absence of liver cancer. Examination of the liver biopsy for plasma cells and testing for antinuclear antibodies and anti-smooth muscle antibody is important, especially if serum globulin levels are greater than 4 g/dL. Patients with elevated levels of liver enzymes who are HBsAg-positive with adult-acquired liver disease need to be assessed for HDV infection by antibody testing, at a minimum [104–107].

Course and complications

The clinical course of CH-B infection is variable and affected by multiple factors, including those related to the patient (including age, gender, immune capacity and response to the virus, genetics, coinfection with other viruses, and habits such as alcohol consumption or smoking) and the virus itself (replication level, genotypes, and molecular variants). Each subgroup of patients with HBV infection has a different clinical course. The individual with persistently positive HBsAg, elevated HBV DNA level, and consistently elevated liver enzymes is the patient with the greatest risk of progression to cirrhosis and the subsequent complications. The next highest risk of progression is in the patient who presents with flares of liver enzymes and reactivation of liver disease as well as HBV DNA levels greater than 10^4 IU/mL. Each cycle of liver enzyme elevation purportedly is due to immune activation, which results in attempts to clear HBV infection. These are often ineffective. Spontaneous seroconversion from HBeAg to anti-HBe occurs at a rate of 1%–10% per annum in patients with CH-B, but seroconversion from HBsAg to anti-HBs, with clearance of HBV from the liver, is uncommon (at or less than 0.5%–1% per year) [108]. The rate of HBsAg seroconversion is higher in patients with more active liver disease (as measured by liver enzymes) than in those with persistently normal liver enzymes, but is in general less than 15% over any 3-year interval and occurs more commonly in genotype A [21,22]. During these immune "attacks" or flares there is ongoing hepatocellular damage and, commonly, progressive fibrosis. Thus, in general, the serum level of HBV DNA is the most important factor for determining risk of progression, but the degree of liver enzyme elevation and the number of flares often correlate over time with the severity of liver injury. Blood testing for progressive liver disease and screening for HCC should also take place more frequently in those patients with established cirrhosis compared with patients with mild or no fibrosis.

The patient with CH-B who has a persistently normal level of liver enzymes (< 19–30 IU/mL) and HBV DNA levels less than 200 IU/mL has a much lower risk for progressive liver disease and cancer, although the overall risk for HCC is still significant. Blood testing at least every 3–6 months is important because annual testing may be insufficient to document a stable patient or to define inactive or reactivated disease. For such patients, the frequency of screening with blood tests should be at least biannually; a more thorough evaluation with testing every 3 months may be justified.

During regular laboratory testing of liver enzymes, quantitative HBV DNA, anti-HBe, and HBeAg testing can establish if a precore or a BCP mutant virus has emerged in the patient. These viral mutants can be suggested by the presence of moderate (HBV DNA > 2000 IU/mL) to high HBV DNA serum levels in the absence of HBeAg. The larger laboratories offer HBV DNA sequencing services to determine the presence of HBV mutants of clinical significance. One widely available commercial test, produced by Innogenetics NV (Ghent, Belgium), is the INNOLiPA assay, which can confirm the presence of the precore and core promoter mutations. Patients with the precore or BCP mutant probably have a higher risk of developing liver cancer and progression to liver disease. In rare circumstances, patients who appear to clear HBsAg but do not develop anti-HBs may have developed surface mutant viruses.

Coinfection

HBV coinfection with hepatitis D (delta virus)

The patient with dual HBV and HDV infection has a typical serological profile of HBsAg and anti-HBe positivity (rarely HBeAg positivity) as well as IgG anti-hepatitis delta (anti-HD) seropositivity and HDV RNA positivity (Table 81.1). Specific immunoassays are available for detection of both IgM- (for both acute and active infection) and IgG-specific anti-HD (seen in chronic disease as well as resolved infection). Serum assays for detecting HDAg and HDV RNA are restricted and can typically only be requested from central reference laboratories or the larger commercial specialist laboratories. Hepatitis delta infection is easy to miss if not considered for all individuals who are persistently positive for HBsAg, or patients with acute liver disease, and testing should include HDV RNA and anti-HD IgG/IgM as well as the standard tests for HBV infection. These tests should be repeated in suspected cases if the first test is negative and aggressive liver disease continues.

In the United States, HDV infection occurs predominantly amongst IDUs in large cities and those who engage in high-risk sexual activity [109]. Ethnic populations who may carry HBV from the Mediterranean region, the Pacific islands, Greenland, the Middle East, or the Orinoco river valley in South America need to be tested for HDV infection as well. Hepatitis delta virus infection can lead to more severe liver disease (fulminant hepatitis) in those patients who acquire HDV and HBV at the same time compared with those patients who acquire acute infection with HBV alone (see chapter on acute hepatitis) [104–107], but often the two diseases are clinically indistinguishable. If they survive, patients with acute coinfection with HBV and HDV have a high rate of clearance of both viruses. When new HDV infection is superimposed on chronic HBV infection, the liver disease commonly accelerates and cirrhosis often develops in a much shorter time. Compared with patients with chronic HBV monoinfection, patients with HDV and HBV coinfection may also be at greater risk for liver cancer, probably because cirrhosis develops at a higher rate [110].

Infection with HDV can be treated with interferon although results are disappointing, with patients rarely clearing HDV and HBV in the long term. Therapy requires at least 1 year of treatment. Therapy with a nucleoside analogue, such as lamivudine, does not suppress HDV infection, probably because it has minimal effect on the HBV covalently closed circular (ccc) DNA levels, the main transcriptional template of HBV, from which HBsAg is synthesized and which HDV then uses to complete its replication. Liver transplantation for patients with acute HDV infection will often be followed by milder liver disease if HBV and HDV infections persist. However, HBIG therapy to prevent graft infection with HBV can also prevent HDV infection of the new graft [111]. Patients with HDV infection typically have low levels of HBV DNA as a result of the suppressive effect of HDV on HBV viral replication. The mechanism for this is unknown. HBeAg and anti-HBe status is variable (Table 81.1).

The manner in which HDV causes liver injury remains controversial. Histological observations of microvesicular steatosis and cytoplasmic eosinophilia in the absence of a mononuclear cell or lymphocytic infiltrate in the liver biopsy specimen of patients with acute HDV infection are consistent with a direct cytotoxic effect of HDV. In vitro molecular studies have supported this view, with experimental evidence that the smaller form of HDAg (S-HDAg) expression in cells results in the production of pyknotic nuclei and shrunken eosinophilic cytoplasm as well as reduced cellular nucleic acid synthesis. By contrast, evidence supporting an immune-mediated cytotoxic pathway is sparse and a direct link between HDV-associated disease expression and the immune response is lacking.

Suppression of markers of HBV replication during HDV superinfection has been observed in humans as well as in the woodchuck and chimpanzee animal models. In over 90% of hepatitis B patients superinfected with HDV, seroconversion occurs from an HBeAg-positive to an HBeAg-negative/anti-HBe-positive state with low or absent serum HBV DNA levels. Serum HBV-specific DNA polymerase activity and intrahepatic HBcAg expression can no longer be detected in these patients. On rare occasions, HDV superinfection has been associated with termination of the HBsAg carrier state and seroconversion to anti-HBs. The mechanism for this interference has not been conclusively established.

HBV coinfection with HIV

Coinfection of HIV with HBV results in more aggressive liver disease with faster progression to cirrhosis and liver failure in approximately one-third of patients, although other patients have minimally active liver disease with little or no evidence of progressive liver disease [112–114]. Why certain patients have progressive liver disease in this setting and others do not is unclear and is not correlated with any specific clinical factor or laboratory test, although the emergence of lamivudine-resistant HBV has been implicated [112]. The discrepancies may be explained by an interaction between the host immune system, T-cell types present (Th1 vs Th2), host factors that predict fibrosis, and levels of HBV and HIV viral replication.

Treatment with lamivudine may slow the progression of liver disease but is problematic from the perspective of increased resistance compared with patients who are not coinfected [115]. Current guidelines for the use of antiretroviral agents in HIV-infected adults and adolescents recommend that if therapy for either HBV or HIV infection, or both, is indicated in the coinfected individual then a fully suppressive antiretroviral regimen should be initiated in order to prevent development of antiretroviral resistance [116]. This

is recommended for the HIV/HBV-coinfected regardless of CD4 count. These guidelines list the combination of tenofovir with either emtricitabine or lamivudine as the preferred nucleoside analogue backbone, as these medications also suppress HBV, along with the addition of the other antiretroviral agents required to create an effective anti-HIV regimen.

It is very important to avoid HBV treatment of an HIV-infected patient with an agent known to have activity against HIV, such as entecavir, unless that patient is on a fully HIV-suppressive highly active antiretroviral therapy (HAART) regimen. Using a single agent known to have activity against both viruses would lead to rapid selection of medication-resistant HIV strains, as this would be equivalent to antiretroviral monotherapy. Because of the high level of cross-resistance with many antiretrovirals and the need for effective nucleoside analogues as the backbone for most HIV treatment regimens, this could leave the patient with few options for durable HIV suppression. It is known that lamivudine, emtricitabine, and entecavir all select for the development of the M184V mutation. The medications currently used in the treatment of HBV and/or HIV that are known to have activity against both viruses include adefovir (Hepsera), emtricitabine (Emtriva, also in the combination antiretroviral medications Truvada and Atripla), entecavir (Baraclude), lamivudine (Epivir-HBV and Epivir, also in the combination antiretroviral medications Combivir, Trizivir, and Epzicom), and tenofovir (Viread; also in the combination antiretrovial medications Truvada and Atripla). In light of the delayed recognition that entecavir has activity against HIV, a problem that resulted in some HIV/HBV-coinfected patients being treated with monotherapy [117], experts have pointed to the need for very careful evaluation of possible anti-HIV activity for all future hepatitis B medications proposed for use in coinfected patients.

It is also important that coinfected patients never be treated with less than two agents with anti-HBV activity in order to slow development of HBV resistance and limit the risk of a clinically significant hepatitis flare in the setting of HAART-induced immune reconstitution [118]. The risk of hepatitis flare with discontinuation of HBV therapy also mandates that in those who need a change in their HAART regimen, medications with HBV activity should not be discontinued without the substitution of other agents that can effectively suppress HBV, unless there has been HBeAg seroconversion followed by an adequate course of consolidation treatment [118].

In cases when HIV treatment is not an option or is not desirable, it is very important that HBV treatment choices be limited to only those medications that do not have clinically relevant dual activity. Of the antiviral agents currently approved for the treatment of HBV, only telbivudine (Tyzeka, Sebivo) has no known activity against HIV. However, current guidelines recommend against its use as monotherapy in HIV/HBV-coinfected patients due to the risk of selection of the M204I mutation in the YMDD motif [118]. Adefovir, which has minimal HIV activity at the approved HBV dose of 10 mg per day, could be used with telbivudine. However, the safest alternative is to use only pegylated interferon therapy as it does not lead to development of medication-resistant HIV or HBV.

As well as the issue of accelerated liver disease progression due to the effect(s) of HIV on HBV replication, other challenges include the immune reconstitution inflammatory syndrome that occurs when an effective HAART regimen restores immune function and increases the capacity to mount an inflammatory response. Another concern is direct hepatotoxicity from the multiple agents that comprise the HAART regimens in common use with HIV disease. However, an analysis of 5272 HIV-infected patients (30% female, 39% intravenous drug users, and nearly 48% HCV/HBV coinfected) with 18 259 person-years of follow-up found that HAART did not significantly increase the risk of liver enzyme elevations but HBV or HCV coinfection did increase risk [119].

HBV coinfection with HCV

Coinfection with HCV and HBV results in increased risk of both cirrhosis and liver cancer. Patients often have one dominant viral disease. Treatment focused on the dominant virus, as revealed by blood tests of viral replication, is probably the best management step [120–125].

Hepatitis A disease

Acute HAV infection sometimes complicates chronic HBV infection. Patients infected with HBV and having an acute HAV infection are at increased risk of developing severe liver disease and death [126]. Vaccination against HAV is advocated for all patients with chronic HBV infection [126].

Treatment

Definitions of response to treatment

Definitions of response to antiviral therapy are important when evaluating patients who are about to undergo antiviral therapy or for previously treated patients who appear to need subsequent treatment. Indications of response are defined as follows:

- biochemical – a decrease in levels of liver enzymes into the normal range
- virological – suppression of viral replication to less than 20 000 IU/mL (potentially useful with interferon therapy) or to a level undetectable by PCR (the goal of therapy with all nucleoside or nucleotide analogues)
- serological – HBeAg seroconversion to anti-HBe as well as HBsAg seroconversion
- histological – improvement in liver biopsy scores, with histological activity index improving by at least 2 points and no worsening in fibrosis.

These responses can be *initial* (occuring during therapy), *end of therapy* (ETR), or *sustained*. A sustained biochemical response is commonly defined as normal levels of liver enzymes at the end of therapy that are maintained for at least 6–12 months following cessation of therapy. A partial biochemical response means a marked fall (> 50%) in liver enzyme levels to the near-normal range, reductions that are typically associated with improvement in histology.

In the past, the virological response was defined as either a reduction of HBV DNA to less than 20 000 IU/mL when pretreatment levels were greater than 20 000 IU/mL, or a greater than 1–2 log reduction from baseline. With the advent of more powerful agents and the concept that patients with any level of viral replication have a higher risk of liver cancer and death due to liver failure, the ability to control HBV replication and bring viral DNA down to undetectable levels (defined as less than 60 IU/mL, or 300 copies/mL – the limits of the PCR COBAS Amplicor assay, the most common assay used in licensing trials) is emerging as the goal of antiviral therapy. If viral load reduction is less than 1 log from baseline every 3 months, and HBV DNA is still detectable by 24 weeks for nucleoside analogues and by 48 weeks for nucleotide analogues, it is recommended that there be a change in therapy.

The timing of a change or addition of therapy depends on the risk of resistance, which is highest with lamivudine and lowest with entecavir. Choices include switching to the most potent agent available or adding medications to create effective long-term combination therapy. The reduction in serum HBV DNA viral levels can correlate with HBeAg loss (either naturally or if treatment is given). Conversion from anti-HBe negative to positive would complete what is termed triple seroconversion, although the rate of HBeAg seroconversion is higher with interferon therapy than with any of the nucleoside or nucleotide analogues after 1 year of treatment. Virological responses can also be termed initial, ETR, or sustained if there is loss of viral replication for 6–12 months after the end of treatment. The terminology "HBeAg seroconversion" is used when the HBeAg is lost (negative) in the long term and anti-HBe is gained, with HBV DNA levels less than 2000 IU/mL and normal ALT levels.

Histological improvement is defined using the histology activity index, the Ishak score, the Metavir score, or one of the modifications. There is no international consensus about which scoring system is best although the US Food and Drugs Administration (FDA) is utilizing a combination of the modified Knodell and Ishak scores. A significant improvement is based on a decrease in the necroinflammation score by two points and no worsening of fibrosis because the fibrosis score typically lags behind changes in inflammation in the liver.

Complete response means normalization of liver enzymes, serological response, virological response, and loss of HBsAg. This complete response is further defined as (before HBsAg seroconversion takes place): HBeAg negativity, anti-HBe positivity, and HBV DNA negativity by the most sensitive molecular test available. Interferon responder patients may still have low levels of HBV DNA but HBeAg seroconversion and normal ALT levels. The HBV DNA tests we use can typically measure down to 60 IU/mL (Table 81.2). Hence, this is synonymous with resolved (HBsAg seroconversion) or controlled (HBeAg seroconversion or long-term DNA negativity) HBV infection. These states do not require the presence of anti-HBs and clinically do not require a follow-up liver biopsy. The use of more advanced molecular testing, such as TMA, which has a sensitivity of 15 IU/mL, and real-time TaqMan/Artus PCR, which has a sensitivity of 50 IU/mL, is improving the quality and reliability of quantitative HBV DNA testing.

Another important perspective on response to HBV treatment is the question of whether HBV infection is ever "cured." As discussed above, the HBV transcriptional template exists in the nucleus of the infected cell as a population of cccDNA molecules organized into a viral minichromosome. These molecules of HBV cccDNA have a long intracellular half-life (Fig. 81.5). There are no clearly identified antiviral agents that inhibit HBV cccDNA generation or processing although clevudine, adefovir, and interferon seem to at least reduce intracellular cccDNA levels.

Medication resistance testing

As discussed in depth below for individual agents, the issue of medication resistance greatly affects the likelihood of success with many of the available treatments. With continued use, the virus is likely to develop resistance to not only an antiviral agent currently being used, but also possibly to future agents where there is cross-resistance. This has been found to be a particular problem with the use of lamivudine, which leads to cross-resistance with many other agents. It has been proposed that lessons learned with HIV resistance assays might translate into more effective management of CH-B. The use of both genotypic and phenotypic assays to assess antiretroviral resistance in HIV-infected patients has been shown significantly to improve the outcome of therapy. Anti-HBV medication resistance testing may become equally useful for making therapy choices. Assays specific for HBV that identify mutations associated with resistance to certain medications are commercially available, although their use is not yet as widespread as that of assays used in HIV treatment. So far there are no commercially available HBV-specific phenotypic assays.

Several consensus groups have released guidelines for the use of antiretroviral resistance testing in HIV-infected patients. No such guidelines exist for HBV medication resistance testing, so its use is at the discretion of individual physicians. It is generally thought that the use of the available assays to identify mutations associated with resistance to specific medications could be important for effective clinical

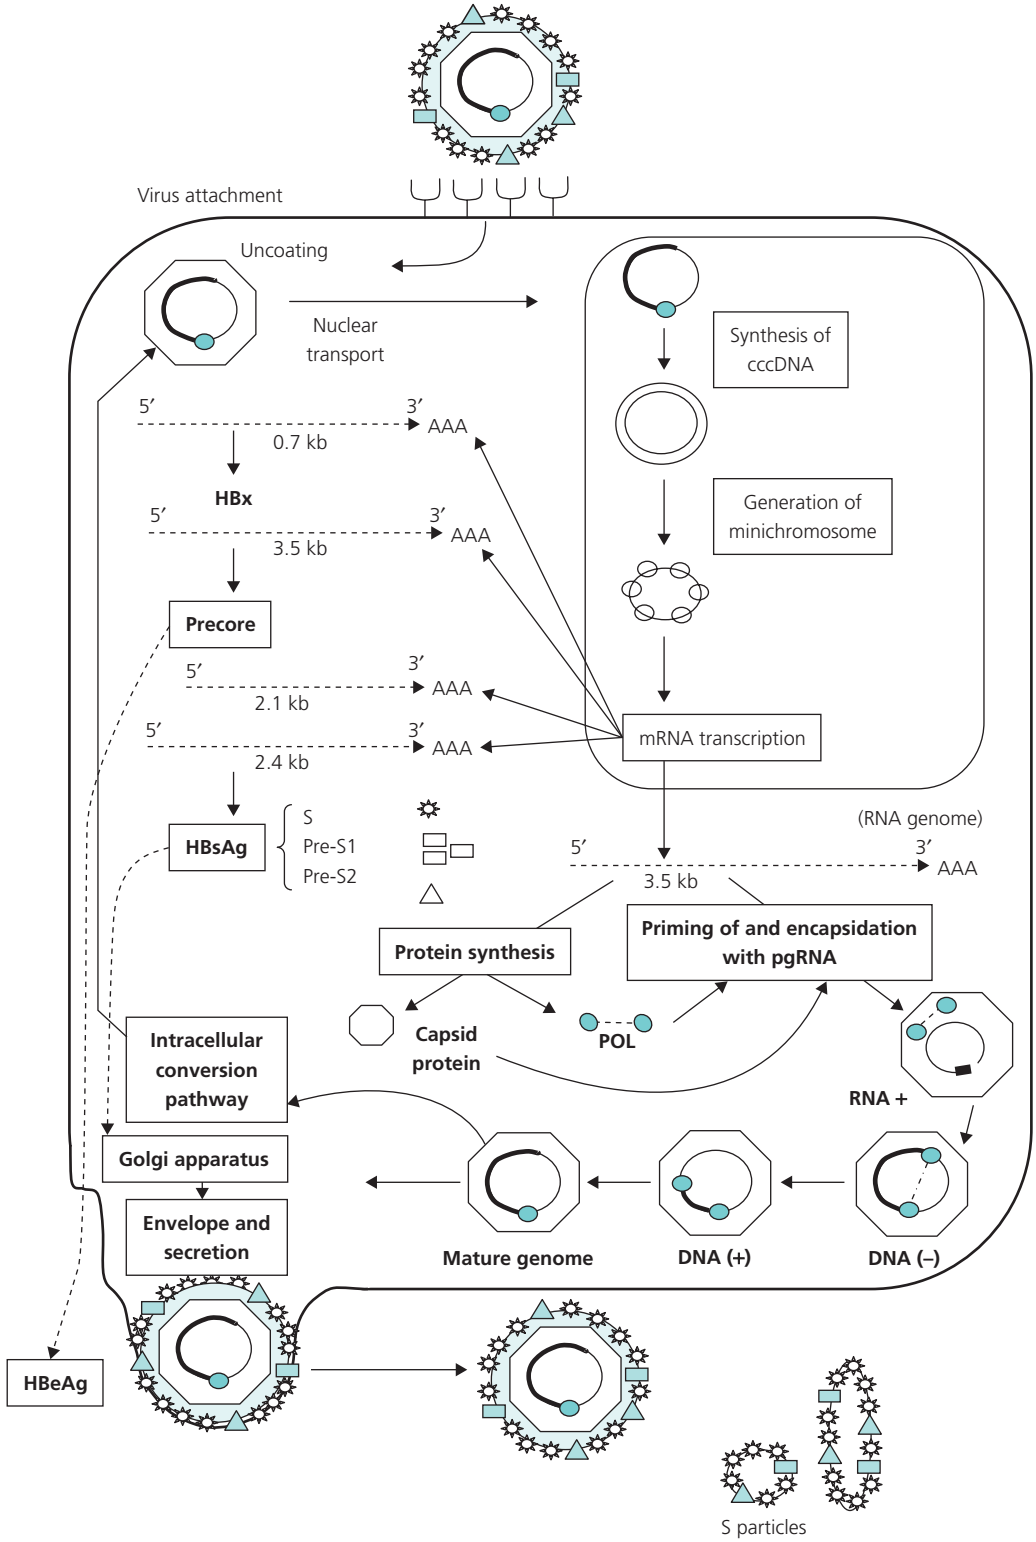

Figure 81.5 Life cycle of covalently closed circular DNA (cccDNA). HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBx, hepatitis B x antigen; pgRNA, pregenomic RNA; POL, "polymerase" (reverse transcriptase); S, S envelope protein.

management. One limitation is that resistance testing may not be accurate for medications that the patient is not currently taking because in that setting there will be no selective pressure to increase the population of the medication-resistant viruses. Thus, although present in minority populations, these resistant viruses may not be identified on initial HBV DNA Pol sequencing (sometimes referred to as "resistance genotyping" but best termed sequencing or using INNOLiPA for resistance). Since these resistant viral populations are present as a minor group, they may not be detected by nucleic acid testing assays. The most common assays are the sequencing assays that can measure down to viral populations of 20% or line probe assays that can measure down or detect viral variants as low as 5% of a given total population. Newer resistance tests that can identify mutations present in only 0.01% of the viral population are in development and should be available soon.

Therapeutic agents

Algorithms for the treatment of CH-B are updated regularly. Clinicians should be aware of the most recent guidelines [44,118], as well as any updates published on the available therapeutic agents, to make the best treatment decisions. Below is information on the individual agents approved for HBV treatment, as well as investigational agents in development.

Interferons

The term interferon is used to describe a large family of naturally occurring peptides that are included within an even larger group of molecules termed cytokines, which modulate immune function. This family of proteins is often involved in the host's control or elimination of acute and chronic viral infections. Interferon directly decreases viral replication by interference with DNA and RNA replication at the genome level. Interferon also indirectly modulates viral replication and viral protein synthesis by activating other immune pathways and modulating the level of other cytokines. The JAK/STAT pathway, responsible for triggering increased synthesis of antiviral signals and enzymes, such as 2′,5′-oligoadenylate synthetase and protein kinase, results in effective antiviral mechanisms within the cell, blocking viral replication at the translational (PKR, protein kinase R) and transcriptional (RNase L) levels. By enhancing major histocompatibility antigen (MHC) expression, interferon increases the identification of cells infected with HBV and leads to both cytolytic and noncytolytic viral clearance. Activation of natural killer (NK) cells and dendritic cells are other key steps in viral clearance.

At least 20 natural forms of interferon exist in humans including α2-interferon (IFN-α2; produced in lymphocytes), IFN-β (produced in fibroblasts), IFN-γ (produced in T cells), and IFN-ω. A number of these interferons (IFN-α2a and IFN-α2b) have been isolated and shown to have direct antiviral effects on HBV replication in humans [127]. Interferon is the only medication that has been proven to reduce and eliminate HBV infection, as shown by a high frequency of HBsAg seroconversion in chronically infected patients given interferon in randomized controlled trials [128,129]. Interferon therapy is not associated with medication resistance. Clearance of cccDNA is a key step in the control of CH-B, and interferon treatment is correlated with cccDNA suppression and clearance. Both patients with HBeAg-positive and HBeAg-negative CH-B benefit from treatment [129,130], demonstrated by improved outcomes in randomized controlled clinical trials (Fig. 81.6).

Over time, there is a cumulative increase in the number of patients who are HBV DNA negative, HBeAg negative, and anti-HBe positive with HBsAg seroconversion. These virological endpoints have been directly linked with a decrease in the number of patients with decompensated liver disease and HCC. Prednisone has been studied in clinical trials and practice and appears to be beneficial only for certain rare subgroups of patients such as those with modest viral replication and near-normal levels of liver enzymes, and is therefore not used in clinical practice [131].

Only an "ideal" subset of patients responds to interferon and clears HBsAg. These are patients with the higher levels of serum liver enzymes that signal a more active, ongoing, and effective immune response; lower serum levels of HBV DNA; and genotype A. The presence of elevated levels of liver enzymes and the presence of hepatic inflammation identify these "ideal" patients, who seem primed in their immune response to clear chronic HBV infection. Levels of HBV DNA also need to be in a mid to low range (< 20 000 IU/mL). Interferons such as IFN-α2b (Intron A; Schering-Plough, Kenilworth, NJ) and pegylated interferon alpha-2a (PEGASYS; Roche Pharmaceuticals, Nutley, NJ), have been approved for the treatment of CH-B in many countries worldwide, including for the treatment of adults and children in the United States. Treatment with IFN-α2b results in HBeAg clearance in 30%–50% of selected patients and HBsAg clearance in up to 15% of patients with long-term follow-up [132].

Results of several large randomized studies of pegylated IFN-α in patients with CH-B have been published [129,130,133,134]. These studies compared the safety and efficacy of pegylated IFN-α2a or IFN-α2b administered either alone or in combination with lamivudine. Janssen and colleagues [134] studied 307 patients with HBeAg-positive CH-B who were given pegylated IFN-α2b, at doses of 100 μg/week for 32 weeks, followed by 50 μg/week for 20 weeks, either with placebo or in combination with lamivudine (100 mg/day). There was no lamivudine monotherapy arm in this study. Patients were followed for an additional 26 weeks of treatment. At 52 weeks, loss of HBeAg was achieved in 29% of the patients treated with pegylated IFN-α2b alone and in 44% of the patients treated with pegylated IFN-α2b

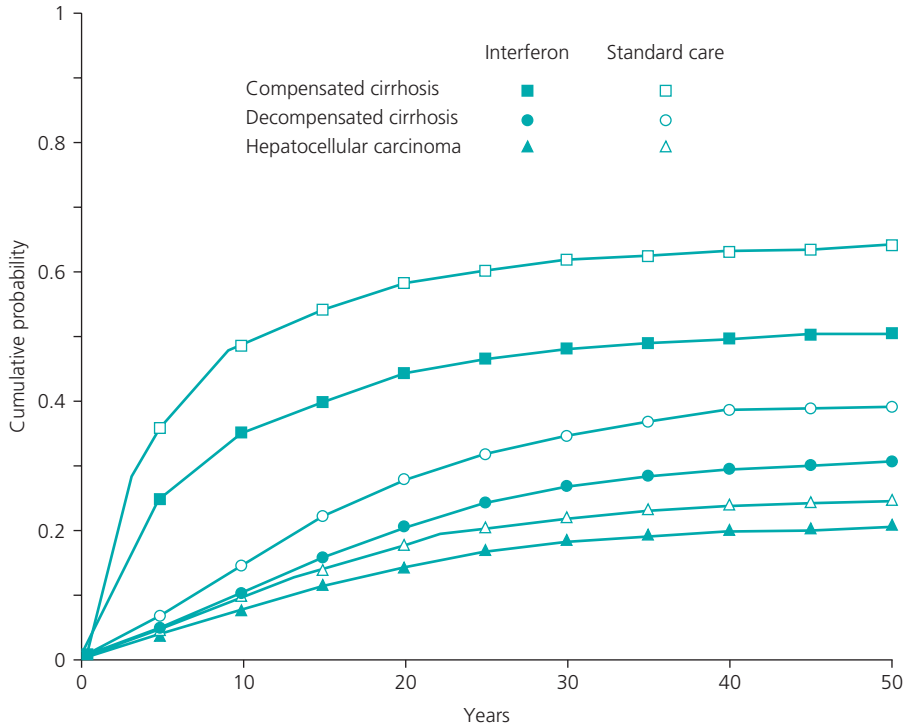

Figure 81.6 Outcomes of interferon treatment for hepatitis B virus infection. From Wong et al. [98], with permission from the American College of Physicians.

in combination with lamivudine ($P = 0.01$). However, at the end of follow-up, the proportions of patients in the two groups with loss of HBeAg were comparable: 36% (49/136 patients) in the pegylated IFN-α2b monotherapy group and 35% (46/130 patients) in the combination therapy group ($P = 0.91$). Clearance of HBeAg at the end of treatment but relapse during follow-up occurred more frequently among the combination therapy group (44%; 57 patients) than among the monotherapy group (29%; 40 patients) ($P = 0.01$). For response defined as suppression of serum HBV DNA or improvement in ALT concentration, there was no difference in response rate between the treatment groups. Response rates as defined by loss of HBeAg varied by HBV genotype ($P = 0.01$): rates were 47% for genotype A (42 patients), 44% for genotype B (10 patients), 28% for genotype C (11 patients), and 25% for genotype D (26 patients).

The ideal dose of the pegylated interferons varies according to the manufacturer (Schering-Plough vs Roche) but typically it is the hepatitis C dose, given once per week subcutaneously for 12 months. Interferon causes significant and various side effects that are well described. It is hoped that they will be reduced with newer forms of interferon or with lower doses used in combination with other forms of less toxic therapy, such as nucleoside or nucleotide analogue antivirals. Some examples of interferon side effects (which are often dose-related) are bone marrow suppression, psychiatric disturbances, alopecia, flu-like syndromes, nausea, weight loss, increased risk of bacterial infections, and hyperglycemia. The immunomodulator thymosin-α1 (Zadaxin, Sciclone Pharmaceuticals, San Mateo, CA), has been shown to be associated with HBeAg seroconversion and triple seroconversion when used as a single agent, but it may be more useful in combination with interferon. It is approved in the United States for treatment of liver cancer.

Nucleoside and nucleotide analogue antivirals

Modified nucleosides such as adenosine arabinoside (ara-A), ganciclovir, famciclovir, and other nucleoside analogues have been studied extensively over the last few decades. Adenosine arabinoside was the initial nucleoside analogue studied for the treatment of HBV infection. Treatment with ara-A resulted in a decrease in levels of HBV DNA in the serum but had significant untoward side effects including, in some patients, an irreversible peripheral neuropathy. Toxicity and weak antiviral effects were the major factors behind the failure of ara-A, ganciclovir, and similar medications. Fialuridine (FIAU), a fluorinated nucleoside with more potency than ara-A, was studied in the early 1990s and in humans was found to have major mitochondrial toxicity that resulted in pancreatitis, acidosis, liver failure, and death. Lobucavir was also studied in humans, but clinical trials were halted when this agent was associated with gynecological cancers in animals. These complications support close short- and long-term scrutiny of these powerful medications that can disrupt host cellular homeostasis and DNA replication. There are four nucleoside analogues approved for the treat-

ment of CH-B in the United States: lamivudine, adefovir dipivoxil, entecavir, and telbivudine.

Lamivudine

Lamivudine (3-thiacytidine, 3TC; Epivir-HBV, Zeffix, GlaxoSmithKline, Philadelphia, PA) was the first FDA-approved oral medication with proven efficacy against HBV, as shown by HBeAg seroconversion and triple seroconversion compared with placebo. Lamivudine is approved throughout the world for the treatment of CH-B. Data to date concerning efficacy include a rate of 17% HBeAg seroconversion at 1 year of therapy with lamivudine (100 mg daily) [28,135–137] and HBeAg seroconversion rates of up to 40%–45% by year 4–5 of therapy. Importantly, in the first trial to compare a nucleoside with placebo in a prospective study, lamivudine (100 mg daily) decreased the rate of liver decompensation events and even decreased the rate of liver cancer [138]. Unfortunately, resistance to lamivudine is common: after 1 year of treatment (150 mg daily) the frequency is greater than 20%; and by 5 years the frequency of resistance rises to 70%–100% [139]. This resistance can be associated with elevations in levels of liver enzymes; flares with decompensation and death or transplant have also been reported. Liaw and colleagues reported that patients infected with lamivudine-resistant HBV had an increasing rate of liver decompensation over the period of their study, approaching the rate of the events in the placebo group [138]. More importantly, resistance to lamivudine affects the sensitivity to the other nucleoside analogues and can affect the response to the nucleotide analogues. For these reasons, lamivudine is considered second-line therapy. Resistance to this agent is considered in more detail under "Lamivudine resistance" below.

Adefovir

Adefovir (adefovir dipivoxil; Hepsera, Gilead Sciences, Redwood City, CA) is a nucleotide analogue of adenine that has a high binding affinity for the HBV polymerase. Adefovir is FDA approved for the treatment of HBeAg-negative and HBeAg-positive CH-B as well as the treatment of lamivudine-resistant hepatitis B. Compared with placebo, adefovir caused reductions in HBV DNA and ALT in patients with the HBV precore and BCP mutants, as well as in those with wild-type virus. All patients were treated with adefovir at 10 mg/day for a minimum of 1 year in the two main placebo-controlled trials. The primary endpoint of treatment was histological improvement, which was achieved in 67% of patients on adefovir and 19% of patients on placebo. The data in the HBeAg-positive patients demonstrated histological improvement in 53% of the treatment group versus 25% of the placebo group [140]. Longer-term data have shown increasing improvement in the majority of adefovir-treated HBeAg-negative patients [141]. After 192 or 240 weeks of treatment, over 83% of patients had improvement in necroinflammation. Ishak fibrosis scores improved compared with baseline in 35%, 55%, and 71% of patients after 48, 192, and 240 weeks, respectively. At 240 weeks, serum HBV DNA levels were less than 1000 copies/mL in 67% of patients, with normalization of ALT in 69% of patients.

Renal injury due to adefovir and the related compound tenofovir is uncommon at the approved/licensed therapeutic doses, occurring at a rate of about 1%–2% per year in the first 2 years, and only rising to 3% after 5 years of adefovir monotherapy [141]. Monitoring of creatinine should be carried out routinely, either as per the product insert, in 6-monthly cycles, or with any suspected changes in renal status or co-administration of medications that may affect renal status.

Cumulative data with both HBeAg-positive and HBeAg-negative populations continue to show improved seroconversion with each additional year of use, and stable long-term suppression (up to 90%) off therapy in those patients with HBeAg seroconversion. Duration of therapy after seroconversion may affect the durability of seroconversion. In one study, of those patients who seroconverted from HBeAg-positive to anti-HBe while receiving adefovir (10 mg daily), seroconversion was maintained in 91% over a median off-treatment follow-up of 3 years [142]. The 9% of patients who reverted to HBeAg-positive status within 16 weeks off therapy had a shorter duration of postseroconversion adefovir treatment. Interestingly, with initial treatment response assessment, there is no difference in terms of viral suppression among the various HBV genotypes.

Resistance to adefovir is low in the first few years of monotherapy (0%, 3%, and 11% in HBeAg-negative patients at 1, 2, and 3 years, respectively [143]) but rises to 29% after 240 weeks in HBeAg-negative patients [141] and 42% after 235 weeks in HBeAg-positive patients [144]. However, the cumulative probability of mutations combined with virological resistance was 20% after 240 weeks in HBeAg-negative patients. Resistance to adefovir is associated with the rtN236T + rtA181T/V mutations (rt, reverse transcriptase).

In patients with preexisting lamivudine resistance who are given adefovir monotherapy, adefovir resistance develops much more rapidly. After 48 weeks of adefovir treatment, adefovir resistance has been seen in 18% of lamivudine-resistant patients compared with 0% in treatment-naive patients [145]. At 2 years, the cumulative incidence of resistance seen with lamivudine-resistant patients treated with adefovir monotherapy was 25.4% [146].

Much better results are seen when adefovir is added to lamivudine therapy (add-on combination). In one study of patients with lamivudine resistance and virological and clinical breakthroughs with lamivudine monotherapy, patients who were switched to adefovir monotherapy were compared with those given adefovir in addition to continuing lamivudine therapy [147]. At 12 months, there were no significant differences between the two groups of patients, with undetectable serum HBV DNA seen in 71% and ALT normalization in 90% of all patients. However, at a median treatment

duration of 40 months, these responses were maintained in all patients with adefovir added to lamivudine, whereas adefovir resistance and resulting virological and biochemical breakthroughs occurred at 15–18 months from start of treatment in 21% of patients on adefovir monotherapy.

The timing of an adefovir addition to lamivudine therapy in patients showing lamivudine resistance appears to be important. In one study that compared the results of adding adefovir on the development of "genotypic resistance only" (defined as 3–6 $\log_{10}$ copies/mL of HBV-DNA and normal ALT levels) with the results of adding adefovir on the development of "phenotypic resistance" (defined as > 6 $\log_{10}$ copies/mL of HBV DNA and high ALT levels), HBV DNA was undetectable by month 3 in all patients with only genotypic resistance compared with only 46% of patients with phenotypic resistance [148]. At 2 years, the rates of virological response were 100% in those with only genotypic resistance when adefovir was added compared with 78% in those with phenotypic resistance when the addition was made. Overall, combination therapy with lamivudine and adefovir, either in naive patients or in those patients with lamivudine resistance, does appear to be of benefit, with the rate of resistance greatly reduced if the two medications are started concomitantly (de novo combination), although there is no additional HBV DNA suppression.

Tenofovir is also a choice, with limited case series data supporting its use in this setting. The best option to reduce medication resistance is not to use agents with a significant or overlapping resistance profile. In patients with adefovir resistance (HBV Pol: rtA181T/V + rtN236T), entecavir is the best option although there are limited data showing that tenofovir can also result in additional viral suppression.

Entecavir

Entecavir (Baraclude, Bristol-Myers Squibb, Princeton, NJ) is a novel oral deoxyguanosine analogue that has demonstrated potent activity against HBV when used in doses of 0.5 mg daily for treatment-naive patients and 1.0 mg daily for lamivudine-experienced patients [149–151]. The potency of entecavir is derived from its efficient cellular phosphorylation, high intracellular concentrations, and competitive inhibition of HBV polymerase at three levels: priming, positive-strand synthesis, and negative strand synthesis [152,153].

In nucleoside-naive HBeAg-positive patients at 48 weeks, entecavir (0.5 mg daily) was superior to lamivudine (100 mg daily) for histological improvement (72% of entecavir-treated patients vs 62% of lamivudine-treated patients), reduction to undetectable serum levels of HBV DNA (67% for entecavir vs 36% for lamivudine), reduction in mean HBV DNA level from baseline (−6.9 $\log_{10}$ copies/mL vs −5.4 $\log_{10}$ copies/mL), ALT normalization (68% for entecavir vs 60% for lamivudine), and HBeAg seroconversion (21% for entecavir vs 18% for lamivudine) [150]. A second study compared the safety and efficacy of entecavir (0.5 mg daily) and lamivudine (100 mg daily) in 638 nucleoside-naive patients with HBeAg-negative chronic hepatitis B [154]. Clinical trial endpoints found that at 48 weeks entecavir was superior to lamivudine for histological improvement (70% of entecavir-treated patients vs 61% of lamivudine-treated patients), reduction to undetectable serum levels of HBV DNA (90% for entecavir vs 72% for lamivudine), reduction in mean HBV DNA level from baseline (−5.0 $\log_{10}$ copies/mL vs −4.5 $\log_{10}$ copies/mL), and ALT normalization (78% for entecavir vs 71% for lamivudine). Improvement in fibrosis, as measured by the Ishak fibrosis score, was similar among both treatment groups (36% for entecavir vs 38% for lamivudine). The 2- and 3-year data for both of these populations continue to show improvement in liver enzymes, increases in the number of patients with serum HBV at undetectable levels, and, in the HBeAg-positive patients, higher rates of HBeAg seroconversion [155,156].

The safety and efficacy of entecavir and lamivudine were also evaluated in lamivudine-refractory patients with HBeAg-positive chronic hepatitis B [157]. Entecavir (1.0 mg daily) was superior to lamivudine in terms of histological improvement (55% of entecavir-treated patients vs 28% of lamivudine-treated patients); achievement of the composite endpoint of HBV DNA less than 0.7 Meq/mL by branched chain DNA (bDNA) and ALT less than 1.25 × ULN (55% for entecavir vs 4% for lamivudine); HBV DNA less than 60 IU/mL through week 48 (21% for entecavir vs 1% for lamivudine); mean reduction in HBV DNA at week 48 (−5.1 $\log_{10}$ copies/mL for entecavir vs −0.5 $\log_{10}$ copies/mL for lamivudine;); and serum ALT less than or equal to 1 × ULN at week 48 (61% for entecavir vs 15% for lamivudine). HBeAg seroconversion at week 48 was similar for both groups (8% for entecavir and 3% for lamivudine).

The safety profiles of entecavir and lamivudine were comparable with respect to the incidence of serious adverse events and of total adverse events. Fewer patients in the entecavir group than in the lamivudine group discontinued because of adverse events. In addition, fewer ALT elevation "flares" occurred among entecavir patients than among lamivudine-treated patients, during both on-treatment and off-treatment periods. In lamivudine-naive patients, resistance to entecavir is approximately 1% after 3 years of treatment. However, in lamivudine-experienced patients, it is over 30% after 3 years.

Telbivudine

Telbivudine (Tyzeka, Sebivo, L-deoxythymidine, LdT; Idenix Pharmaceuticals, Cambridge, MA) is FDA-approved in the United States for treatment of CH-B in adults. Telbivudine (600 mg) has demonstrated superiority to lamivudine (100 mg) at both 1 year [158] and 2 years [159] in terms of HBeAg seroconversions and HBV DNA undetectability for HBeAg-positive disease, and HBV DNA undetectability for HBeAg-negative disease. Resistance to telbivudine is

common after 1–2 years of monotherapy [159]. It is an L-nucleoside that is completely cross-resistant with lamivudine.

Investigational compounds

Compounds approved for other indications or in phase III trials for the treatment of hepatitis B include the following.

Nucleoside or nucleotide antivirals

- Emtricitabine (FTC, Emtriva; Gilead Pharmaceuticals, Foster City, CA); in phase III trials for hepatitis B; approved in the United States for treatment of HIV.
- Clevudine (L-FMAU; Pharmasset, Princeton, NJ); in phase III trials for hepatitis B.
- Tenofovir (Viread; Gilead Sciences, Foster City, CA); in phase III trials for hepatitis B; approved in the United States for treatment of HIV.
- Tenofovir combined with FTC in a single tablet (Truvada; Gilead Sciences, Foster City, CA); in trials for treatment of CH-B and HIV/HBV coinfection; approved in the United States for treatment of HIV.

Nonnucleoside antivirals

- HepeX-B (XTL-001; XTL Biopharm, Cambridge, MA); human monoclonal antibodies; in phase II/III trials for hepatitis B; has orphan drug approval in the United States for liver cancer.

Noninterferon immune enhancers

- Thymosin-α1 (Zadaxin, SciClone, San Mateo, CA); immune stimulator that has orphan drug approval in United States for liver cancer.

Future developments

Future medications that are in development to treat CH-B include:

- interferons fused to albumin
- nucleoside and nucleotide analogue antivirals, including amdoxovir (DAPD; RFS Pharma, Tucker, GA), ANA 380 (LB80380; Anadys Pharmaceuticals, San Diego, CA), pradefovir (Remofovir; Valeant Pharmaceuticals; Costa Mesa, CA; licensed from Metabasis, San Diego, CA), racivir (RCV; Pharmasset; Princeton, NJ), valtorcitabine (LdC; Idenix Pharmaceuticals, Cambridge, MA), and fluoroguanosine (FLG; Medivir AB, Huddinge, Sweden)
- small interfering RNAs (siRNAs) and expressed interfering RNAs (eiRNAs), including HepX (Nucleonics, Horsham, PA)
- therapeutic vaccines, including Hi-8 HBV (Oxxon, Oxford, United Kingdom), HepaVaxx B (Virexx, Edmonton, Alberta, Canada), and HBV core antigen vaccine (Emergent BioSolutions, Rockville, MD).

Treatment might also involve DNA vaccines that provide ongoing internal immune suppression through production of HBV-derived proteins [59,160]. Liposomes may eventually be used to deliver vaccines, as with those originally developed for hepatitis B by means of intramuscular injections.

Genotypic resistance of hepatitis B virus to nucleoside analogues

As discussed previously, the emergence of HBV mutants that show resistance to nucleoside analogues as a result of genetic mutation has been observed. The discussion that follows concerns important amino acid changes in the HBV POL sequence that have been detected in clinical isolates and shown to confer or modify resistance to lamivudine, adefovir, entecavir, and other nucleoside/nucleotide analogues. A standardized numbering system for the HBV POL was proposed by Stuyver et al. [161], and this consensus is widely accepted.

Lamivudine resistance

Initial clinical trials established that treatment of chronic HBV infection with lamivudine was safe and well tolerated, and caused rapid and substantial decreases in viremia. However, decreases in viremia were not stable and rebounded in the majority of cases during treatment or after treatment was stopped [162–165]. As long-term trials progressed, it became apparent that rebounds could occur during treatment, the majority of which have been attributed to the development of medication resistance. This resistance was observed at a greater frequency and at an earlier time point in the transplant setting [166–168] compared with that seen with immunocompetent patients [169–172]. Lamivudine-resistant populations of HBV were also detected in patients who were coinfected with HBV and HIV and who were receiving lamivudine as part of their HAART [173–175]. Although varying frequencies of resistance and different lengths of time preceding the detection of resistance have been reported, the incidence of resistance in both immunocompetent patients and immunosuppressed patients clearly correlates with treatment duration. During the first year of lamivudine therapy, resistance developed in 14%–32% of cases studied [176–178], a frequency that increased to greater than 50% after 2 years [171] and to 70%–100% by 5 years. Lamivudine is universally accepted as second-line therapy due to this resistance issue with its concomitant risk of flare, decompensation, liver disease progression, and death [44].

The site in the HBV reverse transcriptase or "polymerase" most commonly associated with lamivudine resistance is the YMDD motif in the C domain (rtM204V/I). These substitutions changed the conserved YMDD tetrapeptide in motif C to YIDD or YVDD; this is analogous to the base substitutions causing the amino acid substitution M184V in the HIV reverse transcriptase, which likewise confers lamivudine resistance [179]. Mutations that alter the YMDD motif appear to have multiple effects on the biological properties of the polymerase but, in general, they seem to increase fidelity and reduce the ability to process the viral genomic code. Three-dimensional models of the HBV polymerase predict that substitution of

either isoleucine or valine – both of which are smaller than methionine – would increase the size of the dNTP binding pocket and decrease binding affinity for lamivudine triphosphate [180,181].

Numerous different mutational patterns appear to be responsible for the lamivudine resistance, but the majority of cases of HBV resistance to lamivudine affect the rtM204 codon (Fig. 81.4). One pattern is associated with two amino acid substitutions (rtL180M + rtM204V) whereas a second pattern causes a single substitution (rtM204I) [166,168]. A variety of other mutations, which cluster mainly in the polymerase A (rtL80V/I), B (rtV173L and rtL180M) and C motifs, have also been described in association with rtM204V/I [182,183]. In a small number of cases, lamivudine resistance can be caused by selection of the rtA181T/V (B domain) change, which is cross-resistant with adefovir and partially cross-resistant with tenofovir, the two available nucleotide analogues.

Nucleotide changes, which produce the rtM204V/I polymerase mutations, also alter codons in the overlapping surface antigen ORF and may lead to HBV isolates with reduced anti-HBs binding, which may have public health implications for hepatitis B vaccinse or immune escape. The nucleotide change responsible for the rtM204V change also results in an isoleucine to methionine substitution at residue 195 (SI195M) of HBsAg. Several nucleotide substitutions can cause the rtM204I change in the polymerase. Depending on the specific nucleotide substitution, there are three possible alterations to the surface antigen:

- a tryptophan to serine change at position 196 (SW196S)
- a tryptophan to leucine change at position 196 (SW196L) or
- the introduction of a stop codon, which would truncate the surface antigen.

It is unlikely that these surface antigen changes affect medication resistance, but they may perhaps affect antigenicity and subsequent binding of anti-HBs, either natural antibody or through therapeutic administration of HBIG directed at the "a" determinant. Mutations that generate the rtL80V/I or rtL180M are silent for the surface antigen ORF; however, the rtV173L does result in sE164D in HBsAg, which is within the neutralization domain of the envelope and results in reduced anti-HBs binding.

Other mutations that alter the amino acid sequence of HBV POL have emerged under selection pressure of lamivudine in vivo. Although their functional consequences remain largely unknown, two possibilities exist: changes may enhance medication resistance or replication efficiency (or both). Presumably, increases in fidelity and processivity (respectively) are major contributors to each process.

Adefovir and tenofovir resistance

Resistance to adefovir dipivoxil is initially low in the treatment-naive patient given adefovir monotherapy, but it rises over time. It may not be seen in the first year, but then increases to approximately 3% after 2 years and 11% after 3 years [143]. At week 192, the cumulative probability of adefovir resistance is 15%–18% [184,185]. After 240 weeks, it rises to 29% in HBeAg-negative disease [141] and 42% in HBeAg-positive disease [144]. Adefovir resistance is conferred by substitution of threonine for asparagine at codon 236 (rtN236T), which is located in the D domain of the polymerase, a change that does not significantly affect sensitivity to lamivudine. However, another mutation selected in cases of adefovir failure, rtA181T/V, which is located in the B domain of the enzyme, does affect lamivudine sensitivity. The mechanism of rtN236T-induced resistance has been shown to be indirect perturbation of the triphosphate binding site, whereas indirect steric hindrance accounts for resistance caused by rtA181T/V [186]. More importantly, there are data showing the cumulative incidence of adefovir resistance in patients who are lamivudine resistant to be 6.4% at 12 months, but substantially higher (25.4%) at 24 months [146].

Resistance to tenofovir has been proposed in patients coinfected with HIV and HBV who are receiving both lamivudine and tenofovir as part of HAART [187]. The profile of tenofovir resistance includes rtA194T + rtL180M + rtM204V, and the backbone of lamivudine resistance (rtL180M + rtM204V) is required in order for the rtA194T to be associated with medication resistance.

Entecavir resistance

Resistance to entecavir in treatment-naive patients is uncommon in the first 2 years and around 1% by year 3. However, in lamivudine-experienced patients, entecavir resistance emerges quickly and reaches over 30% by year 3. Entecavir resistance requires three mutations in total: rtL180M + rtM204V plus one other mutation of rtT184, rtS202, or rtM250. The initial evidence from phase II and III studies indicated that the accumulation of additional mutations in preexisting lamivudine-resistant HBV polymerase was required for expression of resistance to entecavir [157,188]. Thus, at least three point mutations in most, and up to four or five point mutations in some, are necessary before a rise in HBV DNA levels will occur during treatment with entecavir. Three-year resistance data on entecavir reveal a cumulative rate of medication resistance of 1.1% in lamivudine-naive patients, but in patients with preexisting 180 and 204 mutations, the rate of resistance is over 30% [156], supporting the contention that single-medication therapy for patients with these resistance mutations is not ideal and should be supplanted by combination therapy. The data from the phase II dose-ranging study in lamivudine-refractory patients [151] and the phase III lamivudine refractory study [157] were the basis for the dosage recommendations of 1.0 mg/day for patients with previous exposure to lamivudine who show evidence of lamivudine resistance. The phase III lamivudine refractory study showed a 5.1 $\log_{10}$ decrease in HBV DNA, with 20% of patients becoming HBV DNA negative by PCR, a

rate comparable with or better than that seen with adefovir monotherapy in separate trials. The pattern of resistance to entecavir includes: rtI169T (B domain), rt184G (B domain), rtS202I (C domain), and rtM250V (E domain) in various combinations of rtL180M + rtM204V [188].

Telbivudine resistance

Telbivudine is the β-L-isomer of thymidine. After 24 weeks of therapy, it results in a 4–6 log drop in HBV DNA levels with a daily oral dose of 600 mg. The cumulative rates of resistance at 2 years have been reported as 21.6% for HBeAg-positive patients and 8.6% for HBeAg-negative patients when patients with a 1 log rise from nadir were sequenced for viral resistance mutations [159]. Week 24 viral load has been shown to predict telbivudine resistance at year 2, with minimal resistance seen when viral load is undetectable at week 24 (2% for HBeAg-negative; 4% for HBeAg-positive) but high-level resistance at year 2 in those with elevated viral loads at 24 weeks [159]. These findings would support an algorithm that proposes to change or add a second agent at 6 months if a patient is not HBV DNA negative at that point. Resistance results from the selection of the rtM204I mutation indicate cross-resistance with lamivudine; this substitution has been found in all telbivudine patients with confirmed virological breakthrough. In some breakthrough patients, secondary mutations have been identified, including rtA181T/V; however, these mutations are of uncertain significance, with no breakthrough seen to date with these mutations alone.

Clevudine resistance

Clevudine (L-FMAU) is a pyrimidine nucleoside analogue that has been found to be effective against HBV, causing a 4–5 log decrease in viremia. As with telbivudine, the main resistance selected is the "lamivudine resistance" profile, including rtL180M + rtM204V.

Antiviral cross-resistance of HBV variants

Clinically, a variety of medication-resistant HBV mutants have emerged under the selective pressures of lamivudine, adefovir, and entecavir. Rational design of effective chemotherapeutic strategies for the future will require determination of the sensitivities of these mutants to both existing and novel nucleoside and nucleotide analogues, as they become available. This will be necessary both to provide effective treatment to patients who are already infected with medication-resistant HBV and to prevent, or at least minimize, the possibility of resistance arising in treatment-naive individuals.

Adefovir dipivoxil can inhibit the replication of most strains of lamivudine-resistant HBV (rtM204V/I but not A181T/V). However, as discussed above, the most successful use of adefovir in lamivudine-resistant patients is when it is added to lamivudine rather than substituted as monotherapy, and used at the first appearance of resistance mutations, well before virological failure occurs.

Combination therapy to counter resistance

There is no FDA-approved combination therapy for treating HBV, much less for treating lamivudine-refractory patients. However, there is an emerging body of data suggesting that combination therapy can decrease antiviral resistance, the single factor that is likely to be of the greatest importance for maintaining effective long-term therapy, and that such combination therapy is likely to be more effective in treatment-naive patients rather than when used to add or replace an antiviral agent after resistance develops [189]. Clinical experts are proposing using adefovir with lamivudine from the outset, or using tenofovir with lamivudine, emtricitabine, or entecavir [44], with ever more substantial data to support such a creative approach.

Management of special populations

Alcohol use in patients chronically infected with HBV increases the risk for progression to cirrhosis, results in more rapidly progressive liver disease, and also increases the risk of liver cancer [29,190]. Patients with chronic liver disease should not drink alcohol. Patients with documented chronic HBV infection should be educated about the risks of alcohol use and advised not to drink any alcohol because the threshold for complications of alcohol use is unknown.

Dialysis patients need to be tested for evidence of HBV infection. Those without evidence of immunity need to be vaccinated with a double dose of vaccine, often repeatedly, until anti-HBs seroconversion occurs. Patients who are chronically infected have historically been isolated from other patients in dialysis centers, but advances in the sterile techniques used, the exchange of equipment in dialysis centers, and other improvements in therapy no longer mandate complete separation of such patients.

Treating chronic HBV infection in dialysis patients should focus on the presence or absence of progressive liver disease as demonstrated by biopsy because liver enzymes have little value in managing such patients. Interferon probably has reduced efficacy in dialysis patients because of their relative state of immunosuppression. Adefovir and entecavir can also be used, but dose adjustments must be made to take into account the dominant renal clearance of these medications and potential renal toxicity of adefovir.

The management of HBV infection after liver transplant is complex [29]. The most important step is to prevent graft infection or reinfection; this can start before liver transplant by screening donors for anti-HBc. Recipients who are HBsAg-positive must be screened for HBV DNA replication. Suppressing HBV replication to low levels using nucleoside or nucleotide analogues before the patient enters the operating room is a key step. Ideally, patients should not undergo liver transplantation if they are HBV DNA positive in their serum. Perioperative and postoperative HBIG therapy is used

to bind circulating virus and prevent graft infection [191], and results in improved survival and a much lower rate of HBV graft infection, thereby preventing aggressive liver disease. Lamivudine maintains viral replication at a low level, and when used in combination with HBIG results in a risk of less than 5%–20% for graft infection in compliant patients [192]. Newer nucleoside and nucleotide analogues may also be used in a similar clinical setting. The use of two oral agents may obviate the need for the costly use of HBIG. The emergence of mutant viruses that are resistant to lamivudine is a major problem in the treatment of HBV disease after liver transplant, with over 30%–40% of patients developing resistance, followed by more aggressive liver disease [193]. Combination therapy with adefovir and lamivudine pretransplantation to achieve HBV DNA PCR negativity, followed by maintenance of such combinations with HBIG posttransplant, significantly reduces the risk of severe viral recurrence. The role of entecavir, tenofovir, and combinations of these agents is evolving. It is hoped that in the near future we may be able to eliminate HBIG therapy.

Other solid organ transplant recipients, including bone marrow, heart, and kidney recipients, are at risk for reactivation of HBV disease after organ transplant [194–198]. An expert in hepatitis B management must evaluate these patients before they undergo transplantation. If active HBV replication is present, avoiding or delaying organ transplantation is advised unless successful suppression of HBV disease can be achieved. Some transplant centers will not perform organ transplants on patients who are HBsAg positive. Another clinical possibility is the transmission of HBV from the organ donor to the recipient. In such cases, the risk of transmission is nearly 100% if the donor is HBsAg positive. Donation is rarely performed in this circumstance. A further risk is the presence of anti-HBc in the donor. This poses a small (< 3%) risk of HBV transmission for organ transplant recipients other than liver, but a significant risk to liver transplant recipients, ranging up to 70% [199,200]. Finally, recipients who are anti-HBc positive can reactivate "latent" HBV disease when immunosuppression is initiated [201]. During any chemotherapy or application of immunosuppression, these patients should be treated prophylactically with an oral agent or monitored with liver tests monthly. After solid organ transplant, any patient who develops acute liver disease needs to be assessed by HBsAg testing. Conversely, bone marrow transplants have resulted in HBsAg clearance by adoptive immunity from the donor's immune cells [202].

In summary, chronic HBV infection continues to pose a serious health-care problem worldwide. Emerging molecular, clinical, and treatment information will markedly enhance our ability to manage patients with CH-B and to prevent liver cancer, death, and liver transplantation. Hopefully, in the near future, with the advent of universal infant vaccination combined with treatment of all patients with CH-B, we can reduce the impact of this deadly disease and remove HBV from the top 10 list of causes of death worldwide.

Epidemiology

Background

Chronic hepatitis C virus (HCV) infection has reached pandemic proportions, with an estimated 170 million individuals infected worldwide, which represents an overall prevalence rate of 2% [1–5]. There is a marked geographic and temporal variation in the incidence and prevalence of HCV infection [2,3]. In the United States, the prevalence of antibody to HCV (anti-HCV) in an updated survey was 1.6%, with 1.3% or 3.2 million persons actively infected based on detection of HCV RNA [1]. Data from population-based studies demonstrate that chronic HCV infection, the leading cause of chronic liver disease, is the reason for approximately 40% of liver transplantations, and causes an estimated 8000–10 000 deaths annually in the United States [2].

Incidence

Chronic hepatitis C is the most common chronic bloodborne infectious disease in the United States, even though the number of new infections per year has declined since 1989 by more than 80% to 36 000 cases in 1996 [5]. The incidence of HCV infection has declined yet further since 1996, with the Centers for Disease Control and Prevention (CDC) estimating that there were 26 000 new cases in 2004 [6]. Based on surveillance data, it appears that the incidence of HCV infection rose during the 1960s and 1970s, remained stable in the 1980s, and has subsequently declined. New infections were particularly common among young Hispanic males between 20 and 39 years of age [1,2,5]. Injection drug use is the most common risk factor associated with the transmission of HCV infection and is responsible for as many as 38% of newly diagnosed cases [5].

Prevalence

The worldwide prevalence rates of chronic HCV infection vary from as low as 0.4% in the Western European countries to as high as 22% in Egypt and other parts of Africa [2,7–12]. Approximately 85% of patients develop chronic liver disease after acute HCV infection. Therefore, the past incidence of acute HCV infection is a key predictor of the current prevalence rate of chronic hepatitis C [4]. The Third National Health and Nutrition Examination Survey (NHANES III), conducted from 1988 to 1994, provided data on the past incidence of acute HCV infection using national seroprevalence and age-specific incidence data from the sentinel counties surveillance program [13]. The overall national prevalence of anti-HCV was 1.8%, which corresponds to an estimated 3.9 million individuals infected with HCV. Approximately 65% of these individuals were 30–49 years of age. Serum HCV RNA was detectable in 74% of cases, which corresponds to an estimated 2.7 million actively infected individuals nationwide. Of these chronically infected individuals, 74% were infected with genotype 1 (57% with genotype 1a, and 17% with genotype 1b). The most recent updated estimate of prevalence from NHANES data collected from 1999 to 2002 is that 1.6%, or 4.1 million, have anti-HCV, of which 79.9% are actively infected with detectable serum HCV RNA [1]. In this updated survey, the peak in age-specific prevalence moved from persons aged 30–39 years to those aged 40–49 years. The prevalence rate was higher in non-Hispanic blacks than the other two ethnic groups analyzed, i.e., non-Hispanic whites or Mexican Americans. Injection drug use was the strongest risk factor, but 20 or more lifetime sexual partners and blood transfusion before 1992 were also risk factors for HCV infection.

Demographic characteristics

Infection with HCV has no boundaries and affects individuals from all walks of life, ranging from children to the elderly. The highest incidence of acute hepatitis C is found among individuals between 20 and 59 years of age, with male patients outnumbering female patients [1,2,5]. African Americans

and whites have a similar incidence of acute HCV infection, whereas individuals with Hispanic background have the highest incidence rate. In the general population, the highest prevalence rates of HCV infection are found among individuals between the ages of 30 and 49 years of age, with males predominantly affected [1,2,4]. In contrast to the rate of acute HCV infection, African Americans have a substantially higher prevalence rate of chronic HCV infection when compared with whites. A study conducted to estimate seroprevalence rates of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and HCV among individuals with severe mental illness in the United States showed a 20% prevalence rate of HCV infection, which is 11 times the overall estimated prevalence rate for the HCV infection in the general population [14]. Higher rates of HCV infection were also noted in patient groups with HIV and HBV infection. Individuals with asymptomatic HCV infection are frequently undiagnosed and fail to receive appropriate treatment to eradicate viremia and retard disease progression; they may, therefore, be a source of infection to others [14].

Infection with HCV may differ in the pediatric age group (as compared with adults) with respect to transmission, natural history, and response to treatment. The prevalence of chronic HCV infection in children ranges from 0.05% to 0.4% [15]. The major mode of acquisition has shifted from parenteral transmission to maternal–infant transmission. However, the actual rate of vertical transmission is low, ranging from 4% to 10% [2].

Transmission patterns

Based on age-specific prevalence data, at least three distinct transmission patterns of HCV infection have been established. First, in developed nations such as the United States and Australia, chronic HCV infection mainly affects individuals between the ages of 30 and 49 years, indicating that the risk for HCV infection was at its peak in the recent past (10–30 years ago) and primarily affected young adults [1,2]. Second, in nations such as Japan and Italy, HCV infection mainly affects older individuals, reflecting that the risk for HCV infection peaked in the distant past. Finally, Egypt is a classic example of an ongoing risk for acquiring HCV, i.e., high rates of infection are observed in all age groups. In countries with the first pattern, injection drug use is the most common risk factor associated with chronic HCV infection, whereas in those with the second or third patterns, unsafe injections and contaminated equipment used in health-care facilities were primarily responsible for HCV transmission [1,2]. The contribution of different risk factors predicts the variability in the transmission patterns of HCV infection between various regions and countries.

Modes of transmission

In the United States, the relative importance of the two most common exposures associated with transmission of HCV, blood transfusion and injection drug use, have undergone a substantial change [2,16]. Blood transfusion, which accounted for a significant proportion of HCV infection acquired more than 10 years ago, has been almost completely eliminated as a risk factor for HCV infection because of improved screening of blood and organ or tissue donors. Since 1990, the risk for transfusion-transmitted HCV infection has been almost nonexistent, as demonstrated by the inability of the CDC sentinel counties' viral hepatitis surveillance system to report any transfusion-associated cases of acute hepatitis C [6]. Therefore, the risk of transfusion-related transmission of HCV is negligible. In contrast, injection drug use has consistently been associated with a significant proportion of chronic HCV infections and accounts for 50%–60% of HCV transmission in the United States [1,2,5]. Other known exposures (occupational, hemodialysis, household, perinatal) together account for about 10% of HCV transmission. In up to 10% of individuals with chronic HCV infection, no recognized source of infection can be identified, and most individuals in this category come from a low socioeconomic status. Case–control studies have found no association of increased HCV transmission with military service [16].

The variation in HCV prevalence rates in a certain population is determined by the mode of transmission [2,16]. The highest prevalence rate of HCV infection is associated with high-dose or recurring direct percutaneous blood exposure, which occurred in injection drug users, hemophiliacs who received clotting factor concentrates produced before 1987, and transfusion recipients of HCV-positive blood or blood products before 1992 [2,12,16,17]. Moderate prevalence rates of HCV infection are associated with smaller direct percutaneous exposures, such as experienced by individuals on long-term hemodialysis. Lower prevalence rates are associated with percutaneous or mucosal exposures through high-risk sexual behavior or with low-dose percutaneous exposures experienced by health-care workers. The lowest prevalence rate of HCV infection is found among individuals who lack high-risk characteristics, as exemplified by the screened volunteer blood donor population.

Injection drug use

In the early 1990s, the decrease in the incidence of HCV infection was associated with a sharp fall in HCV infection among injection drug users [4,5]. Up to 65% of injection drug users have detectable anti-HCV within 1 year of starting this high-risk behavior [2,17]. Despite the high proportion of new infections caused by injection drug use, for reasons that are unclear, the dramatic decline in incidence of acute hepatitis C since 1989 correlates with a decrease in cases among injection drug users [2,4,5]. Several differences in risk factors associated with HCV prevalence rates were observed in two populations of young injection drug users from New York City, suggesting that indirect transmission of HCV may occur [17]. Among subjects aged 17–59 years, the strongest factors

independently associated with HCV infection were injection drug use and high-risk sexual behavior. Independent drug-related risk factors included frequent injections, heavy crack smoking, injecting in a shooting gallery, and syringe-mediated sharing. Sharing of drug preparation equipment has been implicated as a possible route of HCV transmission [2,5]. Intranasal cocaine use can also lead to transmission of HCV infection [18]. Other factors independently associated with HCV infection included poverty, having had 12 or fewer years of education, having been divorced or separated, and residence in an urban area as compared with the suburbs [19,20].

Blood transfusion

The current risk of acute infection with any pathogen associated with transfusion has decreased to less than 5% [4]. The exact risk of transfusion-related HCV infection is 0.6% per patient and 0.03% per unit of blood transfused [21–24]. Among donors whose blood units passed all the screening tests, the risks of donating blood during an infectious window period were estimated as follows: for HIV, 1 in 493 000; for HTLV, 1 in 641 000; for HCV, 1 in 103 000; and for HBV, 1 in 63 000 [23]. The incidence of posttransfusion HCV infection has decreased appreciably since the implementation of donor screening using surrogate markers initially and then specific tests for anti-HCV [2,4,5,21,25–27]. In 1984, the sharp decline in the incidence of transfusion-associated hepatitis was noted when donors were screened with alanine aminotransferase (ALT) and anti-HBc. In 1990, anti-HCV testing was added to the screening protocol and resulted in a further decrease in the incidence of transfusion-related hepatitis. Before 1984, transfusion was the most common route of HCV infection; in particular, patients receiving multiple transfusions had the highest risk [2,5]. In hemophiliacs, unheated and dry heat-treated clotting factor concentrates carried a high risk of transmitting HCV infection [28]. In comparison, clotting factor concentrates inactivated by vapor heating had a significantly lower (close to zero) risk of transmitting HCV infection [28,29].

Chronic hemodialysis

The transmission of HCV infection is common among hemodialysis patients. Transmission of infection in this setting has been related to the number of blood transfusions, the duration of hemodialysis, male gender, African American race, diabetes, HBV infection, previous renal transplant, alcohol or substance abuse, and nosocomial transmission of HCV in the dialysis unit [30–34]. Studies have failed to determine the most likely mode of transmission in dialysis units; therefore, emphasis is placed on strict adherence to blood collecting and handling using universal safety precautions, careful attention to hygiene in the dialysis units, and sterilization of dialysis machines to minimize the risk of HCV transmission [30,31,34,35]. Nosocomial transmission of HCV not related to blood transfusions has been reported between patients dialyzed on the same shift and not sharing the same dialysis machine [36]. In dialysis units in Italy and France, the incidence and prevalence rates of HCV infection are 1%–2% and 20%–60%, respectively [37], and the mean prevalence of HCV infection in the analysis of dialysis units from three continents was 13.5%, ranging from 2.6% to 22.9% [30].

Occupational

The reported prevalence rate of HCV infection in health-care workers such as orthopedic and oral surgeons is 1%–2%, which is comparable to the prevalence rate in the general population [38–43]. However, some surveys have demonstrated seroprevalence rates ranging between 0.6% and 4.5% in health-care workers, exceeding the seroprevalence rate of HCV infection in blood donors at the same facility by up to 4.5 times [43–45]. This observation has been supported by other studies that have demonstrated significantly higher prevalence rates of HCV in dentists and oral surgeons as compared with controls [46]. There are no reports documenting transmission of HCV through mucus membranes. However, accidental needlestick exposure and blood splashes to the conjunctiva have been associated with transmission of HCV infection [42,47,48]. The incidence of HCV transmission by accidental needlestick exposure varies from 0% to 10% and has been associated with the viral load in the inoculum, depth of inoculation, and size of needle [5,49–51]. The risk may be higher with needles that have hollow channels compared with non-hollow sharps [50].

Nosocomial transmission of HCV infection has been suspected, and health-care workers have been reported to transmit HCV infection to their patients [36,52]. HCV was detected in the biopsy suction channel after an endoscopic procedure in 27% of patients with chronic HCV infection, and HCV RNA was detected on the biopsy forceps in 6% of cases [53,54]. A thorough disinfection procedure appears to be effective in eliminating the risk of HCV transmission. Percutaneous transmission of HCV as the result of lack of sterile practices and reuse of contaminated supplies in traditional medicine, folk medicine, tattooing, body piercing, commercial barbering, circumcision, and scarification has been documented [55–57]. On the other hand, there are case–control studies that show no evidence of increased HCV transmission associated with exposures resulting from medical, surgical or dental procedures, tattooing, acupuncture, ear piercing, or foreign travel [16].

Sexual transmission

It is estimated that up to 20% of patients with chronic hepatitis C and no identifiable risk factor may have acquired HCV sexually [2,58,59]. HCV RNA has been detected in the semen of as many as one-third of HCV viremic men [58]. Although seminal viral loads are low, semen could be infectious and play a role in the spread of HCV infection. The risk of acquiring

HCV rises in men who have sex with men and in bisexual men [60,61], in heterosexuals with multiple sexual partners [60], with the number of sexual contacts [62], with the presence of other sexually transmitted diseases such as syphilis and HIV [63], in partners of injection drug users [10], in prostitutes and their contacts [64], with failure to use condoms [60,61], with sexual activities involving trauma [60,61,64], and with divorce and separation [3]. Patients with HCV and HIV coinfection have a fivefold greater risk of transmitting HCV to their partners [65]. Male-to-female transmission of HCV is higher than that of female-to-male [66,67]. The risk of sexual transmission of HCV is significantly lower than HBV, HIV, and other sexually transmitted diseases [61].

Vertical transmission

The rate of mother-to-child transmission of HCV is low, ranging from 4% to 10% [2,68–71]. However, based on the prevalence of HCV infection in pregnant woman in the Western world (0.09%–0.25%), a reasonable number of pediatric HCV infections may occur [71]. One prospective trial showed that the transmission rate of mother-to-infant HCV infection is 7.8% in anti-HCV-positive mothers [72]. It has been demonstrated that high maternal viral load and HCV and HIV coinfection are significant risk factors for vertical transmission of HCV, although a threshold HCV RNA has not been identified [2]. Review of the data suggests that the mode of delivery (vaginal versus cesarean) does not affect the risk of transmission of HCV. Most infected infants do not test positive for HCV RNA during the first month after birth, suggesting that infection occurs at the time of delivery rather than in utero. The placenta acts as a barrier and prevents free, direct communication between maternal and fetal blood [73–75]. This barrier is broken at birth, resulting in free communication between the maternal and fetal blood [76]. Elective cesarean delivery is associated with the lowest amount of microtransfusion from mother to fetus [76], suggesting that patients with high HCV load and other risk factors for vertical transmission might benefit from elective cesarean section [66,77].

Molecular virology and pathogenesis

Molecular organization and characteristics

HCV RNA was isolated in 1989 using a random-primed complementary DNA library established from the plasma of patients with suspected non-A, non-B hepatitis infection [78–80]. Using electron microscopy, HCV has been visualized in chimpanzee hepatocytes and human T and B cells [81]. HCV genome is a 9.6-kilobase (kb), single-stranded RNA molecule. The genomic size and molecular organization suggest close association with flaviviruses and pestiviruses [78]. Data from filtration studies indicate that the HCV ranges in size from 30 to 60 nm in diameter [82]. The virus is coated with a bilayer lipid envelope [83]. The crucial structural constituent of the HCV genome is the core protein, which is found at the N-terminal of the polyprotein. The core protein is strictly conserved in HCV genotypes. The coating glycoproteins that form the HCV envelope are referred to as E1 and E2 [84]. The E2 glycoprotein has two hypervariable regions (HVR), HVR1 and HVR2. These hypervariable segments provide HCV with the basic mechanisms for evading the host immune defenses and establishing chronic infectivity [85–88]. Anti-HVR1 antibodies provide protection against HCV infection, supporting the fact that this region harbors a crucial signal for a neutralization factor. HVR1 activates helper T-cell responses during HCV infection. It was noted that the frequency of anti-HVR1 T-cell responses was more pronounced in patients who recovered after interferon (IFN) therapy as compared with individuals who did not respond [89,90]. The HCV must bind to a receptor on the cell membrane to facilitate entry into the cell. It has been shown that E2 envelope proteins have the ability to bind cell membranes [91]. The entry into the cell and exposure to the intracellular acidic environment causes irreversible structural changes in envelope proteins coating the HCV genome [92]. This is followed by release of genomic RNA triggering protein translation. Furthermore, multiple independent adaptive mutations cluster in the HCV nonstructural protein NS5A and confer increased replicative ability in vitro [93].

Genotypes and quasispecies

The open reading frame of HCV RNA demonstrates polymorphism and encodes a polyprotein precursor consisting of approximately 3000 amino acids, varying among different genotypes. HCV is classified into four hierarchical levels, which include genotypes, subtypes/subgenotypes, isolates, and quasispecies [94–98]. HCV appears to exist simultaneously within an individual as a series of related, but immunologically distinct, variants called quasispecies. The existence of these quasispecies may provide a mechanism for the virus to escape the host immune response. The HCV genotype, however, is stable and does not change over the course of infection in an individual. The evolutionary dynamics of the HCV quasispecies during the acute phase of a hepatitis C infection predict whether the infection will resolve or persist [99]. Individuals infected with HCV can develop superinfection with other HCV genotypes leading to eradication or suppression of the primary genotype. Simultaneous infection with multiple HCV genotypes may result in concomitant infection or eventual dominance by one genotype [100]. The genotype distribution showed no relation to the severity of the liver disease, or to the duration of the disease [101].

Pathophysiology and immunopathogenesis

The mechanistic pathways involved in the pathogenesis of chronic HCV infection include direct HCV-induced cyto-

pathic insult to hepatocytes or injury resulting from specific or nonspecific immune responses [102,103]. It has been demonstrated that cytotoxic T cells and cytokines produced by both CD4+ (T helper) and cytotoxic T cells may trigger the inflammatory response in the hepatocyte. The T helper type 2 immunity, as well as the weak HCV-specific T-cell response, is associated with viral persistence [102–104]. The production of interleukin-12 and nitric oxide is critical for the induction of T helper type 1 and innate immunity [104]. Patients infected with HCV mount a humoral immune response to epitopes of HVR1. However, HCV infection may be difficult to eradicate because of the rapidly evolving nature of HVR1, which results in the generation of variants that are not recognized by preexisting antibodies [105]. Treatment-induced control of viremia is associated with the development of HCV-specific T-cell responses with enhanced IFN-γ and low interleukin-10 production [106]. The greater efficacy of combination therapy using IFN-α plus ribavirin may be related to its ability to suppress HCV-specific interleukin-10 production [106]. The resolution of HCV infection is not followed by protective immunity against reinfection with homologous or heterologous strains [107].

Histopathology

Chronic hepatitis C does not have characteristic pathognomic features and demonstrates wide variation of pathological findings [108]. The mechanism underlying hepatocyte and bile duct injury in HCV infection results from the host immune response to the virus and direct viral cytopathogenicity. Acute hepatitis C is histologically indistinguishable from acute viral hepatitis with other causes [108,109]. HCV infection can present histologically as a triad of lymphoid aggregates in portal tracts, epithelial damage of small bile ducts, and microvesicular and macrovesicular steatosis [108]. Antibodies directed against HCV antigens allow the identification of viral proteins by immunohistochemistry using monoclonal or polyclonal antibodies, particularly when frozen tissues are employed [109]. Detection of HCV RNA sequences in fixed liver tissues by in situ hybridization appears to be a more sensitive method than immunohistochemical staining [108,109]. Immunostaining should be performed to rule out other chronic liver diseases.

A number of numerical scoring systems have been used to grade the amount of inflammation and stage and degree of fibrosis in liver biopsy specimens from patients with chronic hepatitis C. The histology activity index (HAI) of Knodell was the original scoring system and has been used in many clinical investigations [110]. With the HAI system, biopsies are graded into four categories: periportal necrosis, intralobular necrosis, portal inflammation, and fibrosis, with inflammatory activity on a scale from 0 to 18 and fibrosis on a scale from 0 to 4 [110]. The HAI was more recently modified by Ishak and colleagues [111] and by the METAVIR system [112], and all of these systems are in current use. The numerical designations used for staging the degree of fibrosis are shown in Table 82.1 [110–113]. These scoring systems provide definitive endpoints for statistical analysis of serial changes in liver histology and have replaced the older descriptive terms, chronic active hepatitis, chronic persistent hepatitis, and chronic lobular hepatitis.

Table 82.1 Scoring of hepatic fibrosis

Fibrosis	HAI [110][a]	METAVIR [112][a]	Ishak [111][a]
None	0	0	0
Portal (some)	1	1	1
Portal (most)	1	1	2
Bridging (few)	3	2	3
Bridging (many)	3	3	4
Cirrhosis (incomplete)	4	4	5
Cirrhosis (established)	4	4	6

Screening and diagnosis

Screening for HCV infection

Primary-care physicians should routinely screen new patients for a history of risk factors associated with HCV infection. During the history and physical examination, findings suggestive of chronic liver disease include encephalopathy, ascites, edema, spider angiomas, palmar erythema, a firm liver edge, and splenomegaly. However, the majority of patients with chronic HCV infection is asymptomatic or has nonspecific constitutional symptoms, such as fatigue and decreased energy levels. Elevated serum ALT levels can predict the prevalence of HCV infection in some populations [114–116]. In summary, a test for anti-HCV should be performed if an elevated ALT level is found, if there is a positive history of risk factors for HCV infection, or if physical findings suggest the presence of chronic liver disease. A sensitive polymerase chain reaction (PCR) test for HCV RNA is warranted in patients who test positive for anti-HCV, particularly those with normal ALT levels or no HCV risk factors, to confirm HCV infection and rule out a false-positive test or recovery from past HCV infection. The latter patients have a detectable anti-HCV but negative serum HCV RNA, and their ALT levels are normal.

Chronic HCV infection may be a multisystem disease, and patients should be screened for cryoglobulinemia by checking serum cryoglobulins and serum creatinine, and performing a urinalysis. More than 50% of patients with chronic HCV infection have cryoglobulinemia, but only 1%–5% experience related symptoms. Additional baseline laboratory tests that are commonly obtained following the initial diagnosis of

chronic hepatitis C include a standard liver panel, complete blood cell count, prothrombin time, tests for coinfection with HBV or HIV, test for immunoglobulin G antibody to hepatitis A virus (anti-HAV) to determine if immunity is present or if vaccination is recommended, antinuclear antibody to exclude coexistent autoimmune hepatitis, α-fetoprotein level, and abdominal ultrasound. If treatment is being considered, a quantitative rather than qualitative serum HCV RNA test and HCV genotype are also obtained. In acute hepatic injury, prothrombin time and, to a lesser extent, total bilirubin are the best indicators of disease severity. Although ALT is useful for detecting acute and chronic hepatic injury, it is not related to the severity of acute hepatic injury and is only weakly related to the severity of chronic hepatic injury [117].

Diagnosis of HCV infection

The discovery of HCV in 1989 led to the development of diagnostic serological and virological tests [118–125]. The diagnostic tests used to detect HCV infection can be divided into two main classes:

- serological tests/assays that detect anti-HCV
- molecular tests/assays that detect, quantify, and characterize HCV RNA [119–121].

Serological assays have been subdivided into screening tests for anti-HCV, such as the enzyme immunoassay (EIA), and supplemental tests, such as the recombinant immunoblot assay (RIBA). Three generations of anti-HCV tests have been developed, and each generation has provided higher sensitivity for detecting anti-HCV. Third-generation anti-HCV tests (EIA-3 and RIBA-3) contain antigens from the HCV core, nonstructural 3, nonstructural 4, and nonstructural 5 genes. The EIA-1 contained a single HCV recombinant antigen derived from a nonstructural gene. The specificity of EIA-1 was 30%–50% in low-risk populations, such as blood donors, and the development of detectable antibodies after acute infection required several months [119]. The use of additional antigens in the EIA-2 and EIA-3 tests has increased the sensitivity and shortened the time to detection after acute infection to a median of 7–8 weeks, but false-positive measurements of anti-HCV by EIA still occur in low-risk populations. EIA-3 did not detect more HCV-infected individuals in a donor population that previously tested negative in EIA-2, but it did detect HCV antibodies earlier in some patients with acute HCV infection. EIA-2 and EIA-3 are significantly more sensitive than RIBA-2 and RIBA-3 [122]. Supplemental anti-HCV tests are designed to resolve false-positive testing by EIA, and are appropriately used in low-prevalence settings in which false-positive anti-HCV tests remain a problem [121,122]. In practice, confirmation of HCV infection is performed by the detection of HCV RNA by PCR or the branched chain DNA (bDNA) assay [118–121]. Transcription-mediated amplification is superior to PCR in identifying patients with sustained HCV RNA clearance [124,125]. The EIA-3 has an estimated sensitivity of 98.9% and specificity of 100% in patients with chronic HCV infection, whereas the sensitivity of RIBA-3 is 78.8% in the hemodialysis population [122,123]. These data provide evidence for the good sensitivity and specificity of EIA-3, particularly in high-risk patient groups, and confirms their use for screening in these populations.

Detection of serum HCV RNA provides evidence of active HCV infection and is useful as a confirmatory test [118–125]. Optimal HCV RNA assays using PCR at present have a sensitivity of less than 100 copies/mL. There are several methods for assessing HCV RNA levels, i.e., various PCR assays, the bDNA assay, and transcription-mediated amplification [118–121,124,125]. Quantitative PCR is the most sensitive test for quantifying hepatitis C viral load, whereas the bDNA test appears to be the most specific method. However, it must be recognized that these molecular tests have their own limitations, which include inadequate dynamic range, the high variability of PCR assays, and the poor sensitivity of the bDNA test [118–125]. Commonly used serum HCV RNA qualitative and quantitative second-generation PCR assays are Amplicor HCV v2.0 and Amplicor HCV Monitor v2.0, respectively. Second-generation assays are one log more sensitive and are genotype independent, compared with their respective first-generation tests (10^2 copies/mL versus 10^3 copies/mL for qualitative tests; 10^3 copies/mL versus 10^4 copies/mL for quantitative tests) [118–121].

An anti-HCV-positive result in a low-risk setting, such as blood donation, should be confirmed with an analytical antibody test. Subsequently, a serum HCV RNA test should be performed on donors with a positive or indeterminate confirmatory test result. On the other hand, an anti-HCV-positive test result in high-risk populations is likely to be a true positive. A quantitative HCV RNA test and genotyping should be performed if therapy is being considered [118,119].

According to data from the CDC, 200 000–700 000 new cases of acute viral hepatitis occurred in the United States each year during the 1980s and 1990s, but this rate has been declining in recent years for all three viruses [1–6]. In 2004, there were an estimated 56 000 new cases of hepatitis A virus (HAV) infection, 60 000 new HBV infections, and 26 000 new HCV infections [6]. From these annual cases, there are about 100 deaths per year from fulminant hepatitis A and 150 deaths from fulminant hepatitis B; hepatitis C has rarely been implicated as a cause of acute liver failure. Although the death rate from acute viral hepatitis is low, many adult patients with HBV infection (5%) and HCV infection (85%) become chronically infected, and a significant percentage of these patients ultimately develop cirrhosis or hepatocellular carcinoma (HCC) over two or more decades. Since 75% of acute viral hepatitis results from infection with either HAV or HBV, initial laboratory investigation should include serological tests to exclude HAV or HBV infection. If these studies are negative, then further testing should be performed to rule out acute HCV infection. Serum HCV RNA is detectable 1–2 weeks

after the onset of infection, whereas antibodies to HCV are not detected until 8–10 weeks after infection with HCV. In clinically stable patients, it may be plausible to wait and check antibodies to HCV.

Natural history

Acute HCV infection

Acute infection with HCV is usually asymptomatic and therefore is not diagnosed and is underestimated. Acute HCV infection is the third most common cause of acute hepatitis associated with jaundice. The most common cause of acute hepatitis in the United States is acute hepatitis A, which accounts for 49% of all cases [27,126]. This is followed by acute hepatitis B (35% of cases) and acute HCV infection (16% of cases) [27]. As many as 43% of cases of acute hepatitis C are associated with intravenous drug use, 17% with sexual exposure to an infected individual or with high-risk sexual behavior, and less than 10% with other risk factors also known to transmit HCV infection [27,127]. No known risk factors can be identified in 31% of patients with acute HCV infection [27].

The incubation period from infection to onset of symptoms can range from 2 to 12 weeks, with an average of 6–7 weeks [128,129]. Serum HCV RNA is detectable within 7–21 days after an acute infection [129]. Serum HCV RNA, in titers of 10^5–10^7 copies/mL, can be detected at the onset of jaundice. Aminotransferase levels are elevated between 14 and 28 days after infection, and anti-HCV becomes detectable approximately 60 days (varies from 20 to 150 days) after the onset of infection [129].

Preicteric period

A wide constellation of clinical features including low-grade fever, decreased energy level, fatigue, nausea, vomiting, right-sided abdominal pain, myalgias, and arthralgia may develop in 15%–20% of patients. This clinical syndrome occurs within 2–12 weeks of acute HCV infection and also lasts for 2–12 weeks. Systemic symptoms may be followed by jaundice. In rare circumstances, patients can develop rash, hives, and arthralgias that are most likely secondary to a serum sickness syndrome precipitated by immune complexes [128,129]. The majority of patients with acute hepatitis C, however, remain asymptomatic.

Icteric period

The nonspecific symptoms that develop in the preicteric phase usually persist during the period of jaundice. Infrequently, jaundice can be a presenting symptom of acute HCV infection and typically lasts for 1–2 weeks. Serum HCV RNA usually becomes detectable with the onset of jaundice. Fulminant liver failure following HCV infection has been reported but is a rare occurrence [27,129].

Resolution versus chronicity

Following the acute onset, HCV infection is self-limiting and resolves after 3–6 months in 15%–30% of cases, with the return of ALT levels to normal and the disappearance of serum HCV RNA, although anti-HCV remains detectable. During convalescence patients report resolution of jaundice, improved appetite, weight gain, and a feeling of well-being. However, nonspecific clinical features may persist for a few months in a small minority of patients who recover from acute HCV infection. A higher rate of HCV eradication is noted in patients with clinically symptomatic acute HCV infection compared with those who are asymptomatic. Therefore, the outcome of HCV infection is dependent on the virus–host immunological interactions in the first few weeks of infection. Patients who recover from acute HCV infection usually do so within the first 12 weeks of infection. Nearly 10% of patients who develop an anti-HCV response will eventually lose the nonneutralizing antibody and evidence of past acute infection [130]. Some patients may not develop an anti-HCV response with short-duration, acute hepatitis C; it is difficult to estimate the proportion of patients with this response. Spontaneous clearance and resolution of HCV infection are rare after 6 months of persistent infection [131]. Up to 75%–85% of adults and 55% of children will develop chronic HCV infection [128,129,132–135].

Chronic HCV infection

Chronic HCV infection develops in as many as 85% of patients after acute infection [136]. The majority of patients with chronic infection have asymptomatic elevation of aminotransferase levels and lack physical findings suggestive of liver disease [137,138]. Fatigue is the most common symptom reported by patients with chronic HCV infection [137]. The correlation of symptoms with histological severity of liver disease is poor in patients with chronic hepatitis C; patients may have fatigue associated with either mild or severe disease. Vague and intermittent right upper quadrant pain is the second most frequent symptom noted in patients with chronic HCV infection. Other less common nonspecific symptoms include low-grade fevers, nausea, vomiting, myalgias, and arthralgia. Up to 15%–20% of patients with chronic HCV infection have psychological or psychosocial problems, which complicate the initial assessment and later decisions regarding treatment. One-third of patients with chronic HCV infection have normal ALT levels, and 25% have ALT levels that are elevated to less than twice the upper limits of normal [136,139]. ALT elevations are persistent in 26% of cases and intermittent in 40%–70% of cases, with resolution to normal range in 17% of patients on long-term follow-up [136,139,140]. Self-limited, intermittent ALT flares have been noted and may be associated with an increase in serum HCV RNA, but not with viral eradication [141]. A 10-fold rise in ALT levels has been associated with severe piecemeal

necrosis [136,137,142]. The titer of serum HCV RNA is not associated with histological severity.

HCV-related cirrhosis

Several studies have confirmed that chronic HCV infection demonstrates minimal clinical progression in the initial two decades after infection [2,138]. However, chronic hepatitis C leads to cirrhosis in at least 20%–25% of immunocompetent patients within 20 years of the onset of infection [138,143]. The median duration of chronic HCV infection required for the development of cirrhosis can vary from 13 years in men who use alcohol and are older than 40 years of age at the time of infection to as long as 42 years in women who avoid alcohol and are less than 40 years of age at the time of infection [143]. The overall risk of cirrhosis is less than 10% over a 10-year period in patients with mild chronic hepatitis, 44% in those with moderate hepatitis, and 100% in those with severe hepatitis with bridging fibrosis [144].

Risk factors associated with rapid progression to HCV-related cirrhosis

Cirrhosis and end-stage liver disease may develop more rapidly under certain circumstances [135]. Factors influencing the rate of progression of fibrosis include gender (male sex), genetic background (Japanese at higher risk compared with Americans), age at exposure (higher risk of cirrhosis with age greater than 40 years at time of HCV infection), duration of HCV infection (longer), route of transmission (blood transfusion greater risk than injection drug use), and coexisting conditions including alcoholic liver disease (daily alcohol consumption of 50 g or more), chronic tobacco use, HIV coinfection, and HBV coinfection [144–155]. Up to 20% of patients with chronic hepatitis B have detectable anti-HCV [151,152]. Alternatively, 2%–10% of patients with anti-HCV demonstrate markers of HBV infection. Coinfection with HBV and HCV results in more severe liver disease compared to patients with isolated HBV or HCV infection.

Clinical presentation of HCV-related cirrhosis

The mean age of patients presenting with HCV-related cirrhosis is 55 years compared with mean ages of 42 years in patients presenting with chronic HCV infection without cirrhosis and 66 years in patients with HCC [146]. Other studies have also confirmed a mean difference of at least 10 years between the diagnosis of cirrhosis and the detection of HCC in patients with chronic HCV infection [153–156]. HCV-related cirrhosis affects men more commonly than women, with a ratio ranging from 1.3 : 1 to 3.2 : 1 [139,157].

The diagnosis of HCV-related compensated cirrhosis is often made incidentally during screening of blood donors or at the time of routine laboratory testing [139]. A wide spectrum of nonspecific symptoms can be noted in patients with compensated and decompensated cirrhosis, including fatigue in 75%, abdominal pain in 24%, and anorexia in 13% [136]. Systemic symptoms are more severe in patients with decompensated cirrhosis, and the annual risk of decompensation is 3.9% [139]. The clinical presentation can be dramatic after hepatic decompensation and manifests with ascites in 48%, variceal bleeding in 22%, hepatic encephalopathy in 8%, jaundice in 6%, or a combination of complications in 17% of patients [139]. Other clinical features noted with hepatic decompensation include lower extremity edema, easy bruising, pruritus, muscle wasting, muscle cramps, and sexual dysfunction. Patients with HCV-related compensated cirrhosis have a mean survival rate of 80% at 10 years, compared with a mean survival of 50% at 5 years once decompensation occurs [139].

Physical findings suggestive of cirrhosis include a palpable firm liver edge in 79%, hepatomegaly in 50%–78%, splenomegaly in 25%–37%, and cutaneous stigmata of advanced liver disease in 31% [139]. The majority of patients with HCV-related cirrhosis have mild to moderate elevation of aminotransferase levels, with less than 5% of patients having ALT levels 10-fold higher than the upper limit of normal [139]. The association between ALT levels and histological severity of chronic HCV is poor [142,158]. Coagulopathy, hypoalbuminemia, hyperbilirubinemia, and thrombocytopenia are associated with a decrease in survival rate at 10 years [139]. The annual risk of HCC in patients with chronic hepatitis C with cirrhosis is 1.4%–3.3% in the United States and Europe, and as high as 6.9% in Japan and Italy [159]. The mean length of time from HCV infection to the development of HCC is 29 years [136,139].

Clinical manifestations and complications

Chronic HCV infection can be associated with extrahepatic organ involvement or lead to complications primarily involving the hepatic parenchyma. Most of these manifestations are directly associated with HCV infection; however, HCC nearly always develops in the setting of HCV-related cirrhosis. For other complications associated with HCV-related cirrhosis, see section on HCV-related cirrhosis.

Extrahepatic clinical manifestations

The prevalence of extrahepatic clinical manifestations is relatively low but can be associated with significant morbidity and even mortality. The precise pathogenesis of these extrahepatic manifestations has not been determined, although the majority represents the clinical consequences of an immune-mediated response [160–163].

Autoantibodies

There is a high prevalence of a variety of autoantibodies, usually in low titers, associated with chronic HCV infection. Antinuclear antibody, antismooth muscle antibody, and antithyroid antibody are detectable in 40%–65% of patients with

chronic HCV infection [164,165]. The clinical significance of most of these autoantibodies is negligible, except for liver–kidney–microsomal type 1 antibodies (anti-LKM1) [165,166]. Patients with anti-LKM1 can be differentiated into two groups, anti-HCV-positive and anti-HCV-negative [167,168]. Type 2 autoimmune hepatitis with high anti-LKM1 titers and negative anti-HCV primarily affects young women with moderate to marked elevation of ALT. These patients are responsive to immunosuppressive therapy and are human leukocyte antigen-DR3-positive. In contrast, patients with chronic HCV infection and a positive anti-HCV associated with a positive anti-LKM1 have distinctive features, such as an equal distribution between men and women, mildly elevated ALT levels, low anti-LKM1 titers, and responsiveness to IFN therapy [169]. Finally, patients with classic type 1 autoimmune hepatitis can have a false-positive anti-HCV, which can be confirmed with the finding of a negative serum HCV RNA [170,171].

Renal disorders

A wide array of renal disorders can occur in association with chronic HCV infection, and renal complications may be the presenting feature of chronic hepatitis C [172–175]. Patients may present with vasculitis secondary to cryoglobulinemia, proteinuria, microscopic hematuria, acute renal failure, or nephrotic syndrome [172]. The pathogenesis of HCV-related renal disorders generally remains undefined; however, deposition of circulating immune complexes in the subendothelial space and mesangium in the glomeruli plays a central mechanistic role. Uremic patients with chronic HCV infection who are undergoing regular dialysis frequently develop immunological abnormalities. The most common HCV-related renal disorder is type I membranoproliferative cryoglobulinemic glomerulonephritis with a chronic course interspersed by acute recurrent episodes. The membranoproliferative cryoglobulinemic glomerulonephritis is usually associated with type II cryoglobulinemia with immunoglobulin M rheumatoid factor, polyclonal immunoglobulin G anti-HCV antibodies, and HCV RNA immunoglobulin M as the principal constituents in cryoprecipitate. The treatment of renal disorders associated with chronic HCV infection is discussed in the section on treatment [176–181].

Endocrine disorders

Infection with HCV may contribute to the development of diabetes mellitus. Both disorders are common; therefore, cross-sectional studies were performed to confirm their close association [182–184]. Patients with chronic HCV infection have an increased prevalence of diabetes mellitus type II. HCV-related cirrhosis can induce insulin resistance and predispose patients to diabetes mellitus. However, the increased prevalence of diabetes is independent of cirrhosis [183]. Further investigation is needed because the pathogenesis may be multifactorial and unique to HCV. In the United States, diabetes mellitus type II occurs more often in individuals with chronic HCV infection who are older than 40 years of age [184].

Autoimmune thyroiditis can be associated with HCV-related liver disease [218,219]. Antithyroid antibodies are found in 5%–13% of patients with chronic HCV infection, predominantly affecting older women [185,186]. Autoimmune thyroiditis is manifested as hypothyroidism in 3%–6% of patients with chronic HCV infection. Interferon-related thyroid disease is more frequently noted in patients with preexisting thyroid antibodies. However, IFN can induce the formation of antithyroid antibodies. Discontinuation of IFN therapy is usually accompanied by resolution of the thyroid disorder. Salivary and lacrimal gland involvement is common in HCV-infected individuals, but HCV antigens are not detectable in affected glands [187]. Testicular atrophy and sexual dysfunction can be associated with HCV-related cirrhosis.

Rheumatological disorders

Rheumatological disorders associated with chronic HCV infection are common and include mixed cryoglobulinemia, vasculitis, sicca symptoms, myalgia, arthritis, and fibromyalgia [187–190]. There is a wide spectrum of clinical manifestations that can be noted and are not characteristic of HCV infection. However, a characteristic joint syndrome is associated with the presence of mixed cryoglobulinemia and characterized by intermittent monoarticular or oligoarticular, nondestructive arthritis affecting large and medium-size joints. Treatment of patients with HCV-associated arthritis is limited and remains controversial.

Cutaneous and mucosal lesions

There are a number of dermatological disorders associated with chronic hepatitis C, with variable responses to IFN therapy [191]. The prevalence of anti-HCV varies from 4%–65% in patients with cutaneous lichen planus or oral lichen planus [191,193]. These estimates were obtained from populations with a high overall prevalence of HCV infection, such as the southern Europe and Japan [193]. Other lesions noted in association with HCV infection include porphyria cutanea tarda, necrotizing cutaneous vasculitis, and Mooren corneal ulcer [188,191]. The high prevalence of HCV infection in patients with porphyria cutanea tarda is based on epidemiological data [188]. The precise role of HCV in the pathogenesis of porphyria cutanea tarda is unknown.

Cardiac dysfunction

Recent studies have demonstrated an association between chronic hepatitis C and hypertrophic cardiomyopathy or dilated cardiomyopathy [194]. In a collaborative research project of the Committees for the Study of Idiopathic Cardiomyopathy, the prevalence of anti-HCV was 11% in patients with hypertrophic cardiomyopathy and 6% with those with dilated cardiomyopathy, both of which were significantly

higher than the prevalence rate of HCV infection in volunteer blood donors in Japan [194]. Various other cardiac abnormalities were found, of which arrhythmias were the most frequent.

Miscellaneous extrahepatic manifestations

Many systemic disorders can be associated with chronic HCV infection including polyarteritis nodosa-type systemic vasculitis [195], colonic vasculitis [196], idiopathic thrombocytopenic purpura [188], celiac sprue [197], Sjögren syndrome [188], polymyositis [198], and multiple myeloma [199]. Systemic sclerosis has been reported in patients with chronic HCV infection, manifested by severe Raynaud phenomenon, progressive skin thickening, painful fingertip ulcers, dysphagia, and Sjögren syndrome [200]. The prevalence of chronic HCV infection in patients with systemic lupus erythematosus is greater than the prevalence of HCV in blood donors from the same population [201]. Patients with coexistent systemic lupus erythematosus and HCV infection tend to manifest a lower frequency of cutaneous systemic lupus erythematosus lesions and anti-double-stranded DNA antibodies, and a higher rate of hepatic involvement, hypocomplementemia, and cryoglobulinemia [201].

Lymphoproliferative diseases

The role of HCV infection in the etiology and pathogenesis of lymphoproliferative diseases is supported by several studies reporting high seroprevalence of HCV in patients with some types of B-cell non-Hodgkin lymphoma [202–206]. HCV demonstrates a high affinity for lymphoid tissue. HCV is associated with type II mixed cryoglobulinemia, a benign monoclonal lymphoproliferative disorder that can transform to overt B-cell non-Hodgkin lymphoma.

Primary hepatic lymphoma

The etiological association between HCV and primary hepatic lymphoma is unclear [202,206]. Numerous reports of primary hepatic lymphoma of B-cell origin in association with HCV infection have been published, and the cell types are typically immunocytoma, marginal zone lymphoma, and diffuse large cell lymphoma. Only a few cases of T-cell lymphoma have been described [206].

Hepatocellular carcinoma

The incidence of HCC in the United States has more than doubled over the past 20 years from 1.4 cases per 100 000 in 1975 to 1977 to 3.0 per 100 000 in 1996 to 1998, primarily related to the impact of HCV infection acquired during the 1960s and 1970s [159,207–209]. The increase affected most age groups above 40 years, with the greatest increase in the group aged between 45 and 49 years [208]. By contrast, the incidence of HCC is as high as 120 cases per 100 000 in China, the Far East, and sub-Saharan Africa [159,210,211]. The occurrence of HCC in association with HCV-related liver disease shows marked geographic variation [159,209–211]. The rate of detectable anti-HCV in patients with HCC can vary from 60%–70% in Spain and Italy, 50% in Japan, and 27% in the United States to less than 10% in Hong Kong [159]. Approximately 20%–25% patients with chronic HCV infection will develop cirrhosis within 20 years from the onset of infection, and HCC develops at a rate of 1.5%–9% per year in patients with chronic hepatitis C and cirrhosis [139,212]. Therefore, there is a 5% risk of developing HCC in patients with HCV infection over a course of 20 years. The risk factors associated with the development of HCC in the setting of HCV infection include age over 60 years, male gender, alcohol use, coinfection with HBV, porphyria cutanea tarda, increased hepatic iron content, and severity of cirrhosis [209,212–214]. The incidence of HCV-related HCC is steadily rising, and HCV accounts for nearly half of all cases of HCC in the United States [208–210].

Ultrasound of the abdomen and measurement of serum α-fetoprotein are reasonable tests in a screening strategy for early detection of HCC in patients with chronic HCV infection and cirrhosis [214]. There is no consensus on the frequency with which these tests should be performed, but most experts recommend an interval of every 6–12 months. Screening is recommended only for patients with known or suspected cirrhosis, because the risk of HCC is low in patients who do not have cirrhosis.

Cholangiocarcinoma

There is also a somewhat higher incidence of cholangiocarcinoma in patients with HCV-related cirrhosis, and cholangiocarcinoma is also associated with poor prognosis [215,216].

Antiviral therapy

Peginterferon plus ribavirin combination therapy is the current standard of care for treatment-naive patients with chronic hepatitis C [217]. The 2002 NIH Consensus Development Conference and recent guidelines recommend that all patients with chronic hepatitis C should be considered as potential candidates for therapy [217–220]. Patients with HCV-related compensated cirrhosis can be cautiously treated, whereas patients with decompensated cirrhosis should be referred to a liver transplant center for consideration for liver transplantation, which is the treatment of choice when liver failure complicates chronic HCV infection.

Interferon-based antiviral therapy

Treatment is recommended by clinical guidelines on the management of chronic hepatitis C in adults who are at the greatest risk for progression to cirrhosis [149,217–220]. These patients have persistently elevated ALT levels for more than 6 months, detectable serum HCV RNA, portal or bridging fibrosis with at least a moderate degrees of inflammation

Table 82.2 Contraindications for interferon and ribavirin therapy

Hematological
Hemoglobin < 12 g/dL in women and < 13 g/dL in men
White blood cell count < 1500/mm^3
Platelet count < 100 000/mm^3
Hepatic
Normal aminotransferase levels
Decompensated cirrhosis
Cardiovascular
Severe coronary artery disease
Unstable angina
Endocrine
Poorly controlled diabetes mellitus
Autoimmune diseases
Untreated thyroid disease
Neuropsychiatric
Seizure disorder
Severe psychiatric illness
Obstetric
Pregnant or unable to practice contraception

and necrosis on liver biopsy, and no evidence of serious coexisting conditions or contraindications to antiviral therapy. Patients who are treated in clinical trials are typically required to have elevated ALT levels of more than 1.5 times the upper limit of normal, clinically compensated liver disease, and no other significant medical or psychiatric illness that contraindicates therapy (Table 82.2).

Virological and biochemical response

Responses to antiviral therapy of chronic HCV infection may be defined on the basis of the biochemical, virological, and histological outcomes. The persistence of a biochemical (normal ALT) or virological (undetectable HCV RNA) response for 6 months or more after cessation of therapy is the operational definition of a *sustained response* [221]. Several studies, including a mean 4-year follow-up of 80 patients and a 10-year follow-up of five patients who all had an initial posttreatment 6-month sustained virological response (SVR), showed long-term sustained response rates of 95%–100% [222–224]. In addition, there was improvement of liver histology, including evidence of regression of hepatic fibrosis in noncirrhotic patients [223]. These studies suggest that some patients may indeed be "cured" of chronic HCV infection and that a benefit on mortality should be expected if cirrhosis, with its risk of HCC, could be prevented. A posttreatment elevated ALT level and detectable HCV RNA that had been normal and undetectable, respectively, during treatment define *relapse* after a course of therapy. *Nonresponse* to antiviral therapy is defined as persistently elevated ALT levels or detectable serum HCV RNA, and a variant of nonresponse called *breakthrough* is characterized by an initial decrease of ALT levels into the normal range or the disappearance of detectable HCV RNA with subsequent elevation of ALT or the presence of detectable HCV RNA while still on treatment [224]. An early virological response (EVR) is defined as a drop in the HCV RNA level of 2-$\log_{10}$ or more compared to baseline [226,227]. Patients with undetectable levels of HCV RNA at 12 weeks are considered to have a complete EVR. Patients with an EVR who demonstrate a drop in HCV RNA greater than 2-$\log_{10}$, but who continue to demonstrate low-level viremia (partial EVR), should be treated for 24 weeks with continuation of therapy beyond 24 weeks in only those who become HCV RNA negative by week 24 of therapy. Analyses of data from two registration trials demonstrated that the EVR was a reliable predictor of subsequent SVR with 97% and 100% positive predictive value in two studies [226,227]. Failure to clear HCV RNA after 12 weeks of combination therapy predicts the lack of an SVR and has been used as a stopping rule for antiviral therapy. However, histological improvement may occur with longer maintenance therapy, and so continuation of therapy may be beneficial in selected cases on an experimental basis.

Aims of antiviral therapy

The primary goal of antiviral therapy in patients with chronic hepatitis C is long-term viral eradication as determined by undetectable HCV RNA in serum and liver [217–220]. Secondary objectives of treatment include normalization of ALT levels and improvement in histology (reduced inflammation and fibrosis) on liver biopsy.

Selective role of liver biopsy

A liver biopsy is the gold standard to assess the severity of underlying liver disease. However, liver biopsy is not mandatory before treatment and is best used selectively [228,229]. Liver biopsy can help to distinguish those patients that are most likely to benefit from therapy, i.e., those with moderate histological disease, from those who may be less likely to benefit, i.e., those with mild disease and no or minimal fibrosis or those with advanced disease and cirrhosis. A decision to perform a liver biopsy can be influenced by many factors, such as patient preferences, presence of relative contraindications, and clinical suspicion of coexistent liver diseases suggested by laboratory abnormalities like high-titer antinuclear antibody with hypergammaglobulinemia or abnormal iron studies. Liver biopsy is costly, invasive, painful, requires prolonged monitoring, and is associated with sampling error [230,231]. Apprehension and anxiety is frequently noted in patients before a liver biopsy is performed. A percutaneous liver biopsy is a blind procedure, which can cause pain in 30%, severe complications in 0.3%, and death in 0.03% of patients [230,231]. In addition, liver biopsy incurs both direct

health-care-related and indirect work-loss-related costs. Based on a cost-effectiveness analysis, it has been recommended that the most suitable strategy in the management of chronic HCV infection is to initiate therapy in all patients and avoid a liver biopsy [232]. Considering these arguments, there is a trend to initiate therapy without performing a liver biopsy. The role of liver biopsy might be thought of as selective rather than mandatory in identifying candidates for antiviral therapy, e.g., for the patient with genotype 1 infection who prefers to defer therapy if mild disease with no or minimal fibrosis is present [217–220]. On the other hand, patients with genotype 2 or 3 infection, with expected high rates of an SVR, may not need a pretreatment liver biopsy.

A number of studies have been performed in patients with chronic HCV infection to investigate the utility of laboratory tests, such as the aspartate aminotransferase to ALT ratio or the platelet count, to establish the severity of liver disease, but none of the proposed predictors are as sensitive and specific as a liver biopsy [233,234]. In one study, a more complex formula correctly classified 46% of patients with or without significant fibrosis into these two respective categories [235]. This formula required three assays that were not routinely performed in patients with chronic HCV infection (α_2-microglobulin, haptoglobin, and apolipoprotein A-1), in addition to three routine tests (γ-globulin, γ-glutamyltransferase, and total bilirubin), but commercial application of these and similar tests are available through referral laboratories. The greatest use of these tests is to confirm suspected mild or advanced fibrosis; the sensitivity and specificity of these tests is poor in patients with intermediate stages of fibrosis [233,234].

The future treatment of chronic hepatitis C may include antiviral drugs and also antifibrotic agents, which might necessitate the performance of a liver biopsy or the identification of reliable serum markers of fibrosis to establish the endpoints of therapy. A wide variety of serum fibrosis markers have been studied to predict the stage of fibrosis, of HCV-related liver disease [233,234,236]. The serum markers that have been studied include procollagen type III N-terminal peptide (PIIINP), 7S fragment of type IV collagen (PIVNP), hyaluronan (HA), matrix metalloproteinase 1 (MMP-1), MMP-2, and tissue inhibitor of metalloproteinases 1 (TIMP-1). The Ishak fibrosis scores of treatment-naive patients, including 205 white and 194 African Americans, with HCV genotype 1 enrolled in the Viral Resistance to Antiviral Therapy of Chronic Hepatitis C study (Virahep-C) were modeled using simple and multiple logistic regression analysis [237]. The model was then validated in an independent cohort of 461 previously untreated patients with HCV. The value of the area under the receiver operating characteristic curve (AUROC) of the Virahep-C model (0.837) was significantly better than in other published models. The AUROC of the Virahep-C model was 0.851 in the validation population. In summary, a model consisting of widely available clinical and laboratory features predicted severe hepatic fibrosis equally well in white and African American patients with HCV genotype 1 and was superior to other published models [237]. The excellent performance of the Virahep-C model in an external validation cohort suggests that the findings are replicable and potentially generalizable.

Interferon-induced viral and immune kinetics

The potency of IFN is determined by measuring antiviral activity in biological assays relative to a number of international reference standards. Further insight into IFN-induced viral kinetics and host immune modulation has been provided by recent studies [238–240]. It has been demonstrated that multitarget, potent CD4+ proliferative T-cell responses are maintained long-term after eradication of HCV infection compared to the focused and weak responses in patients with persistent HCV infection [240]. On the other hand, the HCV-specific CD8+ T-cell response is quantitatively weaker in both responders and nonresponders.

Treatment of naive patients

The four types of IFN-α that have been evaluated in a large number of patients with chronic HCV infection include IFN-α2b [241], IFN-α2a [242], IFN-αn1 (lymphoblastoid interferon) [243], and IFN-αcon-1 (consensus interferon [CIFN]) [244]. In the United States, IFN-α2b, IFN-α2a, IFN-αcon-1, combination IFN-α-2b with ribavirin, peginterferon alfa-2a plus ribavirin and peginterferon alfa-2b plus ribavirin are licensed by the Food and Drug Administration (FDA) for the treatment of chronic HCV infection. The treatment of choice for chronic hepatitis C approved by the FDA is peginterferon alfa-2a or peginterferon alfa-2b plus ribavirin for 24 or 48 weeks.

The FDA originally licensed interferon in 1991 for the treatment of chronic hepatitis C, and the initial strategy of treating patients for 24 weeks yielded 10%–15% sustained response rates. It was later found that 48–72 weeks of therapy increased the response rates up to 20%–25% [221]. Interferon and ribavirin combination antiviral therapy became the standard treatment for chronic HCV infection in 1998 [217–220]. Ribavirin in doses of 1000 mg to 1200 mg daily in two divided doses combined with IFN-α2b in a dose of 3 million units (MU) three times a week for 24 weeks was found to significantly improve the biochemical and virological sustained response rates compared with IFN alone in an early pilot experiment [245]. Phase III American and European trials comparing standard IFN monotherapy with combination IFN-α2b plus ribavirin therapy showed a significant improvement in response rates for all measures of efficacy, including virology, ALT levels, and histology in treatment-naive patients with chronic HCV infection [246,247]. Serum HCV RNA was eradicated in 31%–35% of patients after 24 weeks of combination therapy and in 38%–43% of patients with 48 weeks of combination therapy as compared to 13%–19% of patients given interferon monotherapy. These studies also showed

important differences in the outcome based on genotype, i.e., approximately 30% of patients with genotype 1 versus approximately 65% with genotypes 2 or 3 had an SVR. In addition, patients with genotype 1 had increased rates of SVR with 48 versus 24 weeks of therapy, whereas patients with other than genotype 1 achieved no additional benefit after 24 weeks of combination therapy. These studies indicate that combination therapy should be administered for 48 weeks to patients with genotype 1 but for only 24 weeks to those with genotypes 2 and 3 to achieve maximal SVR rates. Multiple factors, in addition to genotype, are known to predict the likelihood of successful therapy with ribavirin and IFN and may influence the decision of whether or not to administer a course of therapy.

Polyethylene glycol (PEG) is a large, inactive water-soluble polymer that can attach to IFN with a covalent bond [248]. The process of pegylation results in reduced clearance of the pegylated molecule and up to a 10-fold increase in the drug half-life, which allows once a week administration [248]. Peginterferon has improved efficacy because a steady serum level is maintained, but there may be a variable loss in IFN activity determined by the size of the PEG molecule and the site of pegylation [239,248]. The two peginterferons that have been studied include the long branched 40-kDa peginterferon alfa-2a (Pegasys, Roche), which is metabolized by the liver, and the short linear 12-kDa peginterferon alfa-2b (PEG-Intron, Schering), which is excreted by the kidneys [249,250]. Pilot studies demonstrated that the safety profile of peginterferon administered in ascending subcutaneous doses to healthy subjects was comparable to that of standard interferon [249–251]. Peginterferon monotherapy was more efficacious than standard interferon monotherapy in a dose-dependent fashion [249–251]. In one clinical trial, 531 IFN-naive patients with chronic HCV infection were treated for 48 weeks with peginterferon alfa-2a, 180 μg once weekly, and showed an SVR rate of 39% at 24 weeks following discontinuation of therapy, in comparison to a 19% SVR rate with standard IFN-α2a three times a week [249]. In another study, 1219 IFN-naive patients with chronic HCV infection were treated with peginterferon alfa-2b weekly using a weight-based dosing of 1.0 μg/kg or 1.5 μg/kg weekly and with IFN-α2b three times a week in the control group for 48 weeks [250]. The SVR rates were 25% for 1.0 μg/kg peginterferon alfa-2b once weekly, 23% for 1.5 μg/kg peginterferon alfa-2b once weekly, and 12% for IFN-α2b thrice weekly. Therefore, monotherapy with either peginterferon has twice the efficacy of standard IFN monotherapy in terms of SVR rates. The response rates were reduced in patients with genotype 1 and higher viral loads. Both peginterferons were tolerated as well as the standard interferons, with discontinuation rates ranging from 6% to 11% in all treatment groups. Peginterferon alfa-2b was approved and licensed by the FDA in 2001 and peginterferon alfa-2a in 2002. There are no clinical trials comparing the efficacy of the two peginterferons face to face; however, based on available data it is expected that any differences between the two drugs are not significant.

The combination of peginterferon with ribavirin has improved the efficacy of antiviral therapy of chronic HCV infection even further [226,227]. Peginterferon alfa-2b at a weekly dose of 1.5 μg/kg plus ribavirin, 800 mg per day, showed a significantly higher response rate when compared with standard IFN plus ribavirin combination in a large phase III trial [226]. The overall SVR rate was 54% (42%, genotype 1; 82%, genotype 2 or 3). The group treated with peginterferon plus ribavirin combination reported higher frequencies of fever, nausea, and injection site reaction with erythema compared to the control group. The rate at which the drugs were discontinued was similar in the two arms of the study. The dose of ribavirin may not have been ideal, with higher doses achieving yet better results. Two large, phase III studies of peginterferon alfa-2a plus ribavirin reported an SVR rate of 56%–63% (46%–52%, genotype 1; 76%–84%, genotype 2 or 3) [227,252]. These results are probably not significantly different from the results using peginterferon alfa-2b, making these two drugs interchangeable. Therefore, based on these efficacy data, the use of peginterferon monotherapy is only appropriate if there are contraindications to ribavirin use, such as significant baseline anemia or advanced chronic renal failure. Based on data from these trials, peginterferon and ribavirin combination therapy is the standard of care in treating patients with chronic HCV infection [226,227,252]. Table 82.3 compares the SVR rates reported with peginterferon plus ribavirin therapy in the key pivotal trials by genotype and viral load for genotype 1. The treatment duration and ribavirin dose registration study established that 48 weeks of therapy and 1000 or 1200 mg of ribavirin (based on body weights of less than or more than 75 kg, respectively) was needed for an optimal response in patients with genotype 1, whereas 24 weeks of therapy using 800 mg of ribavirin was sufficient therapy for patients with genotypes 2 and 3 [252].

Table 82.3 Sustained virological response with peginterferon and ribavirin treatment in pivotal trials

Treatment [ref.]	Overall	GT 1	GT 1 (HVL)	GT 2 or 3
Peginterferon alfa-2a plus ribavirin [227]	56%	46%	41%	76%
Peginterferon alfa-2a plus ribavirin [252]	63%	52%	47%	84%
Peginterferon alfa-2b plus ribavirin [226]	54%	42%	30%	82%
Weight-based RBV[a]	61%	48%	37%	88%

a Weight-based RBV, > 10.6 mg/kg ribavirin by secondary analysis of the study of Manns et al. [226].
GT, genotype; HVL, high viral load (> 800 000 IU/mL); RBV, ribavirin.

Viral, host and treatment-related variables associated with lower SVR rate include genotype 1, high baseline viral load, advanced fibrosis (bridging fibrosis and cirrhosis), obesity, African American race, older age, contraindications to treatment, previous relapse or nonresponse to treatment, and ribavirin dose [253,254]. Patients with HCV genotype 1 and high viral load (> 600 000–800 000 IU/mL) demonstrated SVR rates of 30%–47% [226,227,252]. Recent data have demonstrated that measurement of HCV RNA at 4 weeks may allow for the individualization of the duration of treatment. Patients with undetectable HCV RNA at week 4 of therapy are characterized as having a rapid virological response (RVR) [255]. A recent retrospective review of treatment duration and ribavirin dose registration [252] showed that 24% of patients with HCV genotype 1 in the 24-week peginterferon alfa-2a plus ribavirin treatment group developed a RVR that was associated with an 89% probability of an SVR [255]. These data are promising but they need to be reproduced in a prospective, controlled trial before treatment recommendations can be modified. Therefore, all patients with HCV genotype 1 should be treated for at least 48 weeks if they develop an EVR at 12 weeks of therapy. On the other hand, data have demonstrated a significantly improved SVR rate of 29% with extended therapy of 72 weeks (versus 17% with the standard 48 weeks) in patients with HCV genotype 1 who develop a partial EVR at week 12 of therapy (> 2-$\log_{10}$ drop but still have detectable HCV RNA) but subsequently become HCV RNA negative at 24–weeks [256]. In particular, patients with low level viremia [< 6000 IU/mL] at 12 weeks benefited from 72 weeks of treatment, whereas patients with undetectable HCV RNA at weeks 4 and 12 had no added benefit from the extended 72 weeks of therapy [256]. Similarly, in a recent prospective clinical trial, 510 treatment-naive patients were treated with peginterferon alfa-2a (180 μg/week) plus ribavirin (800 mg/day) and treated for 48 or 72 weeks. Patients with detectable HCV RNA levels (HCV RNA < 50 IU/mL) at week 4 were randomized to complete 48 or 72 weeks of treatment [257]. The end-of-treatment response rate (61%) was similar in both groups, but the SVR rate was 32% with 48 weeks of therapy (compared with 45% in the 72-week treatment group). In genotype 1-infected patients randomized to 48 weeks or 72 weeks of treatment, SVR rates were 28% and 44%, respectively – a significant difference. The incidence of adverse events was similar in both study arms. Treatment discontinuation was significantly more frequent in the 72-week group (36%) than in the 48-week group (18%). Therefore, the extended 72 weeks (versus the standard 48 weeks) of therapy with peginterferon plus ribavirin significantly increases the rate of SVR in patients with detectable viremia at week 4 of treatment [256,257].

Results from three clinical trials performed in an attempt to curtail the treatment duration for patients with HCV genotypes 2 and 3 to 12, 14, or 16 weeks (rather than 24 weeks) suggested that patients who achieve an RVR with peginterferon alfa-2a or -2b plus ribavirin can discontinue treatment early (12, 14, or 16 weeks) and gain no added benefit by continuing therapy for usual 24 weeks [258–260]. Unfortunately, these data have been marred by flawed study designs, small number of patients enrolled, and unconventional doses of peginterferon and ribavirin. The results of the largest prospective study in patients with HCV genotypes 2 and 3 (n = 1469, the Accelerate trial) demonstrated that 24 weeks of peginterferon alfa-2a 180 μg/week plus ribavirin 800 mg/day was significantly superior to 16 weeks (76% versus 65%) [261]. The lower SVR rate in the 16-week group was associated with a higher relapse rate. Further subanalysis of the Accelerate trial showed that patients with an RVR and low viral load (up to 400 000 IU/mL) might be suitable candidates for shorter therapy (16 weeks). Prospective studies must be performed to reproduce this observation and before modifying treatment recommendations.

Patients with compensated cirrhosis are suitable candidates for treatment, but the SVR rates are lower and there is a small risk of hepatic decompensation induced by therapy [262,263]. Patients with hepatic decompensation tolerate treatment poorly and serious adverse effects, including death, have been reported [263]. However, treatment guidelines have recommended that patients with mild hepatic decompensation can be treated cautiously [262]. A low accelerating dosage regimen of peginterferon and ribavirin achieved an SVR rate of 20%–30% (13% in genotype 1, and 50% in genotypes 2 and 3) in the setting of hepatic decompensation [263]. Ideally, patients with hepatic decompensation should initially be listed for liver transplantation, followed by consideration for cautious antiviral therapy in patients with mild hepatic decompensation. For patients with hepatic decompensation who are poor candidates for liver transplantation, treatment should be individualized by weighing the risks of therapy versus the benefits.

Several studies have demonstrated that hepatic fibrosis improved on serial liver biopsies following interferon-based therapy, especially in patients who developed an SVR [264]. A significant reduction in the rate of hepatic fibrosis was noted in a set of data pooled from 3010 treatment-naive patients with chronic hepatitis C who underwent pretreatment and posttreatment liver biopsies in four randomized clinical trials using 10 different IFN-based regimens [264]. Although, the best results were noted with a peginterferon plus ribavirin combination, all regimens significantly reduced the fibrosis progression rates in comparison to rates before treatment. In particular, advanced fibrosis was reversed in 49% of patients with baseline cirrhosis. Independent predictors of posttreatment minimal fibrosis included age less than 40 years, body mass index less than 27 kg/m^2, HCV RNA level less than 3.5 million copies/mL, SVR, baseline fibrosis stage, and no or minimal baseline activity [264]. Antiviral therapy for chronic hepatitis C is also associated with a decrease in the incidence of HCC. The Inhibition of Hepatocarcinogenesis by Inter-

Table 82.4 Favorable impact of antiviral therapy on the natural history of chronic hepatitis C

Long-term virological response after SVR: **> 95%**
Clinical relevance of detection of small amounts of HCV RNA uncertain
Fibrosis progression rate: **slowed**
Evidence of reversal of fibrosis, including early cirrhosis
Incidence of hepatocellular carcinoma: **reduced**
Especially among patients with SVR
Life expectancy and survival: **improved**

HCV, hepatitis C virus; SVR, sustained virus response.

feron Therapy (IHIT) Study Group in Japan has followed a cohort of more than 3000 Japanese patients with chronic hepatitis C and demonstrated that IFN therapy reduces the risk of HCC by 50% [265]. The risk of HCC was reduced to one-fifth in biochemical and virological responders versus treatment-naive patients. Recent data with long-term follow-up have shown reduced overall death rate and reduced liver-related deaths [266,267]. Thus, evolving data indicate the natural history of chronic hepatitis C is being favorably influenced by antiviral therapy (Table 82.4).

Treatment of variant clinical manifestations

Patients with chronic hepatitis C included in the following section were either excluded from or insufficiently studied in the registration trials. Therefore, treatment recommendations in these subgroups are limited by lack of data and may not be FDA approved.

Acute hepatitis C

Although interferon-based antiviral therapy has not been approved for acute hepatitis C, several clinical trials have shown promising results [368,269]. A study of 44 patients with acute hepatitis C treated with IFN-α2b 5 MU daily for 4 weeks and then three times a week for another 20 weeks showed a remarkable 98% SVR rate 6 months after completion of therapy, i.e., prevention of chronic hepatitis C [268]. In a recent study, patients treated with peginterferon alfa-2b (1.5 μg/kg/week) for 24 weeks (treatment was initiated after a median of 76 days after infection, range 14–150 days) demonstrated an SVR rate of 89% [269]. An ALT level of more than 500 U/L before therapy was the only factor associated with a higher response rate. The adverse effects with peginterferon alfa-2b were significant in this patient population and led to a high number of dropouts [269]. The optimal regimen for acute hepatitis C remains undefined and further studies are needed. Unfortunately, up to 75% patients with acute hepatitis C will develop chronic infection without therapy. Therefore, 24-week treatment with peginterferon at standard doses plus ribavirin at 800 mg/day appears prudent [220]. The SVR rates are promising (89%–98%) if treatment is continued for 24 weeks and initiated within 6 months after the onset of infection [220,268,269].

Children with HCV infection

Chronic hepatitis C infection is usually asymptomatic in children, but significant liver disease may occur [270]. Interferon-based treatment of children with chronic hepatitis C is not yet approved. Preliminary data suggest that an IFN plus ribavirin combination is effective, safe, and well tolerated in children with chronic hepatitis C [270,271]. Prospective controlled trials are ongoing to study the role of combination therapy in children with chronic hepatitis C. It may be prudent to delay therapy in children with mild, asymptomatic chronic hepatitis C and minimize quality of life issues including performance in school.

Normal ALT levels

As many as 25% of patients with chronic HCV infection have persistently normal ALT levels [272]. Most patients with persistently normal ALT levels have mild, nonprogressive histological damage [27,272–274]. However, mildly abnormal liver histology may be encountered in these patients, and the reported rate of cirrhosis varies from 0.3% to as high as 10% in patients with normal ALT levels [275,276]. In these patients, advanced fibrosis was associated with a coexistent significant amount of alcohol consumption [276].

In summary, the degree of ALT elevation does not consistently predict the severity of histological damage and response to therapy. Therefore, treatment in patients with chronic hepatitis C who have normal ALT levels should be individualized [217–220]. This patient population should not be universally excluded from antiviral therapy [272–275]. Patients with persistently normal ALT or histologically mild chronic hepatitis C can be treated if they decide to pursue antiviral therapy, particularly those with debilitating symptoms, unresolving acute hepatitis C, and genotypes 2 or 3.

Mixed cryoglobulinemia and glomerulonephritis

Mixed cryoglobulinemia is characterized by precipitation of cold-insoluble immunoglobulin complexes or cryoglobulins in the serum of 40%–50% of patients with chronic hepatitis C. Cryoglobulin production is triggered by chronic viremia, generation of rheumatoid factor, and stimulation of B cells by antigen–immunoglobulin complexes. In 10% of patients with HCV-related cryoglobulinemia various clinical manifestations, including vasculitis, glomerulonephritis, arthritis, or neuropathies, may develop. Cryoglobulinemia is associated with progressive liver damage and rapid posttransplant HCV recurrence. Monotherapy with IFN has been shown to be beneficial in the treatment of essential mixed cryoglobulinemia and glomerulonephritis associated with HCV infection [177–179,277]. Long-term therapy is usually required to prevent relapse of the underlying disorder [177–179]. In the absence of significant renal impairment, combination therapy with IFN-α and ribavirin provides much better efficacy

and should be the treatment of choice [177,277]. Cryoglobulinemia resolves and its clinical manifestations improve following viral clearance. Other forms of therapy used in the management of HCV-induced cryoglobulinemic glomerulonephritis include cytotoxic therapy and immunosuppressive therapy [180–182]. Cyclophosphamide and corticosteroids, often in combination with plasma exchange, have been used with some success [179–181]. Cyclophosphamide and corticosteroids are effective in providing symptom relief, but may stimulate viral replication. Prolonged use of immunomodulators should be limited to severe forms of vasculitis, aggressive glomerulonephritis, and following failure of antiviral therapy. In patients with severe debilitating illness or acute exacerbation, plasmapheresis may provide rapid but temporary relief. Rituximab, an anti-CD20 monoclonal antibody, has been noted to have clinical efficacy in lupus nephritis, membranous idiopathic nephropathy, and nonrenal manifestations of type II mixed cryoglobulinemia [182]. Preliminary data demonstrate that rituximab therapy is effective and safe in cryoglobulinemia-related glomerulonephritis in the setting of chronic hepatitis C [182].

Autoimmune liver disease

Interferon-based therapy can precipitate a flare-up of coexistent otherwise quiescent autoimmune chronic hepatitis. It is recommended that patients with coexisting chronic autoimmune hepatitis and HCV infection should initially be treated with immunosuppressive therapy to prevent acute exacerbation of autoimmune liver disease [278,279].

Immunocompromised status

The efficacy of IFN plus ribavirin treatment of HCV infection following liver transplantation, in end-stage renal disease, or following renal transplantation, and HIV coinfection is less than optimal [280–286]. End-stage liver disease is the leading cause of death in hospitalized HIV-seropositive patients [287]. An increasing number of patients with either HCV or HIV are being identified as coinfected with both viruses because of the similar routes of transmission. Up to 30% of all patients infected with HIV are also infected with HCV, whereas 10% of those infected with HCV may have HIV coinfection. It has been shown that patients coinfected with HCV and HIV progress more rapidly (up to threefold) than HCV-positive patients without HIV [283,288]. There is a plethora of data indicating that both HCV RNA levels and survival are directly influenced by HIV infection. These results suggest that HIV infection-induced CD4 depletion is independently associated with severity of liver fibrosis in chronic HCV infection [288,289]. In addition, HCV-related hepatitis may occur with initiation of antiretroviral therapy, which is presumably related to an immune restoration syndrome.

It is recommended that patients with HCV and HIV coinfection should undergo preemptive therapy against HCV infection irrespective of ALT levels and histological findings. If chronic hepatitis C is detected early in the course of HIV infection before the initiation of antiretroviral therapy is necessary, treatment of the hepatitis C is advised. However, if there is severe immune deficiency (CD4 count < 200 cells/mm^3), the CD4 count should be improved with antiretroviral therapy and the patient must have been on a stable regimen for at least 3 months before beginning treatment for their chronic hepatitis C. Three pivotal studies have demonstrated that HCV–HIV coinfection can be successfully treated with a peginterferon plus ribavirin combination, with SVR rates about half of those with HCV monoinfection but ranging from 14% to 29% for genotype 1, and 44%–73% for genotypes non-1 [284–286] (Table 82.5). The regimen approved by the FDA for treatment of HCV–HIV coinfection is peginterferon alfa-2a 180 μg/week plus ribavirin 400 mg twice a day for 48 weeks regardless of HCV genotype [284]. Studies with HCV monoinfection have indicated that patients infected with genotype 1 benefit from higher ribavirin dosages (1000 or 1200 mg/day), with an increase in SVR rate. Therefore, ribavirin may be given at dosages as high as 1200 mg daily, depending on the body weight. Peginterferon plus ribavirin does not affect HIV RNA levels, but CD4 counts can decline

Table 82.5 SVR with peginterferon and ribavirin therapy in patients with hepatitis C virus–human immunodeficiency virus coinfection

Trial [ref.]	Treatment	No.	Overall	GT 1	GT 2,3
APRICOT [284]	PEG alfa-2a + RBV 400 mg b.i.d.	868	40%	29%	62%
ACTG [285]	PEG alfa-2a + RBV 600–1000 mg/day	133	27%	14%	73%
RIBAVIC [286]	PEG alfa-2b + RBV 400 mg b.i.d.	412	27%	17%	44%

b.i.d., twice a day; GT, genotype; PEG alfa-2a, peginterferon alfa-2a at 180 μg/week; PEG alfa-2b, peginterferon alfa-2b at 1.5 μg/kg/week; RBV, ribavirin.

during therapy with a return to baseline following discontinuation. Unfortunately, the peginterferon plus ribavirin combination results in a higher rate of adverse effects and subsequent treatment discontinuation in coinfected patients.

At least two of the protease inhibitors used for the treatment of HIV infection, ritonavir and indinavir, can cause serious liver toxicity [290]. Ritonavir leads to late liver toxicity, normally as the result of triglyceride abnormalities. Indinavir, on the other hand, usually causes only a Gilbert-like syndrome, although in some cases it may cause a more significant toxicity. The protease inhibitors, saquinavir and nelfinavir, have only minimal liver toxicity. The use of highly active antiretroviral therapy has prolonged the healthy lifespan of patients infected with HIV, and deaths among individuals with AIDS have declined for the first time in 1996 with the institution of this therapeutic approach [283,290].

African Americans

A recent clinical trial confirmed the findings of two earlier studies that African Americans compared with white Americans with chronic hepatitis C, genotype 1 are less likely to respond to IFN-based antiviral therapy [291–293]. In the most recent multicenter clinical trial, 196 African Americans and 205 white Americans who were treatment-naive patients with HCV genotype 1 infection were treated with peginterferon alfa-2a (180 μg/week) and ribavirin (1000–1200 mg/day) for up to 48 weeks, and the primary endpoint was SVR [291]. Baseline features were comparable, including HCV RNA levels and histological severity, but African Americans had significantly higher body weights, a higher prevalence of diabetes and hypertension, and lower ALT levels. The SVR rate was 28% in African Americans and 52% in white Americans [291]. In multiple regression analyses, the white Americans had a higher SVR rate than the African Americans. Other factors independently associated with higher SVR included female sex, lower baseline HCV RNA level, less hepatic fibrosis, and more peginterferon taken. Racial differences in viral responses were evident as early as treatment week 4. African Americans demonstrated a higher frequency of breakthrough viremia than white Americans (13% versus 6%), but relapse rates were comparable (32% versus 25%). The proportions of patients with serious adverse events and dose modifications and discontinuations were similar among African Americans and white Americans. In summary, African Americans with chronic hepatitis C genotype 1 have lower rates of SVR to peginterferon and ribavirin than white Americans. These differences are not explained by disease characteristics, baseline viral levels, or amount of medication taken and may be explained by racial differences in global transcriptional response to interferon [294].

Adverse effects of interferon and ribavirin

Common side effects associated with ribavirin and IFN treatment, most of which are mild to moderate but may necessitate discontinuation of therapy in 10%–15% of patients, are listed in Table 82.6 [295–297]. The major side effect of ribavirin is a dose-dependent hemolytic anemia, which is reversible and usually stabilizes after 5–6 weeks of treatment. If severe anemia develops, treatment must be discontinued. The off-label use of growth factors (epoetin-α and granulocyte colony-stimulating factor) and antidepressants has come into common use. Patients must be informed that the use of growth factors and antidepressants is not approved by the FDA during antiviral therapy for chronic hepatitis C [295,297]. There are several contraindications to combination therapy with IFN and ribavirin (Table 82.2). Patients with preexisting anemia usually cannot tolerate the degree of hemolysis that occurs with ribavirin therapy and it can be dangerous. Patients with significant cardiovascular disease are particularly at risk should severe anemia develop during therapy. Patients with chronic hepatitis C and premorbid conditions preventing the use of ribavirin, particularly anemia, can be treated with peginterferon monotherapy [295].

Table 82.6 Adverse effects of interferon and ribavirin therapy

Nonspecific	Flu-like symptoms, including headache, fatigue, rigors, and fever
Cutaneous	Injection site reaction, pruritus, rash, dry skin, and hair loss
Respiratory	Cough and dyspnea
Gastrointestinal	Anorexia, nausea, vomiting, and dyspepsia
Neuropsychiatric	Depression, insomnia, anxiety, and irritability

Retreatment of relapsers and nonresponders

A selective approach to retreatment is prudent. Patients with favorable predictors for retreatment (genotypes 2 or 3) and at higher risk for progressive liver damage (stage 2 or greater fibrosis) should be considered for retreatment [298–301]. The primary goal of retreatment is eradication of HCV RNA and an SVR. In patients who fail to clear HCV RNA, secondary goals include, retarding or reversing hepatic inflammation and fibrosis, reducing the risk of HCC, preventing hepatic decompensation, and avoiding liver transplantation. Retreatment response rates have been highly variable, depending in large part on the response to the initial course of the treatment (nonresponse versus relapse). Relapsers demonstrate a significantly higher overall SVR rate to retreatment than nonresponders. The failure to respond to initial interferon-based antiviral therapy may be associated with a suboptimal therapeutic regimen, host variables, disease characteristics,

and viral factors. Retreatment of patients who were previously nonresponders to IFN monotherapy with subsequent peginterferon plus ribavirin achieved overall SVR rates between 16% and 28% [299–301]. Previous nonresponders to IFN plus ribavirin achieved overall SVR rates of 6%–15% following peginterferon plus ribavirin retreatment with higher response rates in patients with favorable predictors. Previous relapsers to IFN monotherapy were noted to have a 47% SVR to retreatment with IFN plus ribavirin, whereas relapsers to IFN plus ribavirin showed an overall SVR rate of 32%–50% with peginterferon plus ribavirin retreatment. Clinical trials testing retreatment strategies for treatment failures to peginterferon plus ribavirin are ongoing and include daily IFN-αcon-1 plus ribavirin, higher doses of peginterferon plus standard doses of ribavirin, extended therapy with peginterferon plus ribavirin and peginterferon maintenance monotherapy [302–304]. Low-dose maintenance peginterferon monotherapy with the goal of prevention of disease progression rather than viral eradication is an option for HCV treatment failures with advanced disease with increasing donor shortage for liver transplantation [303,304].

Novel investigational treatment strategies and agents

The efficacy, adverse effects profile and treatment duration of approved anti-HCV therapy is not ideal and is suboptimal. Therefore, new treatment strategies are being tested and developed with a goal to optimize the current regimens (avoid dose reduction and reduce the risk of adverse effects), the use of additional agents working through novel mechanisms (improve efficacy, reduce adverse effects, and shorten treatment duration), and antifibrotic strategies (retard progression, reverse damage, reduce the risk of hepatocellular carcinoma, and prevent hepatic decompensation). Several novel antiviral compounds are being studied in preclinical and clinical trials [305]. The therapies include those directed against hepatitis C targets (polymerase and protease inhibitors, antisense nucleotides), immunomodulators (histamine and thymosin), silymarin, vaccines, alternative IFNs and IFN delivery systems, ribavirin prodrugs, and L isomers. Clinical trials with two promising protease inhibitors, VX-950 (Vertex Pharmaceuticals) and SCH 503034 (Schering-Plough) are under way. Data from pilot studies showed at least a 2-$\log_{10}$ decline in viral load in every patient treated with VX-950 and SCH 503034 demonstrated a dose-dependent decline in viral load, with a mean reduction of 2.06 $\log_{10}$ from baseline [306–308]. No new drugs are expected to gain FDA approval for the next 3–5 years [305]. Furthermore, IFN will maintain its important status in future multidrug regimen.

Preventive and safety measures

Patient should be informed that, although the risk of transmitting HCV infection by sexual contact is low (3%–5%), HCV is potentially transmissible. Patients should be careful about blood exposure of any type to partners and family contacts. Open wounds must be covered, and razors or toothbrushes should not be shared. Although sexual or intrafamilial HCV transmission is rare, testing sexual partners or other family members if there is a concern regarding infection usually provides reassurance. Patients with chronic HCV infection should be counseled to avoid excessive consumption of alcohol, which can accelerate the progression of hepatitis C when used in moderate or large amounts. It has been recommended that the less alcohol consumed the better, and that complete abstinence is ideal [217–220]. Finally, it is recommended that hepatitis A and B vaccine be given to patients with chronic HCV infection who are not already immune because acute hepatitis A or B superimposed on chronic HCV infection may be more severe [309]. The safety and efficacy of these vaccines have been demonstrated in patients with mild to moderate chronic HCV infection [310], and a more convenient combined hepatitis A and B vaccine was licensed in 2001. The inability to culture the virus and its genetic heterogeneity are obstacles to developing a vaccine against HCV infection [311,312]. Investigational vaccination candidates, including recombinant proteins, peptides, virus-like particles, naked DNA, and recombinant viruses, are being explored.

Economic implications

Current estimates of medical and work-loss costs of HCV-related acute and chronic liver disease are in excess of $600 million annually based on unpublished CDC data. In 1995, the outcomes of hospitalizations were analyzed, focusing primarily on inpatient mortality and health-care cost [313]. It was estimated that HCV-related liver disease resulted in 26 700 hospitalizations and 2600 deaths in acute, nonfederal hospitals in the United States. The cumulative cost for these hospitalizations was $514 million. The cost of a 48-week treatment with peginterferon and ribavirin ranges from $30 000 to $40 000 [220]. The use of erythropoietic growth factors for patients with anemia occurring during HCV combination therapy appears to be cost-effective [314].

Liver transplantation

In the United States, about 8000 patients die each year from complications of HCV-related cirrhosis [2,16]. Chronic hepatitis C with decompensated cirrhosis, alone or in combination with alcoholic liver disease, is the most common indication for liver transplantation in the United States and Europe [27]. Based on statistics obtained from the United Network for Organ Sharing (UNOS), 23% of patients who underwent liver transplantation between 1994 and 1998 carried the diagnosis of HCV infection [315]. There has been a dramatic increase in the number of patients with HCV infection undergoing liver transplantation, and HCV accounts

for up to 50% of liver transplants both in the United States and Europe [316,317].

Candidacy for liver transplantation

Patients who are being considered for liver transplantation must meet one of the following minimal listing criteria:

- Child–Pugh class B or C (Child–Turcotte–Pugh [CTP] score of 7 or greater) in the setting of cirrhosis
- history of gastrointestinal bleeding caused by varices, or a single episode of spontaneous bacterial peritonitis irrespective of CTP score
- small unifocal or multifocal HCC (one lesion < 5 cm in diameter or three lesions < 3 cm involving the same lobe of the liver) with no portal vein invasion or metastases [318,319].

Patients who fulfill the UNOS specified listing criteria for liver transplantation have an estimated 1-year survival from chronic liver disease of less than 90%, which is the likely outcome with liver transplantation at major institutions [319]. In patients with compensated HCV-related cirrhosis, the 4-year to 5-year survival rate is 91% and the estimated risk of decompensation is 18%–20% [139]. Liver transplantation is the treatment of choice for chronic hepatitis C with decompensated cirrhosis, but HCV reinfection poses challenging management issues that may arise either early or late after transplantation [320].

Posttransplantation recurrent infection

Chronic hepatitis C with cirrhosis or HCC is the leading indication for liver transplantation in the United States [321–323]. Of the approximate 6000 liver transplantations performed annually, 45% or 2500 are for hepatitis C. Reinfection with HCV is virtually universal at the time of transplantation, and the rate of fibrosis is accelerated such that the median time to recurrent cirrhosis is less than a decade. Three patterns of recurrence are recognized: evolution over time to chronic hepatitis and cirrhosis (most common), an indolent course of reinfection over at least the first decade, and cholestatic hepatitis with early graft failure (infrequent) [321]. There are a number of conflicting reports in the literature regarding risk factors for poor outcomes after liver transplantation for chronic hepatitis C, but the factors most often cited include high pretransplant viral load (> 1 million IU/mL), high posttransplant viral load (> 10 million IU/mL), genotype 1b, early recurrence within months of transplant, older donor age (> 40–50 years of age), cytomegalovirus infection, prolonged cold and warm ischemia times, nonwhite race, female gender, and treatment of acute rejection [321–323] (Table 82.7). Use of corticosteroid boluses and antilymphocyte therapies are most consistently implicated as detrimental, but the impact of other agents, such as cyclosporine (ciclosporin [rINN]) versus tacrolimus, or the use of mycophenolate mofetil remains controversial. There were some preliminary reports that live donor transplant recipients were at greater risk of recurrence compared with deceased donor recipients, but these observations have not been confirmed and remain uncertain [321–323].

Table 82.7 Risk factors for severe recurrence of hepatitis C virus (HCV) posttransplantation

Host
Human leukocyte antigen matching
Age
Nonwhites
Cytomegalovirus viral coinfection
Absence of pretransplant coinfection with HBV
Presence of immunoglobulin M anti-HCV core antibodies after transplantation
Viral
Genotype 1b
Pretransplant HCV quasispecies
High (> 1×10^6 Eq/mL) pretransplant HCV RNA levels
High serum or liver, early posttransplantation HCV RNA viral load
Allograft
Prolonged rewarming time during allograft implantation
Year of transplant (recent year associated with rapid rate of progression)
Early posttransplant histological injury
Episodes of rejection
Drugs
High level of immunosuppression
Mycophenolate use
OKT3 use
Methylprednisone boluses
High cumulative steroid dose

Natural history of recurrent hepatitis C – rationale for treatment

If HCV infection is not eradicated before transplantation, reinfection occurs in essentially 100% of patients [321–323]. The rate of disease progression is variable, but approximately 25% will develop recurrent cirrhosis within 5 years of transplantation. In follow-up studies of 5 or more years, the outcomes for HCV-positive transplant recipients are worse than those for HCV-negative recipients, with a significant reduction in both patient and graft survival. The goals of HCV management in the transplant setting are primarily to prevent graft loss through recurrent disease. The treatment strategies differ in terms of the timing of the intervention:

- prophylactic therapy, starting at time of transplantation
- preemptive therapy, starting in the early posttransplant period
- treatment of established, often progressive, histological disease.

The latter approach has been the most commonly used. However, there is a lack of well-controlled studies of antiviral therapy for recurrent hepatitis C after liver transplantation to provide solid evidence-based medicine to support this approach. On the other hand, this strategy appears reasonable pending further data.

Prophylactic therapy

HBIG has been an effective means of preventing HBV reinfection following liver transplantation. A similar approach has been examined for HCV. There are indirect data from a cohort study of HBV–HCV coinfected patients that received HBIG (before screening of HCV donors) and had lower rates of recurrent HCV than those who did not receive HBIG [322,323]. Experiments in chimpanzees exposed to HCV and then treated with hepatitis C immunoglobulin (HCIG) found that antibody therapy could prevent or attenuate HCV infection. These studies provide the rationale for use of HCV antibodies to prevent HCV reinfection following transplantation. The studies to date suggest that HCV reinfection is not prevented by HCIG but higher dose therapy may modify the natural history of early posttransplant infection (lower ALT levels and less necroinflammation) [323]. Antibody therapy appears to be well tolerated so this form of therapy may be useful in the early posttransplant period as a bridge to other forms of therapy.

Preemptive antiviral therapy

Preemptive treatment of patients with chronic hepatitis C after liver transplantation before the development of histological recurrent disease makes sense. Studies have shown that preemptive IFN monotherapy can lead to the eradication of HCV infection posttransplantation, but tolerability of therapy has been a limiting factor. In a randomized study of 124 patients transplanted for HCV, only 51 (41%) were candidates for preemptive antiviral therapy by the eighth week posttransplant [324]. Patients with low pretransplant MELD and CTP scores and those who were live donor recipients were most suitable for early initiation of therapy. An SVR was achieved in only 18% receiving standard IFN or peginterferon plus ribavirin compared with 5% treated with monotherapy. In another randomized trial involving 60 patients treated with peginterferon alfa-2a monotherapy, only 8% achieved SVR. Clinical trials using preemptive IFN monotherapy, although generally positive, show only a modest benefit, with SVR rates from 5% to 39% [324–327]. Rates of response appear higher with combination therapy than with IFN monotherapy [326,328,329]. Both response rates and tolerability of therapy vary from study to study. Sicker patients are generally less able to tolerate early initiation of posttransplant antiviral therapy, and live donor liver transplant recipients may be good candidates for treatment.

At the present time, preemptive therapy cannot be recommended universally. If our ability to identify persons at risk for rapidly progressive disease improves, preemptive therapy may be useful in these patients as targeted therapy.

Treatment of established HCV disease

Study protocols for the treatment of established recurrent HCV disease have generally initiated treatment between 6 and 24 months after transplantation. The advantages of initiating treatment when recurrent disease is clinically or histologically apparent rather than as preemptive treatment include lower doses of immunosuppression (may enhance response to antiviral therapy), improved clinical status to better tolerate treatment, lower risk of acute rejection, and cost savings because only those with progressive disease are treated. Potential disadvantages of the "wait and treat recurrent disease" approach include higher viral load and more fibrosis, which may reduce the likelihood of response.

Most of the studies evaluating antiviral therapy for established recurrent HCV disease have been uncontrolled and of small sample size, and with variable IFN/ribavirin doses and treatment duration [330]. Reported SVR rates in IFN monotherapy studies, including peginterferon monotherapy, are more than 20%. Combination of standard IFN and ribavirin is associated with slightly higher rates of response (SVR rates 20%–30%) and the limited data available for peginterferon plus ribavirin report SVR rates of 30%–45%. Combination therapy with peginterferon plus ribavirin is therefore the treatment of choice.

Only two controlled studies have been reported, one with a combination of IFN and ribavirin and the other with peginterferon monotherapy [325,331]. Combination IFN and ribavirin resulted in SVR in 21% of treated patients compared with 0% of untreated controls. The response rates were lower with peginterferon monotherapy (12%) but still superior to untreated patients (0% response). Histological improvements were reported in both responders and nonresponders. Despite titrated regimens using low initial doses of peginterferon and ribavirin, dose reductions and discontinuations were frequent.

The optimal duration of treatment for recurrent HCV disease is unknown. In an immunosuppressed population of liver transplant recipients, longer treatment periods may be necessary to enhance SVR rates. Prolonged low-dose maintenance IFN is being evaluated in several clinical trials for its histological and clinical benefits in patients who fail to clear HCV after combination IFN and ribavirin therapy. This strategy needs to be evaluated in the transplant setting.

In summary, the treatment of recurrent HCV disease is focused primarily on the treatment of recurrent histological disease with hepatic fibrosis of stage 2 or beyond. Although large-scale and controlled studies are lacking, use of peginterferon plus ribavirin would appear to be the treatment of choice. Strategies to improve tolerability are needed because this would be predicted to increase response rates. Fortunately, the use of IFN or peginterferon has only rarely been

associated with precipitation of acute cellular rejection or chronic ductopenic rejection. Finally, this is a patient population for whom new antiviral agents with improved efficacy and tolerability are urgently needed.

Epidemiology

Drug-induced hepatotoxicity is a frequent cause of acute liver injury of exceptional severity, comprising more than 50% of all cases of acute liver failure (ALF) in the United States [1,2] (Fig. 83.1). Hepatotoxicity has been described for a large number of drugs [3], although the number of cases is low given the number of prescriptions written.

Different agents cause liver injury in different ways at different rates. Most reactions are directed against hepatocytes but biliary injury, as well as combined hepatocyte/biliary injury or damage to specific organelles (e.g., mitochondria), produce the different disease patterns observed. While some agents such as isoniazid cause liver injury in as many as 1 in 100 people and fatality in 1 in 10 000, other agents result in liver damage in only 1 in 50 000 or may never cause liver injury.

Few data on the epidemiology of drug-induced liver disease are available. A population-based study from France performed between 1997 and 2000 demonstrated an annual incidence of ~ 13.9 per 100 000 with significantly more cases found in people over 50 years of age [4]. Cases with a fatal outcome are more limited and most studies are subject to underreporting [5]. In developing parts of the world, drug-induced liver disease is much less common and related to very few drugs [6]. However, probably only a small fraction of actual cases are reported, and a true estimate of the incidence of drug-induced liver disease may be impossible to obtain. This is, in part, linked to the difficulty in establishing the diagnosis, as well as to inadequate reporting systems.

The exact number of drug-induced liver injuries per year in the United States is unknown, but the severity of many of these cases and the tragedy involved in a presumed preventable injury makes it imperative that all sensible precautions be taken to avoid such incidents.

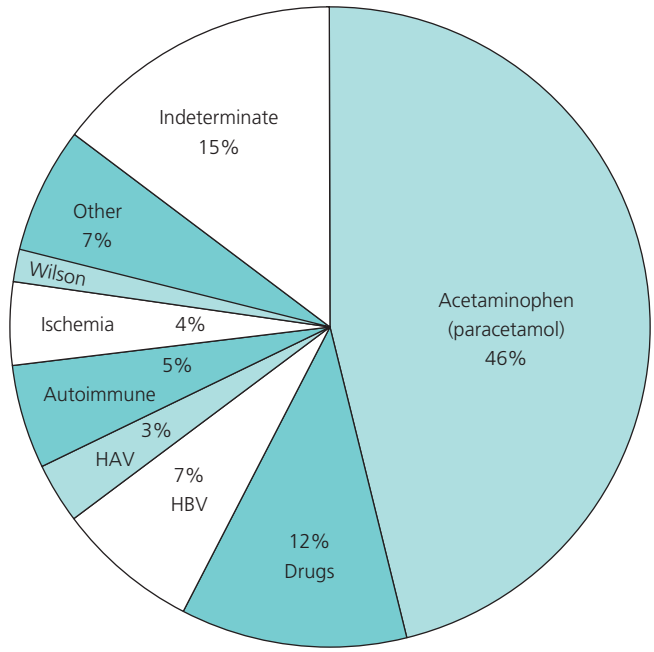

Figure 83.1 Number of cases of acute liver failure among 1033 patients grouped according to etiology in a multicenter study between 1998 and 2006 at 23 sites around the United States participating in the Acute Liver Failure Study Group. Acetaminophen and idiosyncratic drug reactions were the presumed cause in 594 (58%) cases of acute liver failure in this series.

Drug metabolism and mechanisms of hepatotoxicity

The liver, situated between the absorptive surface of the gastrointestinal tract and the target of drug effects throughout the body, is central to the metabolism of foreign substances.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

Since hepatocyte metabolism is required for virtually every drug, it is remarkable how seldom injury to liver cells occurs. Most drugs and xenobiotics cross the intestinal brush border because they are lipophilic. *Biotransformation* is the process whereby lipophilic therapeutic agents are rendered more hydrophilic by the hepatocyte, resulting in excretion of the drug in urine or bile. In most instances, biotransformation changes a nonpolar compound to a polar compound through several steps. Foremost is an oxidative pathway (e.g., hydroxylation) mediated by the cytochromes P450 (CYPs) [7]. This is typically followed by esterification to form sulfates and glucuronides, which results in the addition of highly polar groups to the hydroxyl group. These two enzymatic steps are referred to as phase I (P450 oxidation) and phase II (esterification). Other important metabolic pathways involve glutathione S-transferase, acetylating enzymes, and alcohol dehydrogenase, but the principal metabolic pathways for most pharmacological agents involve P450 and subsequent esterification.

The exact details of the pathogenesis of liver injury remain unclear for most drugs. A single drug may cause its toxic effects in several ways. An oversimplified approach suggests that high-energy unstable metabolites of the parent drug, the result of P450 activation, bind to cell proteins or DNA and disrupt cell function. Perhaps the best example is acetaminophen. Although used universally for nonnarcotic pain relief, acetaminophen taken in large quantities causes profound centrilobular necrosis [8]. The metabolic pathway for acetaminophen involves both phase I and phase II reactions, glutathione detoxification, and the formation of reactive intermediates (Fig. 83.2). Glucuronidation and sulfation occur as the initial detoxifying step because the parent compound contains a hydroxyl group. Since glucuronidation and sulfation capacity greatly exceeds daily needs, even patients with far-advanced liver disease continue to have adequate glucuronidation capacity, which explains why no obvious enhancement of toxicity is observed in patients with cirrhosis who are taking acetaminophen [9].

Enzyme polymorphism

The rarity of drug toxicity begs the question of how an infrequent event (1 in 10 000) occurs. Genetically variant CYP isoenzymes, such as are observed with the metabolism of debrisoquine, partially explain the observed individual variation in responses to drugs. Debrisoquine is an antihypertensive drug marketed in Europe that is hydroxylated by CYP2D6, an isoform that is totally lacking in 5% of healthy individuals, greatly prolonging the half-life of the parent compound in affected individuals [10]. Fast and slow acetylator patterns affect whole races, and have been implicated in isoniazid metabolism, which includes an acetylation step [11]. Genetic variants, which occur relatively frequently, cannot explain the formation of a toxic intermediate in only a rare individual. While there might be other metabolic variant P450

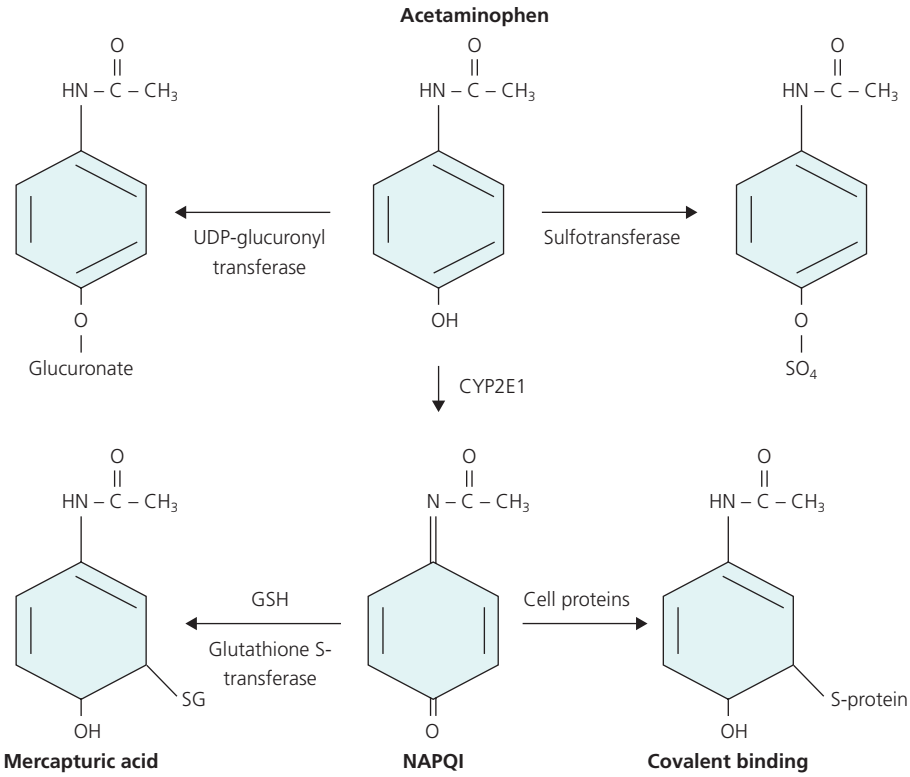

Figure 83.2 Metabolic pathway for acetaminophen. CYP2E1, cytochrome P2E1; NAPQI, *N*-acetyl-p-benzoquinoneimine.

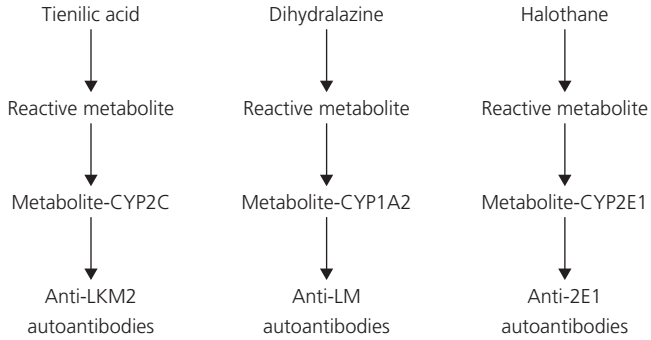

Figure 83.3 Modification of host P450 enzymes renders them immunogenic. Autoantibodies can be detected, which recognize the enzyme–metabolite adducts and the enzyme itself. CYP1A2, cytochrome P1A2; Adapted from Robin et al. [12].

species that are even rarer, little evidence for these has been found in affected patients. Other explanations are necessary.

Most drugs are small organic compounds that are unlikely to evoke an immune response. While some toxic drug reactions are associated with an obvious allergic response, most are not. Nevertheless, immune mechanisms not associated with systemic allergic immunoglobulin E (IgE) reactions or skin hypersensitivity might be involved. Studies suggest that the products of CYP metabolism, the highly reactive intermediates formed within the microsomes, covalently bind to the enzyme itself to form a drug–hapten adduct that disables the enzyme and injures the cell [12]. Haptenization then evokes an immune response directed against the newly formed antigen or neoantigen. P450s have been shown to traffic to the plasma membrane allowing the P450–drug adduct to become the target of a subsequent cytolytic attack (Fig. 83.3). Whether these adducts or smaller peptides that are processed and presented by way of the major histocompatibility complex class I and class II schemes are the targets remains unclear. Still, the association of neoantigens, autoantibodies, and hepatotoxic drugs implicates an immunological mechanism.

Whether the drug causes significant cell necrosis or not, the P450–drug adducts can evoke the immune response. Any subsequent P450–drug adduct present on the hepatocyte surface would evoke a further response. Responses may be antibody-mediated or occur from direct cytolytic attack by primed T cells [12,13] (Fig. 83.4).

Such a combined toxic/immunological mechanism is involved in the liver injury caused by halothane. Halothane was a widely used fluorinated hydrocarbon anesthetic that causes severe, often fatal, liver injury after multiple exposures [13]. Other fluorinated hydrocarbons also occasionally produce the same response [14–16]. While halothane has never been withdrawn, its use has been limited by the advent of safer agents. Both direct cytotoxicity and immune-mediated toxicity are observed in keeping with the clinical observations that severe halothane toxicity occurs with repeat exposures. Still, evidence of injury can usually be identified

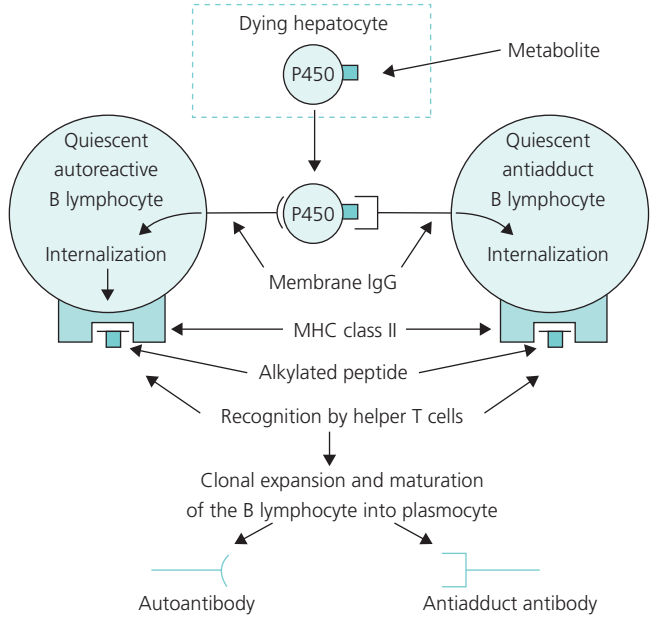

Figure 83.4 Possible models of liver injury due to drugs. Direct toxicity may play a role but immune mechanisms are also operative. In this model, rechallenge or continuing to receive the same drug would simply elicit a preformed cytolytic response. IgG, immunoglobulin G; MHC, major histocompatibility complex. From Robin et al. [12], with permission from Elsevier.

within a week of the first exposure. As befits an immune reaction, the interval to toxicity is shortened and the damage is more severe with each successive exposure.

Specific genetically determined components of the immune response might be important. For example, the binding of peptides for antigen presentation depends on human leukocyte antigen (HLA) configurations that are genetically determined. This variation among individuals is thought to underlie the diverse responses observed in patients encountering the hepatitis B virus. The highly variable severity of reactions observed depends on the fit of antigen peptides in the HLA groove. A specific HLA haplotype has been associated with amoxicillin–clavulanate-induced hepatitis, being found in 57.1% of patients compared with 11.7% of controls [17]. Polymorphisms have also been identified for the interleukin-10 (IL-10) promoter and for tumor necrosis factor-α (TNF-α). These variations in immune responsiveness could modulate the severity of the responses observed. For example, different IL-10 promoter phenotypes are recognized. A C-to-A substitution at position 627 is linked to severe asthma and, by inhibiting IL-10 secretion, an up-regulation of T helper type 2 immune reactions. This same phenotype has been linked to hepatitis C-related liver injury and to the severity of alcoholic liver injury [18,19]. Variant TNF-α phenotypic expression has been implicated in determining the severity of drug reactions related to acetaminophen [20]. A multistep, immune-based mechanism would best explain both the rarity of idiosyncratic reactions, and their severity,

Table 83.1 Factors influencing the metabolic fate of drugs

Age: drug reactions appear to impact the elderly more often, P450s vary [127]. Adults more susceptible than children in some scenarios (acetaminophen, halothane, isoniazid) and less susceptible in others (e.g., aspirin, valproic acid)
Gender: females are more prone to drug reactions statistically, mechanism unknown
Size/weight: effects on women relate to intrinsic gender differences but also to size
Pregnancy: effects of drugs in pregnancy have been poorly studied
Preexisting liver disease: hepatic disease may *protect* against idiosyncratic reactions and may enhance toxicity in dose-dependent hepatotoxins (such as acetaminophen) [131]
Renal disease: slowed disappearance of parent compound yields higher concentrations and affects P450 [132]. Tetracycline toxicity is enhanced in renal disease
Certain foods: grapefruit has an unknown substance that interferes with metabolism [133–135]
Concomitant drugs: drug–drug interactions are common causes of adverse effects (e.g., valproate and chlorpromazine together lead to enhanced cholestasis).
Genetic factors: enzyme polymorphisms (e.g., enhanced phenytoin liver disease in patients with defective epoxide hydrolase activity), human leukocyte antigen phenotypes (nitrofurantoin susceptibility).

as well as the findings of mild, nonprogressive liver injury in some patients – those with "protective" phenotypes. Recent studies suggest that, for specific agents, genetic markers can be identified that associate with the toxic reaction. Such pharmacogenomic observations may bear fruit, particularly for high-risk drugs [21]. While an immunological explanation for many reactions is plausible, the exact mechanism to account for most drug reactions remains obscure. Both cell necrosis and apoptosis have been recognized, and sinusoidal lining cells as well as Kupffer cells are part of the process [22].

There should be little doubt that the metabolic fate of any compound is a complex process. There are other important environmental and host variables outlined in Table 83.1. Often multiple factors are at play simultaneously, including drug interactions, either induction or competition. Common inducing agents include ethanol, phenobarbital, and phenytoin, but cigarette smoke is also a potent inducer of certain P450 species. Induction or substrate competition for available enzyme may not result in hepatotoxicity but strongly impacts plasma drug levels. For example, the effect of ketoconazole on enhancing cyclosporin levels is the result of induction [23], whereas competitive inhibition by ketoconazole increases serum levels of astemizole (Hismanal) with resulting torsades de pointes [24].

Other mechanisms

In drug-induced cholestasis, disruption of specific transport proteins, or processes in hepatocytes or cholangiocytes may be the event that results in cholestasis. Bile salt transport from plasma into the hepatocytes is provided for by two basolateral (sinusoidal) transport systems: the sodium-taurocholate cotransporter, and the organic-anion transporting polypeptide, whereas several canalicular export pumps have been identified [25]. Estrogen may cause multiple canalicular membrane transport changes [26], affecting, among others, the canalicular bile salt pump [27].

Uncoupling or inhibition of mitochondrial respiration may in some instances lead to microvesicular steatosis [28]. Mitochondrial β-oxidation of fatty acids is impaired and this may decrease the cellular energy supply leading to severe liver dysfunction. The mitochondrial β-oxidation may be affected either directly or by impairment of mitochondrial respiration [29].

Drug-induced liver injury may be modulated and enhanced by inflammatory mediators that may trigger hepatocyte apoptosis [30]. Hepatocyte apoptosis is complex and may be controlled by the intracellular energy status [31,32] and by the redox state of the cell [33]. How the specific drugs involved in hepatotoxicity affect hepatocyte apoptosis remains to be studied.

As noted above, new techniques of pharmacogenomics may be helpful in predicting an individual's risk of hepatotoxicity for a given drug based on the discovery of genetic susceptibility profiles associated with liver injury [34].

Classification of hepatotoxic agents

Two main categories of drugs can produce liver disease. One group consists of intrinsic (predictable) drugs, whereas a second group consists of idiosyncratic (unpredictable) drugs. Unfortunately, the vast majority of drugs involved in liver disease belong to the idiosyncratic, and so unpredictable, group.

Intrinsic (dose-dependent) agents

Hepatotoxins of this group produce liver disease in most patients in a dose-related fashion if toxic amounts of the drug are ingested. Furthermore, similar lesions can often be found in animal models [35]. Hepatotoxicity may be caused by the drug itself or, most frequently, by toxic effects of its metabolites. Table 83.2 provides a list of known dose-dependent drugs.

Until recently, occupational hepatotoxic agents, such as carbon tetrachloride [36] and yellow phosphorus [37], were frequently encountered. Since 1980, however, these agents have rarely been seen. Instead, acetaminophen (paracetamol) has emerged as the most dominant intrinsic hepatotoxic drug. Taken in small doses (4 g or less per day) acetaminophen is an extremely safe drug. However, its therapeutic index is low because as little as 10–12 g may cause extensive hepatic necrosis [38,39].

In acetaminophen metabolism, the phase II reactions predominate, with only a small fraction of acetaminophen meta-

Table 83.2 Drugs/toxins in which a dose–response effect is observed

Drug	Response
Acetaminophen	Total dose, single versus multiple time points
Amiodarone	Total dose over time
Bromfenac	Toxicity only occurs after extended use
Cocaine	Dose-related vascular collapse
Cyclophosphamide	Dose-related, worse with previous ALT elevations
Cyclosporine	Cholestasis with toxic blood levels, CYP3A phenotype
Methotrexate	Aminotransferase/fibrosis; single dose/total dose
Niacin	Large doses yield vascular collapse
Oral contraceptives	Prolonged usage yields hepatic adenomas
Tetracycline	Total dose, renal dysfunction
Toxins (yellow phosphorus, carbon tetrachloride, amanita toxin, bacterial toxins)	Total dose

ALT, alanine aminotransferase; CYP3A, cytochrome P3A.

bolized by CYP450, until the quantity of acetaminophen exceeds phase II capacity, at which point significant amounts of a toxic intermediate, *N*-acetyl-p-benzoquinoneimine (NAPQI), are formed, primarily through CYP2E1 (see Fig. 83.2) [40,41]. NAPQI binds covalently to cell macromolecules disrupting mitochondrial and nuclear function [35]. Nitrotyrosine residues can be detected by immunohistochemistry as evidence of oxidative stress in the livers of patients (or experimental animals) demonstrating toxicity [42]. These residues are formed by the rapid reaction of superoxide and nitric oxide (formed by the Kupffer cells) to form peroxynitrite, unless covalent bonding of NAPQI is prevented by its conjugation (via glutathione-S-transferase) to form mercapturic acid, a harmless water-soluble product excreted by the kidney [43]. Depletion of glutathione lowers this last defense against the formation of NAPQI-related intracellular adducts. Starvation and chronic alcohol intake by depleting glutathione enhance toxic injury [44–48], whereas *N*-acetylcysteine, by replenishing glutathione, protects against acetaminophen-induced injury [49]. This direct toxic reaction occurs predictably in all individuals and is not an allergic reaction. The final step leading to cell death remains unclear but may involve an increase in levels of cytosolic calcium altering the cytoskeleton and membrane integrity, leading to "blebbing" of the cell membrane and loss of its integrity [50]. Dose-related necrosis (lysis) of hepatocytes occurs but apoptotic pathways are also implicated. A finding that peroxisomal proliferator activation prevents the liver injury associated with acetaminophen links this liver damage to apoptosis but does not preclude a combined necrosis/apoptosis effect [51,52].

Acetaminophen overdose is the most common cause of acute liver failure with hepatic encephalopathy in several Western countries including the United Kingdom and the United States [39,53,54]. Although the prognosis for acetaminophen-induced acute liver failure is relatively good, with a spontaneous survival (i.e., survival without liver transplantation) of approximately 57% [1]. It is still the leading cause of fatal acute liver failure in the United States [2].

Except for acetaminophen-induced liver disease, intrinsic drug cases are rare.

Idiosyncratic reactions

While acetaminophen is a dose-related toxin, most drug reactions are idiosyncratic, occurring from 1 in 1000 to 1 in 50 000 patients. The etymology of "idiosyncratic" from the Greek loosely translated is "the unique composite of the self" – the particular features of a given individual. This places the emphasis appropriately on the patient's characteristics rather than on the drug itself. Idiosyncratic reactions are not the result of the drug itself because almost everyone can tolerate them, but of something unique about the patient who ingests them and has a toxic reaction. Theories abound to explain these reactions. Any theory of pathogenesis must "explain" the features shown in Table 83.3. The proportion of drug-induced liver disease varies greatly among drug classes as evidence of class effect. Nonsteroidal agents, antibiotics, and anticonvulsants are highly associated with drug-induced liver disease, whereas hormones, antihypertensive drugs, digoxin, and antiarrhythmic drugs are rarely associated. Idiosyncratic reactions occur in small numbers such that some drugs continue to be used when usefulness or uniqueness makes the risk acceptable. Isoniazid is such a drug, virtually the only drug implicated in developing countries, where drug-induced liver injury is otherwise unheard of [55]. Some 15%–20% of individuals receiving isoniazid as a single agent for tuberculosis prophylaxis may develop increased transaminases, but these usually stabilize or improve, so that less

Table 83.3 Idiosyncratic drug reactions

1. Occur rarely
2. A pattern consistent for each drug
3. When similar drugs exhibit similar features, called "class effects"
4. Individual drugs in a class still vary considerably
5. Reactions occur at varying time intervals after first ingestion
6. Reactions vary in severity, but typically severe and fatal if drug continued
7. Mild injury can sometimes disappear with continued use
8. Rarity of most reactions suggests possibility of multiple hits
9. Rechallenge is often met with greater severity, shorter latency

than 1% may develop severe hepatic necrosis [56]. More recently, a lower estimate of severe liver injury of 1 in 1000 has been given for isoniazid from a large tuberculosis public-health clinic [57], because 11 of 11 141 patients developed isoniazid-induced liver disease. This is still a high rate of injury compared to other idiosyncratic drug reactions but the usefulness of the drug has precluded its withdrawal.

Aside from isoniazid, nonsteroidal analgesics may be the most commonly associated drug class capable of inducing idiosyncratic reactions [58]. The newer cyclooxygenase-2 (COX-2) inhibitors have been implicated [59,60]. It is important to recognize that certain classes, principally antibiotics and nonsteroidal antiinflammatory drugs (NSAIDs), are known to be associated with toxic injury whereas for others an association is much less likely.

Adaptation

It has been recognized that many drugs that cause rare idiosyncratic reactions are associated with more frequent aminotransferase elevations that are limited and resolve even if administration of the suspected agent continues [61]. This was known to be true for isoniazid but is recognized as a common feature of the cholesterol-lowering "statin" drugs. How this nascent liver injury is aborted or modulated by the host remains unclear. An interesting correlate is that acetaminophen appears to cause significant aminotransferase elevations in up to 40% of users within the first 2 weeks, if they take the recommended maximum of 4 g/day [62].

Types of drug reactions, clinical pictures

While most liver injury involves direct hepatocyte necrosis/apoptosis, some drugs primarily injure the bile ducts or canaliculi, causing cholestasis without significant hepatocyte damage. Others affect sinusoidal cells or present a particular pattern of liver injury affecting multiple cell types (mixed type). In a rough way, drug reactions can be grouped as hepatocellular, cholestatic or mixed, but these are only general terms and do not apply to all circumstances. An additional way to categorize drug reactions emphasizes the histological changes involved as well as the cell type (Table 83.4).

Table 83.4 Types of drug reactions, with examples

Hepatocellular: isoniazid, trazodone, diclofenac, nefazodone, venlafaxine, lovastatin
Cholestatic: chlorpromazine, estrogen, erythromycin
Mixed: amoxicillin/clavulanate, carbamazepine, herbs, cyclosporin, methimazole
Immunoallergic: halothane, phenytoin, sulfamethoxazole
Granulomatous: allopurinol, diltiazem, nitrofurantoin, quinidine, sulfa drugs
Steatohepatitis: amiodarone, perhexiline maleate, tamoxifen
Autoimmune: nitrofurantoin, methyldopa, lovastatin
Fibrosis: methotrexate, vitamin A excess
Vascular collapse: nicotinic acid, cocaine, ecstasy
Venoocclusive disease: busulfan, herbal medicines

A distinction between the various types of liver injury can be made based on the liver tests for alanine aminotransferase (ALT) and alkaline phosphatase (AP) [63]. The liver injury is considered *hepatocellular* when ALT alone is more than twice the upper limit of normal (ULN) range, or when the ratio (ALT/ULN) : (AP/ULN) is greater than or equal to 5. The liver injury is termed *cholestatic* if AP alone is more than twice the ULN, whereas the term *mixed* designates a situation in which both ALT and AP are more than twice the ULN and the ALT/ULN : AP/ULN ratio is between 2 and 5.

Hepatocellular reactions

Hepatocellular reactions are the most common type of drug-induced liver disease, constituting up to 90% of cases [64]. They are characterized by a hepatocellular pattern of serum liver tests, as defined above. Many drugs have been implicated in hepatocellular type drug-induced liver disease (Table 83.5). Usually, improvement occurs quickly after discontinuation of the drug (1–2 months), and only a few patients develop fulminant, acute liver failure with hepatic encephalopathy [65].

Histological findings include necrosis and cellular infiltration. Necrosis may be zonal (e.g., acetaminophen-induced or

Table 83.5 Agents that may cause liver injury of hepatocellular type

Trazodone
Venlafaxine

CCl_4-induced) or diffuse (e.g., halothane-induced), and the inflammatory response consists of lymphocytes or eosinophils. Massive necrosis may cause acute liver failure and death – the exact quantity of remaining hepatocytes necessary to support life has not been established [8].

Acetaminophen has been the best-understood example of direct hepatocyte toxicity. Liver injury occurs predictably after intentional suicidal overdose [54], and during the unintentional "therapeutic misadventure," in which acetaminophen used in therapeutic or excessive doses for pain relief leads to severe liver injury [44,66]. Enhanced toxicity occurs as a result of the enzyme induction and glutathione depletion by alcohol as well as of fasting as outlined previously [45]. Acetaminophen toxicity is the most common form of acute liver failure observed in the United States [2]. In a medical record review from an urban county hospital in the United States, 71 patients admitted in a 39-month period had actual or *potential* hepatotoxicity due to acetaminophen [53]. Those who ingested acetaminophen accidentally, without suicidal intent, fared worse because they presented for treatment late, and did not realize that they had done anything harmful. This group was more likely to develop severe liver injury and to die from the episode. By contrast, those with suicidal intent took larger doses, presented to a hospital earlier, and received *N*-acetylcysteine, an effective antidote. One-fifth of the suicidal cases had severe injury and the potential for a fatal outcome should not be underestimated. Key features in the accidental group were excessive chronic alcohol intake (usually more than six drinks daily), and the use of acetaminophen for a specific pain problem, but generally exceeding the package recommendations. The extremely elevated aminotransferase values (often greater than 6000 IU/L and sometimes as high as 30 000 IU/L) observed in suicidal and accidental acetaminophen ingestion help to distinguish these cases from viral hepatitis or other drug injury [53]. *N*-Acetylcysteine should be given by nasogastric tube on admission, and for the ensuing 72 h, to provide glutathione substrate. In Europe, intravenous *N*-acetylcysteine is the standard treatment [39]. Expected survival is greater than 80%, although transplantation is occasionally indicated. The incidence of acetaminophen poisoning varies widely throughout the world, but it is becoming more frequent and widespread as indicated by a report from Taiwan [67]. Acetaminophen poisoning is an increasing cause of ALF in children [68–70]. As in adults, two forms are seen: teenagers may overdose with suicidal intent but more ominous are instances of inappropriate overdosing of acetaminophen in small infants because of the parents' ignorance of the high risks involved.

The US Acute Liver Failure Study Group, a national registry established in 1998, reviewed the experience with 275 patients who developed ALF defined as altered mentation and coagulopathy, as a result of acetaminophen toxicity [54,71]. The majority (79%) were women, although the gender breakdown for other etiological categories of ALF is similar, and accidental overdose comprised 48% of patients, compared to 44% who were considered suicides; for 8% the type of overdose could not be determined. More than one-third of patients ingested more than one acetaminophen-containing compound simultaneously. Two-thirds of the unintentional overdose patients were taking a narcotic-containing acetaminophen compound. Both these observations suggest that patients are frequently unaware of the potential for toxicity or even of what is contained in the preparations they are using.

One advance in our understanding that may be useful clinically is the recognition that the reactive metabolite of acetaminophen bound to cell proteins can be measured reliably in plasma from patients with acetaminophen toxicity. This can be of value in cases where no history of overdose is given [72]. Acetaminophen adducts bound to the sulfhydryl group of cell proteins are found in serum in a pattern similar to aminotransferase levels, long after the parent acetaminophen compound has been metabolized. The presence of adducts is a sensitive and specific biomarker test for liver injury due to acetaminophen and it can identify adult as well as pediatric patients who were not previously suspected of being the result of acetaminophen overdose.

Cholestatic reactions

Cholestatic reactions have been described for a number of drugs, some of which are listed in Table 83.6. Cholestasis is best defined as a failure of bile to reach the duodenum [73], and common symptoms are jaundice and pruritus. *Pure cholestasis* with no signs of hepatocellular necrosis is almost exclusively seen in patients taking oral contraceptives, anabolic steroids, or sex hormone antagonists such as tamoxifen [74].

Table 83.6 Drugs involved in cholestatic drug reactions

Pure cholestasis	Anabolic steroids
	Tamoxifen
	Estrogens
Cholestatic hepatitis	Allopurinol
	Amoxicillin/clavulanate
	Azathioprine
	Barbiturates
	Captopril
	Carbamazepine
	Chaparral (herbal)
	Chlorpromazine
	Clindamycin
	Erythromycin
	Flucloxacillin
	Gold salts
	Phenytoin
	Ticlopidine
	Trimethoprim-sulfamethoxazole

Acute *cholestatic hepatitis* is histologically characterized by cholestasis (dilated canaliculi, brown granules in the cytoplasm of hepatocytes) and some degree of liver cell necrosis as well as bile duct injury and inflammatory infiltration with polymorphonuclear leukocytes. Drugs related to this type of reaction include carbamazepine [75], trimethoprim-sulfamethoxazole [76], captopril [77], and ticlopidine [78].

Generally, drug-induced cholestasis needs a longer time to resolve than the hepatocellular type of drug reactions [3]. In some instances progressive destruction of segments of the intrahepatic biliary tree may occur, the so-called *vanishing bile duct syndrome* [79] that occurs after a protracted course (more than 6 months) of drug-induced cholestasis. The result is a state of chronic cholestasis, resembling primary biliary cirrhosis [80]. Approximately 30 drugs have so far been implicated in the vanishing bile duct syndrome, including chlorpromazine [81] and ajmaline [82].

A sclerosing cholangitis-like syndrome with jaundice caused by intrahepatic and extrahepatic strictures of the bile ducts is sometimes observed in patients receiving intra-arterial floxuridine chemotherapy for hepatic metastases of colorectal cancer [83].

Immunoallergic reactions

Drugs may be associated with reactions that are definitely allergic in nature. Hypersensitivity reactions such as fever, eosinophilia, or rash are common. Halothane induces fever, eosinophilia, and antimitochondrial antibodies [13]. Halothane was formerly widely used as an inhalation anesthetic. However, it has been implicated in a high number of very severe cases of liver disease [84]. Halothane causes a hepatocellular injury as evidenced by findings of necrosis – ranging from spotty necrosis to bridging hepatic necrosis and multilobular necrosis – in liver biopsies [85].

Phenytoin (Dilantin) induces the simultaneous onset of fever, rash, lymphadenopathy, or eosinophilia [86]. The mechanisms responsible for the combined allergic and hepatotoxic reaction are unknown, but the slow resolution of the illness suggests that the allergen remains on the hepatocyte surface for weeks or months. With phenytoin, a mononucleosis-like picture may also be seen and is frequently confused with a viral illness or streptococcal pharyngitis [87]. When the offending agent is not discontinued promptly, despite signs of developing hepatitis, a severe Stevens–Johnson drug eruption and prolonged fever may result [88]. As with any therapeutic agent, rapid recognition of the presence of a toxic drug reaction and immediate discontinuation of the compound are the keys to limiting hepatic damage. It is important to remember that features of an allergic reaction may not be obvious. Even in the absence of systemic signs of allergy, eosinophilia or granulomas may be present on liver biopsy.

Sulindac is an NSAID that causes immunoallergic liver disease with a cholestatic pattern of injury in two-thirds of liver injury cases [89]. Sulindac may also cause hepatocellular liver injury and is more frequently implicated in drug-induced liver disease than other NSAIDs, such as ibuprofen.

Steatohepatitis

Steatosis in the liver can be present either in a microvesicular or in a macrovesicular pattern. Macrovesicular steatosis is the most common form and is histologically characterized by hepatocytes containing a single vacuole of fat filling up the hepatocyte and displacing the nucleus to the cell's periphery [28]. Macrovesicular steatosis is typically caused by alcohol, diabetes, or obesity. Sometimes drugs such as corticosteroids or methotrexate may cause these hepatic changes [90].

In microvesicular steatosis, hepatocytes contain numerous small fat vesicles, not displacing the nucleus [28]. These lesions are associated with disruption of mitochondrial DNA with resulting anaerobic metabolism leading to lactic acidosis in the most severe cases. Not uncommonly, macrovesicular and microvesicular lesions are observed concomitantly and in these cases the microvesicular lesions should be given more attention because they are associated with a more severe prognosis [29]. Hepatocellular necrosis may also be present. Acute fatty liver of pregnancy [91] and Reye syndrome [92] are two examples of severe liver diseases caused by microvesicular steatosis.

Drugs involved in microvesicular steatosis include valproate [93], tetracycline [94], fialuridine [95] (Table 83.7). Use of aspirin in children has been associated with Reye syndrome [96] and the incidence of Reye syndrome has decreased since warnings concerning aspirin use in children were issued [97]. The exact causal relationship between aspirin and microvesicular steatosis remains to be studied [92]. A relatively new situation is that of considering the impact of drugs such as the cholesterol-lowering "statins" in the setting of known fatty liver disease caused by the metabolic syndrome. Although these agents may be associated with elevations in aminotransferase levels, they appear to be remarkably safe and can be used without monitoring liver enzyme levels in patients with or without fatty liver disease [98].

Other drug reactions

There are several other types of drug reactions involving the liver that are of lesser importance in terms of number and severity. These include granulomatous reactions, fibrosis,

Table 83.7 Agents that may cause microvesicular steatosis of the liver

Aspirin
Ethionine
Fialuridine
Nucleoside analogues
Valproic acid
Tetracycline (intravenous administration)
Troglitazone

ischemic injury, and chronic autoimmune liver injury (see Table 83.4). The type of reaction observed can be helpful in determining the probable agent because most drugs have a specific injury profile.

A pattern of venoocclusive disease with obliteration of small intrahepatic veins, sinusoidal congestion, and necrosis is frequently observed in patients receiving chemotherapy (e.g., busulfan) following bone marrow transplant [99–101]. Symptoms include rapidly accumulating ascites, painful hepatomegaly, and jaundice occurring shortly after the conditioning regimen has been instituted. Rarely, herbal medicines may cause venoocclusive disease [102].

Treatment

Prompt discontinuation of a suspected drug is mandatory. General supportive therapy may be necessary according to the state of the patient, ranging from none through intravenous fluid replacement to the intensive monitoring and treatment of patients with acute liver failure with hepatic encephalopathy [63,103,104]. Liver transplantation is performed in more than 50% of patients with idiosyncratic drug-induced acute liver failure because spontaneous survival in this setting is less than 20% [1].

Criteria for causal assessment of drug-induced liver injury

How do we decide whether a certain drug is responsible for the liver disease encountered in a certain patient? It is important to understand that we are always trying to assess a possible association from the *past*, unlike most other scoring models that try to predict the *future* [105]. A standardized reporting form developed by an international panel working in France provides a worthwhile causality assessment scoring system [61], called the RUCAM (*R*oussel *U*claf *c*ausality *a*ssessment *m*ethod) (Table 83.8). These guidelines outline the steps that an experienced clinician uses to assess the likelihood of drug reactions [106]. Causality assessment methods typically include temporal relationship, course after cessation of drug, risk factors, concomitant drugs, a search for nondrug causes (viral hepatitis), previous information concerning the drug, and response to rechallenge, which is usually not available. Validation of the RUCAM scoring system suggests that a RUCAM score could be classified as *highly probable* (RUCAM score > 8), *probable* (score 6–8), *possible* (score 3–5), *unlikely* (score 1–2), or *excluded* (score ≤ 0) [107].

A newer model called the clinical diagnostic scale (CDS) was developed in Portugal [108] and tested in the United Kingdom [109]. Features from the CDS include most of the features from the RUCAM plus extrahepatic manifestations such as rash, fever, arthralgia, cytopenia, and eosinophilia [108]. The British study suggests using a CDS score of 9 or more as a strong indicator of drug-induced liver disease [109]. However, a recent Spanish comparison study in 215 patients suggested that the RUCAM system is more accurate than the CDS model [110].

Lessons from drugs withdrawn from the market

Two drugs withdrawn because of severe and fatal liver injury were bromfenac and troglitazone. There are important lessons to be learned from each one, illustrating the difficult issues surrounding drug-induced liver injury. NSAIDs as a class have been associated with considerable hepatotoxicity [111,112]. Bromfenac was an NSAID marketed as Duract, and introduced in 1997 as a short-term analgesic for orthopedic pain. Aminotransferase elevations had been noted during clinical testing of bromfenac, but no instances of severe toxicity had been reported. However, increased aminotransferases were associated with longer use, although the total number of patients undergoing long-term treatment was small. No instances of ALF were observed, but fewer than 1000 patients were studied. There were concerns that long-term use might be hazardous so approval was given with the limitation that the drug should only be used for intervals of 10 days or less. Once released, bromfenac was associated with more than 50 cases of severe liver injury and the drug was withdrawn in June 1998. All patients in whom toxicity was observed had been taking the drug for more than 8 weeks [113,114]. With hindsight, a drug that effectively relieved pain would not be prescribed or used reliably only for a 10-day period. The risk to benefit ratio must be an important consideration in the approval process for any new drug – bromfenac offered little that was new and on that basis should have met an even stricter test for safety.

Troglitazone (Rezulin) was approved by the US Food and Drug Administration (FDA) in January 1997, the first of a new class of compounds, the thiazolidinediones. As an agonist of the nuclear regulatory factor peroxisomal proliferator activator receptor-γ (PPAR-γ), troglitazone reduces insulin resistance and increases insulin-stimulated glucose disposal, resulting in improved glycemic control for patients with type II diabetes. In clinical trials, reversible elevations of aminotransferase levels were observed, occasionally reaching more than eight times the ULN but, again, no examples of ALF. However, once the drug was approved, several reports of severe and fatal liver injury appeared [115–118]. Troglitazone has a variable time frame for demonstrating toxicity, from a few days to several months [119]. The pathogenesis is not understood. Unlike bromfenac, troglitazone was not immediately removed. As a new agent, its benefits were initially thought to outweigh the risks. The drug was recalled in the United Kingdom in 1999. The renewed warning in the package

Table 83.8 Scoring system for assessing causality for hepatocellular types of reactions: a positive score of 6 or more represents a strong causal relationship

Temporal relationship of start of drug to start of illness	
Initial treatment 5–90 days; subsequent treatment course: 1–15 days	+2
Initial treatment < 5 or > 90 days; subsequent treatment course: > 15 days	+1
From cessation of drug: ≤ 15 days[a]	+1
Course	
ALT decreases ≥ 50% from peak within 8 days	+3
ALT decreases ≥ 50% from peak within 30 days	+2
If the drug is continued, inconclusive	0
Risk factors	
Alcohol[b]	+1
No alcohol[b]	0
Age ≥ 55 years	+1
Age < 55 years	0
Concomitant drug	
Concomitant drug with suggestive time of onset	–1
Concomitant drug known hepatotoxin with suggestive time of onset	–2
Concomitant drug with further evidence of involvement (e.g., rechallenge)	–3
Nondrug causes: six are primary: hepatitis A, B, or C, biliary obstruction, alcoholism (AST ≥ 2 × ALT), recent hypotension (heart disease).	
Secondary group: underlying other disease; possible CMV, EBV or HSV infection	
In this category, all causes ruled out	+2
Four or five causes ruled out	+1
Fewer than four causes ruled out	–2
Nondrug cause highly probable	–3
Previous information on hepatotoxicity of the drug in question	
Package insert mention	+2
Published case reports but not in package label	+1
Reaction unknown	0
Rechallenge	
Positive (ALT doubles with drug alone)[c]	+2
Compatible (ALT doubles, compounding features)[c]	+1
Negative (increase in ALT but ≤ 2 × ULN)[c]	–2
Not done	0

For cholestatic reactions:
a ≤ 30 days
b alcohol or pregnancy
c read alkaline phosphatase (or total bilirubin) instead of ALT.
ALT, alanine aminotransferase; AST, aspartate aminotransferase; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HSV, herpes simplex virus; ULN, upper limit of normal.
Adapted from Danan and Benichou [106] and Benichou et al. [107].

insert (in a black box) mandated monthly monitoring during the first 6 months of use. However, the number (> 90) and severity (68 fatal, 10 transplanted) of these cases, as well as doubts over the efficacy of monitoring, led to drug withdrawal in 2000, 3 years after its approval. A factor in the FDA decision was the arrival of two new PPAR-γ agonists, rosiglitazone (Avandia) and pioglitazone (Actos), approved, respectively, in May and July 1999. Although of the same class, these agents do not seem to have the same degree of toxicity. So far, neither drug has shown the 1 : 50 000 incidence of severe hepatotoxicity seen with troglitazone. Although there may be intrinsic differences in the drugs, more careful screening of patients by physicians, monitoring of ALT levels, and early discontinuation of the drug in moderately severe cases may play a part in limiting the severe toxicity associated with this class of drugs [119]. Two drugs found to have significant toxicity were ximelagatran (Exanta) and telithromycin (Ketek). The first was licensed in Europe as a thrombin inhibitor that would work in a similar way to warfarin. Unfortunately, aminotransferase elevations were observed in 7.9% of patients in preapproval trials and examples of toxicity were observed as long as several weeks after

the drug had been discontinued – approval was denied in the United States and the sponsor withdrew the drug from the European market [120]. Ketek was approved in the United States and Europe in 2004 as the first in a new class of antibiotics, the ketolides; they have activity against penicillin-resistant and erythromycin-resistant pneumococci. After more than 50 reports of serious liver injury, the drug has been given more severe restrictions on its use and is to be used only as a "second-tier" drug [121,122].

The drug approval process

How can new drugs get through the drug approval process and still lead to so many deaths that they are ultimately withdrawn? In brief, drug development is divided into three stages: initial research and development, clinical testing for new drug application (NDA), and the postmarketing experience.

Research and development

The initial stage of drug development includes drug discovery and initial testing for efficacy or toxicity in animals or in vitro model systems. Most new compounds fail to make it through this stage, either because of toxicity or lack of efficacy. Compounds may be "discovered" in several ways: synthesized to resemble previous compounds, discovered in the field by purification of naturally occurring peptides (e.g., cyclosporin A), or generated by computer modeling. A compound shown to have a desirable effect in vitro or in vivo then undergoes extensive preclinical testing in a variety of animals using doses up to 50 times that predicted to be useful in humans to ascertain the types of toxicity that might be expected. While metabolic pathways differ in some specific aspects, the similarities between lower mammals and humans are notable. Animals are euthanized after short-term experiments and all their organs are examined; those dying during experiments undergo necropsy to determine the cause of death. Long-term exposure studies are performed looking for carcinogenicity or other delayed effects. Preclinical testing, which may take 5–6 years to complete, is still a crude technique and no substitute for clinical trials in humans. The use of massive dosing in animals may in part compensate for metabolic differences between species, but human trials are ultimately needed. Toxicogenomics offers some promise of early identification of "toxicity" gene expression profiles (i.e., signatures).

Clinical trials

In phase I testing, progressively larger doses of the test medication are given to well-paid healthy volunteers. Routine monitoring includes vital signs, electrocardiogram, assessment of reported side effects, and blood measurements including serum aspartate aminotransferase/ALT, amylase, and creatine phosphokinase. In phase II testing, patients are exposed for the first time and the emphasis shifts from safety alone to safety *and* efficacy. Depending on the intended use of the medication and the prevalence of the disease to be treated, from 500 to 5000 study patients may test the medication for periods of up to a year. In early phase II trials, a progressive dosing scheme identifies the maximal dose that is effective and still safe. If a given dose is effective, it is then determined if there are any short- or long-term side effects. Several NSAIDs have made it to phase II trials only to be withdrawn because of frequent aminotransferase level increases. However, this is where safety concerns regarding idiosyncratic reactions founder. It is easy to pick up common reactions but hard to pick up the truly rare drug injury during the preapproval process. A "signal" of aminotransferase elevations is often associated with more severe toxicity as can be observed with isoniazid and possibly ximelagatran, but most aminotransferase elevations do not lead to severe injury.

Dr Hyman Zimmerman, long recognized as the founder of the study of drug-induced liver injury, stated that if a drug causes enough liver injury to lead to jaundice, even rarely, then 10% of affected patients will develop acute liver failure ("Hy's rule") [90]. Put another way, any drug that in phase II or III testing demonstrates not only aminotransferase elevations, but increases in bilirubin or jaundice, will likely lead to ALF when larger numbers of patients are exposed. This sounds like an imprecise "rule" but it has served well over the years, and there does not seem to be anything better.

How certain can we be that clinical studies identify instances of liver injury? First, all studies are conducted according to previously established guidelines of good clinical practice. In each clinical study, a detailed assessment of liver biochemical parameters is part of every company's NDA filing. Data supporting the safety of the drug include placebo-controlled trials where the incidence of abnormalities must be shown to be similar to that observed in the placebo group. Aminotransferases exceeding three times the ULN generally require discontinuation of the drug. Increased aminotransferase levels *without* bilirubin elevations may not lead to discontinuation during a phase III trial, but frequent or more severe aminotransferase increases (more than 8 times the ULN) or accompanying increases in bilirubin will likely bring a new drug trial to a halt. If any case of ALF occurs, the trial is discontinued, as was the case with fialuridine.

The FDA approves approximately 50 new drugs each year. The approval process takes between 6 months and a year, once the NDA is filed. Approval brings with it instant widespread, intense marketing efforts and the necessity for all US pharmacies to stock the drug. As noted previously, the number of prescriptions frequently rises rapidly into the millions, within a year or less. This fact explains why some drugs only demonstrate problems once they receive FDA approval. Idiosyncratic events occurring in only 1 in 50 000 patients are not going to be recognized in a study of 4500 patients. The "rule of threes" applies: to reliably identify a single case of liver injury due to a drug with 95% confidence, there must

be three times the number of patients studied as the incidence of the drug reaction. In other words, a 1 in 1500 reaction requires 4500 patients to reliably detect a single case; a 1 in 50 000 reaction would require 150 000 patients. No clinical trial will reliably pick up rare drug reactions. Approval by the FDA provides a wider experience than the limited exposure of the carefully controlled clinical trial. It should not be surprising, therefore, that drug reactions are observed in the postmarketing period and not before. However, postapproval drug recall still takes time to evolve while the drug continues to be prescribed despite the recognition of adverse events.

Postmarketing surveillance

The greatly increased number of patients receiving a new drug ensures that untoward or unusual drug effects will be observed. In addition to increased numbers, a wider range of patients than the defined clinical trial population is exposed. For example, most studies do not include patients with renal failure, heart failure, HIV/AIDS, pregnant women, the elderly, or children. Any of these groups may show enhanced toxicity. Even the best-randomized controlled clinical trial is not a "real-life" experience. The difficulty is in identifying these drug reactions quickly and accurately, once the product is released. During clinical trials and the after market period, pharmaceutical companies must report serious adverse events to the FDA within 24 h. A serious adverse event is any unexpected medical occurrence that at any dose results in death, is life threatening, requires hospitalization, or results in permanent disability or a birth defect. Pharmaceutical manufacturers maintain a safety monitoring force that gathers reports, assesses likelihood of the reaction being attributed to their product, and issues a report to the FDA and to clinical investigators if there is still an ongoing trial. However, there is bound to be a bias toward any new product, just as there is bias built in to the design of clinical trials [123].

There are several additional shortcomings to the effectiveness of postmarketing surveillance. First, the reporting system is passive. Physicians and pharmacists are under no obligation to report adverse events. The FDA introduced the Medwatch program to improve surveillance, asking physicians and pharmacists to report on a standardized form all drug reactions they observe. However, it is estimated that less than 10% of severe adverse drug reactions are reported to the company or the FDA. Reasons for underreporting include: failure to recognize "hepatitis" as being due to a drug, concern about malpractice implications, reluctance to get involved, complacency ("too busy"), and so forth. Reports received from pharmacists or drug representatives (or physicians for that matter) seldom contain full clinical information. Privacy issues may preclude further inquiries and raise concern regarding possible legal implications. For all these reasons, a passive reporting system is inadequate. Nevertheless, the main source of information is the Medwatch system, plus case reports [124].

Hepatotoxicity in the patient with chronic liver disease

Hepatologists are frequently asked "Is the patient with liver disease more susceptible to liver injury?" Intuitively, this makes sense, until we realize that hepatotoxic reactions represent the culmination of hepatic enzyme activity. If liver function is impaired, one might predict diminished activity of certain enzyme systems. Patients with liver disease do not appear to be at increased risk for hepatic injury compared with their counterparts without underlying liver problems. Dr Zimmerman put it best [90]: "A stubborn [misconception] has been the view that patients with preexisting hepatic disease are more likely than others to suffer hepatic injury on exposure to drugs that cause liver damage. There is virtually no evidence for this view." What do we know of the liver function of patients with cirrhosis? Many enzyme systems are well preserved even in advanced disease. For example, patients with terminal alcoholic hepatitis still are able to conjugate most of their bilirubin. Therefore, enzyme activity in many instances exceeds the daily requirement, so that even severe liver injury would not be expected to lead to an adverse drug reaction. In general, phase I reactions may be diminished but this is not uniformly so. In severe liver disease the activity of CYP2C19 is greatly decreased whereas that of CYP2D6 is intact [125]. In nonalcoholic steatohepatitis, the enzyme CYP2E1 is increased, particularly in the centrilobular region, so that acetaminophen toxicity should be enhanced in patients with nonalcoholic steatohepatitis [126]. So far, this has not been appreciated clinically; further support in an animal model of nonalcoholic steatohepatitis has been presented [127].

Drug metabolism in patients with cirrhosis can be reduced by as much as 50%. Whether the cells in a patient with cirrhosis are sick or simply reduced in number but functioning normally is not clear. Neither answer is exactly correct. It appears that the physiological changes seen with fibrosis along the hepatic sinusoids results in a widening of the barrier between the bloodstream and the hepatocyte. In support of this, patients with cirrhosis with comparably diminished metabolism of acetaminophen and theophylline normalize theophylline disposal, but not acetaminophen, with oxygen supplementation [128]. The metabolism of theophylline uses CYP1A1 and CYP1A2, which requires oxygen as substrate, unlike acetaminophen conjugation (phase II). The limitation to metabolism is the barrier to oxygen absorption. These studies support the "intact hepatocyte/sick membrane" hypothesis. In summary, dosage adjustments may need to be made in patients with cirrhosis, but these individuals do not appear to have an abnormally sensitive hepatic metabolic system, just less reserve if a hepatotoxic insult were to occur [128,129].

In general, patients with liver disease suffer more renal than hepatic insults. They are particularly prone to nephrotoxicity

as the result of the altered renal circulation of the cirrhotic patient. Nephrotoxicity of aminoglycosides, radiocontrast, and prostaglandin inhibitors such as indomethacin are a frequent problem for patients with cirrhosis, but doses of antibiotics, antipsychotics, and so forth, are seldom adjusted, although any medication with sedating effects may be a problem if metabolism is slowed.

Avoiding further liver injury in the patient with preexisting liver disease is a difficult task. Antituberculous therapy cannot be withheld from patients just because they have alcoholic cirrhosis. In these instances, frequent monitoring appears to be helpful, but the value of this monitoring has not been proven in controlled trials, is seldom adhered to, and can prove expensive. Despite surveillance using liver enzyme levels, acute liver failure has developed in patients treated with isoniazid. In many instances, the presence of preexisting liver disease is subclinical, (e.g., in patients with nonalcoholic steatohepatitis). Whether the diabetic population is more at risk for troglitazone hepatotoxicity because of their diabetic fatty liver is still debated. Nevertheless, a healthy regard for the possibility of increased hepatotoxic reactions in patients with preexisting liver disease, and the use of periodic surveillance during treatment, should allow the maximum chance to avoid prescribing drugs that are harmful.

Clinician's guide to handling new drugs

The best advice in prescribing new pharmaceutical agents is not to prescribe them. It is wise to defer embracing new drugs during their first year of introduction, particularly if they demonstrate no unique advantages over accepted formulations. Marketing hype exceeds real-life experience with any new agent. Physicians must strive to instill in their patients a healthy level of alertness with regard to drug-induced liver injury, particularly for agents with known hepatotoxicity. Physicians and pharmaceutical companies should strike a careful balance between alerting patients to the potential for severe reactions without frightening them so that they avoid needed medications. Monitoring aminotransferase levels is suggested for known hepatotoxins such as isoniazid or diclofenac on a monthly basis but is unlikely to be cost-effective when an adverse reaction occurs in only one in 50 000 patients. Since many drug reactions develop within days, monitoring provides no guarantee [130]. Most fatal drug reactions could be prevented if the offending agent were withdrawn immediately, at the first sign of illness. The patient most likely to be harmed is the one who believes in the complete safety of drugs, does not realize that drug-induced injury is possible, or is encouraged to be compliant when signs of toxicity are beginning.

New drugs should be prescribed with caution, keeping an eye out for case reports. Some of the newer agents implicated in acute liver necrosis are listed in Table 83.9. The diagnosis of drug-induced liver injury necessitates determining the precise timing of the drug ingestion, making a careful record of all drugs ingested, and being particularly suspicious of known hepatotoxic agents begun within 3 months of the onset of illness. After withdrawal of the offending agent, improvement should be rapid, within days. Cautious re-challenge may be made *only* if the toxicity observed was highly questionable and if no other drug is available for a serious problem. If jaundice, coagulopathy, or any degree of encephalopathy is present initially, then hospitalization is required because drug reactions worsen quickly, and fatal outcomes are common.

Table 83.9 Current list of newer drugs reported to cause severe toxicity

Atorvastatin [136]
Agent orange [137]
Carbamazepine [74]
Celecoxib [59]
Clarithromycin [138]
Coumarin compounds [139]
Cyproterone acetate [140]
Fosinopril [141]
Fluconazole [142]
Fluoxetine [143]
Indinavir [144]
Levofloxacin [145]
Losartan [146]
Mesalazine [147]
Metformin [148]
Nefazodone [149]
Norfloxacin [150,151]
Paroxetine [152]
Pemoline [153]
Pravastatin [154]
Ranitidine [155]
Risperidone [156,157]
Telithromycin [121]
Terbinafine [158]
Ticlopidine [77]
Tolcapone [159,160]
Trazodone [161]
Trovafloxacin [162,163]
Valproate [164,165]
Venlafaxine [166]
And don't forget herbs! [102]

Summary, 2190
Key points, 2191

When first described [1,2], autoimmune hepatitis (AIH) was thought to be a potentially fatal form of chronic hepatitis that predominantly affected young women. It is now recognized that this disease may affect all age groups [3,4] and women are affected four times as often as men. All racial groups are at risk of AIH. Its prevalence in Europe is about 1.9 per 100 000 [5]. Spontaneous remission may occur but subsequent relapse is usual; only rarely is the disease curable. Although this disease can be fatal if severe and left untreated [6–8], earlier recognition of the manifestations of AIH has shown that in some instances the disease may be asymptomatic and its course perhaps more benign than was originally thought.

Pathogenesis

There are many features of AIH which suggest the disease is immune-mediated. Certain human leukocyte antigen (HLA) class II alleles are associated with both disease susceptibility and treatment responsiveness [9]. In individuals from North America and Europe the class II HLA-DRB*0301 and HLA-DRB*0401 alleles are more common in individuals with type I AIH. In South America and Japan the HLA pattern associated with AIH is different. A common antigenic peptide which recognizes a positively charged amino acid at positions 67–72 on the DRB allele may be the link [10]. The immune response is complex, involving several promoters such as costimulatory signals for T-cell activation, adhesion between immune synapses, cytokine production, and T-cell receptor configuration. Genetic polymorphisms of one or more of these promoters may be relevant to the pathogenesis of AIH [11].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

AIH may be associated with low serum complement levels and a null allotype at the C4A or C4B gene location (a silent *C4AQ + 0* gene is identified in such patients) [12]. This C4A gene deletion is associated with both relapse on therapy and increased mortality [13].

Immunoglobulin levels are elevated twofold to threefold in active AIH, indicating marked B-cell activation, the cause being multifactorial [14,15]. Several reports imply that the onset of AIH may be precipitated by an acute viral infection in genetically susceptible individuals [16–19]. The induction of AIH in a few patients being treated with interferon for chronic hepatitis C has also been described [20]. Certain drugs (e.g., minocycline) may also induce an AIH-like disease [21–23].

The nonorgan-specific, nonspecies-specific antibodies typically associated with AIH are antinuclear antibodies (ANAs) and smooth muscle (specifically anti-actin) antibodies (SMAs). The detection of these antibodies in up to one-third of individuals with other liver diseases not thought to have an autoimmune basis [24] makes it unlikely that they have any pathogenic role on their own. Another autoantibody, anti-soluble liver antigen (anti-SLA), is described in 11% of patients with type 1 AIH. This antibody is identical to liver/pancreas antibody [25,26]. Anti-SLA may also be detected in 14%–30% of patients given a diagnosis of cryptogenic cirrhosis. This latter observation supports the concept that some patients with a diagnosis of cryptogenic cirrhosis may have an autoimmune basis for their liver disease [27].

Another distinct form of AIH (type 2) has been most often described in Europeans but does occur in North America [28]. In these individuals an antibody against liver and kidney microsomes (anti-LKM1) (specifically cytochrome P450-2D6) can be detected; serum generally tests negative for ANA and SMA. It remains unknown as to whether this antibody has any pathogenic significance. If the immunofluorescence slides are not read carefully, this antibody could be misinterpreted as

Table 84.1 Comparison of the clinical and immunological features of types 1 and 2 autoimmune chronic active hepatitis

	Type 1 (anti-actin)	Type 2 (anti-LKM)	Anti-SLA
Age at presentation (years)	10–25 and 45–70	< 15	Mean 37
Associated disorders	10%	17%	58%
Immunoglobulins

being an anti-mitochondrial antibody (AMA) [29]. Sometimes anti-LKM1 can be detected in the serum of persons with chronic hepatitis C [30].

There are many other autoantibodies described in association with AIH. Asialoglycoprotein receptor antibodies can be detected in 90% of patients with all forms of AIH. This antibody is directed at the receptor for $CD4^+$ T cells [31]. Antineutrophil cytoplasmic antibodies were initially believed to be a hallmark for primary sclerosing cholangitis (PSC) but subsequent case series indicate that these antibodies are not specific and are also common in AIH [32].

A rare condition known as autoimmune polyglandular syndrome type 1 (APS-1) is associated with AIH in 10%–20% of patients. APS-1 is associated with a homozygous mutation in an autoimmune regulator (*AIRE*) gene, which encodes a nuclear transcription factor. A survey of individuals with a variety of autoimmune liver disease did not indicate that this same mutation was present in individuals with AIH [33].

Some patients thought to have AIH are found to test positive for only anti-SLA, and have been categorized as having type 3 AIH. However, more than likely as the symptoms are so similar, these rare patients can be categorized as having type 1 AIH. AIH type 1 is the form most frequently encountered in North America; type 2 appears to be more common in Europe. The latter more commonly affects young persons, generally presents acutely, and is more frequently associated with cirrhosis.

The HLA patterns in type 1 and type 2 AIH are also distinct but this may be partially explained by the very different geographic distribution of these two forms of AIH. The HLA pattern that appears to confer resistance to AIH type 1 confers susceptibility to AIH type 2 (i.e., DRB1*07 and DRB1*15 and DQB1*06) [34], suggesting that the genetic susceptibilities to these two forms of AIH are quite separate. Type 1 and type 2 AIH can often be distinguished clinically by the natural history of the disease, the laboratory parameters for each type, and the different responses to treatment [35] (Table 84.1).

Clinical manifestations

Presenting symptoms

At first presentation the diagnosis of AIH may be missed because the symptoms of a mild, self-limiting, acute hepatitis are very nonspecific [36]. Most often AIH is diagnosed in individuals found to have markedly abnormal liver biochemical tests when they present with jaundice. Occasionally, presentation may be as an acute [37] and sometimes fulminant hepatitis [38]. Careful history-taking may reveal past nonspecific but relevant symptoms such as episodes of malaise, nausea, and arthralgias. There may be a family history of other autoimmune diseases. Sometimes the disease may present de novo with hepatic decompensation (e.g., ascites, variceal hemorrhage). On occasion a complication of AIH (e.g., secondary amenorrhea or delayed menarche) may be the only complaint leading to a visit to the physician. AIH is sometimes entirely asymptomatic, diagnosed as the result of blood tests performed as part of a routine physical examination or as part of the workup for another autoimmune disease.

As with most chronic liver diseases, fatigue is the most common symptom; jaundice is a presenting symptom in more than half. Other gastrointestinal complaints include

anorexia, diarrhea, sometimes pruritus, and occasionally right upper quadrant discomfort. Associated autoimmune diseases include thyroiditis, inflammatory bowel disease, and rheumatoid arthritis. In children there is a very strong link between AIH and sclerosing cholangitis [39,40]; up to 50% are found to have both diseases simultaneously at presentation [40]. This dual presentation is much less frequently observed in adults.

Physical examination

Generally, hepatomegaly is present and jaundice is frequent but there may be no abnormal physical findings noted, particularly if cirrhosis is absent. The spleen may be palpable (50%) and spider nevi may be present but they do not necessarily indicate cirrhosis. Hepatic decompensation is unusual but occasionally patients with *burned-out* disease may present with ascites (20%), hepatic encephalopathy (14%), or bleeding varices (8%). The liver is generally small by this time [36].

Laboratory investigations

The alteration in liver enzymes in AIH is typically hepatocellular. Elevation in serum aminotransferase levels may be quite marked, greater than 1000 IU/L in some cases. A conjugated hyperbilirubinemia is common. Further evidence of liver dysfunction may be present, such as a coagulopathy and hypoalbuminemia. The blood film may reveal a pattern typical of hypersplenism (low total white cell count, platelet count, or hemoglobin), even at presentation in those with already established cirrhosis.

Infection with hepatitis A, hepatitis B, and hepatitis C viruses must be ruled out through serological testing. Other viruses may affect the liver as part of a systemic infection, for example Epstein–Barr virus, adenovirus, parvovirus, and cytomegalovirus (in the immunocompromised individual), and these should be sought if an infectious etiology is considered likely.

If viral hepatitis is excluded, testing for serum ANAs and SMAs should be requested: the immunofluorescence technique is sufficient. Anti-LKM1 and ANA/SMA are nearly always mutually exclusive, and thus anti-LKM1 should be requested once serum tests negative for ANA and SMA. If there is concern that anti-LKM1 may have been misread, then an enzyme-linked immunosorbent assay (ELISA) can be used to confirm the identity of AMA. It is probably not clinically helpful to screen for any other autoantibodies. Only when ANA or SMA are associated with at least a twofold increase in IgG should a diagnosis of type 1 AIH be seriously considered. These two antibodies, generally in low titer, are detected in up to one-third of individuals with other forms of chronic liver disease but the hypergammaglobulinemia is much greater in type 1 AIH. In type 2 AIH, the hypergammaglobulinemia may not be as profound, and even low IgA levels may be observed [34].

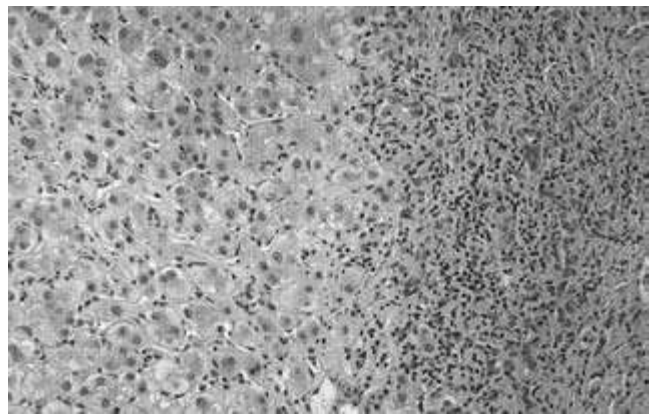

Figure 84.1 Typical histological picture of autoimmune hepatitis.

Liver histology

To confirm a diagnosis of AIH liver histology is essential even though the pattern of disease is not entirely specific. Both viral hepatitis and drug-induced hepatitis may be histologically indistinguishable from AIH. If there is no evidence of hepatic decompensation, liver biopsy can be performed via the percutaneous route, otherwise the transjugular route is necessary. The liver biopsy should be reviewed by an experienced hepatopathologist. The portal tracts and hepatic lobules need to be examined in minute detail looking for evidence of an interface hepatitis at the junction of the portal region and the liver lobule and a lobular hepatitis caused by infiltration with lymphoplasmacytic chronic inflammatory cells (Fig. 84.1). The intrahepatic bile ducts generally appear normal. If there are cholangitic features, then strong suspicion of an associated cholangitis or a misdiagnosis should be entertained. Copper retention within hepatocytes is one of the hallmarks of Wilson disease but may also be seen to a lesser degree in individuals with AIH with or without cholangitic features. Staining for α_1-antitrypsin globules with the periodic acid–Schiff stain (found then to be diastase-resistant) should be negative and there should be no excess iron noted. In those who present with severe disease, large areas of bridging necrosis may be noted. Even when the clinical presentation is acute, it is common for patients to have evidence of chronic liver disease, possibly even established cirrhosis. The composite histological picture is 81% specific and the positive predictive value is 68% [41] when tissue from individuals with AIH is compared with tisssue from those with viral hepatitis and cryptogenic cirrhosis.

Differential diagnosis

There are other liver diseases that may present in a similar fashion to AIH and therefore need to be routinely excluded before a confident diagnosis of AIH can be made. Measure-

ment of serum ceruloplasmin level is essential in those individuals who present when young (< 40 years). If the levels are reduced, measurement of 24-h urinary copper and slit-lamp examination of the eyes for Kayser–Fleischer rings are necessary so as to exclude Wilson disease. Falsely low values for ceruloplasmin may be seen in patients with severe hepatic decompensation from any cause. Falsely high urinary copper may result from severe cholestasis but rarely to the degree (10–20-fold elevated) associated with Wilson disease. There are so many genetic mutations associated with this disease that no one mutation can be used as a specific hallmark.

There are several drugs that may cause the clinical, biochemical, serological, and histological features typical of AIH. The drugs most often associated with typical features of type 1 AIH are minocycline [23] and nitrofurantoin [22]. The picture of type 2 AIH may be mimicked by tienilic acid. Withdrawal of the drug may not be instantly associated with biochemical improvement, although resolution should occur over a matter of months not years.

Fortunately, there are now sensitive and specific tests to identify viral hepatitis. Nevertheless, hepatitis C may mimic both type 1 and type 2 AIH [42]. In individuals from areas where the prevalence of viral hepatitis is high it is possible for chronic viral hepatitis and AIH to coexist.

Cryptogenic cirrhosis is the diagnosis given to patients in whom no obvious etiology can be identified. Czaja and colleagues [43] compared 12 such cases with 94 cases of clear-cut AIH and showed that there was no statistical difference between the two diseases with respect to gender, age, pattern of histological activity at presentation, or frequency of concurrent autoimmune disorders. However, total gammaglobulin and IgG concentrations were significantly lower in those with a diagnosis of cryptogenic cirrhosis. Patients with cryptogenic cirrhosis had no ANA, SMA, anti-LKM1, AMA, thyroglobulin, or microsomal thyroid antibodies in their serum. However, HLA class I and II patterns were similar between the groups, suggesting that the etiology in these individuals was likely autoimmune. All patients were treated with corticosteroid therapy and improved. Other authors have described a similar population [44]. However, so-called cryptogenic cirrhosis may be caused by other silent diseases (e.g., nonalcoholic steatohepatitis) [45] and it is probably unwise to treat "cryptogenic" cirrhosis with immunosuppressive therapy unless there are some autoimmune features present.

Autoimmune hepatitis/primary sclerosing cholangitis overlap syndromes

Particularly in children, overlapping features of AIH and PSC are common [39,40]. It is unclear whether the cholangitis visible on radiological delineation of the biliary tree in children with otherwise obvious AIH is the same cholangitis that may be diagnosed in adults. Both are frequently associated with chronic inflammatory bowel disease. There may be no distinguishing features between individuals with AIH and those with AIH plus PSC (i.e., serum alkaline phosphatase/γ-glutamyltransferase and immunoglobulin values may be elevated in both). The therapeutic response cannot distinguish between the two. Thus a high index of suspicion is needed. Data suggest that in children it is probably appropriate to examine the biliary tree via endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance imaging (MRI), even if the primary diagnosis is AIH [40]. The cholangitis may affect only the intrahepatic bile ducts, although in most individuals progression to extrahepatic disease occurs later in life.

When Boberg and colleagues [46] applied the first AIH scoring system to 114 adults given a primary diagnosis of PSC, they found that two individuals scored *definite* and eight *probable* for AIH. Subsequently the application of the modified AIH scoring system [47] has reduced the number of patients with radiologically proven PSC who score *probable* for AIH. Two publications indicate that the rate of PSC/AIH overlap ranges from 4% [48] to 8% [49] of patients with PSC. In the latter study the patient population was younger, so it may be reporting the pediatric PSC/AIH overlap described by Gregorio and colleagues [40].

The AIH scoring system can be employed to determine the strength of evidence that an individual has AIH (Table 84.2). Factors considered important (by a panel of experts) when making the diagnosis have been weighted either positively or negatively. These include gender, alkaline phosphatase (ALP)/aspartate aminotransferase (AST) (or alanine aminotransferase [ALT]) ratio, elevation of IgG, titer of ANA, SMA or LKM1, AMA status, viral serology, drug history, average daily alcohol intake, liver histology (interface hepatitis, predominant lymphoplasmacytic infiltrate, rosetting of liver cells, biliary changes), and other autoimmune diseases. Additional measures can include seropositivity of other autoantibodies, HLA-DR3 or HLA-DR4, and response to immunosuppressive therapy [47].

Natural history of autoimmune hepatitis

Now that immunosuppressive treatment is the standard of care for symptomatic AIH, the natural history of this disease is rarely observed. Examination of the data from subjects who received placebo in the randomized controlled trials of corticosteroids with or without azathioprine reported in the early 1970s indicate that AIH is a rapidly progressive disease, with a 5- and 10-year survival rate of only 50% and 10%, respectively [4–6] (Fig. 84.3). Death is generally due to liver failure often complicated by sepsis. Hepatocellular carcinoma is rare [50]. However, it is important to note that 30 years ago, when these trials were conducted, most patients presented to their physician with hepatic decompensation and thus the

Table 84.2 Summary of revised score sheet for autoimmune hepatitis

	Score
Gender: female	+ 2
Biochemistry (ALP/AST ratio)[a]

majority had well-established cirrhosis at baseline. With the introduction of routine laboratory checks of liver biochemistry and a heightened awareness of liver disease in general, it is likely that the proportion of individuals diagnosed with less advanced disease is increasing. Sometimes AIH may be diagnosed in the absence of any symptoms. There are no published data on the natural history of asymptomatic AIH.

Treatment, which is successful in more than 80% of affected individuals, has allowed most patients with AIH to lead a normal life, with a life expectancy similar to age- and gender-matched control populations (i.e., 98% at 10 years) [51]. This study also indicated that the 10-year survival in AIH is not dependent on baseline liver histology (Fig. 84.3). For the most part, young women with this disease, if treated appropriately, may have successful pregnancies (corticosteroids or azathioprine should not be stopped during pregnancy). If flareups do occur, they are nearly always in the postpartum period [52].

Unfortunately, most of the complications of AIH are due to side effects from long-term immunosuppressive therapy needed to control liver disease. It is essential to monitor systemic blood pressure, bone mineral density, and blood or urine glucose. Regular eye examinations looking for cataracts should also be performed.

Patients with AIH may develop other autoimmune diseases during follow-up (e.g., thyroiditis and rheumatoid arthritis). Thus patients given a diagnosis of AIH need to recognize their need for lifelong follow-up. The complications of liver failure are as for all liver diseases, namely ascites, hepatic encephalopathy, and variceal hemorrhage. It must be determined if liver failure is due to a flareup of disease, in which case medical therapy is appropriate, or due to burned-out end-stage disease, in which case liver transplantation is probably the best option.

Treatment

For details see Table 84.3. The first therapeutic trials in patients with AIH conducted in the late 1960s and early 1970s

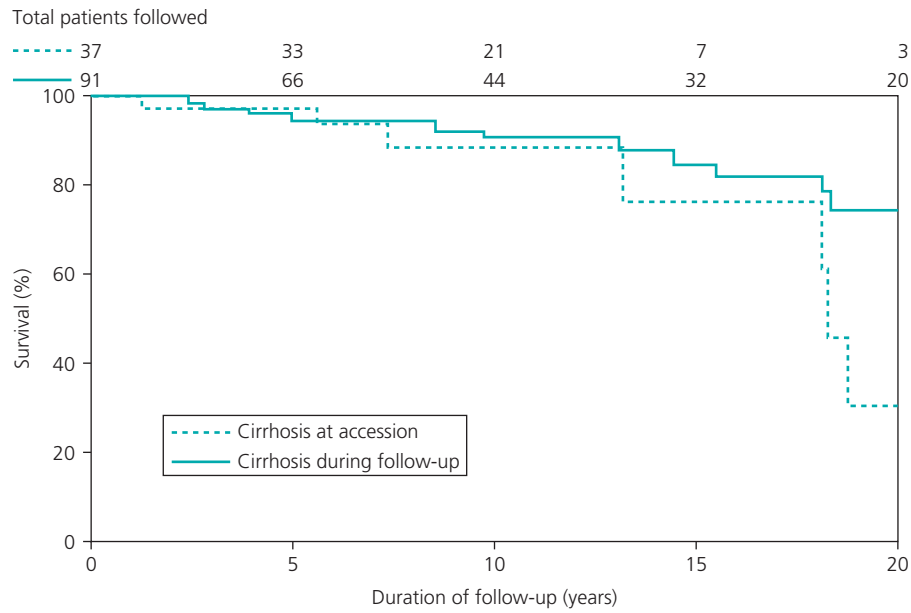

Figure 84.3 Survival of patients with type 1 autoimmune hepatitis: comparison of survival, using death and orthotopic liver transplantation as end points, from development of cirrhosis at accession versus follow-up. From Roberts et al. [51], with permission from Elsevier.

Table 84.3 Suggested therapeutic regimen: for autoimmune hepatitis

Initial therapy Prednisone 30–40 mg/day monotherapy or prednisone 30 mg/day and azathioprine 50–100 mg/day combined therapy
Dose reduction Slowly reduce prednisone (2.5–5 mg every 1–3 months) if ALT in normal range
Maintenance Minimum-dose prednisone or azathioprine to maintain ALT in normal range
Stop therapy If ALT and IgG normal for 1–2 years; liver biopsy indicates inactivity
Retreatment of relapse Reintroduce therapy as for initial treatment
Failure to respond To above, use either high-dose prednisone 40–60 mg/day or another immunosuppressant, or consider liver transplant if appropriate

ALT, alanine aminotransferase.

indicated a highly significant improvement in survival following therapy with corticosteroids [4–6]. The studies from the Mayo Clinic indicated that treatment with high-dose corticosteroid (60 mg daily initially with 20 mg daily as maintenance) and lower-dose corticosteroid combined with azathioprine (30 mg prednisone daily initially, reducing the dose to 10 mg daily as maintenance plus 50 mg daily of azathioprine) were equally effective. Monotherapy with azathioprine 100 mg daily was no better than placebo [7,8]. Several lessons were learned from these trials. First, high-dose corticosteroids are associated with the rapid onset of severe side effects (osteoporosis, diabetes, systemic hypertension, and cataracts) and thus it is wise to treat symptomatic patients from the start with a lower dose of steroids (20–30 mg daily) combined with the steroid-sparing agent azathioprine. As azathioprine takes at least 6 weeks to take effect, it makes sense to start this agent when steroid treatment is initiated. The dose of steroid can be tapered once serum aminotransferase levels have fallen to less than a twofold elevation. Tapering by 2.5–5 mg every 1–3 months with careful monitoring of aminotransferase levels is appropriate. Most patients have a rapid symptomatic and somewhat slower biochemical response within the first few weeks of therapy. There are some patients whose serum aminotransferase levels do not return to normal for many months. A fall in the level of IgG is also a good indicator of response. Liver histology does not improve until the biochemical tests have been normal for at least 6 months. About 20% respond poorly, with 13% achieving only a partial response and only 7% who do not respond to treatment at all [53]. Poor response to immunosuppressive therapy is more common in patients whose liver biopsy shows areas of submassive necrosis [54]. Patients with cirrhosis, even if decompensated, generally respond well to therapy. Therefore even patients being considered for liver transplantation, if they have active disease, should be given immunosuppressive therapy without delay. No randomized controlled trials of therapy in patients who have asymptomatic disease have been conducted. An unsuccessful attempt was made, but patients refused to be included, put off by the long list of side effects attributed to corticosteroids (Gregory P, personal communication, 1997).

Once the serum aminotransferase levels have returned to near-normal values it may be possible to wean the patient off corticosteroids altogether (this was not done in the early trials) and maintain patients on azathioprine alone at a dose of 1–2 mg/kg daily [55,56]. Such a strategy reduces the deleterious consequences of long-term corticosteroid therapy. The white blood cell count needs to be regularly checked because of the potentially toxic effects of azathioprine on the bone marrow. Some patients cannot tolerate azathioprine, mainly because of its gastrointestinal side effects. Alternate-day immunosuppressive therapy is ineffective in AIH.

It is generally advised that immunosuppressive therapy be continued for up to 2 years after the liver biochemical tests have normalized before cessation of immunosuppressive therapy is contemplated. This timing is arbitrary; however it is likely that at least 1 year of therapy is essential. Some would advocate that prior to stopping treatment another liver biopsy should be performed to confirm that the hepatic inflammation has disappeared. A reduction in fibrosis may be observed [57,58] but unfortunately half of those patients not cirrhotic at presentation will progress to cirrhosis despite ongoing immunosuppressive therapy and an apparent biochemical response [59].

In those rare patients with AIH in whom standard therapy with a combination of prednisone and azathioprine fails, other immunosuppressive agents have been tried. Alternatives to classic treatment are also needed for children who may experience devastating growth retardation due to the use of high-dose corticosteroids. However, carefully monitoring corticosteroid therapy is probably still the best treatment in children, although cyclosporine has been used with benefit in children [60] both with type 1 and type 2 AIH [61,62]. A newer agent used to prevent transplant rejection, mycophenolate mofetil, may be preferable as it has less nephrotoxicity, but it often causes diarrhea [63]. Methotrexate has been reported to be of benefit, as has cyclophosphamide in refractory type 1 AIH [64,65].

Budesonide is a corticosteroid that has a 90% first-pass effect in the liver, but which nevertheless appears to have a beneficial effect at this site, causing aminotransferase levels to normalize in AIH [66]. Unfortunately, these encouraging results were not confirmed in another study [67]; in addition steroid side effects were observed in this latter study likely because intrahepatic or extrahepatic portosystemic shunting was present, thus obviating the beneficial properties of budesonide.

Once it is believed that the disease is in long-term remission (sustained normalization of serum aminotransferase and IgG levels, with histological evidence on liver biopsy of quiescent disease), immunosuppressive therapy may be stopped. Unfortunately, the majority (80%) of individuals with AIH who are weaned off treatment will relapse [68], generally within the first few months after treatment cessation but sometimes not until several months or even years later. Reinstitution of immunosuppressive therapy is generally successful.

It is now quite unusual for patients who have been treated for AIH to progress to end-stage liver disease. Risk factors for disease progression include an HLA-DR4-negative phenotype and the presence of anti-LKM1 antibodies as well as massive necrosis on first biopsy and low albumin and high prothrombin time at presentation [69]. However, when liver transplant is necessary, it is extremely successful (5-year survival > 90%), although a pattern of recurrent liver disease similar to AIH may recur in the transplanted liver in up to 40% [70,71]. In most cases this responds to increased immunosuppressive therapy. For this reason attempts at withdrawal of antirejection therapy in those who receive a liver transplant for previous AIH are not recommended.

In addition to specific therapy for liver disease, individuals with AIH may require additional supportive therapy. All should be encouraged to lead an entirely normal life but certain precautions need to be taken, as is the case for anyone on long-term immunosuppressive therapy. In addition the complications of long-term corticosteroid therapy should be anticipated and prevented if possible. Those intending foreign travel should receive appropriate advice from travel medicine specialists, particularly with regard to appropriate vaccinations and how to avoid certain parasitic infections (e.g., *Strongyloides*). All patients on immunosuppressive treatment should learn to recognize any infection early in its course and seek medical attention rapidly.

In young women who are successful in becoming pregnant it is important to check for the presence of esophageal varices in those who are cirrhotic, as nonselective β-blocker therapy may well be required during pregnancy. Advice to the obstetrician to avoid a prolonged second stage of labor is also important. It is quite safe to maintain corticosteroid or azathioprine therapy during pregnancy; sometimes requirements for immune suppression may lessen during the pregnancy. Flareups, if they occur, are most often observed following delivery, although they may occur during pregnancy [52].

Baseline measurement of bone mineral density is wise. Adequate intake of calcium and vitamin D should be recommended to all individuals with AIH given corticosteroids. Preventive bisphosphonate therapy has been shown to be of value.

Summary

Although AIH is one of the less common causes of a chronic hepatitis, it is essential that the diagnosis not be missed, as therapy is so successful, even curative in up to 20%. Once in remission most patients can be maintained in good health on azathioprine monotherapy with no untoward side effects. Treatment of AIH with immunosuppressive agents does not always prevent progression to cirrhosis, but it does significantly reduce the risk of dying of liver failure.

Key points

- Two types of AIH, distinguished by autoantibody status
- Presentation may be with a silent, or a symptomatic or even fulminant hepatitis
- Differential diagnosis: drug-induced hepatitis, Wilson disease, viral hepatitis
- Immunosuppressive therapy markedly improves survival but is curative in only 20% of patients.

Introduction

Primary biliary cirrhosis (PBC) is a chronic liver disease that is defined by its clinical presentation, histological features, and serological findings. The underlying abnormality in PBC is a slowly progressive, non-purulent inflammatory destruction of the biliary epithelial cells lining the small to medium-sized interlobular ducts [1]. The larger biliary ducts are spared. The pathophysiology of bile duct destruction is poorly understood, but the process is felt to be autoimmune in nature. Genetic and environmental factors appear to be important in disease susceptibility and progression. Autoantibodies are a characteristic feature of the disease; over 90% of patients with PBC have antimitochondrial antibodies (AMA) and about 50% have antinuclear antibodies [2] (Table 85.1). Loss of normal biliary drainage eventually leads to a clinical picture of chronic hepatic cholestasis and its potential complications.

Pathogenesis

Antimitochondrial antibodies

PBC is presumed to be an autoimmune disease, although the evidence to support that hypothesis is largely inferential. Clinically, PBC shares features with other autoimmune diseases such as predominance in middle-aged females and frequent coincidence with other autoimmune disorders. In addition, virtually 100% of patients with PBC have circulating autoantibodies, often to mitochondrial and nuclear antigens.

In 1987, Gershwin and colleagues identified the primary structure of the major target antigen of the PBC AMAs [3]. This autoantigen was identified as the human mitochondrial enzyme, dihydrolipoamide acetyl transferase, also referred to as the E2 component of the pyruvate dehydrogenase complex (PDC-E2). PDC belongs to a family of multienzyme complexes involved in cellular respiration called the 2-oxo-acid dehydrogenase complexes. Although PDC-E2 is the major autoantigen in AMAs, patients with PBC may have antibodies to any of the 2-oxo-acid dehydrogenase complexes, including branched chain 2-oxo-acid dehydrogenase complex (BCOADC) and 2-oxoglutarate dehydrogenase complex (2-OGDC), or other components of the PDC complex (E1, E3, X) [4] (Table 85.1).

The role of these autoantibodies in the pathogenesis of bile duct destruction has been the subject of considerable debate. Clinically, AMAs appear 6–10 years before other clinical signs of the disease, and thus may be present at the initiation of the disease process. AMA titer, however, does not correlate with disease severity, and patients lacking AMA have a clinical presentation and course that are similar to those found in patients with AMA. Experimental models have thus far failed to demonstrate that generation of AMAs leads to chronic destruction of bile ducts in PBC. Rats, guinea pigs, rabbits, and rhesus monkeys have all been immunized with the recombinant form of PDC-E2. Antibodies to PDC-E2 were readily induced, but none of the animals developed abnormal liver tests or abnormal histology after 8 months of follow-up [5].

PDC-E2 is a mitochondrial enzyme that is expressed in the intracellular compartment of all aerobic cells and on the surface of biliary and salivary duct epithelial cells in PBC [6]. The events leading to the expression of PDC-E2 on bile duct cells in PBC are still not understood. One hypothesis is that cholangiocytes are first injured by another process, allowing release of intracellular antigens, which are then displayed on the cell surface. Biliary epithelial cells differ from other types of cells in that they do not add glutathione to the lysine-lipoyl domain of PDC-E2 during apoptosis, and so apoptotic cholangiocytes may expose unmodified PDC-E2 to the immune system [7]. Another hypothesis is that mitochondrial antigens are carried to the surface complexed with immunoglobulin A (IgA) during the normal route of IgA excretion into bile. Alternatively, the abnormal surface

Table 85.1 Prevalence of autoantibodies in primary biliary cirrhosis

Autoantibody	Prevalence by immunofluorescence %	Prevalence by immunodiffusion, ELISA, or immunoblottting %
Antimitochondrial	85–95	
Anti-PDC-E2[a]		95–97
Anti-PDC-E1		41–66
Anti-PDC-E3		38
Anti-PDC-X		95–97
Anti-OGDC-E2		39–88
Anti-BCOADC-E2		53–55
Antinuclear	25–70	50–81
nuclear rim/peripheral/peri-nuclear	26	
Anti-gp210 (nuclear pore complex)[a]		10–30
Anti-lamin B (nuclear membrane)[a]		1
homogeneous/diffuse	10	
Anti-histone		81
Anti-DS DNA		10
centromere	10–24	
speckled	10–20	
multiple nuclear dot	4–17	
Anti-sp100/anti-PML[a]		5–40
coarse nuclear speckled/nucleolar		
Anti-Smith (Sm) (small RNP)		24
Anti-Scl-70 (DNA-topoisomerase 1)		24
fine nuclear speckled		
Anti-Ro (SS-A) (small RNP)		25–30
Anti-La (SS-B) (small RNP)		21
negative by immunofluorescence		
Anti-SS DNA		71
Antismooth muscle	20	
Anti-actin		13–52
Antiliver membrane	42	
Anti-asialoglycoprotein receptor		15–23
Anticarbonic anhydrase		8–45
ANCA	16–26	
Anti-platelet		40

a Autoantibodies relatively specific for primary biliary cirrhosis.
ANCA, antineutrophil cytoplasmic antibody; BCOADC, branched chain 2-oxo-acid dehydrogenase complex; DS, double-stranded; 2-OGDC, 2-oxoglutarate dehydrogenase complex; PDC, pyruvate dehydrogenase complex; RNP, ribonucleoprotein; SS, single-stranded.

staining could result from surface expression of an abnormal or partial-length PDC-E2, or another molecule that is cross-reactive with antibodies generated against PDC-E2.

The mechanism underlying loss of self-tolerance to PDC-E2 in PBC remains the missing key to understanding the pathogenesis of PBC. Reactivity to mitochondrial antigens might develop as a result of molecular mimicry, a process in which the immune system erroneously recognizes a self-protein as foreign because of similarity to another previously encountered foreign protein. PDC enzymes are well conserved across species. The immunogenic lipoylated domain of PDC-E2 has a particularly high degree of homology with proteins from *Novosphingobium aromaticivorans*, a gram-negative bacterium that is ubiquitous in soil. Sera from almost all patients with PBC react strongly to these bacterial proteins [8]. The organism itself is identified by DNA in the stool of approximately 25% of patients and controls. The rough mutant of *Escherichia coli* expresses a PDC epitope that is also recognized by PBC AMAs [9], and this bacterium has been found in the urine and feces of patients with PBC more frequently than in the urine and feces of liver disease controls [10,11]. Patients with a history of previous urinary tract infections have a slightly higher risk of PBC (Table 85.2) as compared with controls.

Table 85.2 Risk factors for primary biliary cirrhosis (PBC)

Risk factor	Odds ratio
PBC in an identical twin	57 100
Nagasaki bomb survivor	32.5
PBC in another first-degree relative	10.7
Sjögren syndrome in a first-degree relative	5.8
Systemic lupus erythematosus in a first-degree relative	2.2
Urinary tract infection	1.5–2.4
Smoking	1.6–1.8
Hair dye use	1.5–1.8
Hormone replacement therapy	1.6

Exposure to chemicals, toxins, or xenobiotics (natural substances that are foreign to the body) has also been proposed to be responsible for altering native mitochondrial proteins, rendering them immunogenic. Synthetically altering the inner lipoyl moiety of PDC-E2 to mimic changes that might occur after the interaction of PDC-E2 with halogenated xenobiotics in the environment produces a compound with greater reactivity to PBC serum than the native PDC-E2 itself [12]. Animals immunized with these halogenated compounds develop AMAs [13]. However, these AMAs do not persist, as they do in humans with PBC [14].

Environmental risk factors

Epidemiological data also support a possible connection between chemical exposure and PBC. For example, there is an increased prevalence of PBC in survivors of the Nagasaki atomic bomb explosion [15]. Case–control epidemiological studies of PBC have identified links between PBC and smoking, use of hair dye, and use of hormone replacement therapy (Table 85.2) [16,17]. Although the quantity of cigarettes smoked was not related to the development of PBC, smoking more than 10 pack-years has been associated with more advanced fibrosis, irrespective of age or alcohol history [18]. Similarly, the geographic distribution of patients with PBC listed for liver transplant in New York City clusters in neighborhoods that are close to toxic waste sites, whereas cases of primary sclerosing cholangitis patients awaiting transplant and early-stage disease PBC do not cluster in these same areas [19]. It is important to note, however, that even though case–control studies may show clustering of PBC, a population-based cohort from the United Kingdom did not find evidence of geographic clustering.

Genetics

While weak associations with environmental exposures do exist, a positive family history of autoimmune disease (systemic lupus erythemoatosus, Sjögren disease, or PBC) confers a much stronger risk of developing PBC, emphasizing the clear role of genetic susceptibility in acquiring this disease (Table 85.2). The prevalence of PBC in family members of patients with PBC is approximately 4% (range 1%–7%) [20,21]. Of first-degree relatives with PBC, mother–daughter pairs are the most common. The concordance rate for PBC in monozygotic twins is approximately 66%, which is one of the highest reported concordance rates for any autoimmune disease [22,23]. The prevalence of AMA in family members of probands with PBC is also increased [24]. Exactly which genes are responsible for the familial clustering of PBC remains under investigation. Various human leukocyte antigen (HLA) gene alleles and single nucleotide polymorphisms (SNPs) in immunomodulatory genes have been linked to disease susceptibility, but the lack of a reproducible genetic association in the majority of patients suggests that PBC, like diabetes, is a complex multigenic disease. The most frequently observed HLA association across studies is a weak link with HLA-DR8. In North America and Europe, 11%–36% of white females with PBC carry the HLA-DR8 antigen, as opposed to 4%–9% of control subjects. In Japan, where HLA-DR8 is present in 23% of the normal population, HLA-DR8 is found in up to 79% of patients with PBC. Two independent studies identified a SNP (A49G) in cytotoxic T lymphocyte-associated antigen 4 (a molecule that regulates T-cell activation), which confers susceptibility to PBC [25,26]. The *BSMI* polymorphism of the vitamin D receptor is also associated with PBC. Although the relationship of this SNP to bone disease in PBC is not clear, polymorphisms in the vitamin D receptor are known to affect the immunomodulatory activity of vitamin D. Genes on the X chromosome are of particular interest because of the female preponderance of PBC, as well as the large number of immunoregulatory genes located on the X chromosome. There is a higher frequency of X chromosome monosomy in the peripheral leukocytes of patients with PBC as compared to their frequency in healthy controls, similar to what has been described in scleroderma and other autoimmune diseases [27]. Whether increased X chromosome monosomy results from the disease process (e.g., oligoclonal expansion) or contributes to it (e.g., selective loss of inhibitory genes) is still not known.

Immune-mediated destruction of biliary epithelial cells

Once the autoimmune process is initiated, bile ducts are destroyed in a highly specific manner. There is a growing body of evidence that supports the hypothesis that bile duct destruction occurs through T-cell-mediated mechanisms in PBC. This is not surprising considering the abundance of T lymphocytes in PBC portal tract infiltrates [28].

Both $CD4^+$ and $CD8^+$ T cells have been implicated in the pathogenesis of PBC. In vitro, cytotoxic $CD8^+$ cells are the major lymphocyte subset that binds to cholangiocytes [29]. The frequency of PDC-E2-specific $CD8^+$ cells is 10-fold higher

in the liver than the blood of patients with PBC [30]. Aberrant staining for HLA class II and PDC-E2 on biliary epithelium, however, suggests that $CD4^+$ T-cell recognition of antigens on cholangiocytes may be important. The frequency of the precursors of PDC-E2-reactive $CD4^+$ T cells in the liver and lymph nodes is 100-fold higher than in peripheral blood [31]. About 55% of patients with PBC also have circulating T cells reactive to the purified E2/X component of PDC, compared with only 1%–13% of controls [31,32]. Although bile duct cells express HLA class I and II antigens, and mitochondrial antigens on their surface, the ability of cholangiocytes to present antigens to T cells could not be demonstrated in vitro [29].

Natural killer T cells, which recognize CD1d-presented glycosphingolipids from gram-negative bacteria that lack lipopolysaccharide, are also enriched in the liver of patients with PBC [33]. Following stimulation, natural killer T cells produce large amounts of interleukin-4, which drives the differentiation and growth of T helper type 2 cells. Natural killer T cells regulate autoimmune responses and help fight bacterial infections in the liver. Regulatory T cells, which are important in regulating autoimmune responses, are decreased in liver and blood of patients with PBC [34].

The cytokine profile of the liver in PBC is mixed, but favors a predominant T helper type 1 response. The type 1 cytokine interferon-γ is detected at higher levels in the livers of patients with PBC than in control livers from patients with autoimmune hepatitis or in normal liver tissue from transplant donors [35,36]. Moreover, cells expressing interferon-γ messenger RNA in the liver in PBC are clustered around damaged bile ducts [36]. Patients with PBC are also more likely to have an interleukin-1β gene allele associated with high interleukin-1β production [37].

Biliary cell death ultimately occurs through a combination of apoptosis and necrosis. Fas antigen is present on biliary epithelium, and biliary epithelial cells from patients with PBC have been observed to undergo apoptosis more frequently than control biliary epithelial cells [38]. Death of biliary epithelial cells continues throughout all stages of PBC [39].

Alternative recent hypotheses regarding the pathogenesis of PBC include a graft-versus-host disease related to fetal microchimerism, or an immune response to either endogenous retroviruses or chlamydia pneumonia. Evidence for these events, however, is no more frequent in patients with PBC than in matched controls [40–42].

Clinical manifestations

Clinical presentation

The diagnosis of PBC is suspected when a patient presents with evidence of chronic cholestasis. In the early stages, this may be an asymptomatic elevation of serum alkaline phosphatase levels or γ-glutamyltransferase. Over time, fatigue or clinical signs of chronic cholestasis such as pruritus or hypercholesterolemia may develop. Jaundice occurs late in the disease process and is a poor prognostic sign. Early reports of patients with PBC described primarily patients with jaundice and advanced disease [43,44]. Over time, clinical case series have included a decreasing percentage of jaundiced patients and an increasing number of asymptomatic patients [45]. This phenomenon is attributed to increasing physician awareness of the disease as well as widespread use of serum alkaline phosphatase and specific autoantibody tests to help establish an early diagnosis. With earlier diagnosis, a long presymptomatic stage of PBC has become well recognized. In one study of 45 patients with PBC identified during this asymptomatic stage, 84% remained asymptomatic 5 years after the diagnosis had been originally suspected [45]. Patients with PBC may experience symptoms from associated conditions, such as sicca complex, thyroid disease, or arthritis before symptoms of the liver disease itself [46]. Eventually, however, many patients will experience the insidious onset of fatigue or pruritus [47].

Signs/symptoms

Fatigue is the most common complaint of patients with PBC. It is present in 50%–80% of patients and significantly impacts quality of life. Its etiology remains obscure, and its severity may be disproportionate to other disease manifestations [47]. Randomized controlled trials of ondansetron, a serotonin $5\text{-}HT_3$ receptor antagonist [48], as well as antioxidants [49] have failed to demonstrate an improvement in symptoms. Lifestyle changes, such as adequate rest and regular exercise, may offer some benefit [50]. Concomitant depression, anxiety, or sleep disturbance is not uncommon, and these comorbidities may benefit from pharmacological therapy. However, treatment with the antidepressant, fluvoxamine, did not improve fatigue in one randomized controlled trial [51].

The generalized pruritus of PBC is characterized by periodic exacerbations and improvements. Pruritus is often more severe in the evenings. Dry skin and decreased ultraviolet exposure during the winter months or intense heat and sweating during hot weather may intensify symptoms. Pruritus is more common in women than men [52], and pregnancy or exogenous estrogens may precipitate or worsen the itching. The etiology of the pruritus is still unknown. The serendipitous discovery that bile acid sequestrants improve symptoms has led to the hypothesis that elevated bile acid levels are responsible. However, a poor correlation between serum or skin levels of bile acids and symptoms argues against the idea of bile acids being a direct pruritogen [52]. Bile salts may act as important intermediaries in the generation of pruritus. A centrally mediated mechanism of pruritus, potentially mediated by endogenous opioids, was proposed by Bergasa, who was able to elicit scratching in monkeys by injecting PBC plasma into their brains [53]. Endogenous opioid levels are increased in cholestatic patients, and symptoms of pruritus

are relieved by administration of opioid receptor antagonists. Interestingly, this intervention is often accompanied by symptoms of narcotic withdrawal [52].

Right upper quadrant discomfort is present in about 17% of patients with PBC [54]. It may be present in the absence of hepatomegaly, and it has no correlation with levels of alkaline phosphatase, bilirubin, or aminotransferases, or with histological stage. It is typically non-specific in character, is not progressive in nature, and, in fact, often disappears spontaneously.

Xanthomas and hyperpigmentation may develop in hyperlipidemic patients with PBC [47]. Xanthomas are most often seen around the eyes (xanthelasma), but may also develop over tendons and in palmar–digital creases. Hyperpigmentation, which results from increased melanin deposition, is most often found on the trunk and arms. Skin may also darken in areas that are repetitively scratched, which may result in a butterfly pattern of sparing in the middle of the back. Both xanthomas and hyperpigmentation are more often seen in patients with prolonged cholestasis but can also be seen before cirrhosis is found on biopsy [55].

Serological findings

The laboratory abnormalities seen in PBC reflect its cholestatic and immunological nature. Elevated alkaline phosphatase and γ-glutamyltransferase are the predominant features, although aminotransferases may also be moderately elevated (usually < 500 units/L). Hyperbilirubinemia ensues in later stages of the disease. Prothrombin times may be prolonged because of either malabsorption of vitamin K or deteriorating hepatic synthetic function. Hypercholesterolemia often occurs as a consequence of reduced biliary excretion of sterols and impaired feedback regulation of retained bile acids [56]. In early stages of the disease, it primarily consists of high-density lipoprotein particles. Mild eosinophilia may also be seen in early stages of the disease. Elevated serum and hepatic copper levels also develop as a consequence of chronic cholestasis. Although impressive copper deposition can be seen in the liver, there is no evidence that this contributes to disease progression [57]. As with other etiologies of portal hypertension and cirrhosis, decreased albumin and platelet counts reflect the underlying hepatic synthetic function and hypersplenism, respectively. Elevated erythrocyte sedimentation rates are not uncommon, but are not useful in following clinical status.

Almost 100% of patients with PBC have circulating autoantibodies (Table 85.1). The most sensitive and specific autoantibodies are the antimitochondrial antibodies, present in 90%–95% of patients with PBC and rarely found in other conditions [58]. Antinuclear antibodies are present in 25%–70% of patients with PBC, and the immunofluorescence pattern is typically speckled, homogeneous, nuclear dot, centromere, or rim-like. The target antigens of PBC antinuclear antibodies are predominantly nuclear pore complex, centromeric, and occasionally lamin proteins. Antinuclear dot (anti-sp100, anti-PML, anti-SUMO) or antinuclear pore complex (anti-gp210, anti-lamin B receptor) are relatively specific markers for PBC [59,60], although anti-sp100 can also be found in 10% of patients with systemic lupus erythematosus [61] or hepatitis C [62]. Unlike AMAs, the presence of anti-sp100 and anti-PML antibodies has been linked to faster disease progression [63]. Anticentromere antibodies are specifically associated with patients who have limited scleroderma, also called CREST syndrome [64], a subpopulation that may be more prone to portal hypertensive complications rather than jaundice and liver failure [65–67]. It is not uncommon to find other autoantibodies that are usually associated with other connective tissue diseases, but these autoantibodies are usually an isolated finding that is not accompanied by other clinical features of the connective tissue disease. Hyperglobulinemia is not as prominent as in autoimmune hepatitis, but selective elevations of the IgM fraction are found in 80%–95% of patients with PBC [2]. Levels of IgM may also be increased in up to 20% of patients with common bile duct obstruction and 70% of patients with alcoholic cirrhosis, but in these diseases, IgM elevations are usually accompanied by similar elevations in IgA or IgG [67].

A positive serum test for AMA is characteristic of patients with PBC. When present in higher titers (at least 1 : 80), it is the most specific laboratory abnormality of this disease. Using indirect immunofluorescence, approximately 90%–97% of patients will be AMA-positive [58]. AMAs detected by immunofluorescence are rarely associated with diseases other than PBC, but have been reported in association with syphilis, myocarditis, tuberculosis, collagen vascular disease, and iproniazid therapy [69]. Low titers (1 : 40 or below) of AMAs have also been reported in individuals with other liver diseases such as autoimmune hepatitis [70]. Low titers may also be found in PBC, and these are sometimes transient [71]. Therefore, repeat testing is warranted when the clinician suspects a diagnosis of PBC but the AMA test is initially negative. AMAs that are identified in seemingly healthy individuals may represent subclinical PBC and deserve to be followed up. Most of these asymptomatic individuals will eventually develop an elevated alkaline phosphatase, histological findings compatible with PBC, and fatigue or pruritus [72].

Histology

The hallmark histological finding of PBC is focal and segmental nonsuppurative cholangitis. Various authors have developed histological staging systems that group the histological abnormalities into four distinct stages [73,74] (Fig. 85.1). Stage I, as described by Ludwig and colleagues [73], is characterized by lymphocytes infiltrating the portal tracts. In stage II of Ludwig and colleagues, the degree of inflammation is greater, extending beyond the limiting plate. In all systems, Stage III is defined by the presence of bridging fibrosis, and the presence of cirrhosis represents Stage IV.

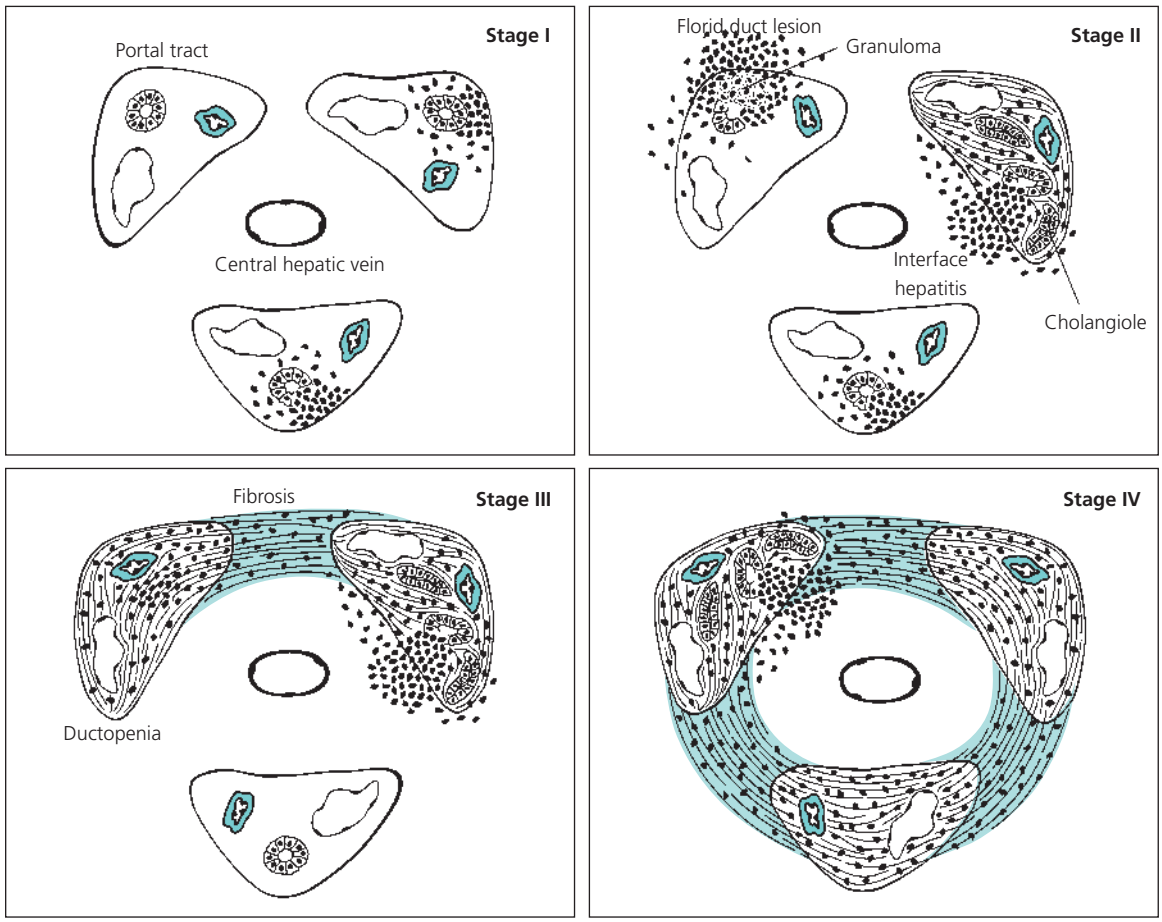

Figure 85.1 Histological progression of primary biliary cirrhosis is categorized into four stages. Characteristic features of each stage are illustrated here, but the lesions are often patchy in nature. Stage I: mononuclear portal tract infiltrates, sometimes involving the bile duct. Stage II: intense mononuclear portal tract infiltrate with interface hepatitis, a florid duct lesion (granulomatous involvement of bile duct), and pseudoductular (cholangiolar) proliferation. Stage III: bridging fibrosis, mononuclear portal tract infiltrates with interface hepatitis, pseudoductular proliferation, and ductopenia. Stage IV: cirrhosis, mononuclear portal tract infiltrates with interface hepatitis, pseudoductular proliferation, and ductopenia.

In earlier stages, bile ducts may show evidence of damage, but are still present in adequate numbers. The most specific (although not pathognomonic) histological finding is the "florid duct lesion," in which the bile duct is surrounded by an intense lymphocytic or granulomatous infiltrate, and the basal integrity of the bile duct has been breached by individual lymphocytes. Granulomas in close proximity to the bile duct are also highly suggestive of PBC. Because of the patchy nature of bile duct involvement in PBC, many portal tracts remain normal or display a nonspecific pattern of mononuclear cell infiltration. The mononuclear infiltrate of PBC consists primarily of T cells, but plasma cells and eosinophils may be seen. The presence of a large number of polymorphonuclear cells or edema surrounding the bile duct, however, should prompt consideration of extrahepatic obstruction. Interface hepatitis (piecemeal necrosis) and foci of lobular inflammation may be present in PBC so the presence of bile duct involvement is an important factor in distinguishing PBC from other forms of chronic inflammatory liver diseases such as autoimmune hepatitis. Bile staining and cholate stasis with feathery degeneration of hepatocytes is evident in some patients, and Mallory hyaline may be found in the affected hepatocytes. Bile ductular proliferation (cholangioles or pseudoducts) is common, particularly along the periphery of the portal tract and is used as a defining characteristic of stage II PBC in the Scheuer staging system [74]. Scattered neutrophils are often found around the proliferating ducts. As the disease advances, ductopenia becomes evident. It is essential to have an adequate number of portal tracts on the biopsy to evaluate the presence of ductopenia. A minimum sample of four portal tracts (with all four portal tracts containing arterioles but no ducts), but ideally 20 portal tracts (with at least 10 portal tracts containing arterioles but no ducts), is needed to make a diagnosis of ductopenia

[75]. Rhodamine and orcein stains for copper and copper-binding protein may be positive in the liver of patients with PBC. The intensity of staining correlates with disease severity, and copper retention may reach levels comparable to that seen in Wilson disease [76].

Epidemiology

The prevalence of primary biliary cirrhosis in the United States and Europe is estimated to be 3.5 per 100 000 individuals (range 0.7–24) with a yearly incidence of 0.9 per 100 000 [20,77]. Some of the highest prevalences have been reported in England and Sweden, where interested researchers have conducted careful epidemiological studies. PBC has been infrequently reported in native Africans [78] and Asians [79]. However, a higher incidence has been reported in persons from India and south Asia who have migrated to western countries [80]. In addition, the prevalence in Japan (5.4 per 100 000) appears to be comparable to that in many European countries [81]. Over the last two decades, the reported prevalence of PBC in North America and Europe has been increasing more rapidly than for any other autoimmune disease [77]. This increase began shortly after the discovery of the AMA and the widespread use of automated chemistry panels, suggesting that greater physician awareness and easier access to diagnostic tests is leading to an increase in the number of patients who are identified at an earlier, frequently asymptomatic phase. Most patients are still identified during middle age, with a median age of presentation between 40 and 55 years.

Women are affected with PBC much more frequently than are men. The reported female : male ratio ranges from 3 : 1 to 22 : 1, with most studies reporting about 12 : 1 [20]. The reason for such a strong female predilection is not known. One hypothesis is that estrogens play an important role in the development or clinical expression of PBC, as has been noted for other autoimmune diseases. The fact that PBC has not yet been reported in a prepubertal female also supports this hypothesis. Of note, whereas many autoimmune diseases improve during pregnancy, the symptoms of PBC may worsen as the result of an increase in cholestasis. While most features of PBC in men are similar to those in women, men have been found to have less pruritus and fewer other autoimmune-associated conditions [50].

Extrahepatic conditions reported to be associated with PBC

PBC is frequently accompanied by other extrahepatic conditions, many of which are also felt to be autoimmune in nature. Up to 84% of patients with PBC manifest features of other autoimmune diseases (Table 85.3).

The most common symptomatic comorbid condition by far is Sjögren syndrome, which occurs in 30%–58% of patients with PBC [2,44,82]. Xerostomia and xerophthalmia of sicca syndrome are the usual manifestations. Vasculitis, renal, pulmonary, or neurological involvement is rarely a clinically significant problem. Evidence of renal tubular acidosis is also present in one-third of patients with PBC, but this association appears to be independent of Sjögren syndrome [83].

Table 85.3 Extrahepatic diseases associated with primary biliary cirrhosis

Extrahepatic disease	Prevalence (%)
Sjögren syndrome	30–58
Gallstones	30–50
Decreased pulmonary diffusion capacity	40–50
Renal tubular acidosis	20–33
Osteoporosis	15–40
Bacteriuria	11–35
Arthropathy	4–38
Rheumatoid arthritis	3–26
Hypothyroidism	11–32
Raynaud phenomenon	7–14
CREST syndrome[a]	3–6
Autoimmune thyroiditis	3–6
Autoimmune anemias	1–2
Psoriasis	1–13
Lichen planus	0.5–6
Ulcerative colitis	0.5–1

a CREST, syndrome of calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias.

The CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias – also called "limited scleroderma") is present in about 5% of patients with PBC [2,44,82,84]. The most common features seen are Raynaud phenomena and telangiectasias. Isolated Raynaud syndrome occurs in an additional 7%–14%. Esophageal dysmotility usually presents as gastroesophageal reflux disease or symptomatic hiatal hernia, but frank dysphagia may be present and can be worsened by concomitant xerostomia from Sjögren. Progressive systemic sclerosis, with involvement of other internal organs such as kidney and heart, is actually rare in patients with PBC.

About 10%–20% of patients with PBC complain of arthralgias [2,82,85], which may have a variety of causes. Because PBC often occurs in older individuals, osteoarthritis is the most common reason for joint pains. Rheumatoid arthritis is, however, more common in patients with PBC than in the general population. One study found that 53% of patients with PBC had circulating rheumatoid factor, although only 7% met the established criteria for the diagnosis of rheumatoid arthritis [85]. Radiological surveys of patients with PBC demonstrate that erosive arthritis is common and may not always be accompanied by a positive rheumatoid factor. Hypercholesterolemic arthropathy and hypertrophic osteoarthropathy are also potential reasons for joint disease in this population [86].

Thyroid disease is another frequent comorbid condition, present in about 20% of patients with PBC [2,44,52,82]. Usually this manifests as hypothyroidism, but Hashimoto thyroiditis is also common. Fatigue is a frequent symptom of PBC. However, hypothyroidism should always be excluded before attributing the fatigue to PBC itself.

Osteoporosis is observed in up to 40% of patients with PBC who are referred for transplant [87]. The severity of the bone disease correlates with the severity of the liver disease, and therefore patients with stage IV disease should be screened with bone densitometry at regular intervals. In an unselected group of stable patients with PBC, osteopenia (defined as a T-score of −1.5 to −2.5) was present in 45% and osteoporosis (defined as a T-score less than −2.5) was present in 15% [88]. Osteoporosis in these patients is the result of both increased resorption and decreased formation of bone [89]. Vitamin D deficiency as the result of malabsorption in later stages of disease may also lead to osteomalacia.

Decreased pulmonary diffusion capacity is common in PBC, but it is usually asymptomatic. It is disputed as to whether this finding is related to Sjögren syndrome, CREST syndrome, or the presence of cirrhosis [90]. Symptomatic pulmonary disease is present with a low frequency (< 1%) and has been reported to be the result of a variety of conditions, including sarcoidosis, interstitial pulmonary fibrosis, fibrosing alveolitis, bronchiolitis obstructing obliterizing pneumonia, primary pulmonary hypertension, and hepatopulmonary syndrome [91–93].

Urinary tract infections are frequent, recurrent, and often asymptomatic in female patients with PBC. Up to 61% of female patients report previous urinary tract infections. Upon random screening, about 20% of female patients with PBC will have bacteriuria, as compared with about 7% of age-matched female patients with other liver diseases, 5% of healthy age-matched females, and 20% of age-matched females with cirrhosis [94]. At least half of patients with PBC with bacteriuria are asymptomatic. When followed over time, an additional 10% will develop bacteriuria over a 3-month interval, and 65% will develop pyuria over a 12-month interval. Recurrent infections are often with a different organism, and treatment of asymptomatic infections does not decrease the recurrence.

Despite the frequent occurrence of circulating immune complexes, immune complex disease has only occasionally been reported to occur in PBC. Systemic lupus erythematosus [95], temporal arteritis [96], and other vasculitis syndromes can be found in patients with PBC, but are not particularly increased in frequency. Several reports of membranous glomerular nephritis and leukocytoclastic vasculitis indicate that IgM complexes can be found in the kidney and skin, suggesting that the elevated IgM levels may play a role [97]. In addition, more than a dozen cases of polymyositis with PBC appear in the literature, many of which are in Asian patients [98].

Numerous case reports testify that celiac sprue can occur in patients with PBC. A single study from Ireland found that 11% of patients with PBC had antiendomysial antibodies, which were often accompanied by villous atrophy [99]. However, three larger studies examining the prevalence of antiendomysial antibodies in unselected patients with PBC failed to find a valid association [100].

Gallstones are found by radiological imaging in 30%–50% of patients with PBC, particularly in later stages of the disease when pigment stones are more likely to be formed [101]. Their presence often leads to confusion and delays in diagnosis of PBC, when the patient presents with cholestatic liver test abnormalities, right upper quadrant discomfort, and gallstones, and a presumptive diagnosis of extrahepatic biliary disease is made.

The incidence of extrahepatic cancer in PBC has been studied because of numerous case reports of cancers found in patients with PBC, as well as reports from the 1980s that the relative risk of breast cancer was increased 4.4-fold compared with the risk in other individuals. More recent population studies, however, have failed to find an increased risk of extrahepatic malignancies in PBC [101,102].

The clinical course of associated conditions is not altered by treatment of PBC [82]. The clinician must maintain a high index of suspicion for those conditions that are commonly encountered in patients with PBC so that these diseases may be recognized and managed appropriately.

Differential diagnosis

The differential diagnosis of a patient who presents with chronic cholestatic liver tests may initially include extrahepatic obstruction, or intrahepatic cholestatic liver diseases, as well as granulomatous and infiltrative diseases of the liver.

Extrahepatic obstruction, from gallstones, tumors, or sclerosing diseases of the bile ducts, should first be excluded with good sonographic imaging or cholangiography. Serological testing for AMA will help to differentiate PBC from other intrahepatic cholestatic liver diseases. In patients who are AMA-negative, cholangiography is usually necessary. Liver biopsy in patients who are suspected of having PBC, can confirm the suspected diagnosis, stage the patient, and rule out other etiologies of liver disease. In patients who are AMA-negative, liver biopsy is essential to demonstrate a nonsuppurative cholangiopathy and to exclude other disorders [47].

A variety of diseases may resemble PBC clinically or histologically, but they do not lead to AMAs. Patients who have had prolonged extrahepatic obstruction may also develop a secondary biliary cirrhosis which histologically resembles primary biliary cirrhosis. A rare variant of primary sclerosing cholangitis affects only the small intrahepatic ducts [104]. However, these biliary lesions are characterized by an exuberant fibrotic reaction ("onion skinning") and less lymphocytic

infiltration. Sarcoidosis or idiopathic granulomatous hepatitis may mimic PBC with similar biochemical liver tests, right upper quadrant discomfort, hepatomegaly, and hepatic granulomas. Typically, the granulomas of sarcoidosis are larger, well-formed granulomas found in the liver parenchyma rather than involving the bile ducts [105]. It is possible to have both conditions concurrently; there are several well-documented cases of patients with AMA-positive PBC who also have multi-organ involvement with sarcoidosis [91]. A rare form of chronic hepatitis C that is cholestatic has also been reported [106], and cirrhotic patients with hepatitis C may present with fatigue and pruritus. Infection with the hepatitis C virus is so prevalent that viral infection with hepatitis C should be excluded in all patients with suspected PBC. It is also important to recognize that a variety of drugs have been implicated as causes of nonsuppurative cholangitis and ductopenia, which in some cases may progress to biliary cirrhosis [107]. Other rare causes of intrahepatic cholestasis, such as lymphoma and idiopathic ductopenia, are best excluded by examining liver tissue.

Differentiating PBC from autoimmune hepatitis can be difficult because of overlapping histological and serological features. A published scoring system by the International Autoimmune Hepatitis Group can be used to facilitate the distinction and is particularly helpful when the AMA test is negative [108]. Antinuclear antibodies are common in both diseases and their titer does not help to distinguish between autoimmune hepatitis and PBC. Rarely, some patients will meet diagnostic criteria for both autoimmune hepatitis and PBC, or will develop autoimmune hepatitis while being treated for PBC, so called "overlap syndrome."

It is clear that a small number of patients have a clinical and histological picture similar to that of PBC, except they have atypical antibody profiles, including the absence of AMAs, higher prevalence of antinuclear antibodies (70%–100%), and lower (although still elevated) total IgM levels [109]. This syndrome has been called "autoimmune cholangitis" or "AMA-negative PBC." It is unclear whether the pathogenesis of this condition is distinct from that of AMA-positive PBC, or whether the serological differences between the two syndromes merely reflect the individual diversity of the humoral immune response. Large series of patients with autoimmune cholangitis have not been extensively examined because the frequency of this disorder is so low that few centers see more than a handful of cases. Interpretation of studies is further complicated by the lack of uniform diagnostic criteria. The limited studies that have been conducted suggest that the natural history and response to treatment of this disorder is similar to that of AMA-positive PBC [110]. Similar immunological disturbances, including the presence of PDC-E2-reactive material on the surface of bile ducts and oligoclonality of T-cell populations, have been noted in both conditions [111,112]. In fact, there is reluctance among many experts to embrace the hypothesis that this syndrome represents a distinct entity from the syndrome of AMA-positive PBC.

Course and complications

Clinical course

PBC may exist for relatively long periods of time in an asymptomatic state [47,113]. Indeed, data from natural history studies suggest that a fraction of asymptomatic patients will never develop symptoms during their natural lifespan [113]. However, approximately 66%–83% of untreated asymptomatic individuals become symptomatic (usually pruritus or fatigue) within 10 years, and only 5% remain asymptomatic after 20 years [114]. Most individuals with established disease eventually progress to cirrhosis. In two studies, the mean time of progression from stage 1 or 2 disease to cirrhosis in untreated patients was 4–6 years [115,116]. Survival is shortened in patients with PBC compared with healthy controls. In a recent large, geographically based cohort of mostly untreated individuals, the median survival was 9 years, although only 42% of deaths were liver-related [114]. Clinical progression is foretold by worsening of specific biochemical parameters, particularly serum bilirubin levels. The mean survival of patients with bilirubin values over 2 mg/dL is 4 years, and for those with bilirubin values over 6 mg/dL, mean survival drops to 2 years [115]. Several mathematical models exist that incorporate bilirubin and other parameters into formulas that are clinically useful to predict mortality and judge timing for transplant referral of individual patients [114,116,117]. The most extensively validated and commonly used survival model is the Mayo Risk Score [116]. The Mayo Risk score calculates an *R*-score based on the following formula (adapted from original to use international normalized ratio [INR], personal communication with Dr E.R. Dickson and Dr Terry Therneau, Mayo Clinic): $R = 0.871 \log_e(\text{bilirubin mg/dL}) + [-2.53 \log_e(\text{albumin gm/dL})] + 0.039 \text{ age (years)} + 0.881 \log_e(\text{INR}) + 5.92 + 0.859$ (edema scores of 0, 0.5, or 1.0 for none, mild, or moderate edema, respectively). The computed *R*-score is then used to predict the fraction of patients expected to survive for: 1 year = $0.970^{(R-5.07)}$, 2 years = $0.941^{(R-5.07)}$, 3 years = $0.883^{(R-5.07)}$, 4 years = $0.833^{(R-5.07)}$, 5 years = $0.774^{(R-5.07)}$, 6 years = $0.721^{(R-5.07)}$, or 7 years = $0.651^{(R-5.07)}$. Notably, in all prognostic models, serum bilirubin values play a prominent role in predicting survival. Serum albumin, age, and time are found to be independent predictors of survival in some but not all prognostic models. The Mayo Risk score has been demonstrated to be useful in judging the appropriate time for transplantation. However, in some populations, it has been found to overestimate mortality [118]. An updated version of the model, which evaluates interval changes in the patient's condition to estimate short-term survival, is less likely to overestimate long-range mortality in patients with early disease [119].

Complications

Once cirrhosis is established, the clinical complications of portal hypertension and deteriorating liver function are similar to those of patients with cirrhosis from other causes. In patients with PBC, presinusoidal fibrosis alone may be sufficient to cause portal hypertension and esophageal varices and associated bleeding complications may precede the development of stage 4 fibrosis [120]. The risk of hepatocellular carcinoma in patients with PBC is also increased compared with healthy individuals [103]. This risk is almost exclusively limited to cirrhotics, and is higher for males. In general, the reported risk of hepatocellular carcinoma in PBC is significantly less than the reported risk of hepatocellular carcinoma in other liver diseases such as hereditary hemochromatosis, hepatitis B, or chronic hepatitis C. One possible exception is the subgroup of males with advanced PBC in whom incidences as high as 20% have been reported [103].

Pruritus is a common, and often vexing, symptom of patients with PBC. Its severity often fluctuates and is not correlated with disease progression. However, in the terminal stages of the disease, pruritus often disappears. Its etiology is unknown, but elevated bile acid levels and endogenous opioid levels have been implicated [121].

Decreased osteoblastic and increased osteoclastic activities contribute to accelerated osteoporosis in patients with primary biliary cirrhosis [89]. The risk increases with disease severity, and regular screening of bone density in cirrhotic patients facilitates treatment. Preserving bone mass is particularly important for patients who ultimately undergo liver transplantation, because bone mass decreases further in the immediate posttransplant period of heavy immunosuppression.

Like osteoporosis, deficiencies of the fat-soluble vitamins are common in patients with PBC, and correlate with disease severity. For this reason, asymptomatic patients with cirrhosis should be screened. Poor bile salt excretion is the primary reason for deficiencies, which may be made worse by treatment with bile acid sequestrants or antibiotics. Vitamin A is frequently the first fat-soluble vitamin to become deficient, and patients may not complain of night blindness. Vitamin D deficiency may cause osteomalacia, and vitamin K deficiency may result in prolonged coagulation times. Vitamin E serum levels may be falsely elevated in patients with hyperlipidemia. A ratio of serum vitamin E to total lipid that is less than 0.8 mg/g is considered deficient.

Treatment

Therapy of PBC

Therapy with ursodeoxycholic acid (UDCA), at a dosage of 13–15 mg/kg/day has become the mainstay of therapy for PBC (Fig. 85.2). The medication may be administered in two or three divided doses, or as a single evening dose. The potential mechanisms of UDCA's beneficial effect on PBC are multiple [122]. UDCA is a bile acid that is less toxic to hepatocytes than other more hydrophobic bile acids. It is normally present in human bile at low concentrations (1%), but when ingested at a daily dosage of 13–15 mg/kg, it replaces about 40% of the bile acid pool. It promotes insertion of bile salt export protein on the canalicular membrane, increasing intracellular and canalicular transport of hydrophobic bile acids, which decreases the toxic effects of bile on the liver during cholestasis. UDCA stabilizes hepatocyte membranes, decreases rates of apoptosis of biliary epithelial cells, and has antioxidant properties such as the ability to inhibit nitric oxide synthetase. UDCA has been found to decrease the expression of adhesion molecules (lymphocyte function-associated antigens I and II, and intercellular adhesion molecule 1), to decrease HLA class I and II expression in the liver, and to decrease T-cell reactivity and cytokine production.

The ability of UDCA to impact the natural history of PBC is still controversial, and the lack of sufficiently long placebo-controlled trials precludes a definitive statement on its effect on survival. However, comparison of the *actual survival* of patients treated with UDCA with *expected survival* calculated from validated models, indicates that UDCA delays progression to cirrhosis in patients with early-stage disease. Five large, randomized, double-blind controlled trials have demonstrated the beneficial effects of UDCA therapy [123–127]. Collectively, these studies randomized 890 individuals to either UDCA or placebo and followed them for an average of 2 years before switching the placebo patients to UDCA. In all trials, UDCA produced a rapid and impressive improvement in serum liver tests, primarily alkaline phosphatase, bilirubin, aminotranferases, and IgM levels. Biochemical improvement was usually noted within the first 1 or 2 months of therapy and improvements continued, with a maximal response seen by about 6 months. Effects on symptoms were unimpressive, although a small number of patients reported an improvement in itching. Four of the five trials reported beneficial effects on histology, primarily improvement in inflammatory features and less ductopenia in the treated groups. No effect on the development of cirrhosis or portal hypertension, or death/transplantation could be detected at 2 years in any of the individual trials. A combined analysis of patients from three of the trials, which included patients that were switched from placebo to UDCA after 2 years, reported an improvement in transplant-free survival after 4–6 years in patients originally randomized to UDCA [128]. The conclusions from this combined study, however, have been disputed by two subsequent larger metaanalyses. One traditional metaanalysis of 11 randomized trials, including 1272 patients, failed to show any difference between UDCA and placebo in the incidence of death or transplantation, or development of liver disease complications such as ascites or gastrointestinal bleeding [129]. The second metaanalysis was a Cochrane Hepato-Biliary Group systematic review, examining 16 randomized trials including 1422 patients. It also

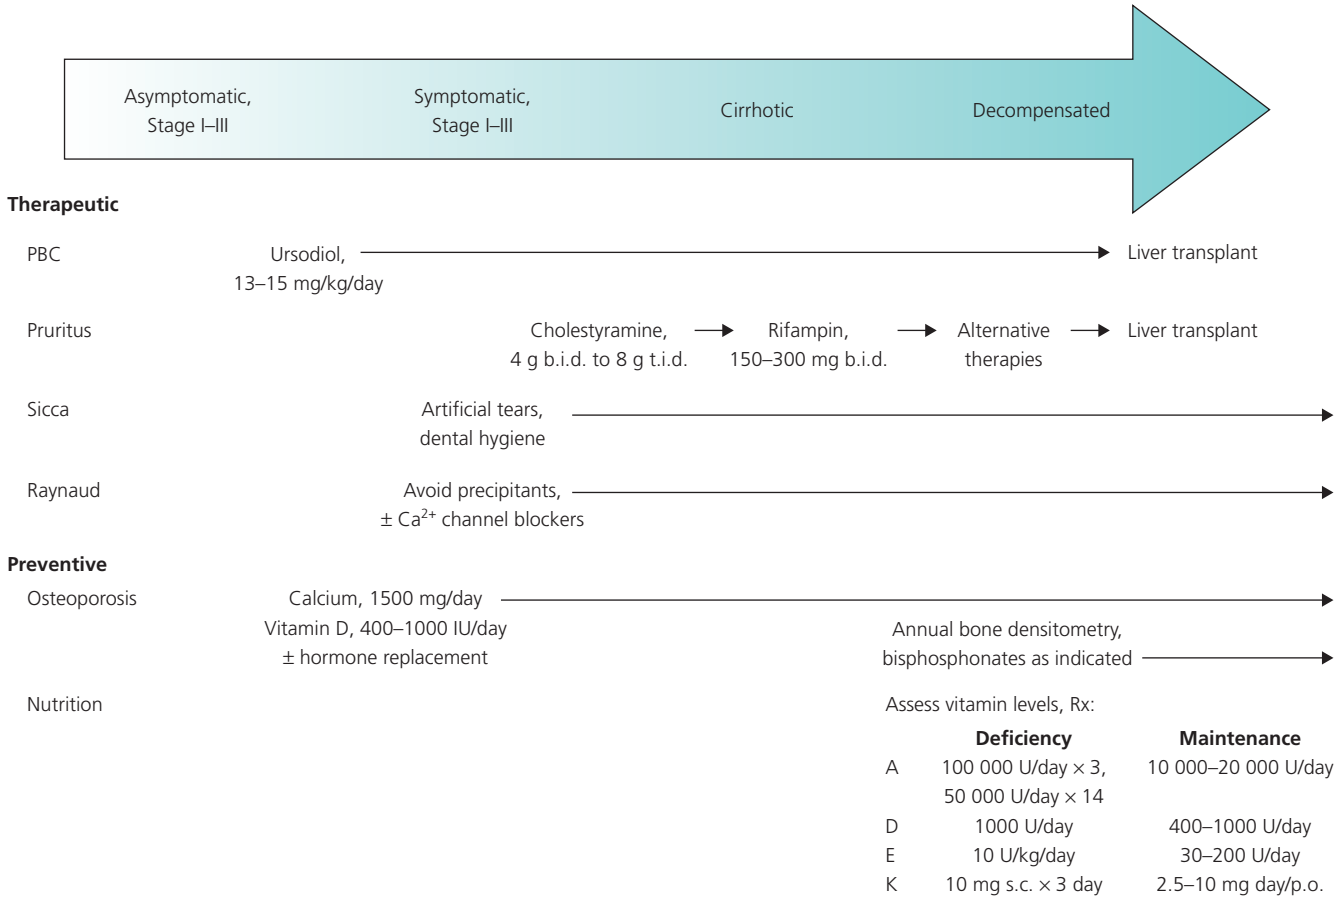

Figure 85.2 Management of primary biliary cirrhosis (PBC) and associated conditions; adapted from Heathcote [173]. Complications of portal hypertension (not shown) are managed in the same manner as in other forms of cirrhosis.

failed to show a difference in mortality or liver transplantation, worsening of histological stage, or development of varices with UDCA treatment. The number of patients developing ascites, however, was lower in persons taking UDCA [130]. The difficulty in clearly demonstrating survival benefits of UDCA is not surprising considering the slowly progressive course of PBC and the relatively short duration of the placebo phase in most randomized controlled trials. A subsequent randomized controlled study which lasted 12 years was still unable to show a mortality benefit of UDCA in PBC [131]. In addition, the potential benefit of UDCA may be greatest when it is started early in the disease course, making it even more difficult to demonstrate survival effects in clinical trials. Follow-up studies of patients treated with UDCA for prolonged periods (10–20 years) demonstrate that patients started on UDCA during stage 1 or 2 have survival rates similar to the general population, but patients started on UDCA in stage 3 or 4 have increased mortality. In fact, survival of patients with late-stage PBC treated with UDCA was no better than predicted survival without any treatment [132]. Progression to cirrhosis appears to be slower in individuals taking UDCA. The incidence of cirrhosis in 183 patients treated with UDCA and followed for 10 years from stages 1, 2 and 3 was 17%, 27%, and 76%, respectively [133]. Importantly, UDCA was extremely well tolerated and safe in all trials. Therefore, because of its excellent safety profile, proven ability to improve markers of cholestasis, and the suggestion of long-term benefits, UDCA is recommended as treatment for all stages of PBC.

The prevailing viewpoint is that bile duct destruction is immune-mediated so immunosuppressive and antiinflammatory drugs have historically been selected as potential medical treatments for PBC. Unfortunately, the results of clinical trials have been disappointing or inconclusive for almost all of them. In striking contrast to UDCA therapy, the major problems encountered in the use of immunosuppressive therapy have been their serious side effects, which have an important cumulative impact in the therapy of a slowly progressive, lifelong disease.

Chlorambucil was evaluated in a controlled trial of 24 patients followed for 4 years [134]. Modest improvements in bilirubin levels, IgM levels, and inflammatory scores were seen in the group given chlorambucil. However, bone marrow depression, requiring cessation of treatment in 17% of

patients, was a significant problem. It was felt that the potentially dangerous side effects of chlorambucil, combined with its modest effects on the disease, made it an impractical therapeutic choice.

D-Penicillamine has been tested in three large controlled clinical trials on 472 patients with long-term follow up [135–137]. Between 22% and 46% of patients experienced serious side effects necessitating discontinuation of the drug. Despite its antiinflammatory, immunosuppressive, antifibrotic, and copper-chelating properties, D-penicillamine was found to have no therapeutic benefit in PBC.

Prednisolone was evaluated in a controlled trial of 36 patients followed for 3 years [138]. There were significant improvements in alkaline phosphatase, aminotransferase, and immunoglobulin levels. Improvements in fatigue, pruritus, and bilirubin levels were transient, and there was a trend toward an improvement in liver histology. These modest benefits were outweighed by the deleterious side effects of prednisolone, especially with respect to accelerated loss of bone density. Budesonide, a corticosteroid with a high first-pass hepatic metabolism, has been tested as a second agent with UDCA [139–141] and found to significantly improve liver histology, liver enzymes, and immunoglobulin levels. However, systemic effects, including bone loss, did occur, particularly in patients with advanced disease.

Cyclosporine (ciclosporin [rINN]) was evaluated in a multicenter, controlled trial in which 349 patients were followed for up to 6 years [142]. Significant improvements in bilirubin, alkaline phosphatase, albumin, aminotransferases, and pruritus were seen, but liver histology was not affected. Survival (time to death or transplant) was modestly prolonged in the cyclosporine group, but complications such as hypertension and renal toxicity were severe enough to discourage cyclosporine from further consideration.

Azathioprine has been tested in two controlled clinical trials [143,144] on a total of 293 patients followed for 2–3 years. Both trials failed to see a survival difference between those treated with azathioprine and those treated with placebo. However, both trials also included a large percentage of jaundiced patients with advanced disease. In the European trial, when patients with higher bilirubin levels were excluded from the analysis, a slight survival advantage was seen in the azathioprine group. Azathioprine was well tolerated by patients with PBC in both studies. Nevertheless, after these trials, azathioprine was largely abandoned as a therapy for PBC.

Colchicine has both antiinflammatory and antifibrotic properties, and so has been seriously considered as a potential therapy for PBC. In some controlled trials [145–147] serum levels of bilirubin, albumin, alkaline phosphatase, cholesterol, and aminotransferases were modestly improved, but symptoms and histological progression were not affected. In one trial [148], a trend toward decrease in liver mortality was seen at 4 years. However, in a Cochrane Database analysis of 10 trials involving 631 patients, no significant differences were detected between colchicine and placebo/no intervention regarding mortality or liver transplantation, liver complications, liver biochemical variables, liver histology, or adverse events [149]. In fact, the authors were unable to exclude a risk of increased mortality from colchicine.

Methotrexate has been reported to improve liver enzymes and histology in selected patients with PBC who do not respond fully to UDCA [150]. However, a randomized double-blind, controlled trial of 265 PBC subjects found that adding methotrexate to UDCA had no impact on survival, histology, or development of portal hypertensive complications after 7 years [151].

Mycophenolate mofetil has been tested as a conjunctive therapy with UDCA in a pilot study of 25 patients who did not achieve biochemical remission on UDCA alone. There were only marginal improvements in alkaline phosphatase and aspartate aminotransferase, and the authors concluded that there was no clinical benefit [152].

At present, UDCA is the only approved recommended therapy for PBC. While it is hoped that UDCA therapy will delay liver disease progression and prolong survival, it is clear that it does not obviate the need for liver transplantation. Patients with complicated cirrhosis or poor estimated survival (Mayo Risk score ≥ 7, model for end-stage liver disease > 15) should be considered for transplant referral.

Transplantation for PBC

In general, patients with PBC have excellent posttransplant outcomes, with a 75% 5-year survival and with 95% of survivors returning to work. AMAs frequently persist after transplant, although often at lower titers than pretransplant. Histological recurrence of PBC in the transplanted liver occurs in up to 32% of recipients [153]. Fortunately, because of the slow progression of recurrent disease, it is not a significant clinical problem. Tacrolimus-based immunosuppressant regimens may be associated with earlier and more frequent recurrence compared with cyclosporine-based regimens. Out of 485 patients transplanted for PBC, the median time to recurrence was 62 months in those receiving tacrolimus, as compared with 123 months in those receiving cyclosporine [154].

Management of complications

Managing the complications of cholestasis comprises a considerable portion of the clinician's treatment of the patient with PBC (Fig. 85.2).

Pruritus

Bile acid sequestrants, such as cholestyramine and colestipol, given at 4–16 g/day in divided doses, improve pruritus in 80%–85% of patients with cholestatic pruritus within 4–11 days. They are the first line of medical treatment for cholestatic pruritus because of their efficacy and safety profile [47].

Unfortunately, compliance with these drugs is sometimes impaired by dislike of the powdered drug delivery system or difficulty in timing other medication doses so that the sequestrant does not inhibit drug absorption (manufacturers recommend that all other medicines be taken at least 1 h before or 4 h after taking the sequestrant). The sequestrants are not absorbed so side effects are limited to the gastrointestinal tract. Rifampin has also been demonstrated to relieve cholestatic itching in small controlled trials [155,156]. The mechanism is unknown but is thought to be mediated through enhancement of the mixed function oxidase system leading to an increase in the rate of bile acid metabolism and excretion or competition for hepatic bile acid uptake. The latter may also lead to an increase in serum bilirubin levels in some patients, which may make monitoring of disease progression difficult. Rare cases of severe hepatotoxicity have been reported. At a total dosage of 300–600 mg/day given in divided doses, the mean time to relief is 2 days, and it is also effective long term. It has been demonstrated by one group to be superior to phenobarbitol therapy [157]. Phenobarbitol, however, is also more effective than placebo. The mechanism of action is likely related to hepatic enzyme induction or sedation. The drug dosage (15–180 mg/day) is titrated to balance efficacy and sedation, but usually much lower dosages are required than for the treatment of epilepsy. Antihistamines are often used to treat itching in patients with PBC, but no controlled trials have demonstrated their efficacy. In fact, there is a lack of evidence that cholestatic pruritus is histamine-mediated. However, anecdotal success in patients with mild itching may be attributable to their sedating properties. Naloxone, naltrexone, and nalmefene, opioid receptor blockers, have been demonstrated to be superior to placebo in alleviating cholestatic pruritus [158]. These drugs can sometimes elicit an opioid withdrawal syndrome of nausea, pallor, colicky abdominal pain, anorexia, and hypertension. The reaction is usually temporary and subsides over 2–3 days of continued treatment. Breakthrough of pruritus and unmasking of chronic pain disorders have also been reported with prolonged therapy. Serotonin may be another important neurotransmitter in the perception of pruritus. A recent pilot study of sertraline, a selective serotonin reuptake inhibitor, at a dosage of 75–100 mg/day demonstrated a beneficial effect on pruritus [159]. However, these findings await confirmation in larger studies. Initial studies of ondansetron, a serotonin $5HT_3$ receptor blocker, showed promise as a new therapeutic agent [160], but a subsequent double-blind, randomized controlled trial showed no benefit [161]. Plasmapheresis and filtration using the molecular adsorbent recirculating system has been used as a desperate measure to control difficult pruritus of cholestasis. In a small number of patients, transient success has been reported lasting anywhere from 24 h to several months. Phototherapy has also been anecdotally successful in ameliorating cholestatic pruritus, but its effectiveness has never been adequately tested in clinical trials. UDCA is associated with little to no relief of pruritus.

Osteoporosis

Accelerated osteoporosis can be a devastating complication of chronic cholestasis, and careful monitoring and preventative treatment are the best therapy. Calcium supplementation (1500 mg/day for postmenopausal females and 1000 mg/day for men and premenopausal females) is well tolerated and widely used as a preventative measure. Estrogen replacement for postmenopausal females is also well tolerated. Estrogens inhibit canalicular transport of bilirubin and have the potential to worsen cholestasis. However, the majority of patients with PBC can benefit from transdermal or low-dose oral estrogen replacement without experiencing a clinically significant increase in cholestasis [162]. Additional therapy is indicated if the bone density decreases into the osteoporotic range (T-score > 2.5 SD) Raloxifene, a selective estrogen receptor modulator that reduces fracture rates in noncholestatic, postmenopausal women, has been tested in a pilot study of nine patients with PBC with promising improvements in bone density [163]. Larger studies in cholestatic patients are required. Alendronate, a bisphosphonate, increases bone density in patients with PBC with few or no side effects [47]. The theoretical risk of inducing variceal hemorrhage has not been reported, although few subjects with varices have actually been treated. Sodium fluoride has also been demonstrated in one trial to increase bone density in patients with PBC [47]. However, less overall experience and increased side effects (severe gastritis) make this drug a less attractive choice compared to alendronate.

Vitamin deficiencies

Deficiencies in the fat-soluble vitamins should be remedied. There is the potential for toxicity from overdoses so levels of vitamins A and D should be monitored in patients receiving supplements.

Hyperlipidemias

Serum cholesterol levels are typically elevated in patients with PBC, even in early stages of the disease. However, two retrospective studies indicate that this does not translate into increased mortality from cardiovascular events [164,165]. Potential reasons for this include:

- onset of disease during middle age rather than childhood resulting in less time for plaque formation
- a favorable high-density lipoprotein : total cholesterol ratio during early stages of the disease
- a favorable lipoprotein profile including the presence of lipoprotein X and low lipoprotein A levels.

Therefore, the decision to intervene medically should be based on factors such as unfavorable lipoprotein profiles, significant personal or family cardiac history, or the presence of painful xanthomas. Patients with PBC are often resistant

to dietary management of hypercholesterolemia, and they may respond paradoxically to clofibrate therapy [166]. Almost all controlled trials of UDCA have shown significant decreases in serum cholesterol levels. Case series have reported efficacy with hydroxymethylglutaryl-coenzyme A reductase inhibitors [167,168] or low-density lipoprotein apheresis [169], but no large randomized clinical trials have been published.

Sicca syndrome

Many patients with PBC have sicca syndrome and are troubled by xerophthalmia and xerostomia. Carboxymethylcellulose lubricants may be used to relieve irritation of the cornea and help prevent ulceration. More severe cases may respond to ocular cyclosporine emulsion, hydroxypropyl cellulose inserts, or punctual occlusion. Xerostomia may be relieved with adequate access to fluids, use of sugar-free hard candies, and prescription moisturizers when necessary. It is important to have regular evaluation by a dental professional because decreased saliva secretion leads to decreased clearance of food particles and increased dental caries.

Treatment of variant forms of PBC

In autoimmune cholangitis, UDCA is effective at improving liver biochemistries, and 3-year clinical outcome is similar to that of AMA-positive PBC [110]. Steroid therapy may modestly improve liver biochemistries in autoimmune cholangitis, as it does in AMA-positive PBC [138], but steroids have been associated with accelerated bone density loss and other undesirable side effects in cholestatic patients. UDCA, therefore, appears to be better tolerated as a long-term therapy than corticosteroids.

Whether patients with overlap syndrome (autoimmune hepatitis + PBC) should be treated with UDCA alone or with UDCA in combination with steroids or azathioprine is debatable. Small, retrospective analyses of cohorts with overlap syndrome demonstrate that patients who do not respond well to an initial trial of UDCA may respond to corticosteroids [170]. However, studies differ as to whether the 2-year outcome is different in dual therapy from UDCA monotherapy [171,172]. No randomized trials have been performed. Thus, clinical judgment must be used to determine the predominant syndrome, balance the risk of medication side effects with possible therapeutic benefit, and initiate therapy accordingly.

The classic triad of diabetes, bronze pigmentation of the skin, and cirrhosis was first described by Trousseau in 1865, and was given the name hemochromatosis by von Recklinghausen in 1889. The seminal study by Sheldon in 1935 identified the role of iron in the pathogenesis of this disease and its hereditary nature. The linkage to human leukocyte antigen (HLA) A3 and localization of the gene to the short arm of chromosome 6 was subsequently established by Simon's group. Feder and colleagues identified the *HFE* gene and the homozygous C282Y mutation in probands with phenotypic hemochromatosis in 1996 using positional cloning [1]. With a prevalence of 1 : 200 to 1 : 250 for homozygosity and 1 : 8 to 1 : 12 for heterozygosity, the C282Y mutation of the *HFE* gene is one of the commonest genetic mutations among persons of northern European descent [2]. Other forms of hereditary hemochromatosis are the result of mutations in other genes regulating iron transport, although these other types are rare in comparison to *HFE*-associated hemochromatosis [3]. The pathophysiology, clinical features, and treatment of hemochromatosis are reviewed in this chapter.

Iron homeostasis

The normal daily turnover of iron is approximately 20 mg. Intestinal absorption mediated by villous enterocytes in the duodenum accounts for only 10% of the turnover; because there is no regulated mechanism for the excretion of iron, regulation of intestinal absorption is crucial for the maintenance of iron homeostasis [4,5]. An incompletely defined signaling pathway between the liver, erythrocytes, macrophages, and enterocytes regulates the intestinal absorption of iron (Fig. 86.1).

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Intestinal absorption

Dietary iron is present either in inorganic form (in vegetables and cereals) or as heme iron (predominantly from hemoglobin and myoglobin in animal proteins). The mechanism for heme absorption has not been elucidated as clearly as that for inorganic iron [5].

Absorption of inorganic iron

Intestinal absorption of inorganic iron involves:

- the reduction of iron from the ferric (Fe^{3+}) to the ferrous (Fe^{2+}) state
- uptake across the mucosal surface of the enterocyte
- transport across the cell to the basolateral aspect
- release into the circulation bound to transferrin [6].

Duodenal ferric reductase (Dcytb) present on the apical plasma membrane of the enterocyte reduces the highly insoluble, and therefore nonabsorbable, ferric (Fe^{3+}) iron to ferrous (Fe^{2+}) iron [7] which is then transported across the apical membrane by divalent metal transporter 1 (DMT1) into the enterocyte [8,9]. Iron is oxidized back to the ferric state by hephaestin, a ferroxidase with homology to ceruloplasmin, and is then exported from the enterocyte to the blood by ferroportin and transferrin receptor (TfR1) located on the basolateral aspect of the enterocyte [7,10].

Iron not exported into the circulation is stored within the enterocyte bound to ferritin and is excreted in the feces by sloughing of senescent enterocytes [6]. Apart from menstrual blood loss, sloughing of senescent enterocytes is the only physiological means of significant iron excretion from the body [11].

Absorption of heme

Heme is transported intact into the intestinal epithelial cells where the iron is released from the heme by the microsomal heme oxygenase system. The only heme transporter identified in the enterocytes is the heme carrier protein 1 (HCP1) [12]. However, the relatively small amount of heme transported by HCP1 suggests that other proteins or cofactors are

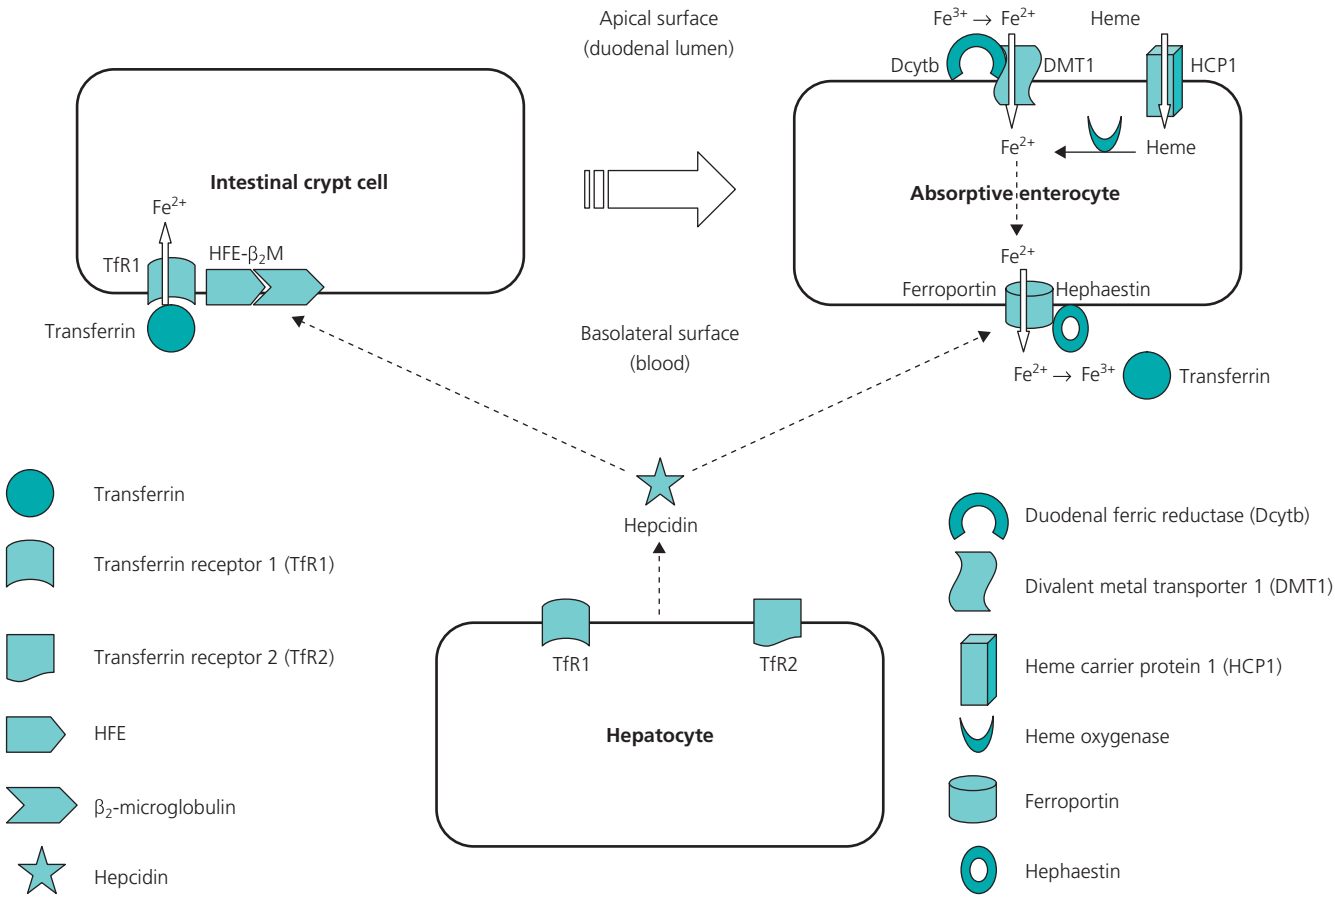

Figure 86.1 Model for control of iron absorption.

also involved in intestinal heme transport [13]. Two other heme transporters, the receptor for feline leukemia virus C (FLVCR) and breast cancer resistance protein (Bcrp) are found in hematopoietic cells, but have not been found to have a role in intestinal iron transport [14,15].

Iron in the circulation

In blood, iron is bound to the plasma protein transferrin, which prevents precipitation of iron in plasma, attenuates the toxicity associated with its redox activity, and facilitates the delivery of iron to cells by binding to TfR1 [16]. Normally, serum transferrin is only about 30% saturated with iron, leaving the remainder readily available for binding free iron.

Iron in the cells

Cellular uptake of transferrin-bound iron is mediated by TfR1, which is expressed on cell surfaces and binds to iron-loaded transferrin to form transferrin–TfR1 complexes. These are then internalized into endosomes where iron is released from transferrin [17]. Export of iron from cells is mediated by the proteins ferroportin [18] and ceruloplasmin [19].

Most of the transferrin-bound iron in the circulation enters hematopoietic cells and ultimately reaches macrophages when senescent red blood cells are phagocytosed [20]. Hepatocytes take up iron by way of TfR1, transferrin receptor 2 (TfR2), and possibly other non-transferrin mediated mechanisms [16].

Genes and proteins related to hemochromatosis

HFE gene and HFE protein

HFE, a 343-amino-acid protein, is a nonclassical major histocompatibility complex (MHC) class I molecule structurally similar to other MHC class I proteins [2]. It is encoded by the *HFE* (previously known as *HLA-H*) gene located on chromosome 6p21.3 and is ubiquitously expressed [2]. In the small intestine, HFE is predominantly expressed in cells in deep crypts, with little or no expression in the villi [21]. The precise role of HFE in iron metabolism is not clear, but its interactions with β_2-microglobulin and TfR1 are considered to be important in the regulation of intestinal iron absorption.

The C282Y mutation, the most common *HFE* mutation associated with hemochromatosis, disrupts a disulfide bridge

in the α3 domain of HFE protein, resulting in a change in the three-dimensional structure of the HFE protein leading to impaired binding with the β_2-microglobulin [22]. Failure of binding with β_2-microglobulin results in defective Golgi processing, accelerated intracellular degradation, and lack of cell-surface presentation of the HFE protein [23].

The nature of the interaction between HFE and TfR1 is less clearly understood. It has been postulated that the interaction of HFE with TfR1 facilitates the entry of iron into crypt cells, and that the HFE mutation impairs this effect, leading to intracellular iron deficiency in the crypts and secondary up-regulation of DMT1 and ferroportin, resulting in increased iron absorption [24]. This model supports the crypt migration hypothesis, which proposes that the iron-deficient crypt cells develop into mature villous cells programmed to absorb excess iron through increased activity of DMT1 and ferroportin 1 (FPN1) [4]. However, this model does not account for the effect of hepcidin, a peptide secreted from the liver that has been found to influence multiple steps in iron metabolism as discussed below. Moreover, this model does not explain the observation that HFE lowers intracellular iron levels independently of its interaction with the TfR1 [24,25].

HAMP gene and hepcidin

The *HAMP* gene located on chromosome 19q13.1 codes for hepcidin, a 25-amino-acid peptide that is secreted from the liver and excreted in urine [26]. Basic amino acids in hepcidin confer on it antimicrobial properties, and four disulfide bridges make it structurally similar to the defensin family of antimicrobial peptides [27]. Hepatic expression of hepcidin is increased in response to infection, inflammation, and iron overload; and decreased in response to anemia and hypoxia. Hepcidin inhibits iron absorption in the small intestine, iron transport across the placenta, and iron release from macrophages [26]. With its effects on multiple steps in iron metabolism, hepcidin is increasingly regarded as a primary regulator of iron homeostasis.

Hepcidin binds to ferroportin, resulting in internalization and lysosomal degradation of ferroportin, so inhibiting iron efflux from cells [28]. However, the mechanism of feedback regulation of hepatic hepcidin expression in response to iron status is not clearly elucidated. Recent observations suggest that proteins of the transforming growth factor-β superfamily, such as transforming growth factor-β and bone morphogenetic proteins, mediate the hepatic expression of *HAMP* by way of a signal transduction pathway involving a class of proteins named SMAD (small mothers against decapentaplegic) [29,30]. It has been proposed that HFE, TfR2, and hemojuvelin (HJV) mediate the upregulation of *HAMP* gene transcription in response to the body iron status and that the impaired hepatic secretion of hepcidin resulting from mutations in either the *HAMP* gene itself or in *HFE*, *TFR2*, or *HJV* is the pathophysiological basis of increased intestinal absorption of iron in various forms of hemochromatosis [31].

HJV gene and hemojuvelin

Hemojuvelin is a 426-amino-acid protein coded by the *HJV* (previously named *HFE2*) gene located on chromosome 1q21 [32]. Like *HAMP*, *HJV* is expressed primarily in the liver, heart, and skeletal muscle [32]; mutations in either gene are associated with a phenotype of juvenile hemochromatosis [33]. The role of hemojuvelin in iron homeostasis has not yet been elucidated, but there is some evidence that it regulates the expression of hepcidin in response to changes in iron concentration [34]. Recent data suggest that the up-regulation of hepcidin expression by hemojuvelin is mediated by bone morphogenetic proteins [35].

TfR2 gene and transferrin receptor 2 (TfR2)

TfR2 is an 801-amino-acid protein encoded by the *TfR2* gene located on chromosome 7q22 [36]. TfR2 is structurally homologous to TfR1, and functions as a receptor for transferrin [36]. However, TfR2 is different from TfR1 in that its expression is mostly confined to the liver [36] and it is not regulated by cellular iron status [37,38]. Initial observations also suggested that unlike TfR1, TfR2 does not interact with HFE in vitro [39]. However, it was demonstrated that TfR2 does interact with HFE in cells, that mutations in *TfR2* and *HFE* do not interfere with this interaction, and that TfR2 competes with TfR1 for binding to HFE [40]. Based on these observations, the interaction between TfR2 and HFE has been proposed to be the molecular basis of a systemic iron sensor in hepatocytes. According to this model, transferrin-bound iron competes with HFE for binding to TfR1. In the presence of elevated transferrin-bound iron, HFE dissociates from TfR1 and binds to TfR2, leading to the formation of a signal transduction effector complex, which subsequently up-regulates the synthesis of hepcidin [40].

FPN1 gene and ferroportin

Ferroportin, a 571-amino-acid protein encoded by the *FPN1* (also known as *SLC40A1*) gene located on chromosome 2q32 [41], is the major iron export protein in enterocytes, macrophages, hepatocytes, and placental cells [18]. Impairment of the iron export function has been postulated to cause retention of iron within cells, especially in reticuloendothelial cells, which have a high iron flux, resulting in tissue iron accumulation (manifested as high serum ferritin) and decreased availability of iron for circulating transferrin (manifested as low serum transferrin–iron saturation; TS, given by serum iron divided by total iron-binding capacity) [42]. Increased intestinal absorption consequent to marginal anemia secondary to impaired delivery of iron to hematopoietic cells also contributes to iron loading in this condition [42]. A subset of patients with *FPN1* gene mutations has a phenotype similar to other types of hemochromatosis, with elevated TS, and parenchymal, rather than reticuloendothelial distribution of iron deposition [43,44]. This phenotype is postulated

to be the result of resistance of ferroportin to negative regulation by hepcidin [45].

Mutations associated with hereditary hemochromatosis

HFE gene mutations

Type 1 hemochromatosis, the most common form of hemochromatosis, is associated with mutations in the *HFE* gene and is inherited as an autosomal recessive trait. The three mutations most commonly associated with hemochromatosis are C282Y, H63D, and S65C. The overwhelming majority of cases with phenotypic *HFE*-associated hemochromatosis are accounted for by the homozygous C282Y mutation. A relatively small proportion of cases with phenotypic hemochromatosis are compound heterozygotes for the C282Y and H63D mutations. The clinical significance of compound heterozygozity of S65C with C282Y or H63D is not clear and is likely to be minimal; similarly, the H63D homozygozity may result in elevated serum iron markers but has not been associated with significantly increased body iron stores [46,47].

The C282Y mutation is primarily found in persons of northwestern European ancestry [2]. The prevalence of the C282Y homozygozity among white patients with phenotypic hemochromatosis varies from 60% in Italy, 70%–90% in France, and 80%–90% in the United States to more than 90% in Ireland and Australia [2]. It has been proposed that the C282Y mutation originated in Celtic or Nordic people, and the current distribution of the mutation reflects the proportion of Nordic or Celtic ancestry of these populations [48]. The H63D mutation has a more widespread distribution, with the allele frequency being > 5% in countries in the Mediterranean region, parts of the Middle East, and the Indian subcontinent [2,49].

The high prevalence of *HFE* mutations in different populations across the globe has prompted the hypothesis that *HFE* mutations may have conferred some selective survival advantage to carriers, possibly through protection from iron deficiency or infectious diseases [49]. In addition, the similar epidemiology of celiac disease and hemochromatosis has led to the hypothesis that *HFE* mutations may have compensated for deficient iron absorption in populations at risk for celiac disease [50].

Other mutations associated with hemochromatosis

Mutations in the *HJV* gene account for the majority of cases of type 2 hemochromatosis, whereas mutations in the *HAMP* gene are much less common [3,32]. Mutations in the *TfR2* gene responsible for type 3 hemochromatosis are extremely rare and are found mostly in southern Europeans and Japanese individuals [3].

Pathophysiology of iron-induced tissue injury

Oxidative stress generated by iron-stimulated free radical production is postulated to be the major mechanism of iron-mediated tissue injury. Proteins such as transferrin and ferritin, which bind free iron; enzymes such as superoxide dismutase, catalase, and glutathione peroxidases, which convert the reactive oxygen species to nontoxic by-products; and antioxidants such as glutathione, α-tocopherol, and β-carotene minimize the toxicity from iron under physiological conditions. However, these defense mechanisms are overwhelmed in conditions of iron overload, leading to free radical-mediated damage of cellular macromolecules. Oxidative stress is also thought to cause hepatic stellate cell activation, leading to fibrogenesis, and ultimately cirrhosis. In addition, iron-mediated immune dysfunction, DNA damage, and stimulation of cellular proliferation are considered to be responsible for hepatocarcinogenesis [51,52].

Clinical manifestations of iron overload

A comparative overview of types of hemochromatosis is given in Table 86.1 [11] and the various clinical manifestations are summarized in Table 86.2 [51].

Type 1 – classic hemochromatosis

The natural history of patients with *HFE*-associated hemochromatosis may progress through three stages with increasing iron accumulation over time. In the initial stage, body iron stores are normal or only mildly to moderately increased (total body iron stores less than 5 g) and there is no end-organ damage. In the second stage, there is moderate iron loading (body iron stores of 10–20 g) and patients may exhibit nonspecific symptoms such as fatigue, lassitude, or arthralgias or arthropathy, particularly involving the metacarpophalangeal joints. In the advanced stage (body iron stores of 20–40 g), cirrhosis is frequently present, often along with diabetes mellitus and hypogonadotropic hypogonadism.

The manifestations in patients identified on the basis of biochemical or genetic markers differ quantitatively from those diagnosed on the basis of classical clinical presentation [53]. The proportion of patients diagnosed with severe end-organ damage appears to have been decreasing over time, possibly because of increased awareness of the disease and earlier diagnosis [54,55]. Most patients (> 75%) with type I hemochromatosis are identified before the development of symptoms; cirrhosis, diabetes, *or* skin pigmentation is present in only a minority (< 25%) at the time of diagnosis and presence of all the three components of the classic triad is rare [56].

Table 86.1 Comparative overview of types of hemochromatosis

	***HFE*-related hemochromatosis**	**Juvenile hemochromatosis**		***TfR2*-related hemochromatosis**	**Ferroportin-related hemochromatosis**
Type	Type 1	Type 2, subtype A	Type 2, subtype B	Type 3	Type 4
Implicated gene and its chromosomal location	*HFE* 6p21.3	*HJV* 1q21	*HAMP* 19q13.1	*TfR2* 7q22	*FPN1* 2q32
Gene product	HFE	Hemojuvelin	Hepcidin	Transferrin receptor 2	Ferroportin
Pattern of inheritance	Autosomal recessive	Autosomal recessive	Autosomal recessive	Autosomal recessive	Autosomal dominant
Distribution of iron accumulation	Parenchymal	Parenchymal	Parenchymal	Parenchymal	Reticuloendothelial
Potential for organ damage	Intermediate	High	High	Intermediate	Low
Age of onset of symptomatic organ disease	4th or 5th decade	2nd or 3rd decade	2nd or 3rd decade	4th or 5th decade	4th or 5th decade
Response to phlebotomy	Excellent: decrease in serum ferritin parallels TS; low risk of anemia	Excellent: decrease in serum ferritin parallels TS; low risk of anemia	Excellent: decrease in serum ferritin parallels TS; low risk of anemia	Excellent: decrease in serum ferritin parallels TS; low risk of anemia	Fair: rapid decrease in TS with persistently high serum ferritin; high risk of anemia

TS, transferrin–iron saturatim. Adapted from Pietrangelo [11], with permission from the Massachusetts Medical Society.

The variable penetrance of the C282Y homozygozity resulting from environmental or genetic factors could also contribute to the clinical heterogeneity of hemochromatosis [53]. Male gender, a diet rich in iron, supplementation of iron or vitamin C, ingestion of alcohol in excess, and hepatitis C infection facilitate iron accumulation [57–60]. Conversely, the presence of chronic blood loss and a diet poor in iron could be protective. Iron loss associated with menstruation, pregnancy, and childbirth keeps penetrance lower in women. Celiac disease, which has similar epidemiology and is associated with HLA DQ2 located in close proximity to the *HFE* locus, has also been found to decrease the penetrance of the C282Y mutation [61]. Polymorphisms or mutations of other genes involved in iron homeostasis have also been hypothesized to modulate the penetrance of C282Y mutation [53].

The risk of decompensated cirrhosis, hepatocellular carcinoma, diabetes mellitus, and cardiomyopathy is 10-fold to 119-fold higher in patients with hemochromatosis than in an age- and sex-matched population without hemochromatosis [62]. Hepatocellular carcinoma is reported to develop in 7.5%–36% of patients with hemochromatosis, and is implicated in up to 45% of the deaths, with other complications of cirrhosis contributing another 20% [62–64]. Among patients with hemochromatosis undergoing liver transplantation, 27% has been found to have primary liver cancer (hepatocellular carcinoma or cholangiocarcinoma), out of which 70% are unsuspected before the time of surgery [64].

The risk factors for hepatocellular carcinoma in hemochromatosis are presence of cirrhosis, increased amount and duration of iron excess, advanced age, alcoholism, tobacco smoking, and concomitant infection with hepatitis C or hepatitis B [65–69]. Only a limited number of cases of hepatocellular carcinoma have been reported in patients with hemochromatosis but without cirrhosis [70]. *HFE* mutations have also been reported to be associated with extrahepatic cancers such as esophageal, gastric, colorectal, and hematological malignancies and melanoma [71–74], but this association has been questioned by others [75–77].

Type 2 – juvenile hemochromatosis

As in type 1 hemochromatosis, hypogonadism, cardiac disease, cirrhosis, diabetes, arthropathies, and skin pigmentation are seen in type 2 hemochromatosis. However, in type 2 hemochromatosis, iron overload is observed from an earlier age, the phenotypic expression is similar in men and women and extrahepatic involvement, especially endocrine and cardiac, are more severe than in type 1 hemochromatosis [78,79].

Table 86.2 Clinical features of hereditary hemochromatosis

Symptoms
Nonspecific, systemic symptoms
Weakness, fatigue, lethargy, apathy
Specific, organ-related symptoms
Abdominal pain secondary to hepatomegaly
Arthralgia

The most common age of presentation is early second decade of life, and hypogonadism, the most common manifestation, develops in nearly all patients [78,80]. Heart failure or cardiac arrhythmias, reported to occur in 69%, dominate the clinical course of the disease and are the most common causes of death, which is common before the age of 30 years [80,81].

Type 3 – *TfR2*-related hemochromatosis

Type 3 hemochromatosis is phenotypically similar to type 1 hemochromatosis with the exception that the severity of iron overload and the age of clinical presentation are intermediate between type 1 hemochromatosis and type 2 hemochromatosis [82].

Type 4 – ferroportin-related iron overload

In contrast to other types of hemochromatosis where elevation of serum transferrin iron saturation precedes elevation of serum ferritin, type 4 hemochromatosis is characterized by elevated serum ferritin from the first decade of life, with elevation in TS developing in the third to fourth decades [83,84]. Another distinct feature of type 4 hemochromatosis is mild anemia, which may be aggravated on phlebotomy [83]. Hepatic involvement is characterized by iron deposition predominantly in reticuloendothelial cells with varying degrees of sinusoidal and portal fibrosis, which rarely progress to cirrhosis [42].

Other iron overload states

In hematological diseases like sideroblastic anemia, hemolytic anemias, and myelodysplastic syndromes, iron overload is the result of increased intestinal absorption secondary to increased demand for iron in the bone marrow consequent to ineffective erythropoiesis [85]. Blood transfusions could contribute to iron overload in these conditions.

Iron overload is frequently observed in chronic liver diseases, particularly in alcoholic liver disease, in the absence of mutations associated with hemochromatosis [86–89]. Stainable liver iron has been found in 31%, increased liver iron concentration in 19%, and liver iron concentration in the hemochromatosis range in 7% of patients with chronic liver disease [90]. Consumption of any amount of alcohol has been shown to decrease the risk of iron deficiency, and consumption of more than two alcoholic drinks per day increases the risk of iron overload [91]. The potential mechanisms of iron overload in association with alcohol intake include increased ingestion of iron (African iron overload), increased intestinal absorption, up-regulation of hepatic transferrin receptors, down-regulation of hepatic hepcidin expression [92], secondary anemia as the result of hemolysis or hypersplenism, ineffective erythropoiesis, hypoxemia as the result of intrapulmonary shunts or ventilation/perfusion mismatch, and spontaneous or surgically constructed portosystemic shunts [93]. Nonalcoholic steatohepatitis has also been reported to be associated with iron overload in up to 58% of patients [94]. The prevalence of *HFE* mutations is higher in these patients, and increased hepatic iron concentration has been found in some studies to be associated with increased fibrosis [95,96]. Chronic hepatitis C is also associated with iron overload, and iron overload in this condition has been found to be linked to more advanced hepatic fibrosis, hepatocellular carcinoma, and reduced response to interferon monotherapy [59,97].

African iron overload has historically been attributed solely to excessive intake of iron derived from traditional beer brewed in iron drums and cans, but has been found to be associated with ferroportin mutations and other inherited and environmental factors such as *HFE* C282Y, heritable anemias, alcohol consumption, and chronic viral hepatitis [98,99].

Neonatal hemochromatosis is a rare syndrome of perinatal hepatic failure associated with increased tissue iron deposits in liver, pancreas, heart, and endocrine glands, with sparing of macrophages. It leads to death in utero or in the early neonatal period [100,101].

Hereditary aceruloplasminemia is a rare autosomal recessive disorder characterized by complete lack of ceruloplasmin ferroxidase activity caused by mutations in the ceruloplasmin gene, resulting in impaired export of iron from cells [102,103]. This disease presents in adulthood with hepatic iron overload, diabetes, peripheral retinal degeneration, dystonia, dysarthria, and dementia. Laboratory findings include mild microcytic anemia, low TS, elevated serum ferritin, magnetic resonance imaging findings suggestive of iron accumulation in the liver and basal ganglia, thalamus, and dentate nucleus of brain, and complete absence of serum ceruloplasmin ferroxidase activity [102,103].

Hereditary atransferrinemia is a rare disorder characterized by iron overload and severe hypochromic anemia, where delivery of iron to the marrow is impaired because of deficiency of transferrin [104].

Diagnosis

Appropriate and early diagnosis of hemochromatosis requires knowledge of the protean manifestations of iron overload, the frequent absence of the classic symptoms of "bronze diabetes," and the vague and nonspecific nature of the symptoms. As both screening tests and confirmatory tests are widely available, the most important factor in making the diagnosis of hemochromatosis is the awareness of clinicians about the possibility of iron overload in at-risk individuals [105,106]. Hemochromatosis should be suspected in all adult patients (especially those in middle age), presenting with fatigue, malaise, arthralgia, hepatomegaly, or elevated serum aminotransferase levels. Children or adolescents with hypogonadotropic hypogonadism or unexplained heart failure should be evaluated for possible juvenile hemochromatosis. A suggested algorithm for the evaluation of suspected hemochromatosis is shown in Fig. 86.2 [107].

Biochemical tests of iron overload

The first tests to be done in those with suspicious symptoms, signs, or liver test abnormalities should be TS and serum ferritin [105]. Together, these tests have a negative predictive value of 97% [108]. No further evaluation is required for hemochromatosis if both these tests are normal [105].

The TS should be the initial screening test because it is the earliest phenotypic abnormality in hemochromatosis [56]. The recommended threshold TS for further evaluation of hemochromatosis is 45%, which has a reported sensitivity ranging from 64% to 98% for detection of C282Y homozygozity [105,109,110]. However, TS may be increased as the result of excessive alcohol consumption [91], inflammatory conditions [105], and other causes of chronic liver disease [88,89] or iron overload. The unsaturated iron-binding capacity, the inverse of the TS, which has similar performance characteristics but is less expensive to perform because

it is a one-step test, could be an alternative to TS for large-scale screening or as part of an automated battery of tests [89].

As TS in fasting samples could be as much as 50% lower than in random blood samples, the test should ideally be performed when patients are fasting and have not taken vitamins or iron supplements for 24 h [111]. The American Association for the Study of Liver Diseases Practice Guideline recommends a random sample for the initial screening test, and a fasting sample for confirmation if the initial value is more than 45% [105]. Serum ferritin is usually measured with the repeat fasting sample, but it can be elevated in inflammatory disorders such as rheumatoid arthritis and in various neoplastic diseases such as lymphoma; it can also be elevated in up to 50% of patients with chronic liver disease in the absence of hemochromatosis [56,91]. Serum ferritin also increases with age, and is higher among men [112]. Therefore, an elevated serum ferritin is much more likely to be associated with iron overload in the presence of an elevated serum TS than if the TS is normal; a notable exception being ferroportin disease, as discussed previously.

Genotyping

Patients with elevated serum TS and ferritin should undergo genotyping for detection of the *HFE* mutations C282Y and H63D [105]. C282Y homozygotes and C282Y/H63D compound heterozygotes do not require any further evaluation for diagnosis of hemochromatosis. Since the majority of white subjects with phenotypic hemochromatosis have one of these two mutation patterns, *HFE* genotyping is sufficient to establish the diagnosis in the vast majority of cases. Liver biopsy is no longer necessary for diagnostic purposes alone among patients with *HFE*-associated hemochromatosis but may be useful to determine the presence of fibrosis, as discussed below. Gene testing for mutations in other iron-related genes is not available.

Liver biopsy

The following are the potential roles of liver biopsy in hemochromatosis.

- Liver biopsy can be used to confirm the diagnosis of hemochromatosis if genotyping is not available or does not reveal C282Y homozygozity or C282Y/H63D compound heterozygozity. Findings diagnostic of hemochromatosis (except type 4 hemochromatosis) include [113]
  - grade 4 stainable iron in hepatocytes, with periportal distribution, and sparing of Kupffer cells
  - hepatic iron concentration (HIC) greater than 80 μmol (4500 mg)/g dry weight
  - hepatic iron index (HII; which is given by [HIC in μmol/g]/age in years) greater than 1.9
- Liver biopsy is useful to exclude coexistent or alternative causes of liver disease
- In patients with a confirmed diagnosis of hemochromatosis, liver biopsy is needed to determine the presence or absence of cirrhosis, which is the single most important adverse prognostic factor [66].

Therefore, liver biopsy is recommended in patients with an increased likelihood of cirrhosis. Elevated serum aminotransferases and a serum ferritin greater than 1000 μg/L at the time of diagnosis are independent predictors of cirrhosis [114] and the combination of absence of hepatomegaly, normal serum aspartate aminotransferase levels, and serum ferritin greater than 1000 μg/L is predictive of absence of severe fibrosis [115]. Therefore, liver biopsy is required in C282Y homozygotes and C282Y/H63D heterozygotes only if serum ferritin is over 1000 μg/L, or if serum transaminases are elevated (Fig. 86.2).

Diagnosis of juvenile hemochromatosis
