The topic of intestinal neuroimmunophysiology [380] has aroused interest because of the intimate spatial relationships between the enteric nervous system and the immune elements of the intestine. These spatial relationships appear to have functional correlates. Ion transport responses stimulated by electrical field stimulation can be reduced by antagonists of inflammatory mediators; conversely, the stimulation of immune cells such as mast cells has measurable effects on enteric nerves and consequent indirect effects on ion transport [344]. Another indirect means whereby immune and inflammatory mediators have been shown to influence ion transport function is by the chronic regulation of epithelial responsiveness. Tissues from sensitized animals are more responsive to the Cl^- secretory effects of histamine and substance P [381]. Long-term exposure to mast cell products has similarly been shown to enhance the responsiveness of cultured colonic epithelial cells to the Cl^- secretagogues carbachol, VIP, and ST_a, without altering their basal electrical properties or their responsiveness to prostaglandins or adenosine [382]. Although the underlying mechanisms of these effects are not known, their existence suggests that the epithelium may be primed to display secretory responses in some settings of intestinal inflammation or infection. The idea that communication between nerves and the immune system is important in disease is supported by the observations that interactions between these systems are highly plastic and can undergo extensive remodeling in pathological states [383]. Sensitization primes the epithelium for rapid antigen transfer from the lumen through the expression of the low-affinity IgE receptor CD23 [384]. This would serve to further amplify abnormal transport responses in the setting of gastrointestinal allergies [384].

Other factors may indirectly influence fluid and electrolyte transport by intestinal epithelial cells. These include acid–base homeostasis [385], gastric and intestinal motility [386], lumenal flow rates [387], intestinal permeability [385], oncotic pressure of the blood, arterial pressure, venous pressure, plasma volume, lumenal pressure [388], and physical and psychological stress [389]. Some of these factors likely have important clinical implications. Retardation of the flow of intestinal contents achieved by the coordinated contraction of gastrointestinal smooth muscle allows more contact time for absorption and may thereby decrease stool volume. Antidiarrheal drugs, particularly the synthetic opiates, act mainly through their effects on gut motility, although neuronal, hormonal, and immunological influences are also involved. Intestinal permeability is increased in diseases that cause mucosal injury, such as inflammatory bowel disease and celiac disease [390]. In theory, an increase in intestinal permeability may allow oncotic and hydrostatic pressure gradients to exert greater effects on electrolyte transport. Increased permeability may also allow macromolecules, normally excluded by the epithelium, to diffuse more readily across the intestinal mucosa. This nonspecific increase in macromolecular permeability should be contrasted with the specific CD23-mediated increase in transcytotic antigen transfer previously suggested [384]. Nevertheless, both mechanisms may amplify the immune responses to transferred macromolecules and thereby further enhance immune regulation of epithelial function.

C SECRETION AND ABSORPTION

15

Pancreatic secretion

Chung Owyang, John A. Williams

Formation and composition of pancreatic juice, 368
Stimulation of pancreatic secretion, 373
Intracellular control of pancreatic secretion, 380
Inhibition of pancreatic secretion, 387
Patterns of secretion, 390

The pancreas is an organ with exocrine and endocrine functions. The secretions of the exocrine pancreas, including digestive enzymes and bicarbonate, affect the digestion and absorption of nutrients. The endocrine pancreas releases hormones that regulate metabolism and the disposition of the breakdown products of food within the body. The combined exocrine and endocrine functions make the pancreas one of the most important and complex organs involved in the assimilation of food.

In humans and other mammals, the exocrine pancreas consists of clusters of acini that form lobules separated by loose connective tissue. Eighty percent or more of the pancreas consists of acini. Each acinus is a sphere composed of 20–50 pyramidal cells arranged with their broad bases around the circumference and their apices pointed toward a central lumen. Each acinus is drained by a ductule; the most proximal cells of the ductules, which extend into the lumen of the acinus, are called centroacinar cells. The ductules drain through a series of ducts of increasing caliber until the main ducts are reached.

Distributed within the pancreas are the islets of Langerhans, containing the cells of the endocrine pancreas. Morphological studies have revealed cell-to-cell contact between the exocrine and endocrine tissue and direct connections between the capillaries of the islets and the acini [1,2]. These morphological arrangements may reflect the regulatory influences of the islet hormones on the function of the exocrine pancreas and vice versa. Of the pancreatic hormones, glucagon, somatostatin, and pancreatic polypeptide inhibit pancreatic exocrine secretion [3–6]. Insulin potentiates the stimulatory effect of cholecystokinin (CCK) on pancreatic exocrine secretion [7]. In addition, exocrine pancreatic secretion can influence pancreatic hormone release.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

The control of pancreatic exocrine function is complex and highly regulated by neural and hormonal factors. The cloning of the CCK receptor with the subsequent recognition that the CCK_1 receptor was virtually absent from the human pancreas [8,9] emphasized the importance of regulation at extrapancreatic sites. The discovery that CCK acts on CCK_1 receptors on vagal afferent fibers to mediate pancreatic secretion [10–12], together with the observations that the most inhibitory mediators of pancreatic exocrine secretion target the dorsal vagal complex [9,13–16], led to a paradigm shift in the understanding of the control of pancreatic secretion and recognition that pancreatic secretion is under neurohormonal control rather than direct hormonal control.

Formation and composition of pancreatic juice

The human pancreas secretes about 1 L of juice daily, consisting mostly of water, electrolytes, and digestive enzymes. The morphological appearance of the different cells of the exocrine pancreas and the results of micropuncture studies suggest that the acinar cells secrete digestive enzymes and that the ductal cells are mainly responsible for an electrolyte secretion that is rich in bicarbonate [17]. This thesis is further supported by animal experiments in which the administration of a toxin or a special diet selectively destroys acinar or ductal cells. Administration of alloxan, which destroys ductal but not acinar cells, results in diminished secretion of fluid and bicarbonate [18]. Ethionine administration damages acinar cells with a concomitant reduction in enzyme secretion, but the secretion of fluid and electrolytes is relatively unaffected [18].

Water and electrolytes

Pancreatic electrolytes are secreted in a clear, alkaline fluid that is isosmotic with extracellular fluid. Evidence suggests that water enters the juice passively along osmotic gradients

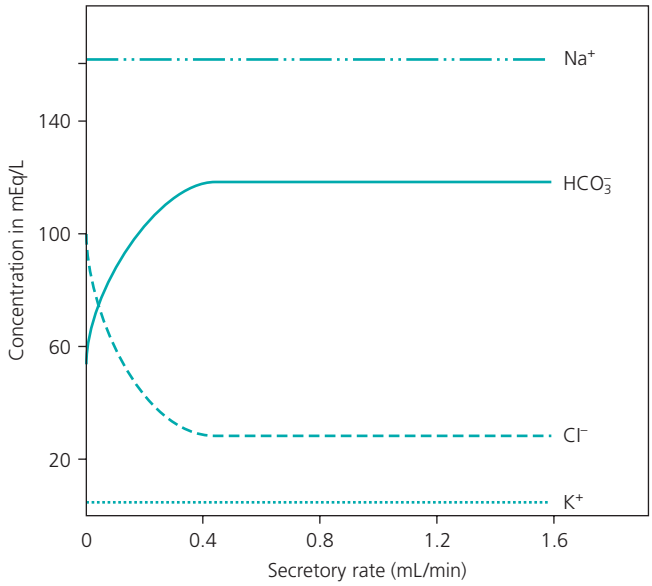

Figure 15.1 Relation of the secretory rate to the electrolyte composition of pancreatic juice.

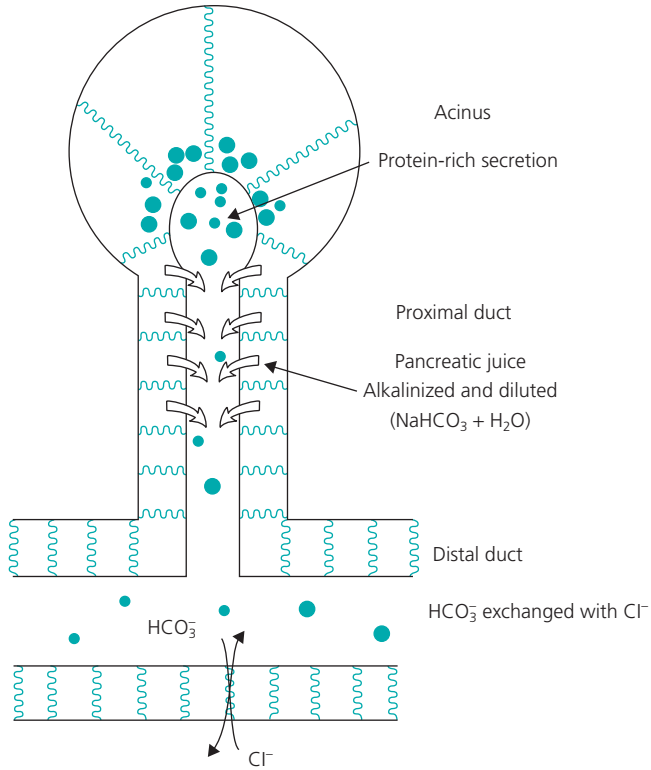

Figure 15.2 Ductal origin of secretin-dependent pancreatic HCO_3^- secretion. Open arrows indicate secretion of $NaHCO_3$ and H_2O from the proximal duct cells. Some of the secreted HCO_3^- is exchanged with Cl^- in the distal ducts (curved, solid arrows). From Raeder [19], with permission from Elsevier.

established by active secretion of electrolytes or other solutes. The major cations in the pancreatic juice are Na^+ and K^+; both are secreted at concentrations similar to their plasma concentrations. The concentrations of both cations are constant and independent of secretory rates (Fig. 15.1). The major anions in the pancreatic juice are HCO_3^- and Cl^-, the concentrations of which depend on flow rates. As the flow rate increases, the HCO_3^- concentration rises asymptotically, approaching a plateau value in humans of ~ 150 mEq/L at 30%–50% of the maximal secretory rate. Because the Cl^- concentration falls reciprocally with the increasing secretory rate, the sum of the two anions remains constant and about equal to the sum of Na^+ and K^+ at all secretory rates. In humans and other animal species, the pancreatic juices also contain Ca^{2+} (1–2 mEq/L) and traces of Mg^{2+}, Zn^{2+}, HPO_4^{2-}, and SO_4^{2-}.

The application of micropuncture and electrophysiological measurements and the use of fluorescent probes and ultrastructural analysis in the study of pancreatic duct cell function have provided important information on the mechanism of ductal electrolyte secretion. Comprehensive reviews of this topic have been published [19,20]. Micropuncture studies in rats, cats, and rabbits show that secreted HCO_3^- originates from the intralobular ducts and small interlobular ducts. In the large ducts, some of the HCO_3^- may be exchanged with Cl^- (Fig. 15.2). Evidence supporting a ductal origin of HCO_3^- in humans comes from studies demonstrating that the biochemical lesion of cystic fibrosis is a defect in cyclic adenosine monophosphate (cAMP) – regulated membrane Cl^- conductance in epithelial cells [21,22]. In the pancreas, this is associated with defective secretion of HCO_3^- [23]. Immunofluorescence studies show that the cystic fibrosis transmembrane conductance regulator (CFTR) is localized to the apical domain of centroacinar cells and intralobular duct cells [24]. CFTR is identical to the small conductance (4 pS) Cl^- channels in the apical plasma membrane of rat pancreatic duct cells, which are regulated by cAMP [25].

Electrophysiological studies have shown that by increasing Cl^- exit into the lumen, the CFTR Cl^- channels facilitate the function of a Cl^-/HCO_3^- exchange protein in the apical membrane. The molecular nature of this exchange has been characterized and the protein is known as SLC26AC. It normally transports two HCO_3^- ions into the lumen for each Cl^- ion absorbed [26]. The net result is recycling of Cl^- and secretion of HCO_3^- [20,27]. CFTR and SLC26AC exhibit intracellular protein–protein interactions, explaining why the exchanger fails to function in the absence of CFTR. The CFTR channel has a limited permeability to HCO_3^- under basal conditions, but when lumenal Cl^- is depleted, the channel switches its selectivity and becomes a major pathway for HCO_3^- exit into the lumen. An additional function of CFTR is to depolarize the duct cell, thereby "affecting" or "increasing" basolateral membrane transport (see discussion at the end of this section).

The mechanism operating at the basolateral membrane of the duct cell is becoming better understood. Originally, HCO_3^- was thought to be derived in duct cells from CO_2 under the influence of carbonic anhydrase, which is present in the duct epithelium [28]. Although H^+ extrusion is often shown to be mediated by a Na^+/H^+ exchanger in the basolateral membrane, this protein is known to play a role in basal cell pH regulation and to account for no more than 1%–2% of stimulated H^+ extrusion (i.e., equivalent to HCO_3^- uptake) [29]. Moreover, experimental evidence and mathematical models indicate that some form of energy input is necessary to obtain the secretion of 150 mM HCO_3^-. Unfortunately, the rat is a poor experimental model because it only secretes HCO_3^- at 70–90 mM. Two competing theories account for higher rates of HCO_3^- secretion in other species. Based on study primarily of pig pancreas, Raeder and colleagues presented evidence for a primary active proton efflux mediated by a vacuolar H^+-ATPase [19]. The ATPase at rest is located in a tubulovesicular compartment and inserted into the basolateral plasma membrane by exocytosis in response to stimulation by secretion [30]. The action of the ATPase to extrude H^+ allows HCO_3^- to accumulate in the cell and to exit by the apical mechanism just described. Colchicine, a microtubule depolymerizing drug, has been shown to block secretion-stimulated insertion of tubulovesicles into the basolateral plasma membranes, causing a 60% inhibition of secretin-invoked HCO_3^- secretion [31].

Details of the other mechanism emerged from work on isolated pancreatic ducts from guinea pigs, which are capable of secreting 150 mM HCO_3^-. Secretion was blocked by omitting Na^+ from the bath but not by inhibitors of Na^+/H^+ exchange or of the vacuolar H^+-ATPase [20]. After analyzing intracellular pH and Na^+ influx, Ishiguro and colleagues concluded that Na^+–HCO_3^- cotransport accounts for 75% of secretion-stimulated HCO_3^- secretion [32,33]. Their model established that the energy of the Na^+ gradient maintained by Na^+,K^+-ATPase on the basolateral plasma membrane [34] serves to drive HCO_3^- into the cell. This model substantiated earlier data demonstrating that fluid secretion from the perfused cat pancreas increases as a function of perfusate HCO_3^- [28].

Some details of the nature of the protein mediating Na^+–HCO_3^- transport have been described. A Na^+–HCO_3^- cotransporter (NBC) was originally cloned from amphibian kidney, and subsequently, at least four NBCs have been characterized molecularly. The NBC1 form has two variants, termed p and k for pancreas and kidney, which differ at the amino terminus as a result of alternate messenger RNA (mRNA) splicing [35]. pNBC1 has been localized to the basolateral membrane of pancreatic duct cells by immunohistochemistry [36]. The human pNBC1 analogue codes for a 1079-amino-acid protein, and when expressed in *Xenopus* oocytes it induces $NaHCO_3$ uptake [35]. The stoichiometry of Na^+ and HCO_3^- varies in different cells; in pancreatic duct cells it appears to be one Na^+ to two HCO_3^- [37]. Because the transporter is electrogenic, it is influenced by the Na^+ gradient, the HCO_3^- gradient, and the membrane potential. In normal duct cells, the transporter mediates HCO_3^- uptake, and this process is enhanced by depolarization induced by Cl^- exit through CFTR [38]. In this model, secretin activates CFTR and thus increases HCO_3^- uptake by way of the pNBC exchanger. The transcellular secretion of anions sets up a lumenal electronegative potential, enabling cations such as Na^+ and K^+ to reach the pancreatic juice by moving passively through the paracellular pathway driven by the electrical gradient that increases in response to stimulation [39]. A cellular model depicting these events in a pancreatic duct cell is shown in Fig. 15.3.

Enzymes

Depending on the species, the enzyme component of pancreatic juice is mixed in various proportions with the aqueous component. Human pancreatic juice contains a concentration of 0.7%–10% protein. Most proteins are enzymes and proenzymes; the remaining proteins are plasma proteins, trypsin inhibitors, and mucoproteins. The four major enzyme groups are amylolytic, lipolytic, proteolytic, and nucleolytic. The proteolytic enzymes, which include trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase, account for most enzymes in the juice and are secreted as inactive proenzymes. After entering the intestinal lumen, trypsinogen is converted by enterokinase, an enzyme secreted by the duodenal mucosa, to the biologically active trypsin. Trypsin autocatalytically activates trypsinogen and converts chymotrypsinogen and other proteolytic enzymes into their active forms.

Pancreatic juice also contains a low concentration of trypsin inhibitor, a polypeptide that, at pH of 3–7, combines with and inactivates trypsin in a 1 : 1 ratio. Trypsin inhibitor also partially inhibits chymotrypsin. Trypsin inhibitor in the pancreas is thought to protect the organ against autodigestion by the small amounts of active trypsin within the pancreas. Because trypsin inhibitor is present in minute quantities, the proteolytic activity of fully activated pancreatic juice in the intestinal lumen is not inhibited. Unlike the proteolytic enzymes, amylase, lipase, and ribonuclease are secreted by the acinar cells in their active forms. Pancreatic juice also contains a 10-kDa peptide called colipase, which is essential for optimal lipolysis [40]. It facilitates lipase action by binding with bile salt–lipid surfaces to increase the interaction of lipase with triglyceride [41]. In the presence of bile salts, colipase lowers the optimal pH of lipase from 8.5 to 6.5, the normal pH in the proximal intestine.

Pancreatic enzymes are synthesized within acinar cells and packaged into zymogen granules [17,42]. The entire process, from synthesis to the point at which the enzymes are ready to be secreted into the lumen, takes about 50 min. Total enzyme synthesis is estimated at 20 mg/g dry tissue per hour or 10 million enzyme molecules per acinar cell per minute

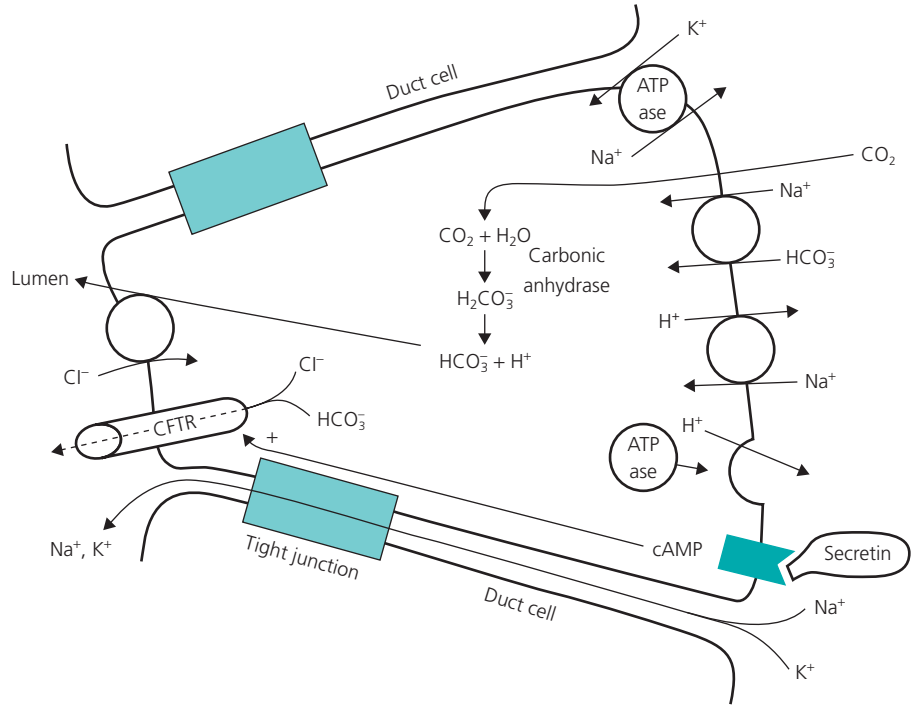

Figure 15.3 Cellular model of ion transport events in the pancreatic duct cells that cause the primary secretion of pancreatic juice. HCO_3^- enters the cell by means of the Na^+–HCO_3^- cotransporter on the basolateral membrane or by the diffusion of CO_2, which becomes hydrated to carbonic acid under the influence of carbonic anhydrase. Transport of H^+ out of the cell by the Na^+/H^+ exchanger or the vascular H^+-ATPase contributes to the provision of intracellular HCO_3^-. Other important components at the basolateral membrane are the secretin receptor, which activates the production of cAMP; a Na^+,K^+-ATPase, which maintains the low level of intracellular Na^+; and a K^+ channel (not shown), which facilitates K^+ exit from the cell. The apical membrane contains the cystic fibrosis transmembrane conductance regulator (CFTR) anion channel and a Cl^-/HCO_3^- exchanger (SLC26A6), which together bring about secretion of HCO_3^- and a net lumenal negative potential. At low lumenal Cl^- concentration, the CFTR channel switches from conducting Cl^- to conducting HCO_3^-. The transcellular electrical gradient between blood and lumenal fluid drives the secretion of Na^+ and K^+. The activation of the CFTR Cl^- channel also depolarizes the duct cells and thereby links the events at the apical membrane to the activation of Na^+–HCO_3^- cotransport at the basolateral membrane.

[43]. Studies in rats showed that CCK plays an important role in the regulation of gene expression of pancreatic enzymes [44]. Intraduodenal infusion of soybean trypsin inhibitor raises plasma CCK and increases trypsinogen I and chymotrypsinogen β mRNA levels fivefold after 48 h. In contrast, soybean trypsin inhibitor infusion has no effect on amylase mRNA levels. Similar effects on pancreatic enzyme mRNA levels are observed after intravenous infusion of CCK to plasma levels comparable to those obtained with soybean trypsin inhibitor. In addition to their effects on gene regulation, CCK and other hormones may exert posttranscriptional control to regulate the synthesis of specific digestive enzymes, because mRNA is translated by ribosomes [45].

Research has begun to reveal the mechanisms by which hormones, especially CCK and insulin, regulate protein synthesis at a translational level and account for the stimulation of pancreatic digestive enzyme synthesis with each meal. CCK and insulin can stimulate acinar protein synthesis in vitro without changes in mRNA [45]. These actions appear primarily at the initiation step in translation and involve the rate-limiting initiation factor eIF4E. Acinar secretagogues and insulin, through a series of steps most likely involving phosphatidylinositol 3-kinase (PI_3K) and the mammalian target of rapamycin (mTOR), lead to the phosphorylation of the binding protein for eIF4E, and thereby the release of eIF4E, which becomes incorporated into a complex that binds the mRNA 5′ cap [46,47]. Through a separate pathway, CCK also activates the phosphorylation of eIF4E, which increases its affinity for the mRNA cap. In addition, mTOR activates ribosomal S6 kinase ($p70^{S6K}$), thereby phosphorylating S6, which increases the translation of messages with terminal polypyrimidine tracts [48]. The importance of the mTOR pathway is shown by the fact that rapamycin can block the stimulation of acinar protein synthesis in vitro [46].

According to the classical model of Palade [49], amino acids are actively transported into the acinar cells, and protein synthesis occurs in the ribosomes. Pancreatic enzymes and a variety of other exportable proteins are synthesized with an amino acid terminal peptide extension called the *signal peptide*, which recognizes a receptor in the rough endoplasmic

membrane and allows the attachment of the ribosome to this membrane [50,51]. Translation is temporarily halted when the signal peptide emerges from the ribosomal subunit and interacts with the signal recognition particle, which is associated with the large ribosomal subunit. The protein–RNA complexes then interact with another protein on the endoplasmic reticulum membrane known as the docking protein [50]. Interaction between the signal recognition particle and the docking protein permits the completion of translocation of the nascent polypeptide into the rough endoplasmic reticulum lumen, after which the ribosomal subunits, signal recognition particle, and RNA dissociate from the endoplasmic reticulum while the protein crosses the endoplasmic reticulum membrane into the cisternae. In fact, most protein synthesis occurs on polysomes that consist of multiple ribosomes simultaneously reading down a single mRNA. When translation is stimulated, the number of ribosomes per polysome increases.

The need for the signal recognition particle and docking protein complex to form on the endoplasmic reticulum before the translation of RNAs containing a signal peptide codon can be completed has important physiological implications. This process ensures that potentially noxious proteins, such as proteinases, cannot gain access to the cytosolic compartment. It also provides a mechanism for sorting the proteins not destined for export from those that must be processed by the endoplasmic reticulum–Golgi pathway and packaged for later secretion [52]. Inside the cisternae of the endoplasmic reticulum, pancreatic secretory proteins interact with chaperones and undergo conformational changes, assuming tertiary and, in some cases, quaternary structures. These structural changes may account for the irreversible segregation of proteins within the rough endoplasmic reticulum. Abnormalities in this process result in the endoplasmic reticulum stress response [53].

The transfer of pancreatic enzyme proteins from the endoplasmic reticulum to the Golgi complex occurs within 20–30 min of synthesis [54]. Their transfer is mediated by vesicles arising from pinched-off transitional elements of the rough endoplasmic reticulum, which act as transport containers for the secretory proteins [54]. Further modification and concentration occur in the Golgi complex and may result partially from the interaction of the predominantly basic secretory proteins with polyanionic substances formed in the Golgi complex [55]. It is also facilitated by the relatively acidic pH within the Golgi complex. After their formation in the Golgi complex, secretory granules move to the apical portions of the acinar cell by a mechanism involving microtubules, where they remain until an appropriate neurohormonal stimulus triggers exocytosis.

Pancreatic enzymes from a single cell probably are secreted in a fixed ratio that is independent of the nature of the stimulus and of the rate of secretion but is determined at the time of synthesis. This phenomenon may be explained by the model proposed by Scheele and Palade [56], which states that secretory proteins are mixed together in the zymogen granule and discharged in parallel. Under certain experimental conditions, nonparallel secretion of pancreatic enzymes may occur. In humans, increasing the doses of CCK infusion results in pancreatic secretion characterized by a greater response of lipase than chymotrypsin concentrations, both of which are greater than the amylase concentration [57]. Similar nonparallel enzyme secretion was reported by Dagorn and colleagues in both rats and humans [58,59].

Several possible explanations for nonparallel secretion have been proposed:

- different rates of enzyme synthesis in response to different degrees of stimulation
- the existence of a soluble cytoplasmic pool of enzyme proteins that are in equilibrium with those contained in zymogen granules
- different enzymatic contents within populations of acinar cells.

Morphological studies show considerable differences in cell sizes in peninsular or teleinsular acinar cells [60]. This, coupled with the observation that the enzyme content and the ratio of amylase to chymotrypsin vary widely among granules taken from the same animal, supports the third hypothesis and suggests that nonparallel secretion is the result of exocytosis from heterogeneous cells within the pancreas [61,62].

Although much controversy exists regarding short-term deviations from parallel secretion, there is little doubt that long-term adaptation of enzymes to diet occurs in animals. Adaptation occurs in rats fed diets containing a preponderance of carbohydrate, protein, or fat, as indicated by increases in the pancreatic content, mRNA levels, and rates of synthesis and secretion of the appropriate class of hydrolytic enzymes by the pancreas [63]. Moreover, the dietary effects are thought to be mediated by specific hormones. Insulin mediates the increased amylase synthesis, and CCK released by protein increases the synthesis of proteases. Although such adaptive changes have not been reported in humans, preferential secretion of lipase occurs in the chronic renal failure associated with hypercholecystokininemia, which is consistent with the adaptive change found in animals receiving chronic administration of CCK [64].

Other biological substances

In addition to producing many digestive enzymes and secretory products that are necessary for nutrient digestion, the acinar cells also secrete a high-density lipoprotein-like substance containing caveolin-1, a membrane protein implicated in cholesterol trafficking and endocytosis [65]. Serine phosphorylation of caveolin-1 directs its entry into the secretory pathway rather than its insertion into the endoplasmic reticulum membrane [65]. Not only does pancreatic juice

contain a significant amount of caveolin-1, but also caveolin-1 is present in zymogen granules from isolated pancreatic acinar cells. Stimulation of the pancreas with CCK also resulted in a large increase in menaquinone-4 secretion, which was accompanied by a marked increase in protein and fluid secretion [66]. These results suggest that menaquinone-4 and caveolin-1 participate in the secretory pathway of acinar cells and have a role in digestive enzyme synthesis or processing.

Stimulation of pancreatic secretion

Mediation of postprandial pancreatic secretion has been ascribed mainly to the hormones secretin and CCK and to vagovagal reflexes that activate cholinergic postganglionic neurons in the pancreas. Considerable knowledge has been gained about these classical regulatory mechanisms, but the picture has become increasingly complicated by evidence suggesting that other regulatory peptide hormones and neurotransmitters are also involved.

Hormonal mechanisms

Secretin

Secretin is synthesized by S-type enteroendocrine cells of the small intestine and is released during a meal. Mutoh and colleagues identified the expression of transcription factor BETA2/NeuroD in the intestinal mucosa cells of mice that also express secretin [67]. This may be the first transcription factor identified that specifically activates cell type-specific expression of an intestinal hormone gene. Secretin is the most potent and efficacious stimulant of pancreatic fluid and HCO_3^- secretion in humans and all other species tested. Duodenal pH is the major regulator of secretin release. A pH of 4.5 is the threshold for secretin release and stimulation of pancreatic HCO_3^- secretion occurs at pH 4.5 [68,69]. Below this pH, pancreatic HCO_3^- output is related to the total amount of titratable acid presented to the duodenum. The increase in postprandial secretin levels in humans amounts to only a few picomolar increments because of the buffering of an appreciable amount of acid produced in the stomach by food and the neutralization of the remaining acid entering the duodenum by pancreaticobiliary secretion [70]. The pH of gastric chyme in the first portion of the duodenum is in the range of 4–5.0 [71]. However, dilute HCl infused into duodenum at a rate of 2–4 mmol/h can increase plasma secretin significantly in humans and dogs [70–73]. H^+ bound to solid food particles may be a potent stimulus of pancreatic HCO_3^- secretion [68]. The slow diffusion of H^+ from the particles stimulates pancreatic HCO_3^- secretion by triggering H^+ receptors located in the more distal small intestine. The mechanism by which HCl stimulates the release of secretin is unclear. Studies of rats indicate that H^+ may release a secretin-releasing factor into the upper intestinal lumen to stimulate the release of secretin [74]. This factor has a molecular weight of less than 5 kDa and is heat stable and trypsin sensitive. The secretin-releasing peptide(s) has not been completely characterized, but investigators have reported that purified porcine pancreatic phospholipase A_2 (PLA_2) stimulates secretin release from rat intestinal secretin-producing cells [75]. Furthermore PLA_2-like immunoreactivity is present in the intestinal mucosa and is released into the lumen during duodenal acidification [76]. Pretreatment with a specific anti-PLA_2 antiserum abolishes the secretin-releasing bioactivity of the intestinal acid perfusate, suggesting that intestinal PLA_2 is a secretin-releasing peptide. Secretin-producing cells appear to have acid-sensing ion channels. Hence, lumenal acid likely stimulates the release of secretin by more than one mechanism.

Nonacid factors may play a role in the postprandial release of secretin. Among the major components of a mixed meal, fatty acids such as oleic acid and other digestive products of fat can increase plasma secretin levels and pancreatic HCO_3^- secretion [77,78]. Bile in the upper small intestine can also stimulate the release of secretin [79]. However, the physiological importance of these nonacid factors in the release of secretin is questionable, because postprandial plasma secretin does not increase in subjects who are achlorhydric or in healthy subjects in whom meal-induced acid secretion is neutralized with $NaHCO_3$.

The pancreas appears to be sensitive to the small amounts of secretin released into the circulation after a meal. Secretin given in a dose that mimics postprandial plasma secretin levels can stimulate pancreatic secretion of water and HCO_3^- [80,81]. Administration of secretin antiserum to conscious dogs greatly reduces the pancreatic HCO_3^- response to a meal [82]. The sites where secretin acts to stimulate pancreatic secretion have not been fully identified. In vitro animal models clearly show that secretin stimulates HCO_3^- secretion by isolated ducts or duct fragments [32,33]. With the use of radiolabeled ligand ^{125}I-labeled secretin and autoradiography, a secretin-binding site was demonstrated on pancreatic acini and duct cells [83]. Binding was not evident on pancreatic islets or vascular structures. This supports, but does not necessarily prove, the idea that secretin acts directly on the pancreas to stimulate pancreatic secretion. Studies have shown that the effect of physiological doses of secretin on exocrine pancreatic secretion is highly sensitive to atropine. In fact, similar to CCK, vagal afferent pathways mediate the effect of secretin on pancreatic exocrine secretion, gastric acid secretion, and motility [84–86]. Receptor autoradiography, immunocytochemical studies, and electrophysiological recordings strongly support the presence of secretin receptors on vagal afferent fibers [87–89]. Close intraarterial injection of secretin (2.5 and 5 pmol) elicits dose-dependent increases in neuronal firing in a subgroup of nodose ganglia neurons. This same group of neurons also contains high-affinity CCK_1 receptors [89]. Injection of a subthreshold dose of CCK-8 (5 pmol) greatly enhances the neural responses to 5 pmol

secretin. This synergistic interaction helps to explain the robust postprandial secretion of pancreatic HCO_3^- and enzyme despite an only modest postprandial increase in levels of CCK and secretin.

Cholecystokinin

CCK is the other gut hormone that plays an important role in pancreatic secretion. It is released by hydrolytic products of digestion such as amino acids and fatty acids. In dogs, proteins do not stimulate pancreatic secretion, but crude enzyme digests of protein that contain peptides and amino acids are effective stimulants of pancreatic enzyme secretion, presumably through the release of CCK [90,91]. Undigested fat is ineffective, but products of lipolysis such as fatty acids are the most potent stimulants of CCK release [78]. Factors that influence the CCK response to fatty acids include their chain length, degree of saturation, concentration, and total load [92].

The mechanism by which nutrients stimulate the release of CCK is not clear. In species such as the rat, in which feedback inhibition of pancreatic enzyme secretion occurs, CCK release may be mediated by a trypsin-sensitive CCK-releasing peptide [93]. Peptone in the duodenum stimulates serotonin (5-hydroxytryptamine, 5-HT) release from the intestinal enterochromaffin cells. The 5-HT released into the submucosa activates the sensory substance P neurons. Signals would then be transmitted to cholinergic interneurons and to epithelial CCK-releasing peptide-containing cells by way of cholinergic secretomotor neurons [93]. In this manner, CCK release may be controlled by the level of active intralumenal proteases [94–96]. Proteins, the major food stimulants of CCK secretion in rats, may bind or inhibit intralumenal endopeptidases, which would otherwise inactivate the CCK-releasing peptide [97]. Research indicates that ethanol-stimulated CCK release is also mediated by a CCK-releasing peptide [98]. In dogs, the mechanism of CCK release may be nutrient dependent [99]. CCK release in response to sodium oleate, but not tryptophan or HCl, is atropine sensitive [99]. It is conceivable that the release of CCK by sodium oleate may be mediated by a CCK-releasing peptide, the release of which is mediated by cholinergic input [97], and further, tryptophan or HCl may stimulate CCK cells directly.

Under fasting conditions, the plasma CCK levels are low, averaging about 1 pmol/L in humans [100–102]. After the ingestion of a meal rich in protein and fat, the CCK concentration increases to 6–8 pmol/L within 10–30 min, followed by a gradual decline to basal levels during the ensuing 3 h [101,102]. Several molecular forms of CCK appear to be released into the circulation postprandially, including CCK-58, CCK-33, CCK-22, CCK-12, and CCK-8 [103]. Their relative contributions to the CCK activity of plasma in basal and stimulated states remain to be determined. In rats, CCK-58 appears to be the only detectable endocrine form of CCK in the circulation [104].

CCK plays an important role in the stimulation of pancreatic enzyme secretion during the postprandial state. The infusion of physiological doses of CCK produces the same levels of pancreatic enzyme secretion as during the postprandial state [105]. Furthermore, the administration of the potent CCK antagonists lorglumide or MK-329 produces a 50%–60% inhibition of meal-stimulated pancreatic secretion in dogs [106]. These antagonists have similar effects on meal-stimulated pancreatic secretion in humans [107].

CCK can stimulate fluid and HCO_3^- secretion to some extent [108]. The effect on HCO_3^- secretion is weak but physiologically relevant because CCK potentiates the action of secretin on the pancreas [109]. In intact dogs and humans, CCK-stimulated pancreatic enzyme secretion is not potentiated by secretin [105,110,111].

The mechanisms by which CCK acts to stimulate pancreatic enzyme secretion remain controversial. In vitro studies using dispersed pancreatic acini demonstrate that CCK-stimulated amylase release is insensitive to atropine or tetrodotoxin, indicating a direct action on pancreatic acini [112]. The effects of cholinergic agonists and CCK on isolated preparations of pancreatic acini are additive, suggesting that CCK may stimulate enzyme secretion by a cholinergically independent mechanism [113]. However, in vivo studies of humans and dogs have shown that pancreatic secretion stimulated by CCK can be blocked by atropine, implying the involvement of cholinergic pathways [114–116]. Furthermore, enzyme output in response to low doses of CCK is reduced in patients after vagotomy compared with normal controls [117]. It appears that CCK can act through atropine-sensitive and atropine-insensitive pathways to stimulate pancreatic exocrine secretion. Human studies have shown that infusions of CCK-8 able to produce plasma CCK levels similar to those observed after ingestion of a standard mixed meal stimulate pancreatic enzyme output predominantly in an atropine-sensitive fashion [114]. Furthermore, studies in rats indicate that physiological doses of CCK act through stimulation of vagal afferent pathways originating from the duodenal mucosa [118] (Fig. 15.4). CCK receptors in the rat vagus nerve have been detected using in vitro receptor autoradiography [119]. As in pancreatic acini, vagal CCK receptors exist in both high-affinity and low-affinity states [11,12,120]. Under physiological conditions, CCK appears to act through high-affinity vagal CCK_1 receptors to mediate pancreatic enzyme secretion [12]. In contrast, the effect of CCK on satiety is mediated by vagal low-affinity CCK_1 receptors [10]. These findings suggest that different affinity states of the vagal CCK receptors mediate different digestive functions. The vagal neurotransmitter used by the CCK_1 receptor to activate the brainstem is likely to be glutamate [121,122], as it has been demonstrated that CCK-8 increases glutamate release from nerve terminals onto neurons of the nucleus tractus solitarius pars centralis (cNTS). With the use of whole cell patch-clamp techniques in thin brainstem slices, it has

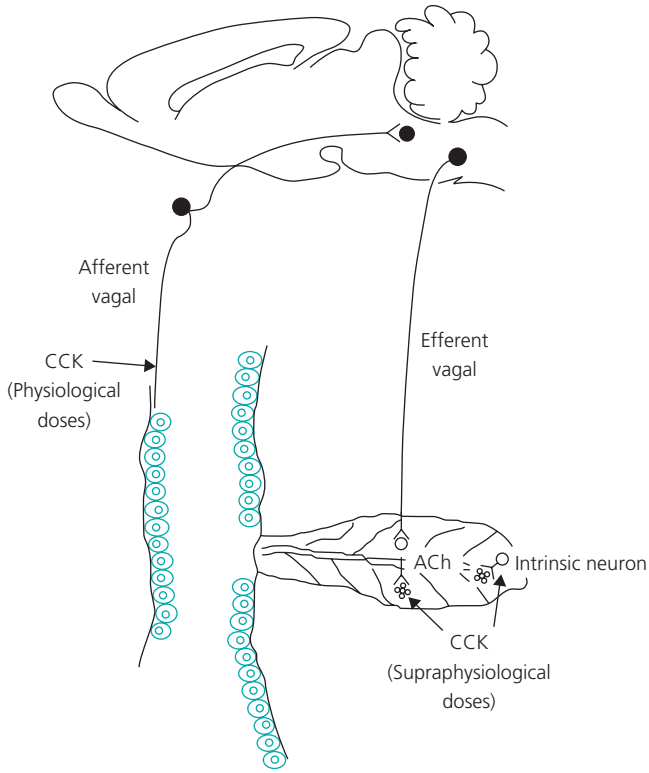

Figure 15.4 Sites and mechanisms of action of cholecystokinin (CCK) to stimulate pancreatic enzyme secretion. Dosages of CCK-8 that produce physiological plasma CCK levels act through stimulation of the vagal afferent pathway, which originates from the gastroduodenal mucosa. In contrast, dosages that produce supraphysiological plasma CCK levels act on intrapancreatic neurons and, to a lesser extent, on pancreatic acini. ACh, acetylcholine. From Li & Owyang [118], with permission from the American Society for Clinical Investigation.

been observed that CCK-8 increases the frequency of spontaneous and miniature excitatory postsynaptic currents in 43% of the cNTS neurons by way of a presynaptic mechanism [123]. In slices from deafferented rats, there was a 50% reduction in the number of cNTS neurons receiving glutamatergic inputs responding to CCK-8 [123]. This suggests that the central terminals of vagal afferent terminals may not be the sole sites for the action of CCK-8 in the brainstem. Although CCK does not cross the blood–brain barrier, the NTS is a circumventricular organ with a leaky blood–brain barrier, fenestrated capillaries, and an enlarged perivascular space that allow the passage of large molecules [124–126]. It is therefore conceivable that CCK may act on other sites of the brainstem, such as the NTS and the dorsal motor nucleus of the vagus (DMV) [123,127,128]. Electrophysiological studies show that CCK-8 induces a concentration-dependent excitation in 60% of pancreas-projecting DMV neurons [127]. This action is mediated by the closure of a K^+ conductance. Under physiological conditions, CCK seems to stimulate postprandial pancreatic enzyme secretion through cholinergic pathways rather than through direct action on the pancreatic acinar cell. Both M_1 and M_3 muscarinic receptors on the pancreatic acini appear to mediate these responses [129,130].

The molecular cloning of the CCK receptor gene and the subsequent recognition that its expression is virtually absent in the human pancreas [8,131] further supported the possibility that CCK acts at an extrapancreatic site. One study indicated that human acini did not respond to CCK agonists, although they responded to a muscarinic agonist [8]. In contrast, the cells responded to CCK agonists after adenovirus-mediated gene transfer of CCK_1 receptors [8]. Quantitative reverse transcriptase–polymerase chain reaction showed that the message levels for CCK_1 receptors were ~ 30-fold lower than those for CCK_2 receptors, which were ~ 10-fold lower than those for M_3 muscarinic receptors. In situ hybridization did not detect CCK_1 receptor mRNAs in adult human pancreas. These observations indicate that human pancreatic acinar cells do not respond to CCK receptor agonists because the level of receptor expression is insufficient.

Serotonin

Intestinal 5-HT appears to play an important role in the mediation of postprandial pancreatic secretion [132–135]. A large amount of 5-HT is present in the mammalian gastrointestinal tract. Serotonergic neurons in the intestinal myenteric plexus may mediate local reflexes. However, the major source of 5-HT in the intestine appears to be gastrointestinal mucosal enterochromaffin cells [136]. Many 5-HT-containing enterochromaffin cells exist in the proximal duodenum and have a morphology consistent with a "sensory" paracrine role [137]. 5-HT is released in response to a wide variety of stimuli [136], including acidification of the duodenum [136], instillation of hypertonic glucose, sucrose, or maltose solutions [132,138], vagal stimulation [139], and mechanical stimulation [140]. Morphological studies have shown that vagal terminal branches come in close contact with the basal lamina, but do not appear to penetrate it [141]. Other studies have shown that 5-HT may increase the discharge of vagal afferent fibers from the stomach and proximal intestine in ferrets [142,143] and may stimulate vagal nodose ganglia activity in rats [133]. This in turn stimulates pancreatic secretion by way of the vagovagal reflex mediated by a cholinergic efferent pathway [132]. 5-HT appears to activate two different groups of afferent fibers innervating the rat jejunum [144]. One group of mucosal nerve fibers is directly activated by stimulation of $5\text{-}HT_3$ receptors and another group responds to contractile activities induced by stimulating $5\text{-}HT_{2A}$ receptors on smooth muscle cells (i.e., mechanosensitive afferents). Direct physiological recordings of the rat nodose ganglia have shown that lumenal factors such as intestinal osmotic stimuli and perfusion of carbohydrates elicit powerful vagal nodose responses that are antagonized by the $5\text{-}HT_{3/4}$ antagonist tropisetron or the $5\text{-}HT_3$

antagonist granisetron [133]. Parallel studies in rats show that lumenal factors such as osmolarity and disaccharides stimulate pancreatic secretion by activating 5-HT_3 receptors whereas mechanical stimulation activates both 5-HT_3 and 5-HT_2 receptors on mucosal afferent fibers in the intestine to induce pancreatic secretion [132]. Pharmacological depletion of 5-HT stores using *p*-chlorophenylalanine, an inhibitor of 5-HT synthesis, abolishes nodose neuronal responses stimulated by lumenal factors [133]. In contrast, pretreatment with 5,7-dihydroxytryptamine, a specific neurotoxin that destroys neurons containing 5-HT without affecting mucosal cells that contain 5-HT, does not affect these responses [133]. These observations suggest that the nodal neuronal responses to lumenal osmolarity and the digestion products of carbohydrates depend on the release of endogenous 5-HT from the mucosal enterochromaffin cells, which acts on 5-HT_3 receptors on vagal afferent fibers. These studies indicate that lumenal stimuli induce 5-HT release, which, in turn, activates 5-HT_3 receptors on mucosal vagal afferent terminals. In this manner, 5-HT acts as a paracrine substance to stimulate pancreatic secretion by way of a vagal cholinergic pathway. It appears that both 5-HT and CCK evoke pancreatic enzyme secretion by stimulating vagal afferent pathways that originate in the duodenal mucosa. These primary vagal afferent neurons contain mainly glutamate and substance P [87], which, on release, stimulate the NTS and subsequently the DMV in the brainstem to mediate postprandial enzyme secretion.

Both 5-HT and CCK are the principal stimulators of postprandial pancreatic secretion. Studies in rats indicate that administration of a CCK_1 receptor antagonist inhibits 54% of postprandial pancreatic protein secretion. The combination of the CCK_1 receptor antagonist and a 5-HT_3 antagonist almost completely abolish exocrine pancreatic secretion [132], suggesting that 5-HT-dependent pancreatic stimulants account for about 50% of postprandial pancreatic secretion.

There is synergistic interaction between vagal CCK and 5-HT receptors in the mediation of pancreatic secretion [135]. Infusion of a subthreshold dose of CCK potentiates vagovagal reflex-mediated pancreatic secretion stimulated by lumenal 5-HT-dependent factors. Discharge recordings of single vagal primary afferent neurons innervating the duodenum reveal distinct groups of nodose ganglia neurons that possess only high- or low-affinity CCK receptors or 5-HT_3 receptors [145]. In one group of nodose neurons, previous exposure to lumenal 5-HT enhanced the subsequent response to a subthreshold dose of CCK. This synergistic interaction provides an explanation of how a small increase in the plasma CCK level is sufficient to produce a robust postprandial pancreatic secretion.

Pancreatic HCO_3^- secretion and secretin release in response to duodenal acidification in rats are inhibited by the 5-HT_3 antagonist ondansetron and the 5-HT_2 antagonist ketanserin[146]. In addition, pancreatic fluid and HCO_3^- secretion stimulated by exogenous secretin are also inhibited by these 5-HT antagonists. Thus, 5-HT appears to regulate acid-stimulated exocrine pancreatic secretion by modulating both the release and action of secretin through two 5-HT receptor subtypes.

Under certain experimental conditions, activation of the 5-HT pathway may inhibit pancreatic exocrine secretion. It has been reported that in isolated guinea pig pancreatic ducts, 5-HT inhibits basal and secretin- or acetylcholine-stimulated fluid secretion. This effect is antagonized by a 5-HT_3 agonist, indicating the involvement of a direct 5-HT_3 inhibitory pathway [147]. In contrast, administration of the 5-HT_3 antagonist azasetron in rats stimulates pancreatic secretion of fluid and protein [148]. Atropine but not vagotomy abolishes this effect, suggesting the involvement of a vagus-independent cholinergic pathway. Researchers have confirmed that guinea pig pancreatic ducts have 5-HT containing cells and identified 5-HT_3 receptors on their basolateral cell membranes [146]. These investigators proposed a distention-stimulated negative feedback on fluid secretion by pancreatic duct cells.

Other hormones and stimulatory factors

Insulin plays a significant role in modulating exocrine pancreatic secretion [7]. Studies have demonstrated that insulin potentiates the secretory response to secretin plus CCK [149], and that ouabain, an inhibitor of Na^+,K^+-ATPase activity, abolishes this stimulatory action of insulin. Insulin potentiates the stimulatory effect of secretin on Na^+,K^+-ATPase activity, without affecting the binding of secretin to pancreatic acini. Physiologically, this action of insulin is important because immunoneutralization experiments in conscious rats show that pancreatic secretion of water, HCO_3^-, and protein stimulated by a meal or by a combined intravenous administration of physiological doses of secretin and CCK-8 is markedly reduced when the circulating insulin is neutralized with a rabbit anti-insulin antibody [150]. Similar observations have been made studying an isolated perfused rat pancreas preparation. These studies indicate that insulin is needed locally for the action of secretin and CCK on the exocrine pancreas. Pancreatic enzyme secretion is often reduced in human diabetics who have no overt pancreatic disease [151]. Similar observations have been made in rats with streptozotocin-induced diabetes [152]. Because physiological doses of CCK act through vagal afferent pathways, it is conceivable that the potentiation between CCK and insulin occurred at the level of the nodose ganglia.

In view of the structural similarity between CCK and gastrin (see Chapter 4), it is not surprising that gastrin stimulates pancreatic enzyme secretion. In the dog, gastrin is about one-third as effective as CCK on a molar basis in stimulating the pancreas. Irrigation of a canine antral pouch with peptone and liver extracts at neutral pH stimulates pancreatic protein secretion, but irrigation with acidified solutions does not

[153]. The stimulatory effects of the protein solution may be caused by the release of gastrin, and the inhibitory effects of acidification may be the result of the suppression of gastrin release. The evidence, however, is indirect; it is unlikely that the postprandial increase in plasma gastrin is sufficient to significantly stimulate pancreatic secretion. In other species, gastrin has much less effect on pancreatic enzyme secretion.

Bombesin (i.e., gastrin-releasing peptide in mammals), a polypeptide isolated from the skin of frogs and the human alimentary tract, stimulates pancreatic secretions that contain small amounts of HCO_3^- and high concentrations of enzymes in humans [154,155]. Bombesin can act directly on the pancreas through specific receptors identified on pancreatic acinar cells [156]. It has been suggested that bombesin exerts its stimulating effect on the exocrine pancreas indirectly by promoting the release of CCK from the mucosa of the small intestine [157]. In other systems, bombesin has been reported to exert its effect by way of a cholinergic pathway [158]. Bombesin stimulates amylase release from rat pancreatic lobules through the release of acetylcholine from intralobular nerves [159]. In contrast, in vivo studies indicate that the action of bombesin in rats is probably direct, because the combined administration of atropine and the CCK antagonist proglumide does not affect pancreatic protein output stimulated by bombesin [160]. Similarly, the stimulatory action of bombesin on pancreatic secretion in humans is not affected by the CCK receptor antagonist loxiglumide [161]. The physiological importance of bombesin in pancreatic secretion was questioned by studies demonstrating that bombesin receptor antagonists do not influence postprandial enzyme secretion in intact rats [162].

The tridecapeptide neurotensin has been shown to stimulate pancreatic secretion in humans and dogs [163,164]. In rats, the mechanism of stimulation appears to be neurally mediated, involving capsaicin-sensitive sensory fibers and cholinergic vagal efferent pathways [165]. Neurotensin is released by intestinal fatty acids, raising the interesting possibility that neurotensin may play a significant role in mediating pancreatic secretion stimulated by fat [164]. However, exogenous infusion of neurotensin in doses that stimulate pancreatic secretion results in a plasma level much higher than that measured after a normal meal [163,164]. Neurotensin stimulates HCO_3^- secretion but decreases enzyme secretion stimulated by secretin and cerulein, a CCK analogue, in humans [163]. These observations do not support a role for neurotensin as a regulator of meal-stimulated pancreatic secretion.

Ghrelin, a novel acylated peptide localized in endocrine cells of the stomach and neurons of the hypothalamic arcuate nucleus [166–168], has been shown to stimulate pancreatic secretion [169]. It acts as an endogenous ligand for the growth hormone secretagogue receptor [166–168], which is found throughout the body, in the pituitary, hypothalamus, stomach, heart, lung, intestine, adrenal cortex, adipose tissue, immune system, human breast carcinoma, and pancreatic islet cells. Growth hormone secretagogue receptor mRNA is expressed in rat pancreas and in the exocrine pancreatic-derived cell line, AR42J [170]. Administration of ghrelin causes a dose-dependent increase in intracellular calcium. However, in vivo rat studies indicate that ghrelin stimulates pancreatic secretion by acting centrally through the vagal cholinergic pathways [169]. Pretreatment with atropine or hexamethonium or acute vagotomy, but not perivagal application of capsaicin, abolishes pancreatic secretion in response to intravenous administration of ghrelin. Furthermore, selective ablation of the area postrema blocks the pancreatic response to ghrelin. Immunocytochemical staining shows a marked increase in the number of cFos-expressing neurons in the area postrema, the NTS, and the DMV after intravenous infusion of ghrelin; selective ablation of the area postrema eliminates this increase [169]. These observations suggest that circulating ghrelin gains access to the brainstem vagal circuitry by way of the area postrema, which represents the primary target on which peripheral ghrelin may act as an endocrine substance to stimulate pancreatic secretion. Further studies are needed to determine whether endogenous ghrelin can reach the central nervous system in sufficient concentrations to interact with the brainstem circuits to regulate pancreatic secretion.

Nitric oxide (NO), a ubiquitous substance that is present in the neurons and vascular endothelium of the pancreas [171], also appears to play a significant role in regulating pancreatic secretion. In rat, inhibition of NO production with N^G-nitro-L-arginine methyl ester (L-NAME) reduces basal amylase secretion by 60% [172]. A NO synthase (NOS) inhibitor also inhibits pancreatic enzyme secretion in response to a meal, duodenal infusion of acid, or intravenous infusion of physiological doses of secretin or CCK in anesthetized and conscious rats [173]. In humans, graded doses of the NOS inhibitor, N^G-monomethyl-L-arginine, dose-dependently reduced pancreatic enzyme secretion stimulated by secretin and cerulein [174]. Because NOS inhibition has no effect on amylase release nor on the changes in intracellular Ca^{2+} concentration in rat pancreatic acini stimulated by carbachol and CCK-8 [175], the effect of NO on exocrine pancreatic secretion is likely to be indirect. NOS is abundant in intrapancreatic nerves [176] and ducts, the enteric nervous system, and the vagus nerve [177]. The source of NO that mediates the action of CCK and secretin on pancreatic secretion is not clear.

Administration of L-NAME reduces CCK-stimulated pancreatic microvascular blood flow and at the same time decreases pancreatic fluid and protein output in cats [178]. This observation may have clinical importance, because inadequate blood flow has been associated with clinical pancreatitis. It has been reported that administration of a NOS inhibitor in rats with edematous pancreatitis causes a decrease in pancreatic blood flow and exacerbates cerulein-induced

pancreatitis [179]. Conversely, treatment with the NO donor L-arginine before and after cerulein injection increases pancreatic blood flow and reduces the severity of cerulein/water-immersion-induced hemorrhagic pancreatitis. These observations suggest that NO may have a protective role against the development of pancreatitis, possibly because it increases pancreatic blood perfusion.

Neural mechanisms

Parasympathetic nervous system

The pancreas is innervated by parasympathetic and sympathetic nerve fibers. The parasympathetic fibers pass to the pancreas directly through the vagus nerves and indirectly through the celiac ganglion, the splanchnic nerves, and perhaps through the intramural plexus of the duodenum.

The functional effect of vagal stimulation of the pancreas varies greatly with the species and with the experimental conditions [180]. In rat, both CCK- and non-CCK-mediated lumenal stimuli evoke pancreatic enzyme secretion through stimulation of a vagal afferent pathway originating from the duodenal mucosa [135,181]. Acute vagotomy or atropine completely abolishes pancreatic secretion stimulated by these agents [135,181]. In dog and rabbit, vagal stimulation has a small stimulatory effect on the output of enzymes, but the increase is smaller in magnitude than with CCK stimulation. This response persists after removal of the stomach and intestine, indicating a direct stimulatory effect on the pancreas. In cat, stimulation of the vagus results in some increase in the secretion rate that does not depend on hormones. Atropine blocks the secretion of enzymes but has no effect on HCO_3^- secretion. In pigs, vagal stimulation results in copious secretion of pancreatic juice with high levels of enzymes and HCO_3^-, even after extirpation of the stomach and intestine.

In humans, the vagus appears to play an important role in the mediation of pancreatic secretion. Insulin-induced hypoglycemia, which is presumed to stimulate the vagus centrally, augments secretin-stimulated pancreatic protein output [182]. Vagotomy reduces the HCO_3^- secretory response to exogenous hormones. Maximal enzyme secretion is not significantly affected, but the sensitivity of the pancreas to submaximal doses of CCK is decreased [117]. Vagotomy reduces pancreatic enzyme responses to intestinal stimulants and food [117,183]. It seems that the cholinergic stimulation primarily modulates the action of gut peptides on pancreatic secretion but has no physiologically relevant effect on the release of CCK or secretin [184].

There are volume receptors and osmoreceptors in the human duodenum. Stimulation of these receptors by distention or administration of a hyperosmolar solution elicits a pancreatic enzyme response mediated by cholinergic neurons [185,186]. Increased firing rates in peripheral afferent vagal neurons and in central sites have been recorded after gastric distention and intestinal perfusion with amino acids and HCl [187–189].

In addition to glutamate, other neurotransmitters in the central nervous system are likely involved in the regulation of pancreatic secretion. Microinjection of the thyrotropin-releasing hormone analogue in the dorsal vagal complex of rats stimulates pancreatic juice flow and enzyme output in a dose-dependent manner [190]. Vagotomy and atropine eliminate this stimulatory effect, indicating that thyrotropin-releasing hormone modulates pancreatic exocrine secretion through the dorsal vagal complex.

Intrapancreatic postganglionic cholinergic neurons regulate enzyme and HCO_3^- secretion. These neurons are activated by central input during the cephalic phase and by vagovagal reflexes initiated by gastric- and intestinal-phase stimulation. Acetylcholine released by the intrapancreatic neurons may act directly on acinar cells or potentiate the action of secretin on HCO_3^- secretion from duct cells in vitro. The interaction of acetylcholine and CCK is additive. The enteropancreatic reflex may also play a role in mediating postprandial enzyme secretion [186]. This is especially important after chronic vagotomy [191].

Sympathetic nervous system

Adrenergic innervation of the pancreas occurs mainly through the splanchnic nerves. In the pancreas, most of the fibers are distributed to the blood vessels, and a few pass to the acini or ducts [109]. One laboratory has shown that rabbit pancreatic ganglia contain high levels of norepinephrine and dopamine [192]. Further, the pancreatic ducts also contain very high amounts of epinephrine and moderate amounts of norepinephrine and dopamine. The physiological significance of these findings remains to be determined.

Activation of the splanchnic nerves usually inhibits exocrine and endocrine pancreatic secretion; stimulation of the nerves decreases the response to pancreatic stimulants, but splanchnicectomy increases it [109,193]. The pancreatic inhibitory effect of splanchnic nerve stimulation appears to be synchronous with and dependent on the intense vasoconstriction that is caused by stimulation of the β-adrenergic receptors on blood vessels. In isolated guinea pig pancreatic acini, norepinephrine alone has no effect on the response to submaximal concentrations of CCK-8 [194]. Epinephrine produces a modest stimulation of enzyme output in mouse and rat pancreas in vitro, and the stimulatory effect is inhibited by β-adrenergic receptor antagonists [195]. No clear pattern emerges from the many studies of regulation of exocrine pancreatic secretion by the sympathetic nervous system. The major role for the adrenergic mechanism appears to be the inhibition of fluid and HCO_3^- secretion, which is mediated partially by vasoconstriction.

Hypothalamic regulation

Although pancreatic secretion is mediated mainly by vagovagal reflexes located within the brainstem, these reflexes are modulated by input from higher centers [196]. Animal

studies have shown that after chronic decerebration, which interrupts the entire descending neural input to the brainstem, there is a 35% reduction in basal pancreatic protein output and a 40% decrease in pancreatic protein secretion stimulated by lumenal perfusion of peptone [197], suggesting that the forebrain plays an important role in modulating the vagovagal reflex in the brainstem. The hypothalamus receives a wide variety of convergent afferent inputs from the viscera and regulates autonomic activities by modulating neuronal input to the autonomic preganglionic neurons. Cholinergic pathways in the hypothalamus play a major role in the stimulation of pancreatic secretion. Microinjection of methscopolamine, a blood–brain barrier-impermeant, cholinergic muscarinic receptor antagonist, into the lateral hypothalamic nucleus or paraventricular nucleus produces inhibitory effects similar to those observed after surgical decerebration [197]. Intracerebroventricular injection of hemicholinium-3 at doses known to deplete the endogenous acetylcholine store produces inhibitory results similar to those produced by methscopolamine. In contrast, microinjection of acetylcholine into the lateral hypothalamic nucleus and the paraventricular nucleus evokes 46% and 40% increases in pancreatic secretion over basal, respectively [197]. Selective lesions of the lateral septal cholinergic neurons or lateral parabrachial nucleus produce significant inhibition of peptone-induced pancreatic secretion [197]. Hence, cholinergic inputs from the lateral septal cholinergic neurons and the parabrachial nucleus to the hypothalamus play a major role in modulating vagal pancreatic efferent nerve activities and pancreatic secretion evoked by the vagovagal reflex.

Enteropancreatic neural reflex

Functional and anatomic enteropancreatic neural connections have been demonstrated by antegrade and retrograde tracer studies; neurons in the ganglia of the myenteric plexuses of the stomach and the duodenum project directly to the pancreas [198]. Activation of the myenteric neurons in the duodenum can influence the exocrine and endocrine pancreatic functions in the rat. These enteropancreatic neural pathways have cholinergic and serotonergic components [198,199]. The cholinergic nerves from the duodenum stimulate intrapancreatic neurons by way of nicotinic synapses. Abundant enteropancreatic serotonergic axons may inhibit pancreatic secretion through presynaptic 5-HT_{1P} receptors on cholinergic nerves [199]. Further studies are needed to define the physiological role of the serotonergic enteropancreatic neural pathways.

Peptidergic nervous system

Immunocytochemical studies have revealed several peptides in the nerve cell bodies and fibers of the pancreas. Among these, nerve fibers and cell bodies containing vasoactive intestinal polypeptide (VIP) are the most abundant [200]. The fibers containing VIP appear to surround the cell bodies of intrapancreatic ganglia and innervate duct cells.

In pigs, VIP is the neurotransmitter that mediates much of the HCO_3^- secretory response to electrical stimulation of the vagus nerve [201]. Vagal stimulation after the administration of atropine increases the pancreatic venous outflow of VIP and pancreatic HCO_3^- secretion; somatostatin blocks both effects [201]. The time courses for increased venous efflux of VIP and for increased HCO_3^- secretion after vagal stimulation are similar. A specific VIP antiserum reduces the HCO_3^- response to vagal stimulation [200]. The importance of intrapancreatic neuronal VIP as a regulator of pancreatic secretion may be species specific. VIP is a weak partial agonist in humans [201]. In some species, VIP may also induce pancreatic vasodilation and increase blood flow in response to the activation of the exocrine pancreas.

The neuropeptide galanin, which has been found in intrapancreatic nerve endings surrounding the endocrine pancreas and within the exocrine pancreas, appears to have a modulatory effect on exocrine pancreatic secretion. Depending on the experimental models used, galanin may stimulate or inhibit pancreatic secretion. With the use of an isolated perfused rat pancreas, it has been shown that porcine galanin in concentrations of 0.001 and 0.01 pmol/L significantly enhances CCK-stimulated amylase secretion and stimulates insulin release [202]. However, higher concentrations of galanin (10 and 100 pmol/L) inhibit insulin secretion and have no effect on CCK-stimulated amylase secretion. Because insulin potentiates CCK-stimulated enzyme secretion, low concentrations of galanin probably act through the release of insulin to stimulate pancreatic secretion. In contrast, galanin appears to be a potent inhibitor of the pancreatic exocrine secretion stimulated by either bombesin, secretin, or CCK in intact animals [203]. Galanin completely inhibits 2-deoxy-D-glucose-stimulated amylase secretion in anesthetized rats and significantly inhibits veratridine-stimulated release of acetylcholine in rat pancreatic lobules [204]. Thus, in intact animals, galanin appears to inhibit pancreatic secretion by inhibiting cholinergic transmission.

Other peptidergic neurotransmitters identified in the pancreas include the carboxyl-terminal tetrapeptide of gastrin/CCK [193,205], gastrin-releasing peptide [206], substance P [193,205], peptide histidine isoleucine [207], neurotensin [208], neuropeptide Y [207,209], enkephalin [193,205], and calcitonin gene-related peptide (CGRP) [210]. Pharmacological studies have found that CCK, gastrin, substance P, gastrin-releasing peptide, peptide histidine isoleucine, neurotensin, and CGRP stimulate, whereas enkephalin and neuropeptide Y inhibit exocrine pancreatic secretion. The physiological relevance of their mediation of pancreatic secretion is unknown.

Intrapancreatic nerves

Pancreatic ganglia share many of the characteristics of the enteric neurons and receive input from the parasympathetic,

sympathetic, and enteric nervous systems. Most pancreatic neurons (86%) are choline acetyltransferase positive [176]. Rabbit pancreatic ganglia contain high levels of norepinephrine and dopamine but 5-HT is absent [192]. All choline acetyltransferase-positive pancreatic neurons possess neuropeptide Y immunoreactivity, and most express NOS [176]. Most pancreatic neurons innervate the acini. Intrapancreatic neurons receive fast and slow excitatory postsynaptic potentials; 5-HT appears to inhibit the slow excitatory postsynaptic potentials through a 5-HT_{1P} receptor in some neurons. 5-HT and 5-HT_{1P} agonists are known to inhibit amylase secretion. Furthermore, intravenous injections of 5-HT_3 receptor antagonists, such as azasetron and granisetron, increase pancreatic protein output in conscious rats [148]. Blockade of this effect by atropine, but not truncal vagotomy [148], is consistent with a site of action on intrapancreatic ganglia and nerves.

Intracellular control of pancreatic secretion

Receptors

Most of the hormones and neurotransmitters that stimulate pancreatic secretion do so by directly regulating acinar and duct cells, but some may regulate indirectly by their actions on nerves or blood vessels. To determine the regulatory pathway, it is important to identify the physiological effects on isolated acinar and duct cells and to localize the high-affinity receptors for each regulator to its target cell. Because of the preponderance of acinar cells in the pancreas, methods to prepare isolated cells or pancreatic acini have been developed. By using amylase secretion as the criterion for functional response, studies of the effects of agonists and antagonists on secretion have identified the presence of specific receptors on acinar cells. The receptors have been confirmed by binding studies with radiolabeled analogues and antagonists [211,212]. Electron microscopic autoradiography and confocal fluorescence microscopy have localized binding to the basolateral membrane domain, although bound ligand may be internalized subsequently by an energy-dependent process [213,214]. Techniques of preparing isolated duct segments or cultured monolayers of duct cells also have been developed [32,215].

Through such studies, acinar cells from a variety of species, including humans, have been shown to bear receptors for CCK, bombesin, acetylcholine, VIP, and secretin. CCK interacts with both CCK_1 receptors, which are highly specific for CCK, and CCK_2 (or gastrin), receptors, which respond to both CCK and gastrin. Much is known about CCK_1 and M_3 muscarinic receptors and their signaling because of their presence on rodent acinar cells; however, the human pancreas contains few CCK_1 or CCK_2 receptors, and little is known about their function on acinar cells. CCK receptors on afferent nerves appear to have properties similar to CCK receptors on acinar cells. Less is known about duct cell receptors because of the relatively small number of these cells in the pancreas and the challenges encountered in studying their physiological functions (e.g., ion transport). Duct cells bear receptors for secretin, ATP, CCK, and acetylcholine and may have receptors for VIP.

Receptors for major pancreatic secretagogues belong to the receptor family characterized structurally by seven hydrophobic transmembrane domains and functionally by their interaction with guanine nucleotide-binding proteins (i.e., G proteins) [216]. M_3 muscarinic receptor, the bombesin receptor, and the CCK_1, and CCK_2 receptors have been cloned and found to possess similar structures. The secretin receptor also possesses seven transmembrane regions but has a somewhat different amino acid sequence [217].

Structure–function studies with site-directed mutagenesis and chimeric receptors have established some general principles of function for the G protein-coupled receptor family [216,218]. The transmembrane segments may form a pocket for the binding of small molecules, such as acetylcholine, and the extracellular amino-terminal end and loops may be important in the interactions with peptide molecules. The third cytoplasmic loop, projecting between the fifth and sixth transmembrane domains, is thought to interact with the appropriate G protein, and the serine and threonine residues in the cytoplasmic carboxyl-terminal end may be involved with regulatory mechanisms, such as desensitization and down-regulation by way of phosphorylation. The function of glycosylation on externally directed sites at the amino-terminal is not yet well established, but these sites may play a role in ligand binding or in the intracellular processing of new receptors and their insertion into the plasma membrane. Numerous techniques are available to elucidate ligand–receptor interactions.

Transmembrane signaling

Although all membrane receptors are integral proteins spanning the lipid bilayer, the pancreatic secretagogue receptors convey information by interacting with G proteins. G proteins are heterotrimeric proteins with unique α subunits and a smaller number of shared $\beta\gamma$ subunits [219]. Acinar cells possess α_s and α_i subunits, which respectively stimulate and inhibit adenylate cyclase. These subunits can be ADP-ribosylated by cholera toxin and pertussis toxin, which respectively activate and inhibit adenylate cyclase, permanently. Acinar cells also possess α_q and α_{11} subunits that activate phospholipase C [220]. The full complement of α and $\beta\gamma$ subunits expressed in acinar and duct cells and their functions require further exploration.

The α subunit possesses the guanine nucleotide-binding site, which, in the resting state, is occupied by GDP. After the receptor binds its ligand, it interacts with the G protein to catalyze the exchange of GDP for GTP. The GTP–α subunit complex dissociates from the $\beta\gamma$ complex and activates its

effector (i.e., phospholipase C, adenylate cyclase). The system is amplified because the lifetime of the GTP–α subunit complex is much longer than that of the hormone–receptor complex. Eventually, GTP is cleaved to GDP by an intrinsic GTPase activity, and the α subunit reassociates with the βγ subunit. It is because of this cycle that secretagogues stimulate GTPase activity in pancreatic membranes and that nonhydrolyzable analogues of GTP, such as GTP γS, activate adenylate cyclase or phospholipase C in pancreatic membranes or permeabilized acinar cells [221].

The final component in transmembrane signaling is the membrane effector that generates the intracellular messenger. There are two major effector enzymes in acinar cell membranes: polyphosphoinositide-specific phospholipase C, which cleaves phosphatidylinositol 4,5-bisphosphate (PIP_2), producing inositol-1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG); and adenylate cyclase, which converts ATP to cAMP [222]. These enzymes are presumed to be similar in structure and function to those expressed in a variety of cells. Multiple forms of phospholipase C have been purified, cloned, and shown to be expressed in many tissues [223]. The β_1 and β_3 forms are differentially activated in rat acini by CCK, carbachol, and bombesin [224]. Adenylate cyclase also has been cloned, and its primary structure is consistent with its role as an integral membrane protein with multiple membrane-spanning domains, although its catalytic site is clearly intracellular [225]. Multiple isoforms of adenylate cyclase exist, some of which are also regulated by G protein βγ subunits, Ca^{2+}, and protein kinases. Adenylate cyclase is clearly the major effector enzyme in duct cells, but there is some evidence for the participation of a phospholipase C. Other membrane effectors in the pancreas may include phosphatidylcholine-specific phospholipase C [226] and phospholipase D [227], phospholipase A_2, Na^+/H^+ ion exchanger, and various ion channels. However, these may be regulated by intracellular messengers rather than directly by G proteins.

Intracellular messengers

The major intracellular messengers involved in the regulation of pancreatic secretion are IP_3, Ca^{2+}, DAG, and cAMP [222,228]. The first three are predominant in the acinar cell and increase after the activation of phosphoinositide-specific phospholipase C by CCK and acetylcholine, whereas cAMP is the predominant messenger in duct cells, where it is produced in response to secretin.

Phosphatidylinositol and its polyphosphate derivatives – phosphatidylinositol 4-phosphate (PIP) and PIP_2 – constitute about 10% of membrane phospholipids. As mentioned, PIP_2 serves as a precursor for IP_3. When acinar cells are stimulated with acetylcholine or CCK, prelabeled PIP_2 and PIP levels fall rapidly, DAG increases, and there is a delayed rise in the level of phosphatidic acid. This indicates the primary breakdown of polyphosphoinositides, with production of DAG, which is subsequently converted to phosphatidic acid by DAG kinase. When the production of the water-soluble inositol phosphatases is assessed after labeling with ^{3}H-labeled inositol, the levels of IP_3, IP_2, IP_1, and the inositol products are all increased. Because IP_3 can only be produced by the hydrolysis of PIP_2, this is presumed to be the primary event, with the activation of a phosphatidylinositol kinase leading to further synthesis of PIP and PIP_2 from phosphatidylinositol.

Although IP_3 production can be measured by prelabeling with ^{3}H-labeled inositol, it is possible to measure the actual mass of cellular IP_3 with the use of a competitive binding assay. Such measurements show a rapid increase in IP_3 levels within 5 s in rat acini stimulated with CCK, carbachol, or bombesin. This 10-fold to 30-fold increase declines quickly after 30–60 s to a smaller, sustained plateau. Coincident with this rapid peak of IP_3 is a rapid increase in DAG of similar magnitude, which is thought to arise simultaneously from the hydrolysis of PIP_2. A later, larger increase may result from the hydrolysis of phosphatidylinositol or phosphatidylcholine by distinct phospholipases [226,227]. These results mean that IP_3 and DAG can act as separate signals and are not necessarily in lockstep. Phosphorylation of IP_3 produces inositol 1,3,4,5-tetraphosphate (IP_4), which can be dephosphorylated to yield inositol 1,3,4-triphosphate. Whether a biological role exists for these other inositol phosphates and for additional degradation products, such as IP_2 and IP_1, has not been verified.

The established function of IP_3 is to bind to a receptor on an intracellular Ca^{2+} storage site and trigger the release of Ca^{2+} into the cytoplasm. The IP_3 receptors are large 260-kDa molecules that form tetramers, which function as ligand-gated ion channels. Three forms of IP_3 receptors (type I, II, and III) are known, and all exist in acinar cells [229]. The sensitivity of these receptors to IP_3 can also be regulated by phosphorylation of the IP_3 receptor channel, and by G protein βγ subunits, Ca^{2+}, and thiol-reactive reagents. Modulation of IP_3 sensitivity may explain how certain agonists can release Ca^{2+} without a measurable increase in IP_3 levels. IP_3 receptors undergo down-regulation in response to prolonged stimulation. Another homologous gated intracellular Ca^{2+} channel, the ryanodine receptor RyR, well known as the Ca^{2+} release channel in muscle is also present in acinar cells. Ryanodine receptors open in response to Ca^{2+} and mediate Ca^{2+}-induced Ca^{2+} release. Another intracellular messenger, cyclic ADP-ribose (cADPR), can also activate ryanodine receptors. Although the activation of cADPR production is not fully understood, investigators have identified a membrane enzyme CD38 with ADP-ribosyl cyclase activity that can be stimulated by CCK and acetylcholine [230].

The morphological identity of the Ca^{2+}-sequestering and releasing organelle in the pancreas is not clear. Probably multiple membrane-bound compartments all related to the endoplasmic reticulum have the ability to take up and release Ca^{2+}. Some investigators have suggested the existence of multiple populations of vesicles with different Ca^{2+} transport

or release characteristics [231]. CCK receptors, but not muscarinic receptors, release Ca^{2+} from a lysosome-related (acidic) organelle through the action of nicotinic acid adenine dinucleotide phosphate (NAADP) [232]. The mechanism of NAADP production and the receptor on which NAADP acts remain poorly understood. Immunocytochemistry is used to localize IP_3 receptors in intact cells [233,234]. All three IP_3 receptor types are present primarily in the apical pole of the cell just under the lumenal membrane and partially overlapping the submembranous network of actin filaments. All three types exist in the nuclear membrane but in fewer numbers. Ryanodine receptors have a more diffuse distribution and are found throughout the acinar cells.

Much of the knowledge about secretagogue-induced changes in the intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) in acinar cells has been obtained by using fluorescent Ca^{2+} probes such as fura-2. These studies have been performed on suspensions of cells or acini and on individual cells with the use of microspectrofluorometry [235] and digital imaging [226,236]. Such studies have shown that high concentrations of CCK, bombesin, and cholinergic analogues cause a rapid 5-fold to 10-fold increase of $[Ca^{2+}]_i$, which declines over 2–5 min to a level slightly above the basal level (Fig. 15.5). This initial large increase is essentially independent of extracellular Ca^{2+}, but the small, sustained plateau increase in $[Ca^{2+}]_i$ absolutely depends on extracellular Ca^{2+}. The initial increase shows a similar time course and dependence on secretagogue concentrations, as does the rapid increase in IP_3, and is presumed to depend on IP_3-stimulated or NAADP-stimulated release of intracellular Ca^{2+}. Much of this released Ca^{2+} is extruded from the cell, as shown by studies documenting an increased efflux of prelabeled $^{45}Ca^{2+}$ and a decline in total acinar Ca^{2+} [228,237]. All three of the major phospholipase C-activating secretagogues (i.e., CCK, acetylcholine, and bombesin) access the same intracellular pool of Ca^{2+}, and after maximal stimulation by one agonist, the addition of another has no added effect. After removal of the agonist, the IP_3-releasable intracellular pool refills over 2–10 min as Ca^{2+} is taken up from the medium and resequestered.

The sustained increase in $[Ca^{2+}]_i$ and the refilling of the intracellular Ca^{2+} pool involve activation of a poorly understood Ca^{2+} entry mechanism. Studies measuring $^{45}Ca^{2+}$ uptake and the influx of Mn^{2+}, which quenches the intracellular fluorescence of fura-2, indicate that the phospholipase C-coupled secretagogues increase Ca^{2+} influx twofold to fourfold [237]. The influx mechanism is blocked by La^{3+} but is not voltage-dependent or sensitive to organic Ca^{2+} channel blockers. Patch-clamp studies have not yet clearly defined a constituent channel. It is better defined as an entry mechanism. The mechanisms controlling Ca^{2+} influx are sensitive

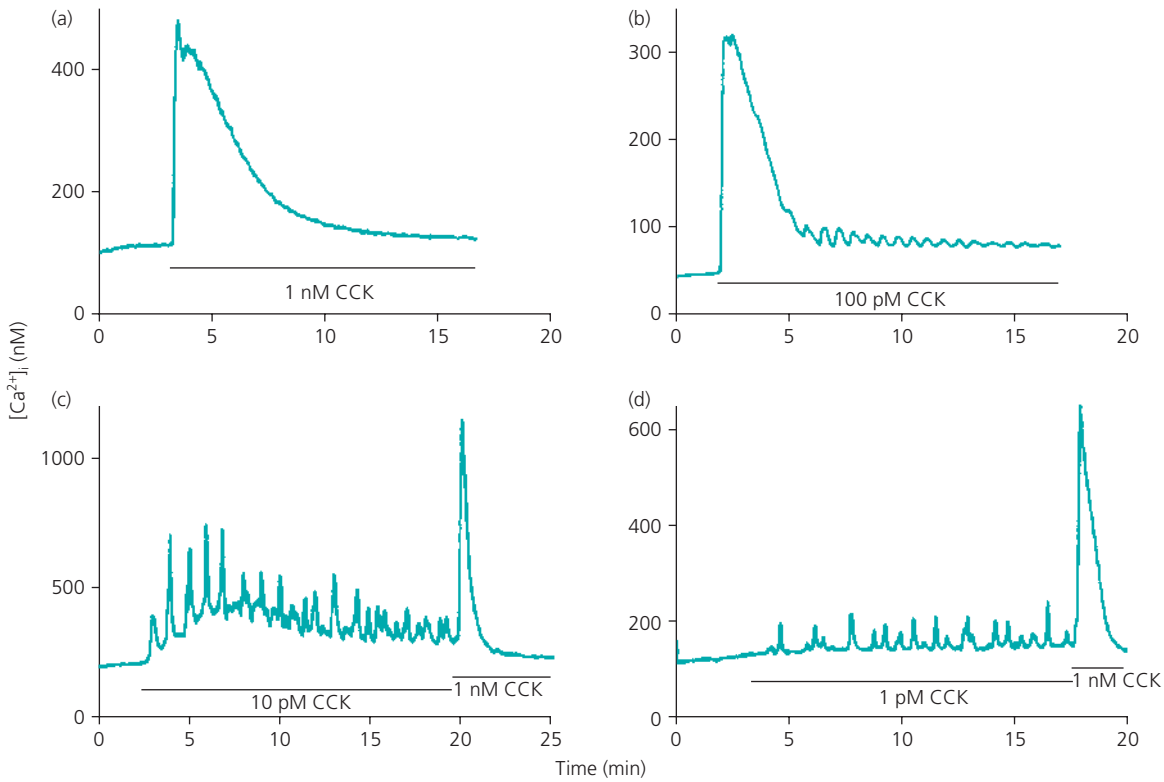

Figure 15.5 Increase in intracellular Ca^{2+} ion concentration ($[Ca^{2+}]_i$) in individual rat acinar cells in response to various concentrations of cholecystokinin (CCK). From Tsunoda et al. [235], with permission from the American Physiological Society.

to the state of the intracellular Ca^{2+} stores, as most directly shown using inhibitors of the microsomal Ca^{2+}-ATPase, such as thapsigargin, which release intracellular Ca^{2+} and activate the Ca^{2+} influx mechanism, bypassing the receptor and the generation of inositol phosphates. Evidence also exists for tyrosine phosphorylation in gating Ca^{2+} influx. That a sustained increase in $[Ca^{2+}]_i$ is important for sustained amylase release is demonstrated by the fact that La^{3+} inhibits the sustained component of amylase release, similar to the removal of Ca^{2+} from the medium [238].

Recordings of the $[Ca^{2+}]_i$ of individual cells of rat and mouse acini have revealed that low physiological concentrations of CCK, acetylcholine, and bombesin induce a different pattern of Ca^{2+} increase characterized by oscillations in $[Ca^{2+}]_i$ increases [235,236,239]. Superimposed on any steady increase are phasic increases in $[Ca^{2+}]$ of up to 250 nmol/L (see Fig. 15.5). These oscillations, which occur between one and four times per minute, are relatively independent of extracellular Ca^{2+} and involve the release and reuptake from the intracellular Ca^{2+} stores. That $[Ca^{2+}]$ oscillations can drive secretion is shown by the fact that the CCK analogue JMV-180 induces Ca^{2+} oscillations and can stimulate maximal amylase release [240].

Confocal digital imaging of Ca^{2+} in acinar cells has shown that the $[Ca^{2+}]_i$ increase is initiated in the apical pole of the cell and then spreads basally [241]. The response to lower agonist concentrations is a series of local increases in Ca^{2+} in the apical pole of the cell [242]. Improved imaging techniques have shown that local Ca^{2+} spikes are the result of pacemaker hot spots of Ca^{2+} release that entrain the surrounding region [243]. Interestingly, in the same cell, different agonists (i.e., carbachol, CCK, and bombesin) initiate $[Ca^{2+}]$ increases in distinct apical areas, indicating compartmentalization of signaling [244,245]. The intracellular application of IP_3, NAADP, or cADPR can all induce Ca^{2+} spiking. Further complicating the process, phosphorylation of IP_3 receptors by protein kinase A can modulate the pattern of Ca^{2+} increase [246]. Besides the apical-to-basal spread of Ca^{2+} in intact acini, Ca^{2+} waves appear to spread from cell to cell around an acinus. Gap junction coupling remains open as these Ca^{2+} waves spread but closes in response to supermaximal stimulation [247]. This cell-to-cell spread [247] increases the cellular sensitivity, allowing acinar activation to be triggered by the most sensitive cell.

Intracellular messenger-induced secretion

The evidence to support the importance of Ca^{2+}, DAG, and cAMP as intracellular mediators of pancreatic secretion is based on the ability of artificial changes in the level of each messenger to influence secretion [211,228]. The discovery that certain antibiotics, such as A23187 and ionomycin, function as Ca^{2+} ionophores and can be used to increase Ca^{2+} influx and trigger secretion provided one of the cornerstones of evidence for the importance of Ca^{2+} in the regulation of pancreatic secretion. The Ca^{2+}-ATPase inhibitor thapsigargin also increases $[Ca^{2+}]_i$ and can be used to define the contribution of Ca^{2+} in stimulating secretion [248]. The discovery that certain phorbol esters can activate protein kinase C in a manner similar to DAG led to extensive studies of the activation of this pathway [249]. Ca^{2+} ionophores and phorbol esters stimulate acinar cell secretion, and their effects are additive or potentiative. In the case of cAMP, derivatives such as dibutyryl cAMP or Br-cAMP, which are lipophilic or phosphodiesterase-resistant, have been used to activate the pathway normally initiated by secretin or VIP. In most species, cAMP derivatives used alone have minimal effects on acinar cell secretion but they potentiate the effects of agents working by way of Ca^{2+} and DAG.

Mechanism of action of intracellular messengers

The intracellular messengers active in pancreatic acinar cells have been identified and characterized but much less is known about the mechanisms by which they act to induce granule exocytosis, fluid secretion, protein synthesis, and gene expression. Although other mechanisms may exist, all of the intracellular messengers activate protein kinases and phosphatases and thereby regulate the state of protein phosphorylation. Considerable data suggest that changes in the phosphorylation of regulatory proteins mediate the action of hormones and neurotransmitters in a variety of tissues.

In support of this postulate, more than 25 phosphoproteins (not all identified) that are regulated by pancreatic secretagogues have been visualized by two-dimensional electrophoresis in pancreatic acini [250,251]. Some are uniquely regulated by Ca^{2+}, phorbol esters, or cAMP, and others are regulated by multiple second messengers. When Ca^{2+} ionophore and phorbol ester are combined, they reproduce all of the phosphorylation changes induced by secretagogues.

Several Ca^{2+}-activated kinases have been identified in pancreatic acinar cells including Ca^{2+}/calmodulin-activated type II and type III kinases and myosin light chain kinase [223,229]. Although some kinases are highly substrate specific, calmodulin-activated type II kinase is a multifunctional kinase that acts on several proteins. Its activation by CCK is supported by its temporary conversion to a Ca^{2+}-independent form [252]. Protein kinase C, originally described as a Ca^{2+}-, phospholipid-, and DAG-dependent kinase [249], is also present in acinar cells. Multiple isoforms of protein kinase C – both classical and atypical forms – are present, including α, δ, ε, and ζ [253]. Research suggests that protein kinase C δ is the isoform involved in mediating amylase release [254]. In addition to Ca^{2+} and cAMP-activated kinases, acinar cells contain the major classes of serine/threonine protein phosphatases (i.e., PP1, PP2A, and PP2B) [255,256]. Whereas some of these are constitutively active and are involved in reversing phosphorylation induced by kinases, PP2B, or calcineurin, is specifically activated by Ca^{2+} through calmodulin. This phosphatase, which is activated

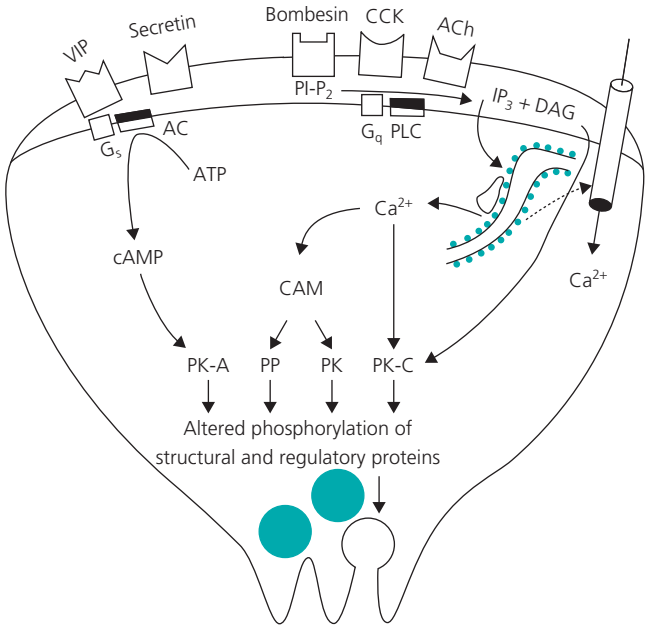

Figure 15.6 Stimulus–secretion coupling of pancreatic acinar cell protein secretion. In one intracellular pathway, receptors for vasoactive intestinal polypeptide (VIP) and secretin couple through a G protein (G_s) to activate adenylate cyclase (AC), and the cAMP produced activates protein kinase A (PK-A). In the other and quantitatively more important pathway, receptors for bombesin, cholecystokinin (CCK), and acetylcholine (ACh) couple through G proteins of the G_q family to activate phospholipase C (PLC). This enzyme hydrolyzes phosphatidylinositol 4,5-bisphophate ($PI\text{-}P_2$) to produce inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 releases Ca^{2+} from intracellular stores in the endoplasmic reticulum, activating Ca^{2+} influx across the plasma membrane. Ca^{2+}, by binding to calmodulin (CAM), activates several protein kinases (PK) and one protein phosphatase (PP). DAG with Ca^{2+} activates several species of protein kinase C (PK-C). This battery of protein kinases and phosphatases, by altering the phosphorylation of diverse proteins, brings about the secretion of digestive enzymes and other cellular effects on growth and metabolism.

by pancreatic secretagogues, is blocked by the immunosuppressant cyclosporine, which also partially inhibits secretagogue-activated amylase secretion [256].

The role of intracellular messengers and effectors in pancreatic enzyme secretion is summarized in Fig. 15.6. Stimulation of secretion normally involves synergistic interactions among intracellular messengers. In the case of acetylcholine and CCK, this includes interactions between Ca^{2+}- and DAG-activated pathways. Agents such as VIP and secretin, which increase cAMP, add a further interaction at the postintracellular messenger level. Proteins localized on the granule and lumenal plasma membrane and several soluble and cytoskeletal proteins may be involved in exocytosis. In pancreatic duct cells, the same intracellular messengers and kinases may regulate ion pumps, carriers, and channels involved in fluid and electrolyte secretion.

Zymogen granules and exocytosis

The terminal steps in secretion involve fusion of the zymogen granules with the lumenal membrane of the acinar cell. These granule dynamics were observed by real-time video imaging [257]. A more dramatic view emerged using confocal microscopy to image a lumenal tracer that enters the granule on formation of a connection to the lumen [258]. This fusion event shares basic mechanisms with other membrane fusion events from yeast to neurons. Two types of proteins, SNARE proteins and small G proteins of the Rab family, appear to play prominent roles (Fig. 15.7). The term SNARE was derived from work with the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors. There are more than 35 mammalian SNARE proteins that share a homologous sequence, the SNARE motif. In the SNARE paradigm, transport vesicles destined to fuse with another membrane possess a set of proteins, termed v-SNARE, that interact with

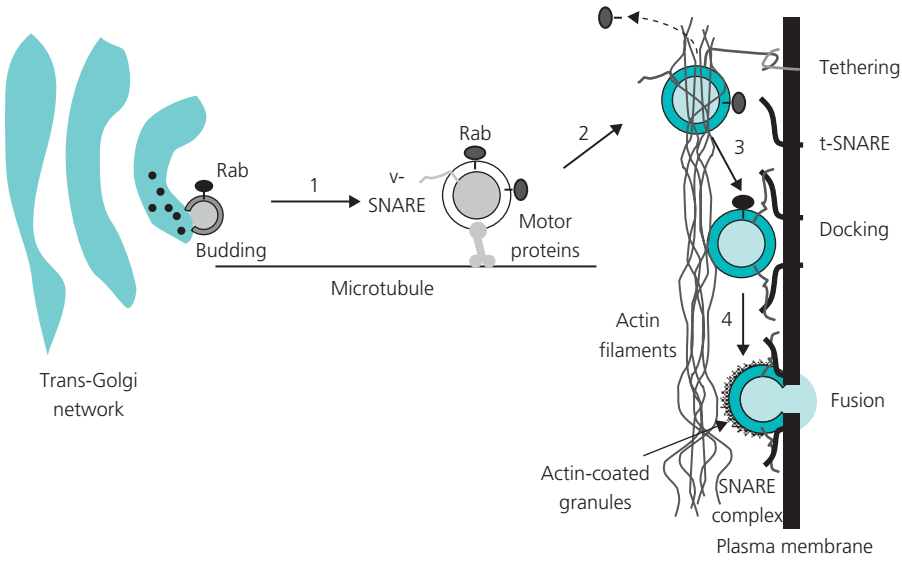

Figure 15.7 Model of the steps in the exocytosis of zymogen granules, including movement to the lumenal membrane, passage through the terminal web of actin filaments, tethering, docking, and fusion. Note, for simplicity, not all of the SNARE complex proteins are shown. From Williams & Yule [273], with permission from Elsevier.

proteins on the target membrane, termed t-SNARE, and with soluble attachment factors [259]. The best-characterized SNARE complex is the synaptic complex made up of synaptobrevin/VAMP on the synaptic vesicle and SNAP25 and syntaxin 1 on the presynaptic plasma membrane. SNARE proteins associate into a complex of four helical bundles with SNAP25 providing two bundles and the other two proteins each providing one. Assembly is by a zipper-like mechanism that may provide the energy for membrane fusion [260]. Modulatory proteins, such as Munc18 and tomosyn, regulate the assembly of SNARE complexes.

Synaptobrevins/VAMPS, which act as v-SNARES on synaptic vesicles, are present on zymogen granules; VAMP2, VAMP3 (cellubrevin), and VAMP8 (endobrevin) have been identified [261,262]. The t-SNAREs on the plasma membrane of neurons include SNAP25 and syntaxin. Multiple isoforms of syntaxin in acini have been identified. Syntaxin 2 is present on the apical plasma membrane [263], and other syntaxins are present on the basolateral membranes and zymogen granules. The interaction of VAMPS and syntaxins in acini remains incompletely understood. VAMP8 and syntaxin 4 have been reported to exist in a complex [261]. SNAP29 has been shown to be associated with VAMP8, and SNAP23 with VAMP2 [264]. Truncated cytosolic peptides of both VAMP2 and VAMP8 inhibited amylase release from permeabilized cells. When syntaxin peptides were tested, only syntaxin 2 inhibited Ca^{2+}-stimulated secretion. These results suggest that a VAMP8, SNAP29, and syntaxin 4 complex may mediate regulated secretion, whereas VAMP2 may mediate constitutive secretion. The role of regulatory proteins, such as Munc18c, which is present on the basolateral membrane, has not been elucidated. Moreover, a Ca^{2+} receptor such as synaptotagmin 1, which is present on synaptic vesicles, has not been identified on zymogen granules.

The additional importance of cytosolic proteins was shown by the observation that permeabilizing acini with α-toxin, which produces small pores that stop protein leakage, prevented the rundown of secretion seen with streptolysin-O permeabilization, which generates large pores [265]. Moreover, cytosol from brain or lacrimal glands restores secretion in streptolysin-O-permeabilized acini. One of the responsible proteins is CRHSP-28, a Ca^{2+}-regulated phosphoprotein, which associates with zymogen granules through a 70-kDa protein [266]. Whether Ca^{2+} in acini regulates directly through a SNARE or cytosolic protein or indirectly by activating a kinase or phosphatase is unknown. An experimental approach that may prove useful in this work is to monitor secretion by measuring the capacitance of patch-clamped acinar cells. Low concentrations of acetylcholine, which are known to induce [Ca^{2+}] oscillations in the apical pole of the cell, also induced an increase in membrane capacitance without an increase in membrane conductance [267].

Work on species of Rab proteins in pancreas has focused on Rab3, because Rab3a is present on synaptic vesicles and an immunoreactive Rab3 species has been identified in pancreas. Studies using polymerase chain reaction amplification and immunocytochemistry with specific antibody have identified conclusively the presence of Rab3D on zymogen granules [268,269] as well as on granules in salivary and lacrimal glands and in chief cells of the stomach. Overexpression of Rab3D in acinar cells of transgenic mice enhances a component of amylase secretion [270], indicating that Rab3D may be rate limiting for secretion. Other Rab proteins have been identified on zymogen granules by immunocytochemistry and mass spectrometry [271]. Of the Rab proteins identified, Rab27B has been related to secretion in other cells. Overexpression in acini of constitutively active Rab27B enhanced amylase secretion, whereas expression of a dominant negative mutant of Rab27B inhibited amylase secretion [272]. Whether Rab3D and Rab27B have distinct effectors or whether they can compensate for each other remains to be determined.

Another cellular component believed to be involved in exocytosis is the actin cytoskeleton [273]. It may serve as a barrier, preventing premature secretion, and it may be involved in the movement of zymogen granules to the cell surface. The former role may be mediated by an actin network under the plasma membrane. Evidence of this role for actin is the observation that introducing the monomeric actin-binding protein β-thymosin into permeabilized acini to shift the monomer–polymer equilibrium induces secretion in a Ca^{2+}-independent manner [274]. Moreover, high concentrations of CCK and β-thymosin, the actin monomer-binding protein, decrease polymerized actin at the apical membrane. In contrast, phalloidin, which binds and stabilizes polymerized actin, inhibits secretion by the permeabilized cells. Filamentous actin has been shown to form a coating on fused granules, and may serve to promote the exit of granule contents after fusion occurs [275]. The small G proteins RhoA and Rac1 have been shown to be activated by secretagogues and to regulate secretion, presumably through effects on actin polymerization [276].

Intracellular pathways leading to growth and gene regulation

Pancreatic secretagogues, particularly CCK, have long been known to induce pancreatic hypertrophy, hyperplasia, and gene expression. Initially, it was assumed that the same intracellular mediators that regulate secretion might mediate these effects. It is clear, however, that nonsecretagogues, such as insulin and epidermal growth factor, can also regulate nonsecretory pancreatic functions and that classical secretagogues, such as CCK, activate novel signaling pathways, many of which involve tyrosine phosphorylation. Furthermore, nonsecretagogue input, such as the extracellular ligation of integrins, can lead to both tyrosyl phosphorylation and an increase in intracellular Ca^{2+} [277]. Increasing evidence that cytokines can affect the pancreas, at least in pancreatitis,

suggests that cytokine receptors also activate intracellular signaling.

G protein-coupled receptors can activate tyrosine kinase signaling pathways in a variety of cells [278]. Most growth factor receptors include an intracellular tyrosine kinase domain, and autophosphorylation of the receptor on tyrosines leads to docking of signaling molecules, such as phosphoinositol 3-kinase, phospholipase C-γ, and adapter molecules, such as Grb2 and Shc. G protein-coupled receptors do not possess tyrosine kinase activity nor are they phosphorylated by tyrosyl. However, CCK is known to increase the tyrosyl phosphorylation of multiple acinar proteins [279] and to activate the mitogen-activated protein kinase (MAPK) cascade involving Ras–Raf–MAP/ERK kinase (MEK)–extracellular signal regulated kinase (ERK) [280,281]. The kinase $p90^{rsk}$, which is downstream of ERKs and acts to phosphorylate nuclear transcription factors and cytoplasmic targets, also is activated by CCK [282].

The early events by which secretagogues may activate Ras and the MAPK cascade leading to ERKs have been studied. In rat acini, CCK, carbachol, and bombesin, as well as epidermal growth factor, increase the tyrosyl phosphorylation of Shc [283], leading to the binding of Grb2 and SOS. Because SOS is a guanine nucleotide exchange factor for Ras, this could mediate an activation of Ras in response to CCK. Shc phosphorylation induced by CCK has been shown to be largely dependent on protein kinase C, whereas that induced by epidermal growth factor was fully protein kinase C independent [283]. In the pancreatic acinar cell line AR42J, which possesses primarily CCK_2 receptors, gastrin has also been shown to increase tyrosyl phosphorylation of Shc [284]. In AR42J cells, gastrin also induces the tyrosyl phosphorylation of the docking protein, insulin receptor substrate 1 (IRS-1) [285]. Because Grb2 also binds to IRS-1, this is a potential alternative means of activating the MAPK cascade. IRS-1 has not been identified in normal acinar cells, although it is overexpressed in some pancreatic cancer cells. The identity of the tyrosine kinase that phosphorylates Shc and IRS-1 and how it is activated remains a major question. Interest has centered on cytoplasmic tyrosine kinases of the Src family, and published data would suggest that somehow protein kinase C activates Src.

Two other MAPK cascades, stress-activated protein kinase (SAPK) and p38 MAPK, lead to activation of Jun kinase. Both of these pathways exist in acinar cells and can be activated by CCK as well as other extracellular signals [286],[287]. Activation of SAPK is an early event in secretagogue-induced pancreatitis, although it is not clear whether it is a cause or an effect [288]. A known effect of p38 MAPK is to activate MAPKAP kinase-2, which phosphorylates the heat-shock protein Hsp27, thereby regulating actin polymerization [287,289]. Both SAPK and p38 MAPK are activated by dual phosphorylation on tyrosine and threonine residues by upstream dual function kinases related to MEKs [290]. These are activated by a serine threonine kinase analogous to Raf that is farther upstream. However, the three MAPK cascades can be activated independently.

Evidence exists for two other signaling pathways in pancreatic acini [222]. The first is the activation of focal adhesion kinase, or $p125^{FAK}$, and its downstream target, paxillin. Both of these molecules are associated with the cytoskeleton and, in other cells, are activated by growth factors and integrins. CCK has been shown to increase the tyrosine phosphorylation of $p125^{FAK}$ and paxillin in rat acini [291]. This effect is probably mediated by the small G protein Rho. The second is the pathway through PI_3K to $p70^{S6K}$, the kinase that phosphorylates ribosomal protein S6. CCK, carbachol, and bombesin activate $p70^{S6K}$ in rat acini by a pathway that can be blocked by PI_3K inhibitors such as wortmannin and, rapamycin, which bind intracellularly to the immunophilin, FKBP-12 [48]. As $p70^{S6K}$ also mediates the initiation of protein translation, this pathway probably underlies, at least in part, the stimulation of protein synthesis in acinar cells by pancreatic secretagogues previously discussed. Identification of intracellular regulation by both conventional and novel pathways is a rapidly developing field, and further progress is expected.

Adaptive growth of the pancreas can occur in response to nutrients and hormones to synthesize more digestive enzymes and prevent malabsorption [45]. Both a high protein diet and hyperphagia induced by pregnancy, lactation, or cold exposure can induce pancreatic growth. Much of this growth is mediated by CCK and can be modeled by feeding trypsin inhibitor to increase endogenous CCK release. Information has emerged on the intracellular signaling pathways responsible for this growth (Fig. 15.8). CCK, in addition to increasing intracellular Ca^{2+}, activates three MAPK pathways and the PI_3K–mTOR pathway, and most of these can be activated in vivo by feeding trypsin inhibitor [222]. One pathway that is key for growth is the Ca^{2+}-activated phosphatase, calcineurin. Two inhibitors of calcineurin, FK506 and cyclosporine, block trypsin inhibitor-stimulated growth [292]. The mTOR pathway has also been shown to be essential for pancreatic growth, as this growth is blocked by rapamycin [293]. These pathways are important regulators of mRNA transcription and translation. Calcineurin-mediated dephosphorylation of the transcription factor NFAT (nuclear factor of activated T cells) is associated with adaptive growth in cardiac and skeletal muscle. CCK leads to NFAT activation in pancreatic acini. The role of the mTOR pathway in translational regulation was discussed earlier (see section on formation and composition of pancreatic juice – enzymes), although whether global or specific protein synthesis affect growth is not fully understood. High levels of protein can also stimulate pancreatic growth, and can do so without CCK [294]. This effect of high protein levels is likely mediated by a direct activation of the mTOR pathway by amino acids, as occurs in a variety of cell types.

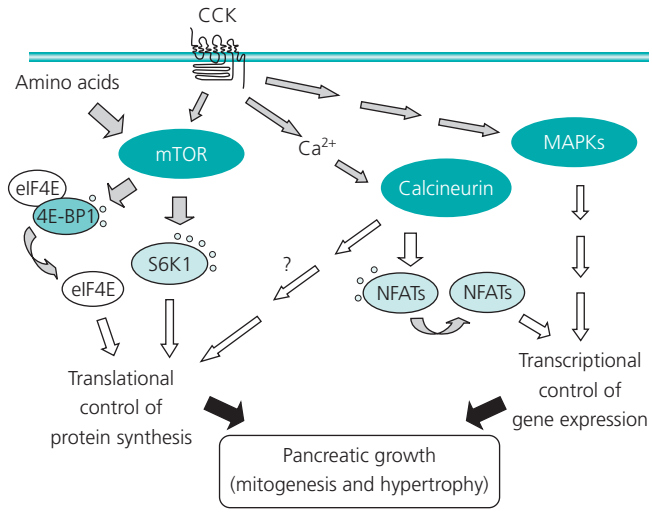

Figure 15.8 Intracellular pathways through which CCK stimulates pancreatic growth. At least three pathways involving calcineurin, mammalian target of rapamycin (mTOR), and mitogen-activated protein (MAP) kinases (extracellular signal-regulated kinases [ERKs] and Jun N-terminal kinases [JNKs]) have been shown to be necessary for the growth of rodent pancreas, either in vivo or in vitro. From Sans et al. [45], with permission from Blackwell Publishing.

Inhibition of pancreatic secretion

The regulation of pancreatic secretion depends on a balance between inhibitory and stimulatory influences on the gland, which are exerted through hormones and the autonomic nervous system. Although much has been written about pancreatic stimulation, less is known about the inhibitory influences on the pancreas.

Inhibitory phase of pancreatic secretion

In humans, hyperglycemia induced by intravenous infusion of glucose inhibits the pancreatic secretory response to a test meal [295]. Similarly, intravenous infusion of amino acids inhibits the human pancreatic enzyme response to intestinal amino acid perfusion [296]. Although the mechanisms responsible for these observations are unknown, the secondary release of inhibitory hormones is postulated. Pancreatic glucagon exhibits characteristics consistent with such an inhibitory hormone. In most of the studies, glucagon inhibits pancreatic secretion stimulated by secretin and CCK, alone or in combination, or by ingestion of a test meal in dogs, cats, rats, and humans [3,297–299]. The inhibitory effect is characterized by reduction of the volume of flow and of HCO_3^- and enzyme secretion.

Pancreatic glucagon is secreted concomitantly with the hyperaminoacidemia observed after the intestinal perfusion of amino acids or after a high-protein meal [228]. This postprandial level of glucagon may be sufficient to inhibit secretin- or CCK-stimulated pancreatic secretion.

Another pancreatic hormone, somatostatin, may also play a role in the inhibition of pancreatic secretion. Somatostatin-containing cells are also present in the upper gastrointestinal tract and the central nervous system. Somatostatin is processed to multiple molecular sizes and interacts with a variety of receptors on acinar cells, dorsal root ganglia, and islets of Langerhans, and on the nerves of the peripheral and central nervous systems. One mechanism to provide a degree of specificity could be the release of different forms of somatostatin. For example, glucagon-like peptide 1, oleic acid, and gastrin-releasing peptide stimulate the secretion of both somatostatin-28 and somatostatin-14, and secretin induces a preferential release of somatostatin-14 [300]. In humans, pharmacological doses of somatostatin cause marked inhibition of CCK-stimulated pancreatic enzyme secretion and modest inhibition of secretin-stimulated HCO_3^- secretion [5,301]. Studies in rats show that somatostatin inhibits 2-deoxy-D-glucose- and CCK-evoked pancreatic enzyme secretion through a vagal pathway [14]. Somatostatin does not act on peripheral vagal afferent or efferent pathways or directly on pancreatic acini; it exerts its inhibitory action at a central vagal site [14]. Somatostatin injected into the dorsal vagal complex significantly inhibits pancreatic secretion evoked by intravenous administration of CCK-8 or 2-deoxy-D-glucose. This suggests that somatostatin is probably acting through the dorsal vagal complex in the brainstem to inhibit pancreatic secretion. Studies in the perfused canine pancreas have demonstrated that somatostatin is released from the pancreas during perfusion with high concentrations of amino acids or glucose [302]. This peptide may exert a paracrine inhibitory effect on the exocrine pancreas.

Six somatostatin receptor (SSTR) subtypes have been cloned from five genes; SSTR2 is expressed in an A and a B form by variant mRNA splicing. SSTR2 receptor agonists (e.g., octreotide) mediate inhibition of pancreatic secretion, whereas SSTR5 inhibits insulin release. Injection of the SSRT2 agonist seglitide into the dorsal vagal complex inhibits CCK-8/2-deoxy-D-glucose-induced pancreatic protein secretion, indicating that the central action of somatostatin is mediated by SSTR2 in the dorsal vagal complex [303]. In addition, SSTR2A has been localized to acinar cells, and to glucagon and pancreatic polypeptide immunoreactive islet cells [304]. Although somatostatin is one of the few peptides to inhibit pancreatic secretion in an isolated pancreas, the role of the acinar cell SSTR may be to modulate the nonparallel secretion of digestive enzymes [305] rather than to inhibit secretion. It is believed that somatostatin inhibits pancreatic exocrine secretion mainly through a central cholinergic mechanism [14].

Intrajejunal perfusion of hypertonic glucose (50%) produces dose-related inhibition of secretin-stimulated pancreatic fluid and HCO_3^- secretion in humans [306,307]. Similar inhibition occurs with intraintestinal hypertonic (9%) NaCl infusion in dogs. At least part of this inhibitory effect has

been attributed to the release of enteric glucagon [296]. Infusion of oxyntomodulin, a 37-amino-acid, glucagon-containing peptide isolated from porcine lower intestine, inhibits basal and cerulein-stimulated pancreatic secretion of HCO_3^- and enzymes [308]. This intestinal glucagon is 10 times more potent than pancreatic glucagon.

Factors in the ileum and colon can inhibit pancreatic secretion. Hage and colleagues showed that infusion of oleic acid into the proximal colon of conscious dogs inhibits secretin-stimulated pancreatic secretion [309]. Similar inhibitory effects have been observed in rats [310]. In the anesthetized cat, infusion of oleic acid or hypertonic solutions of glucose or saline into the colon or terminal ileum inhibits secretin- or CCK-stimulated secretory volume, as well as HCO_3^- and enzyme output from the pancreas [311].

In humans, nutrients (e.g., lipid) in the colon inhibit CCK-stimulated pancreatic enzyme and HCO_3^- output [312]. These late postprandial events may serve as physiological signals to reduce exocrine pancreatic secretion after the digestion and the absorption of nutrients are complete. The inhibitory effect of nutrients in the distal gut on pancreatic secretion appears to be independent of the vagus and splanchnic nerves [311]. Cross-circulation studies in the rat have shown that a humoral factor mediates the inhibition of pancreatic enzyme secretion induced by colonic perfusion of oleic acid.

Harper and colleagues used the term *pancreotone* to describe an inhibitory substance extracted from the colonic mucosa [313]. The function of pancreotone is abolished when the extract is preincubated with trypsin, demonstrating it is a peptide. Peptide YY, a 36-amino-acid peptide named for its amino- and carboxyl-terminal tyrosines, is ubiquitous in the distal small intestine, colon, and rectum [314]. This peptide is released by fat and, to a lesser degree, protein in the distal gut or colon. The infusion of this peptide in dogs significantly inhibits basal and meal-stimulated pancreatic HCO_3^- and enzyme secretion [315]. Physiological experiments demonstrate that intraileal, but not colonic, carbohydrate increases plasma peptide YY levels and decreases amylase secretion in dogs [316]. These observations support the hypothesis that peptide YY is at least a component of pancreotone in dogs. In humans, ileal perfusion of carbohydrate inhibits exocrine pancreatic secretion. Glucagon-like peptide 1 (GLP-1), another ileal hormone, but not peptide YY is elevated in the circulation during ileal infusion of carbohydrate. GLP-1 does not appear to act directly on the pancreas to inhibit exocrine secretion. In anesthetized pigs [317] with cut splanchnic nerves, intravenous infusion of GLP-1 inhibited hypoglycemia-induced pancreatic HCO_3^- and protein secretion. These effects were not observed in vagally stimulated isolated and perfused porcine pancreas [317], suggesting that GLP-1 acts through a central mechanism. Subsequent studies in rats indicated that the inhibitory action of GLP-1 depends on intact vagus nerves [16]. GLP-1 acts on the dorsal vagal complex to inhibit pancreatic enzyme secretion [16]. Similarly, oxyntomodulin, which is released after ileal administration of nutrients, also inhibits pancreatic secretion by a vagal-dependent central mechanism [318]. Because oxyntomodulin does not interact with the receptor for glucagon or truncated GLP-1, its effects appear to involve an oxyntomodulin-specific receptor. Although the mediators of ileal carbohydrate-induced inhibition of exocrine pancreatic secretion have not been firmly identified, it appears that the action of these potential mediators is dependent on central neural pathways.

Pancreatic polypeptide (PP), a peptide closely related to peptide YY, is another hormone that may play an important role in regulating pancreatic exocrine secretion. PP is localized in the islets of Langerhans and between the acinar cells of the exocrine pancreas [319]. Its only apparent physiological actions are to inhibit pancreatic and biliary secretions. The secretion of PP is governed mainly by a cholinergic mechanism [320]. Postprandial release of PP is mediated by a long vagovagal reflex and short local cholinergic pathways [320]. Vagal cholinergic activity is the most powerful stimulant of PP release, and it is also key to most other stimulation of the PP cell [320].

In humans and dogs, infusion of physiological concentrations of PP inhibits basal and stimulated pancreatic secretion [6,321]. In vivo, PP appears to act preferentially by inhibiting vagal stimulation [322]. In vitro, PP inhibits pancreatic enzyme secretion by way of the presynaptic modulation of acetylcholine release [323]. Because its secretion is under cholinergic control and it acts by interfering with cholinergic transmission, PP is an ideal candidate to modulate pancreatic secretion stimulated by the cholinergic enteropancreatic reflex. After ingestion of a meal, the enteropancreatic reflex is activated to stimulate pancreatic enzyme secretion and PP release. PP inhibits cholinergic transmission and reduces pancreatic enzyme secretion. PP may play an important role in the feedback regulation of pancreatic enzyme secretion activated by the enteropancreatic reflex. The primary target of PP appears to be the central nervous system [15]. PP receptors have been identified in discrete locations in the hypothalamus, limbic system, brainstem, and other central locations with the use of receptor autoradiography [324]. In contrast, mRNA for PP is almost undetectable [325], suggesting that peripheral PP is modulating central neural function at sites that have an incomplete blood–brain barrier. Microinjection of PP into the DMV inhibits pancreatic secretion stimulated by CCK, suggesting that the DMV is a site for neural feedback inhibition of pancreatic exocrine secretion [326]. Patch-clamp recordings of pancreas-projecting neurons in the rat DMV show that synapses other than those of the area postrema–DMV circuit may also be involved in mediating the effect of PP on pancreatic exocrine functions. Hence, PP and its structurally related analogues likely act at multiple sites in the brainstem to modulate vagal cholinergic efferent output to the pancreas [327].

Although the list of peptides known to inhibit exocrine pancreatic secretion has expanded, little is known about the mechanisms through which hormones or neurotransmitters inhibit pancreatic enzyme secretion. An important feature shared by these agents is the lack of direct inhibition of the pancreatic acinar cells. Many substances suppress pancreatic enzyme secretion in vivo but do not act directly on the acinar cell to suppress enzyme release. Animal studies suggest that peptides such as PP, somatostatin, CGRP, enkephalin, and pancreastatin inhibit pancreatic enzyme secretion by modulating cholinergic transmission, and most, if not all, act through a central vagal site [303,322,323,328–331]. Intracerebroventricular administration of CGRP inhibitors stimulates (basal) pancreatic secretion in conscious rats and this appears to be mediated by sympathetic noradrenergic efferents through the α-adrenergic receptor [332]. In contrast, CGRP in the central nervous system inhibits pancreatic enzyme secretion stimulated by 2-deoxy-D-glucose and CCK by modulating vagal parasympathetic outflow [333].

Feedback regulation of pancreatic secretion

A series of observations suggest that the intralumenal action of pancreatic proteases plays an important role in regulating pancreatic enzyme secretion [94,334]. The underlying concept of feedback regulation of the pancreas is based primarily on studies of rats that show that diversion of pancreatic juice from the duodenum stimulates CCK release and pancreatic enzyme secretion [95]. However, intraduodenal administration of trypsin or chymotrypsin inhibits the release of CCK and pancreatic enzymes [95]. This phenomenon is specific for activated proteases and is not observed with inactivated trypsin, amylase, lipase, or $NaHCO_3$. Subsequent studies demonstrated that intravenous infusion of proglumide or L364,718, a specific CCK receptor antagonist, abolishes the increase in pancreatic exocrine secretion evoked by diversion of bile–pancreatic juice [95,335]. These observations indicate that feedback inhibition of pancreatic secretion by trypsin is mediated by inhibiting the release or action of CCK.

The elevated plasma CCK levels and the increase in pancreatic secretion after diversion of pancreatic juice appear to be mediated by a trypsin-sensitive substance secreted by the proximal small intestine, originally designated CCK-releasing factor (CCK-RF) [97]. When trypsin is present, this peptide is cleaved and inactivated. CCK-RF may act as a mediator of pancreatic enzyme secretion in response to dietary protein intake in rats. Dietary protein in the intestine competes for the trypsin that would otherwise inactivate CCK-RF [96]. The resulting increase of CCK-RF in the intestinal lumen enhances CCK release, stimulating pancreatic enzyme secretion. Although this appears to be the principal mechanism regulating CCK release in rats, it is not known whether the same mechanism operates in other species.

Many CCK-releasing peptides have been identified, including one from porcine mucosa [336] and another from rat upper intestinal fluid [337]. Herzig and colleagues [336] isolated and purified a CCK-releasing peptide, identical to the porcine diazepam-binding inhibitor, from porcine small bowel mucosal extracts. This trypsin-sensitive peptide, which is secreted intraduodenally, releases CCK and stimulates pancreatic secretion in rats (Fig. 15.9). Diazepam-binding inhibitor-like immunoreactivity has been found in intestinal mucosal cells [338] and this peptide (CCK-releasing peptide) is secreted into the lumen under neural regulation [93]. Peptone in the duodenum stimulates 5-HT release, which activates the sensory substance P neurons in the submucous plexus. Signals are then transmitted to cholinergic interneurons and to epithelial cells containing CCK-releasing peptide by way of cholinergic secretomotor neurons [93]. This enteric neural circuitry, which is responsible for the secretion of CCK-releasing peptide, may in turn play an important role in the postprandial release of CCK. Spannagel and colleagues [337] successfully purified another lumenal CCK-releasing peptide from the jejunal secretion of rats. Partially purified fractions increased the release of CCK and stimulated pancreatic secretion of fluid and protein. Amino acid sequencing and mass spectral analysis of this peptide revealed that it is composed of 70–75 amino acid residues and has a mass of 8136 kDa. The monitor peptide [339] in rat pancreatic juice, which is secreted into the duodenal lumen, is another CCK-releasing peptide. The physiological significance of these releasing peptides is unknown.

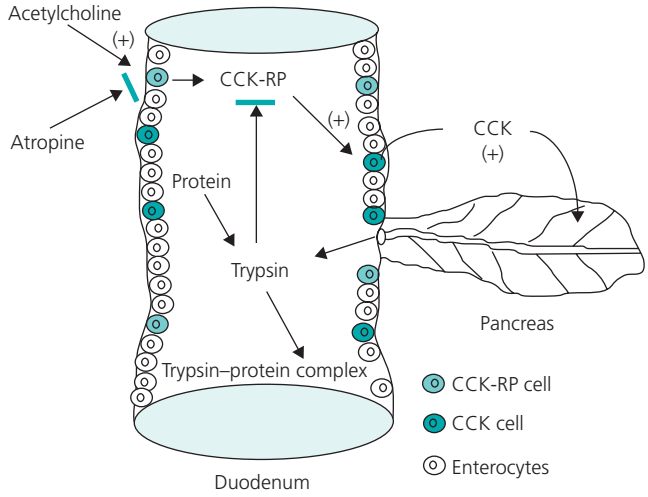

Figure 15.9 The postulated mechanism by which cholecystokinin-releasing peptide (CCK-RP) stimulates the postprandial secretion of CCK. CCK-RP is secreted into the proximal small intestine and inactivated by trypsin. When food enters the duodenum postprandially, protein binds to trypsin and prevents the inactivation of CCK-RP. CCK-RP stimulates CCK cells in the duodenum to release CCK into the bloodstream. CCK, in turn, stimulates pancreatic enzyme secretion. From Herzig et al. [336], with permission. Copyright 1996 National Academy of Sciences, U.S.A.

Despite several attempts to demonstrate a protease-sensitive feedback mechanism in humans, the issue remained controversial because the technical limitations in removing or blocking intralumenal protease activity made human studies challenging. Using a different approach, researchers reported that intestinal administration of trypsin or chymotrypsin in humans suppresses CCK release and partially blocks the pancreatic response to intestinal administration of amino acids or oral ingestion of a test meal [102,340]. These results support the existence of feedback regulation of pancreatic enzyme secretion in humans.

Using an alternative approach, Dlugosz [341] and Hotz [342] and their colleagues observed that duodenal infusion of aprotinin, a trypsin inhibitor, had no effect on basal pancreatic enzyme secretion. Similar findings were reported with the use of the trypsin inhibitor FOY-305 [343]. Neither compound, however, strongly inhibits human chymotrypsin. Liener and colleagues demonstrated that Bowman–Birk soybean trypsin inhibitor, an inhibitor of chymotrypsin and elastase, markedly stimulates pancreatic enzyme secretion in humans [344]. These observations suggest that trypsin and other proteases such as chymotrypsin and elastase should be removed to evoke pancreatic enzyme secretion in humans.

Studies of rats show that biliary secretion may also participate in the feedback regulation of CCK release. Secretion of bile into the proximal intestine inhibits CCK release and pancreatic secretion by protecting pancreatic proteases from autodigestion in the lumen [345].

Postprandial pancreatic enzyme secretion is under hormonal and neural control. Distention of the duodenum and administration of hyperosmolar solutions into the duodenum each elicits pancreatic enzyme secretion without raising plasma CCK levels [186]. This stimulatory effect is inhibited by atropine, suggesting that it is cholinergically mediated. In contrast to amino-acid-stimulated pancreatic enzyme secretion, pancreatic responses to stimulation by volume or osmolality in the duodenum are not suppressed by trypsin [186]. This indicates that feedback regulation of pancreatic secretion by trypsin is stimulus specific and is mediated by inhibiting CCK release. The enteropancreatic reflex is unaffected by intralumenal proteases.

The existence of a feedback regulation of pancreatic enzyme secretion in humans may have important clinical implications. It is conceivable that in patients with chronic pancreatitis, decreased pancreatic enzyme secretion may result in elevated plasma CCK levels, reflecting a failure in the feedback modulation of CCK release. This may cause hyperstimulation of the pancreas and produce pain. Effective enzyme replacement therapy may reduce pancreatic stimulation, decrease intraductal pressure, and diminish pain. Large doses of pancreatic extract have reduced pain in some patients with chronic pancreatitis (see Chapter 69) [346,347]. This exciting observation awaits confirmation.

Patterns of secretion

Basal secretion

Under basal conditions, pancreatic secretion occurs at very low rates, although a small amount of enzymes is always present in the pancreatic juice. Basal secretion rates of enzymes and HCO_3^- are about 10% and 2% of maximal levels, respectively. A pattern of cyclic change in basal pancreatic secretion has been demonstrated in dogs [348] and humans [349], and this is characterized by brief increases in HCO_3^- and enzyme secretion, which recur every 60–120 min during the interdigestive period. These bursts of pancreatic secretory activity are temporarily associated with periods of increased motor activity in the stomach and proximal intestine known as the interdigestive migrating motor complexes (IMMCs) [348,349].

Associated with the bursts of pancreatic secretion are brief increases in gastric acid and biliary secretions [349]. Plasma motilin and PP levels also fluctuate in phase with the IMMC [349,350]. The concentrations of pancreatic enzymes and bile acids during the transient surge of pancreaticobiliary secretion are similar to maximal postprandial outputs, although the concentrations diminish rapidly with the onset of type III duodenal motor activity [349,350]. It has been postulated that the cyclic secretion of pancreatic and biliary juice may be important in the digestion of residual food particles or cellular debris in the gastrointestinal tract during the interdigestive period.

The mechanism of control of the cyclic patterns of pancreatic secretion is unclear. Bursts of increased acid secretion are unlikely to be the principal mediators for the cyclic changes in pancreatic secretion, because removal of gastric acid by aspiration or through a fistula does not affect the pattern of interdigestive pancreatic secretion [349,350]. Infusion of motilin prematurely initiates cyclic pancreatic secretion and shortens the periodicity between peaks [351]. Administration of motilin antiserum abolishes the cyclic pattern of pancreatic secretion [352]. Cholinergic blockade with atropine also markedly decreases trypsin output and abolishes interdigestive motor activity. However, administration of phentolamine, an α-adrenergic blocker, increases basal trypsin output fourfold without disrupting the periodicity of pancreatic secretion [353]. These observations suggest that motilin and the autonomic nervous system are important in the initiation of the cyclic pancreatic secretion that occurs during fasting.

Prandial and postprandial secretion

After the ingestion of a meal, the exocrine pancreas is stimulated to secrete enzymes and HCO_3^-. Total postprandial pancreatic output is about 60%–70% of the output attained in response to maximal stimulation with intravenous infusion of CCK [105]. The stimulatory effect of a meal can be

Table 15.1 Three phases of postprandial pancreatic secretion

Phases	Pancreatic response (%)	Stimulants	Mediators
Cephalic	25	Sight, smell, taste, eating	Vagal innervation
Gastric	10	Distention	Vagal–cholinergic pathways
Intestinal	50–75	Amino acids Fatty acids Ca^{2+}, H^+ Distention	Cholecystokinin, secretin Enteropancreatic reflexes Other hormones (?)

described by separating its components into cephalic, gastric, and intestinal phases (Table 15.1).

Cephalic phase

In humans and experimental animals, pancreatic secretions rich in enzymes are stimulated by the sight, smell, and taste of appetizing food [354]. This cephalic effect in dogs amounts to 25% of the enzyme response to an ordinary meal. In humans, the contribution of the cephalic phase to the postprandial pancreatic enzyme secretion appears to be larger, amounting to 50% of the maximal responses induced by exogenous secretin and CCK [355]. The pancreatic response to sham feeding lasts only for the duration of feeding [355].

The vagus nerve appears to be important in mediating the cephalic phase, because this phase can be completely abolished by vagotomy in rats [356]. Administration of an anticholinergic drug decreases or abolishes the pancreatic response to sham feeding in humans [355]. Efferent cholinergic fibers probably act directly on the pancreas, because vagal stimulation causes pancreatic secretion in dogs even when the pancreas is perfused extracorporeally to eliminate any humoral effects of nerve stimulation [357]. Sham feeding increases gastric acid secretion, but because sham feeding induces a pancreatic response in patients who are achlorhydric, it is unlikely that gastric acid secretion contributes significantly to the cephalic phase of pancreatic enzyme secretion.

Gastric phase

In dogs and humans, gastric distention increases the rate of pancreatic enzyme secretion [358,359]. Gastric distention to a volume of 250–400 mL with a balloon doubles the basal pancreatic protein output [360]. Although the actual contribution of the gastric phase to the total postprandial pancreatic secretion has not been determined in humans, the magnitude of the distention-induced pancreatic response in dogs is about 20% of the maximal CCK response over a range of distention from 300 to 1500 mL [358]. Vagotomy and atropine reduce or abolish the pancreatic response to gastric distention, suggesting that it is mainly mediated by vagal cholinergic pathways [359,360]. The mechanoreceptors appear to be located in the body of the stomach because distention of antral pouches does not stimulate pancreatic secretion, whereas distention of the remaining stomach does [360].

The presence of food in the stomach also releases antral hormones such as gastrin or gastrin-releasing peptide, which can stimulate pancreatic secretion directly or indirectly. However, this possibility is considered unlikely because a transplanted portion of pancreas does not respond to gastric distention in dogs [360]. Moreover, distention of the intact stomach has only a slight effect on gastrin release in humans and dogs [361,362].

The stomach facilitates digestion by fractionating solid food into small particles and by initiating digestion of dietary proteins and lipids by pepsin and gastric lipase, respectively [363,364]. Gastric emptying is important in determining the rate of delivery of acid and nutrients into the duodenum, thereby determining the pattern and magnitude of the intestinal phase of pancreatic secretion. Postprandial pancreatic enzyme secretion is often abnormal in patients after gastric surgery [183].

Intestinal phase

The intestinal phase is the most important phase of postprandial pancreatic secretion. In humans and animals, the delivery of food into the small intestine stimulates pancreatic enzyme secretion to about 70% of the maximal level [183]. The major hormonal mediators of the intestinal phase of pancreatic secretion are secretin and CCK. Intestinal 5-HT also appears to play an important role in the mediation of postprandial pancreatic secretion through the vagal cholinergic pathway [132]. The intestinal mucosa has receptors for important vagal cholinergic reflexes that regulate pancreatic HCO_3^- and enzyme secretion.

The proximal intestine plays an important role in the stimulation of pancreatic HCO_3^- secretion, primarily by the release of secretin. Although duodenal pH is the major regulator for the release of secretin, nonacid factors such as fatty acids and bile may also participate. The physiology of secretin was discussed in a previous section (see section on stimulation of pancreatic secretion – hormonal mechanisms – secretin).

Among the hydrolytic products of digestion, amino acids and fatty acids are potent stimulants of enzyme secretion but have only a weak effect on water and HCO_3^- secretion. Amino acid mixtures are more potent than fatty acids, and among the amino acids, only phenylalanine, valine, and methionine stimulate enzyme secretion in humans, whereas in dogs, phenylalanine, leucine, tryptophan, oligopeptides, and casein are effective [365]. The pancreatic response to intestinal perfusion with amino acids above a concentration of 8 mmol/L depends on the total load administered [366]. This

dependence on load rather than concentration is the result of exposure of longer segments of small intestine to amino acids at a concentration above a threshold value. In humans, the mechanisms responsible for the pancreatic response to amino acids are confined to the duodenum and jejunum; amino acid perfusion into the ileum elicits no response.

Undigested fats are ineffective in stimulating pancreatic secretion, but fatty acids are potent pancreatic stimulants when present in micellar form [78]. Monoglycerols, the other product of lipolysis, also stimulate pancreatic secretion [78,365]. The chain length of fatty acids influences their potency in stimulating pancreatic secretion. In humans, the order of potency is C18 > C12 > C8 [92]. Other factors that influence the pancreatic response to fatty acids include the degree of saturation, the concentration, and the total load, as well as the concentration of bile salts relative to fatty acids [364]. In humans, intestinal perfusion of of monoolein (10 mM) produces a pancreatic enzyme output greater than that stimulated by intestinal amino acids and almost equal to the maximal response to exogenous CCK [367].

The release of CCK and intestinal 5-HT by nutrients and mechanical factors appears to play a major role in mediating the intestinal phase of pancreatic enzyme secretion. Plasma CCK levels increase after oral or intraduodenal administration of fat and protein or amino acids [100–102,368,369]. Administration of proglumide, a CCK receptor antagonist, partially inhibits pancreatic secretory responses to intestinally perfused amino acids and fat emulsions. In contrast, a wide variety of non-CCK-dependent stimuli, such as acid, carbohydrates, and mechanical factors, stimulate pancreatic secretion through intestinal 5-HT [132,135]. The 5-HT, in turn, stimulates submucosal vagal afferent fibers to evoke pancreatic exocrine secretion through a vagal cholinergic pathway. Increased firing rates in peripheral afferent neurons and in central sites have been recorded during intestinal perfusion with amino acids [188,370]. This finding, coupled with the observation that truncal vagotomy or administration of atropine markedly increases the latency of the pancreatic secretory response to intestinal nutrients but not to CCK, indicates the participation of vagovagal cholinergic reflexes [371].

Calcium, which is intimately involved in the action of CCK on pancreatic acinar cells, stimulates the pancreas. In humans, intraduodenal perfusion of Ca^{2+} solutions in concentrations similar to those measured in the duodenum after ingestion of a meal stimulates pancreatic enzyme secretion and gallbladder contraction. Intraduodenal Ca^{2+} concentrations of 12–25 mmol/L induce pancreatic enzyme responses similar to the maximal enzyme output evoked by intravenous infusion of CCK [372]. Intestinal perfusion with $MgSO_4$, $MgCl_2$, and $ZnSO_4$ also stimulates pancreatic enzyme secretion by undetermined mechanisms [373].

The human duodenum contains receptors for volume and osmolality that mediate pancreatic enzyme secretion. Volume distention or hyperosmolar solutions in the duodenum elicit pancreatic enzyme secretion by way of intestinal 5-HT without raising the plasma CCK levels [132,186]. This enzyme secretion is inhibited by atropine, suggesting mediation by cholinergic pathways [186]. The volumes of saline required to induce pancreatic secretion are as low as 1–5 mL/min, within the range observed postprandially in the duodenum. The degree of stimulation by volume receptor or osmoreceptor activation is 15%–20% of the maximal enzyme response to CCK [185]. Therefore, both CCK- and non-CCK-dependent stimuli act in concert to mediate the intestinal phase of pancreatic secretion.

The formation and secretion of bile is one of the central and earliest recognized functions of the liver [1–4]. In addition to the well-known importance of bile in solubilization and digestion of lipids [5], bile formation is necessary for a number of other functions of the liver. These include the obvious such as elimination of toxins, heavy metals and xenobiotics [6,7] and the less obvious such as regulation of whole-body lipid homeostasis [8] and prevention of liver toxicity from endogenously produced bile acids [9–12]. Cholestasis is a term that was initially defined in terms of morphological criteria [13] but has now come to describe a syndrome of liver toxicity that is associated with abnormalities of the bile secretory apparatus. The hepatotoxicity present in cholestasis is due to intracellular accumulation of toxic bile acids and other substrates, alterations in signaling pathways in hepatocytes and bile duct epithelial cells, and the compensatory responses to these events [14,15].

This chapter describes the cellular and molecular processes responsible for bile formation and the mechanisms that result in cholestasis. Knowledge in this field has increased dramatically and many excellent detailed review articles on this subject are available [9–11,15–17]. In particular there have been major advances in understanding the mechanisms responsible for the control of transport in cholestasis and this knowledge has been critical in the development of new but still experimental approaches to therapy of cholestasis. Specific cholestatic states are discussed as examples of the mechanisms involved but the focus of this chapter is on cellular processes and the reader is referred to other chapters for specific discussions of diagnosis and management of cholestatic liver diseases such as drug-induced cholestasis, primary sclerosing cholangitis, primary biliary cirrhosis, and the approach to the jaundiced patient.

Overview of bile formation

Bile is the secretory product of the liver and bile ducts. It flows through the biliary tract and empties into the duodenum. Bile is formed as a result of the transport activities of several different epithelia working in concert. It is initially produced by hepatocytes and its volume and composition are subsequently altered as it passes through the bile ducts [4,18]. Bile is a complex suspension that has an electrolyte composition similar to that of plasma except for a higher bicarbonate concentration. In addition, bile contains significant concentrations of bile acids, phospholipids, cholesterol, proteins, amino acids, and peptides [19]. Heavy metals, particularly copper, are also excreted in bile and biliary excretion is the major mechanism for their elimination.

Anatomy and physiology of bile secretion and enterohepatic circulation

Hepatocytes are specialized epithelial cells with distinct basolateral and apical membrane domains. They are depicted schematically in Fig. 16.1. The sinusoidal, or basolateral, membrane surrounds the majority of the cell and the canalicular, or apical, membrane occupies a small area of the cell surface near the points of contact between adjacent cells. The canalicular membranes, from which numerous microvilli protrude, make up only about 15% of the total surface area [20]. Opposing canalicular membrane domains border an enclosed space called the bile canaliculus measuring about 1–2 μm [4]. At the point of contact of the two cell membranes is the tight junction, also known as the zonula occludens. Tight junctions constitute a permeability barrier

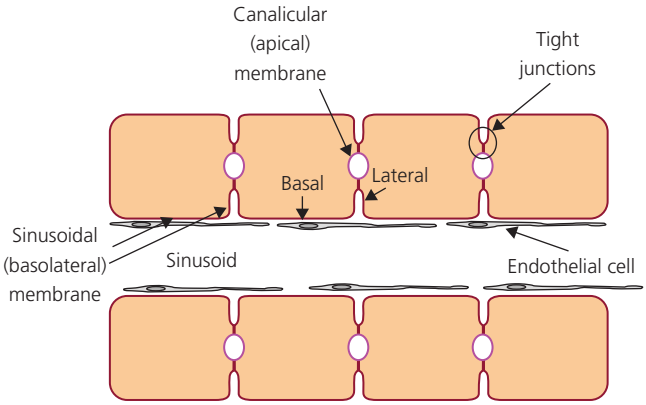

Figure 16.1 Organization of hepatocyte membrane domains. The relationship between the canalicular and basolateral membrane domains is represented for the hepatocyte plates and sinusoidal space. The sinusoidal space and canalicular space are separated from each other by the tight junctional permeability barrier.

that consists of several transmembrane proteins including members of the claudin family and occludin. These proteins form a seal between the membranes of adjacent cells [21]. These tight junctions are cation selective and form a barrier between the bile canaliculus and the sinusoidal space preventing back-diffusion of the secreted organic anions [22,23].

Bile is produced as a result of the osmotic consequences of solute secretion [24]. The hepatocytes directly secrete solutes, primarily bile acids, into the canalicular space and water follows passively driven by osmotic forces across the tight junctions and the cell membranes themselves [19]. The bile canaliculi encircle the hepatocytes in a belt-like fashion and form an interconnecting three-dimensional network. This network communicates with the canals of Hering, which form the transitions to the smallest bile ductules. Flow into the canalicular network thus results in net fluid flux into the biliary tree. Small bile ducts can secrete or absorb fluid and consequently modify the composition and amount of bile [25–27]. They serve as tributaries of the larger ducts. During fasting the sphincter of Oddi contracts and the gallbladder relaxes causing bile to enter the gallbladder for storage, but postprandially the gallbladder remains contracted and the sphincter of Oddi relaxes, resulting in bile bypassing the gallbladder and emptying directly into the duodenum.

Bile acids undergo a process of enterohepatic circulation in which they are absorbed by the intestine, returned to the liver via the portal circulation, taken up into the hepatocytes, and resecreted into the duodenum. In the duodenum and proximal ileum, some bile acids, particularly unconjugated bile acids, are passively absorbed, but conjugated bile acids are primarily absorbed in the terminal ileum. This absorption results from the apical sodium-dependent bile acid transporter (ASBT), a Na^+-dependent transport protein located in the apical membrane of the ileal enterocytes [28]. Within the enterocytes, bile acids interact with a cytosolic bile acid binder, the ileal bile acid binding protein [29,30] and are transported to the basolateral membrane. From here they are secreted into the superior mesenteric vein via a Na^+-independent organic anion exchange protein that is a heterodimeric complex of OSTα and OSTβ [31]. Bile acids then bind to albumin and are transported into the portal venous blood, through the fenestrae between the sinusoidal endothelial cells, and into the space of Disse. They are efficiently extracted by specific transporters present in the basolateral membrane of hepatocytes [32]. The uptake of bile acids occurs predominantly in periportal zone 1 hepatocytes [33]. Although 98% of bile acids are typically extracted from the portal blood during a single pass, the fractional extraction varies considerably according to the particular bile acid molecule. The general scheme for this enterohepatic circulation of bile acids is depicted in Fig. 16.2.

Multiple solutes are responsible for bile flow, but the primary ones are organic anions, and the most important of these are bile acids. Bile acids are amphipathic products of cholesterol metabolism that have several important functions [34]. They are natural detergent molecules that assist in solubilizing the lipid components of bile and are critical for solubilization, digestion, and absorption of lipids in the intestine. In addition they serve as the primary vehicle for cholesterol elimination [8], can specifically trigger apoptosis [35], and have been recognized to be important signaling molecules that bind to transcription factors and regulate gene expression important for lipid homeostasis and hepatic transport [10,11,36,37]. Bile acids are synthesized de novo from cholesterol within the hepatocytes. They are also efficiently recycled through the enterohepatic circulation. Each day 20–40 g of bile acid are secreted into bile but only approximately 3 g are newly synthesized and only 0.5 g are lost through fecal excretion. Under physiological conditions, 70% of the human bile acid pool is composed of cholic acid and cholic acid metabolites while the remaining 30% is chenodeoxycholic acid [38]. Bile acids are conjugated with glycine and taurine after their synthesis, which improves their solubility. These conjugated bile acids are present as anionic salts under physiological pH conditions and are therefore frequently called bile salts. In addition to bile acids, other solutes are also responsible for bile flow. The most important of these is the antioxidant tripeptide, glutathione (GSH), which accounts for most of the bile acid-independent fraction of bile flow [39].

During its transit through the bile ducts, the composition and volume of bile is modified [40]. Some bile acids in the biliary tract are absorbed by the biliary epithelial cells and returned into the portal circulation without entering the intestine. This process is known as cholehepatic shunting and

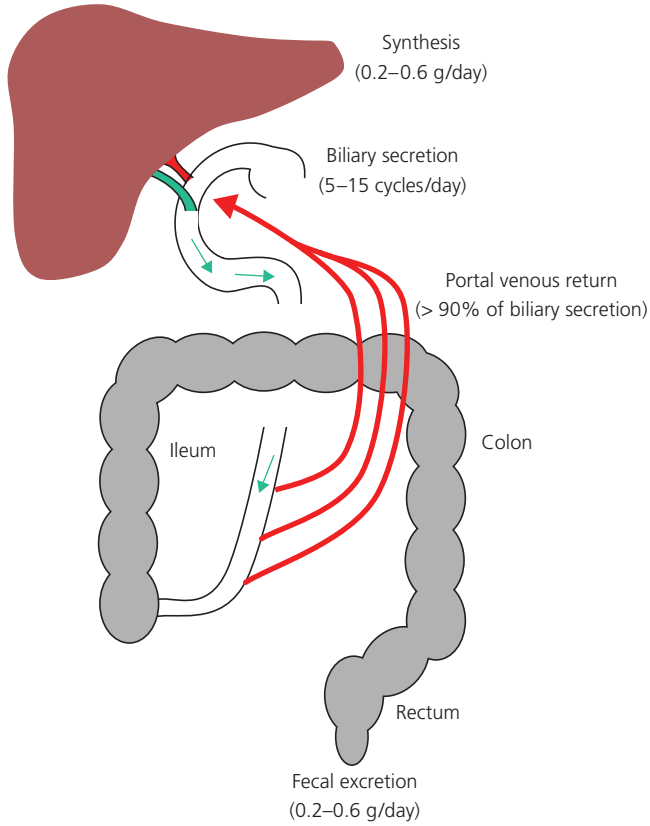

Figure 16.2 Schematic representation of the enterohepatic circulation. The routes of secretion and absorption of bile acids are indicated.

serves to amplify the amount of fluid flow produced by a given net bile acid secretion [41]. Cholangiocytes take up unconjugated bile acids passively after protonation by H^+ equivalents generated from the activity of carbonic anhydrase present in the cholangiocytes [41]. In addition conjugated bile acids can be taken up via the activity of a specific Na^+/bile acid cotransport protein, SLC10A2/ASBT, which is present in the apical membrane of both cholangiocytes and ileal absorptive epithelial cells [28,42]. Intracellular bile acids are then transferred to the basolateral membrane and transported via the periductal capillary plexus into the sinusoids for uptake into the hepatocytes. Cholehepatic shunting plays an important role in bile formation but is also a mechanism of removal of potentially toxic bile acids during pathological states, such as bile duct obstruction where bile acids accumulate proximal to the obstruction in the bile duct. It has also been postulated to play a signaling role where hepatic bile acid secretion can alter the function of the cholangiocytes themselves [43]. These general processes are all mediated by specific transport proteins. The function and regulation of these transporters explain both normal function and pathological manifestations of cholestasis. In order to understand the mechanisms of bile formation and cholestasis, therefore, it is critical to consider the identities and regulation of the specific transport proteins at each of the steps of the process.

Mechanisms of canalicular bile formation

Inorganic ion transport

Hepatocytes possess multiple transport proteins for inorganic ions. These primarily function to generate transmembrane ion gradients, regulate intracellular pH and cell volume, and create the electrical potential difference between the cell interior and the extracellular space. While inorganic ion transport in hepatocytes generates the electrochemical gradients necessary for bile acid transport, it is not directly responsible for bile secretion. This differs from the situation in most fluid-transporting epithelia such as bile duct epithelial cells, where inorganic ion transport is directly responsible for fluid secretion. The inorganic ion transport proteins in hepatocytes are indicated in Fig. 16.3.

The Na^+,K^+-ATPase is present in the basolateral membrane [44] and it utilizes the energy of ATP hydrolysis to exchange Na^+ and K^+, thus generating the low Na^+, high K^+ intracellular environment present in all mammalian cells. A cell-negative membrane potential is generated by the presence of K^+ channels in the plasma membranes [45,46]. The efflux of K^+ through these channels produces a cell-negative diffusion potential. Hepatocytes also have multiple chloride channels in both the sinusoidal and canalicular membranes [47]. This allows chloride to distribute at its electrochemical equilibrium and this process reduces the membrane potential to approximately –30 to –40 mV (cell interior negative) [48].

Several other transporters are primarily involved in pH regulation. These are the Na^+/H^+ exchanger NHE1 [49] and a Na^+/HCO_3^- cotransporter NBC4 [50]. Both of these regulate intracellular pH in response to an acid load. The Na^+/HCO_3^- cotransporter is quantitatively more important in this response [51]. At the canalicular membrane a Cl^- channel [52] and the Cl^-/HCO_3^- exchanger AE2 [53,54] are present. In bile duct epithelial cells this combination of a chloride channel and Cl^-/HCO_3^- exchanger results in electrogenic chloride and bicarbonate secretion (see below). However, chloride is at electrochemical equilibrium in the hepatocyte and there is thus no driving force for net chloride efflux. In hepatocytes, therefore, the AE2 transporter is primarily involved in pH regulation and not fluid secretion.

Cell volume regulation is also extremely important for hepatocytes. Unlike most other cells, hepatocyte function requires cycles of swelling and shrinkage. After a meal the concentrations of amino acids and sugars increase in the portal circulation. Hepatocytes take up large quantities of amino acids and other nutrients and consequently swell [55]. They respond to cell swelling by activation of K^+ and Cl^- channels [56–58]. This produces a net flux of KCl out of the cell and

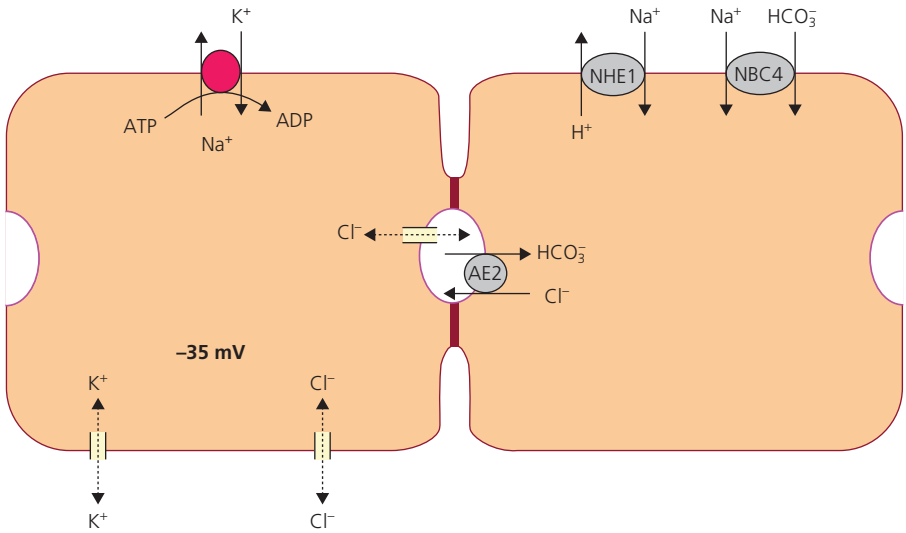

Figure 16.3 Inorganic ion transport pathways of hepatocytes. Ionic gradients are maintained by the Na^+,K^+-ATPase, which in conjunction with K^+ and Cl^- channels maintains the cell interior at an electrical potential of approximately –35 mV with respect to the sinusoid. Chloride is distributed across the membrane passively in accordance with electrochemical equilibrium and there is normally no net driving force for chloride secretion. The Na^+/H^+ exchange protein NHE1, the Na^+/HCO_3^- transporter NBC4, and the anion exchange protein AE2 play important roles in pH regulation.

reduces cell volume. In addition, the chloride channels activated by cell swelling are also permeable to organic substrates such as taurine, and efflux of taurine contributes to volume regulation [59]. Cell swelling activates ion channels by several mechanisms including direct stretch-activated signaling cascades [60,61]. In some cases an autocrine phenomenon of ATP release and binding to purinergic receptors on the cell membrane further activates chloride channels and contributes to cell volume regulation [62].

Organic solute transport

Basolateral (sinusoidal) transport systems

Specific transport proteins at the sinusoidal membrane of hepatocytes account for the ability of the hepatocyte to take up substances from sinusoidal blood and move them into the cells. With few exceptions, the transported molecules do not cross lipid bilayers and their uptake is entirely determined by the properties of the transport proteins present in the sinusoidal membrane. Differences in the identities and quantities of these account for the different uptake properties of hepatocytes in different species, between different individuals, and at different times in the same individual. The most important uptake transporters are SLC10A1/NTCP, the Na^+-dependent bile acid transporter [63], and a family of organic anion conjugate transporters known as the OATP family [64]. Members of the OATP family are responsible for the Na^+-independent uptake of bile acids [10,65] , unconjugated bilirubin, many other organic anions, and even some cationic and amphipathic substances [66,67]. Other important groups of transporters include the OAT family of anion transporters [68] and the OCT family of cation transporters [69]. These transporters are summarized in Table 16.1 and a schematic representation of their localization is shown in Fig. 16.4.

A note on nomenclature

Historically, as the individual transport proteins of the liver were identified they were given names and corresponding acronyms that denoted their function, for example organic anion transport protein (OATP) or bile salt export pump (BSEP). As more of these proteins were discovered and as different species were examined it became clear that most of these proteins were members of families of similar proteins and there was not a one-to-one correspondence of protein functions between species. This led to considerable confusion. Multiple names for the same protein proliferated and in some cases, such as the canalicular membrane phospholipid transport protein, the homologous protein was called mdr2 in mice but MDR3 in humans. Thankfully, the nomenclature of these transport proteins has now been standardized and systematic gene names have been created to classify the proteins by sequence homology. This has been especially helpful for the OATP family in which sequence homology has been used to place the members in evolutionarily related groups. Unfortunately, these systematic names no longer designate function and are thus harder to remember. In the following sections the proteins are introduced using the systematic name in conjunction with the older, more descriptive term. In subsequent sections, for the sake of brevity and in cases where there is no confusion, the descriptive name may be used alone.

Sodium/bile acid cotransport protein (NTCP)

The sodium-taurocholate transport protein SLC10A1/NTCP was the first bile acid transporter to be identified [32,70]. Its expression is highly liver specific, it localizes exclusively to the basolateral membrane of hepatocytes, and it is expressed similarly in periportal and pericentral hepatocytes [71]. Human SLC10A1/NTCP is a 349 amino acid, 50-kDa protein

Table 16.1 Basolateral uptake transporters of the human hepatocyte

Gene symbol	Systematic protein name	Functional protein name	Human gene locus	Predominant substrates	Tissue expression
Primarily liver specific					
SLC10A1	SLC10A1	NTCP	14q24.1	Bile acids, conjugated steroids	Liver, pancreas
SLCO1B1	OATP1B1	OATP-C	12p12	Bile acids, unconjugated bilirubin, organic anions	Liver
SLCO1B3	OATP1B3	OATP-8	12p12	Bile acids, organic anions, digoxin, xenobiotics, peptides	Liver, cancer cell lines
SLCO2B1	OATP2B1	OATP-B	11q13	Sulfated estrogens, DHEAS, BSP	Liver, placenta
Liver and other locations					
SLCO1A2	OATP1A2	OATP-A	12p12	Bile acids, xenobiotics, organic anions, conjugated steroids	Ubiquitous
SLCO3A1	OATP3A1	OATP-D	15q26	E-3-S, prostaglandins, benzylpenicillin	Ubiquitous
SLCO4A1	OATP4A1	OATP-E	20q13.1	Taurocholate, T3, prostaglandins	Ubiquitous
SLCO1C1	OATP1C1	OATP-F	12p12	T4, rT3, BSP	Brain, testes
SLC22A7	SLC22A7	OAT2	6p21.2–p21.1	Organic anions, polyspecific (salicylates, prostaglandin E_2)	Liver, kidney
SLC22A1	SLC22A1	OCT1	6q26	Organic cations, polyspecific (*N*-methylquinine, tetraethylammonium)	Liver, kidney, intestine

BSP, bromosulfophthalein; DHEAS, dehydroepiandrosterone sulfate; E-3-S, estrone-3-sulfate; T3, triiodothyronine; rT3, reverse triiodothyronine; T4, thyroxine.

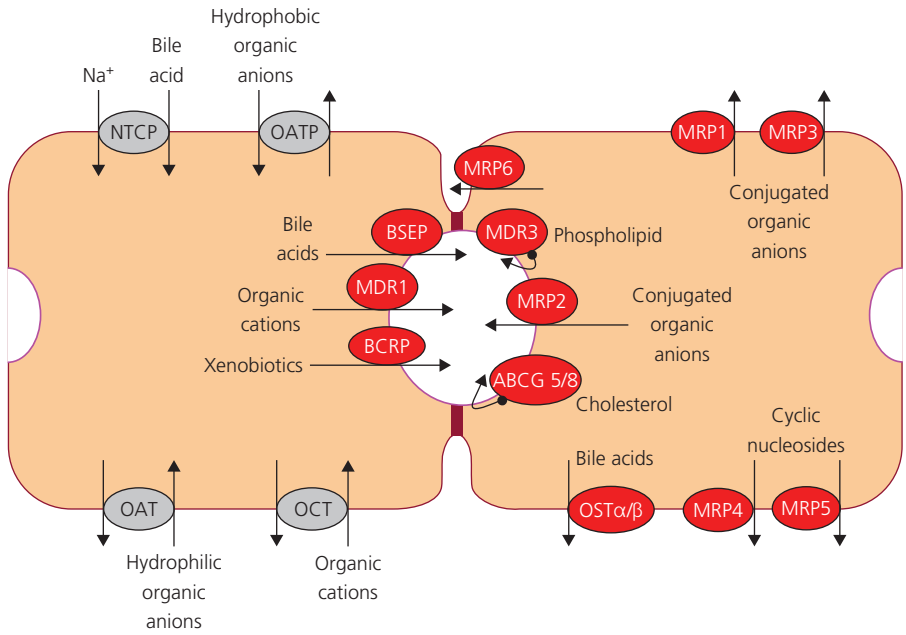

Figure 16.4 Organic ion transporters of hepatocytes. Solute uptake at the basolateral membrane is mediated by a Na^+/bile acid cotransport protein, NTCP, and three families of organic ion exchanger transporters: OATP, the organic anion transporter protein family; OCT, the organic cation transporter family; and OAT, the organic anion transporter family. Export from the hepatocyte into the canalicular space is due to the ATP-dependent transport proteins BSEP, MRP2, MDR1, and ABCB4/MDR3. The ATP-dependent transport proteins MRP1, MRP3, MRP4, MRP5, and MRP6 transport substrates out of the cells into the sinusoidal blood. See text for details.

with a substrate specificity that is primarily limited to bile salts and certain sulfated steroids [11]. Transport is strongly coupled to Na^+, with a stoichiometry of $2Na^+$ transported for one bile acid molecule [72,73]. This coupling strategy results in an electrogenic transport process [74] that greatly increases the driving force for uptake and increases the maximum intracellular bile acid concentrations that can be achieved. It has been estimated that it can elevate intracellular bile acid concentrations at least 10-fold above that in the sinusoidal blood [75]. SLC10A1/NTCP is critical for bile acid transport and is entirely responsible for Na^+-dependent bile acid transport, which accounts for up to 80% of bile acid uptake. SLC10A1/NTCP is strongly conserved among mammalian species.

SLC10A1/NTCP is a member of a small family of sodium/bile salt cotransporters within the superfamily of sodium/solute symporters [76]. In addition to SLC10A1/NTCP, a closely related protein called the apical sodium bile acid transporter SLC10A2/ASBT is expressed at the brush border membrane of ileal epithelial cells and cholangiocytes. It efficiently removes bile salts from the intestinal lumen and allows their return to the liver via the portal circulation [63].

OATP family of transporters

The OATPs are a family of overlapping multispecific transporters with broad tissue distribution and substrate specificity [64]. These transporters are classified within the gene superfamily of solute carriers (SLC) as their own family SLCO. OATP transporters are present in multiple other tissues as well as liver, and they mediate the Na^+-independent transport of bile acids, conjugated estrogens, conjugated bilirubin, cysteinyl leukotrienes, thyroid hormones and many other substrates by a process of anion exchange [77,78]. They are present in many species, but unlike the situation for NTCP, there is no clear correspondence in terms of sequence or substrate specificity between species. The new, species independent, nomenclature divides the OATP family members into six groups based solely on sequence homology [10,64,69]. This system is used in Table 16.1.

The OATPs represent a major mechanism for hepatocellular organic anion uptake and hepatic first-pass clearance of drugs. Numerous drugs are substrates of OATPs, including the antihistamine fexofenadine, opioid peptides, the hydroxymethylglutaryl (HMG)-CoA reductase inhibitor pravastatin, the angiotensin-converting enzyme inhibitor enalapril, and methotrexate [79]. They are anion exchangers and the uptake of substrates into the cell is mediated by the efflux of GSH from hepatocytes into the sinusoid [80]. Since GSH is synthesized in hepatocytes and its intracellular concentrations are much higher than those in sinusoidal blood, efflux of GSH is likely to provide the driving force for electroneutral organic ion uptake [81].

In humans, the OATP family comprises nine members [65], three of which appear to be liver specific, although with marked variation in the level of expression. SLCO1B1/OATP1B1 is highly expressed in hepatocytes and appears to be the primary non-bile acid organic ion uptake transporter [82,83]. It is a 691 amino acid protein that is primarily expressed in the basolateral membrane of hepatocytes and transports bile acids, unconjugated bilirubin, conjugated sterols, eicosanoids, and thyroid hormone. Its significance is demonstrated by its ability to transport albumin-bound unconjugated bilirubin, unlike most of the other members of the OATP family [84]. SLCO1B3/OATP1B3 is another important multispecific transport molecule at the basolateral membrane of human hepatocytes. It is has 80% sequence homology to SLCO1B1/OATP1B1 [85], and also has broad substrate specificity, mediating transport of bile acids, conjugated sterols, bromosulfophthalein, thyroid hormones, and organic cations [66]. In addition, cardiac glycosides including digoxin are transported by SLCO1B3/OATP1B3 [10,79]. SLCO2B1/OATP2B1, expressed predominantly in the basolateral membrane of hepatocytes [66], is the third human liver OATP. It has a more limited substrate specificity than SLCO1B1/OATP1B1 or SLCO1B3/OATP1B3 and does not transport bile acids [66].

The other human OATPs are not primarily hepatic transporters. SLCO1A2/OATP1A2 is a 60-kDa bile salt transporter with ubiquitous expression and broad substrate specificity for xenobiotics [86,87]. It is found primarily in the endothelial cells of the blood–brain barrier where it transports bile salts, organic anions, conjugated steroids, and numerous drugs [88,89]. Expression of SLCO1A2/OATP1A2 is noted to be increased in liver tissues of patients with cholestatic liver disease [90]. SLCO3A1/OATP3A1 and SLCO4A1/OATP4A1 are expressed in many tissues, and SLCO1C1/OATP1C1 expression is limited to brain and testes [64].

OAT/OCT transporters

Several other groups of transporters are present in the basolateral membrane of hepatocytes, although their overall significance is less clear. The OAT family comprises a group of transporters that play a role in anion transport in both liver and kidney [68]. The substrate specificity of OAT family members differs from that of OATP family members in that substrates tend to be more hydrophilic. Nonetheless, there is considerable overlap. SLC22A6/OAT1, the initially identified member of the group, is present only in kidney where it functions as the high-affinity *p*-aminohippuric acid transporter. This is the probenecid-inhibitable transporter that is largely responsible for efficient tubular anion secretion [91]. A similar transporter, SLC22A7/OAT2, is present exclusively in the liver [92], a third family member, SLC22A8/OAT3, is present in both kidney and liver [93], and SLC22A9/OAT4 is present in kidney and placenta [94]. The relative distribution of OATP and OAT family members between kidney and liver plays an important role in the well-known transport differences of these two organs. More bulky hydrophobic anions

Table 16.2 Canalicular export transporters of the human hepatocyte

Gene symbol	Functional protein name	Human gene locus	Predominant substrates	Tissue expression	Disease association
ABCB11	BSEP	2q24	Bile acids	Liver	PFIC II, BRIC 2, ICP
ABCC2	MRP2	10q24	Conjugated bilirubin, organic anions, glutathione conjugates, leukotriene C_4	Liver, kidney, intestine	Dubin–Johnson syndrome

BBB, blood–brain barrier; BRIC, benign recurrent intrahepatic cholestasis; ICP intrahepatic cholestasis of pregnancy; PFIC, progressive familial intrahepatic cholestasis.

(OATP substrates) are preferentially taken up by hepatocytes and excreted largely in bile rather than urine. More hydrophilic organic anions (OAT substrates) are preferentially secreted by the renal tubules and excreted largely in urine rather than bile. Substrates of SLC22A7/OAT2 include *p*-aminohippuric acid, salicylates, and prostaglandin $(PG)E_2$ [95].

The members of the OAT family have a 12-transmembrane-domain structure and function largely as electroneutral anion exchangers [68]. In spite of these similarities they do not share sequence homology with the OATP family. However, they do share homology with the organic cation transporters of the OCT family [96]. While the organic cation transporters appear to play little part in bile formation, their substrates include many important therapeutic drugs and xenobiotics.

Canalicular transport

The secretion of bile salts and other molecules from the cytoplasm of the hepatocytes across the canalicular membrane into the bile canaliculi is the rate-limiting step in bile formation and requires direct energy input [4,19]. It is achieved by the action of several different ATP-dependent transport proteins. These transport proteins are part of the superfamily of ATP-binding cassette (ABC) proteins and share similar structural and functional characteristics with each other [97]. The ABC transport proteins of the canalicular membrane can be divided into two functional classes. The first is the solute transporters such as the cation transporter ABCB1/MDR1, the salt export pump ABCB11/BSEP, the xenobiotic transporter ABCG2/BCRP, and the multispecific organic anion transporter ABCC2/MRP2. The second class of ABC proteins in the canalicular membrane are lipid translocators such as the phospholipid *flippase* ABCB4/MDR3, and the ABC half-transporters involved in cholesterol transport ABCG5/ABCG8 [36]. These transporters are summarized in Table 16.2.

Bile salt exporting protein (ABCB11/BSEP)

In humans, ABCB11/BSEP is the predominant bile salt efflux system of hepatocytes [98]. It is localized in the canalicular membrane and in subcanalicular vesicles [99]. Loss of human ABCB11/BSEP results in near total elimination of biliary bile acid excretion [98], whereas a knockout mouse lacking Bsep displayed only 50% reduction in bile acid secretion [100]. This demonstrates that in mice, unlike in humans, other proteins at the canalicular membrane can transport bile salts. ABCB11/BSEP-dependent bile acid secretion is the primary driver of bile flow and conditions that reduce its function or expression generally result in cholestasis. ABCB11/BSEP inhibition occurs in drug-induced cholestasis caused by rifampicin, cyclosporine (ciclosporin), or conjugated estrogens [101,102]. Inherited BSEP dysfunction results in progressive familial intrahepatic cholestasis type 2 and its less aggressive form, benign recurrent intrahepatic cholestasis type 2 [103] (see below).

Multidrug resistance associated protein 2 (MRP2)

ABCC2/MRP2 is an ABC transport protein that is primarily expressed in the canalicular membrane of hepatocytes [104,105] and serves as a primary high-affinity transporter for conjugated organic anions including conjugated bilirubin [106], GSH conjugates, and cysteinyl leukotrienes [107]. In addition it transports other substrates including sulfated bile salts, conjugated estrogens, antibiotics, and a number of other exogenous compounds [108]. ABCC2/MRP2 also transports unconjugated reduced GSH from the hepatocyte

into the bile [81] albeit with a relatively low affinity [109]. However, since intracellular GSH concentrations are high, it is responsible for a significant fraction of canalicular GSH secretion. It is a member of a family of closely related transport proteins that differ more in their tissue and membrane localization than in their transport function. In humans the MRP family consists of six members. ABCC2/MRP2 is the only MRP detected in the canalicular membrane [36,110].

ABCC2/MRP2 is specifically absent from the canalicular membrane in the human disease Dubin–Johnson syndrome. While ABCC2/MRP2 is important in organic anion and bilirubin transport, it plays little role in bile formation. Patients with Dubin–Johnson syndrome have an almost complete absence of bilirubin conjugates and GSH conjugates in bile and develop a black pigment in their liver, but are otherwise normal. They exhibit up-regulation of other MRP family members in the sinusoidal membrane and as a consequence are able to eliminate MRP substrates into the blood for eventual renal rather than biliary excretion [111].

Multidrug resistance protein 1 (MDR1)

ABCB1/MDR1 is a 1280 amino acid, 170-kDa protein that is responsible for the secretion of a variety of large hydrophobic compounds, especially organic cations [112]. This transporter was first identified as a protein that becomes overexpressed in some cancer cells and consequently renders these cells resistant to a diverse array of chemotherapeutic agents. It was subsequently determined that the mechanism of this multidrug resistance is that ABCB1/MDR1 functions as a drug efflux pump with broad specificity for cationic chemotherapeutic agents [113]. The protein is normally expressed at the apical membranes of several epithelia but most notably in the canalicular membrane of hepatocytes [114] where it functions as an important mechanism for the secretion of drugs and organic cations into bile [115]. No specific endogenous substrate has been identified for ABCB1/MDR1.

Phospholipid transporter: multidrug resistance protein 3 (MDR3)

ABCB4/MDR3 is an ABC transport protein that is expressed in high levels in the canalicular membrane of the hepatocytes where it functions as a phospholipid transporter [116]. Several studies have demonstrated that ABCB4/MDR3 and the homologous protein in mice, mdr2, serve as ATP-dependent phospholipid flippases that translocate phosphatidylcholine (PC) from the inner to the outer leaflet of the lipid bilayer of the canalicular membrane [117,118]. This process is a critical step in the mechanism by which phospholipid is secreted into bile (see below).

ABCB4/MDR3 is a 170-kDa protein that represents the major ABC protein of the canalicular membrane [114]. Knockout mice with disruption of the *mdr2* gene develop progressive hepatic fibrosis and bile duct destruction and have complete absence of phospholipid secretion into bile [119]. A similar syndrome, progressive familial intrahepatic cholestasis type 3 (see below), also occurs in humans with mutations of the ABCB4/MDR3 protein [120]. Defects in this gene also contribute to gallstone susceptibility in association with cholestasis [98,103] and intrahepatic cholestasis of pregnancy [121].

ABC half-transporters

While most members of the ABC transporter family contain two highly homologous domains and function as a monomer, several ABC transporters have just a single domain in which the functional unit is a dimer. Several of these so-called *half-transporters* are important canalicular membrane transporters [122]. ABCG2 or breast cancer resistance protein (BCRP) [102], so-called for its overexpression in breast cancer cells, confers resistance against chemotherapeutic agents such as mitoxantrone, bisantrene, etoposide, prazosin, and flavopiridol by extruding these drugs from the cell. The BCRP protein functions as a homodimer and is present at the canalicular membrane of hepatocytes.

ABCG5 and ABCG8 are two other half-transporter members of the ABCG family. Both ABCG5 and ABCG8 are expressed mainly in liver and intestine [123]. These half-transporters function as a heterodimer and are involved in hepatobiliary excretion of plant sterols and cholesterol. Mutations in either the *ABCG5* or *ABCG8* gene cause sitosterolemia, which manifests as elevated plasma levels of plant sterols especially sitosterol [123], leading to hypercholesterolemia and premature atherosclerosis. Overexpression of *ABCG5/ABCG8* in transgenic mice caused increased biliary cholesterol secretion and reduced intestinal absorption of dietary cholesterol, lending further support for ABCG5/ABCG8 involvement in hepatobiliary excretion of cholesterol [124].

ATP8B1/FIC1

The *FIC1* or *ATP8B1* gene was first identified in 1998 as the mutated gene responsible for familial intrahepatic cholestasis (Byler disease) and benign recurrent intrahepatic cholestasis type 1 [103,125]. FIC1 protein is expressed primarily in small intestine and to a lesser extent in the cholangiocyte and canalicular membrane of hepatocytes [126,127]. FIC1 does not appear to be an important plasma membrane transport protein and therefore the reason that its ablation produces cholestasis is not fully understood. However, findings have suggested that it is a phospholipid translocator capable of translocating phosphatidylserine [128]. Its ability to prevent cholestasis may result from its effects on the activation of nuclear receptors such as FXR that control expression of the other transport proteins [129,130] (see below).

Sinusoidal efflux

Secretion of proteins from the hepatocyte, across the sinusoidal membrane into the blood, is a major function of the

Table 16.3 Sinusoidal efflux transporters of the human hepatocyte

Gene symbol	Functional protein name	Human gene locus	Predominant substrates	Localization	Tissue expression	Disease association
ABCC1	MRP1	16p13.1	Organic anions (glutathione, glucuronide and sulfate conjugates)	Basolateral	Absent/low in normal conditions	
ABCC3	MRP3	17q21.3	Bile acids, sulfated bile acids	Basolateral	Absent/low in normal conditions	
ABCC4	MRP4	13q32	Bile acids, nucleoside analogues and cyclic nucleosides, glutathione	Basolateral	Ubiquitous	
ABCC5	MRP5	3q27	Purine analogues and cyclic nucleosides	Basolateral	Ubiquitous	
ABCC6	MRP6	16p13.1	Unknown	Lateral membrane	Ubiquitous	Pseudoxanthoma elasticum
OSTα/OSTβ	OSTα/OSTβ	3q29/15q22.3	Bile acids, sterols, prostaglandin E_2	Basolateral	Small intestine, kidney, liver	

liver, but under normal conditions, the polarity of organic solute transport primarily involves sinusoidal uptake and canalicular efflux. However, in a number of pathological conditions this polarity is reversed and efflux across the sinusoidal membrane becomes quantitatively important. This is partially accomplished by reversal of gradients and passive transport via carriers such as the OATPs, but the primary mechanism of sinusoidal efflux is via insertion of a series of new transport molecules into the sinusoidal membrane. Five members of the ABCC (MRP) family with somewhat varying substrate specificity and another transporter, OSTα/OSTβ [131], are involved in efflux of organic anions across the basolateral membrane during cholestasis [79] (Table 16.3). This explains the widely recognized increase in plasma conjugated bilirubin that occurs in cholestasis.

ABCC1/MRP1 is involved in cellular efflux of various organic anions including GSH, glucuronide and sulfate conjugates of a number of drugs. ABCC3/MRP3 is an organic anion transporter expressed prominently in liver, kidney, pancreas and gut that primarily transports bile salts. The expression of both ABCC1/MRP1 and ABCC3/MRP3 is low under physiological conditions, but both are substantially induced during cholestatic states. Upregulation of ABCC3/MRP3 is an important rescue mechanism allowing for renal excretion of bile salts and organic anion efflux during conditions such as primary biliary cirrhosis and Dubin–Johnson syndrome [132,133]. ABCC4/MRP4 and ABCC5/MRP5 are both organic anion pumps and have the ability to transport cyclic nucleotides and nucleoside analogues [134]. ABCC6/MRP6 is mainly expressed in liver and kidney. The substrate specificity of ABCC6/MRP6 is still unclear [102].

Another transporter, the heterodimer of OSTα and OSTβ, is primarily a bile acid export transporter that has been identified in intestine as well as in liver and is responsible for the efflux of intestinal bile acids from epithelial cells into blood [31]. It is a unique transporter consisting of a heterodimer between OSTα, a seven-transmembrane-domain protein, and OSTβ, a single transmembrane domain protein. Its transport specificity is primarily for bile acids [131].

Intracellular movement

In addition to transport across the sinusoidal and canalicular membranes, movement of solutes through the cytosol is critical for transport. Many of the solutes transported by hepatocytes are hydrophobic organic ions and as a consequence they tend to bind to proteins, partition into various cellular membrane fractions, and become associated with intracellular organelles. It has been estimated that these interactions reduce the effective diffusion constants for intracellular molecules by a factor of 1000 compared with what would be expected for diffusion in free solution [135]. Several high-affinity intracellular binding proteins are present in hepatocytes. These include bile acid-binding proteins, primarily 3α-hydroxysterol dehydrogenases, which bind bile acids in the low micromolar range [136]; fatty acid-binding protein, which binds free fatty acids [137]; and glutathione-*S*-transferases, which, in addition to the enzymatic activities, serve as binding proteins for bilirubin [138]. Intracellular binding proteins serve to prevent bile acids from partitioning into fixed lipid membranes and organelles [139], and serve as an intracellular sink preventing reflux of bile acids through the sinusoidal membrane.

Transcytotic vesicular transport also plays a role in hepatic transport in some situations. A number of proteins, particularly monomeric IgA, bind to specific receptors at the sinusoidal membrane and undergo receptor-mediated endocytosis, transcellular trafficking, and exocytosis at the canalicular membrane [140]. Other molecules including bulky organic solutes such as class II cations, and proteins such as transferrin translocate via this mechanism [141]. Although copper appears to be transported into vesicles and secreted across the canalicular membrane by exocytosis [142], this process does not play a major role in the transport of other small molecules, such as bile acids.

Biliary lipid secretion

Regulation of lipid homeostasis is a key function of the liver and biliary lipid secretion plays a critical role in this process [143]. In addition to its role in maintenance of whole-body lipid homeostasis, biliary secretion of phospholipids and cholesterol is necessary for prevention of intrahepatic bile acid toxicity and cholestatic bile duct injury. The major lipid components of bile are bile salts, phospholipid primarily as PC, and cholesterol. The monomeric forms of phospholipid and cholesterol have limited aqueous solubility and exist in bile in the form of micelles and vesicles. The mechanism of biliary lipid secretion differs from that of soluble small molecules. The general process is one in which PC and cholesterol are inserted into the canalicular membrane and then subsequently solubilized from the outer leaflet of the canalicular membrane into bile by a bile acid-dependent process [8,144].

Phospholipid secretion depends on several steps. First, cellular PC is inserted into the canalicular membrane. The primary process responsible for this is a membrane–membrane exchange process mediated by the phosphatidylcholine-transfer protein (PC-TP) [145,146]. This protein results in the selective addition of PC to the inner leaflet of the canalicular membrane. Flipping of PC from the inner leaflet to the outer leaflet of the membrane is accomplished by the ABCB4/MDR3 protein [116,147,148]. This step is critical and the absence of a functional flippase in the canalicular membrane results in the complete absence of biliary phospholipids in both humans [120] and mice [119]. Phospholipid is ultimately removed from the outer leaflet of the canalicular membrane and appears in bile as small vesicles. This process is dependent on bile salts. Electron microscopic evidence suggests that it involves direct budding of vesicles off the canalicular membrane [144] in addition to transfer from the canalicular membrane to biliary micelles [149].

Biliary cholesterol transport is also dependent on a series of membrane transporters and intracellular transport processes. Cholesterol enters hepatocytes by several mechanisms including endocytic uptake of low-density lipoprotein (LDL) via the LDL receptor and the LDL receptor-related protein. High-density lipoprotein (HDL) is also an important source for hepatic cholesterol uptake and is part of the *reverse cholesterol transport pathway* by which cholesterol is removed from peripheral tissues and returned to the liver for excretion [150]. HDL binds to the hepatic HDL receptor, SR-BI, which results in the uptake of cholesterol destined for biliary secretion [151,152]. With a normal cholesterol diet, this pathway appears to involve direct lateral diffusion of the cholesterol within the plasma membrane and accounts for most of biliary cholesterol. Intracellularly, cholesterol is bound to several binding proteins including the sterol carrier protein SCP-2. In addition it is transported intracellularly by vesicular transport via endosomes and lysosomes. A second pathway for biliary secretion of cholesterol occurs with high dietary cholesterol in which LDL appears to be the source. This involves a trafficking pathway of endocytosed cholesterol from endosomes to lysosomes and then from lysosomes to the canalicular membrane for excretion. The precise mechanisms of this pathway have not been determined but it involves two proteins that have been associated with Niemann–Pick Disease, NPC1 and NPC2 [153].

Secretion of cholesterol across the canalicular membrane into bile has been shown to involve a heterodimeric transport complex consisting of ABCG5 and ABCG8. Absence of either of these proteins leads to hepatic accumulation of plant sterols in patients with sitosterolemia [123,154] and defects in biliary cholesterol secretion. This role of ABCG5/ABCG8 in cholesterol transport has been confirmed in an animal model, showing that coexpression of both proteins permits their transport to the apical surface [155,156]. Humans and mice lacking ABCG5 and ABCG8 have a marked reduction in biliary cholesterol secretion [157], whereas transgenic mice overexpressing the human proteins have increased biliary cholesterol concentration [158]. Another ABC transporter ABCA1 is ubiquitously expressed and is present in hepatocytes. It mediates cholesterol efflux from cells and is responsible for loading of nascent HDL with tissue-derived cholesterol. Although present in hepatocytes, its role in biliary cholesterol secretion has not been established [159].

Hepatic copper transport

Biliary excretion of copper is the exclusive mechanism by which copper is eliminated from the body and a defect in this process, as occurs in Wilson disease, results in massive accumulation of copper in liver, brain and other organs [160]. Copper is taken up by hepatocytes from the sinusoidal circulation by means of a Cu transporter, CTR1 [161]. Due to its ability to catalyze redox reactions and hence its toxicity, intracellular Cu is tightly bound to specific carrier proteins called chaperones. In hepatocytes, copper is primarily destined for incorporation into cytochrome c oxidase via the chaperone COX17, incorporation into the Cu/Zn superoxide dismutase via the chaperone CCS1, and interaction with the Cu pump protein ATP7B via the chaperone ATOX1 [162]. ATP7B is a P-type ATPase that is required both for Cu incorporation

into ceruloplasmin as well as biliary Cu excretion. It is exclusively found in the liver and is localized primarily in an intracellular trans-Golgi site [163].

ATP7B, the protein that is defective in Wilson disease, is exclusively responsible for copper secretion in bile [164,165]. It is primarily an intracellular Cu transport protein that concentrates Cu in vesicular structures where it can be incorporated into ceruloplasmin, such as occurs in the trans-Golgi. When hepatocellular Cu content is low, ATP7B is primarily located in the trans-Golgi. In response to high Cu conditions, it redistributes and translocates to a closer association with the canalicular membrane where its primary role appears to shift to biliary excretion. It is uncertain whether the primary mechanism of biliary secretion is ATP7B-dependent Cu loading and subsequent fusion of subcanalicular vesicles with the canalicular membrane, or whether ATP7B actually resides in the canalicular membrane and pumps Cu directly into bile [166]. The best evidence suggests that ATP7B resides in subcanalicular vesicles and biliary Cu secretion occurs via a process of vesicular fusion [142].

In addition to ATP7B, other proteins are necessary for biliary Cu secretion. Several diseases, such as Indian childhood cirrhosis and endemic Tyrolean infantile cirrhosis, result in massive hepatic Cu accumulation without a defect in ATP7B. A protein called MURR1/COMMD1 has been identified as the gene defect responsible for copper toxicosis in Bedlington terriers [167]. Abnormalities of this protein result in a defect in the biliary excretion of Cu in humans as well as dogs without any defect in Cu incorporation into ceruloplasmin. Although it is ubiquitously expressed and appears to be necessary for a final step in Cu excretion, its precise function is unknown. It does bind directly to ATP7B and one hypothesis is that it is required for the fusion of copper-loaded vesicles with the canalicular membrane [168]. Because the affected dogs show massive copper accumulation in lysosomes of the hepatocyte, a possible role for MURR1 might be to facilitate degranulation of lysosomal contents into the bile [169]. However, MURR1 is not responsible for most non-Wilson disease hepatic copper toxicosis syndromes in humans and thus other elements of the Cu secretion pathway remain to be determined [170].

Mechanisms of bile ductular secretion

Following the process of fluid secretion into the canalicular space, bile flows through the bile ductular system prior to its emptying into the duodenum. Far from a passive conduit, the biliary epithelium serves many functions including secretion and absorption of fluid and electrolytes [171]. In addition, bile ducts are able to specifically absorb bile acids [172]. This serves to both detoxify bile and amplify bile flow through cholehepatic shunting [173]. The biliary ductules comprise only 3%–5% of the total liver cell population but they can secrete up to 40% of total bile flow in humans [174]. Unlike the situation in hepatocytes, fluid secretion by the biliary epithelium is not the product of organic ion secretion. Rather it is a process of chloride-dependent bicarbonate secretion similar to that which occurs in other salt-transporting epithelia such as the airway epithelium [175]. Biliary secretion is under intense hormonal control, particularly by the secretagogue secretin, which increases intracellular cyclic adenosine monophosphate (cAMP), stimulating secretion of bicarbonate-rich fluid. Other hormones and neuropeptides such as acetylcholine, somatostatin, gastrin, bombesin, substance P, vasoactive intestinal polypeptide (VIP), and endothelin also modulate bile flow [171,176]. Figure 16.5 shows the transport proteins responsible for bile ductular secretion.

The cholangiocytes are the epithelial cells that line the biliary ductules. They play an important role in bile secretion and express transporter systems and water channels necessary for secretory and absorptive functions. The basolateral membrane contains a Na^+,K^+-ATPase that establishes the ionic gradients and a K^+ channel that serves to maintain the intracellular negative potential [177]. An electroneutral $Na^+/K^+/2Cl^-$ cotransporter at the basolateral membrane (NKCC) is driven by the Na^+ gradient and results in the accumulation of intracellular chloride concentrations greater than that which would be expected by electrochemical equilibrium [178]. This is important because of the presence of the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel at the apical membrane facing the ductular lumen [179]. Since Cl^- is above electrochemical equilibrium, a stimulus, such as secretin, that opens the apical membrane chloride channels will result in Cl^- secretion into the lumen [180,181]. A water channel, aquaporin-1, is present in the apical membrane and allows a water flux to be driven by osmotic forces [182].

At the same time, the Na^+ gradient across the basolateral membrane drives two processes that tend to alkalinize the cytosol. These are electrogenic Na^+/HCO_3^- cotransport [183,184] and Na^+/H^+ exchange [185]. The cycle is completed by an apical membrane Cl^-/HCO_3^- exchanger, AE2, which exchanges the secreted Cl^- in the lumen for intracellular HCO_3^- [53]. The net process is one of electrogenic bicarbonate secretion. The entire system is maintained by the Na^+,K^+-ATPase and the energy supplied by this transporter is transduced into net electrogenic bicarbonate secretion from blood to bile, chloride recycling into and out of the cell across the apical membrane, Na^+ and K^+ recycling across the basolateral membrane, and passive Na^+ entry into bile through the tight junctions.

This process of secretin-stimulated fluid secretion occurs primarily in the larger branches of the intrahepatic ducts, those with diameters greater than 15 μm and not primarily in the smallest ducts with diameters less than 8 μm [186]. The CTFR is a critical component of this process. It is a cyclic AMP-dependent apical membrane chloride channel on which this process depends. Similar to the situation in respiratory

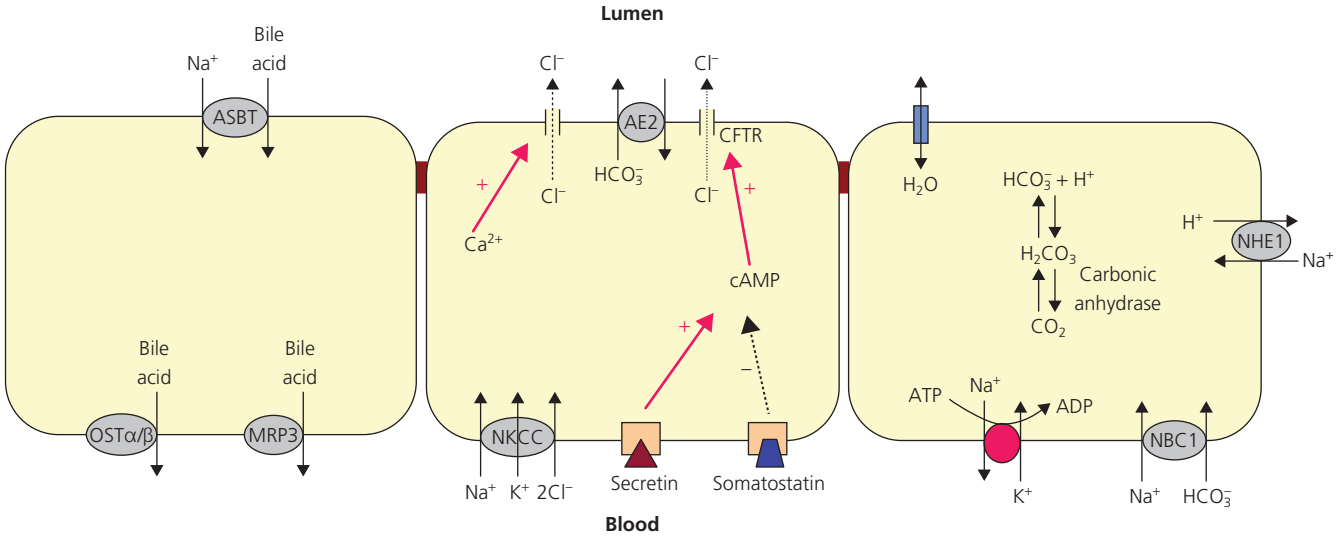

Figure 16.5 Bile duct epithelial cell transport. Electrogenic fluid and bicarbonate transport results from the involvement of multiple transporters. The $Na^+/K^+/2Cl^-$ cotransporter uses the energy of the Na^+ gradient to bring chloride into the cell at concentrations above its electrochemical equilibrium. Chloride is secreted into the lumen primarily via the cAMP-dependent chloride channel CFTR (cystic fibrosis transmembrane conductance regulator). It is exchanged for bicarbonate via AE2 at the apical membrane. The process is primarily regulated by secretin, which increases cAMP levels in the cell. Bile acids are absorbed from the lumen by the ASBT transport protein and transported into the blood by OSTα/OSTβ and MRP3. A water channel, aquaporin-1, is present at the apical membrane. These processes are represented in different cells only for clarity. See text for further details.

epithelia, a defect in this Cl^- channel, as occurs in cystic fibrosis, reduces fluid secretion [187]. Under these circumstances, a calcium-dependent chloride channel can substitute for CFTR and allow some biliary secretion to occur [188].

Hormonal regulation is prominent in ductular secretion. Secretagogues that raise intracellular cAMP, such as secretin, both directly activate the CFTR channel and induce insertion of CFTR, AE2, and aquaporin-1 into the apical membrane [189]. Calcium-mediated signaling induced by secretagogues such as acetylcholine and extracellular ATP also activate K^+ channels and thus stimulate secretion by a CFTR-independent mechanism [190].

In addition to transport of water and electrolytes, cholangiocytes transport bile acids. Bile acids serve both as transported substrates as well as regulators of cholangiocyte function [191]. Uptake of bile salts from the apical membrane of cholangiocytes is mediated by the apical sodium-dependent bile salt transporter SLC10A2/ASBT that is identical to the ASBT found in the brush border of ileocytes [42]. Efflux of bile salts from cholangiocytes across the basolateral membrane into portal circulation is mediated by several different proteins. These include the OSTα/OSTβ transporter [31,131], a truncated form of ASBT [192], the anion exchanger SLCO1A2/OATP1A2 [43], and in part by the ABC transporter ABCC3/MRP3 [65,193].

Mechanisms of regulation of bile formation

A fundamental characteristic of the liver is that it serves multiple different functions and is able to adapt its functional activity to suit physiological and pathophysiological demands. The ability of the liver to produce bile is thus quite variable and under some circumstances can be dramatically reduced. This reduction in the transport activity of hepatocytes and bile ducts manifests itself as cholestasis. Since bile formation is largely a consequence of the activity of organic ion transport proteins, the major mechanisms involved in regulation of bile flow are changes in the function, localization, and expression of these transport proteins. Other changes such as alterations in structure and function of tight junctions [194] and bile duct secretory processes [176,189] also play a role. This allows the liver to adapt to conditions that require changes in bile flow. The liver is able to modify its transport function by several mechanisms. In the short term (minutes to hours) changes in intracellular signaling result in modifications of transport proteins themselves [195], and redistribution of transport proteins between intracellular and plasma membrane pools [196]. In the longer term (hours to days), changes in expression of specific transport proteins play the more significant role.

Alterations in function of hepatocellular transporters

Signaling events within hepatocytes and biliary epithelial cells produce rapid changes in transport [197]. SLC10A1/NTCP is subject to rapid regulation of its function on several levels. First, since it transports two Na^+ ions with each negatively charged bile acid [72], the net transport is electrogenic and its rate is strongly influenced by changes in the intracellular negative membrane potential [74]. Hepatocytes normally have a membrane voltage of –30 to –40 mV but this changes in pathological states [48,198,199] with a consequent increase or decrease in bile acid entry via SLC10A1/NTCP.

In addition, SLC10A1/NTCP is phosphorylated and its phosphorylation state controls its distribution between intracellular and membrane sites [200–202]. The phosphorylation state of SLC10A1/NTCP is controlled by a balance of kinase and phosphatase activity and a cAMP-mediated increase in phosphatase activity reduces the phosphorylation state of SLC10A1/NTCP. The dephosphorylated molecule is preferentially translocated to the sinusoidal membranes from an intracellular pool [200].

Other hepatocyte transport proteins can also be directly phosphorylated but regulation by protein phosphorylation does not appear to be a major mechanism of control. Protein kinase (PK)C phosphorylation sites are present on MRP2 and BSEP [203] and canalicular organic anion transport is modulated by PKC activators [204]. The rat Oatp transporters, SLCO1A1 and SLCO1A4, have also been shown to be phosphorylated [205] and are inhibited by the activity of PKC [206]. There is additional evidence that phosphoinositide (PI)3-kinase plays a role in transporter regulation. It regulates insertion of transporters into the canalicular membrane (see below) and its activation also increases the transport capacity of canalicular membrane vesicles [207]. Thus, although phosphorylation of hepatic transporters does occur, its direct effect on transport activity appears to be minor and its more important effect is related to changes in trafficking of transporters to membrane sites.

Alterations in transporter targeting

Transport proteins exist in at least two separate pools, one at the appropriate plasma membrane, and the other in intracellular vesicles that have the ability to fuse and rapidly insert into the plasma membrane. Translocation between these pools is an important mechanism for rapid changes in the transport capacity of hepatocytes [196,208,209]. Rapid transporter redistribution is induced by bile acid accumulation [210,211], changes in cell volume [212,213], and hormone-induced increases in intracellular cAMP and intracellular calcium signals [209]. Regulated trafficking occurs for the bile acid uptake protein SLC10A1/NTCP, as well as most of the canalicular membrane efflux pumps including ABCB11/BSEP, ABCC/MRP2, ABCB1/MDR1, and ABCB4/MDR3 [208]. It is a more critical mechanism at the canalicular membrane where transport capacity is rate limiting for overall bile flow.

A complex interaction of signaling events controls transporter trafficking and many details are not yet understood. Trafficking of SLC10A1/NTCP is largely controlled by cAMP through it activation of PKA, release of intracellular calcium stores, and subsequent activation of PI3-kinase, calmodulin-dependent kinases and protein phosphatase 2B, which dephosphorylates SLC10A1/NTCP resulting in its translocation to the sinusoidal membrane [214].

The canalicular membrane transport proteins all actively shuttle between the canalicular membrane and an intracellular subapical vesicular pool [196]. Membrane translocation is stimulated by cAMP, cell swelling, or bile acid exposure and is dependent on the generation of lipid signaling molecules through the action of PI3-kinase [215]. Transporter recruitment to the canalicular membrane is entirely blocked by inhibitors of PI3-kinase and the lipid products of PI3-kinase themselves directly stimulate transporter insertion [196]. As discussed above, PI3-kinase therefore plays a dual role in regulation of transport, stimulating transporter insertion and directly modulating transporter activity. The response to cell volume changes also appears to involve PI3-kinase but hepatocyte swelling activates several different members of the mitogen-activated protein kinase family including Erk1/2 and p38 [197] as well as Src kinase.

Intracellular bile acids themselves rapidly increase the cellular capacity for maximal bile acid secretion. This process depends on the function of microtubules [216], and involves transformation of the morphology of a subcanalicular vesicle network from primarily small vesicles to one of elongated tubules [217]. This process results in the insertion of ABCB11/BSEP-containing vesicles into the canalicular membrane [207] and an increase in the capacity of the canalicular membrane to transport bile acids [218]. The mechanisms by which intracellular bile acids promote transport protein insertion into the plasma membrane involve direct activation of PKC isoforms, increases in intracellular calcium, and activation of stress kinases.

Dynamic redistribution of canalicular membrane transporters between intracellular and canalicular membrane sites is important for liver function during physiological conditions. Hepatocytes normally undergo cycles of swelling and shrinkage in response to the solute load imposed by meals and subsequent uptake of amino acids and sugars. Since cell swelling causes insertion of ABCC2/MRP2 and ABCB11/BSEP into the canalicular membrane and cell shrinkage causes their internalization from the canalicular membrane [197], this mechanism coordinates bile secretion rates with meals. Rapid redistribution of transporters appears to be less important for the uptake transporters at the sinusoidal membrane. Although cAMP-dependent translocation occurs for SLC10A1/NTCP, this uptake step is generally not rate

limiting and may not play a major role in regulation of bile formation. Transporter translocation has not been shown to be important for regulation of the OATP family of transport proteins.

Regulation of transporter gene expression

The primary mechanism by which the transport function of the liver is regulated is through changes in the expression levels of individual transport proteins. This mechanism allows the liver to adapt to changing metabolic needs and respond to the presence of drugs and xenobiotics. Coordinated expression changes occur after a number of pathological insults such as inflammation [16,219] and bile duct obstruction [220], and serve to both generate the cholestatic state and protect the liver from accumulation of toxic compounds such as intracellular bile acids. Control of expression of hepatic transport proteins has been actively investigated and a detailed understanding of the processes involved has now emerged [16,221].

Transcription of hepatic transporters, like all other cellular genes, is under the control of 5′ upstream regulatory element sequences and the presence of activator proteins in the nucleus that bind to those elements [222]. Transporter mRNA transcription rates are rapidly altered by changes in the amount or function of these nuclear transcription factors. Regulation of transcription factor activity can occur by activation of the transcription factors themselves, after proteolysis steps that activate or inactivate factors, or most importantly after ligand binding, which creates an active factor complex [222,223].

A major breakthrough in understanding how liver transporter gene expression is regulated came with the discovery that one particular nuclear receptor, the farnesoid X receptor (FXR), is a bile acid sensor [224–226]. FXR is a cytosolic transcription factor that binds bile acids with low micromolar affinity [226,227]. It is a member of a group of type II nuclear receptors that bind an array of hydrophobic ligands. Bile acid binding induces heterodimerization with another member of the family, RXR [228], and the heterodimer serves as the active transcription factor complex [229]. At least 12 different type II nuclear receptors are important in regulating a number of aspects of hepatic function including bile formation, lipid metabolism, drug metabolism, and xenobiotic excretion. In addition to bile acids, other activating ligands include oxysterol cholesterol derivatives, drugs and xenobiotics, fatty acids, and retinoids. The major transcription factors responsible for regulation of hepatic function are listed in Table 16.4.

This system represents a web of interactions whereby changes in the cellular concentration of a ligand, such as bile acid, produces a series of coordinated changes, both positive and negative, in expression of transporters, metabolizing enzymes, biosynthetic pathways, and even the transcription factors themselves. In many cases the activating ligands themselves are substrates for uptake, excretion, degradation or synthesis by the same proteins whose expression they regulate. The system can thus serve important protective functions by limiting accumulation and returning the liver to a state of homeostasis. In some circumstances, such as in cholestasis, these compensatory changes are insufficient to prevent liver injury or can even contribute to injury. The extent to which nuclear receptors control hepatic function, and their proven ability to prevent toxicity in some circumstances makes hepatic nuclear receptors attractive therapeutic targets [17,221,230].

The complexity and coordinated action of the pathway is best illustrated by considering the responses initiated by individual nuclear receptors. FXR is a bile acid-binding protein that preferentially binds the moderately hydrophobic bile acids chenodeoxycholate and cholate, but not hydrophilic bile acids like ursodeoxycholate or extremely hydrophobic ones such as lithocholate. On ligand binding it dimerizes with RXR and activates expression of a number of important genes involved in bile acid and lipid metabolism [231,232]. Key FXR-activated genes are those of the canalicular bile salt export pump ABCB11/BSEP, the canalicular conjugated bilirubin transporter ABCC2/MRP2, the phospholipid flippase ABCB4, the basolateral bile salt export transporter OSTα/OSTβ, and the small heterodimer partner protein (SHP). SHP is important in that it is a member of the nuclear receptor family that lacks DNA-binding properties of its own, but interferes with activation by other nuclear receptors such as RAR/RXR heterodimers, HNF4α, LRH-1 and PPARα. Partially as a result of induction of SHP, FXR activation by bile acids subsequently decreases expression of the bile acid uptake protein SLC10A1/NTCP and 7α-cholesterol monooxygenase (CYP7A1), the first committed step in bile acid synthesis from cholesterol. Elevated cellular bile acids thus decrease their own synthesis and uptake while increasing their excretion. The net effect is to diminish cellular bile acid accumulation and prevent cytotoxicity.

Two other nuclear receptors, PXR and CAR, are primarily xenobiotic receptors and are responsible for the metabolic response of the liver to many drugs as well as the regulation of non-bile acid organic ion transport [233,234]. PXR is activated by many drugs including rifampicin as well as hydrophobic bile salts such as lithocholic acid. On ligand binding and dimerization with RXR it directly activates expression of drug-metabolizing members of the P450 family, CYP3A and CYP2B, as well as the cation transporter ABCB1/MDR1, the anion transporter ABCC2/MRP2, and members of the drug-conjugating family of glutathione-*S*-transferases. CAR, the constitutive androstane receptor, is the only member of the type II nuclear receptor family that has activity in the absence of ligand. It is activated by phenobarbital, and bilirubin is also a ligand. In response to CAR activation there is up-regulation of the drug-metabolizing members of the CYP3A and CYP2B family. In addition, it

Table 16.4 Nuclear receptors/transcription factors regulating hepatic transport protein expression

Nuclear receptor	Alternative name	Ligands	Genes activated	Genes inactivated	Major functions
FXR	NR1H4	Bile acids, especially CDCA, DCA, CA, LCA	BSEP, SHP, MRP2, OATP1B3, ABCB4, PXR, OSTα/β, CYP3A4, UCT2B4, UGT2B7	NTCP, CYP7A1	Major bile acid sensor Increases detoxification and excretion Decreases bile acid synthesis and uptake
SHP	NR0B2			CYP7A1, CYP8B1, NTCP, ASBT, HNF4α	Induced by FXR Inhibits bile acid synthesis and uptake via effects on HNF4α and HNF1α
PXR	SXR, NR1I2	Numerous xenobiotics, rifampicin, statins, LCA, dexamethasone, UDCA	CYP3A4, CYP2B6, MDR1, MRP2, GSTA2, UGT1A1	CYP7A1	Induction of drug metabolism and excretion pathways Considerable overlap with CAR
CAR	NR1I3	Bilirubin, phenobarbital, xenobiotics	CYP3A, CYP2B6, CYP2A6, OATP1B1, MRP2, UGT1A1		Induction of drug metabolism and excretion pathways Considerable overlap with PXR Activated by bilirubin Phenobarbital promotes nuclear translocation
LXRα	NR1H3	Oxysterols, 6α-hydroxy bile acids	ABCG5/8, ABCA1, CYP7A, CYP8B, CYP3A4, SHP		Regulator of cholesterol metabolism and elimination
RXR	NR2B1	9-*cis*-retinoic acid	Required for function of FXR, PXR, LXR, and CAR		Heterodimerization partner for FXR, PXR, CAR , LXR, RAR Activity inhibited by cytokines
RARα	NR1B4	All-*trans*-retinoic acid	NTCP, MRP2, ASBT		
VDR	NR1I1	1α,25-dihydroxyvitamin D3, LCA	CYP3A, SULTs		Induction of bile acid hydroxylation, sulfation, and export
HNF4α	NR2A1		CYP7A1, CYP8B1, NTCP, HNF1α		Activity reduced by bile acids, which reduces HNF1α expression and down-regulates bile acid synthesis
HNF1α	MODY3, TCF1		OATP1B1, NTCP, CYP7A		Major regulator of glucose homeostasis Reduced activity contributes to decreased bile acid uptake and synthesis
PPARα	NR1C1	Fatty acids, fibrates, statins, NSAIDs	ASBT, ABCB4, UGT2B4	CYP7A1	Increases β-oxidation, biliary phospholipid secretion Down-regulates bile acid synthesis

CA, cholic acid; CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; LCA, lithocholic acid; NSAID, nonsteroidal antiinflammatory drug; UDCA, ursodeoxycholic acid.

increases expression of each of the genes involved in bilirubin clearance, including OATP1B1, ABCC2/MRP2, and the conjugating enzyme UDP-glucuronosyl transferase (UGT1A1) [235].

LXR is an oxysterol-binding protein that is critical in the regulation of hepatic lipid metabolism and cholesterol transport [236,237]. Its ligands are primarily oxysterol cholesterol derivatives and fatty acids but it can be activated by bile acids as well. Important proteins that are under the control of LXR are the cholesterol export protein ABCA1, the canalicular cholesterol half-transporters ABCG5/ABCG8, and other genes involved in cholesterol and fatty acid metabolism such as lipoprotein lipase, cholesterol ester transfer protein and apolipoprotein E. PPARα, another hepatic type II nuclear

receptor, binds fatty acids and fibrates and plays a key role in regulation of hepatic fatty acid biosynthesis and oxidation. Its activation up-regulates expression of the canalicular phospholipid transport protein ABCB4, thus promoting biliary phospholipid secretion [238].

Bile acid-induced expression changes

Bile acid transport is regulated by coordinated actions of nuclear receptors, particularly FXR, on specific transport proteins. In cholestatic syndromes, hepatic bile acid concentrations rise, FXR is acitivated, and a bile acid program of transcription changes ensues. The ability of the liver to down-regulate NTCP expression during cholestasis is critical because this transporter is primarily responsible for bile acid entry into the hepatocytes and preventing entry of bile acids while secretion is impaired is necessary to avoid cellular toxicity. Promoter elements that control NTCP expression are complex and vary between species. In humans important elements are HNF1, HNF4α, STAT5 [239], and the RAR/RXR heterodimer [240,241]. Its expression is sharply down-regulated in response to an increase in intracellular bile acids and this is mediated by several mechanisms. First, there is an FXR-mediated increase in SHP expression. This non-DNA binding member of the nuclear receptor family is a negative regulator and inhibits activation by the RXR/RAR heterodimer important for SLC10A1/NTCP expression [242,243]. Second, both NTCP and OATP1B1 expression depend on the nuclear receptor HNF1α, which is itself transactivated by HNF4α. Bile acids inhibit HNF4α-mediated transactivation and may directly inhibit HNF1α as well [241,244].

In contrast to NTCP, which is down-regulated in cholestasis, expression of the canalicular bile salt exporter BSEP is maintained. The promoter elements of the *BSEP* gene include C/EBP-β, HNF3β, and importantly the FXR/RXR heterodimer. BSEP is thus directly up-regulated by bile salt accumulation. This is physiologically appropriate as a mechanism to keep intracellular bile salts low in the face of cholestasis. Other important proteins that must respond to changes in bile acid concentrations are the enzymes involved in bile acid synthesis, CYP7A1 and CYP8B1. Expression of both these proteins is inhibited by an SHP-dependent mechanism [245]. Bile acid conjugation reactions are up-regulated as well via FXR elements in the promoters for the enzymes responsible for conjugation and sulfation. The overall consequences of this bile acid loop are up-regulation of canalicular export and conjugation, and down-regulation of sinusoidal entry and bile acid synthesis in a coordinated fashion that minimizes cellular bile acid toxicity.

Organic anion-induced expression changes

Similar coordinated changes occur for organic anions primarily under the control of PXR and CAR. Rising bilirubin concentrations activate CAR with subsequent effects on expression of transport proteins and drug-metabolizing enzymes. The primary bilirubin uptake protein, OATP1B1, has both PXR and CAR elements in its promoter and the canalicular organic ion transporter, MRP2, has promoter elements for PXR, CAR, FXR, and the RAR/RXR heterodimer [234,246]. These can result in both up-regulation and down-regulation depending on the circumstance. Many drugs stimulate net organic anion transport. Rifampicin and phenobarbital are agonists for PXR and CAR respectively, and thus stimulate expression of both uptake and export transporters. The drug-metabolizing enzymes of the CYP3A and CYP2B families and the bilirubin-conjugating enzyme UGT1A1 all have CAR and/or PXR elements. Consequently elevated intracellular bilirubin and drug concentrations lead to increased expression of the proteins necessary for uptake, metabolism, and excretion. Under normal conditions this serves a detoxification function, although this well-tuned response can be altered by pathological conditions. For example, during inflammation, cytokine-dependent changes in expression levels of the nuclear receptors themselves appear to dominate [240,247] and both OATP1B1 and MRP2 expression are down-regulated [248,249], thus interfering with the detoxification function of the liver. This is discussed in detail below.

Regulation of the cytoskeleton and tight junctions

Alterations in the structure of the cytoskeleton and tight junctions occur in several conditions in which bile flow is reduced. Actin filaments serve as an intracellular scaffolding mechanism and are necessary for the targeted delivery of vesicles and the maintenance of cell polarity. Loss of the normal uniform actin filament distribution and clumping of actin filaments around the bile canalicular membrane have been observed in multiple different models of cholestasis including bile duct obstruction and with cholestatic bile acids and drugs [250,251]. Vesicular transport along microtubules mediated by the molecular motor protein kinesin is also inhibited in cholestasis [252] and these processes together alter transport function by changing the pattern of transport protein insertion and retrieval from the cell membranes.

The paracellular pathway, controlled by the proteins that make up the tight junctional complex, is also altered in cholestasis [194]. Both bile duct obstruction and estrogen-induced cholestasis produce changes in the distribution of the intracellular tight junction protein ZO-1 [253] and a reduction in the number of claudin strands that compose the tight junctional seal [254]. These effects produce an increase in the permeability of the tight junctions to large molecules [254]. Alterations in the organization of tight junction proteins occur in human cholestatic diseases [255] and may contribute to the decrease in bile flow under these conditions.

Regulation of bile duct secretion

Short-term regulation as a consequence of transport protein phosphorylation is the major mechanism of regulation of bile

duct secretion [171,176]. The rate-limiting step for biliary bicarbonate secretion is the activity of the CFTR chloride channel at the apical membrane (see Fig. 16.5). Channel activity of CFTR is controlled by PKA-mediated phosphorylation of its regulatory domain [256,257]. In the biliary epithelium, a secretin-induced increase in intracellular cAMP is the primary mechanism that activates chloride channels and net secretion [180]. In addition secretin also causes a microtubule-dependent insertion of aquaporin-1 water channels into the apical membrane, further enhancing fluid secretion [182].

Other hormones and neuropeptides also play a role in regulation of ductular secretion, particularly in modulating the effects of secretin. Somatostatin interacts with $SSSTR_2$ receptors on the bile duct epithelial cells and decreases cAMP and biliary secretion [258]. Gastrin has no effect on basal secretion but inhibits secretin-induced choleresis [259]. Ductular fluid secretion is stimulated by bombesin [260], VIP [261,262], and acetylcholine [261,262]. It is inhibited by endothelin [263].

An additional mechanism that regulates bile ductular secretion is the presence of micromolar concentrations of ATP in the ductular lumen [264]. In response to cell swelling and other stimuli, hepatocytes are able to release ATP into the canalicular space [265,266]. This ATP interacts with purinergic P_{2U} receptors on the apical membrane of cholangiocytes, which increases intracellular calcium, activates chloride channels, and stimulates secretion [267]. In addition ATP may be released by the cholangiocytes themselves, resulting in a mechanism for both autocrine and paracrine regulation of bile duct function.

Mechanisms of cholestasis

Cholestasis is defined as the cessation or reduction of bile flow in a pathological situation. Cholestasis is a coordinated response of the liver and does not reflect merely nonspecific injury. It may be hereditary, due to genetic defects in transporter proteins or bile duct development, or acquired as a result of exposure to toxins or immune responses. The general principle is that transcellular transport into bile is diminished but at the same time bile acid accumulation in the cell is minimized. Cholestasis is typically associated with the up-regulation of alternative sinusoidal efflux pathways for toxins, conjugated bile acids, conjugated bilirubin, leukotrienes, and GSH. There is frequently preservation of biliary excretion of drugs and an increase in hepatocellular uptake of amino acids, perhaps as a mechanism to support the massive protein synthesis required for the acute-phase reaction.

Other changes in liver function and structure also occur in many cholestatic settings. These include changes in cytoskeletal architecture [251], alterations in tight junctional permeability [254], a decrease in the fluidity of the canalicular membrane [268], alteration in cell polarity, and disruption of cell-to-cell communication via gap junctions [110,220,269]. Generally, cholestasis is associated with disruption of the normal enterohepatic and nephrohepatic circulations. There is increased cholehepatic shunting and an increase in renal elimination of compounds generally excreted in bile as a result of sinusoidal efflux from hepatocytes into blood [10]. This section considers the specific changes that occur in several cholestatic situations. A number of detailed reviews have appeared on this subject [9,10,15,270–273].

Acquired cholestatic syndromes

Inflammatory cholestasis

Cholestasis is frequently associated with inflammation, particularly that caused by Gram-negative bacteremia. Examples include sepsis, alcoholic hepatitis, idiosyncratic drug reactions, total parenteral nutrition, and cholestatic variants of viral hepatitis [274]. Inflammatory cholestasis is one of the most frequent causes of jaundice in hospitalized patients [219]. Inflammatory cholestasis is mediated primarily by cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1β and IL-6, which are released in response to bacterial lipopolysaccharide (LPS) stimulation of activated macrophages and Kupffer cells. The effect of these cytokines has been extensively studied in several experimental models [247,275] and to a lesser extent directly in human disease.

The phenomenon of inflammatory cholestasis is manifested by decreased expression of the transporters responsible for bile acid (NTCP) and organic ion (OATP1B1) uptake, and decreased expression of the canalicular membrane transporters responsible for secretion of bile acids and organic anions (BSEP and MRP2) [249,272,276]. Bile acid synthesis is decreased as well, with reduction in the activity of CYP7A1 [277]. At the same time there is preservation or up-regulation of transport systems responsible for preventing intracellular accumulation of toxic substrates such as the sinusoidal anion efflux pump ABCC1/MRP1 and the canalicular cation efflux pump ABCB1/MDR1.

Although the mechanisms for these changes are multifactorial and only partially understood, they result primarily from cytokine-induced changes in the expression of transcription factors and only secondarily from ligand-induced effects such as the activation of FXR by increased levels of intracellular bile acids [278]. In rodents, LPS causes a decrease in transcriptional activity of the RXRα/RARα heterodimer, and HNF1α. Both of these bind to the *NTCP* promoter and thus the net effect is to decrease NTCP expression. IL-1β plays a major role in this effect as it has been shown to cause export of RXR from the nucleus [279]. Since RXR is the common heterodimer partner for the type II nuclear receptors FXR, PXR, and CAR, its export from the nucleus reduces the expression of multiple genes including those of NTCP, MRP2, BSEP, and OATPs. NTCP expression is further

down-regulated by an additional reduction in transcription factors that bind to specific response elements in the NTCP promoter region, specifically HNF1α [280] and footprint B binding protein [240]. In addition to IL-1β, TNF-α and IL-6 also cause decreases in transporter gene expression [275].

The net result of all these effects is a profound and rather global phenotypic change in the transport function of the liver. There is impaired uptake of bile acids and other organic ions, impaired canalicular secretion of these and many other substrates, and increased sinusoidal export of bile acids, conjugated bilirubin and other molecules that would normally have been secreted into bile. While some of these substances are eliminated by renal excretion, in general this does not keep pace with production and will produce the characteristic cholestatic syndrome of conjugated hyperbilirubinemia and elevated serum bile acids.

Bile duct obstruction

Obstructive cholestasis is a pathological condition resulting from obstruction in the extrahepatic bile duct, commonly caused by choledocholithiasis or neoplasm. Bile duct obstruction rapidly results in an increase in biliary pressure, an increase in biliary and intracellular bile acid concentrations, and a series of adaptive changes in the liver and bile ducts that result in cholestasis [281]. The molecular events occurring after bile duct obstruction have been extensively studied in the model of common bile duct ligation in rats [282,283]. Although there have been fewer studies in humans, the overall picture is similar in both species and several important observations from the rat model help to illustrate the changes in hepatic function that occur in response to obstruction.

Although conceptually simple, bile duct obstruction produces complex effects on the liver. The initial obstruction results in an increase in bile acid concentrations in the bile duct lumen and within the hepatocytes [281] and an increase in the pressure within the biliary tree. This produces a primary effect in which elevated bile acids, primarily by acting as ligands for FXR and other nuclear receptors, induce a series of changes in transporter expression, both positive and negative, in both hepatocytes and cholangiocytes. Secondarily, the chronic obstruction results in inflammation and cytokine production and many of the cytokine effects on transcription factors occur as described for inflammatory cholestasis.

There are several characteristic changes in gene expression [10]. First, there is a decrease in the expression and activity of the sinusoidal uptake transporters for bile acids (NTCP), bilirubin, and other organic ions (OATP family members). Second, there is decreased expression of the enzymes responsible for bile acid synthesis, primarily CYP7A1 and CYP8B1. Third, canalicular secretion of organic anions via MRP2 is strongly down-regulated [249], but canalicular bile acid excretion via BSEP, although decreased, is less severely affected [284]. This results in a decrease in transport with relative preservation of export of bile acids to minimize the toxic accumulation of bile acids in hepatocytes. Finally, transporters involved in detoxification and providing alternative exit pathways for bile acids are up-regulated. These include the canalicular organic cation transporter ABCB1/MDR1, the phospholipid transporter ABCB4/MDR3, and the sinusoidal efflux pumps ABCC3/MRP3 and ABCC4/MRP4 [285,286]. The net effect of these changes is to slow or stop the formation of bile, limit the intracellular accumulation of bile acids, and retain or increase the ability to efflux potentially toxic compounds from the hepatocytes into the blood where they can undergo renal excretion.

Simultaneously, changes in cholangiocytes occur as well [287]. Bile duct cells proliferate, the apical membrane bile acid uptake protein in cholangiocytes, ASBT, is preserved or possibly up-regulated, and the expression of the cholangiocyte basolateral efflux transporter OSTα/OSTβ is increased via the activity of FXR [288]. The net effect of these changes is to allow a greater fraction of biliary bile acids to be reabsorbed by the bile duct.

Gene expression changes after bile duct obstruction are dominated by the effects of bile acid binding to FXR, subsequent increased transcription of the nuclear receptor SHP, and direct inhibitory bile acid effects on two other important transcription factors, HNF4α and HNF1α [16]. As discussed above, the most critical molecular event for prevention of hepatocellular toxicity is the down-regulation of NTCP by mechanisms including an FXR-induced increase in SHP [242], and bile acid-induced inhibition of HNF4α and HNF1α [289]. Finally, SHP also inhibits the ability of the glucocorticoid receptor to activate SLC10A1/NTCP expression and this may play a role as well [290].

Posttranslational mechanisms also play a role in the short-term response to bile duct obstruction [12]. These include relocalization of BSEP and MRP2 from the canalicular membrane to an intracellular site and similar relocalization of NTCP as well. These effects may be partially mediated by an increase in cAMP within the hepatocytes [291].

Estrogen-induced cholestasis

Estrogens and anabolic steroids frequently cause a form of bland hepatocellular cholestasis that manifests clinically as jaundice and pruritis but histologically shows only the morphological characteristics of cholestasis, such as inspissated bile and intrahepatocyte bile plugs, without inflammation or bile duct injury. Sensitivity to estrogen-induced cholestasis varies considerably between individuals and correlates with the risk of development of intrahepatic cholestasis of pregnancy [292,293].

Estrogen-induced cholestasis is a complex process resulting from changes in gene expression, direct inhibition of transport proteins, and possibly other factors. The administration of ethinylestradiol to male rats has frequently been

used as an experimental model to study the pathogenesis of estrogen-induced cholestasis. In this model there is a dramatic decrease in expression of sinusoidal uptake transporters as well as canalicular membrane export transporters. Ntcp expression is reduced and this is associated with a reduction in bile flow [284,294]. In addition, decreased expression of Oatp1A1, the rat OATP responsible for the sodium-independent uptake of bile acids, has also been observed [294]. At the canalicular membrane, Bsep expression is also reduced but as in the other models of cholestasis, this effect is much smaller than that on Ntcp [220]. Repeated administration of ethinylestradiol also reduces Mrp2 protein levels and causes impaired canalicular excretion of Mrp2 substrates such as bromosulfophthalein, bilirubin, and GSH conjugates [249]. In addition to the down-regulation of transporters, there is also evidence that conjugated estrogens can directly inhibit Bsep. The inhibitory site appears to be on the external (bile) side of the canalicular membrane and occurs after the conjugated estrogens have been secreted by ABCC2/Mrp2 [295,296]. The net result is impaired bile acid secretion.

The exact mechanisms of the gene expression changes induced by estrogens are not known and it does not appear that conjugated estrogens themselves are direct ligands for FXR. It is conceivable that once cholestasis is initiated it can be perpetuated by the retained compounds such as hormone metabolites and bilirubin, which act as nuclear receptor ligands and may alter the transcriptional activity of the respective target gene [10]. Recent studies in transgenic and knockout mouse models suggest that estrogen-induced cholestasis and hepatotoxicity requires the estrogen receptor (ER)α and not other nuclear receptors such as ERβ, FXR, PXR, or CAR [297]. Activation of ERα by the estrogen receptor agonist 17α-ethinylestradiol leads to decreased expression of the bile acid transporters (NTCP, OATP1B1 and BSEP), likely through antagonizing HNF4 activity. It also alters the bile acid biosynthesis enzymes CYP7A1, CYP7B1, and CYP8B1. The net result is inhibition of bile acid secretion and alteration of bile acid composition that causes the characteristic hepatocyte degeneration and intrahepatic cholestasis. Although ERα appears to have the primary initiating role, the changes in bile acid concentrations clearly have secondary effects, although these may not be enough to prevent toxicity. It is notable that an FXR agonist, 6-ethylchenodeoxycholic acid, has protective effects in estrogen-induced cholestasis [298], suggesting that FXR-mediated gene expression changes may be compensatory but insufficient to provide full protection.

Intrahepatic cholestasis of pregnancy

Intrahepatic cholestasis of pregnancy (ICP) is a reversible form of cholestasis that may develop in susceptible individuals during the third trimester of pregnancy. This syndrome is characterized by pruritus and cholestasis during the third trimester and accounts for about 20% of pregnancy-associated liver disorders [292,293]. An increased risk for stillbirths and subsequent gallstones in these individuals has been described [121]. Serum bile acids are normal and γ-glutamyltranspeptidase (GGT) may be normal to elevated. Another subtype of ICP with elevated serum bile acids and normal GGT has also been described.

While the causative mechanism of ICP has not been determined, several well-demonstrated gene associations have begun to provide insights into this disorder. First, there is a strong genetic and or environmental component to this phenomenon. For example, up to 14% of pregnancies in the Chilean population may be affected [299], and other regional and familial clusterings have been observed [300,301]. Polymorphisms of the gene for the canalicular membrane phospholipid transporter ABCB4/MDR3 have been identified in high frequency in patients experiencing ICP [302,303]. The elevated bile acid subtype of ICP has also been associated with dysfunction of ABCB11/BSEP [304,305]. However, a group of Finnish women with ICP failed to exhibit genetic mutations of *ABCB11/BSEP*, *ATP8B1/FIC1* or *ABCB4/MDR3*, suggesting the etiology of ICP may be heterogenous [306] and that cholestatic estrogen metabolites may play a critical role.

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is an autoimmune disease that develops in genetically susceptible individuals exposed to an environmental trigger. The inflammatory process of PBC primarily affects the small bile ducts and manifests as intense pruritus initially and jaundice in late stages.

Knowledge of adaptive changes in transporter gene expression in PBC is limited due to lack of animal models and is derived mainly from patient liver biopsy specimens. Available data suggest that the alterations in transporter gene expression in PBC are stage specific [133,307]. In early stages of PBC (Ludwig stage I and II), expression of bile salt and organic anion transporters is well preserved [276]. In later stages (III and IV), OATP1B1 and to a lesser extent NTCP expression are down-regulated, while MRP3 and MDR1 expression are up-regulated. MRP2 expression decreases with progressive cholestasis [307]. Unlike ICP and familial cholestasis syndromes, neither *BSEP* nor *ABCB4/MDR3* gene mutations are more frequent in patients with PBC than controls [308]. Eventually, immune-mediated bile duct injury in PBC results in progressive cholestasis. The resulting inflammation with production of cytokines together with regurgitated toxic bile acids leads to the observed changes in transporter expression [10]. Together, these changes represent adaptive rather than causative changes in chronic cholestasis.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is characterized by inflammation, fibrosis and obstruction of large and medium-sized intrahepatic and extrahepatic bile ducts [309]. The

disease course is variable and prognosis is difficult to predict because of the lack of good models. The majority of patients with PSC have a history of inflammatory bowel disease, particularly ulcerative colitis [310].

Changes in transporter proteins in PSC have been studied less systematically than for PBC. Recently, the ABCB4 knockout mouse has been suggested as a model for PBC [311]. These mice do not secrete phospholipids and this results in high biliary concentrations of toxic free bile salts that weaken tight junctions and damage basement membranes. This allows leakage of bile salts into the portal area inducing inflammation and subsequently concentric rings of fibrosis by activation of myofibroblasts [14].

The steroid and xenobiotic receptor (PXR) mediates protection against bile acid-induced liver injury in cholestatic animal models [312]. Functional polymorphisms of the *PXR* gene influencing disease susceptibility or disease progression in patients with PSC have been evaluated and it has been suggested that *PXR* gene variants may modify disease course in PSC [313]. It is interesting to note that ursodeoxycholic acid and rifampicin are known ligands for PXR, which may explain their therapeutic benefits at least in the early stages of PSC.

Hereditary cholestasis syndromes

Several inherited defects in hepatic transport proteins result in clinically significant cholestatic liver diseases. In addition they provide fundamental insights into the function of the transporters and the consequences of their failure. Progressive familial intrahepatic cholestasis (PFIC), also known as Byler disease, is an autosomal recessive disorder that was first described in an Amish kindred [314]. It is now known that there are several distinct subtypes of this disorder and molecular and genetic studies have identified the genes responsible for three of these.

PFIC I is caused by a defect in a protein produced by the familial intrahepatic cholestasis (*FIC*)*1* gene. This gene maps to chromosome 18q21–22 and at least five mutations have been identified [315]. The *FIC1* gene encodes a P-type ATPase that may be involved in the transport of aminophospholipids. It is expressed in the liver, small intestine and pancreas, and a defect can cause cholestasis, diarrhea, or pancreatitis. How deficiency of FIC1 activity leads to cholestasis is unclear, but a reduction in FIC1 activity appears to cause reduced FXR activity and nuclear translocation resulting in diminished canalicular secretion of bile acids secondary to down-regulation of ABCB11/BSEP [129]. Biochemical findings include normal serum GGT but high serum bile acid concentrations [316]. Liver transplantation is presently the main therapeutic option for this progressive disease, although some success with external partial bile diversion through a jejunal stoma has been described [317–319].

Benign recurrent intrahepatic cholestasis (BRIC) is a clinically milder variant of PFIC I. It is a recurrent cholestatic disorder of adults that was first described by Summerskill and Walshe in 1959 [320]. Houwen and colleagues [321] have mapped the genetic defect in BRIC to the *FIC1* gene. While PFIC I leads to progressive liver disease, BRIC is a milder nonprogressive disease presenting either in childhood or adulthood. DNA sequencing of the *FIC1* gene showed that deletions, frameshifts and nonsense mutations appear to lead to the PFIC I phenotype while missense mutations were found in the patients with BRIC [322,323], suggesting that the *FIC1* gene mutation in BRIC may have residual activity, while the protein is absent or nonfunctional in patients with PFIC I. Another subset of BRIC has been described as BRIC 2 disease, which results from ABCB11/BSEP dysfunction [324]. There has also been a suggestion that temporary endoscopic nasobiliary drainage may induce long-lasting remission of cholestasis in BRIC patients [325].

PFIC II is a subtype of Byler syndrome that presents with permanent jaundice from the onset and progressive liver failure but is caused by a different genetic abnormality. The PFIC II locus has been mapped to the *ABCB11/BSEP* gene on chromosome 2q24 [103]. Immunostaining of the liver of these patients shows an absence of BSEP at the canalicular membrane [98]. These patients have a near total absence of bile acids from the bile and consequently develop bile acid hepatotoxicity due to accumulation within the hepatocytes. The relatively severe phenotype and progressive liver failure resulting from absence of ABCB11/BSEP in PFIC II demonstrates the importance of this molecule in preventing the toxic effects of bile acid accumulation in hepatocytes [326]. It is noteworthy therefore that ABCB11/BSEP expression is relatively preserved in most acquired cholestatic syndromes. Total loss of ABCB11/BSEP, as in PFIC II, results in severe liver toxicity, while ABCB11/BSEP expression is somewhat preserved in BRIC 2 [327].

PFIC III is a subtype that presents as somewhat more aggressive disease and, unlike PFIC I and PFIC II, affected patients have a high GGT and normal serum bile acids [120]. It is caused by a mutation of the *ABCB4/MDR3* gene on chromosome 7q21 [328] and leads to near absence of PC secretion into the bile. Since phospholipids are crucial for forming micelles with bile acids, the absence of biliary phospholipid increases free bile acid concentrations in the biliary tract. The consequences of this are injury and proliferation of bile ductules, resulting in the release of GGT. Heterozygous *ABCB4/MDR3* mutations are associated with milder diseases that manifest in adulthood. Recent studies suggest that defects in *ABCB4/MDR3* may be involved in hereditary susceptibility to cholelithiasis in association with cholestasis as well as cholestasis of pregnancy [329,330].

Dubin–Johnson syndrome

Dubin–Johnson syndrome is a rare autosomal recessive disorder characterized by chronic predominantly conjugated hyperbilirubinemia. Serum bile salt levels are normal and

hepatobiliary transport of bile salts is unaffected. This syndrome results from the absence of ABCC2/MRP2 protein in the canalicular hepatocyte membrane because of mutations of the *ABCC2/MRP2* gene [331,332]. Absent ABCC2/MRP2 function may be compensated by increased expression of ABCC3/MRP3 at the basolateral membrane, as suggested by immunofluorescence studies [132].

Prospects for pharmacotherapy

The goal of therapy for cholestatic disease is to first eliminate the primary cause of the injury and, if that is not possible, to secondarily prevent the hepatic injury that results primarily from the accumulation of bile acids and other toxic metabolites. As discussed above, the response to cholestasis and bile acid accumulation already serves this purpose but in many cases it is inadequate to prevent liver injury and in some cases the response itself may exacerbate injury. With increased understanding of how nuclear receptors regulate liver function there is active research effort to use this information to develop specific and more effective treatments for cholestasis.

Ursodeoxycholic acid (UDCA) and rifampicin have both been used as treatments for cholestasis and appear to act partly by nuclear receptor-mediated changes in gene expression. In a landmark randomized control study [333], 10 otherwise healthy individuals with cholelithiasis undergoing elective cholecystectomy were each assigned to receive UDCA (1 g/day for 3 weeks), rifampicin (600 mg/day for 1 week), or no medication prior to surgery. Subsequently, wedge liver biopsy specimens were analyzed for changes in gene expression. UDCA stimulated the expression of BSEP, ABCB4/MDR3 and MRP4. UDCA also became the predominant bile acid and lowered the biliary cholesterol saturation index, providing functional support for the observed increased expression of the canalicular phospholipid transporter ABCB4/MDR3. Rifampicin enhanced bile acid detoxification as well as bilirubin conjugation and excretion as reflected by increased expression of CYP3A4, UGT1A1, and MRP2. The beneficial effects of UDCA and rifampicin were therefore complementary in the treatment of cholestatic liver diseases [333].

Effects of UDCA on expression of hepatobiliary transporters takes place at multiple transcriptional and posttranscriptional levels and results in increased expression of transporters, promoting elimination and detoxification of potentially harmful compounds [334,335]. UDCA stimulates CYP3A4/CYP3A11 expression in human hepatocytes [336,337], while CYP7A1, the key enzyme system for bile acid synthesis, is down-regulated [338]. UDCA effects on transporter and enzyme expression, except up-regulation of BSEP, are independent of FXR, although other nuclear factors including PXR and CAR may be involved [339].

Activation or inhibition of specific nuclear receptors with synthetic agonists/antagonists offers tremendous therapeutic possibilities but is complicated by the many interactions and potential undesired effects of some target compounds. FXR, as master controller of bile acid-mediated effects, is an obvious target [340]. FXR activation increases expression of BSEP and ABCB4 thus increasing bile salt and phospholipid content of bile. Both of these effects are potentially beneficial for cholesterol gallstone disease. However, reduced expression of CYP7A1 would reduce de novo bile acid synthesis and could have the opposite effect. Perhaps for these reasons, initial experimental results with specific FXR agonists have produced contradictory findings. FXR agonists have shown hepatoprotective effects in models of obstructive [341] and estrogen-induced [298] cholestasis, but FXR inhibition is beneficial in other models suggesting a complex role of FXR in the response to cholestasis [342].

PXR and CAR are both involved in the response to xenobiotics and promote excretion and detoxification. Rifampicin, long known to relieve cholestasis-associated pruritis [343], is a ligand for PXR and activation of this nuclear receptor induces expression of drug export proteins MRP2 and MDR1 as well as the cytochrome P450 isoforms that detoxify hydrophobic bile salts [312,344]. PXR agonists have been shown to prevent lithocholic acid-induced liver toxicity [344] and may have potential for reducing liver toxicity from other cholestatic conditions. It is likely that knowledge of the control of expression of hepatobiliary transporters and detoxification enzymes will lead to the development of a new generation of nuclear receptor agonists/antagonists to enhance cytoprotective responses, prevent toxicity and improve the long-term outcome of patients with cholestatic liver diseases.

D NUTRITION

17 Carbohydrate assimilation

Eric Sibley

Structure and intake of carbohydrates, 429
Carbohydrate digestion, 433
Absorption of monosaccharides, 437

Carbohydrate assimilation in the gastrointestinal tract requires the breakdown of carbohydrate molecules into their constituent building blocks, monosaccharides, for absorption and transport into the circulatory system. The process of carbohydrate digestion involves the hydrolysis of starch in the lumen of the intestine (*lumenal digestion*) and the hydrolysis of oligosaccharides and disaccharides by enzymes located in the apical membrane of enterocytes (*mucosal digestion*). Following these phases of digestion, the process of carbohydrate assimilation is completed with the transport of monosaccharides across the apical and then basolateral membranes of enterocytes [1,2].

Structure and intake of carbohydrates

Carbohydrates account for 40%–60% of the average caloric energy intake in humans. The primary carbohydrates in the human diet are starches and simple sugars, including disaccharides such as sucrose and lactose, and monosaccharides such as glucose and fructose [3–5]. The basic molecular structure of carbohydrates consists of a series of aldehyde and ketone sugars linked by hydroxyl groups [6]. Monosaccharides consist of a single aldehyde or ketone unit and have the molecular formula $(CH_2O)_n$. Disaccharides consist of two monosaccharide units and oligosaccharides contain three to nine monosaccharide units. Polysaccharides consist of more than nine monosaccharide units joined in long linear or branched chains, as occurs in starches.

The linear and closed-ring forms of the major monosaccharides are shown in Figure 17.1. The five-carbon hexose sugars D-glucose and D-galactose are the major monosaccharides used as fuel sources and are derived from the three-carbon precursor D-glyceraldehyde (Fig. 17.1a,b). The hexose sugars form six-member rings called pyranoses. D-fructose is the major six-carbon ketone sugar and is derived from the three-carbon precursor D-hyroxyacetone (Fig. 17.1c). Fructose forms a five-membered ring called a furanose. The presence of asymmetric carbon atoms allows for stereoisomerization and, thus, a diversity of chemical structures for these sugars.

The various monosaccharide units, which form the building blocks of disaccharides, oligosaccharides, and polysaccharides, are joined by glycosidic linkages. The linkages are covalent chemical bonds, normally formed between the carbon-1 on one sugar and the carbon-4 on the other, and resulting in the removal of a molecule of water. An α-glycosidic bond is formed when the hydroxyl group on carbon-1 is below the plane of the sugar ring and a β-glycosidic bond is formed when it is above the plane. The type of glycosidic bond linking monosaccharides to form oligosaccharides and polysaccharides determines the distinct biological properties of the resultant molecules. For example, the α-(1,4)-glycosidic bond linking two D-glucose molecules to form the disaccharide maltose is easily hydrolyzed by intestinal enzymes (Fig. 17.2). However, the β-(1,4)-glycosidic bond linking two D-glucose molecules to form cellobiose, the structural building block of cellulose fiber, cannot be hydrolyzed by human saccharidases.

The two major starch polysaccharides in the human diet are amylose and amylopectin (Fig. 17.3). Amylose is a linear chain of glucose molecules linked by α-(1,4)-glycosidic bonds. Amylopectin is a branching chain of α-(1,4)-linked glucose molecules with an α-(1,6)-linkage occurring every 15–25 molecules [7]. Starches comprise about 50% of the total amount of carbohydrate consumed in the average adult diet, or about 22% of total calories [3,7].

Sucrose and lactose are the most common disaccharides available as human fuel sources (see chemical structures, Fig. 17.2). Sucrose is a natural sugar of most fruits and vegetables and consists of glucose and fructose molecules linked by an α-(1,4)-glycosidic bond [8]. Sucrose ingestion accounts

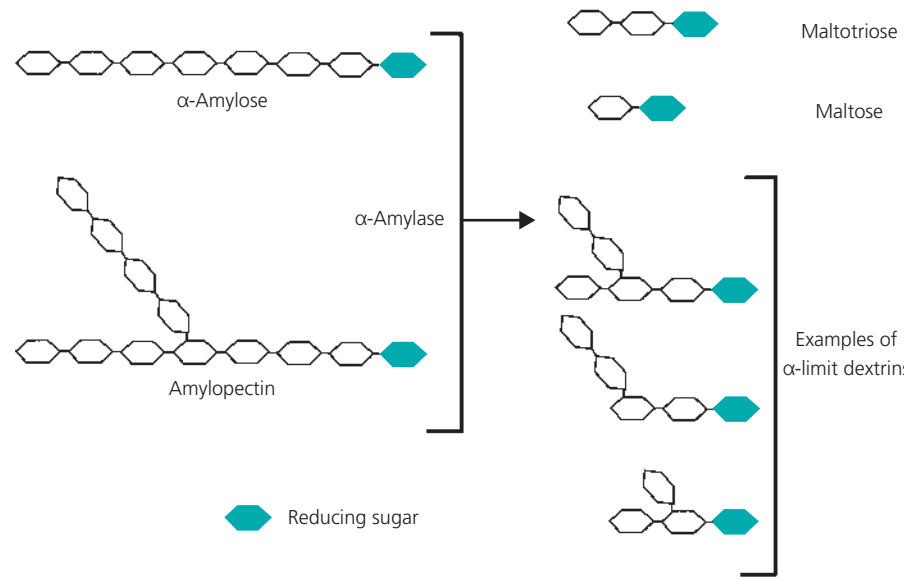

Figure 17.3 Starch digestion products. α-Amylose and amylopectin, the two molecular forms of starch, are digested by lumenal α-amylase into maltotriose, maltose, and a series of α-limit dextrins, a few examples of which are shown.

for about 30% of the carbohydrate intake in the adult diet in the United States [3,9]. Lactose consists of glucose and galactose molecules linked by a β-(1,4)-glycosidic bond. Lactose is the major carbohydrate in milk. Lactose is also used as a food additive in many processed foods. Lactose accounts for about 10% of the total carbohydrate calories consumed by the population in the United States. Individual lactose consumption varies widely, age and lactose tolerance being dependent factors. Maltose is a disaccharide comprising two glucose molecules linked by a α-(1,4)-glycosidic bond and accounts for 1%–2% of carbohydrates consumed (see Fig. 17.2).

Fructose and glucose are the primary monosaccharides

Table 17.1 Food content of fructose, glucose, sucrose, and sorbital

Food	Fructose (g/100 g edible portion)	Glucose (g/100 g edible portion)	Sucrose (g/100 g edible portion)	Sorbitol (g/100 g edible portion)	Excess free fructose (g)

in foods and are present in varying amounts in fruits and vegetables (Table 17.1). The average daily intake of glucose and fructose in the human diet is estimated to be about 20 g/day and 90 g/day, respectively, in the United States [3,9]. The fructose intake has increased significantly with the use of high-fructose corn syrup as a nutritive sweetener in foods. There is concern that the increasing consumption of refined carbohydrates, such as in corn syrup, is correlated with the rising prevalence of type II diabetes in the United States [10].

Nondigestible carbohydrates

The human diet also contains a significant amount of nondigestible carbohydrates. These carbohydrates consist of nondigestible, nonstarch polysaccharides, largely in the form of plant fibers that comprise the structural components of plant cell walls. As previously mentioned, cellulose fiber is formed from the cellobiose polysaccharide. The multiple types of fiber in different plants can be categorized into soluble and insoluble forms [11]. The different forms of dietary fiber are shown in Table 17.2.

Table 17.2 Structure, properties, and metabolism of dietary fiber

Fiber type	Structure	Properties	Colonic metabolism
Insoluble			
Cellulose	Linear polymer of β-(1,4)-linked glucose	Microfibrils in crystalline form	Moderate
Soluble			
Hemicellulose (xyloglucans, xylans, β-glucans)	Linear polymer of β-(1,4)-linked D-glucan with substituted xylosyl units	Water soluble; binds to cellulose to disperse fibrils	Moderate
Pectin	Galacturonic acid polymers	Acts as cellular glue for cellulose fibrils in cell walls	Extensive
Gums (guar gum, gum karaya, gum arabic)	Complex polysaccharides containing galactose, mannose, glucuronic acid, and other sugars	Used in processed foods; as additives they may contribute < 2% of a food	Extensive
Noncarbohydrate			
Lignins			None
Phenolic esters			None
Cutin			None
Waxy materials			None
Suberin			None

The human diet also consists of nondigestible sugars such as stachyose and raffinose, which are present in legumes, and sugar alcohols such as sorbitol, xylitol, mannitol, lactilol, and maltitol, which are used as sweeteners [1,3,12]. Humans lack digestive enzymes capable of efficiently hydrolyzing these nondigestible carbohydrates. Thus, dietary fibers and nondigestible sugars pass through the gastrointestinal tract undigested. On reaching the colon, the nondigested carbohydrates are metabolized by intestinal bacterial flora to yield short-chain fatty acids, hydrogen, carbon dioxide, and methane [13,14]. The short-chain fatty acids generated by the colonic bacteria can be absorbed by the colonic mucosa and serve as a primary source of energy for colonocytes [15–17]. The nutritional aspects of human dietary intake of digestible and nondigestible carbohydrates are described in Chapter 21.

Carbohydrate digestion

Lumenal digestion

On consumption of dietary food sources, carbohydrates are passaged through the alimentary tract for digestion and absorption. Starch hydrolysis is initiated during a lumenal digestion phase and completed by a mucosal digestion phase. The hydrolytic enzyme α-amylase initiates the digestion of starch in the lumen of the alimentary tract [18–20].

Salivary and pancreatic amylase

Two different isoenzymatic forms of α-amylase – salivary and pancreatic – mediate the lumenal phase of starch digestion. Both amylase isoenzymes have a high level of activity for the cleavage of internal α-(1,4)-glycosidic linkages [18]. Therefore, the terminal products of lumenal digestion of α-amylose are maltose and maltotriose (see Fig. 17.3). α-Amylase, however, has no activity for the hydrolysis of α-(1,6)-linkages, terminal glucose residues, or α-(1,4)-bonds adjacent to α-(1,6)-linkages [18]. Thus, the terminal products of lumenal digestion of amylopectin are maltose, maltotriose, and α-limit dextrins, which are a series of oligosaccharides containing four or more glucose molecules linked by α-(1,6)-glycosidic bonds [7,18,19]. Lumenal starch hydrolysis is an efficient process that is completed in the proximal jejunum [19,21]. A percentage of starch consumed, however, reaches the colon undigested and is metabolized by colonic bacteria.

Salivary α-amylase is synthesized and secreted into the alimentary tract by the parotid gland. The optimal enzymatic activity of salivary α-amylase is limited to the narrow pH range of 6.6–6.8. Therefore, although salivary α-amylase initiates starch digestion, its contribution is minor because it is rapidly inactivated in the acidic environment of the stomach. Pancreatic α-amylase is synthesized in the acinar cells of the pancreas and secreted into the small intestine by way of the pancreatic duct. Starch digestion is mediated largely by pancreatic amylase, which is secreted into the intestinal lumen in amounts exceeding that required for the hydrolysis of starch.

The genes encoding salivary amylase (*AMY1*), and pancreatic amylase (*AMY2*), are present in a clustered gene family located on human chromosome 1 at locus 1p21 [22]. As would be expected, *AMY1* is expressed in the parotid gland and *AMY2* is expressed in the pancreas [23].

Clinical symptoms of starch maldigestion occur only in severe cases of pancreatic insufficiency in which lumenal amylase activity levels are reduced to less than 10% of normal [24] (see Chapter 69). Some salivary amylase activity persists even at an acidic pH because of stabilization by short-chain glucose polymers [25]. Such stabilization of salivary amylase may allow for partial starch digestion in neonates and in patients who have chronic pancreatic insufficiency [4,26]. Human milk contains amylase activity, which facilitates carbohydrate digestion in infants [27]. For additional information on the structure, synthesis, and secretion of amylase, see Chapter 15.

Mucosal digestion

The terminal digestion of dietary carbohydrates is mediated by hydrolytic enzymes located on the apical brush border membrane of epithelial cells lining the small intestinal mucosa. These saccharidases are responsible for the hydrolysis of the products of lumenal starch digestion (i.e., maltose, maltotriose, and α-limit dextrins) and of ingested disaccharidases (i.e., lactose and sucrose). The oligosaccharide products of lumenal starch digestion are hydrolyzed to glucose monomers by the membrane-bound brush border digestive enzymes maltase–glucoamylase, sucrase, and isomaltase (also called α-dextrinase) (Fig. 17.4). The enzymatic action of the brush border saccharidases results in the production of monosaccharides that can be transported across the apical membrane. Table 17.3 outlines the characteristics of each enzyme. The enzyme activity, gene and protein structure, and spatiotemporal expression pattern are described below for the mucosal saccharidases.

Sucrase–isomaltase

Sucrase–isomaltase, also called sucrase–α-limit dextrinase, is a bifunctional brush border membrane enzyme with two active sites. The sucrase active site is capable of hydrolyzing the α-(1,4)-glycosidic bonds of short oligosaccharides including maltose, maltotriose, and sucrose. The isomaltase active site is also capable of hydrolyzing α-(1,4)-glycosidic bonds and is the only saccharidase capable of hydrolyzing the α-(1,6)-glycosidic linkage in the α-limit dextrins [28,29]. The sucrase active site is the only intestinal enzyme capable of hydrolyzing sucrose to glucose and fructose. The enzyme also accounts for 90% of intestinal isomaltase activity and 80% of maltase activity [30].

The human sucrase–isomaltase gene (*SI*) is located on chromosome 3 at locus 3q25-26 [31], and is estimated to be

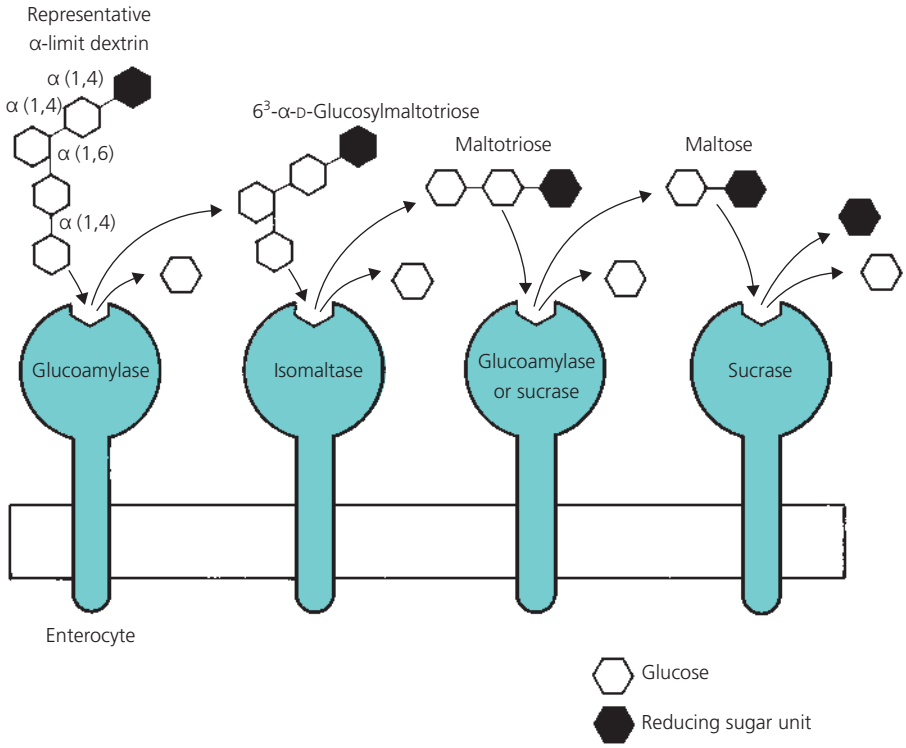

Figure 17.4 Overall process of digestion to monosaccharides. The hydrolysis of α-limit dextrins is a collaborative effort between multiple brush border enzymes.

Table 17.3 Human brush border proteins with carbohydrase activity

Brush border protein	Size of proprotein chains (kDa)	Size of protein chains (kDa)	Site of protein cleavage	Major substrates	Comments
Sucrase–isomaltase	185 (nonglycosylated); 210 (high mannose); 245 (fully glycosylated)		Extracellular (trypsin)		Size estimates from Naim et al. [34]
Sucrase		130		Sucrose	
Isomaltase		145		Maltose and α-limit dextrins	
Lactase–phlorizin hydrolase	210 (nonglycosylated); 215 (high mannose); 225 (fully glycosylated)	160; 145	Intracellular and extracellular		Size estimates from Jacob & Naim [69]
Lactase				Lactose	Single chain contains both active sites
Phlorizin hydrolase				Glycosylceramides	
Maltase–glucoamylase	255 (nonglycosylated); 285 (high mannose); 335 (fully glycosylated)	335	None	α-(1,4)-linked glucose oligomers	
Trehalase	65.5 (calculated from cDNA)	75	None	Trehalose	Anchored to membrane by glycosylphosphatidylinositol; based on cloned rabbit enzyme

about 55 kilobases (kb) in size [32]. The coding sequence of the human *SI* mRNA is 5481 bases long and encodes a 1827-amino-acid polypeptide [32]. The translation and post-translational processing of the sucrase–isomaltase protein has been studied extensively. Sucrase–isomaltase is initially synthesized in the enterocyte as a single glycoprotein chain. The protein is glycosylated as it is transported to the brush border membrane, where it is it is cleaved by lumenal trypsin to yield the sucrase and isomaltase units [28,30,33,34]. The two subunits reassociate noncovalently by forming hydrostatic bonds and exist as a membrane-bound dimer [35] (see Table 17.3).

Spatially, along the longitudinal (anteroposterior) axis of the small intestine, sucrase–isomaltase protein activity is four- to fivefold greater in the jejunum than in the ileum; however, sucrase mRNA expression appears to be similar in the two regions [36,37]. Sucrase–isomaltase is expressed transiently in the colon of humans during fetal development and is absent in the newborn colon [38–40]. Along the crypt–villus axis, there is little sucrase RNA, protein, or enzyme activity in the crypt, maximal activity in the lower and mid-villus cells, and decreased activity in the villus tip cells [33,37,41–44]. Transcriptional regulation of the sucrase–isomaltase gene has been characterized in cell culture and in transgenic animals [37,45,46]. Similar to other enterocyte genes, the sucrase–isomaltase promoter can be activated in cell culture by intestine-specific transcription factors including Cdx2 [47,48], HNF1 [48–52], GATA4 [48], and GATA5 [51].

Temporally, the expression of sucrase–isomaltase is minimal at birth and then is induced dramatically at the time of weaning in most mammalian species. In humans, however, sucrase–isomaltase expression is induced prenatally (10–14 weeks' gestation) and is maximal at birth [53,54]. This precocious expression pattern allows for the digestion and absorption of solid sugars prior to weaning in human infants.

Clinical deficiency of sucrase–isomaltase results in the inability to digest and absorb dietary sucrose [55]. The condition manifests during infancy on the introduction of sucrose in fruits and juices or glucose polymers in infant formula. A late-onset deficiency has also been described in adults. The inability to digest sucrose produces signs and symptoms of malabsorption including diarrhea, increased gas production, and abdominal distention. Sucrase–isomaltase deficiency occurs with a frequency of 0.2% in North American people and a frequency of greater than 10% in the Inuit people of Greenland and Alaska. Genetic studies support autosomal recessive inheritance. Several different mutations in the sucrase–isomaltase gene have been described, which lead to the synthesis of a transport-incompetent or functionally altered enzyme [56,57]. Treatment for congenital sucrase–isomaltase deficiency consists primarily of the avoidance of sucrose in the diet. Sacrosidase, produced from *Saccharomyces cerevisiae*, is a β-D-fructofuranoside fructohydrolase that hydrolyzes sucrose. It is reported to be safe and effective in preventing symptoms of intolerance in patients with sucrase–isomaltase deficiency [58].

Lactase–phlorizin hydrolase

The disaccharide lactose is the major carbohydrate in milk and is produced exclusively in the mammary glands by lactose synthase. As previously described, lactose consists of a glucose molecule and a galactose molecule linked by a β-(1,4)-glycosidic bond. The digestive enzyme lactase–phlorizin hydrolase (also known as lactase) catalyzes the hydrolysis of lactose to yield glucose and galactose, which can then be absorbed across the intestinal mucosal membrane. Lactase is a brush border membrane protein and has phlorizin hydrolase, glycosyl-ceramidase, and β-galactosidase enzymatic activities [59,60]. Lactase is the only intestinal enzyme that cleaves the β-(1,4)-glycosidic bond in lactose to yield glucose and galactose. Lactase activity is therefore essential for the survival of newborn mammals.

The human lactase–phlorizin hydrolase gene (*LPH*) is located on the long arm of chromosome 2 at loci 2q21 and consists of 17 exons spanning about 55 kb [61,62]. The human *LPH* cDNA encodes a single polypeptide chain containing 1972 amino acids [63]. The human lactase enzyme is a membrane-bound glycoprotein that is initially synthesized as a 210- to 220-kDa immature peptide [64,65]. Extensive evidence indicates that the precursor peptide is processed by glycosylation and cleavage and finally inserted into the brush border membrane as a mature 145-kDa subunit homodimer [28,64,66–74] (see Table 17.3).

Lactase gene expression is spatially restricted along both vertical and longitudinal axes in the gut [75,76]. Along the vertical axis, immature enterocytes derived from stem cells in the crypts migrate from the crypt to the villus tip, differentiate, and begin to express the lactase protein. Along the longitudinal axis, the lactase gene is expressed maximally in the distal duodenum and jejunum with significantly lower expression in the proximal duodenal and distal ileal segments of the intestine [76,77]. Transcriptional regulation of the lactase gene has been characterized in transgenic mice [78–80] and in cell culture. The lactase promoter is activated in cell culture by cooperative interaction between intestine-specific transcription factors including Cdx2 [81–85], GATA family members [51,86–89], and HNF1 [51,82,89,90].

During gut development and maturation, lactase enzyme activity is maximal in the small intestine of preweaned mammals and declines markedly during maturation. In most mammalian species, the maturational decline in lactase expression begins at the time of weaning [28,59,91–93]. The age of onset of this maturational decline in humans is variable, ranging from the toddler years to young adulthood [94–96]. After this decline, the level of lactase activity is 5%–10% of childhood levels in most populations worldwide [28,97]. The temporal decline in lactase activity is largely the

result of a decline in the high level of lactase mRNA expression in the enterocytes of the small intestine. Studies in humans and other mammals indicate that regulation of gene transcription is the primary mechanism mediating changes in lactase expression during gut development and maturation [98–101]. In vivo characterization of fragments of the lactase gene promoter in transgenic mice has revealed that 1 kb of the pig lactase promoter and 2 kb of the rat lactase promoter are capable of mediating a decline in reporter transgene expression after weaning [79,80]. Characterization of the specific mechanisms mediating the temporal decline in lactase gene expression is ongoing [102–104].

As described, the temporal decline in human lactase gene expression occurs with maturation in most populations worldwide. In some adults, however, high levels of lactase activity persist in adulthood. This hereditary persistence of lactase is common primarily in people of northern European descent and in select African populations [94,96,105]. It is believed that selection has played a major role in determining the prevalence of lactase persistence in different human populations. Factors that may have contributed to such selection include the nutritional benefit of milk in dairy farming populations and improved calcium absorption in areas of decreased solar irradiation (e.g., northern Europe) [96].

The hereditary persistence of lactase is attributed to inheritance of an autosomal dominant mutation that prevents the normal maturational decline in lactase expression [94,96,105]. Based on analysis of allelic human lactase mRNA transcript levels, it was initially determined that the hereditary lactase persistence/nonpersistence phenotype is controlled by a *cis*-acting DNA element on chromosome 2 in the general region of the lactase gene [105]. Subsequently, linkage disequilibrium and haplotype analysis in humans resulted in identification of genetic variants located –13 910 base pairs (bp) and –22 018 bp upstream of the human lactase gene that are associated with lactase persistence/nonpersistence phenotypes [106]. The –13 910 bp variant ($C/T_{-13\,910}$) is a single nucleotide polymorphism, C to T. Complete correlation between the lactase nonpersistence phenotype and homozygosity for the C nucleotide polymorphism at position –13 910 was described in the initial population studied. The report also described complete correlation between the lactase persistence phenotype and the presence of an allele with a T nucleotide at position –13 910. The –22 018 bp variant ($G/A_{-22\,018}$) was also associated with the lactase persistence trait, although not completely correlated.

Although strongly correlated with the lactase persistence/nonpersistence phenotypes, the $C/T_{-13\,910}$ variant has not yet been shown to be causative of the traits, nor has a functional mechanism for lactase nonpersistence been clearly defined [104]. Some investigators hypothesize that the DNA in the region of the –13 910-bp variant functions to regulate human lactase gene transcription. Transfection experiments have shown that the DNA in the region of the $C/T_{-13\,910}$ lactase persistence/nonpersistence variant can interact with the Oct1 transcription factor and function as a *cis* element capable of enhancing differential transcriptional activation of the lactase promoter in cell culture [107–109]. If determined to be functional, however, the $C/T_{-13\,910}$ variant may not account for all of the variation in lactase expression, as exceptions to the phenotypic correlations have been described [110–112].

As distinguished from the primary decline in intestinal lactase activity that occurs with hypolactasia in adults, secondary lactase deficiency can result from injury of the small intestinal mucosa. Such injury may occur with gastrointestinal infections (e.g., viral enteritis), inflammatory bowel disease (e.g., Crohn's disease), hypoxic ischemia, radiation, or chemotherapy, resulting in villus destruction, loss of total enterocyte number, and relative lactase deficiency. Rare cases of primary congenital lactase deficiency have been described, mainly in Finnish kindreds. The gene defect in congenital lactase deficiency is inherited in an autosomal recessive fashion and is reported to be due to a separate gene in the vicinity of the lactase gene on human chromosome 2 [113].

The clinical manifestations of reduced lactase activity (primary or secondary) can be symptoms associated with lactase intolerance. In individuals with reduced lactase activity, lactose consumed in excess cannot be fully digested in the small intestine. Bacteria in the distal ileum and colon ferment the undigested lactose to yield short-chain fatty acids, hydrogen, carbon dioxide, and methane. The fermentative products and undigested lactose molecules can result in symptoms of flatulence, diarrhea, and abdominal pain characteristic of lactose intolerance [97]. The maturational decline in lactase activity, adult-onset hypolactasia, and lactase nonpersistence render much of the world's adult human population intolerant of excessive consumption of milk and other dairy products. Therefore, the term lactase deficiency is somewhat of a misnomer. In the United States, the prevalence of lactose malabsorption is 80%–95% in African American and Asian American populations and 25% in the white American population [94,97]. Diagnosis of lactose intolerance is often made on clinical grounds and in response to an empirical trail of dietary avoidance. Biochemical methods for assessing lactose malabsorption in the form of the lactose breath hydrogen test and the direct measurement of lactase enzyme activity in small intestinal tissue biopsy samples are also used for diagnosis. Treatment of lactose intolerance consists primarily of avoiding lactose-containing foods or supplementing the diet with exogenous lactase derived from microbial sources [114–116].

Maltase–glucoamylase

Maltase–glucoamylase is present on the brush border membrane of enterocytes and catalyzes the removal of glucose from the nonreducing end of short glucose polymers at α-(1,4)-

glycosidic bonds [117]. The enzyme also has low enzymatic activity for the hydrolysis of α-(1,6)-glycosidic bonds [118].

The human maltase–glucoamylase gene (*MGAM*) is located on chromosome 7 at locus 7q34. The maltase–glucoamylase gene has structural homology with the sucrase–isomaltase gene, suggesting evolution from a common ancestral gene [119]. The maltase–glucoamylase gene spans approximately 82 kb with 48 identified exons. The 6513-bp cDNA contains an open reading frame that encodes a 1857-amino-acid protein. Maltase–glucoamylase is synthesized as a single-chain polypeptide precursor and is heavily glycosylated to produce a 335- to 355-kDa mature protein [120,121]. The maltase–glucoamylase enzyme does not undergo intracellular or extracellular proteolytic cleavage and is expressed in the brush border membrane as a monomeric protein [120] (see Table 17.3).

In humans, maltase–glucoamylase is expressed prenatally, with similar levels after birth and into adulthood. A disorder involving the absorption of short polymers of glucose and starch resulting from primary maltase–glucoamylase deficiency was initially detected with a prevalence of 1.8% in children with chronic diarrhea [122]. A report of a patient with congenital maltase–glucoamylase deficiency with associated lactase and sucrase deficiencies raises the possibility of a rare global carbohydrate digestive disorder caused by a shared regulator [123].

Trehalase

Trehalose is a disaccharide found in mushrooms, yeast, algae, and insect hemolymph. Trehalase is a brush border enzyme that specifically hydrolyzes trehalose to its two constituent glucose molecules [124,125]. The human trehalase gene (*TREH*) is located on chromosome 11 at locus 11q23 [126]. The gene encodes a 583-amino-acid protein with a molecular mass of about 75 kDa [127] (see Table 17.3).

The mouse trehalase gene is expressed in a gradient along the anteroposterior axis of the small intestine, with maximal trehalase mRNA expression in the proximal small intestine and significantly decreased expression in the distal intestine. Levels of primary and mature trehalase RNA transcripts increase dramatically during the third postnatal week in mice [92,128–130]. In humans, trehalase is expressed at comparable levels in the fetal and adult small intestines [92].

Isolated trehalase deficiency is essentially undescribed outside of Greenland, where at least 8% of the population have been reported to have trehalase deficiency. This deficiency can result in severe diarrhea after the ingestion of mushrooms [124,125,131–134].

Absorption of monosaccharides

The products of lumenal and mucosal hydrolysis of starches and sugars are the constituent monosaccharides, primarily glucose, galactose, and fructose. These monosaccharides, present at the enterocyte brush border membrane, must be transported across both the apical and basolateral enterocyte membranes and into the portal circulation to be utilized as nutrient sources. The transport function, gene and protein structure, and spatiotemporal expression pattern of the intestinal sugar transporters mediating monosaccharide absorption are described in the following sections.

Glucose and galactose absorption

The apical membrane absorption of glucose and galactose is mediated by a sodium-dependent active transport mechanism in which each monosaccharide is transported along with two sodium ions into the enterocyte (Fig. 17.5). This classical model of sugar absorption appears to be complemented by another apical membrane transport mechanism under conditions of high glucose concentration. These apical membrane sugar absorption mechanisms involve the SGLT1 and GLUT2 transporters. Glucose and galactose are transported across the enterocyte basolateral membrane into the portal circulation by a facilitative diffusion mechanism involving GLUT2.

SGLT1 and apical sugar transport

SGLT1 has been characterized as the sodium/glucose cotransporter [135]. It is capable of mediating the apical membrane transport of glucose or galactose into the enterocyte. Sodium ions enter the enterocyte by way of the electrochemical gradient, which is maintained by the Na^+,K^+-ATPase, a sodium pump that extrudes sodium ions across the basolateral surface (see Chapter 14). By coupling transport to the sodium gradient, the SGLT1 transporter actively transports glucose and galactose molecules into the cell [136–140]. Transport studies suggest that there is a stoichiometry of two sodium ions for every hexose molecule [138,140]. An alternating access kinetic model has been proposed for SGLT1-mediated sugar transport. The initial binding of the two sodium ions to SGLT1 increases the transporter's affinity for sugar. On binding with sugar, the protein undergoes a conformational change that allows transport of the sodium and sugar molecules across the membrane. The ligand-free protein then cycles back to the original conformation. The gene for the sodium–glucose cotransporter, *SGLT1* (also called *SLC5A1*, solute carrier family 5 [sodium/glucose cotransporter], member 1), is located on human chromosome 22 at locus 22q13.1. *SGLT1* encodes a 664-amino-acid transmembrane protein, estimated to be about 73–75 kDa in size [138,141]. The protein is expressed on the apical surface of the intestinal epithelial cell and exists in the membrane as a homotetramer with 14 membrane-spanning domains [46,138,141–143].

The biological properties of SGLT1 have been characterized by expressing the transporter in oocytes, cultured mammalian and insect cells, and bacteria, and by reconstitution of

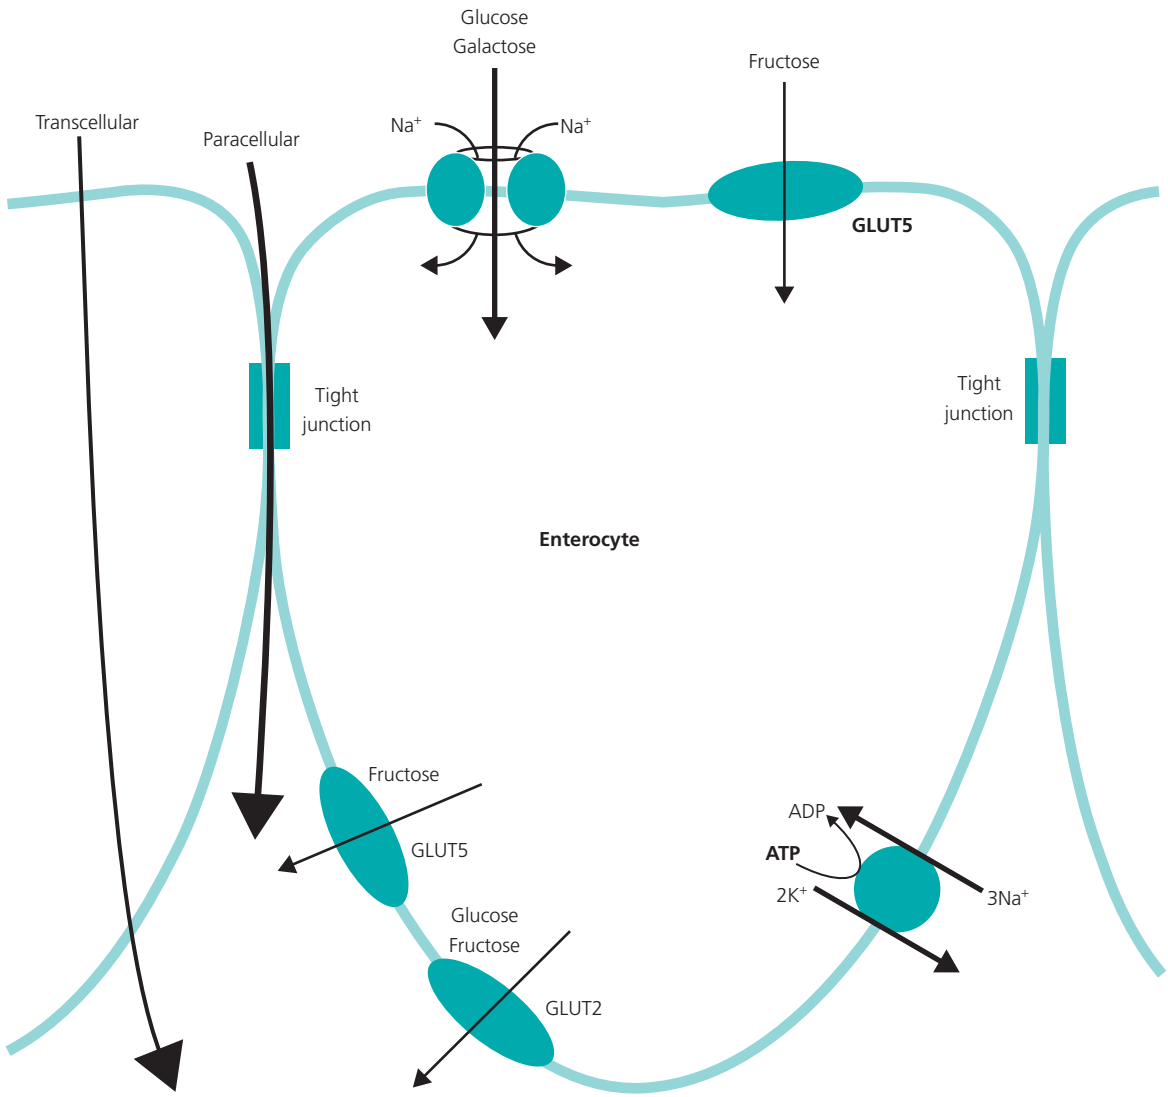

Figure 17.5 Transport processes in the enterocyte responsible for the movement of monosaccharides across the intestinal epithelium. Studies in some animals suggest that GLUT2 may also exist in the apical membrane when lumenal glucose levels are high.

the purified recombinant protein in proteoliposomes [144]. Strong support for the importance of the cloned transporter as a major sodium/glucose cotransporter in the intestine has been provided by the identification of a variety of mutations in the coding region of *SGLT1* in families with hereditary glucose and galactose malabsorption [145]. Expression of the mutant *SGLT1* cDNAs results in proteins that are nonfunctional for D-glucose transport, often as a result of cellular trafficking abnormalities [136,145–150]. Short-term induction of glucose transport results from an increase in the number of SGLT1 transporters at the brush border membrane and is mediated by changes in exocytosis and endocytosis of membrane vesicles that contain the SGLT1 protein [151]. Such changes in membrane vesicle recruitment are regulated by protein kinase A- and protein kinase C-dependent processes [151].

SGLT1 and glucose absorption play a major role in intestinal water transport [152–155]. The human SGLT1 transporter can cotransport approximately 264 water molecules for every molecule of glucose absorbed in enterocytes. It is estimated that ingestion of an average carbohydrate diet results in 5–6 L of water being transported by way of this SGLT1 cotransport mechanism in the human intestine. Increased intestinal water transport coupled to glucose absorption is the rationale for adding glucose to oral rehydration solutions used to treat conditions of clinical dehydration.

Congenital defects of the SGLT1 protein resulting from missense and nonsense mutations have been reported as rare clinical causes of severe glucose–galactose malabsorption in infancy [136,145–150,156]. Inheritance of glucose–galactose malabsorption occurs in an autosomal recessive manner. Affected children present in the neonatal period

with life-threatening acidic diarrhea and dehydration while consuming breast milk or standard infant formulas. Treatment consists of rehydration and initiation of a glucose- and galactose-free diet. As fructose is tolerated, most of the carbohydrate initially can be given as fructose.

GLUT2 and basolateral sugar transport

Glucose and galactose are transported out of the enterocyte into the portal circulation by the GLUT2 transporter located on the basolateral membrane. Transport of these sugars out of the cell occurs by way of a sodium-independent facilitative diffusion mechanism (see Fig. 17.5) [157]. The transport properties of the GLUT2 protein have been studied by expressing it in *Xenopus* oocytes [158–160]. The transporter has a high-level capacity for glucose transport with a high K_m for glucose (> 17 mM) in the intestine [158–160]. Evidence suggests that this protein can also transport fructose [161].

The human glucose transporter 2 gene, *GLUT2* (also called *SLC2A2*, solute carrier family 2 [facilitated glucose transporter], member 2), is located on chromosome 3 at locus 3q26.1-q26.3 [162]. The gene consists of 11 exons and 10 introns spanning approximately 30 kb [163]. The *GLUT2* cDNA encodes a 500-amino-acid protein with 12 membrane-spanning domains (Fig. 17.6). The GLUT2 transporter protein is present predominately on the basolateral membrane of enterocytes and renal tubular cells [160]. Studies show that GLUT2 protein can also be recruited to the apical membrane of enterocytes.

GLUT2 and apical sugar absorption

In addition to the well-characterized role of GLUT2 in mediating the transport of monosaccharides across the basolateral enterocyte membrane and into the circulation, it also appears that GLUT2 is capable of mediating apical membrane transport of sugars into the enterocyte under certain experimental conditions [164,165]. GLUT2 was first located at the apical enterocyte membrane in a diabetic rat model in which diabetes enhanced fructose absorption by approximately 60% [166]. Intestinal apical membrane vesicles revealed significant GLUT2 protein in diabetic rats but not in normal control rats. In addition, immunocytochemical detection revealed GLUT2 protein at the apical membrane [167–169]. GLUT2 located in the basolateral membrane is recruited to the apical brush border membrane in mice after perfusion with, or ingestion of, substances of high glucose [165] or fructose [168] concentration. Based on these data, a modification of the classical model of glucose absorption has been proposed [170]. In this modified model, under conditions of low lumenal glucose concentration (less than that in plasma), SGLT1 mediates high-affinity glucose transport into the enterocyte against a concentration gradient. Under conditions of high lumenal glucose concentration, GLUT2 is recruited to the apical membrane and mediates additional facilitated absorption of glucose. The significance of this modified model in humans is unclear, as patients with defective SGLT1-mediated glucose transport (as occurs in glucose–galactose malabsorption) lack significant glucose absorption. It has been proposed, however, that apical GLUT2 recruitment may be dependent on SGLT1-mediated glucose transport, thereby accounting for the lack of glucose absorption in such patients [164].

Fructose absorption

The fructose monosaccharide is transported across the apical intestinal brush border membrane by a sodium-independent facilitated diffusion mechanism involving the GLUT5 transporter. Although GLUT5 is the predominant fructose transporter at the brush border membrane, GLUT2 may assist

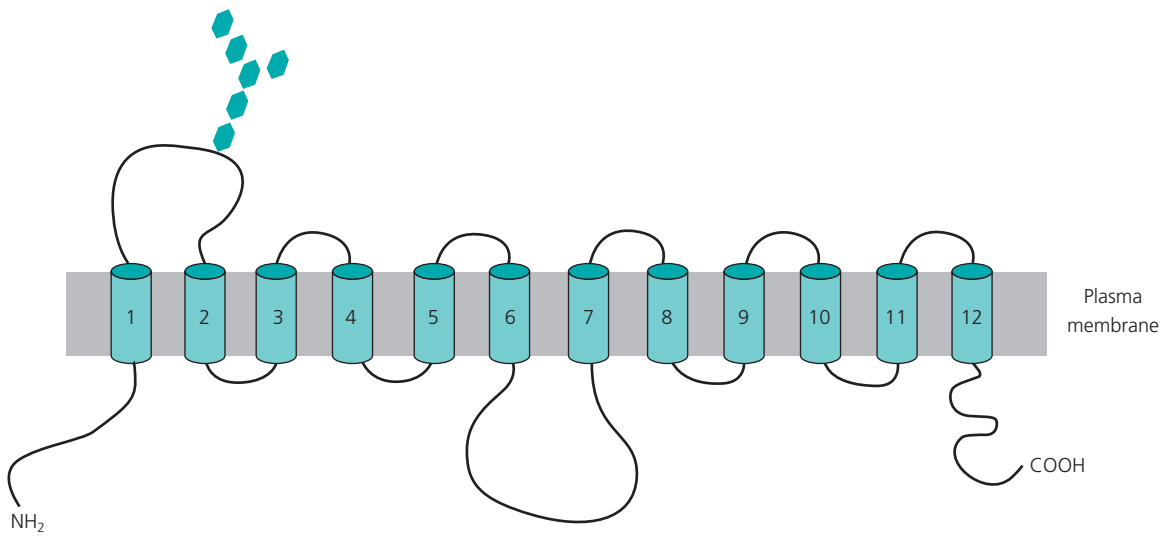

Figure 17.6 GLUT2 glucose transporter. This model of the monomer is suggested by the primary amino acid sequence. From Elsas and Longo [158], with permission from Annual Reviews, www.annualreviews.org.

Table 17.4 Glucose transporters

	Protein size (kDa)	Sites of expression	Function
Facilitative glucose transporters			
GLUT1	55	Many tissues; abundant in erythrocytes, blood–brain barrier, placenta, transformed cells in culture	Basal glucose transport; transport across blood–tissue barriers
GLUT2	58	Liver, pancreatic β-cells, kidney, small intestine	Low-affinity glucose transport; release of absorbed glucose across basolateral membrane of kidney and intestine
GLUT3	54	Many tissues; abundant in brain	Basal glucose transport
GLUT4	55	Skeletal and cardiac muscle, brown and white adipose tissue	Insulin-stimulated glucose uptake
GLUT5	50	Small intestine, kidney, testes, adipose tissue, skeletal muscle	Fructose transport across enterocyte apical membrane
Sodium-dependent glucose transporters			
SGLT1	75	Intestine, kidney	Intestinal and renal absorption of glucose and galactose

in the absorption of excess lumenal fructose [164,165]. Only a small amount of fructose is metabolized in the enterocyte [3]. Most intracellular fructose appears to be transported across the basolateral membrane by GLUT2 for delivery into the circulation [171,172]. GLUT5 expression on the basolateral membrane suggests that it may also transport fructose out of the enterocyte [173]. GLUT5 and GLUT2 are members of a family of genes that encode facilitative sugar transport proteins [158–160,165,171]. The GLUT family of genes, their transport properties, and their tissue distributions are outlined in Table 17.4.

GLUT5 and sugar transport

The GLUT5 transporter is the protein responsible for most apical membrane fructose transport. The gene encoding the GLUT5 transporter, *SLC2A5* (solute carrier family 2 (facilitated glucose/fructose transporter), member 5), is localized on chromosome 1 at locus 1p36.2. GLUT5 is a 501-amino-acid transmembrane protein that transports fructose and glucose molecules [174]. Analysis of this amino acid sequence suggests that there are 12 membrane-spanning domains. Human GLUT5 mRNA and protein are expressed in the small intestine, kidney, testes, adipose tissue, and skeletal muscle [175,176]. This uniporter is fairly exclusive for fructose, with a K_m of 6–14 mM [177].

Expression of the GLUT5 protein is induced by the presence of its substrate fructose [174,178–181]. Precocious expression of GLUT5 in suckling animals is also induced by lumenal fructose [182]. A sugar-response element has been localized to the first 272 bp of the GLUT5 promoter [179]. In addition, fructose stimulation results in increased GLUT5 mRNA stability mediated by cAMP signaling and by binding to PABP (polyadenylated-binding protein)-interacting protein 2 (Paip2) [179]. Although GLUT5 is the predominant fructose transporter at the brush border membrane, GLUT2 may assist in the absorption of excess lumenal fructose. GLUT2, located in the basolateral membrane of mice fed a meal devoid of sugar, is recruited to the apical brush border membrane on ingestion of a meal with a high level of fructose [168].

Fructose is not as well absorbed as glucose. Therefore, ingestion of high levels of fructose in the diet can lead to carbohydrate intolerance. In children, drinking excessive amounts of juices with high levels of fructose may cause nonspecific diarrhea, excessive intestinal gas, and recurrent abdominal pain [183]. In children and adults, fructose malabsorption has been associated with irritable bowel syndrome [184,185]. Previous studies support the hypothesis that isolated fructose malabsorption in children does not result from the expression of mutant GLUT5 protein [186]. Investigators have therefore speculated that children with fructose intolerance may exhibit defective GLUT2 intestinal membrane insertion and recruitment.

Types of dietary lipids

Because dietary lipids and many lipophilic vitamins and drugs are carried by chylomicrons and are transported in lymph, it is important to understand the processes involved in the digestion, uptake, intracellular metabolism, and packaging of dietary lipids into chylomicrons. Considering the excellent reviews of intestinal lipid absorption [1–4], this chapter will both update current knowledge on the digestion, uptake, and transport of dietary lipids, and provide a comprehensive look at the current understanding of the role of the transporters in enterocytes in the uptake of lipids.

Dietary fat, simply defined, is the component of a diet that can be extracted by organic solvents [5]. An array of compounds comprises dietary fat, from the highly nonpolar hydrocarbons to the highly polar phospholipids and glycolipids. The classification of these various lipids and their behavior in an aqueous medium has been thoroughly reviewed by Carey and Small [6]. Classification of a lipid as polar or nonpolar depends on its interaction with water. Nonpolar lipids are insoluble in the bulk water phase and therefore do not interact with water (Fig. 18.1). Cholesteryl ester, hydrocarbons, and carotene are examples of nonpolar lipids. Polar lipids can be further classified into one of three groups: insoluble nonswelling amphiphiles, insoluble swelling amphiphiles, and soluble amphiphiles. The insoluble nonswelling amphiphiles include triacylglycerol (TG), diacylglycerol (DG), nonionized long-chain fatty acids (FAs), cholesterol, and fat-soluble vitamins. Nonswelling amphiphiles are so named because they interact little with water in the bulk phase; hence, when added to water, a thin monolayer of lipid molecules is formed. The second group of polar lipids, the insoluble swelling amphiphiles, includes monoacylglycerol (MG), ionized FAs, and polar lipids. Like the insoluble nonswelling amphiphiles, when added to water, the insoluble swelling amphiphiles form a monolayer on the surface of water. Further, this group of lipids has the unique ability to interact with water to form a laminated lipid–water structure that is known as a liquid crystal structure. In the liquid crystal state, nonpolar groups of lipid molecules face one another, which results in the sandwiching of water between the polar groups. This unique behavior is referred to as "swelling", hence the designation swelling amphiphiles. Soluble amphiphiles, the third group of lipid molecules, possess strong polar groups, which render these molecules soluble in water at low concentrations. This group of lipids can be divided further into soluble amphiphiles with lyotropic mesomorphism and those without. Sodium salts of long-chain FAs are examples of soluble amphiphiles with lyotropic mesomorphism. When the lipid concentration in solution reaches the critical micellar concentration, monomers aggregate to form micelles. In the micelle, the polar group of monomers faces the surrounding aqueous medium, whereas the nonpolar group faces inward. In the case of sodium oleate molecules, when the critical micellular concentration is reached but before micelle formation, there is an intermediate liquid crystal phase, a phenomenon known as lyotropic mesomorphism. In contrast, soluble amphiphiles without lyotropic mesomorphism do not form the intermediate liquid crystal phase before micelle aggregation. Bile salts, secreted by the liver, are an example of soluble amphiphiles without mesomorphism.

The major focus of this chapter will be the digestion, absorption, and transport of TG, which is undoubtedly the predominant dietary lipid. Readers also interested in cholesterol absorption should refer to the excellent review by Dawson and Rudel [7], as well as those by other investigators [8,9].

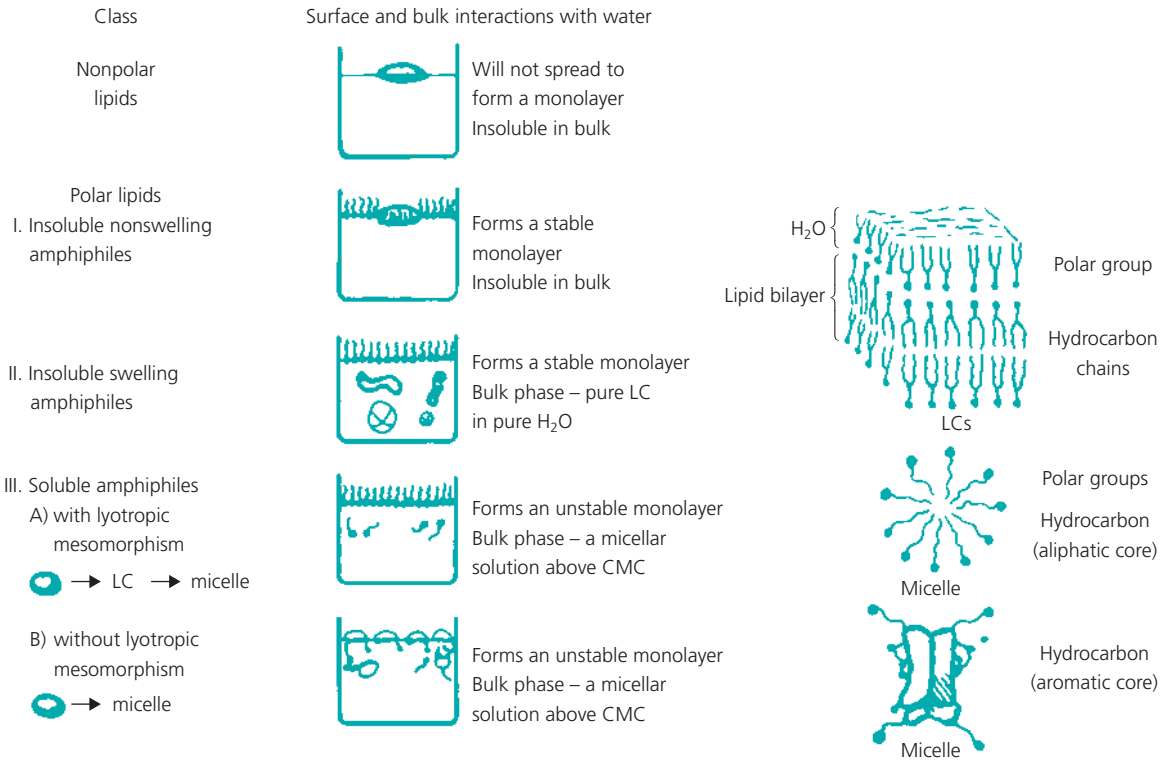

Figure 18.1 Classification of lipids based on their ability to interact with water. Nonpolar lipids: octadecane, carotene, squalene, cholesteryl oleate, cholesteryl linoleate, and paraffin oil. Polar lipids: I – triacylglycerols, diacylglycerols, long-chain protonated fatty acids, and fat-soluble vitamins. II – phospholipids, monoacylglycerols, monoethers, and α-hydroxy fatty acids. IIIA – sodium salts of long-chain fatty acids; many anionic, cationic, and nonionic detergents; and lysophosphatidylcholine. IIIB – bile salts, sulfated bile alcohols, and saponins. CMC, critical micelle concentration; LC, liquid crystal. From Carey and Small [6], with permission from Elsevier.

Dietary fat constitutes a significant source of calories in the Western diet – as much as 30% of the total caloric intake, or 90–100 g/day. Dietary intake of fat has received considerable attention in the last few decades, as diets with high levels of fat have been linked to high levels of serum lipids, especially cholesterol, and increased risk of coronary heart disease [10–12]. It is generally accepted that diets with high levels of saturated FAs are more cholesterolemic (i.e., tending to raise the level of serum cholesterol) than diets with high levels of polyunsaturated FAs [13]. Trans FAs have double bonds, yet they behave more like saturated FAs and are considered just as atherogenic as saturated FAs [14,15]. The Surgeon General of the United States recommends that all individuals should maintain overall fat consumption at or below an average level of 30% of the total caloric intake, and that no more than 300 mg cholesterol should be consumed in one day. This standard has also been adopted by the American Heart Association.

Over the past decade, there has been increased effort to modify, either chemically or biologically, the FA profile of naturally occurring TG to obtain a particular physical property or physiological function. A new approach to optimize the metabolic benefits of specific lipid mixtures has been the development and manufacture of structured triacylglycerols (STGs). STGs are produced by the chemical interesterification of both medium-chain and long-chain FAs incorporated on the same glycerol backbone by hydrolysis and random reesterification [16,17]. These FA molecules are chemically distinct and offer unique advantages depending on their constituent physical mixture of medium-chain FAs and long-chain FAs. For example, STGs that contain medium-chain FAs may provide a useful vehicle for rapid hydrolysis and absorption because of their smaller molecular size and greater water solubility compared to long-chain FAs. The STGs are manufactured both for their potential clinical benefits and for their lower fat-producing value. The clinical applications of STGs have been thoroughly reviewed [18–20]. The benefits of STGs include improved absorption of linoleic acid by patients with cystic fibrosis [21,22], and also a protein-sparing effect in STGs derived from safflower oil [23] and fish oil [24]. Although STGs retain some characteristics of medium-chain and long-chain TG, they may provide an alternative lipid source that could overcome the gastrointestinal intolerance related to the sole use of medium-chain or long-chain TG in patients with malabsorptive diseases. Studies from our laboratory have shown that

STGs promote the lymphatic absorption of both vitamin A and vitamin E better than the constituent physical mixture with a similar FA composition. Note that the enhanced delivery of vitamins A and E into lymph by STGs is limited to healthy animals but also includes animals with impaired gastrointestinal absorption caused by ischemia/reperfusion injury [25,26]. Ascertaining the capability of STGs to enhance the lymphatic absorption of lipid soluble drugs is worthy of investigation.

Lumenal digestion of dietary lipids

Gastric lumen

The digestion of dietary lipids in humans begins in the stomach. The initial step involves the enzyme acid lipase, which is secreted by the gastric mucosa. Acid lipase has its highest activity in the acidic environment of the stomach. The distribution of gastric lipase varies in different parts of the human stomach, with the highest activity detected in the fundus (Fig. 18.2) [27]. Human gastric lipase has a pH optimum ranging from 3.0 to 6.0 [27,28], and it hydrolyzes medium-chain TG more efficiently than long-chain TG [29]. The main hydrolytic products of gastric lipase are DG and FAs [27,28,30]. Gastric lipase does not hydrolyze phospholipids or cholesterol ester. Human gastric lipase has been cloned; it has 379 amino acid residues [31], and interestingly, there is considerable homology (78%) between the amino acid sequences of rat lingual lipase and human gastric lipase. Little homology exists between human gastric lipase and human pancreatic lipase.

The digestion of TG by gastric lipase in the stomach plays an important role in lipid digestion, particularly in neonates. Milk fat, the primary source of nourishment for neonates, largely consists of medium-chain TG, which, as mentioned, are more efficiently hydrolyzed by acid lipases. Furthermore, the pancreatic lipase system is not fully developed in the neonate [32]; gastric lipases therefore play a crucial role in the neonatal digestion and absorption of milk fat.

The integral role played by gastric lipases in lipid digestion in adults is especially evident in patients with cystic fibrosis, who maintain the ability to absorb dietary lipid, despite markedly or completely inhibited pancreatic lipase secretion [33]. Gastric lipase activity in the stomach is not compromised in patients with cystic fibrosis; in fact, gastric lipase activity is high in these patients when they are maintained on diets with moderate and high fat levels [34]. The specific activity of adult human gastric lipase is much lower in vivo than in vitro; interestingly, the relatively low specific activity observed in vivo is sufficient to digest a significant portion of the TG ingested [35].

The stomach is the major site for emulsification of dietary fat, an important prerequisite for efficient hydrolysis by pancreatic lipase. Gastric chyme is propelled forward through the antrum to the pylorus by the peristaltic waves of the corpus (Fig. 18.3). Liquid is squirted into the duodenum along with small solid particles in the chyme. The pylorus closes, and the antrum contracts forcefully, grinding the solid particles. As a result of these contractions, the antral contents are retropelled from the terminal antrum back into the corpus. The squirting of the antral contents into the duodenum, the grinding action of the antrum, and the retropulsion of antral contents back to the corpus provide most of the mechanical action involved in the initial emulsification of dietary TG. The DG and FAs resulting from the action of acid lipases in the stomach and the phospholipids normally present in the diet further aid the emulsification of dietary fat.

Intestinal lumen

The lipid emulsion enters the small intestine as fine lipid droplets less than 0.5 μm in diameter, [36,37]; therefore the emulsification process that occurs in the stomach ensures

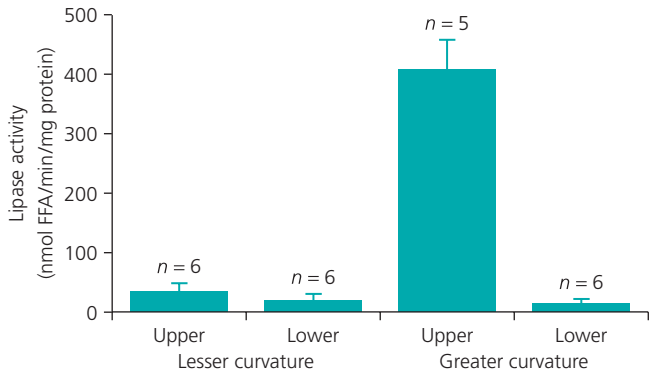

Figure 18.2 Lipolytic activity in the human stomach measured at four sampling sites in the gastric mucosa. FFA, free fatty acid. From Abrams et al. [27], with permission from Elsevier.

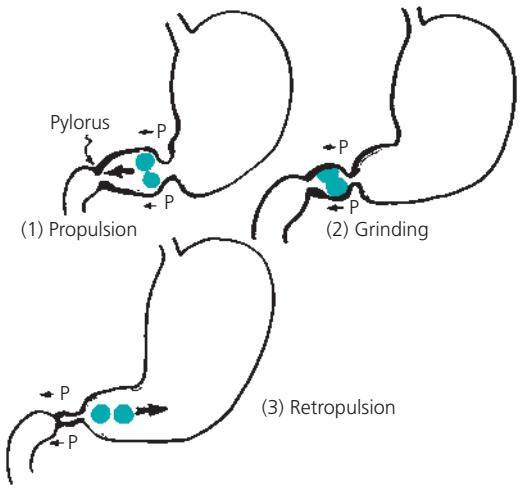

Figure 18.3 The consequences of antral peristalsis. From Kelly [288], with permission.

that lipid is emptied efficiently from the stomach. The combined action of bile and pancreatic juice in the small intestine produces a marked change in the chemical and physical form of the ingested lipid emulsion. Pancreatic lipase is responsible for most of the digestion of TG in the upper part of the intestinal lumen. Pancreatic lipase is active at the interface between the oil and aqueous phases [38–41]. Verger used the monolayer technique to elucidate the effects of the oil–water interface on lipolysis [42]. The application of a monomolecular lipid film at the air–water interface facilitates characterization of the effect of physicochemical properties of the interface, and also the effects of the surface area on the rate of lipolysis. The monolayer technique requires only a small amount of lipid, an advantage when using rare synthetic lipids. A problem with this technique, however, is the denaturation of enzymes that occurs at the lipid–water interface [43,44]. The velocity of lipolysis is dependent on those factors that modify both the physicochemical properties of the interface as well as the surface area [45–47]. The landmark paper of DiMagno and colleagues [48] convinced gastroenterologists that the human pancreas secretes more lipase than is needed to digest the fat ingested. Carriere and colleagues [49] challenged this concept with the measurement of the specific activity of human pancreatic lipase on dietary TG, which is three orders of magnitude lower than the very high specific activity measured under the usual in vitro experimental conditions. They proposed that the lipase activity in the human small intestine is not as high as believed, providing an explanation for why fat absorption takes a long time despite the seemingly large amount of lipase typically secreted by the human pancreas.

Pancreatic lipase acts mainly at the *sn*-1 and *sn*-3 positions of the TG molecule to release 2-monoacylglycerol (2-MG) and free FAs [46,50–52]. Although 1-monoacylglycerol (1-MG) is formed from 2-MG through isomerization in an aqueous medium, 2-MG is probably the predominant form in which MG is absorbed by the small intestine because 1-MG formation is slower than 2-MG uptake [53]. Further hydrolysis of 1-MG or 2-MG by pancreatic lipase results in the formation of glycerol and FAs [54]. Although pancreatic lipase hydrolyzes 1-MG more efficiently than 2-MG, the absorptive rate is so fast that most of the 2-MG is absorbed before degrading or isomerizing to form 1-MG.

Pancreatic lipase is abundant in pancreatic juice, accounting for 2%–3% of the total protein [55]. Its high concentration in pancreatic secretions and its high catalytic efficiency ensure the efficient digestion of dietary fat. Most humans absorb between 90% and 95% of the fat ingested. Consequently, only severe pancreatic deficiencies result in the malabsorption of fat. Pancreatic lipase has been purified from a number of species, including humans [56–59]. Porcine pancreatic lipase is a glycoprotein that contains 449 amino acid residues and a carbohydrate chain of about 2000 Da attached to asparagine at position 166 [60–62]. For pancreatic lipase to exert its enzymatic activity, it must anchor itself at the interface. The serine residue at position 152 plays an important role in this binding site [63].

Pure pancreatic lipase functions extremely inefficiently when acting in a bile salt–lipid mixture, but in pancreatic juice, lipase hydrolyzes TG extremely effectively. This interesting observation led to the discovery of the cofactor known as colipase. In 1969, Morgan and colleagues made the crucial observation that colipase is necessary for efficient lipase activity only if bile salt is present [64]. Studies performed in the laboratories of Professor Borgström in Lund and Professor Desnuelle in Marseille investigated the biochemistry of colipase and its interaction with pancreatic lipase. Colipase has been purified from a number of animal species [65–68]. The mechanism of how colipase works has been discussed in detail by Erlanson-Albertsson [69], who observed that TG lipid droplets covered with bile salts are not accessible to pancreatic lipase. However, the binding of colipase to the TG–aqueous interface allows the lipase molecule to access the lipid–aqueous interface. With the use of site-directed mutagenesis, Freie and colleagues [70] demonstrated that a valine residue at position 407 and a leucine at position 412 are important in the interaction of lipase with colipase and the bile salt micelles. The bile salt micelle, in addition to its role in transporting digested lipids to the enterocytes, also plays a crucial role in the lipolysis of TG by pancreatic lipase. Pancreatic lipase binds with colipase at a 1 : 1 molar ratio [71].

Digestion of phospholipid

The digestion of phospholipid occurs in the small intestine; gastric lipase is incapable of digesting phospholipid. In bile, phospholipid (predominantly phosphatydylcholine [PC]) is found in mixed micelles along with cholesterol and bile salts. In the intestinal lumen, PC distributes itself between the mixed micelles and the TG droplets, with a preference for the micellar phase over the oil phase [72]. PC is then acted on by pancreatic phospholipase A_2 (PLA_2) at the *sn*-2 position to yield a FA and lysophosphatidylcholine (LPC) [73,74]. Some phospholipase A_1 (PLA_1) activity may also occur in pancreatic juice as a result of the presence of pancreatic lipase [75]. PLA_2 was first purified and characterized from porcine pancreas [76]; it has a molecular weight of about 14 000 Da and is secreted as an anionic zymogen that is activated by tryptic cleavage of an amino-terminal heptapeptide [76–78]. PLA_2 requires calcium for activation [79,80] and its activity requires the presence of bile salts [81]. It has multiple isoforms [82,83] and apparently requires a bile salt : PC molar ratio of 2 : 1 for optimal activity [84]. It is heat stable, and acts most efficiently within a pH range of 8–9 [81].

Porcine, canine, and human phospholipases have been sequenced [85–88]. Richmond and Hui [89] reported the genomic organization of the PLA_2 gene of the mouse and showed that the mouse protein was highly homologous to

the rat, dog, and human proteins. Although most intestinal PLA_2 activity is derived from pancreatic juice, the intestinal mucosa likely contributes some where the enzyme is concentrated in the brush border [90].

Digestion of cholesteryl ester

Most dietary cholesterol is present as the free sterol, with only 10%–15% existing as the sterol ester [91]. Cholesteryl ester entering the small intestine must first be hydrolyzed before free cholesterol can be absorbed. The enzyme involved in the hydrolyzation process is cholesterol esterase, also known as carboxylic ester hydrolase or sterol ester hydrolase. It has been purified from porcine [92,93], rat [94], and human [95,96] pancreas. Human cholesterol esterase has a molecular weight of about 100 kDa [95], whereas rat cholesterol esterase has a molecular weight of 70 kDa [94]. Rat, bovine, and human pancreatic cholesterol esterases have been cloned [97–99] and seem to be well conserved among species, sharing 78% homology in rat and human. With the use of site-directed mutagenesis, DiPersio and colleagues [100] showed that substitution of the serine at position 194 with threonine or alanine abolished enzyme activity, thus identifying part of the catalytic site of pancreatic cholesterol esterase. This laboratory further demonstrated that histidine in position 435 is probably also a component of the catalytic triad of this enzyme [101]. The third component of the trio is an aspartic acid residue at position 320 [102]. Human cholesterol esterase likely shares the same catalytic sites as those of the rat esterase.

Human cholesterol esterase has a broad specificity and can hydrolyze TG, cholesterol esterases, and phosphoglycerides [103]. Cholesterol esterase activity is greatly enhanced by the presence of bile salts, particularly trihydroxy bile salts such as sodium cholate. A unique property of cholesterol esterase is its unique ability to self-associate. For example, the presence of trihydroxy bile salts promotes the self-aggregation of the enzyme into a polymeric form [94]. The self-association of cholesterol esterase protects the enzyme from proteolytic inactivation, so retaining its activity. Cholesterol esterase isolated from the pancreas exists mainly as dimers and tetramers [96].

Micellar solubilization and uptake of dietary lipids by enterocytes

Hofmann and Borgström discovered the importance of micellar solubilization in the uptake of lipid digestion products by enterocytes [104,105]. This concept was later challenged by Carey and associates, who discovered the coexistence of unilamellar liposomes and bile salt–lipid mixed micelles in the small intestine [37]. Only recently has the uptake of lipid digestion products by enterocytes been accepted as a passive process. However, several investigators have raised the possibility that some lipids may be taken up by the enterocytes by way of carrier-mediated processes that are energy dependent. This theory will be reviewed in the next section.

Importance of micellar solubilization

Understanding the importance of micellar solubilization of 2-MG and FAs in their uptake by enterocytes requires an understanding of the role of the unstirred water layer – a concept introduced by Dietschy and colleagues [106–108]. The brush border membrane of the enterocytes is separated from the bulk fluid phase in the intestinal lumen by an unstirred water layer (Fig. 18.4). This unstirred water layer mixes poorly with the bulk fluid phase; consequently, solute molecules in the bulk phase gain access to the brush border membrane by diffusion across the unstirred water layer. The solubility of FAs and MG in an aqueous medium is extremely low so very few molecules gain access to the brush border membrane (see Fig. 18.4, arrow 1). In contrast, the micellar solubilization of MG and FAs greatly enhances the number of molecules available for uptake by the enterocytes (see Fig. 18.4, arrow 2). Micellar solubilization increases the aqueous concentration of FAs and MG many fold. Despite the slower rate of diffusion of the micelle relative to the monomolecular FA molecule (because of size differences), micellar solubilization still markedly enhances the diffusion of FA and MG molecules across the unstirred water layer. The same mechanism applies to the transport of lipid-soluble drugs and compounds across the unstirred water layer to the enterocytes.

If micellar solubilization is so important in the absorption of lipid-soluble molecules such as fatty acids and cholesterol, is the absorption of lipid-soluble molecules purely a function of the degree of solubilization by micelles? The answer is "No." Several investigators have demonstrated that trihydroxy bile acids are more effective in promoting cholesterol absorption than dihydroxy bile acids [109–111]; however, the degree of solubilization was not measured in these experiments. Watt and Simmonds [111] showed a linear relationship between the amount of cholesterol taken up by the small intestine and the micellar cholesterol concentration, demonstrating the importance of micellar solubilization in the uptake of cholesterol. With the use of the nonionic surfactant Pluronic F-68 (BASF, Mount Olive, NJ) to promote the micellar solubilization of cholesterol but not its uptake by enterocytes, Watt and Simmonds demonstrated that the uptake of cholesterol by the enterocytes is dependent on the planar structure of the bile acid [111]. The role of bile salt in intestinal cholesterol uptake thus extends beyond its participation in cholesterol solubilization. This is further illustrated by the fact that chenodeoxycholyl taurine (CDC-tau) is a better micellar solubilizer of cholesterol than cholyl taurine (C-tau), even though cholesterol uptake is significantly greater with C-tau than it is with CDC-tau [112–114].

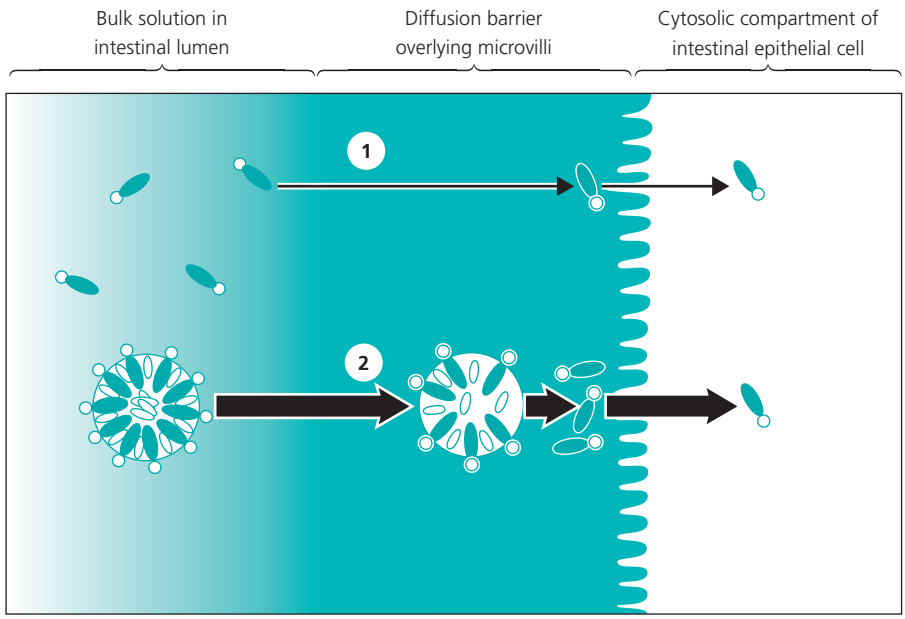

Figure 18.4 The effect of bile salt micelles (or vesicles) in overcoming the diffusion barrier resistance presented by the unstirred water layer. In the absence of bile acids, individual lipid molecules must diffuse across the barriers overlying the microvillus border of the intestinal epithelial cells (arrow 1). Hence, uptake of these molecules is largely diffusion limited. In the presence of bile acids (arrow 2), large amounts of these lipid molecules are delivered directly to the aqueous–membrane interface so that the rate of uptake is greatly enhanced. From Westergaard and Dietschy [108], with permission from the American Society of Clinical Investigation.

A particularly important point about the study of Watt and Simmonds [111] is that the uptake of cholesterol by a hydrophobic acceptor (silicone tubing) was the same for the cholesterol micellar solubilized with either Pluronic F-68 or bile acid. This suggests that the uptake of cholesterol by the enterocytes is an active process possibly mediated by a transporter. This supports an earlier finding by Sylven [115], who found that both cholesterol and β-sitosterol (plant sterol) are present in the human diet, although cholesterol, unlike β-sitosterol, is well absorbed by the small intestine. Sylven observed that the ability of the small intestine to discriminate between cholesterol and β-sitosterol absorption is energy-dependent and compromised by deprivation of blood supply [115]. The possibility that transporters are present at the brush border membrane is witnessed in patients with sitosterolemia, a condition in which the intestine fails to discriminate between cholesterol and β-sitosterol [116–118]. The importance of bile salts in facilitating the uptake of lipid-soluble molecules, including drugs, by the small intestine may therefore extend beyond their detergent properties to potential therapeutic applications. This topic will be discussed in the section on mucosal transporters.

Importance of unilamellar vesicles

When human jejunal contents collected during the digestion of a lipid meal are spun in an ultracentrifuge, there is a solid particulate layer on the bottom of the tube, a clear micellar layer in the middle, and an oily phase on the top [105]. The oily phase consists mostly of TG, partial glycerides, and FAs. The clear micellar phase consists of bile salts, FAs, and MG. However, when Porter and Saunders [119] carefully analyzed the aqueous phase after ultracentrifugation and after the intestinal contents had passed through a series of filters with progressively smaller pores (the smallest being 100 nm in diameter), they found that the resultant fraction did not display a clear micellar phase. Instead, a slightly turbid phase was observed. Furthermore, the micellar phase exhibited a concentration gradient of lipids. The full implication of this finding was not appreciated until later, when Patton and Carey observed the digestion of fat in vitro using light microscopy [120]. These investigators observed the constituent presence of at least three phases during fat digestion:

- the oil phase (mainly TG, partial glycerides, and FAs)
- the calcium soap phase (Ca^{2+} ions and protonated long-chain FAs)
- the viscous isotropic phase (MG and FAs).

Therefore, to divide the intestinal contents into an oil phase and a micellar phase oversimplifies the process of fat digestion.

Carey and colleagues [37] proposed that when the bile salt concentration in the lumen exceeds the critical micellar concentration, the lipid in the intestinal lumen is incorporated into mixed micelles, and that these probably assume the form of mixed disc-like particles, more or less saturated with lipids, with a hydrodynamic radius of about 20 nm. Further increases in the amount of lipid in the aqueous phase lead to the formation of liquid crystalline vesicles (liposomes) with hydrodynamic radii of 40–60 nm [37,121]. This finding may have important clinical implications. Patients with low intralumenal bile salt concentrations [122], or those with biliary fistulae [123], seem to be able to absorb fat well. Carey and colleagues proposed that the liquid crystalline vesicles play an important role in the uptake of FAs and MG by enterocytes [37] in these types of conditions. Woollett and

colleagues [124] addressed this question in a study of human subjects with inborn errors of bile acid synthesis who were being treated with supplemental bile acid therapy. The study commenced 3 weeks after the withdrawal of the supplements, and involved the administration of a lipid meal with or without bile acid added. With the absorption of the more polar phospholipids and fatty acids, it would appear that lipids incorporated in either the micelle or the vesicle are taken up by the enterocytes as well. In contrast, cholesterol uptake by the enterocytes is dependent on the cholesterol being incorporated into mixed micelles and the uptake from vesicular cholesterol is very poor.

The aqueous phase may contain liquid crystalline vesicles in addition to mixed disk-shaped micelles [125]. Both cholesterol and LPC are presumably incorporated into both the disc-shaped micelles and into liquid crystalline vesicles before their uptake by enterocytes. Shoemaker and Nichols [126] observed that bile salts and lysophospholipids form submicellar aggregates that can coexist with artificial phospholipid vesicles in an aqueous medium. Shoemaker and Nichols subsequently provided convincing evidence that these submicellar aggregates serve as an efficient shuttling mechanism for the transfer of lysophospholipids between membranes [127]. The existence of these submicellar aggregates in the intestinal lumen, and their role in delivering lysophospholipids and, potentially, lipid-soluble drugs, to the enterocytes for absorption, remain to be demonstrated.

Mucosal brush border membrane lipid transporters

It was generally believed that FAs and MG were absorbed by the enterocytes through simple diffusion [1]. Strauss demonstrated simply and elegantly that the uptake of FAs is passive and not temperature dependent [128]. The MG and FAs enter the enterocytes as monomers [1]. Studies by Stremmel have indicated the existence of a FA-binding protein associated with the brush border membrane that plays a role in the uptake of FAs by enterocytes [129]. The idea that FAs may be taken up by enterocytes by way of a carrier-mediated process was implied by Chow and Hollander [130] who showed that linoleate uptake by the small intestine reflects a concentration-dependent dual mechanism of transport. At low linoleate concentrations, FAs are taken up by way of a carrier-dependent process, whereas at a higher linoleate concentration, FAs are taken up predominantly by passive diffusion. Stremmel also raised the possibility that some lipids, especially FAs, may be taken up by enterocytes by way of carrier-mediated processes [129,131]. Although Stremmel mainly focused on FA uptake, he observed that this FA-binding protein was also capable of transporting cholesterol, but not cholesterol ester. This finding came after the discovery that cholesterol uptake by a jejunal loop treated with the antibody against this FA-binding protein was significantly reduced. This protein is mainly present in the apical and lateral regions of the villus (where tight junctions are located) and in the crypt [131]. The results of this research suggest that this FA-binding protein is a plausible candidate transporter for an array of lipid molecules, including cholesterol. This conclusion, however, raised questions. First, this transporter was later identified to be the mitochondrial glutamic oxaloacetic aminotransferase, which is an intracellular enzyme not involved in lipid absorption [132]. Second, why do crypt cells express this protein when they are not involved in fat absorption?

Thurnhofer and colleagues first described the presence of a binding protein in the small intestinal brush border membrane that facilitates the uptake of cholesterol by the small intestine [133–136]. The protein has an apparent molecular weight of about 14 kDa as determined by sodium dodecyl sulfate–polyacrylamide gel electrophoresis, or a value of 11.5 kDa if determined by gel filtration on Sephadex G-75 SF (Pharmacia, Döbendorf, Switzerland). With the use of the brush border membrane, Thurnhofer and colleagues [135] demonstrated that cholesterol uptake is most effective from cholate-mixed micelles and is characterized by short half-times of seconds. As expected, proteolytic treatment of the brush border membrane vesicles significantly reduced the capacity of these vesicles to take up cholesterol. When polyclonal antibodies raised against the 14-kDa protein were present in the incubation medium, cholesterol uptake by these vesicles was significantly reduced. This 14-kDa protein was later identified as SCP-2 (synaptonemal complex protein 2), which is an intracellular protein [137]. Thus, the identity of the plasma membrane-bound cholesterol transport protein, if it exists, remains obscure. These searches were fruitless, in part, because of problems associated with the use of hydrophobic ligands as the bait, which often bind nonspecifically to proteins in the brush border preparations. The cross-contamination of the brush border membrane with proteins from other subcellular fractions is another complication.

A number of other proteins have also been shown to bind lipids. These include GP330 (also called megalin), CD36, and caveolin. GP330, a member of the low-density lipoprotein receptor gene family, is an endocytic receptor expressed in many absorptive epithelia, including the kidney proximal tubules, type II pneumocytes, mammary epithelium, and thyroid follicular cells [138]. GP330 is involved in the renal uptake of polybasic drugs [138–140], vitamin B-12 [140], cholesterol-carrying lipoproteins [141], albumin [142], and proteases [139]. The failure of the forebrain of GP330 knockout mice to develop has been attributed to the deficient supply of cholesterol to the brain of the fetus through the maternal–fetal lipoprotein transport system [143]. The expression of GP330, or a related protein, in the intestine remains uncertain [138]. Moreover, whether or not GP330 participates in cholesterol uptake by the small intestine remains unknown. Hauser and colleagues [144] provided evidence that the scavenger receptor BI (SRBI) is involved in

intestinal uptake of cholesterol. Schulthess and colleagues [145] demonstrated that the uptake of cholesterol mediated by scavenger receptors is inhibited by an amphipathic α-helix of 18 amino acids, lending further support to the involvement of SRBI in intestinal cholesterol absorption. Van Bennekum and colleagues [146] have provided additional information that SRBI is involved in intestinal cholesterol uptake and that this uptake can be inhibited by ezetimibe, which is a potent inhibitor of cholesterol uptake by enterocytes.

A membrane transporter for FAs has been identified in adipocytes. This FA transporter is inhibited by sulfo-*N*-succinimidyl derivatives of long-chain FAs [147–151] and by 4,4′-diisothiocyanostilbene-2-2′-sulfonate. It has an apparent molecular weight of 88 kDa, an isolectric point of 6.9, and a strong sequence homology to CD36 and PAS IV. PAS IV is a protein enriched in the apical membranes of lipid-secreting mammary cells during lactation, and cloning of this binding protein revealed that it bears 85% homology to CD36, which is present in human platelets and lactating mammary epithelia [148]. Northern blot analysis revealed that the message is abundant in the heart, intestine, fat, muscle, and testis [149–151]. Fatty-acid transporters have been localized to the brush border membrane, and expression is highest in the jejunum, less abundant in the duodenum, and least in the ileum [151]. Research has shown that a high-fat diet, rich in long-chain FAs, but not medium-chain FAs, results in increased fatty acid transporter expression [152]. With the use of the lymph fistula mouse model, Nauli and colleagues [153] have demonstrated that CD36 is involved in promoting the uptake of cholesterol by the small intestine, and although it does not seem to be involved in the uptake of fatty acids by the small intestine, it plays an important role in the packaging of absorbed fatty acids as TGs into chylomicrons.

Other potential binding proteins have been identified. One binding protein for long-chain FAs was cloned in adipocytes by Schaffer and Lodish [154]. Recently, Stahl and colleagues [155] identified the presence of FATP4, a member of the large family of fatty acid transport proteins, in the small intestine. Moulson and colleagues [156] reported that a wrinkle-free phenotype is associated with the spontaneous autosomal recessive mutation of the gene for FATP4, resulting in a very tight and thick-skinned phenotype. This observation was confirmed in a subsequent report by Herrmann and colleagues [157], which showed that the lack of FATP specifically in the epidermis of the skin results in the same phenotype. Hall and colleagues [158] showed that FATP4, in addition to its role in the uptake of FAs, might also exhibit acyl-coenzyme A (CoA) synthetase activity. As yet, the role of FATP4 in the uptake of FAs in vivo is unclear. Caveolin is another protein that binds cholesterol [159]. Caveolin was the first-reported protein associated with caveolae, the non-clathrin-coated invaginations present on the cell surface that function to bind glycolipids [160], cholesterol [161], glycosyl-phosphatidylinositol-linked proteins [162], and other proteins for potocytosis [163]. It is unknown if caveolin plays a role in the intestinal absorption of cholesterol and FAs.

The investigation of transporters involved in cholesterol absorption has yielded two exciting developments. The first involves the drug ezetimibe, a potent inhibitor of intestinal cholesterol absorption [164–166]. Earlier studies showed that photoaffinity derivatives of ezetimibe specifically labeled the SRBI protein [167]. In vitro studies from two independent laboratories showed that mammalian cells transfected with SRBI cDNA display an increased ability for cholesterol uptake from micellar substrates in comparison to mock-transfected cells with constitutively low SRBI expression [167–169]. Most importantly, the increased capacity for cholesterol uptake by SRBI-transfected cells was indeed subject to ezetimibe inhibition in both of these studies [167,169]. When considered together, these data support a role for SRBI on the membrane of enterocytes as the cholesterol transporter responsible for cholesterol absorption from the intestinal lumen. The distribution of SRBI along the gastrocolic axis (mostly in the duodenum and the jejunum) and on the apical side of the brush border membrane is also consistent with the hypothesis that SRBI participates in cholesterol absorption [169–171]. Another cholesterol transporter that has been implicated in cholesterol absorption is the NPC1L1 (Niemann–Pick C1-like 1) protein. Altmann and colleagues [172] demonstrated that NPC1L1 plays an important role in the absorption of cholesterol by the small intestine. NPC1L1 is expressed mostly in the duodenum and the jejunum, although substantial protein levels may be measured in the ileum. Davies and colleagues observed that the inactivation of NPC1-L1 results in the reduction of intestinal cholesterol absorption, and the prevention of diet-induced hypercholesterolemia [173]. As expected, Davis and colleagues reported that cholesterol/cholate feeding results in the down-regulation of intestinal NPC1L1 messenger RNA (mRNA) expression in wild-type mice [174]. NPC1L1 deficiency results in an up-regulation of intestinal hydroxymethylglutaryl–CoA synthase mRNA expression, an increase in intestinal cholesterol synthesis, down-regulation of ABCA1 mRNA, but no change in ABCG5 and ABCG8 mRNA expression. The studies of Altmann [172], Garcia-Calvo [175], and Iyer [176] and their colleagues seem to imply that NPC1L1 is expressed in the intestinal epithelial cells, probably at the apical membrane.

The second exciting development in the area of cholesterol absorption is the discovery that cholesterol absorption in the small intestine is regulated by ATP-binding cassette (ABC) transporters. Repa and colleagues [177] reported that intestinal absorption of cholesterol is regulated by the expression of the reverse cholesterol transporter ABCA1. In turn, ABCA1 is regulated by the formation of heterodimers of retinoid X

receptors (RXRs) with either oxysterols (LXRs) or with the bile acid receptor (FXR). Berge and colleagues identified seven different mutations in two adjacent genes encoding two ABC transporters ABCG5 and ABCG8 in β-sitosterolemic patients [178]. The same group hypothesized that ABCG5 and ABCG8 normally cooperate to restrict the intestinal uptake and biliary secretion of sterols. Mutation of these genes results in the excess uptake of sterols, including plant sterols such as β-sitosterol. Lee and colleagues [179] reported the mutation of ABCG5 in nine unrelated patients with sitosterolemia. Although these new findings are of integral importance in our mechanistic understanding of how the gut discriminates between the uptake of cholesterol and plant sterols, many questions remain. First, the mechanism of how the various ABC transporters in the gut regulate cholesterol absorption is still not clear. Second, are ABC transporters involved in the reverse transport of other lipid-soluble compounds, including lipid-soluble drugs? Lastly, it would seem that the physiological and therapeutic manipulations of ABC transporters are potential ways to modify intestinal cholesterol absorption in animals and humans. This subject has been reviewed by Wang [180].

Intracellular metabolism of dietary lipids

It is not known how the various absorbed lipids migrate from the site of absorption to the endoplasmic reticulum, where biosynthesis of complex lipids occurs. A FA-binding protein (FABP) in the small intestine has been isolated and characterized by Ockner and Manning [182]. It has been suggested that FABP plays an important role in the intracellular transport of absorbed FAs. This is partly supported by the findings that FABP concentration is greater in villi than in crypts, greater in the jejunum than in the ileum, and greater in the intestinal mucosa of animals fed a high-fat diet than in those fed a low-fat diet [181,182]. There are at least two FABP types in enterocytes – the I-FABP and L-FABP. The preceding letter indicates the organ from which the form was first isolated (i.e., I = intestine and L = liver). These two FABPs differ in their binding specificities. I-FABP binds strongly with FAs, and L-FABP binds with long-chain FAs, LPC, retinoids, bilirubin, carcinogens, and even selenium [183–185]. Considering the results of nuclear magnetic resonance binding studies, Cistola and colleagues [186] speculated that the binding of I-FABP is involved in the intracellular transport of FAs, whereas L-FABP is involved in the intracellular transport of MG and LPC. However, these functions of FABP have not been tested rigorously in vivo. A comprehensive review of the binding proteins of FAs has been published by Storch and Thumser [187].

Demonstrating the in vivo functions of the FABPs is challenging. One strategy has been to knock out the gene of a particular FABP. This, however, has not yielded definitive results because other FABPs are often capable of compensating for the deficit in function that the knocked out FABP assumed. For example, when Shaughnessy and colleagues [188] used the adipocyte FABP knockout mouse model to study its function, the keratinocyte FABP compensated for the absence of the adipocyte FABP. Using the I-FABP knockout mouse model, investigators found that males have higher plasma TG levels and heavier body weight than wild-type mice [189], implying that fat absorption is probably normal in these genetically modified animals. The female knockout mice weighed more than the wild-type mice but less than the male knockout mice. When the investigators who had generated the mice determined if fat absorption was compromised, they found no difference between I-FABP null animals and wild-type animals [190]. As noted earlier, one should not conclude from these data that I-FABP is not physiologically important for fat absorption, as other intracellular FABPs may be compensating for the lack of I-FABP. Newberry and colleagues [191] reported that the L-FABP animals did not exhibit fat malabsorption, but the kinetics of intestinal lipid secretion was slower in the null animals than in the wild-type animals. Investigation of how these FABPs function in a concerted manner to facilitate fat absorption in the intestine is ongoing in a number of laboratories.

Two sterol carrier proteins, SCP1 (47 kDa) and SCP2 (13.5 kDa), have been isolated and characterized [192,193]. SCP1 is important in the microsomal conversion of squalene to lanosterol [194], whereas SCP2 (also known as the nonspecific lipid transfer protein) participates in the microsomal conversion of lanosterol to cholesterol [195]. In addition, SCP2 is involved in the intracellular transport of cholesterol from cytoplasmic lipid droplets to mitochondria and also in the translocation of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane [196]. Further, SPC2 appears to be involved in the intracellular trafficking of PC and FAs, and it may play a role in peroxisomal FA–CoA binding [197–200].

Intracellular metabolism of monoacylglycerols and fatty acid

2-MG and FAs are reconstituted to form TG, mainly by way of the MG pathway. As shown in Figure 18.5, 2-MG is reacylated into TG by the consecutive action of MG acyltransferase and DG acyltransferase (DGAT) [201,202]. The enzymes involved in this MG pathway reside in a complex called TG synthetase [201,203], which has been purified by Lehner and Kuksis [204]. It is thought that the synthesis of TG from DG is catalyzed by the enzyme acyl-CoA : diacylglycerol acyltransferase. The gene for this enzyme, *DGAT1*, has been isolated, and a knockout mouse has been generated. Interestingly, this mouse is able to synthesize normal

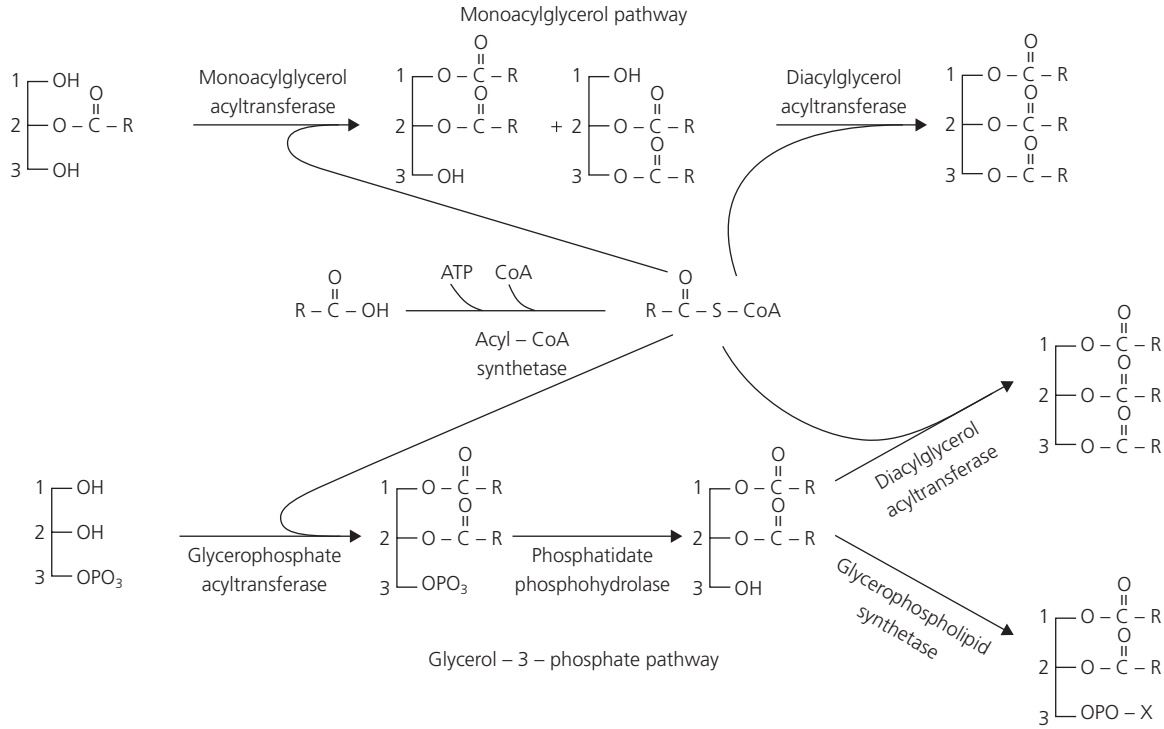

Figure 18.5 Pathways of triacylglycerol biosynthesis in the intestinal mucosa.

amounts of TG in the intestinal mucosa [205], which implies that another enzyme may be involved in the formation of TG from DG. This notion is supported by data from Oelkers and colleagues [206] showing that a lecithin cholesterol acyltransferase-like gene produces an enzyme that mediates DG esterification in yeast. Further, data generated from the DGAT knockout animals [204] suggest that a related protein is also present in intestinal epithelial cells.

Several studies have demonstrated that the enzymes involved in the MG pathway are located on the cytoplasmic surface of the endoplasmic reticulum [207]. This finding has important implications for the understanding of the intracellular packaging of lipoproteins. The data indicate that TG is formed at the cytoplasmic surface of the endoplasmic reticulum, and then enters the cisternae of the endoplasmic reticulum. Because TG has a low solubility in phospholipid bilayers (~ 3 mol%), Atkinson and Small [208] postulated that TG molecules rapidly saturate the membrane. Once the solubility of TG is exceeded, the TG splits the bilayer and forms a small lens. As the lens grows, it bulges into the cytoplasmic or cisternal side of the endoplasmic reticulum. Finally, this protrusion pinches off from the membrane and forms lipid droplets in the cytoplasm or precursors of lipoproteins in the cisternae of the endoplasmic reticulum. Using ultrastructural studies, Wetterau and Zilversmit [209–211] showed that a protein in the liver, small intestine, and several other organs promotes the transfer of TG and cholesterol esterase between membranes. The function of this transfer protein will be discussed in the section of disorders of intestinal lipid transport.

A second pathway in the intestinal mucosa leading to TG formation is the α-glycerophosphate pathway [201,202]. This pathway involves the stepwise acylation of glycerol-3-phosphate to form phosphatidic acid (see Fig. 18.5). In the presence of phosphatidate phosphohydrolase, phosphatidic acid is hydrolyzed to form DG, which is then converted to TG. The relative importance of the MG pathway and the α-glycerophosphate pathway depends on the supply of 2-MG and FA. During normal lipid absorption, when the level of 2-MG is adequate, the 2-MG pathway facilitates the conversion of 2-MG and FA to form TG and aids in inhibiting the α-glycerophosphate pathway [201,202,212]. Conversely, when the supply of 2-MG is lacking or insufficient, the α-glycerophosphate pathway becomes the major pathway for the formation of TG.

Phospholipids

Some absorbed LPC is reacylated to form PC (213–216). The remaining absorbed LPC is hydrolyzed to form glycero-3-phosphorylcholine [217]. The liberated FA is used for TG synthesis, whereas the glycero-3-phosphorylcholine is readily transported by way of the portal circulation for use in the liver [218]. Another reaction that occurs in the intestinal mucosa is the combining of two molecules of LPC to yield one molecule of PC and one molecule of glycero-3-phosphorylcholine [104,219].

Cholesterol

Exogenous cholesterol absorbed by the enterocytes enters a pool of free cholesterol within the enterocytes in which cholesterol from endogenous sources is also stored. Endogenous cholesterol is derived from three sources:

- nondietary cholesterol absorbed from the lumen (biliary cholesterol and cholesterol from cells shed from the intestinal mucosa)
- cholesterol derived from plasma lipoproteins [220]
- cholesterol synthesized de novo [221–223].

The cholesterol from each source is handled uniquely. For example, cholesterol derived from the intestinal lumen does not mix evenly with the free cholesterol pool and is preferentially esterified in the enterocytes for export into lymph as TG-rich lipoproteins [224–226]. Stange and Dietschy observed that very little newly synthesized cholesterol is transported into lymph during fasting [225]. However, during active lipid absorption, significantly more newly synthesized cholesterol is incorporated into the TG-rich lipoproteins that are transported in lymph. Cholesterol synthesis and the uptake of lipoproteins by the small intestine are discussed in articles and reviews by Spady and colleagues [220, 228], Dietschy and colleagues [227], and Stange and Dietschy [225].

Cholesterol is transported mainly as esterified cholesterol and almost exclusively by the lymphatic system. The rate of esterification of cholesterol regulates its lymphatic transport [229]. Two proposed enzymes involved in cholesterol esterification are cholesterol esterase (230,231) and acyl-CoA cholesterol acyltransferase (ACAT) [230,232,233]. The distribution and regulation of ACAT in the small intestinal epithelium has been studied extensively. The rat jejunum and ileum both have high specific activities of ACAT, albeit slightly higher activity in the jejunum than the ileum. Conversely, the specific activity of ACAT in the guinea pig, rabbit, and human is significantly higher in the jejunum than in the ileum [234–236]. This enzyme is stimulated by ingestion of a diet with high levels of cholesterol [234,235]. However, it is not clear whether this increase in ACAT activity is caused by the high levels of cholesterol or by the increase in microsomal cholesterol that is isolated from these animals for the purpose of conducting the ACAT bioassay.

With the use of immunocytochemistry, Gallo and colleagues [237] demonstrated that intracellular cholesterol esterase is derived from pancreatic cholesterol esterase. A later study by Field [238] confirmed the presence of cholesterol esterase in the enterocyte. It remains unclear how pancreatic cholesterol esterase is taken up by the enterocyte. An understanding of this process is of biological and therapeutic interest because it will facilitate the delivery of peptides to the body through the gut. Normally, most peptides are digested by the proteases and peptides located both in the lumen and in the brush border membrane of the enterocytes.

Most investigators believe that ACAT plays a more important role in mucosal cholesterol esterification than does cholesterol esterase. Several substantiated observations support this hypothesis. First, ACAT displays the highest activity in the segment of the small intestine that is most actively involved in cholesterol absorption [234–236]. Second, the ACAT activity that is present in the intestinal epithelium adequately accounts for all of the cholesterol esterase transported by the small intestine [239]. Third, Watt and Simmonds [240] failed to demonstrate an effect of the diversion of pancreatic juice (the origin of mucosal cholesterol esterase) on the absorption and esterification of lumenal dietary cholesterol in rats with lymph fistulae. Finally, using a number of specific ACAT inhibitors, several studies have shown a reduction in lymphatic cholesterol output [230,241–243]. ACAT inhibitors continue to be synthesized, and interested readers are referred to the report by Lee and colleagues [244] for more information.

Chang and associates have played a pivotal role in the purification and identification of ACAT proteins [245–247]. Two ACAT proteins have been identified – ACAT1 and ACAT2. With the use of immunohistochemistry, Chang and colleagues [233] reported that ACAT1 is present in fetal and adult hepatocytes, and ACAT2 is present only in fetal hepatocytes. Furthermore, Chang and colleagues [246] found that the ACAT activity in the small intestine can be immunodepleted by antibodies raised against ACAT2, and that most of the ACAT2 is located at the apices of the villi. The role of ACAT2 in intestinal cholesterol absorption is supported by the findings of Buhman and colleagues [248], who reported that ACAT2 knockout mice are resistant to diet-induced hypercholesterolemia because they have defective cholesterol esterification and poor cholesterol absorption by the small intestinal epithelial cells.

Formation of intestinal chylomicrons and very-low-density lipoproteins

Despite the wealth of information gathered over the last 30 years about intestinal lipid absorption, the mechanism of the intracellular assembly, modification, and secretion of lipoproteins from small intestinal epithelial cells is not fully understood. This is partly because of the complexity of the processes involved, and the lack of good experimental models to study the various steps. Intestinal cell culture systems (e.g., CaCo-2 cells) have been used extensively to study the formation and secretion of lipoproteins [3, 249–252] and the genetic expression and posttranslational modification of apolipoproteins [253]. During fasting, very-low-density lipoproteins (VLDLs) are the only lipoproteins produced by the small intestine [254–256]. After a meal, the small intestine produces predominantly chylomicrons (CMs) [256,257]. The distinction between intestinal CMs and VLDLs is based

on an operational criterion. Lipoproteins that have a Svedberg flotation (S_f) rate exceeding 400 are classified as CMs; those with an S_f rate of 20–400 are defined as VLDLs [258]. Numerous studies support the idea that intestinal CMs and VLDLs represent lipoproteins produced by two separate pathways. Ockner and colleagues [254] showed that the intraduodenal infusion of palmitate causes a marked increase in VLDL transport, but that VLDL output remains unchanged when oleate and linoleate are infused. In contrast, CM output is markedly increased when oleate and linoleate are infused. The FA composition of the VLDL-TG is different from that of the CM-TG, suggesting the presence of two different pathways for VLDL and CM assembly. An ultrastructural and biochemical study conducted by Mahley and colleagues [259] showed that intestinal Golgi vesicles contain either CMs or VLDL particles and that little mixing of particle sizes occurs; conclusive evidence of separate biosynthetic pathways for the assembly of these distinct lipoproteins. Further evidence was provided by Vahouny and colleagues [260], who demonstrated that although puromycin had no significant effect on the incorporation of radioactive leucine into VLDL peptides in male rats, the incorporation of radioactive leucine into CM peptides was markedly inhibited.

Studies conducted by Tso and colleagues [261,262] have shown that rats fed as little as 0.5 mg/h of a hydrophobic surfactant Pluronic L-81 (BASF, Mount Olive, NJ) (L-81) have markedly impaired lymphatic transport of TG and cholesterol. These studies further demonstrated that L-81 inhibited lipid transport by blocking the formation of intestinal CMs, but not the formation of VLDL particles. With the use of this unique tool, Tso and colleagues further showed that intraduodenal infusion of egg PC in rats resulted mostly in the lymphatic transport of VLDLs, and that this transport was not affected by the administration of L-81 [263]. However, when triolein was infused, the lymphatic transport of lipid was inhibited because the feeding of triolein resulted primarily in the formation of CMs [261,262]. These results led Tso and colleagues to propose two pathways for the formation of intestinal lipoproteins – one that forms predominantly CMs and one that forms predominantly VLDLs (Fig. 18.6) [263]. Moreover, these investigators proposed that the pathway forming predominantly CMs is inhibited by L-81, but the pathway forming predominately VLDLs is not, and that preCM and preVLDL particles are packaged in the Golgi apparatus into either preCM or preVLDL-containing vesicles. The Golgi-derived vesicles containing either preCMs or preVLDLs probably correspond to the vesicle types observed by Mahley and colleagues [259]. This hypothesis is supported by the study conducted by Nutting and colleagues [264]. This laboratory measured the appearance time for CMs in control rats and for VLDLs in L-81-treated rats. The appearance time (defined as the time between placement of radioactive FA into the intestinal lumen and the appearance of radioactive lipid in lymph) was 10.8 min in control rats – significantly shorter than the 16.2 min in the L-81-treated rats. This difference in appearance time further supports the hypothesis that CMs and VLDLs are packaged separately in enterocytes. Finally, this in vivo observation can be duplicated in cell culture systems. With the use of CaCo-2 cells, Luchoomun and Hussain [266] also demonstrated that L-81 inhibits CM formation but not VLDL formation by enterocytes.

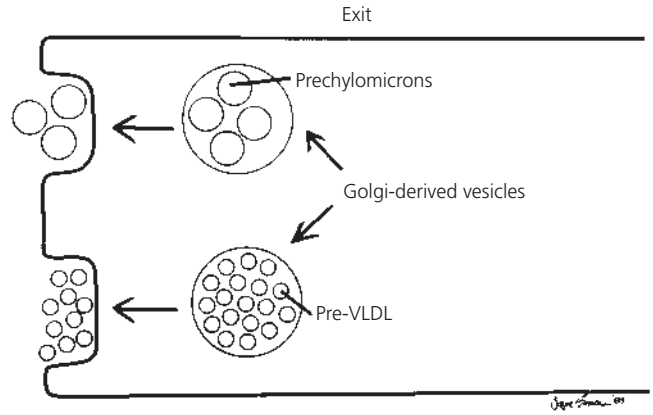

Figure 18.6 Packaging and secretion of intestinal chylomicrons and very-low-density lipoproteins (VLDLs). Golgi-derived vesicles contain either prechylomicron or pre-VLDL particles. Mixing of prechylomicron and pre-VLDL particles in these vesicles seldom occurs.

The fact that the infusion of PC results in the formation of VLDL whereas the infusion of TG results in the formation of CM is certainly of interest with respect to the delivery of lipid-soluble vitamins and drugs. Not only is the amount of drug that can be carried by a VLDL particle (smaller) different from that able to be carried by a CM particle, the difference in the metabolism of VLDL and CM particles may also affect the delivery of fat-soluble vitamins and drugs to different parts of the body. This is an interesting but poorly explored area of investigation.

The CaCo-2 cells have been used extensively to study the uptake as well as the formation and secretion of TG-rich lipoproteins. Based on their CaCo-2 studies, Hussain and colleagues proposed a sequential assembly model to study VLDL and CM formation [265]. This model provides information on the assembly of primordial lipoprotein particles, the synthesis of TG-rich lipid droplets, and the core expansion involving the fusion of primordial lipoproteins with lipid droplets. Readers interested in the details of this model are referred to an excellent review by Hussain [3]. CaCo-2 cells differ from the enterocytes in the small intestine in a number of important ways. First, CaCo-2 cells are derived from human colon carcinoma. Second, the CaCo-2 cells use the glycerol-3-phosphate pathway for the formation TG from fatty acids and glycerol, whereas intestinal epithelial cells use the MG pathway for the formation of TG [267]. Third, the intestinal epithelial cells synthesize only apolipoprotein (apo) B48, whereas CaCo-2 cells synthesize both apo B-48

and apo B-100. Lastly, the intestinal epithelial cells produce mainly CM particles during active fat absorption, whereas CM particles are never the major lipoproteins produced by the CaCo-2 cells. Therefore, although CaCo-2 cells have certainly been used successfully as surrogates of intestinal epithelial cells, cautious interpretation of the data generated by the CaCo-2 cells is warranted.

Clinical disorders of intestinal lipid transport

In humans, the liver secretes only apo B-100, and the small intestine secretes only apo B-48 [268–270]. Both apo B-100 and apo B-48 are encoded by the same gene [271,272]. The biogenesis of apo B-48 involves a unique mechanism by which the CAA codon encoding Gln at 2153 of the apo B-100 mRNA is changed to UAA (a stop codon), thus forming apo B-48. Rat apo B-48 has a molecular weight of about 240 kDa [273] and is an extremely hydrophobic protein [274]. Each CM or VLDL particle has one apo B-48 [275]. The absolute requirement of apo B for the formation of CM is well illustrated by the apo B knockout animals. We do not know, however, whether the production of apo B is physiologically rate limiting in the formation of CM by the enterocytes. Data from several laboratories indicate that the supply of apo B is probably not the rate-limiting step for forming CM. Hayashi and colleagues [276] demonstrated that apo B output in lymph, an indication of the number of CM produced by the small intestine, does not change after intraduodenal infusion of lipid, despite the fact that lymphatic TG output increases sevenfold to eightfold. These data support the finding by Davidson and colleagues [278] that lipid absorption does not lead to an increase in apo B synthesis.

Abetalipoproteinemia is a rare genetic disorder involving the complete failure of the liver and gut to make TG-rich lipoproteins [278,279]. It is believed that patients with abetalipoproteinemia have difficulty synthesizing apo B. Glickman and colleagues [269] reported that apo B synthesis, as determined by ^{3}H-labeled leucine incorporation, is decreased but not abolished in patients with abetalipoproteinemia, suggesting that failure to synthesize apo B by the gut and liver may not be the only reason that these patients do not produce CM and VLDL. This was later confirmed by the finding that abetalipoproteinemia results from the mutation of the microsomal TG transfer protein gene [280–283]. The role of microsomal TG transfer protein in the formation of chylomicrons by the small intestine is well covered in the reviews by Berriot-Varoqueaux and colleagues [284] and Hussain [3].

Anderson disease is another disorder in which there is a deficiency in the ability of the small intestine to form CMs [284–286]. Anderson disease is also known as chylomicron retention disorder because although observable CM particles are present in the enterocytes, there are none in the intercellular spaces, which suggests that the secretion of CMs is defective. Dannoura and colleagues has demonstrated that patients with Anderson disease do not have a defect in those genes that code for known apoproteins or microsomal TG transfer protein, suggesting that this condition is caused by a an unknown factor crucial for the secretion of chylomicrons [287]. There is no animal model available with which to study this perplexing disorder.

The digestion and assimilation of proteins differ from that of carbohydrates and lipids in a number of aspects. Unlike the carbohydrates in the diet, which consist of quantitatively significant amounts of monosaccharides (e.g., glucose and fructose) and disaccharides (e.g., sucrose and lactose) in addition to polysaccharides (e.g., starch and glycogen), dietary amino acids are ingested predominantly in the form of proteins rather than in the form of free amino acids or small peptides. Dietary carbohydrates are absorbed by the enterocytes exclusively as monosaccharides. Therefore, the polysaccharides and disaccharides in the diet must be completely digested in the intestinal lumen to monosaccharides before absorption can occur. In contrast, the digestion of proteins in the intestinal lumen is incomplete, resulting in the generation of a mixture of free amino acids and small peptides in which peptides predominate. A major proportion of the protein digestion products are absorbed by the enterocytes as small peptides, which are subsequently digested to free amino acids inside enterocytes. Thus, whereas specific transport systems exist in the small intestine only for the absorption of monosaccharides, distinct transport systems exist in this organ for the absorption of not only free amino acids but also small peptides. Furthermore, unlike dietary carbohydrates, which consist predominantly of only three structurally different monosaccharides (glucose, galactose, and fructose), dietary proteins comprise a much greater number of structurally and physicochemically diverse amino acids. Consequently, the enzymes and transport systems involved in the digestion and absorption of proteins outnumber those involved in the digestion and absorption of carbohydrates. Moreover, unlike dietary lipids and their digestion products, which are highly hydrophobic, dietary proteins and their digestion products are largely hydrophilic. Therefore, bile salts, which play an obligatory role in the solubilization of dietary lipids to facilitate their digestion and assimilation, do not play a direct role in the digestion and assimilation of dietary proteins. However, bile salts and bile salt–facilitated fat digestion may influence protein digestion indirectly because bile salts and fat digestion products in the intestinal lumen are important modulators of cholecystokinin secretion, a process that has a profound influence on the secretion of pancreatic enzymes involved in protein digestion.

Nutritional aspects of dietary proteins

The recommended daily allowance for dietary proteins in humans, when expressed per kilogram of body weight, declines in an age-dependent manner. In adults, this value is 0.75 g/kg; it is twice as much in newborns. The recommended daily allowance for dietary proteins increases during illnesses such as sepsis and during trauma; it also increases in women during pregnancy and lactation. The protein content of the average daily American diet is 70–100 g, which is more than adequate to meet the recommended daily allowance. Dietary proteins are required for two purposes: (1) to provide the amino acids that are nutritionally essential under all conditions (i.e., methionine, threonine, tryptophan, valine, isoleucine, leucine, phenylalanine, and lysine) and the amino acids that are conditionally essential under specific physiological and pathological conditions (i.e., cysteine, tyrosine, glutamine, histidine, and arginine); and (2) to provide nitrogen for the synthesis of nutritionally nonessential amino acids and other biologically important nitrogen-containing compounds. The nutritive value of various dietary protein sources depends on their content of the essential amino acids as well as on their digestibility. Proteins from animal sources have a high content of essential amino acids. Egg and milk proteins are routinely used as reference standards for

comparison of protein quality. Proteins from certain specific plant sources are "incomplete" because they lack or contain only limited amounts of some of the essential amino acids. However, by complementation with proteins that contain the missing amino acids, it is possible to overcome this deficit in a complete diet. Just as the essential amino acid content varies, the digestibility of different proteins also varies considerably. Protein digestibility is influenced by the type of protein and by the method of food processing before ingestion. Generally, plant proteins are less digestible than animal proteins. The relative contributions of animal proteins and plant proteins in the daily intake of dietary proteins differ markedly between developed and developing countries. For example, in North America and Western Europe, animal proteins contribute about 60%–70% of the total proteins in the diet. In contrast, this contribution is as low as 20% in Africa, the Middle East, and the Far East.

In addition to the proteins in the diet, substantial amounts of endogenous proteins enter the gastrointestinal tract and are digested and assimilated just like the dietary proteins. These endogenous proteins arise partly from saliva and gastric, biliary, pancreatic, and intestinal secretions, and partly from desquamated epithelial cells of the gastrointestinal tract. The secretions account for about 20–30 g of endogenous proteins per day, and desquamated cells account for an additional 30 g per day.

Digestion of proteins

The digestion of proteins occurs in two phases, defined by the site of digestion along the gastrointestinal tract: a gastric phase and an intestinal phase. The overall scheme of protein digestion in the gastrointestinal tract is depicted in Fig. 19.1.

Gastric phase

Protein digestion begins in the lumen of the stomach with the action of proteases elaborated by the chief cells. These enzymes, called pepsins, belong to the category of acidic proteases that are active at acid pH. The carboxyl group of aspartate, an anionic amino acid, at the catalytic site of these enzymes plays an obligatory role in the enzymatic activity. The enzymes are secreted as inactive precursors into the gastric lumen (i.e., pepsinogens), where they are autocatalytically activated to pepsins under acidic conditions (Fig. 19.2). Pepsinogens possess an amino-terminal region that is positively charged because of the high content of cationic amino acids. At neutral or alkaline pH, this region is folded in such a way that it masks the catalytic site. This inactive state is stabilized by electrostatic interaction between the cationic amino-terminal region and the acidic amino acids present at the catalytic site in pepsinogens, which are ionized at neutral or alkaline pH. In the acidic environment of the gastric lumen, these acidic amino acids are protonated, so that electrostatic interaction is destabilized, uncovering the catalytic site. The unmasked active site removes the amino-terminal region, consisting of about 40 amino acids, from pepsinogens by autocatalytic digestion to generate the active forms of the enzymes, the pepsins. Pepsins are endoproteases that hydrolyze internal peptide bonds in proteins and liberate large peptide fragments. Pepsins act preferentially on peptide bonds formed by the aromatic amino acids phenylalanine and tyrosine, as well as by the branched-chain amino acid leucine (Fig. 19.3). The action of these enzymes on proteins in the

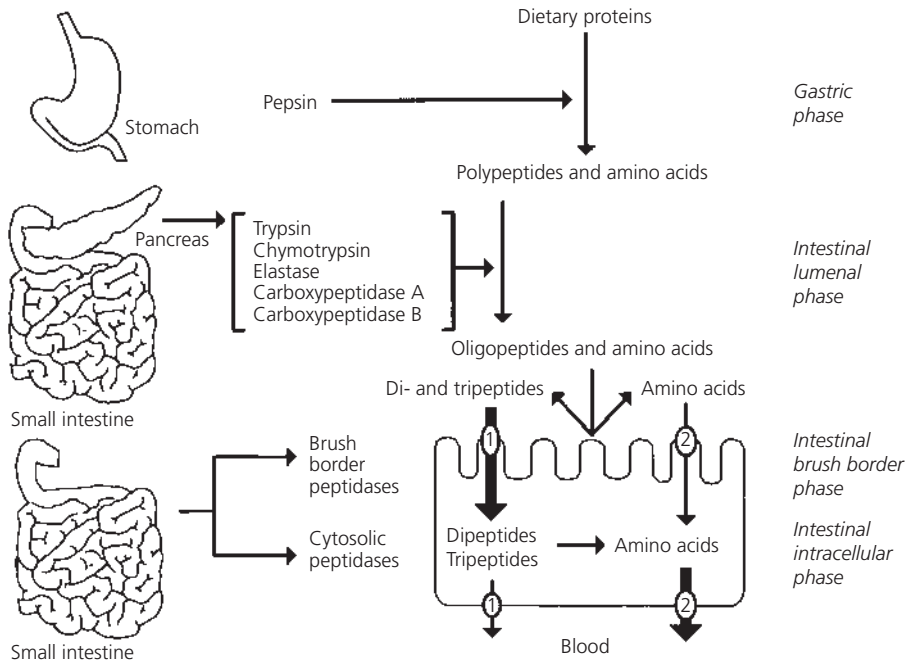

Figure 19.1 Digestion of dietary proteins and absorption of digestion products in the gastrointestinal tract. 1, Transport system for dipeptides and tripeptides; 2, transport systems for free amino acids.

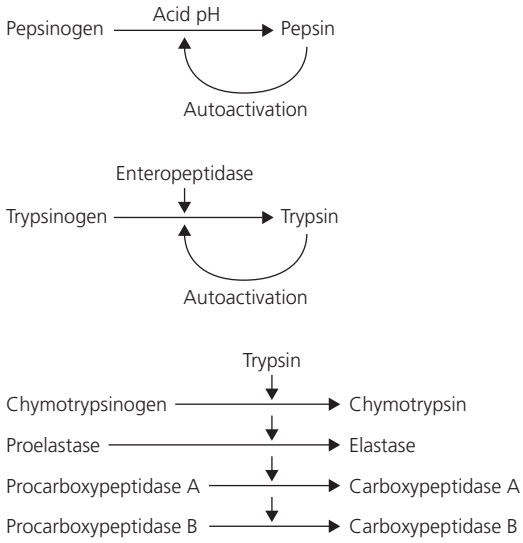

Figure 19.2 Activation of gastric and pancreatic zymogens.

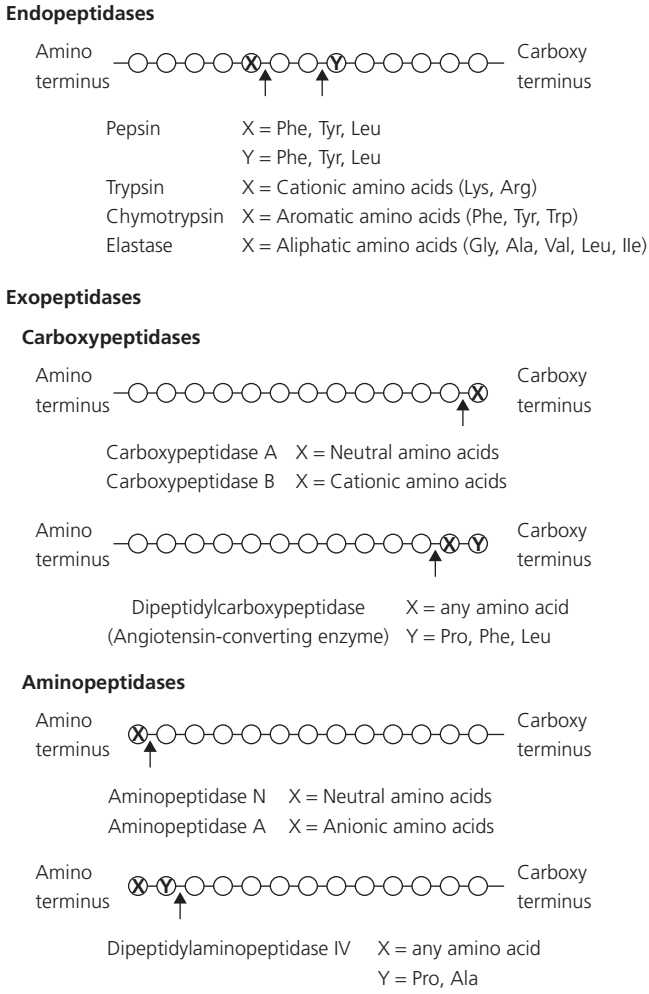

Figure 19.3 Substrate specificity of proteases and peptidases involved in the digestion of proteins in the gastrointestinal tract.

gastric lumen results in a mixture of large polypeptides and smaller oligopeptides.

Gastric juice contains HCl, secreted by the parietal cells, and thus has a pH of less than 2. The acid pH aids the digestive action of pepsins in three ways: (1) proteins are denatured, rendering them more susceptible to proteolytic attack; (2) pepsinogens are converted autocatalytically to active pepsins; and (3) the catalytic mechanism mediated by the carboxyl group of the aspartate residue in the active site of pepsins is effective. Pepsins are not active at a pH greater than 4. Therefore, the digestive action of pepsins on proteins is restricted to the stomach. The acidic contents of the stomach are neutralized by the pancreatic and intestinal secretions in the duodenum, leading to the inactivation of pepsins.

The products of protein digestion by pepsins in the stomach lumen may play an essential role in modulating gastric functions, such as acid and pepsinogen secretion and gastric emptying. These products may also act as stimulants for the release of cholecystokinin in the duodenum, thus influencing pancreatic secretion. Despite the apparent functional consequences of the action of pepsins on proteins, the gastric phase is not essential for overall protein digestion inasmuch as protein digestion and assimilation are not significantly impaired by partial or total gastrectomy.

Intestinal phase

The intestinal phase of protein digestion consists of three stages, defined by the exact location of digestion in the intestine: the lumenal phase, the brush border phase, and the intracellular phase (see Fig. 19.1). The lumenal and brush border phases occur before the protein digestion products are absorbed into enterocytes across the brush border membrane. In the intracellular phase, the absorbed peptides are digested inside enterocytes. Protein digestion comes to an end at this stage. The final products of digestion leave the enterocytes across the basolateral membrane and enter the portal circulation.

Lumenal phase

The lumenal phase of protein digestion in the small intestine is mediated by pancreatic proteases and peptidases. This phase begins in the duodenum, where the pancreatic juice enters the small intestine. The exocrine pancreas produces three endoproteases and two exopeptidases, and each of these enzymes is synthesized and secreted as an inactive precursor (i.e., a zymogen). The inactive forms of the three endoproteases are trypsinogen, chymotrypsinogen, and proelastase. The inactive forms of the two exopeptidases are procarboxypeptidase A and procarboxypeptidase B. Activation of these inactive zymogens is initiated in the duodenum by enteropeptidase (formerly known as enterokinase), an enzyme associated with the brush border membrane in the duodenum. Enteropeptidase is an integral membrane protein and consists of a heterodimer linked with disulfide

bonds. The heavy chain is anchored to the brush border membrane, and the light chain contains the catalytic site. This enzyme is synthesized by enterocytes, initially as a single polypeptide precursor, which is then processed to the heterodimeric form [1]. The only known substrate for enteropeptidase is trypsinogen. The action of enteropeptidase on trypsinogen results in the proteolytic removal of a hexapeptide from the amino terminus of trypsinogen, generating trypsin, the catalytically active form. This is the key step in the activation of pancreatic proteases because, thus generated, trypsin can activate trypsinogen autocatalytically and can also activate the remaining pancreatic zymogens (see Fig. 19.2). The action of trypsin leads to the conversion of chymotrypsinogen to chymotrypsin, proelastase to elastase, procarboxypeptidase A to carboxypeptidase A, and procarboxypeptidase B to carboxypeptidase B.

Trypsin, chymotrypsin, and elastase are endoproteases capable of hydrolyzing the internal peptide bonds in proteins and polypeptides. The substrate specificities of these enzymes are given in Figure 19.3. Trypsin hydrolyzes peptide bonds formed by the carboxyl group of cationic (i.e., basic) amino acids (lysine and arginine); chymotrypsin hydrolyzes peptide bonds formed by the carboxyl group of aromatic amino acids (phenylalanine, tyrosine, and tryptophan); and elastase hydrolyzes peptide bonds formed by the carboxyl group of aliphatic amino acids (glycine, alanine, valine, leucine, and isoleucine). Carboxypeptidase A and carboxypeptidase B are exopeptidases, capable of hydrolyzing the terminal peptide bonds on the carboxyl terminal of polypeptides. Carboxypeptidase A cleaves carboxyl-terminal peptide bonds if the amino acid at the terminus is a neutral amino acid (aromatic or aliphatic), and carboxypeptidase B cleaves carboxyl-terminal peptide bonds if the amino acid at the terminal is a cationic amino acid (lysine or arginine) (see Fig. 19.3). These two enzymes thus release free amino acids from polypeptides. Pancreatic endoproteases and exopeptidases function in a complementary manner to carry out the efficient digestion of proteins. Chymotrypsin and elastase generate oligopeptides that contain neutral amino acids at their carboxyl termini, and these peptides are subsequently acted upon by carboxypeptidase A. Trypsin generates oligopeptides that contain cationic amino acids at their carboxyl termini, and these peptides are subsequently acted upon by carboxypeptidase B. The action of these pancreatic enzymes on proteins in the intestinal lumen produces a mixture of oligopeptides and free amino acids, of which oligopeptides constitute a major fraction (60%–70%) of the total amino nitrogen.

Brush border phase

The amino acids generated by the concerted action of pancreatic enzymes on proteins are absorbed as such into enterocytes across the brush border membrane. In contrast, before absorption, the oligopeptides undergo further hydrolysis by the action of a battery of peptidases associated with the brush border membrane, resulting in a mixture of free amino acids, dipeptides, and tripeptides.

The intestinal brush border membrane exhibits a particularly high level of aminopeptidase activity. Aminopeptidases are exopeptidases that are capable of hydrolyzing the terminal peptide bonds on the amino termini of oligopeptides. This provides functional complementation to the carboxypeptidases present in the pancreatic juice. In addition to several aminopeptidases, the intestinal brush border membrane also contains endopeptidase and dipeptidase activities. The two major aminopeptidases associated with the intestinal brush border membrane are aminopeptidase N and aminopeptidase A. The substrate specificity of these two enzymes is given in Figure 19.3. Aminopeptidase N hydrolyzes the aminoterminal peptide bond of an oligopeptide if the amino acid at the terminus is a neutral amino acid. Aminopeptidase A, in contrast, hydrolyzes the aminoterminal peptide bond of an oligopeptide if the amino acid at the terminus is an anionic amino acid. In addition to these enzymes, two other peptidases are associated with the intestinal brush border membrane. Dipeptidylcarboxypeptidase is an exopeptidase (also called angiotensin-converting enzyme) that hydrolyzes the peptide bond adjacent to the carboxyl-terminal peptide bond. Dipeptidylaminopeptidase IV is also an exopeptidase, but it hydrolyzes the peptide bond adjacent to the amino-terminal peptide bond. Thus, unlike aminopeptidase N and aminopeptidase A, which release free amino acids from oligopeptides, dipeptidylcarboxypeptidase and dipeptidylaminopeptidase IV release dipeptides from oligopeptides. The substrate specificities of these two enzymes are such that the dipeptides released are generally of the X-proline type, where X represents any amino acid (see Fig. 19.3). Animal studies have established unequivocally the essential role of dipeptidylcarboxypeptidase and dipeptidylaminopeptidase IV in the intestinal assimilation of oligopeptides [2–5].

Intracellular phase

The end products of protein digestion by gastric and pancreatic proteases and by peptidases associated with the intestinal brush border membrane comprise a mixture of free amino acids and small peptides. The peptides consist primarily of 2–6 amino acids. Of the total amino acid content in the intestinal lumen, the peptide-bound amino acids represent a predominant fraction. The absorption of free amino acids into enterocytes across the brush border membrane is mediated by a number of distinct amino acid transport systems. Peptides consisting of two or three amino acids are absorbed intact across the brush border membrane by a specific peptide transport system. Once inside the enterocyte, these peptides are hydrolyzed to free amino acids in the cytoplasm by various intracellular peptidases. The peptidases exhibit a preference for dipeptide and tripeptide substrates. The similarity between the substrate specificities of the intracellular peptidases and the peptide transport system is of functional

importance because the transport system makes the peptide substrates available for the intracellular peptidases by importing them across the brush border membrane from the intestinal lumen. The intracellular peptidases that have been characterized in detail include an aminotripeptidase, which releases the amino acid present at the amino terminus of the tripeptide, and several dipeptidases, which show differential substrate specificities toward dipeptides containing specific amino acids. Among the dipeptidases, iminodipeptidase (also called prolidase) is of special interest because of its restricted specificity toward dipeptides of the X-proline or X-hydroxyproline type. Peptide bonds formed by the imino acids proline and hydroxyproline in proteins are generally resistant to hydrolysis by proteases and peptidases involved in the digestion of proteins in the intestinal lumen. Consequently, in the intestinal lumen the imino acids exist to a large extent as iminodipeptides, which are transported intact into the enterocyte by the peptide transport system. These dipeptides are then efficiently cleaved by the intracellular prolidase.

Amino acids, which are either transported as such into the cell in the free form or generated inside the cell by the action of intracellular peptidases, exit the cell across the basolateral membrane by way of specific amino acid transport systems and then enter the portal circulation.

Absorption of protein digestion products

Peptide absorption

The intestinal brush border membrane possesses a specific transport system that accepts dipeptides and tripeptides as substrates. Free amino acids are not recognized by this system. The most interesting feature of this transport process is that it uses a transmembrane electrochemical H^+ gradient rather than a transmembrane electrochemical Na^+ gradient as the driving force [6–8]. The physiological significance of this feature is obvious because there is evidence for the existence of an acid pH microclimate on the lumenal surface of the intestinal brush border membrane that creates a H^+ gradient across the brush border membrane in vivo. This acid pH microclimate is generated and maintained by the combined action of the Na^+/H^+ exchanger in the brush border membrane and the Na^+,K^+-ATPase in the basolateral membrane of the enterocyte (Fig. 19.4). Another interesting and functionally important feature of the intestinal peptide transport system is its broad substrate specificity. This system accepts as substrates dipeptides and tripeptides consisting of neutral amino acids, anionic amino acids, and cationic amino acids. There is only a single peptide transport system in the intestine that is capable of handling the large number of chemically and structurally diverse di- and tripeptides that are expected to be generated from the digestion of dietary proteins.

The peptide transporter from the small intestine of various animal species, including human, has been cloned [7–10].

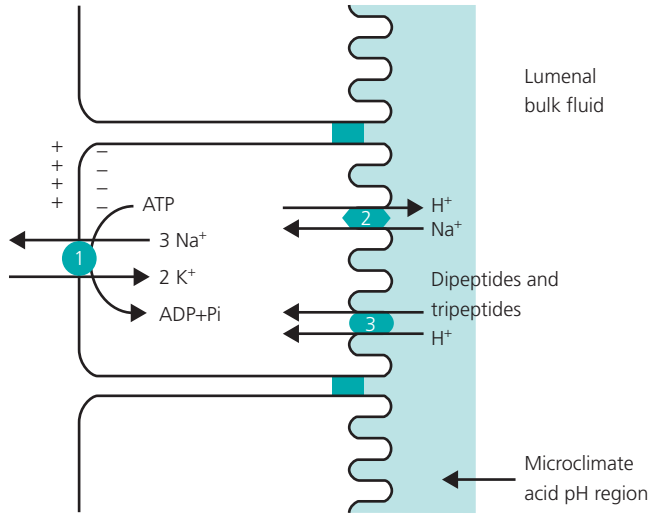

Figure 19.4 Generation of an electrochemical proton gradient across the intestinal brush border membrane. 1, Na^+,K^+-ATPase; 2, Na^+/H^+ exchanger; 3, H^+/peptide cotransporter.

The human protein, known as PEPT1 or PepT1, consists of 708 amino acids, with a predicted core molecular size of 79 kDa. Hydropathy analysis of the primary amino acid sequence shows the presence of 12 transmembrane domains. The gene for this protein is located on human chromosome 13. This transporter is a member of a superfamily of H^+-coupled peptide transporters expressed in animals, yeast, bacteria, and plants. It is expressed in the small intestine (duodenum, jejunum, and ileum), but not in the esophagus and stomach. It is also expressed in the colon, but at much lower levels than are found in the small intestine [11,12]. In the small intestine, the expression is restricted to the absorptive epithelium. Studies of cloned intestinal peptide transporters have established that the transporter recognizes a variety of neutral, anionic, and cationic dipeptides as substrates [13], explaining its broad substrate specificity. The mechanism of the transport process is a simultaneous translocation of H^+ and peptide substrate. The transport process is electrogenic, resulting in a net transfer of a positive charge per transport cycle into the cell, irrespective of the net charge of the transported peptide substrate.

Amino acid absorption

The absorption of free amino acids from the intestinal lumen into enterocytes is mediated by amino acid transport systems expressed in the intestinal brush border membrane [14,15]. Several distinct amino acid transport systems have been functionally characterized in the intestinal brush border membrane, and these transport systems exhibit significant overlap in substrate specificity [16]. It is interesting to note the differences between the processes of peptide absorption and amino acid absorption in terms of the number of physiologically occurring amino acids and peptides and the number

of transport systems that are involved in their absorption. About 20 different amino acids constitute dietary proteins. Absorption of these amino acids in the free form is mediated not by a single transport system but by several distinct transport systems. In contrast, the theoretically possible number of structurally different dipeptides and tripeptides arising from dietary proteins during the digestive process is several times greater than the number of structurally distinct amino acids (400 dipeptides and 8000 tripeptides). Nevertheless, a single transport system (PEPT1) mediates the absorption of all of these diverse peptides. Another notable difference between the peptide and amino acid absorptive processes is in the energetics. The energy source for the peptide transport process is the electrochemical H^+ gradient; a Na^+ gradient is not directly involved. In contrast, several amino acid transport systems are dependent on the Na^+ gradient as the driving force. Some amino acid transport systems, however, are independent of any ion gradient.

The different amino acid transport systems known to be present in the intestinal brush border membrane, their substrate specificities, and their dependence on Na^+ and other ions are given in Table 19.1. The major transport system responsible for the absorption of neutral amino acids across the intestinal brush border membrane is the Na^+-dependent system B^0. The molecular nature of this transport system has been elucidated [17,18]. The protein responsible for this transport activity is called B^0AT1 and the gene encoding this protein is located on human chromosome 5. Immunolocalization studies have established unequivocally that the expression of B^0AT1 is restricted to the brush border membrane of the absorptive epithelial cells in the small intestine [18,19]. This transporter is defective in Hartnup disease, an inheritable amino acid transport defect specific for neutral amino acids.

System $B^{0,+}$ is also present in the brush border membrane. This unique amino acid transporter mediates the Na^+- and Cl^--coupled electrogenic transport of neutral as well as cationic amino acids across the brush border membrane [20]. The protein mediating this transport activity is known as $ATB^{0,+}$ and the gene coding for the protein is located on human chromosome X [21]. Interestingly, this transporter is expressed predominantly in the ileum and colon, not in the proximal part of the small intestine [22–24].

A separate transport system that is specific for anionic amino acids exists in the intestinal brush border membrane. It is known as X^-_{AG} (i.e., the transport system for the negatively charged amino acids aspartate and glutamate) and is Na^+ dependent. The protein responsible for this transport activity has been cloned and functionally characterized [25]. Because this transporter is also expressed in glutamatergic neurons in the brain, where it functions in the neuronal reuptake of glutamate (an excitatory amino acid), system X^-_{AG} is currently classified as a member of the excitatory amino acid transporter (EAAT) family. The glutamate transporter expressed in the intestinal brush border membrane is known as EAAT3. This transporter is defective in the inheritable amino acid transport defect known as dicarboxylic aciduria, which is associated with defective absorption of anionic amino acids in the intestine and kidney.

A specific transport system that mediates the Na^+-coupled transport of alanine, serine, cysteine, glutamine, and asparagine has been cloned from the small intestine [26]. This transporter was originally thought to be responsible for the transport activity known as system B^0 in the intestine; therefore, it was named ATB^0. However, subsequent studies have shown that this transporter functions as an obligatory amino acid exchanger, a characteristic not found with system B^0. Accordingly, this transporter is currently identified as ASCT2 (i.e., the second isoform of the transporter responsible for the transport activity known as ASC, specific for the amino acids alanine, serine, and cysteine) rather than ATB^0. The ASCT2 protein is localized to the brush border

Table 19.1 Amino acid transport systems in the intestinal brush border membrane

Transport system	Molecular identity	HUGO nomenclature	Substrates	Ion dependence	Genetic disease
B^0	B^0AT1	*SLC6A19*	Neutral amino acids	Na^+	Hartnup disease
$B^{0,+}$	$ATB^{0,+}$	*SLC6A14*	Neutral amino acids, cationic amino acids	Na^+, Cl^-	
X^-_{AG}	EAAC1/EAAT3	*SLC1A1*	Anionic amino acids	Na^+, K^+, H^+	Dicarboxylic aciduria
ASC	ASCT2/ATB^0	*SLC1A5*	Neutral amino acids (Ala, Ser, Cys, Gln, Asn)	Na^+	
$b^{0,+}$	$b^{0,+}$AT–rBAT (heterodimer)	*SLC7A9–SLC3A1*	Neutral amino acids, cationic amino acids, cystine	None	Cystinuria
IMINO	SIT1/IMINO	*SLC6A20*	Imino acids	Na^+, Cl^-	
PAT	PAT1	*SLC36A1*	Small neutral amino acids	H^+	
β	TauT	*SLC6A6*	β-Amino acids (taurine, β-alanine)	Na^+, Cl^-	

HUGO, Human Genome Organization; SLC, solute-linked carrier.

membrane in the small intestine and hence may play an essential role in the entry of glutamine into enterocytes from the lumen [27].

Another transport system in the intestinal brush border membrane recognizes neutral and cationic amino acids as high-affinity substrates. This system, $b^{0,+}$, is Na^+ independent and, interestingly, it also recognizes the disulfide amino acid cystine as a substrate. System $b^{0,+}$ is a heterodimer consisting of a light chain (known as $b^{0,+}$AT) and a heavy chain (known as rBAT) [28–30]. The light chain possesses 12 putative transmembrane domains and exhibits a membrane topology typical of most transport proteins. The heavy chain is responsible for directing the recruitment of the light chain specifically to the enterocyte brush border membrane. The genes coding for the heavy chain and the light chain are located on human chromosomes 2 and 19 respectively. This transporter is defective in cystinuria, an inheritable amino acid transport defect specific for cationic amino acids.

Additional amino acid transport systems known to be expressed in the intestinal brush border membrane include IMINO, PAT, and β. System IMINO is a Na^+-dependent transporter with specificity toward the imino acids proline and hydroxyproline. The protein responsible for this transport activity has been cloned recently [31,32]. It is identified as SIT1 (Na^+-coupled imino acid transporter 1) or IMINO. PAT is a transport system for small aliphatic amino acids, and its transport function is coupled to a transmembrane electrochemical H^+ gradient rather than to a transmembrane Na^+ gradient. The protein responsible for this transport activity has been identified at the molecular level. It is known as PAT1 (proton-coupled amino acid transporter 1) [33]. Taurine is a nonprotein amino acid that has its own specific transport system in the small intestine for active absorption, coupled to Na^+ and Cl^- gradients [34]. The protein mediating this transport activity is known as TauT [35].

Fate of absorbed protein digestion products

At the end of the intracellular phase of protein digestion within the enterocyte, after the absorption of small peptides and free amino acids from the intestinal lumen across the brush border membrane and subsequent hydrolysis of the absorbed peptides inside the cells, free amino acids constitute the predominant form of the protein digestion products in the enterocyte cytoplasm. It is probable, however, that a small but significant portion of the protein digestion products may exist in the form of small peptides that are absorbed by way of the brush border membrane peptide transporter but are resistant to hydrolysis by intracellular peptidases. There is some evidence for the presence of a peptide transport system in the basolateral membrane of intestinal epithelial cells [36]. However, it is not PEPT1, and its molecular identity remains unknown. Free amino acids in the cytoplasm of the enterocyte enter into various metabolic pathways, such as degradation, conversion into other amino acids, and incorporation into cellular proteins; they also enter the portal circulation by way of specific amino acid transport systems in the basolateral membrane. Glutamine, glutamate, aspartate, and arginine are preferentially used by the enterocyte as metabolic fuel.

The intestinal basolateral membrane possesses a set of amino acid transport systems that are different to those in the brush border membrane (Table 19.2) [14,15]. The amino acid transport systems in the basolateral membrane function to export amino acids from the enterocyte into the portal circulation during periods of feeding. They also participate in the import of amino acids from the portal circulation into the enterocyte for cellular metabolism when amino acids are not available from the intestinal lumen, such as between meals. Of the amino acid transport systems present in the basolateral membrane, systems y^+L and A are of particular importance. System y^+L is an amino acid exchanger that mediates

Table 19.2 Amino acid transport systems in the intestinal basolateral membrane

Transport system	Molecular identity	HUGO nomenclature	Substrates	Ion dependence	Genetic disease
y^+L	y^+LAT1–4F2hc (heterodimer)	*SLC7A7–SLC3A2*	Neutral amino acids	Na^+	Lysinuric protein intolerance
			Cationic amino acids	None	
	y^+LAT2–4F2hc (heterodimer)	*SLC7A6–SLC3A2*	Neutral amino acids	Na^+	
			Cationic amino acids	None	
A	ATA2/SNAT2	*SLC38A2*	Neutral amino acids	Na^+	
GLY	GLYT1	*SLC6A9*	Glycine	Na^+, Cl^-	
y^+	CAT1	*SLC7A1*	Cationic amino acids	None	
L	LAT2–4F2hc (heterodimer)	*SLC7A8–SLC3A2*	Neutral amino acids	None	

HUGO, Human Genome Organization; SLC, solute-linked carrier.

the Na^+-independent efflux of cationic amino acids from intestinal cells into the blood coupled to the Na^+-dependent influx of neutral amino acids from the blood into intestinal cells [28–30]. There are two isoforms of this transport system and both are heterodimers consisting of a common heavy chain, known as 4F2hc, and an isoform-specific light chain, known as y^+LAT1 and y^+LAT2. Mutations in the gene coding for y^+LAT1 are responsible for the inheritable amino acid transport defect known as lysinuric protein intolerance. System A is a Na^+-coupled transport system for neutral amino acids, including glutamine, that plays a role in the entry of amino acids from the blood into intestinal cells for use in cellular metabolism. System A consists of at least three subtypes, Na^+-coupled neutral amino acid transporter 1 (SNAT1), SNAT2, and SNAT4 [37]. Of these three isoforms, SNAT2 is expressed in the small intestine. Other amino acid transport systems present in the basolateral membrane include GlyT1 (a Na^+- and Cl^--coupled transporter for glycine), CAT1 (a Na^+-independent transporter for cationic amino acids), and system L (a heterodimer consisting of the heavy chain 4F2hc and the light chain LAT2), which functions as a Na^+-independent obligatory amino acid exchanger [14,15].

Physiological and clinical significance

Compelling evidence exists for the absorption of protein digestion products predominantly in the form of small peptides rather than free amino acids. Therefore, the physiological importance of the intestinal peptide transport system in the maintenance of protein nutrition is clearly evident. In addition, the intestinal peptide transporter has been shown to interact with several pharmacologically relevant drugs that possess peptide-like chemical structures. These drugs are efficiently absorbed from the intestinal lumen after oral administration by way of the peptide transporter. Consequently, the peptide transporter in the intestine is an important determinant of the bioavailability of orally active peptidomimetic drugs [38–40]. Examples of peptidomimetic drugs that are absorbed in the intestine by way of the peptide transporter include several β-lactam antibiotics (e.g., cephalexin [cefalexin], cefadroxil, cephradine [cefradine], and ceftibuten), angiotensin-converting enzyme inhibitors (captopril and lisinopril), the antitumor agent bestatin, and inhibitors of renin and thrombin. The transporter is also responsible for the enhanced oral bioavailability of the prodrugs valacyclovir (valaciclovir) and valganciclovir. The parent drugs acyclovir (aciclovir) and ganciclovir are not recognized as substrates by the intestinal peptide transporter; however, when a valine residue is added to these drugs by way of an ester linkage, the resultant derivatives become substrates for the transporter.

The peptide transport process in the intestine also has the potential for therapeutic applications. Peptide-based formula solutions have many advantages over amino acid-based elemental solutions for enteral nutrition [41]. The efficacy of peptide-based enteral solutions is facilitated by the intestinal peptide absorptive process. The osmolality of these solutions can be kept low while amino acid content and composition are maintained. Furthermore, amino acids are absorbed more efficiently and more evenly from peptides than from an equivalent mixture of free amino acids. Another clinical application of the peptide transport system is the practice of including heat-labile and water-insoluble amino acids such as glutamine, cysteine, and tyrosine in the form of peptides in enteral solutions to promote their absorption.

The amino acid transporter $ATB^{0,+}$ also has the potential for drug delivery [42]. It has broad specificity among the amino acids, accepting the neutral as well as cationic amino acids as substrates. In addition, it can transport a variety of amino acid-based drugs and prodrugs.

Regulation of amino acid and peptide absorption

The capacity of the small intestine to absorb protein digestion products changes significantly under various physiological and pathological conditions. The underlying mechanisms of these changes may be nonspecific, such as alterations in the absorptive surface area, or specific, such as alterations in the number and activity of particular transporters. The transport systems responsible for the absorption of amino acids and peptides are present in the small intestine even before birth in several animal species, including humans. The ability of the small intestine to absorb amino acids and peptides, when expressed per wet weight of intestinal tissue, is maximal at birth and during early development, decreasing thereafter with age. Several hormones have been shown to alter the intestinal amino acid and peptide transport systems. Somatostatin and vasoactive intestinal polypeptide inhibit these transport processes, whereas epidermal growth factor, neurotensin, cholecystokinin, and secretin enhance them. Studies of cultured cells indicate that various intracellular second messengers regulate the intestinal peptide transporter. In Caco-2 cells, a human intestinal cell line, the peptide transporter is stimulated by insulin [43], leptin [44], and growth hormone [45]. The transporter is inhibited by thyroid hormones [46], protein kinase C [47], and cyclic adenosine monophosphate (cAMP) [48]. There is evidence of direct coupling between the peptide transporter and the Na^+/H^+ exchanger by way of the transmembrane H^+ gradient in Caco-2 cells [49]. Therefore, the observed effects of some of these regulators (e.g., protein kinase C and cAMP) on peptide transporter activity are likely mediated indirectly by alterations in the activity of the Na^+/H^+ exchanger.

In animal studies, the expression of the intestinal peptide transporter has also been shown to be modulated by dietary protein content and protein digestion products [50,51]. Even

though the peptide transporter is expressed along the entire small intestine, the diet-induced changes in its expression are specific to certain regions. A high-protein diet increases the steady-state levels of the transporter-specific messenger RNA in the middle and distal regions of the small intestine. The expression of the brush border peptidases dipeptidyl-carboxypeptidase and dipeptidylaminopeptidase IV, which release dipeptides from oligopeptides, is also enhanced by a high-protein diet, again only in the middle and distal regions of the small intestine. This coordinated regulation of the peptide transporter and the peptidases that generate the substrates for the transporter is likely to be of physiological importance. Similarly, the protein digestion products, particularly certain specific dipeptides and amino acids, also enhance the expression of the peptide transporter in the intestine. Up-regulation of the peptide transporter by dipeptides has been demonstrated in Caco-2 cells [52,53].

Although the peptide transporter is expressed at very low levels in the large intestine under normal conditions, it is up-regulated in short bowel syndrome [11], Crohn's disease, and ulcerative colitis [54]. Note that the intestinal peptide transporter can transport the bacterial peptide *N*-formyl-Met-Leu-Phe (a chemotactic peptide) [54,55]. The enhanced expression of the peptide transporter in the large intestine in Crohn's disease and ulcerative colitis may have a pathogenic role in these inflammatory diseases by facilitating the entry of this bacterial peptide into intestinal epithelial cells and consequently affecting local immune function [54–56]. Bacterial and parasitic infections have also been shown to influence the expression and activity of the intestinal peptide transporter [57,58].

Protein–energy malnutrition

Protein–energy malnutrition represents the most common type of malnutrition, seen primarily in developing countries. This condition is classified into two subtypes: kwashiorkor and marasmus. In kwashiorkor, intake of protein is inadequate, but energy intake in the form of carbohydrate and fat is adequate. In marasmus, the intake of both protein and energy is inadequate. The crucial clinical features that differentiate these two subtypes are the degree of body wasting and the presence or absence of edema. Kwashiorkor is characterized by edema and a body weight that is 60%–80% of that expected for the given age. This condition is also associated with fatty liver. Inadequate protein intake in the presence of adequate energy in kwashiorkor results in decreased hepatic synthesis of blood proteins and β-lipoprotein. Muscle wasting does not occur in kwashiorkor, but there is growth impairment because of decreased amino acid supply in the form of dietary proteins. Decreased levels of albumin in the blood cause edema, and decreased levels of β-lipoprotein in the liver cause defective handling of lipids, leading to fatty liver. Children with kwashiorkor may appear healthy because of the edema, but there are profound metabolic disturbances associated with the condition. Marasmus is characterized by the absence of edema and a body weight that is less than 60% of that expected for the given age. Insufficient energy intake in marasmus results in decreased levels of glucose in the blood, which leads to elevated levels of glucogenic hormones such as glucocorticoids. Muscle proteins are degraded to provide glucogenic amino acids for hepatic gluconeogenesis in an attempt to maintain the blood levels of glucose. Degradation of muscle proteins helps to maintain the levels of amino acids in the circulation and the hepatic synthesis of blood proteins. Therefore, edema is absent in marasmus. Both kwashiorkor and marasmus manifest a decreased cell-mediated immune response that reduces the ability to fight infection.

Defects in digestion and absorption of proteins

A number of defects, primary as well as secondary, associated with the impairment of protein digestion and assimilation are known to occur in humans (Table 19.3).

Primary defects

Defects in the digestion of proteins can be caused by genetic diseases involving the expression and activity of any of the proteases or peptidases necessary for the digestive process. Cases of a genetic deficiency of pancreatic trypsinogen have been reported [59,60]. Because trypsin is a key enzyme in the activation of other pancreatic zymogens (e.g., chymotrypsinogen), a deficiency of trypsinogen results in a marked impairment of protein digestion, noticeable in early infancy. Infants with trypsinogen deficiency fail to gain weight and present with hypoproteinemia and edema. These infants improve dramatically if fed protein hydrolysates instead of intact proteins. Several cases of a genetic deficiency of enteropeptidase have been reported [61]. Infants with enteropeptidase deficiency present with symptoms similar to those observed in cases of trypsinogen deficiency, which include failure of growth, hypoproteinemia, and edema. Because enteropeptidase deficiency leads to an impairment in the activation of trypsinogen, and consequently impairments in the activation of other pancreatic proteases, the digestion of proteins is markedly affected in these patients. Treatment with activated pancreatic enzymes results in improvement of protein digestion and assimilation. Genetic defects in enteropeptidase and trypsin cause impairment not only in protein digestion but also in the digestion of fat. This is because trypsin is obligatory for the activation of procolipase to colipase, a protein necessary for the hydrolytic action of pancreatic lipase on dietary triglycerides after emulsification with bile acids. Similarly, because pancreatic

Table 19.3 Primary and secondary defects associated with an impairment of protein digestion and assimilation

Disease	Defective protein and metabolic abnormality	Clinical features
Primary defects		
Digestive process		
Trypsin deficiency	Genetic defects in trypsinogen; impairment of activation of pancreatic zymogens involved in protein digestion	Impaired growth and weight gain, hypoproteinemia, edema
Enteropeptidase deficiency	Genetic defects in enteropeptidase; impairment of trypsinogen activation leading to impairment of activation of other pancreatic zymogens involved in protein digestion	Impaired growth and weight gain, hypoproteinemia, edema
Prolidase deficiency	Genetic defects in prolidase; impairment in the hydrolysis of proline-containing peptides	Impaired collagen turnover, skin abnormalities, increased urinary excretion of proline-containing peptides
Absorptive process		
Cystinuria	Genetic defects in $b^{0,+}$, a heterodimeric transporter ($b^{0,+}$AT–rBAT) for cystine and cationic amino acids; disease-causing mutations are found in either of the subunits ($b^{0,+}$AT and rBAT)	Increased urinary excretion of cystine and cationic amino acids, nephropathy secondary to cystine calculi
Hartnup disease	Genetic defects in B^0AT1, a transporter for neutral amino acids; impairment in the endogenous synthesis of niacin	Increased urinary excretion of neutral amino acids, pellagra, cerebellar ataxia, mental retardation
Lysinuric protein intolerance	Genetic defects in a heterodimeric transporter (y^+LAT1–4F2hc) for neutral and cationic amino acids; disease-causing mutations are found only in the y^+LAT1 subunit	Increased urinary excretion of cationic amino acids, protein intolerance, hyperammonemia, diarrhea, vomiting, coma
Secondary defects		
Cystic fibrosis	Genetic defects in a cAMP-activated Cl^- channel in exocrine tissues, including pancreas; impairment of exocrine tissue function	Impaired digestion and assimilation of dietary proteins and fat secondary to decreased exocrine pancreatic function, impaired lung function, and increased lung infections
Celiac sprue	Defect not known; presence of autoantibodies to tissue transglutaminase	Intolerance to dietary gliadin, enteropathy, nutrient malabsorption, and diarrhea on gliadin ingestion
Dermatitis herpetiformis	Defect not known; presence of autoantibodies to epidermal transglutaminase	Intolerance to dietary gliadin, enteropathy, dermatitis
Tropical sprue	Defect not known	Impairment of digestive and absorptive function of intestine, malabsorption of nutrients, diarrhea

proteases play an essential role in the intestinal absorption of vitamin B-12, genetic defects in enteropeptidase and trypsin may also interfere with the absorption of this vitamin.

With the exception of enteropeptidase deficiency, no other documented inheritable defects in peptidases associated with the intestinal brush border membrane are known in humans. However, a mutant rat strain is available that exhibits a genetic deficiency of dipeptidylaminopeptidase IV [5]. These mutant rats are apparently normal with no alteration in growth rate if fed a diet with protein constituents with a modest proline content [5]. However, if the dietary protein source is changed to gliadin, a proline-rich protein, the enzyme-deficient mutant rats experience a significant weight loss, whereas wild-type rats do not. These studies show that, as a result of the unique substrate specificity of dipeptidylaminopeptidase IV, a functional role for this enzyme becomes evident under physiological conditions only if the diet contains proline-rich proteins. These observations also point to the physiological advantage of the presence of multiple peptidases in the intestinal brush border membrane with significant overlapping substrate specificities.

An inheritable deficiency of the intracellular dipeptidase prolidase is known in humans [62]. In healthy persons, this enzyme is expressed not only in the intestine but also in several other tissues, such as the kidney; its functions are multiple, including an important role in collagen turnover. It is therefore not surprising that manifestations of prolidase deficiency are pleiotropic. However, no information is available on the intestinal assimilation of proteins in these patients. It is likely that prolidase deficiency does not lead to detectable

alterations in the intestinal assimilation of proteins under normal dietary conditions, as seen in the mutant rat strain lacking dipeptidylaminopeptidase IV.

Defects in the absorption of protein digestion products can be caused by diseases involving the expression and activity of amino acid and peptide transport systems in the intestine. Several inheritable amino acid transport defects have been identified in humans. Cystinuria is an autosomal recessive disorder characterized by the increased excretion of cationic amino acids (lysine and arginine) and cystine [63]. The disease is associated with a defect in the renal reabsorption of these amino acids. A similar defect also occurs in the small intestine, leading to impaired absorption of cationic amino acids and cystine from the intestinal lumen. This suggests that an identical transport system is involved in the absorption of these amino acids in the kidney and the intestine. The primary clinical problem associated with the disease is nephropathy resulting from renal stones enriched in cystine. This disulfide derivative is poorly soluble in water (300 mg/L). In cystinuria, the concentration of cystine is greater than this solubility level in the renal tubule because of defective reabsorption, and this results in the formation of cystine stones. This disease is caused by mutations in either the light chain ($b^{0,+}$AT) or the heavy chain (rBAT) of the heterodimeric transporter $b^{0,+}$ [64]. Thus, two genes, one on chromosome 2 (heavy chain) and the other on chromosome 19 (light chain), are associated with cystinuria. Because system $b^{0,+}$ is present predominantly in the brush border membrane of the intestinal and renal tubular epithelial cells, the transport defect in cystinuria is restricted to this membrane. Therapeutic strategies are directed toward facilitating cystine excretion in the urine by increasing urine volume, alkalinizing the urine to increase cystine solubility, and using penicillamine, which reacts with cystine to form a more soluble mixed disulfide.

Hartnup disease is also an autosomal recessive disorder of amino acid transport, but this condition is associated with impaired absorption of neutral amino acids (Ala, Ser, Cys, Thr, Gln, Asn, Val, Ile, Leu, Met, Phe, Tyr, and Trp) in the kidney and the intestine [65]. Consequently, this disease is associated with the hyperexcretion of several neutral amino acids in urine. The symptoms of the disease, which include photosensitive skin rash, ataxia, and neurological complications, are similar to those of pellagra (i.e., niacin deficiency). These symptoms occur despite an apparently normal dietary intake of niacin but disappear in response to niacin therapy. In humans, endogenous synthesis of niacin from the neutral amino acid tryptophan contributes significantly to normal niacin requirements. In Hartnup disease, the endogenous synthesis of niacin is most likely impaired because of defective intestinal absorption of tryptophan coupled with defective renal reclamation of tryptophan. Because people in industrialized nations generally consume a nutritious diet rich in protein, the disease is relatively benign, except for symptoms of niacin deficiency, cerebellar ataxia, and occasional psychological problems. However, in developing or underdeveloped nations, where suboptimal protein intake is common, the disease is characterized by more severe clinical symptoms, including mental retardation. The amino acid transport system B^0, expressed in the intestinal and renal brush border membrane, is defective in this disease [66]. The protein responsible for this transport system is B^0AT1, and loss-of-function mutations in the gene encoding this protein, located on human chromosome 5, have been demonstrated in patients with Hartnup disease [17,18].

Interestingly, persons with cystinuria or Hartnup disease usually do not show obvious symptoms of protein malnutrition, despite the clearly established defects in the intestinal absorption of specific amino acids. This was puzzling until it was discovered that intestinal absorption of the affected amino acids (i.e., cationic amino acids in cystinuria and neutral amino acids in Hartnup disease) is normal if the amino acids are given in the form of dipeptides [67–70]. Because protein digestion products are absorbed across the intestinal brush border membrane mainly in the form of small peptides, these individuals obtain significant amounts of the affected amino acids through the peptide transport mechanism despite the amino acid transport defect in this membrane. These observations are of historical importance in peptide transport research because they provided early indisputable evidence that the transport mechanisms available for free amino acids and peptides in the intestine are different [71].

Lysinuric protein intolerance is an autosomal recessive disorder caused by impaired absorption of the cationic amino acids lysine and arginine in the intestine and the kidney [72]. The absorption of ornithine, also a cationic amino acid, is impaired as well. Persons with this disease show decreased plasma levels and increased urinary excretion of these three amino acids. Deficiency of arginine and lysine, which are essential amino acids, causes impairment of protein synthesis, resulting in growth retardation and neurological complications. In addition, because arginine and ornithine are the amino acids involved in the urea cycle and hence in the elimination of ammonia, patients with this disease exhibit decreased urea cycle activity and consequently hyperammonemia. Dietary intake of protein induces diarrhea, vomiting, and, in extreme cases, coma. Treatment strategies, which are related to the prevention of hyperammonemia, include dietary protein restriction and ornithine supplementation. The intestinal and renal handling of cystine is not affected in lysinuric protein intolerance, indicating the difference between the molecular defects associated with this disease and those associated with cystinuria, which also involves the renal and intestinal absorption of cationic amino acids. The transport defect in lysinuric protein intolerance is restricted to the basolateral membrane in intestinal and renal epithelial cells [73]. Transport of cationic amino acids across the brush border membrane of these cells is not affected. Linkage analysis [74] assigned the gene for lysinuric protein intolerance

to the long arm of chromosome 14. The defect in this disease occurs in one of the isoforms of the amino acid transport system y^+L [64]. The transporter defective in this disease is a heterodimer consisting of a heavy chain (4F2hc) and a light chain (y^+LAT1). Loss-of-function mutations in the gene coding for the light chain y^+LAT1 have been demonstrated in patients with this disease [75,76]. Even though the heavy chain is obligatory for the proper function of the transport system under in vivo conditions, no mutations have been detected in the gene coding for this subunit (4F2hc) in any of the patients with lysinuric protein intolerance. This is in contrast to cystinuria, also a disease associated with a defective heterodimeric amino acid transporter, in which mutations in either the light chain or the heavy chain lead to the disease.

There are no documented cases of genetic defects in the gene coding for the intestinal peptide transporter PEPT1 in humans. Studies of genetic polymorphisms in the gene encoding this protein have reported a very low level of genetic variability [77,78]. Most of the polymorphisms in the gene are found either in intronic or noncoding regions or in exonic coding regions that do not cause any change in amino acids. Nonsynonymous polymorphisms in the coding region do occur, but most of them have no significant effect on the transport function of the protein. Two exceptions are the nonsynonymous polymorphisms P586L and F28Y, which exert a significant effect on the function of the transporter and are demonstrable in heterologous expression systems. The P586L mutant exhibits defective plasma membrane expression [77] and the F28Y mutant exhibits reduced substrate affinity [78]. The physiological and pharmacological consequences of these mutations for the intestinal absorption of protein digestion products and peptidomimetic drugs have not been investigated.

Secondary defects

Impairment of protein digestion and absorption occurs as a secondary defect in several diseases, including cystic fibrosis, celiac sprue, dermatitis herpetiformis, and tropical sprue. In cystic fibrosis, the primary defect occurs in the CFTR (cystic fibrosis transmembrane conductance regulator) protein, a cAMP-regulated Cl^- channel. The defective function of this protein leads to complications involving diverse organs, such as the lung, pancreas, gastrointestinal tract, and sweat glands. In the exocrine pancreas, the absence of the Cl^- channel in the apical membrane of pancreatic ductal epithelial cells results in failure to secrete salt and water into the duct. This leads to the retention of digestive enzymes in the pancreas and, ultimately, the destruction of pancreatic tissue. Pancreatic insufficiency associated with this disease causes impairment of the digestion and assimilation of protein and fat.

Celiac sprue, or gluten-induced enteropathy, is characterized by an inability to tolerate gluten, a protein found in wheat, barley, and rye. The dietary intake of gluten induces inflammation in the intestine, leading to the blunting and flattening of the villi. Histological findings include villous atrophy, crypt hyperplasia, and intraepithelial lymphocytes. These structural abnormalities reduce the mucosal surface area and result in a deficiency of enterocyte-associated digestive enzymes and transport proteins. This causes a generalized impairment of the digestive and absorptive function of the intestine, including protein malabsorption. The classical symptoms in patients with celiac sprue during active disease include diarrhea, abdominal bloating, weight loss, and anemia due to iron, folic acid, and vitamin B-12 deficiencies. Celiac sprue is an immunologically mediated disorder with a strong genetic component, and immunoglobulin A antibodies to endomysium, a structure of the smooth muscle connective tissue, are specific indicators of the disease. The endomysial autoantigen has been identified as the tissue transglutaminase [79]. Gliadin, which is the major protein component of gluten and the principal causative agent in celiac disease, is a preferred substrate for this enzyme. The exact genetic component that underlies the sensitivity to gluten-induced enteropathy has not been identified. However, if gluten-containing foods are avoided entirely in the diet, patients with celiac sprue recover completely, with the intestinal morphology and structure returning to normal.

Dermatitis herpetiformis is another malabsorption syndrome associated with blunting and flattening of the mucosal villi and consequently impaired digestion and absorption of dietary nutrients. This disease has much in common with celiac disease because both conditions are associated with intestinal sensitivity to gluten [80]. However, patients with dermatitis herpetiformis exhibit unique dermatological symptoms, manifest as pruritic bullous rashes. Intestinal involvement is much milder compared with celiac disease. Patients with dermatitis herpetiformis have immunoglobulin A antibodies against epidermal transglutaminase. As in celiac disease, strict adherence to a gluten-free diet relieves the symptoms of dermatitis herpetiformis. Thus, celiac disease and dermatitis herpetiformis seem to represent two different manifestations of the same disease.

Tropical sprue is a serious gastrointestinal disease, also characterized by a generalized impairment of the digestive and absorptive function of the intestine. A disease of unknown etiology, it occurs among the residents of tropical areas. The gastrointestinal manifestations of tropical sprue are strikingly similar to those observed in celiac sprue.

Folate

Structure, sources, and requirements

Folate in the form of oxidized folylmonoglutamate, or folic acid, contains a pteridine ring linked to *p*-aminobenzoic acid and glutamic acid. Folates appear in the diet and in endogenous storage as folylpolyglutamates with up to six additional glutamates in γ-peptide linkage to folylmonoglutamate. Whereas the term *folic acid* refers to the oxidized monoglutamyl form of the vitamin, reduction in the 5-, 6-, 7- and 8-positions and methylation at the 5-position of the pteridine ring produce 5-methyltetrahydrofolate (5-MTHF), the circulating form of the vitamin. Dietary sources of folate include green leafy vegetables (i.e., foliage), orange juice, grains (in particular, breakfast cereals that are fortified with folic acid), and organ meats such as liver. The Dietary Reference Intake (DRI) for folate from all sources is quantified in dietary folate equivalents (DFEs). This term accounts for the fact that monoglutamyl folic acid that is marketed as a vitamin supplement or as a fortificant in the diet is 1.7 times more available than the natural food folates that occur as folylpolyglutamates in the diet [1]. In calculating DFEs, the amount of supplemental folic acid, as either a grain fortificant or in tablet form, is multiplied by 1.7 and added to the amount of natural food folate present in the mixed diet. The DRI for folate is set at 400 μg of DFE per day for adults, 600 μg/day during pregnancy, and 500 μg/day during lactation. Since 1998, all grain products in the United States have been fortified with folic acid at 140 μg/g to ensure a daily intake equal to or more than the DRI for folate.

Folate absorption and homeostasis

Folates are absorbed in the duodenum and upper jejunum. During the process of intestinal absorption, dietary folylpolyglutamates are hydrolyzed at the epithelial cell (enterocyte) brush border membrane, followed by active transport of the folylmonoglutamate derivative into the absorbing enterocyte. Studies that followed the movement of labeled compounds across the human jejunal epithelium during jejunal perfusion or when excreted in the urine after oral administration showed the importance of the hydrolytic step, because the absorption of monoglutamyl folic acid was about 85%, compared to about 50% absorption of complex dietary polyglutamyl folates in adult human volunteers [2]. The 85 : 50, or 1.7 : 1, ratio of the absorption of the two different folates provides the basis for the DFE calculation. A study of orally administered, dual-labeled folates largely confirmed the differences in the absorbability of monoglutamyl and polyglutamyl folates in healthy human subjects [3]

Two intestinal brush border proteins – glutamate carboxypeptidase II (GCP2, or folate hydrolase) and the reduced folate carrier – are required, respectively, for the sequential hydrolysis of dietary folylpolyglutamates and the transport of folylmonoglutamate derivatives across the enterocyte brush border and basolateral membranes [4,5]. GCP2 was characterized in pig and human intestine and is a brush border membrane protein with a molecular size of 120 kDa that contains a single 5′ membrane-spanning domain and an extracellular catalytic domain and shares an identical sequence with two other proteins: brain *N*-acetylated α-linked acidic dipeptidase and prostate-specific membrane antigen [6,7]. In its functionally active enzyme form, purified human intestinal GCP2 has an optimal pH of 6.5 and a K_m value of 0.6 μmol/L and is an exopeptidase that releases intermediate products of folylpolyglutamates in a stepwise fashion ending with the folylmonoglutamate derivative [8]. By contrast, the human reduced folate carrier is a 65-kDa brush border membrane protein with 12 membrane-spanning domains that operates at an optimal pH of 5.0 and has a K_m value of 0.5–1.5 μmol/L [9]. Studies that used isolated intestinal brush border membrane vesicles defined a saturable carrier system

for monoglutamyl folates with a preference for reduced and methylated forms [10,11]. As folate is transported through the absorbing enterocyte, pteroylmonoglutamate is reduced and methylated, and 5-MTHF is transported across the intestinal basolateral membrane by the reduced folate carrier to the portal vein and the liver [12].

The uptake of 5-MTHF by hepatocytes involves binding to the liver plasma membrane and carrier-mediated transport into the cell. The binding step is regulated in part by the high-affinity folate receptor, folate-binding protein, a 37-kDa protein that operates at a pH of 6.5–7.5 and has a K_m value in the nanomolar range. Folate-binding protein is attached to the membrane by a glycosylphosphatidylinositol anchor [13]. However, 5-MTHF transport obeys the kinetics of the reduced folate carrier, which also expresses its activity in the liver plasma membrane [5]. Within hepatocytes, uptake of 5-MTHF is followed by conversion to folylpolyglutamates for storage and metabolism. After reconversion to monoglutamyl forms for membrane transport, about 10% of the liver folate pool undergoes biliary secretion as 5-MTHF to an enterohepatic folate circulation, while the remaining nonhepatic folate pool circulates in the blood to other tissues [14]. The urinary excretion of 5-MTHF is regulated by filtration and then efficient reuptake by folate-binding protein and the reduced folate carrier in the renal tubular epithelial cells [15]. About 1% of the total body folate pool is excreted daily in the urine and 0.1% in the feces of nonhuman primates [16].

Folate functions and methionine metabolism

The metabolism of folate is intrinsically tied to methionine metabolism and to the synthesis, nucleotide balance, and methylation of DNA. Figure 20.1 depicts these interactions in the liver. Folates enter the liver either as 5-MTHF from the diet and from intestinal folate metabolism or in the form of supraphysiological folic acid from fortified cereals [17] or as supplemental vitamin preparations [18]. Folic acid generates 5,10-MTHF by way of dihydrofolate and tetrahydrofolate

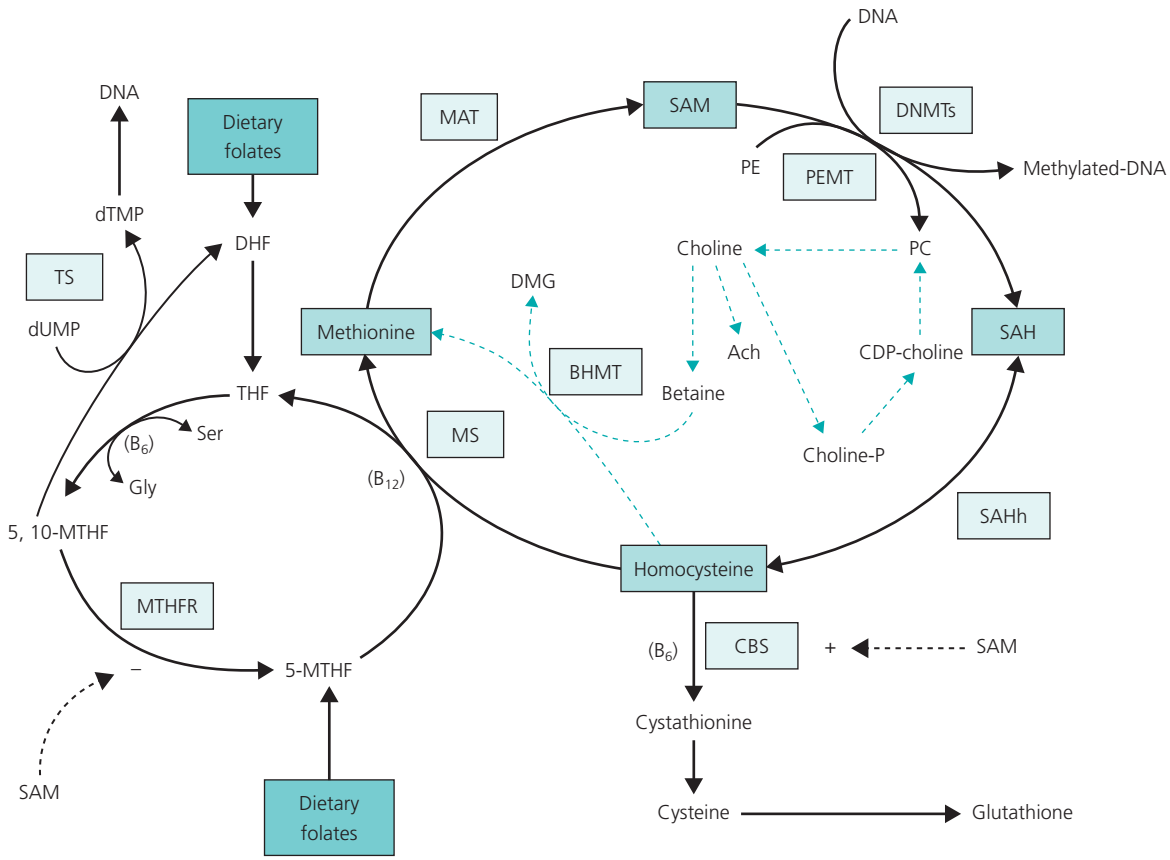

Figure 20.1 Interactions of folate and methionine metabolism. BHMT, betaine homocysteine methyltransferase; CBS, cystathionine β-synthase; CDP-choline, cytidine diphosphorylcholine; choline-P, phosphoryl choline; DHF, dihydrofolate; DNMTs, DNA methyltransferases; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; GSH, glutathione; MAT, methionine adenosyltransferase; MS, methionine synthase; 5-MTHF, 5-methyltetrahydrofolate; 5,10-MTHF, 5,10-methylenetetrahydrofolate; MTHFR, methylenetetrahydrofolate reductase; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PEMT, phosphatidylethanolamine methyltransferase; SAH, *S*-adenosylhomocysteine; SAM, *S*-adenosylmethionine; SAHh, SAH hydrolase; THF, tetrahydrofolate; TS, thymidylate synthase.

(THF) and their respective reductases. 5,10-MTHF is the substrate for two reactions: those of MTHF reductase (MTHFR) for the production of 5-MTHF, and of thymidylate synthase (TS) for the regeneration of THF and the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP) in the synthesis of DNA. The activity of MTHFR and its regulation by *S*-adenosylmethionine (SAM) are central to DNA synthesis: when MTHFR is less active, as in 677C→T homozygotes or when the level of its inhibitor SAM is increased, more 5,10-MTHF is available as a substrate for TS and the synthesis of dTMP from dUMP for proper DNA nucleotide balance and function. Conversely, when the level of SAM is low as a result of folate deficiency, MTHFR is more active and less 5,10-MTHF is available for TS with resultant nucleotide imbalance and altered DNA synthesis, leading to macrocytosis of nascent red blood cells and increased risk for several cancers. In the form of 5-MTHF, folate plays a central regulatory role in methionine metabolism as the substrate for the methionine synthase (MS) reaction that uses cobalamin as a cofactor and generates endogenous methionine from total homocysteine (tHcy). In the alternate salvage pathway, methionine is generated from tHcy by way of the betaine homocysteine methyltransferase (BHMT) pathway with the substrate betaine, which is a dietary substance and a derivative of choline. Both endogenous and exogenous methionine are converted to SAM by methionine adenosyltransferase (MAT), an enzyme that is produced by two genes: *MAT1A*, which is expressed in the liver, and *MAT2A*, which is expressed in nonhepatic tissues [19]. Through many methylation reactions, including DNA methylation and the synthesis of phosphatidylcholine from phosphatidylethanolamine by way of phosphatidylethanolamine methyltransferase, SAM is metabolized to *S*-adenosylhomocysteine (SAH), which is also generated from tHcy through the reversible SAH hydrolase (SAHH) reaction. Whereas SAM is the universal methyl donor, methylation reactions are inhibited by SAH [20]. SAM also regulates the synthesis of glutathione by stabilizing the cystathionine β-synthase (CBS) reaction and hence the tHcy transsulfuration pathway [21].

Causes of folate deficiency and aberrant folate and methionine metabolism

The principal causes of clinical folate deficiency are inadequate diet, intestinal malabsorption, and altered metabolism as a result of genetic aberrations and toxins such as alcohol.

Dietary deficiency

Since mandatory fortification of the US diet in 1998, the incidence of folate deficiency in the United States has decreased from 22% to 1.7% of the population, while the mean serum folate level of healthy people who do not use vitamin supplements has risen from 4.6 nmol/L to 10.0 nmol/L (from 11 ng/mL to 23 ng/mL) [22]. However, folate deficiency as the result of inadequate diet is common in impoverished populations, in developed countries where the diet does not contain fortified grains, and in susceptible populations including infants, elderly people, and chronic alcoholics whose diets are inadequate. For example, folate deficiency with low serum folate levels was found in more than 80% of chronic alcoholics in the United States in the prefortification era [23], and low levels of red blood cell folates were measured in 35% of chronic alcoholics in Portugal, which does not have a folate fortification policy [24]. The current incidence of folate deficiency in chronic alcoholics living in the United States, who presumably obtain folic acid from fortified diets, is not known. The body stores of folate are sufficient for about 4 months; therefore, before folic acid supplementation of the US food supply, the risk for dietary folate deficiency was high in these susceptible populations.

Malabsorption

Intestinal folate malabsorption and deficiency are associated with diseases and surgical procedures that affect absorbing enterocytes in the duodenum and jejunum, such as celiac disease, severe Crohn's disease, extensive gastric bypass surgery for severe obesity, and extensive small bowel surgery. For example, a Finnish study found that about one-third of adolescents with celiac disease had low serum folate levels, which was double the incidence in control subjects [25]. Sequential intestinal perfusion studies showed malabsorption of both monoglutamyl and polyglutamyl folates in untreated patients with celiac disease, which normalized after treatment with a gluten-free diet [2]. Multivitamin supplementation after gastric bypass surgery has lowered the potential for folate deficiency [26]. Whereas folate deficiency is not considered a risk for patients with inflammatory bowel disease who use mesalamine drugs, sulfasalazine inhibits the absorption of both monoglutamyl and polyglutamyl dietary folates [27]. Studies in the prefortification era identified a high incidence of folate deficiency in chronic alcoholics that was mainly ascribed to poor diet [23], and also demonstrated a significant component of intestinal folate malabsorption in a population of active alcohol consumers [28].

Genetic abnormalities of methionine metabolism

Despite the potential for a variety of functional polymorphisms in the regulatory genes involved in folate and methionine metabolism (see Fig. 20.1), clinically significant polymorphisms affecting folate metabolism are few and focus mainly on those of MTHFR. A thermolabile form of MTHFR occurs in TT homozygotes of the 677C→T variant, who represent 10%–15% of the general population and express moderate hyperhomocysteinemia especially when the polymorphism is combined with low folate levels [29]. A second MTHFR polymorphism at 1298A→C was thought to cause neural tube defects [30], but it does not appear to interact with 677C→T nor to cause elevated homocysteine levels [31]. While functional polymorphisms have been

described in the folate metabolizing genes, *GCP2* and *RFC1* (reduced folate carrier 1), their single or combined effects on folate absorption and status appear to be insignificant [31].

Clinical effects of folate deficiency and aberrant methionine metabolism

Because folate ultimately is required to maintain nucleotide balance during DNA synthesis, its deficiency is expressed by increased apoptosis with compensatory increased proliferation of cells with rapid turnover in the blood-forming bone marrow and in the intestinal mucosa. As indicated in Fig. 20.1, folate deficiency also affects the methionine metabolic cycle, resulting in elevated levels of circulating tHcy. Several common clinical conditions have been linked to folate deficiency with abnormal DNA metabolism and aberrant methionine metabolism.

Anemia and diarrhea

The main clinical expression of overt folate deficiency is megaloblastic anemia, with findings of macrocytic red blood cells with increased mean corpuscular volume and hypersegmented neutrophils in the peripheral blood, which are expressions of reduced levels of DNA and delayed erythropoiesis. Megaloblastic anemia is also a hallmark of cobalamin deficiency, and results from decreased MS activity as the result of folate deficiency with insufficient substrate MTHF or insufficient cofactor cobalamin resulting in diminished production of THF, methionine, and SAM (see Fig. 20.1). Consequently, the level of 5,10-MTHF is reduced by insufficient substrate THF and SAM inhibition. A reduced level of 5,10-MTHF decreases TS production of thymidine from uracil, thereby promoting the DNA nucleotide imbalance and reduced synthesis. Macrocytic enterocytes are evident in small intestinal biopsy specimens from alcoholic patients with folate-deficient megaloblastic anemia [32] and are associated with the diarrhea of chronic alcoholism caused in part by abnormal fluid and electrolyte transport in the intestine [33].

Folate deficiency and neural tube defects

Neural tube defects are errors of fetal spinal cord development that occur within the first 2 weeks of pregnancy and result in anencephaly and spina bifida. Neural tube defects occur at a rate of 1–2 per 1000 live births and probably more frequently in spontaneous abortions. The association of neural tube defects with folate deficiency is based on findings that red blood cell folate levels in early pregnancy correlate with the risk for delivery of a child with a neural tube defect [34] and on the results of trials in which neural tube defects were prevented by periconceptional supplementation with folic acid [35]. About 20% of infants with a neural tube defect and their mothers have the homozygous 677C→T polymorphism of the *MTHFR* gene [36], but it is uncertain whether this variant plays a major role in determining the risk for neural tube defects unless it is associated with folate deficiency. In spite of early high expectations, the public-health policy of folic acid fortification of the US food supply has reduced the incidence of neural tube defects by only about 50% [37].

Cardiovascular disease

Hyperhomocysteinemia clearly increases the risk for stroke and coronary heart disease [38]. A metaanalysis of 15 studies of proven coronary artery disease showed that an increment of 5 μmol/L in the serum level of tHcy above the normal range constitutes a coronary heart disease risk similar to an increase in total cholesterol of 20 mg/dL above normal [39]. The prevention of cardiovascular disease by lowering homocysteine levels with folic acid supplements has been the focus of many clinical trials. A metaanalysis of 12 randomized clinical trials involving 17 000 patients with preexisting vascular disease concluded that folic acid supplementation had no effect on the risk of recurrent stroke or coronary heart disease or on mortality. The authors do not exclude the possibility that lowering homocysteine levels by folic acid supplementation may reduce the incidence of primary cardiovascular events in susceptible populations [40].

Colon cancer

The association of folate deficiency with an increased risk for colon cancer was established by a prospective sigmoidoscopic and dietary survey of more than 20 000 health professionals. The data revealed that a diet containing relatively low folate levels together with the consumption of more than two alcoholic drinks per day increased adenoma risk twofold [41]. A subsequent 6-year prospective study of more than 40 000 male health professionals found a threefold increased risk of colorectal cancer in alcohol consumers ingesting a low-folate diet, whereas a high-folate diet was protective against colorectal cancer despite alcohol consumption [42]. A Norwegian study found a threefold increased risk of large precancerous colorectal adenomas in patients with low red blood cell folate levels, that increased to eightfold in smokers who carried the T allele of the *MTHFR* 677C→T polymorphism [43]. The increased risk of colon cancer can be ascribed to the effects of folate deficiency in promoting DNA nucleotide imbalance, strand breaks, impaired repair, and aberrant DNA methylation [44]. Conversely, the Norwegian study found increased colorectal adenoma risk in smokers with high red blood cell folate levels [43], and a U-shaped curve described the relationship between high plasma folate levels and colorectal cancer risk in a Swedish case–control study [45]. Folate therefore plays a dual role with respect to colon cancer; folate deficiency enhances the likelihood of the initiation of colon cancer through its deleterious effects on DNA, and excessive folate enhances cancer cell proliferation by promoting cell division and the potential methylation of tumor suppressor genes [46,47].

Alcoholic liver disease

The contributory role for folate deficiency and elevated liver homocysteine and SAH in the pathogenesis of alcoholic liver disease has been well established and is summarized in a 2007 symposium report [48]. Studies from European countries where the diet is not fortified with folic acid indicate a continued high incidence of folate deficiency together with elevated serum homocysteine levels in chronic alcoholics [24,49]. In addition to poor diet and intestinal malabsorption, folate deficiency in alcoholism is caused by decreased uptake of folate by the liver and enhanced excretion in the urine [16]. Because liver folate stores are reduced in alcoholic liver disease [50], the combination of these factors accelerates the risk for folate deficiency in these patients. Abnormalities of the methionine metabolic cycle caused by experimental induction of alcoholic liver disease include the inhibition of MS, MAT1A, and SAHH, each of which contribute to increased levels of tHcy and SAH in the liver, and decreased SAM levels (see Fig. 20.1) [19,51]. Reduction in SAM levels was correlated to reduced levels of the principal antioxidant glutathione in the liver of ethanol-fed micropigs [52], while oxidative liver injury was prevented and glutathione levels were preserved by the administration of SAM to ethanol-fed baboons [53]. Elevated levels of homocysteine and SAH appear to activate stress signal pathways in the endoplasmic reticulum leading to increased hepatocellular apoptosis and lipid synthesis [54,55]. While ethanol exposure plays a significant role in altering methionine metabolism, the importance of folate deficiency was underscored by the observation that all these features of alcoholic liver disease were enhanced in micropigs fed a diet that combined both ethanol and the absence of folic acid, compared to either factor alone [52].

Assessment of folate deficiency

Folate deficiency should be suspected in any anemic patient with an elevated mean corpuscular volume of red blood cells, and then confirmed by a measurement of a low level of serum or red blood cell folate. Each of the latter tests can be performed by a radioisotope-binding assay. The serum folate level is more labile and dependent on recent dietary intake, whereas the red blood cell folate level is a more accurate measure of tissue stores. Depending on the laboratory, folate deficiency is defined by a serum folate level less than 7 nmol/L (3 ng/mL), while a level of red blood cell folate level less than 305 nmol/L (140 ng/mL) is predictive of tissue folate deficiency [1]. Measurement of the plasma tHcy level is a more sensitive functional assay for folate deficiency. Since 5-MTHF is the substrate for the MS reaction that converts tHcy to methionine, a low folate level is represented by an increased tHcy level. Normal ranges of tHcy vary among laboratories, and mean normal values for different age groups range from 6.6 to 13.4 μmol/L [1]. In addition to folate deficiency, factors that increase tHcy include male sex, increasing age, smoking, coffee consumption, and decreased renal function with an elevated serum creatinine level [56]. However, because cobalamin is an essential cofactor for the MS reaction, its deficiency is also reflected by an elevated tHcy level, as well as by the same tissue expressions found in folate deficiency (see Fig. 20.1 and Table 20.1). Therefore, folate deficiency can be defined metabolically by high tHcy and normal cobalamin status, as described in the next section.

Folate toxicity

Evidence from many research groups suggests that a considerable portion of supplemental folic acid is absorbed unchanged, and that high circulating levels of folate may alter immune function, increase cancer risk, and promote worsening of cognitive function in elderly subjects [57]. At least 40% of aging Americans take supplemental folic acid at 400 μg/day and consequently their serum folate levels often exceed 40 nmol/L, which is at least double the highest serum folate level in those who do not use supplements [47], and their level of unmetabolized folic acid constitutes more than 15% of serum folate that exceeds 50 nmol/L [58]. A study of postmenopausal women showed that immune function as measured by natural killer cell toxicity was improved by folic acid supplementation at 400 mg/day, but worsened in linear fashion with the increasing levels of unmetabolized serum folic acid in those who took larger doses of supplemental folic acid [18]. Furthermore, the risks for prostate cancer in men and breast cancer in postmenopausal women increased significantly in relationship to increasing plasma folate levels [59,60], especially when associated with the use of folic acid supplements [60]. A study of 1300 elderly people reported an increased risk for megaloblastic anemia and reduced cognitive function in those persons with low vitamin B-12 status who took supplemental folic acid [61]. This interesting relationship of folate and vitamin B-12 is explored in greater detail in the next section.

Vitamin B-12 (cobalamin)

Folate and vitamin B-12 have complex and different mechanisms of absorption, and each has a broad range of clinical effects. Because these vitamins interact metabolically, many of the clinical signs of deficiency are similar, although their structures, food sources, and modes of absorption are dissimilar (Table 20.1).

Structure, nomenclature, and metabolic functions

Vitamin B-12, or cobalamin, contains a central cobalt atom surrounded by a planar corrin ring that is formed from four reduced pyrrole rings linked together and attached at a right angle to a nucleotide containing ribose, phosphate, and 5,6-dimethylbenzimidazole. In its active coenzyme forms, the cobalt atom is bound to specific moieties, resulting in methylcobalamin and adenosylcobalamin, whereas cyanocobalamin is the pharmaceutical and interchangeable form of the

Table 20.1 Folate and cobalamin

	Folate	Cobalamin
Dietary source	Green vegetables, orange juice, fortified grains	Animal protein exclusively
Daily requirement	Adult: 400 µg DFE Pregnancy: 600 µg DFE Lactation: 500 µg DFE	Adult: 2.4 µg Pregnancy: 2.6 µg Lactation: 2.8 µg Older than age 50: supplement
Site of intestinal absorption	Jejunum	Ileum
Regulatory proteins in absorption	Glutamate carboxypeptidase II Reduced folate carrier	R protein (haptocorrin) Intrinsic factor Cubulin Transcobalamin II
Function	Transfer of one-carbon moieties, methylation, DNA synthesis	DNA synthesis, myelin maintenance
Risks for deficiency	Dietary inadequacy Chronic alcoholism Pregnancy Intestinal malabsorption, especially celiac disease Elderly with unbalanced diet	Elderly with achlorhydria Postgastric bypass surgery Chronic use of proton pump inhibitors Pernicious anemia Ileal disease or resection: short bowel syndrome, Crohn's disease, radiation enteritis Intestinal bacterial stasis syndrome
Clinical signs of deficiency	Megaloblastic anemia Hyperhomocysteinemia:cardiovascular risk, neural tube defects	Megaloblastic anemia Cognitive deficit Subacute combined degeneration
Diagnosis	Low serum and red cell folate Elevated serum homocysteine with normal methylmalonic acid	Low serum vitamin B-12 Elevated serum homosysteine and serum methylmalonic acid Low serum holotranscobalamin

DFE, dietary folate equivalent.

vitamin. There are only two known enzymatic reactions that require cobalamin and serve to bind it in tissues. Methylcobalamin is the cofactor for MS and participates in the transfer of the methyl group from 5-MTHF to tHcy, producing methionine and THF (see Fig. 20.1). Cobalamin deficiency therefore reduces activity of MS, elevates tHcy, and "traps" 5-MTHF in a nonfunctioning role. The MS product THF is reduced so less 5,10-MTHF is available for the TS reaction, which results in less generation of thymidine from uracil, nucleotide imbalance, and decreased DNA synthesis with risk of megaloblastic anemia (see Fig. 20.1). Adenosylcobalamin is involved in a separate reaction as a cofactor for methylmalonyl-coenzyme A (CoA) mutase in the conversion of methylmalonyl-CoA to succinyl-CoA. Accordingly, cobalamin deficiency also uniquely results in the elevation of the level of serum methylmalonic acid, which is a side product of methylmalonic CoA [62]. In this section, the term *cobalamin* is used to describe dietary sources, metabolic pathways, and clinical manifestations of deficiency. The term *vitamin B-12* is used to describe the pharmacological and supplemental forms of the vitamin.

Dietary sources and requirements

Cobalamin originates from intestinal bacterial synthesis with subsequent transfer to cells; it therefore appears in the human diet exclusively bound to animal proteins. The usual sources of cobalamin are all animal products, including meat, fish, shellfish, poultry, eggs, milk, and other dairy products. The adult DRI for cobalamin is 2.4 µg/day (2.6 µg during pregnancy and 2.8 µg during lactation), which accounts for an average 50% absorption from all dietary sources. Because cobalamin absorption declines with aging, persons older than 50 years are advised to take supplements containing vitamin B-12 or to ingest food that is fortified with vitamin B-12, such as most breakfast cereals [62].

Intestinal absorption and metabolism of cobalamin

The intestinal absorption of dietary animal-protein-bound cobalamin involves gastric, upper intestinal, and ileal stages, and an enterohepatic circulation (Fig. 20.2). Abnormality in any of these steps may result in cobalamin deficiency. In the presence of gastric acid and pepsin, cobalamin is severed

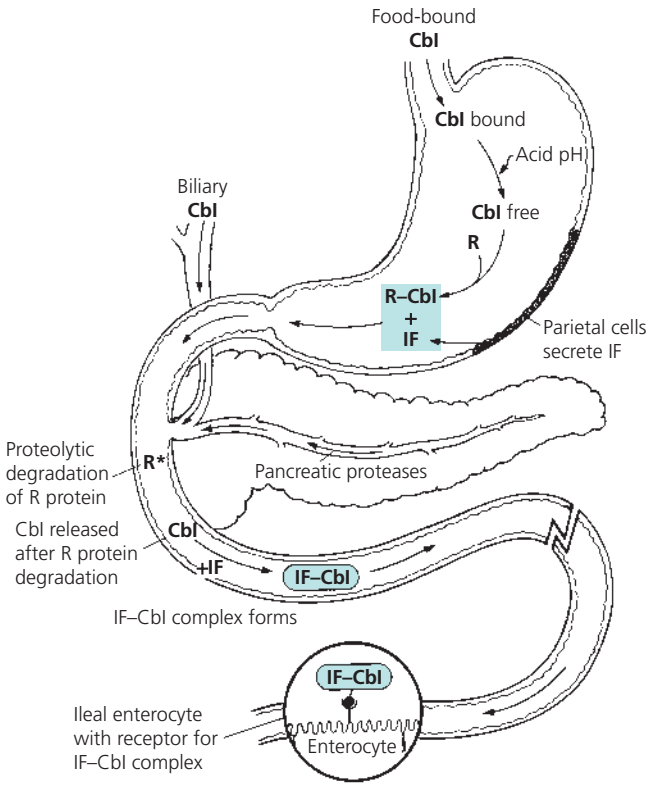

Figure 20.2 Sequential steps in the gastrointestinal absorption of dietary protein-bound cobalamin (Cbl). Gastric acid is required to liberate both methylcobalamin and adenosylcobalamin from dietary protein. In the acidic gastric environment, cobalamin is then bound to salivary R proteins, and gastric parietal cells secrete intrinsic factor (IF). After neutralization of the gastric contents in the upper duodenum and pancreatic protease digestion of the R protein–cobalamin complex, free cobalamin then binds to IF. After transit to the terminal 50 cm of ileum, the IF–cobalamin complex interacts at the microvillus surface with the specific ileal receptors cubulin and amnionless, and is then internalized and binds to megalin and transcobalamin II. From Sitrin [307], with permission from Lippincott, Williams and Wilkins.

from its protein bond and then is transferred to R protein (also called haptocorrin), which is secreted by salivary and parietal cells [63]. The release of cobalamin and its transfer to R protein is optimal at pH 1–1.3, a level that is not achieved by achlorhydric individuals, who mostly include persons older than 65 years who develop gastric atrophy as part of the aging process [64]. The third gastric step involves the secretion of intrinsic factor (IF) from acid-secreting parietal cells. However, IF is ineffective as a cobalamin binder at the acid pH of the healthy stomach, and it follows the R protein–cobalamin complex into the duodenum. Here, the complex is degraded by pancreatic proteases, and at the neutral pH of the duodenum, cobalamin is quickly bound to the protease-resistant IF and in this state traverses the small intestine to the ileum [63,65]. The absorption of cobalamin by ileal enterocytes requires several binding proteins. First, the cobalamin–IF complex is bound to a specific membrane receptor on the ileal enterocyte called cubulin, which collocates with another enterocyte receptor called amnionless (AML). Each of these receptors is active in ileal enterocytes and in renal tubular cells. Subsequent transfer across the ileal enterocyte involves the intracellular cleavage of the cobalamin–IF/cubulin/amnionless complex [66]. Cobalamin then binds to transcobalamin II, a 43-kDa protein with molecular homology to IF that is synthesized in ileal enterocytes and complexes with a protein called megalin, which carries cobalamin out of the ileal mucosa to the portal circulation [67,68]. The transcobalamin II–cobalamin complex, known as holotranscobalamin, accounts for 10%–20% of all circulating cobalamin and is essential for its transport to all cells of the body. Holotranscobalamin is taken up by cells by endocytosis, which is followed by liberation of the two coenzyme forms methylcobalamin and adenosylcobalamin [63]. In an enterohepatic cycle, about 1.4 μg/day of endogenous cobalamin is secreted into the bile as a complex with R protein [69]. The circulating cobalamin is then released from biliary R protein by pancreatic trypsin and then rapidly bound to IF for subsequent passage to the ileal receptor site, where about half, or 0.7 μg/day, is reabsorbed and the other half is excreted in the stool (62).

Clinical expressions of cobalamin deficiency

Folate and cobalamin are required as substrate and cofactor for the MS reaction (see Fig. 20.1), the clinical expression of cobalamin deficiency as megaloblastic anemia and hyperhomocysteinemia is indistinguishable from that of severe folate deficiency. However, because cobalamin also participates in the methylmalonyl-CoA mutase reaction, its deficiency may also be expressed in the nervous system as subacute combined degeneration of the posterior columns of the spinal cord, which is characterized by the loss of position and vibratory sensation and other features of peripheral neuropathy of the lower extremities. Cobalamin deficiency also has more subtle and frequent effects on the central nervous system that include neuropsychiatric disorders such as ataxia, paresthesias, memory loss, cognitive dysfunction, and more severe dementia, even in the absence of anemia [70]. A prospective study of elderly subjects found that the presence of baseline hyperhomocysteinemia predicted the 8-year risk of developing dementia as well as overt Alzheimer disease [71]. A subsequent study showed that the relationship of hyperhomocysteinemia to cognitive defects depends on the adequacy of the serum cobalamin level [72]. Others confirmed this association and also showed that cobalamin-deficient subjects taking folic acid supplements had the most severe cognitive decline [61]. This observation can be explained by the interactions of cobalamin and folate metabolisms (see Fig. 20.1), such that excessive folic acid promotes the use of residual cobalamin by the MS reaction, thereby depleting stores that would otherwise be available for the methylmalonyl-CoA mutase reaction required for brain functions.

Causes of cobalamin deficiency

Cobalamin deficiency has many potential causes owing to the complexity of the mechanisms of its absorption processes.

Dietary inadequacy

The daily requirement of cobalamin of 2.4 μg [62] is very small compared to its body pool size (1–2 mg); therefore, it takes many years to become deficient from dietary inadequacy alone. In populations living in developed countries, only true vegans who do not take vitamin supplements are at risk for dietary cobalamin deficiency, because cobalamin is present in dairy products and in most multivitamins. However, the worldwide incidence of dietary vitamin cobalamin deficiency is substantial, and many populations living in the Indian subcontinent, certain parts of Africa, and in rural Central America obtain less than 1 μg/day and have a higher incidence of megaloblastic anemia, delayed childhood development, and neurological complications [73].

Abnormal gastric events

Gastric acid is required for the release of food-bound cobalamin from dietary protein as the first step in cobalamin absorption so achlorhydric individuals are at risk for cobalamin deficiency. Achlorhydria of aging is the most common cause of cobalamin deficiency in the United States. According to the criteria of elevated levels of methylmalonic acid and tHcy and a serum cobalamin level of less than 222 pmol/L (300 pg/mL), at least 15% of ambulatory individuals older than 65 years are cobalamin-deficient in the United States, with greater prevalence in Hispanic Americans and less in African Americans [73,74]. A similar incidence of age-related cobalamin deficiency has been reported in European countries [63]. The increasing prevalence of age-related cobalamin deficiency, which is 40% in persons older than 80 years [63], could be related to a greater prevalence of *Helicobacter pylori*, which predisposes to more severe gastric atrophy and malabsorption of food-bound cobalamin [75].

Pernicious anemia was first described by Thomas Addison in the early 19th century, and is recognized as an autoimmune disorder characterized by the absence of IF in the gastric juice in association with achlorhydria. Almost all patients have gastric and serum antibodies to either parietal cells or IF, and most have elevated serum gastrin levels [63]. The type A atrophic gastritis pattern of pernicious anemia involves the fundus and upper body of the stomach, in contrast to the more common type B atrophic gastritis of elderly patients, which involves the lower stomach and antrum. Pernicious anemia may be associated with other autoimmune diseases, including Hashimoto thyroiditis, adrenal atrophy, and Sjögren syndrome, and carries increased potential for the development of gastric adenocarcinoma, lymphoma, and carcinoid tumors [63] While the overall incidence of pernicious anemia in the United States is about two cases per 1000 per year [73], it increases with aging, and a survey of over 700 elderly subjects in Los Angeles reported incidences among men and women at 1.4% and 2.7%, respectively, with a somewhat greater incidence in African Americans than in white subjects [76]. Because IF is also required for the absorption of endogenous cobalamin in the enterohepatic circulation, cobalamin deficiency develops more rapidly in patients with untreated pernicious anemia than in strict vegans or elderly persons with achlorhydria. There is an increased risk of gastric neoplasms so persons with proven pernicious anemia should have endoscopic surveillance every 3 years [63]

Many other clinical conditions involving the stomach or small intestine cause cobalamin malabsorption. For example, a case–control study of patients older than 65 years reported that chronic use of proton pump inhibitors is associated with a fourfold greater risk of cobalamin deficiency [77]. Surgical causes of cobalamin deficiency include total gastrectomy and gastric bypass surgery for obesity, each of which is associated with food-bound cobalamin malabsorption secondary to achlorhydria. A survey performed early in the era of gastric bypass surgery found that two-thirds of patients developed cobalamin deficiency within 12 months of surgery [78] However, a more recent survey found a 12% incidence of postoperative cobalamin deficiency among routinely screened patients [26]. Persistent duodenal hyperacidity may inactivate pancreatic trypsin and prevent the transfer of cobalamin from gastric R protein to IF; thus, cobalamin deficiency is a recognized component of Zollinger–Ellison syndrome [79].

Abnormal pancreatic and upper intestinal events

Although cobalamin malabsorption was described in 50% of patients with pancreatic insufficiency, including patients with cystic fibrosis, actual deficiency is uncommon in these patients [80]. During passage through the jejunum, the cobalamin–IF complex is susceptible to bacterial cleavage or uptake; cobalamin deficiency with megaloblastic anemia is an increasingly recognized clinical expression of bacterial overgrowth syndromes in the elderly [81,82]. Intestinal infestation with the fish tapeworm *Diphyllobothrium latum*, which is found in rural Finland, also causes cobalamin deficiency through competition for the cobalamin–IF complex [83].

Abnormal ileal events

According to retrospective studies of patients with ileal resections of various lengths, at least 50–80 cm of the terminal ileum participates in the ileal uptake and transfer of cobalamin, so that patients with inflammatory disease affecting longer lengths of intestine or those who have had surgical resection of the terminal ileum are at increased risk for cobalamin deficiency [84] Diseases that interrupt enterohepatic cycling, such as Crohn's disease affecting the terminal ileum, radiation enteritis [85], and ileal bypass surgery or resection (86), promote increased loss of endogenous cobalamin in the feces. Surgical resection of the ileocecal valve increases the risk for cobalamin deficiency by permitting the migration of

colonic bacteria and subsequent small intestinal bacterial overgrowth. Because the terminal ileum is the site for both dietary cobalamin absorption and the reabsorption of endogenous cobalamin from its enterohepatic circulation, cobalamin deficiency may become evident within several months of surgical resection of more than 50 cm of terminal ileum [86].

Genetic causes of cobalamin malabsorption

Rare congenital deficiency of IF results from the failure of its synthesis by gastric parietal cells. The gastric mucosa and acid secretion are normal and IF antibodies are absent in this condition. Cobalamin deficiency is usually apparent between the ages of 1 and 5 years [87]. The Imerslünd–Grasbeck syndrome, caused by defective cobalamin transport by ileal enterocyctes that results from mutations in cubulin (*CUBN*) or amnionless (*AMN*), has a prevalence of 1 : 200 000 in people of Scandinavian descent, and is usually clinically evident in early childhood but may also be first recognized in adulthood. This autosomal recessive disease represents the failure of synthesis or membrane insertion of cubulin or amnionless and is expressed in both the ileum and the renal tubule by the early onset of cobalamin deficiency and proteinuria [88]. Very rare congenital transcobalamin II deficiency is also an autosomal recessive condition, and is expressed in the first year of life with pancytopenia and megaloblastic anemia [89].

Diagnosis of cobalamin deficiency

Cobalamin deficiency should be suspected in any person who presents with macrocytic anemia with an elevated mean corpuscular red blood cell volume, cognitive decline, glossitis, or classical signs of subacute combined degeneration of the spinal cord that include loss of proprioceptive and position sense. Cobalamin is conventionally measured in the serum by a radioassay with high specificity and sensitivity, with values less than 250 pmol/L considered subnormal [74,90]. The measurement of holotranscobalamin is potentially a more accurate assessment of the amount of cobalamin that is available for cellular uptake, but its utility relative to the cobalamin assay is still uncertain [91]. Measurements of the metabolites tHcy and methylmalonic acid (MMA) are both useful to confirm cobalamin deficiency. An elevated tHcy is nonspecific and does not distinguish between cobalamin deficiency and folate deficiency, whereas the measurement of MMA is costly and often not easily available. MMA measurement has been recommended to confirm cobalamin deficiency when the serum cobalamin level is in the intermediate range between 125 and 250 pmol/L. However, there is also a gray area of uncertain MMA normality; a value greater than 0.75 μmol/L is confirmatory of cobalamin deficiency [90].

The Schilling test of cobalamin deficiency, which was widely available until recently, involved measuring the 24-h urine excretion of labeled cobalamin with and without the inclusion of exogenous IF. This test was used to differentiate dietary causes (normal absorption), pernicious anemia (low absorption corrected with exogenous IF), ileal malabsorption (low in either case), and intestinal bacterial overgrowth (low then corrected with oral antibiotics). However, this "gold standard" test is seldom available as a result of the unavailability of exogenous IF, the need for the use of radioactive dosages, and cumbersome urine collections. The clinician must rely on a careful history to distinguish potential causes before determining the best approach to the treatment of cobalamin deficiency. For practical purposes, dietary cobalamin deficiency occurs in strict vegans or cultural vegetarians, such as Indian immigrants, who allow no source of animal food in their diet and do not use vitamin supplements; it may also occur in patients with long-standing malnutrition secondary to anorexia nervosa [92]. Cobalamin deficiency secondary to the gastric achlorhydria of aging is mainly a diagnosis of exclusion of pernicious anemia and other causes of malabsorption in individuals older than 60 years. Surgical causes including gastric resection or bypass and ileal resection and ileal diseases such as Crohn's disease or radiation enteritis should be self-evident from the history. Intestinal bacterial overgrowth is also diagnosed by symptoms of bloating and history of intestinal diseases such as ileocecal resection, partial bowel obstruction, scleroderma, or autonomic visceral neuropathy of diabetes. The diagnosis of pernicious anemia is problematic with the unavailability of the Schilling test, and is approached by using generally nonspecific testing. While the sensitivities of tests for serum and gastric juice antibodies to IF and parietal cells approach 100%, their specificities are only about 50%–70% [63,90]. Similarly, elevated levels of serum gastrin and pepsinogen are sensitive findings but nonspecific, as is the finding of gastric atrophy by endoscopy. In a series of 120 patients with proven pernicious anemia with antibodies to IF, 91% had low serum pepsinogen values and 87.5% had elevated serum gastrin values [93].

Treatment of cobalamin deficiency

The treatment of cobalamin deficiency is based on both its detection and the identification of its cause. Since cobalamin deficiency secondary to the achlorhydria of aging or gastric surgery is caused by malabsorption of food-bound dietary cobalamin but not of unbound crystalline pharmaceutical vitamin B-12, it can usually be treated by supplemental oral vitamin B-12 at over-the-counter doses of 350 μg/day crystalline vitamin B-12 supplement [94]. Since patients with pernicious anemia lack both IF and gastric acid, they can absorb neither crystalline cobalamin nor dietary food-bound cobalamin and must be treated with parenteral vitamin B-12, starting at 1000 μg/day for a week, then weekly for a month, and then in monthly 1000-μg doses, ideally after training in self-injection. A study of 33 patients with cobalamin deficiency caused by atrophic gastritis with or without pernicious

anemia reported that an oral dose of 2000 μg/day was as effective in correcting the deficiency as a parenteral dose of 1000 μg/month [93]. Patients who develop cobalamin deficiency in the presence of bacterial overgrowth, ileal disease, or surgical resection, each of which limits the absorption of the cobalamin–IF complex, should be similarly treated with regular parenteral cobalamin injections.

Vitamin C

Vitamin C (ascorbate) is a weak acid that acts as a reducing agent that produces dehydroascorbate and subsequently oxalate [95]. Most mammals, except primates and guinea pigs, synthesize ascorbate from glucose [96]. Vitamin C is obtained from fruits and vegetables in the diet, fortified foods and beverages, and vitamin supplements. The DRI for men is 90 mg and for women is 75 mg [97], which, after ingestion as a supplement, produce plasma concentrations of about 50 μM (Table 20.2). However, these same amounts from fruits and vegetables may produce lower plasma concentrations because of the lower bioavailability of ascorbate from food compared to that of pure vitamin C [98]. As a result of increased oxidative stress, smokers require a higher daily intake: 125 mg for men and 110 mg for women [99]. Assuming a variety of five or more servings of fruits and vegetables, the daily dietary intake often exceeds 200 mg. Many vitamin supplements contain ascorbic acid at a variety of doses from 60 to 1000 mg. The dehydroascorbic acid content of foods is estimated to be 10%–20% of the total vitamin content [100].

Ascorbic acid can be measured in plasma by high-performance liquid chromatography (HPLC), whereas there is no sensitive or specific assay for dehydroascorbic acid [101]. Ascorbic acid undergoes carrier-mediated transport by sodium-dependent vitamin C transporters (SVCT) 1 and 2 [102]. SVCT1 is localized to intestine, liver, and kidney, and SVCT2 is distributed in other tissues. Flavonoids in fruits and vegetables may decrease absorption by inhibiting the SVCT1 transporter [98]. Dehydroascorbic acid is transported by facilitated glucose transporters and immediately reduced intracellularly to ascorbic acid [103]. Once absorbed, ascorbic acid, but not dehydroascorbic acid, circulates unbound in plasma [104] and is available for tissue transport by SVCT2

Table 20.2 Other water-soluble vitamins

	Vitamin C	Thiamin	Pyridoxine	Niacin	Riboflavin
Dietary source	Fruits, vegetables, fortified food and beverages	Whole grain, fortified cereals, pork	Meat, fish, poultry, non-citrus fruit, fortified cereals	Tryptophan , fish, legumes, fortified cereals	Milk, eggs, fortified cereals
Daily requirement	Men 90 mg; women 75 mg; smokers 125 mg (men) 110 mg (women); pregnancy 80 mg; lactating 120 mg	Men 1.2 mg; women 1.1 mg; pregnancy and lactation 1.4 mg	Men and women 1.3 mg; pregnancy 1.9 mg, lactation 2.0 mg	Niacin equivalents (NE is 60 mg tryptophan): men 16 NE, women 14 NE; pregnancy 18 NE, lactation 17 NE	Men 1.3 mg; women 1.1 mg; pregnancy 1.4 mg, lactation 1.6 mg
Absorption	Carrier-mediated through SVCT1	Active Na^+-dependent transport, passive diffusion higher dose	Hydrolysis and passive transport	Active tryptophan; passive niacin	Active Na^+-dependent transport
Function	Antioxidant reducing agent; collagen synthesis, neurotransmitter synthesis	Carbohydrate and energy metabolism	Heme synthesis, cofactor for alanine transaminase, CβS	NAD and NADP redox reactions, DNA repair	Redox, especially glutathione reductase; cofactor for MTHFR
Clinical signs of deficiency	Scurvy	High-output heart failure, peripheral neuropathy, Wernicke–Korsakoff syndrome	Elevated homocysteine, altered cognition, glossitis, peripheral neuropathy	Pellagra in malnutrition, AIDS, Hartnup disease, carcinoid syndrome	Glossitis, peripheral neuropathy, elevated homocysteine in TT homozygous MTHFR 677C→T
Toxicity	False-negative hemoccult; hyperoxaluria renal stone potential	None known	Sensory neuropathy in gram amounts	Flushing, exacerbation of peptic ulcer	None known
Diagnosis	HPLC plasma	Erythrocyte transketolase	HPLC	Urine metabolites	Erythrocyte glutathione reductase

HPLC, high-pressure liquid chromatography.

against its concentration gradient into muscle, adrenal, and pituitary tissues, and into circulating neutrophils, monocytes, and lymphocytes [105]. Vitamin C levels are also regulated by glomerular filtration and reabsorption by SVCT1 in the proximal renal tubule [106]. At doses less than 100 mg/day, there is a steep relationship between the ingested dose and the steady-state fasting plasma concentrations of ascorbate, which are saturated at 60–70 μM at oral intakes greater than 100 mg/day. As the ingested dose increases, the amount that is absorbed decreases; for example, 80% of a dose of less than 100 mg is absorbed, compared to less than half of a 1250-mg dose [107]. Even with maximally tolerated pharmacological oral doses of 2–3 g at intervals of several hours, plasma concentrations do not exceed 220 μM [105].

The only certain health benefit of ascorbic acid ingestion is to prevent scurvy, a potentially lethal condition [107]. Scurvy is relatively rare in Western countries, but it may occur under conditions of inadequate diet in substance abusers, alcoholics, and in persons with cancer. Clinical features of scurvy occur at plasma ascorbate concentrations less than 4–5 μM and include bleeding of the gums and around the hair follicles of the lower extremities and lassitude and depression, while more severe deficiency may result in joint effusions, intestinal bleeding with hypotension, and death [108]. Scurvy can usually be corrected with several hundred mg of intravenous or oral ascorbic acid, given daily for several days. Vitamin C deficiency without overt scurvy occurs at plasma concentrations of 5–20 μM, and is reported in persons whose diet consists of fast food [109]. Malabsorption of vitamin C is associated with extensive Crohn's disease, short bowel syndrome, and celiac disease. Vitamin C deficiency also occurs in patients with renal disease undergoing hemodialysis, since each hemodialysis session reduces plasma ascorbate concentrations by as much as 70% [110]. Controversial evidence suggests that eating five or more daily servings of fruits and vegetables that are high in ascorbic acid may prevent some cancers, improve blood pressure, and decrease the risks for cardiovascular disease and stroke [111]. Ascorbate is secreted in gastric juice and enhances iron absorption by reducing Fe^{3+} to Fe^{2+} [112]. Therefore, vitamin C supplements should be avoided by patients with hemochromatosis, thalassemia, or diseases requiring chronic red blood cell transfusions [113]. Diarrhea or bloating occurs in subjects who ingest doses of more than 2–3 g at one time. False-negative results on hemoccult tests can occur with intakes of more than 250 mg vitamin C. Supplemental doses exceeding 1000 mg increase urinary oxalate excretion in patients with known hyperoxaluria. Studies have indicated no increased incidence of renal stones in subjects who ingest at least 1 g of ascorbate daily; however, these studies excluded subjects with a history of renal stone formation who may be at greater risk [113]. Furthermore, patients with end-stage renal disease should avoid consuming more than 200 mg ascorbate daily because compromised renal regulation may increase plasma levels and thus promote hyperoxaluria and stone formation [107,113].

Thiamin

Thiamin, in its active form as thiamin pyrophosphate, is involved in carbohydrate and energy metabolism as a coenzyme for pyruvate dehydrogenase and for the decarboxylation of α-ketoacids. Thiamin is present in fortified or whole grain cereals and breads, and in pork. The DRI for thiamin is 1.2 mg for men and 1.1 mg for women, and 1.4 mg during pregnancy and lactation (Table 20.2) [114]. Thiamin is absorbed by a dual process in the jejunum. At low concentrations (0.2–2.0 mM), thiamin is absorbed by an active Na^+-dependent transport that involves phosphorylation, and at higher concentrations, it is absorbed by passive diffusion [115]. The body pool size of thiamin is about 30 mg, with a half-life of 9–18 days, and plasma and red blood cell levels are sustained by rapid urinary excretion of excess absorbed thiamin. Thiamin deficiency is common in chronic alcoholics because of a combination of poor intake and reduced absorption. Ethanol interferes with Na^+,K^+-ATPase-mediated active transport across the basal enterocyte membrane, which drives thiamin absorption [116]. Other causes of thiamine deficiency include extensive diuretic use and extreme malnutrition of any cause, such as chronic recurrent vomiting, anorexia, and malabsorption syndromes. The clinical signs of thiamin deficiency are related to the heart and the nervous system. Classical wet beriberi, which often accompanies starvation, is characterized by cardiomyopathy with high-output cardiac failure, whereas the principal sign of dry beriberi is progressive stocking–glove polyneuropathy of the lower extremities. The extensive use of diuretics promotes thiamine deficiency in patients with congestive heart failure, whereas the left ventricular ejection fraction improves with thiamine replacement [117]. Additional neurological features of thiamin deficiency occur in chronic alcoholics and are classified under the Wernicke–Korsakoff syndrome as nystagmus and ocular paresis, cerebellar dysfunction with a wide-based gait, and global confusion [118] With the increasing popularity of gastric bypass surgery for obesity, acute Wernicke–Korsakoff syndrome with delirium has been recognized as a severe complication of prolonged postoperative vomiting that may occur with insufficient size of the gastric outlet [119]. Because body stores of thiamin are regulated by carbohydrate metabolism, the administration of intravenous glucose to a malnourished patient may precipitate an acute demand for residual endogenous thiamin with resultant overt thiamin deficiency manifest by cardiac failure and confusion. Patients with Alzheimer disease have decreased levels of brain thiamin pyrophosphate, but do not respond to thiamine therapy [120]. Thiamin status is most accurately assessed by a functional assay of erythrocyte transketolase before and after the addition of thiamin pyrophosphate [121].

Pyridoxine

Pyridoxine, or vitamin B-6, is a coenzyme for many amino acid reactions and exists in six forms: pyridoxine, pyridoxal, pyridoxamine, and the phosphorylated forms of each. Its main food sources include meat, fish, poultry, noncitrus fruits, and fortified cereals. The DRI is 1.3 mg for adult men and women; this rises to 1.5 mg for those older than 50 years, 1.9 mg during pregnancy, and 2.0 mg during lactation (Table 20.2) [122]. The phosphorylated forms of pyridoxine are absorbed after hydrolysis by brush border alkaline phosphates, followed by passive transport of nonphosphorylated forms through the enterocyte. Phosphorylation is restored in the liver, and the principal circulating form of vitamin B-6 is pyridoxal phosphate (PLP) in a complex with albumin. The body pool size of pyridoxine is 60–100 mg. Pyridoxine deficiency is one of the common features of chronic alcoholism and, owing to the role of pyridoxine in heme synthesis, it is characterized by microcytic sideroblastic anemia, as well as by peripheral neuropathy, cheilosis, and glossitis. Pyridoxine deficiency in alcoholism is caused by hepatic degradation of the PLP–protein complex by acetaldehyde followed by rapid urinary excretion of the unbound vitamin [123]. The more than twofold elevation of serum aspartate aminotransferase relative to alanine aminotransferase measured in patients with alcoholic hepatitis may be caused by the greater requirement of the latter enzyme for PLP [124]. Pyridoxine is an essential cofactor for cystathionine β-synthase in the transsulfuration elimination pathway of tHcy (see Fig. 20.1) so its deficiency contributes to hyperhomocysteinemia in elderly patients and other susceptible individuals, and may play a role in the enhanced risk of diseases associated with decreased cognitive function [125]. Pyridoxine toxicity was described in women in whom severe sensory neuropathy of the hands and fingers developed after ingestion of 2–6 g/day for 2 months for premenstrual stress [126]. Plasma PLP can be measured by HPLC [121].

Niacin

Niacin is expressed biologically by its two coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Both forms are involved in a vast number of redox reactions involved in the generation of energy from carbohydrates, fats, proteins, and ethanol. NADP is also involved in fatty acid and cholesterol biosynthesis, and NAD is the substrate for poly(ADP-ribose)polymerase, which is involved in DNA replication and repair [127]. Dietary niacin is derived from animal protein as tryptophan, and as nicotinic acid and nicotinamide from enriched or whole grain cereals, leafy vegetables, and legumes. Since 60 mg tryptophan is metabolized to 1 mg niacin, one niacin equivalent is the same as 1 mg niacin or 60 mg tryptophan. The DRI of niacin is 16 mg of niacin equivalents for men and 14 mg for women, with 18 mg during pregnancy and 17 mg during lactation (Table 20.2) [128]. Both nicotinic acid and nicotinamide are absorbed passively and completely from the stomach and the small intestine, while low concentrations are absorbed by sodium-dependent facilitated diffusion. Pellagra is the classical disease of niacin deficiency and occurs in populations whose diets contain insufficient animal protein as a source of tryptophan, in particular if corn is used as a grain staple. Once prevalent as a cause of mental illness among the very poor in the southern United States, pellagra was eliminated after Goldberger's classic finding that the missing vitamin occurred in grains other than corn [129]. Still occurring in persons living in areas of Africa and other less-developed countries where there is a scarcity of animal protein, in malnourished chronic alcoholics [130], and sometimes in patients with acquired immunodeficiency syndrome [131], pellagra is clinically manifest by the "three Ds" of diarrhea, dementia, and dermatitis. The dermatological manifestation is a scaly red rash of sun-exposed areas. Characteristic signs of pellagra may also occur in Hartnup disease of congenital impaired tryptophan absorption and in the carcinoid syndrome, in which endogenous trytophan is diverted into serotonin synthesis [132]. Niacin in doses exceeding 1–3 g/day is often used in the treatment of combined hyperlipidemia. The common toxic side effects of flushing and exacerbation of peptic ulcer disease are greatly minimized by the use of lower doses of niacin together with a statin [133]. Niacin status is assessed by measurement of the urinary ratio of its metabolites, *N*-methyl-2-pyridone-5-carboxamide and *N*-methylnicotinamide [121].

Riboflavin

Riboflavin, or vitamin B-2, exists in coenzyme forms as flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), each of which is involved in redox reactions. The term flavoprotein refers to enzymes that use flavins as cofactors. The food sources of riboflavin include milk, eggs, and fortified cereals. The DRIs for riboflavin are 1.3 mg for men, 1.1 mg for women, 1.4 mg during pregnancy, and 1.6 mg during lactation (Table 20.2) [134]. During the process of assimilation, dietary FAD and FMN are released from food protein by gastric acid and then hydrolyzed by intestinal phosphatases. Riboflavin is absorbed in the proximal small intestine by a Na^+-independent, carrier-mediated system [135] that is maximal at an oral dose of about 25 mg and includes an enterohepatic cycle. Riboflavin circulates in the plasma bound to albumin and enters cells by carrier-mediated transport; excretion in the urine accounts for most of its turnover [136]. Riboflavin metabolism appears to be unaffected by liver disease; similar pharmacokinetics were measured in healthy volunteers and in patients with cirrhosis [137]. A major function of flavin coenzymes is the regulation of redox reactions. For example, FAD is essential as a cofactor for glutathione reductase, which regenerates glutathione, the principal antioxidant substrate for the protection of

cellular functions [138,139]. In addition, FMN is required for the generation and activation of pyridoxal phosphate from nonphosphorylated forms of pyridoxine [140]. FAD plays a role as a cofactor for MTHFR in reducing homocysteine (see Fig. 20.1), particularly in individuals who are homozygous for the 677C→T polymorphism [141]. Riboflavin deficiency is often associated with deficiencies of other water-soluble vitamins in the setting of malnutrition associated with chronic alcoholism, celiac disease, and anorexia of any cause. The clinical manifestations include intense glossitis (magenta tongue), cheilosis, angular stomatitis, seborrheic dermatitis, and peripheral neuropathy [136]. Riboflavin status is assessed by determining the level in the urine using HPLC or by colorimetric measurement of erythrocyte glutathione reductase before and after the addition of FAD [121].

Fat-soluble vitamins

Vitamins A, D, E, and K are unlike the water-soluble vitamins by virtue of their solubility in lipid solvents, their predominant roles as cell-signaling molecules, and their sequestration or storage in cellular organelles. By virtue of their nonpolar properties, the fat-soluble vitamins are usually found in the lipophilic core or domain of proteins, cellular membranes, or micellar structures. As a consequence, the essential features of digestion and assimilation of the fat-soluble vitamins involve the interaction of receptors and transporters for fat-soluble vitamins with intestinal mixed micelles and lipoprotein particles [142]. Table 20.3 summarizes sources, requirements, selected functions, mechanisms

Table 20.3 Fat-soluble vitamins

	Vitamin A	Vitamin D	Vitamin E	Vitamin K
Dietary source	Carotenoids: green, yellow vegetables; vitamin A: liver, milk, butter, eggs	Fish oils, liver, fortified milk and cereals, egg yolk	Soy, corn, sunflower, safflower oils, almonds, avocado	Dark green leafy vegetables, intestinal bacteria
Daily requirement	900 µg RE men 700 µg RE women 750 µg pregnancy 1200 µg lactation	200 IU, to age 50 400 IU, ages 50–70 600 IU, older than age 70 (1300 IU, older than age 50)[a]	15 mg adults 19 mg lactation	120 µg men, 90 µg women, 90 µg pregnancy and lactation
Absorption	Pancreatic esterase, micelle incorporation, facilitated transport, carotenoids cleaved by intestinal monooxygenase	Micelle incorporation, facilitated diffusion	Micelle incorporation, passive and facilitated diffusion	Phylloquinone: micelle incorporation, passive and facilitated diffusion Menaquinone: uncertain
Function	Vision, cell differentiation, immune (particularly T- and B-cell) function	Calcium absorption and homeostasis	Antioxidant	Blood clotting: γ-carboxylation of clotting factors II, VII, IX, X; bone mineralization through osteocalcin
Clinical signs of deficiency	Night blindness, xerophthalmia, corneal ulceration, hyperkeratosis, infection risk	Rickets (children), osteoporosis, potential for immune compromise	Abnormal peripheral vision, peripheral neuropathy, hemolysis (newborns)	Decreased blood clotting, osteoporosis
Risks deficiency	Protein malnourishment in infants, chronic alcoholism, intestinal malabsorption (e.g., short bowel syndrome, celiac disease)	Lack of sunshine, intestinal malabsorption (e.g., short bowel syndrome, celiac disease)	Intestinal malabsorption, especially short bowel syndrome, cholestasis	Intestinal malabsorption, prolonged use of antibiotics
Over consumption	Nausea and irritability, blurred vision, growth retardation, enlargement of liver and spleen, hair loss, bone pain, increased spinal fluid pressure, skin changes	Nausea and weight loss, irritability, soft tissue calcification, kidney damage	Possible increase in coagulation/prothrombin time	Few signs
Diagnosis	HPLC	Competitive protein binding of 25(OH)D	HPLC	Prothrombin response to vitamin K

a New consensus. From Heaney [161].
HPLC, high-pressure liquid chromatography; RE, retinol equivalent: 1 µg retinol or 24 µg mixed carotenes.

of absorption, and clinical features of the fat-soluble vitamins. Symptoms of mild deficiencies of the fat-soluble vitamins may develop as a consequence of decreased absorption of dietary lipid or abnormal systemic metabolism of lipids [143].

Vitamin A

Vitamin A includes dietary retinol in its esterified form and the provitamin carotenoid precursors of retinal. The relationships among the most important of the vitamin A precursors, β-carotene, and the essential retinoids that include retinal, retinol (vitamin A), and retinoic acid are shown in the following equations:

(1) β-carotene → 2 retinal (R-CHO) ↔ 2 retinol (R-CH_2OH)
(2) Retinol (R-CH_2OH) + fatty acid (often palmitic acid, R′-COOH) ↔ retinyl ester (R-O-CO-R′)
(3) Retinal (R-CHO) → retinoic acid (R-COOH)

Carotenoids comprise a group of more than 700 compounds that most often contain red, yellow, and orange pigments in their isolated states and are found in many fruits and vegetables [144]. In plants and many single-cell organisms, carotenoids serve as mediators of photoenergy-related processes. For a carotenoid to be essential in animals, a β-bond and three methyl groups in the terminal ring structure must be connected to an unsaturated chain of 10 or more carbons. β-Carotene is abundant and therefore is an excellent biomarker of the intake of fruits and vegetables. Lycopene is another carotenoid found in fruits and vegetables, especially tomatoes. Lutein and zeaxanthin are carotenoids found in green leafy vegetables that are associated with a decrease in the risk of cataracts. Other sources of vitamin A in animal products include retinol in its retinyl ester form, which is found in liver, eggs, and milk products [142,144]. Carotenoids and retinoids that are released from food during digestion are first partitioned into micelles within the intestinal lumen. The retinoids in the micelles are hydrolyzed by specific pancreatic esterases to retinol, whereas the carotenoids are cleaved to form retinal. The movement of retinyl esters and carotenoids into the enterocytes involves both active and facilitated transport mechanisms. Within the enterocyte, retinol is transported to the smooth endoplasmic reticulum for reesterification and eventual incorporation into chylomicrons in preparation for subsequent transport as retinyl esters by the lymphatics to the liver. In contrast, retinoic acid, which constitutes less than 5% of the total vitamin-related products (see equation 3), can be transported by way of the portal circulation by mechanisms similar to those for free fatty acids [142]. Within the enterocytes, β-carotene is cleaved by β-carotene-15,15′-monooxygenase [144] to two molecules of retinal (see equation 1), which is the aldehyde form of retinol. Retinal is converted to retinol by NADH-requiring retinol dehydrogenase, which is identical to alcohol dehydrogenase. Since the availability of purified β-carotene in oil is only half that of retinol (see equation 1), the retinol activity equivalent (RE) of supplemental β-carotene is considered to be 2 : 1, while the average availability of dietary β-carotene in mixed vegetable and fruit diets is only 8% (1/12) that of retinol. Therefore, after absorption and bioconversion, as much as 24 mg or more of mixed dietary β-carotenes is required to yield the same amount of retinol as 1 mg of dietary retinol [145]. The intestinal absorptions of vitamins E and K are decreased in the presence of high doses of vitamin A, whereas vitamin A absorption may be enhanced in the presence of high doses of vitamin E. At high doses, vitamins A and E can be absorbed directly from water-miscible emulsions that are commercially available [146]. The DRIs for vitamin A as REs are 300–900 μg for children and adolescents, 900 μg for adult men, and 700 μg for adult women (Table 20.3) [147]. Retinyl esters are stored in the liver as fat droplets in the hepatic stellate cells. Carotenoids that reach the liver intact are transported together to the circulation in association with very-low-density lipoprotein and are eventually converted to retinoids by tissue oxygenases. In the liver, active exchange of retinyl esters and other retinoids occurs between hepatic stellate cells and parenchymal hepatocytes [142]. Excess vitamin A is rapidly converted to retinyl ester and is sequestered in lipid vacuoles within the hepatic stellate cells. As vitamin A is needed, retinyl ester is hydrolyzed and released as retinol bound to retinol-binding protein (RBP). When released into the circulation, RBP exists as a complex not only with vitamin A, but also with another protein, transthyretin, which binds thyroxine. The primary targets for the RBP–transthyretin complex are the epithelial cells of the fetus, gastrointestinal mucosa, reproductive tract, pulmonary secretory cells, and salivary gland. Within targeted cells, vitamin A interacts with cellular-binding proteins that control its subsequent cellular translocation and metabolism; e.g., oxidation to retinal or to retinoic acid [142].

Vitamin A is essential for normal vision, for dark adaptation, and for epithelial cell differentiation [147,148]. Retinal is a necessary structural component of rhodopsin or *visual purple*, the light-sensitive pigment within the rod and cone cells of the retina. Retinal is covalently associated with rhodopsin and facilitates conformational changes in rhodopsin when excited by photons of light. This interaction is the first step in a cell-signaling cascade that causes excitation of the optic nerve. If inadequate quantities of vitamin A are present, vision is impaired. The identification of two families of nuclear receptors, retinoic acid receptors (RAR) and retinoid receptors (RAX), has helped to explain the role of vitamin A in cell differentiation. RAX and RAR are essential for the regulation of over 600 genes, particularly those involved in epithelial and immune cell differentiation; skin lesions and increased susceptibility to infection are common signs of vitamin A deficiency [142,145]. Further, the epithelial layers of cells become hyperkeratotic and may undergo metaplasia. Defects in the corneal epithelium can result in xerophthalmia, which may progress with the appearance of conjunctival white deposits known as Bitot spots, eventual corneal ulceration,

scarring, and permanent blindness. Moreover, vitamin A deficiency also results in decreased fluid secretion and phagocytic activity of natural killer cells. Fortunately, international vitamin A supplementation programs have resulted in improvements in innate immune function and have significantly reduced life-threatening infections in children worldwide [145]. Nevertheless, much of the world's preventable blindness continues to be the result of vitamin A deficiency [149].

Vitamin A status may also be influenced and augmented by other dietary factors. Protein deficiency contributes to decreased RBP production [142]. Vitamin A deficiency is also common in patients with alcoholic liver disease [143]. Alcohol metabolism increases the microsomal CYP2E1 ethanol-oxidizing enzyme, which in turn influences the rate of catabolism and biliary excretion of hepatic retinoids. The process in which the function of hepatic stellate cells is transformed from vitamin A storage to active collagen production with the initiation of fibrogenesis is increased as stores of retinoid are depleted in response to alcohol and other toxic agents [150]. In contrast, the signs of supplemental vitamin A hepatotoxicity are enhanced by chronic alcoholism [151]. Excessive alcohol consumption also can interfere with the metabolism of supplemental carotenoids and result in the production of carcinogens, particularly in alcoholics who smoke [142]. In the setting of chronic alcoholism, vitamin A deficiency may also induce the development of esophageal squamous cell cancer [152]. In spite of evidence that retinoids may prevent carcinogenesis in vitro, the use of vitamin A and carotenoids in cancer prevention is unproven. For example, the incidence of lung cancer was increased by 28% among smokers participating in the Carotene and Retinol Efficacy Trial (CARET) [153]. While the incidence of breast cancer was found to be inversely proportional to total daily vitamin A intake in one study of premenstrual women [154], a Swedish study showed no relationship between serum retinol levels and breast cancer risk [155]. The increased consumption of dietary lycopene from tomatoes may be associated with a reduced risk of prostate cancer [156]. Vitamin A toxicity can occur with long-term daily ingestion of 25 000–50 000 IU, amounts that are easily obtained from over-the-counter supplements. Signs of vitamin A toxicity include liver failure, headache, vomiting, and desquamating rash [147]. Doses of vitamin A in this range can lead to alopecia, ataxia, and bone and muscle pain. Carotenoids, in contrast, are generally nontoxic, and may be ingested in gram amounts on a daily basis with no deleterious effects [142]

Vitamin A is measured by HPLC of plasma or serum. Radial immunodiffusion assays are also available. The relative dose–response assay is used in field studies and consists of measuring RBP before and after a standard oral dose of vitamin A. Because apo-RBP accumulates in the liver during vitamin A deficiency, an increase of circulating RBP after the administration of a bolus of vitamin A is indicative of vitamin A deficiency [157]. However, because levels of plasma RBP are decreased in severe protein–calorie malnutrition, acute and chronic infection, and trauma, a liver biopsy is the gold standard for the assessment of vitamin A status. The dichotomy of normal serum levels with low hepatic levels of vitamin A was demonstrated in patients with liver disease of different etiologies, including progressive alcoholic liver disease [158].

Vitamin D

Vitamin D is the generic term for a group of sterols that regulate calcium absorption and homeostasis. Vitamin D receptors are also present in the pancreas and on various cells involved in immune function [142]. The principal forms of vitamin D are vitamin D-3 (cholecalciferol), which includes the endogenous form of the vitamin, and vitamin D-2 (ergocalciferol), which is derived from plant sources. Vitamin D-3 is synthesized from 7-dehydrocholesterol in skin on exposure to sunlight and is found in the diet in fish oils, egg yolks, and fortified milk [159]. Persons living in temperate and tropical climates receive most of their vitamin D-3 by synthesis in the skin. However, synthesis of vitamin D in the skin is compromised in the far northern or southern hemispheres, where sunlight is less intense and more variable in amount, and it is less in dark-skinned than in light-skinned peoples. In 1997, the recommended DRI of vitamin D for healthy adults aged 50 years and younger was 200 IU (equivalent to 5 μg/day), 400 IU for persons aged 50–70 years, and 600 IU for those older than 70 years [160]. However, evidence indicates that these amounts are insufficient for the maintenance of normal bone density [159], and a growing consensus indicates that a minimal amount of 1300 IU is required to increase serum vitamin D to a level sufficient to prevent osteoporosis and fracture risk [161]. A study of serum vitamin D levels suggests that the relative potency for vitamin D-2 in humans is about one-third that of vitamin D-3 [162], and recommended preventive supplemental doses should be based on the use of vitamin D-3.

Like other fat-soluble vitamins, dietary vitamin D is absorbed after micellar solubilization in the upper intestine and subsequent facilitated diffusion across the enterocyte membrane. Vitamin D is then incorporated into chylomicrons for entry into the circulation by way of the lymphatics. Two hydroxylation steps are required for the activation of vitamin D. Both vitamins D-3 and D-2 are converted in the liver to 25-hydroxycholecalciferol [25(OH)D3], which is the principal circulating form of the vitamin. Within proximal renal tubular cells, 25(OH)D3 is the substrate for 1α-hydroxylase in the synthesis of 1α,25-dihydroxycholecalciferol ($1,25(OH)_2D3$), which is the functional form of the vitamin. The activity of renal 1-hydroxylase and the production of $1,25(OH)_2D3$ is tightly up-regulated by circulating levels of parathyroid hormone, which is increased in response to low serum calcium, and also increases renal tubular calcium reabsorption while promoting phosphate excretion. The main action of $1,25(OH)_2D3$ is to promote

intestinal calcium absorption and to act with parathyroid hormone to enhance bone remodeling [163]. The $1,25(OH)_2D3$ also regulates gene transcription by interacting with vitamin D membrane receptors and nuclear receptors in many different tissues, and carries the potential to inhibit cell proliferation in breast, colon, lung, and prostate tumor cells [163]. A specific vitamin D-binding protein (DBP), also known as group-specific component (Gc) or vitamin D-binding α-globulin, delivers $1,25(OH)_2D3$ and other active forms of vitamin D to targeted cells. DBP is a member of the albumin, α-fetoprotein, and albumin/afamin gene family [164].

Vitamin D and calcium are poorly absorbed in malabsorption diseases that are characterized by decreased biliary secretion and micelle formation, such as primary biliary cirrhosis or short bowel syndrome, and in diseases involving mucosal abnormality such as celiac disease. A study of Swedish subjects showed that the positive serology indicative of celiac disease was 10-fold more likely among osteoporotic than nonosteoporotic adults [165]. The amount of vitamin D required to treat deficiency in intestinal malabsorption syndromes is not established, and doses up to 50 000 IU of vitamin D-2 (ergocalciferol) three times a week may be required to sustain normal plasma levels of 25(OH)D3 in patients with short bowel syndromes [159].

Osteoporosis with increased risk of bone fracture is the major disease associated with vitamin D deficiency due to insufficient sun exposure or inadequate diet, which reduces calcium absorption and secondarily increases parathyroid hormone. The latter in turn increases the resorption of calcium from bone, which facilitates its eventual loss. If such loss is significant, it may cause osteomalacia in adults or rickets in children, and, most significantly, it increases the risk of osteoporosis in postmenopausal women and elderly men [161]. Several studies have found that bone density can be improved and osteoporosis can be prevented by supplemental vitamin D-3 (cholecalciferol) up to 800 IU daily in combination with calcium up to 1200 mg/day [166, 167]. More recent recommendations include a minimal dose of 1300 IU vitamin D to sustain an adequate serum level of 25(OH)D3 at more than 80 nmol/L to reduce fracture risk [161]. Because vitamin D receptors have been found in numerous types of cells, treatment with $1,25(OH)_2D3$ (calcitriol) has also been reported to be efficacious for conditions ranging from diabetes to psoriasis [168]. In view of its regulatory effects on cell differentiation, several studies suggest that vitamin D supplementation may be beneficial in the prevention of certain cancers. These included a small study on preventive recurrence of prostate cancer [169], and a case–control study that showed an inverse association of plasma levels of 25(OH)D3 with the risk of precancerous colonic adenomas [170]. Vitamin D toxicity occurs after prolonged use of vitamin D-3 at doses greater than 10 000 IU/day by otherwise healthy humans, and is associated with hypercalcemia accompanied by lethargy, confusion, constipation, polyuria, and abnormal elevation of the serum level of 25(OH)D3 (> 800 nmol/L) [168]. Vitamin D status is determined by HPLC measurement of 25(OH)D3 in the plasma. Whereas most laboratories report a level of 50 nmol/L (20 ng/mL) as the lower limit of normal, emerging evidence indicates that calcium absorption and the prevention of osteoporosis fractures is optimal at 25(OH)D3 plasma levels higher than 80 nmol/L (32 ng/mL) [161].

Vitamin E

Vitamin E comprises eight tocopherols, of which two, α-tocopherol and γ-tocopherol, are the most important to human nutrition. The predominant natural form of vitamin E is the RRR isomer of α-tocopherol [171]. The major food sources of vitamin E include polyunsaturated vegetable and seed oils, whole grains, nuts, and green leafy vegetables. The DRIs of vitamin E are 6–11 mg for children, 15 mg for adults of all ages, 15 mg during pregnancy, and 19 mg during lactation [172]. The intestinal absorption of dietary vitamin E includes deesterification by pancreatic esterases, followed by bile-dependent incorporation into intralumenal micelles, diffusion, or facilitative transport into enterocytes, and incorporation into chylomicrons for transfer by way of the lymphatics. After peripheral hydrolysis of chylomicrons, vitamin E as *RRR*-α-tocopherol returns to the liver with chylomicron remnants and is then transferred by hepatic α-tocopherol transfer protein to high-density or low-density lipoprotein. The subsequent transfer to tissues occurs by receptor-mediated endocytosis of low-density lipoprotein. As a consequence, plasma levels of α-tocopherol vary according to the total plasma lipid concentration and often correlate with values for total cholesterol. Once within cells, vitamin E is incorporated into lipid membranes, about 40% into nuclear membranes and the remaining 60% into lysosomal, mitochondrial, and outer cell wall membranes. The efflux of vitamin E from cells is less well understood, but it appears to be dependent on the ATP-requiring transporters associated with the cholesterol transporter family, [173].

Tocopherols are unique because they act at a chemical level as antioxidants, although possible roles in cell signaling have also been described [173,174]. Vitamin E protects unsaturated fatty acids found in the phospholipids of cell membranes. Cell membranes contain vitamin E at a concentration of about 1 mg per 5–10 g of membrane lipid; a concentration sufficient to retard membrane lipid oxidation. Membrane lipids are constantly engaged in the process of turnover and repair, and vitamin E in membranes is consumed while inhibiting the formation of lipid-derived oxidation products. By prolonging the initiation time before a free-radical chain reaction occurs, vitamin E gives cells time to replace damaged membrane lipids through the process of normal cell turnover [174].

Vitamin E deficiency occurs mainly in patients with malabsorptive disorders involving the biliary circulation, pancreas, and intestinal mucosa. Some infants can also be at risk because

their body stores of vitamin E are lower. Children with biliary atresia or other causes of cholestasis become depleted more rapidly than older children and adults with malabsorption diseases [175]. Vitamin E deficiency is manifested by neurological damage involving the posterior columns, cranial nerves, brainstem, and peripheral nerves with loss of balance and peripheral neuropathy, and by retinal damage with visual field defects [173]. A water-soluble form of vitamin E, RRR-α-tocopherol glycol (Aquasol E), is better absorbed than the dietary, fat-soluble natural vitamin and hence is more effective in the treatment or prevention of vitamin E deficiency in malabsorption diseases such as short bowel syndrome [175].

Vitamin E supplementation in the form of RRR-α-tocopherol at daily doses up to 800 IU has been used in several trials for the prevention of cardiovascular disease with conflicting and nonconclusive results; furthermore vitamin E carries the risk of increasing bleeding when combined with aspirin [173]. Other diseases associated with an inconclusive preventive effect of vitamin E supplementation include Alzheimer disease, several cancers, and cataracts [173]. One study suggested a positive effect of vitamin E in combination with ursodeoxycholic acid in the reduction of liver fat in patients with nonalcoholic steatohepatitis [176]. Although many food sources of vitamin E contain both α and γ forms of tocopherol, the functional potency of supplemental γ-tocopherol is only about 10% that of α-tocopherol; hence only the latter form should be used in preventive trials [173]. Vitamin E status is assessed by HPLC measurement of plasma levels. Normal values of α-tocopherol are greater than 12 μmol/L (5 μg/mL). However, since the plasma level of vitamin E is regulated in part by plasma lipid levels, more correct values include α-tocopherol at greater than 8 mg per the sum of triglycerides and total cholesterol levels, or 2.8 mg per g total cholesterol [173].

Vitamin K

Vitamin K activity is associated with phylloquinone (K1) and menaquinone (K2-5) derivatives of 1,4-naphthoquinone [177]. The main dietary sources of phylloquinone are dark green leafy vegetables and some vegetable oils. Recent comparisons of the forms of vitamin K in the liver suggest that menaquinones produced by enteric bacteria provide substantially less vitamin K than dietary phylloquinone [142]. The major function of vitamin K is to activate blood clotting by serving as a cofactor for microsomal synthesis of γ-carboxyglutamic acid (Gla) residues, which permit the formation of specific calcium-binding sites in prothrombin (factor II) and factors VII, IX, and X. Gla residues are also found in proteins C and S, which are anticoagulants by virtue of their ability to inhibit factor V [177]. Vitamin K is also essential for the γ-carboxylation of osteocalcin, an osteoblast protein that is also up-regulated by $1\alpha,25(OH)_2D3$. Therefore, deficiency of vitamin K may contribute to osteoporosis, whereas vitamin K supplementation has been shown to prevent bone fractures [178].

There is no precise DRI for vitamin K, and the recommended adequate intake for dietary phylloquinone is 120 μg/day in men and 90 μg/day in women, while uncertain amounts are derived from intestinal bacterial synthesis of menaquinone (Table 20.3) [179]. As a fat-soluble vitamin, phylloquinone requires micellar solubilization before diffusion into enterocytes and uptake with chylomicrons. Phylloquinone circulates with chylomicrons with a high triglyceride level and very-low-density lipoproteins, and blood levels are dependent on plasma lipid concentrations. In contrast, menaquinones are synthesized by anaerobic intestinal bacteria and their route of absorption remains unclear [177].

Vitamin K deficiency may occur in neonates as a result of immature metabolic pathways, insufficient intestinal bacterial synthesis, and low levels in breast milk. Hemorrhagic disease of the newborn is prevented by a single injection of phylloquinone to all neonates, as recommended by the American Academy of Pediatrics [180]. Phylloquinone deficiency in adults occurs in biliary diseases, malabsorption disorders such as the short bowel syndrome, and celiac disease. Ineffective use of vitamin K occurs in individuals adhering to long-term regimens of the antagonist coumadin and in patients with severe liver disease that leads to impaired synthesis of coagulation factors irrespective of vitamin K adequacy. Also, long-term oral regimens of antibiotics may suppress menoquinone-synthesizing anaerobic bacteria and lead to vitamin K deficiency [177]. A large study of elderly people found that those in the highest quartile of dietary vitamin K intake had a reduced risk of hip fracture compared to those in the lowest quartile of vitamin K intake, although there was no relationship of these findings to bone mineral density measurements [181]. Vitamin K deficiency can be assessed by a prolonged prothrombin time that responds to parenteral vitamin K administration [177] and by direct measurement of plasma levels of phylloquinone by HPLC [121].

Minerals

This section describes the sources, requirements, absorptive mechanisms, functions, and clinical causes and effects of deficiencies of the macrominerals calcium and magnesium and of the trace minerals iron, zinc, and copper (Table 20.4).

Calcium

Sources and bioavailability

Milk and other dairy products provide up to 75% of dietary calcium; the remainder comes from vegetables such as spinach, cabbage, kale, and various beans. The bioavailability of calcium from milk, dairy products, and meat is high, perhaps because the smaller peptides formed during digestion keep calcium in an absorbable, soluble form [182]. Calcium is

Table 20.4 Minerals and trace elements

	Calcium	Magnesium	Iron	Zinc	Copper
Dietary source	Milk, dairy products, fortified juices, green vegetables, beans	Vegetables, fruits, dairy, animal products	Meat, fish, poultry, fortified cereals	Animal protein, seafood, especially oysters	Meat, grain, nuts
Daily requirement	1000 mg, men and women 19–50 years; 1200 mg, men and women older than 50	420 mg men 320 mg women	8 mg men 18 mg women, 8 mg postmenopause	11 mg men 11 mg women	0.9 mg men and women
Absorption	Active transport by way of vitamin D; passive diffusion	Active transport, passive diffusion	Active transport, passive diffusion	Active transport, passive diffusion	Active transport, passive diffusion
Function	Bone formation; muscle and nerve function	Bone metabolism; nerve, muscle, cardiac functions	Oxygen transport as heme, energy metabolism, neurotransmitter synthesis	Cofactor for many enzymes involved in nucleic acid, protein, lipid, carbohydrate metabolism	Connective tissue synthesis, bone growth, ferroxidase activity
Clinical signs of deficiency	Bone loss, tetany	Cardiac arrhythmia, osteoporosis, tetany	Microcytic anemia, fatigue, pallor	Eczema, alopecia, delayed growth	Bone abnormalities, hypopigmentation, impaired growth
Diagnosis	Bone density scan	Serum magnesium	Hemoglobin, iron-binding capacity, ferritin, transferrin receptor	Serum zinc	Serum copper, red cell superoxide dysmutase

less available from meat products and plants [183]. Plant fiber that contains phytate has a negative effect on calcium absorption. Although not directly affecting calcium absorption, high intakes of caffeine and protein have a negative effect on calcium balance by increasing urinary losses [183]. Adequate intakes for calcium include 1000 mg/day for adults under 50 years, 1200 mg/day for adults over 50 years, and 1300 mg/day for teenagers and young pregnant and lactating women [184]. These levels can most reliably be achieved from supplements and fortified beverages [182].

Absorption and homeostasis

Calcium is ionized at low gastric pH and is absorbed actively in the duodenum and by passive diffusion from the ileum [185]. In addition, about 7% of total calcium absorption occurs by active and passive processes in the colon [186]. Active absorption by way of calcium-binding proteins dominates at low levels of calcium intake, whereas passive diffusion makes a significant contribution to net calcium uptake at high levels of intake [187]. Transepithelial calcium transport in the upper part of the duodenum is dependent on vitamin D ($1,25(OH)_2$D-3) and consists of three mechanisms. First, brush border uptake occurs down a steep electrochemical gradient from the lumen to the cytoplasm through calcium channels that are not voltage gated [185]. Second, rate-limiting transport of calcium ions through the enterocytes occurs by carrier-mediated facilitated diffusion from the brush border membrane to the basolateral membrane [188]. Diffusion of calcium is facilitated by the cytosolic calcium-binding protein known as calbindin 3 (CALB3, or D9K). Transcellular calcium transport increases in a linear fashion according to the cellular content of calbindin [189]. Another calcium-binding protein, calbindin 1 (CALB1, or D28K), is induced by vitamin D and binds four calcium ions, compared to two for calbindin 3 [190]. Third, the extrusion of calcium through the basolateral membrane is mediated by calcium ATPase and the Na^+/Ca^{2+} exchanger, and occurs against an electrochemical gradient [191]. Vitamin D has some effect on both the uptake and the extrusion phases of calcium by increasing the gene expression of membrane-bound calcium ATPase [192]. Passive absorption of calcium occurs by paracellular diffusion down a chemical gradient in all sections of the small intestine [185] and accounts for the major part of calcium absorption when intake is adequate or high. During pregnancy, calcium absorption increases significantly, which may be a response to the high fetal requirement. Lactation, however, does not result in a similar increase in calcium absorption.

Disorders of calcium homeostasis

Intestinal calcium absorption decreases with age, possibly because of lower circulating concentrations or decreased responsiveness of the intestine to vitamin D [193]. Achlorhydria reduces the absorption of calcium carbonate [194], and long-term regimens of proton pump inhibitors increase the risk for osteoporosis and hip fractures [195]. Gastric

surgery often disrupts calcium absorption because of the lack of gastric acid, resulting in osteomalacia as a late complication [196]. However, patients with achlorhydria can absorb calcium normally from milk because of the solubilizing effect of milk peptides, which are not as pH-dependent. Diseases of the small intestine such as celiac disease, Crohn's disease, and short bowel syndrome often result in osteomalacia, usually as a consequence of vitamin D deficiency [196]. Also, increased fat excretion in malabsorption disorders also causes losses of calcium bound to fatty acids. Renal disease can result in lower production of $1,25(OH)_2D3$ and thus decreased calcium absorption. Therefore, $1,25(OH)_2D3$ is used in the management of chronic renal disease to preserve calcium absorption. Whereas some drugs, like glucocorticoids and phenytoin, directly inhibit calcium absorption in the intestine, thiazides increase the renal reabsorption of calcium and thereby decrease parathyroid hormone secretion and its effect on $1,25(OH)_2D3$ synthesis, indirectly reducing calcium absorption. Vitamin D intoxication also increases calcium absorption [197]. Osteoporosis, which is the principal result of calcium deficiency, is caused by a combination of inadequate levels of vitamin D and calcium. Calcium supplementation is often required to prevent osteoporosis and hip fracture – the latter being a leading cause of nursing home admission, and carrying up to 20% mortality [198]. In addition to other measures such as exercise and adequate vitamin D supplementation, calcium should be provided at 1200 mg/day for those at risk of osteoporosis. A case–control study demonstrated that high calcium intake was associated with a decreased risk of colorectal cancer in men with elevated levels of insulin-like growth factor [199]. Doses of calcium higher than 2500 mg/day may be toxic and can induce hypercalciuria and the formation of kidney stones [184].

Magnesium

Sources and bioavailability

Magnesium is abundant in whole grains, nuts, seeds, broccoli, spinach, beans, dairy products, meat, and mineral waters that are high in magnesium. The DRI for magnesium is 420 mg for adult men and 320 mg for women, with 400 mg during pregnancy and 360 mg during lactation [200].

Absorption and homeostasis

Magnesium absorption occurs primarily in the ileum and the colon and much less is absorbed in the duodenum [201]. Human studies over a wide range of magnesium intakes show a saturable absorption curve that is indicative of an active transport mechanism, as well as a linear function that is compatible with passive diffusion [202]. The efficiency of absorption with a normal dietary intake of magnesium is 21%–27% in adult men and women [203]. Magnesium homeostasis is largely regulated by renal excretion and the efficiency of magnesium absorption increases during deficiency.

Deficiency

Magnesium deficiency secondary to low dietary intake is uncommon and difficult to diagnose because of a lack of reliable markers [204]. The serum or plasma magnesium level is relatively tightly regulated and, although used for clinical decision-making, may not reflect actual tissue levels. Congenital primary hypomagnesemia is an uncommon disorder that is correlated to a specific defect in the intestinal absorption of magnesium [205]. Hypomagnesuria, hypocalcemia, hypokalemia, and tetany often occur in association with convulsions [206], which are corrected by the administration of magnesium. The hypocalcemia of magnesium deficiency is caused by the decreased responsiveness of osteoclast parathyroid hormone receptors and the inhibition of parathyroid hormone secretion, which then decreases the renal production of $1,25(OH)_2D$-3, thereby decreasing the intestinal absorption of calcium [207]. Vitamin D does not correct the hypocalcemia, whereas correction of magnesium levels restores calcium levels to normal. Experimentally induced magnesium deficiency in human volunteers resulted in hypocalcemia, hypokalemia, nausea, vomiting, arrhythmia, and personality changes that were resolved by magnesium replacement [204]. Clinical conditions that contribute to magnesium depletion include malabsorption syndromes [208] such as celiac disease and the short bowel syndrome, renal dysfunction, and treatment with diuretics, which may induce excessive magnesium losses [209]. Endocrine disorders that cause magnesium depletion include diabetes, hyperparathyroidism, and hyperthyroidism [210]. Chronic alcoholism and protein–calorie malnutrition are often associated with poor magnesium status [211,212]. Potassium depletion, protein catabolism, and chronic acidosis all reduce cellular magnesium levels and, consequently, levels of magnesium in muscle and bone [204].

Iron

Sources, forms, and bioavailability

The human diet contains both heme iron and nonheme iron, which are absorbed and metabolized differently. The efficiency of iron absorption from heme is 20%–25%, whereas that of nonheme iron ranges from 3% to 10% [213]. Heme iron is present in myoglobin and hemoglobin in meat, poultry, and fish, and it is the presence of globin that increases its absorption. While heme iron absorption is relatively unaffected by dietary factors, food components may have widely different effects on the absorption of nonheme iron. Ascorbic acid has a strong enhancing effect on nonheme iron absorption [214], whereas phytate, tannins, and other polyphenols are inhibitory [215]. Long-term studies of children and lactating and premenopausal women given high daily doses of calcium (500–1000 mg) for 6–12 months showed no change in iron status as assessed by hemoglobin or serum ferritin levels [216–218]. The DRI for iron is 8 mg for men and women older than 50 years; 15 mg

for young women aged 15–18 years, and 18 mg for older premenstrual women (Table 20.4) [219].

Absorption and homeostasis

Heme and nonheme iron are absorbed by way of different pathways and their levels are affected to different degrees by dietary components, physiological conditions, and iron status. Heme-carrier protein 1 (HCP1) was isolated from mouse duodenal plasma membrane. A highly hydrophobic transporter with 12 transmembrane regions, HCP1 has a high expression level in the duodenum and is present on the apical membrane during iron deficiency and in the cytoplasm of iron-loaded mice [220]. Intracellular heme oxygenase breaks down the heme group, releasing iron into the nonheme pool for incorporation into intracellular ferritin and for export out of the cell [221]. Several mechanisms involved in the mucosal regulation of nonheme iron absorption have been discovered (Fig. 20.3). Duodenal cytochrome b (Dcytb) reduces ferric iron (Fe^{3+}) to the more absorbable ferrous (Fe^{2+}) form [222]. Divalent metal transporter (DMT1, also called DCT1 or NRAMP2) is located in the brush border membrane and is involved in the regulation of nonheme iron uptake by the enterocyte. DMT1 is primarily located in villus tip cells and is up-regulated during iron deficiency and down-regulated in situations of iron excess [223]. In addition to Fe^{2+}, many other cations are taken up by brush border DMT1, including Zn^{2+}, Cu^{2+}, Cd^{2+}, Co^{2+}, Mn^{2+}, Ni^{2+}, and Pb^{2+} [224]. Within the mucosal cell, the expression of the iron storage protein ferritin is regulated by the intracellular concentration of iron, such that ferritin synthesis is low when iron status is low and increases when iron is present in excess [225]. The transferrin receptor (TFR) contains five iron-responsive elements that regulate the stability and turnover of iron stores. TFR is located both in endosomal compartments and in the basolateral membrane of the enterocyte [226]. Iron transfer from the enterocyte into the portal circulation requires the oxidation of Fe^{2+} to Fe^{3+}, a process that is facilitated by hephaestin (Hp), a copper-containing ferroxidase that is associated with the basolateral membrane [227]. The oxidation process allows Fe^{3+} to be incorporated into apotransferrin (apoTF) in the circulation. In combination with the hemochromatosis protein (HFE), TFR permits the successful binding of apoTF-bound iron and its reuptake back into the intestinal cell [228]. The export of iron out of the enterocyte is also mediated by ferroportin 1 (FPN1, also called IREG1 or MTP1) [229]. FPN1 is a membrane-bound protein of 62 kDa, with 10 transmembrane regions. FPN1 contains iron-responsive elements [230] and is up-regulated during iron deficiency and down-regulated during iron excess [231]. Hepcidin, an antimicrobial peptide produced by the liver, modulates enterocyte iron transport and is believed to be the communication link between liver iron stores and intestinal iron uptake, facilitating increased iron absorption during iron deficiency and decreased iron absorption during iron repletion [232]. Hepcidin levels parallel liver iron stores in adults and evidence indicates that hepcidin binds to FPN1, stimulating FPN1 internalization and degradation, and so reducing iron absorption when liver iron stores are high [233] (see Fig. 20.3).

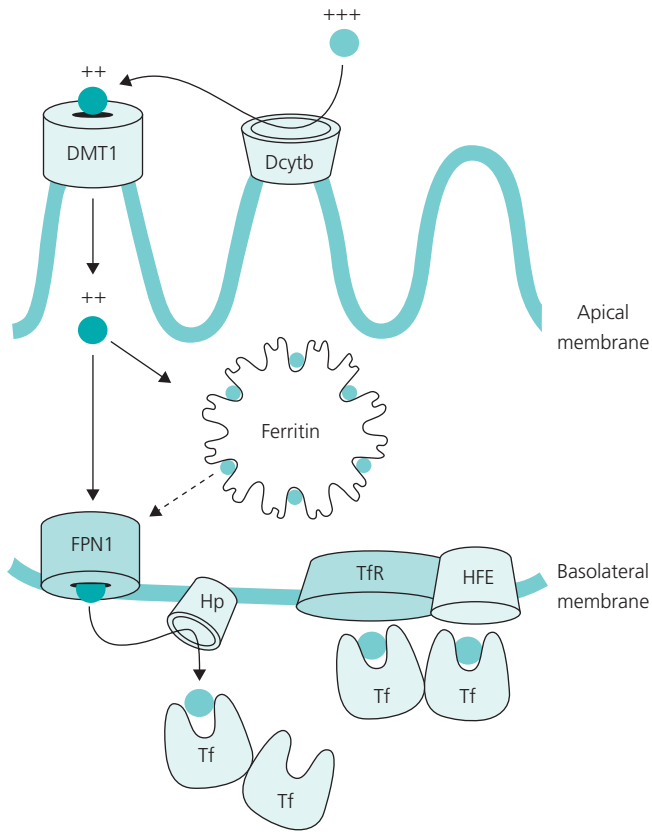

Figure 20.3 Interaction of potential mechanisms for the regulation of iron absorption by the mucosal cell. Dcytb, duodenal cytochrome b; DMT1, divalent metal transporter 1; FPN1, ferroportin 1; HFE, hemochromatosis gene product; Hp, hephaestin; Tf, transferrin; TfR, transferrin receptor.

Disorders of iron homeostasis

Hereditary hemochromatosis is an autosomal recessive genetic disorder of defective regulation of iron absorption that leads to severe iron overload in various tissues of the body, particularly the liver [234]. The gene frequency of hereditary hemochromatosis is about 1 in 300; it varies with ethnicity and is highest among Northern Europeans. To prevent cirrhosis of the liver secondary to iron loading, patients are either phlebotomized regularly or given chelation therapy with desferrioxamine. The most common form of hereditary hemochromatosis involves mutations in the hemochromatosis gene *HFE*, which leads to inappropriately low levels of hepcidin [235], an inappropriately high degree of iron absorption, and hepatic iron overload. More than 95% of patients with hereditary hemochromatosis have a missense mutation in the *HFE* gene at 282C→Y, which affects a highly

conserved cysteine residue and is expressed at low levels in most tissues including the small intestine. *HFE* is highly expressed in liver and appears to be involved in the down-regulation of iron absorption that normally occurs when iron stores are high, possibly by way of binding to the transferrin receptor. The homozygous mutation at 282C→Y causes a defect in HFE protein trafficking and cell surface expression as a consequence of the inability to bind β_1-microglobulin [236]. An additional *HFE* mutation at 63H→D does not cause iron overload [237], but compound heterozygotes 63H→D/282C→Y develop iron overload with less severe clinical features of hereditary hemochromatosis than patients who are homozygotes for 282C→Y [238]. Iron overload develops in β_1-microglobulin-deficient mice, indicating that HFE must interact with β_1-microglobulin to regulate iron absorption [239]. There are also patients with hereditary hemochromatosis who have mutations in other proteins involved in iron homeostasis, such as hepcidin and transferrin receptor 2 (TFR2). Mutations in TFR2 cause iron loading disease with symptoms similar to those manifest in hemochromatosis as a result of defective HFE [240]. Hemojuvelin, a third member of this regulatory network to be identified [241], is expressed in hepatocytes and is mutated in most cases of juvenile hemochromatosis. Sickle cell disease and β-thalassemia are also genetic disorders that lead to abnormal iron metabolism. Whereas hereditary hemochromatosis is characterized by the preferential loading of iron into parenchymal cells, iron first accumulates in the reticuloendothelial cells in sickle cell disease or β-thalassemia [242]. Clinically, the primary cause of mortality in hereditary hemochromatosis is cirrhosis and hepatocellular carcinoma, whereas it is cardiomyopathy in β-thalassemia, [243]. The toxicity of iron overload is minor in sickle cell disease compared to β-thalassemia.

Deficiency and excess

Iron deficiency as the result of a dietary lack of iron is the most common single nutrient deficiency worldwide, afflicting up to 1 billion people in both less developed and industrialized countries. It is estimated that 500–600 million persons have iron deficiency anemia. In infants and young children, iron deficiency anemia causes delays in cognitive and motor development [244], and adult iron deficiency anemia is typically associated with impaired immune function and energy metabolism [245]. Iron deficiency is diagnosed by the serum ferritin concentration, which is directly proportional to body iron stores and decreases when the body becomes depleted of iron. A serum ferritin value less than 12 μg/L is used as the cutoff for iron deficiency and correlates with lack of stainable iron in the bone marrow. Progressive iron deficiency impairs hematopoiesis, resulting in microcytic anemia. Since the level of serum ferritin, but not of TFR, increases during infection and inflammation, a rising circulating serum TFR level is considered to be a more accurate additional test for iron deficiency [246]. The TFR–log ferritin ratio was proposed as an accurate method to detect iron deficiency in patients with chronic renal disease [247]. The second most common cause of iron deficiency is occult or overt chronic gastrointestinal blood loss from a wide variety of lesions. Excessive menstrual bleeding may contribute to iron deficiency in premenopausal women. Iron deficiency secondary to intestinal malabsorption is often the only clinical feature of celiac disease [25]. Bariatric surgical procedures that exclude the duodenum such as the Roux-en-Y–gastric bypass are significant causes of occult iron deficiency [248]. Iron overload can also occur in a significant proportion of individuals with hereditary hemochromatosis, homozygous thalassemia, or sideroblastic anemia secondary to pyridoxine deficiency [249]. Therefore, an overly zealous approach to providing iron to large population groups may harm individuals who have large iron stores. Concern has also been raised that high iron stores, although not yet characterized as iron overload, can lead to increased free radical formation and chronic disease. For example, Finnish men with serum ferritin levels greater than 200 μg/L have a significantly higher risk for coronary heart disease and non-insulin-dependent diabetes (diabetes type II) than men with normal serum ferritin levels [250]. Adverse effects of iron supplements on infant growth have been reported [251], and a study on children in Zanzibar had to be interrupted because iron supplementation caused increased morbidity and mortality [252].

Zinc

Sources, forms, and bioavailability

Zinc is a cofactor for a diversity of enzymes and transcription factors. Severe zinc deficiency affects many metabolic pathways and tissues, impairing growth, development, reproduction, and immune function [253]. The daily dietary intake of zinc is about 10–15 mg, and generally meets the requirement of men but is often marginal for women, particularly during pregnancy and lactation. The DRI for men is 11 mg; for non-pregnant women it is 8 mg; for young women aged 18 years and younger it is 13 mg; and for pregnant and lactating women it is 14 mg. For women ages 19–50 years the DRI is 11 mg and for women older than 50 years it is 12 mg [253]. The best dietary sources of zinc are meat, meat products, and seafood. Whole grains and cereals are relatively high in zinc, but bioavailability is often low because of the presence of chelating phytates in the diet. Multivitamin and mineral tablets often contain zinc, and some cereal products are fortified with zinc. Phytates in cereals and legumes have a strong inhibitory effect on zinc absorption as a consequence of their chelating properties [254]. Attempts to increase the bioavailability of zinc from human diets include alternative food processing, phytase treatment, and the development of genetically modified cereals that are lower in phytate [255]. The protein content of the diet is positively correlated to zinc absorption, most likely because of the formation of amino acids and small peptides that facilitate zinc uptake by the

enterocyte [256]. Iron in high doses can reduce zinc absorption from oral supplements [257], but this does not occur when both are given with a meal [258].

Absorption and homeostasis

The efficiency of zinc absorption from the diet is about 15%–35% in adults [259]. Active transport dominates at low or normal intake, whereas passive diffusion contributes more significantly at high intake [260]. Metallothionein is a low-molecular-weight (~ 6 kDa) zinc-binding protein, present in the cytosol of the enterocyte. Metallothionein also binds copper and cadmium but induces zinc only at very high intake levels [261]. Members of the ZIP (Zrt-, Irt-like protein) family transport zinc from the extracellular space or organelles into the cytoplasm [262]. The ZIP4 transporter was discovered when mutations in its gene were linked to the human recessive genetic disorder acrodermatitis enteropathica [263]. Since zinc supplements alleviate zinc deficiency in patients with acrodermatitis enteropathica, it is obvious that other zinc transporters exist on the apical membrane of the enterocyte. The ZIP5 protein is expressed on the basolateral membrane of the enterocyte, and may be responsible for zinc transport from the systemic circulation into the enterocyte when dietary zinc is low [262]. ZIP14 is involved in the uptake of zinc by the liver in response to acute inflammation and infection [264]. ZIP14 expression in the liver rises in response to IL-6 during the acute-phase response [262,264], suggesting that the induction of ZIP14 is responsible for the hypozincemia associated with infection. The ZNT family of zinc transporters has nine members in the human genome. ZNT1 production is regulated by dietary zinc [265] and has been implicated in the regulation of zinc homeostasis by controlling zinc efflux, whereas ZNT2 and ZNT4 are involved in the flux of zinc in the endosomes, possibly regulating the intracellular trafficking of zinc. These membrane transporters all have six transmembrane-spanning domains and a conserved histidine-rich region predicted to have a cytoplasmic loop that likely functions to bind zinc [266,267]. Experiments showing zinc sequestration by endosomal vesicles during overexpression of ZNT2 suggest that this transporter may be important for controlling intracellular transport of zinc by the enterocyte [268]. All three transporters occur mainly in villus cells, and the ileum is the major site for ZNT1. ZNT4 is involved in the secretion of zinc by the mammary gland, and mutations of the gene cause the "lethal milk" defect in mice [269]. ZNT3 is localized to synaptic vesicles in some types of neurons [270], and ZNT8 is associated with the secretory granules of pancreatic beta cells [271].

Deficiency and excess

While severe zinc deficiency is rare and is usually seen only in patients with acrodermatitis enteropathica, marginal zinc deficiency is common [272]. The diagnosis of milder forms of zinc deficiency is difficult, partly because the plasma zinc level is affected by many factors other than zinc. Zinc supplementation trials show positive effects on the growth of infants and children [273], pregnancy outcome [274], and infantile diarrhea [275]. Zinc deficiency is a leading cause of preventable deaths in children worldwide [276]. A meta-analysis of zinc supplementation in children reported significant increases in height and weight, with the greatest effects observed in children with stunted growth [277]. Pooled analyses of trials evaluating the effect of daily zinc supplementation on infectious disease reported a robust decrease (~ 40%) in death related to diarrhea and pneumonia [278]. The consistent positive effects on the treatment of infant diarrhea prompted the inclusion of zinc into oral rehydration solution [279], the administration of which reduces stool output and duration of diarrhea [280].

Disorders of zinc homeostasis

Acrodermatitis enteropathica is an inborn autosomal recessive disorder of zinc metabolism with a gene frequency of about 1 in 10 000, and is manifested by eczema, dermatitis, anorexia, compromised immune function, and poor growth when infants are weaned [281]. Patients require daily doses of zinc, usually 30–50 mg, and higher doses during periods of rapid growth, such as at puberty. If doses are too high, however, copper deficiency can result, causing other clinical problems [282]; therefore, both the zinc status and the copper status of these patients must be monitored. More generalized malabsorption may be a secondary problem resulting from mucosal damage caused by local zinc deficiency. Patients treated with zinc appear to absorb zinc normally [282]. Rarely, the features of acrodermatitis enteropathica occur in patients being treated long-term with total parenteral nutrition formulas that do not contain zinc.

Copper

Sources and bioavailability

Copper is relatively abundant in meat, grains, and nuts, but is scarce in milk and dairy products. Copper intakes are relatively close to the DRI of 0.9 mg for men and women [283]. Environmental factors, such as soil, water source, fertilizer use, processing, and cooking, affect the copper content of the diet [284]. Copper absorption from the diet is efficient, and few dietary components strongly affect its bioavailability [285]. High intakes of iron or zinc, however, may lower the copper status if the ratio between these elements and copper remains high for a long period [286]. Also, ascorbic acid may lower copper absorption in animals by reducing well-absorbed divalent cupric to monovalent cuprous copper [287], although young adult volunteers given high levels of ascorbic acid daily (600 mg) showed no change in copper status [206].

Absorption and homeostasis

Copper absorption is mediated by both active transport and passive diffusion [287]. Animal studies suggest that the

duodenum is the major site of absorption, but some absorption also occurs in the stomach and ileum [287]. Copper is also excreted in bile and only 15% is reabsorbed through the enterohepatic circulation [287]. Cellular copper homeostasis is maintained by a delicate balance of copper uptake and efflux, which are mediated by highly conserved membrane proteins [288] that include copper-transporting P-type ATPases [289]. Cytoplasmic low-molecular-weight copper-binding proteins steer copper ions to their incorporation into proper apoproteins [288]. The expression of human copper transporter 1 (CTR1) increases the uptake of copper in yeast cells and transfected human fibroblasts [290], whereas the *Ctr1* knockout mouse is embryolethal [291]. Ceruloplasmin and hephaestin are copper-dependent enzymes involved in iron homeostasis (see previous section on iron absorption and homeostasis), and the heterozygous *Ctr1* knockout mice has decreased tissue levels of iron, most likely a consequence of impaired delivery of copper to its apoproteins. Studies of CaCo-2 cells exposed to excess levels of copper show that Ctr1 is internalized by endocytosis [292]. Ctr1 also localizes to the hepatocyte membrane in adult mouse liver and may participate in copper uptake by the liver [293]. The copper-transporting ATPase ATP7A is responsible for copper export from the enterocyte [294], while ATP7B, which is predominantly expressed in the liver, transports copper into the secretory pathway for incorporation into apoceruloplasmin [295].

Disorders of copper homeostasis

Menkes disease is an X-linked recessive disorder of copper absorption and results in copper deficiency at a very young age [296]. The incidence of Menkes disease is between 1 in 50 000 to 1 in 100 000 live births. Symptoms include pallor, lax skin, bone fractures, osteoporosis, altered pigmentation of skin and hair (secondary to low levels of melanin formation), growth failure, mental retardation, and microcytic anemia (secondary to low levels of ceruloplasmin and hephaestin). Oral copper treatment is ineffective and patients often die at a young age. The gene was identified in mouse models, with altered ATP7A Menkes disease (MNK) expressions [289,297]. Thus, copper is blocked in the enterocyte, and little copper is transported into the systemic circulation, resulting in severe copper deficiency. In Wilson disease, excessive amounts of copper accumulate in the body, particularly in the liver and the brain, and clinical symptoms include cirrhosis, eye lesions (specifically Kayser–Fleisher rings), kidney malfunction, and neurological problems [298]. Despite very high levels of copper in the liver, serum levels of copper and ceruloplasmin are low. Treatment includes chelation therapy with drugs such as penicillamine or trientine, but high oral doses of zinc (40–50 mg/day) are also effective because they inhibit copper absorption [299]. Wilson disease is an autosomal recessive disorder, occurring in 1 in 30 000 live births. This disorder of copper metabolism has also been shown to be caused by a defective transporter, in this case ATP7B or the WD protein [300]. Copper absorption per se does not appear to be dysregulated in these patients; rather, tissue copper metabolism, particularly in the liver, is affected, causing an excessive cellular accumulation of copper. The outcome for these patients, if treated, is usually good, although continuous monitoring of copper, zinc, and iron status is necessary.

Deficiency and excess

Risks for copper deficiency include low iron stores in the liver of premature infants, a rapid growth rate, malabsorption syndromes, and increased copper losses [301]. Low serum levels of copper are associated with anemia that is refractory to iron supplementation because of low ferroxidase and hephaestin activities and are accompanied by neutropenia, bone abnormalities, hypopigmentation of hair and skin, impaired growth, and an increased incidence of infections [302]. Decreased phagocytic capacity of neutrophils and impaired cell immunity affect the immune system [303]. Acute copper toxicity is rare and is usually caused by the consumption of contaminated foods or beverages, or by the accidental or deliberate ingestion of large quantities of copper salts [304]. Symptoms include nausea, vomiting, and diarrhea. Indian childhood cirrhosis has been reported in families consuming milk boiled or stored in brass or copper containers [305]. Children consuming such milk may ingest up to 1 mg of copper per kilogram of body weight per day, which is enough to explain the observed liver damage. Infants and children in the Austrian Tyrol were reported to have died of liver cirrhosis secondary to chronically high levels of copper intake [306]. In these cases, inheritance followed the typical pattern of a mendelian recessive trait in individuals who were particularly sensitive to copper exposure. Whether a genetic disorder of copper metabolism is present in patients with liver cirrhosis is not known, but the possibility should be explored in light of the new findings of copper transporters in humans.

D NUTRITION

21 General nutritional principles

David H. Alpers, Beth Taylor, Samuel Klein

Basic nutritional principles, 508 Altered nutritional states, 532

Basic nutritional principles

Body composition

The human body consists of 35 components that are organized into five levels of increasing complexity: atomic (e.g., nitrogen, potassium), molecular (e.g., water, protein), cellular (e.g., body cell mass, intra- and extracellular fluid), tissue (e.g., skeletal muscle, adipose tissue), and whole body (e.g., weight, height). A healthy, lean man is composed of 55%–60% water, 15%–20% fat, 15%–20% protein (one-half in skeletal muscle), 1% glycogen (four-fifths in muscle, one-fifth in liver), and 4% minerals [1]. Although sophisticated techniques are available to measure each body component, the definitions of some commonly used terms can be confusing. *Fat mass* represents all body triglycerides, which are present in adipose tissue, muscle, and liver. *Adipose tissue* is about 83% fat (e.g., triglyceride), 15% water, and 2% protein. *Fat-free mass* refers to total body mass minus total fat mass. *Lean body mass* is defined as total body mass minus adipose tissue. The body also can be divided into cellular and extracellular mass. *Body cell mass* is defined as the cellular components of all tissues (35%–45% of the body weight in healthy men, 30%–40% in women) and can be measured by total exchangeable potassium [2]. *Extracellular mass* is defined as the heterogeneous group of tissues and fluids supporting the body cell mass.

Diet for healthy people

Many guidelines have been developed over the years for general use by the US population for health maintenance and disease prevention. Although these have been published at different times and represent the input of a large number of experts with diverse interests, all expert panels have reported remarkably simple and consistent recommendations for healthy adults. Two of these sets of guidelines are widely disseminated.

The 2005 *Dietary Guidelines for Americans,* developed by the US Department of Health and Human Services and the US Department of Agriculture, provides guidelines for a healthy diet and body weight [3] (Table 21.1). These guidelines are similar to those recommended by the American Heart Association [4]. Both reports recommend the following:

- consume a variety of fruits, vegetables, and whole-grain products
- balance energy intake with energy needs and prevent gradual weight gain over time by making small decreases in energy intake while increasing physical activity
- limit intake of foods that contain high levels of saturated fatty acids, and keep consumption of *trans* fatty acid as low as possible
- limit dietary salt intake and alcohol consumption
- engage in regular physical activity.

Although the recommendations listed in Table 21.1 are generalized for all Americans, special considerations may be needed for African Americans and other minority groups.

In the last 25 years, the prevalence of obesity has increased markedly throughout the world. The World Health Organization [5] and the National Institutes of Health (NIH) [6,7] have proposed guidelines for classifying weight status by body mass index (BMI) (Table 21.2).

It is often helpful to estimate a patient's energy requirement when making recommendations of calorie intake. The Harris–Benedict equation is a useful tool for estimating resting energy requirements (Table 21.3). For estimates of overall energy use, the *recommended daily allowance* (RDA) figures are simple and useful (Table 21.4).

Most guidelines suggest an *adequate intake* (AI) of calcium (1300 mg/day for adolescents, 1000 mg/day for adult men and nonpregnant women aged 19–50, and 1200 mg/day for adults older than 50 years) [8]. Milk contains the highest concentration of calcium – 280–300 mg/225-g (8-oz) cup. There is as yet no convincing evidence that additional protection against osteopenia is achieved by ingesting calcium over the recommended AI. Salt (NaCl) should be limited to

Table 21.1 Dietary guidelines for adult Americans, 2005

Theme	Guideline	Practical recommendations
Aim for fitness	Do not become obese	Maintain body mass index between 18.5 and 24.9 kg/m^2
	Be physically active on a daily basis	To reduce risks of chronic disease, engage in 30 min of moderate exercise (e.g., brisk walking) daily. To help manage body weight, engage in 60 min of moderate exercise daily
Build a healthy base	Enjoy a wide variety of foods	Increase intake of low-energy, nutrient-dense foods (e.g., fruits, vegetables)
	Consume a variety of fruits, vegetables, and grains daily. Eat more dark-green and orange vegetables. Eat at least 85 g (3 oz) of whole-grain cereals, breads, crackers, rice, or pasta	Consume 2 cups of fruit, 2½ cups of vegetables, 170 g (6 oz) of grains daily, 28 g (1 oz) ≈ 1 slice bread, 1 cup breakfast cereal, or ½ cup cooked rice, cereal, or pasta
	Maintain calcium intake	Consume lactose-free products or other calcium sources, such as fortified foods and beverages, if you are unable to ingest milk or milk products
	Maintain moderate protein intake	Consume 150 g (5½ oz) daily of low-fat lean meats and poultry
		Vary your protein sources by choosing fish, beans, peas, nuts, and seeds
Choose sensibly	Choose a diet low in saturated fats and cholesterol	Keep total fat intake between 20% and 35%, and combined saturated and *trans* fatty acids to < 10% of total calories. Limit cholesterol intake to < 300 mg/day
	Moderation in salt intake	Consume < 2300 mg (~ 1 tsp salt) sodium per day. Persons with hypertension, African Americans, and middle-aged and older adults should consume ≤ 1500 mg/day
	Choose and prepare foods and beverages with little added sugars or intense sweetners	
	Do not smoke	
	Drink alcoholic beverages in moderation, if at all	Limit alcoholic drinks to one or two per day
Food safety	Avoid microbial foodborne illness	Clean hands and surfaces prior to contact with food. Cook foods to a safe temperature. Chill perishable food promptly. Avoid unpasteurized milk or milk products, raw or partially cooked eggs, and raw or undercooked meat and poultry

Amounts are based on a daily intake of 8350 kJ (2000 kcal).
Adapted from US Department of Health and Human Services, US Department of Agriculture [3] and Krauss et al. [4].

Table 21.2 Disease risk associated with body mass index

	Obesity class	BMI (kg/m^2)	Disease risk
Underweight		< 18.5	Increased
Normal		18.5–24.9	Normal
Overweight		25.0–29.9	Increased
Obesity	I	30.0–34.9	High
	II	35.0–39.9	Very high
Extreme obesity	III	≥ 40.0	Extremely high

Additional risks: (i) waist circumference > 100 cm (40 in) in men and > 90 cm (35 in) in women; and (ii) poor aerobic fitness.
BMI, body mass index.
Adapted from National Institutes of Health, National Heart, Lung, and Blood Institute [7].

6 g/day or less, and alcohol to 28 g (1 oz) of pure alcohol per day (28 g is the equivalent of two cans of beer, two small glasses of wine, or two average cocktails).

The implementation of the published recommendations depends on two other federally supported guidelines. The RDA [9–13] is the level judged to be high enough to ensure an adequate intake for the majority of the normal population, not the minimal intake necessary to avoid negative balance. The values for the RDA vary with age and gender. These values should not be confused with the US RDAs, standards set by the US Food and Drug Administration in 1973 for the purposes of food labeling for the entire population. The term "US RDA" has been replaced by *reference daily intake* (RDI) and *daily reference value* (DRV). The latter provides for total and saturated fat, cholesterol, total carbohydrates, dietary fiber, sodium, potassium, and protein – nutrients for

Table 21.3 Formulas for estimating resting energy expenditure

Harris–Benedict equation [41]
Men = 66 + (13.7 × W) + (5 × H) – (6.8 × A)
Women = 665 + (9.6 × W) + (1.8 × H) – (4.7 × A)

Owen et al. [43]
Men = 879 + (10.2 × W)
Women = 795 + (7.18 × W)

World Health Organization [56]

Age (years)	Male	Female
0–3	(60.9 × W) – 54	(61.0 × W) – 51
3–10	(22.7 × W) – 495	(22.5 × W) + 499
10–18	(17.5 × W) + 651	(12.2 × W) + 746
18–30	(15.3 × W) + 679	(14.7 × W) + 996
30–60	(11.2 × W) + 879	(8.7 × W) + 829
> 60	(13.5 × W) + 987	(10.5 × W) + 596

A, age (years); H, height (cm); W, weight (kg).

Table 21.4 Calculation of energy requirement

Level of activity	Activity factor (× REE)	Average energy expenditure[a] (kcal/kg per day)
Very light		
Men	1.3	31
Women	1.3	30
Light		
Men	1.6	38
Women	1.5	35
Moderate		
Men	1.7	41
Women	1.6	37
Heavy		
Men	2.1	50
Women	1.9	44

a Estimated from World Health Organization equations for median weights of persons aged 19–74 years; activity factor 1.0 = 100.4 kJ/kg (24.0 kcal/kg) for males, 97 kJ/kg (23.2 kcal/kg) for females.
REE, resting energy expenditure.
Adapted from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine [13].

which no US RDA was available [12,13]. The RDI and DRV are the basis for the daily values that appear on all food labels in the United States, and reflect DRVs and RDIs for a 2000-calorie reference diet. The new recommended dietary intake levels are called *dietary reference intakes* (DRIs), a collective term that includes the *estimated average requirement* (EAR), the RDA, the AI, and the *tolerable upper intake level* (UL) (Table 21.5) [8–13]. These terms were developed by the Institute of Medicine in the United States along with Health Canada. The EAR is the daily nutrient intake value estimated to meet the requirements of half of an age- and gender-specific group. It often is derived from balance studies and is used in setting the RDA, the intake level sufficient to meet the nutrient needs of most people within a given life-stage and gender group. The RDA also includes a factor to account for variation within the group, usually estimated at 10% (i.e., coefficient of variation, or CV). If insufficent data are available to calculate an EAR, AI is used, based on observed intake consistent with good health. The UL is the maximum amount of a nutrient that can be ingested without posing a health threat and was included because so many nutrients are ingested at levels far exceeding those possible from the diet.

These guidelines account for group, and in some cases individual, variability, but they are not meant for use in patients with either acute or chronic diseases. Rather, they should be used as baseline estimates for planning individual nutrient intake. Such adjustments are particularly important in diseases characterized by malabsorption or catabolism, in contrast to simple lack of intake. Confirmation of sufficient nutrient provision can then be monitored by tests specific for each macro- or micronutrient (see Chapter 107).

MyPyramid is a food guide that incorporates recommendations from the 2005 *Dietary Guidelines for Americans* and is available on the US Department of Agriculture (USDA) website (www.mypyramid.gov). MyPyramid is part of an overall food guidance system designed to meet the need for a more individualized approach to improving diet and lifestyle. Five basic food groups are emphasized: grains, vegetables, fruits, low-fat milk and milk products, and meat and beans. The concept assumes that meals are built on a basis of grains, fruits, and vegetables, and supplemented with low-fat milk products and other protein sources in the meat group. MyPyramid comes with a warning to use fats and sweets sparingly and advocates a sensible balance between food and physical activity.

Glycemic index

The glycemic index of a food represents the relative increase in blood glucose that occurs over 2 h after consuming that food compared with either glucose or white bread [14]. Glycemic load is defined as the product of the glycemic index of a food and the amount of carbohydrate in a serving. Diets of foods with a low glycemic index and low glycemic load have been proposed to improve glycemic control in diabetes and to enhance weight loss in obesity. Glycemic control is better in subjects who have type 2 diabetes if a portion of carbohydrate intake is replaced by fat [15]. A study of overweight adolescents showed that altering dietary glycemic load by reducing both total carbohydrate content (45%–50%

of energy intake) and consuming foods with a low glycemic index resulted in greater weight loss compared with a conventional low-fat (25%–30%) diet [16]. However, additional research is needed to clarify the long-term efficacy of diets with a low glycemic load for patients with diabetes or obesity.

Chemoprevention of gastrointestinal cancers

One of the special applications of dietary recommendations for healthy people is to prevent gastrointestinal cancers. The general recommendations for such diets are similar to those that support health in the entire population. However, it has been estimated that about one-third of all cancers are related to diet, and that most colorectal cancer in the United States might be prevented by dietary alterations [17]. Although epidemiological data have suggested associations between overall diets or environment and the risk for cancer incidence or mortality, it has proved difficult to identify the dietary components that might influence such risks, and to demonstrate their benefit in a prospective fashion [18–20]. Table 21.6 summarizes many of the data associating risks for colorectal cancer with dietary components. Few of the reported associations have been convincing. When dietary components have been identified and tested prospectively, the data, in general, are negative, even when premalignant end points are examined, such as colorectal polyps [21].

Epidemiological evidence (case–control and cohort studies) has suggested that people with cancer have a lower intake of raw, fresh, leafy green, or cruciferous vegetables, as well as raw or fresh fruits, especially citrus fruits, but a prospective analysis of 285 526 women showed no association between total or specific vegetable consumption and the risk of breast cancer [22]. Similar findings were noted in a prospective study of risk for colorectal cancer [23]. Although the ingestion of such foods has increased in the United States, the average intake is less than 0.7 servings of vegetables or fruits per day. Moreover, a large cohort study (Iowa Women's Health Study of more than 40 000 women) showed no protective effect of vegetables or fruits on colorectal carcinoma incidence, except for garlic [21]. The antioxidant vitamins A, C, and E are among those compounds thought to be responsible for the possible effects of vegetables and fruits on carcinogenesis. A meta-analysis of 14 randomized trials of antioxidant supplements found no evidence that these could prevent gastrointestinal cancer [24]. In fact, the supplements seemed to increase overall mortality, an effect that may be related to high-dose vitamin E supplementation [25]. Other studies have tested the addition of individual or combinations of vitamins (or β-carotene) on the incidence of colorectal adenoma formation, but have found little prophylactic efficacy [17,26]. Epidemiological studies have provided positive associations between current vitamin use and decreased cancer risk. However, the past use of supplements (including multivitamins) may modestly reduce the risk of colorectal cancer, and blunt the effects of added supplements in controlled trials [27].

The other dietary component that has been most extensively studied is fiber. Two extensive reviews have examined the descriptive and case control studies of the association of dietary fiber with colorectal cancer [28,29]. Most studies showed some inverse correlation, suggesting a protective effect of fiber. In the Health Professionals Follow-up Study involving men, a 64% reduction in cancer was noted in those with the highest quintile of fiber intake (> 28.3 g/day) compared with those on the lowest intake (< 16.6 g/day) [30]. Results from two large studies of women, the Nurses Health Study [31] and the Iowa Women's Study [32], showed no effect. However, two large prospective epidemiological studies reported protection against colorectal cancer [33] and colonic adenomas [34] in subjects with high fiber intake. Prospective studies suggest that an effect of fiber may occur only in men. Interventional studies using fiber supplements often yield inconclusive results [17,28,29].

The data regarding the effect of other dietary components on the incidence of colorectal cancer or adenomas are too fragmentary or incomplete to permit strong recommendations [17]. Some evidence suggests an effect of folate, and its role is being tested in interventional studies. Alcohol (> 30 g/day) may increase the incidence of adenomas in the distal colon and rectum. Although many case control and cohort studies suggested that calcium protected against the development of colorectal cancer, other studies with larger cohorts showed no effect. The role of vitamin C has not been confirmed [35]. The results of interventional studies are conflicting, and the end point used has been colonic cell proliferation, not adenoma or carcinoma incidence.

Although numerous studies examining the role of nutrition in prevention of gastrointestinal cancer exist, the interventional studies do not support specific dietary recommendations, as most of the data only demonstrate associations between diet and cancer prevention. However, intake levels of fruits, vegetables, fiber, and calcium as outlined in the Dietary Guidelines for Americans should be given specific dietary recommendations, as most of the data only demonstrate associations between diet and cancer prevention. Intake levels of fruits, vegetables, fiber, and calcium, as outlined in the Dietary Guidelines for Americans, should be recommended.

Energy metabolism

The human body continuously consumes energy for the maintenance of ionic and osmotic gradients, cell transport, nerve conduction, intermediary metabolism, biosynthesis, heat generation, and the performance of involuntary and voluntary mechanical work. Energy is provided largely by the mitochondrial production of high-energy phosphate bonds generated by the oxidation of fat, carbohydrate, and protein. After the hydrolysis of carbohydrates to simple sugars, fats to fatty acids and glycerol, and proteins to amino

This table presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97%–98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover the needs of all individuals in the group, but lack of data or uncertainty in the data prevent specification with confidence of either percentage of individuals covered by this intake.

a As cholecalciferol. 1 μg cholecalciferol = 40 IU vitamin D.

b In the absence of adequate exposure to sunlight.

c As niacin equivalents (NE). 1 mg of niacin = 60 mg tryptophan; 0–6 months = preformed niacin (not NE).

d As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

e Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

acids, most of these small molecules are converted to the acetyl unit of acetyl coenzyme A (CoA), generating a small amount of ATP in the process. Acetyl-CoA is a common breakdown product of the three macronutrients. Acetyl-CoA, carrying most of the chemical energy of the original macronutrients, enters the citric acid cycle and undergoes oxidative phosphorylation, the final common pathways in the oxidation of food molecules (Fig. 21.1). Many amino acids enter the citric acid cycle as α-ketoglutarate or oxaloacetate rather than as acetyl-CoA.

A portion of the energy released during substrate oxidation is not used to perform work and is dissipated as heat. Therefore, energy production is traditionally measured in terms of heat production. One kilocalorie (kcal), equal to

f As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2*S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

g Because 10%–30% of older people may malabsorb foodbound vitamin B-12, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with vitamin B-12 or a supplement containing vitamin B-12.

h In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 µg from supplements or fortified foods in addition to food folate from a varied diet.

i It is assumed that women will continue consuming 400 µg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period – the critical time for formation of the neural tube.

j As retinol activity equivalents (RE). 1 RE = 1 µg all-*trans*-retinol, 12 µg β-carotene, 24 µg α-carotene, or 24 µg β-cryptoxanthin.

Data are compiled from the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine [9–11].

4.184 kilojoules (kJ), is the amount of heat required to raise the temperature of 1 kg of water by 1°C. Normally, body temperature is carefully maintained within narrow limits so that heat production equals heat loss. Energy production can be determined directly (direct calorimetry) by measuring the transfer of heat from the body to water circulating in specially designed chambers or suits. Energy production also can be measured indirectly (indirect calorimetry) by measuring carbon dioxide (CO_2) production and oxygen (O_2) consumption, because the amount of heat produced during substrate oxidation is proportional to the amount of CO_2 produced and O_2 consumed [36]. The relationship between CO_2 production and O_2 consumption can be used to estimate the relative oxidation of different substrates [37].

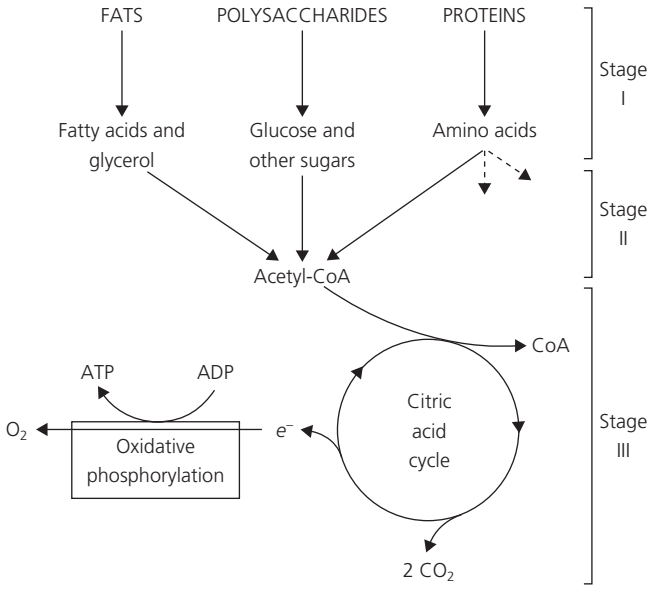

Figure 21.1 Stages in the extraction of energy from foodstuffs. CoA, coenzyme A. From Stryer L. Biochemistry, 3rd edn. New York: WH Freeman, 1988:325.

Dietary carbohydrates, fats, and proteins can be used as fuel soon after their ingestion, or they can be stored by the body for subsequent oxidation. Endogenous energy stores (Table 21.7), which are continuously being mobilized and oxidized, become a critical source of fuel during postabsorptive conditions and when energy intake is inadequate to meet energy demands. The largest source of endogenous energy is triglyceride in adipose tissue, which is uniquely designed to store fuel. Triglycerides have a high energy density and release 39.3 kJ/g (9.4 kcal/g) when oxidized. Adipose tissue is composed almost entirely of triglycerides in an oil form, which constitute 85% of adipocyte weight. In comparison, glycogen, the other major source of endogenous fuel, generates only 17.2 kJ/g (4.1 kcal/g) on oxidation. Glycogen takes up a considerable amount of space because it is stored in liver and muscle tissue as a gel containing 2–4 g of water for every gram of glycogen [38]. The mobilization of adipose tissue yields 25–33 kJ/g (6–8 kcal/g), whereas the mobilization of glycogen yields only 4–8 kJ/g (1–2 kcal/g). The energy stored in the adipose tissue of a lean man can provide enough fuel for him to survive 2 months of total energy restriction [39], whereas the energy present as liver glycogen is consumed within 24 h of fasting. Certain cells and tissues, such as the brain, prefer glucose as a fuel, and others, such as bone marrow, erythrocytes, leukocytes, renal medulla, eye tissues, and peripheral nerve tissue, require glucose because they cannot oxidize fatty acids. None of the macronutrients is completely absorbed; some are excreted in the feces. Based on the average digestibility of fat (95%) and carbohydrate (97%), the digestible energy derived from fat is 37.6 kJ/g (9.0 kcal/g), and that from carbohydrate is 16.7 kJ/g (4.0 kcal/g).

Table 21.7 Body energy stores

Tissue	Fuel	Energy
Adipose tissue	Triglyceride	585 000 kJ (140 000 kcal)
Muscle	Glycogen	8400 kJ (2000 kcal)
	Triglyceride	12 500 kJ (3000 kcal)
Liver	Glycogen	1250 kJ (300 kcal)
	Triglyceride	2100 kJ (500 kcal)

Components of energy expenditure

Total energy requirements include the sum of *resting energy expenditure* (REE), the thermic effect of physical activity (TEPA), the thermic effect of feeding (TEF), and adaptive thermogenesis (AT). The resting energy expenditure is the energy consumed while lying quietly awake in the postabsorptive state. Normally, REE accounts for about 70% of total daily energy expenditure. Energy requirements of different tissues and organs are heterogeneous, however. Energy consumption by the body's most metabolically active organs – the brain, liver, kidney, and heart – accounts for 60% of REE; these constitute only 5% of total body mass (Table 21.8). By contrast, adipose tissue, which accounts for about 20% and 30% of body weight in lean men and women, respectively, consumes less than 5% of REE.

Across mammalian species, REE is related to body weight; REE is proportional to the three-fourths power of body weight ($\text{weight}^{0.75}$) [40]. Several equations have been used to estimate resting energy requirements in humans based on

Table 21.8 Postabsorptive energy requirements

	Mass		Energy expenditure	
Tissue	**g**	**% Total**	**kJ/day (kcal/day)**	**% Total**
Gut	2000	3	1250 (300)	13
Brain	1400	2	1675 (400)	18
Liver	1600	2.2	1840 (440)	19
Heart	300	0.4	985 (235)	10
Kidneys	300	0.5	835 (200)	10
Adipose tissue	14 000	20	290 (70)	4
Skeletal muscle	28 000	40	1675 (400)	18

measurements of REE in healthy subjects (see Table 21.3) [41–44]. These equations generate values that are usually within 10% of measured values in healthy volunteers but are less accurate in persons who are at the extremes of weight (i.e., extremely lean or obese) or who are ill. Starvation and severe hypocaloric feeding decrease the resting metabolic rate to values some 15%–20% below that expected for actual body size, whereas illness and injury can increase energy requirements.

Physical activity usually accounts for 15%–20% of total energy expenditure. The precise contribution of the TEPA to total energy expenditure depends on the intensity and duration of activities. At rest, skeletal muscle accounts for 20% of total energy requirements. However, during moderate- to high-intensity aerobic exercise, energy consumed by working muscles can increase more than 50-fold, causing a 15-fold increase in total energy expenditure.

The TEF represents the energy costs of digestion, absorption, transport, metabolism, and storage of nutrients, and it also may involve AT. Eating or infusing nutrients increases the metabolic rate by about 5%–10% of the ingested or infused calories and depends on the specific foods consumed. Normally, 12%–20% of the energy in ingested protein, 6%–12% of carbohydrate energy, and 2%–3% of fat energy is expended.

Adaptive thermogenesis is a proposed mechanism for wasting excess energy to maintain a constant body weight despite fluctuating amounts of energy intake, or for maintaining body heat during exposure to different environmental temperatures [45]. The concept of a "dual control" system for AT has been introduced [46]. In addition to a "rapid reaction" control system function as the attenuator of energy balance, under conditions of positive energy balance AT may be regarded as a "slow reaction" control system, functioning specifically as an accelerator for fat deposition [45]. It has been proposed that energy expenditure and heat production for AT and TEF involve brown adipose tissue, a specialized, highly vascularized, thermogenic tissue innervated by sympathetic nerves [47]. Brown adipose tissue is packed with large mitochondria possessing an uncoupling protein that uncouples ATP synthesis from respiration [48,49]. In this situation, the rate of substrate oxidization does not depend on the availability of ADP precursor, and the reaction can continue at high rates, permitting even small quantities of brown adipose tissue to increase heat production markedly. Radioimmunoassays for the uncoupling protein have demonstrated the presence of brown adipose tissue in humans of all ages [49]; other studies suggest that uncoupling protein expression also can be induced in white adipose tissue [50]. The physiological importance of AT in energy metabolism in humans is not clear. In societies where food is plentiful and the level of daily physical activity is low, the variations in AT among individuals may be important in determining their trend toward weight maintenance or weight gain.

Proteins

Proteins are composed of amino acids joined together by peptide bonds. Twenty different amino acids are commonly found in human proteins. Differences in the sequences of amino acids in proteins permit diverse structures and functions; proteins serve as enzymes, carriers, receptors, hormones, and structural elements. The amino acid sequence determines the location of sites for covalent attachment of carbohydrate and ultimately determines the protein's three-dimensional configuration and specific function. Nitrogen also is present in the body in the form of free amino acids. Free amino acids are in a dynamic state, whether they are being incorporated into tissue proteins, undergoing catabolic reactions, or being used for the synthesis of other nitrogen-containing compounds [51].

Protein quality

Protein quality is related to the ability of the protein to support metabolic homeostasis and growth, which is determined by amino acid content and bioavailability. Some amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, and possibly arginine) are considered essential because their carbon skeletons cannot be synthesized by the body. These amino acids must be consumed in the diet for normal function and survival. Other amino acids (glycine, alanine, serine, cysteine, cystine, tyrosine, glutamine, glutamic acid, asparagine, and aspartic acid) are nonessential because their carbon skeletons can be produced endogenously. In general, the greater the ratio of essential to nonessential amino acids, the better the quality of protein.

The ability to digest protein and absorb its component amino acids also affects protein quality. True absorption ranges from 97%–99% for proteins in meat, milk, and eggs, to 75% for proteins in potatoes and navy beans [52,53]. Protein bioavailability also can be affected by food preparation. For example, some lysine is lost by heating in the presence of reducing sugars. By contrast, heating increases the

bioavailability of soy protein by inactivating the trypsin inhibitor present in soybeans [54]. In general, the proteins of eggs, milk, fish, red meat, and poultry are high in biological value, and the protein in wheat gluten is low [52,53,55].

Nitrogen balance

Nitrogen balance is the difference between intake and output. Nitrogen is excreted primarily in the urine as urea, creatinine, porphyrins, ammonia, and uric acid. The relative proportions of these compounds can vary, but urea usually accounts for about 80% of urinary nitrogen. During fasting conditions, urinary nitrogen reaches a low level of about 2 mg/kcal of REE, or about 40 mg/kg of body weight. About 1–3 g of nitrogen is normally lost per day from fecal and other sources [13]. Fecal nitrogen losses reflect unabsorbed protein in the diet and in intestinal secretions and sloughed epithelial cells. The amount of endogenous protein that normally enters the intestinal lumen is about 50 g/day. Absorption of exogenous and endogenous protein is so efficient that fecal nitrogen is normally only 1–2 g/day. Minor amounts of nitrogen are lost through intact skin, nasal secretions, semen, menstrual fluid, and hair cuttings.

Nitrogen balance can be used to estimate protein balance because about 16% of protein consists of nitrogen, and it is assumed that almost all body nitrogen is incorporated into protein or amino acids. A positive balance (i.e., intake greater than losses) represents a net increase in total body protein, whereas a negative balance (i.e., losses greater than intake) demonstrates net protein catabolism. One gram of nitrogen represents about 6.25 g of protein, which is equivalent to 30 g of hydrated lean body mass.

Nitrogen balance is affected by protein intake and quality, energy intake, and nutritional status. Inadequate energy intake increases protein requirements. When protein intake is suboptimal, nitrogen balance can be improved by increasing energy intake. Therefore, nitrogen balance reflects both protein intake and energy balance. Most normal adults can maintain nitrogen equilibrium by ingesting 0.5 g of high-quality protein per kilogram of body weight per day. The range of recommended intake for adults is 0.5–0.8 g/kg/day [13,51,56,57], which provides a margin of safety to allow for decreased biological availability and increased requirements in subsets of the population. The average protein in a Western diet has only 75% of the biological value of egg protein [51,58]. Intravenously administered amino acids are as effective in promoting nitrogen balance as oral protein [59].

Infancy is a time of intense growth, and the protein requirements per unit of body weight for infants are higher than those for adults. The healthy infant also requires a higher proportion of essential to nonessential amino acids [60]. The growth spurt of adolescence, the only extrauterine period during which growth velocity increases, occurs between 10 and 13 years of age for US girls and between 12 and 15 years of age for US boys, and contributes about 15% of final adult height and 50% of adult weight [61]. The guidelines for protein and calorie needs in infancy, childhood, and adolescence are summarized in Table 21.9. The nutritional demands of a normal pregnancy average about 335 000 kJ (80 000 kcal) – that is, roughly 1250 kJ/day (300 kcal/day) – and 950 g of protein (i.e., 3.5 g/day). The Food and Nutrition Board of the Institute of Medicine has set the RDA for protein during pregnancy at 1.1 g/kg/day, an increase of 25 g/day over the RDA for nonpregnant women aged 25 years or older [13]. For lactating women over 25 years of age whose average daily output of milk is 850 mL, a protein intake of 1.3 g/kg/day, or 25 g/day of additional protein, is recommended by the Food and Nutrition Board [13].

Protein metabolism

Body proteins are in a state of constant flux, with protein synthesis and breakdown occurring simultaneously. Normal daily protein turnover is 1%–2% of total body protein and results largely from the degradation of muscle and hepatic proteins. Protein degradation involves the enzymatic hydrolysis of protein to its constituent amino acids. More than 75% of the amino acids released by protein breakdown are reused for the synthesis of new proteins; the remaining amino acids are oxidized. Proteases within cell lysosomes are responsible for most protein degradation [62–66]. However, proteases are also found in plasma membranes and in the cytosol. The carbon skeletons of amino acids can be oxidized for energy or used for the synthesis of glucose, ketone bodies, and fatty acids [2]. Nitrogen can be released as ammonia into the bloodstream and delivered to the liver, where it is converted to urea.

The metabolism of amino acids involves the transfer of nitrogen between organs from the periphery to the liver (Fig. 21.2). The liver is a workhorse for amino acid metabolism and is the site of synthesis for urea and plasma proteins. It is the main site of catabolism for the essential amino acids, with the exception of the branched-chain amino acids leucine, isoleucine, and valine, which are degraded in muscle and kidney.

Skeletal muscle preferentially takes up the branched-chain amino acids after each meal and is the primary site of metabolism for these amino acids. Although leucine, isoleucine, and valine constitute only 8% of dietary amino acids, they make up 60% of the amino acids in the systemic circulation [67,68]. When muscle proteins are catabolized, the branched-chain amino acids undergo transamination, yielding alanine, glutamine, and branched-chain keto acids. The keto acids are used by the muscle as fuel, and alanine and glutamine are exported and taken up predominantly by the liver and intestine, respectively [67]. These two amino acids account for more than 50% of the total amino acid nitrogen released from muscle [68–70]. The kidneys also take up glutamine, which is the major substrate for renal ammonia production [71].

Table 21.9 Dietary reference intake values for energy and protein in individuals by life-stage group

			Protein[b]					
	Energy EER[a], kJ/day (kcal/day)		AI or RDA (g/day)		EAR (g/kg/day)		RDA (g/kg/day)

a Based on energy expenditure plus energy deposition for moderately active Americans and Canadians up to age 18, but only for energy expenditure < 18 years.
b Based on nitrogen equilibrium plus protein deposition, except for 0–6 years (average consumption of protein from human milk) and < 18 years (nitrogen equilibrium only).
c Total for a 3-month-old.
d Total for a 9-month-old.
e Total for a 24-month-old.
f Total for a 6-year-old.
g Total for an 11-year-old.
h Total for a 16-year-old.
i Total for a 19-year-old.
j For subjects older than 19 years subtract 42 kJ/day (10 kcal/day) for males and 29 kJ/day (7 kcal/day) for females.
k Based on AI only.
EER, estimated energy requirement; AI, adequate intake, the observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status. The AI is not equivalent to an RDA; EAR, estimated average requirement, the intake that meets the estimated nutrient need of half of the individuals in a group; RDA, recommended dietary allowance, the intake that meets the nutrient needs of almost all (97%–98%) individuals in a group. The EAR and RDA for protein for the first half of pregnancy are the same as those of a nonpregnant woman.
Adapted from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine [13].

Lipids

Lipids are a heterogeneous group of compounds that are soluble in organic solvents. Lipids include triglycerides (fat), sterols, glycolipids, phospholipids, and fat-soluble vitamins. These compounds serve as a source of energy, structural components of cell membranes, carriers of essential nutrients, and precursors for the synthesis of steroid hormones, prostaglandins, thromboxanes, and leukotrienes. Dietary lipids are composed mainly of triglycerides, which contain mostly saturated and unsaturated long-chain fatty acids with a 16- to 18-carbon chain length.

Lipid metabolism

The use of fat as a fuel requires the hydrolysis of triglyceride to free fatty acid and glycerol and the tissue uptake of free fatty acids for subsequent oxidation. Hormone-sensitive lipase within adipocytes hydrolyzes adipose tissue triglycerides and releases free fatty acids into the bloodstream, where they are bound to plasma proteins and delivered to other tissues. Lipoprotein lipase at the lumenal surface of the capillary endothelium hydrolyzes plasma triglycerides and releases free fatty acids for local tissue uptake. Fatty acids are transported across the cell membrane by passive diffusion, facilitated diffusion, and active transport. Membrane and cytosolic fatty acid-binding proteins are important in transporting fatty acids across the cell membrane and in directing fatty acids from the cell membrane to different metabolic sites. This intracellular fatty acid transport system enhances fatty acid uptake by maintaining a fatty acid concentration gradient and prevents potentially toxic interactions between fatty acids and intracellular organelles. Long-chain fatty acids are delivered across the outer and inner mitochondrial membranes by a carnitine-dependent transport system. Inside the mitochondria, fatty acids are degraded by β-oxidation to acetyl-CoA, which enters the tricarboxylic acid cycle (see Fig. 21.2).

Ketone bodies are produced solely by the liver and are generated by the partial oxidation of fatty acids. Ketone body production increases when the rate of fatty acid production is

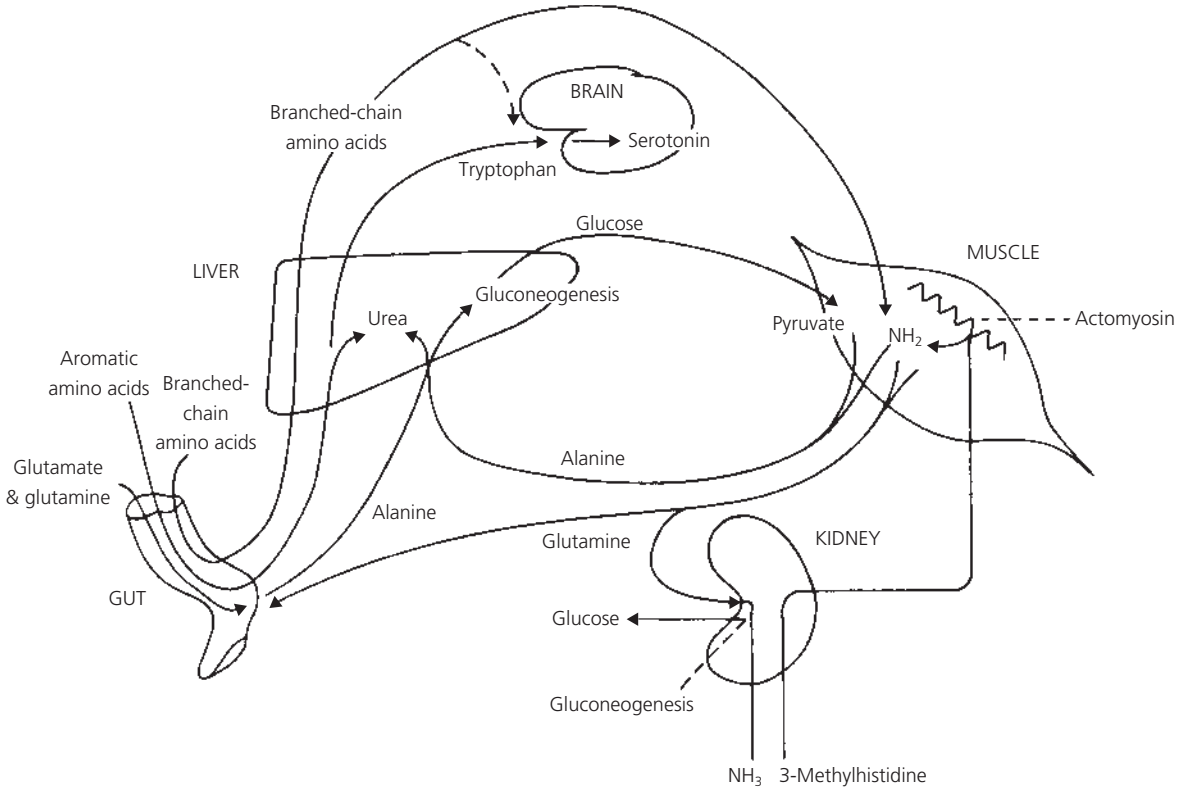

Figure 21.2 Interactions of organs in the metabolism of some major amino acids. Adapted from Munro HN. Interactions of the liver and muscle in the regulation of metabolism in response to nutritional and other factors. In: Arias IM, Popper H, Schachter D, et al. (eds). The Liver: Biology and Pathobiology. New York: Raven Press, 1982:681.

much greater than the rate of fatty acid oxidation, such as during starvation or uncontrolled diabetes mellitus. In these conditions, ketone bodies become an important fuel and are released into the bloodstream for delivery to extrahepatic tissues. Ketone bodies represent a water-soluble fuel derived from water-insoluble fatty acids. Ketone bodies can cross the blood–brain barrier to replace glucose as the major fuel for the brain, sparing plasma glucose for consumption by other tissues [72].

The biosynthesis of fatty acids is mediated by fatty acid synthase, a multienzyme complex embodied in a single polypeptide chain. It elongates the molecule by sequential addition of two-carbon units and stops with the formation of palmitic acid, a 16-carbon fatty acid. The formation of malonyl-CoA from acetyl-CoA is the committed step in fatty acid biosynthesis and the most important step of regulation. The enzyme that catalyzes this step, acetyl-CoA carboxylase, is stimulated by citrate. Citrate is abundant when ATP and acetyl-CoA are abundant, a condition appropriate for fat synthesis. Palmitoyl-CoA, the end product of fatty acid synthesis, antagonizes the activation of acetyl-CoA carboxylase by citrate.

Essential fatty acids

Most fatty acids can be synthesized by the liver, but humans lack the desaturase enzyme needed to produce the *n*-3 double bond (between carbons 3 and 4, counted from the methyl end) and the *n*-6 double bond (between carbons 6 and 7) in the fatty acid series. Essential fatty acids are important constituents of cell membranes and precursors of the eicosanoids [73]. Arachidonic acid (C20:4, *n*-6), a precursor of eicosanoids, prostaglandins, leukotrienes, prostacyclins, and thromboxanes, is synthesized from linoleic acid [73,74]. Vegetable oils, such as corn, soybean, sunflower, peanut, and cottonseed oils, are rich sources of linoleic acid [73,74]. Linoleic acid (C18:2, *n*-6) should constitute at least 2%, and linolenic acid (C18:3, *n*-6, -9, -12) at least 0.5%, of the daily energy intake to prevent the occurrence of essential fatty acid deficiency, usually manifested as a specific alteration in the plasma fatty acid profile and a skin rash. An elevated ratio of triene to tetraene (> 0.4) is characteristic of essential fatty acid deficiency as a result of increased production of eicosatrienoic acid, a fatty acid containing three double bonds (i.e., triene) derived from oleic acid (C18:1), and of decreased arachidonic acid production, a tetraene derived from linoleic acid elongation [75,76]. Essential fatty acid deficiency is rare in adult humans because of sufficient essential fatty acids stored in adipose tissue. However, continuous infusion of lipid-free total parenteral nutrition (TPN) can cause abnormalities of the triene-to-tetraene ratio within

10 days because of increased plasma insulin concentrations, which inhibit lipolysis and the release of essential fatty acids [76].

Fish oils

Fish oils are ω-3 polyunsaturated fatty acids (PUFAs) found in marine animals, particularly fatty fish, such as herring, salmon, bluefish, and tuna [77,78]. Epidemiological studies suggest a possible protective effect of fish oils, especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), against cardiovascular disease and breast cancer [79–82]. In sufficient doses, fish oil prolongs the bleeding time and decreases the production of the proaggregating substance thromboxane A_2 [83–86]. Animal models suggest that fish oils have an inhibitory effect on coronary atherosclerosis and intimal hyperplasia [77,83,84]. The significant hypotriglyceridemic effects of fish oils have been confirmed repeatedly in healthy persons and in persons with various degrees of hyperlipidemia [85–92]. In a study involving 11 323 patients with a recent myocardial infarction, a 45% reduction in sudden death was noted at 42 months. Interestingly, the reduction of sudden cardiac death started to be significant at 4 months. This suggests that the benefit of PUFAs may not be mediated only by antiatherosclerotic and antithrombotic effects, but may also involve antiarrhythmic effects [77,81,83,84]. The effects on serum cholesterol and low-density lipoprotein (LDL) levels have varied [77,92,93]. The ω-3 fatty acids generally suppress cellular inflammatory responses by changing the end products of eicosanoid synthesis [77,90,94–96]. Dietary supplementation with fish oil suppresses the production by monocytes of the polypeptide cytokines interleukin-1 (IL-1) and tumor necrosis factor (TNF), suggesting an additional mechanism by which fish oils may exert an antiinflammatory effect [94,97]. Successful outcomes of numerous randomized trials led the American Heart Association to release the following guidelines in 2002:

- all adults should eat fish, especially fatty fish, at least two times per week
- patients with documented coronary heart disease should consume about 1 g of EPA and DHA (combined) per day
- an EPA and DHA supplement may be beneficial for patients with hypertriglyceridemia [98].

Structured triglycerides

Structured triglycerides are lipids that have been chemically or enzymatically altered. They are used in nutritional admixtures and generally are prepared with reesterification of a long-chain fatty acid in the *sn*-2 position and medium-chain fatty acids in the *sn*-1 or -3 position of the glycerol molecule. Studies conducted in different animal models of burn injury, endotoxic shock, trauma, and ischemia/reperfusion injury have shown that the use of structured triglycerides improves protein and energy metabolism and increases intestinal absorption, compared with physical mixtures of long-chain and medium-chain fatty acids [99–105]. A study of patients with cancer of the upper gastrointestinal tract found that structured triglycerides reduce gastrointestinal complications and improve hepatic and renal function [106].

Carbohydrates

Carbohydrates, which constitute most of the earth's organic matter, are important sources of metabolic fuel. In the United States, carbohydrates normally account for about 50% of ingested calories; about 60% is complex carbohydrate, primarily starch, and most of the remainder is sucrose and lactose [107]. About 10–20 g of indigestible carbohydrate (i.e., soluble and insoluble fibers) are consumed daily. They all undergo hydrolysis in the colon to yield glucose, other simple sugars, and short-chain fatty acids. Some cells and tissues, such as erythrocytes, leukocytes, renal medulla, eye tissues, and peripheral nerve tissue, do not have the capacity for citric acid cycle activity and require glucose as a fuel for anaerobic glycolysis. The brain prefers glucose as a fuel. Daily glucose requirements include 40 g/day for anaerobic tissues and 140 g/day for the brain [108].

Absorbed glucose that is not directly oxidized can be stored as energy in the form of glycogen or fat, which requires about 5% and 25%, respectively, of the original substrate oxidative energy potential. Glycogen is a branching, long-chain polymer of glucose molecules that has water and electrolytes between the chains. It is found in most tissues but significant amounts are stored only in the liver and skeletal muscle. The primary function of hepatic glycogen, amounting to about 100 g in a healthy adult, is to maintain blood glucose levels. Plasma glucose is an essential fuel for glucose-dependent tissues. Glycogen in skeletal muscle serves to supply glucose to the muscle itself during physical activity.

Glycolysis

The conversion of glucose to pyruvate in the cytosol of cells is known as glycolysis, a process that results in the generation of ATP but does not require oxygen. Pyruvate represents a major metabolic junction; it can be reduced to lactate, transaminated to form alanine, or enter the mitochondria and undergo carboxylation to oxaloacetate or oxidative decarboxylation to acetyl-CoA (Fig. 21.3).

Citric acid cycle and oxidative phosphorylation

The citric acid cycle (i.e., tricarboxylic acid cycle, or Krebs cycle) represents a series of reactions that occur in mitochondria. Carbohydrates, lipids, and amino acids enter the cycle after being metabolized to acetyl-CoA, and are completely oxidized to CO_2 and water. Vital biosynthetic intermediates are produced by the cycle, which plays a major role in gluconeogenesis, lipogenesis, and amino acid transamination and deamination. As acetyl-CoA is oxidized, reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide ($FADH_2$) are formed, which transfer

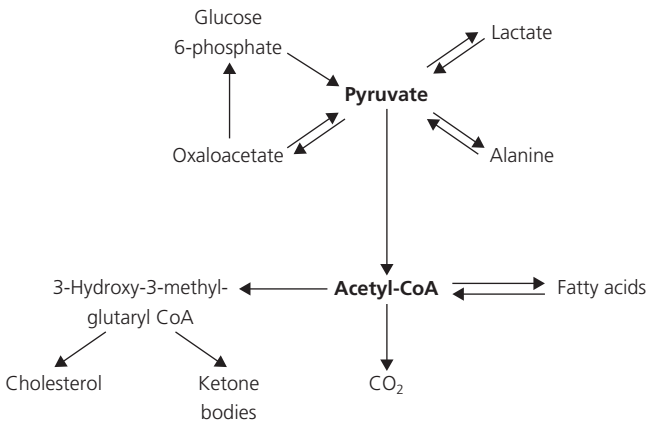

Figure 21.3 Major metabolic end products of pyruvate and acetyl-coenzyme A in mammals. From Stryer L. Biochemistry, 3rd edn. New York: WH Freeman, 1988:633.

the electrons to the respiratory chain in the inner mitochondrial membrane. In the mitochondria, the transfer of high-energy electrons from NADH or $FADH_2$ down the electron transport chain is coupled to the generation of ATP, a process known as *oxidative phosphorylation*. Glycolysis (i.e., anaerobic respiration) yields a net of only 2 ATPs per molecule of glucose, whereas aerobic metabolism (i.e., citric acid cycle and oxidative phosphorylation) yields 36 ATPs for each molecule of glucose oxidized.

Glucose production

Hepatic glycogenolysis is responsible for most of the glucose produced endogenously in the fed and postabsorptive states. Other mechanisms for glucose production are active and become critically important when hepatic glycogen is depleted, such as during prolonged starvation and endurance exercise. Gluconeogenesis is the process by which glucose is synthesized from noncarbohydrate precursors, lactate, glycerol, and most amino acids (principally alanine). Gluconeogenesis occurs primarily in the liver, but the kidneys also produce glucose, especially during prolonged fasting.

The Cori and glucose–alanine cycles provide mechanisms for generating plasma glucose for glucose-dependent tissues from 3-carbon intermediates released from peripheral tissues [109]. The *Cori cycle* (or lactic acid cycle) resynthesizes glucose that has been partially metabolized to lactate by peripheral tissues. Lactate produced principally by muscle, erythrocytes, and adipose tissue is transported to the liver and kidneys, where it is converted to glucose (gluconeogenesis) and released into the bloodstream. The *glucose–alanine cycle* shuttles glucose from the liver to muscle and alanine from muscle to liver. In this cycle, pyruvate is transaminated to alanine, which is transported to the liver and converted to glucose, which is then returned to muscle through the bloodstream.

Fiber

The accepted definition of dietary fiber is plant cell-wall components, both polysaccharides and noncarbodydrate components, that resist digestion by enzymes of the small intestine. The polysaccharide compounds in dietary fiber, which are the structural and matrix components of plant cell walls, consist primarily of cellulose, hemicelluloses, and pectins [110], as well as fructooligosaccharides and resistant starches. Examples of foods with high cellulose content include wheat bran, apple and pear skin, and strawberries; foods with notable hemicellulose content include whole grains; and foods with high levels of pectins include bananas, apples, and oranges. Cellulose is a β1-4-linked polymer of glucose and the main structural component of plant cell walls. Hemicellulose consists of branched polymers of pentose and hexose sugars. Other noncellulose polysaccharides include pectins, which are complex mixtures of colloidal polysaccharides, and several polysaccharides not associated with the cell wall, including mucilages and gums. These compounds are branched polymers containing many uronic acids that hold water and form gels. They are highly branched in growing plants and become less branched as the support structure develops. They act as adhesives and are insoluble in the unripe fruit, becoming soluble only as the fruit matures. Undigested oligosaccharides, such as those associated with flatus (e.g., stachyose and raffinose), are soluble and not included in the definition of fiber.

Fructooligosaccharides are mixtures of β2-1-linked β-D-fructose monomers. These molecules include inulin-type fructans (linear polymers) and levans (branched fructans) and are present in many edible plants, such as wheat grains and members of the onion family. The daily consumption of oligofructoses by North American populations is estimated at 1–12 g, slightly more in Western Europe [111]. The β-C2 linkage makes these polymers resistant to hydrolysis by human digestive enzymes, and they are fermented and metabolized in the colon to short-chain fatty acids. This colonic fermentation produces a change in the microflora, enhancing bifidobacteria and decreasing *Bacteroides* organisms, clostridia, and other anaerobes. Fructooligosaccharides are the best studied of the prebiotics, defined as "a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth or the activity of one or a limited number of bacteria in the colon and thus improves host health" [112].

Resistant starches (RSs) are defined as starches that enter the colon: RS1 is physically inaccessible starch because of the particle size or entrapment in food; RS2 and RS3 are resistant to amylase action because of their compact (unbranched) structure, by being either unbranched (RS2) or made retrograde (RS3) – that is, altered during food processing [113]. Most resistant starches are produced during food preparation. Intake of such starches with a typical Western diet is estimated to be 5–10 g/day.

Other components of dietary fiber include polyphenols (especially flavonoids) and other cell wall-associated nonpolysaccharide substances. Polyphenols are products of plant metabolism and range from single-ring phenols to highly polymerized compounds, such as tannins and lignins. Only lignins are included in the determination of dietary fiber, although they constitute about 12% of plant organic compounds. Lignins include a group of phenylpropane polymers of varying sizes, because they are continually polymerized as the plant ages. They reinforce the cellulose support structure and inhibit microbial cell wall digestion. Lignins are thus resistant to all anaerobic digestion systems and are not partially metabolized in the colon, as are the cell wall polysaccharides. They represent only a small part of the human diet (~ 0.2%).

Phenolic acids and aldehydes, such as vanillin, are common, but the most common of the plant phenolics are flavonoids, consisting of two aromatic rings linked through three carbons that form an oxygenated heterocyclic ring [114]. Flavonoids and other polyphenols are ubiquitous in plants and beverages. They contribute to the bitterness of tea and other beverages [9]. Polyphenols usually account for less than 1% of the dry matter of plants, but they can reach concentrations of 4000–7000 mg/mL in red wines and fruit juices [114]. The typical adult dietary intake of polyphenols in the United States is 1–1.1 g/day, with flavonoids accounting for about 4% of the total. Like other fiber components, polyphenols are degraded and their metabolites are absorbed in the colon, but the effect of these compounds on short-chain fatty acid production and microflora depends on the type of compound and the microorganisms present. Polyphenols bind proteins and precipitate them in the intestinal lumen, and they can decrease the absorption of nitrogen, fat, and some minerals, including iron.

Interest in polyphenols generally has focused on their antioxidant properties, particularly in relation to carcinogens and LDL oxidation. Some evidence suggests that moderate consumption of tea, a rich source of flavonoids, may protect against several forms of cancer, cardiovascular diseases, and kidney stone formation [115]. The blacker the tea, the more the polyphenols have been oxidized, lowering the possible effective role of these compounds. Herbal teas are not true teas (which derive from the shrub *Camellia sinensis*) and have a much lower flavonoid content. Tea contributes more than 60% of dietary flavonoids, onions about 13%, and grapes, apples, red wine, and dairy products most of the rest. The consumption of 1–2 cups of tea a day has been associated with health benefits in epidemiological studies [116], including 50% decreased mortality from stroke in men and 20%–40% decreased from cancer of the mouth, pancreas, colon, esophagus, skin, lung, prostate, and bladder. These data show only associations, not causation, and the results must be confirmed by prospective intervention studies. However, phenolics can, under some conditions, act as prooxidants [116], so the consumption of large amounts of phenolics as foods or supplements cannot be recommended until more data are available.

The heterogeneity of dietary fiber has inspired numerous classification schemes, including those based on source, chemistry, structure, water solubility, detergent solubility, physicochemical properties, and physiological actions. *Crude fiber* was a term commonly used until the early 1970s. It refers to the residue of plant material that remains when food is extracted by dilute acids and alkalis. Although crude fiber is the measurement still referred to in most food tables, it underestimates by 80%–90% the amount of material in foods that is undigestible by human digestive enzymes [13,117].

The physiological effects of dietary fiber on gastrointestinal function are complex because of their heterogeneity and the changes in the lumenal environment along the gastrointestinal tract. Combinations of fibers may have effects that differ from those of individual purified preparations, and the same purified fiber can have different effects depending on how finely or coarsely it is ground. The quantitative measurements of the fiber content of foods alone do not always allow prediction of their biological action.

Many physical properties of dietary fiber are physiologically important, including hydratability, viscosity, ion-exchange properties, and adsorptive capacity. Hydratability relates to the ability of a fiber to form viscous gels. It is a function of the physical and chemical composition of the fiber, including particle size, the age of the plant, and the chemical properties of the surrounding solvent. Some dietary fibers, such as lignins and pectins, have a significant capacity to bind and exchange ions, particularly calcium, iron, magnesium, zinc, and phosphorus, and to adsorb materials such as bile salts, proteins, and bacterial cells [13].

Fermentation of fiber by colonic bacteria generates volatile short-chain fatty acids, acetate, propionate, and butyrate, which serve as a systemic fuel and as the preferred energy substrate of colonocytes [118]. In general, water-insoluble fibers (e.g., wheat bran, bagasse) are less subject to fermentation and hold more water than do the water-soluble fibers (e.g., vegetable fiber, pectins, gums). Therefore, water-insoluble fibers have a greater effect on stool mass than watersoluble fibers. However, the ingestion of degradable fiber stimulates bacterial growth and generates a fecal mass composed largely of bacteria. Although the total number of bacteria can be affected by diet, there is no convincing evidence that dietary changes produce major changes in the composition of colonic microflora [119].

The rate of gastric emptying and the rate of digestion and absorption are influenced by fiber components. Guar gum and pectins increase the viscosity of the chyme and slow gastric emptying, but particulate fibers (e.g., wheat bran) appear to promote more rapid gastric emptying [117]. Fiber can decrease or increase mouth-to-anus transit time depending on fiber type, particle size, and bulk-forming capacity [120].

Intestinal transit time and stool bulk are inversely related. A large particle size (e.g., coarse wheat bran) produces a greater increase in stool bulk and a greater decrease in transit time than does a small particle size (e.g., finely ground bran). The mechanism by which fiber decreases colonic transit time is unknown but may be related to an increase in colonic peristalsis secondary to increased fecal mass [120].

If dietary fiber prevents colon carcinoma (see "Chemoprevention of gastrointestinal cancers" above), it might do so by several mechanisms: a decrease in colonic transit time, so that the time that colonic mucosa is exposed to carcinogens is shortened; adsorption of carcinogenic sterols or other carcinogens; dilution of potential carcinogens by increasing stool volume; and alteration of the relative number of anaerobic and aerobic bacteria in the colon [121]. The treatment of irritable bowel syndrome with a high-fiber diet (especially a diet that includes wheat bran and commercial fiber supplements) has produced conflicting results, but overall no benefit has yet been demonstrated [122]. Several studies have shown that bran and other fiber supplements are effective in preventing constipation, but the side effects include flatulence, distention, and bloating, perhaps related to a long colonic residence time and bacterial fermentation [123].

Fiber may prevent and treat hemorrhoids by decreasing straining during defecation. Straining causes engorgement of the vascular cushion lining the distal rectum and anal canal, making it more vulnerable to shearing stress. The passage of hard fecal masses through the anal canal exacerbates these shearing forces and displaces the vascular cushion caudally, where it may be trapped temporarily by contraction of the anal sphincter [124]. A trial of fiber is a reasonable initial therapeutic approach for many patients who have hemorrhoids.

Micronutrients: minerals and vitamins

The RDAs and AIs are based on the amount of a nutrient needed for an individual to avoid deficiency, or on the average daily amount that populations must consume to prevent deficiency (see Table 21.5). Statistically, the RDA is set as two standard deviations above the mean requirement, so that 97% of healthy persons are covered. The RDAs thus exceed the needs of many healthy persons. They are established only for healthy persons and were never intended as guidelines for therapy. For some nutrients (e.g., sodium, chloride, potassium), the evidence suggests that daily requirements are much lower than the content of the average diet in the United States. The Food and Nutrition Board has provided an estimated minimal requirement for these nutrients (Table 21.10). The RDIs and DRVs were established in 1993 for the purposes of food labeling and are derived from the 1989 RDAs for micronutrients [125]. What appears on food labels are neither DRVs nor RDIs but daily values, reflecting the recommendations for a 2000-calorie reference diet.

Table 21.10 Adequate intakes for healthy persons for sodium, chloride, and potassium

Age	Sodium (mg/day)	Chloride (mg/day)	Potassium (mg/day)
0–6 months	0.12	0.18	0.4
7–12 months	0.37	0.57	0.7
1–3 years	1.0	1.5	3.0
4–8 years	1.2	1.9	3.8
9–12 years	1.5	2.3	4.5
19–50 years	1.5	2.3	4.7
50–70 years	1.3	2.0	4.7
> 70 years	1.2	1.8	4.7

The adequate intake (AI) does not allow for prolonged losses by vomiting, diarrhea, or excessive dieting. The AI is not equivalent to the recommended dietary allowance (RDA).
Adapted from Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine [12].

Minerals

Sodium [12]

Sodium, the principal cation in extracellular fluid, is necessary for maintenance of intravascular fluid volume and membrane potentials [125–127]. Total body sodium ranges from 48 to 60 mEq/g and is dependent on body size. The range for intake is 0.2–10.3 g/day. A 70-kg man has about 83–97 g of sodium in his body, about one-fourth of which is in the skeleton and cannot be exchanged. The kidney regulates sodium excretion by aldosterone action in the distal tubule in response to intravascular volume. Obligatory sodium losses are small compared with body stores. The minimum requirement to replace sweat, fecal, and urinary losses per day is about 0.18 g (8 mmol). Because almost all sodium is absorbed in the intestine, renal regulation of excessive sodium absorption is crucial.

Sodium is abundant in foods, not only as the chloride salt but as the bicarbonate, glutamate, phosphate, caseinate, benzoate, nitrate, propionate, sulfate, and citrate salts, among others. It is also present in many condiments, such as catsup, meat tenderizer, prepared mustards, olives, pickles, sauces, butter, margarine, and salad dressings. Water softeners can increase the content of sodium in water. Medications may contain sodium, although only a few contain enough to cause a problem.

Deficiency from inadequate intake alone is rarely encountered. Increased losses from the gut (e.g., vomiting, diarrhea, or drainage) or kidney (e.g., diuresis, salt-wasting renal disease, adrenal insufficiency) or excessive perspiration are the usual causes. Approximate mean concentrations of sodium in various fluids (in mmol/L) are sweat, 30–70; saliva, 10–20;

gastric juice, 70; bile, 145; pancreatic juice, 130; jejunal secretion, 115; ileal secretion, 100; and normal stool, 5.

Potassium [12]

Potassium is the primary cation in intracellular fluid, in which its concentration is 140–160 mEq/L [12,126–128]. The 2% of total body potassium present in the extracellular fluid is important in influencing resting membrane function, particularly in the cardiac muscle. The kidney is the major site of potassium excretion, which is normally regulated not by filtered load but by the action of aldosterone and systemic pH in the distal tubule. It is absorbed efficiently in the upper intestine but secreted in the colon, another aldosterone-sensitive tissue. Colonic secretion is aided by the electronegativity of the lumen. As with sodium, the amount lost in the stool is volume dependent. Most adults consume between 2 and 3.5 g daily. Abundant food sources (i.e., > 200 mg per portion) include meats and fish, vegetables (especially potatoes), nuts, fruits, and milk. In unprocessed foods, the usual anions are organic (e.g., citrate), whereas in processed foods with added potassium, the anion usually is chloride. Most salt substitutes use potassium chloride to replace sodium chloride, and contain about 2000 mg potassium per teaspoon. Moderate potassium deficiency occurs usually without hypokalemia, and is characterized by increased blood pressure in response to salt intake, increased risk of kidney stones, and increases in bone turnover. Hyperkalemia causes cardiac arrhythmias, muscle weakness, and glucose intolerance.

Calcium [8]

Calcium is the most abundant cation in the body. About 99% resides in bone; the other 1% is a crucial mediator for neural transmission, myocardial function, excitation and contraction of muscle, coagulation, cell division, maintenance of intercellular tight junctions, and enzyme function [8,129–132]. Many factors affect the intestinal absorption of calcium: lumenal pH, lumenal binders, transit time, the presence in the diet of the few foods that are rich in calcium, and vitamin D status [8,131]. The process is inefficient in that only about 33% of the daily calcium requirement is absorbed by the intestine, in part due to an obligatory loss of calcium each day from the intestine and kidney. During periods of growth or new bone formation, the calcium requirement increases. The risk for a negative calcium balance is great, especially during childhood, adolescence, pregnancy, or lactation. The RDA for adults is 1000 mg/day (see Table 21.5), but typical diets in the United States provide only about 750 mg/day [8]. Unlike many of the other RDAs, these recommendations are meant not as nutrient requirements for individuals, but as an average requirement for nearly all healthy persons in a particular life-stage or gender group. The debate continues regarding the need for calcium guidelines based on the relationship between calcium intake and bone health [133]. The RDA was raised for adolescents to 1300 mg/day, based on increased bone growth during this life stage. The increased recommendation in older persons to 1200 mg/day is based on decreased calcium absorption in that group. Milk and dairy products are the richest source of calcium (providing about 60% of dietary calcium), and it is most bioavailable in those sources in the form of calcium citrate, but, there is little evidence for its superiority in promoting bone mineralization [134]. Each 225-g (8-oz) cup of milk contains about 280–300 mg of calcium. Green leafy vegetables are a good source, but the bioavailability is more irregular than that in milk products because the calcium is present as the phytate, oxalate, or other organic anion salt. These salts are poorly ionized and absorbed. The single universal requirement for calcium intake at each life-stage without reference to intake of protein, sodium, or phytate has been challenged, based on the observation that calcium intakes are low in parts of the world where fracture rates are low, but protein intake also is low, whereas phytate intake is high [135]. Other rich dietary sources are fish with edible bones, such as sardines and salmon.

Lumenal calcium is most actively transported in the duodenum, but in humans most calcium is absorbed in the ileum [129]. About 150–300 mg is secreted into the lumen each day. After glomerular filtration, about 98% of calcium is reabsorbed by the renal tubules [132]. Normal levels of serum calcium are tightly regulated by the action of parathyroid hormone and vitamin D and are not related to total body stores, except when deficiency is severe. Bone density is not a sensitive indicator of calcium deficiency, but it is a measure of body stores, and its determination can detect decreases in bone mass exceeding 1%–2% [136]. Ionized serum calcium is a measure of the hormonally regulated calcium concentration. Half of serum calcium is protein bound, 10% is complexed with anions, and 40% is ionized and physiologically active. Under most circumstances, ionized serum calcium reflects body stores, but when acutely altered, its concentration may be low in the presence of normal total body calcium [137].

Magnesium [8]

Magnesium is the second most abundant intracellular cation. About 70% of the total is in bone, and the rest is in soft tissues. Less than 1% is in extracellular fluids, where 20%–30% is bound to protein. Serum magnesium levels do not closely mimic body stores. The magnesium concentration in cells is high, like that of potassium, but magnesium leaves the cells less readily. Magnesium is important for neuromuscular transmission, and it is an essential cofactor in many enzyme reactions, including oxidative phosphorylation and nucleic acid synthesis. It also plays a role in wound healing, myocardial contractility, membrane stability, and coagulation [138–141].

The RDA averages about 350 mg (29 mEq) for adults: 400–420 mg for men and 310–320 mg for women. The typical

adult diet in the United States provides 20–40 mEq/day. Food sources are well distributed, but nuts, cereals, seafood, meats, legumes, and green vegetables are rich food sources [138,139]. Like that of calcium, the intestinal absorption of magnesium is relatively inefficient (i.e., 30%–40%), and most absorption occurs in the ileum. However, magnesium differs from calcium in that there is little obligatory intestinal loss, so magnesium balance is maintained even with a low dietary intake if no abnormal losses occur. Loss from the body occurs in regulated function, mostly through the kidney (2%–3% of the filtered load) [138–141]. Serum magnesium is the standard for assessing body stores, but it is falsely elevated by hemolysis and does not always reflect either intracellular stores or active extracellular ionized magnesium [125,137].

Phosphorus [8]

Phosphorus is the major intracellular anion (100 mmol/L) [141–143]. It is essential for normal membrane function, regulation of enzyme systems, and generation and storage of energy. It affects the delivery of oxygen to tissue by regulating the concentration of 2,3-diphosphoglycerate in red blood cells. However, 80%–85% of total body phosphorus resides in bone.

The requirements for phosphorus parallel those of calcium. The new RDA is only 700 mg/day for adults, somewhat below the DRI for calcium, although daily intakes in the United States range from 1000 to 1500 mg. Like magnesium, urinary phosphorus excretion does not reflect a low dietary intake, so balance studies are misleading. Moreover, the efficiency of phosphorus absorption varies with the food source and the dietary calcium-to-phosphorus ratio. In general, if protein intake is adequate, so is phosphorus intake [8]. Phosphorus is a constituent of all cells and is abundant in most foods, especially meats, dairy products, and carbonated beverages. The amount of phosphorus in food additives is increasing, a change that can lead to decreased bone mass [144]. Phosphorus is a component of some gut lavage preparations (e.g., Fleet, Accu-Prep, Visicol, Fleet Phospho-soda). The absorption of phosphorus requires hydrolysis of the organic phosphates in food by intestinal alkaline phosphatase and is promoted by the action of 1,25-dihydroxyvitamin D-3. Five sodium-dependent phosphate cotransporters (NPT) have been identified [143]. It is the NPT2b form, expressed in the small intestine, that mediates phosphate absorption. Net absorption is 60%–80% of ingested phosphorus. The kidney adjusts phosphate excretion over a wide range, mostly using NPT2a but also NPT2c and NPT3, so deficiency from low intake or malabsorption is rare. In fact, reabsorption can increase to 99.8% if the dietary intake of phosphorus is low [141].

Iron [11]

The body stores of iron are not regulated by increased or decreased excretion, but rather by control of the rate of intestinal absorption, which is increased during deficiency. Daily losses normally occur from the gastrointestinal tract, skin, and urine. Fecal losses predominate, ranging from 6 to 16 mg/day, most of which is unabsorbed dietary iron. About 1 mg of endogenous iron is lost in the stool per day. Additional losses occur from the uterus in women, amounting to 0.5–1.0 mg/day averaged over a whole month. The requirements for iron per kilogram of body weight are highest during infancy (because of low body stores), periods of rapid growth (adolescence and pregnancy), and periods of excessive loss (menstruation).

The RDA assigned by the 2001 DRI Committee for all age groups of men and postmenopausal women is 8 mg/day; the RDA for premenopausal women is 18 mg/day [11]. The recommended intake during pregnancy is 27 mg/day. At birth, even the child of an iron-deficient mother has normal stores because the fetus has priority for available iron. Milk is a poor dietary source of iron, but the AI for infants aged 0–6 months has been set at 0.27 mg/day, based on the daily amount of iron in ingested milk (~ 0.35 mg/L). It is assumed that milk intake and requirements correlate with body size. Therefore, this AI may not be sufficient for infants with a lower milk intake. Three months after birth, the requirement for iron increases because of growth, and the RDA of 11 mg/day for infants aged 7–12 months assumes that feedings complementary to milk are in place. It is during this period that the infant is most at risk for iron deficiency. During adolescence, the hemoglobin level rises 0.5–1.0 mg/dL per year, requiring 50–100 mg of iron per year, and 300 mg during adolescence.

Food iron is available in a variety of red meats, nuts, seeds, and egg yolks. Milk products, potatoes, and fresh fruit are poor sources. Iron availability can vary by as much as 10-fold between meals with similar iron content [145]. Iron in vegetables varies according to growth conditions of the plant. Heme iron in vegetables is not so readily available for absorption as that in meat. Heme iron requires reduction to the ferrous state (by ascorbic acid) for maximal absorption. Heme iron accounts for less than 40% of dietary iron in the United States. The iron content of some foods (e.g., bread flour) is increased by fortification. Iron supplements can decrease absorption efficiency of dietary iron. Vegetarians are at risk for dietary iron deficiency because of the more limited absorption of nonheme iron. Iron is involved in many reactions as a cofactor for enzymes (heme or otherwise) and as a major constituent of heme as an oxygen-carrying cofactor.

Iron is absorbed primarily in the duodenum and upper jejunum. The absorption of inorganic iron is enhanced by gastric acid, ascorbic acid, and other organic acids, including the amino acids histidine, lysine, and cysteine, which form iron chelates [11,146]. Absorption is decreased when iron forms an insoluble complex in the lumen with dietary phytates or phosphates, or with antacids or other medications. In the duodenal lumen, dietary iron is reduced to the ferrous state by ferric reductase (Dcytb, duodenal cytochrome b),

transported into the cell by the divalent metal transporter, DMT1, and released by way of ferroportin into the circulation [147]. Hephaestin is another protein that facilitates iron release from the enterocyte. Hepatocytes take up iron, either free or bound to transferrin (Tf), by Tf receptor 1 or 2. The TfR2 receptor is the major sensor of circulating Tf–iron complexes and influences the expression of hepcidin, the protein that downregulates ferroportin-mediated iron release from enterocytes, macrophages, and hepatocytes [148]. Hepcidin levels are inappropriately low in hereditary hemochromatosis, and are increased in patients with inflammatory conditions. Hepcidin appears to be the major gatekeeper for iron absorption. Normally about 10% of iron is absorbed, but in iron deficiency states this can increase to 30%. After absorption, iron is stored as ferritin in the liver, spleen, and bone marrow. The functional compartment of iron (hemoglobin, myoglobin) accounts for most of the total body iron, ranging from about 2180 to 2750 mg for the average woman and man, respectively.

Zinc [11]

The body contains 1.5–2.5 g of zinc, so that it is the second most abundant trace mineral after iron. Although the turnover of isotopic zinc in adults is 6 mg/day, balance studies show that 12.5 mg of dietary zinc is needed to maintain positive balance [11]. The daily loss of 2.5 mg/day is mostly in feces, and absorption ranges from 20% to 40% of dietary zinc, depending on the fiber content of the diet (inversely related). Zinc bioavailability from a vegetarian diet is moderate (30%–35% is absorbed) with phytate:zinc ratios of 5:15. More zinc may be needed in diets that are high in legumes, whole grains, seeds, and nuts, because in those diets the phytate:zinc ratio may approach 15. The 2001 DRI Committee report set the RDA at 9 and 8 mg/day for girls and boys aged 9 to 13 years, respectively, and at 8 and 11 mg/day for adult women and men, respectively [11]. The RDA for pregnancy is 13 mg for adolescents and 11 mg for women older than 18 years. During lactation, the RDA is increased by 1 mg/day.

Like other divalent cations, zinc is absorbed inefficiently along the entire length of the small intestine. A series of zinc transporters have been identified in humans. Zinc transporters have a binding domain that is rich in histidine residues. These transporters are thought to be important in absorption, and include: ZnT1, which is expressed in duodenal and jejunal villi; DCT1, which directs the influx of iron, zinc, copper, cadmium, and manganese; and ZnT1 and ZnT2, which mediate the efflux of the same minerals [149]. Zinc absorption is decreased by lumenal binders (phosphate and others), as is the absorption of calcium and magnesium [150]. Inorganic iron, especially when ingested as a supplement, impairs inorganic zinc absorption [151]. Absorption can be enhanced, however, by animal proteins and sulfur-containing amino acids, and by hydroxy acids [152]. Zinc absorption may be increased during states that increase demand for the mineral, including infancy, pregnancy, and lactation.

Zinc plays a critical role in the growth and function of cells. It is a cofactor for many enzymes that participate in the metabolism of carbohydrate, fat, and protein [11]. It is necessary for cell growth and proliferation, sexual maturation, reproduction, and dark adaptation and night vision, and it may play a role in wound healing and immune defenses. Finally, it may activate or inhibit enzymes, modify membrane functions, or bind to DNA transcription factors.

Copper [11]

Copper is an essential trace mineral for humans. Estimates of copper requirements are based on balance studies, fecal and other losses, and absorption at each life stage [11]. Obligatory losses for adults are about 580 μg/day, and absorption averages about 25% of dietary copper intake. Most absorbed copper is excreted in bile, although some biliary copper is reabsorbed by way of an enterohepatic circulation [153]. When intestinal and biliary losses occur, the copper requirement increases. The AI for infants is based on intake of milk (120 μg/L) and is set at 200 μg/day for infants aged 0–6 months and 220 μg/day for infants aged 7–12 months. The RDA is 900 μg/day for men and women aged 19 years or older [11].

The body contains about 100 mg of copper, 30 mg of which is bound to proteins and enzymes. The liver contains about one-third of the body stores of copper, mostly in enzymes, including ceruloplasmin, cytochrome oxidase, superoxide dismutase, tyrosinase, lysyl oxidase, and histaminase [154]. Copper is important for normal skeletal and nervous system development, erythropoiesis, leukopoiesis, and iron absorption, and as an antioxidant.

Copper absorption is efficient (35%–70%) compared with the absorption of other trace elements, but the efficiency is reduced in the elderly. Copper absorption and intracellular metabolism are complex processes [155]. A high-affinity copper transport protein, hCtr1, may transport copper across the apical enterocyte membrane by endocytosis. There is no free copper in the cell because it is bound to chaperones (e.g., to CCS, the chaperone for copper and zinc, and to metallothioneins 1 and 2) [155]. The Menkes disease protein, ATP7A, is a membrane-associated P-type ATPase that is required for copper secretion into the portal vein. Hephaestin is a multicopper oxidase that is a membrane-bound analogue of ceruloplasmin required for iron (but not copper) secretion from the intestine [156]. Absorbed copper is transferred in plasma to ceruloplasmin and albumin, and it is taken up by the liver by hCtr1-mediated transport. It is distributed to various cellular compartments by a series of small cytoplasmic copper chaperones [155]. In all tissues apart from the liver, ATP7A mediates copper efflux in the Golgi apparatus and subsequently in the plasma membrane, as the protein moves to the plasma membrane. In the liver, copper is guided to ATP7B, a copper-transporting ATPase, by the Wilson disease protein,

ATOX1, a metal chaperone [157]. Copper is then bound to glutathione and metallothionein. The multicanalicular organic anion transporter, cMOAT, transports the copper–glutathione complexes into bile. When intracellular levels of copper increase, ATP7B is redistributed to exocytic vesicles for delivery to bile, similar to the process for the Menkes gene protein ATP7A in nonhepatic cells.

Other trace minerals

Selenium is essential to the antioxidant system, being a component of more than 20 selenoproteins, including six glutathione peroxidases [10,158]. Thus, its function is linked with that of vitamin E. Chromium potentiates the action of insulin at the cell receptor level and plays a role as a cofactor for insulin [159]. Manganese is a cofactor for many enzymes with widely varying functions, from superoxide dismutase to hydrolases and kinases, but a deficiency state in humans has not been identified [11]. Iodine is an essential component of the thyroid hormones and is thus integral to their function [11,125]. Iodine is transported by the sodium/glucose cotransport family solute carrier SLC5 [160]. Fluoride is concentrated in bones and teeth and is required for normal growth. The major source of fluoride is fluoridated water. Although deficiency of most of these minerals occurs in humans, the occurrence of such deficiency is unusual in developed countries. For this reason, they are used in clinical practice primarily as TPN supplements.

Vanadium, nickel, cobalt, tin, and silicon are considered essential in mammals because deficiencies have been produced experimentally, but human deficiencies have not been reported [11]. Other elements, including cadmium, lead, boron, aluminum, arsenic, mercury, strontium, and lithium, have not yet been proved essential. Most of these elements, with the exception of boron, are probably present in sufficient quantities as contaminants in TPN solutions [161].

Vitamins

Thiamin (vitamin B-1) [9]

Thiamin is essential for the function of many enzyme systems and plays a major role in energy production. Thiamin pyrophosphate is a coenzyme in the oxidative decarboxylation of α-ketoacids to aldehydes, and it catalyzes transketolase activity in the pentose phosphate cycle. It is important for nucleotide synthesis and provides cofactors for fatty acid synthesis. Blood pyruvate levels increase with thiamin deficiency. The requirement usually is related to the intake of energy, especially carbohydrate. The RDA for adults is 0.5 mg thiamin for every 4184 kJ (1000 kcal) in the diet [9]. Allowances are based on the effects of varying dietary thiamin and the relationship with signs of clinical deficiency or with urinary excretion of thiamin or serum transketolase activity. Thiamin is synthesized by many plants. It is abundant in all foods and is added to many commercial baked products and cereals. Because thiamin is lost easily in the cooking and processing of food, its content in food varies according to preparation. Thiamin is transported into cells by the SLC19 folate/thiamin transporter family; specifically, the A2 and A3 types [162]. In polarized cells, such as enterocytes, thiamin is found at the apical and basolateral membranes (Table 21.11).

Riboflavin (vitamin B-2) [9]

Riboflavin is a major component of two essential coenzymes: flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). It forms the active portion of these coenzymes, which are involved in biological oxidations. Riboflavin requirements are linked with metabolic function, like those for thiamin. However, unlike the requirements for thiamin, those for riboflavin are unrelated to food energy intake. The RDA is set at 1.1 mg/day and 1.3 mg/day for adult women and men, respectively [9]. Requirements have been assessed by measuring urinary excretion and by observing signs of deficiency. Riboflavin is available in all leafy vegetables, in meats and fish, and in milk and eggs. The average Western diet contains about 2.7 mg/day. The vitamin can be lost during food processing and by the action of ultraviolet light. Absorption is efficient and occurs by an active carrier-mediated process in the small intestine. Riboflavin enters the plasma as free flavin mononucleotide (FMN) or riboflavin, and after dephosphorylation of flavin adenine dinucleotide (FAD) and FMN, is reformed into FAD and FMN inside the enterocyte. The vitamin is rephosphorylated to permit transport across the basolateral membrane, and is excreted from the kidney unmetabolized [163].

Niacin (vitamin B-3) [9]

The term "niacin" encompasses nicotinic acid and its amide form, nicotinamide. It is a component of two coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which participate in more than 50 metabolic reactions. Humans can synthesize about 1 mg of niacin from 60 mg of the amino acid tryptophan. Deficiency depends on the limited availability of niacin and tryptophan [164]. The RDA is reported in niacin equivalents (NEs) (1 NE = 1 mg of niacin = 60 mg of tryptophan). The RDA has been estimated at 14 mg and 16 mg NE daily for women and men aged 14 years or older, respectively [9]. Average Western diets provide 16–24 NE/day. Nicotinic acid is present in most foods, except fats and oils. Meat, fish, and grain products are good dietary sources. Much is lost during grain processing, but it is added as fortification to the finished products. Niacin is well absorbed in the small intestine by a sodium-independent, acid-sensitive process.

Pyridoxine (vitamin B-6) [9]

The term "vitamin B-6" refers to three naturally occurring pyridines: pyridoxine, pyridoxal, and pyridoxamine. All forms function similarly. Vitamin B-6 is essential for the function of

Table 21.11 Mechanisms of absorption of water-soluble vitamins

Vitamin	Source of ingested vitamin	Transporter	Extent documented	Intracellular regulation
Thiamin (B-1)	Diet, bacteria	Human thiamin transporters 1 and 2 SLC19A2 and SLC19A3 genes	Small bowel? colon, apical < basolateral	Ca^{2+}/calmodulin
Riboflavin (B-2)	Diet	Na-independent carrier-mediated	Small bowel, colonocytes	PKA, Ca^{2+}/calmodulin
Niacin (B-3)	Diet, metabolism (from tryptophan)	Na-independent, acid-dependent	Small bowel	Tyrosine kinase
Pyridoxine (B-6)	Diet	Na-independent		PKA-mediated
Biotin	Diet, bacteria	Na-dependent multivitamin transporter (SMVT)	Small bowel	PKC, Ca^{2+}/calmodulin, biotin (extracellular)
Pantothenic acid	Diet, bacteria	SMVT	Small bowel, colonocytes	
Folate	Diet, bacteria	Reduced folate carrier	Small bowel, pancreas, apical > basolateral	Tyrosine kinase, cAMP, pH-dependent
Cobalamin (B-12)	Diet	Cubilin–amnionless complex	Small bowel, proximal renal tubule, choroid plexus, apical	Development
Ascorbate (C)	Diet	Na-dependent vitamin C transporter SVCT1 (SLC23A1 gene), facilitated glucose transporters GLUT1, GLUT3, and GLUT4 for dehydro-L-ascorbate	Small bowel, apical SVCT2 basolateral	PKC-mediated Ascorbic acid (extracellular)

cAMP, cyclic adenosine monophosphate; PKA, protein kinase A; PKC, protein kinase C.

many aminotransferases and amino acid decarboxylases. It is involved in the metabolism of all amino acids and in the synthesis of acetylcholine, porphyrin, arachidonic acid, dopamine, serotonin, and bile acids. Requirements are increased with a higher protein intake. The RDA for adults aged 19–50 years is 1.3 mg/day for average protein intake. Low levels of all three forms are present in all foods, with meats, fish, and grains being good sources. The vitamin B-6 allowance has been estimated by using a ratio of 0.016 mg of vitamin per gram of protein ingested. Because energy and protein intakes are lower in the older population, RDAs are increased for persons older than 50 years, and the estimates for women (i.e., 1.5 mg/day) are lower than those for men (i.e., 1.7 mg/day) [9]. Vitamin B-6 is synthesized by microorganisms in the intestine, primarily in the colon, where the vitamin is not absorbed. Vitamin B-6 is rapidly absorbed in the small intestine by a sodium-independent transporter, and is excreted in the urine as the metabolized product, 4-pyridoxic acid. Certain drugs are pyridoxine antagonists (e.g., isoniazid, hydralazine, penicillamine). A deficiency of vitamin B-6 and other B vitamins can occur in chronic alcoholics.

Folate (folacin, folic acid) [9]

"Folacin" is a generic term for compounds that have a structure and function similar to that of folic acid, that is, pteroylglutamic acid (PGA). The many forms differ in the degree of reduction of the double bonds in the ring structure (e.g., tetrahydrofolate), the presence of 1-carbon groups (e.g., methyltetrahydrofolate), and the number of glutamyl residues in the peptide chain (e.g., folate pentaglutamate). Folate functions as a carrier of 1-carbon groups from donor to recipient molecules and is necessary for the synthesis of nucleic acids, the initiation of protein synthesis, and the synthesis of acetylcholine and methionine. Three other vitamins – cobalamin, ascorbic acid, and niacin – are involved in converting folate to its active coenzyme forms [9,165]. Pteroylglutamic acid is the form of folate used commercially, and it is a relatively poor substrate for dihydrofolate reductase. As a result, tissue utilization is poorer for PGA than for natural methylated or reduced folates found in food. However, folate requirements have been based on replacement with PGA.

The RDA for folate has been modified dramatically from the 1989 estimate of 200 μg/day for adults to 400 μg [9]. This change was the result of recognition of the role of folate in reducing the incidence of neural defects [166], and the role of elevated serum homocysteine concentrations as a cardiovascular risk factor [167]. Dietary folate is reported in folate equivalents, in recognition of the greater bioavailability of synthetic folic acid compared with natural folate. The RDA

for women aged 14–50 years is 400 μg/day, and should comprise synthetic folic acid plus dietary folate. During pregnancy, the amount of synthetic folic acid is specified at 400 μg/day [9].

The vitamin is abundant in citrus juices, enriched cereals and breads, legumes, liver, nuts, and green leafy vegetables. To prevent neural defects, the US Food and Drug Administration (FDA) has, since 1998, required that all cereal grains are fortified with 140 μg of folate/100 g of grain [168]. It is estimated that this supplements the average daily dietary intake (50–500 μg) by 215–240 μg, and the incidence of neural defects has decreased by about 25%. Folate occurs in food largely in the polyglutamate form, and its bioavailability generally is high. However, boiling, steaming, or frying can lead to significant losses. Folate is absorbed in the proximal small intestine through active transport mediated by the reduced folate carrier, the apical SLC19A1 sodium/folate cotransporter [162]. It is converted in the liver and other tissues to the 5-methyltetrahydrofolate form and is stored as polyglutamate [169]. Total body stores are relatively small and can be depleted in a few months if dietary intake is negligible. Folate can enter the serum or the bile and be reabsorbed, undergoing an enterohepatic circulation amounting to about 100 μg/day. In diseases that cause malabsorption, body stores of folate are lost more rapidly than in simple dietary deficiency.

Cobalamin (vitamin B-12) [9]

Cobalamin contains a cobalt atom to which are bound active groups, including hydroxy-, methyl, and nitro- moieties. The vitamin functions as a carrier for methyl and hydrogen groups. It is required for reactions catalyzed by two enzymes, methionine synthase and methylmalonic acid mutase, and thus participates in methionine and succinyl-CoA synthesis. The total body content of cobalamin is 2–2.5 mg, most of which is in the liver, and the half-life is 1.5–3.5 years. Thus, daily losses average about 1.3 μg/day. The RDA was set at 2 μg/day for adults, based on 70% absorption efficiency [9]. However, because 10%–30% of adults older than 51 years may have protein-bound cobalamin malabsorption, the new RDA has been set at 2.4 μg/day [9]. Although this malabsorption probably is caused by reduced pepsin and gastric acid secretion, most elderly persons have some intrinsic factor. Thus, it is recommended by some experts that most intake in older persons be in the form of a dietary supplement, to ensure its adequacy [170]. The vitamin is synthesized only by bacteria and enters animal tissues after the ingestion of contaminated foods or production in the gut lumen. It is found only in animal products, including meat, fish, eggs, and milk. The average Western diet contains 5–15 μg/day. Cobalamin is relatively stable during cooking and processing.

The absorption of cobalamin is complex [171]. In food, it is bound to enzymes from which it is released by gastric proteases. It is bound to haptocorrin in the stomach, released from haptocorrin by the action of pancreatic enzymes, and then bound to intrinsic factor, with which it is absorbed in the ileum by the process of receptor-mediated endocytosis. The receptor for the intrinsic factor–cobalamin complex, cubilin, is a large, multifunctional protein that also binds apolipoproteins [172]. Studies of the mutations in Imerslund–Grasbeck syndrome (congenital vitamin B-12 malabsorption) have uncovered a 45–50-kDa transmembrane protein that colocalizes with cubilin, called amnionless (AMN) [173]. The amino-terminal portion of AMN directs endocytosis, and is essential for cobalamin absorption, whereas the carboxy terminal is necessary for embryonic development. In the enterocyte, the vitamin is released from intrinsic factor, bound to transcobalamin II, and delivered to the tissues complexed to that protein. It is released into the bile bound again to haptocorrin, and 5–10 μg/day undergoes an enterohepatic circulation. As with folate, body stores are lost more rapidly if malabsorption is present because endogenous as well as dietary cobalamin is lost.

Ascorbic acid (vitamin C) [10]

Ascorbic acid is an essential cofactor for several hydroxylation reactions and plays a key role in the synthesis of collagen. It may also function as an antioxidant for vitamins A and E, and is involved in the formation of norepinephrine (noradrenaline) and serotonin. This role in neurotransmitter synthesis may explain the fatigue and weakness seen in scurvy [174]. A daily intake of 10 mg of ascorbic acid cures clinical signs of scurvy but does not maintain body stores. The previous RDA of 60 mg/day produced wide fluctuations in plasma levels. The ascorbic acid requirement is also compounded by its possible chemoprotective value in some disorders (e.g., colon cancer, heart diseases, cataracts), at doses far in excess of those needed to prevent scurvy. Intake of 200 mg of ascorbic acid per day is needed to begin to saturate tissues, an intake that approximates the vitamin C content of diets (~ 225 mg/day) that allow maximal protective effects of the vitamin [175]. The new DRI values represent a compromise between the old RDA value and those needed for chemoprevention, and are set at 75 mg/day and 90 mg/day for adult women and men, respectively [10]. During pregnancy and lactation, the RDA should be increased by 10 mg/day and 45 mg/day, respectively. The vitamin is especially concentrated in green vegetables and citrus fruits, although it is widespread in foods. The vitamin C content of food depends on the state of ripeness and on the method of preparation because ascorbic acid is sensitive to heating and oxidation. It is well absorbed in the small intestine by two sodium-dependent cotransporters (SVCT1 and SVCT2) at intakes of up to 180 mg/day [176]. Over that amount, the proportion appearing in the stool increases, and at high doses (> 3–4 g/day), diarrhea can result.

Biotin [9]
Biotin is a coenzyme for various carboxylases and is important in the metabolism of carbohydrate, protein, and fat [177]. It is produced by colonic bacteria and absorbed in the small bowel and colon by facilitated diffusion. Because of this endogenous production, an RDA has not been determined, but the AI for adults has been estimated at a DRI of 30 μg/day [9]. Absorption of the vitamin is mediated by a sodium-dependent multivitamin transporter (SMVT) [178].

Pantothenic acid [9]
Pantothenic acid is a precursor of CoA, which is essential for the metabolism of fats, carbohydrates, and proteins and for the synthesis of steroids and porphyrins [9,179]. It is widely distributed in foods, especially animal tissues, whole-grain cereals, and legumes. Microflora may produce some pantothenic acid, but the data in humans are not clear. Although an RDA has not been established, the estimated AI for older adolescents and for adults is 5 mg/day. Pantothenic acid is well absorbed in the intestine by means of SMVT, and is excreted unchanged in the urine.

Vitamin A [11]
Vitamin A is the collective term for vitamin A alcohol (retinol) and its related biologically active forms. It is essential for growth and development, the maintenance of epithelial cells, the stability of cell membranes, reproduction, and vision in dim light [11,180]. The β-carotenes are precursors of vitamin A and appear to have additional beneficial functions, probably as antioxidants [181]. The DRI allowance for vitamin A is based on many nutritional studies and amounts to 900 μg of retinol per day for men and 700 μg/day for women [11]. The recommendations for β-carotene are even more complex because no reproducible biological activities are available to establish adequate intake. Some epidemiological studies show correlations between low serum levels (still in the normal range) and protection from cancer, but intervention studies have not been positive [182]. Moreover, some carotenoids (e.g., lutein) are accumulated in the retina preferentially, whereas others (e.g., lycopene) lack provitamin A function but exhibit other biological activity. The data were judged by the DRI Committee to be insufficient to make a recommendation on the required percentage of dietary vitamin A that must be derived from provitamin A carotenoids [11].

Vitamin A synthesis is limited to plants and microorganisms. Its activity in foods usually is expressed in international units (IUs) and an equivalent value established with retinol activity, accounting for both vitamin A and provitamin compounds in the diet. The previously accepted 6:1 equivalence of β-carotene to vitamin A has been questioned because of the inefficient bioconversion of plant carotenoids. Thus, the new conversions are 1 retinol equivalent (RE) = 1 μg of all-*trans*-retinal, or 12 μg of β-carotene, or 24 μg of mixed carotenes. One RE is also equivalent to 3.3 IU of retinol activity or 10 IU of β-carotene activity. This means that older food tables have overestimated the vitamin A activity in foods. This change may be of special importance in less-developed countries that rely mostly on vegetable products for their vitamin A. Animal products are rich sources, including liver, kidney, dairy products, and eggs. Carotenoids, especially β-carotene, are found in green and yellow vegetables. There are more than 400 carotenoids in foods, only about 60 of which have provitamin A activity. In the United States, dairy products and margarines are supplemented with retinyl esters, and these products are the major dietary source of the vitamin.

Vitamin A, ingested in the form of long-chain retinyl esters, is hydrolyzed to retinol by lipases and esterases in bile and pancreatic secretions or in milk. More than 80% of the vitamin is absorbed passively by an as yet unknown mechanism, reincorporated into retinyl esters, packaged into chylomicrons, transported in the lymphatic circulation, and stored in the liver, which controls release of the vitamin [11,183]. Carotene is absorbed passively, but less well than vitamin A (40%–60%). Most is hydrolyzed to retinol inside the enterocyte, and a small amount is absorbed intact. After vitamin A is released from the liver, it is transported in the plasma as a trimolecular complex with retinol-binding protein and transthyretin [183]. If stores are adequate, any excess vitamin A is excreted in bile. A small amount is excreted in urine along with other metabolites. About 10% of hepatic retinol is converted to retinoic acid, which in turn is conjugated with glucuronide and undergoes enterohepatic circulation. As in the case of folate, cobalamin, and 1,25-dihydroxyvitamin D, this enterohepatic circulation leads to the loss of endogenous as well as dietary vitamin A if malabsorption occurs.

Vitamin D [8]
Vitamin D is the designation for a group of sterols and their metabolites that have antirachitic activity [8]. Cholecalciferol (vitamin D-3) is formed in the skin from 7-dehydrocholesterol by the action of ultraviolet light, and about 100 IU/day (10 μg = 400 IU) is produced in persons living in the temperate zone [184]. Ergocalciferol (vitamin D-2) is present in plants. Vitamin D is a provitamin, with the active metabolite being 1,25-dihydroxyvitamin D. The active vitamin promotes the intestinal absorption of calcium and phosphorus, in conjunction with parathyroid hormone. The vitamin is necessary for normal bone formation and regulates calcium and phosphorus metabolism in bone and kidney [185]. Vitamin D may play an important role in the prevention of chronic diseases other than osteoporosis, such as cancer and diabetes [184], but more studies will be needed before it is known if providing additional vitamin D will alter the outcomes in these diseases.

Table 21.12 Potential candidates for functions/indicators of vitamin D sufficiency

Indicator	Vitamin D effect on function	Indicator of insufficiency
Serum (s) Ca^{2+}, P	Normal serum levels maintained	↓ [Ca]s, ↓ [P]s
Calcium absorption	Optimizes absorption	↓ % absorption of Ca^{2+}
Parathyroid hormone (PTH)	Active transport of Ca^{2+}, restores [PTH]s	↑ [PTH]s
Fracture risk	↓ PTH levels to normal, ↓ bone turnover	↑ Risk related to D status
Muscle strength	Active transport of PO_4, ↓ PTH, restores intracellular [PO_4]	↓ Muscle strength
Bone turnover	Normalizes turnover	↓ Turnover, ↑ resorption
Immunomodulation	Maturation of antigen-presenting cells	↑ T-cell proliferation, ↓ killer cells
Cell proliferation	↓ Proliferation	More cells in G1 vs G2 phase

A major problem in determining an estimated average requirement (EAR) for vitamin D is that the indicator for adequacy is not clear (Table 21.12) [186]. The potential indicators to identify insufficiency reflect the multiple actions of vitamin D. Because more than 90% of circulating 25-hydroxyvitamin D-3 is derived from skin and is endogenously produced, daily requirements have not been established [186]. The DRIs are based on AIs. Because vitamin D deficiency is more prevalent in older adults, the recommended AI for adults older than 50 years is twice that of younger adults (10 vs 5 μg/day, or 400 vs 200 IU), and for adults older than 70 years it is tripled (15 μg/day) [8]. However, some experts feel that the AI should be as high as 800 IU/day, based on the amount needed to achieve levels of $25(OH)_2$-vitamin D sufficient to suppress parathormone levels [184].

Vitamin D occurs naturally in foods of animal origin, such as fish-liver oils, eggs, liver, and dairy products. Fortified foods supply the major dietary sources, although most vitamin D is made endogenously. Vitamin D is absorbed in the small intestine along with other lipids, but it requires bile salt micelle formation for efficient absorption. It is transported in the lymph with chylomicrons and other lipoproteins. The serum content of vitamin D is not limited by the content of the specific vitamin D-binding protein, and the ingestion of excessive doses can produce toxic levels of vitamin D or its metabolites in the serum. Vitamin D is stored in fat depots (e.g., liver, adipose tissue) and muscle, and it is released slowly. The 25-hydroxyl group is added in the liver, and the 1-hydroxyl group in the kidney. 1,25-Dihydroxyvitamin D and other polar metabolites are excreted in the bile and undergo an enterohepatic circulation. Malabsorption disorders produce earlier deficiency because endogenous as well as exogenous vitamin is lost. Small amounts of the vitamin are excreted in the urine.

Vitamin E [10]

The term "vitamin E" refers to two groups of lipid-soluble compounds, tocopherols and tocotrienols, that are found in plants. α-Tocopherol is the most active and abundant of these compounds. These compounds function as fat-soluble antioxidants and free-radical scavengers, in conjunction with the selenium–glutathione peroxidase system. The natural form is complex, covering eight different structures produced by plants (tocopherols α, β, γ, and δ, plus corresponding tocotrienols) [187]. Tocopherols contain a phytyl tail with three places that could be in either L- or R-configuration. Commercial vitamin E is a mixture of tocopherols and tocotrienols. α-Tocopherol is all *RRR*-α-tocopherol. The bioavailability of these forms varies, but the capsule form of vitamin E may be relatively less readily available [188]. The RDA previously was based on the assumptions that the diet had no more than 0.1 ppm of selenium, average amounts of sulfur amino acids, a ratio of vitamin E to PUFAs of 0.4, and less than 1.5% linoleic acid in a diet containing 7500–12 500 kJ (1800–3000 kcal). Later recommendations also consider the possible role of vitamin E as an antioxidant in preventing disease, the increased intake of PUFAs in the United States, and the serum vitamin E values from NHANES III (Third National Health and Nutrition Examination Survey, 1998–1994) [10]. Thus, the new DRIs are set about 50% higher than the 1989 levels (15 mg/day for adults). The vitamin is abundant in the lipids of green leafy plants, in vegetable oils, and in seeds. Foods high in PUFAs also are excellent sources of vitamin E [10,187].

Vitamin E is absorbed passively from the small intestine with other lipids, and its absorption, like that of other fat-soluble vitamins, requires bile salt micelles. Only about 40% of an oral dose is absorbed. The natural form is an acetate ester; bile salt-dependent pancreatic esterase also is required for absorption. There is no specific serum carrier for vitamin E. Because it is bound to LDL and other lipoproteins, serum levels are proportional to total lipids. The vitamin is delivered to the liver after the action of lipoprotein lipase, and from the liver it is delivered in lipoproteins to adipose tissue, where it is stored. Tocopherol-associated proteins (TAPs) may be important in lipoprotein transfer. α-Tocopherol transfer protein (TTP) activity is mediated by the ABCA1 transporter. Both TTP and TAP belong to a family of hydrophobic ligand-binding proteins with a *cis*-retinal-binding motif sequence (CPAR-TRIO) shared with cellular retinol-binding protein,

but the mechanism of hepatic secretion of vitamin E is unclear [189]. Excess vitamin E is excreted in bile or metabolized by β- or ω-oxidation by cytochrome P450-dependent hydroxylases [190]. Vitamin E destroys tissue peroxides that promote the oxidation of LDL [189] and prevents platelet adhesion by an antioxidant-independent mechanism [191]. These effects are the basis for the potential effect of the vitamin in preventing ischemic damage.

Vitamin K [11]

The term "vitamin K" designates naphthoquinone compounds with antihemorrhagic activity. They are crucial for the production of plasma clotting factors II (prothrombin), VII, IX, and X. Two forms occur naturally: vitamin K-1 (phylloquinones) in green plants and vitamin K-2 (menaquinones) in bacteria. Colonic bacterial synthesis provides an estimated 2 μg/kg of body weight, and absorption of that source presumably occurs by backwash into the terminal ileum. The RDAs of 1989 were based on the function of the vitamin for clotting proteins, but the requirement may be greater for the nonhepatic vitamin K-dependent proteins, especially those in bone [192]. Because of the lack of data on which to estimate an average requirement, the DRIs are based on AIs, set at 90 μg/day and 120 μg/day for adult women and men, respectively [11]. Therapeutic sources of vitamin K are synthetic compounds. Vitamin K (150 μg/day) is included in the new FDA recommended guidelines for adult parenteral multivitamins [193]. The best food sources are green leafy vegetables, and they are considered to be the major source of the vitamin despite some endogenous production.

Vitamin K is passively absorbed in the small intestine, a process that requires bile salt micelles and pancreatic enzymes. Unlike the other fat-soluble vitamins, vitamin K is not stored in large amounts in adipose tissue. The plasma form is carried on lipoproteins, but the storage form is primarily long-chain menaquinones. The vitamin is concentrated in the liver and is excreted in bile, stool, and urine [11,194]. Vitamin K acts by carboxylating selected glutamic acid residues of proteins to form α-carboxyglutamic acid (Gla), which binds calcium [194]. The coagulation function of the vitamin K-dependent hepatic proteins (e.g., prothrombin and factors VII, IX, and X) and the function of the bone proteins (e.g., osteocalcin, matrix Gla protein) are proportional to the degree of carboxylation. Dietary intake of 200–500 μg/day of vitamin K has been suggested as necessary for optimal γ-carboxylation of osteocalcin [195]. Other vitamin K-dependent proteins of unknown function are present in other tissues.

Conditionally essential nutrients

Choline

Choline can be synthesized in sufficient amounts to support normal metabolism of healthy animals and humans, and so was not considered an essential nutrient. However, in some pathological conditions this nutrient is conditionally essential; it is also essential for normal neonatal metabolism [196]. Choline is a precursor for acetylcholine, phospholipids, and the methyl donor betaine. It is absorbed from the intestine by transporter proteins, but it is not clear whether this process is mediated by the same high-affinity choline transporter, CHT1, that mediates endocytosis in neural tissue. Foods with high choline content include liver, eggs, peanut butter, and milk, and lower amounts occur in all raw foods. Human intake is estimated to be about 0.6–1.0 g/day. Gut flora degrade choline to many products, including betaine and methylamines. A choline deficiency syndrome has never been described in humans, but the Food and Drug Nutrition Board of the Institute of Medicine classifies choline as an essential nutrient [9], based on a study that showed lower plasma choline and phosphatidylcholine levels in subjects fed a choline-free diet for 3 weeks. In addition, some data suggest a partial reversal in hepatic abnormalities following choline supplementation [197]. The AI for infants is set at 17–18 mg/kg, and for adults at 550 mg/day for men, and 425 mg/day for women. A 20% lipid emulsion for TPN provides 11.6–132 mmol/L of phosphatidylcholine. The tolerable upper intake level (UL) for choline is 3.5 g/day, as higher amounts may cause hypotension and a fishy body odor from a metabolite, trimethylamine.

Carnitine

Carnitine is not an essential nutrient for adults, although it may be conditionally essential for neonates [196]. It functions to transfer long-chain fatty acids into mitochondria, improves glucose disposal, and may reduce insulin resistance [198]. Carnitine is made in the liver and kidney, and ingested mostly in milk and meats. Various disease states can alter carnitine status, including renal tubular dysfunction (Fanconi syndrome), chronic renal failure and hemodialysis, and certain medications including zidovudine and valproic acid [198]. Levocarnitine (Carnitor) is approved for such deficiencies, and produces modest effects at 2 g/day when given to patients with anemia caused by renal failure, pain in chronic diabetic neuropathy, and cardiac ischemia.

Arginine

Arginine is not considered an essential amino acid by the Food and Drug Nutrition Board of the Institute of Medicine [13]. However, sepsis appears to produce a conditional deficiency [199]. Arginine is a precursor for nitric oxide, and its potential benefits are related to replacing nitric oxide (NO) in severe illness. It can be given safely, and although laboratory end points can improve, its clinical efficacy is still uncertain [200]. Most studies use arginine in therapy as a component of commercial products that also contain *n*-3 fatty acids, branched-chain fatty acids, and nucleotides. There is no reason to recommend arginine or other immunoactive substances to critically ill patients [201].

Glutamine

Glutamine, along with aspartate, is an important energy source for the small intestine, but it has not been classified as an essential amino acid [13]. A special role for glutamine has been suggested for the treatment of critically ill patients, because it is the most abundant extracellular amino acid – it is used at high rates by many tissues, including the central nervous system and immune cells, and its levels fall during critical illness [202]. Supplemental glutamine has been reported to improve some immunological markers and reduce rates of infectious complications in some studies [203]. Glutamine has also been used in the treatment of mucositis caused by chemotherapy or radiotherapy [204]. The problems with assessing the considerable literature on glutamine are many, and include the greatly different patient populations, the variety of end points tested, the relatively short follow-up, the lack of adequately powered studies, and the lack of reproducible improvement of significant clinical end points [205]. Further studies are needed before glutamine supplementation can be recommended for use in critically ill patients.

Altered nutritional states

Starvation

The metabolic response to starvation enhances survival by increasing the use of adipose tissue triglycerides as a source of fuel, preventing severe hypoglycemia, conserving lean tissue, and decreasing the metabolic rate. The duration of survival during starvation depends on the amount of body fat and lean body mass. In lean men, death occurs after about 60 days of starvation [39], whereas obese persons can survive complete energy deprivation for more than 1 year without obvious adverse consequences [206].

Marked metabolic adaptations occur within the first 24 h of fasting. The mobilization of adipose tissue triglycerides, ketone body production, and the oxidation of plasma fatty acids increase, whereas hepatic glucose production and plasma glucose oxidation decrease [207].

The rate of lipolysis of adipose tissue triglycerides increases because of a decrease in circulating insulin, an increase in plasma epinephrine (adrenaline) concentration, and an increase in the lipolytic response to catecholamines [208–210]. After 3 days of fasting, lipolysis of adipose tissue triglycerides increases to more than double the values observed after an overnight (i.e., 12-h) fast. The increases in lipolysis and plasma fatty acid concentrations promote rates of fatty acid oxidation. The increased delivery of free fatty acids to the liver in conjunction with a decrease in the plasma ratio of insulin to glucagon stimulates hepatic ketone body production [211]. The rate of ketogenesis is maximal by 3 days of starvation; plasma ketone body concentration increases 75-fold by 7 days [212]. Ketone bodies are water soluble and able to cross the blood–brain barrier. As plasma ketone body concentrations increase, ketone body oxidation by the brain increases; by 7 days of starvation, ketone bodies provide 70% of the brain's energy needs [213]. The shift in fuel use by the brain helps spare the limited supply of plasma glucose for glucose-requiring tissues.

Whole-body glucose production decreases by more than half during the first few days of fasting because of a marked reduction in hepatic glucose output [214]. Only 15% of hepatic glycogen stores remain after 24 h of fasting [215]. Therefore, the contribution of gluconeogenesis from plasma precursors to total hepatic glucose output increases as the rate of hepatic glycogenolysis declines. As fasting continues, the conversion of glutamine to glucose in the kidney represents almost 50% of total glucose production.

Normally, about 70 g of amino acids is mobilized from protein stores and about 10 g of nitrogen is excreted in the urine [216]. During starvation, it is critical to slow down the rate of protein breakdown to prevent clinically significant protein losses. If protein breakdown proceeded at a normal rate throughout starvation, a potentially lethal amount of muscle protein would be catabolized in less than 3 weeks. The increase in ketone bodies [217] and starvation-induced inactivation of thyroid hormone – conversion of triiodothyronine (T_3) to reverse T_3 [218] – directly inhibit muscle protein breakdown.

Energy expenditure is conserved during fasting because of a decrease in physical activity caused by fatigue and a decrease in the resting metabolic rate, which decreases by 10%–15% at 7 days because of the diminished size and function of metabolically active tissues [219], increased conversion of active thyroid hormone to its inactive form [220], and suppressed sympathetic nervous system activity [221].

Maximum adaptation occurs as starvation continues. After 14 days of fasting, the rates of lipid, carbohydrate, and protein metabolism reach a plateau. Adipose tissue provides more than 90% of daily energy requirements. Muscle protein breakdown decreases to less than 30 g/day, causing a marked decrease in urea nitrogen production and excretion. Fluid requirements decrease because the diminished osmotic load from urea causes a decline in urine volume to 200 mL/day. Total glucose production decreases to about 75 g/day, providing fuel for glycolytic tissues (40 g/day) and the brain (35 g/day) while maintaining a constant plasma glucose concentration. Energy expenditure decreases by 20%–25% after 30 days of fasting [222] and remains relatively constant thereafter despite continued starvation.

During the terminal phase of starvation, body fat mass, muscle protein, and the size of most organs are markedly decreased. The weight and protein content of the brain remain relatively stable throughout starvation. In rodent models, when fat stores are depleted, the energy derived from body fat decreases and muscle protein catabolism increases. Death occurs when 30% of muscle protein is lost [223].

Metabolic response to illness and injury

The metabolic response to illness and injury is characterized by hypermetabolism, negative nitrogen balance, insulin resistance and hyperglycemia, and increased mobilization and oxidation of adipose tissue triglycerides. These events are produced by a complex cascade of endogenous mediators that cause a predictable physiological response. Increased production and secretion of the counterregulatory hormones (e.g., catecholamines, glucagon, and glucocorticoids) and cytokines are probably responsible for most of the observed responses to illness and injury.

In the 1930s, the classic work of Cutherbertson [224] on long-bone fractures provided the basis of our understanding of the metabolic response to injury. Cuthbertson demonstrated that the response to injury could be divided into two phases: the early ebb phase (12–24 h after trauma) and the subsequent flow phase. The ebb phase is characterized by decreases in blood pressure, oxygen consumption, cardiac output, and body temperature. The flow phase is characterized by hypermetabolism and increases in oxygen consumption, cardiac output, body temperature, and the urinary excretion of nitrogen, potassium, and phosphorus. Subsequently, Moore [225] divided the flow phase into the catabolic and anabolic phases. The restoration of tissue perfusion marks the beginning of the catabolic phase and lasts for days to weeks, depending on the severity of injury, medical intervention, and the premorbid health of the patient. This phase is characterized by catabolism, heat production, negative nitrogen balance, and hyperglycemia [224,225]. It ends after volume deficits are corrected, infection is controlled, pain is eliminated, and oxygenation is restored. At this point, net anabolism may occur, resulting in a slow reaccumulation of protein and body fat.

Hormone and cytokine mediators

During the flow phase, the secretion of several hormones is increased, and they act synergistically to generate alterations in intermediary metabolism. Catecholamines increase lipolysis and hepatic glucose production. Glucagon increases hepatic gluconeogenesis and glycogenolysis. Cortisol enhances protein breakdown and increases hepatic gluconeogenesis.

Cytokines, produced by macrophages, lymphocytes, Kupffer cells, and endothelial cells, are also critical mediators of the metabolic response. Tumor necrosis factor is believed to be the primary cytokine mediating many of the responses to infection and trauma, including fever, increased acute-phase protein synthesis, protein catabolism, hypotension, decreased lipoprotein lipase activity, and metabolic acidosis [226–230]. Interleukin-1 and TNF act synergistically in promoting tissue injury and stimulating the release of counterregulatory hormones [231]; IL-1 causes fever, hypotension, and increased insulin and glucagon secretion, and it affects the concentrations of plasma divalent cations. The liver is stimulated by IL-1 to synthesize metallothioneins, which sequester zinc, and IL-1 mediates the sequestration of iron in hemosiderin and ferritin, depriving invading organisms of these trace elements [228–235]. Other aspects of the acute-phase response stimulated by IL-1 include fibrinogen and C-reactive protein production by hepatocytes and the release of lactoferrin by neutrophils [232,233]. Interleukin-1 enhances immunoglobulin production by B lymphocytes and is a potent stimulus for the synthesis and release of IL-2 by T lymphocytes [232,233,236]. Interleukin-6 is also inducible by TNF and functions primarily as a stimulator of the hepatic acute-phase protein response and lymphocyte proliferation [231,236]. Interleukin-8 is inducible by TNF and IL-1 and is a potent neutrophil chemoattractant [236].

Energy metabolism

Increases in metabolic rate correlate directly with the severity of illness and injury [237]. For example, the REE increases after uncomplicated surgery by about 10%, after long-bone fractures by 20%, and after multiple trauma by 50%. The REE rarely exceeds twice the normal rate regardless of the extent of injury [223]. In fact, even patients with severe burns usually do not experience an increase in REE by more than 50% for any prolonged period [238]. In certain types of injury, a temporary resetting of the hypothalamic thermoregulatory set point is responsible for a 1–2°C elevation of body temperature known as *posttraumatic fever* [226,239]. The REE increases about 12% for each 1°C increase in core body temperature. Because the central temperature set point is higher, the comfort temperature for an injured patient is elevated, and elevating the ambient temperature decreases the energy requirement [223].

Protein metabolism

Illness or injury increases protein synthesis and protein breakdown. The increase in protein breakdown is greater than the increase in protein synthesis, resulting in negative nitrogen balance. Skeletal muscle is the major site of protein catabolism, but increased catabolism of extracellular proteins, including acute-phase reactants, coagulation system proteins, and complement system proteins, also occurs [232,240–242]. Considerable protein synthesis is directed toward host defense, including phagocyte activity, hormones, cytokines, intracellular proteins, immunoglobulins, complement, coagulation system proteins, and acute-phase reactant glycoproteins [232].

The composition of amino acids released by muscle does not reflect the composition of muscle proteins. The branched-chain amino acids of skeletal muscle are metabolized within the muscle cell for energy, and transamination generates glutamine and alanine. As a result, alanine and glutamine, which constitute only 12% of muscle protein, make up 50%–60% of the amino acids released into the plasma by muscle. Conversely, branched-chain amino acids make up 15% of the muscle protein but only 6% of the

amino acids released [232,237]. Glutamine is taken up and metabolized by the kidneys at an accelerated rate, providing additional ammonium for excretion to help maintain acid–base balance in the face of the acidosis that frequently accompanies critical illness [237]. In addition to carrying amino groups from the periphery to the liver and kidney, glutamine serves as a major energy source for the lymphocytes, fibroblasts, and the gastrointestinal tract [243]. Alanine is captured by the liver for gluconeogenesis, and its nitrogen contributes to the increase in ureagenesis [244].

During severe illness, nitrogen losses may reach 20–40 g/day. This represents catabolism of 600–1200 g of lean body mass per day. Providing exogenous nitrogen and energy may [245] or may not [246] decrease the rate of catabolism, but it enhances protein synthesis and thereby decreases negative nitrogen balance [243,247].

Carbohydrate metabolism

The stress response is marked by hyperglycemia, in large part related to hepatic gluconeogenesis fueled by lactate, pyruvate, glycerol, alanine, and other glucogenic amino acids. Hepatic glucose production may exceed 500 g/day and is resistant to suppression by insulin [248]. Peripheral insulin resistance decreases skeletal muscle glucose uptake, which also contributes to hyperglycemia [226]. Glucose consumption by wounds and injured extremities is increased to provide fuel for inflammatory cells, such as fibroblasts, macrophages, and leukocytes. These cells metabolize glucose anaerobically and can release large quantities of lactate into the bloodstream, which is subsequently recycled to glucose by the liver.

Lipid metabolism

Fat is a major oxidative fuel in critically ill patients, even when exogenous carbohydrates are administered. The rate of lipolysis correlates directly with the severity of illness [249]. The increased delivery of fatty acids to the liver stimulates very-low-density lipoprotein (VLDL) production. However, the rate of VLDL secretion is not adequate to remove the excessive supply of fatty acids and thus contributes to hepatic fat accumulation. Hypertriglyceridemia can occur because of both increased VLDL production and decreased peripheral lipoprotein lipase activity and VLDL clearance.

The newborn intestinal circulation, 557

The ultimate function of the gastrointestinal tract is to assimilate nutrients and water from the external environment and make them available to cells throughout the body; in this context, the blood and lymph circulations provide the conduits for transferring absorbed nutrients and water to the entire body. The vascular supply to the gastrointestinal mucosa is particularly well suited for the absorptive and secretory functions of this tissue in that it can accommodate a high rate of blood flow, has a large exchange surface area, and permits easy permeation of nutrients and water, yet largely retains proteins within the plasma compartment. This chapter summarizes current concepts regarding circulatory control and function in the gastrointestinal tract during normal physiological conditions. The chapter also reviews mechanisms by which the gastrointestinal and hepatic circulations interact, discusses unique features of the newborn intestinal circulation, and summarizes information relevant to the pathophysiology of intestinal ischemia.

Anatomy of the gastrointestinal circulation

Extramural vessels

Arteries

In humans, the major arteries supplying the stomach and intestines are the celiac, superior mesenteric, and inferior mesenteric arteries. The celiac artery supplies the stomach, the first portion of the duodenum, a portion of the pancreas, and the liver. The superior mesenteric artery supplies the remainder of the pancreas and duodenum, the jejunum, the ileum, and the colon through two-thirds of the transverse segment. The inferior mesenteric artery supplies the remainder of the colon and rectum, except the distal rectum, which is supplied by rectal arteries arising from the internal iliac arteries. Along the mesenteric border of the intestine, arterial and venous branches form multiple arcades, anastomose with one another, and provide a pathway for collateral blood flow. The arcades give rise to vasa recta, which branch to encircle the intestine and ultimately pierce the circular muscle [1–3].

Veins

Blood from the stomach, pancreas, and intestines drains into the portal vein; the exception is the blood from the distal rectum, which drains into the internal iliac veins. The vessels that drain the intestines course within the mesentery, except those vessels supplying retroperitoneal portions [1–3].

Intramural vessels and microcirculation

Stomach

In the human stomach, submucosal arterioles branch into capillaries at the base of the gastric glands, pass perpendicularly through the mucosa, form a lumenal capillary network, and drain into mucosal venules only at the most lumenal level of the lamina propria (Fig. 22.1). These venular branches converge on infrequent mucosal collecting venules, which then pass directly to the submucous venous plexus without receiving any direct capillary tributaries within the mucosa [4].

Small intestine

Small arteries pierce the muscularis layers and give rise to 1A submucosal arterioles that in turn generate an extensive, anastomosed series of 2A arterioles. These arterioles function as a pressure manifold for 3A arterioles, which descend into the mucosa to form the villus microcirculation; in addition, 4A arterioles branch from the 3A vessels and ascend into the muscularis layers. A tufted pattern of capillaries, derived from the tubular capillary plexus surrounding the epithelium of the crypts, supplies the basal 70%–80% of the villus and also drains into the venule high in the villus (Fig. 22.2) [2,5].

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

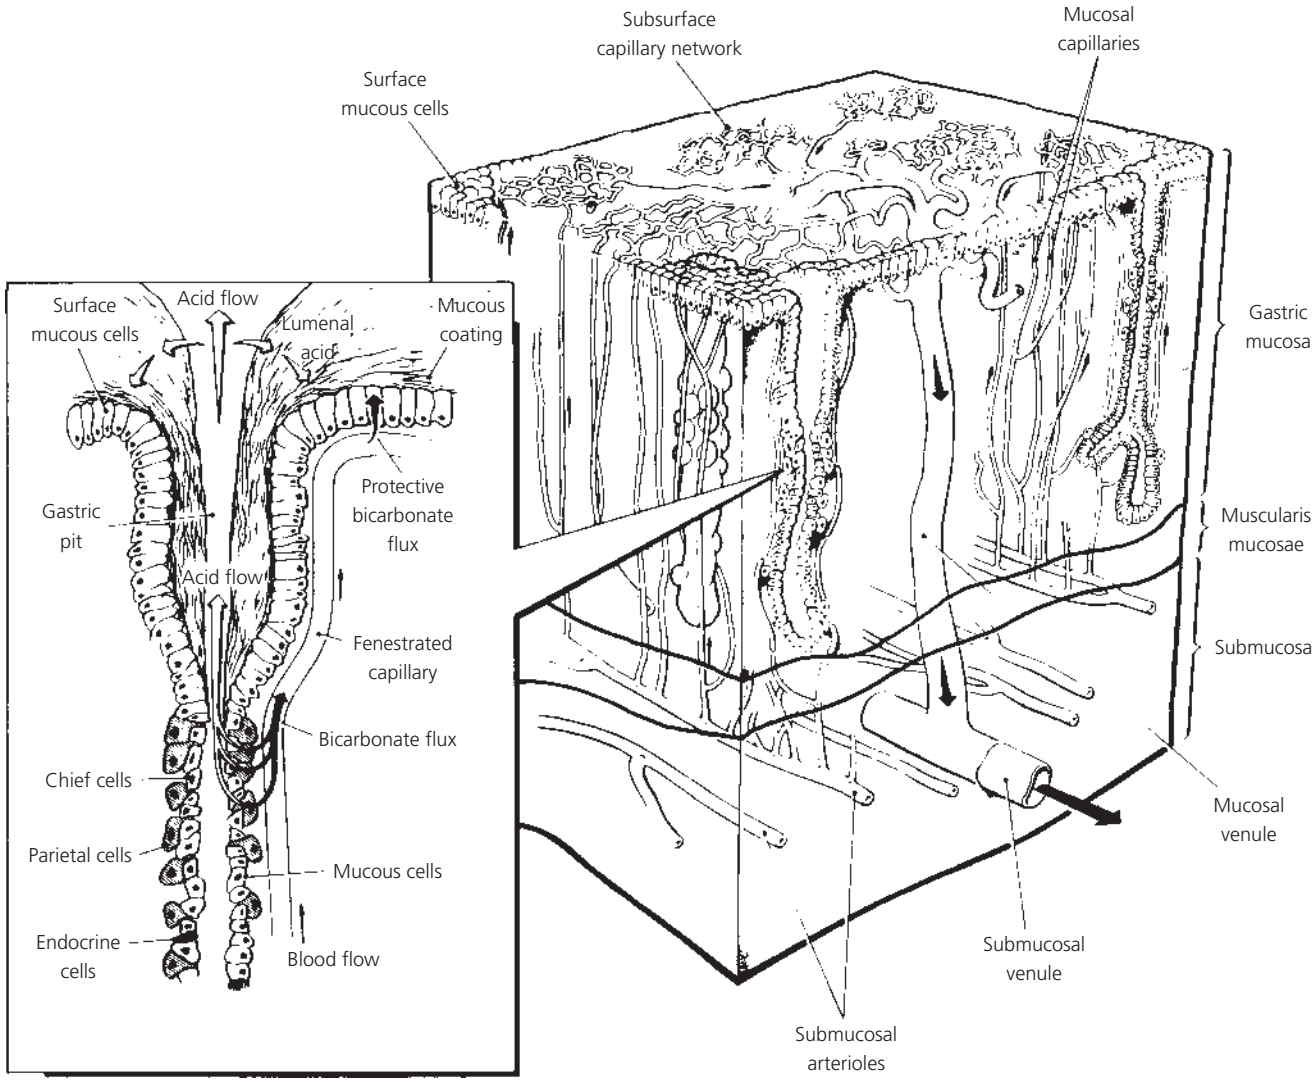

Figure 22.1 The vascular organization in gastric mucosa **(right)**. The proposed mechanism for the vascular transport of bicarbonate is toward the surface mucous cells from deeper within the mucosa (inset left). From Gannon et al. [4], with permission from Elsevier.

Colon

The colonic mucosa is devoid of villi; therefore, the arterioles and their capillary branches pass to the epithelial surface between the crypts to form a network of capillary plexuses around the crypts. The colonic capillaries are much closer o the epithelial cells than are the villus capillaries in the small intestine [6].

Mechanisms of blood flow regulation

Intrinsic systems

It is well recognized that blood flow in the gastrointestinal tract is maintained within narrow limits. This circumstance reflects, in part, the existence of intrinsic vascular regulatory systems; i.e., mechanisms that originate and remain within the intestinal parenchyma and its attendant circulation and that can be identified under isolated or in vitro conditions. Three well-identified systems merit review: the myogenic and metabolic mechanisms, and the system involving nitric oxide (NO) derived from the endothelial isoform of nitric oxide synthase (eNOS). Integration of these systems occurs at a molecular level and their relative activities are most certainly modified by other vasoactive stimuli (peptides, hormones, neural input) that arise from intrinsic or extrinsic sites.

Myogenic vascular response

Vascular smooth muscle cells contract when stretched, a phenomenon termed the myogenic response. The molecular basis for the myogenic response is incompletely understood, although an excellent review is available [7]. The myogenic response has been repeatedly demonstrated within the

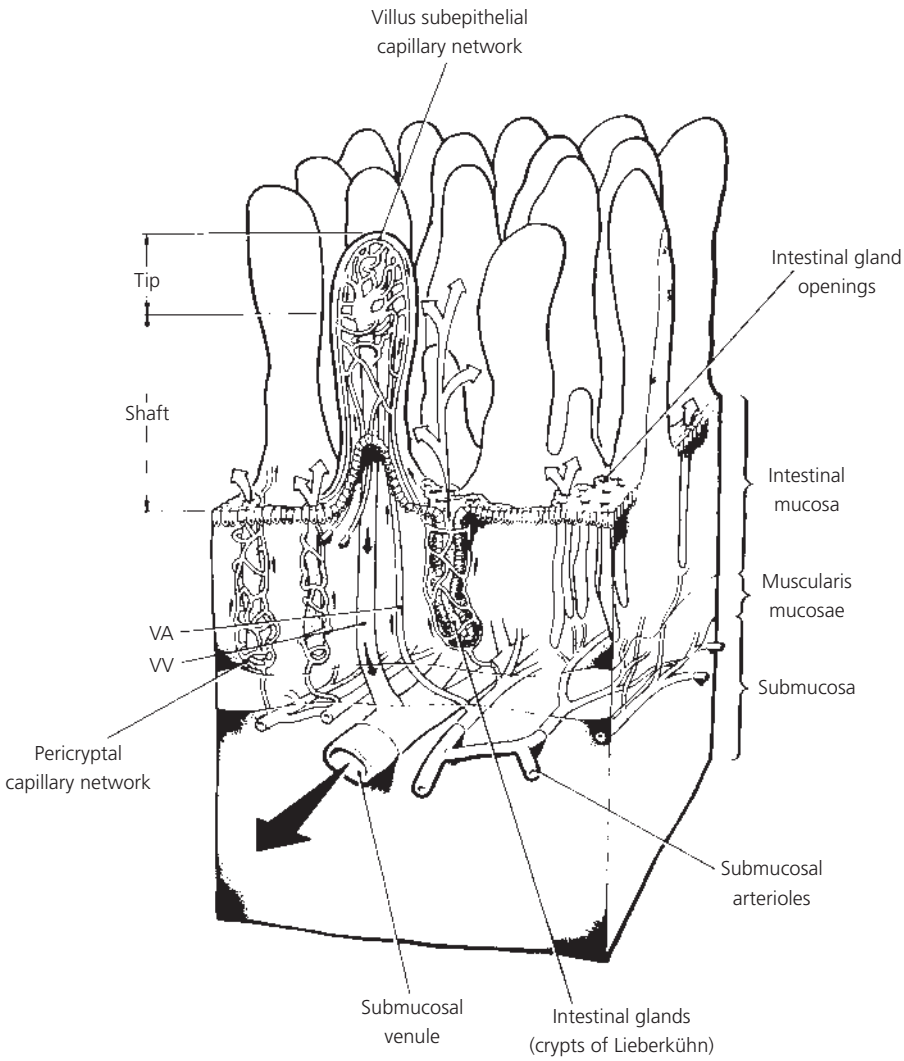

Figure 22.2 Mucosal microcirculatory patterns typical of human and rabbit small intestine. VA, villus arteriole; VV, villus venule. Adapted from Frasher and Wayland [5], with permission from Elsevier.

intestinal circulation, most commonly by noting vasoconstriction in response to increased intravascular pressure [8–13]. Intrinsic myogenicity of the intestinal vasculature has at least two physiological roles. First, it contributes to the basal vascular tone and so participates in setting vascular resistance across the intestine; in this context, the myogenic mechanism generates vascular tone that is fully independent of extrinsic neural stimuli [7,14]. Second, it serves to regulate vascular wall tension and in this capacity participates in pressure-flow autoregulation [8,11,15,16] and helps preserve homeostasis of capillary filtration [9,17–20].

Metabolic vascular regulation

A consistent experimental observation is that the intensity of vasoregulation within the intestine is contingent on its momentary rate of O_2 utilization (O_2 demand), convincing evidence that a factor produced by the gut parenchyma is indexed to tissue metabolic activity, and that this factor regulates the gut circulation. This concept is the basis of the metabolic theory of local blood flow regulation, which states that tissue oxygenation, not blood flow, is the principal variable regulated by intrinsic vascular control mechanisms. The theory partitions microvascular control into two sites: resistance vessels and precapillary sphincters. The former regulate the flow of blood, and hence O_2 delivery to the capillary level, wherein O_2 delivery is defined as the product of blood flow rate and O_2 concentration. Precapillary sphincters govern perfusion of individual capillaries, and hence the surface area available for O_2 diffusion from capillary-to-cell (Fig. 22.3). The metabolic feedback signal serves to vasodilate resistance vessels and open precapillary sphincters. Anything that reduces the O_2 delivery-to-demand ratio (e.g., hypotension, hypoxemia, or the increased tissue O_2 demand during digestion) increases production of the metabolic feedback signal, an action that increases net O_2 transport to the gut parenchyma and restores O_2 homeostasis [21].

An important aspect of the metabolic theory is that precapillary sphincters are more sensitive to the metabolic feedback

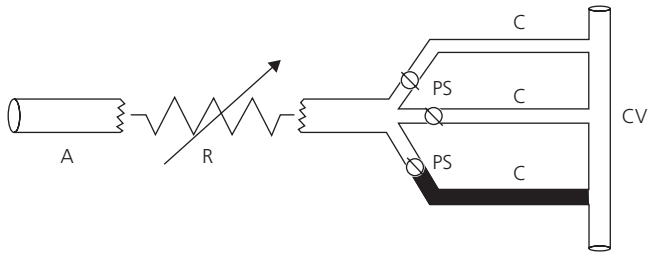

Figure 22.3 Schematic representation of the physiological control sites within the intestinal circulation based on the metabolic theory of local blood flow regulation. Arterioles (A) act as variable resistors, i.e., as resistance vessels (R) that determine the rate of flow into the capillaries (C). Precapillary sphincters (PS) govern perfusion of individual capillaries and exist in an "open" or "closed" state. In the figure, the lowermost capillary is perfused (PS "open"), while the upper capillaries are not perfused (PS "closed"). In response to a reduction in the O_2 delivery-to-demand ratio, the first response would be an opening of the previously closed PS; thereafter, as necessary to maintain capillary Po_2, arteriolar resistance would decrease. CV, collecting venule.

signal than resistance vessels [21]. Hence, the first response to a reduction in the O_2 delivery-to-demand ratio is the opening of closed precapillary sphincters, an effect that has been experimentally confirmed by noting increases in the capillary filtration coefficient ($K_{f,c}$) and the arteriovenous O_2 content difference across the intestine in response to a reduction in the O_2 delivery-to-demand ratio [12,22–24]. Dilation of resistance vessels, and hence augmentation of flow, only occurs when capillary Po_2 is no longer sufficient to drive the capillary-to-cell O_2 diffusion process. This phenomenon has been used to explain why the intrinsic regulation of intestinal blood flow is enhanced when the intestinal metabolic rate, and hence tissue O_2 demand, is increased [10,25,26].

The identity of the metabolic theory is unknown, although several reports support adenosine as a viable candidate for this role. Adenosine is a powerful intestinal vasodilator [27] that is generated during metabolic utilization of adenosine triphosphate (ATP), and its accumulation in venous blood has been demonstrated under conditions where tissue oxygenation might be reduced, such as after arterial hypoxemia or occlusion, or during the active transport of nutrients. The role of adenosine in local vasoregulation has been assessed with the use of substances such as theophylline, a competitive antagonist; by the enzyme adenosine deaminase, which converts adenosine to inosine; and by dipyridamole, an inhibitor of adenosine reuptake. These agents have been shown to attenuate or completely abolish the vasodilation associated with reductions in arterial pressure, release of an arterial occlusion, hypoxemia, and absorption of nutrients [28–32].

Other studies suggest that molecular O_2 itself dictates vascular tone, either directly or through the generation of endothelium-derived autocoids. Microvascular studies demonstrate an inverse correlation between villus Po_2, measured directly with O_2-sensitive electrodes, and the rate of blood flow within the submucosal and villus microvasculature [33,34]. Reduction of Po_2 within vascular smooth muscle generally causes its relaxation, possibly because of the effects of Po_2 on ion channels, such as the ATP-dependent K^+ channels [35,36]. Alternatively, a considerable body of evidence supports a role for the vascular endothelium as an O_2-sensing organ; release of vasorelaxing autocoids such as prostacyclin and NO can occur in response to endothelial hypoxia, this ultimately leads to a reduction in vascular resistance that, in turn, increases the rate of blood flow and hence of O_2 delivery [37,38]. In this context, tissue Po_2 functions as the controlled variable (in accordance with the metabolic theory), whereas secondary agents such as NO and prostacyclin are the effecter mechanisms (the feedback signal).

Nitric oxide

The eNOS-derived NO has emerged as a pivotal 'final common pathway' in vasodilation, and its role in intestinal vascular regulation has been established by anatomical [39,40] and physiological [41–44] studies. The eNOS generates NO during the reduction of L-arginine to L-citrulline, in the presence of Ca^{2+}, calmodulin, O_2, tetrahydrobiopterin, and reduced nicotinamide dinucleotide phosphate. The principal mechanism of NO-based vasodilation is the activation of soluble guanylate cyclase in adjacent vascular smooth muscle, an action that initiates the following cascade: increased cyclic guanosine monophosphate production, reduced Ca^{2+} concentration, cell relaxation, and a net increase in vessel diameter (Fig. 22.4). Excellent reviews of eNOS biochemistry and molecular biology are available [45,46].

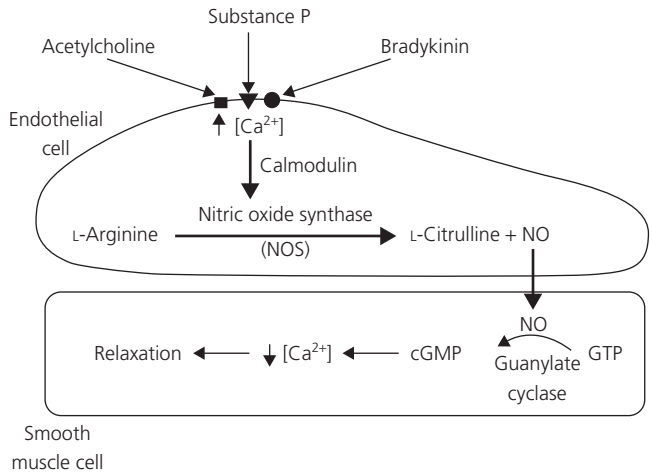

Figure 22.4 Mechanism of nitric oxide (NO)-mediated relaxation of vascular smooth muscle. NO generation by the endothelial cell enzyme NO synthase is induced by certain stimuli, such as acetylcholine, substance P, and shear stress. The endothelial cell-derived NO produced by these stimuli readily diffuses into the underlying smooth muscle cells, where it binds to and consequently activates soluble guanylate cyclase (sGC). The cyclic guanosine monophosphate (cGMP) produced by sGC promotes smooth muscle relaxation by lowering intracellular calcium.

The most convincing evidence for NO-based intestinal vasoregulation comes from microvascular studies using NO-sensitive microelectrodes placed immediately adjacent (~ 10 μm) to submucosal vessels. Periarteriolar NO concentration exceeds the dissociation constant for soluble guanylate cyclase; in addition, this variable is directly correlated to arteriolar diameter and increases in response to shear stress, hypoxemia, and nutrient absorption, perturbations that lead to arteriolar dilation [43,47,48]. Moreover, attenuation of eNOS activity with L-arginine analogues causes relative vasoconstriction of the intestine, indicating that constitutive eNOS activity (and hence NO production) participates in gut vasoregulation [44]. The eNOS-derived NO also participates in flow-induced dilation within the intestine; i.e., the vascular phenomenon by which an increase in flow rate increases vessel diameter [41].

Extrinsic systems

Central nervous system

The gastrointestinal tract is innervated by postganglionic (sympathetic) fibers emanating from celiac, superior mesenteric, and inferior mesenteric ganglia [49]. Both anatomical and physiological studies demonstrate innervation of this type in virtually all portions of the gut circulation, from conduit vessels (e.g., the superior mesenteric artery) to microvessels (e.g., submucosal arterioles) to the mesenteric venous vasculature (e.g., the splanchnic capacitance vessels). Identified neurotransmitters include norepinephrine, ATP, and neuropeptide Y [50,51]. These fibers provide the sole neurogenic vasoconstrictor stimuli to submucosal arterioles [50].

Direct stimulation of the postganglionic mesenteric nerve fibers causes brisk vasoconstriction; however, this effect is not sustained, even in the face of continued nerve stimulation. This process is termed autoregulatory escape (Fig. 22.5) [52–54]. A similar phenomenon occurs during intraarterial infusion of the neurotransmitter norepinephrine [55]. Autoregulatory escape occurs only in arteriolar smooth muscle, not in venous smooth muscle [52]. It is unaltered by β-receptor blockade [53] or by administration of atropine [54]. Three mechanisms commonly invoked to explain autoregulatory escape are redistribution of blood flow from the mucosa to the submucosa, adaptation of adrenergic receptors to continued nerve stimulation, and accumulation of vasodilator metabolites during tissue hypoxia generated during nerve-induced ischemia. The lattermost explanation is the most widely accepted [56–59]. Consistent with this theory is experimental evidence that the propensity for blood flow to escape from sympathetic vasoconstriction is significantly greater in the metabolically active mucosa than in the muscularis [60]. Adenosine appears to play at least a partial role in autoregulatory escape [55], whereas a role for histamine [54,55] and prostaglandins [54] has not been substantiated. Evidence also implicates a role for vasodilator peptidergic neurons in effecting autoregulatory escape after sympathetic nerve stimulation but not during infusion of norepinephrine [61,62]. One neurotransmitter sub-stance produced by these fibers is vasoactive intestinal polypeptide [63].

Extrinsic preganglionic afferent (sensory) fibers that arise from dorsal root ganglia also innervate the gastrointestinal vasculature [50]. Substance P and calcitonin gene-related peptide serve as neurotransmitters for these fibers. Stimulation of extrinsic afferents with capsaicin causes vasodilation of submucosal arterioles [64–66].

The gastrointestinal tract receives extensive cholinergic, parasympathetic innervation by way of the vagus nerve (stomach, small intestine) and pelvic nerve (colon), although the role of these fibers in the regulation of gut perfusion is unclear. Early studies failed to demonstrate significant change in gut vascular tone after direct stimulation of the vagus or after vagotomy [67,68]; subsequent work, however, has revealed vasodilation of intestinal submucosal arterioles in response to vagal stimulation [69].

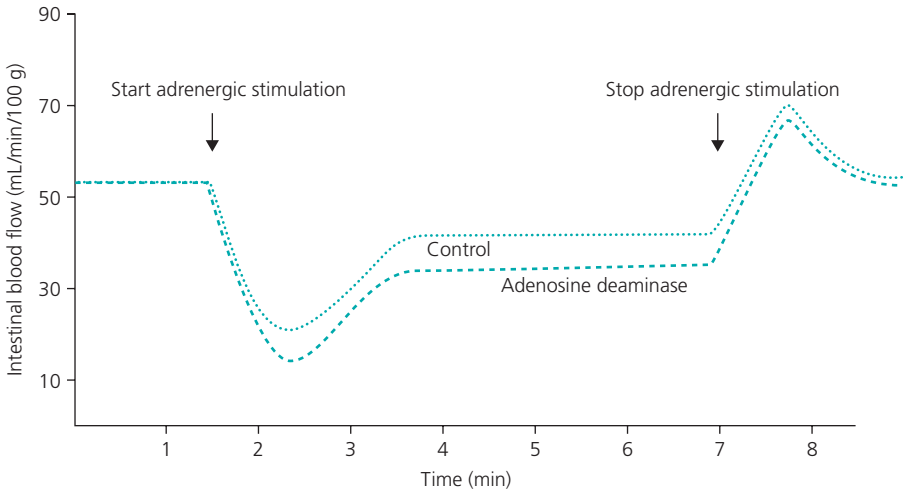

Figure 22.5 Autoregulatory escape from adrenergic stimulation in autoperfused piglet small intestine. Adenosine deaminase pretreatment reduced the steady-state escape response to norepinephrine infusion, whereas pretreatment with chlorpheniramine, a histamine H_1 blocker, had no effect. Data from Crissinger et al. [55].

Enteric nervous system

The gastrointestinal tract is endowed with a complex nervous system that contains sensory and motor neurons capable of function in the absence of extrinsic neural input [70]. It might be cogently argued that this regulatory system is actually *intrinsic* to the gut; however, the myenteric and submucosal neurons that constitute the enteric nervous system receive extensive input from extrinsic fibers arising from the celiac ganglia [50], and so the enteric nervous system is closely integrated at the central nervous system. Submucosal arterioles are innervated by afferent and efferent fibers that emanate from both myenteric and submucosal neurons. Myenteric long fibers are believed to synapse with submucosal neurons that in turn innervate submucosal arterioles [50]. Direct stimulation of the myenteric ganglia induces vasodilation of the submucosal arterioles [71] that is mediated by various neurotransmitters, including acetylcholine [72], substance P [72], calcitonin gene-related peptide [73], and neuropeptide Y [74]. In addition, a reflex arc connecting afferent fibers arising from the villi to the submucosal and myenteric ganglia, and thence to submucosal arterioles, has been identified. Chemical and mechanical stimulation of the mucosal activates this reflex arc and induces submucosal arteriolar vasodilation [73,75]. This phenomenon suggests that the enteric nervous system may participate in generating vasodilation in response to mucosal events, such as nutrient absorption, as well as the mucosal inflammation associated with ulcerative colitis [50]. Reviews of the role of the enteric nervous system in gut vascular regulation are available [50,73].

Circulating vasoactive substances

Circulating vasoactive substances that affect gastrointestinal blood flow include catecholamines, vasopressin, and angiotensin. Norepinephrine, a predominantly α-adrenergic receptor stimulant, causes intestinal vasoconstriction, a decrease in capillary density, and a reduction in O_2 uptake [59,76,77]. With continuous intraarterial infusion, the intense initial vasoconstriction is followed by the return of blood flow towards control levels despite continued norepinephrine infusion. Epinephrine can cause either α-receptor-mediated vasoconstriction at high doses or β-receptor-mediated vasodilation at low doses, as well as a variable response in O_2 uptake [59,78,79].

Both vasopressin and angiotensin II are potent physiological vasoconstrictors that reduce blood flow and increase vascular resistance in all gastrointestinal organs. These agents cause generalized vasoconstriction, with a disproportionate selective reduction in mesenteric blood flow at doses that have been measured in pathophysiological states of hypotension [80]. Vasopressin causes a decrease in capillary density and a reduction in intestinal O_2 uptake, whereas angiotensin II reduces or does not affect splanchnic O_2 uptake [81]. In normal rat intestine, α-adrenergic and vasopressin activity account for most extrinsic vasoconstrictor tone, whereas vasopressin and angiotensin II account for most extrinsic vasoconstrictor tone in portal hypertensive rat intestine [82]. Renin–angiotensin and vasopressin systems are also involved in the intestinal vasoconstrictor response to hemorrhage and hypovolemia, and significant attenuation of this increase in vascular resistance occurs only when both systems are blocked simultaneously [83,84], even in the presence of an intact sympathetic system.

Response of the intestinal circulation to systemic circulatory perturbations

Pressure–flow autoregulation

Pressure–flow autoregulation, or more simply, autoregulation, is a physiological response designed to maintain blood flow at a relatively constant level in the face of fluctuation in the pressure gradient across an organ or tissue. The relationship among flow, pressure, and resistance is given by the equation flow = (Pa – Pv)/R, where Pa and Pv are arterial and venous pressures, respectively, and R is resistance. Assuming that Pv remains constant, evidence of autoregulation would include an increase in R (vasoconstriction) in the face of increased Pa (hypertension), or a reduced R (vasodilation) in response to a lowered Pa (hypotension). Autoregulation can be elicited in the stomach [85,86], small intestine [25,87–95], and colon [11,12,96,97], although it is not the intense phenomenon observed in the renal and cerebral circulations (Fig. 22.6).

Autoregulation is generally ascribed to intrinsic control mechanisms, and both myogenic [91,92] and metabolic [10,25,86,98] mechanisms have been evoked to explain the phenomenon. The myogenic response, i.e., vasoconstriction in response to an increase in pressure and vice versa, would reflect the inherent tendency of the circumferential arterial vascular smooth muscle to contract or relax as a function of

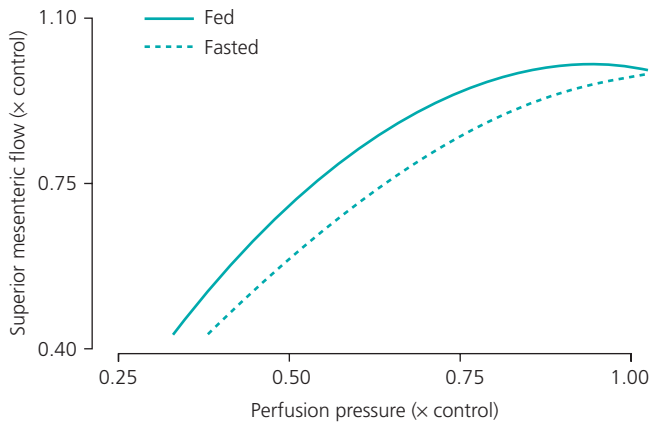

Figure 22.6 Responses of intestinal blood flow to step reductions in perfusion pressure in fed (solid line) vs fasted (dashed line) dogs demonstrate an increased intensity of autoregulation during enhanced functional activity. From Granger & Norris [26], with permission from the American Physiological Society.

the prevailing intravascular pressure, insofar as that pressure affects the stretch stimulus applied to the muscle cells [7]. The metabolic response is less straightforward. For example, hypotension would initially compromise gut perfusion and reduce O_2 delivery. This circumstance reduces the O_2 delivery-to-demand ratio and elicits production of the vasodilator metabolic feedback signal previously described. However, active regulation of precapillary sphincters designed to enhance capillary surface area and hence the diffusive flux of O_2 from capillary-to-cell is the first response to hypotension. This response is indicated by a rise in the capillary filtration coefficient $K_{f,c}$, a marker of the perfused capillary density, as pressure falls [22,24,26]. Evidence of autoregulation (vasodilation) only occurs when capillary Po_2 falls below the level needed to drive O_2 diffusion to maintain tissue oxygenation, the variable controlled by the metabolic mechanism [99]. This circumstance explains why the efficacy of autoregulation is significantly enhanced when the oxidative requirements of the intestine are increased by feeding [10,25,26].

Alterations in arterial blood gas tensions (hypoxemia) and hematocrit

Alterations in arterial blood gases and hematocrit also affect gastrointestinal blood flow. Arterial hypoxemia increases the perfused capillary density and causes vasodilation, and hence increased perfusion in denervated intestinal preparations [99,100]. The vasodilation and increased perfused capillary density tend to minimize the reduction in O_2 uptake induced by the limited O_2 delivery. When blood flow is held constant, the intestine maintains O_2 consumption within 48% of control during arterial hypoxemia. When both blood flow and capillary density are free to increase, however, O_2 uptake remains within 26% of control despite the hypoxia. Similar to hypoxia, hypercapnia induces a marked relaxation of resistance vessels [100]. In contrast to hypoxia, hypercapnia causes the precapillary sphincters to constrict and the capillary density to decrease.

Alterations in arterial hematocrit also influence gastrointestinal blood flow and oxygenation [101–104]. An inverse linear correlation exists between the intestinal blood flow and hematocrit, and a direct linear correlation between the arteriovenous O_2 difference and hematocrit in both the intestine and the stomach. The relation between intestinal O_2 uptake and hematocrit is parabolic (Fig. 22.7) [101], showing a maximal uptake at a hematocrit of 48.7% – i.e., the optimal hematocrit. Intralumenal placement of nutrients increases the optimal hematocrit to 57.1%. In the stomach, the optimal hematocrit is 38.2% during resting conditions, and it increases to 45.7% during pentagastrin stimulation.

Venous pressure elevation

Studies of the stomach, small intestine, and colon in adult animals indicate that vascular resistance rises in response to

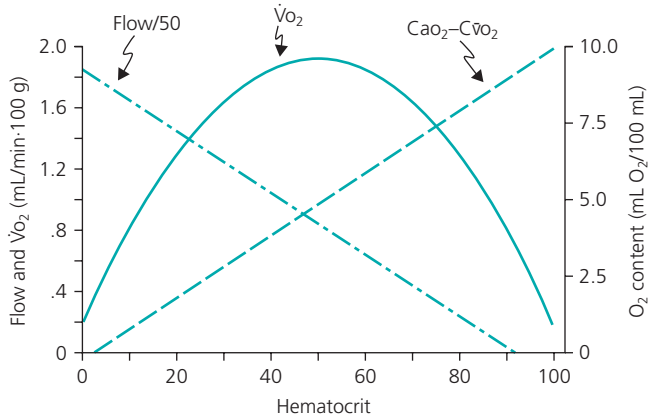

Figure 22.7 Effect of hematocrit on canine intestinal blood flow, O_2 consumption ($\dot{V}o_2$), arterial O_2 content, and arteriovenous O_2 difference ($Cao_2 – C\bar{v}o_2$). From Shepherd & Riedel [101].

venous pressure elevation, findings consistent with a myogenic mechanism (Fig. 22.8) [8–13,15,17–19,96,97,105]. Acute venous hypertension in the adult intestine elicits vasoconstriction as a result of rising precapillary (arteriolar) resistance whereas postcapillary resistance falls [106]. Capillary exchange capacity increases in the stomach and the colon but decreases in the small intestine during venous hypertension [107]. Despite the intense capillary derecruitment initiated by venous hypertension in the small intestine, O_2 extraction increases disproportionately to the reduced blood flow, and

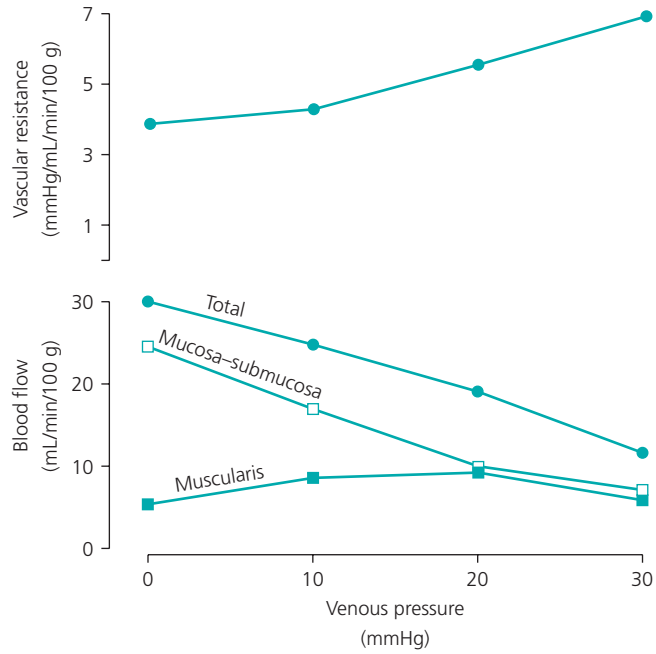

Figure 22.8 Intestinal vascular responses to acute venous hypertension in cats. The increase in vascular resistance and the decrease in blood flow during acute venous pressure elevation are consistent with the myogenic theory of intrinsic vasoregulation. Data from Granger et al. [17].

consequently, O_2 consumption rises [19]. The elevated intestinal O_2 utilization during venous hypertension has been attributed to increased villus motility [108]. There are conflicting reports regarding the influence of enhanced oxidative metabolism on the vascular responses to elevations in venous pressure. Some investigators have observed that increased O_2 demand significantly reduces or abolishes the rise in vascular resistance [26,97], whereas others have noted an exaggerated resistance response to venous pressure elevation [109].

Acute venous hypertension also alters the distribution of blood flow within the bowel wall [17,110]. As venous pressure is elevated, the percentage of total blood flow directed to the mucosa and submucosa is reduced, whereas the muscularis receives a larger fraction of the total blood flow. These observations indicate that the constriction of arteriolar and precapillary sphincter smooth muscles elicited by venous hypertension takes place in the mucosal and submucosal layers, and that the vasculature of the muscularis dilates in response to venous hypertension.

O_2 uptake–blood flow relation: functional implications

Considerable attention has been devoted to the interaction between gastrointestinal blood flow and O_2 uptake, and the relevance of this interaction to mucosal function and integrity. Figure 22.9 depicts the observed relation between intestinal blood flow and O_2 uptake when blood flow is altered with a pump or by graded reductions in perfusion pressure [22]. O_2 uptake remains virtually constant over a wide range of blood flow levels (i.e., it is independent of blood flow), and it is compromised only when blood flow reaches a critically low level. Below this level, O_2 uptake is dependent on blood flow. Resting blood flow in the small intestine, stomach, and colon is usually greater than the critical blood flow at which O_2 uptake is dependent on blood flow [13,111–113].

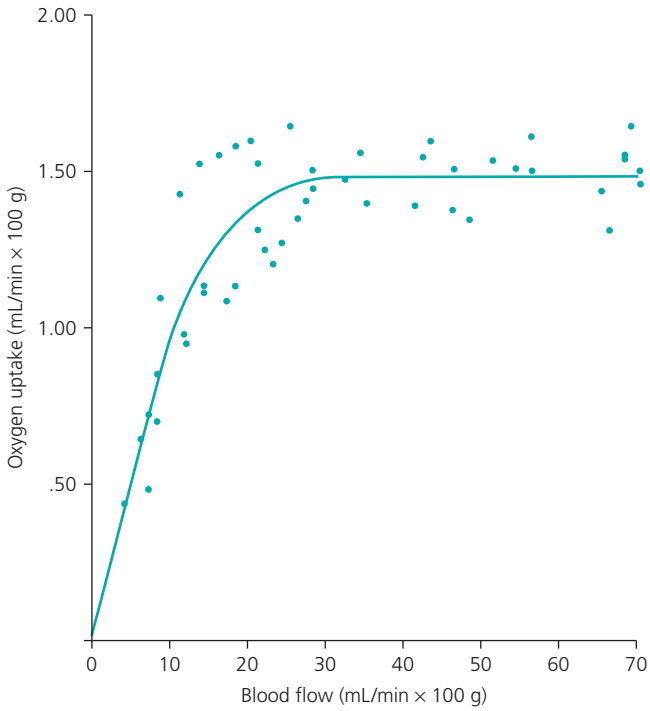

Figure 22.9 Relation between intestinal blood flow and O_2 uptake in feline jejunoileum when blood flow is altered with a pump or by graded reductions in perfusion pressure. From Granger et al. [22], with permission from the American Physiological Society.

The reduction in O_2 uptake that occurs when blood flow falls below a critical level can be explained in terms of the normal relation between mitochondrial O_2 consumption and cell Po_2. This relation predicts that O_2 uptake remains constant over a wide range of cell Po_2 levels, and uptake is reduced only when cell Po_2 falls to a low level, the critical Po_2. The resting cell Po_2 is normally well above the critical Po_2. Evidence indicates that graded reductions in blood flow produce concomitant reductions in cell Po_2 without altering O_2 uptake in the stomach [81]. At very low rates of blood flow, however, the rate of O_2 diffusion to the cells is so low that the intracellular Po_2 falls below the level required to maintain normal oxidative metabolism. The reduction in O_2 uptake observed at low blood flow may simply reflect a depression in oxidative metabolism caused by the limited O_2 availability.

Many conditions alter the relation between O_2 uptake and blood flow such that O_2 uptake is dependent on blood flow even when it is increased above normal. These include lumenal distention [114], alterations in hematocrit [115], and devascularization [96]. All these conditions are thought to reduce tissue oxygenation severely in discrete or generalized regions of the stomach or gut. Lumenal distention and devascularization reduce tissue oxygenation by compromising blood flow, whereas a low hematocrit limits O_2 delivery, even at high blood flows. Normal physiological conditions can also influence the relation between O_2 uptake and blood flow. Stimulation or inhibition of oxidative metabolism will shift the plateau of the blood flow–O_2 uptake curve upward or downward, respectively (Fig. 22.10) [81]. Stimulation of intestinal motility or enhancement of active transport raises the plateau of the blood flow–O_2 uptake curve [24]. Conversely, decreasing the temperature of isolated bowel segments lowers the plateau. Another important aspect of the blood flow–O_2 uptake relation in the small bowel is that it will predict the influence of blood flow reductions on O_2-requiring processes, such as absorption and secretion. For example, it has been shown that the reductions in glucose absorption produced by graded decrements in blood flow parallel the decline in O_2 uptake [116], suggesting that O_2 availability limits solute transport when cell Po_2 falls.

The relation between blood flow and O_2 uptake has also been useful in explaining some of the reported observations regarding the influence of blood flow on gastric acid

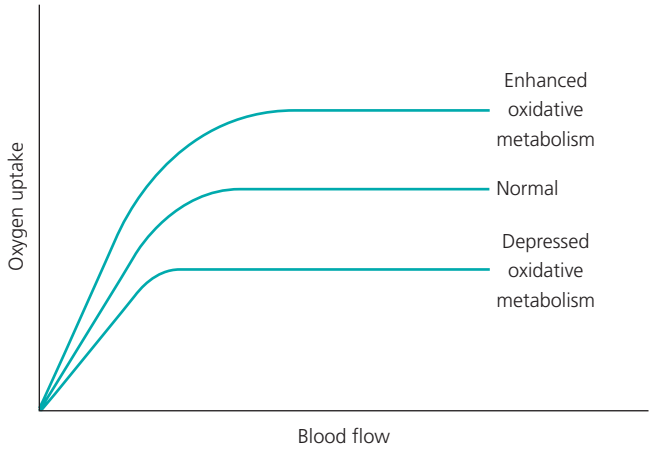

Figure 22.10 Relation between blood flow and O_2 uptake during stimulation or inhibition of oxidative metabolism. From Kvietys & Granger [81], with permission from the American Physiological Society.

secretion [117]. The production of gastric acid is an energy-consuming process that results in an increase in gastric O_2 uptake. The consistent finding that acid secretion and O_2 consumption are highly correlated raises the question of whether acid secretion in the stomach is dependent on blood flow. The answer to this question largely depends on the type of surgical preparation. In some preparations, many vessels supplying the stomach are occluded, and the end result is flow-dependent O_2 uptake. In this situation, an increase or decrease in blood flow is associated with a corresponding change in acid secretion. In normally perfused preparations, however, acid secretion and blood flow exhibit a relation similar to that observed between O_2 consumption and blood flow; acid secretion is dependent on blood flow at low blood flow rates and is independent at higher flow rates. This explains why vasoconstrictors tend to reduce gastric acid output and why some vasodilators (i.e., acid secretagogues) increase acid output whereas others (i.e., nonsecretagogues) do not.

Postprandial hyperemia

The term *postprandial hyperemia* is used to describe the increase in blood flow that occurs in response to a meal. The anticipatory–ingestion phase of digestion is characterized by transient increases in heart rate, cardiac output, and aortic pressure; however, gastrointestinal blood flow is either unchanged or slightly increased [118–122]. These transient hemodynamic responses appear to be mediated by activation of the sympathetic nervous system, because they can be attenuated by adrenergic blocking agents [120].

In conscious animals, blood flow to the stomach and proximal bowel increases 30–90 min after ingestion of a meal [118–121]. Blood flow to the ileum increases 45–120 min postprandially, whereas colonic blood flow generally does not increase [123–125]. Transient decreases in distal colon blood flow have been observed 30 min after a meal, a response attributed to tonic contractions produced by the gastrocolic reflex [125]. Blood flow in the superior mesenteric artery of conscious animals typically increases by 25%–130% after ingestion of a meal [118–120,126]. The splanchnic vasodilation may last for 4–7 h, depending on the nature and quantity of the meal [127,128]. A smaller increase (10%–60%) in blood flow is observed in isolated bowel segments in adult animals after intralumenal placement of digested food or nutrient solutions. This is consistent with findings in human subjects wherein intraduodenal perfusion with a test meal elicits a 35%–45% increase in superior mesenteric artery blood flow, with no gender differences in postprandial splanchnic flow [129].

Constituents of chyme responsible for postprandial hyperemia

Considerable effort has been devoted to defining the lumenal stimuli responsible for postprandial hyperemia. Lumenal placement of undigested food does not elicit hyperemia, whereas digested food significantly increases blood flow [130]. The latter observation indicates that hydrolytic products of food digestion initiate the hyperemia.

Bile appears to play an important role in postprandial intestinal hyperemia. Gallbladder bile at 10% concentration, the steady-state concentration in the proximal bowel in the early postprandial period, does not increase jejunal blood flow, yet it appears to render glucose and long-chain fatty acids vasoactive [131]. At a concentration of 33%, gallbladder bile renders both short-chain fatty acids (e.g., caproic acid) and amino acids vasoactive and further enhances glucose-induced hyperemia. Although intralumenal placement of endogenous or synthetic bile does not have a direct vasoactive effect in the jejunum, bile more than doubles blood flow in the ileum [130,132]. Bile acids are largely responsible for bile-induced hyperemia, an assertion supported by the observation that cholestyramine abolishes the vasodilator effects of endogenous bile on ileal blood flow [132].

Ingestion of meals with high levels of protein in humans and gastric placement of protein in conscious rats produces marked increases in splanchnic blood flow. In isolated loops of proximal small bowel, a high-protein diet (64%) increases blood flow by the same extent as a high-carbohydrate diet (68%) [133]. Although hydrolyzed proteins are known to induce postprandial hyperemia, the specific hydrolytic products of protein digestion that mediate the response remain unknown.

Solubilized long-chain fatty acids appear to be the most potent lumenal stimulus of postprandial intestinal hyperemia. Oleic acid (10–20 mM) solubilized in 10% gallbladder bile produces a 20%–60% increase in intestinal blood flow [131,134,135]. Evidence suggests that this increase in blood flow may be a response to epithelial cell injury [136].

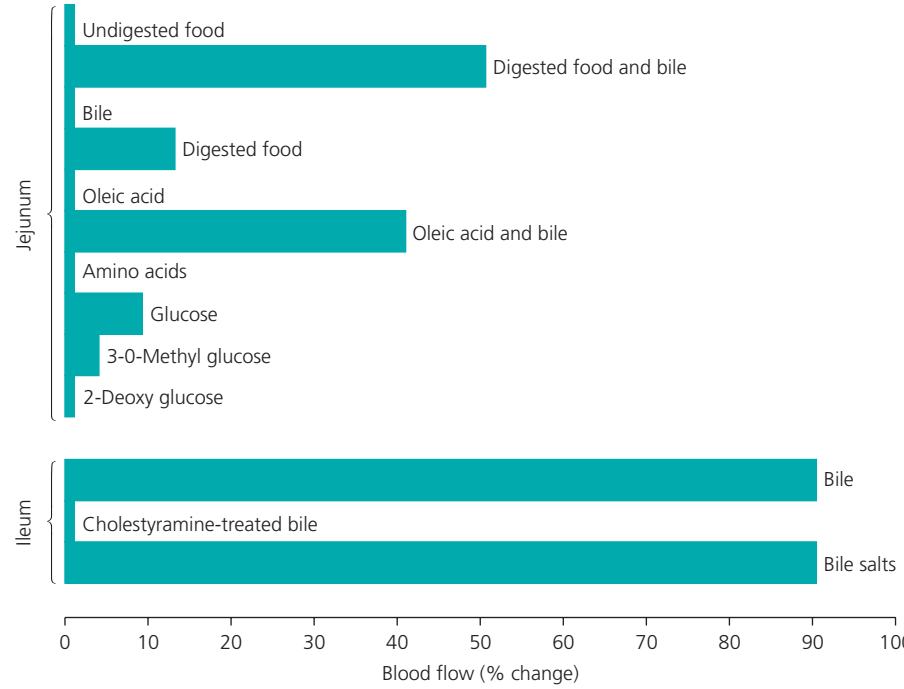

Figure 22.11 Effects of intralumenal placement of various constituents of chyme on intestinal blood flow. From Granger et al. [137], with permission from S. Karger AG, Basel.

Relatively little is known about the vascular response of the gut to the lumenal placement or ingestion of other dietary lipids. Short-chain fatty acids (e.g., caproic acid) do not alter blood flow, even in the presence of 10% gallbladder bile. Although lipids produce the largest intestinal hyperemia, the vascular responses elicited by protein and carbohydrate are not insignificant in that the three major dietary components of food – that is, fats, proteins, and carbohydrates – appear to act synergistically on blood flow when placed in the bowel lumen (Fig. 22.11) [137].

Mechanisms of postprandial hyperemia

Numerous mechanisms relevant to the gut vasodilation that occur during the digestive/absorptive phase have been investigated. The current consensus is that the final vascular effect reflects the integration of multiple inputs and that this orchestration is relatively region specific; i.e., that the inputs relevant to the stomach, jejunum, and ileum are unique.

Tissue metabolic rate

Nutrient absorption is an energy-dependent process and increases intestinal metabolic rate; hence, tissue O_2 demand increases after feeding under in vivo conditions, as well as in gut loops in vitro. This effect reduces the O_2 delivery-to-demand ratio and activates the metabolic mechanism previously described. Mathematical modeling of the intestinal circulation predicts expansion of capillary surface area and intestinal vasodilation in response to this perturbation [138] and these predications have been experimentally confirmed [26]. However, a metabolic mechanism alone does not account for all facets of postprandial hyperemia. For example, intralumenal placement of solubilized oleic acid induces a brisk hyperemia in the absence of any change in tissue O_2 uptake, and hence demand [139].

The putative role of tissue Po_2 as a stimulus for postprandial hyperemia has also been assessed on a microvascular level. Mucosal suffusion with isotonic glucose reduces villus Po_2 from ~ 17 to ~ 8 mmHg and simultaneously increases flow through the villus arteriole [99]. If the Po_2 of the mucosal suffusate is increased so that the glucose suffusion does not reduce villus Po_2, the villus arteriolar vasodilation is attenuated [33]. Once again, however, a metabolic mechanism cannot entirely account for intramural microvascular regulation during glucose suffusion; thus, vasodilation of upstream submucosal arterioles also occurs in response to glucose, despite the fact that periarteriolar Po_2 is unchanged at the submucosal level.

Adenosine

As previously discussed, adenosine has been proposed as an integral component of the metabolic mechanism, possibly functioning as the putative metabolic feedback signal. Adenosine is released into the venous effluent of isolated jejunal gut loops in response to intralumenal placement of a predigested meal [140]. Moreover, theophylline (an adenosine receptor antagonist), dipyridamole (blocks adenosine reuptake), and adenosine deaminase attenuate the magnitude of food-induced vasodilation [31,140]. Other work, however, failed to demonstrate an effect of adenosine antagonism on the magnitude of postprandial hyperemia [29].

Na^+-induced hyperosmolarity/nitric oxide

Na^+ is cotransported during the active uptake of glucose or amino acids across the villus membrane [141]. Ultimately, this process can lead to the activation of eNOS and resultant NO-induced vasodilation insofar as intracellular Na^+ homeostasis is maintained by the exchange of Na^+ for Ca^{2+}, and intracellular Ca^{2+} is a potent stimulus for eNOS [142]. The perivascular concentration of Na^+ increases within both the villus and the submucosal arterioles during glucose absorption [143]. Furthermore, the temporal sequence of increased perivascular Na^+ noted at the villus arterioles and thereafter at the submucosal arterioles is consistent with the timing of the vasodilation of these vessels during glucose absorption [34]. Movement of cotransported Na^+ to the submucosal space during villus glucose absorption may occur by way of the lymphatic system, as indicated by an increase in lymph osmolarity after mucosal glucose suffusion [144]. The anatomical juxtaposition of the extensive submucosal lymphatic plexus and submucosal arterioles is ideally suited for the flux of lymph-borne Na^+ to adjacent arterioles [145]. It also appears that Na^+-induced eNOS activation occurs within the lymphatic system with subsequent diffusion of NO to the immediately adjacent submucosal arteriole, leading to vasodilation [146,147].

The eNOS-derived NO may also participate in dilation of the small arteries that lie upstream from the submucosal arteriolar plexus [48]. These vessels, the vasa recta, represent the terminal portion of the mesenteric arterial arcade and are a vital portion of the intestinal resistance vasculature [148]. The perivascular concentration of NO increases at this site during glucose infusion; moreover, downstream blockade of the immediately adjacent venule reduces both the postglucose infusion rise in periarteriolar NO concentration and the subsequent vasodilation. The subsequent rise in flow rate through the arteriole would generate an additional mechanostimulus for eNOS activation; i.e., shear stress [41].

Gastrointestinal hormones

Feeding induces the production of vasoactive peptides and hormones by the gut. This effect was initially believed to contribute to postprandial hyperemia; however, subsequent work determined that postprandial concentration of these agents is below that necessary to induce a vascular effect [149]. The effects of cholecystokinin illustrate this circumstance. Intraarterial infusion of cholecystokinin induces vasodilation, but only if it is given at concentrations well above those noted after feeding [150,151]. In contrast, the peptide neurotensin, produced by gut neuroendocrine cells in response to feeding [153,154], does induce vasodilation at physiologically relevant concentrations [152]. Interestingly, the vascular effect of neurotensin appears to be region-specific: neurotensin-induced vasodilation occurs in the ileum [152], but not in the jejunum [151].

Enteric nervous system

While it is well accepted that extrinsic nerves play no role in the digestive/absorptive phase of postprandial hyperemia, some evidence supports a role for the enteric nervous system in this process [149]. Afferent fibers from neurons of the submucosal ganglia innervate the villi and synapse with efferent fibers that reach submucosal arterioles [75]. Vasoactive intestinal peptide, an effective intestinal vasodilator, is one of several neurotransmitters localized to these neurons [153]. VIP release and jejunal vasodilation occur in response to lumenal instillation of a bile–oleic acid mixture [154], and to mechanical stimulation of the mucosal surface [73].

Interactions between gastrointestinal and liver circulations

General considerations

Blood draining the gastrointestinal tract, pancreas, and spleen accounts for about 80% of the resting blood supply to the liver, with the remaining 20% of liver blood flow derived from the hepatic artery. This dual supply of blood to the liver reflects a combination of well-oxygenated blood from the high-pressure hepatic artery that mixes with poorly oxygenated blood from the low-pressure portal vein. Because of the higher O_2 content of arterial blood, the hepatic artery and portal vein contribute roughly equal amounts of O_2 to the liver in the fasting state. Within the liver, these vessels give rise to numerous smaller vessels, called the hepatic arterioles and terminal portal venules, which empty into sinusoids (the capillary network of the liver). Blood flow in the liver may be modulated at each of these anatomical sites. The sinusoidal capillaries radiate toward the periphery of the acinus, where they connect with the terminal hepatic venules and ultimately into progressively larger branches of hepatic veins and inferior vena cava [129,155].

A unique feature of the liver circulation is the role of capillary (sinusoidal) constriction in the regulation of intrahepatic vascular resistance and blood flow. This ability of sinusoids to constrict has been attributed to stellate cells that reside in the space of Disse in close contact with sinusoidal endothelial cells. Stellate cells exhibit anatomical features that are remarkably similar to smooth muscle-like pericytes, which have been implicated in the sprouting and remodeling of capillaries and may represent the anatomical equivalent of the precapillary sphincter that controls the perfused capillary density in other vascular beds. A variety of vasoconstrictors, including endothelin-1, angiotensin II, and vasopressin, are known to elicit stellate cell contraction that colocalizes with sinusoidal constriction. The gaseous monoxides, NO and carbon monoxide, also appear to play an important role in modulating stellate cell contraction, possibly through the activation of soluble guanylyl cyclase. The interplay of NO with vasoconstrictors like endothelin-1 may be a major

determinant of liver blood flow, especially after liver injury, which is often associated with stellate cell activation and an enhanced contractility. It has been proposed that exaggerated stellate cell contractility may contribute to the increased intrahepatic resistance and portal hypertension that can accompany liver injury. Through this effect on portal vein pressure, the stellate cell-mediated sinusoidal constriction may exert a significant influence on blood flow in those tissues, including the gastrointestinal tract, that are drained by the portal vein [129,156–158].

Inadequate blood perfusion of the gastrointestinal tract can result in impairment of organ function, tissue necrosis, and mortality. Although the liver receives most of its resting blood flow from venous drainage of the gastrointestinal tract, it appears to be relatively well protected against the deleterious consequences of gastrointestinal hypoperfusion. This protection largely results from the unique hydrodynamic interaction between portal venous and hepatic arterial blood flows that has been termed the hepatic arterial buffer response. With the hepatic arterial buffer response, an increased blood flow in the portal vein leads to an increased hepatic arterial resistance, whereas a reduction in portal vein flow produces hepatic arterial dilation. Adenosine washout from the space of Mall has been proposed as a major determinant of the alteration in hepatic arteriolar tone that accompanies changes in portal venous blood flow. The adenosine washout hypothesis predicts that adenosine levels are inversely related to portal venous blood flow and that adenosine exerts a potent dilator effect on hepatic arterioles. Although the reciprocal relationship between hepatic arterial and portal vein blood flows tends to maintain a constant total blood flow through the liver, hepatic arterial flow can only compensate for about 30% of the change in portal venous inflow. However, compensation relative to O_2 delivery is much greater because of the higher O_2 content of hepatic arterial blood compared to the portal vein blood. For example, it has been shown that liver O_2 supply remains relatively normal during hemorrhage until the blood loss exceeds 30%. The liver is more effective in maintaining constant O_2 consumption than tissues in the gastrointestinal tract because the extraction of O_2 from hepatic blood is highly efficient. This highly efficient O_2 extraction results from the small diffusion distances for O_2 transport between blood and hepatocytes. The combined effects of a large capacity for efficient O_2 extraction and the hepatic arterial buffer response ensures that the liver can tolerate substantial reductions in gastrointestinal blood flow without impairment of hepatocellular function [155,159].

Portal venous hypertension

Whereas exposure of the splanchnic circulation to an acute elevation in portal venous pressure is likely to elicit a myogenically mediated constriction of splanchnic arterioles, chronic portal hypertension tends to dilate the splanchnic vasculature. Furthermore, chronic portal hypertension has a significant impact on other regional vascular beds and on systemic hemodynamics. Blood flow to the gastrointestinal tract, kidneys, and skeletal muscle is significantly elevated. This presumably results from an increase in circulating vasodilators (e.g., glucagon) and a decrease in vascular sensitivity to vasoconstrictors (e.g., norepinephrine). The widespread dilation of arterioles results in a reduction of peripheral vascular resistance and a corresponding reduction of arterial blood pressure. In addition, cardiac output is elevated as a consequence of the increased venous return associated with the splanchnic and peripheral vasodilation. The elevated portal pressure results in the opening of portosystemic shunts to divert portal blood from the liver and reduce portal pressure. These shunts generally run along the esophagus (i.e., esophageal varices). The increase in portal pressure impairs venous drainage from the spleen into the portal vein, resulting in the accumulation of blood within, and distention of, the spleen (i.e., splenomegaly) [160–162].

Organ blood flow is determined by the arterial–venous pressure gradient and vascular resistance. It follows then that portal pressure is determined by portal venous inflow and portal venous resistance. The relationship between portal venous flow and portal pressure at a normal portal vascular resistance is depicted in Fig. 22.12 as a solid line. In this instance, an increase in portal venous flow will produce a proportional increase in portal pressure (point A to point B; flow-induced portal hypertension). When portal vascular resistance is increased, the relationship between portal pressure and portal venous flow is shifted upward and to the left, as depicted by the dashed line. At any given portal venous inflow, an increased portal vascular resistance will result in an increase in portal pressure (point A to point C;

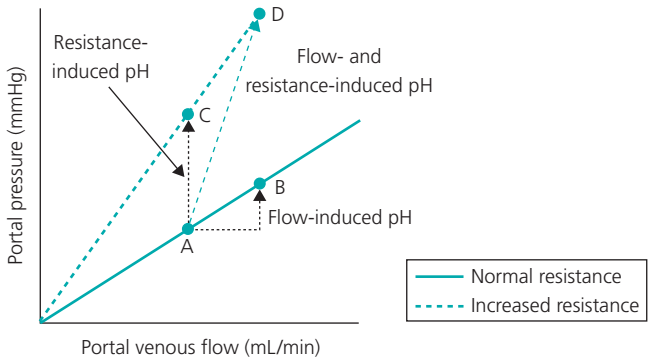

Figure 22.12 Hypothetical relationship between portal pressure and portal venous flow in the presence of a normal (solid line) or elevated (broken line) portal vascular resistance. Even when portal vascular resistance is normal, an increased portal blood flow (from point A to point B) can result in an increased portal pressure – that is, portal hypertension. An elevation in portal vascular resistance in the absence of increased portal blood flow (point A to point C) can also lead to portal hypertension. When both portal blood flow and vascular resistance are increased (point A to point D), the increase in portal pressure is more substantial. From Benoit et al. [163], with permission from Elsevier.

resistance-induced portal hypertension). Portal pressure can be further increased by a concomitant increase in portal venous flow and portal vascular resistance (point A to point D; flow- and resistance-induced portal hypertension). Indeed, the latter situation appears to reflect the vascular changes that account for the elevated portal pressure observed in some experimental models of chronic portal hypertension, and it is likely to account for the portal hypertension associated with some forms of liver disease. With a portal vascular resistance that is 40% higher in the portal hypertensive state than in the control state, it is predicted that increased portal inflow and increased portal vascular resistance account for 40% and 60% of the increase in portal pressure, respectively [163].

The portal hypertensive state leads to the development of collaterals (mostly along the esophagus; esophageal varices) to shunt blood from the congested portal vein, around the liver, to the systemic circulation (i.e., portosystemic shunting). Because a large proportion of portal venous blood bypasses the liver as a result portosystemic shunting, the hepatic degradation of different compounds, including circulating vasodilators, such as glucagon, is reduced. The diminished catabolism of circulating vasodilators increases their concentration in the plasma, allowing these agents to relax arteriolar vascular smooth muscle and reduce splanchnic vascular resistance. Another important action of some of the vasodilators that accumulate in chronic portal hypertension (e.g., glucagon) is to reduce the sensitivity of the splanchnic arterioles to vasoconstrictors such as norepinephrine, vasopressin, and angiotensin. The consequences of the direct and indirect actions of the accumulated circulating vasodilators include increased splanchnic blood flow and higher shear rates in splanchnic arterioles. Mechanical and humoral factors also exert an influence on NO generation by eNOS. The increased NO production that accompanies portal hypertension appears to result from endothelial cell responses that include increased intracellular Ca^{2+}, serine threonine protein kinase (AKT) activation, and the production and mobilization of molecular chaperones. However, some studies have revealed that eNOS-deficient mice exhibit a hyperdynamic state during portal hypertension, suggesting that eNOS-derived NO is not required for the induction of this vascular response. The net result of the vasodilation induced by all of these mechanisms is perpetuation of the portal hypertensive state [160–162,164–167].

Physiology and biochemistry of ischemia

Ischemic damage to the intestine occurs when splanchnic blood flow falls to a level at which the delivery of O_2 and other nutrients is insufficient to maintain oxidative metabolism and hence cell integrity. Blood flow to the gastrointestinal tract may be reduced during generalized nonocclusive ischemia (e.g., circulatory shock and congestive heart failure, especially in patients treated with cardiac glycosides) and in occlusive disorders (e.g., embolism, atherosclerosis, thrombosis) that primarily involve the mesenteric circulation. The mortality of acute mesenteric ischemia in adults has been reported at 70%–90% [168], primarily because of the difficulty of making an early diagnosis before bowel infarction occurs. Surgical intervention (e.g., embolectomy, intestinal resection) [169] and local intraarterial infusion of vasodilators (e.g., papaverine) [170] are used to treat acute mesenteric ischemia, but the mortality of this disease continues to be significant. Experimental nonocclusive mesenteric ischemia in dogs has been treated successfully with intravenously administered selective mesenteric vasodilators (e.g., urotensin I, sauvagine, and corticotropin-releasing factor) [171], thereby potentially obviating the risk of an indwelling angiographic catheter, but the use of these drugs in humans remains to be investigated.

Alterations of intestinal morphology with ischemia

The response of the intestine to decreased blood flow can range from no damage to transmural necrosis [172], and a gradient of sensitivity to ischemic injury has been demonstrated from the villus tips to the muscularis [172–174]. Mesenteric ischemia is associated with characteristic mucosal lesions that progress from subepithelial edema within 30 min after total vascular occlusion, to loss of epithelial cells along the villus after 1 h of total occlusion, to total loss of villi after 2 h of occlusion [172,173]. Within 30–60 min after total mesenteric artery occlusion, changes indicative of cellular failure appear, such as mitochondrial vacuolization and decreased O_2 uptake, loss of ATP, and release of lysosomal enzymes [174].

Changes in vascular and mucosal permeability with ischemia

Increases in the capillary filtration coefficient and microvascular permeability in the small intestine have been observed after ischemia [175]. The osmotic reflection coefficient of ileal capillaries to plasma proteins decreases after 1 h of ischemia and reperfusion; this is indicative of increased vascular permeability. Furthermore, the increase in permeability is derived from an increase in the number of large (20 nm) pores; the small-pore (5 nm) population is unaffected. In the intestine, the increase in the capillary filtration coefficient observed after ischemia and reperfusion is not solely a result of increased capillary surface area.

Increases in mucosal permeability induced by ischemia and reperfusion have been estimated based on the clearance of solutes ranging from 700 to 70 000 d [176,177]. The ischemia/reperfusion-induced increases in mucosal permeability are dependent on both the duration and severity of the ischemic insult (Fig. 22.13) [178]. Mucosal permeability increases significantly after 1–2 h of mesenteric artery occlusion in adult animals.

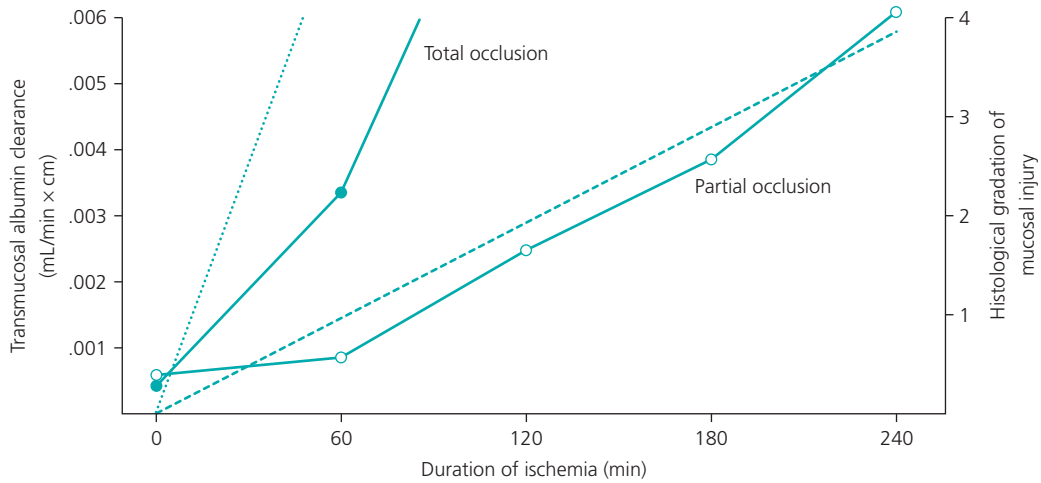

Figure 22.13 Comparison of quantitative morphological data (dotted and broken lines) and mucosal albumin clearance results (solid lines). From Parks et al. [178], with permission from Elsevier.

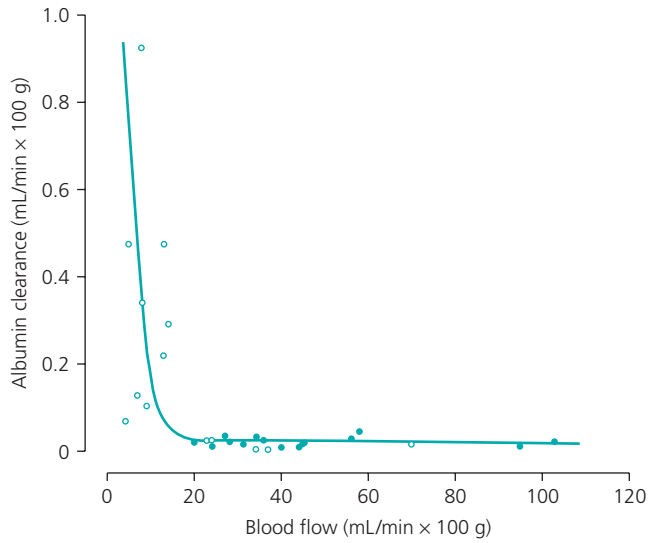
Blood flow, oxygenation, and ischemic injury

Ischemic injury to the intestine occurs when blood flow is reduced to a level that compromises delivery of O_2 and other nutrients to the tissue. Although the correlation of tissue Po_2, mucosal blood flow, and mucosal injury has not been investigated, reduction of blood flow to levels that do not affect O_2 uptake is not associated with any evidence of mucosal damage in adult animals [33]. Furthermore, substantial increases in mucosal albumin clearance are not seen until the blood flow falls to levels at which O_2 consumption is reduced by about 50% (Fig. 22.14) [33].

The importance of collateral blood flow in the prevention of intestinal ischemia is well recognized in humans [179–181] and in adult animals [182–184]. Intestinal collateral blood flow may occur through anastomotic connections at several levels of vessel branching, including the main arterial trunks (i.e., celiac, superior, and inferior mesenteric arteries) [179,182], extramural vessels (i.e., arterial arcades, marginal arteries) [184,185], and intramural vascular plexuses located within the intestinal wall itself [179,185]. Quantitative studies in adult animals have shown that collateral channels among the major arterial trunks and between adjacent bowel segments both play a role in the prevention of intestinal ischemia. In the adult cat, perfusion through collateral vessels after occlusion of the superior mesenteric artery maintained flow to the small intestine and proximal colon to



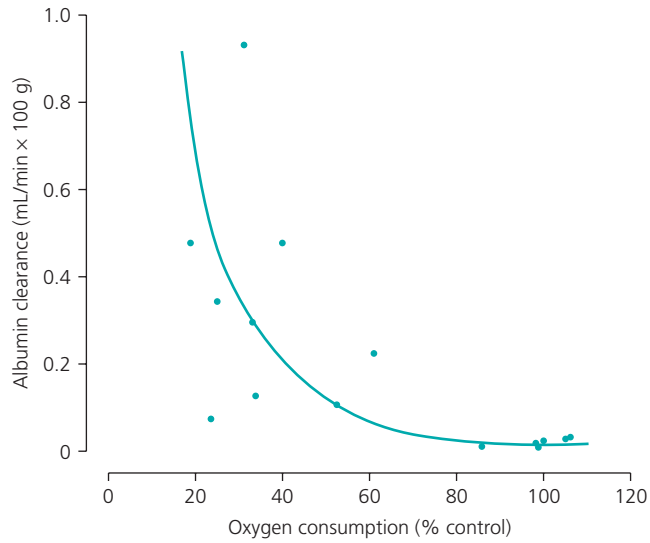


Figure 22.14 Relation between blood flow in control (closed circles) and during ischemia (open circles) and mucosal albumin clearance during reperfusion of canine jejunum (left). Relation between intestinal O_2 consumption in control and during ischemia and mucosal albumin clearance during reperfusion of canine jejunum (right). Substantial increases in albumin clearance were not seen unless blood flow was reduced to below 20 mL/min × 100 g or O_2 consumption was reduced to about 50% of the control values. From Bulkley et al. [294], with permission from Elsevier.

within 30%–65% of preocclusion flow [182]. However, the efficiency of collateral perfusion by way of the celiac and inferior mesenteric arteries is substantially lower in dogs after superior mesenteric artery occlusion [183]. In adjacent segments of canine small bowel, collateral vessels maintain blood flow in one segment at about 55% of its control level when the artery to that segment is totally occluded. The percentage of collateral flow attributed to extramural vessels is 67%, whereas that attributed to intramural vessels is 33% [184].

Possible mechanisms of injury or villous necrosis

Ischemic injury in the intestine appears to be related, either primarily or secondarily, to the effects of tissue hypoxia. In some species, the hypoxic stress induced by ischemia is exacerbated by the presence of a countercurrent exchange mechanism [141]. A role for hypoxia is supported by the observation that intralumenal perfusion with oxygenated saline solution markedly attenuates mucosal injury during ischemia induced by hypotension [186], whereas perfusion with nitrogenated saline solution does not attenuate injury. Possible mechanisms of mucosal injury induced by tissue hypoxia include depletion of high-energy phosphates necessary to produce protective substances, such as mucus, leading to increased susceptibility to the action of intralumenal proteases [187]; accumulation of histamine, leading to increased microvascular permeability [188]; production of metabolic acidosis, leading to release of lysosomal enzymes and cellular digestion [189]; conversion of xanthine dehydrogenase to xanthine oxidase, an enzyme that can produce cytotoxic O_2-derived free radicals during reoxygenation [190]; and attraction of circulating granulocytes into the mucosa, or activation of resident leukocytes within the mucosa, with release of neutrophilic proteases and oxidants to initiate or propagate mucosal injury [191].

It has been shown that changes in the intestinal mucosa induced by circulatory shock lead to an increased vulnerability to the digestive action of trypsin and chymotrypsin. Inhibition of pancreatic proteases by aprotinin [192] or previous ligation of the pancreatic ducts [193] significantly attenuates ischemic mucosal injury. In addition, an intralumenal injection of trypsin exacerbates mucosal injury [192]. The digestive action is caused by enzymes already present along the intestinal wall before shock, because removal of the pancreas has no effect if the animal is subjected to shock immediately after pancreatectomy [194]. Inhibition of pancreatic elastase and bile salts, both of which contribute to the loss of protective brush border glycoproteins [195,196], decreases mucosal injury. It has been proposed that if impairment of mesenteric blood flow prevents the steady regeneration of these brush border glycoproteins, then the mucosa becomes accessible to the digestive action of the pancreatic endopeptidases present along the intestinal wall and lumen [187]. Research has provided strong support for self-digestion by pancreatic enzymes as a major mechanism for the gut injury and multiorgan failure associated with hemorrhagic shock [197].

A role for reactive oxygen metabolites in the pathogenesis of injury associated with reperfusion of the ischemic bowel has received considerable attention during the past 20 years. The digestive system is particularly well endowed with the enzymatic machinery capable of generating significant quantities of reactive oxygen metabolites. For example, the intestine and liver are the richest sources of xanthine oxidase [198], an enzyme that catalyzes the production of both superoxide and hydrogen peroxide. Xanthine oxidase activity in the small intestine is located primarily within the mucosa, with a gradient of activity from villus tip to base [199]. In addition, the intestine contains a large, resident population of phagocytic cells (i.e., neutrophils, eosinophils, macrophages), which, when activated, produce considerable quantities of superoxide, hydrogen peroxide, and hypochlorous acid [200]. Oxidants generated by either xanthine oxidase or activated phagocytes can injure cells by a variety of mechanisms, including lipid peroxidation, degradation of the extracellular matrix, protein and carbohydrate decomposition, and DNA strand breakage [201]. Cellular enzymatic defense mechanisms against these oxidants include superoxide dismutase, which converts the superoxide anion to hydrogen peroxide and O_2, and catalase and glutathione peroxidase, which detoxify hydrogen peroxide [202]. Another important oxidant defense is reduced glutathione, which serves both as a cosubstrate for the glutathione peroxidase-catalyzed decomposition of hydrogen peroxide and as a free radical scavenger [201].

A large body of experimental data supports the hypothesis that reactive oxygen metabolites mediate the microvascular and mucosal permeability changes after reperfusion of the ischemic intestine and stomach in adult animals [191,203–207]. Superoxide dismutase (which scavenges superoxide anions), catalase (which detoxifies hydrogen peroxide), and dimethylsulfoxide (which scavenges hydroxyl radicals and decomposes hypochlorous acid) attenuate the vascular permeability changes observed after reperfusion of the ischemic intestine [203].

A role for xanthine oxidase in the increased vascular permeability and morphological changes induced by reperfusion has been proposed based on the following observations: attenuation of injury by pretreatment with allopurinol or pterin aldehyde, which are inhibitors of xanthine oxidase [204,208,209]; increased vascular and mucosal permeability during intraarterial infusion of hypoxanthine–xanthine oxidase, a superoxide anion-generating system [210]; attenuation of injury by soybean trypsin inhibitor, a substance that prevents the conversion of xanthine dehydrogenase to xanthine oxidase [205]; and attenuation of reperfusion injury by administration of a tungsten-supplemented, molybdenum-deficient diet, which inactivates xanthine oxidase [211].

Evidence to support a role for granulocyte-mediated injury after ischemia and reperfusion is also accumulating. Ischemia may lead to neutrophil activation, release, or production of neutrophilic oxidants (e.g., superoxide, hydrogen peroxide, hypochlorous acid, *N*-chloramines) and proteases, and subsequent tissue injury [200,212–214]. A fivefold to sevenfold increase in myeloperoxidase activity, which is an index of granulocyte number, occurs during ischemia, whereas reperfusion induces an 18-fold increase in myeloperoxidase activity in feline intestine [206]. Both neutrophil depletion and prevention of neutrophil adherence significantly attenuate the increased intestinal microvascular permeability induced by ischemia and reperfusion in cat intestine [191], suggesting that neutrophils, which migrate into the mucosa, mediate the injury produced by reperfusion of the ischemic bowel.

It has also been proposed that xanthine oxidase-derived oxidants may serve as chemoattractants for granulocytes in postischemic adult intestine. Allopurinol (an inhibitor of xanthine oxidase) [200], superoxide dismutase (a superoxide scavenger and inhibitor of neutrophil adherence) [200], catalase (a scavenger of hydrogen peroxide) [215], deferoxamine (an iron chelator) [215], dimethylthiourea (a hydroxyl radical scavenger) [215], and IB4 (a CD18-specific monoclonal antibody inhibitor of neutrophil adherence) [216] all inhibit reperfusion-induced granulocyte accumulation in the small intestine.

The view that leukocyte–endothelial cell adhesion plays an important role in the pathogenesis of ischemia and reperfusion injury, as well as in other inflammatory conditions of the gastrointestinal tract [217,218], has led to an increased interest in defining the factors that modulate leukocyte adherence and emigration in postcapillary venules. Intravital microscopic techniques have been used to monitor and quantify leukocyte–endothelial cell adhesion in venules exposed to ischemia and reperfusion [219–222]. During the final 10 min of a 60-min 80% reduction in mesenteric blood flow, the numbers of adherent and emigrated leukocytes increase fourfold and threefold, respectively. At 60 min after reperfusion, sevenfold and eightfold increases in adherence and emigration are noted. Electron microscopic analyses of postischemic mesenteric venules reveal that more than 85% of the leukocytes that emigrate into the adjacent interstitial compartment are neutrophils [223]. The recruitment of adherent leukocytes after reperfusion is associated with a corresponding accumulation of adherent platelets, with each blood cell exerting an influence on the recruitment of the other. Evidence suggests that platelet attachment to leukocytes and the products of platelet activation greatly enhance the inflammatory response to ischemia/reperfusion [220–222].

Several chemical mediators produced by endothelial or parenchymal cells have been implicated in the leukocyte–endothelial cell adhesion elicited by mesenteric ischemia and reperfusion. A growing body of evidence implicates xanthine oxidase-derived superoxide as a major mediator in this process. A role for superoxide is supported by reports that superoxide dismutase, whether administered before ischemia or after reperfusion, effectively reduces the number of adherent and emigrated leukocytes in mesenteric venules exposed to ischemia and reperfusion [219,224]. Superoxide dismutase is also effective in attenuating the adherence of neutrophils to endothelial cell monolayers exposed to anoxia and reoxygenation [224]. A similar antiadhesive action has been reported to occur with allopurinol [219,225], suggesting that xanthine oxidase is a likely source of the superoxide produced after reperfusion. Xanthine oxidase, rather than neutrophils, also appears to be responsible for generating the oxidants that mediate reperfusion-induced lipid peroxidation in intestinal mucosa. This contention is based on reports showing that although both allopurinol and CD18-specific monoclonal antibodies prevent the reperfusion-induced increase in mucosal myeloperoxidase activity, only allopurinol prevents the rise in tissue-conjugated dienes, an index of membrane lipid peroxidation [226,227].

A likely explanation for the proadhesive action of superoxide is that it inactivates an antiadhesion molecule that is normally produced by endothelial cells. NO, a product of L-arginine metabolism in endothelium that is rapidly inactivated by superoxide, may be such an endogenous antiadhesion molecule. NO donors are very effective in preventing the recruitment of leukocytes, platelet–leukocyte aggregation, and tissue injury associated with ischemia/reperfusion [228]. Inhibitors of NO production lead to a dramatic increase in the number of leukocytes adhering to and emigrating from mesenteric venules [229]. This adhesion response can be prevented or reversed by simultaneous exposure of venules to an NO synthase inhibitor and either L-arginine (but not D-arginine) or nitroprusside, which spontaneously generates NO. The observations that NO synthase inhibitors promote leukocyte adherence whereas superoxide dismutase reduces reperfusion-induced adherence are consistent with the view that the enhanced formation of superoxide by postischemic endothelial cells leads to NO inactivation and consequently results in enhanced leukocyte adhesion. Such a mechanism would explain why superoxide dismutase exerts an antiadhesive effect in postischemic tissues, because the enzyme would prevent inactivation of NO. NO also stabilizes mast cells through a mechanism that involves superoxide [230].

Catalase also has been shown to attenuate reperfusion-induced leukocyte adherence in mesenteric venules [225]. This observation is consistent with reports that demonstrate that hydrogen peroxide is produced by endothelial cell monolayers exposed to anoxia and reoxygenation [231], and hydrogen peroxide promotes neutrophil adherence to cultured endothelial cells and in mesenteric venules [232,233]. The levels of hydrogen peroxide required to promote adherence are well within the range of the hydrogen peroxide concentration produced by activated neutrophils. Both in vivo and in vitro studies indicate that hydrogen peroxide-induced

neutrophil adherence is mediated by platelet-activating factor (PAF) [232,233]. PAF receptor antagonists effectively attenuate the neutrophil adherence induced by hydrogen peroxide in feline mesenteric venules [216] and isolated canine carotid arteries [234]. The hydrogen peroxide-induced, PAF-mediated leukocyte adherence is prevented mostly by monoclonal antibodies directed against the common β-subunit of CD11/CD18.

The proposed role of reactive oxygen (hydrogen peroxide, superoxide) and nitrogen (NO) species in mediating the endothelium-dependent inflammatory responses observed in the gastrointestinal microcirculation after ischemia/reperfusion is summarized in Fig. 22.15. Ischemia/reperfusion leads to an increased production of superoxide and hydrogen peroxide by the enzyme xanthine oxidase, with a corresponding reduced production of NO by eNOS. The enhanced generation of oxidants results in the activation and deposition of complement, and phospholipase A_2-mediated production of leukotriene B_4 and PAF. Oxidants also mediate the initial expression of P-selectin by mobilizing the leukocyte rolling receptor from its preformed pool (Weibel–Palade bodies) in endothelial cells. Firm adhesion of leukocytes, which is mediated by β_2-integrins (CD11/CD18), is induced by the engagement of activated complement, leukotriene B_4, and PAF with their receptors on rolling leukocytes. Sustained rolling and adhesion of leukocytes on endothelial cells is ensured by an oxidant-dependent synthesis of endothelial cell adhesion molecules, such as E-selectin and intracellular adhesion molecule-1. Oxidants, derived from either endothelial cells or leukocytes, elicit this biosynthetic response by activating specific nuclear transcription factors (e.g., nuclear factor-κB) that bind to the genes for these adhesion molecules. The inflammatory responses to ischemia/reperfusion are amplified by mediators released from mast cells and macrophages that normally reside near postcapillary venules [235].

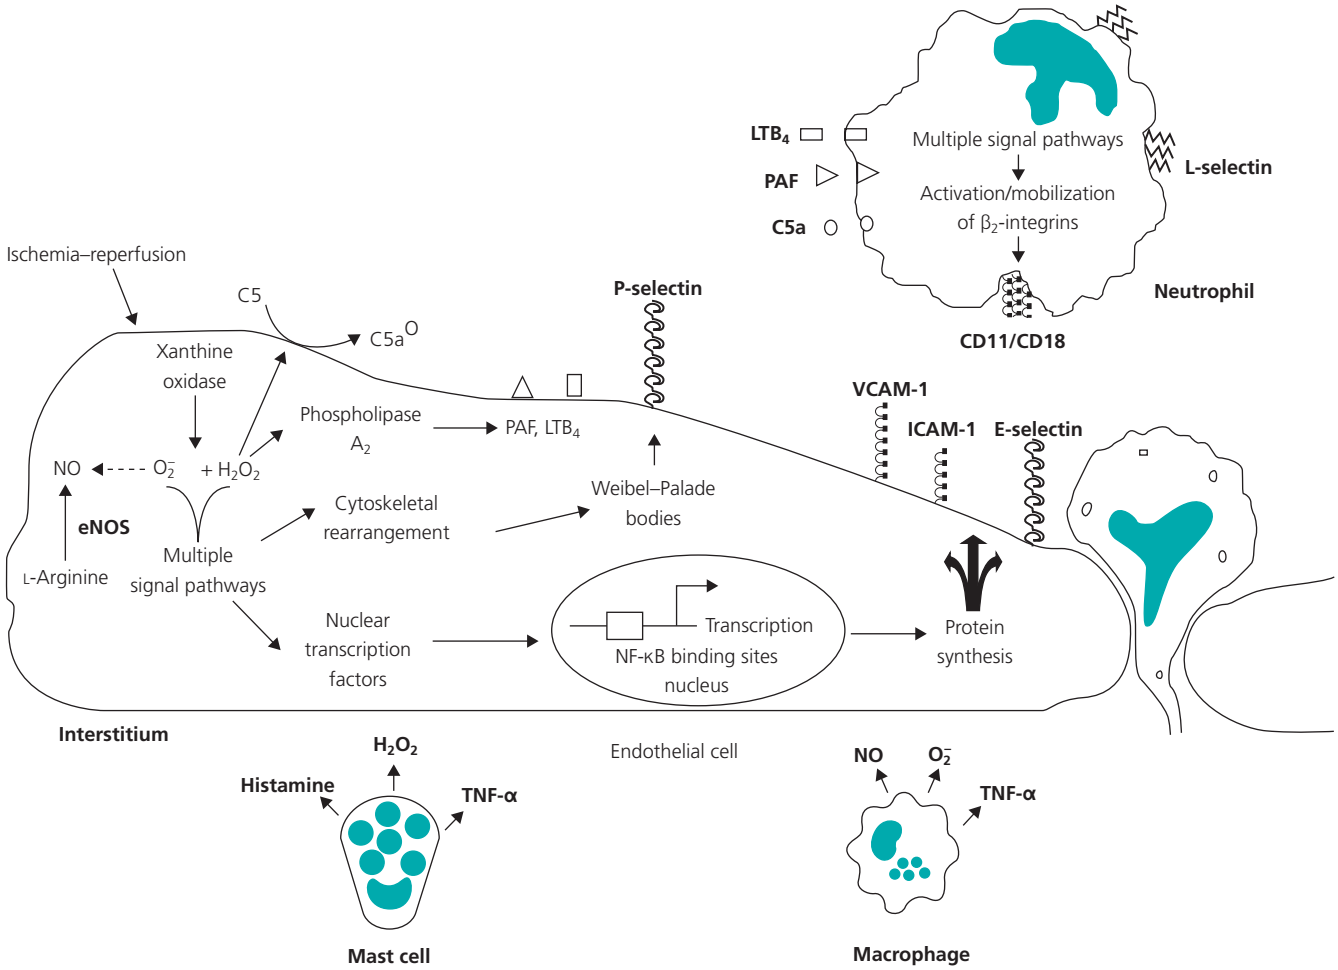

Figure 22.15 Mechanism proposed to explain the endothelium-dependent inflammatory responses observed in the postischemic microvasculature. C5a, complement 5a; CD11/CD18, leukocyte adhesion glycoprotein; eNOS, endothelial nitric oxide synthase; H_2O_2, hydrogen peroxide; ICAM, intracellular adhesion molecule; LTB_4, leukotriene B_4; NF-κB, nuclear factor-κB; NO, nitric oxide; O_2^-, superoxide; PAF, platelet-activating factor; TNF-α, tumor necrosis factor-α; VCAM, vascular cell adhesion molecule. The newborn intestinal circulation

At birth, the intestine assumes sole responsibility for the assimilation of water and nutrients; in addition, it begins a period of rapid growth. During subsequent postnatal life, dietary composition changes from one exclusively of milk to one of varied composition. It thus might be expected that the intestinal hemodynamics in the newborn would be unique when compared to the adult circumstance, a predication that has been experimentally confirmed.

Basal hemodynamic conditions

The basal, or preprandial, hemodynamic conditions within the piglet intestine change significantly during the first postnatal month, during which time the diet transitions from milk to cereal (Table 22.1). Highlights of these changes include:

- a progressive reduction of intestinal vascular resistance and concomitant fall in blood flow
- a progressive reduction of intestinal O_2 consumption (Vo_{2i}) [236].

A similar change in Vo_{2i} and gut vascular resistance and blood flow has been reported in lambs [237–239].

Factors established to induce intestinal vasoconstriction during early postnatal life

Extrinsic neural stimuli

Although sympathetic nerves are present in the intestine at birth, functional maturation of these nerves occurs during early postnatal life [240]. Intestinal denervation causes only a modest reduction of basal vascular resistance in newborn piglets, suggesting that the role of tonic adrenergic stimuli in setting resistance is minimal at birth [241]. Direct stimulation of the mesenteric nerve trunk generates vasoconstriction to a greater extent in weanling than newborn piglets; as well, Vo_{2i} is compromised only in older subjects [242]. "Escape" from adrenergic-induced vasoconstriction [53] occurs in both newborn and weanling subjects, and in the latter group, it is mediated in part by adenosine [55].

Table 22.1 Baseline hemodynamic conditions in swine perinatal intestine.

	3-day-old (newborn)	30-day-old (weanling)
Arterial pressure (mmHg)	75 ± 1	89 ± 1*
Capillary pressure (mmHg)	6 ± 1	6 ± 1
Mesenteric vein pressure (mmHg)	1 ± 1	1 ± 1
Total vascular resistance (mmHg/mL/min/100 g)	0.74 ± 0.06	1.82 ± 0.08*
Capillary filtration coefficient (mL/min/mmHg/100 g)	0.361 ± 0.040	0.203 ± 0.020*
(a–v)O_2 (mL O_2/dL)	2.9 ± 0.2	4.3 ± 0.3*
O_2 consumption (mL O_2/min/100 g)	3.01 ± 0.24	2.00 ± 0.12*

Capillary filtration coefficient reflects the perfused capillary density; (a–v)O_2 is the arteriovenous O_2 content difference across the intestine. O_2 consumption is calculated by the Fick equation as the product of flow and (a–v)O_2. Mean ± SE, $n = 12$.
* $P < 0.01$ vs 3-day old intestine.
Data from Warwick and Williams [1].

Intrinsic myogenic tone

The myogenic response – the intrinsic vasoconstriction noted in response to augmentation of intravascular pressure [7] – is present to a greater extent in the newborn than the weanling intestinal circulation [243–245]. The intensity of this response is reduced when tissue O_2 availability is compromised by ischemia, but only in weanling intestine [245]. Protein kinase C participates in the mediation of the myogenic response in small arteries from newborn, but not from weanling piglets [243].

Endothelin-1

The vasoconstrictor peptide endothelin-1 imparts basal vasoconstrictor tone in an age-dependent manner. This effect is more substantial in newborn intestine, as evidenced by two observations:

- blockade of endothelin receptors leads to vasodilation in newborn intestine
- the concentration of endothelin-1 in the newborn mesenteric venous effluent exceeds the arterial concentration.

These observations indicate a net production of the peptide within the newborn intestinal vasculature [14,246]. This developmental pattern reflects, in part, the postnatal ontogeny of endothelin receptors, whose expression is substantially greater in the newborn than weanling mesenteric artery [247,248].

Angiotensin II

Mesenteric artery rings from newborn piglets contract in response to the vasoconstrictor peptide angiotensin II, indicating the presence of the angiotensin II receptor AT1 within the newborn intestinal circulation. Blockade of AT1 receptors in vivo under resting conditions does not affect vascular resistance; however, intestinal vasoconstriction in response to cardiac tamponade is largely mediated by angiotensin II and the magnitude and duration of this effect is significantly greater in newborn than weanling piglets. While the angiotensin system plays a minimal role in setting basal vascular resistance in newborn intestine, it participates in the response to specific circulatory perturbations [249].

Platelet-activating factor

Platelet-activating factor, a proinflammatory phosphoglyceride [250], is well established as a cause of intestinal

vasoconstriction in adult animals [251]. It also reduces intestinal perfusion in the newborn piglet [252]. Indeed, intraarterial infusion of PAF causes hemorrhagic necrosis of the intestine in a manner indistinguishable from that induced by infusion of lipopolysaccharide.

Factors established to induce intestinal vasodilation during early postnatal life

Nitric oxide

The eNOS-derived NO is the principal vasodilator stimulus in the postnatal intestine and its effect is age-dependent, being more potent in newborn than weanling intestine [14,44]. The age specificity of this action is attributable, in part, to the postnatal change in eNOS expression, which increases on postnatal day 1, but then wanes between postnatal days 10 and 30; interestingly, this reflects posttranscriptional regulation insofar as eNOS messenger RNA expression remains stable during the first postnatal month [253].

Although direct measurement of eNOS activity has not been performed within the postnatal intestinal circulation, one factor known to activate eNOS, the mechanostimulus of flow [254], plays a prominent role in vascular regulation during early postnatal life. The application of flow induces vasodilation to a greater extent in newborn than weanling intestine; moreover, the release of NO by small mesenteric arteries in response to a flow stimulus is greater in newborns [255,256]. Further, flow-induced dilation overrides myogenic vasoconstriction in small mesenteric arteries from newborn piglets but not weanling piglets [14].

Substance P, adenosine

Substance P, a peptide neurotransmitter produced within the perinatal intestine [257], relaxes mesenteric artery rings in vitro and vasodilates the newborn intestinal circulation in vivo in a NO-dependent manner; this effect, although present, is less robust in weanling intestine [258]. Adenosine, an established intestinal vasodilator [81], contributes to the vasodilation that attenuates adrenergic-induced vasoconstriction during sustained mesenteric nerve stimulation (i.e., "escape") [55].

Response of the newborn intestinal circulation to specific perturbations

Hypotension (pressure–flow autoregulation)

Autoregulation in response to manipulation of arterial pressure is weak in the weanling intestine, and absent in the newborn (Fig. 22.16); indeed, prior induction of hypoxia, ischemia, or a postprandial state, factors that generally enhance autoregulation [10,259,260], have no effect on the efficacy of autoregulation in the newborn intestine under in vitro conditions [261,262]. Also, the newborn intestine cannot expand the perfused capillary density in response to reduced perfusion pressure, whereas weanling intestine has this capacity [236]. This circumstance, coupled with a lack of autoregulation, renders the newborn intestine profoundly susceptible to tissue hypoxia. Systemic hypotension generated under in vivo conditions also compromises intestinal perfusion in an age-specific manner, having a greater impact in the newborn [263,264]. The effect of venous pressure fluctuation is also age-dependent. Acute venous hypertension induces intestinal vasoconstriction that is more pronounced in the newborn [243,244].

Hypoxemia

Arterial hypoxemia, a circulatory perturbation common in sick human infants [265], induces intestinal vasoconstriction and tissue hypoxia to a greater extent in newborn than weanling intestine [266–268]. This effect is mediated locally, insofar as it occurs to an equal extent under both in vitro [266] and in vivo [269] conditions.

Sustained ischemia

Mechanically induced, sustained reduction of the intestinal flow rate to about 50% of baseline leads to progressive vasoconstriction, and hence to worsening intestinal ischemia in newborn animals, but not in weanling animals [270]. This age-specific phenomenon is mediated, in part, by at least two factors:

- a reduction of eNOS-derived NO production
- angiotensin II.

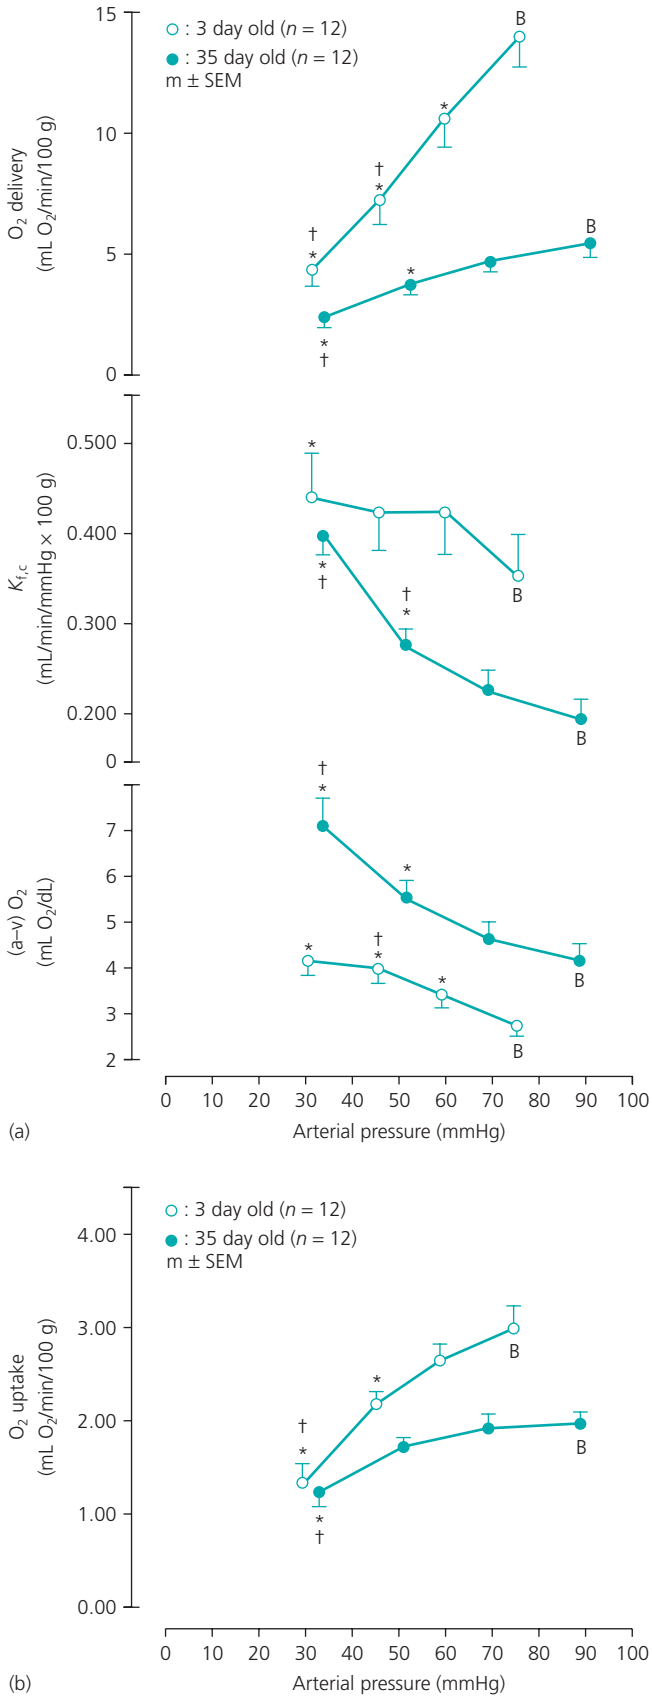
Moreover, exposure of the intestinal circulation of newborns, but not of weanlings, to sustained low flow conditions enhances its response to the vasoconstrictor effect of norepinephrine, angiotensin II, and vasopressin; the mechanisms of this effect are not known [271].

Postprandial hyperemia

Postprandial hyperemia occurs to a similar extent in newborn and weanling intestines [238,272,273]. Interestingly, Crissinger and Burney [272] observed that instillation of artificial formula directly into an in vivo gut loop in 1-day-old, never-nursed piglets decreased total gut perfusion. However, flow rate to the mucosal and submucosal layers of the gut increased in response to formula instillation in this age group; therefore, increased O_2 delivery to the site of nutrient absorption was achieved by redistribution of flow within the gut wall; i.e., mucosal hyperemia occurred at the expense of the muscularis layers [272]. This group also determined that postprandial hyperemia occurred in response to protein (5% casec), bile-acid solubilized fat (5% corn oil), and carbohydrate (5% glucose) to a similar extent in 3-day-old to 30-day-old piglets, showing that postprandial hyperemia occurred irrespective of the nutrient composition of the meal [274].

Putative clinical relevance of postnatal intestinal hemodynamics

Interest in the physiology of postnatal intestinal blood was sparked by its potential relevance to the pathogenesis of



neonatal necrotizing enterocolitis, the most common acquired gastrointestinal disease of infancy [265]. The histopathology of necrotizing enterocolitis clearly implicates preceding ischemia [275,276] and existing thought proposes that the triad of ischemia, inflammation, and exposure to nutrients (i.e., feeding) are the principal factors in disease pathogenesis [277,278].

Intestinal perfusion in the human fetus and infant has been measured by Doppler ultrasonography. This approach has limitations: the technique measures flow velocity or pulsatility, rather than flow per se, and is limited to observations of the superior mesenteric artery. The latter circumstance is especially troubling insofar as the vasculopathy relevant to necrotizing enterocolitis likely occurs within the intramural microvasculature [279]. With these caveats stated, however, several observations merit discussion. Blood flow velocity in the superior mesenteric artery increases within 30 min of feeding in full-term infants; interestingly, milk elicits a greater and more sustained increase [280], although human milk and cows' milk-based formula generated a similar response [281]. Premature infants deemed "at risk" for the development of necrotizing enterocolitis demonstrated decreased superior mesenteric artery flow velocity, although this finding was not ultimately predictive of the occurrence of necrotizing enterocolitis in these infants [282]. Superior mesenteric artery flow velocity in preterm infants with established necrotizing enterocolitis is reduced [282] or increased [283,284] with respect to control. This disparity likely reflects the relative irrelevance of superior mesenteric artery flow in necrotizing enterocolitis pathogenesis.

An alternative means to study the human intestinal circulation in necrotizing enterocolitis is by the in vitro assessment of arterioles removed from the submucosa and mesentery of intestine resected for this disease [285]. When compared to arterioles from control intestine, those removed from necrotizing enterocolitis-afflicted gut showed a greater basal vascular resistance that was attenuated by blockade of endothelin-1 receptors; concomitantly, this tissue demonstrated a greater concentration of endothelin-1. Interestingly, Weir and colleagues [286] demonstrated Doppler evidence of reduced

Figure 22.16 Relationships between perfusion pressure and various hemodynamic parameters in 3-day-old (newborn; milk-fed) and 35-day-old (weanling; cereal-fed) swine. Data were collected using blood-perfused in vitro gut loops. **(a)** O_2 delivery (product of blood flow and arterial O_2 concentration; here, the latter term is fixed, so that the data directly reflect blood flow); $K_{f,c}$ (a marker of the perfused capillary density; under these experimental conditions, an increase in $K_{f,c}$ indicates an expansion of the perfused capillary density, and vice versa); the arteriovenous O_2 content difference across the gut loop. **(b)** Tissue O_2 uptake, or consumption. Data from Nowicki & Miller [236], with permission from the American Physiological Society.

superior mesenteric artery flow velocity in infants as a function of the plasma endothelin-1 concentration.

Finally, a substantial body of work indicates an important role for PAF in the vascular pathogenesis of necrotizing enterocolitis [287]. PAF induces intestinal damage in newborn piglets similar to the damage caused by necrotizing enterocolitis in humans, whereas administration of PAF receptor antagonists attenuates this damage [252,288,289]. Plasma levels of PAF are elevated in infants with necrotizing enterocolitis [290,291]. Interestingly, PAF acetylhydrolase, the enzyme responsible for PAF inactivation, is present in human milk, and exclusive use of human milk in feeding preterm infants reduces the incidence of necrotizing enterocolitis [292,293].

Early development, 567
Organogenesis, 576
Developmental physiology, 586
Disorders of development, 590

Developmental biology seeks to understand how organisms are formed. Central to the field are questions about differentiation, morphogenesis, and growth – the processes that give rise to our physical appearance, physiology, and (when perturbed) diseases. Despite many years of intensive research, our understanding of the molecular mechanisms that guide normal vertebrate development remains primitive. Perturbations in these processes, resulting in congenital malformations or functional diseases, are all the more difficult to study because developmental insults may occur weeks or months before a defect is detectable.

While an understanding of how the body is formed is interesting and important in its own right, studies of development can also have a clinical impact. Exploiting developmental processes offers the promise of creating "cell therapies" – growing tissues ex vivo for use in tissue transplantation and augmentation, or coaxing cells in vivo to acquire characteristics that restore function. Fulfilling this promise will undoubtedly require a more complete delineation of developmental mechanisms.

The chapter has been divided into several sections to facilitate an appreciation for the complexity of the development of the gastrointestinal system. *Early development* outlines the basic mechanisms by which the embryo achieves a spatial "pattern," setting the stage for further developmental steps. *Organogenesis* focuses on the known molecular mechanisms that guide development of the liver, the pancreas, and the lumenal gastrointestinal tract. *Developmental physiology* samples important events during the functional maturation of the gastrointestinal tract. *Disorders of development*, the fourth and final section, focuses on specific diseases that highlight the relationship between molecular events and clinical consequences.

The embryology of the human gastrointestinal tract involves many temporally and spatially regulated tissue interactions and the creation of many varied structures. Atlases are excellent resources for detailed consideration of key aspects of embryology [1,2]. The ensuing discussion focuses on the mechanisms of gastrointestinal development. What hurdles must be surmounted to create a gastrointestinal tract with normal form and function and how can these processes be controlled for therapeutic benefit?

Early development

The complex anatomy of adult mammals has its origins in a single fertilized egg. The transformation from egg to newborn occurs in many steps marked by discrete events (Fig. 23.1). The fertilized egg initially grows in cell number through cleavage divisions into a blastocyst, an asymmetrical collection of cells containing the precursors of both embryo and placenta, which implants in the uterine wall. After implantation, the *endoderm*, from which the epithelium of all gastrointestinal organs is derived, is formed through the process of *gastrulation*. Subsequently, the endoderm is segmented (*patterned*) into domains, which become *committed* to give rise to specific organs. Finally, solid organ buds grow into the gut tube, and organogenesis proceeds with the processes of *differentiation* and *morphogenesis*.

Many studies of gastrointestinal development have been performed in model organisms, including fruit flies (*Drosophila*), frogs (*Xenopus*), zebrafish, and mice. Despite differences in anatomy and timing of development (see Fig. 23.1), most studies suggest that developmental mechanisms in the mouse are comparable to those in the human. Information gained from model organisms can therefore reasonably be extrapolated to humans because of the remarkable conservation of mechanisms throughout evolution. The terminology used in developmental biology is listed and defined in Box 23.1.

Gastrulation and tube formation

To understand gastrointestinal form and function, it is necessary to recognize the steps that precede organogenesis. The

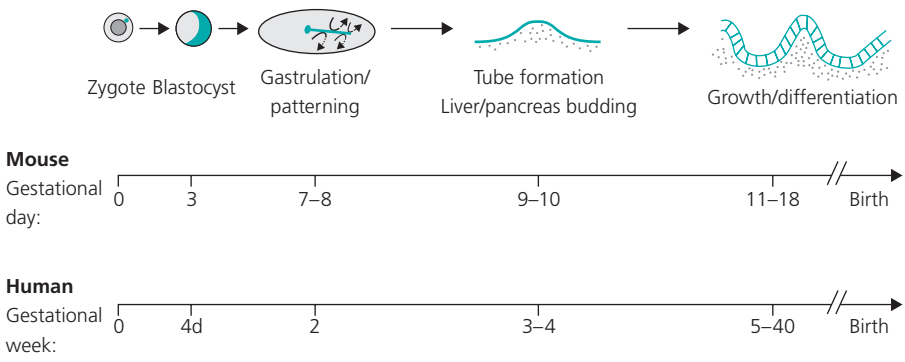

Figure 23.1 Overview of gastrointestinal development. Timelines for milestones of mouse (18-day gestation) and human (40-week gestation) embryogenesis. See text for details of individual steps.

Box 23.1 Terms in developmental biology

Gastrulation – the process by which cells migrate through the primitive streak of the epiblast to form the three germ layers of the embryo: ectoderm, mesoderm, and endoderm. The *endoderm* gives rise to the epithelium of the lumenal gastrointestinal tract, pancreas, liver, and lung, as well as parts of several pharyngeal organs (e.g., thyroid).

Fate/Specification – the assignment of predictive identifying information to a precursor cell or group of cells. Under normal circumstances, cells will adopt their specified *fate*, although cells may retain the *potential* to adopt other fates until the final fate *commitment* occurs. The set of fates that will be adopted in the absence of any external influence is determined by marking cells at one point in time and compiling a map of all the different types of cells derived from the marked cells.

Patterning – the regulated assignment of fates over a large area in a manner that ensures the proper positional relationship between tissues.

Differentiation – the acquisition by a cell of specialized features. Differentiation is generally associated with commitment or loss of potential.

Inductive signals – signals that impart fate-determining information. Such signals may be *permissive* (permit the expression of a previously assigned fate) or *instructive* (cause the cell to divert from a previously assigned fate).

Homeotic transformation – an alteration in the fate of a large tissue segment, such that it adopts the fate of a different tissue segment.

Morphogenesis – the assembly of a higher order structure in development (i.e., the creation of a two-dimensional structure from one dimension, or a three-dimensional structure from two dimensions).

Stem cells – "undifferentiated" cells exhibiting two properties: the capacity to give rise to multiple differentiated cell types, and the capacity for "self-renewal" (i.e., dividing to give rise to additional stem cells).

Embryonic stem cells – cell lines derived from the in vitro culture of dissociated blastocysts. These cells most closely resemble cells from the *inner cell mass* – the portion of the blastocyst that gives rise to the embryo proper. Embryonic stem cells themselves retain the capacity to give rise to all tissues in the animal, including gametes.

Transcription factors – proteins with the ability to bind DNA and activate (or repress) mRNA transcription. These factors are categorized into families according to structure; structural domains include homeobox, forkhead, zinc-finger, high mobility group (HMG) -box elements. In addition, components of some signaling pathways can themselves act as transcription factors (e.g., SMAD proteins).

Imprinting – the differential marking of maternally inherited and paternally inherited alleles of a gene, with resultant effects on gene expression and phenotype. Imprinting is most commonly achieved by differential DNA methylation, which occurs early in embryonic development.

most important of these is *gastrulation*, the process by which three distinct germ layers – ecotoderm, mesoderm, and endoderm – are formed. After implantation in the uterus, the embryo exists as a disc of cells called the epiblast. Two structures – the node and the primitive streak – appear in the posterior half of the epiblast layer, and cells migrate posteriorly toward and down through the primitive streak, giving rise to new layers of cells – the embryonic mesoderm and embryonic endoderm (Fig. 23.2). As a consequence of gastrulation, the three axes of the embryo are also established: the antero-posterior or rostral–caudal axis is defined by the location of the primitive streak (posterior); the dorsal–ventral axis is defined by the ectoderm (dorsal) and endoderm (ventral); and the left–right axis is defined by the other two axes.

How the cells that migrate through the primitive streak are instructed to become mesoderm or endoderm is incompletely understood. Phylogenetic analyses of organisms including fish, frogs, and mice point to a conserved pathway for endoderm

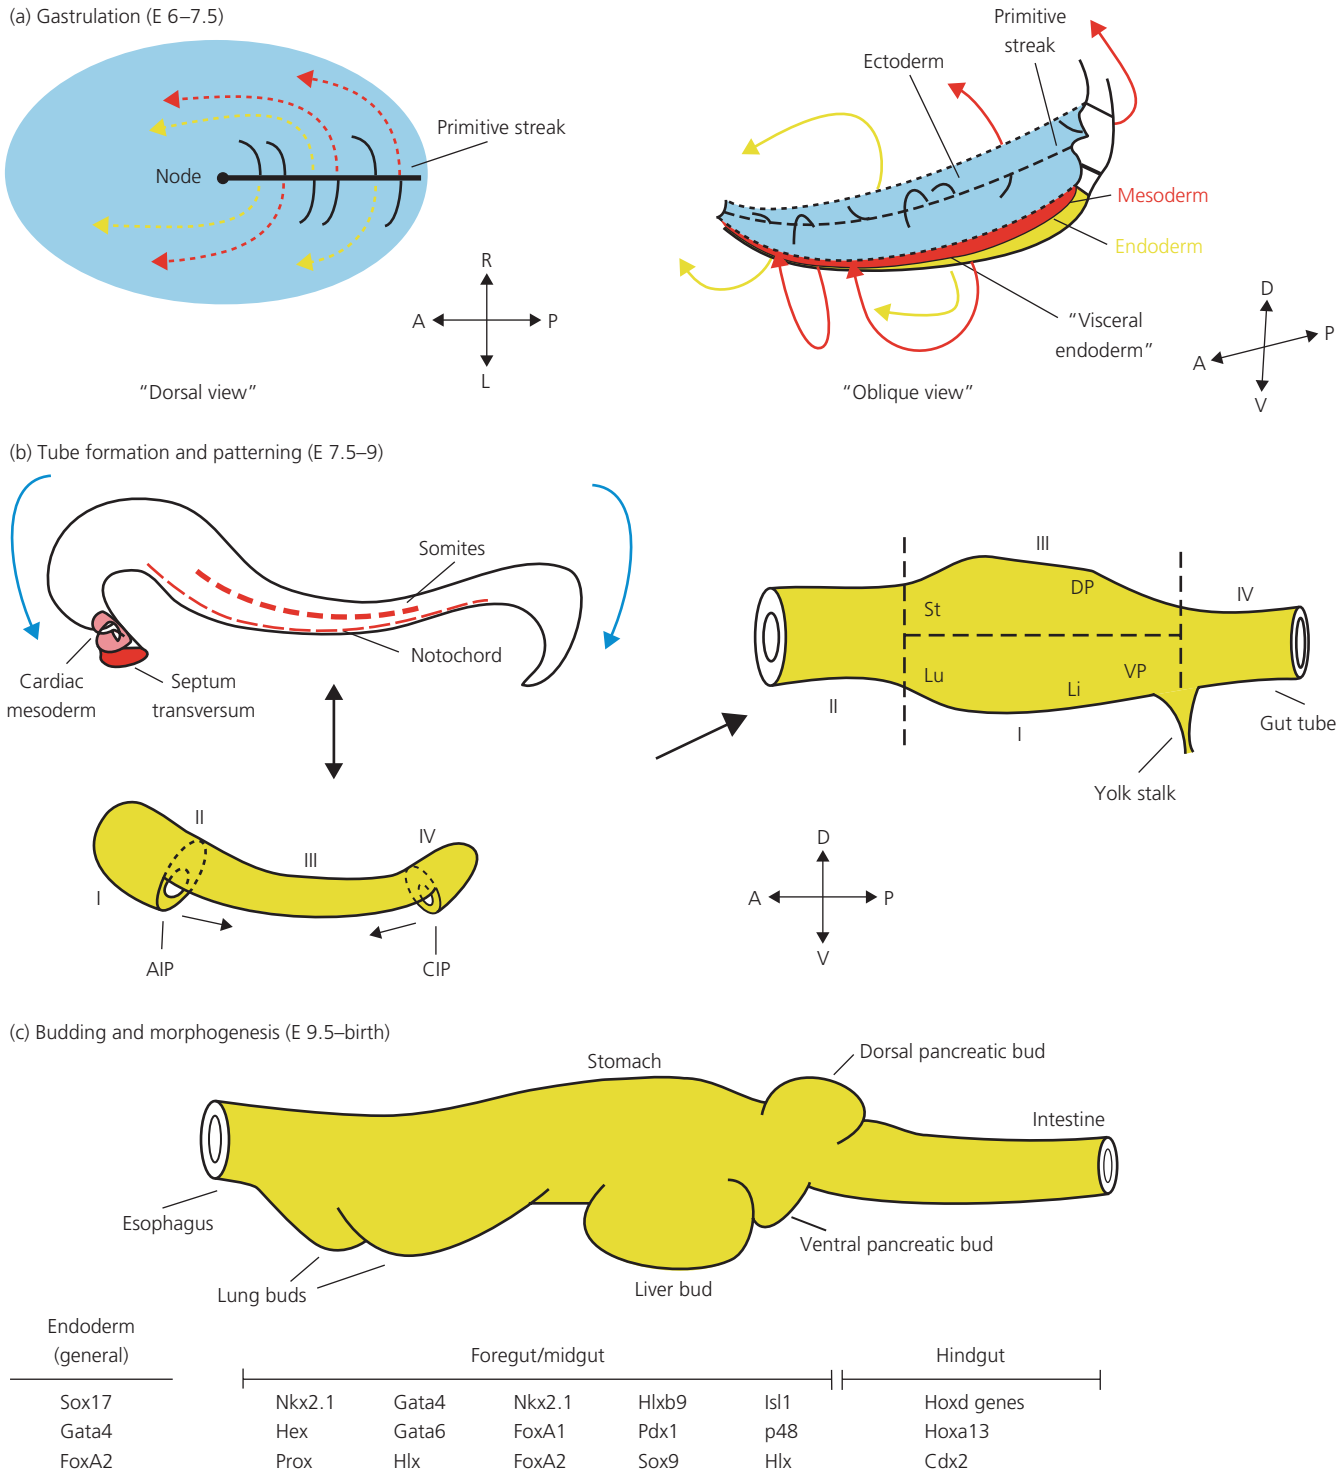

Figure 23.2 Major events in early mammalian endoderm development. **(a)** Gastrulation. (*left*) The embryonic epiblast (blue) viewed from above. Epiblast cells (solid black) migrate down through the primitive streak, becoming mesoderm (dashed red) or endoderm (dashed yellow) cells. (*right*) Oblique view of migrating epiblast cells, in which formation of the new mesoderm and endoderm is visible. **(b)** Tube formation and patterning. (*left*) The mesoderm and ectoderm have been pulled back to reveal the endoderm below. At this stage, the anterior endoderm is adjacent to the cardiac mesoderm and septum transversum (which mediate liver induction) whereas more dorsal portions of the endoderm are in contact with the notochord (which mediates pancreas induction). The folds of the anterior intestinal portal (AIP) and caudal intestinal portal (CIP) form the gut tube as they migrate towards each other at the midline. Blue arrows indicate the process of turning, by which the embryo switches from a convex to a concave shape, with the endoderm on the "inside". The roman numeral designations are derived from fate-mapping studies and indicate the prospective regions of endoderm that will give rise to later endoderm derivatives. (*right*) The relative position of endoderm domains changes with the completion of gut tube folding; the region that previously constituted the most anterior portion of endoderm (I) shifts to the ventral midline and gives rise to lung (Lu), liver (Li), and ventral pancreas (VP). **(c)** Budding and morphogenesis. Budding of endoderm derivatives begins shortly after the gut tube is formed and involves many transcription factors. DP, dorsal pancreas; E, embryonic day; St, stomach. Adapted from Stanger & Melton [240].

development that involves the transforming growth factor-β (TGF-β)-related nodal pathway and several classes of DNA-binding transcription factors that belong to the homeobox, forkhead (winged helix), zinc finger, and high mobility group (HMG) families [3].

The tubular structure of the gut arises from two ventral invaginations that form at the anterior (proximal) and posterior (distal) ends of the embryo after gastrulation (see Fig. 23.2). These will eventually form the structures of the foregut and hindgut, respectively. The anterior fold, or anterior intestinal portal, and caudal intestinal portal, move towards each other and meet in the midline of the embryo at the level of the yolk sac. As a result, ventral structures close to the midline (e.g., lung, liver, and ventral pancreas) derive from endoderm that is distinct and distant from the endoderm that gives rise to dorsal structures (e.g., dorsal pancreas). This arrangement means that the dorsal and ventral portions of the pancreas are independently induced, although these tissues eventually combine to form one functioning organ.

Several genes have been identified that are required for tube formation of the gut (Table 23.1). One of these genes encodes GATA4, a zinc finger-containing, DNA-binding protein. Although endoderm is able to develop in *Gata4* mutant mice, formation of the anterior intestinal portal is faulty and results in failure to form a foregut [4–6]. Other genes that are required for tube formation or closure include those for the forkhead-winged helix DNA-binding transcription factor FOXA2 (previously HNF3B), which has additional roles in foregut and midgut development, and the protease *furin*, which may be necessary to process TGF-β signals [7–9]. A critical and conserved role for two other families – the HMG domain-containing SOX factors and the homeodomain-containing MIX factors – has been demonstrated [10,11]. GATA4-like and FOXA-like factors are involved in gut development in organisms as distantly related to mammals as the fruit fly *Drosophila* and the nematode *Caenorhabditis elegans* [12], whereas the involvement of SOX and MIX factors appears to become important only in higher organisms including zebrafish, *Xenopus*, and mammals.

Pattern formation

Patterning refers to the stereotypical commitment of cells to certain *fates*, constituting in its grandest form the establishment of the "body plan" – the spatial arrangement of all tissue types in three-dimensional space. In the endoderm, patterning establishes the correct relationship, along the anteroposterior axis, of domains that will give rise to the respiratory tract and the gastrointestinal organs. Our understanding of how embryos are patterned comes largely from classical studies in *Drosophila*, which identified homeobox-containing transcription factors (*Hox* genes, in particular) as the major determinants of the body pattern [13]. A testament to the remarkable conservation of biological mechanisms across evolution, these studies have confirmed the critical role that *HOX* genes (and related homeobox-containing genes) also play in establishing the body plan of all higher organisms, including humans.

HOX genes, of which there are 39 in humans, have a distinct organization in the genome. Specifically, *HOX* genes are arranged sequentially within each of four distinct "clusters" (A, B, C, and D). This chromosomal organization of the *HOX* genes mirrors their expression in the embryo, so-called "co-linearity" of expression (e.g., the mouse *Hoxa* cluster consists of 12 genes; *Hoxa1* is expressed more anteriorly in the embryo than *Hoxa2*, which is expressed more anteriorly than *Hoxa3*, and so forth). Loss-of-function or gene knockout analyses in flies and mice have shown that these carefully regulated expression boundaries dictate the *pattern* of the ectoderm and mesoderm. Malformations in *Hoxa2* mutants are therefore more anterior (head) than those in *Hoxa3* mutants (neck and chest); this property holds true for all *Hox* clusters and genes. Conversely, enforced expression of a *Hox* gene in an ectopic segment causes a shift in the identity of that segment to an anterior or posterior fate. This respecification of fate is referred to as *homeotic transformation*.

On the basis of the key role that *Hox* genes play in establishing the anteroposterior pattern of the ectoderm and mesoderm, it would be logical to assume that these genes function similarly in the endoderm. Indeed, there are rare cases of homeotic transformations resulting from the misexpression of homeobox-containing proteins; for example, *Cdx2* is expressed in the early preimplantation embryo and its expression is maintained in the endoderm throughout development [14]. Although *Cdx2*-deficient embryos die before implantation, animals heterozygous for *Cdx2* develop colonic lesions that exhibit an anterior histology [15,16]. Conversely, misexpression of *Cdx2* in the stomach causes intestinal metaplasia [17,18], a more posterior phenotype. Thus, *Cdx2* seems to pattern the endoderm by directing cells to adopt a more posterior fate.

With the exception of *Cdx2*, the rarity of homeotic transformations in the endoderm suggests that homeobox-containing genes are only indirectly responsible for regulating the anteroposterior pattern of the endoderm. Although many *Hox* mutations result in intestinal malformations [19–22], these phenotypes are not specific to the endoderm. Nevertheless, several *Hox* genes are expressed in the endoderm, and the boundaries of *Hox* expression in the endoderm correlate with organ boundaries [23–25].

After gastrulation, the developing gut tube is surrounded by mesoderm from the so-called lateral plate. It has long been appreciated that patterning is normally influenced by interactions between mesoderm derivatives (mesenchyme) and endoderm derivatives (epithelia). Epithelial–mesenchymal interactions can be demonstrated by transplantation experiments in which pieces of endoderm and mesoderm from

Table 23.1 Transcription factors in gastrointestinal development

Gene class	Region	Function
HMG-box genes		
SOX17	Endoderm	Formation of definitive endoderm
SOX10	Enteric nervous system	Development of neural crest derivatives
SOX9	Intestine	Formation of pyloric sphincter
GATA genes		
GATA4	Endoderm	Anterior intestinal portal and foregut development
GATA6	Liver	Liver bud outgrowth, regulates HNF4
FOXA genes		
FOXA1 (*HNF3A*)	Endoderm, liver	FOXA1/A2 cooperate to specify the liver
FOXA2 (*HNF3B*)	Endoderm, liver	FOXA2 required for foregut and midgut development
FOXA3 (*HNF3G*)	Liver	Liver gene transcription
Onecut factors		
HNF6 (*OC1*)	Liver, pancreas	Bile duct, pancreatic duct, and islet development
OC2	Liver	Bile duct development
bHLH genes		
HES1	Liver, pancreas, intestine	Notch signaling; numerous roles in differentiation
NGN3, *NEUROD*	Pancreas, intestine	Pancreatic, gut endocrine cell specification
PTF1/p48	Pancreas	Early development of pancreas; exocrine transcription
MATH1	Intestine	Secretory vs enterocyte cell fate specification
Homeobox genes		
HEX	Liver	Growth of early liver bud
PROX1	Liver, pancreas	Growth of early liver bud, endocrine differentiation
HNF1B	Liver	Cholangiocyte formation
PDX1	Pancreas	Growth of pancreatic progenitor cells
HLXB9	Pancreas	Budding of dorsal pancreas, β-cell development
ISL1	Pancreas	Budding of dorsal pancreas, islet development
NKX2.2	Pancreas	β-cell development
NKX6.1	Pancreas	β-cell development
PAX4	Pancreas	β-cell development
PAX6	Pancreas	Islet development (α cells > β cells)
ARX	Pancreas	α-cell development
HLX	Intestine, liver	Early growth of liver and intestine
NKX2.5	Intestine	Formation of pyloric sphincter
CDX2	Intestine	Anterior–posterior patterning of intestine
HOXA/*HOXD* clusters	Intestine	Anterior–posterior patterning
Other		
HNF4	Liver	Terminal differentiation of hepatocyte
SMAD2	Endoderm	Endoderm development

HMG, high mobility group; bHLH, basic helix-loop-helix

different regions are recombined [26–29]. When tissues from postgastrulation embryos are recombined in this way, the fate of the endoderm is largely dependent on the type of mesoderm with which it is cultured; thus, anterior endoderm becomes "posteriorized" when recombined with posterior mesectoderm, and posterior endoderm becomes "anteriorized" when recombined with anterior mesoderm/ectoderm [30]. The mesoderm may be capable of providing the endoderm with a pattern because the mesoderm itself has already been patterned by *Hox* gene activity. Such a mechanism

regulates endoderm development in *Drosophila*, in which the nonoverlapping mesodermal expression of four homeobox genes (*Sex combs reduced*, *Antennapedia*, *Ultrabithorax*, and *abdominal-A*) guides the pattern of the adjacent endoderm [12].

Finally, other molecules may participate in endoderm patterning. Among these is the vitamin A-derivative, retinoic acid. Embryos exposed to excess doses of retinoic acid exhibit congenital malformations resulting from the transformation of anterior embryonic structures to more posterior fates, a "posteriorization" phenotype that also involves the endoderm [31,32]. The mechanism by which retinoic acid influences patterning in such a global fashion remains unclear.

Fate and potential

Although it is clear that after gastrulation, the fate of epithelial cells is strongly influenced by adjacent mesenchyme, cells in the epiblast contain information about their future identity and position even before gastrulation has occurred. This has been shown through the construction of *fate maps*, in which individual cells are marked at one time-point and their progress is traced during development. Fate maps of the epiblast illustrate a stereotyped pattern of development, in which the endoderm is largely derived from cells that surround the anterior primitive streak before gastrulation [33,34]. However, assignment of cell *fate* may not be irreversible, and cells may remain capable of adopting identities other than their assigned fates. This capacity to change fate in response to environmental cues is referred to as *potential.* Fate and potential represent important and distinct properties of a cell during development. Plasticity of this type, which is common throughout development, probably provides the embryo with a way of correcting errors that may occur during embryogenesis.

It is generally accepted that a loss in the potential (or *competence*) of cells to form different tissue types accompanies gastrulation. The ability of cells within the very early embryo to become any cell type (*totipotency*) is therefore reduced within each germ layer to a more limited set of possibilities after gastrulation. This progressive *commitment* means that the parenchymal cells of the gastrointestinal organs are derived exclusively from endoderm, and at later stages, different organs are derived only from specific portions of the endoderm. This classical notion of progressive commitment has been challenged by studies in which cells appear to be capable of traversing germ layer boundaries. As will be discussed in the section on transdifferentiation, such cellular behavior certainly occurs but whether it contributes significantly to normal tissue homeostasis is not clear.

How is the balance between competence and commitment achieved during development? Attention has focused on the importance of *chromatin* in the regulation of tissue competence. Chromatin defines the structural state of DNA–protein complexes that determine the "availability" of DNA for transcription factor binding. A model in which competence and commitment are achieved through sequential changes in chromatin has been suggested by studies of the regulatory region of the liver-specific albumin gene [35]. Such studies have used in vivo footprint analysis to characterize the binding of GATA and FOXA, endodermally expressed transcription factors previously discussed, to the albumin enhancer in several different cell types. In neural tube cells, which lack GATA and FOXA, the albumin enhancer is empty. In dorsal endoderm, the albumin enhancer is bound by GATA and FOXA (even although albumin is not transcribed in these cells), whereas in cells of the budding liver, the albumin promoter is bound by these and other factors and is transcriptionally active. Consistent with this model, FOXA factors are capable of modifying chromatin [36], and hepatic competence is specifically blocked in *Foxa1*/*Foxa2* mutant murine embryos [37].

Signaling in development

The assignment of cell fate in the endoderm is achieved through cell–cell signaling between neighboring cells or between adjacent cell layers. Such signals can be divided into two classes: *permissive* signals, which allow a tissue to progress to a fate that has already been assigned, and *instructive* or *inductive* signals, which divert a tissue to a new fate that would not otherwise have been followed. Instructive signals play an important role in regulating patterning by committing multipotent cells to specific lineages.

Developmental signals have traditionally been identified through transplantation studies, in which different embryonic structures (e.g., epithelium and mesenchyme) are cocultured. The resulting fate (or absence thereof) indicates whether signals are present or absent, and if present, whether the signals are permissive or instructive. Several features of development complicate the study of the specific ligands that mediate this intercellular communication. As development is a highly dynamic process, cells and cell layers are in constant motion relative to each other. Cell or tissue interactions may exist only transiently – long enough for a signal to be received, but not long enough to be easily characterized experimentally. Furthermore, signaling often occurs in a *reciprocal* manner. For example, the epithelium may respond to signal "A" from the mesenchyme by supplying signal "B", which in turn prompts the mesenchyme to secrete signal "C", and so forth. The number of secreted factors encoded in the genome is vast, leading to the potential for a level of signaling complexity that may preclude straightforward analysis.

While additional layers of complexity will undoubtedly be discovered, it appears that a limited repertoire of signals controls development. At least four signaling *modules*, each consisting of a family of ligands, receptors, and signal-modifying factors, are used iteratively during development: the fibroblast growth factor (FGF), hedgehog (Hh), bone morphogenetic

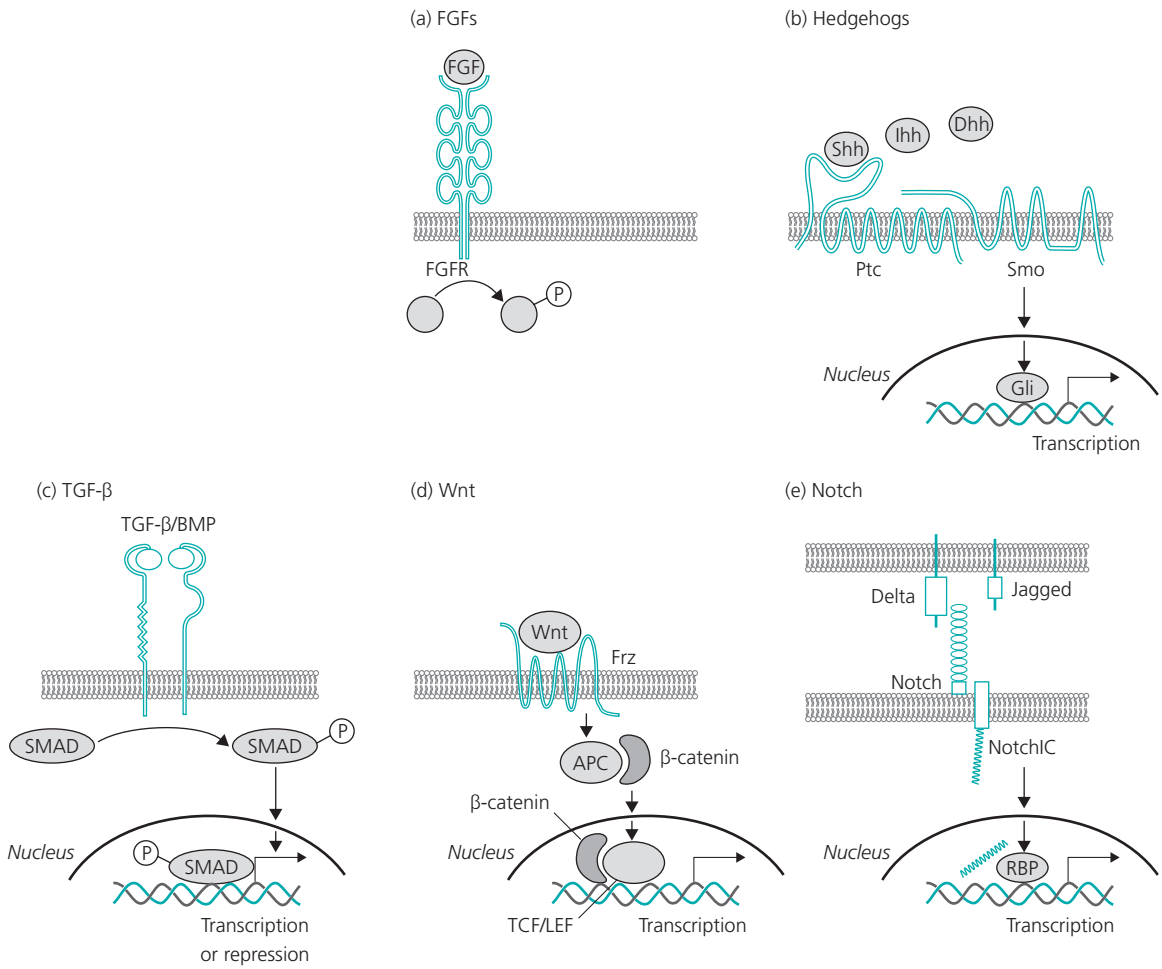

Figure 23.3 Ligand–receptor pairs in gastrointestinal development. **(a)** Fibroblast growth factor (FGF) signaling. Binding of an FGF ligand to one of four FGF receptors (FGFRs) leads to receptor dimerization and activation of FGFR tyrosine kinase activity. Phosphorylation of target proteins leads to the activation of multiple pathways, including Ras, phosphatidylinositol 3-kinase, phospholipase C, and STAT pathways. **(b)** Hedgehog signaling. All three hedgehog ligands – Sonic hedgehog (Shh), Indian hedgehog (Ihh), and Desert hedgehog (Dhh) – are capable of binding to the Patched receptor (Ptc). Ligand binding causes the membrane-bound signaling mediator Smoothened (Smo) to activate downstream transcription factors in the Gli family. These factors migrate to the nucleus and activate transcription. **(c)** Transforming growth factor (TGF)-β/bone morphogenetic protein (BMP) signaling. TGF-β family members bind to a heterodimeric membrane receptor complex consisting of a type I receptor and a type II receptor. The activated receptor complex phosphorylates SMAD transcription factors, which migrate to the nucleus where they mediate or repress transcriptional activation. **(d)** Wnt signaling. Binding of a soluble Wnt ligand to one of the seven transmembrane Frizzled (Frz) receptors results in the activation of the canonical Wnt pathway, in which adenomatous polyposis coli (APC) dissociates from β-catenin, allowing the latter to migrate to the nucleus where it becomes part of a transcriptionally active complex that includes T-cell factor/lymphoid enhancer factor (TCF/LEF) transcription factors. **(e)** Notch signaling. Cell–cell signaling is mediated by an interaction between one of the membrane-associated Notch ligands, Delta or Jagged, and one of the four Notch receptors on an adjacent cell. Ligand binding causes the intracellular portion of the Notch receptor (NotchIC) to migrate to the nucleus where it activates the retinol-binding protein (RBP) transcription factor.

protein (BMP), and BMP-related tumor growth factor (TGF) families (Fig. 23.3, Table 23.2). In addition, two other classes of signaling modules, Wnt and Notch, act predominantly in regulating differentiation within established organs. Cross-talk between signaling modules active in specific tissue layers (in particular epithelial HH and mesenchymal FGF and BMP) exemplifies the reciprocal nature of epithelial–mesenchymal signaling.

Fibroblast growth factors

The FGFs comprise a large family of ligands that are capable of variably binding to four FGF receptors. As both ligands and receptors are subject to a significant degree of regulation of splicing, the combinatorial ligand–receptor repertoire is vast and subject to complex variability in binding specificity and tissue-specific expression. FGF receptor signaling is largely mediated by the tyrosine kinase activity of the receptor, acting

Table 23.2 Soluble signals in gastrointestinal development

Tissue	Signal	Source	Function
Liver	FGF	Cardiac mesoderm	FGF 1, 2, and/or 8 specify prehepatic endoderm, promote liver bud outgrowth
	BMP	Septum transversum mesenchyme	BMP4 (and other BMPs?) cooperates with FGFs in specification, outgrowth
	HGF	Septum transversum mesenchyme	Mediate hepatoblast growth and suppress apoptosis
	???	Blood vessels	Expansion of liver bud into septum transversum mesenchyme
	Jagged 1	Portal mesenchyme	Specification or survival of cholangiocyte precursors (ductal plate)
Pancreas	Shh	[Endoderm]	Shh repression signals pancreatic specification
	FGF/activin	Notochord	Candidate mediators of Shh repression
	FGF10	Pancreatic mesenchyme	Outgrowth of pancreatic bud, pancreatic epithelium
	Delta/Jagged	???	Notch-mediated inhibition of pancreatic progenitor cell differentiation
	TGF-β family	???	Regulation of endocrine vs exocrine fate decisions
Intestine	Shh	Epithelium	Epithelial–mesenchymal cross-talk (Shh–BMP) regulates intestinal pattern
	BMP	Mesenchyme	Shh mediates radial pattern of gut. BMP regulates intestinal stem cell niche
	GDNF	Mesenchyme	Migration and/or survival of enteric neurons
	Endothelins	Mesenchyme	Migration and/or survival of enteric neurons
	Frizzled	???	Ligands for Wnt regulation of intestinal stem/progenitor cells
	Delta/Jagged	???	Ligands for Notch regulation of intestinal stem/progenitor cells
General	TGF-β family/Nodal	???	Regulation of endoderm specification

through Ras and phospholipase C pathways [38]. FGFs are expressed in the primitive streak, mesodermal structures of the postgastrulation embryo, and in developing organs, and they have important roles in endoderm patterning (possibly through a concentration gradient) and in organogenesis of the liver, pancreas, and intestine (see the section on organogenesis) [30,39,40].

Hedgehogs

The hedgehog genes were first identified through studies of *Drosophila*, and their names, like those of other developmental genes (e.g., *Notch*), arise from the characterization of mutants in that experimental model. There are three mammalian hedgehogs – Indian, Sonic, and Desert – all of which bind to the membrane receptor Patched (Ptc). In the absence of ligand, Ptc acts as a repressor of the signaling mediator Smoothened (Smo); on ligand binding to Ptc, Smo is derepressed and activates Gli transcription factors. Importantly, cells are able to distinguish different concentrations of hedgehog ligand. In traveling long distances, hedgehogs are able to create patterns through a gradient effect, in which cell fate depends on whether a high, intermediate, or low concentration of ligand is sensed. Sonic hedgehog (Shh) is particularly important in gastrointestinal development. Shh is expressed in the endoderm at the time of formation of the gut tube (in the anterior and caudal intestinal portals) and participates in the specification of the pancreas and regionalization/morphogenesis of the gut.

Bone morphogenetic proteins and the TGF-β superfamily

BMPs are members of the TGF-β superfamily of secreted proteins, a family that also includes the activins. Receptors for TGF-β family members are serine–threonine kinases that modulate the activity of TGF-β–responsive transcription factors (termed SMADs) through phosphorylation. The relevance of BMPs to gut development was also first suggested by studies in *Drosophila*, which showed that the BMP orthologue *decapentaplegic* responds to hedgehog signaling and is necessary for midgut development. Such reciprocal signaling between TGF-β and hedgehog family members is conserved in mammals, and represents one example of epithelial–mesenchymal signaling. Specifically, Shh is expressed in the epithelium of the developing gut, and induces expression of particular BMPs in the adjacent mesenchyme.

Wnts

Wnt ligands play a critical role in the formation of differentiated cell types in the embryo, a process called *cell fate determination*. Wnts are a family of secreted factors (there are at least 19 known mammalian Wnts) that bind "frizzled" receptors on the membrane. A complex series of events follow receptor binding. In the best characterized, or canonical, pathway, Wnt signaling leads to the release of β-catenin from the adenomatous polyposis coli (APC) protein, and the former then moves to the nucleus where it activates T-cell factor/lymphoid enhancer factor (TCF/LEF) transcription factors.

Box 23.2 Cancer and its relationship to development: cancer stem cell hypothesis

The observation that developmental signaling pathways are often activated in adult tumors has forged a bridge between the fields of developmental biology and cancer biology. The notion that cancer recapitulates development dates to the 19th century (reviewed by Sell [244]) and is embodied in the hypothesis that tumors arise from stem cells in adult tissues that retain an embryonic phenotype. Strong evidence for such a model exists in hemopoiesis but it remains to be determined whether stem cells represent a target for malignant transformation in solid organs.

Further evidence for a link between development and cancer comes from the "reemergence" of signals normally prominent in development during the course of tumor initiation and progression. Wnt signaling, normally important during embryogenesis, is activated in many hepatoblastomas and pancreatoblastomas in children. Mutations in the type 1A BMP receptor (BMPR1A) or the downstream signaling element SMAD4 are common in juvenile polyposis syndrome.

Links between developmental signals and tumorigenesis are not limited to cancers that occur in children or inherited cancers. Like their inherited counterparts (see Box 23.4), most sporadic colorectal cancers exhibit activated Wnt signaling. Many adult pancreatic adenocarcinomas exhibit a reactivation of PDX1, Sonic hedgehog, and Notch signaling, which are either completely absent or only present in a subset of cells in the adult pancreas. Furthermore, several gastrointestinal malignancies (esophageal and gastric, in particular) are preceded by metaplasia. This replacement of one tissue type with another may reflect the emergence of more primitive cells with a greater capacity for growth.

Similarly, the concept of "cancer stem cells" – special cells within a tumor that provide the tumor with an inexhaustible supply of new cancer cells – is based on this apparent link between development and cancer. The *cancer stem cell hypothesis* posits that most cells within a tumor have a limited capacity for division and are themselves generated from cells with an unlimited capacity for division. In several tumors (breast and brain, in particular), a small subset of tumor cells have been identified and shown to be uniquely capable of reconstituting the tumor [245,246].

This cancer stem cell hypothesis has enormous implications for cancer therapy. Most cancer therapies are assessed by their effect on tumor mass, the easiest assay for antitumor activity. However, if the cancer stem cell hypothesis is true, these agents would primarily target a cell population with a limited self-renewal capacity – analogous to a "transient amplifying population" – and may inefficiently kill the cancer stem cells. Stem cells that normally reside in adult tissues seem to be more resistant to chemotherapy than other cells [247], giving additional plausibility to this model. Therapies that target stem cells, if specific therapies can be found, may provide more durable cures and simultaneously generate less toxicity.

Despite the involvement of Wnt signaling in multiple developmental systems, including the intestine, developmental disorders with prominent gastrointestinal tract manifestations have not yet been associated with perturbed Wnt signaling. Rather, alterations in Wnt signaling are predominantly associated with carcinogenesis, particularly in the colon (colon adenocarcinoma), liver (hepatoblastoma), and pancreas (pancreatoblastoma) (see Box 23.2).

Notch

Like Wnt, Notch signals regulate the differentiation of cells within established tissues (Fig. 23.4). Of note, a role for Notch in the formation of endoderm itself has also been postulated [41,42]. There are four mammalian Notch receptors, which are activated by two classes of ligands, Delta and Serrate/Jagged. In contrast to ligands from the other important signaling modules, including Wnts, FGFs, BMPs, and hedgehogs, Delta and Serrate/Jagged are transmembrane ligands and so Notch mediates signals that cells receive only from their nearest neighbors. Ligand engagement leads to the detachment of the intracellular portion of the Notch receptor from the membrane, where it travels to the nucleus and alters the transcriptional program of the cell. Like Wnt signals, Notch signals are subject to complex regulatory inputs at all stages of the signal transduction pathway, from ligand binding to cytoplasmic and nuclear activation of downstream mediators.

The role of these signaling modules in adult homeostasis remains to be fully defined. However, it is known that some signals are necessary for function throughout life. For example, Notch and Wnt signals maintain the proper balance of cell types in both the embryonic and the adult intestine. It is not clear how developmental specificity is achieved when signals from a single family are used repeatedly. It is likely that signals are interpreted in the context of cellular identity, thereby causing the same signal to have different effects on different tissues (i.e., pancreas vs liver vs intestine).

Transdifferentiation

Several publications have challenged the notion that commitment imposes a nearly absolute boundary between different lineages. Several investigators have reported that certain somatic cells, particularly the cells derived from bone marrow, have the capacity to give rise to many different tissues in vitro and in vivo, including the cells of skin, lung, kidney, muscle, and all of the gastrointestinal organs [43]. A significant fraction of this apparent plasticity may actually reflect the effect of cell fusion between the bone marrow-derived cells and other differentiated cells, giving rise to tetraploid cells with the characteristics of hepatocytes, cardiomyocytes, and neurons [44–46]. Although it is possible that bone marrow-derived cells can transdifferentiate, albeit with low efficiency, into other somatic cells, the physiological significance of such a rare event is unclear [47], and the paradigms of lineage commitment established by developmental biologists during

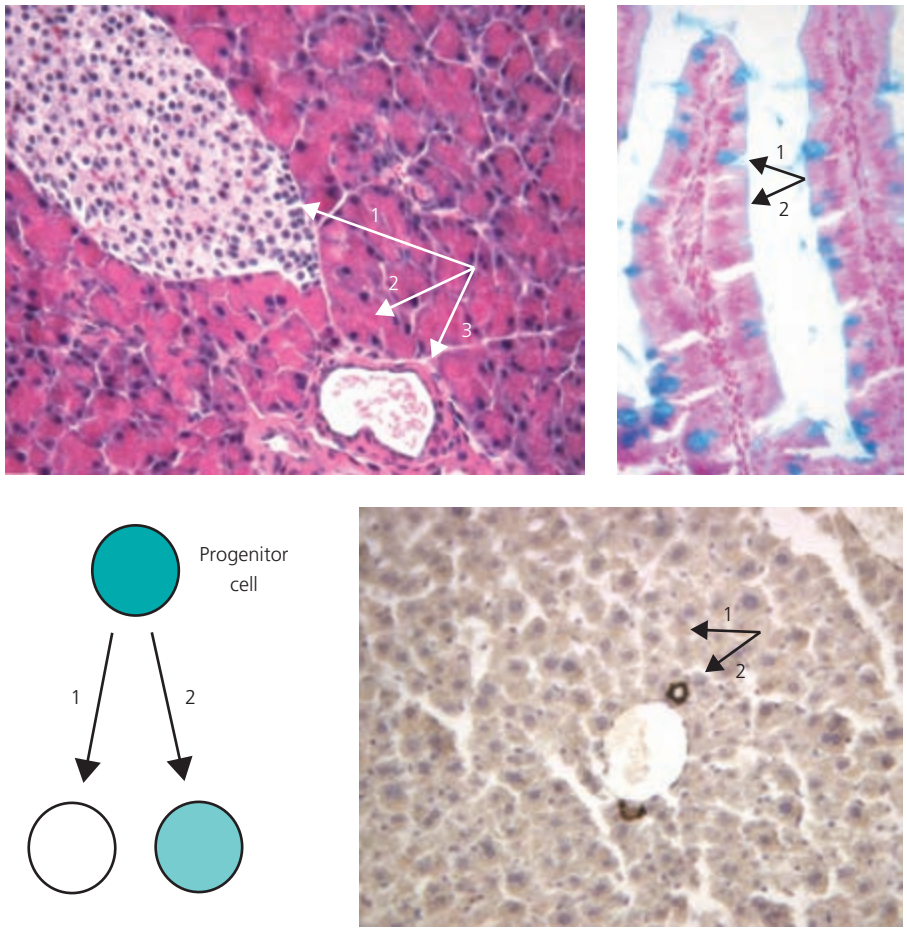

Figure 23.4 Control of gastrointestinal development by Notch. (*Lower left panel*) The fate of a multipotent progenitor cell (dark green) is influenced by whether it receives a signal from a Notch ligand (Delta or Jagged). In this example, active Notch signaling causes the cell to adopt fate 1 (white), whereas absence of signaling results in fate 2 (light green). Evidence supports distinct roles for Notch in various gastrointestinal tissues. In the pancreas (*upper left panel*), a Notch signal prevents the differentiation of the progenitor cell into any of the mature pancreatic cell types – islet (1), acinar (2), or ductal (3). In intestinal progenitor cells (*upper right panel*), activation of Notch signaling promotes the formation of enterocytes (2). The formation of secretory cells (1), such as the goblet cells visualized here with Alcian blue staining, is inhibited by Notch signaling. In the liver (*lower right panel*), Notch signaling is required for the proper formation of bile ducts (2), visualized by staining for cytokeratin 19. It is not known whether Notch acts in the liver by repressing the hepatocyte fate or through some other mechanism.

the 20th century remain largely intact. Nevertheless, the capacity of adult somatic cells to contribute to multiple lineages, whether by fusion or through developmental plasticity, points to the potential feasibility of cell therapy.

Conclusions

Early development of the gastrointestinal tract is characterized by gastrulation and endoderm formation, followed by midline migration of anterior and posterior invaginations (i.e., the anterior and caudal intestinal portals), resulting in a gut tube. The endoderm is patterned into organ domains along its anteroposterior axis through the activity of homeobox-containing transcription factors and epithelial–mesenchymal signaling. Cell fate remains plastic during the initial stages of development, with tissue identity depending on reciprocal signals that are refined until the commitment to a particular fate is made. Unanswered questions still remain concerning gastrointestinal development.

Organogenesis

After gastrulation, the endoderm undergoes more easily recognizable changes of organogenesis. Studies delineating the development of the gastrointestinal tract were performed over the 20th century and the timing of most key biochemical, physiological, and morphological events during human development was established at least 30 years ago [48]. Accordingly, this section will focus primarily on the mechanisms that underlie these remarkably complex and integrated events.

The same signaling pathways described in the previous section on early development are used in the specification of organ domains and the growth and differentiation of tissues. Sometimes, a single signal is involved in the development of two different organs, or one signal may mediate two different effects in the same tissue. In these instances, it is cellular *context*, the identity of the cell on which a given signal acts, that determines the signaling outcome.

Organogenesis can be divided into several overlapping phases:

- *specification* – a direct consequence of the patterning processes previously described, results in the commitment of cells to restricted tissue fates
- *budding* – of liver and pancreas
- *morphogenesis* – the formation of a three-dimensional structure that facilitates the physiological function of the tissue (e.g., hepatic sinusoids and intestinal villi

• *cell fate determination* – the restriction of specific lineages within the tissue (e.g., hepatocytes and cholangiocytes).

Importantly, these components of organogenesis do not occur sequentially or independently, but rather, they occur in parallel, in a coordinated fashion. Finally, differentiation programs are implemented within those lineages, allowing the expression of physiological function (discussed further in the section on developmental physiology).

Liver

Specification

The liver provides a good example of how a prepatterned mesenchyme can influence epithelial fate. The developing cardiac mesoderm, which gives rise to the heart, lies adjacent to the anterior endoderm fated to give rise to the liver (see Fig. 23.2b). Experiments performed decades ago showed that cardiac mesoderm plays a critical role in the formation of the liver. These studies consisted of transplantation assays in which pieces of endoderm and mesenchyme were independently assembled. Such experiments demonstrated that an interaction between endoderm and cardiac mesoderm, during a critical time window (four to six somites), is necessary for the endoderm to activate a liver program [26]. As the cardiac mesoderm moves anteriorly, the space adjacent to the prehepatic endoderm is replaced by the septum transversum, a mesoderm derivative that later gives rise to part of the diaphragm. Other signals mediate the outgrowth of the expanding liver bud into the septum transversum mesenchyme (see also Chapter 79)

Tissue transplantation studies using molecular markers have confirmed an important role for embryonic mesenchyme in liver development. For example, ventral endoderm expresses albumin (a marker of liver specification) when it is cocultured with cardiac mesoderm. However, other studies suggest that a more complex regulatory circuit underlies the process. For example, *dorsal* endoderm expresses albumin when it is simply removed from its adjacent endoderm. This surprising result implies that the normal function of cardiac mesenchyme is permissive rather than inductive, in that it may allow the expression of a "default" liver program [49]. Such a default mechanism may also apply to the ventral pancreas, which forms from a lip of anterior endoderm that constitutes the "leading edge" of the anterior intestinal portal. This piece of endoderm exhibits "bipotential" pancreatic/hepatic properties; i.e., it expresses pancreatic genes if cultured on its own, but represses the pancreatic program and expresses albumin if cocultured with signals from the cardiac mesoderm [39]. Although it is enticing to interpret these experiments as an indication that intrinsic endoderm fates are reprogrammed by specific mesenchymal elements, further confirmation of this model is required. In particular, the assay for reprogramming in these studies (e.g., detection of albumin transcription) may not be a reliable marker of liver specification, and it remains unclear what mechanism would initially program the default fates.

What are the specific signals that mediate these inductive effects? It is likely that a combination of FGF and BMP signals are involved in hepatic specification. Several FGFs are made by the cardiac mesoderm. FGFs are both sufficient and necessary for isolated anterior endoderm to activate albumin expression [50], and BMPs expressed by the septum transversum mesenchyme appear to act in concert with these FGFs [51]. The transcription factors Foxa1 and Foxa2 are critical mediators of these signals within the adjacent endoderm, as liver specification fails to occur in mice with a targeted inactivation of both of these genes [37].

Budding

After hepatic specification by the cardiac mesoderm, the formation of a bud that will become the liver begins. The first morphological evidence of budding is a thickening of the adjacent endoderm into a "hepatic diverticulum", which is followed by the outgrowth of liver cells into the septum transversum mesenchyme. FGFs are also necessary for this outgrowth, although their role in budding appears to be permissive and their actions alone are not sufficient for liver bud outgrowth [50]. BMPs (specifically BMP4) are independently required for liver budding into the septum transversum, as demonstrated with the use of *Bmp4* mutant mice and the BMP antagonist noggin [51]. Endothelial cells within the septum transversum mesenchyme may be the specific source for growth-promoting signals, as *Flk1* mutant embryos (which are incapable of forming mature endothelial cells or blood vessels) exhibit liver specification but fail to undergo liver budding [52].

Many genes are required after endoderm specification for outgrowth into the septum transversum. These include three homeobox-containing transcription factors, Hex, Prox1, and Hlx, and zinc-finger transcription factor GATA6. *Hex* is expressed during gastrulation in the first endoderm cells to pass through the primitive streak that ultimately give rise to the liver (these are the cells that constitute the anterior-most cells of the endoderm before it folds back on itself during formation of the anterior intestinal portal). Mice lacking *Hex* form a small hepatic diverticulum, but subsequent outgrowth and budding fails to occur [53,54]. *Hlx* and *Prox1* mutant mice also exhibit growth arrest at the bud stage, although the livers of *Prox1* mutant mice ultimately reach nearly a third of the size of a normal liver [55,56]. *Hex* and *Prox1* are expressed in the hepatic epithelium, whereas *Hlx* is normally expressed in the septum transversum mesenchyme.

As previously described, the GATA4 zinc finger transcription factor binds to the albumin promoter before albumin expression, suggesting a role in liver specification [35]. Another GATA family member, GATA6, also plays an important role in liver development. GATA6 regulates HNF4, an important transcriptional regulator of hepatocyte genes (described in

the section on morphogenesis and cytodifferentiation), and liver bud outgrowth is retarded in mouse embryos lacking *GATA6* [57]. Further studies are needed to determine whether a regulatory relationship exists between *Hex*, *Hlx*, *Prox1*, and *GATA6*, given the similar phenotypes that mutations of these genes exhibit. Further studies are also required to determine the signaling hierarchy between soluble FGFs and BMPs and the activity of these transcription factors; for example, *Hex* expression can be induced by BMP signaling [58].

Morphogenesis and cytodifferentiation

After this migration into the septum transversum, epithelial cells intercalate with mesenchymal cells, eventually leading to the formation of the hepatic sinusoids, which support embryonic hemopoiesis. These morphogenetic changes are accompanied by dramatic growth of the liver, which seems to require mesenchymal factors. The most important of these is hepatocyte growth factor (HGF), which signals through the c-met receptor. Mutation of either *Hgf* or c-*met* leads to marked liver cell apoptosis in some but not all analyses [59,60]. This signaling pathway also seems to modulate the response to injury in adult liver [61,62]. Mutations in several other genes, including components of the tumor necrosis factor (TNF)–nuclear factor-κB signaling pathway, lead to similar developmental apoptosis phenotypes [63–65]. Hepatocyte apoptosis in many adult liver diseases is mediated by a TNF-like "death receptor" pathway [66], suggesting that these cell death signaling mechanisms remain active throughout life.

The two major parenchymal cell types of the liver – hepatocytes and bile ducts – are believed to arise from multipotent embryonic "hepatoblasts." Intrahepatic bile ducts are derived from "ductal plates", precursor structures that form around branches of the portal vein. Inductive signals from the portal vein induce surrounding hepatoblasts to form the ductal plate, which can be recognized by the expression of distinctive cytokeratin (CK) molecules, such as CK19 (Fig. 23.5a). Mature intrahepatic bile ducts emerge after remodeling of the ductal plate, which involves selective apoptosis of duct precursors. Little is known about the development of the extrahepatic bile ducts and the gallbladder, which are thought to be directly descended from the gut tube.

Several signaling pathways are involved in biliary specification and morphogenesis. Among those first identified were liver-enriched "hepatocyte nuclear factors" (HNFs). HNFs belong to several different transcription factor families and contribute to the expression of liver-specific genes. Inactivation of either HNF6 (a member of the onecut transcription factor family) or HNF1B (a homeodomain factor) perturbs biliary development [67,68]. The reduced HNF1B expression in the livers of *Hnf6* mutant mice suggests that HNF6 likely acts through HNF1B [67]. Alternatively, HNF6 and the onecut transcription factor OC2 act through activin/TGF-β family member(s) to regulate biliary fate decisions. The liver normally exhibits a gradient of TGF-β signaling activity, with high activity near the ductal plates and low activity in the remaining parenchyma. In livers lacking both HNF6 and OC2, this gradient is disrupted, resulting in high levels of activin/TGF-β signaling throughout the liver and the appearance of cells exhibiting features of both hepatocytes and cholangiocytes. Thus, onecut transcription factors may shape a gradient of activin/TGF-β signaling to allow localized induction of the bile ducts.

In addition, there is convincing evidence that Notch signaling is important for biliary development. Mutations in the Notch ligand Jagged 1 (JAG1) result in Alagille disease, a clinical syndrome that includes a paucity of intrahepatic bile ducts [69,70]. The molecular pathogenesis of Alagille syndrome is discussed further in the section on disorders of remodeling.

A cellular differentiation program is executed after the assignment of biliary or hepatocyte fate. Evidence that this program is distinct from the assignment of hepatocyte cell fate comes from the targeted inactivation of HNF4. Remarkably, this transcription factor binds to nearly half of the actively expressed genes in the liver [71]. Among the genes whose expression "defines" the hepatocyte are albumin, apoplipoproteins A and B, and transferrin. Despite exhibiting normal morphogenesis, HNF4-deficient embryos exhibit reduced expression of all of these genes, demonstrating a role for this transcription factor in hepatocyte differentiation, but not liver specification and morphogenesis [72]. Although other transcription factors, including gene products whose importance in liver development has just been described (e.g., HNF1B, HNF6, FoxA), bind to liver-specific promoters, the function of these transcription factors is redundant, as their replacement by other factors preserves liver development [73].

Summary

FGF and BMP signals from the cardiac mesoderm and septum transversum mesenchyme induce a portion of the ventral foregut endoderm to become liver. Budding and parenchymal growth involves homeobox-containing transcription factors and mesenchymal factors, such as HGF, that mediate proliferation and suppress apoptosis. Poorly understood epithelial–mesenchymal interactions mediate the morphogenesis of hepatic sinusoids, which support hemopoiesis during fetal life. Biliary development involves the formation of periportal ductal plates and subsequent remodeling, a process that requires Notch and TGF-β signals and the activity of several onecut transcription factors. In hepatocytes, other transcription factors like HNF4A are required for the expression of the hepatocyte program.

Pancreas

With some important exceptions, development of the pancreas follows a pattern that is similar to that of the liver.

[226], with permission from the Company of Biologists, Ltd. **(e)** Periportal expansion of bile ducts in a patient with the ductal plate abnormality characterisitic of congenital hepatic fibrosis.

Specifically, signals from adjacent mesoderm specify the pancreatic endoderm, FGFs mediate pancreatic growth, and a variety of signaling components (including Notch and homeobox-containing transcription factors) regulate the differentiation of the parenchymal cell types – exocrine, endocrine, and duct cells.

Specification

Unlike the liver, the pancreas forms from two distinct pieces of foregut endoderm – a dorsal pancreatic domain and a ventral pancreatic domain (see Fig. 23.2c) – that later fuse into a single integrated gland. Patches of endoderm on opposite sides of the gut tube must therefore somehow be instructed to become pancreas. Transplantation studies similar to those previously described have shown that the dorsal pancreatic region of the endoderm is specified before the 13-somite stage, a period when this endoderm is in contact with the notochord [74]. At a slightly later stage, the prepancreatic endoderm is in contact with the aorta (dorsally) and the vitelline veins (ventrally). Thus, the notochord or blood vessels could be mesenchymal sources for inductive pancreatic signals, akin to the cardiac mesoderm for the liver.

Indeed, evidence suggests that both the notochord and the blood vessels are important for pancreatic specification and growth. Isolated dorsal endoderm fails to express pancreatic markers when cultured on its own, but a pancreatic program

is induced on reassociation with the notochord [75]. Similarly, coculture of dorsal endoderm with aortic cells (or other endothelial cells) induces a pancreatic program, whereas removal of aortic precursor cells from the embryo causes a failure in pancreatic development [76].

The most important consequence of mesenchymal signaling appears to be the repression of Shh expression. Shh is expressed throughout the entire gut tube, with the notable exception of the prepancreatic regions (both dorsal and ventral), where it is excluded. The notochord is directly responsible for repressing Shh in the dorsal prepancreatic endoderm, possibly through the activity of FGF2 or activin β-B [77]. Repression of Shh alone is able to reproduce the pancreatic inductive activity of notochord [77], and blocking Shh signaling with the inhibitor cyclopamine causes ectopic pancreas formation [78]. Furthermore, Shh repression must be maintained throughout pancreatic development, as ectopic expression of Shh after pancreatic budding causes conversion of the mesenchyme to an "intestinal type" and inhibits further development [79]. Shh repression is therefore both necessary and sufficient for pancreas specification. It is unclear what structure serves the function analogous to that of the notochord to repress Shh expression in the ventral prepancreatic endoderm.

Budding

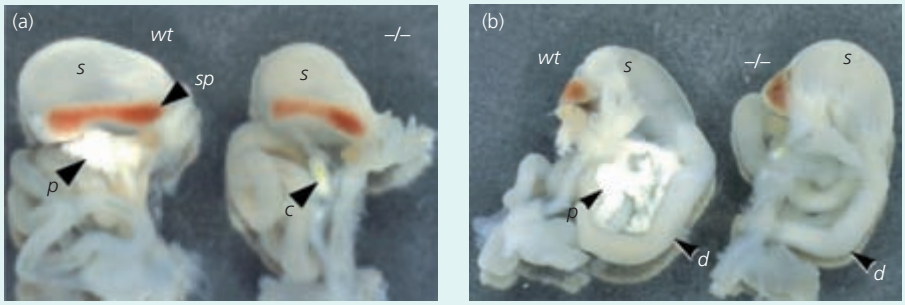
The pancreatic buds form at about 3–4 weeks of embryonic development (E9.5 in the mouse), with formation of the ventral bud lagging behind that of the dorsal bud. One of the earliest and most important genes to be expressed in the nascent buds is the homeobox transcription factor PDX1. All mature pancreatic cell types are derived from cells that expressed PDX1 [80] and ectopic PDX1 expression in the intestine is sufficient to promote the early steps of pancreas formation [81]. Although pancreatic buds form in *Pdx1*-deficient embryos, further pancreas development is arrested at this stage [82,83], a phenotype that has also been observed in humans (see Box 23.3) [84]. In adults, PDX1 is a major transcription factor for insulin, and deletion of *Pdx1* in adult mice causes diabetes [85]. Several other transcription factors are expressed in the early progenitor cells of the pancreas, including p48/PTF, Hes1, and Nkx6.1. In contrast to *Pdx1*, the genes for these transcription factors are not required for the formation of progenitor cells but instead are associated with specific phenotypes in later pancreatic lineages (see section on morphogenesis and cytodifferentiation).

As noted, the means of specification differ for the dorsal and ventral pancreata (notochord for dorsal, unknown for ventral). This differential regulation recurs later, as several genes exhibit distinct activities in dorsal vs ventral pancreatic development. One of these is *Hlxb9*, which encodes a homeobox transcription factor that is required for dorsal, but not ventral, pancreatic budding in mice [86,87]. Similarly, mouse embryos lacking the LIM homeobox gene *Isl1* do not develop a dorsal pancreas, most likely because Isl1 function is required in the dorsal mesenchyme [88]. Mesenchymal *Isl1* expression is maintained in *Hlxb9* mutants, suggesting that *Isl1* is not downstream of *Hlxb9* [86,87]. As there are no profound functional or histological differences between the postnatal derivatives of the ventral (head and uncinate process) and dorsal (body and tail) pancreas, it is unclear why *Isl1* and *Hlxb9* mutations cause such selective phenotypes.

Once formed, the ventral pancreas rotates across the midline to meet the dorsal pancreas. The two pancreatic derivatives undergo complete functional and anatomic integration,

Box 23.3 Pancreatic agenesis

PDX1 homeodomain-containing transcription factor (also known as IDX1, STF1, and IPF1) is absolutely required for development of the pancreas [248], and mice lacking the gene develop a small pancreatic bud, but further pancreatic development is arrested [82]. Pancreatic agenesis is a rare condition in humans [249]. In one patient with pancreatic agenesis [250], sequencing of the *PDX1* gene (*IPF1*) revealed a homozygous frameshift mutation that resulted in a truncated protein [251]. Thus, PDX1 seems to function similarly in mice and humans. Heterozygous mutations in PDX1 caused maturity-onset diabetes of youth (MODY) in a subset of patients, reflecting the protein's later role as the major transcriptional regulator of insulin gene expression [252].



(a,b) Modeling pancreatic agenesis in the mouse. Images of dissected mouse stomach (*s*), spleen (*sp*), duodenum (*d*) and pancreas (*p*) from wild-type (*wt*) and mutant mice lacking the Pdx1/IPF1 gene (*–/–*). In the absence of Pdx1/IPF1, the pancreas does not develop and is instead replaced with a cystic structure (*c*). Image from Offield et al. [82].

and the ventral ductal system (duct of Wirsung) serves as the major conduit for pancreatic secretion through the major papilla. Failure of integration results in the common anatomic variant *pancreatic divisum*, which is marked by persistence of the dorsal duct of Santorini and drainage through the minor papilla.

Morphogenesis and cytodifferentiation

These mutant phenotypes demonstrate that early pancreas organogenesis occurs in two steps: an early phase of pancreatic budding (which requires ISL1), and a later phase of outgrowth and branching (which requires PDX1). Wessells and Cohen [74] suggested a two-step process after observing that the substitution of heterologous mesenchyme for pancreatic mesenchyme supported later stages of development but not early budding. For many years, investigators looked for "mesenchymal factors" that control pancreatic growth, branching, and differentiation [89].

FGF10 was discovered to be such a pancreatic mesenchymal factor. In the lung, FGF10 expression causes budding and branching of the pulmonary epithelium [90]. This growth is "stereotyped" – primary, secondary, and tertiary branch formation is spatially and temporally regulated to ensure a consistent branching pattern. Although pancreatic branching does not appear to be stereotyped, FGF10 has a strikingly similar function in the development of the pancreas. FGF10 is expressed in the mesenchyme and drives the proliferation of progenitor cells expressing PDX1 during branching by binding to the FGFR2b receptor on epithelial cells [91]. Consistent with this, *Fgf10* mutant mice exhibit arrested pancreas development at the bud stage [92]. An additional activity of FGF10 during pancreas growth is to keep the expanding pancreatic epithelium in an undifferentiated state. This is achieved through the activation of Notch signaling, a potent regulator of pancreatic differentiation [93–97].

The different compartments of the mature pancreas include exocrine cells that make digestive enzymes, ducts that carry these enzymes to the gut, and hormone-producing endocrine cells. The exocrine pancreas is the largest compartment, comprising over 80% of the pancreatic mass. The transcription of exocrine-specific genes is dependent on the PTF1 transcriptional complex, which contains a pancreas-specific factor called p48. Like PDX1, p48 is expressed in the early stages in multipotent pancreatic progenitor cells [98], and it is the major transcription factor for the expression of exocrine-specific genes [99]. The transcription factor p48 is required for exocrine differentiation, as null mutant mice develop an endocrine pancreas but lack exocrine cells [100]. Another transcription factor, MIST1, is required for the assembly of the exocrine secretory machinery [101].

During the growth of the pancreatic epithelium within the bud, endocrine cells arise in waves of differentiation (glucagon-producing α cells preceding insulin-producing β cells); these cells delaminate from the epithelium and reaggregate postnatally into the islets of Langerhans (which also include somatostatin-producing δ cells and pancreatic polypeptide-producing cells). The development of these different endocrine lineages is complex and regulated by multiple factors. The bHLH transcription factor Neurogenin 3 (NGN3) is both necessary and sufficient for endocrine differentiation in the pancreas [79,81,102,103]. *NGN3*, and its target gene *BETA2/NEUROD*, are regulated by Notch signals [104] and the one-cut transcription factor HNF6 [105]. Additional transcription factors involved in the delineation of different endocrine lineages in appropriate numbers include NKX6.1, NKX2.2, PAX4, and PAX6 [106].

Of note, islets are not derived from the monoclonal expansion of endocrine precursor cells, but rather from the coalescence of distinct endocrine cells or endocrine precursors [107]. The derivation of endocrine β cells from embryonic progenitors has led many investigators to hypothesize that adult β cells are generated by a similar mechanism. The aggressive search for putative "adult stem cells" in the pancreas has yielded ambiguous results. One laboratory that used a genetic labeling method failed to show that adult stem/progenitor cells give rise to β cells, suggesting that the adult β cell mass is maintained principally by replication [108].

Summary

The repression of Shh signaling induces the formation of dorsal and ventral pancreatic buds from the endoderm. Signals provided by blood vessels, as well as mesenchymal FGF10, promote the outgrowth of multipotent pancreatic progenitor cells into a branched epithelium. Complex signals, including members of the Notch and TGF-β families, as well as numerous bHLH and homeodomain proteins, regulate the subsequent differentiation of pancreatic endocrine, exocrine, and ductal lineages.

Gastrointestinal tract

Specification

Although the gastrointestinal tract is composed of a single continuous tube, it is partitioned into discrete domains from anterior to posterior (esophagus, stomach, small intestine, and colon) that are separated by sphincters (lower esophageal sphincter, pylorus, and ileocecal valve). Each domain has a distinct function and a unique architecture. Similar to the liver and the pancreas, the different functional domains of the intestine are patterned after gastrulation through a repertoire of homeobox genes and epithelial–mesenchymal cross-talk.

Homeobox-containing genes are expressed in a regionalized manner in the gut epithelium and mesenchyme [15,24], and several examples of "homeotic transformations" have been observed after the dysregulated expression of homeobox genes. *Hoxa13* and *Hoxd13* are expressed in the hindgut, and ectopic expression of either of these *Hox* genes in the midgut leads to acquisition of hindgut characteristics [109,110]. The *Hox* gene *Hoxa5* is expressed in stomach mesenchyme, and

is necessary for gastric fate specification [111]. Sphincters constitute a special case of endoderm patterning, as they reside at boundaries between intestinal segments. Again, *Hox* genes are important for the process of sphincter formation. *Hoxa13/Hoxd13* mutant mice have defects in anal sphincter formation, and mice with a large deletion in the *Hoxd* cluster (*Hoxd4–d13*) lack an ileocecal valve [21,22].

In addition to the expression of homeobox genes, epithelial–mesenchymal signaling is also essential for the establishment of an intestinal pattern. In some cases, such as the murine cecum, a clear hierarchy of epithelial–mesenchymal signaling (through FGFs in cecal development) mediates organ growth [112]. In other cases, it is less clear whether transcription factors (such as homeobox-containing proteins) establish an initial pattern that is refined by further epithelial–mesenchymal signaling, or whether epithelial–mesenchymal signaling establishes the pattern of transcription factor gene expression. An alternative possibility is that the basement membrane, an aggregate of extracellular matrix strategically placed between epithelial and mesenchymal cells, regulates cross-talk between the two tissue layers [113].

Pyloric sphincter development is a particularly instructive example of this complex specification process. In the chicken, the pyloric sphincter forms at the junction of the gizzard (caudal stomach) and the small intestine. Two transcription factors – the homeobox factor Nkx2.5 and the HMG-box factor Sox9 – are both markers of the mesenchyme of the pyloric sphincter, and ectopic expression of either gene is sufficient to convert the gizzard into pyloric sphincter-like epithelium [114–116]. Moreover, mesenchymal BMP4 is both necessary and sufficient to induce the expression of these transcription factors [114,116,117]. This result is surprising, because BMP4 is expressed widely throughout the gut mesenchyme. The specificity of BMP4 activity to induce sphincter development likely reflects specific spatial regulation of its own expression and spatial regulation of its receptor [117,118]. Moreover, the ability of the downstream factor Nkx2.5 to induce pyloric sphincter development is spatially regulated; Nkx2.5 can induce pyloric sphincter development when it is expressed anteriorly (in the gizzard), but not posteriorly (in the duodenum) [115]. These studies provide insight into the final steps regulating the development of the pyloric sphincter but a deeper question remains. What regulates the regulators?

Complex signals that are both intrinsic and extrinsic to the developing epithelium regulate tissue identity. The extent to which these or similar inductive events contribute to common congenital anomalies, including intestinal stenoses and atresias, duplications, and anorectal malformations, is unknown. However, congenital anomalies of the gastrointestinal tract are commonly associated with malformations in other organ systems or chromosomal abnormalities, including trisomy 21 (Down syndrome), suggesting that the regulatory signals involved in patterning are disrupted widely.

The clinical relevance of these regulatory networks may extend beyond putative relationships to congenital errors. Intestinal metaplasia, an adult premalignant lesion in which portions of the esophagus or stomach are replaced with intestinal mucosa, may represent reactivation of developmental programs. Studies of BARX1, a homeobox-containing transcription factor that is expressed transiently in the gastric mesenchyme, provide support for this concept. BARX1 mediates gastric specification by inhibiting Wnt signaling, and mouse embryos with a targeted disruption of the gene exhibit a homeotic transformation of stomach to intestine [119]. One interpretation of this result is that intestinal differentiation represents a "default" state for gut endoderm that must be overcome (through inhibition of Wnt signaling) to allow stomach specification. Although unproved, this model may explain why intestinal metaplasia of the stomach and esophagus is common, whereas the converse, gastric metaplasia of the midgut or hindgut, is uncommon. Furthermore, the model gives rise to the testable hypothesis that intestinal metaplasia in later life may result from the unopposed reactivation of Wnt signaling after injury.

Morphogenesis

The lumenal gastrointestinal tract acquires it shape through rotational changes at a gross level, and through tissue remodeling at a microscopic level. Left–right (L–R) asymmetry of the intestine is generated through the same mechanisms that regulate the L–R axis of the body plan. This process involves the clockwise movement of cilia, which promotes the asymmetric distribution of inductive signals [120]. Dysregulation of cilium function leads to randomization of L–R asymmetry and clinical phenotypes including situs inversus.

The intestine undergoes tremendous growth during the initial embryonic period, and elongates about 1000-fold between the 5th and 40th weeks of human development [121]. To accommodate a large embryonic liver, the intestine exists outside the abdominal cavity for much of its early embryonic life ("physiological herniation"). Early in development, the growing midgut and hindgut undergo a two-step rotation (Fig. 23.6) totaling 270° (counterclockwise orientation viewing the embryo en face). Both growth and looping of the intestine require the action of HLX, a homeobox transcription factor that is expressed in the midgut and hindgut mesenchyme and that is also required for liver development (see section on budding of the liver). *Hlx* mutant mouse embryos have a shortened and single-looped gut that undergoes normal differentiation [55]. Many congenital anomalies are related to errors in these gross movements of the intestine, most notably midgut malrotation with risk of ensuing volvulus.

Although our understanding of this dramatic intestinal growth and rotation remains mainly descriptive and phenomenological, the mechanisms controlling the cross-sectional makeup of the intestine are better understood. The

stereotyped circumferential arrangement of cells according to each intestinal segment has been referred to as the *radial axis* of the gastrointestinal tract: innermost epithelium, lamina propria, muscularis mucosae, submucosa, outer muscular layers, and serosa. Each intestinal segment has a unique epithelial and mesenchymal composition; e.g., the stratified squamous epithelium and thin submucosa and muscular layers of the esophagus vs the columnar epithelium and thickly muscled mesenchyme of the stomach.

Shh–BMP cross-talk appears to be important for determining the composition of the radial axis in each intestinal segment. This conclusion is based on several lines of evidence. First, Shh is expressed throughout the gut epithelium (except for the pancreas, as discussed in the section describing the specification of the pancreas) and is a potent activator of mesenchymal BMP expression so that the two signaling pathways regulate each other. Second, ectopic BMP expression affects the degree of muscularity of the mesenchyme along the anteroposterior axis [110], suggesting that it regulates mesenchymal morphology. Third, Shh signaling is necessary for normal crypt–villus structure [122], and Shh regulates mesenchymal fate according to the distance from the epithelium [123]. These results are consistent with a model in which a concentration gradient of Shh (expressed by the epithelium) organizes the mesenchymal rings of the gut, possibly through the activity of BMPs. According to this model, mesenchymal cells closest to the epithelium are induced to adopt a lamina propria or submucosal fate, whereas only those cells furthest from the epithelium adopt a muscle fate [123].

The intestinal lumen forms after 7–8 weeks of gestation (human) and consists of two processes, designated canalization and morphogenesis. The failure of canalization is thought to account for some cases of duodenal atresia, a partial or complete obstruction of the duodenum that occurs with a frequency of 1 in 5000 to 1 in 10 000 births. Morphogenesis involves polarization of the epithelium and transformation of a stratified epithelium to a columnar epithelium. As discrete villi emerge from the stratified epithelium, a distinct crypt–villus architecture is acquired. Research has revealed the importance of cytoskeletal regulation in villus morphogenesis. Mice lacking the "bridge" protein ezrin, which links membrane proteins to the actin cytoskeleton, exhibit abnormal villus morphogenesis, with nascent villus structures that are unable to break away from each other [124]. $Ez^{-/-}$ mice have normal intestinal differentiation and polarity, showing that Ezrin acts specifically to regulate the formation of new villi, presumably by binding to unidentified membrane proteins.

Cell proliferation and kinetics

The adult small intestinal epithelium has a rapid and regular turnover, with the average lifespan of intestinal enterocytes measured in days [125]. To support this constant need for new cells, the intestine recapitulates the embryonic processes of differentiation from stem cells throughout life (Fig. 23.7).

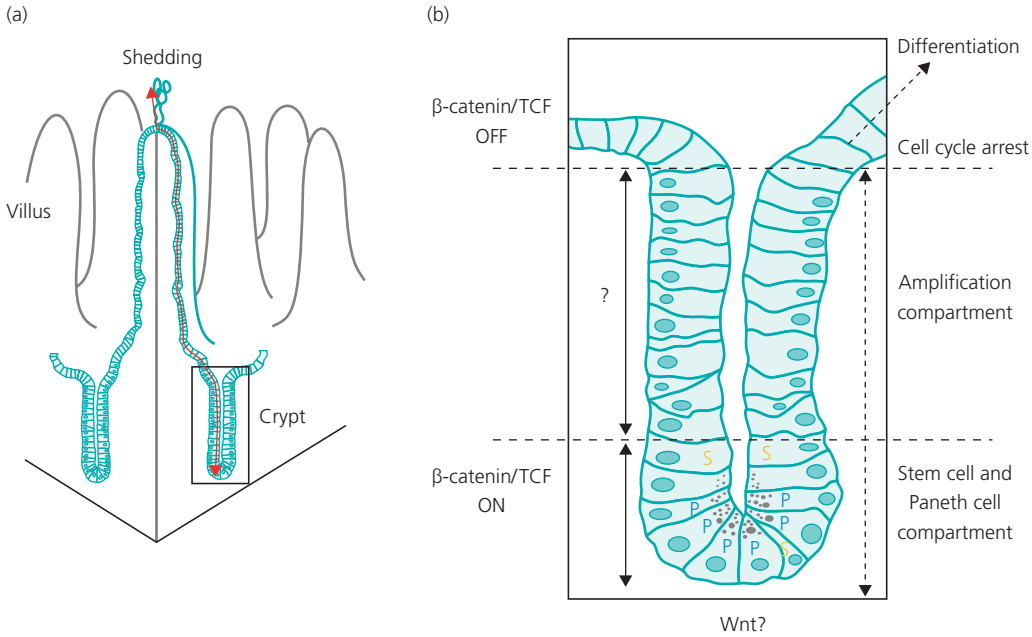

Figure 23.7 Small intestinal maturation. **(a)** Maturation of the crypt–villus axis. Stem cells near the base of the crypt give rise to a transient amplifying multipotent population of cells that reside in the middle and upper portions of the crypt. These cells give rise to mature enterocytes, enteroendocrine cells, and goblet cells, which migrate up the villus and are eventually shed into the intestinal lumen. Paneth cells are also derived from the transient amplifying population, but these cells migrate down to the crypt base where they intermingle with stem cells. **(b)** Small intestinal crypt. Schematic showing the crypt is divided into compartments. At the base are stem cells (S), which are thought to reside slightly above the crypt base, and Paneth cells (P). Canonical Wnt signaling is active in these cells. Above this compartment is the transient amplifying population, containing actively dividing cells. Cells withdraw from the cell cycle as they reach the crypt–villus interface and adopt an absorptive or secretory fate. Adapted from Sancho et al. [242].

Stem cells are specialized cells that can generate multiple differentiated cell types ("multipotentiality") and also produce more stem cells ("self-renewal"). Intestinal stem cells reside near or at the bottom of the crypts and are characterized by their relatively low rate of cell division and long life [126].

Progenitor cells with a more limited potential and shorter half-life coexist with stem cells in the crypts [127]. A subset of stem cell-derived progenitor cells, known as the *transient amplifying population*, undergoes rapid cell division within a region of the crypt–villus axis known as the *proliferative zone* (see Fig. 23.7). Mesenchymal factors, including the winged helix transcription factor Fkh6 [128], and several intercellular signaling pathways regulate cell division in this zone.

Wnt signaling is an important regulator of stem cell maintenance and differentiation in many developmental systems [129]. Wnt signals act during villus maturation by regulating the pool of undifferentiated progenitor cells. Inactivation of the Wnt signaling mediator Tcf4, or inhibition of Wnt signaling with the soluble inhibitor Dickkopf1 (Dkk1), results in the loss of the proliferative zone [130,131]. Conversely, activation of Wnt signaling leads to an expanded proliferative zone [132,133]. Because Wnt ligands are expressed in both the epithelial and the mesenchymal compartments of the intestine [134], their precise source is unclear.

Like Wnt, Notch signals seem to play an important role in the regulation of intestinal progenitor cells [135,136]. This regulatory mechanism appears to be conserved in organisms as distantly related as zebrafish and *Drosophila* [137–139]. Finally, hedgehog signals also appear to regulate intestinal progenitor cells [140,141].

Despite these advances, relatively little is known about the factors that regulate the behavior of intestinal stem cells themselves: when and whether to self-renew or differentiate. Studies of intestinal stem cell biology have been hampered by an absence of stem cell markers and in vitro culture systems. The unique properties of stem cells are conferred by attributes of the cellular microenvironment, which has been termed the *stem cell niche*. In other stem cell systems, notably *Drosophila* germ cells and hemopoietic stem cells, characterization of the niche has revealed several factors that promote maintenance of the stem cell state. Although no equivalent description exists for the intestinal stem cell niche, one group of investigators has proposed that BMP signals (provided by mesenchymal cells at the crypt base) regulate Wnt signals to maintain the stem cell compartment [142].

Cytodifferentiation

The differentiated cells of the intestine can be divided into *absorptive* and *secretory* cells on the basis of the function of various cells. The precise identity and relative abundance of absorptive and secretory cells varies along the anteroposterior axis. The major secretory cells of the stomach (and their

secretory products) are parietal cells (acid), chief cells (digestive enzymes), and endocrine G cells (gastrin). By contrast, the major secretory cells of the small intestine are goblet cells (mucous), Paneth cells (antimicrobial peptides), and enteroendocrine cells (myriad hormones). Nevertheless, the genetic mechanism that regulates the development of these different cells is shared between different segments of the gastrointestinal tract.

As in the pancreas, Notch signaling plays a critical role in the regulation of intestinal cell fate by mediating the expression of several downstream bHLH proteins – NGN3, BETA2/NEUROD, HES1, and MATH1. The general conclusion from studies of mice with mutations of these proteins is that differentiation of the secretory cell lineage is triggered by repression of Notch signaling and HES1, with the resulting derepression of MATH1 [143,144]. Additional signals control the selection of different intestinal secretory cell lineages (endocrine, goblet, and Paneth). One of these signals, NGN3, is absolutely required for endocrine cells to form in the intestine, but not in the stomach; by contrast, the formation of goblet and Paneth cells is normal in *Ngn3*-deficient mice [145,146]. Other complex signals and lineage relationships underlie the development of the 10 or so different types of enteroendocrine cells [147].

There is additional evidence that Notch signals are coordinated with Wnt signals to regulate the balance between progenitor cell proliferation and cytodifferentiation. Either embryonic activation of Notch or inhibition of Wnt results in the loss of secretory cell lineages [131,134,137]. Furthermore, Wnts have a special role in ensuring proper compartmentalization of the crypt–villus axis by regulating another family of cell–cell signaling molecules known as ephrins [148].

The intestine is maintained throughout life by stem cells so the question arises whether the same mechanisms that regulate stem cell differentiation in the embryo also do so in the adult. Indeed, several studies suggest that Notch signals function in both embryonic and adult intestinal homeostasis. In particular, the inhibition of Notch signals using pharmacological γ-secretase inhibitors (which block Notch signaling by preventing proteolytic maturation of the receptor) results in the conversion of crypt proliferative cells into goblet cells [136,149,150]. Conversely, the activation of Notch signaling through the misexpression of a constitutively active mutant form of Notch prevents the development of secretory cell lineages [151].

Wnt signaling also plays a role in adult intestinal homeostasis. Activation of Wnt signaling in the adult intestine causes a marked expansion of the proliferative zone, but has minimal effect on the differentiated cells of the villus [132,152]. Activation of Wnt signaling through the loss of the *APC* gene and the subsequent activation of β-catenin is known to be a key step in colorectal carcinogenesis (see Box 23.4 and Chapters 24, 63, and 65), suggesting that intestinal stem cells or transient amplifying cells are most sensitive to the inactivation of *APC* and represent a likely target for malignant transformation [153].

Despite the observation that Notch and Wnt signals mediate similar activities in the intestine, the precise relationship between these two pathways is unknown, as is the mechanism by which they regulate a balance between proliferation and

Box 23.4 Wnt signaling and colorectal cancer

One of the clearest links between developmental signals and carcinogenesis is exemplified by the role of Wnt signaling in intestinal differentiation and colorectal cancer. Complex cellular events occur after the Wnt ligand binds to a Frizzled receptor, and most colon cancers harbor mutations that lead to activated Wnt signaling. The best-characterized signals, referred to as the canonical arm of the Wnt signaling pathway, involve the stabilization of β-catenin in the nucleus and the formation of β-catenin/TCF-4 transcriptional complexes (see section on signaling in development).

Most Wnt signaling pathway mutations found in colorectal cancer occur in the genes encoding β-catenin or its regulator, adenomatous polyposis coli (APC). These mutations result in pathway activation; they occur as an early event in most sporadic colorectal cancers and cause the familial adenomatous polyposis colorectal cancer syndrome. It is postulated that persistent Wnt signaling in villi (an epithelial population in which Wnt signaling is normally absent) imposes a crypt stem/progenitor cell phenotype [253,254]; this self-renewal phenotype might allow villus cells to accumulate the additional mutations needed for carcinogenesis according to the prevailing model [255].

The first *Wnt* gene to be identified was *Int1*, a candidate oncogene in mammary tumorigenesis [256]. Subsequent studies showed *Int1* to be orthologous to the *Drosophila* segment polarity gene *Wingless*. Furthermore, *Wnt* genes were discovered to play a near-ubiquitous role in organ development. As mentioned, Wnt signaling plays a critical role in the biology of the intestine. Regulation of Wnt signaling appears to be important in the normal patterning of the stomach and intestine [257]. Abrogation of Wnt signaling in the embryonic or adult intestine leads to a depletion of intestinal progenitor cells [258–260]. Moreover, defective Wnt signaling also perturbs the proliferative compartment of the intestine and the ability of cells to differentiate into secretory cell types [258,259].

Among the remaining challenges is the question of how cells with active Wnt signaling are normally kept in check. One possible mechanism involves the β-catenin/TCF-4 target Ephrin (*Eph*) genes, which function to regulate compartmental boundaries within the crypt–villus unit [261]. Mice that harbor mutations in both *APC* and *EphB* have a marked acceleration in tumor formation compared to mice with a mutation in APC alone [262]. These results suggest that EphB normally constrains the growth of cells with active Wnt signaling and that loss of Eph function may serve as a "second hit" by relieving this constraint.

differentiation. The studies described above are intellectually satisfying because they establish links between embryonic development, adult stem cells, and cancer. Nevertheless, they merely hint at the complexity underlying the regulation of intestinal differentiation. Hurdles facing the field include a lack of markers that uniquely identify the various precursor populations (unipotent and multipotent progenitor cells and stem cells), and an understanding of how proliferation and differentiation are coupled and the mechanism by which the appropriate ratio of absorptive and different secretory lineages is achieved.

Summary

The formation of sphincters during midgestation divides the gut tube into segments – esophagus, stomach, small intestine, and large intestine – that prefigure their distinct morphologies and functions. The mechanism of sphincter formation is incompletely understood but involves significant epithelial–mesenchymal cross-talk. Similar cross-talk is involved in the morphogenesis of the different intestinal segments. Subsequently, intestinal development proceeds by differentiation from stem cells, a process that depends on Wnt and Notch signaling, among other pathways. Such signals control proliferation and differentiation in the adult intestine and are dysregulated during carcinogenesis.

Conclusions

After gastrulation, the gut tube is exposed to regional signals. In prespecified organ domains, the epithelium responds by growing into adjacent mesenchyme, resulting in the budding of lung, liver, and pancreas. In the remaining gut epithelium, reciprocal signaling with mesenchyme results in the formation of sphincters or regionally distinct submucosae. Complex morphogenetic changes and cytodifferentiation occur in each of these developing organs, giving rise to organized tissues. Tissue-specific gene expression begins, setting the stage for further refinement of regulated expression and function. In the adult intestine, differentiated cell types are generated throughout life from stem cells that reside within the crypts, an ongoing process that recapitulates many developmental events. In the liver and the pancreas, by contrast, the replication of existing cell types appears to be a major mechanism for tissue maintenance.

Developmental physiology

The development of complex anatomical structures with distinct differentiated cell lineages would be purposeless if it did not facilitate function. The functions of the gastrointestinal tract include assimilation of nutrients, detoxification and elimination of waste, maintenance of blood glucose, and synthesis of plasma proteins. In addition, the gastrointestinal tract subserves secondary roles in water and electrolyte balance and immunological defense. The physiology of the intestine, pancreas, and liver is the subjects of entire textbooks [154] and is beyond the scope of this chapter. Again, the emphasis within this chapter is on mechanism.

The connection between form and function is reflected in an economy of mechanism. Many genes exhibit dual function and are involved in both development and physiological regulation. As previously described, FOXA2 and GATA4 bind to the albumin promoter as part of a program of endoderm commitment, and are thus involved in both patterning as well as the functional expression of a liver-specific gene. There are several other similar instances of developmental "parsimony"; e.g., the *Pdx1* and *p48* genes play important roles in pancreatic development and are also the major transcriptional regulators of insulin and of several exocrine genes, respectively [83,99]. Similarly, the *CDX2* homeobox gene plays an important role in endoderm patterning [15,17,18,155] and also functions as a major transcription factor for the expression of brush border enzymes and intestinal carbonic anhydrase [156–158]. Such economy is not surprising because the use of a limited set of genetic tools reduces the need for cellular reprogramming during specification and differentiation. Fortuitously, this arrangement facilitates mechanistic understanding, as identification of the genes that regulate development provides a list of candidate regulators of function, and vice versa.

Maturation of the gastrointestinal tract

After parturition, the gastrointestinal tract faces two environmental challenges. Immediately after birth, the individual must adjust from a diet that is predominantly parenteral (provided by the maternal circulation), to one that is completely enteral (consisting of colostrum and breast milk). Later, at weaning, the gastrointestinal tract must be able to assimilate nutrients from a vast array of solid foods. These adjustments occur in a hormonal milieu that is increasingly under the control of the infant. Therefore, unlike structural development, which follows a set of preprogrammed genetic events, functional development is likely to be considerably more dependent on environmental forces [159]. Furthermore, a comprehensive understanding of functional development must incorporate studies of both humans and model organisms, which may differ in important ways.

Gastrointestinal "maturation" refers to the progressive attainment of features of adult gastrointestinal physiology during development. Given the imprecise nature of such a definition, several surrogate markers are used to understand how the physiology of the gastrointestinal tract changes over time. These include biochemical measurements of intestinal enzyme and hormone activities, morphological grading, mutant analysis, and measurements of permeability, motility, and immune performance. It has been suggested that the human gastrointestinal tract is structurally and functionally mature at the time of parturition, whereas the rodent gas-

trointestinal tract is altricial, or immature, at birth. However, given the comprehensive nature of maturation, and the fact that the neonatal diet of all mammals is similar (i.e., milk), the implications of such a distinction are unclear. The following sections provide snapshots of some well-studied events during intestinal maturation.

Carbohydrate digestion and absorption

A focal point in the study of intestinal maturation has been the characterization of the major brush border enzymes that digest carbohydrates. One enzyme is lactase–phlorizin hydrolase (LPH), which cleaves lactose, the major dietary carbohydrate of breast milk. In rats, LPH is expressed at high levels early in embryogenesis, whereas peak expression in human embryos occurs during the third trimester. LPH expression declines with age in both species. The observation that LPH expression across species is highest after birth and subsequently lower likely reflects the critical requirement for lactase during nursing [160].

Another well-studied brush border enzyme is sucrase–isomaltase (SI), a bifunctional disaccharidase. In contrast to LPH, the expression of SI is discordant between humans and other mammals. In rats and pigs, SI expression is undetectable before a dramatic burst of expression in the postnatal period, corresponding to the time just before weaning when the major carbohydrate source shifts from milk to starch. By contrast, SI expression in humans begins in the first trimester and reaches its peak level just before birth [160]. The earlier expression of SI during human ontogeny is not understood, and it is unclear whether differences in enzyme expression levels reflect differences in overall functional maturation between species.

Protein digestion and absorption

The embryo has only a limited capacity to digest proteins, a result of the late expression of digestive zymogens, the low-level expression of the activating enzyme enterokinase, and the insensitivity of embryonic pancreatic exocrine cells to the action of secretagogues (see section on hormonal control of gastrointestinal development). Furthermore, the gastric pH is neutral until birth, dropping rapidly from 6.0 to 2.2 in the first day of life [161]. Instead, other systems handle the limited protein load delivered to the intestine pre- and perinatally. Brush border and microvillar peptidases and dipeptidases, which complete peptide digestion, are present in the fetal small intestine at levels of activity comparable to levels in the adult small intestine. High levels of amino acid transporters in the newborn permit the uptake of free amino acids.

Macromolecular transport also plays an important role in the digestion of proteins and lipids in the fetus and the neonate [162–164]. In experimental animals, the small intestinal epithelium is more permeable to amino acids and peptides in the immediate postnatal period than when the intestine is mature. Macromolecular tracers infused into the amniotic fluid or the intestinal lumen late in gestation are absorbed into the enterocytes of humans, monkeys, guinea pigs, and rats, reflecting a high rate of pinocytosis [164]. This process is extremely active in the first 2 weeks postnatally and decreases at the time of weaning. This mechanism accounts for the absorption of intact maternal immunoglobulins and other proteins from milk.

In parallel with pinocytosis, enterocytes exhibit high levels of lysosomal proteases, such as cathepsins and other peptidases, during the first 2 weeks postnatally. These intracellular enzymes provide a mechanism for protein digestion before the appearance of the pancreatic proteolytic enzymes. Intact proteins also are absorbed in premature and term human infants during the first few months of life. Macromolecules may continue to cross the healthy adult small intestine, but the quantity is low compared to those in the newborn. The relative permeability of the intestine during the first months of life may play an important role in conferring tolerance or sensitivity to dietary proteins during the development of immune function.

Lipid digestion and absorption

Fats and unhydrolyzed triglycerides are present in the stools of human neonates at a rate that is higher than that of adults, a phenomenon that correlates with the low activity of pancreatic lipase and the low intralumenal concentrations of bile acids. Although pancreatic lipase levels rise significantly during the third trimester, lipase activity at week 32 of gestation is only 50% of term levels, which are themselves only 10% of adult levels. Fat digestion in human neonates is aided by "preduodenal" lipases (lingual and gastric lipases) and maternal milk lipase. Lingual lipase rises to adult levels by 2 years of age [165]. Gastric lipase appears as early as 10–13 weeks into gestation and reaches adult levels by 16 weeks [166]. Gastric lipase appears to be a major determinant of lipolytic activity in gastric aspirates of premature infants. As with peptides, the newborn intestine exhibits increased permeability to both triglycerides and cholesterol [167].

The synthesis of bile acids from cholesterol and their conjugation with taurine and glycine can be demonstrated in organ culture in vitro with human liver tissue obtained from fetuses after 15 weeks of gestation [168]. Biliary secretion is observed as early as the 22nd week of gestation. Bile acid reabsorption occurs in the neonate by passive diffusion throughout the small intestine, but active sodium-dependent ileal transport of bile acids does not occur until weaning in rats, rabbits, and humans [169]. As a result, the bile acid pool is reduced in neonates; this is of particular concern in premature infants, in whom 10%–20% of ingested fat may not be absorbed.

Dietary control of gastrointestinal development

The expression of SI, LPH, and other brush border enzymes seems to be mostly under autonomous control, because their

normal expression pattern does not change significantly with delayed or early weaning or early introduction of dietary sucrose [170]. Indeed, transplanted human fetal intestine is able to undergo normal cytodifferentiation in an immunodeficient "nude" mouse host [171]. However, other aspects of gastrointestinal development, particularly growth, are regulated by diet. Exposure of the gut lumen to nutrients begins in utero with the swallowing of amniotic fluid, which contains amino acids and carbohydrates, and which the embryo uses to meet some of its nutritional requirements.

The importance of the lumenal environment is supported by studies in which the timing, the composition, or the route of delivery of nutrition is varied. Ligation of the embryonic sheep esophagus causes reversible and specific inhibition of growth of the gastrointestinal tract [172]. Although normally absent in human amniotic fluid, galactose can nevertheless be absorbed by the embryonic jejunum. Intraamniotic infusion (and therefore increased enteral delivery) of galactose induces an increase in the mucosal transport of galactose by the rabbit intestine, as well as an overall increase in mucosal weight, suggesting that the fetal intestine is competent to respond to small changes in enteral carbohydrate composition [173]. Consistent with this, intestinal growth in the first day of life depends on the composition of milk [174]. Importantly, it is not simply the metabolic consequences of feeding that provide a signal; the intestinal mucosa itself must be exposed to these nutritional components. For example, infant rats given enteral nutrition exhibit greater intestinal growth than rats given the same nutritional support intravenously [175]. A requirement for lumenal stimulation has long been appreciated in the "adaptation" observed after massive intestinal resection – a compensatory increase in intestinal surface area that depends on enteral feeding [176]. It is possible that this adaptation reflects a reemergence of an early developmental program that regulates intestinal size and surface area. Indeed, microarray analysis of gene transcription during development and adaptation supports this hypothesis [177].

Hormonal control of gastrointestinal development

A possible regulatory role for corticosteroids and thyroid hormone in intestinal development has been extensively explored because of the dramatic increase in the level of both hormones observed in rats immediately before the spike in SI activity and coinciding with a reduction in LPH activity. Direct effects on the activity of several disaccharidases have been documented after the administration of exogenous hormones. Notably, prenatal administration of cortisone reduces the incidence of necrotizing enterocolitis in a rat model, presumably by accelerating the maturation of the mucosal barrier [178]. Conversely, intestinal maturation is slowed by treatments that reduce levels of circulating corticosteroids. Similar effects are seen with enhancement or inhibition of thyroid hormone expression, although some of these effects may be mediated through corticosteroids [160]. Importantly, mice lacking corticotropin-releasing hormone or thyrotropin-releasing hormone do not exhibit an overt gastrointestinal phenotype [179,180]. The regulation of gastrointestinal maturation by other hormones and circulating growth factors has also been investigated through similar approaches. In particular, cholecystokinin, gastrin, insulin, and members of the insulin-like growth factor (IGF), epidermal growth factor (EGF), and TGF families have been the focus of numerous studies.

These analyses have yielded much evidence for the involvement of hormones and systemic growth factors in gastrointestinal development, the description of which is beyond the scope of this chapter. However, differentiation between primary and secondary effects is challenging, and for the most part, the precise functions of these molecules in development remain to be delineated. It is worth noting the phenotype resulting from a deficiency of gastrin, which is abundantly expressed in the pancreas and proximal intestine during embryonic development. Mice with a targeted inactivation of the gastrin gene exhibit a deficiency of acid-producing parietal cells [181,182], suggesting a role in cellular differentiation rather than maturation per se.

Despite the lingering controversy over the precise role of hormones in intestinal maturation, it is clear that the responsiveness of some gastrointestinal tissues to hormones changes over the course of fetal and postnatal life. The responsiveness of the exocrine pancreas is an example of such regulation. Pancreatic digestive and lipolytic enzymes are detected in the early bud stage, and high levels of protein are detected in the acinar cells before term. Despite the abundance of these proteins, embryonic acini are insensitive to secretagogues until after birth [183]. Similarly, sensitivity to the acid-secretory action of gastrin develops during the first week of life; poor expression of the gastrin receptor in the immediate postnatal period renders newborns relatively insensitive to gastrin [184].

Finally, the intestine and the pancreas are major endocrine organs in their own right. As the source of insulin, the pancreas is the major regulator of glucose homeostasis. The intestine contains numerous peptides that regulate motility, ion transport, feeding, and satiety, and has been dubbed "the largest endocrine organ" in the body [185]. Previous sections have outlined the mechanisms by which endocrine cells arise in the pancreas and the gut. For a more detailed description of the ontogeny and regulation of the gastrointestinal endocrine system, we refer the reader to Williams Textbook of Endocrinology [186].

Development of the enteric nervous system

The enteric nervous system (ENS) regulates multiple aspects of gastrointestinal physiology, including peristalsis and smooth muscle activity, sphincter tone, glandular output,

microcirculation, and possibly, inflammation [187]. Through these activities, the ENS controls the response to feeding by coordinating intestinal transit, secretion, and continence. The cells that give rise to the ENS migrate from the neural crest during the first trimester, induced by complex and poorly understood signals. Similar to other neural crest derivatives, the ENS is part of the peripheral nervous system, constituting its largest subdivision. Although the ENS receives input from the vagus nerve, it possesses marked independence from the central nervous system, exhibiting function even after complete dissociation from all brain and spinal inputs. On the basis of its size and autonomy, the ENS has been referred to as the "second brain" [188]. Although many adult disorders may be related to ENS dysfunction, only Hirschsprung disease is clearly attributable to developmental errors in ENS formation (see section on disorders of specification and formation).

Fate mapping in the chick has shown that enteric neurons are largely derived from rostral (vagal) and caudal (sacral) precursors that migrate from the neural tube and intermingle to populate the entire gut tube [184]. Although some details remain controversial, studies in mice have confirmed the general picture of neural crest migration mapped out by studies in the chick. The ENS is composed of two types of ganglionated plexuses: the Auerbach (myenteric) plexus, which is located in the outer muscular layer and regulates gastrointestinal tract motility and function of extralumenal organs, and the Meissner (submucosal) plexus, which regulates enteral secretory activity [190]. Enteric neurons can be further subclassified according to the neurotransmitters (e.g., vasoactive intestinal polypeptide and serotonin) and enzymes (e.g., tyrosine hydroxylase and choline acetyltransferase) they express. Although the mechanisms that mediate the migration and terminal differentiation of neural crest precursors are unknown, neuronal subtypes appear to arise in overlapping developmental waves [191]. The functional roles of these neuronal subtypes and specific neuropeptides in gastrointestinal physiology are described elsewhere in this textbook (see Chapters 2 and 47).

In contrast to the neural crest-derived cells of the enteric plexuses, interstitial cells of Cajal (ICCs), which serve as the "pacemakers" of the intestine, arise from intestinal mesenchyme [192,193]. The development of these cells requires the function of another receptor tyrosine kinase, c-Kit. Mice with reduced or absent c-Kit function exhibit abnormal slow-wave activity in the small intestine and develop paralytic ileus [194,195]. It has been discovered that a category of mesenchymal tumors known as gastrointestinal stromal tumors (GISTs) have activating mutations in *KIT* that confer constitutive kinase activity in the absence of ligand [196,197]. Ultrastructural similarities between ICCs and GISTS, and other shared features, has led researchers to propose that GISTs arise from ICCs [198] or from a common ICC–smooth muscle precursor cell [199].

The ability to inactivate specific genes in the mouse has provided additional mechanistic details regarding ENS development. In particular, a central role for the c-Ret tyrosine kinase pathway in the development of most enteric neurons has been demonstrated through targeted inactivation of pathway components (see the discussion of Hirschsprung disease). Furthermore, important neural crest subpopulations have been recognized from the more limited phenotypes that result from the targeted mutation of other genes. For example, the basic helix-loop-helix protein MASH1 is required for the development of a subset of enteric neuronal precursors with noradrenergic features, and endothelin B signaling is required to prevent the differentiation of neuronal precursors that will enervate the distal colon [200]. The significance of these different subtypes is unclear, and the mechanisms by which they achieve regulatory integration require further study.

The ENS begins to function early in embryonic development, but its maturation continues well into postnatal life. Fetal swallowing is first detectable during the first trimester [201], and by term, the fetus swallows about 450 mL amniotic fluid (half of the total amniotic volume) per day [202]. A spectrum of neuropeptides is detectable between weeks 11 and 18 of human development [203]. Peak numbers of both neurons and ganglion cells are achieved during the second trimester and decrease during the third trimester [204]. Although the structural elements of the esophagus and stomach are largely developed by midgestation, gastroesophageal motility does not fully mature until after birth. Lower esophageal sphincter pressure increases dramatically during the last trimester and again postnatally [205], achieving adult levels by 3–6 weeks of age. Despite this, free gastroesophageal reflux is common postnatally and persists in up to 10% of infants for the first year [206].

Mucosal immune system

The gastrointestinal tract, particularly the small intestine, contains a highly complex mixture of immune cell populations. The gut-associated lymphoid tissue (GALT) encompasses organized aggregates dominated by lymphocytes (Peyer patches) and a diffuse heterogeneous population of lymphocytes, monocytes, or macrophages, and other cells, such as eosinophils and mast cells in the lamina propria. Intraepithelial lymphocytes are also scattered throughout the surface epithelium. Structures resembling Peyer patches are evident as early as 11 weeks into human gestation; by 14 weeks, $CD4^+$ and $CD8^+$ lymphocytes can be detected. By the end of the second trimester, Peyer patches histologically resemble the adult structure indicating that antigen exposure or bacterial colonization are not necessary for their development; however, germinal centers do not form until after birth. Mice carrying a null mutation for TNF-α do not develop Peyer patches or lymph nodes, and splenic organization is markedly abnormal; if the 55-kDa receptor for TNF-α

is disrupted, lymph nodes and splenic tissue develop normally, but Peyer patches are still absent, suggesting that the 55-kDa receptor provides specificity for Peyer patch development. Other targeted mutations that result in the absence of Peyer patch development in mice include knockout of the inhibitory helix-loop-helix transcription factor Id2, lymphotoxins, and the lymphotoxin-β receptor. Mice lacking Peyer patches do not develop oral tolerance. Targeted disruption of the homeodomain-containing the transcription factor gene *Nkx2.3* in mice results in significant defects in intestinal development and also smaller Peyer patches and loss of expression of the mucosal addressin cell adhesion molecule 1 (MadCam1), which is normally responsible for B-cell and T-cell homing to peripheral lymphoid organs. Research has shown that full maturation of the immune system and specifically Peyer patch formation is dependent on postnatal bacterial colonization.

Lamina propria lymphocytes are first detected after 11 weeks of gestation. Macrophages are present at 12 weeks, but increase greatly in number postnatally. Recruitment and maturation of mucosal lymphocytes depend on retinoic acid, presumably produced by intestinal epithelial populations. During fetal life, lymphocytes consist of increasing numbers of scattered T cells and B cells. In contrast to αβ T cells, γδ T cells, which make up 5%–15% of small intestinal and 40% of colonic intraepithelial lymphocytes, can develop extrathymically as well as in the thymus. The γδ T cells undergo clonal expansion soon after birth but with further maturation they become clonally restricted and unique in each individual. Targeted deletion of γδ T cells in mice results in a lack of mucosal B cells that produce immunoglobulin A (IgA) but has no effect on αβ T-cell development, which is thought to occur intrathymically. IgA- and IgM-producing plasma cells are not found in the lamina propria until after birth and antigenic exposure. Intraepithelial lymphocytes appear at 11 and 12 weeks of gestation. Fetal lamina propria lymphocytes are mostly $CD4^+$ as in the adult lamina propria, and fetal intraepithelial lymphocytes are often $CD4^-$ $CD8^-$; $CD8^+$ cells become more predominant after birth.

As mentioned, exposure to the lumenal flora is necessary for maturation of the mucosal immune compartment. In rats, suckling and germ-free animals have fewer intestinal lymphocytes than adults, and weaning – associated with intestinal maturation and increasing bacterial colonization – is also characterized by marked development of the mucosal immune system. Cyclosporine (cyclosporin), an inhibitor of T-lymphocyte activation, retards normal lymphocyte development in the small intestine. Natural killer activity of intraepithelial and lamina propria lymphocytes is absent before birth, rising dramatically after weaning.

Conclusions

The genes and signals that give rise to the primitive structures of the gastrointestinal tract become progressively invested with functionality during embryogenesis and postnatal life. Some features (e.g., synthesis of pancreatic hormones, neuropeptides, and certain digestive enzymes) are largely under autonomous control, whereas other features (e.g., intestinal growth and development of mucosal immunity) are highly dependent on interactions with the environment.

Disorders of development

The previous sections have described the basic events and mechanisms that allow the normal development of the gastrointestinal tract, the pancreas, and the liver. While dysgenesis may result from disturbances of any one of these steps, errors in gastrulation or endoderm formation do not present clinically because the global importance of these early steps for further development render them lethal during embryonic development. The range of observable clinical phenotypes is therefore confined to those that are compatible with advanced embryonic development. It should be emphasized that developmental disorders involving the gastrointestinal tract are most commonly observed as part of multigenic disorders. Of these, the most common is Down syndrome (trisomy 21 syndrome), which is associated with duodenal atresia, tracheoesophageal fistula, Hirshsprung disease, and imperforate anus. Detailed molecular genetic analysis of karyotypic abnormalities and correlation with clinical phenotypes may provide further insight into developmental mechanisms. In the following sections, several disorders have been selected to illustrate key events in organ formation and organogenesis along with their (known) molecular underpinnings.

Disorders of specification and formation

Congenital gastrointestinal malformations may occur in the setting of Down syndrome or other syndromes, or they may occur as isolated findings. For example, anorectal malformations are common birth defects that may be found in isolation or as part of a syndrome, such as the VACTERL syndrome (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb abnormalities). Clinical features of anorectal malformations are discussed in Chapter 66.

The etiology for most congenital malformations is unknown. Certain anomalies result from lesions in a single gene (e.g., see Box 23.3: Pancreatic agenesis), whereas others may be associated with a disruption of a signaling pathway (e.g., see Box 23.7: Meckel syndrome and the discussion of heterotopias). Another class of congenital syndromes may reflect a common final pathophysiological pathway that can be disrupted by any of a number of events. Hirschsprung disease is an instructive example of this last class.

Hirschsprung disease

As previously described, neural crest cells migrate from the neural tube during midgestation to give rise to the ganglion

cells of the ENS. Absence of these cells (aganglionosis) in the colon results in Hirschsprung disease, a male-predominant disorder that most commonly presents in the perinatal period. Absent peristalsis in the affected segment of colon causes constipation (or failure to pass meconium), distal obstruction, and megacolon. Hirschsprung disease always affects the rectum; more proximal segments are affected in a few patients, and rarely, the small bowel (see Chapter 47 for a detailed clinical discussion). Although Hirschsprung disease can be inherited in an autosomal or recessive fashion, most cases exhibit nonMendelian inheritance with a genetic component. Hirschsprung disease is commonly associated with Down syndrome.

Receptor tyrosine kinase RET

Heterozygous mutations in RET, a transmembrane tyrosine kinase (chromosome 10q11.2), represent the most common genetic alteration in persons with Hirschsprung disease. The gene for RET is expressed in ENS precursors, whereas those for its ligands (which include GDNF and neurturin [NRTN]), are expressed in the mesenchyme of the developing gut. On binding to one of its cognate ligands, RET normally activates a membrane complex that includes a glycosylphosphatidylinositol-anchored signaling component (GFRA1–4) [200]. Mutations in the RET gene cause disease by reducing kinase function, which interferes with the proper differentiation, survival, or migration of these cells. Such mutations are present in up to 50% of patients with familial disease. A small percentage of patients with sporadic disease have inactivating RET mutations, and polymorphisms in the gene may also play a role [200,207,208]. Mutations in the RET ligand GDNF have also been found in patients with Hirschsprung disease [209,210], and mutations in the NRTN ligand may contribute to disease severity [211]. Furthermore, polymorphisms in the homeobox transcription factor PHOX2B, a putative regulator of RET [212], are associated with Hirschsprung disease [213]. Consistent with a specific role for RET in neural crest cell biology, a high frequency of activating mutations occur in patients with multiple endocrine neoplasia type 2, who develop a spectrum of neural crest-derived tumors [214].

Sox10

Mutations in genes with no apparent link to RET signaling are also associated with Hirschsprung disease. One of the first models of Hirschsprung disease was Dominant megacolon (Dom), a naturally occurring mouse mutant that exhibited pigmentary defects and aganglionosis [215]. Mutations in the SRY-related transcription factor SOX10 are responsible for the Dom phenotype [216,217]. In contrast to most mouse models of Hirschsprung disease, haploinsufficiency of SOX10 is sufficient to cause colonic aganglionosis in *Sox10*$^{+/-}$ mice. *SOX10* mutations are also found in patients with Waardenburg–Shah syndrome, who exhibit Hirschsprung disease, pigmentary defects, and deafness. Thus, like RET, SOX10 also likely has a general role in the development of neural crest derivatives.

Endothelins

Mutations in endothelin 3 (EDN3) and its receptor (EDNRB) have been found in patients with isolated Hirschsprung disease or the Waardenburg–Shah syndrome. Similar to RET, EDNRB is expressed in neural crest cells before and during migration, whereas its ligand is expressed by the gut mesenchyme; mutations in these genes account for about 10% of Hirschsprung disease cases [218]. In addition, a mutation in an endothelin-processing enzyme (ECE1) has been found in a patient with Hirschsprung disease [219].

The final common pathology in Hirschsprung disease is aganglionosis so the disorder may reflect defects in the specification, migration, or survival of enteric neurons. Much work remains to be done to understand precisely how the identified genes function in normal ENS development and how mutations in these genes result in a Hirschprung disease phenotype. Given that most patients with Hirschsprung disease lack identifiable mutations, polygenic contributions are likely to be important. Alternatively, "errors" in migration, without a genetic contribution, may play a role in some cases.

Disorders of differentiation and patterning

Clinical phenotypes caused by the developmental failure to form a particular cell type are rarely observed. It is likely that many mutations affecting critical regulatory pathways (e.g., Notch signaling) are incompatible with life. Alternatively, redundancy or plasticity lead to adaptive compensatory changes that permit normal or nearly normal differentiation in a mutant background.

Instead, disorders that affect patterning leading to *misplacement* of differentiated tissues occur with some frequency. These conditions may be the result of an acquired (metaplasia) or congenital (heterotopia) tissue placement. Metaplasia is often the harbinger of malignant transformation, as mentioned in the section on the specification of the gastroeintestinal tract and discussed in greater detail in Chapter 42. While the possible mechanism of heterotopia is discussed in the following section, note that the mechanism of metaplasia is entirely unknown. In particular, it is not clear whether the premalignant intestinal epithelium that replaces the normal squamous mucosa of the esophagus is a consequence of *transdifferentiation* between the two cell types or the growth and replacement of squamous cells by a quiescent stem/progenitor cell that exists within the esophgagus.

Heterotopias

The presence of ectopic cell types (heterotopia) is observed in several tissue types, although in some cases the displacement is the result of faulty migration (e.g., subependymal heterotopia). Heterotopias involving gastrointestinal derivatives

also occur, and ectopic placement of gastric, pancreatic, and liver tissues have all been described, and may occur in the setting of congenital gastrointestinal duplications. Of the simple heterotopias, two types occur with relative frequency: inlet patches and pancreatic heterotopias.

Inlet patches consist of a segment of gastric mucosa within the cervical esophagus and occur with a frequency of up to 4.5% in autopsy studies. Inlet patches contain true gastric mucosa and most exhibit oxyntic histology. Most cases are asymptomatic, although some may be complicated by infection with *Helicobacter pylori*, inflammation, bleeding, and malignant transformation [220]. Inlet patches are sometimes associated with intestinal metaplasia and pancreatic heterotopia.

Pancreatic heterotopias, also known as pancreatic rests, consist of ectopic pancreatic tissue, most often located within the proximal gastrointestinal tract. Autopsy studies estimate their frequency to range from 0.5% to 14%, although the true prevalence is probably on the lower end of the scale [221]. As with inlet patches, most pancreatic heterotopias are asymptomatic.

Both of these conditions are believed to be congenital, but the causes are unknown. One study shed light on a possible mechanism: the segmental absence of a developmental signal. As discussed in the section on pancreatic organogenesis, a key signal during the specification of the pancreas is the *repression* of Shh expression in the endoderm. Consistent with hedgehog repression being sufficient to specify pancreatic development, the exposure of mouse embryos to the drug cyclopamine, an inhibitor of Shh signaling, results in ectopic pancreas formation with an anatomic distribution that mimics that of human pancreatic heterotopia (stomach > duodenum > small intestine; Fig. 23.8a; Box 23.5. Thus, the failure of a patch of endoderm to receive a hedgehog

Box 23.5 Annular pancreas

The pancreas forms from two buds – a ventral bud and a dorsal bud – that only later fuse into a single integrated gland during the rotation of the abdominal viscera (at which time the ventral portion rotates *behind* the duodenum to meet the dorsal portion). Dysregulation of this process is thought to result in annular pancreas, a condition in which the duodenum is encircled by pancreatic tissue. Annular pancreas was first described in 1818 by Tiedemann [263] and is the most common congenital anomaly of the pancreas to present in childhood, although nearly half of cases are first recognized in adults [264], in whom it presents with early satiety, nausea, and vomiting [265,266]. In pediatric patients, the disorder is associated with other congenital anomalies, and it is more common in patients with Down syndrome.

The etiology of annular pancreas is not understood, although several theories have been proposed, including hypertrophy or failure of atrophy of the left ventral pancreatic bud, fusion of heterotopic pancreatic rests, and malrotation [264]. Others have suggested that annular pancreas is not a cause of duodenal obstruction at all, but is instead secondary to duodenal obstruction from other causes. A mouse model of annular pancreas was serendipitously discovered while looking at the role of hedgehog signaling in pancreas development. Inactivation of Indian hedgehog (Ihh) and rarely Sonic hedgehog (Shh) results in a high frequency of an annular pancreas that encircles the duodenum [267]. This observation provides an experimental framework for determining whether rare cases of familial annular pancreas [268], or the more common annular pancreas associated with Down syndrome, are caused by disruptions in hedgehog signaling.

Radiographic image and images from Hebrok et al. [267].

signal could result in the specification of an ectopic patch of pancreatic tissue. Similarly, the cervical esophagus could be particularly susceptible to the absence of a normally inhibitory signal during development, giving rise to an inlet patch. This presumptive mechanism could account for the development of ectopic tissues in other organs as well (see also the discussion of Meckel syndrome in Box 23.6.

Disorders of remodeling

Much is known about remodeling – the molding of patterned tissue through growth and development – in certain tissues, especially the developing central nervous system. By contrast, little is known about remodeling during gastrointestinal development. How are the vascular supplies of the intestine, pancreas, and liver tailored to physiological need? What mediates the integration of the ventral and dorsal pancreatic ductal systems (the failure of which causes pancreatic divisum)? How are the different endocrine cells in the pancreas guided to coalesce into the islets of Langerhans? Since the pathophysiology of some developmental disorders (e.g., Hirschsprung disease) may have a component of defective remodeling, the following discussion focuses on biliary tract remodeling as an example.

Abnormal biliary development

As discussed in the section on morphogenesis and cytodifferentiation in the liver, the ductal plate – two adjacent rings of specialized cells surrounding branches of the portal vein

Box 23.6 Meckel syndrome

Meckel diverticulum is the most common congenital malformation of the gastrointestinal tract, occurring with a frequency of 2% of births [269]. The disorder reflects a persistence of the vitelline duct – the embryonic structure connecting the gut to the yolk sac. Meckel diverticula are generally located near the terminal ileum, and in about 50% of patients the diverticulum contains ectopic tissue, most commonly gastric or pancreatic, but occasionally also colonic, duodenal, jejunal, hepatic, and endometrial [270]. Secretion of gastric acid (and in some cases pancreatic bicarbonate) causes ulceration of adjacent small intestinal mucosa; the disorder commonly presents as unexplained gastrointestinal hemorrhage in a child or young adult (see Chapter 46; see also Fig. 23.8a). Note that heterotopia is distinct from metaplasia, which represents an acquired replacement of one tissue type with another over time.

What mechanism might account for the defective patterning leading to heterotopia?

Bossard and Zaret [271] observed that 3% of mouse embryos exhibit an albumin-expressing ectopic bud at the site of the vitelline duct, near the terminal ileum, which led them to propose that Meckel diverticula result from the loss of normal mesenchymal inhibitory signals at the site of the vitelline duct. According to this attractive model, heterotopic tissue forms not as a result of ectopic cells "left behind" by the nonregressed vitelline structure, but because a signal required for patterning and specification was disrupted by the error in regression. (See section on heterotopias in Disorders of development.)

– gives rise to the intrahepatic bile ducts. Ductal plate remodeling appears to occur in two steps:

- formation of discrete tubules within the two-cell-thick layer of the ductal plate
- elimination of remaining cells through apoptosis or attrition.

The intrahepatic bile ducts anastomose with the extrahepatic biliary system (the origin of the extrahepatic system is unclear but it may derive directly from the gut).

Developmental or neonatal biliary disorders fall into two categories: ductal plate malformations and bile duct paucity. Ductal plate malformations refer to a collection of overlapping disorders that are characterized by faulty remodeling of the intrahepatic bile ducts, resulting in the persistence of the embryonic ductal plate configuration (see Fig. 23.5; [222]). Congenital hepatic fibrosis is an autosomal recessive disease with variable histological and clinical features in which the portal tracts and bile ducts exhibit fibrosis and a ductal plate configuration. The histopathology of congenital hepatic fibrosis is seen in association with both autosomal recessive and autosomal dominant polycystic kidney disease. A related disorder, Caroli syndrome, is characterized by the ductal dilation of Caroli disease (type IVA/type V choledochal cysts, see Chapter 76) with the superimposed fibrosis of congenital hepatic fibrosis, suggesting an overlapping pathophysiology [222]. While the shared histopathological characteristics observed in these and similar abnormalities (e.g., von Meyenburg complexes) are intriguing, the etiology of these disorders remains completely unknown.

Insight into one potential mechanism for biliary malformation comes from studies of patients with a paucity of

intrahepatic bile ducts, also known as Alagille syndrome. Although bile duct paucity is the sine qua non of Alagille syndrome, patients may also have several extrahepatic manifestations, including abnormalities of the great vessels, skeletal and ocular malformations, as well as characteristic facies (see Chapter 108). Two studies in 1997 showed that mutations in the Notch ligand JAG1 are responsible for Alagille syndrome and strengthened the link between this developmental signaling pathway and the disease [69,70].

Consistent with the hypothesis that the formation of the ductal plate is induced by Notch signaling, JAG1 is expressed by portal veins and hepatic arteries [223–225], and mice with compound heterozygous *Jagged*/*Notch* mutations exhibit a paucity of intrahepatic bile ducts [226]. These studies suggest that Alagille syndrome may result from the faulty specification of bile ducts in the absence of Notch signaling. However, an analysis of ductal plate development in mice with defective Notch signaling suggests that Notch has a more direct role in remodeling. Embryos deficient in the Notch target Hes1 develop ductal plates with normal appearance at the appropriate developmental time, but these ductal plates fail to form the tubular structures that precede normal duct development [227].

Notch may therefore mediate biliary development in at least one of two ways. Notch signals may serve as the inductive signal emanating from portal veins or they may be involved in the remodeling of the biliary system. Either mechanism is compatible with the hepatic phenotype observed in Alagille syndrome. As previously mentioned, the onecut transcription factors HNF6 and OC2 play an important role in biliary specification. As 30% of patients with Alagille syndrome lack *JAG1* mutations [228], it is possible that disease-causing mutations in these onecut transcription factors or in other elements of the Notch pathway remain to be discovered.

Biliary atresia, a more common syndrome of bile duct paucity, is characterized by the loss of the extrahepatic bile ducts (see Chapter 73). Biliary atresia is a heterogeneous disorder that presents with two major clinical patterns – a prenatal form that presents almost immediately after birth and is associated with other congenital anomalies, and a perinatal form that presents in the first few weeks of life. Although the etiology of both forms is poorly understood, defective morphogenesis of the bile ducts may play a role in the prenatal form of the disease [229]. Congenital anomalies affecting body symmetry, such as cardiac anomalies, intestinal malrotation, and abdominal situs inversus, often accompany the prenatal form of biliary atresia [230]. Mice with a mutation of the *inversin* gene exhibit abdominal situs inversus and a defective extrahepatic biliary tree [231,232]. Furthermore, missense mutations in *JAG1* have been observed in patients with severe refractory biliary atresia, suggesting that this Notch ligand contributes to disease progression [233]. Consistent with a connection between intra- and extrahepatic ductal pathology, some patients with biliary atresia exhibit the histological characteristics of ductal plate malformation observed with congenital hepatic fibrosis [222].

Disorders of growth control

Several rare disorders that affect the growth of specific parts of the body highlight another developmental phenomenon: genomic *imprinting*. In mammals, which contain sets of paired chromosomes, the maternally inherited chromosome differs from the paternally inherited chromosome both in terms of primary sequence (polymorphisms) and in additional epigenetic (noninherited) differences. Epigenetic differences are conferred by DNA methylation, a process that occurs early in embryonic development and results in the differential expression of genes from maternal and paternal alleles. Imprinting is enormously important in normal development, and improper allele-specific methylation is a major cause of defective embryos and newborns after nuclear transplantation (cloning). Several human disorders that exhibit growth abnormalities and an increased cancer susceptibility are linked to abnormalities in genomic imprinting, and we will focus on one of these: Beckwith–Wiedemann syndrome.

Beckwith–Wiedemann syndrome

This disorder is characterized by variable growth defects, including generalized overgrowth (pre- and postnatal) as well as macroglossia, visceromegaly, and hemihypertrophy (enlargement of one half of the body). Patients with Beckwith–Wiedemann syndrome have an increased frequency of several tumors, including Wilm tumor, hepatoblastoma, and pancreatoblastoma. In the last decade, it has become clear that Beckwith–Wiedemann syndrome is linked to chromosome 11p15, a region containing several imprinted genes.

Two genes in this imprinted region are thought to play a causative role in Beckwith–Wiedemann syndrome: *CDKN1C* (a negative regulator of cell proliferation that acts by inhibiting cyclin-dependent kinase) and *IGF2* (a major regulator of fetal growth). Classical mutations of either of these genes affect growth. For example, mutations in CDKN1C have been described in patients with Beckwith–Wiedemann syndrome [234], and the overexpression of *IGF2* in mice is sufficient to cause an overgrowth syndrome [235]. However, the more common mechanism of gene activation (*IGF2*) or inactivation (*CDKN1C*) is related to abnormalities in methylation-dependent imprinting.

Under conditions of normal imprinting, *CDKN1C* is expressed from the maternal allele and *IGF2* is expressed from the paternal allele. Two different patterns of abnormal imprinting are associated with the development of Beckwith–Wiedemann syndrome. In most cases, abnormal methylation results in the loss of *CDKN1C* expression from both alleles, whereas in a few cases, abnormal methylation results in *IGF2* expression from both alleles [236]. Notably, the converse pattern of dysregulated methylation (resulting in loss of *IGF2* expression from both alleles) is associated with Silver–Russell

Box 23.7 Unanswered questions in gastrointestinal development

What makes the endoderm endoderm? After gastrulation, the cells of the endoderm are uniquely competent to give rise to the gastrointestinal organs. What intrinsic properties of the cell confer this restricted competence? A favored view is epigenetic modification, including chromatin condensation.

What patterns the endoderm? How are the various organ domains partitioned and coordinated with the remaining "body plan" (e.g., skeleton)? Epithelial–mesenchymal signaling clearly plays a key role in coordinating patterning. Although some of the ingredients involved in such signaling have been identified, the recipe is far from complete.

How are three-dimensional structures generated (i.e., morphogenesis)? Complex organized three-dimensional structures arise from simple epithelial buds. In the liver, for example, the three circulatory systems (arterial, portal venous, central venous) must be correctly organized in space with the canalicular and ductal biliary systems. How is this spatial organization achieved with such precision?

What are the differences between embryonic and adult intestinal stem/progenitor cells? Embryonic and adult stem/progenitor cells exhibit different features. Adult intestinal stem cells can give rise to all epithelial cell types. Further, they can mediate villus elongation but cannot mediate gut tube elongation in the manner of embryonic cells. It is unclear whether embryonic gut epithelial cells are true stem cells or committed progenitors with a limited capacity for self-renewal.

Are there adult stem/progenitor cells in the pancreas and liver? Is all tissue maintenance in the pancreas and the liver mediated by cell replication? What is the role, if any, of "facultative stem cells" (e.g., oval cells) in the response to certain types of pancreatic or hepatic injuries?

What are the signals that stimulate functional maturation? The intestine undergoes dramatic physiological changes both before and after birth. Some of these changes appear to be responsive to changes in the environment (e.g., intestinal growth and adaptation), whereas others appear to be "intrinsic" (e.g., the timing of brush-border enzyme expression). To what extent are these functional parameters responsive to environmental changes (and therefore amenable to therapy) and are there underlying principles that dictate which aspects of gastrointestinal physiology are intrinsic or regulated?

What is the mechanism of metaplasia? Does metaplasia arise from the transdifferentiation of one cell type into another (e.g., squamous esophageal epithelium to columnar intestinal epithelium) or does a metaplastic tissue arise from rare progenitor cells (e.g., a rare intestinal stem cell that resides in the esophageal mucosa)?

What is the cellular basis of gastrointestinal cancers? Do cancers arise from normal adult stem cells in adult tissues or from differentiated cells that "dedifferentiate" to acquire the characteristics of stem cells? Are such cancers maintained by "cancer stem cells" – rare cells within the tumor that have an enhanced or unlimited capacity for self-renewal?

syndrome, a congenital disorder characterized by growth retardation and asymmetry [237–239]. Although the mechanism by which dysregulation of *CDKN1C* or *IGF2* results in isolated growth phenotypes is not known, it is likely that alterations in cell proliferation underlie both the abnormal growth and the tumor propensity in patients with Beckwith–Wiedemann syndrome.

Conclusions

Despite a detailed conceptual framework for understanding the events that govern normal patterning, organogenesis, and physiological adaptation of the gastrointestinal tract, the pathogenesis of congenital disorders of the gastrointestinal tract is poorly understood, reflecting the numerous questions about gastrointestinal development that remain unanswered (Box 23.7). To date, most insights have come from human (reverse) genetics and serendipitous similarities between animal and human phenotypes. Specific challenges to further advances include the association of many developmental disorders with complex genetic syndromes and the separation in time between a developmental lesion and its phenotypic manifestations.

E MISCELLANEOUS

24 Neoplasia of the gastrointestinal tract

Barbara H. Jung, C. Richard Boland, John M. Carethers

Normal cellular control mechanisms, 604
Molecular carcinogenesis, 607
Tumor formation and behavior, 622
Clinical markers of neoplasia, 626

The gastrointestinal tract, including the hollow organs of the gut, pancreas, liver, and biliary tree, is the site of more cancers and the source of more cancer mortality than any other organ system in the body. However, no simple etiological explanation can unify all gut tumors.

The most notable feature of international cancer epidemiology is the wide variability of tumor incidence from country to country by organ site. For example, an esophageal cancer belt extends from northeastern China through central Asia into northern Iran [1]. In parts of these regions, the incidence of squamous cell carcinoma of the esophagus is more than 100-fold higher than that in adjacent low-incidence regions. In the United States, three- to fourfold differences in the incidence of esophageal cancer occur between the sexes and among races [2]. In Japan, the incidence of gastric carcinoma is about 10 times higher than it is in the United States. Colorectal cancer was historically less common in Japan, compared to being the most common gastrointestinal malignancy in North America, Western Europe, and much of the industrialized world. However, over the past decade, the incidence of colorectal cancer in Japan has risen to the same level as, or perhaps higher than, in the West [3]. These marked differences in cancer risk are not based on racial or genetic factors. When people migrate from a high-incidence region to a low-incidence region, the organ-specific rates of some cancers change to match that of the new region, usually within two generations. Collectively, the epidemiological observations strongly indicate the importance of environmental factors in gastrointestinal carcinogenesis; however, individual genetic differences may influence the effects of these factors.

Worldwide, people are exposed to different types of foods, the gastrointestinal flora differs as a result of dietary and host factors, and certain mucosal infections occur with different frequencies. Gastrointestinal carcinogenesis, therefore, is a complex problem to understand and to modify. For example, tobacco smoke causes cancers of the oral and respiratory tracts, and by eliminating smoke from the environment, the risks of tumor development can be controlled. However, everyone consumes some kind of diet, and the elimination of specific items results in the introduction of replacement nutrients. Moreover, the diet consists of a complex combination of macronutrients (i.e., fat, carbohydrate, protein, fiber) and micronutrients (i.e., vitamins, minerals, other agents present in tiny concentrations) that affect cancer risk. Directly acting carcinogens or indirectly acting procarcinogens also are part of each person's diet. Mucosal infections with human papillomavirus and *Helicobacter pylori* probably contribute to the genesis of cancers of specific gastrointestinal organs.

Ultimately, changes at the genetic level can alter the growth characteristics of healthy gastrointestinal cells. Although many deleterious genetic events must occur for a normal cell to become malignant, inactivation of a gatekeeper gene or a pathway specific to each tissue may be required to initiate the neoplastic process [4]. This concept is evident in familial syndromes such as familial adenomatous polyposis, in which thousands of benign colonic adenomas develop at a young age; it can also be applied to the development of sporadic colorectal cancer. After the initial gatekeeper alteration, successive genetic events propel the cell toward the malignant phenotype. The loss of gatekeeper function and the successive genetic events lead to an uncoupling of cellular growth control mechanisms that typically regulate a normal gastrointestinal cell. These include loss of cell cycle control checkpoints, abrogation of programmed cell death, and dysregulation of intracellular signaling pathways. Some genetic perturbations have been identified as markers for the presence of neoplasia as well as prognostic factors for malignancy, but their clinical use has not been fully evaluated.

Our understanding of carcinogenesis in the gastrointestinal tract is far from complete so it is necessary to understand the principles of regulation of normal, nonneoplastic gastrointestinal cell growth before considering the abnormal events. The mechanisms of tumor development appear to be distinct among the gastrointestinal organs, but general pathogenetic principles apply at the cellular and molecular level for most tumors.

Normal cellular control mechanisms

Cell cycle checkpoints

The cell replication cycle consists of five phases [5]. Resting diploid cells not involved in active replication may be in the G0 or G1 phase. G1 represents the postmitotic period before the initiation of new DNA synthesis as the cell prepares to divide. The cell may spend a variable period of time in G1. Cells not involved in replication may be described arbitrarily as resting in the G0 phase. After receiving the signal to divide, cells enter a phase of active DNA synthesis, the S phase. After duplication of the entire genome, the tetraploid cell pauses briefly in the G2 phase before entering mitosis (the M phase). After cell division into two identical daughter cells, the cell reenters the G1 phase. As the genome becomes more complex with tumor progression, the S and M phases may be prolonged, altering the apparent fraction of cells involved in replication. This complicates a direct comparison of the proliferative activity of tumors with that of normal tissue.

Each transition from one phase of the cell cycle to the next is regulated by a family of cyclin-dependent kinases (CDKs) and their activating partners, the cyclins (Fig. 24.1). The CDK–cyclin complexes are positively and negatively regulated by phosphorylation. The formation and activation of a CDK–cyclin complex requires proper completion of the previous cell cycle phase before the subsequent phase is entered [6,7]. If DNA is damaged by ultraviolet light in the G1 phase of the cell cycle, passage into the S phase will not occur until the damage is repaired. Likewise, if DNA is not replicated with complete fidelity during the S phase, passage into G2 and mitosis are prohibited until an exact copy of the DNA is duplicated. The CDK–cyclin complexes receive input from other cellular proteins that relay information regarding the integrity of each checkpoint. The gene products of the tumor suppressor genes retinoblastoma (*RB1*) and *TP53*, Rb protein and p53, relay information to G1 phase CDK–cyclins to regulate the initiation of DNA synthesis (S phase) [7]. CDK inhibitors, such as $p21^{WAF1/CIP1}$, regulate specific CDKs to prevent entry into the next phase of the cell cycle and to allow repair of damaged DNA during cell cycle arrest [8]. These cell cycle checkpoints are lost in oncogenesis. The CDK–cyclin complexes themselves may be altered in some tumors and, in the gastrointestinal tract, changes occur in the regulators that relay information to CDK–cyclin complexes. These genetic perturbations allow the neoplastic cell to cycle with disregard for mutations and chromosomal rearrangements, essentially establishing progeny cells that differ from the parent. This generation of genetic diversity is a form of genomic instability and a hallmark of oncogenesis.

Programmed cell death

Deregulated proliferation is the sine qua non of the neoplastic process. An increase in the proliferation rate of cells can occur either by increased mitosis or by a decreased cell death rate. Programmed cell death is a physiological process that plays an essential role in normal tissue turnover and embryonic development [9]. This process has been shown to require energy, macromolecular synthesis, and de novo gene transcription [10]. The morphological changes of programmed cell death, first described in 1972 by Kerr and colleagues [11] and termed *apoptosis*, affect single scattered cells

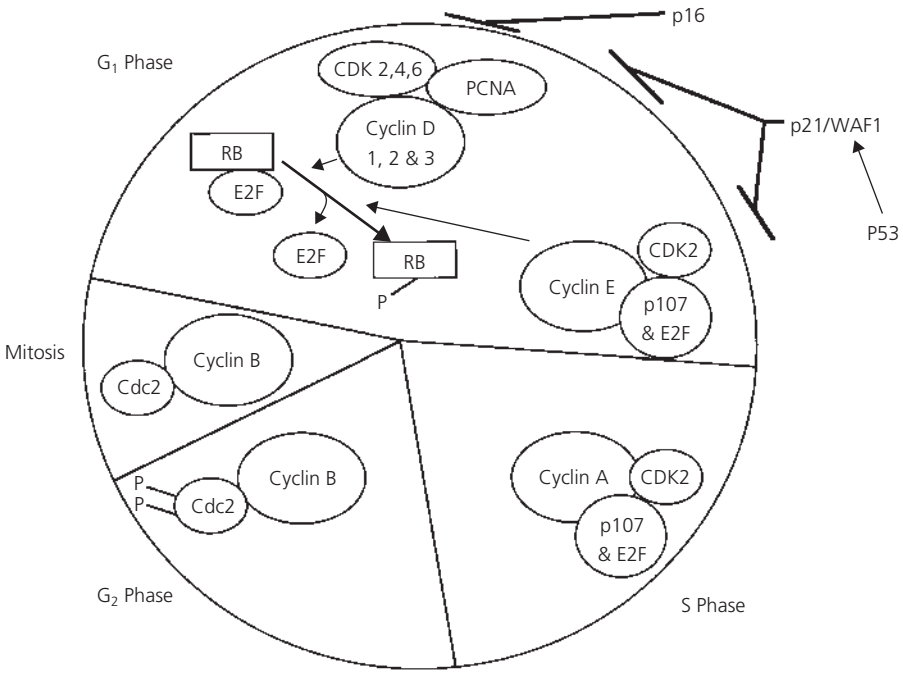

Figure 24.1 Cell replication cycle. Transition through each phase of the cell cycle is regulated by cyclins and cyclin-dependent kinases (CDKs) to ensure completion of one phase before initiation of the subsequent phase. Each cyclin–CDK complex is positively and negatively regulated by phosphorylation. Inhibitors of CDKs include p21 and p16, both of which prevent transition to the S phase of the cell cycle. The transcriptional regulator E2F transactivates genes that are important for S phase entry. E2F is bound by the retinoblastoma protein (RB) until RB is phosphorylated, thus releasing E2F. RB phosphorylation is initiated by cyclin D-dependent kinases and accelerated by cyclin E–CDK2 complexes. P, phosphorylated; PCNA, proliferating cell nuclear antigen.

with characteristic changes in the nucleus (i.e., karyorrhexis), preservation of cytoplasmic organelles, cellular shrinkage, and the formation of apoptotic bodies. The initiation of programmed cell death may involve a sustained increase in intracellular calcium, which activates several calcium-dependent enzymes. These enzymes, in turn, activate stored or newly synthesized transglutaminases (involved in the cross-linking of cytoplasmic proteins), proteases (e.g., caspases) that aid in disruption of the cytoskeleton and cell shrinkage, and endonucleases that cleave DNA into uniformly sized fragments. Once activated, programmed cell death is irreversible.

Activation of a cell death program is best illustrated by the normal turnover of the colonic epithelium. In healthy colonocytes, the surface epithelium is constantly renewed about every 6 days by cellular proliferation and differentiation of crypt cells. The proliferating compartment is in the lower third of the crypt, characterized by mitoses and upward migration from anchored stem cells. As the cells move up the crypt, differentiation and maturation occur, and the capacity to divide is lost. Eventually, cells die and are shed. In this way, programmed cell death of colonocytes maintains a uniform number of cells in the mucosa. The expression of *APC*, the adenomatous polyposis colon gene, controls, in part, the programmed cell death of colonocytes [12], functioning to maintain a normal rate of cell turnover. Other cellular proteins, such as those of the *BCL2* gene family, may also play significant roles in programmed cell death in the gastrointestinal tract.

Activation of programmed cell death is the target of many therapeutic interventions in the treatment of gastrointestinal tumors. Both radiation and chemotherapy can induce apoptosis in tumors of the gastrointestinal tract, in addition to direct toxic tissue injury (i.e., necrosis) [9]. Apoptosis has been proposed to be the mechanism by which the nonsteroidal antiinflammatory agent sulindac and the cyclooxygenase-2 inhibitor celecoxib lead to the involution of colonic adenomas in patients with familial adenomatous polyposis [13,14]. Interference with programmed cell death may be as important as deregulated cell proliferation in some gastrointestinal tumors.

Intercellular and intracellular growth control pathways

Cells that make up the tissues of the gastrointestinal tract are in contact with neighboring cells to form a tight epithelial barrier. In addition to functioning as a barrier, the epithelial junctions that interconnect neighboring cells distribute information about the cell's local environment, such as the presence of a contiguous cell (e.g., cell–cell adhesion and recognition at the zona adherens), and they may allow the direct passage of ions and small molecules through specialized pores called *gap junctions* [15]. Passage of ions and small molecules through gap junctions allows cells to be coupled and permits groups of cells to behave as a syncytium in regard to ion transfer. Cell–cell adhesion is primarily mediated through the intracellular adhesion molecule E (epithelial)-cadherin, which forms homeotypic interactions (i.e., with other E-cadherin molecules) and anchors the zona adherens to the actin cytoskeleton inside the cell [16]. Dysregulation of cell–cell adhesion disrupts normal intercellular communication and allows transformed cells to separate from each other and to spread locally, invading regional tissue. Proteins from the catenin family (α, β, γ) bind to E-cadherin and to the actin cytoskeleton, but any signal relayed by the catenins for cellular adhesion is not known. Importantly, β-catenin, a protooncogene that can transactivate genes associated with cellular proliferation, has its cytoplasmic levels regulated by the adenomatous polyposis coli (APC) protein when its intercellular concentration rises (Fig. 24.2) [17–19]. APC targets β-catenin for degradation; and if β-catenin escapes this homeostatic regulation, it can move to the nucleus, where it associates with T-cell factor-4 (TCF-4) to transactivate genes that promote cell growth and prevent programmed cell death.

Another mode of intercellular communication exists between epithelial cells and other cells that line the gastrointestinal tract. Growth factors are proteins that bind as a ligand to a receptor on the same (autocrine) cell or neighboring (paracrine) cell. Growth factors modulate growth characteristics of the cell. Once the growth factor is bound to its specific receptor, an intracellular signal is amplified and transmitted to the nucleus of the cell to induce or inhibit gene activation; this in turn modifies growth characteristics, metabolism, and ion transport. Although many growth factors use tyrosine phosphorylation at the start of their intracellular signaling pathway, other ligand–receptor complexes often use other pathways, such as serine/threonine phosphorylation, calcium and phosphoinositol formation, and the generation of cyclic nucleotides. Two important examples highlight the signal transduction process in normal and neoplastic growth in the gastrointestinal tract: the KRAS and transforming growth factor-β1 (TGF-β1) signaling pathways.

The protooncogene Kirsten-RAS (*KRAS*) encodes an intracellular protein that binds the cyclic nucleotide guanosine tri- or diphosphate (GTP/GDP). On cell surface ligand–receptor activation (e.g., epithelial growth factor binding to its receptor), the KRAS protein is activated and exchanges the bound GDP for GTP (Fig. 24.3). Active KRAS molecules then interact with downstream intracellular molecules, transmitting a growth response to the nucleus. To turn off this activity, KRAS is deactivated by the hydrolysis of GTP to GDP, which returns KRAS to the inactive GDP-bound state [20]. This signal transduction process is perturbed with a mutant KRAS protein. Stabilization of mutant KRAS in its active state permits continuous signal transduction, allowing the cell to undergo unregulated proliferation. This process may be caused by mutations that inhibit the intrinsic GTPase

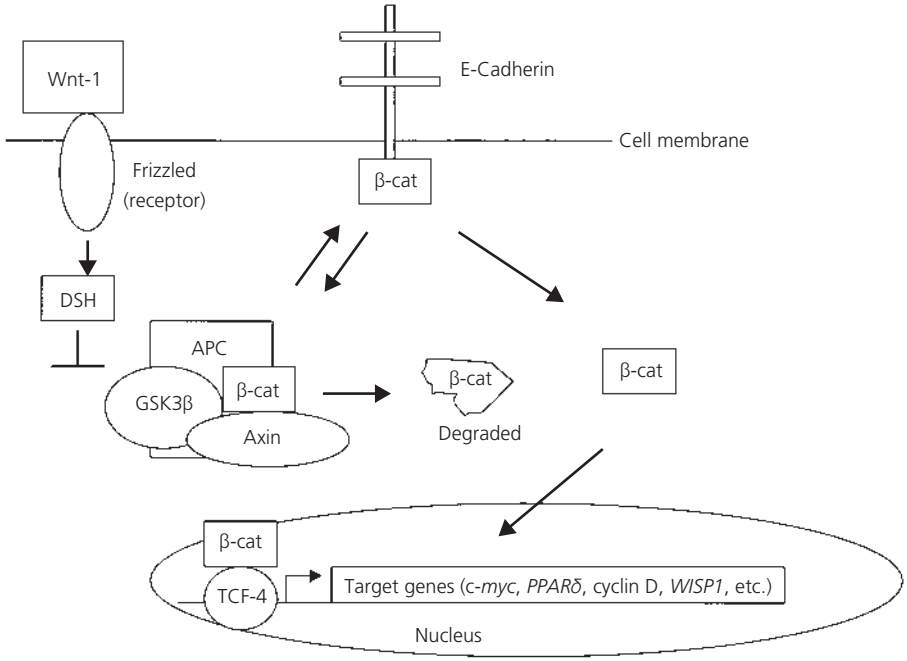

Figure 24.2 Adenomatous polyposis coli gene (*APC*) regulation of β-catenin and its function as a tumor suppressor gene. Normal APC protein, in association with axin and glycogen synthase kinase-3β (GSK3β), binds, phosphorylates, and targets cytoplasmic β-catenin (β-cat) for degradation. Degradation of β-catenin prevents its translocation into the nucleus, where it can initiate the transcription of genes by converting the transcriptional repressor T-cell factor-4 (TCF-4) to a transcriptional activator to promote cellular proliferation and prevent cell death. Cytoplasmic β-catenin can bind to E-cadherin, usually in association with α-catenin. During embryogenesis, blockage of APC-mediated degradation can occur through the Wnt-1 signaling pathway (through the frizzled receptor and disheveled [DSH] signaling protein). Presumably, inactivation of APC would have the same consequences as Wnt-1 signaling.

activity of KRAS, allowing KRAS to stay in its active conformation, or by inducing an active conformation that does not require the binding of the guanine nucleotides [20]. Indeed, the most common mutations of *KRAS* in pancreatic and colon cancers involve codons 12, 13, and 61, corresponding to areas in the GTP/GDP binding domains of the KRAS protein [20]. In pancreatic cancers, mutant *KRAS* has been reported in 95% of tumors [21,22], whereas it occurs in about half of colorectal cancers [23–25] and is uncommon in gastric cancers [26]. *BRAF*, one of three known *Raf* genes, acts as a downstream RAS activator and is somatically mutated in a wide range of cancers [27]. In colon cancer, *BRAF* mutations occur at a high rate in microsatellite unstable colorectal tumors [28] that contain an epigenetic alteration of *hMLH1* [29].

TGF-β1 is a ligand that inhibits the growth of gastrointestinal epithelial cells [30]. To exert its growth-suppressive effect, TGF-β1 in its latent form is activated through an interaction with the insulin-like growth factor II receptor (IGF2R) present on the cell surface (Fig. 24.4) [31]. Activated TGF-β1 then binds to the TGF-β1 type II receptor (TGFBR2), which subsequently phosphorylates (as a serine/threonine kinase) the TGF-β1 type I receptor (TGFBR1), forming a heterotrimeric complex of TGF-β1, TGFBR2, and TGFBR1 [32,33]. The conjoined receptor complex then phosphorylates (as a serine threonine kinase) intracellular proteins that cascade to ultimately affect the transcription of growth-suppressing genes in the nucleus. In particular, SMAD2 (SMAD, small mothers against decapentaplegic) and SMAD3 are phosphorylated by activated TGFBR1, which allows them to bind individually to SMAD4 and subsequently translocate to the nucleus. Similarly, activin, a TGF-β family member, binds to its primary receptor, the activin type II receptor (ACVR2), which in turn binds to and phosphorylates the activin type I receptor (ACVR1). This leads to downstream SMAD phosphorylation, association with SMAD4, and translocation to the nucleus, stimulating the transcription of genes involved in growth suppression (Fig. 24.4) [34]. Ligands from another TGF-β family member, bone morphogenetic proteins (BMPs), bind to another serine/threonine kinase type I receptor (BMPRIA) and type II receptor (BMPRII) (35), which then induce phosphorylation of SMAD1, SMAD5, or SMAD8, association with SMAD4, nuclear translocation, and the ensuing transcriptional effects [361,37]. Inactivation of these pathways occurs in some gastrointestinal tumors. For example, many colonic and gastric tumors that exhibit microsatellite instability – a laboratory marker for the inactivation of the DNA mismatch repair (MMR) system – develop mutations in *TGFBR2* [38–40] or *ACVR2* [41] or in both [42]. Other tumors with microsatellite instability but with normal *TGFBR2* have mutations in *IGF2R* [43]. These mutations prevent expression of the receptor on the cell surface. The absence of either TGFBR2 or IGF2R prevents activation and binding of the TGF-β1 ligand and abrogates its growth-suppressive action. Some colon tumors without microsatellite instability have mutations in the kinase domain of *TGFBR2* [44]. Germ-line mutations in *BMPRIA* cause juvenile polyposis, an autosomal dominantly transmitted hamartomatous polyposis syndrome associated with an increased risk of colon cancer [45]. Inactivation of the potential downstream signaling proteins SMAD4 and SMAD2 also has been found in some gastrointestinal cancers [46,47]. Likewise, germ-line mutations in the downstream effector of BMP signaling,

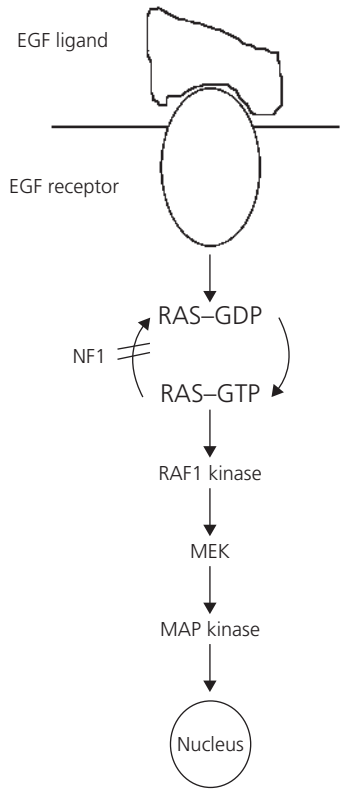

Figure 24.3 RAS intracellular signaling. Cell surface ligand binding to a receptor, such as epithelial growth factor (EGF) to the EGF receptor, triggers the activation of GDP-bound RAS and the exchange of GDP for GTP. RAS–GTP can activate subsequent steps in the intracellular signaling cascade (RAF1 kinase → mitogen-activating protein [MAP] kinase kinase [MEK] → MAP kinase), which leads to the expression of genes that promote cellular proliferation. The tumor suppressor protein neurofibromatosis 1 (NF1) is an activating protein for RAS, keeping RAS in the GTP-bound state. The activation of RAS by mutation allows continued signaling of this pathway.

SMAD4, may lead to juvenile polyposis [48]. The key point is that essential growth-regulatory pathways may be deactivated at any one of several points in the serial cascade.

TGF-β1 may also induce proliferation in colon cancer cells [49], and somatic mutations of *TGFBR2* microsatellite unstable tumors have been reported to predict improved survival [50]. These observations indicate that TGF-β1 may be influencing proliferative as well as suppressive pathways, and when the suppressive pathway is inactivated by somatic mutation, proliferation may become the dominant phenotype.

RNA and protein degradation

Cells can regulate gene products at the posttranscriptional level. Specific inhibitory RNA molecules can bind and target transcripts for degradation [51] as a way to control transcript output; a process that can become dysregulated in neoplastic transformation. Likewise, targeted protein degradation, which can occur much faster than protein synthesis, can control cellular protein levels. Ubiquitination, which involves the addition of multiple 76-amino-acid ubiquitin monomers to proteins, is a major pathway of protein degradation. Proteins with polyubiquinated tails are recognized and processed by the 26S proteasome, which recycles the ubiquitin [52]. Alterations in ubiquitination have been postulated to be associated with loss of growth regulation, as evident in a subset of colon cancers with ubiquitination-resistant β-catenin mutations [53].

Telomerase

The shortening of telomeres at the end of chromosomes during aging causes a decrease in cellular replication. Tumor cells may acquire immortality by continuous telomere maintenance that is predominantly the result of the transcriptional up-regulation of the limiting component of telomerase, hTERT (human telomerase reverse transcriptase). Oncogenic activity is known to stimulate the hTERT promoter [54]. Furthermore, there is evidence that telomerase plays a role in other aspects of carcinogenesis, as silencing of hTERT increases apoptosis [55]. Inhibition of telomerase has become an attractive target for cancer therapeutics [56].

Many of these regulatory pathways are active simultaneously. They are often redundant and sometimes interconnected, but they typically provide a homeostatic balance for normal cellular growth. Alteration of one or more of these pathways may lead toward cellular proliferation and away from controlled growth and regulated cell turnover by programmed cell death, initiating and exacerbating transformation into neoplastic cells. The complexity of cellular growth mechanisms affords the neoplastic cell many opportunities for a pathway to become deregulated. In gastrointestinal carcinogenesis it appears that more than one pathway is affected, which may be necessary for transformation. Specific pathway inactivations are more common in certain types or subtypes of tumors, creating opportunities for therapeutic intervention of gastrointestinal tumors as biotechnology advances.

Molecular carcinogenesis

Mechanisms by which DNA is damaged

The current concept of carcinogenesis in the gastrointestinal tract begins with damage to normal cellular genes. This can occur through a variety of mechanisms. Mutations occur spontaneously because of predictable instability of the purine and pyrimidine bases themselves. The most common spontaneous mutation is depurination, which occurs after disruption of the *N*-glycosyl linkages between the purine base and the ribose chain. In another spontaneous event, deamination, cytosine is converted to uracil, or 5-methylcytosine to thymine. These single base mutations, if not repaired, lead to nucleotide complementary mispairing during the next

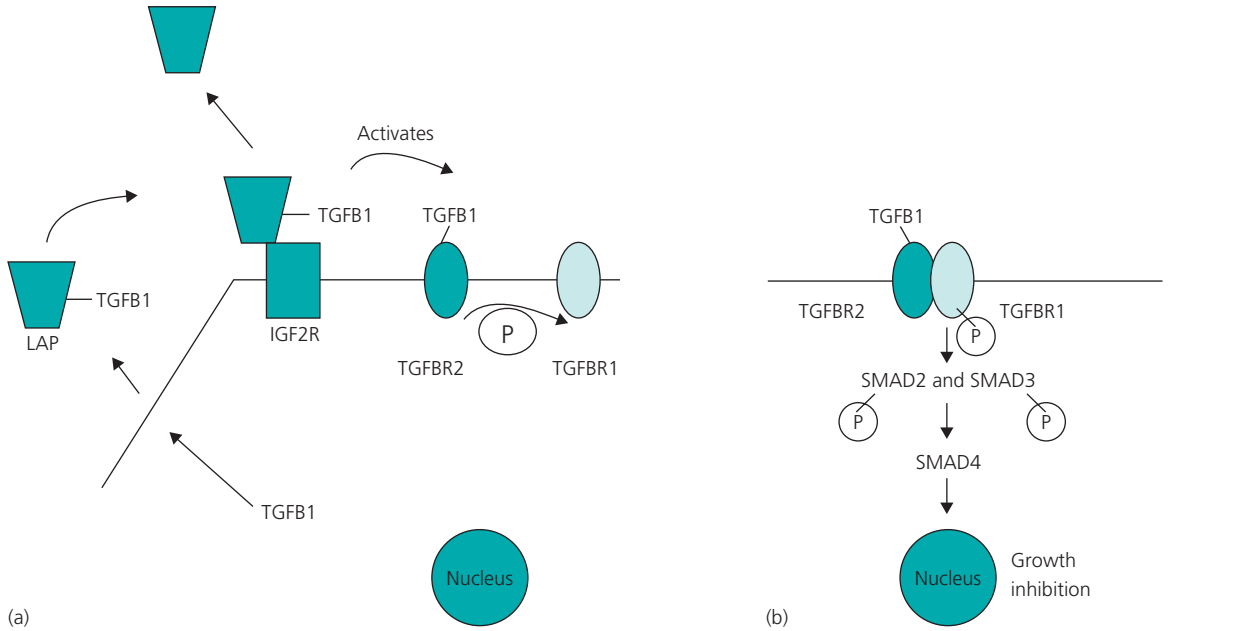

Figure 24.4 Transforming growth factor β-1 signaling. **(a)** TGF-β1 can be produced in an autocrine fashion by epithelial cells, and it is bound by a latency-associated peptide (LAP) once outside the cell. To activate TGF-β-1, LAP is cleaved by the insulin-like growth factor II receptor (IGF2R), leaving TGF-β1 free to bind to the TGF-β1 receptor type II (TGFBR2). This action, in turn, phosphorylates (P) the TGF-β1 receptor type I, which then forms a heteromeric complex with TGFBR2. **(b)** Subsequent intracellular signaling of TGF-β1 (and the TGF-β family member activin) to the nucleus occurs through the SMAD family of proteins, ultimately causing growth suppression. Mutations in *IGF2R*, *TGFBR2*, *ACVR2*, *SMAD2*, and *SMAD4* have been described that uncouple the growth-inhibitory effects of TGF-β1 on the colonocyte.

round of replication. Both events are common and subject to revision by families of DNA repair enzymes.

Several environmental factors predictably damage DNA, including viral infections, chemical carcinogens, and radiation in the form of ultraviolet radiation, ionizing electromagnetic radiation such as x-rays and γ-rays, and particle radiation such as electrons, α particles, and heavy ions (Table 24.1). Radiation injury damages DNA by producing strand breaks. As an internal organ, the gastrointestinal tract is usually not exposed to sufficient radiation for it to be a major factor in gastrointestinal carcinogenesis. However, very high doses of x-rays administered under unusual circumstances have been implicated as a pathogenetic factor in some intestinal cancers. Viral oncogenesis has been documented in several non-human tumor models and in squamous cell carcinoma of the esophagus and anus in humans [57,58]. JC virus, a DNA virus encoding a T antigen, is present in the gut and has been implicated in colorectal carcinogenesis [59,60]. There is evidence to suggest a role for viruses in the genesis of adenocarcinomas of the gastrointestinal tract, such as the role of hepatitis B and C viruses in causing hepatomas. Chemical carcinogens are thought to be most important in initiating adenocarcinoma in the gastrointestinal tract because of their access to the gut mucosa. This form of injury tends to produce mutations in single nucleotide bases.

Table 24.1 Carcinogenic agents

Radiation injury
Ultraviolet radiation
Especially important for skin
Most important wavelengths, 290–320 nm
Ionizing radiation
Electromagnetic radiation (e.g., x-rays, γ-rays)
Particulate radiation
Electrons, protons, neutrons, α particles, heavy ions
Viral oncogenesis
Human papillomavirus
Squamous cell carcinoma of the esophagus
Anal carcinoma
Genital cancers
Epstein–Barr virus
Burkitt lymphoma
Nasopharyngeal carcinoma
Hepatitis B and C viruses
Hepatoma
Human T-cell leukemia viruses
Human polyomavirus
JC virus

Single base-pair mutations are characterized as *transitions* when they change one purine to another or change one pyrimidine to another. They are characterized as *transversions* when they produce a change between nucleotide classes. Losses of base pairs in the DNA sequence are called *deletions*, and gains are called *insertions*. Some single base-pair changes are silent and do not result in amino acid changes. Mutations that change the amino acid in the protein product are called *missense mutations*, and they are characterized as conservative if the amino acid change occurs within the same class (i.e., from one neutral amino acid to another). Missense mutations can be serious if they result in the appearance or removal of charge, cysteines, phosphorylation or glycosylation sites, or other amino acids critical to the folding and function of the protein. Changes that create a stop codon within an open reading frame are called *nonsense mutations*. Nucleotide insertions and deletions (which do not occur in groups of three) create a frameshift, which commonly produces a series of missense and nonsense changes downstream on the DNA strand.

Chemical carcinogenesis

Chemical carcinogens are ubiquitous in the human diet but may not reach all the digestive organs in their active forms [61,62]. Typically, proximate carcinogens are highly reactive, short-lived chemical compounds that bind nucleic acids, proteins, and other macromolecules near the site of their generation. Chemical carcinogens usually have a narrow range of host and tissue specificity. The microbial flora of the gastrointestinal tract and mucosal enzymes are important factors in the activation and inactivation of many carcinogens. For example, cycasin, an extract made from cycad nuts, produces intestinal tumors when administered to most rodents [63]. This compound is a glycoside that must be hydrolyzed by intestinal bacteria to produce methylazoxymethanol, which is unstable and spontaneously decomposes, giving rise to a reactive carbonium ion capable of methylating nucleic acids. Cycasin does not give rise to tumors in germ-free rodents because they lack the necessary glycosidases produced by the intestinal flora.

Mechanisms by which genes are damaged

Point mutation

The significance of point mutations in gene damage was first appreciated when it was determined that animal tumor viruses carry mutated forms of cellular protooncogenes. Transfection of these mutated genes into NIH3T3 cells transformed the fibroblasts into cells that assumed a malignant morphology in vitro, no longer exhibited contact inhibition, and could form tumors when injected into nude mice. A transforming oncogene was first found in the Rous sarcoma virus, and later the *HRAS* gene was found to be oncogenic in this laboratory setting [64,65]. *RAS* gene mutations have been demonstrated in about half of colorectal cancers and in most pancreatic cancers [22,24,25]. Point mutations may be produced in DNA by the administration of alkylating agents; for example, treatment of rats with the carcinogen 1,2-dimethylhydrazine (DMH) results in the alkylation of DNA throughout the genome [66]. After exposure to such an agent, the host attempts to repair damaged DNA, or in some instances, the cell responds to the damage by initiating programmed cell death [9,10]. The action of a carcinogen triggers a dynamic response; the DNA is altered first, and the host then attempts to limit the impact of mutational damage, possibly sacrificing some damaged cells to prevent the replication of a damaged genome.

Carcinogens may produce characteristic damage based on the chemistry of the interaction between the reactive compound and certain susceptible sites in purines and pyrimidines [67]. A single genetic locus may be more likely to undergo a specific mutation, depending on the mutagen involved [68]. Some mutations are silent, but the appearance of others results in a growth advantage for the cell, and the error is amplified through clonal expansion of the mutant cell.

In rats treated with DMH, G-to-A mutations in *KRAS* develop in 66% of the colon cancers, indicating a strong selection for this mutation [69]. Other mutations may occur in locations that result in the inactivation of a gene essential for cell survival, and the cell is immediately eliminated. *KRAS* mutations may occur anywhere in the gene. Mutational inactivation of the guanine nucleotide regulatory region of the *RAS* gene (at codons 12, 13, and 61) needs to occur in only one cell in the colon after carcinogen exposure because this cell will expand clonally, outgrow those around it, and create large numbers of progeny cells.

Chronic inflammation is a common setting in which cancer develops in the gut, as in chronic esophagitis, chronic atrophic gastritis, and inflammatory bowel disease. Active forms of oxygen, such as hydroxyl and superoxide radicals, hydrogen peroxide, and singlet oxygen, arise as by-products of chronic inflammation and oxygen stress. These reactive species also mediate damage induced by ionizing and ultraviolet radiation. Reactive oxygen species create several forms of DNA damage, including strand breaks and single base changes. The two most common mutations induced by reactive oxygen molecules are the creation of 8-hydroxypurines, which result in misreading of those residues and adjacent pyrimidines. Because mispairing occurs in all four bases with almost equal frequency, it is not possible to predict what mutation this mechanism will induce. Evidence suggests that inflammation induces relaxation of DNA mismatch repair, permitting new mutations to be replicated, exacerbating the situation [70]. Furthermore, increased activity of certain nucleotide excision repair enzymes in response to oxidative stress can create additional mutations in microsatellite sequences [71]. Microsatellite instability in chronically inflamed, but not neoplastic, colonic tissues occurs as a result of these processes [72].

DNA rearrangement

Gene expression may be modified by the gross rearrangement of DNA sequences. For example, in chronic myelogenous leukemia, a translocation occurs in which sequences from chromosome 22 are accidentally spliced in frame with the cellular oncogene *ABL* (i.e., the oncogene originally isolated from the Abelson murine leukemia virus and formerly designated v-*abl* or c-*abl*). The translocation creates a chimeric messenger RNA that translates into an abnormally large mutant ABL protein [73]. A similar rearrangement appears in Burkitt lymphoma, in which a reciprocal translation occurring between chromosomes 8 and 14 juxtaposes a portion of the immunoglobulin gene with the oncogene *MYC*. In this instance, *MYC* is not mutated, but the rearrangement causes an amplification of gene expression [74]. The protooncogene *BCL2* was first discovered in human B-cell follicular lymphoma as a t(14;18) chromosomal translocation, which placed *BCL2* under the control of the heavy immunoglobulin chain promoter [75]. Elevated levels of BCL2, a 26-kDa protein, have since been measured in adenocarcinomas of the colon and other tumors without this translocation [76]. BCL2 functions to inhibit programmed cell death and is often highly expressed in tumors resistant to chemotherapy [77].

DNA amplification

DNA rearrangements can increase gene expression without the creation of additional copies of the gene. A normal cellular gene may also become a transforming gene through DNA amplification. This mechanism has attracted attention because resistance to methotrexate may be caused by amplification of the gene for dihydrofolate reductase [78]. Amplification of members of the *MYC* oncogene family is predictive of disease progression in neuroblastomas [79]. Some tumor cell lines have a large number of minichromosomes that exist independently as "double minutes" or are inserted into chromosomes (as homogeneously staining regions). Both represent examples of gene amplification. Amplification of *ERBB2* has been reported by several groups studying stomach cancers [80,81]. Other examples of amplified cellular oncogenes found in tumor cell lines include mutated *KRAS*, *MYB*, and *MYC* [82–84].

Altered methylation of DNA

Only a small percentage of the total genome is expressed in each tissue. One mechanism to control gene expression is to silence the genes through the stable, covalent methylation of the base cytosine at C–G sequences commonly found in promotors. DNA methylation is maintained by specific methyltransferases, and the pattern of methylation is inherited in a stable way through successive generations of cells in a given tissue. A wide variety of genes are substantially hypomethylated in primary colorectal cancers in comparison with the adjacent normal mucosa [85]. These genes include the γ-globulin gene, which is normally hypomethylated only in blood precursor cells, and the γ-crystallin gene, which is normally hypomethylated only in embryonic lens tissue [85,86]. Hypomethylation occurs in even the smallest adenomas. The implications of hypomethylation are not clear [87]. For example, an assessment of tumor formation in $Apc^{(Min/+)}$ mice using DNA methyltransferase (DNMT1) hypomorphic alleles to reduce genomic methylation resulted in a decrease of macroscopic intestinal tumors, in conjunction with the development of multifocal liver tumors [88]. Accordingly, although increases in DNA hypomethylation and hypermethylation in a sample of gastric and colon cancer specimens correlated with the patients' ages, only hypomethylation correlated with genomic damage, possibly because it precedes loss of diploidy [89].

Epigenetic alterations of DNA by methylation of promotor sequences in critical growth regulatory genes such as *p16*, *IGF2*, and *PTEN* have been described in microsatellite unstable tumors [90–92]. The mechanism for promoter methylation is unknown, but there is evidence that the MMR system is not directly responsible for this activity [91]. The promotor of the MMR gene *hMLH1* has been shown to be hypermethylated in about 10% of sporadic colorectal tumors (and is hypomethylated in the surrounding normal tissue) with absence of *hMLH1* expression [93]. This indicates that DNA methylation is a mode of MMR gene inactivation in some sporadic tumors. The correlation between microsatellite instability and promoter methylation suggests that methylation abnormalities precede microsatellite instability in sporadic colorectal cancers, and that other genes with methylated promoters in microsatellite unstable tumors are additional targets of this poorly understood process. The primary mammalian DNA methyltransferase, DNMT1, does not appear to play a key role in regulating this process [94].

Acetylation and deacetylation

Histone acetylation and deacetylation have been shown to be mechanisms for controlling gene expression. Acetylation and deacetylation of DNA-bound histones change DNA conformation to permit or prevent RNA polymerase access to the DNA to initiate transcription. In addition, individuals who are rapid acetylators of potentially carcinogenic compounds display an increased risk of developing colon cancer [95,96].

DNA deletion

Cell proliferation is regulated by a family of genes known as *tumor suppressor genes*. These genes prevent inappropriate cell proliferation and regulate the number of cells in a tissue. Unlike oncogenes, these genes play a role in carcinogenesis through their inactivation.

Even before the first tumor suppressor gene was identified, the presence of such genes was predicted by Knudson [97], who proposed that some human cancers arise through a recessive mechanism in which both alleles of a tumor suppressor gene are independently inactivated. This concept was par-

ticularly important because it provided a framework for the inheritance of enhanced susceptibility to specific cancers. Loss of the first allele could occur as a dominantly inherited trait that is transmitted vertically in the germ line. Inactivation of the first allele can be phenotypically silent because the activity of the remaining second allele is sufficient to maintain the nonmalignant phenotype. However, such individuals are at extremely high risk for the development of cancer because only a single further inactivation mutation in a single cell may be required to trigger tumor development, usually at younger ages than occurs in the general population. In contrast, the formation of sporadic tumors requires that two individual events occur independently, which decreases the likelihood of their occurrence in the same cell and increases the likelihood that they will occur later in life. Mutation of one allele followed by loss of DNA at the second allele (through chromosomal instability) is the "two-hit" mechanism for the complete inactivation of tumor suppressor genes. Loss of heterozygosity in gastrointestinal carcinogenesis is discussed in detail in the section on genomic instability and multistep carcinogenesis.

Inactivation of DNA repair

Nucleotide excision repair

DNA damaged by ultraviolet radiation, chemicals, and toxins is repaired by a complex of proteins that effectively excise the damaged DNA and replicate the interrupted strand using the complementary DNA strand as a template. Collectively known as the nucleotide excision repair complex, the component proteins are designated XP (xeroderma pigmentosum) or ERCC (excision repair cross-complementing) in reference to the discovery of defective nucleotide excision repair in patients with xeroderma pigmentosum [98]. The XP and ERCC proteins are capable of recognizing and binding to damaged DNA, unwinding the DNA double helix by virtue of helicase activity, and excising 27–29 nucleotides containing the damaged DNA [99–101]. The excision gap is then filled in by DNA polymerases. Some of the nucleotide excision proteins form an important transcription factor, TFIIH, which is involved in regulating the activity of all protein-encoding genes [102,103]. Consequences of nucleotide excision repair defects include xeroderma pigmentosum, a disease characterized by sunlight-induced photodermatoses that result in skin cancers and neurological abnormalities [99,100]. Cockayne syndrome and trichothiodystrophy, diseases characterized by neurological abnormalities and mental retardation without a major increase in skin cancers, are caused by mutations that impair the transcription function of nucleotide excision proteins [99,100]. Malfunctioning nucleotide excision repair in cancers of the gastrointestinal tract has not been reported.

Base excision repair

The MutY homologue (*MYH*) gene encodes a member of the nucleotide excision repair pathway that is involved in repairing oxidative damage to DNA. Biallelic germ-line *MYH* mutations predispose to the development of colorectal adenomas in the absence of an *APC* mutation and with a family history compatible with recessive inheritance [104]. Similar to the clinical situation that occurs with xeroderma pigmentosum caused by mutations in nucleotide excision repair genes, *MYH* mutations cause a rare, recessive disease. The affected persons appear to have sporadic (i.e., nonfamilial), attenutated adenomatous polyposis. Carriage of a single mutated *MYH* allele may confer a slight increase in the risk of colorectal cancer, but this remains controversial [105].

DNA mismatch repair

Unlike nucleotide excision repair, inactivation of the DNA MMR system is common in tumors of the gastrointestinal tract. Point mutations can occur in critical growth-regulatory genes and can accumulate in cells with a defective DNA MMR system (Fig. 24.5). The MMR system is responsible for maintaining the replicative fidelity of DNA. Germ-line mutations in *hMSH2*, *hMLH1*, *hPMS2*, and *hMSH6* have been identified and clearly linked to hereditary nonpolyposis colorectal cancer, and somatic inactivation of *hMLH1* by promoter hypermethylation has been identified in sporadic tumors [93,106–109]. No germ-line mutation in *hMSH3* has been identified in families with this syndrome [110]. The proteins that comprise the MMR system bind to nucleotide base–base mismatches of double-stranded DNA or loops of inaccurately replicated repetitive sequences (termed microsatellite DNA) and target the DNA area for excision, resynthesis, and ligation [111]. The DNA sequences repaired by the MMR system have apparently escaped the normal editing function of DNA polymerase. Base mispairing, if not corrected by the MMR system, may cause nucleotide transitions or transversions, allowing a novel base to alter the authentic genetic sequence [112]. Such point mutations in genes that regulate cell growth may promote neoplastic growth.

Inherited premutations

Premutations may elevate familial cancer risk [113]. For example, a T-to-A mutation causing a substitution of lysine for isoleucine at codon 1307 in the *APC* gene is present in 6.1% of Ashkenazi Jews [113]. This missense mutation in itself is not thought to alter the function of the APC protein severely because most *APC* mutations are nonsense mutations, yielding a truncated protein. However, the T-to-A mutation converts the sequence AAATAAAA to $(A)_8$, a repetitive nucleotide tract that is relatively unstable during transcription and replication. In fact, the T-to-A premutation is associated with the acquisition of other nonsense mutations within and surrounding the $(A)_8$ tract, causing truncation of the APC protein [113]. This type of point mutation, which creates an intrinsically unstable repetitive DNA sequence, may lead to further mutations as a mechanism to inactivate gene function.

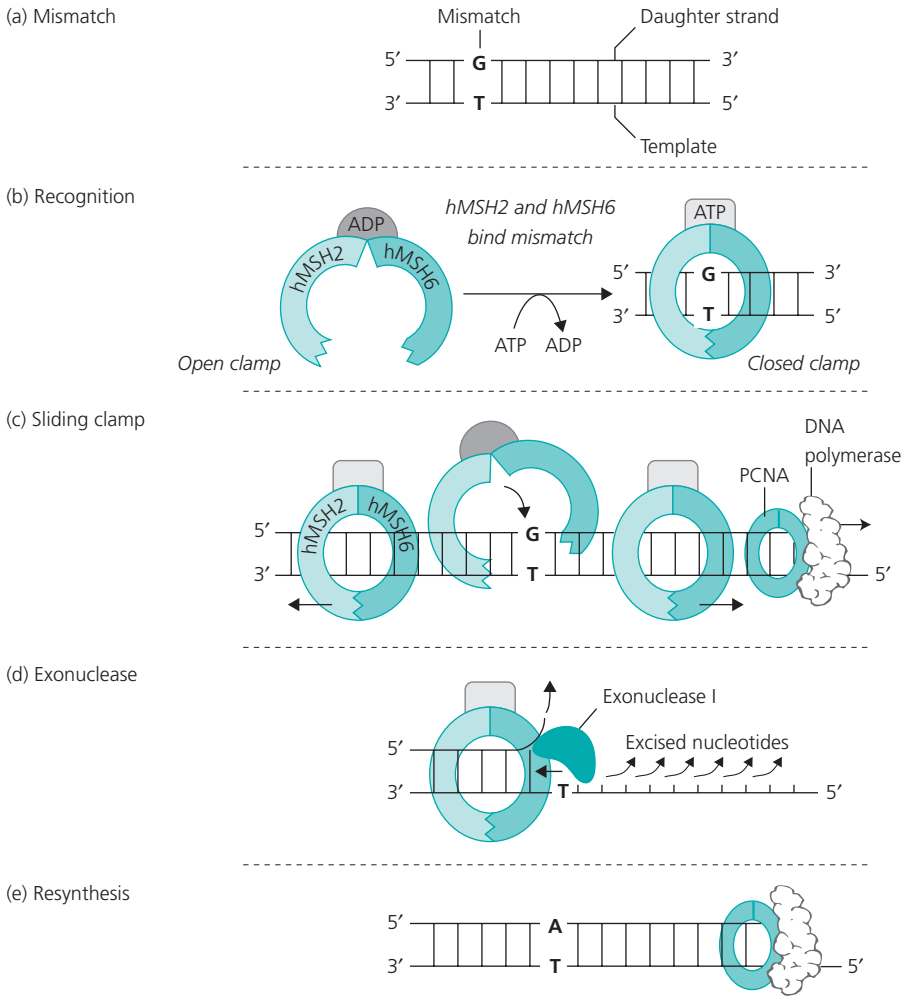

Figure 24.5 DNA mismatch repair (MMR). After DNA replication, mistakes that apparently have escaped the editing function of DNA polymerase are bound by the MMR proteins and targeted for repair. Single base mispairs and insertion or deletion loops of one base pair at microsatellite sequences are recognized by hMutSα (heterodimer of hMSH2 and hMSH6), and insertion or deletion loops of more than one base pair are recognized by hMutSβ (heterodimer of hMSH2 and hMSH3). Subsequent recruitment of hMutLα (heterodimer of hMLH1 and hPMS2) to the altered DNA targets the area for excision, resynthesis, and ligation. Inactivation of the MMR proteins would permit these types of mutations to be passed to progeny cells.

Genetic mechanisms of tumor development

Gatekeeper, caretaker, and landscaper genes

Gatekeeper genes are cellular genes that directly regulate tumor growth by suppressing cell growth or promoting cell death. By definition, gatekeepers are tumor suppressor genes. It has been suggested that each human cell has only one or a few gatekeeper genes that are specific to that cell type. The esophagus, stomach, small intestine, colon, liver, and pancreas are different histologically, and the cells of these tissues express a different array of genes to perform their unique functions. The gastrointestinal organs probably do not share gatekeeper genes. Only the gatekeeper gene of the colon, *APC*, has been clearly identified [114]. Inactivation of a gatekeeper gene is the rate-limiting step for the initiation of tumor growth, and demonstrates a specific tissue distribution of that tumor [4]. As a tumor suppressor gene, inactivation requires alteration of the maternal and paternal alleles, fulfilling the Knudson two-hit hypothesis [97]. Restoration of the gatekeeper function in vitro leads to suppression of the neoplastic growth.

Caretaker genes contribute to genomic stability, typically as part of a DNA repair process (e.g., *hMLH1* and *hMSH2*). Inactivation of a caretaker gene leads to genomic instability by increasing the rate of accumulation of mutations in a cell, which ultimately results in a constellation of altered genes that are associated with neoplastic behavior. This phenomenon might be likened to a constant and excessive exposure to mutagens. Therefore, caretaker genes normally serve to inhibit the development of neoplasia, and conceptually can be thought of as tumor suppressor genes. Restoration of caretaker function to a cancer cell will not affect its growth because these indirectly acting genes are not required for neoplasia.

Defects in landscaper genes create an abnormal stromal environment for the epithelium, which contributes to neoplastic transformation [115]. For instance, chronic inflammation in ulcerative colitis affects the colonic epithelium, initially with the inflammation, but ultimately it may cause neoplastic changes and progression to cancer. The regeneration that occurs to replace damaged epithelium may

increase the probability of somatic mutations in an abnormal microenvironment.

There is increased evidence for the role of stromal cells on tumor initiation and progression [116]. The loss of TGF-β responsiveness in mouse fibroblasts results in increased tumorigenesis in skin, foregut, and prostate [117]. Epithelial-mesenchymal interactions may also explain the link between cancer and inflammation. Deletion of the I-κB kinase (IKK) complex, an activator of the transcription nuclear factor-κB (a key mediator of signaling in inflammation), in myeloid cells but not epithelial cells leads to a decrease in tumor size in a colitis-associated mouse model of cancer [118]. Selective deletion of SMAD4, a key downstream molecule in growth suppressive signaling, in T cells, leads to spontaneous gastrointestinal cancers in mice, likely through the abundant production of T helper type 2 cytokines [119].

Genetically, tumor initiation is caused by inactivation of both alleles of a gatekeeper gene. This may occur as the result of an inherited mutated allele (i.e., a germ-line mutation), coupled with somatic loss within a specific cell, or as the result of two somatic hits within a specific cell. For a caretaker gene to initiate neoplasia, both alleles must be inactivated; in addition, the resulting genomic instability must inactivate both alleles of the gatekeeper. It is believed that inherited susceptibility syndromes involving gatekeeper genes are associated with extremely high rates of cancer development, whereas inherited syndromes involving caretaker genes are associated with cancer rates lower than those of gatekeeper genes because some minimal number of additional mutations must occur [4,115]. Inherited caretaker mutations would still be associated with cancer rates much higher than those in the general population.

Oncogenes

The traditional concept of tumor initiation and promotion is inadequate to explain the full complexities of carcinogenesis. No single mutation or altered gene is sufficient to cause cancer in most cells. Multiple mutations, genetic deletions, and chromosomal rearrangements have been found in cancers that have been studied carefully. However, some single genes, when activated, can cause the phenotype of a cultured fibroblast cell line to become recognizably malignant. These initial cancer-causing genes were called *oncogenes*, and they were discovered by studying viruses that could transform chicken cells [120]. A number of oncogenes have been identified, and each can be activated by a point mutation that alters the activity of the gene product or by genetic rearrangement that results in an increase in gene expression (Table 24.2) [121].

Some oncogenes produce growth factors (e.g., *SIS*), and when production is not regulated, the overproduced peptide ligand binds repeatedly and continuously to the receptor to cause unremitting stimulation. Other protooncogenes produce growth factor receptors (e.g., *ERBB2*, *CSF1R*, *KIT*). The

Table 24.2 Classification of oncogenes and gene products according to function

Class 1 – Growth factors	
sis	PDGF β-chain growth factor
int-2	FGF-related growth factor
hst (*KS3*)	FGF-related growth factor
FGF-5	FGF-related growth factor
int-1	Growth factor?
Class 2 – Receptor and nonreceptor protein tyrosine kinases	
src	Membrane-associated nonreceptor protein-tyrosine kinase
yes	Membrane-associated nonreceptor protein-tyrosine kinase
fgr	Membrane-associated nonreceptor protein-tyrosine kinase
lck	Membrane-associated nonreceptor protein-tyrosine kinase
fps/fes	Nonreceptor protein-tyrosine kinase
abl/bcr-abl	Nonreceptor protein-tyrosine kinase
ros	Membrane-associated receptor-like protein-tyrosine kinase
egfr	Membrane-associated receptor-like protein-tyrosine kinase
erbB	Truncated EGF receptor protein-tyrosine kinase
neu	Receptor-like protein-tyrosine kinase
fms	Mutant CSF-1 receptor protein-tyrosine kinase
met	Soluble truncated receptor-like protein-tyrosine kinase
trk	Soluble truncated receptor-like protein-tyrosine kinase
kit (W locus)	Truncated stem cell receptor protein-tyrosine kinase
sea	Membrane-associated truncated receptor-like protein-tyrosine kinase
ret	Truncated receptor-like protein-tyrosine kinase
jak1/3	Protein tyrosine kinase
fak	Nonreceptor protein-tyrosine kinase
Class 3 – Receptors lacking protein kinase activity	
mas	Angiotensin receptor
Class 4 – Membrane-associated G proteins	
H-*ras*	Membrane-associated GTP-binding/GTPase
K-*ras*	Membrane-associated GTP-binding/GTPase
N-*ras*	Membrane-associated GTP-binding/GTPase
gsp	Mutant activated form of $G_s\alpha$
gip	Mutant activated form of $G_i\alpha$
Class 5 – Cytoplasmic protein-serine kinases	
raf/mil	Cytoplasmic protein-serine kinase
pim-1	Cytoplasmic protein-serine kinase
mos	Cytoplasmic protein-serine kinase (cytostatic factor)
cot	Cytoplasmic protein-serine kinase?
Class 6 – Cytoplasmic regulators	
crk	SH-2/3 protein that binds to (and regulates?) phosphotyrosine-containing proteins
Class 7 – Nuclear transcription factors	
myc	Sequence-specific DNA-binding protein
N-*myc*	Sequence-specific DNA-binding protein?
L-*myc*	Sequence-specific DNA-binding protein?
myb	Sequence-specific DNA-binding protein

Table 24.2 (*cont'd*)

lyl-1	Sequence-specific DNA-binding protein?
p53	Mutant form may sequester wild-type p53 growth suppressor
fos	Combines with c-*jun* product to form AP-1 transcription factor
jun	Sequence-specific DNA-binding protein; part of AP-1
erbA	Dominant negative mutant thyroxine (T_3) receptor
rel	Dominant negative mutant nuclear factor-κB-related protein
vav	Transcription factor?
ets	Sequence-specific DNA-binding protein
ski	Transcription factor?
evi-1	Transcription factor?
gli-1	Transcription factor?
maf	Transcription factor?
pbx	Chimeric E2A-homeobox transcription factor
Hox2,4	Transcription factor?
Unclassified	
dbl	Cytoplasmic truncated cytoskeletal protein?
bcl-2	Plasma membrane signal transducer/apoptosis
Cox-2	Prostaglandin synthase
Survivin	Inhibitor of apoptosis protein (IAP)
Thx3	Transcription repressor
Evi1	Viral integration site

EGF, epithelial growth factor; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor.
Adapted and updated from Hunter [121].

most intensively studied protooncogenes are those involved in cellular signal transduction, including *SRC*, *RAS*, and *RAF* gene families. These oncogenes are activated by point mutations that maintain the protein in a configuration such that signal transduction events are activated, regardless of whether the appropriate ligand or receptor is in place. Some of the protooncogenes, including *MYC*, *JUN*, and *FOS*, encode transcription factors, often nuclear phosphoproteins, that interact with DNA and regulate gene transcription. Many of these genes were found because they had become incorporated into viral genomes, and because their expression had been deregulated by mutation or rearrangement, they created oncogenic viruses. In each case, these genes were capable of transforming cultured fibroblasts after infecting the cells. These oncogenes initially were designated v-oncogenes (e.g., v-*src*) because of their viral origin. Soon it was found that cellular protooncogenes could undergo activation in situ by point mutation or other genetic rearrangement and become oncogenic in the absence of a viral vector.

Tumor suppressor genes

Boveri hypothesized as early as 1914 that the relentless growth of a malignant tumor was as likely to result from the inactivation or deletion of genes that inhibit proliferation as from enhanced activity of genes that promote growth. Tumors often have grossly abnormal karyotypes, and losses of chromosomal arms occur frequently [122]. Advances in molecular biology, specifically the use of restriction fragment length polymorphism and microsatellite analysis, have permitted the examination of specific chromosomal locations for genetic losses.

Using such techniques, Vogelstein and colleagues [123] reported the widespread losses of genetic material in colorectal cancers and the deletion of specific genetic loci in a large proportion of tumors. These investigators reasoned that identifiable hot spots for genetic loss would be the location of tumor suppressor genes that were relevant in the development of colorectal cancer. This hypothesis proved to be correct, and the concept has led to identification of numerous tumor suppressor genes in human cancer (Table 24.3) [124–126]. The mechanism of their activation may differ from gene to gene, but in all cases, it is the inactivation of the protein function that plays a role in carcinogenesis.

Perhaps the most important of these is the *TP53* gene, which normally acts to prevent the cell from initiating DNA replication or cell division. It serves as a critical regulatory gene to prevent inappropriate proliferation [127]. When DNA is damaged, the p53 protein becomes activated, which switches on the transcription of a variety of genes. These include activation of *WAF1/CIP1*, a gene encoding a 21-kDa protein that inhibits CDK2, thus arresting the cell in the G1 phase of the cell cycle and preventing the replication of damaged DNA [8,128,129]. The p53 protein also stimulates the transcription of *GADD45*, and the gene product in turn complexes with proliferating cell nuclear antigen, a necessary component for the synthesis of DNA [130]. By stimulating the synthesis of WAF1/CIP1 and GADD45, p53 effectively halts DNA replication and stimulates DNA repair. It also plays a critical role in programmed cell death, or apoptosis, when DNA is damaged, perhaps beyond repair [8,131–133]. Mutation of *TP53*, therefore, would prevent cell death in the wake of DNA damage.

Inactivation of *TP53* in cancer involves two steps. Often, one *TP53* allele undergoes a missense point mutation, typically in a portion of the molecule involved in the binding to DNA. It is controversial how the presence of one wild-type allele together with one mutated copy of the p53 protein alters the growth characteristics of a cell. However, most colon cancers have lost the wild-type *TP53* gene, leaving a single mutated copy of the gene in the nucleus [134]. The peanut fungus *Aspergillus fumigatus* produces aflatoxin β1, which may cause hepatocellular carcinoma by mutating *TP53* at a critical codon [135]. Other mechanisms have developed in certain cancers to inactivate p53 by interrupting its evolutionarily conserved regions (Fig. 24.6). These include the binding of viral proteins to p53 (i.e., JC virus or simian virus 40 T antigen, human papillomavirus E6 protein, and adenovirus E1b protein), and binding of amplified cellular

Table 24.3 Tumor suppressor genes involved in human cancers

Tumor suppressor gene	Chromosome location	Proposed function	Somatically mutated neoplasms	Inherited syndrome	Typical inherited neoplasms or traits
TP53/p53	17p13.1	Transcription factor, apoptosis, response to DNA damage	Most types of human cancers	Li–Fraumeni cancer syndrome	Sarcomas, carcinomas of breast and adrenal cortex, leukemia, brain tumors
RB1	13q14.1–q14.2	Cell cycle and transcriptional regulator, E2F binding	Retinoblastoma, osteosarcoma, carcinomas of the breast, prostate, bladder, and lung	Familial retinoblastoma	Retinoblastoma, osteosarcoma
APC	5q21–q22	Regulation of β-catenin, microtubule binding	Colorectal adenomas and cancer, carcinomas of the stomach and pancreas	Familial adenomatous polyposis, Gardner syndrome, Turcot syndrome	Colorectal cancer, duodenal and gastric cancers, medulloblastoma
hMSH2 *hMLH1* *hPMS1* *hPMS2* *hMSH6/GTBP*	2p22–p22 3p21.3 2q31–q33 7p22 2p16	DNA mismatch repair	Colorectal cancer; carcinomas of the ovary, endometrium, urinary tract, head and neck; small cell lung cancer	HNPCC, Muir–Torre syndrome, Turcot syndrome	Colorectal cancer, carcinomas of the endometrium, stomach, kidney, ureter, glioblastomas
NF1	17q11.2, 2p22–p21	GTP-activating protein for RAS, microtubule binding	Schwannomas	Neurofibromatosis type 1	Neurofibromas, neurofibrosarcomas, AML, brain tumors
NF2	22q12.2	Links membrane proteins to cytoskeleton	Schwannomas and meningiomas	Neurofibromatosis type 2	Acoustic neuromas, meningiomas, gliomas, ependymomas
WT1	11p13	Transcriptional repressor	Wilms tumor	Wilms tumor	Wilms tumor
BRCA1	17q21	Interacts with RAD51, repair of double-stranded DNA breaks	Ovarian cancer	Familial breast cancer 1	Breast cancer, ovarian cancer
BRCA2	13q12.3	Interacts with RAD51, repair of double-stranded DNA breaks	Ovarian cancer	Familial breast cancer 2	Breast cancer, male breast cancer, pancreatic cancer
VHL	3p26–p25	Regulates transcriptional elongation by RNA polymerase II	Renal clear cell carcinoma, pheochromocytomas, hemangioblastomas	Von Hippel–Lindau syndrome	Renal clear cell carcinoma, pheochromocytomas, retinal angiomas, hemangioblastomas, pancreatic cancer
CDKN2A/p16	9p21	Inhibition of CDK4 and CDK6	Melanoma	Familial melanoma	Melanoma, pancreatic cancer, dysplastic nevi
MEN1	11q13	Unknown	Parathyroid tumors	Multiple endocrine neoplasia type I	Pancreatic islet cell gastrinomas, parathyroid hyperplasia, pituitary adenomas
PTEN/MMAC1	10q23.31	Tyrosine phosphatase	Glioblastomas, carcinomas of the kidney, prostate, breast	Cowden disease, Lhermitte–Duclos disease, Bannayan–Riley–Ruvalcaba syndrome, juvenile polyposis syndrome	Carcinomas of the breast and thyroid, intestinal and skin hamartomas
CDKN1C/p57(KIP2)	11p15.5	Cell cycle regulator	Unknown	Beckwith–Wiedemann syndrome	Wilms tumor, organomegaly, hemi-hypertrophy, hepatoblastoma, adrenocortical cancer

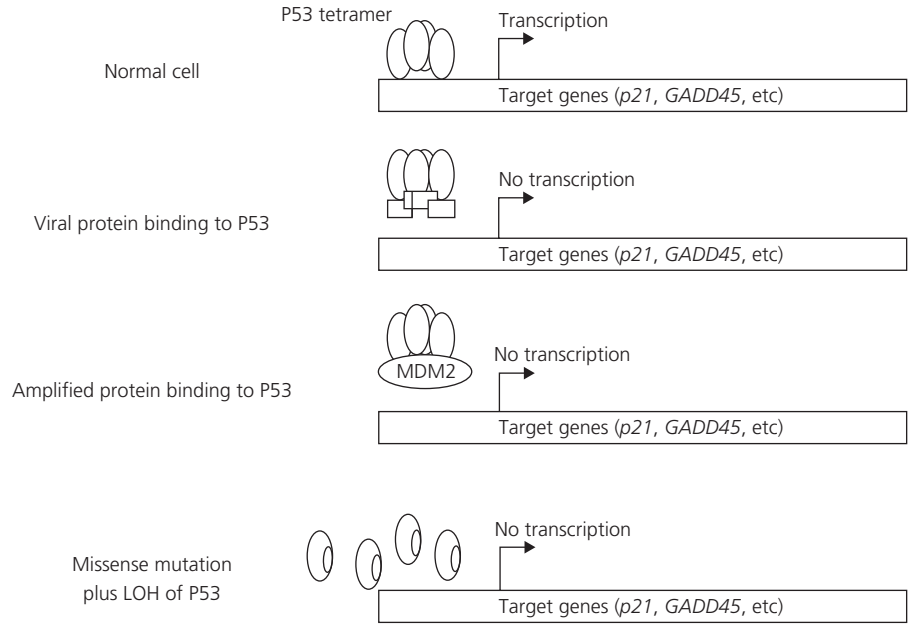

Figure 24.6 Some mechanisms for inactivating p53. The p53 protein binds as a tetramer to a p53-binding site in the promotor region of a target gene to activate genes involved in growth suppression and DNA repair. Viral proteins such as the simian virus 40 T antigen, human papillomavirus E6, and adenovirus E1b can bind p53 protein to prevent its transactivating function. Similarly, amplified cellular proteins such as MDM2 can bind p53 protein to prevent promotor binding. In colon cancer, the typical p53 inactivation involves a missense mutation of one allele and loss of heterozygosity (LOH) of the second allele, leaving only mutated protein available. The mutated p53 protein may have limited or no binding to promotor sites to initiate transcription at target genes.

proteins to p53 (e.g., MDM2 oncoprotein in sarcomas) [59,136]. Mutant *TP53* (with concomitant lack of normal *TP53*) appears to be overexpressed in tumors, including colorectal tumors, and can be detected by immunohistochemical methods [137]. This overexpression often is the result of enhanced stability of the mutant p53 protein, allowing its accumulation within the cell [136,137].

The tumor suppressor gene concept accommodates the notion of familial predisposition to cancer. The first example of this was found in familial retinoblastoma, in which there are germ-line mutations at the *RB1* locus [124]. The *RB1* gene has a tumor suppressor function in many tissues, including the gastrointestinal tract, but its inactivation is the limiting step (gatekeeper) only for the development of retinoblastoma [138,139]. In familial retinoblastoma, every retinal epithelial cell contains one copy of a mutated *RB1* gene and one wild-type gene. The chance occurrence of a mutation in the wild-type *RB1* allele in any cell is sufficient to inactivate completely the tumor suppressive activity of the *RB1* gene. Because this event needs to occur in only a single cell to produce a tumor, the incidence of retinoblastoma is high in families with a mutated *RB1* allele. Essentially every child who inherits the mutated *RB1* allele is at risk for the development of bilateral tumors at an early age. In contrast, unaffected individuals require two inactivational hits in a single cell, one on each allele, for retinoblastoma to occur; accordingly, sporadic tumors are rare. Retinoblasts disappear from the eye after early infancy, so this disease is not seen later in life.

Germ-line mutations at tumor suppressor gene loci may be associated with a normal phenotype at birth, but they are associated with very high risks for cancer. This is the outcome in Li–Fraumeni syndrome, in which there is a germ-line mutation in the *TP53* gene; affected individuals are phenotypically normal at birth but develop breast cancers, sarcomas, and brain tumors at an early age [124]. An animal model for this disorder exists in mice made deficient for the *p53* gene by homologous recombination; these mice can survive with no copies of the *p53* gene, which underscores the redundancy and adaptability of the control of cell growth [140]. Two more genes, *TP73L* (*p63*) and *TP73*, produce proteins that have some functions similar to those of p53 protein [141–144]. Similar to p53, both p63 and p73 can form homooligomers, bind DNA, activate transcription from p53-responsive genes, and induce apoptosis [143–145]. However, in contrast to p53, both p63 and p73 give rise to multiple functionally distinct protein isoforms, some of which can function as "dominant negative" proteins, blocking the function of the corresponding full-length protein [146]. In addition, *TP73L* and *TP73* are only rarely mutated in tumors and so do not function as classical tumor suppressor genes. Furthermore, unlike $p53^{-/-}$ mice or patients with Li–Fraumeni syndrome, $p63^{-/-}$ and $p73^{-/-}$ mice are not tumor prone but instead manifest multiple developmental abnormalities [147–149]. Germ-line *TP73L* mutations in humans cause ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome, an autosomal dominant disorder characterized by ectrodactyly, ectodermal dysplasia, and cleft lip with or without cleft palate [150]. Although *TP73L* and *TP73* have some overlapping functions and interactions with *TP53*, they are not tumor suppressor genes like *TP53*, and mutations do not pose the same high risk for cancer as *TP53* mutations.

E-cadherin is a calcium-dependent cell–cell adhesion molecule expressed in adherent junctions and coded by the *CDH1* gene. Dysfunctional E-cadherin may render cells less matrix-bound and more prone to metastasis. Germ-line mutations in the *CDH1* gene have been identified in

hereditary diffuse gastric cancer, and somatic mutations of *CDH1* may be associated with sporadic gastric cancer [151].

Clonal expansion

A variety of genetic techniques have demonstrated that neoplasms are derived from a single cell, but most human cancers have multiple mutations, and it is unlikely that a single cell undergoes all these genetic changes at once [152].

The concept of multistage carcinogenesis assumes that the gastrointestinal epithelium undergoes a constant barrage by factors that threaten to damage the DNA, but the mutations occur one by one at critical locations in genes related to the control of cell growth or survival. Some of these mutations may inhibit the function of a gene essential for the life of the cell, which is lethal to that cell. Other mutations provide the cell with a slight growth or survival advantage over the rest of the cells in the tissue. In these instances, the mutated cells proliferate faster than the surrounding cells and gradually represent a larger proportion of the tissue. In other instances, a mutated cell may be less capable of repairing DNA damage, which facilitates the accumulation of mutations in succeeding generations. This expanded pool of cells continues to be susceptible to additional mutations.

The redundancy in the cellular mechanisms regulating proliferation means that loss of any individual function is insufficient for the transformation of a normal cell. The accumulation of cooperating lesions is required to overcome the regulated cell growth. Periodically, an individual cell within an expanding clone experiences another mutation that adds to its growth or survival advantage, and the progeny of this cell then overgrows the population from which it originated. Successive waves of clonal expansion occur by the chance accumulation of new mutational events, which add to the survival advantage of the cell in an evolutionary manner. In early-stage neoplasms, there is evidence for only a small number of mutational events; later in neoplastic progression, however, the cell has a larger number of genetic lesions [22,153]. Figure 24.7 demonstrates tumor progression as successive expansions of cellular clones with new growth characteristics.

Genomic instability and multistep carcinogenesis

Through the elegant work performed in several laboratories, a conceptual interpretation of the genetic basis of colorectal cancer and other cancers has been developed [153]. This framework accommodates the growing evidence that most cancers develop slowly and that multiple genes are involved in the process. Certain types of genetic damage tend to occur early, and different types occur later. It is not yet clear how strictly the sequence of events is followed in most neoplasms, but not all cancers appear to accumulate every mutation or chromosomal deletion during their development.

Some type of genomic instability is required to account for the mutations that occur in multistep carcinogenesis. In most

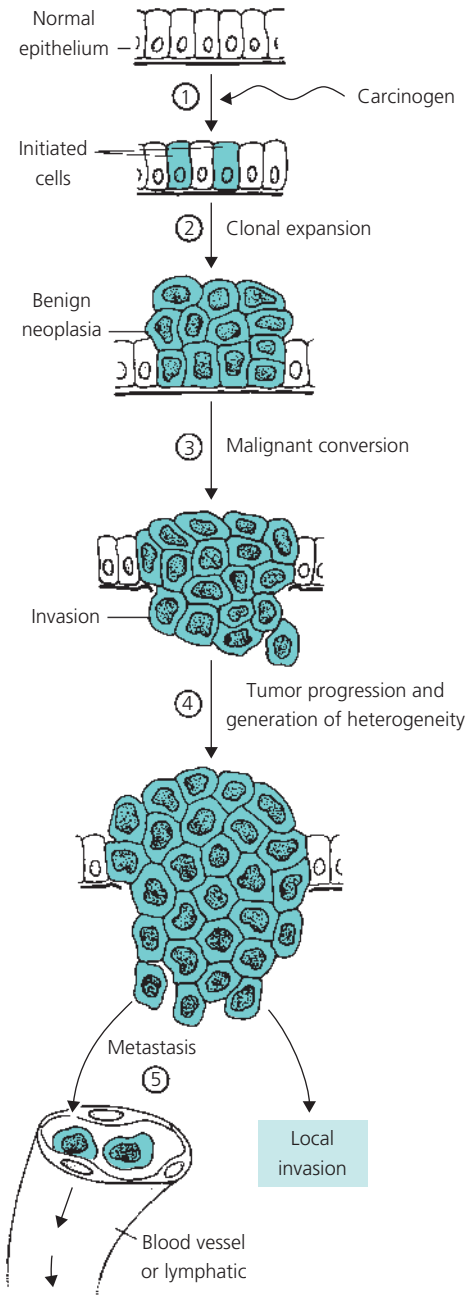

Figure 24.7 Tumor progression. This scheme illustrates the natural history of carcinogenesis. The first step represents a genotoxic event caused by a carcinogen. When a critical number of genes are mutated (the specific site and number remain speculative), a cell becomes neoplastic (step 1). Clonal expansion gives rise to a benign neoplasm (step 2). Unless additional events occur, a benign neoplasm may persist or grow indefinitely without becoming malignant. However, if additional genetic events occur, cells appear within a benign neoplasm that are capable of malignant behavior, such as invasion and metastasis (step 3). A malignant neoplasm may invade locally and damage the host and surrounding organs. However, the genome of the malignant neoplasm is intrinsically unstable, and despite its monoclonal origin, the cancer becomes more heterogeneous with time (steps 4 and 5). Clinically, the generation of tumor cell heterogeneity increases the likelihood of metastasis to one or more distant sites.

colorectal cancers, the process could be called chromosomal instability. Chromosomal segments or entire chromosomes are deleted, duplicated, or rearranged, so that the normal diploid nucleus is changed into an aneuploid one. A common finding in this pathogenic pathway is the allelic mutation of a tumor suppressor gene (e.g., *APC* or *TP53*), followed by the loss of the remaining normal allele (termed *loss of heterozygosity*, or LOH) [123,154]. As an increasing fraction of allelic arms is lost, the prognosis for colorectal cancer worsens. Patients with tumors that have lost more than 20% of the tested alleles are significantly more likely to die from their disease than those with tumors that have not, and this characteristic is a more powerful prognostic factor than the Dukes stage or the histological grade of the tumor [154].

It is not known what specific cellular function becomes disturbed, resulting in multiple LOH episodes throughout the genome. Chromosomal instability occurs in the smallest adenomas, suggesting that it occurs very early during colorectal neoplasia [155]. It has been hypothesized that structural changes to the chromosomes and abnormal mitoses are operative in the development of chromosomal instability. Mitotic checkpoint gene mutations, such as those found in *BUB1*, have been found, but only rarely in colorectal cancers [156]. A mutant APC protein, which is inactivated in the earliest stages of colonic neoplasia, is associated with defective chromosome segregation [157,158]. Wild-type APC localizes to the kinetochore during mitosis and forms complexes with BUB1 and BUB3 mitotic checkpoint proteins [158]. Although mutant APC may contribute to ongoing chromosomal instability in a colonic cell, it is not clear how this causes the initial chromosomal instability responsible for APC inactivation. Other proteins, such as human securin, a protein necessary for completion of the anaphase portion of mitosis, may help maintain euploidy [159]. Telomerase dysfunction also has been implicated as a mechanism for chromosomal instability in mouse models [160]. Foreign proteins such as T antigen from the polyomavirus JC Mad-1 strain have been found in colorectal cancers [59,161]. T antigens are capable of inducing aneuploidy in cells and are known to inactivate important cell cycle proteins, such as p53 and R protein [59,161]. The checkpoint gene *MAD2*, when inactivated, may contribute to chromosomal instability and cancer development in RB-mutated tumors [162] through the formation of abnormal centrosomes, which are organelles involved in cytoskeletal and mitotic organization in genomic homeostasis [163]. However, many questions remain, especially because aneuploidy appears to possess both tumor-promoting and tumor-suppressing properties [162].

The early stages of carcinogenesis in the colon appear to occur slowly, with the accumulation of mutations and LOH at a variety of chromosomal loci. However, transition to the malignant stage is associated with widespread genomic instability and LOH, which accelerates the likelihood that tumor suppressor loci will be lost, including genes that may suppress metastatic behavior. Studies have shown that mutation of one *TP53* allele coupled with LOH of the second allele coincides with the appearance of carcinoma within an adenomatous polyp, making *TP53* the gatekeeper for malignant transformation in the colon [35,164,165]. This model of multistep carcinogenesis reflects the consequences of gene dysfunction. A malignancy occurs when a sufficient combination of these mutated genes accumulates. In some instances, a sequential pattern for the occurrence of their metastasis may be required.

The following sequence of events appears to be relevant to the *chromosomal instability* pathway of tumorigenesis in the human colon (Fig. 24.8) [35,153]. Hypomethylation of DNA occurs in the smallest adenomas and may be one of the early events in carcinogenesis, but the mechanism by which this occurs, the specific genes involved in the process, and its role in carcinogenesis are unknown [85,86]. Mutations (and LOH) at the *APC* locus are also found in small adenomas, and these events have been linked to dysregulated proliferation on the basis of their role in familial adenomatous polyposis [166]. Mutations at the *APC* locus are typically nonsense mutations or insertions and deletions that produce frameshifts resulting in downstream stop codons. Mutations in the *KRAS* and *TP53* genes are found in larger adenomatous polyps and are thought to play a mechanistic role in supporting neoplastic growth. Indeed, activation of *KRAS* mutations seems to facilitate the exophytic growth of adenomatous polyps whereas *KRAS* mutations are more rare in flat adenomas and cancers [167].

Point mutations play a prominent role in the early stages of neoplastic progression, typically by inactivating the function of tumor suppressor genes. It has been hypothesized that mutant APC proteins may bind to the wild-type proteins and interfere with their function through a dominant negative mechanism [168]. In the case of *KRAS*, mutations inactivate the portion of the protein involved in switching off signal transduction [20,169]. In the case of *TP53*, the mutations, which occur in a broad region in the middle of the p53 protein, interfere with the ability of the protein to activate gene expression in the nucleus [136]. It is uncertain whether one mutant p53 protein can bind to and inactivate the wild-type protein and act through a dominant negative mechanism.

A second form of genomic instability that does not result in LOH events is involved in the genesis of about 12%–15% of colon cancers. These tumors demonstrate multiple errors in DNA sequences throughout their genome, which result from a failure to edit errors made during DNA replication [170–172]. This was first observed in microsatellite sequences, which are repetitive sequences that require the DNA mismatch repair system for proper replication because of an intrinsic tendency to be copied inaccurately. In certain tumors, deletion mutations occur in the DNA microsatellite sequences; this is termed microsatellite instability. Microsatellite sequences are ubiquitous throughout the genome, and half

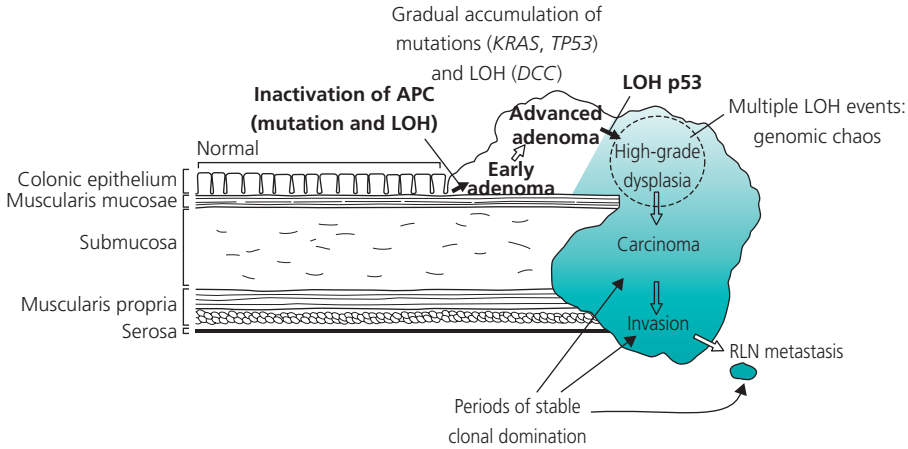

Figure 24.8 Chromosomal instability model of genetic events mediating neoplastic progression during colorectal tumorigenesis. This type of genomic instability is present in familial adenomatous polyposis and in about 85% of sporadic colorectal cancers in which segments or whole chromosomes are deleted, duplicated, or rearranged, forming aneuploid tumors. *APC* is inactivated by mutation and loss of heterozygosity (LOH) at the transition between normal colonic epithelium and adenomatous epithelium. Thereafter, successive rounds of clonal expansion occur, with accumulation of mutations (i.e., *KRAS, TP53*, others) and LOH (i.e., chromosome 18q) that allow acceleration of growth and dominance over less-advantaged clones. *TP53* inactivation by LOH of 17p13.1 first occurs in high-grade dysplasia, and defines the transition between benign and malignant neoplasia. Successive genetic events as well as prior genetic changes enable the colon cancer to invade and metastasize to regional lymph nodes (RLNs), and ultimately to distant organs such as the liver. From Boland et al. [35].

or more may be mutated in tumors that have microsatellite instability.

Tumors with microsatellite instability demonstrate significantly less LOH than usually occurs in colorectal cancers with chromosomal instability. Thus, either chromosomal instability or microsatellite instability develops as the type of instability within a tumor genome [173]. Microsatellite instability is more common in cancers of the proximal colon and is associated with diploid tumors and increased patient survival [170,174]. This hypermutable phenotype appears to be the mechanism for rapid neoplastic progression in Lynch syndrome and in sporadic tumors that exhibit microsatellite instability [172,175].

Lynch syndrome and about 10%–12% of sporadic colorectal tumors exhibit microsatellite instability. An analysis of repetitive sequences in tumor tissue led to the identification of other inactivated genes in these tumors, suggesting a second pathway for developing neoplasia. Each of these targeted genes contains a microsatellite within its (exonic) coding sequence, making it susceptible to mutation in the absence of DNA MMR activity. For example, a repeat of 10 adenines in the *TGFBR2* gene has undergone frameshift mutation in 85% of colorectal tumors with microsatellite instability, inactivating this receptor [30,39], and the cell escapes growth suppression from the ligand TGF-β1. In the remaining 15% of tumors with microsatellite instability, it is estimated that frameshift mutations of *IGF2R* at its polyguanine sequence uncouple TGF-β1 growth suppression [43]. Another important target of microsatellite instability is *BAX*, a member of the *BCL2* gene family. BAX heterodimerizes with BCL2 within the cell, and the ratio of the two heterodimers determines the cell's commitment to programmed cell death. *BAX* contains a polyguanine $(G)_8$ tract that is mutated in 50% of colorectal cancers with microsatellite instability, and in 64% of gastric adenocarcinomas with microsatellite instability [176,177]. Mutation of *BAX* (by diminishing the ratio of BAX to BCL2) prevents programmed cell death. Other genetic targets include the MMR genes *hMSH3* and *hMSH6*, which may broaden and accelerate the accumulation of mutations [178]. A comprehensive search using a genetic database for coding microsatellites and subsequent colorectal tumor analysis revealed nine genes that were mutated in more than 20% of the tumors [179]. Aside from *TGFBR2*, *BAX*, and *hMSH3*, these included the *ACVR2* (activin type II receptor), *SEC63* (human homologue of a yeast DnaJ-like endoplasmic reticulum translocon component protein gene), *AIM2* (an interferon-inducible gene), *NDUFC2* (NADH-ubiquinone oxidoreductase B14.5B subunit gene), *COBLL1*/*KIAA0977* (probable human homologue of the mouse embryonal protein *cordon-bleu*), and *PA2G4*/*EBP1* (homologue of the mouse cell cycle protein p38-2G4) [179]. Subsequently, *ACVR2* has been shown to be mutated in the polyadenine tract of exon 10 in most microsatellite unstable colon cancers, causing the loss of ACVR2 protein expression [41] and an associated increase in local tumor growth [42]. Furthermore, reconsitution of mutated *ACVR2* leads to restitution of growth inhibitory signaling in colon cancer cells [180]. The role of the other often-mutated genes in the pathogenesis of tumors with microsatellite instability is not known.

Several lines of evidence indicate that the Wnt signaling pathway, including the gatekeeper APC or other proteins in

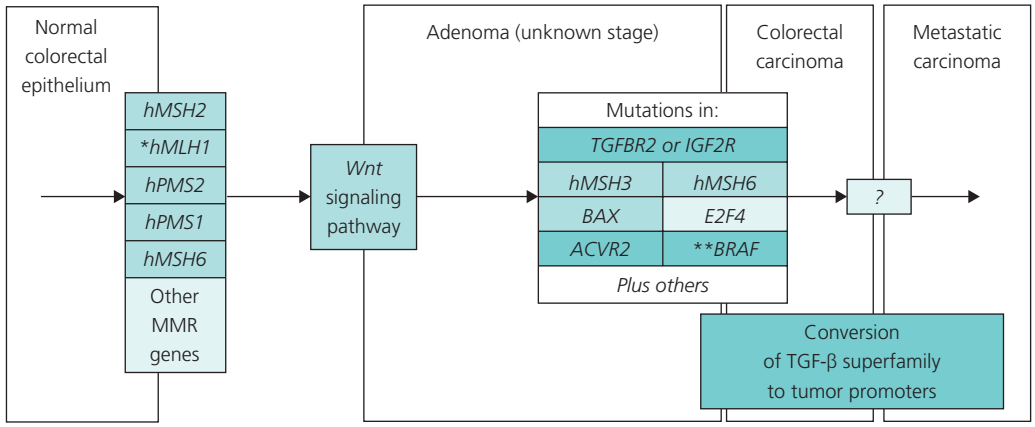

Figure 24.9 Colorectal tumor progression in microsatellite unstable tumors. This type of genomic instability is present in hereditary nonpolyposis colorectal cancer (germ-line mutation of a DNA mismatch repair [MMR] gene) and in about 15% of sporadic colorectal tumors (hypermethylation of the MMR gene promotor *hMLH1*). These tumors tend to be diploid because chromosomal arrangements typically do not occur. Biallelic inactivation of an MMR protein occurs to disrupt the DNA MMR system completely. The Wnt signaling pathway, including the gatekeeper protein APC and other proteins in this pathway, are deregulated. Many genes with encoded microsatellites are targeted for mutation in microsatellite unstable tumors, including *hMSH3*, *TGFBR2*, and *BAX*. Mutations in *TGFBR2*, *ACVR2*, *BRAF*, and *BAX* appear at the transition point during malignant conversion. Other mutated genes are likely to be involved in forming the final tumor and in mediating metastasis. **hMLH1* is hypermethylated in sporadic cancers only. ***BRAF* mutations occur in sporadic microsatellite unstable tumors and are not seen in Lynch syndrome tumors.

this signaling pathway, are also affected in microsatellite unstable tumors (see Fig. 24.2). Some *APC* mutations have been found in colorectal tumors with microsatellite instability [181]. In addition, β-catenin, a protein that binds to and is normally degraded by the APC protein, undergoes a stabilizing mutation in microsatellite unstable primary tumors and cell lines [182]. Activating mutations in β-catenin signal the cell to proliferate incessantly [183,184], and the mutations prevent interaction with the APC protein and its subsequent targeting for degradation. TCF-4, to which β-catenin binds as a partner in the nucleus for transcriptional activation, is mutated at its polyadenine site in 39% of primary colorectal cancers with microsatellite instability [185]. Simultaneous analysis of various components of the Wnt pathway in microsatellite unstable colorectal cancer indicates that there is often a perturbation in the Wnt signaling pathway, including mutations in APC, β-catenin, TCF-4, or axin I (involved as a scaffold protein and negative regulator of Wnt signaling) [186,187]. Taken together, colorectal tumors exhibiting microsatellite instability appear to have initiated their growth through deregulation of Wnt signaling, which has the identical consequence as inactivating the gatekeeper APC.

As described for the chromosomal instability pathway of tumorigenesis, inactivation of several genes likely promotes the progression of the neoplastic process in tumors with microsatellite instability, but a common sequence of genetic alterations has not been elucidated. Mutations of *TGFBR2*, *BAX*, and *ACVR2* appear to be late in the adenoma–carcinoma progression because these mutations tend to occur in high-grade dysplasia at the interface between adenoma and carcinoma [42,188,189], although both *BAX* and *TGFBR2*, but not *ACVR2*, are often mutated in adenomas from relatives of patients with Lynch syndrome [174]. A proposed scheme for the progression of microsatellite unstable colorectal cancer is presented in Figure 24.9.

Much has been learned about multistep carcinogenesis through studies of colon cancer, and the principles may be applicable to cancers of many types. Multiple genetic events are required to overcome the redundancy in regulatory controls in the cell. These events accumulate during successive waves of clonal expansion and cooperate to produce tumor progression. The exact impact on growth regulation is not entirely known for any single genetic lesion. A small proportion of cancers lack the genetic events seen in most others so it is reasonable to speculate that there are additional mechanisms of tumor progression, and there is evidence for alternative pathways [91,167].

CpG island methylator phenotype

A third pathway in colon carcinogenesis involves widespread hypermethylation of gene promoters as the mechanism for epigenetic inactivation and gene silencing [91]; this pathway has been termed the CpG island methylator phenotype (CIMP) [190]. In fact, sporadic colorectal cancers with microsatellite instability lose DNA MMR activity as a consequence of hypermethylation of *hMLH1* [191,192], so those tumors are actually a subset of the CIMP tumors. Other genes often inactivated by hypermethylation at promoter CpG islands include the cell cycle regulator *CDNK2A/p16*, the angiogenesis inhibitor *THBS1*, the estrogen receptor growth suppressor *ESR1*, the metastasis suppressor *TIMP3*, and the O^6-methylguanine DNA methyltransferase DNA repair gene *MGMT* [193], and even *APC* [194]. CpG islands are regions of DNA 0.5–2 kilobase pairs long, rich in cytosine-guanine

dinucleotides, that are found in the 5′ region of about half of all human genes. Methylation of cytosines within the CpG islands is associated with loss of gene expression and can be observed not only physiologically (as with X chromosome inactivation and aging), but also in neoplasia. In a study of colorectal cancers, the CIMP phenotype segregated with tumors that demonstrated microsatellite instability [190]. However, in a study of colonic adenomas, the CIMP and microsatellite instability pathways appeared to be distinct [193], and CIMP cancers were associated with distinctive epidemiological, histological, and molecular features [195]. The CIMP phenotype seems to occur early in colorectal tumorigenesis, but the mechanism for its occurrence is not known.

Loss of genetic imprinting and cancer

Alteration in genetic imprinting is another type of epigenetic aberration seen in cancer. Imprinting refers to the silencing of one parental allele in cells by selective promoter methylation. Loss of imprinting (LOI) is a process that occurs in some neoplastic tissues in which the imprinted allele is inappropriately reexpressed as the result of a loss of promoter methylation. LOI of the insulin like growth factor II gene (*Igf2*) doubles the number of inherited tumors in *Min* mice [196]. LOI of the *IGF2* gene may also occur in humans with colorectal cancer, and the inappropriately expressed allele can be assayed with a DNA-based blood test [197].

While carcinogenesis of the colon has been studied most intensely as a result of availability and accessibility of a common precursor lesion, it appears that other gastrointestinal cancers may have distinct patterns of genomic instability. In gastric cancer for example, microsatellite stable, unstable, and CIMP subsets have been recognized [198]. In hepatocellular carcinoma, chromosomal instability occurs in association with *TP53* mutations, hepatitis B viral infection, and poorly differentiated cancers, while chromosomally stable cancers often harbor activated β-catenin [199,200].

Tumor formation and behavior

Molecular histology

Much of the understanding of the genetics of gastrointestinal tract carcinogenesis has come from analyzing various histological stages of tumors. Neoplasia originates from a single cell that has developed a genetic alteration, and then grows at variable rates to larger sizes with differing histological morphology. In the colonic adenoma there is continued mitosis and lack of cellular differentiation, so that the principal proliferative compartment moves from the base of the crypt to involve the entire crypt. Persistent replication of cells near the crypt surface, in concert with retarded cell maturation and extrusion, results in an increased number of replicating surface cells. Continued proliferation coupled with a lack of cell death leads to a downward infolding of epithelial cells, which branch and interpose themselves between normal crypt elements. This process results in the characteristic branching glandular pattern of tubular adenomas. As the polyp continues to grow, the growth pattern of the underlying mesenchyme may be enhanced [201,202]. If mesenchymal proliferation matches the rate of epithelial growth, resistance to continued epithelial proliferation is unimpeded, resulting in long, finger-like projections of the glandular elements. This histological picture is characteristic of villous adenomas. Perhaps more commonly, an adenoma demonstrates a combination of these two histological types, a tubulovillous adenoma. Villous adenomas tend to be larger than tubular adenomas, consistent with the concept that the villous histology is associated with enhanced growth characteristics. Subsequently, some adenomas develop pathological and biological characteristics of carcinoma, giving rise to the malignant polyp. Malignant cells at some point develop the capacity to invade locally and the potential to spread to distant organs.

Each histological stage of neoplasia has been characterized genetically by analyzing the cells in the specimen. Immunohistochemistry, RNA and DNA extraction, sequencing, and in situ polymerase chain reaction are some of the techniques used to determine the genetic abnormalities of the cells. The sequential biological process of tumor formation has been correlated with specific morphological characteristics of tumors in their various stages [35,42,167].

As mentioned, the general features of the colorectal neoplastic model may be applicable to other gastrointestinal neoplasms. In esophageal, pancreatic, and hepatic neoplasms, however, it is difficult to obtain tissue samples at each stage of a multistep process. These tumors do not have a readily identifiable precursor lesion to obtain and study. Tumors of these organs, particularly of the esophagus and pancreas, are often diagnosed in advanced stages, precluding an opportunity to obtain specimens at early stages of the disease. However, it has been recognized that most esophageal adenocarcinomas arise from the esophageal mucosa with intestinal metaplasia (see Chapter 35, Barrett esophagus and esophageal adenocarcinoma), and that a subset of pancreatic cancers arises from pancreatic intraepithelial neoplasia (see Chapter 70 Nonendocrine tumors of the pancreas). The natural history of these lesions is still not fully appreciated, nor are they readily accessible for scientific study.

Loss of proliferative control and clonal expansion

Proliferation is normally tightly regulated and confined to one compartment of the epithelial unit within the gastrointestinal tract. During inflammation and epithelial repair, cell death and turnover increase, regulation is relaxed, and the rate of proliferation increases to compensate for the losses. When a sufficient number of cells have been produced, the rate of proliferation slows to retain homeostasis.

A chance genetic event may occur in one cell that has not

yet been committed to programmed cell death, enabling it to undergo more cycles of replication than its neighboring cells. When this event affects a gatekeeper gene or pathway function, neoplasia may be initiated. In the colon, the proliferative pool of cells migrates from its normally restricted site near the base of the crypt toward the apex of the crypt. Abnormal clusters of cells may be seen in magnified histological preparations of grossly normal-appearing colonic mucosa stained with methylene blue, and these have been termed *aberrant crypt foci* [203]. Aberrant crypt foci are collections of thickened epithelium with asteroid-shaped or oval glandular lumens [204]. The number of aberrant crypt foci appears to be higher in patients with a previous history of colon cancer, and even higher in patients with familial adenomatous polyposis [203]. Not all aberrant crypt foci are associated with the same types of mutations, and they likely represent more than one distinctive lesion. Most aberrant crypt foci have a nonneoplastic histological appearance, and these contain *KRAS* mutations [204–208]. However, histologically dysplastic aberrant crypt foci (which are much less common) may contain *APC* mutations [205,207]. The abnormalities in APC in these latter lesions suggest that dysplastic aberrant crypt foci may be the earliest neoplastic lesions identifiable in the colon. Dysregulation of the Wnt signaling pathway, of which APC is a part, appears to be critical for the initiation of colonic neoplasia [114,166]. Loss of the Wnt signaling pathway uncouples the cell from programmed cell death, and the resulting increase in β-catenin enhances homotypic intercellular adhesion [12,209]. Because these cells continue to proliferate and adhere to one another, but are incapable of invasion, they tend to expand locally and develop into adenomas. Additional growth without invasion permits the formation of a polypoid lesion. This pattern of development of colonic neoplasia is not necessarily typical of neoplasia of the esophagus, stomach, and pancreas.

The liberation from typical growth restraints allows the cell to grow at a faster rate than any surrounding cell. Subsequently, if additional genetic alterations occur in one of these cells, further acceleration of growth may occur. Each advantage gained in growth, beginning with the adenoma and subsequently progressing to carcinoma, occurs by successive waves of clonal expansion. Each clone gains its advantage by a genetic alteration within the cell that allows more successful proliferation than its predecessors. In the colon, it appears that mutations in the *KRAS* gene, and possibly the *TP53* gene, participate in this process. Alterations in the KRAS signaling pathway may permit enlargement of the adenoma to an exophytic mass [167]. Flat cancers that have mostly been observed in Japan tend to lack *KRAS* mutations [167,210,211]. In microsatellite unstable tumors, clonal expansion may be mediated in part by alterations in the Wnt signaling pathway or the TGF-β1/activin signaling pathway, by escape from BAX-mediated programmed cell death, and by *BRAF* mutations [28–30,39,41,42,176,177,180,186,187].

The development of adenomas is a reversible biological event in the colon, at least by gross appearance. Small, sporadic adenomatous polyps may spontaneously disappear, and small rectal adenomas often spontaneously disappear from patients with familial adenomatous polyposis after subtotal colectomy [212]. Patients who have hundreds of colonic adenomas may experience regression of these lesions after the administration of the nonsteroidal antiinflammatory drug sulindac or the cyclooxygenase-2 inhibitor celecoxib [14,213–215]. The mechanism underlying adenoma involution in response to sulindac or celecoxib has been attributed to the activation of programmed cell death by way of unknown mechanisms [13,14]. The incidence of gastrointestinal cancer is significantly reduced in patients taking aspirin and other nonsteroidal antiinflammatory drugs (see Chapter 65 Malignant tumors of the colon). Pharmacological therapies that may block neoplastic progression at this early stage are being evaluated, but the search is complicated by need for an agent with excellent safety profiles.

Malignant conversion

At least two genetic mechanisms permit destabilization of the cellular genome and the appearance of cancer. Both mechanisms involve the breakdown of a homeostatic mechanism by which the genome is faithfully reproduced.

Chromosome instability reflects a failure in the symmetric separation of sister chromosomes and results in LOH events throughout the genome. When LOH occurs at a tumor suppressor gene locus, additional clonal expansion may be greatly favored. The inability to divide the tetraploid nucleus into two perfect diploid pairs at mitosis results in the random generation of aneuploid cells. Cells that accumulate extra chromosomal pieces become hyperploid, and those that lose chromosomal arms become hypoploid. Randomly occurring events that provide a growth advantage result in clonal expansion of the favored cell. Flow cytometry has been used to detect expanded clones with abnormal DNA contents [216,217]. Highly aneuploid tumors exhibit increased virulence [216,218]. The abnormal clones occur focally rather than diffusely throughout the tumor, and evidence suggests that metastatic lesions are derived from these aneuploid clones [219]. In the colon, the histological appearance of high-grade dysplasia coincides with the complete genetic inactivation of *TP53* in chromosome-unstable tumors [35].

A second type of genetic lesion capable of increasing the rate of mutation is inactivation of the DNA MMR system. This form of genomic instability leads to *microsatellite instability*, and allows an accumulation of mutations throughout the genome. Microsatellite instability leads to an increase in point mutations, as well as insertion/deletion mutations at simple repetitive DNA sequences (microsatellites). Cancer cells with microsatellite instability are typically diploid [171]. The polymerase chain reaction can detect the presence of the

inaccurately copied microsatellite DNA. Because of the high mutation rate, it is probable that tumors with MMR defects may progress to carcinoma at a more rapid pace than other tumors [172,175]. Malignant conversion in colorectal tumors with microsatellite instability involves mutation of *TGFBR2*, *ACVR2*, and *BAX*, all of which appear in high-grade dysplasia at the adenoma–carcinoma transition [42,188,189,220].

Malignant cells are capable of continued growth, invasion, and formation of distant metastases. The malignant phenotype is intrinsically unstable and gives rise to additional phenotypic diversity. Malignant tumors are dynamic by virtue of ongoing genomic instability. Some of the newly created cells lose proteins that are essential for survival and die. Other genetic events result in the generation of more virulent clones that overgrow and replace the parent tumor.

Metastasis

The metastasis of tumor cells is not a random or accidental process. In fact, most circulating tumor cells will not give rise to a metastasis. For a tumor to metastasize, it must degrade the basement membrane and associated matrix components, migrate through the subtending connective tissue, enter into a lymphatic or blood vessel, migrate away from the parent tumor, avoid a gauntlet of naturally occurring defense mechanisms, emigrate from the efferent vessel, lodge at a site favorable for growth, and recruit a sufficient blood supply (Fig. 24.10) [221,222]. Metastasis occurs as a late event in the natural history of a tumor, because time is required for the gradual evolution of cells capable of all these behaviors.

The characteristics required for metastasis are specific. A malignant neoplasm, for example, may acquire the ability

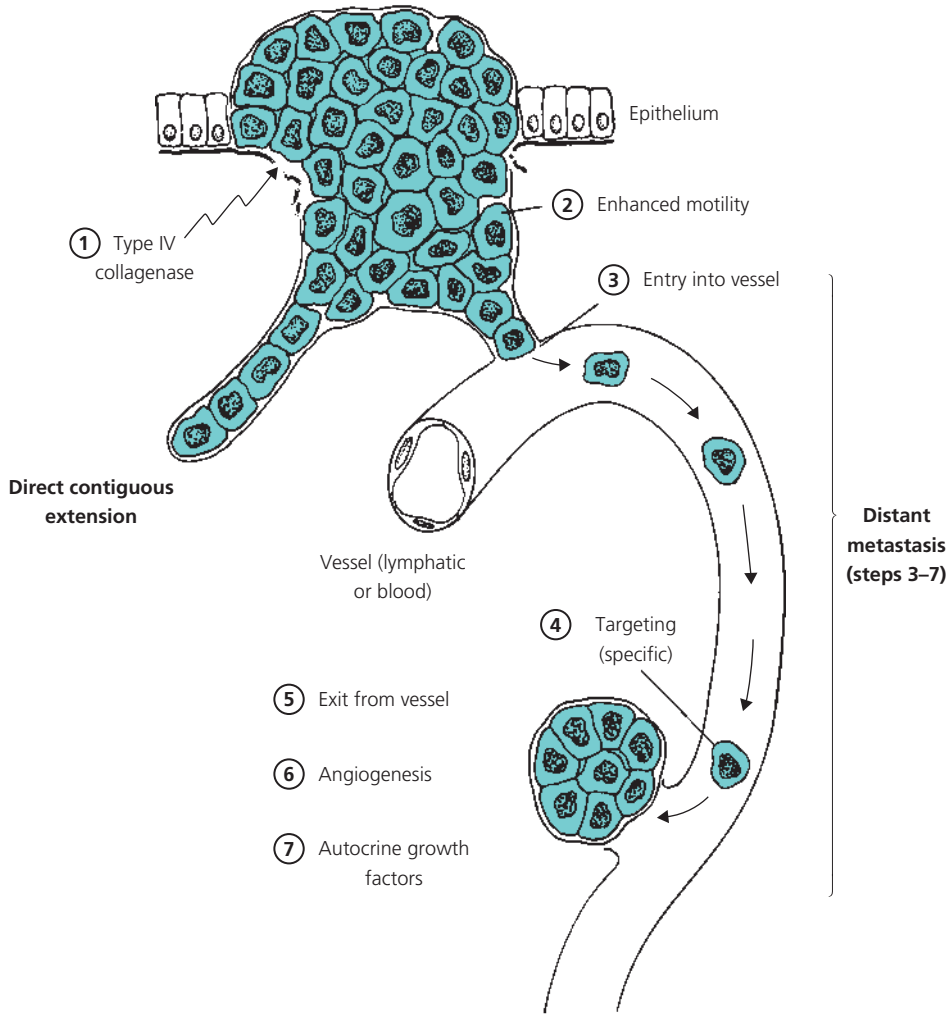

Figure 24.10 Tumor metastasis. Successful tumor metastasis requires several coordinated events. Specific collagenases are required to transgress the basement membrane (step 1). The tumor may grow by direct contiguous extension into surrounding organs. Alternatively, tumor cells may enter a vascular structure for distant metastasis to occur. The spread of malignant cells is enhanced by the development of cellular motility (step 2). Access to a vascular structure is permitted by the expansion of the growing tumor, the motile cells, and the ingrowth of blood vessels, which is stimulated by angiogenesis factors (steps 3 and 6). Entry into the circulation is not sufficient to ensure distant metastasis. Specific targeting mechanisms and adaptations that would enhance survival at a distant site are required for distant metastatic spread.

to digest the basement membrane and slowly expand into the submucosa; however, it may not acquire other properties required for entry into the circulation or for survival at an ectopic site. Such a tumor is pathologically malignant and may become a bulky mass, but there may be a relatively long period during which it can be detected and successfully removed. Alternatively, a highly metastatic clone of cells emerging from a malignant tumor may give rise rapidly to a large number of metastatic units, from which the host may suffer a brisk and relentless downhill clinical course. However, this is likely a dynamic process that may be modeled by selective forces defined by the severity of the microenvironment, allowing a variety of clones to coexist in a heterogeneous tumor mass [223].

Anoikis, Greek for "loss of home", describes the phenomenon whereby normal epithelia undergo apoptosis when detached from the extracellular matrix [224]. Consequently, tumor cells need to be anoikis-resistant to metastasize [225]. The underlying mechanisms rendering tumor cells resistant to anoikis are not fully understood, but may require the stimulation of survival signals that are not dependent on contact with the extracellular matrix. Molecules that change in expression, distribution, and function during the epithelial-to-mesenchymal transition and are causally involved in the process include growth factors (such as TGF-β and IGF1) [226], transcription factors (SMADs and SNAIL) [227], cell adhesion molecules (integrins and extracellular matrix proteins) [226], and cell–cell adhesion molecules (E-cadherin) [228], as well as extracellular proteases (matrix metallproteinases and caveolin) [229]. Molecular candidates in the development of anoikis-inducing agents to block cancer progression to metastasis include galectins, caveolin, and tyrosine kinase receptor B [227,229–231] and are at the center of the development of anoikis-inducing agents to target cancer progression to metastasis [230].

Current insight into the metastatic process is insufficient to predict the clinical course of a malignancy by studying tumor cells in vitro. Tumor cells are often present in the portal and peripheral circulation at the time of colectomy for a colon cancer [232,233]. However, the presence of cytologically identifiable tumor cells in the circulation has no prognostic significance because most of these cells are incapable of growing at a distant site and are susceptible to cytolysis by natural killer lymphocytes and other immunological mechanisms. Clumps of cells appear to be more likely to survive as a metastasis, perhaps because individual cells in the clump have only some of the functions required for successful metastasis, but the entire "social unit" is capable of growing communally.

Tumor cells and patient survival can be affected by local immune cells. The presence of cytotoxic T cells may be a better predictor of patient survival than TNM (tumor/node/metastasis) staging [234]. The type, density, and location of these T cells infiltrating the tumor may protect or slow the metastatic capacity of the primary tumor.

Tumor cells require a blood supply to survive. Oxygen can normally diffuse 100–200 μm from a blood vessel, which is roughly 4–10 cell diameters, depending on the tumor. To facilitate their growth at metastatic sites, tumors stimulate the growth of capillaries. Tumor-associated angiogenesis appears to be mediated by a variety of different tumor growth factors, including angiogenesis factors. The presence of such growth factors can be demonstrated by the tumor's ability to recruit endothelial cells to form capillaries in vitro [235]. Inhibition of vascular endothelial growth factor (VEGF) in mouse models of colon cancer blocks tumor growth and induces apoptosis by inhibiting angiogenesis and endothelial cell survival [235]. Evidence suggests that the expression of transcripts in the endothelium of tumor blood vessels differs from that in the endothelium of nontumor vessels [236]. VEGF is a key mediator in this process. Bevacizumab, a humanized monoclonal antibody that recognizes VEGF receptors, neutralizes the biologically active forms of VEGF that interact with these receptors. In addition, bevacizumab has shown antiangiogenic and antitumor activity in several cancer types, and therefore is used in combination with fluorouracil-based chemotherapy as a first-line treatment for metastatic cancer of the colon or rectum [237].

Not all cells in a primary tumor have identical metastatic potential. From a primary tumor, it is possible to clone cells with an enhanced capacity for metastasis and a propensity to metastasize to specific organs. For example, certain experimental tumor cells form lung metastases in rodents, but others do not. When these metastatic colonies are removed from the rodent's lungs and their numbers are expanded in culture and injected into another animal, each successive cycle produces a larger number of pulmonary metastases. The propensity of the highly metastatic cell line to grow in the lung appears to result from a specific interaction between the injected cells and the pulmonary capillary bed. Lung lesions are seen even after left ventricular injection of the cells, in which the lung is not the first capillary bed encountered, and after transplantation of lung tissue to a subcutaneous location. By means of the same technique, other cell lines can be developed with an enhanced propensity to metastasize to the liver or to specific sites within the brain [238,239]. Site-specific metastasis appears to be mediated by cell surface membrane glycoproteins. Removal of the glycoproteins from the tumor cell surface membranes interferes with the specificity of metastasis. By fusing membrane vesicles from metastatic cells to those of nonmetastatic cells, it is possible to confer homing specificity to the recipient cells.

Therefore, the sites to which malignant cells metastasize in patients with cancer may appear to be random, or based purely on the blood supply of an organ, but the process is more complicated. For example, although tumor cells may be present in the portal blood or peripheral circulation at the time of surgical resection of a colon cancer, hepatic metastases occur only in some instances. Metastases may be

present in the lung, bone, and other distant sites, such as the brain, even in the absence of hepatic metastases. Tumor cells can migrate through the hepatic sinusoids without establishing a malignant deposit in the liver. The phenomenon of cells specifically seeding at the metastatic site is called "homing". Homing may be mediated by factors secreted by the primary tumor to prepare the metastatic sites, including the upregulation of fibronectin and matrix metalloproteinases. This change in local microenvironment in preparation of the cancer cell's arrival is termed the *premetastatic niche*, which may explain the different patterns of metastasis of various tumors [240].

Primary colon cancer differs from metastatic colon cancer in part because metastatic cancer cells express sialylated mucin-associated carbohydrate structures that may play a role in adhesion to the target endothelial glycoproteins and the target cell basement membrane [37]. Other carbohydrate structures found on colon cancer cells appear to bind to molecules such as laminin, a normal component of the basement membrane. Metastases from several gastrointestinal cancers rely to some degree on mutations in growth factor mediators. This observation has been exploited by the development of growth inhibitors to reduce the tumor burden of patients. Gefitinib inhibits epidermal growth factor receptor and has been shown to reduce tumor growth [241]. Imatinib mesylate, which binds and inhibits tyrosine kinase, reduces the tumor burden in chroni myeloid leukemia and many gastrointestinal stromal tumors [242]. The activities of VEGF are mediated by two receptor tyrosine kinases. Bevacizumab has both a direct antiangiogenic effect as well as a local effect, allowing more efficient delivery of chemotherapy by altering tumor vasculature, and has shown promise in treating metastatic colon cancers [243,244].

Metastasis genes

The genetic basis of metastasis is complex and not well understood. One gene has been identified that is associated with distant metastasis in colorectal carcinoma. The *NM23* gene (also designated *NME*) seems to function as a metastasis suppressor gene, inasmuch as it is deleted in distant metastases from some colorectal cancers [245]. Patients without allelic deletions of this gene have a significantly better prognostic outlook. The cellular mechanism by which the *NM23* locus confers metastatic capability is uncertain, but transfection of the gene into certain tumor cell lines inhibits their ability to migrate in response to chemoattractants [246]. *NM23* gene mutation has been reported from human colorectal cancer metastases, suggesting that it may undergo a two-step inactivation, like other tumor suppressor genes [247]. NM23 was down-regulated in colon cancer specimens from patients with poor prognoses, congruent with metastasis suppressor function [248].

Other potential metastasis suppressor genes may be located on the long arm of chromosome 18. Chromosome 18q is lost in 80% of patients with stage IV colorectal cancer [249]. The deleted in colorectal cancer (*DCC*) gene, located on chromosome 18q21, is one putative metastasis suppressor gene, and was identified during the study of commonly deleted regions on chromosome 18q in colorectal cancers [250]. *DCC* encodes a unique protein with homology to neural cell adhesion molecules and other related cell surface glycoproteins. This similarity has led to the hypothesis that the product of the *DCC* gene is involved in cell–cell adhesion and cell matrix interactions, which may be important in preventing tumor growth, invasion, and metastases. Expression of *DCC* was reportedly absent in most colorectal cancers metastatic to the liver, but it was lost in only a minority of nonmetastatic cancers [251]. However, germ-line inactivation of the murine homologue of *DCC* failed to support a tumor-suppressive function for its protein [252]. Other studies have indicated that DCC is a netrin-1 receptor, which, when engaged by a ligand, mediates signals for proliferation. In the absence of ligand, DCC can induce apoptosis [253]. The dependence of DCC on netrin-1 binding suggests a potential role for DCC in colon cancer metastasis.

Additional tumor suppressor genes on chromosome 18q include the TGF-β1 signaling molecule genes *SMAD2* and *SMAD4* [254]. One possibility is that the loss of several of the genes located on 18q cooperates to enhance tumor virulence and metastatic potential.

Other putative metastasis suppressor genes include *S100A4*, which is a direct β-catenin/TCF target that induces colon cancer cell migration and invasion in vitro and metastasis in vivo [255]. Matrix metalloproteinase 9, produced by human colon cancer epithelia, appears to play a role in processes underlying metastasis; it regulates metastatic behavior in vitro, including degradation of extracellular matrix components and formation of organelles involved in migration and hematogenous seeding of mouse lungs by human colon cancer cells in vivo [256].

Clinical markers of neoplasia

Biological tumor markers and oncofetal proteins

Some gastrointestinal cancers acquire and elaborate cell surface determinants that recapitulate structures transiently expressed during normal fetal development. These oncofetal proteins are often glycoproteins and can usually be detected in the plasma. Carcinoembryonic antigen (CEA) was first detected with antibodies developed after rabbits were immunized with colorectal cancer cells; these antibodies are largely directed to the carbohydrate moieties of the glycoprotein [257,258]. Subsequently, elevated levels of CEA were demonstrated in patients with colorectal cancer and other cancers. However, the limitations of CEA measurements in the population as a whole have precluded the use of CEA as a screening or diagnostic marker. Poor sensitivity and

specificity in asymptomatic populations render it less than useful for detecting early, potentially curable cancers [259]. Other conditions besides colorectal cancer are associated with elevated plasma levels of CEA, including cancers of the stomach, pancreas, and liver, nonmalignant diseases of the liver such as alcoholic hepatitis, inflammatory bowel disease, and tobacco use [260]. CEA levels measured at the time of diagnosis may be correlated to the prognosis of colorectal and other cancers (i.e., the higher the CEA elevation, the more advanced is the cancer stage at diagnosis) [261,262]. Nonetheless, this information cannot be used to predict outcome. CEA is recommended as an adjunct in the staging of colon cancers, as well as in surveillance and monitoring the response to systemic therapy, if the levels are elevated at the time of diagnosis and fall after successful resection [263].

Other oncofetal proteins have been used to screen for the presence of gastrointestinal cancer. As with CEA, poor sensitivity and specificity and elevated levels in nonmalignant conditions have limited their usefulness in screening. The determinants for many other markers reflect modifications of blood group antigens (e.g., Lewis blood group) and mucin glycoproteins. Table 24.4 shows some tumor markers and their associated cancers.

Genetic tumor markers

Cancer cells develop as a consequence of multiple genetic insults that affect normal growth regulatory mechanisms. Detection of mutations in tissue samples would therefore suggest the presence of cancer or precursor neoplasia. Techniques in molecular biology, largely through use of the polymerase chain reaction, allow the detection of minute amounts of tumor cells or free nucleic acid in biological samples. For example, *KRAS* mutations have been detected in DNA purified from feces, but benign and malignant colorectal tumors could not be differentiated [264]. In addition, *KRAS* mutations have been detected in the stool of patients with pancreatic adenocarcinoma as well as chronic pancreatitis [265]. The detection of *KRAS* mutations in feces as a means of differentiating neoplasia from inflammation is difficult, and differentiating between colonic and pancreatic neoplasia likewise is problematic. *KRAS* mutations also have been detected in the plasma of patients with colorectal cancer [266]. The detection of *KRAS* mutations in pancreatic juice may eliminate the colon as a source of the mutation, but still cannot distinguish benign from malignant disease [267].

Mutation in *TP53* has been associated with poor prognosis in several malignancies, including colon cancer [268], and the loss of normal *TP53* signals the transition from benign to malignant colorectal neoplasia [35]. Tumors with mutations in *TP53* tend to respond poorly to therapy, whereas malignancies that rarely have *TP53* mutations (e.g., Wilms tumor, testicular cancer, acute lymphoblastic leukemia) often respond to cytotoxic chemotherapy [269]. The finding of *TP53* mutations in the urine of patients with bladder cancer and in the stool of patients with colorectal cancer suggests that detection may eventually be useful for screening [270,271]. The presence of mutated *TP53* suggests the presence of a neoplastic process; however, it may not indicate loss of the second, normal *TP53* allele that is seen in malignant transformation. Distinguishing a benign adenoma from colorectal cancer, as with *KRAS*, may be impossible. The costs and utility of advanced molecular diagnostics in colon cancer in comparison with those of conventional screening methods have not been addressed.

Detection of naked DNA by microsatellite analysis of the serum [272] and plasma [273] of patients with head and neck cancer and of patients with small cell lung cancer, respectively, indicates that these tumors release large amounts of DNA into the blood. For the most part, microsatellite alterations in the circulating tumor DNA were similar to those in the primary tumor. Enrichment of the tumor DNA in the blood may occur. Aberrantly methylated *hMLH1* promoter DNA has also been detected in the serum of patients with microsatellite unstable tumors [274]. LOH can be detected in the serum, which requires higher concentrations of DNA than that needed for the detection of microsatellite instability

Table 24.4 Examples of oncofetal antigen markers in the gastrointestinal tract

Marker	Epitope	Site of primary tumor with serum elevation	Site of other tumors with serum elevation
CEA	Multiple glycosylation sites on an immunoglobin-like protein	Colorectum	Stomach, pancreas, biliary tract, liver
CA 19-9	Sialylated Lewis A	Pancreas	Stomach, biliary tract, liver, colorectum
CAM 17.1	Sialyl blood group antigen	Pancreas	Biliary tract
CA 50	Sialylated Lewis A	Pancreas	Stomach, biliary tract, liver, colorectum
CA 242	Mucin-like antigen	Colorectum	Pancreas
CA 72-4	Mucin-like glycoprotein (sialosyl-2-6α-*N*-acetylgalactosaminyl)	Pancreas, ovary	Colorectum
CA 125	Mucin-like molecule	Ovary	Colorectum

CA, carbohydrate antigen; CEA, carcinoembryonic antigen.

[275]. However, plasma or serum microsatellite alterations in benign or nonneoplastic tumors have not been identified.

The status of chromosome 18q in a tumor may have prognostic significance for patients with colorectal cancer. Rates of survival associated with stage II (Dukes B2) colorectal cancer and LOH at chromosome 18q were similar to those associated with stage III cancer [249]. The survival rates of patients with stage II cancer and no LOH at chromosome 18q were similar to those of patients with stage I cancer. The status of chromosome 18q was determined from the resected tumor and suggested that patients with stage II disease and LOH at chromosome 18q should be offered chemotherapy because patients with stage III disease have been shown to derive survival benefit from chemotherapy [276]. It is not known what genes on chromosome 18q may be metastasis suppressor genes that, if lost from the tumor, may allow spread to the regional lymph nodes (stage III) or distant organs [254].

Data are insufficient to endorse the routine use of p53, RAS, 18q loss of heterozygosity, DCC, thymidine phosphorylase or synthase, and dihydropyrimidine dehydrogenase in the treatment of patients with colon cancer [263].

One promising approach has been the detection of *APC* mutations in fecal DNA [277]. Mutations in *APC* generally initiate colorectal neoplasia, and detection of such mutations would be expected to segregate with neoplasia. In a feasibility study, *APC* mutations were detected in 57% of patients with polyps or cancer, but in none of the control patients without colorectal neoplasia [277]. However, it is technically difficult to identify every alteration in *APC*, and some neoplasms retain wild-type copies of *APC*. Future improvements in proteomics may increase the sensitivity of these assays.

Assaying multiple genetic targets as part of one complete assay is another approach to detect neoplasia. There is some genetic heterogeneity in colorectal tumorigenesis that may extend to other cancers of the gastrointestinal tract. One group assayed mutations of *KRAS*, *TP53*, and *APC* genes, *BAT-26* (a microsatellite instability marker), and highly amplifiable long-strand DNA from human fecal material [278]. *Long-strand DNA* refers to DNA that has not been degraded during apoptosis; it may be present in cells that have escaped programmed cell death. With the use of the panel of multicomponent markers, the sensitivity for detecting neoplasia was 82% for adenomas and 91% for cancers [278]. When *KRAS* was excluded from the analysis, the specificity for detecting neoplasia increased from 93% to 100%, with a positive predictive value for colorectal neoplasia of 100% and a negative predictive value of 85% [278]. A multitarget assay detecting 21 different mutations in stool proved somewhat better than Hemoccult testing, but still failed to detect most neoplastic lesions identified by colonoscopy [279].

The use of genetic tumor markers for screening and determining survival is therefore limited. As our understanding of tumor biology progresses and the sophistication of biotechnology improves, genetic tumor markers will likely play a role in the treatment of patients with cancer.

Genetic profiles affecting patient outcome

Research to understand the molecular mechanisms leading to cancer is ultimately driven toward the goal of being able to apply this knowledge to individual patient treatment. It is known that patients with microsatellite unstable colon cancer have a better clinical outcome than those with chromosomally unstable colon cancers [50]. On the other hand, microsatellite unstable colon cancers do not respond to adjuvant chemotherapy with 5-fluorouracil [280,281]. Although *BRAF* mutations typically occur in microsatellite unstable cancers with no influence on patient outcome, *BRAF* mutations are associated with a poor outcome in patients with microsatellite stable colon cancers [282]. In Barrett esophagus, the size of a clone with *TP53* LOH or ploidy abnormality predicts progression to cancer [283]. While these studies are encouraging, prospective studies are needed to validate individual genetic markers in patient treatment. High-throughput technologies allow the assessment of gene expression profiles of individual tumors to predict their response to chemotherapy. For example, in vitro drug sensitivity data may be validated with response data from cell line studies and coupled with gene array patterns. In the future, such approaches may greatly to develop chemotherapeutic regimens that are customized for individuals [284].

25 The human intestinal microbiota and microbiome

Ruth E. Ley, Jeffrey I. Gordon

Describing microbes: species and phylotypes, 635
The microbiota, 636
Metabolic food webs, 641
Linking phylogeny to function, 642
Prospectus, 642

Our adult bodies are colonized by a multitude of microbes whose collective genome, the *microbiome*, complements and enhances our own genome with genes we have not had to evolve on our own. In the decade before the sequencing of the human genome was completed, scientists anticipated that the number of genes it encoded would be close to 100 000. It came as a surprise that the number of genes encoded in the human genome is in the range of 20 000. Yet, if we consider the genes of our microbial partners, in addition to those encoded in our primate genome, 100 000 is likely an underestimate of our gene content. From this perspective, we are "supraorganisms" coated with a number of microbial cells that is 10 times greater than the sum of all our human somatic and germ cells.

The intestine contains the largest collection of microbes among all of our body "habitats" (locations for microbial colonization). In the colon, for example, anaerobic bacteria reach densities of 10^{11} per gram of lumenal contents. Together, gut microbes form a community, or *microbiota*, that has a major impact on health through interactions with host cells (including components of the innate and adaptive immune systems), through extraction of nutrients and energy from the diet, and through complex biotransformations of a variety of ingested compounds, including potential carcinogens. Long-standing questions abound concerning this ecosystem. How is the gut microbiota assembled and maintained over a lifetime? How personal is each individual's microbiota? How does its composition contribute to well-being or disease predisposition and pathogenesis? The answers to these and other questions are starting to emerge with the application of new experimental technologies to define gut microbial community composition and gene content, such as high-throughput, massively parallel DNA sequencers. Equally important, advances in the computational methods used to analyze the vast amount of data emanating from studies of the DNA, messenger RNA, protein, or metabolite content of the gut microbiota, coupled with the application of principles gleaned from the fields of ecology, evolutionary biology, and population genetics, are illuminating the properties and operations of this remarkable microbial "organ."

Describing microbes: species and phylotypes

Our knowledge of the composition of microbial communities stems from over a century of culture-based work and from almost three decades of culture-independent, nucleic-acid-based analyses. Traditionally, cultured microbes have been identified (typed) on the basis of their phenotypic and physiological properties – a rapid and efficient method for detecting specific microbes with previously described properties. However, culture-based approaches have severe limitations; the most problematic is that at least 60%–80% of the microbial cells in the human gut have not been isolated and grown in pure culture in the laboratory [1]. Because of the difficulties involved in isolating microbes in culture, surveys of diversity (who is there and in what abundance) using a culture step are particularly susceptible to bias.

Molecular phylogenetics is an alternative method for microbial identification that does not rely on a culture step; the central tenet of this approach is that an organism is identified by its evolutionary relationship to others. All living cells have a common ancestor so they contain genes whose history can be traced back to the same gene in their last common ancestor. The modern descendants (homologues) of these ancient genes may perform the same or similar functions in each descendant living cell and can, depending on the degree of conservation/evolution, share a large

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

proportion of identical sequence. To measure evolutionary (phylogenetic) distances, homologous genes from different microbes are sequenced, their nucleotide or protein sequences are aligned, and the differences between pairs of sequences are tallied. Comparison of the pairs of sequences of multiple organisms reveals an evolutionary map (phylogeny) of the organisms. This allows classification of previously unknown organisms because each organism is given a coordinate on the evolutionary map; each organism is identified by its evolutionary distance from others.

The gene most widely used to build the tree of microbial life encodes an RNA molecule that is a component of the small-subunit of ribosomes (SSU rRNA: this is 16S rRNA in Bacteria and Archaea and 18S rRNA in Eukarya). This gene is sometimes referred to as a barcode for life. Roughly 1500 base pairs in length, its high level of nucleotide sequence conservation across all three domains of life, Eukarya, Bacteria, and Archaea (~ 50% identity, or % ID), allows a confident alignment, yet there is enough variation to infer evolutionary relationships. Like other components of central information-processing pathways in the cell, rRNA genes are thought to be transmitted primarily from mother cell to daughter cell and so the rRNA gene phylogeny of a microbe is its *vertical lineage*. In contrast, genes encoding proteins can also be exchanged between microbes from different lineages (particularly among Bacteria), a process termed *lateral gene transfer* (i.e., lateral with respect to the rRNA phylogeny). Phylogenies of these laterally transferred genes can be incongruent with the rRNA phylogeny [2]. As a consequence, distantly related microbes may have similar phenotypes. Lateral gene transfer partly accounts for the failure of traditional microbiology to build a coherent and universal classification scheme for microbes based on their physiological or phenotypic characteristics [3].

Although physiological and phenotypic characteristics are used to define genera and species in clinical microbiology, genus/species names often do not map well on the rRNA gene phylogenies derived from reference "type" strains and their associated clinical isolates [4]. The bacterial genus *Clostridium* is a particularly egregious example of the disparity between classifications based on phenotype and those based on 16S rRNA phylogeny [4]. The *Clostridium* genus was once described as "free-living, unicellular, nonbranching, nonphotosynthetic, rod-shaped, anaerobic, heterotrophic, and forming endospores." However, these descriptors apply to many genera named according to their 16S rRNA phylogeny, such as *Eubacterium*, *Syntrophospora*, *Paenibacillus*, *Caloramator*, *Oxalophagus*, *Oxobater*, *Moorella*, *Thermoanaerobacter*, and *Filifactor* [4].

Phylotypes (phylogenetic types) are branches of the phylogenetic tree, and *species-level phylotypes* are closely related clusters of branches. The % ID between any two SSU rRNA gene sequences in a species-level phylotype is typically greater than or equal to 97%. Note that the use of the 97% ID cutoff to delimit a species is based on attempts to match the SSU rRNA gene sequence % ID to previously described species that have been classified according to their phenotype; so rather than being a rule, it is a rule of thumb. Indeed, the species-level phylotype may not include the set of strains described for the species by phenotypic matching. Furthermore, inclusion in a species-level phylotype is not necessarily a good predictor of the gene content of the entire genome. For example, *Escherichia coli* isolates with identical 16S rRNA gene sequences can share only 30% of their genes [5], but are still considered *E. coli* – the genes they do have in common confer the essence of the species. Studies of the differing genome content of strains of the same species (≥ 99% rRNA gene identity) have led to the concept of the *pan-genome*, which is defined as the sum of all genes present in all isolates [6,7]. One of the only generalizations that we can make at present is that bacteria whose 16S rRNA gene sequences are below the threshold of 97% ID have genomes whose gene content is less than 40% similar [8].

Terms

Microbiota refers to the microbial community, and *microbiome* refers to the sum of all the genes encoded in all of the genomes of the microbiota. We use *phylotype* to describe clusters of related 16S rRNA gene sequences characterized by levels of pairwise sequence identity (i.e., phylotypes may describe deep or shallow levels of diversity that may loosely correspond to groups [operational taxonomic units], such as divisions [also known as phyla], genera, species, or strains). We deliberately omit the use of the word "prokaryote" because the prokaryote/eukaryote dichotomy is inconsistent with the three known *domains* of life on Earth (Bacteria, Archaea, Eukarya), and so represents an outdated concept [9].

The microbiota

Methods to determine community composition

To characterize the microbial diversity (i.e., presence and abundance of phylotypes) in a mucosal biopsy or stool sample using molecular phylogenetics, bulk DNA is extracted, and SSU rRNA genes are amplified by polymerase chain reaction (PCR). When the goal is to encompass the greatest possible breadth of diversity, the PCR primer pair used most often is the "universal" primer pair 515F and 1391R, which recognizes SSU RNA genes from members of all three domains of life (the numbers associated with these primers correspond to nucleotide positions [from 5′ to 3′] in the *E. coli* 16S rRNA gene sequence). When members of the domain Bacteria alone are targeted, the Bacteria-specific forward primer 8F is paired with the universal reverse primer 1391R, or with the Bacteria-specific reverse primer 1492R. After PCR amplification and subsequent cloning and sequencing of the 16S rRNA gene amplicons, the sequences are deposited in public databases so that they can be shared with other

researchers. These sequences provide the context for interpreting any new sequence, so allowing immediate comparisons with data from other samples and studies.

Data sets

To date, the two largest data sets of 16S rRNA gene sequences obtained from the human gut consist of 13 335 16S rRNA sequences from three unrelated healthy adults [10], and 18 348 sequences from 14 unrelated adults [11]. Eckburg and colleagues specifically addressed the composition of the normal gut microbiota [10]: each of the three individuals contributed biopsy samples from six regions of their colons, plus one stool sample. Ley and colleagues addressed the effect of obesity and weight loss on gut microbial ecology [11]: stool was collected from 12 obese individuals at four time-points over the course of 1 year, before and while they lost weight on either one of two types of low-calorie diet. Bacteria were surveyed in both studies. Eckburg and colleagues [10] also targeted members of Archaea (~ 1500 sequences), but neither Eckburg nor Ley and their colleagues targeted Eukarya. From these and earlier studies [1,12], broad patterns emerged.

How many species of bacteria are in the human gut?

This a challenging question. Even setting aside the fact that the term "species" has no generally accepted definition in microbiology [13], the technical difficulties faced in searching for an answer are enormous. Obtaining an answer involves attempting to "count the uncountable" in a densely packed microbial society of 10–100 trillion organisms that differs from person to person in an exponentially growing human population whose microbes may be undergoing evolution faster than they can be counted. However, because most reviews and discussions of the human gut microbiota begin with a statement about the "number of species in the human gut", it is important to know the source of these figures, if only to highlight the limits of our present capabilities, what we can know from current methods, and the likely accuracy of statistical extrapolations of "species" data.

The oft-quoted number of 400 species [14] stems from a statistical extrapolation based on 113 different species cultured from the feces of 20 Japanese–Hawaiian subjects (13–30 species per specimen [15]). The more recent estimates of 800–1000 species [16,17] are derived from statistical analyses of 16S rRNA gene sequence data sets. Figure 25.1 shows such an analysis of the combined data sets generated by Eckburg [10] and Ley [11] and their colleagues. At the 97% ID level, the total number of species-level phylotypes is 4000–5000. In this analysis, the number of phylotypes is tallied as sequences are added. Because of the high degree of interpersonal differences, each new person studied adds a substantial number of new species (see Fig. 25.1).

How many people must be sampled before few or no new species-level phylotypes are encountered? This question can only be answered once interpersonal variability is well constrained for humans of both sexes with a wide variety of characteristics, spanning the human life cycle, as well as different demographic factors (e.g., rural vs urban), socioeconomic groups, cultures, diets, and health states. Clearly, more information is needed before generalizations can be made with confidence about the fine-scale (species-level) characteristics of "the" human gut.

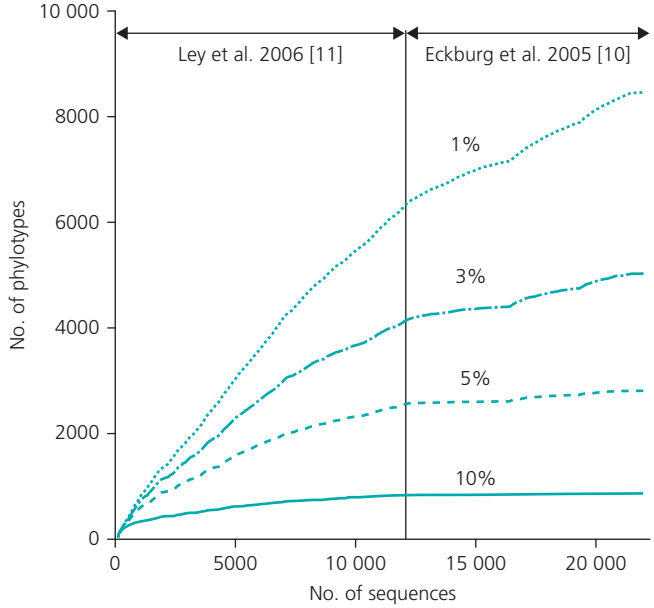

Figure 25.1 Abundance of 16S rRNA gene sequence phylotypes in the human gut. Phylotypes are tallied at different levels of sequence divergence (% identity [% ID]): 1% divergence in 16S rRNA gene sequence identity corresponds grossly to strain level, 3% to species level, 5% to genus level, and 10% to family level. Sequence data for each subject from the studies of Ley et al. [11] and Eckburg et al. [10] were added sequentially. Note that the three inflections in the 1%, 3%, and 5% lines from the data generated by Eckburg and colleagues correspond to the high number of sequences in each of the three subjects in the study. Sequences from both data sets were aligned using the NAST algorithm [67] and phylotypes were generated using the computer program DOTUR [68] (for details, see ref. 11).

Within a *single* distal gut, mucosal communities sampled at different points along the colon are more similar to one another than to communities sampled from the same regions of another individual [10]. The community composition might be expected to change consistently from the proximal to the distal end of the colon, but no consistent order for the colon biopsy samples was observed for the three subjects in the study by Eckburg and colleagues [10] (Fig. 25.2).

These types of conclusions, obtained from large SSU rRNA sequence data sets, could only be reached because of the development of new computational tools. One such tool, the UniFrac metric [18], which was used to display the relationships between all the mucosal biopsy and stool samples in Fig. 25.2, is a measure of the evolutionary distance between the sets of 16S rRNA gene sequences from different samples.

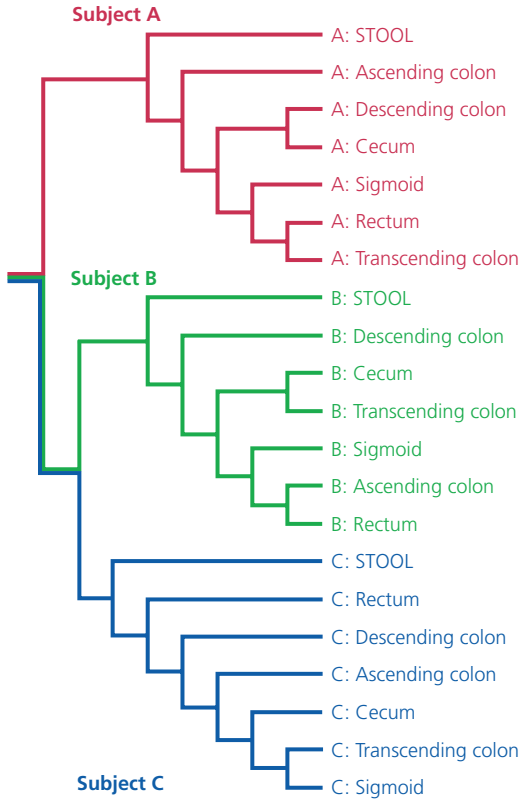

Figure 25.2 Dendrogram illustrating the similarities in bacterial diversity between mucosal and stool samples of three healthy individuals (Subjects A, B, C) from the study of Eckburg et al. [10]. The more similar the communities, the closer together they are on the phylogenetic tree: each subject's samples cluster to the exclusion of the others. There is no consistent rank order to the similarity of communities residing at the different mucosal biopsy sites. However, the stool sample for each subject is the furthest removed from the set, indicating that stool is a mix of mucosal and lumenal communities, but each stool can clearly be attributed to its host. The dendrogram shown was generated with UniFrac, which measures the fraction of total branch length of the 11,831-sequence neighbor-joining tree occupied by each community (for details, see ref. 11).

All sequences from all mucosal and stool communities were assembled into one large phylogenetic tree. For each sample, the fraction of tree branch length that is either unique to its set of sequences, or shared with other sets, is computed using the UniFrac metric: this allows quantification of community overlap on the tree. Communities with the most overlap share the most lineages, and so, are the most similar.

Using UniFrac and other tools to compare communities, the emerging view is that a highly diverse and personalized microbiota, consisting of hundreds, and perhaps thousands, of species-level phylotypes *per person*, resides in our distal gut. Stool is a mix of mucosal and lumenal communities; Eckburg and colleagues [10] determined that the colonic mucosal communities for each person were more closely related to the corresponding stool sample than to any samples from the other individuals (see Fig. 25.2). This underscores the usefulness of stool for providing a general view of an individual's gut microbial community – stool is easy to obtain and representative of the colonic mucosal community.

A detailed spatial analysis of community structure in the intestine is needed but awaits the development of reliable sampling methods that can be applied to individual human hosts. Issues to be addressed about the biogeography of the gut microbiota include the nature of variation along the length of the small intestine and colon, along the crypt-to-villus axis in the small intestine, along the crypt-to-surface epithelial cuff axis in the colon, and from the lumen through the mucus layer to the surface of epithelial cells, as well as variations surrounding or within pathogenic lesions.

Who is there? Bacteria, Archaea, viruses, and eukaryotes

Most cells that comprise the human gut microbiota are bacterial. The roles of the rarer, nonbacterial members of the community are not well known, but the consistent presence of these organisms in the human gut microbiota hints at their importance in the functioning of the system.

Of the numerically dominant Bacteria, two divisions (deep evolutionary lineages, or phyla) predominate: Bacteroidetes and Firmicutes. A few other divisions are represented at low levels. In the large-scale surveys previously described, the Firmicutes and the Bacteroidetes together accounted for most of all the 16S rRNA sequences in each human host studied. Within the Firmicutes, the majority of phylotypes belonged to the clostridial clusters XIVa (*Clostridium coccoides* group) and IV (*Clostridium leptum* group), although most of these were novel and unrelated to species present in publicly accessible culture collections. The remaining sequences belonged to seven other divisions of Bacteria, which, together with divisions described in previous studies [17], brings the total number of divisions detected either in biopsy samples or feces to 10 (Firmicutes, Bacteroidetes, Actinobacteria, Fusobacteria, Verrucomicrobia, Lentispharae, Cyanobacteria, Synergistes, Spirochaetes, Proteobacteria). Some members of the Actinobacteria (i.e., *Bifidobacterium* and *Atopobium*, which are gram-positive organisms with a high guanine and cytosine content), and some members of the Firmicutes (e.g., clostridial cluster IX) may be underrepresented in molecular surveys; for example, fluorescent in situ hybridization studies have revealed higher than expected cell counts for this cluster [19]. The ~ 100 other divisions of Bacteria known from environmental studies [20] either do not find the human gastrointestinal tract a hospitable habitat, or are so rare that their detection requires larger or more focused surveys.

Although only two divisions, Firmicutes and Bacteroidetes, dominate in the gut, the diversity of lineages within those divisions is great. In the data set from the three adults in the study by Eckburg and colleagues [10], over half (7555) of the 13 335 sequences were sampled only once, and each unique sequence can be considered as a strain. The high number of

strains sort into a dramatically lower number of species-level phylotypes: 395 when the threshold for defining membership in a given species is set at ≥ 99% 16S rRNA sequence identity [10]. The number of phylotypes decreases dramatically as their defining phylogenetic resolution becomes coarser (in other words, as the % ID is lowered). This pattern is repeated in other studies of the microbiotas of humans [11,17], and mice [21], and is much more extreme than that which is observed in environmental habitats, such as soil and ocean water, which contain a higher level of intermediate lineages [22]. The evolutionary relationships of the human gut bacteria can be visualized as a grove of 10 palm trees, with a few deep lineages in each division represented by a fan of branches at the top of a given palm. This contrasts with other environments, where more intermediate branches give rise to a pattern more akin to an oak tree. One challenge in the study of gut microbiology is to discern the biological implications of the extreme fan-like phylogenetic architecture [22].

Archaeons are present in most (50%–80%) humans surveyed [23]. Methanogenic archaeal phylotypes can comprise more than 10% of all anaerobe cells in feces [24]. Despite their abundance, the diversity of methanogens appears to be remarkably low. In the single time-point survey of three adults, *Methanobrevibacter smithii* was the only archaeal phylotype encountered [10]. *Methanosphaera stadtmanae* and other members of the Crenarchaeote and Euryarchaeote archaeal divisions are rarer [25]. Archaea are the only known producers of methane. The niche (profession) occupied by mesophilic methanogenic Archaea in the gut is to improve the efficiency of polysaccharide fermentation by preventing build-up of H_2 and other reaction end products. The roles of non-methane-producing Archaea are completely unknown.

A culture-independent study of DNA viral diversity in human feces revealed 1200 different genotypes [26]. Most (81%) were siphophages and prophages within bacterial genomes [26]. A similar survey of the RNA viral diversity in feces revealed that most of the viruses were plant pathogens – the most abundant member, pepper mottle virus, was detected in ~ 70% of 18 fecal samples from healthy donors on two continents [27]. This plant virus likely has a dietary origin. Its capacity to infect plants after passing through the human gastrointestinal tract suggests that we may act as reservoirs for disseminating this and other plant viruses [27].

The fungal components of the normal human intestinal microbiota have not been surveyed with culture-independent methods, but studies in mice and culture-based studies in humans suggest a dynamic and complex community. An 18S rRNA gene sequence diversity study in mice revealed commensals from all four fungal divisions [28]. A culture-based study of feces obtained from Apollo 14 and 15 astronauts, before and after their space flights, revealed a variety of yeast-like fungi (*Candida* species, *Cladosporium* species), at least one filamentous fungal morphotype (*Cladosporium elatum*), a high degree of interpersonal variation, and changes over time [29].

Understanding patterns of diversity: insights from ecology

The patterns of diversity in the gut can be understood using ecology [22]. Conceptual frameworks and hypotheses developed to explain patterns of diversity in plants and animals (macroecology) can be applied to microbial ecology because the data sets are large enough for rigorous statistical comparisons. In macroecology, community composition can depend strongly on the order in which species initially enter a community, a phenomenon known as multiple stable states [30]. In microecology, the influence of the inoculating community on the composition of the later community is evident in mice [21], in fish [31], and in artificial systems [32]. These observations also fit with the predictions of the neutral theory of community assembly, which states that most species will share the same general niche (profession), or the widest niche, and so are likely to be functionally redundant [33]. In the gut, neutral community assembly would result in a high level of microbial lineage variability between guts, but the broad functions encoded in the microbiomes would be the same. Indeed, the very broad functions are the same regardless of the high interpersonal variability: all gut microbiotas help digest the diet [34].

Provenance of the lineages

Cell densities increase from 10^4 cells/mL near the stomach to 10^{11} in the colon. The community in the distal intestine likely is influenced by those further upstream in the mouth, esophagus, stomach, or small intestine. Upstream community members have the potential to translocate to the distal regions of the intestine, either as entrenched residents or as tourists, and indeed, upstream communities may act as reservoirs for recolonization after disturbances (i.e., diarrheal diseases). The microbiota of the stomach shows considerable overlap in composition with the microbiota of the mouth; the mouth has high taxonomic richness, with ~ 700 species-level phylotypes [35]. A single study of the stomach revealed 128 species-level phylotypes, 40% of which had been previously identified in the mouth [36]. Despite the overlap in phylotype composition, their abundance is habitat-specific [35]. Among Firmicutes for example, the genus *Streptococcus* is abundant in the mouth [35], where attachment to surfaces is a selection criterion, but not in the colon, where *Clostridium*, *Eubacterium*, and *Faecalibacterium* species (i.e., members of clostridial cluster XIVa) dominate. If colonization of the lower intestine by upstream residents does occur, therefore, it does not result in the dominance in the colon by the translocated microorganisms. Instead, lineages typical of the distal gut and those typical of the mouth [35] and stomach [36] are likely adapted to their body habitats.

How is our gut microbiota acquired? Pathogens and commensals alike can be said to use the oral–fecal route for host-to-host transmission. In contrast to gut pathogens, which proliferate in environmental reservoirs outside their hosts (e.g., members of the Proteobacteria such as *Vibrio cholera*), gut commensals do not appear to grow in the environment [17]. As a consequence, commensals are most likely to rely on the direct contact of parents and offspring for their transmission. One testable prediction of a parent-to-offspring transmission hypothesis is that microbial communities will be more similar if hosts are related rather than unrelated. In laboratory experiments using families of C57BL/6J inbred mice in which littermates were raised in separate cages after weaning, the family tree could be recapitulated on the basis of gut microbial community structure. Mothers that were sisters had more similar microbiotas than did an "unrelated" but genetically identical C57BL/6J mother [21]. These kinship effects were seen across multiple generations; i.e., in the mothers' offspring and in the mothers' mother so the microbiota and microbiome can be viewed as a heritable genetic factor [22].

Mice are coprophagous. The extent to which human families share microbial diversity remains to be seen, but multiple lines of evidence suggest that mother-to-baby transmission of microbes is a fundamental feature of human biology. Human babies are born germ-free and acquire their gut microbiota from their early environmental exposures: the vagina, feces, skin, and breast milk of their mothers figure prominently as sources of inoculum [37–39]. Birth is a critical period for inoculation: babies delivered by cesarean section show altered patterns of colonization compared to babies delivered vaginally [40]. Direct mother-to-baby transmission has been shown for certain groups of bacteria. For example, the probiotic strain *Lactobacillus rhamnosus* GG, when taken during pregnancy, has been detected in the infant gut up to 24 months after delivery and cessation of maternal consumption of the probiotic [41]. Strains of *Lactobacillus* species and *Enterococcus faecium* isolated from the breast skin and milk of mothers have been matched, by randomly amplified polymorphic DNA analysis, to strains isolated from their babies' feces [38]. Such direct matching of a few hundred isolates picked randomly from bacterial communities suggests that the same bacterial strains are not only present in both mother and child but also colonize to dominance. It is tempting to speculate that the dominance of *Lactobacilli* in the vagina, and their presence in breast milk, are evolutionarily advantageous strategies – when propelling one's newly born, germ-free offspring into the microbial world, immediate dosing with friendly and useful microbes enhances survival.

Another factor that could account for similarities between mother and infant microbiotas is host genotype selection; i.e, related individuals share genetic traits that could select particular lineages of microbes. To tease apart the effect of a shared human genome compared with the effects of the mother and early environment on community composition, two studies have surveyed the microbiota of monozygotic and dizygotic twins and their families [42,43]. Both studies used DNA fingerprinting methods (denaturing and temperature gel gradient electrophoretic techniques, in which mixed PCR amplicons in a sample are separated on gels according to base compositional differences) that yield qualitative estimates of community similarities but no sequence data. Both studies reported the highest similarities between the microbiotas of monozygotic twins.

The twin studies revealed a remarkable pattern: whether the similarities between siblings are the result of a shared early environment or a shared genotype, they persist into adulthood despite the erosional potential of time, cohabitation with marital partners, and the different environmental exposures brought about by separate lives. In an ongoing study of the microbiotas of 12 unrelated adults over the course of 1 year, Ley and colleagues [11] showed that the lineages present were generally stable over time. Methanogen population levels are also stable over time within individuals [44]. Lineage composition appears resilient to antibiotic treatment, but induces a transient shift in their relative abundances [45,46]. Changes in diet [47] and weight loss [11] also affect the relative abundance of lineages. One manifestation of the resiliency of the intestinal microbiota is that its lineages can be maintained, although their relative abundance may change under certain conditions.

The community and its properties

Gut microbes are thought to be highly functionally redundant, such that many different combinations of microbes will still perform basic services. The genes involved in basic services, which can be thought of as host-imposed essential requirements, can be ascertained by comparing the gene complement in the gut microbiome to that in nongut microbes. With the use of a metagenomics approach, in which bulk DNA is isolated from an intact microbial community and then randomly sequenced, Gill and colleagues [34] identified some of these basic services. They compared the genes present in the microbiomes of two unrelated healthy adults to the genes found in all other sequenced bacteria deposited in public databases and in the human genome. The gut microbiomes were enriched in genes involved in energy production and conversion, carbohydrate transport and metabolism, amino acid transport and metabolism, coenzyme transport and metabolism, secondary metabolite biosynthesis, transport and catabolism, and methanogenesis [34]. As might be expected, the gut microbiome has been selected in part for its role in nutrient and energy extraction from the diet.

An example of the impact of differences in microbial community composition impacting energy metabolism comes from studies of obesity. 16S rRNA-based comparisons of the

distal gut microbiota in genetically obese (*ob/ob*) mice and their lean (+/+ or *ob/+*) littermates disclosed that increased adiposity is associated with a division-wide decrease in the proportion of Bacteroidetes and a corresponding division-wide increase in the proportion of Firmicutes [21]. Using metagenomic methods, Turnbaugh and colleagues [48] observed enrichment in the representation of genes involved in polysaccharide metabolism in the microbiomes of genetically obese (*ob/ob*) mice relative to the microbiomes of their lean wild-type (+/+) littermates. The investigators' prediction that the *ob/ob* microbiome was more efficient at energy extraction from a diet was borne out by biochemical assays; compared to lean mice, the *ob/ob* mice had higher levels of short-chain fatty acids in their ceca and less energy remaining in fecal pellets. A direct demonstration of the *ob/ob* microbiome's increased capacity for energy harvest from the diet came from an experiment in which the gut microbiota from *ob/ob* and lean littermates were transplanted to lean germ-free, wild-type mice, and their weights were monitored for 2 weeks. Although food consumption and initial body weight were the same for both groups of mice, the recipients of an *ob/ob* gut microbiota exhibited twice the increase in percentage body fat compared to recipients of a "lean" gut microbiota.

A similar division-wide shift in the ratio of Bacteroidetes and Firmicutes has been observed in the gut (fecal) microbiota of unrelated adult obese humans compared to that of lean humans [11]. Furthermore, the change in relative abundance of the Bacteroidetes was correlated with weight loss on two types of diets (fat-restricted, carbohydrate-restricted), indicating that there is a dynamic linkage between adiposity and gut microbial ecology. Together, these studies suggest that the nutrient and energy value of food should be considered in the context of the consumer's gut microbial ecology.

Metabolic food webs

The relationship between host and microbiota, particularly the dynamics of food webs, including their thermodynamic interactions, are beneficial in most humans. However, the microbial ecology of obesity shows how entire communities may contribute to host pathology. The "behavior" of the community as a whole is an emergent property of the community that is shaped by a multitude of microbe–microbe and microbe–host interactions.

Microbes in the gut are at the intersection of two forms of selective pressure: bottom-up, where intermicrobial competition would drive microbes into distinct functional roles, and top-down, where the host would select for functional redundancy to insure against "reactor failure" [22]. Indeed, gut bacterial species display both overlap and specialization in their fermentative abilities. They generally are capable of a wide range of fermentative activities [19], but divide up the available substrates in a number of ways: by differing in substrate use (see review by Louis and colleagues [49]), by varying the order in which common substrates are used [50], and differing the selection of substrates for attachment [51].

The genome sequences and in vivo behavior of Bacteroidetes species illustrate the plasticity necessary to thrive in a changeable gut environment. Full genome sequences of *Bacteroides thetaiotaomicron*, *B. vulgatus*, and *B. distasonis* show that these species can deploy a large arsenal of genes involved in the acquisition and metabolism of polysaccharides, and that the suite of genes involved in these processes varies between species and can be laterally transferred [52]. *Bacteroides thetaiotaomicron* has the greatest arsenal. Its genome includes 208 paralogues of two outer membrane proteins, SusC and SusD; which are involved in the binding and importing of starch and maltooligosaccharides; 246 predicted glycoside hydrolases and polysaccharide lyases; and a large array of environmental sensors (50 extracytoplasmic function-type σ factors, 25 anti-σ factors, and 32 novel hybrid two-component systems) [52]. The carbohydrate foraging behavior of *B. thetaiotaomicron*, when introduced into the ceca of germ-free mice maintained on standard chow diets with high levels of polysaccharides, includes attachment to small nutrient platforms, consisting of partially digested food particles, and to host mucus, and sequential deployment of its arsenal in response to substrate depletion [50]. For a bacterium like *B. thetaiotaomicron*, which lacks adhesive organelles, attachment to substrates (seating at the "dining table") is determined in part by the suite of glycan-specific SusC/SusD outer membrane-binding proteins it produces, the composition of which is dictated by the menu of available glycans. Attachment presumably increases the efficiency of oligo- and monosaccharide harvest by adaptively expressed bacterial glycoside hydrolases, and their subsequent distribution to other members of the microbiota. This activity, together with the ability of *B. thetaiotaomicron* to endure during episodes of low nutrient availability when it turns to host polysaccharides as a nutrient source [50], contribute to the maintenance of microbial diversity within the system.

The combined activities of diverse members of the microbiota result in interactions that can be very complex, and involve multiple pathways for the processing of given substrates, including the reuse of fermentation products. Thus, there are multiple options for the fate of any given metabolite, and for the types of bacteria that will be involved. Bifidobacteria can ferment carbohydrates to produce lactate, which is then converted to either butyrate or propionate depending on the mix of species and the types of carbohydrate [53,54]. *Roseburia* and *Faecalibacterium* species (clostridial cluster XIVa) are key butyrate producers and are consumers of acetate [19]. They also produce H_2 that can be

consumed by acetogenic bacteria, so that in coculture with an acetogen, H_2 is consumed to produce acetate, which is then used as a substrate by the butyrate producer [19,55]. Methanogenic Archaea and sulfate-reducing bacteria compete with acetogens for H_2 – a competition that may be influenced by the pH of the gut, such that acetogens thrive in acidic conditions [56].

Changes in the chemical environment of the gut can not only alter the competitive balance between functionally redundant microbes, but can also impact the host. The activity of methanogens removes carbon from the system in the form of gas (CH_4) but also depletes the level of H_2, thereby enhancing the thermodynamic yield of the whole system (buildup of H_2 from microbial fermentation of polysaccharides slows down the process). Moreover, because short-chain fatty acids generated from polysaccharide fermentation are absorbed by the host, changes in the proportions of acetate, propionate, and butyrate produced in the gut can affect the overall energy balance of the host [57–59].

Linking phylogeny to function

Most phylotypes encountered in culture-independent surveys of the human gut microbiota lack cultured representatives so their role in the community is not known. New approaches for cultivation are yielding such organisms [19,60,61]. These methods include *gel microdroplet technology*, which allows high-throughput culture of microorganisms in a simulated natural environment, where cells are separated by emulsion but metabolites and signaling molecules can flow freely [62].

Researchers are also beginning to explore culture-independent approaches for linking phylotype identity and function [63]. These include tracking labeled substrates into cells in situ, a technique known as stable isotope probing [64]. Although stable isotope probing has yet to be used in vivo, it has been applied to a model intestine reactor inoculated with a human gut microbiota. The ^{13}C-labeled glucose was added and "heavy" (^{13}C-enriched) RNA identified the bacteria that fermented the glucose (the labeled RNA was recovered by ultracentrifugation through cesium chloride gradients; reverse transcription–PCR, cloning, and sequencing of the transcripts was used to ascertain which organism was using the labeled substrate. Further, the metabolic products have been identified by nuclear magnetic resonance spectroscopy [65]. Fluorescence in situ hybridization, flow cytometry, whole-genome amplification, and shotgun-sequencing have been used to obtain a partial genome sequence for a member of the TM7 phylum found in the mouth, providing a first look at a group of organisms with no available cultured representatives [66].

Prospectus

A better understanding of the intestinal microbial ecosystem is required to define health and characterize disease susceptibility, and to design, as well as predict, the outcome of therapeutic interventions, whether these interventions use prebiotics, probiotics, antibiotics, or man-made drugs. This will require greater understanding in several areas:

- interpersonal variability in gut microbiomes, in terms of both the organisms and gene lineages present and the metabolic functions
- variables controlling community membership, including age and aging, plus genetic, demographic, environmental, and lifestyle factors
- genetic and metabolic networks that are modulated by the microbiota.

To this end, the International Human Microbiome Project aims to sequence the genomes of multiple cultured representatives of the human (gut) microbiota, and to compare SSU rRNA and metagenomic data sets of the microbiomes of communities harvested from a range of locations along the cephalocaudal axis of the gastrointestinal tract of healthy subjects, including twin pairs and their mothers, as well as those with various diseases, such as inflammatory bowel disease. One key challenge will be to define "distances"; i.e., how similar or far apart are the microbiomes (and transcriptomes, proteomes, and metabolomes) of gut microbial communities from a single human, his or her relatives, and unrelated individuals, and how do differences manifest themselves on different timescales? With distances defined (e.g., using methods analogous to UniFrac), statistical tools will have to be developed to integrate the data sets into a unified framework that will facilitate the identification of the components of the microbiome that impact digestive health and disease. With a concerted, integrated interdisciplinary research effort directed to this complex and dynamic microbial organ, characterizing and deliberately manipulating its elements should one day be a part of the gastroenterologist's diagnostic armamentarium and therapeutic arsenal.

Phase 2 enzymes, 650
Phase 3: transporters, 651

General principles

In order for drugs to be absorbed when taken orally, they must generally be fat soluble (lipophilicity). Lipophilicity can also be an undesirable property for a drug. Once inside the body, lipophilic drugs tend to sequester into fat and bind in blood to plasma proteins and are therefore not readily eliminated in urine. If eliminated in bile, highly lipophilic drugs tend to be reabsorbed from the digestive tract and thus undergo enterohepatic cycling. For these reasons, most drugs that gain entry into the body would remain there for a long time if it were not for the body's ability to convert (metabolize) drugs into more water-soluble and hence more readily excreted metabolites. An additional critical process in elimination is active transport of drugs and their metabolites, which involves a growing list of membrane proteins. The liver is the major organ involved in drug metabolism and transport. For some xenobiotics, the small intestine also plays a major role.

Discovery of drug-metabolizing enzymes

A major breakthrough promoting study of drug metabolism was the development of techniques to isolate the endoplasmic reticulum from whole pieces of tissue. During this process, endoplasmic reticulum breaks up into small spheres called microsomes. It was discovered that under certain experimental conditions, liver microsomes could produce most of the metabolites generated from drugs (and other xenobiotics) by the liver in vivo. The reactions characterized generally involved insertion of an oxygen atom into the drug (usually a hydroxylation) or covalent binding (conjugation) of the drug to polar ligands such as glucuronic acid, sulfate, or glutathione. Many drugs had to first undergo hydroxylation in order to produce a reactive site on the molecule suitable for conjugation reactions. This typical sequence of events led to the division of xenobiotic metabolism into two categories: phase 1 (often hydroxylation reactions) and phase 2 (conjugation).

It is now appreciated that most (but not all) of what was described as phase I microsomal metabolism is the result of a large family of enzymes termed *cytochromes P450*, now referred to simply as P450s or CYPs (pronounced "sips").

Liver P450s

The vast majority of drugs in clinical use today are metabolized by liver P450s. Although 57 P450 genes have been identified [1], relatively few of these are important for drug metabolism [2]. The P450s involved in drug metabolism fall predominantly into three gene families, termed CYP1, CYP2, and CYP3 [3]. Within each P450 family, there are subfamilies designated by capital letters. Each subfamily generally contains multiple members, designated by Arabic numbers usually reflecting the order in which they were discovered.

A list of the major P450s involved in human drug metabolism is shown in Table 26.1. The most abundant single P450 in human liver is CYP3A4, and it has been estimated that this specific P450 may be involved in the metabolism of over 50% of drugs used clinically [4]. Only a few of the many substrates for CYP3A4 are listed in Table 26.1.

Some of the principles of P450 metabolism are shown in Fig. 26.1. Drugs either passively diffuse, or are actively transported, into the liver during passage through sinusoidal

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Table 26.1 Characteristics of major human liver P450s

P450	Substrates	Inhibitors	Inducers
CYP1A2	Tacrine Theophylline Tolcapone[a] Dihydralazine[a]	Fluvoxamine Cimetidine Ciprofloxacin	Cigarette smoke Charcoal-broiled foods Omeprazole
CYP2A6	Acetaminophen[a] [74] Halothane[a] Nicotine	8-Methoxy-psoralen	None known
CYP2B6	Efavirenz Bupropion Carbamazepine[a]	None known	Rifampin, phenytoin, carbamazepine, phenobarbital, St John's wort
CYP2C8	Paclitaxel Rosiglitazone	None known	Rifampin, phenytoin, carbamazepine, phenobarbital, St John's wort
CYP2C9	Diclofenac[a] Warfarin Tienilic acid[a] Phenytoin	Fluvoxamine	Rifampin, phenytoin, carbamazepine, phenobarbital, St John's wort
CYP2C19	Omeprazole Mephenytoin Diazepam Phenytoin[a]	Sulfinpyrazone Ticlopidine Fluvoxamine	None identified
CYP2D6	Debrisoquine Dextromethorphan Metoprolol and other β-blockers Perhexiline Amitriptyline and other neuroleptics Encainide Codeine	Fluoxetine and other SSRIs Quinidine	None identified
CYP2E1	Acetaminophen[a] Ethanol Tolcapone[a] Isoniazid[a] Halothane[a]	Disulfiram Ethanol	Ethanol Isoniazid
CYP3A4	Erythromycin Cyclosporine Docetaxel Carbamazepine[a] Midazolam/triazolam Lovastatin and other statins Saquinavir and other protease inhibitors Trazodone[a] Nefazodone[a] Troglitazone[a]	Ketoconazole (other azoles) Troleandomycin Rotinavir	Rifampin, phenytoin, carbamazepine, phenobarbital, St John's wort
CYP3A5	Similar to CYP3A4	Similar to CYP3A4	None identified

a Drugs metabolized to reactive metabolites implicated in hepatotoxicity.
SSRI, selective serotonin reuptake inhibitor.

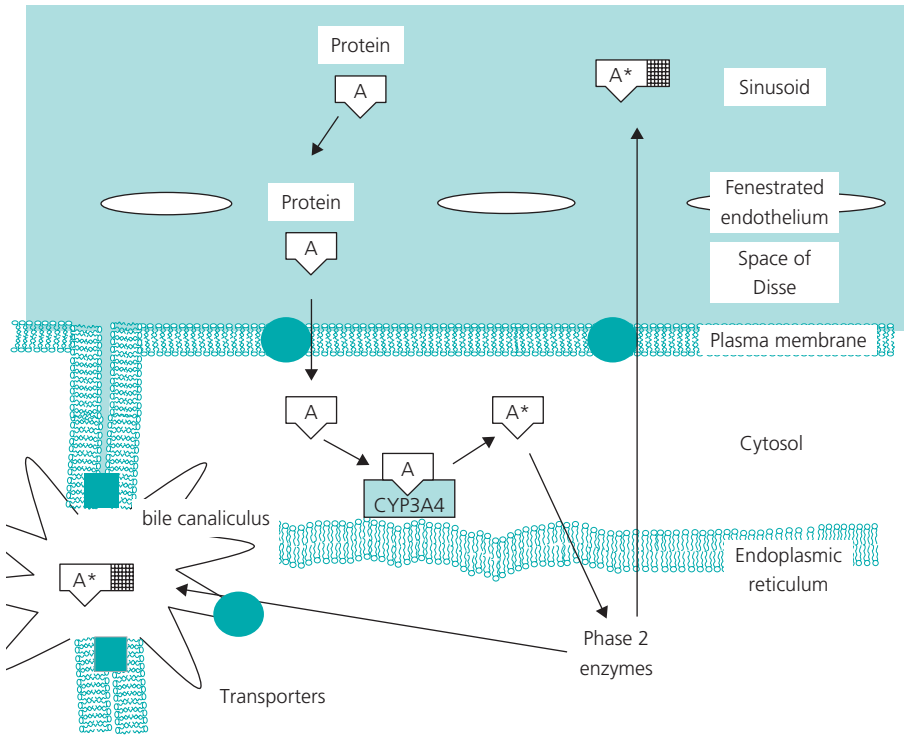

Figure 26.1 Elimination of drugs by the hepatocyte. Lipophilic drugs, such as drug A, exist in sinusoidal blood largely bound to proteins. Drugs can diffuse through the endothelial cell fenestrations into the space of Disse while still protein bound. Drugs then enter the hepatocyte by active transport, or passive diffusion. Once inside the cell, a drug will typically encounter a specific P450 (CYP3A4 in this example) capable of binding to the drug, and converting it to more water-soluble and chemically reactive metabolites (A*). This is referred to as Phase 1 metabolism. Typically, the resultant metabolite undergoes conjugation to a polar ligand in a reaction catalyzed by Phase 2 enzymes. The resultant conjugated metabolite is then secreted by efflux transporters into the biliary canaliculus for elimination in bile, or it will be secreted back into sinusoidal blood (also by efflux transporters) for ultimate excretion in urine. Efflux of metabolites from the hepatocyte is commonly referred to as Phase 3; the dark circles indicate efflux transporters.

blood (illustrated by drug A in Fig. 26.1). Once inside the liver, drugs diffuse to the particular P450s capable of metabolizing them. With some drugs, a single P450 is involved in the majority of the metabolism. The P450 inserts an oxygen atom into the drug, usually in the form of a hydroxyl group. In some cases, however, the immediate product of P450 catalysis is unstable, and rearrangement of the molecule (such as *N*-dealkylation) can rapidly occur.

Intestine P450s

P450 enzymes are detectable throughout the human digestive tract, including the esophagus, stomach, small bowel, and colon [5]. The concentration of total P450 enzymes is highest in the jejunum, and gradually declines to lower levels in the ileum and colon. The major P450 in small bowel enterocytes is CYP3A4, which accounts for at least 70% of the total P450 [6,7]. Other P450s detected in the digestive tract include CYP3A5, CYP2C9, CYP2C19, and CYP1A1 [8,9]. Notably, CYP2C8, CYP2B6, CYP1A2, and CYP2E1 have not generally been detected in the intestine. In most cases studied, P450s are not found in the intestinal crypt cells but appear, probably as a result of transcriptional activation of the corresponding genes, as the epithelial cells migrate out of the crypt toward the villus tip. This location is appropriate for metabolism of xenobiotics in the gut, because absorption is thought to occur chiefly in the upper part of the villus.

The only intestinal P450 shown to catalyze significant drug metabolism is CYP3A4. This was originally demonstrated by intrajejunal administration of the CYP3A4 substrates cyclosporine (ciclosporin) [10] and midazolam [11] during the anhepatic phase of the liver transplant operation. In each case, up to 50% of detectable drug absorbed into portal blood had been converted into metabolites characteristically produced by CYP3A4. Other studies quantitated intestinal metabolism by administering unlabeled and stable-labeled CYP3A4 substrates by intravenous and oral routes, respectively. Such studies have shown that the intestine is a major site for metabolism of verapamil [12] and midazolam [13].

The importance of intestinal CYP3A4 has also been highlighted by drug interactions produced by grapefruit juice [14,15]. A growing number of drugs have enhanced oral availability when consumed with grapefruit juice (compared with water or orange juice) (Table 26.2). This interaction has been shown to result from both competitive and mechanism-based inhibition of CYP3A4. In addition, the enterocyte content of CYP3A4 actually falls within hours of drinking a single glass of grapefruit juice [16,17], presumably because the inactivated enzyme undergoes rapid intracellular degradation [17]. The ingredients in grapefruit juice responsible for CYP3A4 inhibition appear to be furanocoumarins (also called psoralens) [17–19]. Furanocoumarins are not present in most other types of fruit juice. Grapefruit juice does not appear to inhibit liver CYP3A4, at least when consumed in usual quantities [15,16]. This presumably reflects insufficient

Table 26.2 Some drugs affected by grapefruit juice

Drug	Mean fold increase in AUC[a]	Reference
Simvastatin	13.5	Lilja et al., 2000 [141]
Lovastatin	15.0	Kantola et al., 1998 [142]
Atorvastatin acid	1.8	Ando et al., 2005 [143]
Midazolam	1.5	Kupferschmidt et al., 1995 [144]
Triazolam	1.5	Hukkinen et al., 1995 [145]
Saquinavir	2.0	Kupferschmidt et al., 1998 [146]
Halofantrine	2.8	Charbit et al., 2002 [147]
Nifedipine	3.0	Bailey et al., 1991 [148]
Carbamazepine	1.5	Garg et al., 1998 [149]
Buspirone	9.2	Lilja et al., 1998 [150]
Cyclosporine	1.6	Yee et al., 1995 [151]

a Area under the blood concentration vs time curve divided by that observed when drug was taken with water or orange juice.

concentrations of furanocoumarins reaching the liver after absorption. Grapefruit juice can therefore be used experimentally to knock out intestinal CYP3A4 (although it may affect some drug transporters as well) [20,21]. If grapefruit juice does not affect the oral availability of a drug, then intestinal CYP3A4 cannot be contributing much to first-pass metabolism.

The aggregate CYP3A4 in the intestine is probably less than 10% of that in the liver [22]. For significant metabolism to occur in the intestine, it seems likely that a drug must be very rapidly metabolized by CYP3A4, be administered in relatively small amounts, or have a prolonged absorption phase (i.e., prolonged contact with the enzyme). It has been proposed that the physiological role of intestinal CYP3A4 may primarily be to limit entry into the body of potentially harmful dietary compounds. One study [23] suggested that CYP3A4 may convert aflatoxin B1 to reactive metabolites that bind to macromolecules within enterocytes. This, in effect, traps the metabolites within the cells. As the enterocytes are normally sloughed into the digestive tract, the aflatoxin metabolites are eliminated in stool.

Interindividual differences in P450 activity

Although elimination of drugs generally requires multiple processes (Fig. 26.1), the rate-limiting step is often conversion to metabolites by P450s. Hence, interpatient differences in the activity of a certain P450 can account for variation in the pharmacokinetics of drugs metabolized by that P450 [24,25]. In some cases, variation in P450 activity is due to genetic polymorphisms in the P450 genes. For example, approximately 5% of whites completely lack CYP2D6 activity and therefore are CYP2D6 *poor metabolizers* [26]. Patients who are CYP2D6 poor metabolizers have increased sensitivity to the effects of several drugs, including some medications commonly used to treat cardiac arrhythmias, psychosis, and depression. The incidence of CYP2D6 poor metabolizers varies substantially across different ethnic populations [27]. For example, poor metabolizers are present in less than 1% of Japanese. It should also be noted that 5% of whites have gene duplication of CYP2D6 resulting in an *ultrarapid metabolizer* phenotype [26]. These individuals exhibit unusually rapid clearance of at least some CYP2D6 substrates, and this can account for therapeutic failure of some medications.

CYP2C19 activity is absent in approximately 5% of whites, but absent in up to 20% of Asians [27]. CYP2C19 poor metabolizers have been shown to have higher blood levels of omeprazole than others when treated with usual therapeutic doses [28]. This is expected since omeprazole relies on CYP2C19 for its elimination (Table 26.1). This appears to explain why CYP2C19 poor metabolizers have a higher cure rate for *Helicobacter* infection when treated with omeprazole-containing regimens [28].

Allelic variation can result in diminished catalytic function of other P450s, including CYP2C9, resulting in exaggerated effects of warfarin and phenytoin [29,30]; CYP2A6, which may influence cigarette smoking behavior [31]; and CYP2B6, which appears to influence response to efavirenz. [32]. Polymorphisms that appear to affect CYP3A4 activity have been identified [33] and, although not yet linked to drug pharmacokinetics, may be associated with risk of certain cancers [34]. In addition, approximately 20% of whites and 50% of African Americans express CYP3A5 in liver and intestine, and this enzyme appears to metabolize most of the same substrates as CYP3A4. Patients who express CYP3A5 generally have increased dosing requirements for tacrolimus and several other drugs [21,35].

Nongenetic factors such as concomitant disease, diet variation and malnutrition can also underlie large interindividual differences in the activities of liver P450s [36,37]. Diet also likely largely explains why, for a given individual, the relative activity of CYP3A4 in liver does not correlate well with the relative activity of CYP3A4 in the intestine [38,39]. In rats, ethanol treatment and removal of iron or selenium from the diet results in marked reduction in intestinal P450 activity while having little effect on P450 activity in the liver [40–42], a phenomenon similar to the effect of grapefruit juice [15].

Drugs represent an additional cause for nongenetic variation in activity of P450s. This is the basis for many drug interactions.

P450s and drug interactions

Many drug interactions are explained by the ability of one drug to inhibit a P450 involved in the metabolism of another

drug. Inhibition of P450 activity can occur by a variety of mechanisms [43] but the most common form of inhibition reflects simple competition between two drugs for metabolism by the same P450 (i.e., one drug interferes with the ability of the other drug to bind to the substrate-binding site of the P450, reducing its rate of metabolism by the enzyme). Whether two drugs vying for metabolism by the same P450 will result in a clinically important interaction depends on a number of factors. These include the intracellular concentrations of each drug, the relative affinities of each drug for binding to the enzyme active site, and the importance of the P450 to the overall elimination of the drug, Additional important variables are the relative safety (therapeutic index) of the drugs involved and whether the metabolites generated by the P450 are pharmacologically active.

Some clinically important interactions involving inhibition can be inferred from Table 26.1. For example, when patients treated with tricyclic antidepressants are also started on certain selective serotonin reuptake inhibitors (SSRIs), blood levels of the tricyclics will tend to rise due to CYP2D6 inhibition [44]. Of course, patients who are CYP2D6 poor metabolizers will not experience this drug interaction; the inhibition of CYP2D6 by another drug in effect turns a patient into a CYP2D6 poor metabolizer, a process termed *phenocopying*. In addition, cyclosporine blood levels can rise to toxic levels in organ transplant recipients who receive concomitant treatment with erythromycin or ketoconazole and this appears to largely result from inhibition of CYP3A4 [45]. Many interactions between drugs used in HIV patients involve P450 inhibition [46]. Ritonavir is a potent inhibitor of CYP3A4 and is used to boost blood levels of certain protease inhibitors [47]. Some drug interactions involving inhibition of CYP3A4 can largely occur in the intestine, presumably due to higher concentration of the inhibitor at that location after oral delivery [13].

Some medications are such potent and selective inhibitors of specific P450s that they can be used in experimental settings to pharmacologically knock out the enzyme in a human subject. The drugs most frequently used to intentionally inhibit specific P450s are noted in Table 26.1. If elimination of a drug is not affected by the inhibitor, then it can be assumed that the inhibited P450 does not represent a major pathway for elimination of that drug. Some of the most useful P450 inhibitors are not competitive inhibitors but mechanism-based inhibitors [43,48]. Mechanism-based inhibition is irreversible, and occurs when the inhibitor is converted by the target P450 to a metabolite that damages the enzyme, often by covalently binding to the enzyme protein. This appears to be the mechanism by which a single therapeutic dose of disulfiram (Antabuse) results in greater than 90% inhibition of CYP2E1 activity which lasts for hours [49]. Another example of a potent mechanism-based inhibitor is the antibiotic troleandomycin which, when administered in the usual therapeutic dose, produces greater than 90% reduction in liver CYP3A4 activity that also persists for hours [50]. Examples of other mechanism-based inhibitors include the CYP1A2 inhibitor furafylline [51] and the CYP2A6 inhibitor methoxsalen [52].

In addition to inhibition, a medication can sometimes result in an increase in the activity of a particular P450. In most cases, this induction results from increased hepatocyte concentrations of a specific P450. Some medications that can induce P450s are listed in Table 26.1. Induction of P450 activity can occur by several mechanisms, but most commonly reflects an increase in the rate of transcription of the corresponding gene [53]. In some instances, the cellular receptor involved in transcriptional activation of P450s has been identified [54]. For example, induction of CYP3A4 by rifampin, some antiseizure medications, and St John's wort appears to involve a nuclear receptor termed the human pregnane X receptor (PXR) [55], also termed the steroid xenobiotic receptor (SXR) [56] or the pregnane-activated receptor (PAR) [57]. The inducing drug binds PXR and then forms a heterodimer with another receptor (RXR). The complex then binds to regulatory elements in the *CYP3A4* gene. This results in increased transcription of the *CYP3A4* gene, which in turn results in increases in the hepatocyte concentration of CYP3A4 [54]. It appears that PXR also mediates induction of CYP2B6, CYP2C9, and CYP2C19 by rifampin and certain antiseizure drugs in both liver [58–60] and intestine [61,62]. Some drug interactions due to induction of CYP3A4 can chiefly result from increased intestinal metabolism [63].

Induction of CYP1A2 involves a different receptor termed the aryl hydrocarbon (Ah) receptor [64]. Aryl hydrocarbons in cigarette smoke and the drug omeprazole (in high doses) bind to the Ah receptor, mediating transcription of the *CYP1A2* gene and increased production of the enzyme. This accounts for why cigarette smokers tend to require higher doses of theophylline, tacrine, and clozapine [65]. Some P450s, such as CYP2D6, CYP2A6 and CYP3A5, do not appear to be inducible.

Other examples of clinically significant drug interactions resulting from induction can also be deduced from Table 26.1. When transplant recipients are treated with rifampin or certain antiseizure medications, blood levels of cyclosporine can fall to subtherapeutic levels due largely to induction of CYP3A4 [45]. These patients risk organ rejection unless their daily dose of cyclosporine is increased. Likewise, individuals treated with rifampin or antiseizure drugs risk therapeutic failure of oral contraceptives due to induction of CYP3A4 and probably other enzymes and may require increased doses of warfarin (due to CYP2C9 induction) [66–68]. As with inhibition, induction can also be used to assess the contribution of an inducible P450 to the disposition of a drug. For example, if treatment of subjects with rifampin does not increase clearance of a drug, it is unlikely that CYP3A4 is a major pathway for metabolism.

CYP1A1 is not detectable in liver and is generally at low levels in the intestine. However, consumption of chargrilled meats causes marked induction of the enzyme in the intestine [69]. Some evidence suggests that induction of CYP1A1 in small intestine may be protective by reducing absorption of potentially harmful substances present in chargrilled meats, including polyaromatic hydrocarbons [69].

P450s and drug-induced liver injury

It is generally believed that liver injury results from reactive metabolites generated in the liver from otherwise harmless drugs [70]. The identical P450s involved in the safe metabolism of drugs are those that have been most implicated in the production of hepatotoxic metabolites [71] (see Table 26.1 for examples). In general, P450s are expressed in highest concentration in zone 3 hepatocytes, and this partly accounts for the predominance of pericentral (zone 3) necrosis in some forms of drug-induced liver injury (such as that due to acetaminophen) [72]. Interspecies differences in P450 catalytic activities and regulation probably contribute to the imperfect ability of preclinical animal studies to identify human hepatotoxins [71].

Several methods have been used to determine which P450 is responsible for production of toxic metabolites. For example, if an antibody or chemical that specifically inhibits a certain P450 causes significant reduction in the production of the reactive metabolite in liver microsomes, it is assumed that this P450 is involved [73]. In some instances, it is possible to use selective P450 inhibitors to identify the responsible P450s in clinical studies. This strategy is suggested by the listing of specific inhibitors in Table 26.1. For example, acetaminophen is believed to cause toxicity in the liver due to production of the *N*-acetyl-*p*-benzoquinone imine (NAPQI) metabolite. The total production of NAPQI from an oral dose of acetaminophen can be estimated from the production of thiol metabolites eliminated in urine. When healthy volunteers were given a dose of acetaminophen together with a CYP2E1 selective inhibitor (disulfiram), urinary production of NAPQI derivatives fell an average of 69% [74], indicating a major role for CYP2E1 in the production of this metabolite. In contrast, treatment with rifampin, which would induce multiple other P450s (Table 26.1), did not increase urinary elimination of the thiol metabolites [74].

Similar clinical research has been done with halothane. Severe halothane liver toxicity is thought to result from metabolism to a trifluoroacetyl (TFA) intermediate which becomes trifluoroacetic acid that can be readily measured in plasma and urine [75]. Plasma and urine levels of trifluoroacetic acid fell 70% when patients receiving halothane anesthesia were pretreated with the CYP2E1 inhibitor disulfiram [76]. A small reduction in TFA production was also observed when these patients were pretreated with the CYP2A6 inhibitor 8-methoxsalen, but no change was observed after treatment with troleandomycin, a potent inhibitor of CYP3A4 [77]. These studies indicate that the major enzyme involved in the production of the TFA intermediate from halothane in vivo is CYP2E1, with a minor contribution from CYP2A6 and no contribution from CYP3A4.

Anti-P450 antibodies are sometimes also present in patients recovering from liver injury caused by some drugs [78]. In at least some instances, it appears that the antibodies are generated to P450s that are covalently bound to reactive metabolites produced from these drugs. The presence of these antibodies may therefore indicate which P450 is involved in producing reactive metabolites, and may also be helpful in causality assessment. Unfortunately, anti-P450 antibodies have been associated with only a few types of drug-induced liver injury and work in this area remains experimental.

Phase 2 enzymes

In general, phase 2 enzymes have not been as well characterized as the P450s. The best-studied phase 2 enzymes are the uridine 5′-diphosphate (UDP)-glucuronosyltransferases, the glutathione *S*-transferases, and the sulfotransferases, which catalyze conjugation to glucuronic acid, glutathione, and sulfate, respectively. *N*-Acetyltransferases and thiopurine methyltransferase are also discussed.

UDP-glucuronosyltransferases

Conjugation to glucuronic acid results in enhanced water solubility; for this reason, glucuronide conjugates are usually readily excreted into urine. Glucuronide conjugates are also excreted into the bile and, because of their water solubility, generally pass in the stool unless deconjugated by colonic bacteria. In addition, glucuronidation generally results in reduced pharmacological activity. However, glucuronides can occasionally retain pharmacological activity. An example of this is morphine glucuronide, which has roughly 50-fold greater opioid activity than morphine itself [79].

As with the P450s, the UDP-glucuronosyltransferases (UGTs) arise from a multigene family of microsomal enzymes, some of which are inducible [80]. UGT genes comprise two families termed UGT1 and UGT2. The UGT1 family contains eight enzymes (designated by Arabic numerals) and the UGT2 family contains seven enzymes. There is considerable catalytic specificity of UGTs toward drugs, although such characterization is progressing relatively slowly. One problem has been that unlike P450s, which exist on the outside of microsomes, the UGTs are present on the inside of the microsomes. It is therefore often necessary to permeablilize microsomes to assess UGT activity, and this may introduce problems in data interpretation [81].

The complement of UGTs expressed in liver and intestine is not identicial [82]; there are liver UGTs that do not appear

to be expressed in the digestive tract (such as UGT2B4) and other UGTs expressed in intestine but not liver (such as UGT1A8). It has been proposed that UGTs present in the colon may provide a protective function by glucuronidating compounds that are deconjugated by colonic bacteria [83].

Multiple polymorphisms of the UGT1 family have been identified [80]. The best-studied polymorphisms involve UGT1A1, which is the enzyme primarily responsible for bilirubin conjugation. Variation in the *UGT1A1* gene have been shown to account for Gilbert and Crigler–Najjar (types 1 and 2) hyperbilirubinemia and have been associated with toxicity from irinotecan [84]. Drug interactions due to alterations in UGT activity have been described. For example, anticonvulsants have been shown to induce some UGTs and may account for some drug interactions, particularly in patients treated for HIV [85]. Induction of UGTs can involve several receptors, including PXR, CAR, and the Ah receptor [54]. Inhibition of UGTs has been proposed to account in part for the pharmacokinetic interaction between gemfibrozil and cerivastatin [86] and for a few other drug–drug interactions [87]. Nonetheless, it appears that drug interactions due to induction or inhibition of UGTs are generally of low magnitude and rarely clinically significant [88].

Some glucuronides (particularly acyl glucuronides) have been shown to be reactive molecules, and may be involved in drug-induced liver injury [89]. For example, a glucuronide metabolite of diclofenac has been shown to covalently bind multiple proteins in the hepatocyte, and this covalent binding may contribute to hepatotoxicity rarely associated with this drug [90].

Glutathione *S*-transferases

Glutathione *S*-transferases (GSTs) involved in liver or intestinal drug metabolism are cytosolic enzymes belonging to eight separate gene families designated α, μ, θ, π, ζ, σ, κ, and ω [91]. Each family has several members designated by arabic numbers. For example, GSTM1 is the first of five members of the μ gene family. GSTs are expressed in many organs in addition to liver and intestine. The complement of GSTs present in liver and intestine is not identical [92]. GSTs typically function to detoxify electrophilic metabolites of drugs, such as the reactive metabolite produced from acetaminophen (NAPQI). In general, the reactions catalyzed by GSTs are not rate limiting in drug elimination. An exception may be busulfan, which requires glutathione conjugation catalyzed by GSTA1 for elimination. Studies have suggested that busulfan oral availability is limited by GST1A1 activity in the intestine [93].

Polymorphisms in GSTs are common [94]. GSTM1 and GSTT1 are absent in 40% and 15% of whites, respectively. Polymorphisms in these and other GSTs have been linked to susceptibility to a variety of diseases, including asthma, cancer, diabetes, heart disease, and drug-induced liver injury. An example of the latter is hepatotoxicity due to tacrine; patients who lack both GSTM1 and GSTT1 appear to have increased incidence of treatment-associated ALT elevations [95].

Sulfotransferases

Human liver and intestine are capable of sulfating a variety of xenobiotics using sulfotransferases (SULTs). This usually enhances solubility and decreased biological activity. In humans, there are three SULT families, SULT 1, SULT 2, and SULT 4, which contain at least 13 members [96]. The catalytic activity of the sulfotransferases varies considerably among individuals, and polymorphisms in specific sulfotransferases have been identified. Some sulfotransferases are inducible, at least in liver, and this appears to involve the same nuclear receptors involved in P450 and UGT induction [97]. For example, one study suggested that the loss of efficacy of birth control pills during treatment with antiseizure medications or rifampin may be due to induction of sulfation, and not just induction of CYP3A4 (Table 26.1) [98].

N-Acetyltransferases

There are two *N*-acetyltransferase enzymes termed NAT1 and NAT2. NAT2 is polymorphic; up to 50% of whites lack NAT2 activity and are therefore slow acetylators [99]. Slow acetylators have reduced clearance of isoniazid and sulfamethoxazole and may therefore be at higher risk of dose-dependent toxicities from these drugs. The data suggest that slow metabolizers are probably more susceptible to idiosyncratic hepatotoxicity from isoniazid, especially when risk is adjusted for a CYP2E1 polymorphism [100]. NAT2 polyumorphism has also been linked to susceptibility to certain cancers. Slow acetylators appear to be at higher risk for bladder cancer but at lower risk for colon cancer [101].

Thiopurine methyltransferase

Thiopurine methyltransferase (TPMT) catalyzes the *S*-methylation of the thiopurine drugs mercaptopurine, azathioprine, and thioguanine. The methylated products are pharmacologically inactive. There exists a genetic polymorphism in TPMT such that 0.3% of whites completely lack the enzyme (10% have reduced activity) [102]. Children with certain childhood leukemias and who are deficient in TPMT activity exhibit life-threatening myelosuppression when receiving standard doses of thiopurine drugs [103]; screening for TPMT deficiency is therefore recommended. The role for screening patients treated with lower doses of thiopurines, such as patients with autoimmune hepatitis and inflammatory bowel disease, is controversial [104,105].

Phase 3: transporters

The ability of many and perhaps most drugs to cross cell membranes relies on specific transport proteins that can be

Table 26.3 Characteristics of some major human drug transporters

Protein	Substrates	Inhibitors	Inducers
Uptake			
OATP1B1 (SLC1B1)	Cerivastatin, pravastatin, rifampin, hormone conjugates	Gemfibrozil	Unknown
OATP1A2	Fexofenadine	Citrus juices	Unknown
OAT4 (SLC22A1)	Tetracycline, ketoprofen, zidovudine	Unknown	Unknown
Efflux			
MDR1 (ABCB1)	Digoxin, cyclosporine, fexofenadine, paclitaxel, erythromycin, HIV protease inhibitors, loperamide, simvastatin acid	Quinidine, itraconazole, clarithromycin, verapamil	PXR activators[a]
MRP2 (ABCC2)	Irinotecan, methotrexate, vinblastine, mycophenolate, many phase 2 metabolites	Cyclosporine	Unknown
MRP3 (ABCC3)	Methotrexate, doxorubicin, vincristine, acetaminophen glucuronide	8-Methoxy-psoralen	PXR activators[a]
BCRP (ABCG2)	Methotrexate, doxorubicin, topotecan, irinotecan active metabolite (SN-38)	Omeprazole, pantoprazole	PXR activators[a]

a Presumed inducers would include rifampin, phenytoin, carbamazepine, phenobarbital and St John's wort.

divided into two functional categories: efflux transporters and uptake transporters.

Efflux transporters

It has long been appreciated that elimination of drugs and metabolites into bile must involve active transport mechanisms, and the specific proteins involved have now been identified. Some properties of major efflux transporters are listed in Table 26.3. The major canalicular drug transporters that have been identified are the multidrug resistance protein (MDR)1, multidrug resistance associated protein (MRP)2, and the breast cancer resistance protein (BCRP) (Fig. 26.2). As their names suggest, each of these transporters was first discovered in cancer cells as a basis for resistance to multiple chemotherapies [106–108]. Each of these transport proteins utilize ATP and are members of the ATP-binding cassette (ABC) superfamily, which accounts for the gene nomenclature (Table 26.3). MDR3 transports phospholipids and bile salt excretory protein (BSEP) transports bile acids. Polymorphisms in MDR3 have been linked to intrahepatic cholestasis of pregnancy [109] and polymorphisms in BSEP have been linked to inherited forms of cholestasis [110].

MDR1, MRP2, and BCRP are also expressed in the apical membrane of enterocytes, where they function to reduce or prolong absorption by pumping drugs or their metabolites back into the intestinal lumen. It has been proposed that the transporters and metabolizing enzymes function synergistically in the intestine to limit entry of potentially harmful xenobiotics in the diet [111,112]. It also seems likely that inhibitors of these transporters could be added to certain drug formulations to improve oral availability [113].

MRP3, MRP4, MRP5, and MRP6 are also efflux transporters and function to pump drugs and metabolites from within the hepatocyte into the space of Disse. For example, MRP3 largely accounts for efflux of acetaminophen glucuronide into sinusoidal blood after it is formed in the hepatocyte [114].

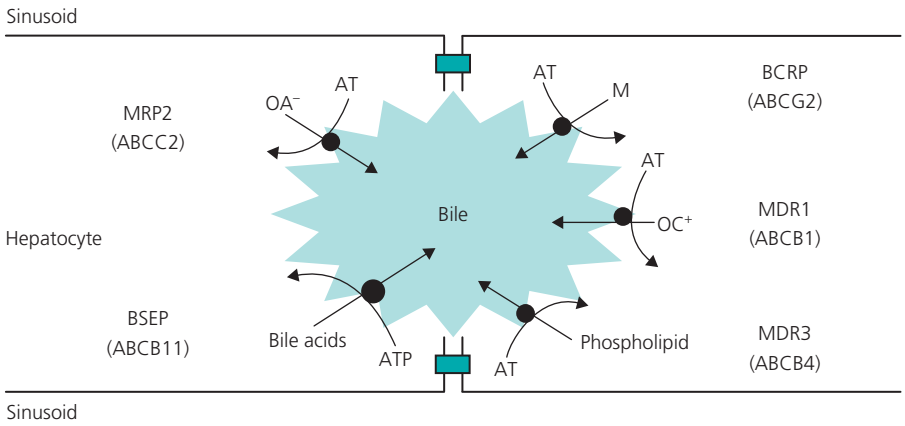

Figure 26.2 Basolateral membrane transport proteins in the hepatocyte. The basolateral membrane contains both efflux and uptake transporters that largely control the entrance and exit of drugs and their metabolites. The major transporters involved in uptake of drugs belong to the OAT and OATP families. The major drug efflux transporters are members of the MRP family and MDR1. Adapted from Chandra & Brouwer [152].

Some of these transporters also appear to be present in enterocytes, where they aid absorption by pumping drugs into the body across the basolateral membrane [115]. Characterization of the substrates for these transporters is an active area of investigation.

Uptake transporters

Uptake of drugs into hepatocytes and enterocytes also involves transporters. Major liver uptake transporters are shown in Fig. 26.3. Uptake transporters do not utilize ATP but sodium independent cotransport (the gene designation SLC stands for *solute carrier*). The best-characterized uptake transporters in liver are the organic anion transporting polypeptides (OATP) and the organic anion transporters (OAT). The sodium taurocholate cotransporting polypeptide (NTCP) transports bile acids into the hepatocyte and the organic cation transporters (OCT) in liver are not well characterized. Only some OATP and OAT transporters are present in the intestine. In addition, there are intestine-specific transporters such as PEPT1, which is involved in the absorption of various peptide drugs, including some cephalosporin antibiotics [116]. One strategy is to improve absorption of some drugs by linking them to peptide substrates for PEPT1 [115].

Drug transporters as a basis for interpatient variation in pharmacokinetics and drug interactions

As previously discussed, it is believed that metabolism catalyzed by cytochrome P450s is generally rate limiting in the elimination of drugs. However, it is becoming clear that transporters may be rate limiting in the elimination of some drugs and their metabolites. Genetic polymorphisms have been reported for most of the efflux and uptake transporters discussed above, and emerging data suggest that polymporphisms can partly account for interpatient variation in efficacy and/or safety of some drugs [117], including simvastatin [118], pravastatin [119], cyclosporine [120], and nelfinavir [121]. Some of these polymorphisms have also been linked to susceptibility to certain diseases, including inflammatory bowel disease [122]. Genetic deficiency in MRP2 activity appears to account for Dubin–Johnson syndrome [123]. Given the broad substrate specificity of this transporter, it is somewhat surprising that patients with Dubin–Johnson syndrome have not yet been reported to be sensitive to any drugs.

It is also clear that some drug interactions can occur because of inhibition or induction of transporters [124], and these can be inferred from Table 26.3. For example, gemfibrozil inhibits OATP1B1 [125] and this may partly account for the increased incidence of muscle injury observed in patients concomitantly receiving gemfibrozil and cerivastatin [126]. Some interactions thought to be due to inhibition or induction of CYP3A4 may result in part by inhibition or induction of MDR1. For example, terfenadine is metabolized by CYP3A4 to the pharmacologically active antihistamine fexofenadine, which is largely eliminated from the body unchanged. Terfenadine blood levels rose to sometimes dangerous levels in patients treated with CYP3A4 inhibitors (including macrolide antibiotics such as clarithromycin and itraconazole) [127] and it was assumed that this predisposition would be removed by replacing terfenadine with fexofenadine. However, most of the drug interactions described with terfenadine were still observed with fexofenadine. Fexofenadine is a substrate for MDR1, and the similarity in drug interactions between fexofenadine and terfenadine likely results because potent inhibitors of CYP3A4 also inhibit MDR1 [128]. In addition, lower blood levels of fexofenadine were observed during treatment with rifampin [129] and other PXR activators [130] and this appears to be

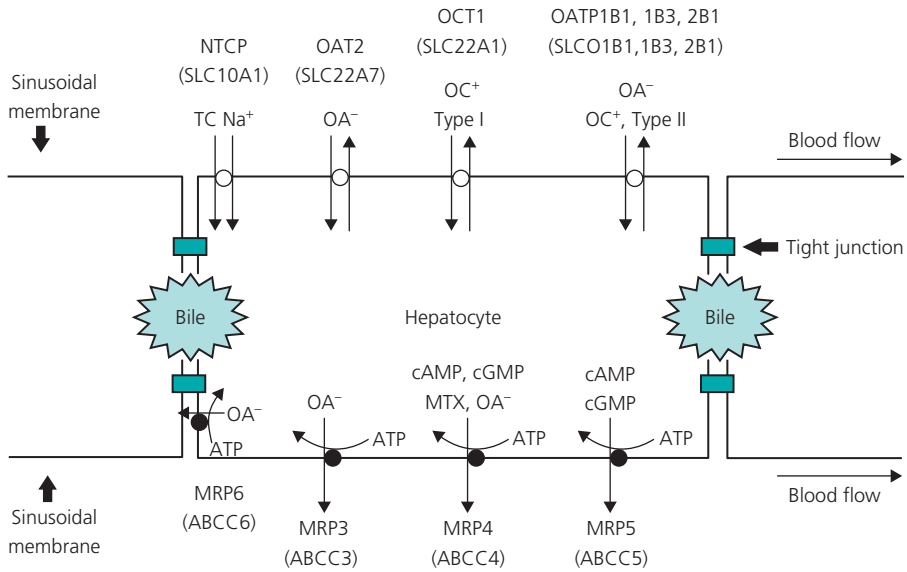

Figure 26.3 Canalicular efflux transporters. The major canalicular efflux transporters that pump drugs and metabolites into bile are MDR1, MRP2, and BCRP. Adapted from Chandra & Brouwer [152].

explained by PXR-mediated induction of MDR1. MDR1 induction in the intestine also appears to significantly contribute to reduction in erythromycin blood levels during treatment with rifampin [131] and may well contribute to interactions between PXR activators and other dual CYP3A4/MDR1 substrates (such as cyclosporine) [132]. Evidence suggests that MRP3 and BRCP are also part of the cassette of genes that are transcriptionally activated by PXR, although the clinical relevance of this remains unclear [133].

Some drug interactions involving uptake transporters appear to largely occur in the intestine. For example, several citrus juices enhance the oral availability of fexofenadine and this appears to result from inhibition of OATP1A2 by as yet unidentified substances [134].

Role of transporters in drug-induced liver injury

It seems reasonable to assume that transporters will be found to play important roles in mechanisms underlying drug-induced liver injury, although work is just beginning in this area. For example, it has been shown that certain drugs inhibit BSEP and thereby lead to accumulation of potentially toxic bile acids within the hepatocyte [135]. This has been proposed as a mechanism underlying hepatotoxicity of bosentan [136] and troglitazone [137]. One study demonstrated that a major metabolite of troglitazone (M-1) potently inhibited some OATPs and proposed that this may contribute to the hepatotoxicity observed with this compound [138].

Transporters may also be involved in helping the hepatocyte recover from drug-induced liver injury. For example, during recovery from hepatotoxicity due to acetaminophen or carbon tetrachloride, there is downregulation of several hepatic OATPs and upregulation of MRP3 and MRP4 in rodents [139]. This presumably protects the injured cell from further drug injury by decreasing uptake and increasing efflux of the drugs and their metabolites. One study has suggested similar changes in transporter expression during liver injury in humans [140].

Overview of liver fibrosis

Liver fibrosis is the accumulation of extracellular matrix (ECM) proteins, mainly collagen, that occurs in most types of chronic liver disease [1]. The main causes of liver fibrosis in industrialized countries include chronic hepatitis C virus (HCV) infection, alcohol abuse, and nonalcoholic steatohepatitis (NASH). The accumulation of ECM proteins distorts the hepatic architecture by forming a fibrous scar and the subsequent development of nodules of regenerating hepatocytes defines cirrhosis [2]. Cirrhosis produces hepatocellular dysfunction and increased intrahepatic resistance to blood flow, resulting in hepatic insufficiency and portal hypertension, respectively.

Hepatic fibrosis was historically thought to be a passive and irreversible process, due to the collapse of the hepatic parenchyma and its substitution by a collagen-rich tissue [3]. Currently, it is considered a model of the wound healing response to chronic liver injury [4]. Liver fibrosis received little attention until the 1980s, when the hepatic stellate cell (HSC), formerly known as the lipocyte, Ito cell or perisinusoidal cell, was identified as the main collagen-producing cell in the liver [5]. This cell type, first described by von Kupffer in 1876, undergoes a dramatic phenotypic activation in chronic liver diseases with the acquisition of fibrogenic properties [6]. The molecular mechanisms leading to HSC activation and increased collagen synthesis in liver fibrosis have been identified using cultured HSCs and experimental models of chronic liver injury in rodents [7,8]. Besides HSCs, portal myofibroblasts and cells of bone marrow origin have also been shown to have fibrogenic potential [9]. The demonstration that even advanced liver fibrosis is reversible has greatly stimulated researchers to identify antifibrotic therapies [10]. However, the most effective therapy to treat hepatic fibrosis is still to remove the causative agent [11]. A number of drugs are able to reduce the accumulation of scar tissue in experimental models of chronic liver injury. Renin–angiotensin system blockers and antioxidants are promising drugs, yet evidence-based therapies are not yet available [12].

The onset of liver fibrosis is usually insidious and most of the related morbidity and mortality occur after the development of cirrhosis [13]. In the majority of patients, progression to cirrhosis occurs after an interval of 15–20 years. The natural history of liver fibrosis is influenced by both genetic and environmental factors. Epidemiological studies have identified polymorphisms in a number of candidate genes that may influence the progression of liver fibrosis in humans [14]. These genetic factors may explain the broad spectrum of responses to the same etiological agent found in patients with chronic liver diseases. Conceptually, the process of hepatic fibrosis must, at some point, consist of the stimulation of excessive ECM molecule synthesis by one or more populations(s) of cells (or an increase in the population of ECM-producing cells), or a decrease in the rate of ECM degradation or turnover.

This chapter reviews our current understanding of the pathogenesis of hepatic fibrosis and highlights those elements of the process for which intervention has been attempted. The etiology and cellular and molecular mechanisms of liver fibrosis will be detailed. The mechanisms of transition of advanced fibrosis to cirrhosis are also discussed. Finally, the basis for pathophysiologically based therapies will be detailed.

Etiology of liver fibrosis

Etiological factors of liver fibrosis are depicted in Table 27.1. The main causes of fibrosis in industrialized countries are HCV infection and alcoholic liver disease, which account for more

Primary biliary cirrhosis
Primary sclerosing cholangitis
Graft-versus-host disease
Hepatotoxic agents
Drugs: methotrexate, α-methyldopa, amiodarone, others
Vitamin A intoxication
Metabolic diseases
Nonalcoholic steatohepatitis
Wilson disease
Hemochromatosis
α_1-Antitrypsin deficiency
Type IV glycogen storage disease
Tyrosinemia
Vascular diseases
Chronic right-sided heart failure
Budd–Chiari syndrome
Venoocclusive disease
Inferior vena cava thrombosis
Miscellaneous
Secondary biliary cirrhosis
Cryptogenic

than half of cases [2]. Other major causes are hepatitis B virus (HBV) infection; autoimmune hepatitis; chronic cholestasis, namely primary biliary cirrhosis and primary sclerosing cholangitis; and genetic metabolic diseases (hemochromatosis and Wilson disease). Due to the current epidemics of obesity, NASH is increasingly recognized as a major cause of fibrosis, yet its actual prevalence is still unknown.

Chronic viral infections

Chronic viral infections are a common cause of liver fibrosis. More than 170 million people worldwide are chronically infected with HCV [13]. Most infected patients develop chronic viral infection. The natural history of patients with chronic HCV is characterized by a slow progression of liver fibrosis. Following infection, cirrhosis may develop after an average of 20–30 years. In some patients, the rate of fibrosis progression is much faster, and cirrhosis develops after 10–15 years, whereas in others the rate of progression is negligible. Several factors are associated with fibrosis progression rate: duration of infection, older age, male sex, alcohol consumption, and HIV coinfection. Metabolic disorders such as obesity and diabetes are emerging as independent cofactors of fibrogenesis [15]. Moreover, genetic factors may also play a role. Current antiviral therapies cure chronic HCV infection in half of infected patients [16]. Viral clearance is associated with improvement of the degree of fibrosis in many patients. Globally, HBV infection is the single most common cause of fibrosis, although the prevalence rate is influenced by geographic region [17]. HBV is endemic in parts of Asia where millions of individuals are infected. About 5%–10% of acutely infected adults become chronically infected. The natural history of liver fibrosis due to chronic HBV infection can vary dramatically between individuals [18]. Some individuals with chronic HBV will have clinically insignificant or minimal liver disease and never develop complications. Others will have clinically apparent chronic hepatitis that can progress to fibrosis and cirrhosis. Patients with chronic HBV and *replicative* infection defined by the presence of detectable HBeAg have a generally worse prognosis and a greater chance of developing advanced fibrosis or cirrhosis than those without HBeAg. The response to therapy in patients with chronic HBV infection is excellent and liver fibrosis can reverse in patients in whom viral infection has been cured [19]. Hepatitis delta virus (HDV) is a defective transmissible pathogen dependent on HBV for replication. Liver fibrosis progresses rapidly to cirrhosis in patients with dual infection with HBV and HDV [20]. Coinfection of HIV with hepatitis viruses is a common cause of liver fibrosis [21]. Importantly, advanced liver fibrosis and cirrhosis are the main causes of mortality among HIV-infected individuals in industrialized countries, in which highly active antiretroviral therapy is widely available. Both HBV and HCV are more common in HIV-infected individuals than in the general population as a result of shared risk factors for viral acquisition. Populations of injecting drug users are at particularly high risk for HIV/HCV coinfection. Coinfection with HIV results in greater likelihood of chronicity and enhanced viral replication in the setting of both HBV and HCV infections. Current evidence suggests that HIV infection may have a negative impact on HBV-related fibrosis progression, although the mechanisms for this are unclear [22]. HIV coinfection hastens HCV-related liver disease, with faster fibrosis progression to cirrhosis, end-stage liver disease, and occurrence of hepatocellular carcinoma.

Alcoholic liver disease

Alcoholic liver disease (ALD) is one of the commonest causes of liver fibrosis worldwide [23]. Although cumulative alcohol dose undoubtedly plays a role in determining fibrosis risk, only a small proportion of heavy drinkers go on to develop the more advanced forms of ALD–hepatitis, fibrosis and cirrhosis. Both genetic and environmental factors are associated with fibrosis progression in these patients [24]. Patients developing alcoholic hepatitis are at high risk of progressing to advanced fibrosis and cirrhosis [25]. This condition is characterized by evidence of hepatocyte necrosis and apoptosis, leukocyte infiltration, and perisinusoidal–pericellular fibrosis. The only effective maneuver leading to

fibrosis regression in these patients is alcohol abstinence. Until now, the development of specific antifibrotic treatments has been hampered by the lack of detailed knowledge of disease mechanisms [26]. This situation might now be changing with improved insight into the pathogenesis obtained from studies that focus on the roles of inflammation, endotoxin, and immunity.

Metabolic causes

Among causes of metabolic origin, nonalcoholic fatty liver disease (NAFLD) has emerged as a major cause of liver fibrosis [27]. NAFLD is a frequent syndrome encompassing fatty liver alone and a subset of patients develop hepatocellular injury, inflammatory changes, and slowly progressive fibrosis [28]. In the general adult population, NAFLD prevalence ranges between 20% and 30%, while the prevalence of NASH is 1%–5%. The presence of necroinflammation has been associated with a significant risk of progression to advanced fibrosis and eventually liver cirrhosis and hepatocellular carcinoma [29]. Age over 45 years, obesity, and diabetes have also been associated with an increased risk of liver fibrosis and progression to cirrhosis. Hereditary hemochromatosis is the most common genetic cause of liver fibrosis [30]. Liver biopsy remains important in management to determine the presence or absence of fibrosis, particularly among patients with serum ferritin levels greater than 1000 ng/mL or elevated liver enzymes. Factors such as moderate alcohol consumption can accelerate the progression of fibrosis [31]. Decompensated cirrhosis due to hemochromatosis carries a bad prognosis unless liver transplantation is performed. Moreover, patients with hemochromatosis are at high risk of developing hepatocellular carcinoma, which is a major cause of mortality among these patients. Wilson disease is an autosomal recessive disorder of copper metabolism that may result in liver fibrosis [32]. Thus far, more than 200 mutations have been detected, causing impairment of ATP7B function and, ultimately, copper accumulation. Resultant liver damage leads to steatosis, inflammation and progressive fibrosis. Wilson disease should be suspected in a patient with liver fibrosis of unknown origin and neurosychiatric symptoms. α_1-Antitrypsin deficiency is the most common genetic cause of liver fibrosis in children [33]. α_1-Antitrypsin is the main protease inhibitor in human plasma. Polymers accumulate within the endoplasmic reticulum of the hepatocyte forming inclusion bodies that are associated with neonatal hepatitis, progressive fibrosis, and juvenile fibrosis. In adults, α_1-antitrypsin deficiency may cause severe liver injury and is a common finding in patients with hepatic fibrosis of unknown origin. Heterozygosity for the Pi*Z allele may also predispose to liver fibrosis in patients with ongoing liver injury (HCV infection or NASH). Other metabolic causes of fibrosis include glycogen storage diseases, galactosemia, and congenital tyrosinosis. Even diabetes mellitus itself has been associated with the development of fibrosis.

Autoimmune liver diseases

Several autoimmune liver diseases may result in liver fibrosis. Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease characterized histologically by chronic nonsuppurative destruction of interlobular bile ducts leading to advanced fibrosis, cirrhosis, and liver failure [34]. Affected patients are typically middle-aged women with abnormal serum concentrations of alkaline phosphatase. Identification of PBC is important, because effective treatment with ursodeoxycholic acid has been shown to halt fibrosis progression and improve survival without need for liver transplantation [35]. Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by strictures of the biliary tree. It is closely associated with inflammatory bowel disease, particularly ulcerative colitis, although the precise etiology remains unknown [36]. Small-duct PSC is a distinct clinical entity associated with a benign course. Patients eventually show progressive fibrosis and cirrhosis. Autoimmune hepatitis is characterized histologically by interface hepatitis and serologically by the presence of non-organ- and liver-specific autoantibodies and increased levels of IgG [37]. Its onset is often ill-defined, frequently mimicking acute hepatitis. Liver damage is likely to derive from an immune reaction to liver cell antigens. Fibrosis often develops and its progression is attenuated and even reversed if effective immunosuppressant therapy is initiated.

Other causes

Cardiac fibrosis includes a spectrum of hepatic derangements that occur in the setting of right-sided heart failure. It should be suspectd in patients with hepatic fibrosis of unknown origin with clinical signs of right-sided heart failure. Prolonged biliary obstruction (secondary biliary fibrosis) can result in liver fibrosis. It can be caused by gallstones, bile duct or head of pancreas carcinoma, biliary tract infections or strictures and, in children, biliary atresia. This latter condition is the main cause of advanced liver fibrosis requiring liver transplantation among children. When fibrosis is in its earlier stages and the cause of biliary obstruction is resolved, histological improvement has been documented. Granulomatous diseases can cause liver fibrosis. These diseases include sarcoidosis and infections (mycobacterial infections and schistosomiasis). Hepatotoxic drugs can also cause liver cirrhosis and fibrosis. Drug-induced liver disease account for between 10% and 40% of adult patients with elevated enzymes. Liver injury can be cytotoxic, cholestatic, or mixed. Most cases resolve after withdrawal of the drug, but in a few undiagnosed cases the liver disease can progress to cirrhosis. Drug-induced liver disease can mimic autoimmune hepatitis or venoocclusive disorders. The plethora of herbal and traditional agents ingested by many people should always be considered in any patient with liver fibrosis of unknown origin. Venous outflow obstruction (e.g., Budd–Chiari syndrome, venoocclusive disease) can result in severe liver fibrosis and

cirrhosis [38]. Budd–Chiari syndrome is a rare disorder caused by hepatic venous obstruction mainly due to thrombosis. Most cases are due to an underlying hypercoagulable disorder due to myeloproliferative disorders or abnormalities in the coagulation cascade. Fibrosis progresses rapidly, leading to severe portal hypertension and liver failure in some patients. In these acute or subacute cases, pharmacological or mechanical thrombolysis can be effective. Transjugular portosystemic shunt is also used for restoring a normal venous outflow. Hepatic venoocclusive disease is a common complication of bone marrow transplantation. Perivenular fibrosis develops and can result in jaundice and portal hypertension. Hepatic fibrosis of unknown etiology, termed *cryptogenic*, is diagnosed less frequently as modern techniques are available to identify the causative disease. The diagnosis of cryptogenic fibrosis is made when all known causes of liver disease are excluded. Therefore, medical history, consumption of alcohol or drugs, virological tests, tests for metabolic diseases, tests for autoimmune diseases, and careful imaging of the liver should be performed. Importantly, studies suggest that many patients with cryptogenic fibrosis and cirrhosis show features of the metabolic syndrome, including obesity, diabetes, and dyslipemia. Therefore, a role for NASH in the pathogenesis of cryptogenic fibrosis has been suggested [39].

Cellular mechanisms of liver fibrosis

Hepatic fibrosis is the result of the wound healing response of the liver to repeated injury [2]. After an acute liver injury (e.g., viral hepatitis), parenchymal cells regenerate and replace the necrotic or apoptotic cells. This process is associated with an inflammatory response and limited deposition of ECM. If the hepatic injury persists, then eventually liver regeneration fails and hepatocytes are substituted by abundant ECM including fibrillar collagen. The distribution of this fibrous material depends on the origin of the liver injury.

The cellular mechanisms of liver fibrosis have now been uncovered. The most relevant finding, which has greatly stimulated research in this field, was the identification of activated HSCs as the major source of ECM in the fibrotic liver [40]. This assumption is based on the following data.

- In vitro studies performed in the early 1980s clearly demonstrated that the collagen found in cultures of primary hepatocytes was due to contaminating HSCs within the cell monolayers [41]. Further studies confirmed that cultured HSCs synthesize and secrete large amounts of collagen and other ECM proteins, while other cells types (i.e., hepatocytes, sinusoidal endothelial cells) only secrete modest amounts of these proteins [5].
- Studies using immunocytochemistry, in situ hybridization, and transgenic mice identified collagen expression in damaged livers in activated HSCs rather than in parenchymal cells [42] (Fig. 27.1).
- Studies assessing gene expression in rat and human HSCs freshly isolated from normal livers showed that quiescent HSCs express low levels of mRNA encoding ECM proteins, while HSCs activated in culture or in vivo show a marked upregulation of these genes and secrete large amounts of collagen [43].
- HSCs isolated from rat and human livers with advanced fibrosis markedly overexpress genes encoding ECM proteins, which is not observed in other hepatic cell types [44].

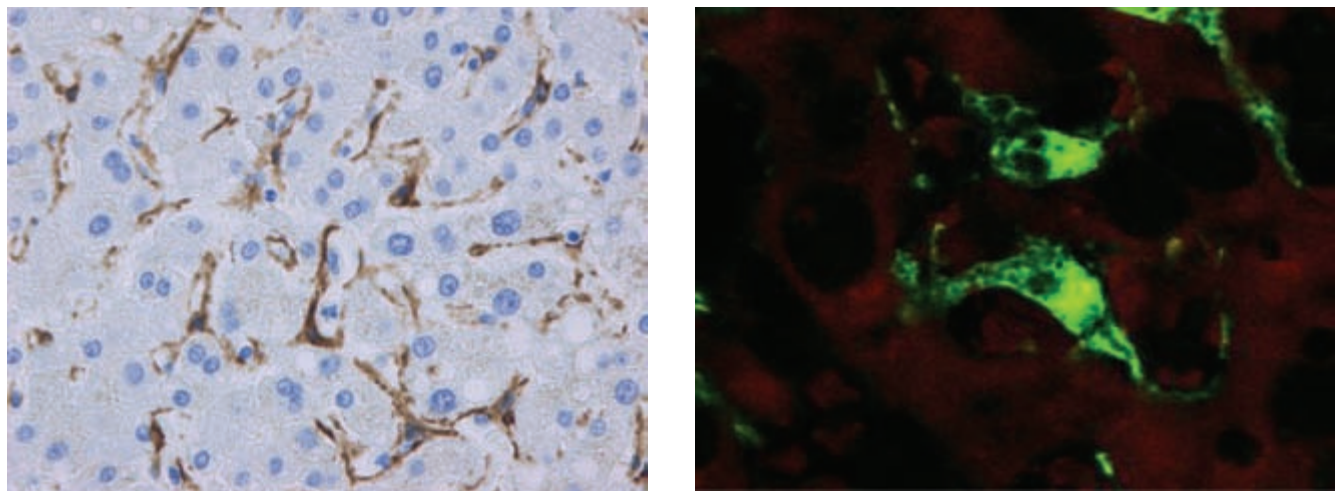

Figure 27.1 Identification of activated hepatic stellate cells in fibrotic livers. **(a)** Demonstration of α-smooth muscle actin (SMA) immunoreactivity in a liver biopsy of a patient with hepatitis C virus-induced liver fibrosis (magnification × 400). **(b)** Identification of activated hepatic stellate cells expressing green fluorescence protein-procollagen α1(I) in transgenic mice with bile duct ligation (magnification × 600).

• Studies assessing both experimental models of liver fibrosis and human fibrogenesis have demonstrated a positive correlation between the degree of fibrosis and the accumulation of activated HSCs in the damaged liver [45].
• Substances that inhibit the activation or proliferation of HSCs also attenuate the progression of hepatic fibrosis in experimental models of chronic liver injury [46–48].

Activation of HSCs is a key step in liver fibrogenesis. HSCs from normal liver represent about 15% of the total liver population and show a *quiescent* phenotype (rich in vitamin A fat droplets). When freshly isolated and cultured, quiescent HSCs show a low proliferative rate and very modest fibrogenic potential, little cytokine secretion, and lack of contractile properties [43,49]. Therefore, the main function of these quiescent HSCs is considered to be the storage and metabolism of vitamin A [6]. However, following liver injury of any etiology, HSCs undergo a process termed *activation*, which represents a transition into proliferative, fibrogenic, proinflammatory, and contractile myofibroblasts [50] (Fig. 27.2). Therefore, substances that inhibit activation of HSCs are of major importance in attenuating their fibrogenic response. In the 1990s, a number of studies characterized the cellular and molecular mechanisms underlying HSC activation. The initiation phase of this process is probably due to paracrine stimuli from injured neighboring cells, which include hepatocytes, Kupffer cells, sinusoidal endothelial cells, platelets, and infiltrating inflammatory cells [51,52]. Some of these cells (i.e., hepatocytes, Kupffer cells) promote HSC activation by producing lipid peroxides leading to oxidative stress [53–55]. Moreover, antioxidants can attenuate liver fibrogenesis by inhibiting HSC activation [56]. A number of cytokines released by damaged neighboring cells can also activate HSCs. These include transforming growth factor (TGF)-β1, platelet-derived growth factor (PDGF), and endothelin-1, which stimulate transcription factors such as Sp1, c-myb, NF-κB, c-jun/AP1, STAT-1 and SMAD proteins that regulate gene expression [8,57,58]. Activated HSCs perpetuate their own activation by several autocrine loops, including the secretion of TGF-β1 and upregulation of its receptors [51]. Based on its importance, several therapeutic options under evaluation are aimed at inhibiting HSC activation (i.e., antioxidants, substances blocking TGF-β1 activity).

One important feature of activated HSCs is their proliferative phenotype. Following liver injury there is a marked accumulation of α-smooth muscle actin-positive cells at the sites of active liver fibrogenesis [7,59]. Growth factors for HSCs and their intracellular signaling pathways have been largely characterized in culture [60]. The most powerful growth factor for HSCs is PDGF, but stimulation of other tyrosine kinase receptors by epidermal growth factor (EGF), fibroblast growth factor (FGF), or insulin-like growth factor (IGF) also results in increased HSC proliferation [8].

Resistance to apoptosis of activated HSCs is considered a key event in liver fibrogenesis [61]. Soluble survival factors are likely to be important to HSC survival. During liver injury, hepatocytes and HSCs express IGF type 1, a potent prosurvival factor. In addition, overexpresion of TGF-β1 in the injured liver may promote stellate cell survival. In contrast to these factors, PDGF, which is potently mitogenic for HSCs, has relatively little antiapoptotic activity. The separate regulation of proliferation and survival in HSCs provides a further control on HSC numbers. Moreover, adipokines such as leptin and factors regulating collagen degradation, such as tissue inhibitor of metalloproteinases (TIMP)-1, may also act

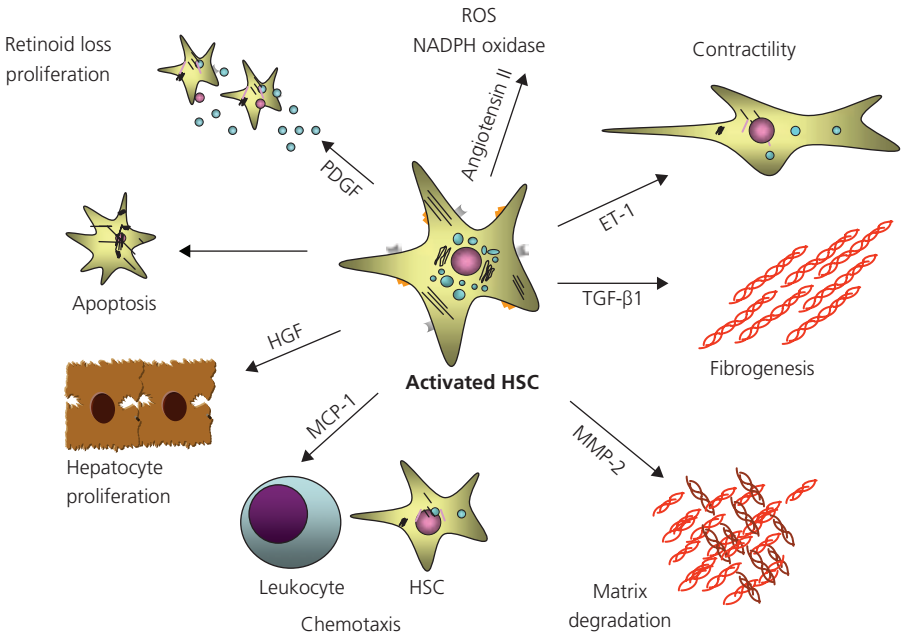

Figure 27.2 Biological properties of activated hepatic stellate cells (HSC) that participate in liver fibrogenesis. ET-1, endothelin-1; HGF, hepatocyte growth factor; MCP-1, monocyte chemotactic protein type 1; MMP, metalloproteinase; PDGF, platelet-derived growth factor; ROS, reactive oxygen species; TGF, transforming growth factor.

as survival factors for activated HSCs [62,63]. The ECM may also provide key survival signals [64]. There is a striking correlation between the degradation of the collagen I-rich matrix during recovery from liver fibrosis and apoptosis of activated HSCs. Preliminary studies indicate that the phenotype of activated HSCs is greatly influenced by the composition of the adjacent subcellular matrix. For example, activated HSCs cultured on a collagen I matrix maintain an activated phenotype with an increased propensity to apoptosis, as compared with cells grown on basement membrane-like matrix [65]. When activated cells are transferred to this latter surface, they revert to a quiescent state with increased resistance to apoptosis, associated with expression of the antiapoptotic protein Bcl-2. These data clearly support the notion that activated HSCs are more susceptible to apoptosis than quiescent cells. A decreasing concentration of soluble survival factors, the degradation of specific matrix components, or separation of cells from matrix contact, either separately or in combination, may then be critical for precipitating an apoptotic response in HSCs. Removal of activated HSCs from the injured liver by promoting their apoptosis is another potential target for treatment. Apoptosis of activated HSCs plays a critical role in the spontaneous recovery from experimental fibrosis in different experimental models (carbon tetrachlolide administration, bile duct ligation) [66]. Conversely, resistance to apoptosis and the consequent prolonged survival of activated HSCs may contribute to the progression of hepatic fibrosis [67]. Further studies are required to delineate the factors and mechanisms regulating apoptosis in HSCs and to design therapeutic strategies aimed at promoting apoptosis of activated HSCs in experimental liver fibrosis.

Migration of HSCs could contribute to their accumulation at sites of liver injury. Following activation, cultured HSCs migrate in response to several stimuli, including growth factors (PDGF), vasoactive substances (angiotensin II, endothelin-1), and chemokines (monocyte chemotactic protein-1) [68,69]. Chemotaxis of HSCs requires Ca^{2+} influx and involves the phosphatidylinositol 3-kinase/Akt pathway. Although the importance of migration of HSCs in vivo has not been determined, substances that inhibit migration of HSCs could theoretically reduce their accumulation in injured liver.

The interaction of HSCs with the ECM is also of major importance in the profibrogenic behavior of activated HSCs. One of the earlier changes observed after chronic liver injury is the change in the composition of the space of Disse. Proteins including type IV collagen, fibronectin, proteoglycans, and urokinase-type plasminogen activator are released by sinusoidal endothelial cells and accumulate around the hepatic sinusoids [70]. These factors contribute to the activation of resident HSCs by the stimulation of latent cytokines such as TGF-β [71]. Of particular interest is a *fetal* isoform of fibronectin, [EIIIA]Fn, which is synthesized de novo by the damaged liver and contributes to the activation of resident HSCs [72]. Once HSCs are activated, they secrete fibrillar collagens and other ECM proteins, which also accumulate in the space of Disse. This altered microenvironment can amplify the fibrogenic activity of HSCs by different mechanisms. First, fibrillar collagens can bind to discoidin domain receptors and activate intracellular signaling pathways [55]. Second, the altered ECM can serve as a reservoir for a number of growth factors (PDGF, TGF-β, FGF) and matrix metalloproteinases (MMPs), which are released and reach neighboring cells including HSCs [73]. This implies that proteolysis of the ECM during liver inflammation can initiate reparative processes by the released growth factors and MMPs. Third, HSCs express a number of integrins, heterodimeric transmembrane proteins whose ligands are matrix molecules rather than cytokines, which transduce the extracellular signals from the ECM into the cells [74]. Several activities of HSCs can be regulated by integrins, including cell proliferation, contraction, migration, and collagen synthesis [75]. Moreover, integrins can also activate latent TGF-β, thus amplifying the fibrogenenic action of this key cytokine. Therefore, pharmacologically modulating the interaction between HSCs and the surrounding ECM could limit liver fibrosis. In this regard, the common presence of Arg-Gly-Asp (RGD) within many integrin ligands has prompted the use of competitive RGD antagonists to block integrin-mediated pathways in experimental liver fibrogenesis [76]. Finally, HSCs express CD44, the hyaluronic acid receptor [77]. Activation of CD44 is involved in cell migration and is required for liver fibrogenesis.

HSCs also play an active role in hepatic inflammation [78]. Activated HSCs migrate in response to cytokines released by monocytes and also secrete a number of proinflammatory cytokines and chemokines that could participate in the activation of lymphocytes and the recruitment of white blood cells, thus amplifying the inflammatory response [79]. The mechanisms involved in cytokine secretion by HSCs include activation of the transcription factor NF-κB. In fact, inhibition of NF-κB by proteosome inhibitiors or by an adenovirus expressing the IκB super-repressor markedly blunt cytokine secretion by activated HSCs [80]. Moreover, activated human HSCs express receptors for a number of chemokines that activate several intracellular pathways stimulating the inflammatory action of these cells [81]. In addition, HSCs can take up and process antigens and, under stimulation with cytokines, express the cell machinery required for antigen presentation and thereby modulate the growth of lymphocytes [82]. In fact, the development of liver fibrosis in most human liver diseases is preceded by chronic inflammation of the hepatic parenchyma, and treatments inhibiting liver inflammation may also attenuate the progression of liver fibrosis [83]. Therefore, the use of substances with combined antifibrotic and antiinflammatory effect should be considered in antifibrotic therapy.

Hepatic cell types other than HSCs may also have fibrogenic potential (Fig. 27.3). Studies in transgenic mice have

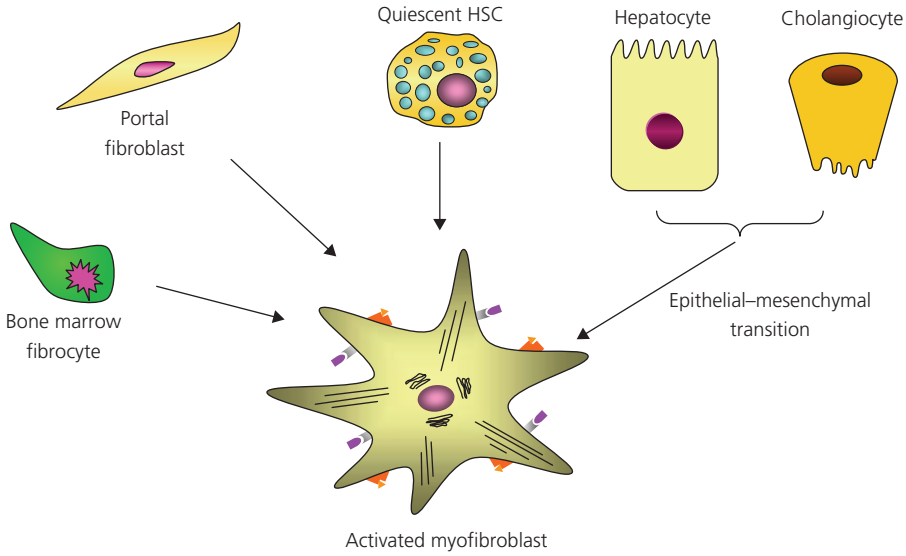

Figure 27.3 Different sources of myofibroblastic cells with fibrogenic potential in livers with chronic damage. HSC, hepatic stellate cell.

shown that myofibroblasts derived from small portal vessels proliferate around biliary tracts in cholestasis-induced liver fibrosis to initiate collagen deposition [84]. HSCs and portal myofibroblasts differ in specific cell markers and response to apoptotic stimuli [9]. Culture of $CD34^{+}CD38^{-}$ hematopoietic stem cells with various growth factors has been shown to generate HSCs and myofibroblasts of bone marrow origin that infiltrate human livers undergoing tissue remodeling [85]. These data suggest that cells of bone marrow origin can be a source of fibrogenic cells in the injured liver. Other potential sources of fibrogenic cells are circulating fibrocytes [86]. In mice with bile duct ligation, the majority of bone marrow-derived cells coexpress collagen and CD45, suggesting that these cells represent a unique population of fibrocytes. Interestingly, fibrocytes cultured in the presence of TGF-β1 differentiated collagen-producing myofibroblasts, potentially contributing to liver fibrosis. Finally, epithelial-to-mesenchymal transition, a TGF-β1-driven mechanism that participates in renal fibrosis, may also occur during chronic liver injury [87]. The relative importance of each cell type in liver fibrogenesis may depend on the origin of the liver injury. While HSCs are the main fibrogenic cell type in pericentral areas, portal myofibroblasts may predominate when liver injury occurs around portal tracts.

A complex interplay among different hepatic cell types takes place during hepatic fibrogenesis [2,88]. Hepatocytes are targets for most hepatotoxic agents, including hepatitis viruses, alcohol metabolites, and bile acids. Damaged hepatocytes release reactive oxygen species (ROS) and fibrogenic mediators and induce infiltration by inflammatory cells [89]. Apoptosis of damaged hepatocytes stimulates the fibrogenic actions of liver myofibroblasts [61]. Inflammatory cells, either lymphocytes or polymorphonuclear cells, activate HSCs to secrete collagen. Activated HSCs secrete inflammatory chemokines, express cell adhesion molecules, and modulate the activation of lymphocytes [78]. Therefore, a vicious circle in which inflammatory and fibrogenic cells stimulate each other is likely to occur. Fibrosis is influenced by different T-helper subsets, the Th2 response being associated with more active fibrogenesis [90]. Kupffer cells are resident macrophages that play a major role in liver inflammation by releasing ROS and cytokines [91,92]. A role for macrophages in hepatic wound healing has been proposed [93]. Macrophage depletion when liver fibrosis was advanced resulted in reduced scarring and fewer myofibroblasts. In contrast, macrophage depletion during recovery led to a failure of matrix degradation. These findings suggest that macrophages regulate both ECM formation and degradation in liver fibrogenesis. In chronic cholestatic disorders (i.e., primary biliary cirrhosis and primary sclerosing cholangitis) epithelial cells stimulate the accumulated portal myofibroblasts to initiate collagen deposition around damaged bile ducts. Finally, changes in the composition of the ECM can directly stimulate fibrogenesis. Type IV collagen, fibrinogen, and urokinase-type plasminogen activator stimulate resident HSCs by activating latent cytokines such as TGF-β1 [94]. Fibrillar collagens can bind and stimulate HSCs via discoidin domain receptor DDR2 and integrins. Moreover, the altered ECM can serve as a reservoir for growth factors and MMPs [73].

Molecular mechanisms of liver fibrosis

Liver fibrosis is associated with major alterations in both the quantity and composition of ECM proteins [95]. In advanced stages, the liver contains approximately six times more ECM, including collagens (I, III and IV), fibronectin, undulin, elastin, laminin, hyaluronan, and proteoglycans. Accumulation of ECM results from both increased synthesis and decreased degradation [24]. Decreased activity of ECM-

removing MMPs is mainly due to overexpression of their specific inhibitors (i.e., TIMPs).

Type 1 collagen is a major ECM component in the fibrotic liver. The mechanisms of increased collagen synthesis in liver fibrosis have been described in HSCs. Type 1 collagen synthesis in HSCs is regulated at the transciptional and posttranscriptional levels [96]. In particular, increased collagen mRNA stability plays a key role in the increased collagen synthesis found in activated HSCs. In these cells, posttranscriptional regulation of collagen is governed by sequences in the 3′ untranslated region via the RNA-binding protein αCP2 as well as a stem–loop structure in the 5′ end of collagen mRNA [97]. Mutations that alter the structure of this stem–loop region lead to rapid degradation of collagen mRNA. Interestingly, this region not only influences mRNA stability, but also controls export of α1(I) collagen mRNA from the nucleus to the cytoplasm and the translation of the different fibrillar chains of collagen. These data suggest that blocking the activity of this stem–loop region decreases collagen synthesis by HSCs. In this regard, an RNA-binding protein binds this 5′ stem–loop region in activated but not quiescent HSCs, suggesting that it could play an important role in collagen synthesis by activated HSCs.

Mechanisms of liver fibrosis include oxidative stress, hypoxia, and angiogenesis. Oxidative stress is believed to play a major role in the pathogenesis of liver fibrogenesis [55]. It results from increased ROS production and decreased removal in the fibrotic liver. Several differentially localized and expressed enzymatic systems contribute to ROS formation in the liver, including endothelial nitric oxide synthases, cytochrome P450 monooxygenases, and NAPDH oxidase [98]. In the healthy liver, hepatocytes produce low amounts of ROS and Kupffer cells, the resident macrophages of the liver, are well equipped to release ROS in response to bacterial stimuli. Antioxidant systems such as superoxide dismutase and catalase efficiently remove excess ROS to maintain the normal cell homeostasis. In chronic liver diseases, there is increased ROS production as well as decreased activity of antioxidant systems, resulting in oxidative stress [91]. This feature is commonly detected in patients with alcohol abuse, HCV infection, iron overload, or chronic cholestasis, as well as in most types of experimental liver fibrogenesis [99–101]. In these conditions, oxidative stress is not only a consequence of chronic liver injury but it contributes to excessive tissue remodeling and fibrogenesis. The cellular and molecular mechanisms leading to oxidative stress in chronic liver diseases are under extensive investigation. Evidence has accumulated showing that HSCs contain a nonphagoctyic form of NADPH oxidase. Activation of this enzyme could therefore modulate the fibrogenic actions of these cells. The finding that cytokines produced at the sites of tissue repair (i.e., angiotensin II or PDGF) activate NADPH oxidase in HSCs, enhancing their inflammatory and fibrogenic actions, supports this hypothesis [69,102]. Thus, the NADPH complex has emerged as a novel regulator and potential target in the pathogenesis of hepatic fibrosis.

Hypoxia is a common environmental stress factor associated with various pathological conditions including fibrogenesis. Several lines of evidence indicate that liver parenchyma in chronically injured liver suffers from hypoxia. Hypoxia seems particularly relevant in ALD, where decreased oxygen delivery is commonly found in perivenular areas. Low oxygen tension in cultured HSCs results in increased proliferation and collagen gene expression [103]. Hypoxia can result in angiogenesis, which is also associated with fibrogenesis [104]. Hepatic neovascularization and the expression of vascular endothelial growth factor (VEGF), a potent angiogenic factor, increase in parallel with fibrogenesis. The CD31-immunopositive neovessels are mainly localized along the fibrotic septa. Cytokines promoting angiogenesis include angiotensin II and leptin [105,106].

Several cytokines regulate ECM synthesis and mediate liver fibrogenesis. Among them, TGF-β is considered the most powerful fibrogenic cytokine in the liver [94]. In HSCs, TGF-β favors the transition to myofibroblast-like cells, stimulates the synthesis of ECM proteins, and inhibits its degradation [107,108]. TGF-β is synthesized in a latent form linked to a glycoprotein (latent TGF-β binding protein, LTBP), which serves as an anchor in the ECM. Proteolytic cleavage of LTBP is a prerequisite for the release and generation of bioactive (mature) TGF-β. Binding of active TGF-β to cell surface receptors results in the phosphorylation and activation of the Smad family of intracellular signaling proteins. Phosphorylated Smad2 and Smad3 recruit the common mediator Sma4 and translocate into the nucleus, regulating gene transcription. Several nuclear oncoproteins, such as Ski and SnoN, as well as Smad7, repress the activity of Smad proteins and limit TGF-β's biological actions [109]. Therapies aimed at disrupting TGF-β synthesis or signaling pathways have decreased fibrosis in experimental models [110,111].

Growth factors such as PDGF, EGF, IGF, and FGF amplify the fibrogenic response by inducing growth and migration of resident HSCs [112]. Among them, PDGF is the most potent proliferative cytokine known for HSCs by binding to a specific tyrosine kinase cell surface receptor [8]. Binding of PDGF to its receptor initiates phosphorylation signaling cascades that lead to increased DNA synthesis and cell proliferation [113]. Following HSC activation there is upregulation of PDGF receptors in HSCs, which in turn secrete this potent mitogen. PDGF activates the focal adhesion kinase (FAK)/phosphatidylinositol 3-kinase (PI3K)/Akt (protein kinase B) signaling pathway that transduces mitogenic signals for the cell and which is critical for cellular chemotaxis [114]. PDGF also activates the Ras/Raf/MEK/extracellular signal-regulated kinase (ERK) signaling pathway and the mitogen-activated protein kinase (MAPK)/Jun N-terminal kinase (JNK) signaling pathway, transducing mitogenic signals for the cell [115]. PDGF, as well as other cytokines that

stimulate tyrosine-kinase receptors such as EGF, FGF, or IGF, regulate HSC proliferation. The expression of growth factors, mainly PDGF, is markedly increased in hepatic tissue after both acute and chronic liver injury [116]. Transgenic mice overexpressing PDGF develop liver fibrosis and genetic or pharmacological abrogation of PDGF results in attenuated liver fibrosis in rodents with chronic injury [117].

Angiotensin II is another cytokine that plays an important role in liver fibrogenesis [12]. Angiotensin II is the main effector of the renin–angiotensin system, which is a key mediator of renal or cardiac fibrosis. Following phenotypic activation, HSCs express AT_1 receptors, the activation of which mediates cell contraction, migration, and proliferation [118] (Fig. 27.4). Moreover, angiotensin II stimulates collagen synthesis and TGF-β expression [69]. These effects are blocked by AT_1 receptor antagonists and are blunted in mouse HSCs lacking AT_{1a} receptors [119]. Importantly, activated HSCs are capable of generating mature angiotensin II, suggesting that it can act in an autocrine or paracrine manner [120]. The molecular mechanisms mediating the inflammatory and fibrogenic effects of angiotensin II in HSCs have been partially delineated [69]. Angiotensin II increases intracellular calcium concentration and induces NADPH oxidase-derived ROS, stimulating intracellular pathways such as PI3K/Akt and MAPKs. It increases AP-1 DNA binding, while NF-κB activity is stimulated in rat, but not human, HSCs [121]. Angiotensin II also stimulates the Smad signaling pathway through upregulation of TGF-β1 [122]. The most convincing evidence supporting a role for the renin–angiotensin system in experimental liver fibrosis is the finding that blockade of the generation of angiotensin II or its binding to AT_1 receptors markedly attenuates experimental liver fibrosis. Remarkably, a high number of studies using four different experimental models of liver fibrosis have yielded similar results (Table 27.2) [47,48,123–129]. A role for AT_1 receptors in liver fibrosis is indicated by data showing that mice lacking AT_{1a} receptors are protected against liver fibrosis after prolonged bile duct ligation [119]. Besides angiotensin II, other vasoactive peptides play a role in liver fibrogenesis. Vasoconstrictors such as endothelin-1 and norepinephrine usually exert fibrogenic effects on activated HSCs and participate in experimental liver fibrogenesis [130–133]. In contrast, vasodilator substances such as adrenomedullin, prostaglandin $(PG)E_2$ and nitric oxide inhibit proliferation and collagen synthesis in HSCs and attenuate fibrogenesis [134,135]. In advanced liver fibrosis, there is a predominance of vasoconstrictors over vasodilators. Whether this unbalanced expression contributes to the progression of liver fibrosis remains unclear.

Adipokines have been implicated in the pathogenesis of liver fibrosis [136]. The adipose tissue, previously considered a passive storage site for excess energy, is now recognized as a hormonally active system, producing numerous molecules, known as adipokines, that exert local, central and peripheral

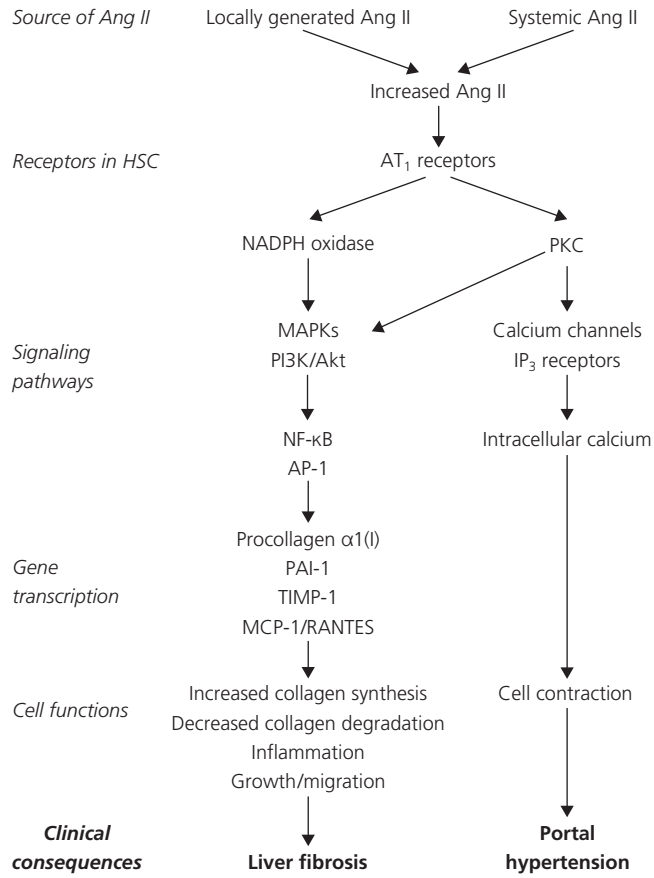

Figure 27.4 Mechanisms of the pathogenic effect of the renin–angiotensin system in the liver. Increased angiotensin II (Ang II) binds to type 1 angiotensin receptors (AT_1) located in activated hepatic stellate cells (HSCs). AT_1 receptors activate a nonphagocytic NADPH oxidase to generate reactive oxygen species that stimulate redox-sensitive intracellular pathways. Increased gene transcription leads to mitogenic, fibrogenic, and inflammatory properties, promoting fibrogenesis. Ang II increases intracellular calcium and induces cell contraction, increasing intrahepatic vascular resistance and participating in the pathogenesis of portal hypertension. actions [137]. Among adipokines, leptin has received special attention. Leptin is produced by HSCs and acts on HSCs and endothelial cells inducing inflammatory and fibrogenic events [106,138,139]. This effect includes increased collagen synthesis and decreased expression of matrix-degrading enzymes such as MMP-1 and protection from apoptotic cell death by increased expression of TIMP-1 [140]. Rodents lacking either leptin or leptin receptor do not develop liver fibrosis after repeated injury [139,141]. These results clearly indicate that leptin mediates liver fibrogenesis. Adiponectin is an adipokine with opposite results. It is produced locally in

the liver and inhibits liver fibrosis both in vitro and in vivo [142]. In patients with NASH, the leptin/adiponectin ratio increases, suggesting that these cytokines may play a role in the development of liver fibrosis (Fig. 27.5). Finally, a recent report indicates that resistin is overexpressed in human fibrotic livers and exerts inflammatory actions on HSCs [143].

Data on intracellular pathways regulating liver fibrogenesis is mainly derived from studies using cultured HSCs, while their role in vivo is progressing through experimental fibrogenesis studies using knockout mice [60]. Several MAPKs modulate major fibrogenic actions of HSCs. ERK, which is stimulated in experimentally induced liver injury, mediates proliferation and migration of HSCs [115]. In contrast, JNK regulates apoptosis of hepatocytes as well as the secretion of inflammatory cytokines by cultured HSCs [144]. The FAK/PI3K/Akt signaling pathway mediates agonist-induced fibrogenic actions in HSCs [115]. TGF-β1-induced Smad signaling pathway stimulates experimental hepatic fibrosis and is a potential target for therapy [109,111]. The peroxisome proliferator activated receptor (PPAR) pathway regulates HSC activation and experimental liver fibrosis. PPAR-γ ligands inhibit the fibrogenic actions in HSCs and attenuate liver fibrosis in vivo [145]. NF-κB may have both a profibrogenic and inhibitory action on liver fibrosis [146]. Other transcription factors are involved in HSC activation and may participate in liver fibrogenesis [147]. Other studies have suggested a role for intracellular pathways signaled by Toll-like receptors and β-cathepsin [148].

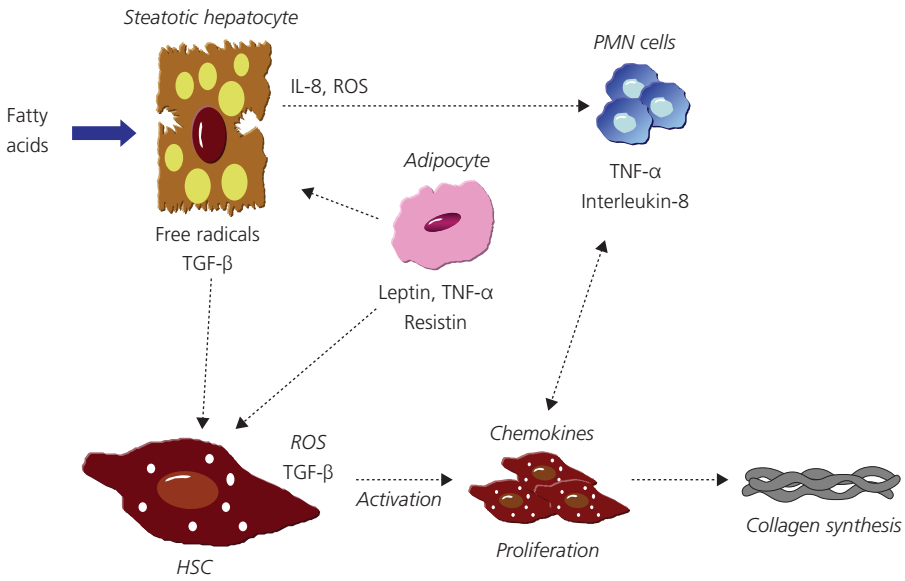

Figure 27.5 Pathogenesis of liver fibrosis in patients with nonalcoholic steatohepatitis. Steatotic hepatocytes take up circulating fatty acids and release interleukin (IL)-8 and reactive oxygen species (ROS) that contribute to recruitment of inflammatory cells. Adipocytes release adipokines and induce fibrogenic actions in hepatic stellate cells (HSC), which in turn interact with inflammatory cells. Accumulation of HSCs results in collagen deposition. PMN, polymorphonuclear; TGF, transforming growth factor; TNF, tumor necrosis factor.

Fibrosis remodeling and resolution

In contrast with the traditional view that cirrhosis is an irreversible disease, recent evidence indicates that even advanced fibrosis is reversible [149]. In experimentally induced fibrosis, cessation of liver injury results in fibrosis regression [150]. In humans, spontaneous resolution of liver fibrosis can occur after successful treatment of the underlying disease. This observation has been described in patients with iron and copper overload, alcohol-induced liver injury, chronic HCV, HBV and HDV infection, hemochromatosis, secondary biliary cirrhosis, NASH, and autoimmune hepatitis [2]. The time to achieve significant regression may take years and varies depending on the underlying cause and the severity of the liver disease. Chronic HCV infection is the most extensively studied condition; successful therapy with interferon (IFN)-α plus ribavirin leads to viral clearance and results in fibrosis improvement. Importantly, nearly half of patients with cirrhosis reverse to a significant degree [151]. Whether this beneficial effect is associated with improvements in long-term clinical outcome, including decreased portal hypertension, is unknown.

Increased collagenolytic activity is a major mechanism of fibrosis resolution [149]. Fibrillar collagens (I and III) are degraded by interstitial MMPs (MMP-1, MMP-8 and MMP-13 in humans, MMP-13 in rodents). During fibrosis resolution, MMP activity increases due to a rapid decrease in the expression of TIMP-1. Partial degradation of fibrillar collagen occurs, and the altered interaction between activated HSCs and ECM favors apoptosis [150]. Removal of activated HSCs by apoptosis precedes fibrosis resolution. Stimulation of death receptors in activated HSCs and a decrease in survival factors, including TIMP-1, can precipitate HSC apoptosis [66].

Activated HSCs are the main hepatic cell type implicated in collagen degradation in fibrotic liver [152]. Following cell activation, HSCs express virtually all the key components required for matrix degradation. In particular, they are a key source of MMP-2, as well as stromelysin/MMP-3. Importantly, through the activation of TIMP-1 and TIMP-2, activated HSCs can also inhibit the activity of interstitial collagenases, which degrade fibrillar collagen, thus favoring the accumulation of ECM [153]. This hypothesis is supported by studies of experimental liver fibrosis and in human liver disease, in which TIMP-1 expression is markedly upregulated in cirrhotic compared with normal liver, whereas expression of collagenases remains unchanged [154]. Moreover, transgenic mice overexpressing TIMP-1 rapidly develop liver fibrosis following injury [117]. Administration of TIMP-1 antibodies to rats with established fibrosis partially removes collagen from the liver, suggesting that this approach may be useful in patients with chronic liver diseases [155].

Genetic determinants of liver fibrosis

Hepatic fibrosis is a condition in which multiple genes interact with environmental factors [2] (Fig. 27.6). Well-characterized causative agents of liver fibrosis include chronic HCV infection and alcohol abuse. However, not all patients exposed to a similar causative agent develop the same degree of liver fibrosis. For example, while viral factors (i.e., genotype, viral load) do not influence fibrosis progression in patients with HCV, host factors (i.e., age, gender) seem to play an important role [13]. Large-scale studies have allowed the identification of patients with rapid fibrosis progression per unit time (*rapid fibrosers*) and those with slow fibrosis progression (*slow fibrosers*) [156]. The genetic deter-

minants involved in these different individual behaviors are largely unknown, but candidate genes are currently under evaluation. Although association studies have yielded promising results, many of the candidate genes identified in animal models have not yet been tested in humans. A rational approach is to identify candidate genes in experimental studies and then to carry out association studies to investigate whether functional polymorphisms of these genes influence fibrosis progression in patients.

During the last few years, numerous association studies have investigated the role of gene polymorphisms in the progression of liver fibrosis or development of cirrhosis in patients with different types of chronic liver disease. Gene variations influencing the course of prevalent liver diseases have been identified (Table 27.3). However, studies examining the role of mutations in genes encoding alcohol-metabolizing enzymes and of *HFE* C282Y heterozygosity in the hemochromatosis gene have yielded divergent results. Common methodological limitations of genetic epidemiological studies include low sample size, leading to lack of statistical power, and no investigation of gene–environment interactions.

The role of genetic variations in patients with ALD has been widely studied. ALD results from a complex interaction between behavioral, environmental, and genetic factors [157]. Although a positive correlation between cumulative alcohol intake and degree of liver injury has been reported, extensive individual variability exists. For similar ethanol consumption, some subjects only develop macrovesiculovacuolar steatosis, while others develop cirrhosis. Genes encoding alcohol-metabolizing enzymes and proteins involved in liver toxicity such as antioxidants and proinflammatory

Table 27.3 Main genes with polymorphisms that influence the progression of liver fibrosis in patients with chronic liver diseases

Gene	Liver disease
Interleukin-10	ALD/HCV
Transforming growth factor-β1	HCV/NASH
Interleukin-1β	ALD/PBC/HBV
Interleukin-1 receptor	ALD/PBC
Angiotensinogen	HCV/NASH/HBV
Mannose-binding lectin	HCV

Microsomal epoxide hydrolase	HCV
HFE	HCV/NASH
CD14	ALD
Cytotoxic T-lymphocyte antigen-4	ALD
Manganese superoxide dismutase	ALD
Apolipoprotein E	HCV

AIH, autoimmune hepatitis; ALD, alcoholic liver disease; HBV, hepatitis B virus; HCV, hepatitis C virus; NASH, nonalcoholic steatohepatitis; PBC, primary biliary cirrhosis.

cytokines have been the main subjects of investigation in genetic studies. The main enzymes involved in alcohol metabolism in humans are alcohol dehydrogenase (ADH), aldehyde dehydrogenase (ALDH), and cytochrome P450IIE1 (CYP2E1). It has been recognized for many years that genetic factors influence the activity of these enzymes and the rate of alcohol metabolism. Because of its fibrogenic potential, variations in the generation of acetaldehyde may explain individual differences after abusive alcohol consumption. The majority of studies have been performed in Asia, where the prevalence of polymorphisms of these enzymes is very high. Although it is well accepted that genetic polymorphisms in *ADH2*, *ADH3*, *ALDH2* and in the 5′-flanking region of *CYP2E1* are involved in individual susceptibility to alcoholism [158], their role in the progression of ALD remains controversial. Some studies indicate that the c2/c2, c2/c1 and c3/c2 alleles of the *ADH2* gene and the c2/c2 allele of *CYP2E1* gene, which result in increased enzymatic activity and acetaldehyde production, predispose to more advanced ALD [159]. However, these results have not been confirmed in other investigations [160]. Polymorphisms in genes encoding proinflammatory

cytokines known to participate in the pathogenesis of ALD have also been investigated. A single nucleotide polymorphism (SNP) located in the promoter region of the tumor necrosis factor (TNF)-α gene, which results in increased cytokine production, is associated with more severe steatohepatitis [161]. Polymorphisms in interleukin (IL)-1β and IL-1 receptor antagonist genes have been related with inherited susceptibility to ALD [162]. Similarly, patients with the *A* allele of the IL-10 gene and cytotoxic T-lymphocyte antigen (CTLA)-4 are more prone to develop severe fibrosis, suggesting an important role for the immune system in progression of ALD [163]. Another gene implicated in the pathogenesis of ALD is CD14, which is a cell receptor for lipopolysaccharide. Both clinical and experimental data indicate that activation of Kupffer cells and HSCs by gut-derived endotoxin is an important mediator in liver injury. An SNP in the promoter region of the CD14 gene that confers increased protein synthesis is a risk factor for developing alcoholic cirrhosis [164]. Finally, genetic variations of superoxide dismutase, a powerful antioxidant, are a risk factor for developing severe ALD [165]. This is consistent with a major role for oxidative stress in the hepatic toxicity of ethanol and may support the use of antioxidants in these patients.

PBC is a heterogeneous disease. Some patients have persistent minor histological changes, while others progress to cirrhosis. The current hypothesis of the pathogenesis of PBC is that an initial environmental factor (i.e., infection by *Chlamydia pneumoniae*) triggers an immunological reaction against bile duct epithelial cells [166]. T lymphocytes and cytokine secretion mediate persistent bile duct damage. Accumulation of bile salts and inflammatory cells induce activation of HSCs and progressive fibrosis. Genes encoding human leukocyte antigen class II (HLA-II) haplotypes and proinflammatory cytokines can influence individual susceptibility to develop chronic biliary damage. Twin and family studies strongly suggest a genetic predisposition to PBC [167]. Variations in immunoregulatory genes such as HLA-II alleles, proinflammatory cytokines (TNF-α, IL-1β), CTLA-4, and vitamin D receptor influence disease susceptibility [168]. Moreover, genetic polymorphisms may influence disease progression. HLA-II alleles (DRB1*0801, DQA1*0401, DQB1*0402) and polymorphisms in IL-1β, interleukin receptor antagonist, and TNF-α genes are associated with faster disease progression, although these results have not been confirmed by other studies [169]. These data indicate that a complex interplay between genes encoding immunnoregulatory proteins regulates disease progression. Interestingly, some alleles of the apolipoprotein E gene influence response to the standard therapy, ursodeoxycholic acid [170], suggesting that genetic polymorphisms may predict therapeutic response. Less is known about genetic variants influencing disease progression in PSC, although HLA-II alleles and polymorphisms in TNF-α and stromelysin genes can affect disease susceptibility [171]. Finally, other results have suggested that gender, HLA-II alleles, and polymorphisms in genes encoding proinflammatory cytokines can influence both susceptibility and disease progression in type 1 autoimmune hepatitis [172].

Many studies have analyzed the factors influencing fibrosis progression in patients with chronic HCV infection. The natural history of patients with chronic HCV is characterized by a slow progression of liver fibrosis [13]. Following infection, cirrhosis may develop after an average of 20–30 years. In some patients, the rate of fibrosis progression is much faster, and cirrhosis develops after 10–15 years, whereas in others the rate of progression is negligible. The pathogenesis of HCV-induced liver fibrosis is poorly known, partly due to the lack of a rodent model of persistent HCV infection. HCV escapes surveillance of the HLA-II-directed immune response and infects hepatocytes, causing oxidative stress and inducing the recruitment of inflammatory cells [173]. Both factors lead to HSC activation and collagen deposition. Moreover, HCV proteins (i.e., core protein) stimulate secretion of profibrogenic cytokines by hepatocytes and can directly induce fibrogenic actions in HSCs [174]. Although factors such as duration of infection, gender and alcohol consumption influence fibrosis progression, genetic factors may also play a role. Genetic variations are involved in susceptibility to persistent HCV infection, response to antiviral therapy, and progression of liver disease. Different HLA-II alleles and polymorphisms of genes involved in the immune response (manose-binding lectin, haptoglobin, mannan-binding lectin, solute carrier family 11 member 1) influence susceptibility and resistance to persistent HCV infection [175,176]. Similarly, variations in IL-10 and MxA, an interferon-induced protein, can determine individual response to interferon therapy [177]. Variations in genes involved in the immune response to HCV infection seem to influence disease progression. The TAP2 (transporter associated with antigen processing 2) *0103 allele, which predisposes to stronger antiviral activity and low viral load, is associated with slower disease progression in HCV-infected patients [178]. Variations in mannose-binding lectin and specific HLA-II alleles (DRB1*0405, DQB1*0401), which are involved in host defense against viral infections, and complement C5a also influence cirrhosis development [179]. The role of polymorphisms in proinflammatory cytokines is unclear. While one report indicates that the *TNF2* allele is more frequently found in patients with cirrhosis than in those with less severe liver disease [180], other studies have not confirmed these results. Variations in genes encoding key cytokines involved in human fibrogenesis may regulate fibrosis progression. These cytokines include angiotensin II and TGF-β, which play an important role in experimental liver fibrosis. Polymorphisms in the angiotensinogen gene, the angiotensin II precursor, as well as the TGF-β1 gene are major determinants in fibrosis progression in a series of patients with chronic HCV [181]. Interestingly, patients having mutations in both genes pro-

gress more rapidly than those having only one polymorphism. Similarly, variations of metalloproteinases also influence fibrosis progression [182]. The role of genetic variations of the *HFE* gene is controversial. The available studies investigating the role of C282Y heterozygosity have yielded contradictory results [14]. A few studies have attempted to generate prognostic genetic chips including several polymorphisms. Richardson and colleagues described a six-gene polymorphism panel able to predict fibrosis progression in these patients [183]. Another study that included a large number of patients in whom whole gene analysis was performed identified DEAD box polypeptide 5 and carnitine palmitoyltransferase 1A as major genetic determinants of fibrosis progression [184]. In patients with chronic HBV infection, polymorphisms in the IL-1, TNF-α and angiotensinogen genes influence fibrosis progression [185–187].

Little is known about factors influencing fibrosis progression in patients with NASH, a common cause of chronic liver disease [39]. Obesity, type 2 diabetes mellitus, and dyslipidemia are the most common conditions associated with NASH. At the time of diagnosis, almost one-third of the patients show established fibrosis. However, only a small porportion of these patients progress to liver cirrhosis. Potential fibrogenic factors include oxidative stress, iron accumulation, and hyperglycemia. Genetic variations can explain susceptibility to develop NASH in patients with obesity or diabetes [188]. Genetic factors influencing fibrosis progression in these patients are under investigation. While one study has shown that *HFE* C282Y heterozygosity is associated with faster fibrosis progression [189], other studies have not confirmed these results [190]. In morbidly obese patients, genetic variations in ther angiotensinogen and TGF-β1 genes influence fibrosis development [191].

In patients with hereditary hemochromatosis, additional gene variations such as a polymorphism in the myeloperoxidase promoter can accelerate the progression of fibrosis [192].

Pathogenesis of liver fibrosis/cirrhosis

Advanced fibrosis distorts the hepatic architecture by forming a fibrous scar and the subsequent development of nodules of regenerating hepatocytes defines cirrhosis (Fig. 27.7). While hepatic fibrosis is potentially reversible, established cirrhosis is usually an irreversible process [193]. Established cirrhosis results when bridging fibrosis is eventually accompanied by regenerative nodules. In early phases, incomplete septal cirrhosis can be found. It is characterized by the presence of very slender septa radiating from enlarged fields toward the center of the lobule. There are distended efferent vessels around the septum. This type of cirrhosis produces only portal hypertension and no liver failure is usually observed. The prognosis of these patients is acceptable if the portal hypertension is controlled. If the cause of liver injury (e.g., HCV infection, alcohol abuse) is not removed, the hepatic wound healing response to injury progresses and early cirrhosis develops. At this stage of the liver disease, thin fibrous septa with dissecting nodules are present. As liver damage progresses, wide scars containing clusters of regenerative hepatocytes are common and advanced cirrhosis develops. This stage of the disease is characterized by the accumulation of abundant fibrillar collagen, which is resistant to the collagenolytic actions of MMPs. Moreover, advanced cirrhosis comprises major changes in hepatic microcirculation, endothelial integrity and function, and abnormal hepatocyte organization. In this phase of the disease, cirrhosis is basically irreversible regardless of cessation of the causative agent.

Formation of nodules is the hallmark of advanced cirrhosis. Nodules are divided into dissection and regenerative nodules. Dissection nodules contain remnants of portal tracts and central veins. They contain thin fibrous septa as well as dilated sinusoids especially at their periphery that look like multiple central veins produced by the inflow of arterial blood coming from the surrounding wide scars. Regenerative nodules arise in the midst of scars favored by the rich arterial blood of scar tissue. They are round nodules with a fibrous pseudocapsule with bile ductules due to obstruction of bile flow. Because of their size, they compress the vessels of the capsule, contributing to the perpetuation of the cirrhosis. Importantly, regenerative nodules may undergo dysplastic and malignant changes.

According to the degree of fibrosis and the type of nodule, cirrhosis can be classified into different progressive stages: incomplete septal cirrhosis (incomplete bridging fibrosis, no nodules), early cirrhosis (thin bridging fibrosis with dissecting nodules), moderately advanced cirrhosis (thick bridging fibrosis with dissecting nodules), and advanced cirrhosis (wide septa with regenerative hyperplastic nodules). Histopathologically, advanced cirrhosis can be divided into micronodular and macronodular varieties. Micronodular cirrhosis is characterized by uniformly small nodules (< 3 mm in diameter) and regular bands of connective tissue. Typically, nodules lack portal organization; terminal (central) hepatic venules or portal tracts are difficult to identify. Macronodular cirrhosis is characterized by nodules that vary in size (3 mm to 5 cm in diameter) and which contain some normal lobular structure (portal tracts, terminal hepatic venules). Broad fibrous bands of varying thickness surround the large nodules. Collapse of the normal liver architecture is suggested by the concentration of portal tracts within the fibrous scars. Mixed cirrhosis (incomplete septal cirrhosis) combines elements of micronodular and macronodular cirrhosis. Regeneration in micronodular cirrhosis can result in macronodular or mixed cirrhosis. Conversion from micronodular to macronodular cirrhosis takes more than 2 years.

Vascular changes play a major role in the pathogenesis of advanced cirrhosis [194]. Complete septa may link central veins to central veins, creating anastomoses between

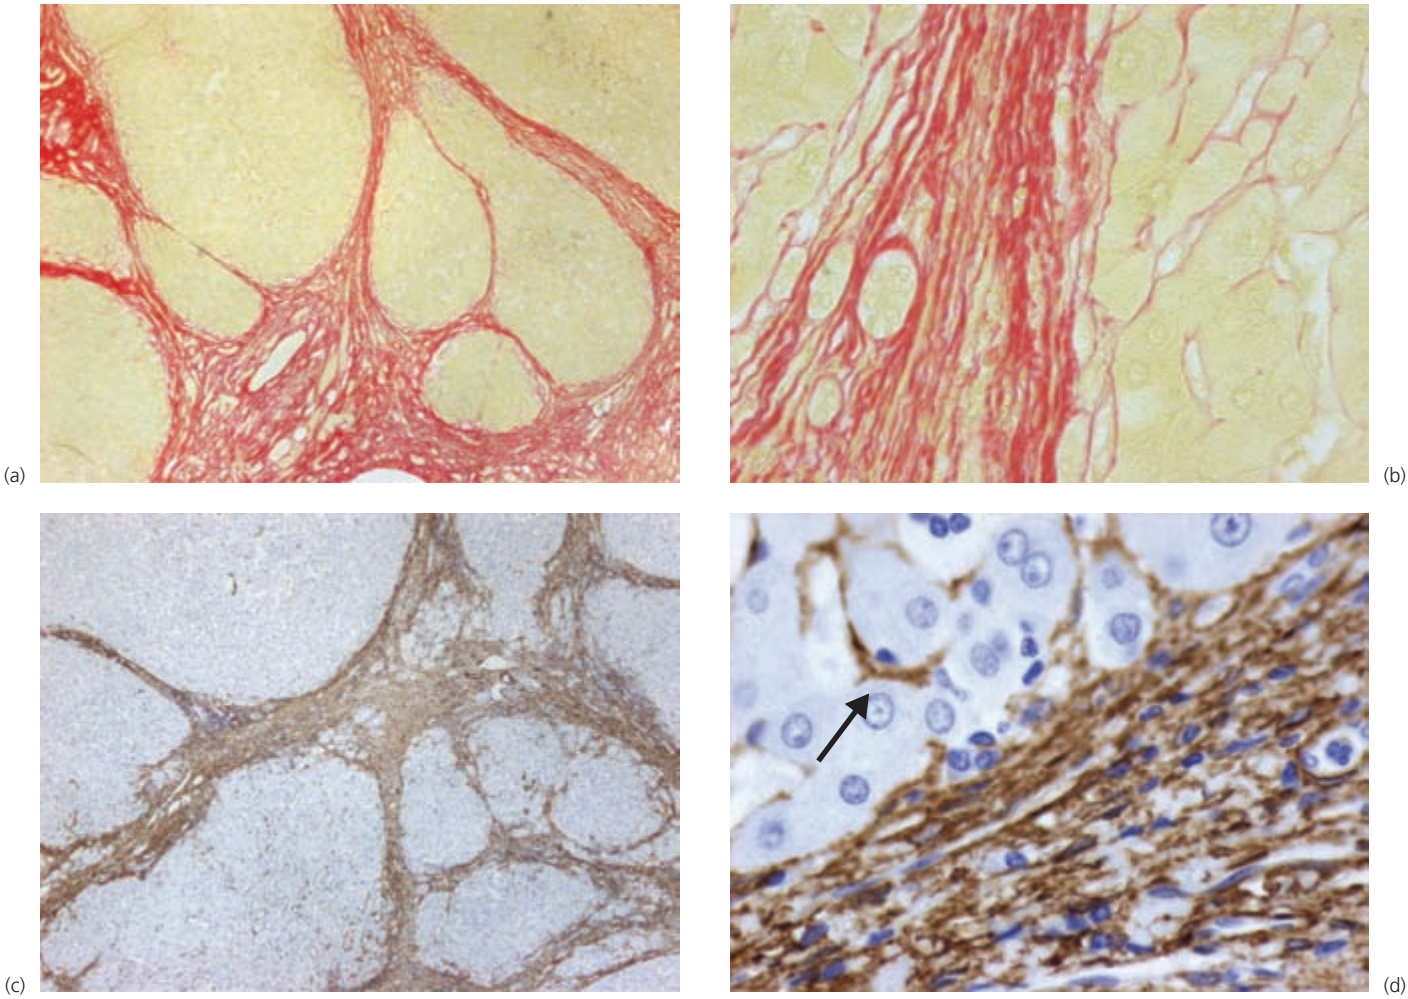

Figure 27.7 Histological appearance of liver cirrhosis in a patient with chronic hepatitis C virus infection. **(a,b)** Sirius red staining reveals bridging fibrosis with the development of regenerative nodules (magnification × 200). **(c,d)** Accumulation of myofibroblastic fibrogenic cells in the fibrous septa, as assessed by positive staining for smooth muscle α-actin cells. Most fibrogenic cells derive from perisinusoidal stellate cells (arrow) (magnification × 400).

draining vessels. Septa linking adjacent portal tracts create vascular anastomoses between afferent vessels of the portal tracts involved. Vascular structures in central–central and portal–portal septa are not the major determinants of a detrimental change in intrahepatic circulation. The key phenomenon in the emergence of a truly cirrhotic state is the development of fibrous vascularized septa linking portal tracts and central veins. Therefore portal–central bridging fibrosis creates direct anastomoses between the afferent (hepatic artery, portal vein) and efferent (centrolobular veins) vessels of the liver, allowing a fraction of the blood to bypass the lobular parenchyma, without functionally contacting a metabolically active parenchyma. In advanced cirrhosis, most of the hepatic blood supply appears to pass through the liver via these channels. Further vascular changes in developing and established liver cirrhosis are due to vascular thrombosis. Thrombosis of medium and large portal veins and hepatic veins is a common occurrence in cirrhosis, and these lesions are important in causing progression of cirrhosis. Investigations on neoangiogenesis in cirrhosis have focused attention on hypoxia of liver tissue. Hypoxia may result from several mechanisms: impairment in sinusoidal permeability and perfusion, intrahepatic shunts, vasoconstriction and thrombosis and capillarization of sinusoids. Liver tissue hypoxia aggravates fibrosis progression, so that fibrosis and hypoxia may aggravate each other in the presence of persistent parenchymal injury, leading to a vicious circle, which disrupts normal tissue repair and thereby promotes the development and progression of cirrhosis.

Pathophysiologically oriented antifibrotic therapies

There is no gold-standard treatment for liver fibrosis. Experimental studies have revealed targets to prevent fibrosis pro-

Table 27.4 Main antifibrotic drugs to treat liver fibrosis

Agent	Antifibrotic effects in hepatic stellate cells	Antifibrotic effect in experimental fibrosis	Antifibrotic effect in humans
Angiotensin inhibitors	Consistent positive data	Consistent positive data	Retrospective study
Colchicine	Not tested	Limited data	Discrepant results
Corticosteroids	Limited data	Limited data	Effective in autoimmune hepatitis
Endothelin inhibitors	Not tested	Limited data	Not tested
Interferon-α	Consistent positive data	Consistent positive data	Effective in chronic hepatitis C
Interleukin-10	Limited data	Consistent positive data	Isolated reports in chronic hepatitis C

Tocopherol	Consistent positive data	Limited data	Isolated reports in NASH

NASH, nonalcoholic steatohepatitis; PPAR, peroxisome proliferator activated receptor; TGF, transforming growth factor.

gression in rodents [11] (Table 27.4). However, the efficacy of most treatments has not been tested in humans. This is because of the need to perform serial liver biopsies to accurately assess changes in liver fibrosis and the requirement of long follow-up studies. The development of reliable noninvasive markers of liver fibrosis will positively impact the design of clinical trials. The ideal antifibrotic therapy would be the one that is liver-specific, well tolerated when administered for prolonged periods of time, and effective in attenuating excessive collagen deposition without affecting normal ECM synthesis.

Removal of the causative agent is the most effective maneuver in the treatment of liver fibrosis. This strategy has been shown effective in most etiologies of chronic liver diseases [10,19,151,195,196]. For patients with cirrhosis and clinical complications, liver transplantation is currently the only curative approach [197,198]. In randomized clinical trials using IFN-α plus ribavirin in patients with chronic HCV infection, persistent clearance of viral infection is associated not only with resolution of hepatic inflammation but also with improvement in liver fibrosis [151]. Moreover, long-term treatment with IFN-α is commonly associated with improvement of liver fibrosis, including in patients with cirrhosis [199]. These findings raise the possibility that IFN-α has an intrinsic antifibrotic effect independently of its antiviral effect. This hypothesis is supported by experimental models in which IFN-α inhibits the fibrogenic action of HSCs and prevents the development of liver fibrosis [46].

Because inflammation precedes and promotes the progression of liver fibrosis, antiinflammatory drugs have been proposed. Corticosteroids are only indicated for the treatment of hepatic fibrosis in patients with autoimmune hepatitis and acute alcoholic hepatitis [195]. Inhibition of the accumulation of activated HSCs by either inhibiting their activation/proliferation or promoting their apoptosis is another strategy. Antioxidants such as vitamin E, silymarin, phosphatidylcholine, and *S*-adenosyl-L-methionine inhibit HSC activation, protect hepatocytes from undergoing apoptosis, and attenuate experimental liver fibrosis [56,200,201]. Antioxidants exert beneficial effects in patients with alcohol-induced liver disease and NASH [202].

Disrupting TGF-β1 synthesis or signaling pathways prevents scar formation in experimental liver fibrosis [94]. This strategy includes inhibition of key members of the TGF-β superfamily such as bone morphogenetic protein-7 [203]. Moreover, administration of growth factors (e.g. IGF, hepatocyte growth factor and cardiotrophin) or their delivery by gene therapy attenuates experimental liver fibrosis [204,205]. Inhibition of growth factors involved in liver fibrogenesis (i.e., PDGF-BB) is also useful to attenuate liver fibrosis in rats [206]. However, these approaches have not been tested in humans and may favor cancer development.

Substances that inhibit key signal transduction pathways involved in liver fibrogenesis have also potential to treat liver fibrosis [11]. They include pentoxifylline (phosphodiesterase inhibitor), amiloride (Na^+/H^+ pump inhibitor), and *S*-farnesylthiosalicylic acid (Ras antagonist). Stimulation of pathways with antifibrogenic actions (e.g., STAT1) can also reduce collagen deposition [207]. Ligands of PPAR-α or PPAR-γ such as thiazolidinediones exert beneficial effects in experimental liver fibrosis and in patients with NASH [208,209]. Drugs that interfere with PI3K/Akt pathways, such as rapamycin, have been shown to inhibit fibrosis in rats [210]. The usefulness of rapamycin in humans deserves further investigation. Pharmacological manipulation of nuclear factors can also modulate liver fibrosis in vivo. For example, stimulation

of the nuclear pregnane receptor inhibits liver fibrosis in rats [211,212].

Promoting apoptosis of activated HSCs is an alternative approach to the treatment of liver fibrosis. Substances such as gliotoxin induce apoptosis of cultured cells and remove activated HSCs from fibrotic livers [213–215]. These effects can also be achieved by inhibiting antiapoptotic factors in HSCs such as κB kinases or by using proteasome inhibitors [216,217]. Another substance that causes death of HSCs is anandamide [218]. Anandamide is an endogenous cannabinoid and belongs to a family that has been shown to modulate hepatic fibrogenesis both in vitro and in vivo. Endocannabinoids bind to CB1 and CB2 receptors, which exert powerful profibrogenic and antifibrogenic effects, respectively [219,220].

Inhibition of the renin–angiotensin system is probably the most promising strategy for treating liver fibrosis [12]. There is overwhelming experimental data indicating that pharmacological or genetic inhibition of this system attenuates liver fibrogenesis in rodents. Renin–angiotensin inhibitors are widely used as antifibrotic agents in patients with chronic renal and cardiac diseases and appear to be safe when administered for prolonged periods of time [221]. Little information is available on liver fibrosis. Transplanted patients receiving renin–angiotensin inhibitors as antihypertensive therapy show less fibrosis progression than patients receiving other types of drugs [222]. Moreover, AT_1 receptor blockers reduce liver fibrosis in patients with NASH [223]. Large prospective clinical trials should be performed to confirm these promising data. Other vasoactive substances are potential targets to treat liver fibrosis. Endothelin-1 type A receptor blockers and vasodilators (PGE_2 and nitric oxide donors) exert antifibrotic activity in rodents, yet the effects in humans are unknown [131]. Cyclooxygenase (COX)-2, a key enzyme in the generation of vasodilatory prostaglandins, is a novel target to treat liver fibrosis. However, COX-2 inhibition has yielded contradictory results, probably due to differences in specificity between the inhibitors used. In particular, COX-2 inhibitors with intrinsic PPAR-γ activity have net antifibrotic effect [224]. Finally, the mineralocorticoid receptor antagonist spironolactone also suppresses liver fibrogenesis in rodents [225].

Different herbal compounds, many of them traditionally used in Asian countries to treat liver diseases, have been demonstrated to have antifibrotic effects [11]. They include sho-saiko-to, glycyrrhizin, and savia miltiorhiza. An alternative approach is to inhibit collagen production or promote its degradation [226]. Inhibitors of prolyl-4 hydoxylase and halofuginone prevent the development of experimental liver cirrhosis by inhibiting collagen synthesis. MMP-8 and urokinase-type plasminogen activator stimulate collagen degradation in vivo [227]. Antibodies that block tissue inhibitors of metalloproteinases such as TIMP-1 reverse established liver fibrosis, suggesting that they may be useful for patients with advanced liver diseases [155]. The efficacy of these drugs in humans is unknown and may result in undesirable side effects.

A limitation of the current antifibrotic approaches is that antifibrotic drugs are not efficiently taken up by activated HSCs or may produce unwanted side effects. Cell-specific delivery to HSCs could provide a solution to these problems. Promising preliminary results have been obtained using different carriers (e.g., cyclic peptides coupled to HAS recognizing collagen type VI receptor or PDGF receptor) [228]. Drugs such as pentoxifylline or mycophenolic acid are efficiently released into activated HSCs and reduce liver fibrogenesis [229,230]. Interestingly, this approach could also be useful for treating portal hypertension, a condition that involves chronic contraction of activated HSCs.

Why does the liver need to regenerate?

The liver receives all absorbed products digested by the gastrointestinal tract through the portal circulation. While many of the absorbed compounds are in the broad category of nutrients, an equal number do not belong to the chemistry of normal metabolic pathways and as such are classified as xenobiotics. Many of the xenobiotic compounds are water soluble and can be excreted by the liver through the bile or released into the bloodstream and excreted by the kidneys. A subclass of xenobiotics comprises medicinal drugs and plant alkaloids and these are lipophilic (not water soluble) and processed through a complex set of enzymes (drug-metabolizing enzymes). These enzymes include multiple members of the family of proteins known as cytochrome P450 (CYP), as well as several enzymes involved in conjugation of lipophilic xenobiotics with smaller moieties (e.g., sulfate, acetyl, glucuronide, and other hydrophilic moieties). During the course of these complex reactions, intermediary metabolites generated by the pathways of xenobiotic detoxification acquire electrophilic properties and thus can react directly with cellular nucleophiles (proteins, RNA and DNA). These electrophiles, often generically described as *free radicals*, bind to cellular nucleophiles through covalent bonding and may either inactivate them (e.g., proteins) or permanently change them (e.g., formation of DNA adducts leading to mutations) [1]. Massive covalent bonding of xenobiotics activated to free radicals is toxic to hepatocytes and leads to cell death via necrosis or apoptosis. The potency of the toxic xenobiotic or the amount ingested may be such that most of the hepatocytes die, leading to fulminant hepatitis. In most situations, although a large number of hepatocytes die, the surviving hepatocytes restore the liver architecture and the liver can function; however, permanent residual scars can be visualized internally or on the surface of the liver. Such events are not uncommon in animals living in the wild. Scars on the surface of the liver are so common that they were used in ancient times during animal sacrifices to divine the future. There were clay libraries in ancient Babylon with hundreds of liver samples, instructing ancient soothsayers on all possible scars seen on the surface of the liver and their meaning in terms of predicting the future. The existence of such liver scars in wild animals suggests that massive toxic liver injury in natural settings is very common. Liver regeneration emerged through evolution as a survival adaptation to allow longevity of the organism in a natural, but often nutritionally hostile, environment.

Experimental models and clinical settings

Liver regeneration aims to restore hepatic mass. Hepatocyte proliferation occurs in any situation associated with chronic liver disease or massive injury to the liver, leading to loss of hepatic parenchyma. Chronic hepatic inflammation due to viruses or autoimmune mechanisms is associated with variable rates of hepatocyte death, easily seen as apoptotic bodies. Immunohistochemical staining with nuclear cell cycle

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

markers such as proliferating cell nuclear antigen (PCNA) in these cases often shows that the vast majority of surviving hepatocytes are engaged in the cell cycle (G1 to M), in contrast to normal healthy livers in which more than 99% of hepatocytes are not in the cell cycle (G0 stage) [2]. This can be demonstrated even in the mildest forms of liver disease and is also true in the most severe cases of fulminant hepatitis. Acute liver damage (e.g., as a result of acetaminophen overdose) is also associated with hepatocyte death (centrilobular area) and compensatory proliferation of the surviving hepatocytes. Studies with patients suffering from Dubin–Johnson syndrome have been very instructive. In these patients, deposition of a melanin-like substance makes hepatocytes black; newly regenerated hepatocytes do not yet have melanin accumulation and appear white. When these individuals acquire acute viral hepatitis, it can be easily determined from the percentage of hepatocytes of different color that, in a standard clinically overt episode of acute viral hepatitis, more than 90% of the original hepatocytes die [3]. However, compensatory proliferation of the surviving hepatocytes maintains liver histology and function until the virus is cleared and health is restored. Easier to demonstrate is hepatic regeneration following hepatic resections (e.g., to remove solitary tumors, cysts, repair trauma). Up to 70% of the liver may be removed, but liver mass is restored within 8–20 days, depending on the magnitude of the resection, the nutritional status of the patient, age, and so on [4].

Experimental models to study liver regeneration typically employ rodents (rats or mice). Administration of a chemical toxin such as carbon tetrachloride (CCl_4) or acetaminophen causes centrilobular necrosis, since most of the CYP proteins reside in the centrilobular hepatocytes, and CCl_4 (and acetaminophen) require interaction with CYP proteins to be converted into the active electrophilic metabolites that cause hepatocyte death. CYP protein is much less expressed in periportal hepatocytes compared with centrilobular hepatocytes; thus, the periportal hepatocytes are unable to activate CCl_4 and acetaminophen and are spared from damage [5]. Injury caused by most of the hepatotoxic chemicals follows this pattern of histology. Very few chemicals, such as allyl alcohol, produce hepatic injury that is predominantly periportal, and the mechanisms leading to this type of injury are not fully understood [6]. Induction of acute centrilobular necrosis is easily achieved with proper dosing of chemicals and remains a simple way to cause acute liver injury followed by hepatic regeneration. On the other hand, experimental models using this approach are difficult to study because massive hepatocyte necrosis within a localized lobular zone leaves an area of destruction in which dead cells need to be first removed by macrophages and other inflammatory cells prior to initiation of regeneration. Thus, chemical injury models suffer from an inherent difficulty in distinguishing between events related to acute inflammation and early events associated with liver regeneration.

A less complicated model for studying liver regeneration is two-thirds partial hepatectomy (PHx). The liver of rats and mice has five separate lobes. Each lobe has its own pedicle containing vascular structures, bile duct branches, and nerve branches. Higgins and Anderson first described partial hepatectomy in 1931 [7]. Following a small longitudinal mid-abdominal incision, mild abdominal pressure leads to externalization of three of the five liver lobes. These lobes can be easily removed after ligation of their fibrovascular pedicles. The remaining two lobes stay within the abdominal cavity. They start growing in size and restore the mass (but not the five-lobe shape) of the liver within 5–6 days after PHx. Since PHx is not associated with formation of necrotic tissue within the remaining liver lobes, one can study the earliest events after PHx and thus use this model to dissect the earliest pathways associated with the regenerative process without the interference of the complications associated with the inflammatory response seen with CCl_4 treatment.

Unless otherwise stated, our presentation of hepatic regeneration will focus on events leading to liver regeneration after PHx.

Cellular kinetics during liver regeneration after partial hepatectomy

In some tissues such as the skin and intestine, tissue restoration proceeds only from a small fraction of the overall cell population (i.e., *stem cells*). This is not the case in the liver. The entire hepatic cell population remaining after PHx participates in proliferative events that restore liver mass. In rats, PHx is followed by entry of hepatocytes into DNA synthesis within 12 h. The fist peak of hepatocyte mitoses is seen at 24 h. (Patterns of feeding and lighting of the experimental animals can moderately alter the timing of these events. Also, in mice, these phenomena occur about 12 h later than they do in rats [8].) Most of the hepatocytes (> 98%) can be labeled by tagged DNA precursors (tritiated thymidine or bromodeoxyuridine) in the first 24 h after PHx. A similar 24-h labeling pulse given 24–48 h after PHx labels only 50%–60% of the hepatocytes. Thus, the original 30% of hepatocytes doubles following PHx, becoming 60% at 24 h, and slightly more than half of these proliferate to add another 35%–45% of the number of hepatocytes in the original liver (prior to PHx). Thus, by the end of 48 h, the total number of hepatocytes is 100% of the original (or slightly more than 100%: a small wave of apoptosis often follows the end of proliferation after PHx [9]). The first wave of proliferation starts from the periportal hepatocytes [10], with matrix metalloproteinase (MMP)-9 expression seen at 3 h after PHx in this region [11]. The second wave of proliferation occurs predominantly in the pericentral areas. Hepatocyte proliferation, as evidenced by mitoses, nuclear labeling, etc., proceeds as a wave from the periportal to the pericentral region of the lobule [10]. It is

not clear whether the other liver cells types, such as biliary epithelial cells or stellate cells, proliferate following the same zonation pattern. Hepatocytes are the first cell types to enter into proliferation. Biliary epithelial cells and stellate cells follow after a 12–24 h delay, whereas endothelial cells go through a broad proliferative stage 2–6 days after PHx [12].

As discussed later, following PHx, hepatocytes receive several proliferation-related signals from their immediate environment and from the peripheral blood [13–16]. Hepatocytes undergo rapid changes in gene expression and activation of receptors and transcription factors. During proliferation, hepatocytes generate paracrine growth signals consisting of proteins known to be mitogenic to the other populations of liver cells. Proliferation-related events typically cease for most cell types by day 5–6 after PHx. Hepatocytes are typically smaller at the end of their proliferation at 48 h. The size of the now quiescent hepatocytes becomes gradually larger as liver weight slowly increases from days 3–6 after PHx [8].

Functional and structural changes in liver histology during regeneration

Perhaps the most fascinating aspect of liver regeneration is that hepatocytes exhibit minimal alterations in structure and function while regeneration is proceeding. Liver continues to provide all essential functions, from production of plasma proteins to bile acid conjugation, drug metabolism and synthesis of bile, with only minimal changes. Albumin concentrations drop by about 5%–10%; glucose tends to be a little lower but within normal limits. This is remarkable for the following reasons. Firstly, more than 95% of the hepatocytes undergo at least one full DNA synthesis cycle and mitotic division during this process. Secondly, hepatocytes tend to be polyploid. Most human hepatocytes are binucleate, with $2n$ ploidy per nucleus. In the rat and mouse, most hepatocytes are polyploid, with ploidies ranging from $4n$ to $32n$ per nucleus [17,18]. At the end of regeneration, hepatocyte ploidy tends to be less but returns to normal (polyploid) levels within 21 days after PHx [19]. Other changes are also detected. A mild degree of accumulation of fatty droplets appears in hepatocytes in the first 48 h after PHx. Recent studies have determined that changes in fatty acid metabolism and lipid biosynthesis occur during the regenerative process [20]. As hepatocytes enter into mitosis, transient alterations in the structure of bile canaliculi, including transient restructuring of tight and gap junctions, can be observed. However, the bile canaliculi and their function are maintained [21,22]. As hepatocytes proliferate prior to initiation of angiogenesis, newly formed small hepatocytes become arranged in hypovascularized clusters [23]. Angiogenesis is led in large part by growth factors produced by newly proliferated hepatocytes, which stimulate formation of fenestrated endothelium that becomes organized into regular sinusoids. This process eliminates the hypovascularized hepatocytic clumps and restores the characteristic hepatocyte plates [24]. Hepatocyte plates of a liver that has undergone regeneration are, on average, thicker (two cells thick) than the plates of a normal liver (one cell thick) [25]. However, it should also be emphasized that regeneration after PHx does not result in an increased number of lobules. There is no evidence for formation of new portal triads. The existing lobules increase in size.

General functional aspects of cell signaling during liver regeneration

There are common aspects of the experimental approaches used to investigate signals associated with liver regeneration. One approach is to study changes related to specific molecules during the process and examine linkage of these changes to signaling mechanisms. Another approach is to eliminate specific potential signals (by generating genetically engineered mice, using silencing RNA or specific inhibitors) and study the effect of blockade on liver regeneration. There are literally hundreds of studies following these approaches. However, some general conclusions have been drawn from these studies that are applicable to all signaling associated with regeneration.

- PHx triggers multiple and concurrent signaling pathways within minutes. These pathways involve the receptors of, for example, hepatocyte growth factor (HGF), epidermal growth factor (EGF), interleukin (IL)-6, tumor necrosis factor (TNF), transforming growth factor (TGF)-β1, norepinephrine, and Notch.
- Blocking several signals causes different degrees of delay in the regenerative process. However, no block completely arrests liver regeneration. Regenerative signals are highly redundant: the regenerative process can occur even when signaling receptors are eliminated, because the required pathways for activation and completion of the cell cycle can be approached through alternative routes. (Perhaps the only exception to this is the documented inability of the liver to fully regenerate after targeted inactivation of the HGF receptor [cMet], but this is observed only after a full two-thirds PHx.)
- In addition to signals operating in the liver, changes involving multiple growth factors and cytokines (HGF, EGF, IL-6, TNF, norepinephrine, TGF-β1) also occur in the peripheral blood. Liver regeneration is also associated with DNA synthesis and mitoses in hepatocytes or hepatic tissue fragments transplanted in extrahepatic sites.

Extracellular signals leading liver into regeneration

Such signals include growth factors and cytokines and their specific receptors. In addition, other ligand–receptor signals

are also involved, such as Notch/Jagged, catecholamines and α_1-adrenergic receptors, and angiopoietins. The evidence implicating these signals and their potential roles during regeneration is described in this section.

Hepatocyte growth factor and its receptor cMet

HGF was discovered in 1989 on the basis of its mitogenic properties on hepatocytes in culture and the fact that it rises dramatically in the peripheral blood within 1 h after PHx [26–28]. There is an extensive literature on HGF, which has effects on many tissues besides liver [29,30]. Another protein called scatter factor (SF) was subsequently found to be identical to HGF and the name HGF/SF is often used to refer to the protein [31]. This section focuses on HGF in the context of its role in liver regeneration and biology. The HGF receptor cMet recognizes HGF as its only ligand and mediates all the biological effects of HGF [32,33]. General aspects of the biology of HGF and cMet pertinent to this review include the folowing.

- HGF is produced by mesenchymal connective tissue cells, including hepatic stellate cells [34] and fenestrated sinusoidal endothelial cells [35]. cMet is a receptor tyrosine kinase [36–39]. In addition to its direct role as a signaling receptor, cMet also binds the cell death-associated receptor Fas on the plasma membrane of epithelial cells, thus raising the threshold concentration that Fas ligand has to achieve in order to induce apoptosis [40]. cMet is generally present on epithelial cells, but also on endothelial cells. In liver, cMet is expressed by hepatocytes, endothelial cells, biliary epithelial cells, and stellate cells [41]. In the brain, there are select groups of neurons that express either HGF or its receptor [42].
- The full-size HGF molecule is composed of an amino-terminal hairpin loop and four kringles (comprising the HGF heavy chain). This protein is attached to a light chain by S–S bonds. The light chain has an inactive pseudoprotease motif. The whole molecule has high homology to other proteins related to coagulation and fibrinolysis, which also bear kringles but have an active protease site. These proteins include plasminogen, thrombin, and plasminogen activators [28,36].
- HGF is produced as a single-chain molecule and becomes activated to the heterodimeric form by proteolytic cleavage. This is mostly mediated by the urokinase plasminogen activator (uPA), free or attached to the urokinase receptor (uPAR) [43]. Other proteases have also been shown to cleave HGF in vitro, including plasminogen and bradykinin. Another protease, known as HGF activator, is highly homologous to coagulation factor XII and appears to act as a soluble protein [44].
- The single-chain inactive HGF precursor is a heparin-binding protein and as such is present in high concentrations in the extracellular matrix (ECM) of several tissues. It is present in high concentration in the sparse ECM of the liver, concentrated primarily in the periportal region [45].
- Homozygous deletion of HGF or its receptor is associated with embryonic lethality. There are abnormalities in many embryonic tissues, most prominently related to abnormal structure of the placenta, small liver [46,47], and abnormal erythropoiesis (Michalopoulos G, unpublished observations).
- Sustained short-term infusion of HGF causes proliferation of hepatocytes in normal rats [48] and doubling of liver weight in mice within 5 days [49].

While HGF plays a role in the biology of most tissues, it appears to have specific functions related to liver regeneration and liver biology in general. The model emerging as to the role of HGF and cMet in liver regeneration is as follows.

- There is a rapid (within 5 min) increase in uPA activity following PHx [50]. This generates a cascade of proteolytic events involving activation of plasminogen to plasmin [51] and subsequent activation of MMP-9 [11].
- As the hepatic ECM undergoes rapid remodeling, the bound HGF single-chain precursor is rapidly converted within the liver to the active two-chain form. This reaction is catalyzed by uPA [50]. Mice deficient in urokinase have defective liver regeneration due to insufficient activation of HGF [52,53]. Activated HGF is available to act locally and also escapes to the peripheral blood, where it quickly rises within 30–60 min after PHx [54]. The form of HGF appearing in the plasma is the active heterodimeric form [55]. (Other ECM-bound molecules also rise in the plasma after PHx, including TGF-β1 and hyaluronic acid; see relevant sections.)
- The HGF receptor is activated within 15–30 min after PHx [56].
- The above events result in a decrease in HGF in hepatic ECM. However, the synthesis of new HGF begins at 3 h after PHx [57], and both single-chain and heterodimeric forms rise rapidly in the liver, with a peak at 48 h after PHx [55]. The source of the new HGF is primarily hepatic stellate cells [34] and, to a lesser extent, fenestrated sinusoidal endothelial cells [35]. The latter respond to production of vascular endothelial growth factor (VEGF) by proliferating hepatocytes and synthesize HGF by signaling of the VEGF receptor 1.
- In addition to HGF generated in the liver, HGF mRNA also rises in the lungs [58] by mechanisms that are not clearly understood but which may involve IL-1, IL-6 [59], and norepinephrine [60].

Despite all the evidence that HGF is associated with mitogenic signaling very early during regeneration, targeted inactivation of cMet on hepatocytes does not block the early signaling events associated with liver regeneration. However, these mice fail to complete regeneration, and hepatocytes become arrested at some point in the cycle at late S or G2 [61]. In a similar study, it was shown that targeted inactivation of cMet in the liver interferes with activation of extracellular signal-regulated kinase (ERK)1/2, and hepatocytes had decreased rate of entry into S phase [62]. The nature of the block is not clear, but it appears that some of the

signals expected to be delivered by cMet early in the regenerative process are not redundant and cannot be substituted by other receptor tyrosine kinases involved in the process, such as the EGF receptor.

Epidermal growth factor receptor and its associated ligands

The EGF/EGF receptor (EGFR) signaling system involves a very complex array of receptors, coreceptors and multiple ligands and operates on most epithelial cells [63,64]. EGFR is a member of the Erb family of receptor tyrosine kinases, a family that consists of four members. EGFR is also known as ErbB or HER. The other Erb members are ErbB-2 (HER-2, NEU), ErbB-3 (HER-3), and ErbB-4 (HER-4). HER-4 is not expressed in adult or embryonic liver. More than 10 ligands exist for EGFR, including EGF, TGF-α, amphiregulin, heparin-binding EGF (HB-EGF), Cripto, Epiregulin, and Betacellulin. The receptor system and many of the ligands are ancient (in a phylogenetic sense) and have been described in species as primitive as nematodes [65]. EGFR forms homodimers, or it can form heterodimers with ErbB-2. The latter also possesses a kinase domain. Binding of ligands to either the homocomplexes or heterocomplexes triggers phosphorylation of tyrosine sites and activation of the receptors. Activation of EGFR is evident at 60 min after PHx [56,66]. Although all ligands of EGFR bind to the same receptors, their effects are nonetheless significantly different in terms of intensity of elicited response. Also, while many ligands are expressed during regeneration, some deliver more essential signals than others. The basis for such differences in the effects induced by EGFR ligands has been discussed in many reviews [67]. Basically, binding of ligands causes activation of the receptor, which is followed by endocytosis through clathrin pits and processing through the endosome system of membranes and vesicles. EGFR–ErbB-2 complexes are stable through endosomal processing and tend to be recycled back to the plasma membrane, whereas EGFR–EGFR complexes are typically processed for degradation. The complexes between EGFR and ErbB-2 also tend to stay bound to ligand and thus signal for longer periods of time. Thus, much of the observed differences in signaling between EGFR ligands can be explained by their differential affinity for EGFR–EGFR or EGFR–ErbB-2 complexes on the plasma membrane, and the different signaling capabilities of the two complexes [68–71]. All EGFR ligands are directly mitogenic on hepatocytes in primary culture, without requiring the presence of any other cytokines to exert this effect. The EGFR ligands implicated in regeneration are discussed in the following sections.

Epidermal growth factor

EGF is synthesized in multiple exocrine glands, and is found in their exocrine fluids. It is also secreted as an endocrine product from the same sites. Brunner glands of the duodenum are very active in secretion of EGF and the endocrine component of this function sends EGF directly and continually to the liver [72]. EGF injected into the liver through the portal vein is sequestered in large amounts in one pass and accumulates in periportal sites [73]. Mouse salivary glands also produce much EGF, and removal of salivary glands in the male mouse delays and decreases the regenerative response [74]. Sustained injection of EGF leads to hepatic enlargement [75]. However, there is no evidence of a rise in EGF in plasma after PHx. This is not surprising, given the high affinity and capacity of the liver to sequester EGF present in the portal circulation. Even though the role of EGF per se is enigmatic and often disputed, it should be noted that EGF is a direct mitogen for hepatocytes [76]. In view of the fact that (i) EGFR is activated within 30–60 min after PHx, (ii) EGF is always present in the portal circulation, and (iii) the EGF per hepatocyte ratio should increase threefold after two-thirds PHx, EGF is a good candidate for being the original trigger of the whole set of subsequent events following PHx. However, this is highly speculative because studies in mice with homozygous deletion of EGF have not been carried out.

Transforming growth factor-α

This EGFR ligand is produced as a large precursor of 28 kDa, which is inserted into the plasma membrane. The inserted precursor can have effects on adjacent cells expressing EGFR, without ever leaving the originating cell [77,78]. The extracellular portion is cleaved off by specific proteases, such as TACE/ADAM17, generating the active free ligand [79]. TGF-α is the stronger ligand for EGFR in terms of its mitogenic effects on hepatocytes [80]. TGF-α is also produced by hepatocytes as they undergo proliferation. TGF-α mRNA increases dramatically after PHx, but the overall increase in protein is rather small [81,82]. EGFR is expressed in hepatocytes as well as endothelial cells and biliary epithelium. It is not clear whether TGF-α has an autocrine function on hepatocytes that synthesize it or whether it has only a paracrine function on cells adjacent to hepatocytes expressing EGFR. Injection of TGF-α through the portal vein induces hepatocyte DNA synthesis, clearly demonstrating that TGF-α can be a mitogen for hepatocytes [83]. On the other hand, liver regeneration proceeds normally in mice with homozygous deletion of TGF-α [84]. This is not surprising given the availability of multiple EGFR ligands that can complement the function of TGF-α in its absence. Deletion of EGFR itself is not associated with any hepatic abnormalities during development [85], but the response of $EGFR^{-/-}$ mice to PHx has not been studied.

Heparin-binding epidermal growth factor and amphiregulin

HB-EGF and amphiregulin are two additional members of the EGFR ligand family. Injection of HB-EGF to mice subjected to only one-third PHx accelerated DNA synthesis to

levels seen with mice subjected to two-thirds PHx. Mice deficient in HB-EGF have delayed liver regeneration [86]. Similarly, mice deficient in amphiregulin also have decreased hepatic regenerative activity [87]. The results observed in mice deficient in either of these EGFR ligands contrast with those obtained with mice lacking TGF-α and are surprising because TGF-α is overall a stronger mitogen for hepatocytes than these two ligands. Details of the differences in interaction between amphiregulin, HB-EGF and TGF-α with EGFR in the liver need to be better understood.

Tumor necrosis factor-α

TNF has numerous functions on many cell types, depending on cell status and function. In many situations, as in tumor cells, TNF triggers apoptosis. In other cell types, TNF triggers activation of NF-κB and promotes cell survival. The outcome of interaction between TNF and target cells depends on the redox status [88], concentrations of free radicals, and TRAF proteins [89,90]. This is discussed further in the section on NF-κB. TNF is produced by hepatic macrophages (Kupffer cells) [91]. It rises in the peripheral blood after PHx [92]. TNF is not a direct mitogen for hepatocytes. In culture, it enhances the effect of EGF or HGF. Similarly, TNF enhances the mitogenic effect of subthreshold levels of HGF or TGF-α on liver when these growth factors are injected in vivo [83]. Antibodies neutralizing TNF injected at PHx block activation of Jun N-terminal kinase (JNK) and delay the regenerative response [93]. More significantly, there is delay and decrease in liver regeneration in mice with homozygous deletion of TNF receptor 1 (TNFR1) [92,94,95]. The mode by which TNF functions is not entirely clear. It is associated with activation of NF-κB and there is substantially decreased NF-κB activation in TNFR1$^{-/-}$ mice [96]. Even though NF-κB does not play an essential role during liver regeneration [97], the multiplicity of functions associated with NF-κB activation in most cell types suggests that the observed rapid activation of NF-κB after PHx (see below) must play an important role in the process. TNF has also been linked with increased production of the plasma membrane metalloproteinase TACE/ADAM17 associated with proteolytic activation of many entities, including TNF itself and TGF-α [98]. The latter is intercalated in the plasma membrane through a defined transmembrane motif. TACE/ADAM17 cleaves the extracellular portion of TGF-α and generates the smaller active form. This event has been observed in hepatocyte cell lines overexpressing TGF-α, and if it occurs in the context of liver regeneration, it must be a later event because TGF-α mRNA does not rise until about 3 h after PHx. TNF also induces production of IL-6 in hepatic macrophages [99]. IL-6 appears to have some effects on liver regeneration on its own, and administration of IL-6 corrects some of the deficiencies in liver regeneration seen in TNFR1-deficient mice [92]. The overall effects of TNF are multiple and it is thought that TNF provides a priming effect on hepatocytes, making them susceptible to the effects of growth factors (EGF and HGF). The concept is more useful for highlighting cooperative effects between TNF and the growth factors and should not be interpreted as denoting a hierarchy of events in which the effects of TNF precede those of the growth factors. Events triggered by TNF as well as those triggered by HGF, EGF, and Notch are concurrent and interdependent.

Interleukin-6

IL-6 is an intriguing cytokine. It is one of the earliest cytokines expressed during embryonic development (by the fertilized ovum). It attaches to a soluble receptor and forms a complex, which in turn binds to gp130, a receptor that IL-6 shares with other cytokines such as oncostatin M, leukemia inhibitory factor, and ciliary neurotrophic factor. Each one of the latter cytokines also has a unique soluble receptor, forms a complex, and binds to gp130 [100]. As with the EGFR ligand system, many of the functions of the different cytokines that bind to the shared gp130 receptor differ in intensity from one another, leading to a spectrum of responses. IL-6 is produced by macrophages and has been well known for years as the inducer of the hepatic acute-phase response. This response appears in acute body-wide infections and diffuse inflammatory conditions. A large repertoire of proteins is synthesized by hepatocytes during the acute-phase response, including serum amyloid proteins, complement components, and proteins of the opsonin group [101–105]. Mice with homozygous deletion of IL-6 have an overall normal phenotype but appear to be sensitive to parasitic and fungal infections [106]. The same mice were reported as suffering from deficient hepatic regeneration and increased mortality after PHx [107]. However, subsequent studies with IL-6$^{-/-}$ mice found very few deficiencies in the regenerative response [9]. In addition, mice with homozygous deletion of the shared gp130 receptor also have a normal regenerative response [108]. As already mentioned, a common feature associated with all extracellular signals associated with liver regeneration is the redundancy of the associated pathways. Most evidence suggests that the role of IL-6 in hepatic regeneration is not as essential as originally thought. However, this should not be meant to imply that IL-6 does not play a role. All studies agree that activation of the transcription factor STAT3 is deficient in IL6$^{-/-}$ and gp130$^{-/-}$ mice, and STAT3 is well known to be activated at the early stages of entry into the cell cycle in most proliferating cells [109]. IL-6 also rises in the plasma after PHx and replaces the regenerative defects seen in TNFR1-deficient mice [92]. In addition to its other properties in relation to liver, IL-6 is a direct mitogen for biliary epithelial cells in culture [110]. It is also highly expressed in spontaneously growing hepatic organoid cultures and its expression is suppressed by dexamethasone [111]. Double transgenic mice with overexpression of both IL-6 and its soluble receptor targeted to the liver have liver enlargement and focal areas of hepatocyte hyperplasia [112].

Norepinephrine

Several studies have associated small signaling molecules acting through G protein-associated receptors with comitogenic signals. Norepinephrine (NE) and epinephrine are in this category of molecules and act through α- and β-adrenergic receptors [113]. NE enhances the effects of HGF and EGF in hepatocyte cultures and the effect can be blocked by the α_1-specific blocker prazosin [114,115]. In relation to EGF, this is also associated with a heterologous downregulation of EGFR [116]. However, NE is more intriguing because it has a multiplicity of other effects related to liver regeneration. It partially inhibits the mitoinhibitory effects of TGF-β1 on hepatocytes [117]. NE increases production of EGF from salivary glands and Brunner glands of the duodenum [72,118]. Since NE quickly rises in the plasma after PHx, an NE-dependent increased output of EGF would enhance the EGFR-mediated signals for hepatocytes (in addition to the direct effects of NE on EGFR itself through the α_1-adrenergic receptor). In addition, NE induces expression of HGF in fibroblasts [60], suggesting that the rise in plasma NE levels after PHx may be a contributory signal related to increased expression of HGF in liver itself and extrahepatic tissues (lungs, spleen) during hepatic regeneration. From a different perspective, it has also been shown that, in addition to its traditional sources of production (peripheral sympathetic neurons and adrenal medulla), NE is also synthesized by hepatic stellate cells and increases their proliferation in cell culture [119]. In view of all this, it is not surprising that blockade of the α_1-adrenergic receptor or resection of the sympathetic nerves of the liver blocks the first wave of DNA synthesis after PHx and delays the overall process by 24 h [120,121].

Transforming growth factor-β1

TGF-β1 is a member of a family comprising three proteins (TGF-β1, TGF-β2, TGF-β3). Other polypeptides such as activin, inhibin and bone morphogenetic proteins are also members of the broader group of related proteins [122–124]. The active form of TGF-β1 is produced after removal of another protein attached to it by disulfide bonds, a reaction catalyzed by several proteases including plasmin [125]. The TGF-β1 receptor is assembled by interaction between three plasma membrane proteins (TGF-βRI, TGF-βRII, TGF-βRIII). Binding of TGF-βRI to TGF-βRII induces serine phosphorylation of TGF-βRI [126]. This activates a serine-threonine kinase function that phosphorylates downstream targets including that of the Smad family of proteins [127].

TGF-β1 is produced by most mesenchymal-derived cells including fibroblasts, myofibroblasts, and hepatic stellate cells. It is also produced by many epithelial cells and most carcinomas, including hepatocellular carcinomas [128]. It stimulates synthesis of most ECM proteins produced by connective tissue cells, including collagen types I, IV and VI. TGF-β1 is a mitoinhibitor for hepatocytes in primary culture and in a dose-dependent manner blocks the mitogenic effects of HGF and EGF [129,130]. Its inhibitory effects are partially reversed by NE [117]. In view of this, it is surprising that TGF-β1 mRNA rises soon (within 3 h) after PHx and remains elevated until 72 h after PHx [131,132]. TGF-β1 levels in plasma also increase rapidly after PHx and prior to the rise of TGF-β1 mRNA in the liver, in a manner similar to that of HGF [8,133]. This is not surprising because TGF-β1 is present in the ECM immediately adjacent to hepatocytes and bound to the protein decorin [134]. It is probably released in the peripheral blood during remodeling of the hepatic ECM following PHx along with HGF, hyaluronic acid, and other matrix components [8,133]. It is unlikely that TGF-β1 released in the plasma exercises any effects in liver because circulating TGF-β1 is inactivated by binding to α_2-macroglobulin, and the complex is processed and destroyed by intracellular proteolytic pathways involving endosomes in hepatocytes and most epithelial cells [135,136]. TGF-β1 also binds to the insulin-like growth factor (IGF)II/mannose-6-phosphate receptor, and the complex is endocytosed and processed for proteolytic degradation [137–139]. Expression of TGF-β1 receptors I and II in regenerating hepatocytes decreases dramatically after PHx, and it is likely that by this mechanism regenerating hepatocytes become resistant to the mitoinhibitory effects of the rising concentrations of TGF-β1 during regeneration [140]. In addition, signal transduction pathways initiated from TGF-β1 and proceeding through Smad proteins are inhibited during liver regeneration by upregulation of the transcription factors SnoN and Ski [141]. Immunohistochemical studies have shown that TGF-β1 is eliminated in a wave-like way from the periportal to the pericentral areas of the lobules as regeneration proceeds in the same direction. Immediately behind the residual TGF-β1-positive front, there is a front of hepatocytes in mitosis [139]. The multiple mechanisms by which the potential mitoinhibitory effect of TGF-β1 on hepatocytes is eliminated during regeneration suggest that the role of TGF-β1 is not that of an ineffective mitoinhibitor but rather that of a necessary effector for cells other than hepatocytes. As mentioned above, TGF-β1 stimulates production of most proteins of the ECM which, following the early remodeling events, is reconstituted 3–5 days after PHx. TGF-β1 also stimulates formation of capillary tubes in endothelial cells [142], and may be involved in the late angiogenic events that reconstitute the hepatic sinusoidal network at the end of regeneration. TGF-β1 is also a *motogen* for normal and neoplastic hepatocytes [143–145], and its presence may be important for the mediation of events requiring cell migration during tissue remodeling, especially at the late stages of regeneration.

In view of its mitoinhibitory effects on hepatocytes, it has been often hypothesized that TGF-β1 is involved in the termination of liver regeneration. Infusion of TGF-β1 prior to and immediately after PHx suppresses regeneration for 72 h in mice [146]. Liver regeneration in transgenic mice

overexpressing TGF-β1 in hepatocytes under the albumin promoter is slightly suppressed but not by any means eliminated [147]. The overall role of TGF-β1 in the early and late stages of regeneration is further in the section Extracellular matrix changes and angiogenesis.

Notch and Jagged

Notch and Jagged are members of two families of proteins whose members are intercalated in plasma membranes. The names derive from specific phenotypic alterations resulting from mutations of these proteins in *Drosophila*. Jagged proteins, as well as Delta proteins, bind to Notch. This causes an allosteric reconfiguration of Notch and makes it susceptible to specific proteases, including presenilin. Following binding of Jagged or Delta, the extracellular portion of the Notch–ligand complex is cleaved by TACE/ADAM17 protease (an enzyme that also cleaves TNF and TGF-α precursor). The intracellular portion of Notch is cleaved by presenilin and the Notch intracellular domain (NICD) is transferred to the nucleus. There it functions as a coactivator of expression of specific genes associated with the cell cycle, including c-Myc and cyclin D_1 [148,149]. The Notch/Jagged/Delta system is involved in fate determination of cell lineages and has effects on multiple tissues, including nervous system and bone marrow. Mutations in Jagged-1 are associated with Alagille syndrome affecting multiple tissues including liver, where it causes a paucity of intrahepatic bile ductules [150,151]. Activation of Notch and migration of NICD to the nucleus occur prior to entry into the cell cycle in most quiescent and fully differentiated cells. NICD appears in hepatic nuclei within 15 min after PHx and is associated with increased expression of the dependent genes HES1 and HES5 [152]. Both Notch and Jagged increase in hepatocytes, endothelial cells, and biliary cells 24–72 h after PHx. Recombinant Jagged-1 protein is mitogenic for hepatocytes in primary culture, although it is not as potent as HGF or EGF. However, Jagged-1 enhances the mitogenic effects of HGF or EGF [152]. Knockdown of Notch-1 or Jagged-1 proteins by silencing RNA decreases the regenerative response [152]. Silencing RNA would have effects on all cell types of the liver expressing Notch or Jagged. In another study, however, targeted deletion of Notch-1 selectively to hepatocytes was carried out. In these animals, there was a gradually increasing proliferation of all cells of the liver and emergence of hepatic nodular hyperplasia and periportal fibrosis. However, liver regeneration was also decreased in this study [153]. The combined results suggest that Notch and Jagged proteins interact between multiple cell types and that the effects seen depend on which cell type is affected by the experimental approaches taken. Based on paradigms from other tissues and results from the liver literature, it is highly likely that Notch and Jagged proteins are involved in the detailed morphogenetic events of the liver from entry into regeneration to final quiescence.

Other factors implicated in liver regeneration

Members of the fibroblast growth factor (FGF) family of proteins are mildly mitogenic to hepatocytes in culture. FGF-1, FGF-2, and keratinocyte growth factor are expressed by hepatocytes during liver regeneration. It is not clear whether this generates an autocrine mitogenic loop or whether this constitutes a paracrine loop by which hepatocytes stimulate proliferation of adjacent cell types responding to FGF (endothelial cells, stellate cells) [154,155]. Stem cell factor (SCF) may also play a role. Hepatocyte proliferation after PHx is decreased in mice with homozygous deletion of SCF. Administration of SCF to IL-6-deficient mice enhances hepatocyte proliferation after PHx and ameliorates some of the deficiencies in regeneration seen in $IL6^{-/-}$ mice [156].

Intracellular events occurring during regeneration

PHx rapidly induces a series of alterations in gene transcription and activation of transcription factors. Most of these studies have been conducted using extracts from whole liver. Since most of the RNA and cytoplasm in the liver derives from hepatocytes, it is fair to assume that most of the findings described in the literature involve primarily hepatocytes. This is especially true at the earliest stages after PHx, because hepatocytes are the first cells in the liver to enter into DNA synthesis. The end point of the intracellular events occurring in hepatocytes after PHx is a delicate balance between hepatocytes continuing to provide vital functions to maintain body homeostasis (especially glucose regulation) while performing all functions associated with cell proliferation. In addition, given the smaller mass of the remnant liver, some functions (e.g., gluconeogenesis) need to be enhanced so that the output from the smaller remnant liver is sufficient to cover the functions normally provided by the intact organ [157].

Many of the intracellular changes described during liver regeneration, such as posttranslational modifications in cell cycle proteins such as cyclin D_1, histone synthesis, and upregulation of enzymes related to DNA synthesis, are seen in most eukaryotic proliferating cells. Other events appear to be more (though not entirely) liver specific. A group of genes, collectively called *immediate early genes*, are rapidly upregulated within 30 min after PHx and include many gluconeogenic enzymes and IGF-binding protein (IGFBP)-1 [109,158,159]. Later, as with other proliferating cells, hepatocytes show enhanced transcription of several proto-oncogenes including c-Myc, Ras proteins, p53, and others [160,161]. Changes in gene expression are generally the result of altered status of transcription factors, the proteins which regulate gene expression. Several studies have focused on changes in specific transcription factors early during liver regeneration and these are probably responsible for

mediating most of these events. It is likely that others will emerge as more studies focus on liver regeneration.

NF-κB

This transcription factor is a complex of two subunits (p65 and p50) with another protein (inhibitor of κB, IκB-α). Activation of NF-κB results from action of the IκB-β kinase (IKK) which leads to the phosphorylation of IκB-α and its detachment from the p65/p50 complex. The latter migrates into the nucleus and acts on target sites on gene promoter sequences to enhance transcription of target genes. Prominent among these are several genes that enhance cell survival and block apoptosis, such as BCL-X_L, BFL1, and GADD45β [162,163]. Activation of NF-κB occurs within 30 min after PHx [164]. Mice with liver-targeted expression of a form of IκB resistant to the action of IKK-β (super-IκB) are unable to fully activate NF-κB. In these mice, PHx results in massive hepatocyte apoptosis [165]. In another experimental approach, however, there was an inducer-dependent and hepatocyte-targeted expression of super-IκB that resulted in blocking activation of NF-κB. In this system, PHx did not lead to hepatocyte apoptosis, and liver regeneration proceeded normally [97]. The above data suggest that, as with all other molecules involved in liver regeneration, NF-κB is not critically required for regeneration. In its absence, vital functions performed by NF-κB are assumed by other complementing molecules. However, this should not imply that NF-κB does not play a very important role under normal circumstances. Activation of antiapoptotic genes is an important aspect of cell physiology and is likely required for hepatocytes prior to fully engaging in the proliferative process. It has been assumed that the rapid activation of NF-κB seen after PHx is the result of TNF and that activation of NF-κB is a pivotal event in determining hepatocyte apoptosis vs proliferation. This view is reinforced by the finding that activation of NF-κB is dramatically decreased in mice with homozygous deletion of TNFR1. However, numerous studies with other cell types have shown that receptor tyrosine kinase ligands including EGF and HGF can also cause rapid activation of NF-κB in multiple cell types and that this activation is associated with protective effects of these growth factors on target cells [166]. Thus, in view of the fact that multiple and concurrent signaling through growth factors and cytokines occurs early in regeneration, the activation of NF-κB should be viewed as an important event, but it is likely that many contributing signals trigger the pathways leading to its activation. These alternative pathways may be the ones responsible for normal completion of the regenerative process in TNFR1 deficient mice.

STAT3

Signal transducer and activator of transcription (STAT)3 is one of seven members of a family of proteins that are phosphorylated by Janus kinases (Jak) following activation of a variety of plasma membrane receptors. There are more than five members in the family. STAT3 activation occurs within 1 h after PHx and lasts up to 8 h [167,168]. STAT3 migrates to the nucleus and triggers expression of many genes associated with cell cycle alterations including the components of AP-1 transcription factor (jun and fos complex). STAT3 activation is deficient in mice with homozygous deletion of IL-6 [107,169]. As with NF-κB, multiple cytokines and growth factors activate STAT3 in different cell types, and it is likely that several pathways are responsible for activation of STAT3 after PHx. HGF and EGF also activate STAT1 and STAT5 in hepatocyte cultures, and STAT3 and STAT5 can dimerize [170,171]. In mice with targeted elimination of STAT3 from hepatocytes, the regenerative response after PHx was substantially reduced. Activation of STAT1, not normally seen after PHx, occurred in these mice and probably accounts for completion of the regenerative response [172].

C/EBPα and C/EBPβ

C/EBPα and C/EBPβ (CCAAT/enhancer-binding protein α and β) are transcription factors with a leucine zipper motif that are involved in regulation of many genes associated with carbohydrate and lipid metabolism. C/EBPα is the dominant form expressed in hepatocytes. Its expression is relatively restricted to liver and adipose tissue; on the other hand, C/EBPβ is relatively ubiquitous. Mice with homozygous deletion of C/EBPα have alterations in carbohydrate and urea cycle enzymes and die from hypoglycemia soon after birth [173]. Levels of C/EBPα increase whereas those of C/EBPβ decrease after PHx. This affects both whole cell and nuclear concentrations of the two factors [174,175]. Hepatocytes from C/EBP$\alpha^{-/-}$ mice have increased response to growth factors in cell culture [176]. Because of these findings, it is considered that C/EBPα per se has antiproliferative effects but this has not been critically tested. It is not clear whether mice deficient in C/EBPβ have enhanced regeneration, but studies with these mice have shown that the effect of HGF requires the presence of C/EBPβ [177].

β-Catenin

In quiescent liver, β-catenin protein is bound to E-cadherin under the plasma membrane. In hepatocytes and many other cell types, β-catenin becomes part of a signaling system whereby Wnt family members generate signals activating specific gene transcription patterns. Any β-catenin circulating free in the cytoplasm is phosphorylated on serine or threonine residues by a complex composed of glycogen synthase kinase 3β (GSK3β), axin and adenomatous polyposis coli protein (APC). This labels β-catenin for ubiquitination and further destruction by proteasomes. When Wnt proteins bind to their receptor proteins (members of the Frizzled family), the intracellular protein Disheveled becomes activated and inhibits GSK3β, allowing accumulation of β-catenin in the cytoplasm. Accumulating β-catenin enters the nucleus, where it forms complexes with members of the Tcf family

of transcription factors and regulates expression of many cell cycle-related proteins, including cyclin D_1 and cMyc [178–180]. A unique relationship of β-catenin with hepatic proliferative events has emerged from studies of liver cancer. Mutations rendering β-catenin resistant to tagging and ubiquitination are commonly seen in hepatocellular carcinomas and hepatoblastomas [181–183]. β-Catenin levels rise within 15 min after PHx and the protein appears in nuclei in the same period of time, remaining elevated for at least 6 h [184]. The protein APC rises sharply after β-catenin becomes elevated and results in rapid decrease in β-catenin levels in the cytoplasm, after the pulse of β-catenin has entered the nucleus. Thus, the mitogenic events of β-catenin after PHx are limited to a very early pulse of nuclear entry followed by a sustained presence of β-catenin in the nucleus [184]. However, the pathway leading to this process is probably not the canonical Wnt-driven pathway. In hepatocytes and other cell types, β-catenin is also bound to the HGF receptor cMet, as well as EGFR and platelet-derived growth factor receptor (PDGFR) in other cell types. HGF stimulation causes rapid translocation of β-catenin to the nucleus in hepatocyte cultures [185]. Thus, it appears that β-catenin is a very important component of the signaling pathway controlled by cMet and (presumably) EGFR, and it acts within minutes after PHx. This finding places into perspective the association of hepatic neoplasia with mutations rendering β-catenin resistant to proteolytic degradation.

Notch and Jagged

The Notch/Jagged signaling pathway is also rapidly activated after PHx, with NICD appearing in hepatocyte nuclei within 15 min after PHx.

Extracellular matrix changes and angiogenesis

Matrix remodeling

Matrix remodeling is an integral part of cell and tissue growth. It occurs in normal tissues as well as in neoplasms. Much of our knowledge related to matrix remodeling derives from studies of cancer invasion and metastasis [186]. A major pathway of matrix remodeling proceeds from uPA. Active uPA, free or bound to its receptor, activates plasminogen into plasmin. The latter activates MMP-9 which in turn acts as a protease for many ECM proteins. A complex network of positive and negative feedback mediated by tissue inhibitors of metalloproteinases (TIMPs) and plasminogen activator inhibitors (PAIs) provides fine control of the above series of events [187]. Notable is the fact that many of the components of this system are also associated with parallel events of activation or deactivation of growth factors and cytokines. uPA itself is a major activator of single-chain HGF to the active two-chain form [43]. Plasmin activates TGF-β1 by removing an inactivating bound protein [188]. This pathway becomes active very shortly after PHx. uPA activity increases dramatically within 5 min after PHx. This is followed by activation of plasminogen to plasmin within 15–30 min after PHx and subsequent activation of MMP-9 within 1 h after PHx [11,50,51]. These events are associated with release of both HGF and TGF-β1 from their binding sites immediately adjacent to the cell. Released HGF is then cleaved, appearing in the plasma in the active form [55] with subsequent activation of the HGF receptor within 30 min after PHx [56]. Other ECM proteins are also affected by this process [51]. Gene expression of proteins associated with ECM turnover also increases, with significant inductions in mRNA of TIMP-1, TIMP-3, TIMP-4, MMP-2, MMP-9, MMP-13, MMP-14, and MMP-24 [189]. Increased expression of MMP-9 is seen first in periportal hepatocytes within 3 h after PHx [11]. Another prominent pathway associated with matrix remodeling proceeds through a family of membrane-bound metalloproteinases. These proteins act in synergy with TIMP-2 to activate MMP-2. The latter is observed within 6–8 h after PHx [11]. Mice with homozygous deletion of uPA have impaired regeneration, manifesting with delays in DNA synthesis and decreased activation of HGF [52,53]. Conversely, mice with deficiency in the uPA inhibitor PAI-1 have enhanced HGF activation and accelerated regeneration [53]. Also, in mice in which the inhibitory TIMP-1 gene has been deleted, there is more active regeneration, with higher levels of activated HGF and early peak of DNA synthesis [189]. Deficiency of TIMP-3 on the other hand is also associated with deficiency in liver regeneration due to defective activation of TNF [190]. While many studies have focused on the initial remodeling of ECM after PHx, not much is known about the pathways leading to restoration of ECM at the end of regeneration.

Angiogenesis

Angiogenesis is also important to the regenerative process, and typically vessels are laid down in conjunction with new ECM. Proliferation of hepatocytes precedes that of endothelial cells, and clumps of small undervascularized hepatocytes arise at days 2–3 after PHx [191,192]. However, the latter produce a range of angiogenic factors including VEGF and angiopoietins 1 and 2 [193,194]. Increases in VEGF receptors Flt-1 and Flk-1/KDR, angiopoietin receptors Tie-1, Tie-2, and PDGFR-β are seen in isolated membranes from hepatic endothelial cells at days 2–5 after PHx. All these receptors are tyrosine phosphorylated and therefore activated during this process [195]. The period of proliferation of the sinusoidal endothelial cells is broad and stretches from day 2 to 5 after PHx. The undervascularized hepatocyte clumps are penetrated by the endothelial cells stimulated by the paracrine effects of growth factors produced by hepatocytes. This penetration is associated with rearrangement of the hepatocytes into plates and deposition of new ECM [8].

Paracrine signaling interactions between different cell types during liver regeneration

The multiplicity of signals generated during liver regeneration allow for a plethora of cell–cell interactions between the various hepatic cell types. As discussed, hepatocytes produce most ligands of EGFR, including TGF-α, amphiregulin, and HB-EGF. These ligands are likely to have effects on most adjacent cells expressing EGFR, including endothelial cells. Stellate cells express both HGF and TGF-β1 and respond to FGF-1, FGF-2 and PDGF produced by hepatocytes. HGF and TGF-β1 have effects on hepatocytes, endothelial cells, and biliary epithelium. VEGF and angiopoietins are produced by hepatocytes and act on endothelial cells, which in turn (via activation of VEGF receptor 1) produce HGF that then stimulates hepatocytes. Macrophages (Kupffer cells) produce both TNF and IL-6. This complex network of interactive cell–cell stimuli (Fig. 28.1) illustrates that liver regeneration is a highly integrated process in which all cells participate and depend on each other, so that the net result is not just replenishment of hepatocytes but formation of a complete tissue structure.

What starts and ends liver regeneration: a semispeculative view

(For further details and references on this section, see discussion of specific points in the preceding sections.) Studies of liver regeneration in many ways resemble those of astrophysicists trying to understand the origin of the Big Bang that led to the creation of the universe. While the earliest events are well tabulated and understood, the primary trigger (if such a single trigger exists) is not clear.

Initiation

With regard to liver regeneration, the earliest documented events after PHx are rising uPA activity (within 5 min), β-catenin in the nucleus (5 min), NICD in the nucleus (15 min), tyrosine phosphorylation of EGFR and cMet (30 min), activation of NF-κB (30 min), and changes in expression of many genes (within the first 30 min). While the rapid emergence of all these events is clear, it is not apparent which, if any, is the single (or multiple) trigger(s) leading to these events. PHx removes two-thirds of the liver and this is mathematically associated with a threefold increase in blood flow through the remaining hepatic lobules. It is doubtful that a mere

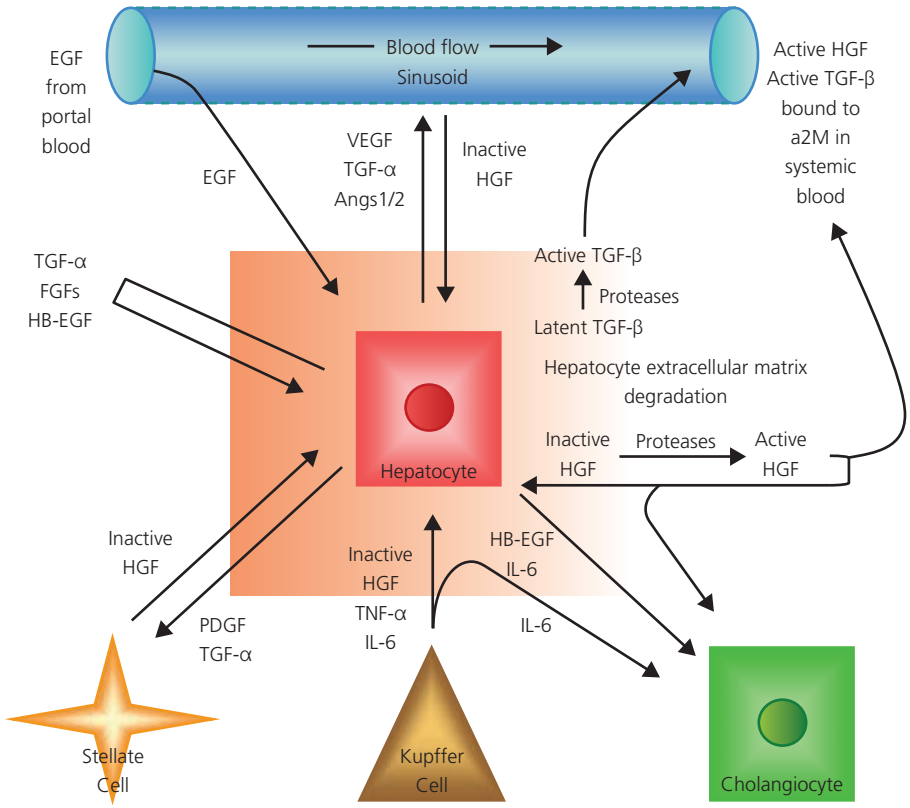

Figure 28.1 Signaling molecules contributing to liver regeneration, deriving or impinging on hepatocytes and the other hepatic cells. Hepatocytes play a key role in the process as being the first to enter into DNA synthesis after partial hepatectomy. a2M, α_2-macroglobulin; Angs, angiopoietins; EGF, epidermal growth factor; FGF, fibroblast growth factor; HB-EGF, heparin-binding epidermal growth factor; HGF, hepatocyte growth factor; IL, interleukin; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

increase in flow through the liver would trigger all these events, because flow fluctuations through organs (though not as extreme as threefold) are a routine part of daily physiology. On the other hand, increased flow of blood has the consequence of increased (threefold) ratios of blood-borne signaling molecules delivered to hepatocytes. Of all the signals described above, EGF is the only one constantly present in the portal circulation in high levels, derived from Brunner glands of the duodenum. This would make EGF a good candidate for the trigger of the earliest events. A serious caveat, however, is the fact that EGFR phosphorylation is not seen before 30 min after PHx. Insulin is another well-known signaling molecule delivered to liver constantly via the portal circulation. However, insulin is not a mitogen for hepatocytes [76,115]. Insulin deprivation (after portacaval shunt) leads to hepatic atrophy, which is subsequently restored (with hepatocyte DNA synthesis and mitoses) following administration of insulin to the animals bearing the portacaval shunts [196,197]. However, insulin administration to normal livers does not cause DNA synthesis. It has been speculated that the increased flow of nutrients to the residual hepatocytes may trigger intracellular events independent of growth factors, which may in turn lead to the subsequent series of events at the level of the whole organ. While this is an attractive hypothesis, there is no known link that would connect such nutrient-driven triggers with all other known events (e.g., changes in levels of growth factors and cytokines). It is highly likely that the threefold increase in circulating growth factors and nutrients triggers the whole series of events, but the molecular signaling pathways that would connect these events to those occurring in the first 60 s of the programme that leads to liver regeneration are not yet understood. Perhaps the best perspective for understanding the dynamic process leading to the early triggers of regeneration is to investigate why hepatocytes in normal liver do not continually proliferate. Normal hepatocytes in a quiescent liver are surrounded by ECM containing both growth factors (HGF and EGF in periportal sites) and mitoinhibitors (TGF-β1 bound to decorin). The process of matrix remodeling triggered by uPA should release single-chain inactive HGF. Activation of single-chain HGF immediately after PHx is mediated by uPA. Antibodies against urokinase block activation of HGF in whole tissue regenerating liver homogenates [50]. Active HGF appears in the plasma within 30 min after PHx. Matrix remodeling also releases TGF-β1, and causes a parallel rise in plasma TGF-β1, which is inactivated by binding to α_2-macroglobulin. Thus, early matrix remodeling results in an acute change of balance between mitogenic growth factors (e.g., HGF, HB-EGF) and mitoinhibitors (TGF-β1). Alterations of this balance in resting hepatocytes in a normal quiescent liver can trigger hepatocyte DNA synthesis (Fig. 28.2). Injection of DNA constructs expressing dominant-negative TGF-β receptor 1 or dominant-negative activin receptor causes hepatocyte DNA synthesis in normal rat liver without PHx [198]. This can only be understood if it is hypothesized that normal hepatocytes are in a quiescent state because of a continued *tonic* effect between mitogens and mitoinhibitors. Inhibition of the tonic effect of the

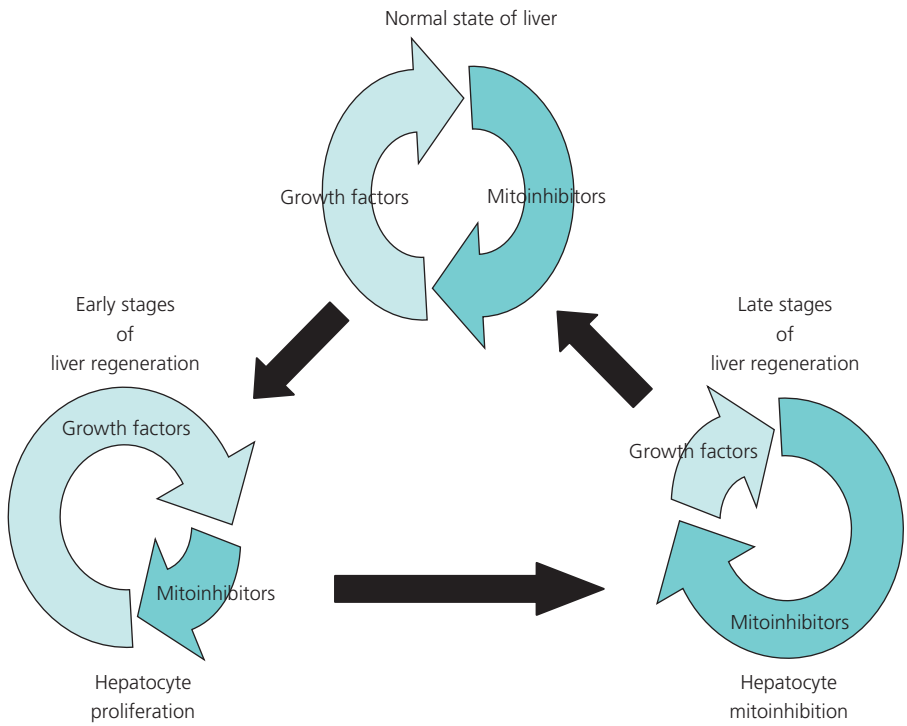

Figure 28.2 In normal (quiescent) livers, hepatocytes exist in a state of tonic balance between mitogens, such as hepatocyte growth factor (HGF) and epidermal growth factor, and mitoinhibitors such as transforming growth factor (TGF)-β1. Most of these molecules are bound to the matrix surrounding hepatocytes, especially in periportal areas of the hepatic lobule. Matrix remodeling after partial hepatectomy alters the balance between mitogens and mitoinhibitors. HGF becomes activated by urokinase and acts locally and through the plasma, whereas TGF-β1 released into the plasma is eliminated by binding to α_2-macroglobulin. Resynthesis of the hepatic matrix at the end of regeneration restores the balance between mitogens and mitoinhibitors and hepatocytes enter into a state of quiescence.

mitoinhibitor TGF-β1 (by the dominant-negative TGF-β1 receptor 1) would only cause hepatocyte DNA synthesis if the mitogens surrounding the hepatocytes were also causing a continual tonic event. Similar findings occur when follistatin, a protein that binds activin, is injected into animals [199]. The role of activin and inhibin, members of the same broad family to which TGF-β1 also belongs, has not been discussed so far. Activin is made by hepatocytes, but its role in either initiation or termination of hepatic regeneration has not been fully explored. Mice overexpressing activin in the liver have normal or accelerated liver regeneration [200].

Termination

Equally (or more) speculative are the events occurring at the termination of the regenerative process. The controversies regarding the role of TGF-β1 as the termination trigger have been discussed in the previous section. An additional study also indicated that deletion of TGF-β1 receptor II was associated with normal termination of liver regeneration [201]. However, no other single molecule has emerged as a good candidate for termination of the regenerative process. Nevertheless, many studies have shown that hepatocytes in primary culture, and stimulated to grow by HGF and EGF, stop growing when exposed to complex preparations of ECM such as collagen type I gels [202,203] or the high laminin and collagen type IV extract of EHS sarcoma known by its commercial name of Matrigel [204,205]. The effect is powerful and reversible. Disruption of the hepatic matrix by collagenase in live animals enhances the effect of HGF on hepatocytes [48], whereas perfusion of liver of anesthetized animals with collagenase (for the purpose of hepatocyte isolation) causes entry of the isolated hepatocytes into the cell cycle [204]. It is quite likely that termination of the regenerative process occurs when (and because) the hepatic ECM is restored. This would bring about the binding of, and increased concentrations of, mitoinhibitors such as TGF-β1 immediately next to hepatocytes. It would also bring about sequestration (and thus inactivation) of growth factors such as HGF and HB-EGF. The combined tonic effect of the two would counteract each other and result in a state of quiescence causing the exit of hepatocytes from the cell cycle.

Proportionality

Another intriguing aspect of liver regeneration is the proportionality of the response. Whereas two-thirds PHx triggers the grand scale of events, smaller resections result in regeneration on a smaller scale. Also, livers from small animals transplanted into large animals grow to a larger size proportionate to the size of the new body that they occupy [206]. Conversely, livers from large animals transplanted in toto into smaller animals decrease in size (by hepatocyte apoptosis) until the size becomes correct for the new animal [8,133]. Is there a *hepatostat* that determines the correct size of the liver in relation to the rest of the body and what relation would there be between such a homeostatic mechanism and the signaling pathways? The studies associated with demonstrations of proportionality involve complex surgical procedures and thus have not been easily adapted to frequently employed experimental models, even though the phenomena studied are very intriguing. Most of the signals associated with liver regeneration (e.g., HGF, EGF, TNF, IL-6, norepinephrine) normally have low but measurable levels in peripheral blood. In addition, liver is the primary site of sequestration and removal from the peripheral blood of HGF [207], EGF [73], and norepinephrine [120]. It is reasonable to hypothesize that the proportionality of the regenerative response and the adjustment of hepatic size based on body size are regulated by the same signals in peripheral blood that rise dramatically during the earliest stages of regeneration. In this scenario, even though circulating levels of these signaling molecules are normally very low, they do provide critical signaling for hepatocyte survival. A liver larger than normal would sequester and deplete these signaling molecules, thus eliminating their antiapoptotic signals and triggering hepatocyte apoptosis. A liver smaller than normal would allow plasma levels of these molecules to rise, triggering hepatic enlargement by a process akin to regeneration. In support of this hypothesis is the fact that sustained elevation of plasma HGF by injection of the protein [49,208] or forced expression via specific HGF-expressing plasmids [209] leads to hepatic enlargement and doubling of liver weight in normal mice. This has not been shown to the same extent for the other signaling molecules, but injection of EGF and TGF-α is associated with DNA synthesis in normal livers, and injection of TNF enhances the effect of coinjected HGF and causes DNA synthesis in hepatocytes [210]. Thus, HGF, EGF, TNF, IL-6, norepinephrine, and perhaps other currently unknown signaling molecules in the peripheral blood do collectively function as a hepatostat that regulates liver mass in proportion to body size.

Alternative pathways to liver regeneration: oval cells and stem cells

Hepatocytes are at the center of the regenerative process following PHx, and they produce and receive multiple paracrine and endocrine stimuli that interact to restore whole hepatic tissue. There are circumstances, however, both in experimental and clinical settings, during which hepatocytes are unable to participate and drive the regenerative process. Experimentally, hepatocyte proliferation can be blocked using genotoxic agents that generate bulky DNA adducts, such as acetylaminofluorene (AAF), or agents that cross-link DNA, such as retrorsine [211–213]. Treatment with these reagents prior to PHx prevents hepatocytes from entering into the cell cycle. Under these circumstances, a large population of small cells with oval-shaped nuclei emerges in the

periportal areas. These cells, named *oval cells* after the shape of their nucleus, proliferate actively and dominate the immediate periportal areas from days 3–10 after PHx. Immediately after their appearance, they express genes and proteins of both biliary and hepatocytic specificity [6,214–220]. For example, they express cytokeratins 7 and 19 (biliary markers) as well as α-fetoprotein (a marker of embryonic hepatocytes) and albumin, a marker of adult hepatocytes. They tend to be arranged in infiltrating sheets or form small ducts. They infiltrate deeply into the lobule, reaching into the centrilobular areas. They eventually transform into small and then normal-size hepatocytes and repopulate the entire lobule [221–223]. Infiltration of oval cells into the lobule is accompanied by concurrent proliferation of stellate cells synthesizing matrix and expressing HGF and SCF. Oval cells themselves express cMet as well the SCF receptor (c-Kit) [224,225]. In addition, oval cells also express certain hematopoietic markers (e.g., Thy-1) [214], not seen normally in either bile duct cells or hepatocytes.

The origin of these cells has been much debated. The preponderance of evidence strongly suggests that these cells are derived from the biliary compartment, most likely from the small extraportal ductules linking hepatocytes with the intraportal bile ducts. These ductules are known as canals of Hering. The evidence for the biliary origin of oval cells is as follows.

- Following PHx and administration of AAF, hepatocyte-associated transcription factors are expressed in the portal biliary ductules within days [226]. This suggests that the biliary compartment is undergoing gene reprogramming toward the hepatocytic lineage.
- Administration of the biliary toxin methylene diamiline (DAPM) prior to AAF and PHx eliminates the appearance of oval cells [227].

These findings demonstrate that under circumstances in which hepatocytes cannot proliferate, biliary epithelial cells can function as facultative stem cells for hepatocytes. Recent evidence shows that the opposite phenomenon is also true. When proliferation of biliary epithelium is blocked (e.g., by DAPM) and biliary epithelium needs to repair by proliferation (e.g., following bile duct ligation), hepatocytes of the immediate periportal area transform into biliary epithelium and become biliary ductules. Up to 50% of the biliary epithelium can be replaced by cells derived from hepatocytes under these circumstances [228,229]. These findings demonstrate that under some specific circumstances, hepatocytes can function as facultative stem cells for biliary epithelium. The term *facultative* implies that the cells that are the source of the apparent stem cells do not perform a stem cell function as their full-time mission. These cells (hepatocytes and biliary epithelium) are fully differentiated and perform specific functions. However, they can differentiate from one cell to another through a gradual process of transient amplification in cell numbers (Fig. 28.3). These findings raise an obvious question: are there true hepatic stem cells? Few issues have

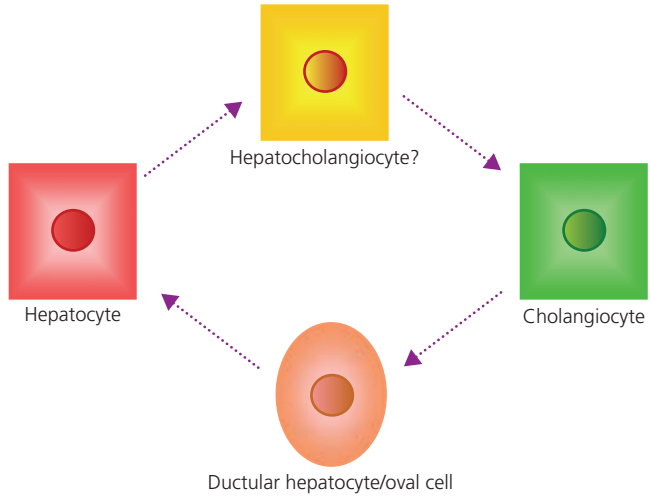

Figure 28.3 Hepatocytes and biliary epithelium (cholangiocytes) function as facultative stem cells for each other by undergoing transient redifferentiation and amplification of the cell population. These pathways allow restoration of cellular compartments whose proliferative capacity is impaired, as in hepatocytes during fulminant hepatitis or cholangiocytes during chronic immune attack (e.g., primary biliary cirrhosis or chronic rejection posttransplant).

divided liver biologists as this one. Of the two alternate views, one suggests that oval cells are derived from true hepatic stem cells, which perform no other function and whose mission is to rescue hepatic tissue under circumstances of blocked hepatocyte proliferation [230,231]. The alternative view is that true hepatic stem cells do not exist and that both hepatocytes and biliary epithelium can function as facultative stem cells for each other [228]. The majority of the evidence supports the second alternative. Also in support of the absence of true, full-time hepatic stem cells is the obvious comparison between the histology of liver and other tissues. Examination of the histology of the liver does not reveal a group of cells that correspond to full-time hepatic stem cells. Such cells are readily seen in the intestine, skin, ependyma of the brain, and bone marrow. This is not the case for the liver.

The capacity of one hepatic epithelial cell to undergo transdifferentiation into the other is very important in a clinical setting. Proliferation of cells with properties akin to oval cells is often seen in human histopathology. In the human, these cells are called *ductular hepatocytes* [232,233]. They appear in situations of massive hepatic injury, such as after administration of large amounts of toxins like acetaminophen, and overwhelming viral infections (hepatitis B or C virus). These cells are seen most obviously during the course of fulminant hepatitis [234]. Most clinical situations that induce liver damage and which therefore require regeneration of hepatic parenchyma do not result from clean hepatic resections. Viruses and toxins are likely to interfere with the capacity of hepatocytes to proliferate. The activation of transient transdifferentiation and amplification of biliary epithelial cells so

that they transform into hepatocytes may be the only pathway to rescue the liver until the proliferative capacity of the hepatocytes is restored. Biliary epithelium is also chronically damaged, most often from immune attack (e.g., primary biliary cirrhosis or biliary epithelium loss in transplanted livers during chronic rejection). Under these circumstances, hepatocytes in the immediate periportal area often express biliary markers, suggesting that an attempt is being made to rescue the biliary epithelium by transdifferentiation of hepatocytes [235].

Often forgotten in this debate is the vast clonogenic potential of the mature adult hepatocyte. This is most aptly demonstrated in rodent models. An extreme example is that of mice with fumarylacetoacetate hydrolase (FAH) deficiency. These mice cannot properly degrade tyrosine and die soon after birth. Administration of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) prevents accumulation of the toxic metabolites resulting from lack of function of FAH, and mice can be kept alive for a normal lifespan. When NTBC is withdrawn, hepatocytes undergo massive cell death (from necrosis and apoptosis) inducing fulminant liver failure and death of the animal. Injection of normal (FAH-positive) hepatocytes during fulminant hepatic failure results in massive recolonization of the liver by FAH-positive hepatocytes. (Typically the donor of the normal FAH-positive hepatocytes also bears a transgene such as β-galactosidase, which allows FAH-positive hepatocytes to be stained blue by a chemical reaction specific to β-galactosidase.) Livers of the first generation of rescued mice were used as the source of FAH-positive hepatocytes to rescue a second generation of FAH-deficient mice subjected to liver failure. These rescued mice were again used as the source of FAH-positive hepatocytes to rescue a third generation of FAH-deficient mice from liver failure, and so on. This was done for 10 serial rescues and FAH-positive hepatocytes derived from a single original donor mouse were able to rescue liver failure indefinitely. It was estimated from these studies that, at least for the mouse, one hepatocyte could generate enough progeny for 50 mouse livers [236,237]. The vast clonogenic potential of hepatocytes is rather unusual for a fully differentiated cell, and provides a future opportunity for transplanting hepatocytes to recolonize and rescue human livers under conditions in which endogenous hepatocytes are permanently damaged [238].

Another issue that has received much attention is the possibility that hepatocyte precursors or oval cells are generated from cells derived from the bone marrow [239,240]. Injection of bone marrow cells from FAH-positive mice into FAH-deficient mice subjected to liver failure rescued the mice by the emergence of FAH-positive hepatocytes derived from bone marrow precursors, probably from the myelomonocytic series. Subsequent studies demonstrated that FAH-positive hepatocytes that emerged from the injected bone marrow cells did not derive from transdifferentiation of bone marrow cells but from fusion of FAH-positive bone marrow cells with FAH-deficient hepatocytes [241]. Fusion between the two cell types restored the missing functional FAH gene and converted specific FAH-deficient hepatocytes into FAH-positive fusion hybrids. The fusion products rapidly populated and restored the entire liver, as though there had been an injection of true hepatocytes. Currently, there is convincing evidence that most if not all cases in which bone marrow cells apparently transdifferentiate into other cell products (e.g., muscle, neurons) are due to fusion between bone marrow cells and targets in cells of the peripheral tissues. Claims that hepatocytes in transplanted livers are replaced to a large extent by bone marrow cells of the recipient [242] have not been verified by other groups [243].

Clinical aspects of liver regeneration: cirrhosis and fulminant hepatitis

Hepatocytes proliferate to restore loss of hepatocytes. Such loss occurs to some extent in most aspects of liver disease. The proportion of hepatocytes leaving the quiescent state and entering into the cell cycle can be easily monitored by performing immunohistochemistry for a cell cycle marker such as PCNA or Ki67. No more than 1%–5% of hepatocytes are labeled in a normal resting liver. The proportion of PCNA-positive hepatocytes can easily rise to 20%–50% even with a mild increase in the number of dying hepatocytes [2]. In clinically obvious cases of viral hepatitis, in which it is estimated that eventually 90% of hepatocytes die [3], PCNA-positive cells can reach 95% of the population. The same high percentages are seen in cirrhotic nodules of cirrhosis due to chronic toxins, such as alcohol. In cirrhosis due to metabolic etiologies, e.g., hemochromatosis or α_1-antitrypsin deficiency, there are typically two populations of hepatocytes. One population bears the brunt of the metabolic defect (iron deposition, accumulation of α_1-antitrypsin globules); typically, in this subpopulation the proportion of cells in the cell cycle is low. However, a second subpopulation of hepatocytes is always seen which represents cells that are much less affected. In this subpopulation of hepatocytes, the proportion of cells in the cell cycle is very high [244,245]. It is notable that hepatocellular carcinomas emerging in the context of these types of cirrhosis typically comprise neoplastic cells that do not carry the metabolic defect [246]. Neoplasia is often associated with allelic loss. Elimination of some specific gene alleles may confer some protection to the preneoplastic cell (e.g., deficiency in iron uptake in the context of hemochromatosis, loss of α_1-antitrypsin genes) such that it becomes protected from the offending metabolic agent. This setting of *differential resistance* [247,248] tends to selectively promote growth of specific preneoplastic cell populations and eventually leads to neoplasms that frequently do not carry the metabolic defect.

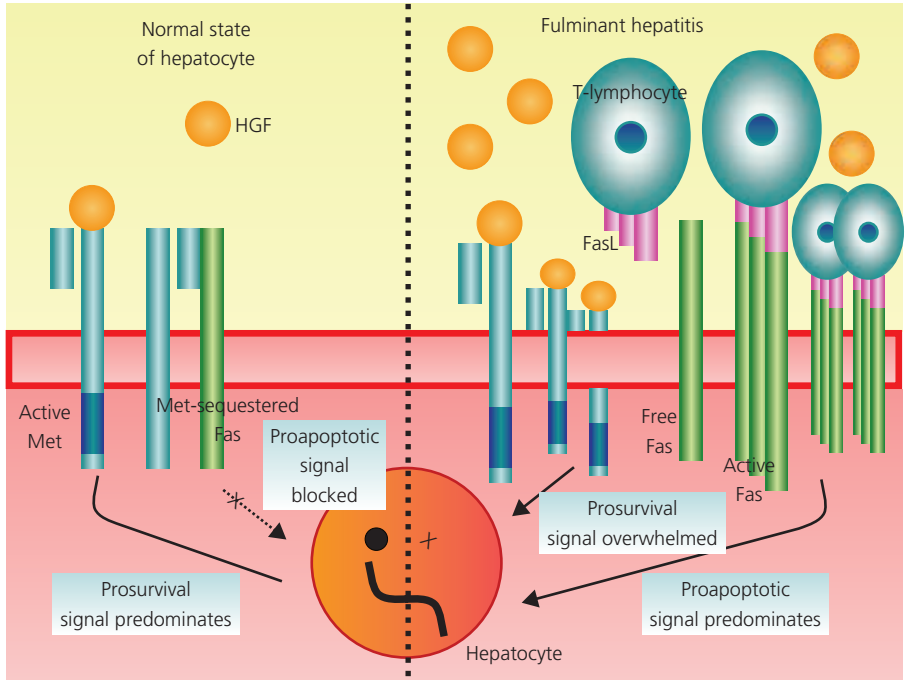

Figure 28.4 Effect of high hepatocyte growth factor (HGF) concentrations during fulminant hepatitis. HGF receptors (cMet) are normally in excess of available HGF and the surplus of cMet molecules dimerize and sequester the apoptosis-inducing receptor Fas. When HGF levels rise to very high levels during fulminant hepatitis, cMet receptors become fully occupied by HGF, and Fas is released and becomes available to form trimers, which can bind Fas ligand and induce apoptosis in hepatocytes.

Fulminant hepatitis remains a puzzling situation from the point of view of regeneration. It is often assumed that fulminant hepatitis is caused by failure of the hepatocytes to regenerate. However, this is untrue. The PCNA labeling index in fulminant hepatitis reaches almost 100% [2]. It is conceivable that the offending agent leading to fulminant hepatitis is so robust that cells die before they proliferate. Supporting evidence for this inability of hepatocytes to effectively proliferate is the increase in numbers of transiently amplifying and transdifferentiating ductules (ductular hepatocytes), which express hepatocytic markers such as albumin, α-fetoprotein and hepatocyte-associated transcription markers such as HNF4 (Michalopoulos G, unpublished observations) [234]. Another way to assess the signaling dynamics of fulminant hepatitis is to examine the role of HGF. The latter reaches extremely high levels during fulminant hepatitis [249–252]. There is an inverse correlation between HGF levels and prognosis of the patient. The mechanism for this paradox is not entirely clear. However, it has been shown that under normal circumstances, the HGF receptor (cMet) dimerizes with the apoptotic receptor Fas on hepatocyte plasma membranes [40]. This prevents Fas from forming trimers and becoming activated by Fas ligand. Typically, receptor occupancy of 10%–20% is sufficient to exert the maximal effect. This would leave the residual receptors unbound to HGF and bound to Fas. HGF displaces Fas from binding to Met. When HGF concentrations reach extremely high levels, it is likely that most of the Fas bound to Met is released and available for activation by Fas ligand and induction of apoptosis. In this scenario, extremely high HGF concentrations may have a deleterious effect on hepatocytes and further accentuate hepatocyte death instead of promoting regeneration (Fig. 28.4).

Augmentative hepatomegaly

This phenomenon is seen in experimental and clinical settings with rodents or humans receiving a variety of lipophilic drugs such as barbiturates, dilantin, diazepam, and peroxisome proliferators. Treatment with these agents induces a dose-dependent enlargement of the liver, which may reach up to 80% above normal size [253–255]. The same phenomenon is seen in some physiological conditions, such as pregnancy or hyperthyroidism [256]. The mechanisms mediating this response are not clear. Most of the molecules inducing this phenomenon (including estrogens) are ligands for nuclear hormone receptors. Several studies have shown that activation of this pathway does not proceed through the typical cell cycle-related events seen during liver regeneration [257–259]. The hepatomegaly is achieved through a mixture of hepatocyte proliferation and hepatocyte enlargement [260]. The proportion of each process that is utilized varies from one agent to another, suggesting a multiplicity of pathways. There is more hepatocyte hypertrophy than hepatocyte proliferation in the response induced by barbiturates. Barbiturates activate the constitutive androstane receptor (CAR) and the pregnane X receptor (PXR). CAR appears to be the chief mediator of signaling leading toward hepatocyte proliferation, but the pathways are not clear [261,262].

Withdrawal of the agents in experimental settings is associated with a gradual decrease of the liver to normal size through a wave of apoptosis. While the gene expression patterns used during this phenomenon do not mimic those of classic regeneration, some of the proteins involved in regeneration may still play a role. For example, estrogens act very similarly to norepinephrine in hepatocyte cultures by enhancing the mitogenic effect of HGF and EGF and by antagonizing the mitoinhibitory effect of TGF-β [263]. It is not clear how this effect relates to activation of the estrogen receptor by estrogens. Augmentative hepatomegaly is also induced (in rodents, but not clearly in humans) by compounds that are members of the class of peroxisome proliferators [264]. These compounds activate the peroxisome proliferation associated receptor (PPAR)-α, -β, -γ, and -δ to various degrees. Hepatocyte proliferation is very prominent in this response. It is interesting that the enlarged livers induced by all xenobiotics respond poorly to two-thirds PHx. Several growth factor receptors (EGFR) are downregulated by treatment with phenobarbital, whereas there is an increase in expression of TGF-β1 receptors [265–267].

Augmentative hepatomegaly has serious clinical implications and should be not overlooked. Hepatic enlargement changes the ability of the liver to metabolize drugs. The larger size of the liver implies that some of the doses need to be adjusted upward to compensate for the increased degradation of drugs by the enlarged liver. However, this cannot be done across the board, because augmentative hepatomegaly is also typically associated with increase in many members of the CYP family of enzymes, which metabolize lipophilic drugs and often generate free radicals. This renders individuals with augmentative hepatomegaly very sensitive to drugs that can be otherwise tolerated by normal individuals [268]. Typical is the hypersensitivity of humans receiving phenobarbital to small doses of acetaminophen and the occurrence of fulminant hepatic failure at high frequency in patients receiving both drugs.

Conclusions

Liver regeneration is a signature hepatic response to all situations associated with loss of hepatic parenchyma. As with all vital functions perfected through millions of years of evolution, the pathways leading to the phenomenon have sufficient redundancy to guarantee the response regardless of any signaling defects. Key players in the phenomenon are the receptors of the growth factors HGF and EGF. However, multiple cytokines, including TNF, IL-6 and norepinephrine, as well as other receptors such as Notch, are also involved in optimizing the early and later stages of the response. The net result is proper maintenance of liver mass in relation to body weight and adjustment of liver mass to sufficient size to guarantee responses to changing homeostatic needs.

Molecular biological approaches to the diagnosis and treatment of gastrointestinal diseases

David A. Brenner, Robert Schwabe, Christoph Oesterreicher

DNA, 703
Techniques in molecular biology, 703
Applications of molecular biology to the clinical laboratory, 708
Amplification refractory mutation system, 710

The development and application of the science and techniques of molecular biology has had a profound impact on the diagnosis of gastrointestinal diseases. Furthermore, molecular biology has revolutionized the conceptual approaches to these diseases. An understanding of the regulation of gene expression encompasses key concepts: deoxyribonucleic acid (DNA) transcription, ribonucleic acid (RNA) translation, posttranslational control, and the effects of DNA mutations on gene expression.

DNA

The genetic material of all known organisms and many viruses is DNA, which consists of chemically linked subunits. Each subunit, called a nucleotide, contains a nitrogenous base (a purine [adenosine and guanine] or pyrimidine [cytosine or thymine]), a pentose sugar, and a phosphate group (Fig. 29.1). Nucleotides are linked by phosphodiester bonds forming single-stranded nucleic acids.

The DNA double helix consists of two chains that are complementary and antiparallel. They are complementary because adjacent nucleotides always pair in a specific way: adenine to thymine and guanine to cytosine, so that the base sequence of one strand determines that of the other (see Fig. 29.1). They are antiparallel because the 3′ to 5′ orientation of the sugar–phosphate backbone of one chain is opposite the 5′ to 3′ orientation of the other chain.

Transcription

Transcription is the synthesis of RNA from its DNA template and is catalyzed by DNA-dependent RNA polymerases. A gene includes all DNA sequences required for the synthesis of the RNA, including transcribed and regulatory sequences. Promoters are the regulatory sequence immediately 5′ to the transcription unit and are required for proper transcription initiation. Enhancers are orientation- and position-independent regulatory sequences that increase the transcription rate of a given transcription unit.

Translation

Translation is the synthesis of proteins from the information encoded in its messenger RNA (mRNA). The genetic code consists of groups of three nucleotides called codons that specify the amino acid sequence or define sites for the initiation or termination of translation.

Techniques in molecular biology

Enzymes used in molecular biology techniques

Most of the methodology used in molecular biology involves the application of specific enzymes. These enzymes can be classified into four groups: restriction endonucleases, polymerases, ligases, and modifying enzymes. Many of these enzymes have been cloned and changed by mutation to enhance performance and reduce cost.

The restriction endonucleases comprise a large group of enzymes that recognize specific nucleotide sequences and cleave double-stranded DNA at precisely these locations. Restriction endonucleases are found naturally in bacteria and are important for degrading foreign DNA. The cleavage sites recognized by the restriction endonucleases are typically four to eight nucleotides in length. Digestion products may have either 5′- or 3′-overhanging nucleotides, also called cohesive termini or sticky ends, or the digestion may result in blunt-ended molecules. Joining ends of DNA is accomplished with DNA ligases. DNA ligases catalyze the formation of a

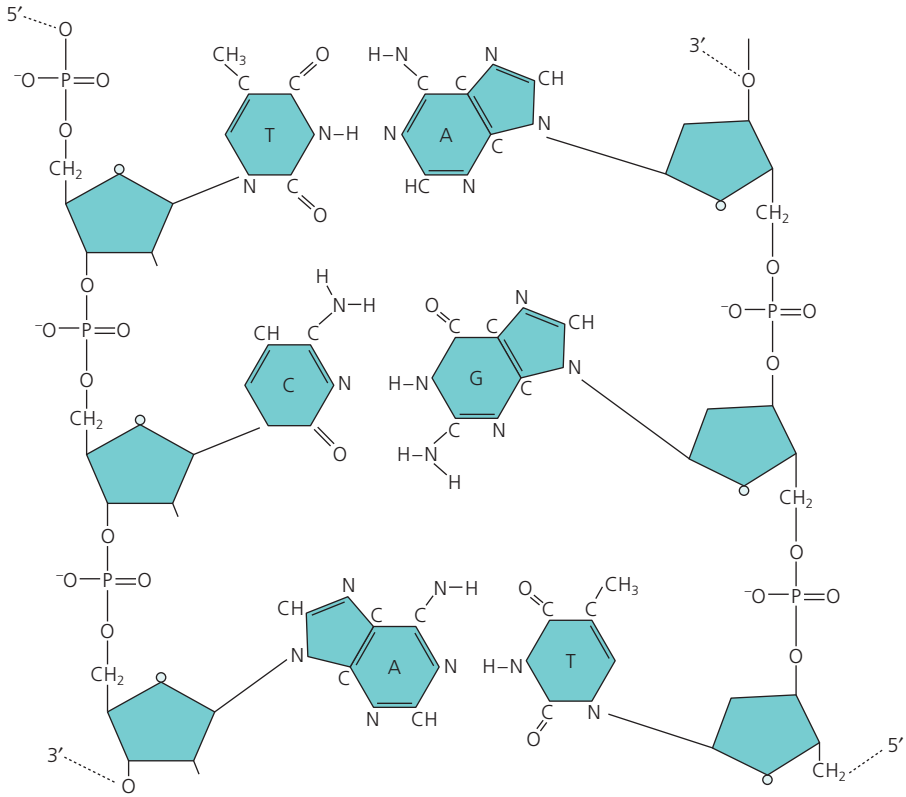

Figure 29.1 DNA double helix. A nucleotide consists of the deoxyribose sugar and phosphate backbone with a nitrogenous base (A, C, G, or T). Adenine (A) always pairs with thymidine (T), and guanine (G) always pairs with cytosine (C). The two nucleotide chains run in antiparallel directions, one strand runs in the 5′ to 3′ direction, and the other strand runs in the 3′ to 5′ direction. From Rippe et al. [78].

phosphodiester bond between the 5′ phosphate and the 3′ hydroxyl ends in duplex DNA. Recombinant DNA molecules can be generated efficiently by digesting double-stranded DNA with appropriate restriction endonucleases, isolating the pieces of interest, and ligating the pieces to create recombinant molecules.

Another major group of enzymes is composed of the polymerases, which catalyze the synthesis of nucleic acids from nucleic acid templates. These enzymes are classified by the type of nucleic acid that is synthesized and the type of nucleic acid template that is replicated. All polymerases synthesize DNA in a 5′ to 3′ direction and complementary to the template strand. The DNA-dependent DNA polymerases synthesize DNA from DNA templates. In addition to synthesis activity, many of the polymerases possess exonuclease activity, an enzymatic property that removes nucleotides one at a time from the ends of the polynucleotide chain, thereby functioning as a biological "proofreader". The exonuclease activity has been used extensively in the laboratory to label double-stranded DNA uniformly.

Another group of DNA-dependent DNA polymerases is used extensively in the polymerase chain reaction (PCR) – the heat-stable DNA polymerases, such as *Taq I*. Originally isolated from *Thermus aquaticus*, *Taq I* has been cloned and engineered genetically to improve its performance. This enzyme is active over a broad temperature range and is stable with repeated temperature cycling.

The RNA-dependent DNA polymerases synthesize a complementary DNA (cDNA) copy of an RNA template. These enzymes are called reverse transcriptases and typically are derived from either retroviruses or the Moloney murine leukemia virus. Reverse transcriptase creates cDNA copies of a population of mRNA molecules. Single-stranded cDNA molecules are converted into double-stranded DNA and cloned into appropriate vectors to generate cDNA libraries. These cDNA libraries are used to isolate genes of interest.

Blotting techniques

Nucleic acids and proteins are readily detected by fixing these molecules to a nitrocellulose membrane and identifying them by hybridization with specific probes. The detection of specific DNA sequences was described originally by E.M. Southern in 1975 [1], and subsequently termed Southern blotting. This technique was modified for the detection of RNA sequences and named Northern blotting. Specific proteins are detected by Western blotting.

Southern blotting

Southern blotting involves digesting high-molecular weight DNA (e.g., genomic DNA) with restriction endonucleases and separating the generated DNA fragments according to size by agarose gel electrophoresis. The DNA fragments are denatured in the gel into single-strand DNA and subsequently transferred (blotted) from the gel to a solid support,

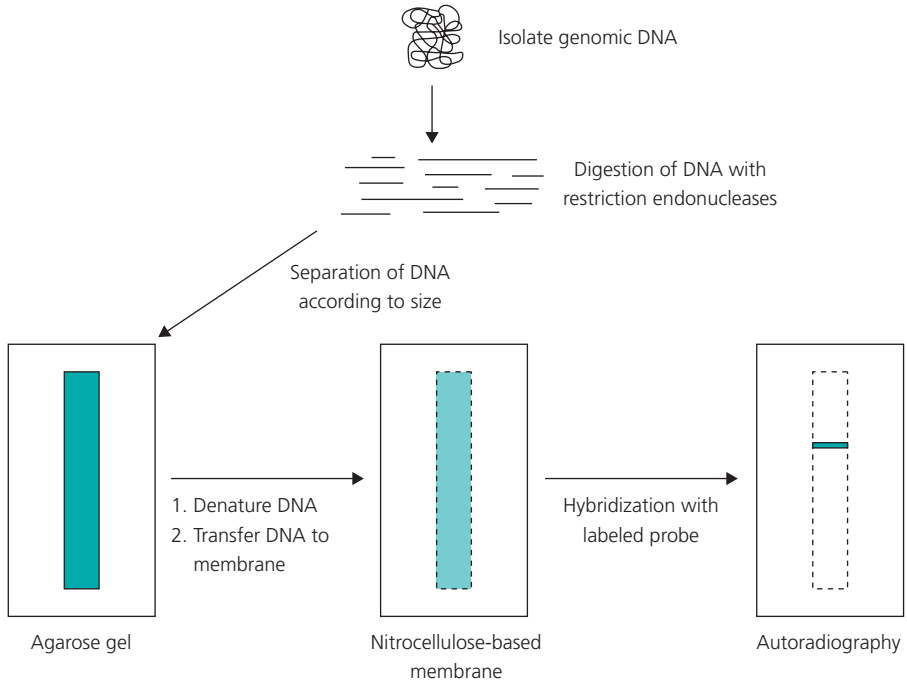

Figure 29.2 Southern blotting. Detection of specific DNA sequence in a complex mixture of DNAs (such as genomic DNA) by hybridization with a labeled probe. The hybridization depends on the normal base-pairing of the probe nucleic acid with the complementary genomic DNA sequence. From Rippe et al. [78].

typically a nitrocellulose membrane. The transferred DNA and a radiolabeled DNA or RNA bind to each other in complementary base-pair fashion to form a hybrid, a process called hybridization. The radiolabeled signals are detected by autoradiography, through exposure to x-rays (Fig. 29.2).

Northern blotting

Northern blotting is an adaptation of the Southern blotting method and is used for the detection of RNA. RNA is isolated, separated by electrophoresis in formaldehyde–agarose gels, transferred to nitrocellulose membranes, and hybridized to specific RNA or DNA probes. Standards of known size allow estimation of the size of RNA of interest. This technique measures the steady-state levels of a particular mRNA under set experimental conditions. Steady-state mRNA levels do not, however, indicate the stage at which gene expression may be regulated. Some conditions may affect the rate at which the gene is transcribed, whereas other conditions may affect the turnover rate, or stability of the mRNA molecule.

Western blotting

Western blotting (immunoblotting) is a method used to detect and quantify specific proteins using antibodies. Moreover, Western blotting can be applied to determine posttranslational modifications, such as phosphorylation, acetylation, or nitrosylation, which often reflect changes in protein activity or function. The procedure involves extracting proteins from a given source, separating the proteins based on their size by electrophoresis in a polyacrylamide gel, and transferring them from the gel to a nitrocellulose membrane. Once transferred, the proteins are spotted for binding to a specific antibody. A primary antibody binds to the protein of interest and is subsequently detected using a secondary antibody complexed to an enzymatic detection system. A substrate that emits light or fluoresces when activated by the enzymatic detection system allows visualization of the antigen–antibody complexes (Fig. 29.3). The radioimmunoassay and enzyme-linked immunosorbent assay techniques were derived in principle from the Western blotting method.

In situ hybridization and immunohistochemical detection

The study of gene expression often requires the detection of proteins or mRNAs within single cells or tissues (in situ analysis). In situ hybridization examines the expression of mRNA whereas immunohistochemical detection indicates the presence of specific proteins. In situ hybridization provides a sensitive method to locate specific cells that express a gene of interest. The technique involves fixing tissue sections to slides, treating the sections with reagents to increase cellular permeability, and then hybridizing the tissue with either labeled RNA or DNA probes. Probes labeled with enzymes or fluorescent tags (fluorescent in situ hybridization) afford excellent resolution and rapid detection, and their use avoids the safety problems associated with radioactive isotopes. In situ hybridization has been used successfully to localize genes on chromosomes, to identify tissues and specific cells in which viruses are replicating, and to locate cells that express messages in low abundance.

Immunohistochemical analysis allows for the localization of proteins to individual cells within tissue samples or to subcellular compartments. Similar to other protein detection

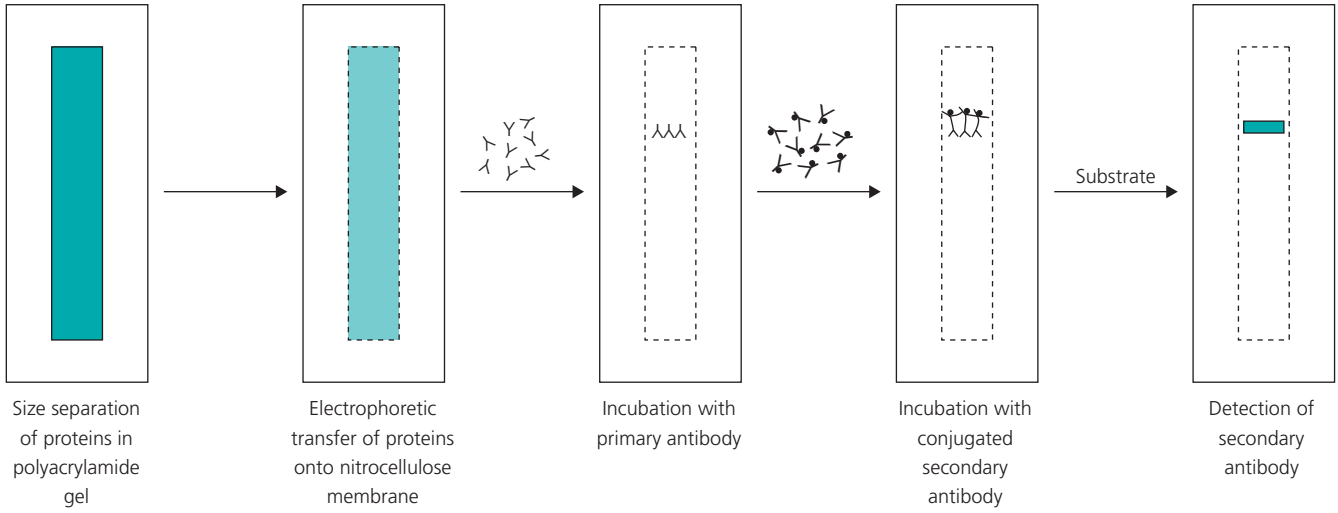

Figure 29.3 Western blotting. Detection and quantification of specific proteins using antibodies. Proteins are separated by size on a polyacrylamide gel and transferred electrophoretically to a nitrocellulose membrane. The primary antibody binds to the protein of interest, and the secondary antibody binds to the primary antibody. The secondary antibody contains a detection system that allows identification of the proteins. From Rippe et al. [78].

methodologies, immunohistochemical analysis uses specific antibodies to bind to the protein of interest, followed by antigen–antibody detection using secondary antibodies directed against the primary antibody.

DNA sequencing techniques

Many applications of molecular biology require determination of the DNA sequence, such as a gene or cDNA. The more popular method of sequencing DNA is called dideoxy sequencing or chain termination sequencing, as originally developed by Sanger and Coulsen [2]. This method is based on the ability of DNA polymerase to synthesize a complementary strand of DNA from a template. Specific complementary primers are hybridized to the DNA template and then DNA polymerase is added to allow elongation of the synthesized strand. Four reactions, each containing four deoxynucleotide triphosphates (dNTPs), one of which is radiolabeled and one of which is a dideoxynucleotide triphosphate (ddNTP), are performed. When the polymerase incorporates the ddNTP in the newly synthesized DNA strand, chain elongation terminates. When one of the four possible ddNTPs (ddATP, ddCTP, ddGTP, ddTTP) is included in each of four reactions, and the reaction products are separated in electrophoretic sequencing gels, a typical sequencing ladder is obtained from which the nucleotide sequence can be read easily. Dideoxy sequencing is automated. The success of the human genome project depended on high-throughput automated DNA sequencing.

Polymerase chain reaction

PCR allows for the rapid amplification of small amounts of nucleic acids [3]. The numerous clinical applications include diagnostic detection of infectious agents, tissue typing, prenatal diagnosis of genetic diseases, and analysis of allelic sequence variations. In the laboratory, PCR methodology is used for DNA sequencing, cloning, gene isolation, and analysis of gene expression.

The basis of PCR is simple but elegant (Fig. 29.4). Two primers are designed that are complementary to the flanking regions of the sequence to be amplified. The primers are added to the template DNA along with a DNA-dependent DNA polymerase that allows new chain synthesis. The reaction mixture is heated to denature (separate the strands) the template DNA, followed by cooling to allow for hybridization of the primers to the template. The DNA polymerase is then allowed to synthesize complementary strands from each primer. Adding the primers in vast excess and repeating the cycles of denaturation, annealing (binding of the primer to the template), and synthesis result in an exponential rate of amplification of the target sequence. The efficiency of PCR has been improved with the discovery of heat-stable DNA polymerases, like *Taq* polymerase, and newer genetically altered enzymes. These heat-stable polymerases retain their enzymatic functions despite thermal cycling. The detection of PCR products has classically been achieved by the addition of ethidium bromide, which intercalates DNA and fluoresces in this hydrophobic environment when exposed to ultraviolet radiation. In quantitative real-time applications, PCR products are detected either by specific probes that fluoresce after binding or nonspecifically by the intercalating fluorescent stain SYBR green, and are monitored after each cycle. Comparison to a known standard, e.g., defined amounts of plasmid or a virtual standard using cDNA samples, allows absolute or relative quantification of PCR products in the linear phase of the PCR. The PCR technology has been used extensively for the detection of genetic mutations in patients.

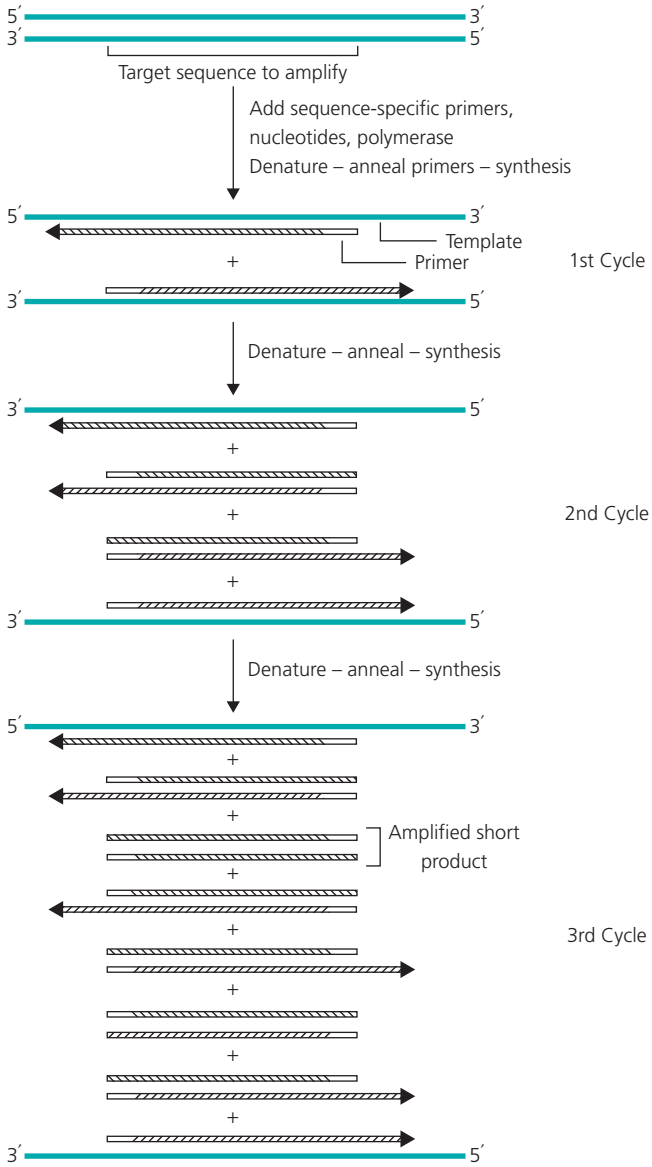

Figure 29.4 Amplification of DNA by the polymerase chain reaction (PCR). The template DNA contains the target sequence of interest. Specific DNA primers hybridize to the 5′ ends of the target sequence. The reaction also requires a heat-stable DNA-dependent DNA polymerase (such as *Taq I*) and four deoxynucleotides. Repeated cycles of denaturation (usually at 94°C), annealing of primers to template DNA, and DNA synthesis (usually at 72°C) results in the exponential amplification of the target DNA. From Rippe et al. [78].

Microarrays

Microarray technology allows the quantification of an extremely large number of transcripts in a specific sample to detect differences in gene expression. Previously, the analysis of gene expression was conducted one gene at a time (e.g., by Northern blotting or PCR as previously discussed). Microarray technology is based on the ability to create chips that contain thousands of probes to detect and quantify the presence of specific targets in a sample. The probes may be cDNAs that are amplified from plasmids or oligonucleotides synthesized onto the array matrix. Microarray analysis of gene expression consists of four steps:

- generating labeled cRNA from a specific tissue or cell
- hybridization of cRNA to the array
- scanning of the chip
- data analysis.

Microarray-based technology is not restricted to the detection of RNA expression, but can also be used to detect single nucleotide polymorphisms (SNPs) (see section on SNPs), protein binding to promoters (ChIP-chip technology, i.e., chromatin immunoprecipitation combined with gene microarray technology), and genomic changes (comparative genomic hybridization) in DNA samples.

For microarray-based gene expression analysis, labeled cRNA is generated after reverse transcription of RNA into a cDNA and a second step in which cDNA is transcribed into cRNA labeled either with radioactivity or a fluorescent label. If different fluorescent labels are used for the experimental and control RNA, then both targets may be incubated on the same microarray. The labeled targets are then hybridized to the probes, which enable the complementary target and probe sequences to bind specifically. The array is then washed to remove nonhybridized probes, reduce nonspecific hybridization, and minimize background. The specific hybridization is then detected by quantifying the amount of label that has annealed to the probe (i.e., either radioisotopic or fluorescence detection) (Fig. 29.5). Biological and technical variation can mask the effects on gene expression so quality checks are required at different steps; e.g., before the chip analysis by assessing RNA quality and during data analysis to identify bad hybridization, corrupt chips, and RNA degradation, which all create typical patterns [4]. Microarray array analysis generates a vast amount of data. To detect those genes that show reproducible differences is the most basic and important step of microarray analysis. A large number of different methods are applied and their success largely relies on a sufficient number of replicates. Microarray analyses generate unusually large sets of data so standard tests (e.g., *t* tests) are not appropriate because they will identify a large number of genes just by chance (e.g., 500 genes in a 25 000-probe microarray using a *P* value of 0.05). The commonly applied statistical algorithm in microarray analysis is the false discovery rate described by Benjamini and Hochberg [5]. Differentially expressed genes are usually displayed as a color-coded heat map with one color showing up-regulated genes and another color showing down-regulated genes. To achieve easier interpretation, differentially expressed genes are often placed clusters of similarly expressed genes or functionally related genes. Using the gene ontology database and specific software tools, further information regarding biological functions and activation of specific pathways can be extracted from the data.

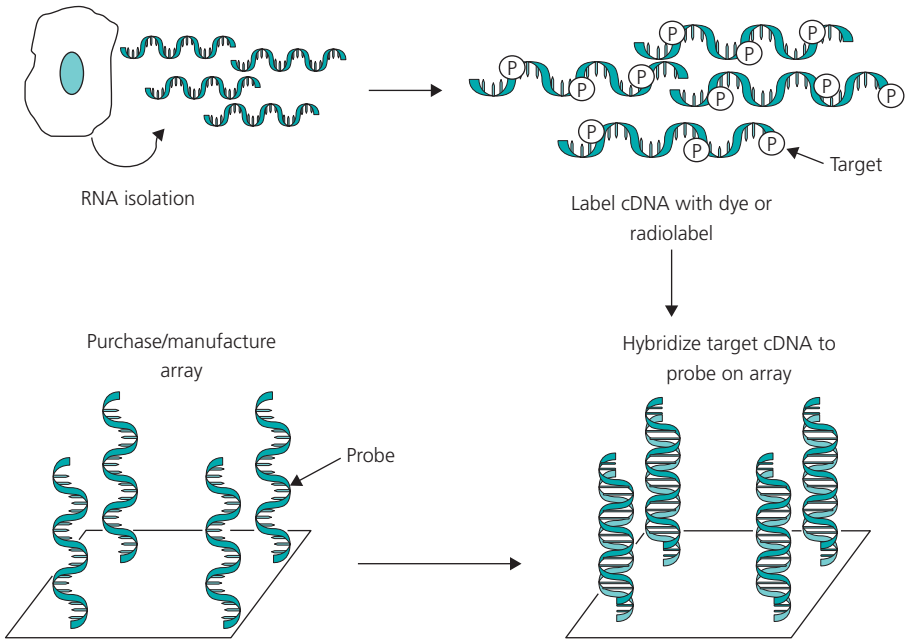

Figure 29.5 DNA microarrays for studying gene expression. RNA from a tissue of interest is converted into a labeled cDNA probe and hybridized to thousands of genes. The relative expression of genes representing the entire human genome can be detected on a single chip.

Microarray analysis is an extremely powerful tool to expand our understanding of the biology of liver disease. Micoarray-based gene expression profiling of diseases, such as infection with hepatitis C virus, nonalcoholic steatohepatitis, and hepatocellular carcinoma, has led to the identification of genes that are abnormally expressed in these diseases and may thus provide the basis for novel therapeutic approaches [6]. Profiling of the response to interferon in patients infected with hepatitis B virus or hepatitis C virus has provided insight into the therapeutic action of interferons [7]. Gene expression profiling has facilitated the classification of hepatocellular carcinoma into different groups, and consequently, enabled the prediction of survival [8]. Researchers have identified a novel subtype of hepatocellular carcinoma that is derived from hepatic progenitors and carries a poor prognosis [9]. It is likely that gene expression profiling and genomic characterization of hepatocellular carcinoma will enter clinical medicine to further classify patients to allow tailored therapies.

Applications of molecular biology to the clinical laboratory

Clinical laboratories are rapidly developing approaches to detect a variety of mutations. The different technical approaches available may be categorized as either targeted or screening mutation detection strategies.

Targeted mutation detection entails straightforward and largely routine procedures by which DNA samples may be analyzed for previously identified mutations using an assay designed for maximum specificity. This approach targets known mutations in potentially large cohorts of clinically indicated patients as well as in disorders marked by one or a few common alleles, and may confirm or establish clinical diagnoses. Furthermore, in families at risk for a particular genetic disease, targeted mutation detection allows for rapid screening of an entire family for the mutation identified in the proband, thereby permitting accurate carrier determinations. Rapid testing of large numbers of patients also permits an assessment of the mutation's frequency among disease-causing alleles, thereby determining which mutations are most prevalent in different patient populations and guiding the creation of effective clinical mutation testing panels.

By contrast, mutation screening analyzes genes for all the sequence variants present. By definition, these strategies are not predicated on allele specificity but rather are designed for highly sensitive detection for all possible variants. In principle, all sequence variants present will be detected without regard to advance knowledge of their pathogenic consequences. If evidence for a sequence variant is found, the sample must be sequenced to identify it fully. Only when combined with appropriate genetic data and in vitro functional studies can investigators distinguish between disease-causing mutations and polymorphisms without clinical consequence. From a basic research perspective, mutation screening is a critical and obligatory final step toward identifying genes that underlie genetic disease. Screening may also be applied toward the detection of mutations in diseases marked by many different mutations (allelic heterogeneity), and may also aid in the establishment of correlations between genotype and phenotype.

Use of restriction endonucleases to detect mutations

Mutations represent a fundamental change in the local DNA sequence, and may involve single nucleotide substitutions, small deletions or insertions, or more complex rearrangements. Beyond their potential for clinical consequences, gene mutations may also, by virtue of their changes in nucleotide sequence, create novel recognition sites for restriction endonucleases or destroy preexisting ones. For example, a DNA fragment harboring a mutation might *not* be cleaved with a particular restriction enzyme that normally cleaves wild-type DNA. Conversely, a different mutation might create a novel restriction site not present in the wild-type DNA. In either case, mutated DNA would produce a restriction digestion pattern distinct from that seen with nonmutated DNA when the digestion products are compared after electrophoresis on either agarose or polyacrylamide gels. An example of this commonplace approach applied to mutation detection in cystic fibrosis [10] is shown in Fig. 29.6. Other examples include mutation detection in Wilson disease [11], intrahepatic cholestasis of pregnancy [12], progressive familial intrahepatic cholestasis [13], and α_1-antichymotrypsin deficiency [14].

Using restriction enzymes to distinguish between alleles is a commonplace technique. This method also has advantages over approaches associated with radioisotope usage and their collateral costs and concerns. The large variety of restriction endonucleases that are commercially available represents a substantial resource to molecular laboratories, and the wide variety of recognition sequences associated with these enzymes affords the investigator many choices for designing straightforward mutation detection strategies.

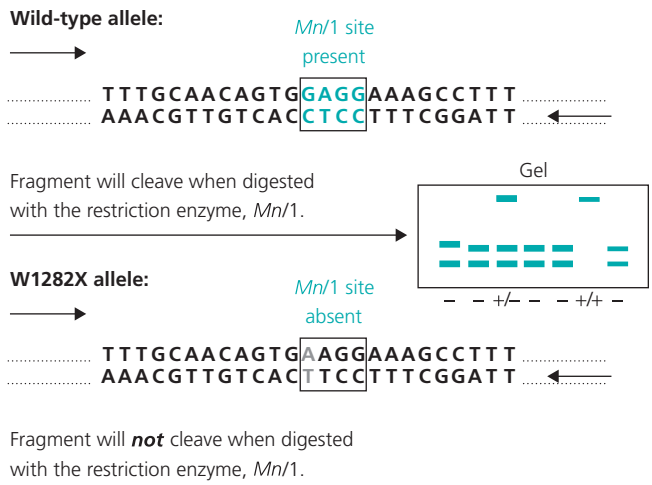

Figure 29.6 Restriction endonuclease-mediated detection of the W1282X mutation that causes cystic fibrosis. A restriction recognition site (CCTC/GAGG) present for the endonuclease *Mnl*1 in the normal CFTR exon 20 is ablated by the W1282X mutation. Arrows: PCR primers. Gel at center right shows W1282X-negative (–), W1282X heterozygote (+/–), and W1282X homozygote (+/+) patterns.

Despite this large supply of different restriction endonucleases, less than half of the known DNA sequence variants independently alter restriction digestion patterns for a commercially available enzyme. In addition, some enzymes are either unreliable or prohibitively expensive for use in routine, high-throughput analyses.

Single nucleotide polymorphisms

A SNP is a specific position in the genome in which the sequence differs only at a single base pair. SNPs account for more than 90% of all human genetic variation and are evenly distributed throughout the human genome at a frequency of 1 every 100–300 bases [15]. To date, nearly 3 million SNPs have been described and more than 10 million are estimated to exist. SNPs should clearly be differentiated from point mutations because they represent normal variations of sequence and do not necessarily cause disease. Point mutations, in contrast, are directly capable of causing disease, such as the H1069Q mutation of the *ATP7b* gene that causes Wilson disease. So, not every SNP is a point mutation, but every point mutation is a SNP. The functional consequence of a SNP is determined by its location within the genome. SNPs within the coding region of a gene can lead to an altered base triplet that potentially codes for a different amino acid, affecting protein structure and function [16].

SNPs in the coding region of genes are the cause of most recessively or dominantly inherited monogenic disorders (e.g., cystic fibrosis); however, they can also influence the course of polygenic diseases (e.g., liver fibrosis). Monogenetic disorders are caused by mutations within one gene, but it is believed that complex traits such as colon cancer, inflammatory bowel disease, or liver fibrosis are caused by a complex interplay of many genes, each of which contributes to the disease trait or phenotype.

Genotyping of SNPs is possible through electrophoretic techniques, such as restriction fragment length polymorphism analysis, in which a restriction enzyme cuts a PCR product at the site of the SNP, thereby generating DNA fragments of different sizes, which are then made visible by agarose gel electrophoresis. This approach is reasonable to screen or test for one particular SNP. However, the explosion of information about new SNPs underscores the need for more robust and scaleable genotyping techniques.

An international project, known as the Human Haplotype Map (Hap-Map) Project, aims to define SNP-based haplotype blocks in a number of populations. This work takes advantage of the fact that the probability of inheritance or independent transmission of two segments of DNA is proportional to their interlocus chromosomal distance. Hence, loci that are located close to each other segregate together and are generally inherited together as so-called haplotype blocks.

The underlying biological principle is that genetic markers in close proximity to the responsible mutant genes are in linkage disequilibrium and can therefore be evaluated as

surrogates for the presence of alleles at other loci. It is estimated that the average size of haplotype blocks ranges from 11 to 44 kilobases [17]. The use of tag-SNPs that cover the entire genome should help identify common haplotypes predisposing to common complex diseases.

Another approach to study a large number of SNPs involves the use of mass spectroscopy. SNPs are genotyped using a primer extension assay. In this assay, DNA fragments of differing size are produced depending on the allele of the assayed SNP and discriminated on the basis of mass.

The methods to perform large-scale SNP analysis are rapidly evolving with the use of microarray chip technology, which allows screening for 3000, 5000, 10 000 or even 100 000 SNPs on a patient in one experiment [18]. For this purpose, genomic DNA is first digested with restriction endonucleases and subsequently ligated to adapters, which then serve as templates for a generic single primer. PCR products are size fragmented and then hybridized with a chip.

Other approaches use molecular inversion probe (MIP) genotyping. This technique uses MIPs to produce inverted sequences, which undergo a unimolecular rearrangement and then are amplified by PCR using common primers and analyzed using universal sequence tag DNA microarrays [19].

Whole genome genotyping is made possible by bead arrays. The whole genomic DNA is amplified, fragmented, denatured, and hybridized to an array of allele-specific probes that are attached to the array by beads. After primer extension with biotin-conjugated oligonucleotides, the SNPs are then stained and evaluated directly on the array by immunohistochemical detection methods [20,21].

Proteomics is an emerging discipline that aims to study the various constituents of the entire human proteome (sum of human proteins) and how they interact with themselves and the environment. This is accomplished by two-dimensional gel electrophoresis, which separates proteins by charge (the first dimension) and mass (the second dimension). After staining, a two-dimensional matrix of dots represents different proteins that can be isolated and further characterized by mass spectroscopy. This approach identifies differentially expressed proteins between samples on a larger scale than simple Western blotting. With the use of labelled methionine, this technique also identifies differences in protein translation between different samples [22].

Polymerase chain reaction-mediated, site-directed mutagenesis

When confounding factors impede the design of facile restriction-based assays, laboratories may use a modification of this approach. PCR-mediated, site-directed mutagenesis is a technique by which a novel restriction digestion pattern can be purposefully generated in association with virtually any mutation. This strategy is known by a variety of names other than PCR-mediated, site-directed mutagenesis [23,24], including restriction site generating PCR [25] and amplification-created restriction site [26]. These techniques, identical in approach, involve the design of one PCR primer that abuts the mutation locus and includes typically one or two nucleotides mismatched relative to the template DNA. If properly designed, this mutagenic primer will bind specifically to its target DNA and support multiple rounds of PCR amplification. All PCR products generated will include not only the mutation locus under study but will also incorporate the base change inherent to the mutagenic primer. The combination of the mutation and the novel base change of this primer creates a novel restriction pattern specific to the different alleles at this locus where none was present previously. This methodology has become commonplace, including applications for mutations in the *ras* oncogene [27], *BRCA1* [28], β-thalassemia [29], medium-chain acyl-coenzyme A dehydrogenase deficiency [30], hereditary hemochromatosis [31], and α_1-antitrypsin deficiency

Amplification refractory mutation system

In the protocol for the amplification refractory mutation system, also known as allele-specific PCR, primers are designed that will amplify only one of the alleles present at the locus of interest [32]. This is accomplished with primers that are substantially mismatched relative to one allele, but that have sufficient complementarity to anneal to, and amplify, the other allele. Typically, the amplification refractory mutation system is designed to amplify one allele, whereas a separate reaction will be specific for the other allele at that locus. This technique has also been applied to cystic fibrosis [33], primary biliary cirrhosis [34], and the drug-metabolizing liver enzyme, cytochrome P450 CYP2D6 (debrisoquine 4-hydroxylase) [35].

In the absence of any advance knowledge of the likelihood of mutations being present in a DNA fragment, screening strategies are applied. Various technologies are available for the detection of any and all sequence variants that may occur. Many of these approaches require subsequent DNA sequencing to elucidate the nature of the mutations detected. These approaches, nonetheless, complement targeted mutation detection strategies because all sequence variants will be detected, not just those that have been previously reported and have highly specific assays available.

Single-stranded conformational polymorphism analysis

Single- and double-stranded DNA fragments may assume distinct secondary structures after they are denatured. These structures are highly dependent on their nucleotide sequences, so that a DNA fragment with a mutation will have an altered structure relative to the normal fragment. The screening strategy of single-stranded conformational polymorphism (SSCP or SSCA) takes advantage of the different

rates at which these fragments will migrate through polyacrylamide gels [36]. After amplification of a genomic fragment, the PCR product is typically digested into smaller fragments. It is then partially denatured to single strands and transferred immediately to ice. The sample is then electrophoresed on a non-denaturing polyacrylamide gel. Both double-stranded and single-stranded fragments will be apparent on the gel as distinctly migrating bands. The presence of a mutation or polymorphism within the PCR product will be apparent through band mobility shifts in either the double- or single-stranded fragments or both, when compared to DNA fragments without sequence variants (Fig. 29.7). The wide range of applications for SSCP includes mutation screening in Wilson disease [37], Alagille syndrome [38], progressive familial intrahepatic cholestasis [39], and cystic fibrosis [40]. The use of permutations of SSCP, such as conformation-sensitive gel electrophoresis (CSGE), has also been reported [41].

Many mutation-screening strategies are predicated on heteroduplex formation. Two single-stranded fragments of DNA, such as synthesized PCR products, will form fully matched, stable homoduplex structures at appropriate chemical and temperature conditions if they have 100% sequence complementarity. DNA fragments that differ at a small number of nucleotides will also form duplexes, but these fragments will fail to pair when the nucleotides are not matched. These heteroduplexes may have subtly altered conformational properties and become substrates for specific chemical as well as enzymatic reactions. When amplifying a DNA fragment from an individual who is heterozygous for a nucleotide substitution, the final PCR product will include both homoduplex structures for each allele, as well as heteroduplexes derived from the imperfect annealing of dissimilar fragments. Whenever heterozygosity is established, either through gel electrophoresis or chemical analysis, direct sequence analysis is used to identify the underlying mutation or polymorphism. A heteroduplex detected in a large gene allows DNA sequencing efforts to be targeted toward the fragment that gave rise to the heteroduplex, making mutation detection more efficient.

Chemical and enzymatic cleavage

Heteroduplex DNA may be cleaved in a sequence-specific manner using either chemical or enzymatic agents. Chemical cleavage of DNA mismatches (CCM) involves agents that modify specific bases when present in the single-stranded form. In imperfectly annealed, heteroduplex fragments, the nucleotide mismatch manifests as a localized single-stranded region with bases vulnerable to chemical modification. Hydroxylamine modifies unpaired cytosines, whereas osmium tetroxide modifies unpaired thymines. Piperidine is then added to cleave the mismatched products, which are then electrophoresed to resolve the digested fragments [42]. Every possible single-base mismatch, as well as small insertions and deletions, is subject to chemical cleavage. Phenylketonuria [43], acute intermittent porphyria [44], and hemophilia A [45] are among the disorders for which CCM has been used. Not only will the presence of a mutation be established, but its approximate location within the fragment will also be apparent from the size of the digestion products.

An enzymatic protocol for mismatch-directed cleavage using T4 endonuclease VII avoids the chemical toxicity of the CCM reagents [46,47]. In vivo, T4 endonuclease VII resolves the complicated structures of genetic recombination by recognizing kinks and loops produced in recombining DNA. These transient structures are similar in nature to the

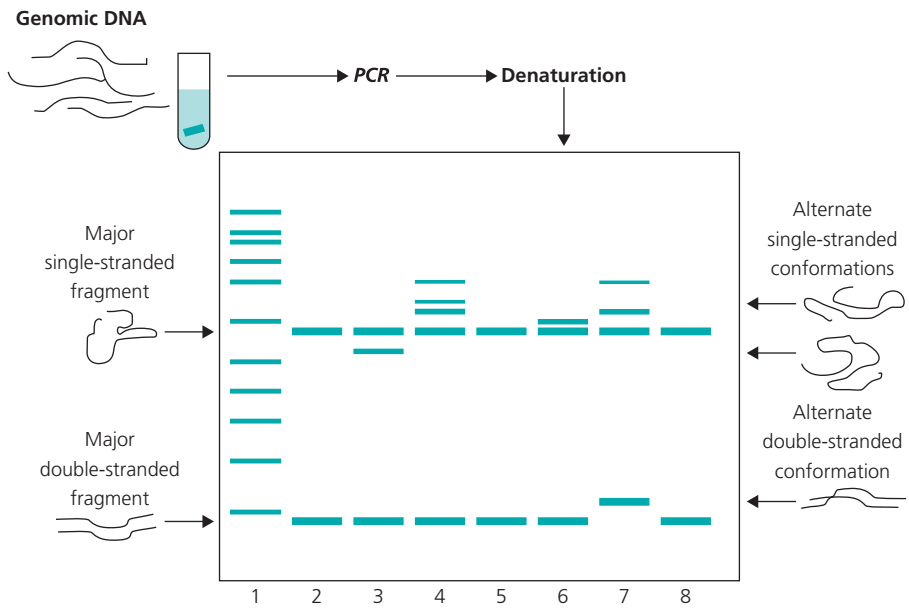

Figure 29.7 Single-stranded conformational polymorphism analysis (SSCP or SSCA). The polymerase chain reaction (PCR) product is denatured, placed on ice, and electrophoresed on nondenaturing polyacrylamide gels. Lane 1, size marker; lanes 2, 5, and 8, no bands of altered mobility are seen in samples with the wild-type sequence; lanes 3, 4, 6, and 7, bands of altered mobility establish presence of sequence variants. Different variants may yield different electrophoretic patterns. Multiple bands reflect distinct fragment conformations.

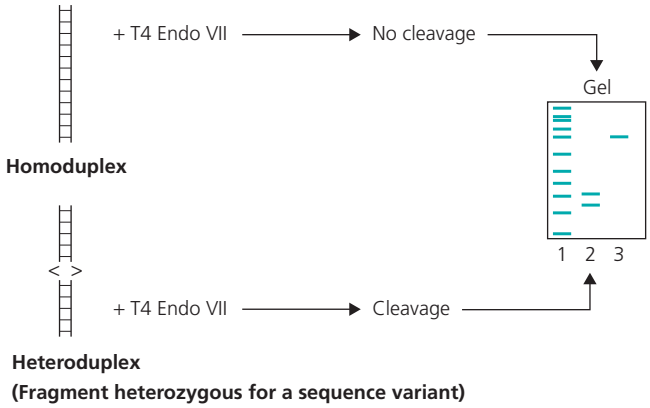

Figure 29.8 T4 endonuclease VII-mediated cleavage. Homoduplex polymerase chain reaction (PCR) fragments have no localized single-stranded domains and are not cleaved by T4 endonuclease VII. Electrophoresis produces a single uncut band (lane 3). Heteroduplex PCR fragments are cleaved by T4 endonuclease VII, giving cleaved fragments (lane 2). Lane 1, size marker.

mismatch-bearing fragments that typify heteroduplexes. Enzyme mismatch cleavage (EMC) cleaves heteroduplex fragments, allowing the digestion products to be characterized by electrophoresis (Fig. 29.8). Mutation detection using EMC has been described for hereditary nonpolyposis colorectal cancer (HNPCC) [48] and for hereditary pancreatitis [49]. As with CCM, some positional information is also be generated.

Heteroduplex analysis

The conformational changes associated with heteroduplex structures often lead to fragments with altered electrophoretic mobility. Heteroduplex fragments may be separable from homoduplex forms, thereby establishing heterozygosity for a sequence variant in that sample. A method that exploits the differential migration of homoduplexes from heteroduplexes uses mutation detection enhancement (MDE) gels (BioWhittaker Molecular Applications, Rockland, ME). This proprietary gel matrix is formulated to enhance the electrophoretic separation between homoduplex and heteroduplex fragments in a straightforward manner [50]. After PCR, DNA products are renatured slowly to enhance heteroduplex formation and are subsequently electrophoresed on MDE gels. Heteroduplex and homoduplex fragments migrate on a gel with different mobilities, an effect that is directly related to the subtle structural differences between them. This technique has been used for mutation detection in Wilson disease [51], acute intermittent porphyria [52], Duchenne muscular dystrophy [53], and hereditary breast cancer (*BRCA1*) [54].

Denaturing gradient gel electrophoresis

The differential conformational properties of heteroduplex fragments may be exploited by other methodologies. As a result of their mismatched bases, heteroduplexes will denature into single strands more readily than their homoduplex counterparts. Denaturing gradient gel electrophoresis (DGGE) uses a chemical gradient within the electrophoretic gel to take advantage of this difference [55,56]. The chemicals involved, typically urea or formamide, denature PCR fragments from double- to single-stranded forms. PCR of heterozygous samples yields heteroduplex fragments with altered denaturation properties. Once denaturation of a fragment occurs, its migration through the gel will effectively cease. The appearance of these slowly migrating bands on DGGE gels is indicative of heterozygosity for a DNA sequence variant in the underlying sample. This "melting process" is sensitive not only to the nature of the mismatch and the underlying mutation but also to the sequence of the fragment as a whole. DGGE is another widely used technique, having found utility for detecting mutations in cystic fibrosis [57], erythropoietic protoporphyria [58], tuberous sclerosis [60], and hereditary breast cancer [61], and *TP53* mutations in hepatocellular carcinoma [59].

Protein truncation test

The current method involves reverse transcription PCR (RT-PCR), in which total RNA is used to produce single-stranded cDNA. PCR amplification, using a forward primer that includes the gene's regulatory sequences necessary for transcription and translation (Fig. 29.9), results in a functional protein-coding segment. Protein synthesis is completed by adding this segment to an in vitro translation/transcription system that includes radiolabeled amino acids and results in a labeled protein. A novel, lower molecular-weight band indicates the presence of a truncated polypeptide, representing a truncating mutation in that sample. The position of the band indicates the relative size of the product, from which the position of the genomic alteration can be extrapolated (see Fig. 29.9). Confirmation of the mutation is achieved by genomic sequencing.

Missense mutations do not usually result in size alterations of proteins; therefore, other procedures must be used for missense detection, so maximum analytical sensitivity is often combined with scanning techniques for nontruncating mutations. Using this approach, the sensitivity for *BRCA1* and *BRCA2* mutation detection is nearly 90%.

Real-time polymerase chain reaction

Allele-specific mutation detection is also amenable to automation. The Perkin-Elmer 7700 TaqMan allelic discrimination protocol enables high-throughput genotyping using real-time PCR. This strategy entails the use of a short DNA probe with a fluorescent dye attached to one end and a quenching agent linked to the other end. This probe is designed to match perfectly one allele at a particular locus but to be mismatched relative to other alleles. As the synthesis of the PCR product advances, the DNA polymerase

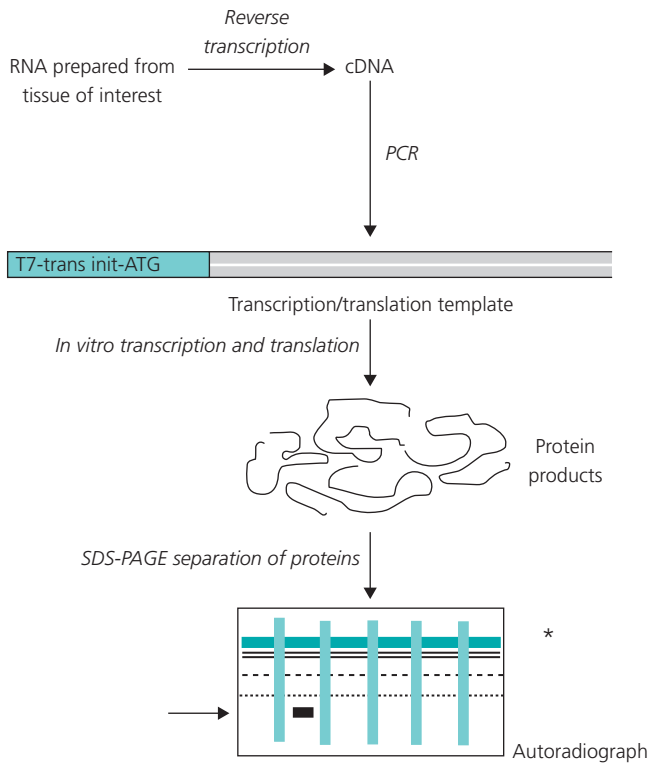

Figure 29.9 The protein truncation test. RNA is usually isolated from peripheral blood lymphocytes from whole blood collected in the presence of anticoagulant citrate dextrose solution or EDTA. (The quality of RNA isolated from tissue is dependent on rapid freezing of tissue to – 70°C or below.) Coupled in vitro transcription/translation kits, using a rabbit reticulocyte extract, are commercially available. A labeled amino acid, usually ^{35}S-labeled lysine, is added to the in vitro assay to label the synthesized proteins for autoradiography. The arrow adjacent to the autoradiograph indicates the presence of a band of lower-than-expected molecular weight, representing a truncated protein. The asterisk identifies the full-length, nontruncated protein.

5′-exonuclease activity digests any probe in its path, releasing the fluorescent dye from the quencher and generating a fluorescent signal. If the probe is mismatched relative to the template, its affinity for the template will be greatly reduced under appropriately stringent conditions. Probe not bound to the template will neither be digested nor generate signal. A similar probe may be designed to detect the other alleles, and these assays may be pooled as long as each probe carries a different, separately detectable, fluorescent dye. Real-time PCR approaches to mutation detection have been reported for α_1-antitrypsin deficiency [62], hemochromatosis [63], Tay–Sachs disease [64], and the study of mephenytoin metabolism by CYP2C19 (mephenytoin 4-prime-hydroxylase) variants [65,66].

Genetic testing for inherited colon cancer

Familial adenomatous polyposis (FAP), which also includes attenuated FAP, Gardner syndrome, and most cases of Turcot syndrome, is an autosomal dominant syndrome. More than 90% of patients with FAP have a mutation in *APC*, which encodes a tumor suppressor gene.

Genetic testing for FAP often starts with the protein truncation test, which can help localize the mutation in the FAP gene. Cell-free expression systems can be used as a bridge between genomics and proteomics by converting nucleic acid sequence (usually in the form of RNA) into protein sequence. The protein truncation test detects mutations that alter the reading frame of the expressed protein, so-called truncating mutations, which lead to a shortened protein product. This method is particularly useful in detecting mutations in large genes that are frequently altered by nonsense and frameshift mutations (the result of small insertions or deletions) in addition to large deletions. Examples of the underlying disorders include FAP [66], cystic fibrosis [67], Duchenne and Becker muscular dystrophies [68], neurofibromatosis type 1 [69], and hereditary breast and ovarian cancer defined by the tumor suppressor genes such as *BRCA1* and *BRCA2* [70,71].

Genetic testing is performed by sequencing the *APC* gene to identify the mutations, which may be preceded by SSCP or DGGE to localize the mutation. DNA for genetic testing is extracted from the white blood cells of a peripheral blood sample. Direct DNA sequencing correctly identifies up to 95% of mutations. Southern blotting identifies additional large deletions or rearrangement mutations [72,73].

Hereditary nonpolyposis colorectal cancer

HNPCC is characterized by early-onset colorectal, endometrial, gastric, and genitourinary cancers in patients with a strong family history of cancer. HNPCC is inherited as an autosomal dominant trait. It results in mutations in one of the DNA mismatch repair genes, most frequently in *MLH1* or *MSH2* and rarely in *MSH6* or *PMS2*. Mismatch repair proteins are responsible for correcting errors that occurred during DNA replication, typically the addition or deletion of one or more nucleotides. Defects in mismatch repair are readily detected in microsatellite DNA, which are sequences found throughout the human genome that contain mononucleotide, dinucleotide, or trinucleotide repeats. These short stretches of repetitive DNA are prone to mutations, which, in patients with HNPCC, are not repaired. Colon cancer that is caused by defects in mismatch repair genes often demonstrates errors in microsatellite DNA, and these cancers are said to exhibit high microsatellite instability (MSI) [74,75].

Several strategies are used for the genetic testing of families with suspected HNPCC. Testing for MSI is often the first step. MSI testing requires the availability of both tumor tissue and normal tissue. As a rule, five specific DNA microsatellites are evaluated for mutations, and if at least two of the five are abnormal, the tumor is considered MSI-high (Fig. 29.10). A corresponding approach to MSI testing is immunohistochemical analysis of the colon cancer. Specific antibodies are

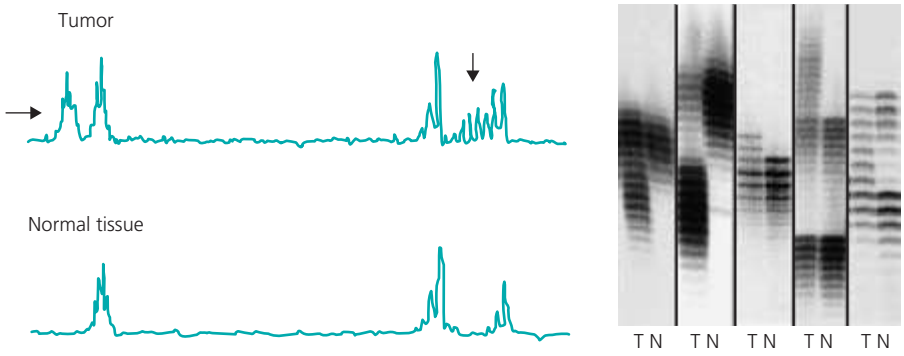

Figure 29.10 Microsatellite instability assay. DNA is extracted from both normal tissue (N) and tumor tissue (T). Microsatellite regions that are unstable because of a mismatch repair defect are amplified by polymerase chain reaction (PCR). The PCR products are detected by either capillary electrophoresis of fluorescently labeled DNA (*left*) or gel electrophoresis (*right*).

used to immunostain for the DNA mismatch repair proteins MLH1, MSH2, and MSH6. Failure to stain for the protein indicates that the corresponding gene is not being appropriately expressed and perhaps results from a germ-line mutation [76,77].

Patients with MSI-high tumors or absence of the DNA mismatch repair proteins after immunohistochemical analysis are tested for mutations in *MLH1* and *MSH2*, which account for at least 90% of the HNPCC mutations that are detected.

A ESOPHAGUS

30 Esophagus: anatomy and developmental and structural anomalies

Ikuo Hirano

Embryology, 719
Adult anatomy, 719
Histology, 723
Developmental anomalies, 725
Structural anomalies, 729

The majority of developmental and structural anomalies covered in this chapter are important but infrequently encountered. Certain entities, including esophageal heterotopic gastric mucosa (inlet patch) and Schatzki rings, are prevalent but only occasionally produce clinical manifestations. With the widespread use of upper gastrointestinal endoscopy, recognition and understanding of both common and uncommon esophageal pathology is of relevance to clinical care. The embryology and normal gross anatomy and histology of the esophagus are reviewed as background pertinent to all esophageal disorders.

Embryology

During the first 2 weeks of gestation, the human embryo forms a bilaminar disc with adjacent layers comprising ectoderm and endoderm [1,2]. In the fourth week, the tracheobronchial diverticulum forms on the ventral surface of the endodermally derived foregut adjacent to the pharyngeal gut. This diverticulum gradually separates from the dorsal foregut with formation of the esophagotracheal septum that separates the trachea and esophagus. During the sixth week of gestation, the muscularis layers form, derived from the splanchnic mesoderm. The striated muscle of the upper esophagus is derived from branchial arches 4, 5 and 6 with innervation by corresponding branches of the vagus nerve. Vagal neural crest cells derived from the ectoderm populate the foregut, forming the enteric nervous system. Unlike the midgut and hindgut, axial migration of the neural crest cells is not an important factor in the development of the foregut enteric nervous system [4]. Complex interactions between the gut microenvironment regulated by control regulatory genes coordinate the development of the myenteric and submucosal plexuses. Growth factors have a direct and indirect effect on neural crest cell migration [5].

The esophageal epithelium rapidly proliferates and almost completely occludes the lumen in the seventh and eighth weeks, leaving residual channels. A single esophageal lumen returns in the tenth week lined by a superficial layer of ciliated epithelial cells. In the fourth month, the ciliated cells are replaced by stratified squamous epithelium, a process that continues until birth. Residual islands of ciliated epithelium at the proximal and distal ends of the esophagus remain and give rise to esophageal glands.

Adult anatomy

Gross anatomy

The proximal origin of the esophagus is at the pharyngoesophageal junction that anatomically corresponds with the anterior thyroid cartilage and physiologically with the upper esophageal sphincter (UES). The UES is identified manometrically as a 2–3 cm focus of elevated resting pressure between the hypopharynx and the esophagus. The UES primarily comprises the transversely oriented cricopharyngeus with contributions from the inferior pharyngeal constrictor and thyropharyngeus muscles [6–9]. The cricopharyngeus is a C-shaped muscle that has attachments to the lateral aspects of the cricoid cartilage at the level of the C5–6 vertebral interspace. The inferior fibers of the cricopharyngeus merge with the circular muscle of the esophageal body, which courses through the posterior mediastinum to end at the esophagogastric junction corresponding with the T10 vertebral level.

The esophageal lumen can distend to approximately 2 cm in anteroposterior diameter and up to 3 cm in lateral diameter. The resting length of the adult esophagus is variable

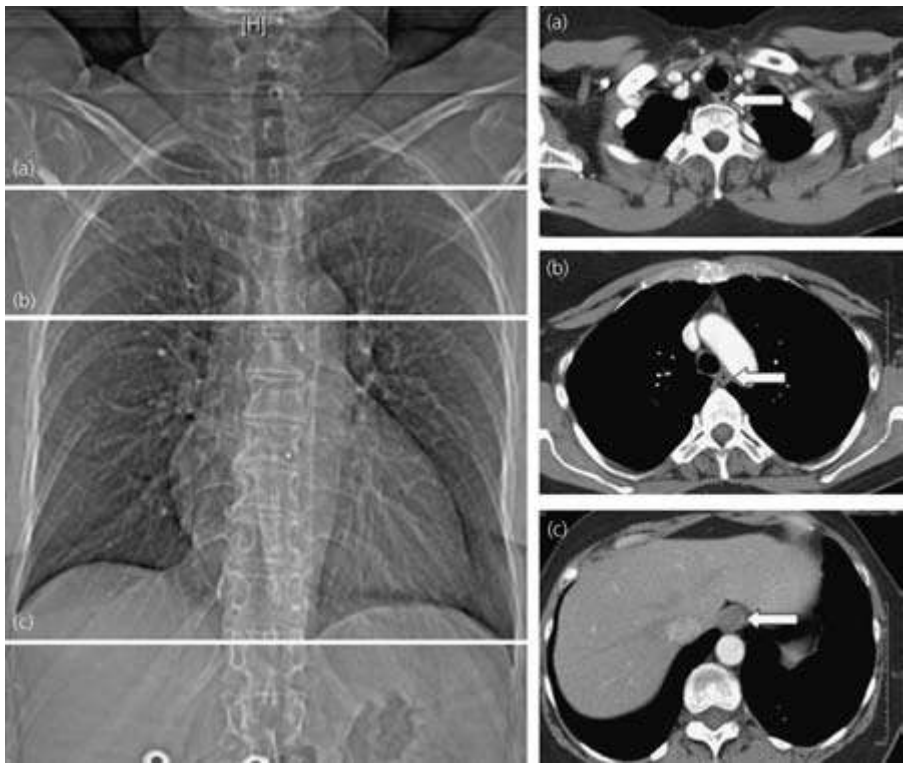

Figure 30.1 Cross-sectional computed tomography of the thorax demonstrating the relationships between the esophagus and adjacent structures. **(a)** Image at the level of the cervical esophagus with the trachea anteriorly and thoracic spine posteriorly. The carotid arteries and jugular veins are situated laterally. **(b)** Image at the level of the thoracic esophagus with the aortic arch visible anteriorly and left laterally and trachea right anterior. **(c)** Image at the level of the abdominal segment of the esophagus with the liver anteriorly and aorta posteriorly.

but ranges from 18 to 26 cm [10]. Significant shortening of the esophagus occurs during both deglutition and transient lower esophageal sphincter (LES) relaxation that can axially displace the esophagogastric junction by several centimeters. The cervical esophagus extends from the pharyngoesophageal junction to the suprasternal notch and is about 4–5 cm long. At this level, the esophagus is surrounded by the trachea anteriorly, the vertebral column posteriorly, and the carotid sheaths and thyroid laterally (Fig. 30.1a).

The thoracic esophagus passes just posterior to the tracheal wall and courses to the right and posterior to the aortic arch that corresponds with the T4 vertebral level and posterior to the tracheal bifurcation and left main stem bronchus (Fig. 30.1b). At the T8 vertebral level, the esophagus turns left and crosses anterior to the aorta at the level of the diaphragmatic hiatus. At the T10 vertebral level, the esophagus passes through the diaphragmatic hiatus and enters into the cardia of the stomach at an oblique angle.

The abdominal portion of the esophagus varies in length from 0.5 to 2.5 cm [11]. At this level, the left lobe of the liver lies anteriorly, the caudate lobe of the liver lies to the right, the fundus of the stomach is to the left, and the right crus of the diaphragm and aorta lie posteriorly (Fig. 30.1c). The intraabdominal segment of the esophagus is compressed by physiological events that increase intraabdominal pressure and therefore provides resistance to esophageal reflux under such circumstances. The borders of the esophageal hiatus are formed by the diaphragmatic crura and median arcuate ligament, if present. The crura arise from the first four lumbar vertebrae, intervertebral discs, and anterior longitudinal ligament. The fibers of the left and right crura pass upward and anteriorly to form the muscle borders of the hiatal ring and then insert into the transverse ligament of the central tendon of the diaphragm [12–14]. At the level of the diaphragm, the phrenoesophageal membrane extends from the hiatal margin to insert into the circumference of the esophagus both above and below the diaphragm [15,16]. With age, the esophagus is less firmly fixed to the hiatus and adipose tissue is incorporated into the membrane [17]. The membrane is absent in patients with hiatal hernia [18].

The esophagogastric junction is represented intralumenally by the cephalic margin of the longitudinal mucosal folds in the gastric cardia [19,20]. These folds are best appreciated when a hiatal hernia is present and used as an anatomical landmark for the esophagogastric junction in patients with Barrett esophagus. In patients without Barrett esophagus, the esophagogastric junction corresponds with the squamocolumnar mucosal junction or Z line that is demarcated by the abrupt disappearance of the visible vascular pattern and a color change from white-tan to the reddish orange, slightly granular appearance of gastric mucosa [19]. Manometrically, the junction is defined by the LES, which has both intrinsic smooth muscle and extrinsic skeletal muscle components [21]. The smooth muscle of the LES generates myogenic tone that is modulated by neurotransmitters from the enteric and autonomic nervous system. The extrinsic

component of the LES represents contractions of the crural diaphragm.

Blood supply

The arterial blood supply to the esophagus is segmental, with limited vascular overlap (Fig. 30.2). The cervical esophagus is supplied mainly by branches of the inferior thyroid artery. Branches of other arteries, such as the common carotid, subclavian, vertebral, and ascending pharyngeal, may provide additional blood supply. The thoracic esophagus is supplied by branches of the aorta and the right intercostal and bronchial arteries. The abdominal esophagus is supplied by branches of the left gastric, short gastric, and left inferior phrenic arteries.

The venous anatomy of the esophagus is depicted in Fig. 30.3. Fine intraepithelial channels drain into a subepithelial superficial venous plexus that connect with intrinsic veins in the submucosa. At the level of the gastroesophageal junction, the superficial venous plexus and deep intrinsic veins communicate with their gastric counterparts [22]. Perforating veins connect the deep intrinsic veins to adventitial veins. At the level of the cervical esophagus, the adventitial veins drain into the inferior thyroid vein, deep cervical vein, vertebral vein, and peritracheal venous plexus.

At the thoracic level, adventitial veins drain into the azygous vein on the right, the hemizygous vein on the left, and the intercostal veins when the hemizygous vein is absent. At the gastroesophageal junction, the portal systemic circulation involves venous drainage of the esophagus, stomach, pancreas, spleen, diaphragm, and retroperitoneum. Anatomical studies have suggested a high-pressure watershed region between the portal and azygous systems in the region of the gastroesophageal junction that is prone to venous dilation in portal hypertension [23]. Esophageal varices may extend up to the level of the aortic arch, the upper limit of the venous drainage of the lower esophagus by way of the azygous vein system into the superior vena cava. Varices in a location cephalic to this level have been termed *downhill varices*. This

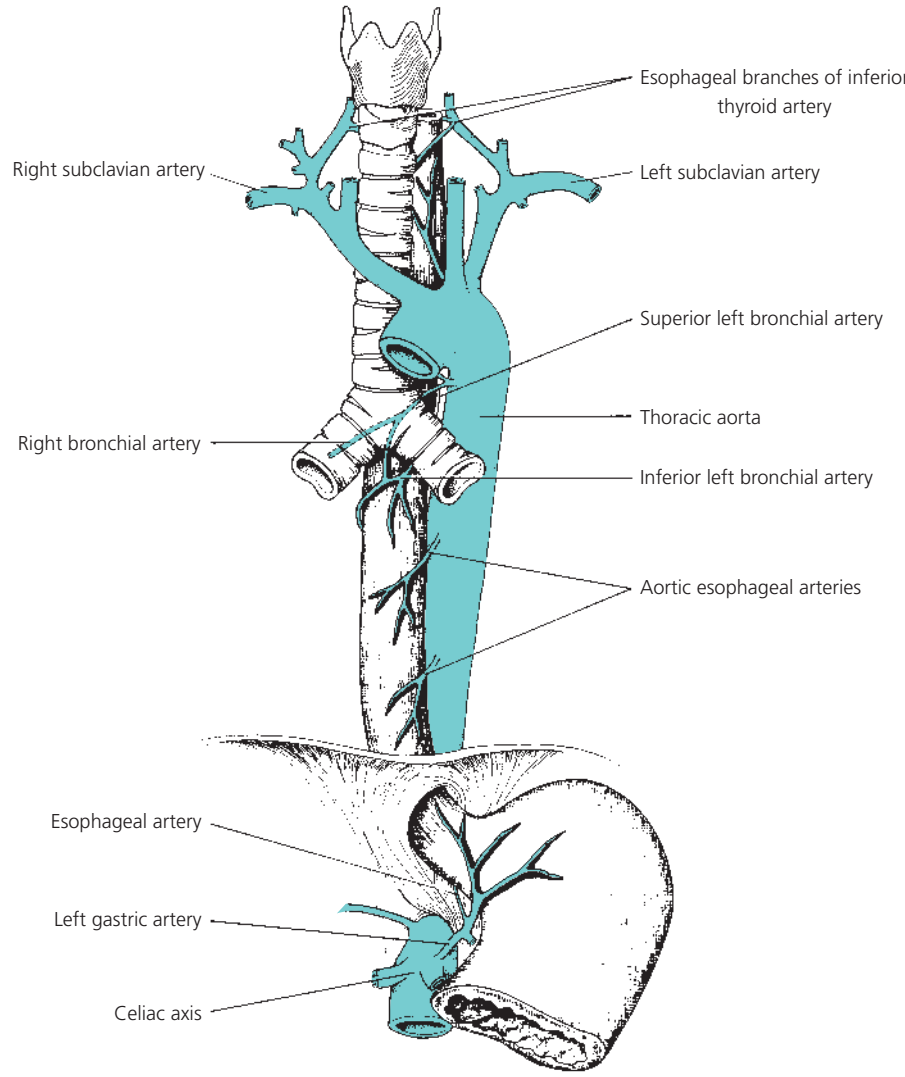

Figure 30.2 Arterial system of the esophagus.

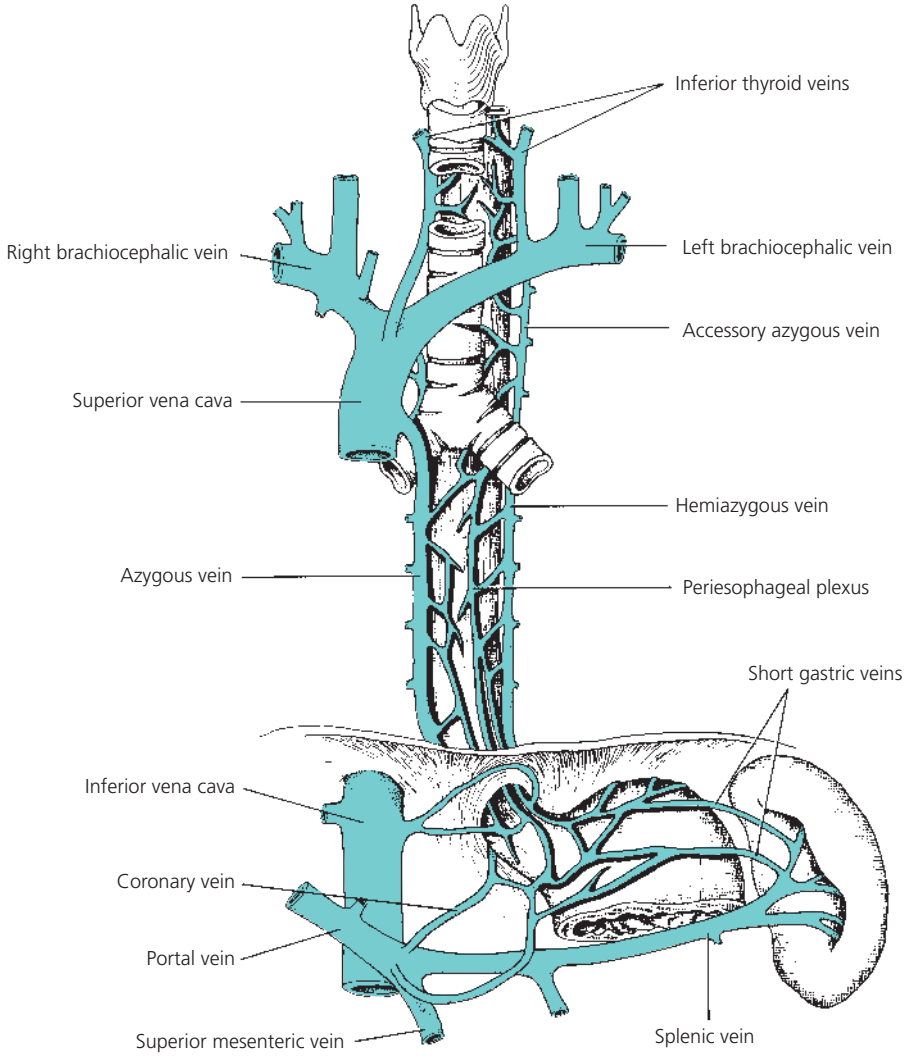

Figure 30.3 Venous drainage of the esophagus.

description refers to the anatomical site of venous obstruction above the level of the varices, in either the cervical venous system or the superior vena cava. The varices then develop below the site of venous obstruction, whereas the more commonly encountered distal esophageal varices develop in a location cephalic to or above the portal venous flow.

Innervation

Motor innervation of the esophagus is dominated by the vagus nerve, which supplies parasympathetic innervation to the esophagus (Fig. 30.4). Vagal fibers responsible for motor innervation of the upper esophageal sphincter and striated muscle esophagus originate from cell bodies in the nucleus ambiguus. The distal esophagus and LES derive vagal projections from the dorsal motor nucleus. Vagal afferent fibers responsive to chemical, thermal and mechanical stimuli have cell bodies in the nodose ganglia with projections to the nucleus solitarius. The cervical esophagus is innervated by the recurrent laryngeal nerves, which arise from the vagus. Branches of the vagus nerves and the left recurrent laryngeal nerve innervate the upper thoracic esophagus. The left and right vagus nerves intertwine with sympathetic fibers to form the esophageal plexus [24,25]. Out of the esophageal plexus, the anterior and posterior vagus trunks form at a variable distance above the diaphragm [24]. Below the diaphragm, the anterior (i.e., left) vagus trunk splits into anterior gastric branches and hepatic branch. The posterior (i.e., right) vagus trunk splits into posterior gastric branches and a branch to the celiac plexus.

Sympathetic innervation is supplied by the superior cervical ganglion, sympathetic chain, major splanchnic nerve, thoracic aortic plexus, and celiac ganglion. Cell bodies for spinal afferent nerves originate in the dorsal root ganglia and project to the spinal column and brainstem nucleus gracilis and nucleus cuneatus [26]. Spinal afferents mediate nociception from both mechanical sensation and chemosensation [27]. The enteric nervous system is responsible for direct neural innervation of the smooth muscle of the esophagus

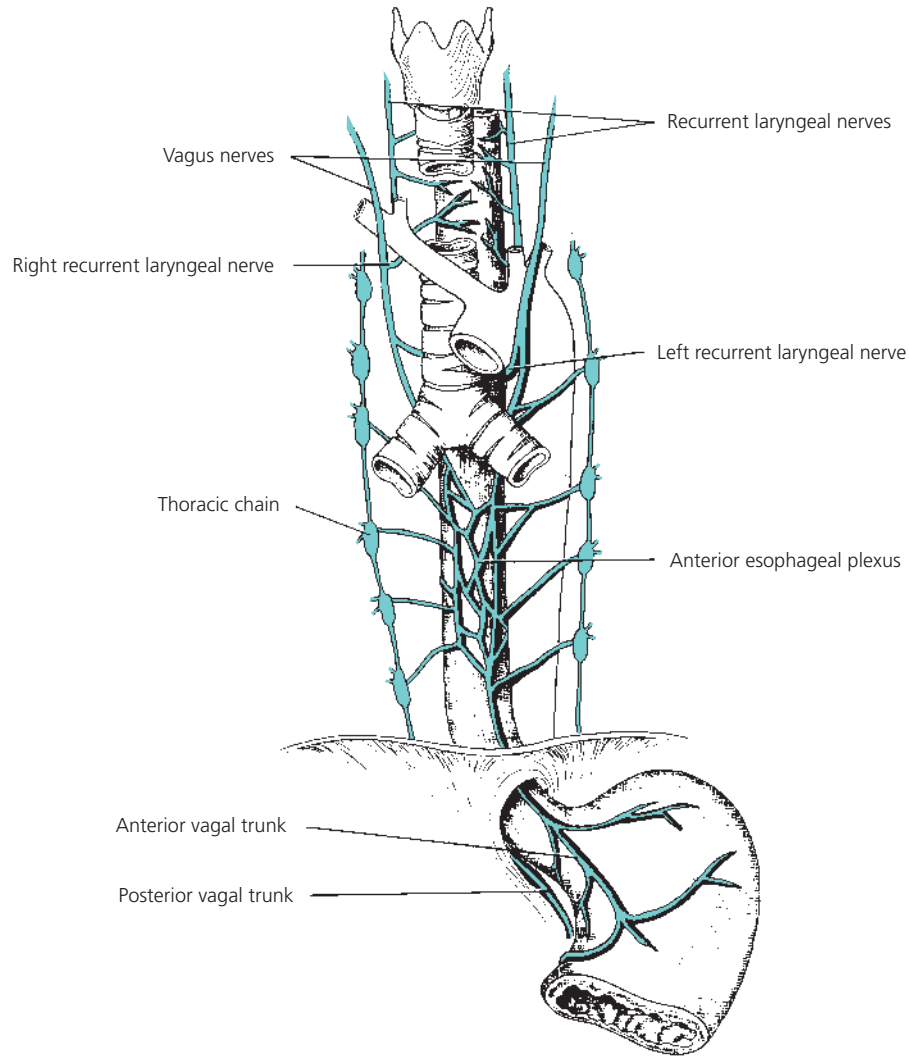

Figure 30.4 Innervation of the esophagus.

and LES. Interestingly, the enteric nervous system is present within the striated portion of the esophagus but its function is unclear.

Lymphatics

Lymphatic vessels in the mucosa and submucosa of the esophageal wall extend through the muscularis propria before emptying into adventitial lymph nodes (Fig. 30.5). Cervical lymph nodes drain the proximal esophagus, while more inferiorly the lymphatics drain into the paraesophageal lymph node chain. Internal jugular, tracheal, tracheobronchial, posterior mediastinal, and pericardial nodes drain adjacent esophageal segments. In contrast to the arterial supply, the lymphatic drainage of the esophagus is not segmental. Multiple interconnections exist between nodal chains. This arrangement accounts for the frequent wide intramural and mediastinal lymphatic spread of esophageal carcinoma.

Histology

Light microscopy

Similar to other regions of the digestive tract, the esophageal wall comprises a mucosa, submucosa, and muscularis propria (Fig. 30.6) [28]. The esophagus does not have a serosa but only a loose connective tissue that comprises the adventitia. The absence of a serosal layer allows esophageal perforations and malignancies to disseminate more readily and makes esophageal anastamosis and surgical repair more difficult.

The esophageal mucosa is composed of nonkeratinized stratified squamous epithelium, connective tissue of the lamina propria, and the muscularis mucosa. The squamous epithelium resembles that of the skin and oral cavity and is composed of a basal cell layer known as the stratum basale or germinativum, the stratum intermedium or spinosum, and a superficial layer known as the stratum superficiale or corneum.

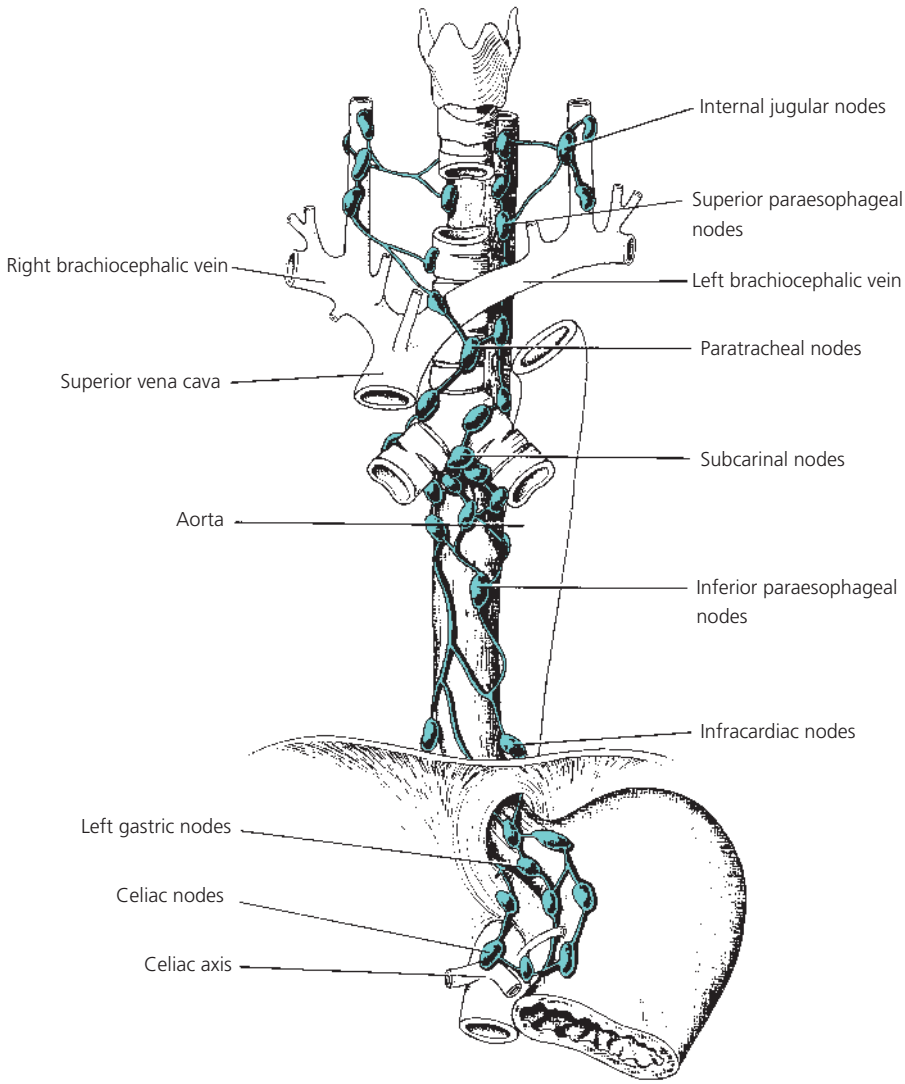

Figure 30.5 Lymphatic system of the esophagus.

The inner aspect of the epithelium undulates owing to protrusions of the lamina propria called dermal papillae or rete pegs. The papillae contain vasculature and normally extend less than two-thirds of the overall thickness of the mucosal layer. The basal cell layer is composed of basophilic cylindrical cells that have the capacity to divide and repopulate the superficial layers [28]. The cell turnover rate for the squamous epithelium is 5–8 days. Cells of the stratum spinosum contain glycogen and membrane-coating granules believed to play a role in cell cohesion [29,30]. The presence of glycogen in the superficial mucosal cells accounts for their brownish black staining by Lugol iodine applied for chromoendoscopy. In the stratum superficiale, the squamous epithelial cells are more flattened and oriented parallel to the surface. Tight junctions and intercellular mucin secretions form a protective seal between cells. Dilation of the intercellular spaces has been demonstrated to be significantly increased in patients with both erosive and nonerosive reflux disease [31,32]. This observation may explain the sensitivity of nonerosive reflux patients to acid perfusion and may serve as a histological marker for reflux disease. Acid and neutral mucosubstances are found on all layers of epithelial cells and may play a protective role [33].

The esophagus contains cells that are a part of the gut-associated lymphoid tissue. Cytotoxic T cells (i.e., intraepithelial lymphocytes) and Langerhans cells are found in the squamous epithelium. The presence of mucosal neutrophils or eosinophils is indicative of inflammatory conditions such as reflux esophagitis or eosinophilic esophagitis. T helper cells and B lymphocytes are seen primarily in the lamina propria [28,34,35].

The muscular components of the esophageal wall include the muscularis mucosa and muscularis propria. The muscularis mucosa is composed of longitudinally oriented smooth muscle cells that separate the lamina propria from the submucosa (Fig. 30.6). The submucosa consists primarily of

Figure 30.6 **(a)** Cross-section from the middle third of the esophagus shows a mixture of skeletal and predominantly smooth muscle in the muscularis propria. The submucosal glands are clearly shown. At one point, there is an esophageal cardiac gland in which a small focus of glandular epithelium interrupts the squamous mucosa. This is a normal finding, seen in at least 1% of all esophagi (magnification × 2.5). **(b)** Longitudinal section of esophageal wall (magnification × 10). Courtesy of Rodger C. Haggitt MD, Seattle, WA, USA.

loose connective tissue. The vascular network known as the Heller plexus, the submucosal or Meissner plexus of the enteric nervous system, mucin-secreting glands, lymph follicles, and lymphocytes are located at the level of the submucosa. Esophageal submucosal glands are found in the proximal esophagus and near the esophagogastric junction. The muscularis propria is composed of an inner circular and an outer longitudinal layer, the inner circular layer being the thicker of the two (Fig. 30.6). The first centimeter of the proximal esophagus is striated muscle alone, whereas the muscle of the next 6–8 cm consists of interdigitated striated and smooth muscle. The remaining length is smooth muscle alone. In situ, longitudinal muscle fibers run in an elongated spiral. Circular muscle fibers run in an elliptical course, with some fibers leaving their bundle to join higher or lower bundles [3]. Below the diaphragm and proximal to the angle of His (i.e., the abdominal or submerged segment), an area has been described in fixed gastroesophageal specimens in which the inner circular muscle layer thickens and the fibers become semicircular and interlaced. Oblique fibers of gastric type from the greater curve are also present at this level [36].

The myenteric, or Auerbach, plexus is interspersed between the inner circular and outer longitudinal muscle coats. The ganglion cells can be identified as lavender-colored larger cells clustered in small groupings on hematoxylin and eosin staining. The adventitial layer consists of connective tissue with networks of nerve plexus, vascular structures, and elastic fibers. Other specialized elements can be seen in the esophageal wall. Islands of gastric mucosa, sebaceous glands, taste buds, and foci of hyperplastic epithelial cells with intranuclear glycogen (i.e., glycogenic acanthosis) have been described [37–39]. The latter condition is commonly seen during esophagoscopy as scattered, focal, white, sessile lesions, a few to several millimeters in diameter. Glycogenic acanthosis is of no clinical consequence. It stains more intensely with Lugol iodine than the surrounding typical mucosa.

Developmental anomalies

Congenital tracheoesophageal fistula and esophageal atresia

Because of a shared embryologic origin, congenital disorders affecting the esophagus often involve abnormalities of the respiratory tract. During embryogenesis, the process of elongation and separation of the trachea and esophagus can be disrupted. If fusion of the tracheoesophageal septum is incomplete, the result is a tracheoesophageal fistula (TEF). Five basic types of TEF and atresia have been described (Fig. 30.7). Esophageal atresia with lower-pouch fistula is by far the most common [40,41]. Esophageal atresia and congenital TEF occur in 1 in 2400 to 1 in 4500 individuals [42]. Hydramnios and prematurity are common in infants with atresia or TEF [43–45]. Up to 50% of infants may have other associated congenital anomalies that include cardiac, genitourinary, gastrointestinal, skeletal, and central nervous system anomalies [42]. VACTERL is an acronym used to describe the combined occurrence of vertebral, anal, cardiac, tracheoesophageal, renal and limb anomalies in the same patient.

Symptoms vary with the type of tracheoesophageal anomaly. In infants with atresia alone, the diagnosis is often made after birth, with signs of retention and regurgitation of

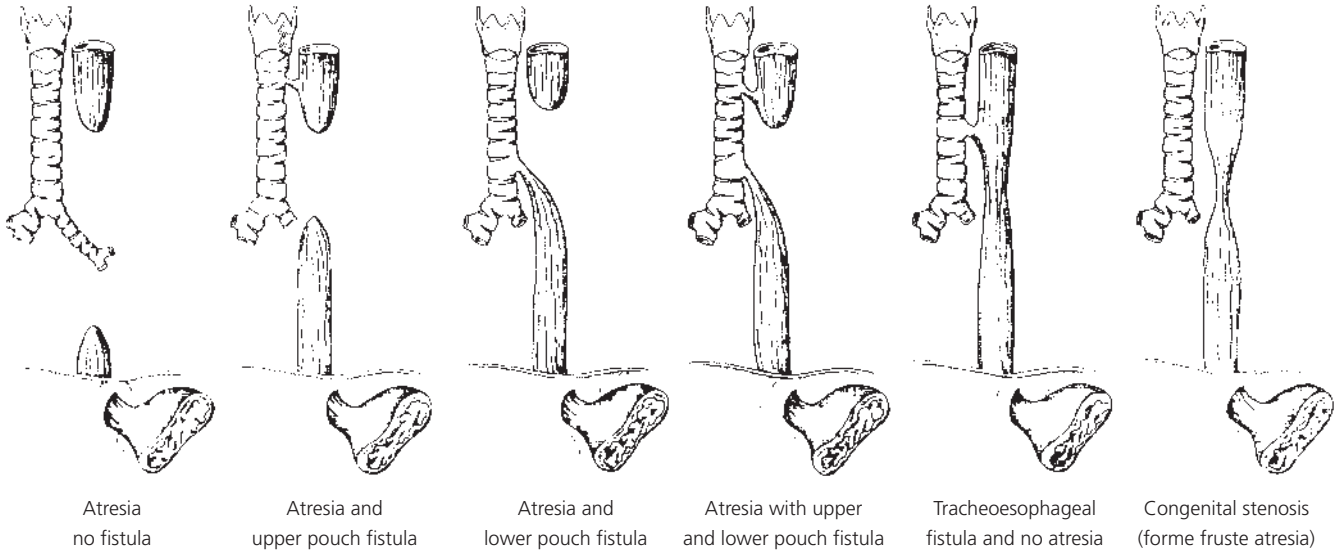

Figure 30.7 The spectrum of esophageal atresia, tracheoesophageal fistula, and congenital stenosis. Atresia with lower pouch fistula (*third from left*) is the most common anomaly.

saliva and feedings. Infants with proximal fistula exhibit respiratory distress during feedings. In infants with atresia and distal fistula, excessive salivation and regurgitation occur along with cyanosis and pneumonia secondary to reflux of gastric contents. The fifth type, isolated TEF or H-type fistula, leads to cough and choking with feedings, recurrent pneumonia, and intermittent abdominal distention. In rare cases, this anomaly may present in adulthood given the absence of associated esophageal atresia. In such cases, secondary causes of TEF such as infection, chronic inflammation and cancer need to be excluded. Adult patients present with a history of recurrent aspiration pneumonia and bronchiectasis [46–49].
